(Received 3rd Sep 2019; accepted 15th Nov 2019)

Abstract. Dark septate endophytic fungi (DSEF) can promote the growth response of host plants and can increase their resistance to heavy metals. In this study, six isolated DSEFs were proven to be able to form microsclerotia with plants. The objective of this study was to investigate the promoting and inoculation effects of these six DSEFs. Molecular analysis showed that the DSEFs may be new additions to the fungal flora of Taiwan and may be new species in the world. Screening and selection of Zn-resistant DSEFs showed that only two strains, CkDB5 and RrtHH10, were Zn-resistant. Evaluation of the Zn resistance range of CkDB5 and RrtHH10 revealed that the former presented lower EM_{50} values than the latter, and that both strains showed the same minimum inhibitory concentration values. As the Zn concentration increased, twisting and looping of the mycelial morphology of the strains was observed. Resynthesis experiments proved that CkDB5 and RrtHH10 could promote the growth response of tomato. The biomasses of CkDB5-inoculated plants was up to four times higher than that of the controls. This study showed that, of the six DSEFs, only CkDB5 and RrtHH10 showed Zn-resistance. CkDB5 is a fungus with particularly high Zn resistance, and it could facilitate tomato growth.
Keywords: *dark septate endophytic fungi, growth response, half maximal effective, resynthesis, Zn-resistant*

Introduction

Heavy metals are some of the most toxic inorganic substances known to mankind, and they can contaminate the environment (Upadhyaya et al., 2010). Phytoremediation removes heavy metals through synthesis with plants and microorganisms; to date, it remains the best strategy for heavy-metal recovery with the least harmful effects to the environment (Diagne et al., 2015; Helmisaari et al., 2007). Mycorrhizae promote the growth (Azcón-Aguilar and Barea, 1997; Schmid et al., 1995) and tolerance (Gibson and Mitchell, 2005; Lin et al., 2011) of host plants. Mycorrhizal associations have also been shown to enhance the tolerance of host plants to Zn and Cu (Bradley et al., 1981). Some fungi can alleviate toxic metal stress under certain circumstances (Smith and Read, 1997).

Dark septate endophytic fungi (DSEFs), which are commonly found in the roots of healthy plants, present dark pigmentation and septate hyphae (Mathew and Malathy, 2008) and are often sterile in culture (Newsham, 1999; Piercey et al., 2004). DSEFs refer to miscellaneous groups of anamorphic ascomycetous fungi that can colonize the intracellular or intercellular tissues of roots, and maintain an important functional relationship with host plants. DSEFs can enhance the growth and mineral nutrition of hosts (Fernando and Currah, 1996; Jumpponen et al., 1998; Lin, 2016; Shivanna et al., 1994). Several studies have indicated that some endophytes could promote the growth of host plants in soils that have been contaminated by heavy metals (Monnet et al., 2001; Sun et al., 2011; Xu et al., 2015; Zhang et al., 2010).

Li et al. (2012) suggested that fungal endophyte colonization in Pb- Zn contaminated plants is moderately abundant and that some isolates adapt remarkably well to Pb^{2+} and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_389400

Zn^{2+}. These findings indicate a potential application in phytoremediation. Diao et al. (2013) indicated that Zn is an essential micronutrient required by a wide variety of cellular processes. However, excessive Zn can be toxic to organisms (Jaeckel et al., 2005). Zn is also proposed in the 13-metal contamination list published by the US Environmental Protection Agency (Ramos et al., 2002). In the laboratory, many researchers have demonstrated that DSEF isolates could facilitate the growth of host plants. However, the Zn resistance of these DSEFs to various metal concentrations remains unknown. The purpose of this study is to examine the response of six DSEFs to Zn.

Material and methods

Strains

Six DSEFs were used in this study. Strains CkDB2 and CkDB5 were previously isolated from the roots of *Cinnamomum kanehirae* (120°47'37.33" E, 23°28'16.12" N) from a plantation located in Dabang Township, Chiayi County, Taiwan (Hong et al., 2014). Strain CoLG3 was previously isolated from the roots of *C. osmophloeum* (120°47'15" E, 23°43'47" N) in a plantation located in Lugu Township, Nantou County, Taiwan. Strain MoAL5 was previously isolated from the roots of *Mahonia oiwakensis* (120°48'45" E, 23°30'46" N) in a plantation located in Alishan Township, Chiayi County, Taiwan (Tan et al., 2016). Strain RhYM6 was previously isolated from the roots of *Rhododendron hyperythrum* (121°33'40" E, 25°09'20" N) in a plantation located in Beitou District, Taipei City, Taiwan. Finally, strain RrtHH10 was previously isolated from the roots of *R. rubropilosum* var. *taiwanalpinum* (121°17'21" E, 24°09'58" N) in a plantation located in Renai Township, Nantou County, Taiwan. These six strains were deposited at the Tree Mycorrhiza Laboratory of National Chiayi University.

Seeds

The seeds of ARIA tomatoes (*Solanum lycopersicum* L.) used in this experiment, were kindly provided by the Known-You Seed Co., Ltd.

DNA extraction, sequencing and phylogenetic analysis

The methods described by Phosri et al. (2007) were followed. Mycelia for deoxyribonucleic acid (DNA) extraction, amplification, and sequencing were scraped from the surfaces of PDA cultures. Genomic DNA was extracted using Puregene Proteinase K. Total fungal DNA was used as the template for amplification with primers ITS1-F and ITS4 (Gardes and Bruns, 1993). Polymerase chain reaction (PCR) products were sequenced by Genomics BioSci and Tech Company. Sequences were assembled and related sequences were analyzed using the basic local alignment search tool (BLAST) searches. The phylogenetic relationships were analyzed by Molecular Evolutionary Genetics Analysis software (Tamura et al., 2011). Bootstrapping was performed using neighbor-joining (Saitou and Nei, 1987).

Screening and selection of Zn-resistant DSEFs

Screening and selection of Zn-resistant DSEFs was performed using the methods of Ban et al. (2012) and Zeng et al. (2008) with modifications. The Zn-resistance of the six DSEFs was determined by placing two 0.5 mm^3 plugs of the mycelium from each DSEF

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_389400

into an Erlenmeyer flask (125 mL) containing 25 mL of modified Melin-Norkrans liquid medium (MMN) (Marx, 1969). Each DSEF was placed in 6 flasks, 3 with Zn ($ZnCl_2$, 1 mg/mL) and another 3 without. After 14 days of cultivation, the flasks were autoclaved (liquid cycle at 121 °C for 20 min), harvested by filtration (filter paper, AdvanTec No. 1), dried to a constant mass at 70 °C, and weighed.

Evaluation of metal tolerance range

Strains that survived cultivation in Zn medium were evaluated for their Zn tolerance range using the method of Ban et al. (2012) with modifications. The sensitivity of select DSEFs to Zn was evaluated by measuring their minimum inhibitory concentration (MIC) and the effective concentration inhibiting 50% of mycelial growth (EC_{50}). Petri dishes with MMN medium (Marx, 1969) were used to cultivate the selected DSEFs for 14 days. Each DSEF was exposed to six Zn concentrations (0, 0.4, 0.8, 1.2, 1.6, and 2.0 mg/mL) in three replicates. Two 0.5-cm diameter plugs were removed from the edge of 14-day-old colonies and placed in flasks. All treated samples were harvested after incubation in the dark for 14 days, after which the flasks with medium were autoclaved (liquid cycle at 121 °C for 20 min), filtered (filter paper, AdvanTec No. 1), dried to a constant mass at 70 °C, and weighed.

Observation of mycelial morphology under different concentrations of Zn

All mycelium treatments were observed. After 14 days of cultivation in different concentrations of Zn, several mycelia were obtained and carefully placed onto slides. Lactophenol cotton blue (BD BBL™) was applied to stain hyphae, and morphological observations were made using a light microscope; photos were taken for recording purposes (Hutton et al., 1994; Piercey et al., 2002; Sigler and Flis, 1998).

Evaluation of the growth responses of tomato inoculated with DSEFs

After the desired DSEFs were screened, they were applied to the roots of ARIA tomatoes under different environments with or without Zn. Pure resynthesis was done through the method proposed by Dalpé (1986). After surface cleaning, tomato seeds were sterilized with 10% sodium hypochlorite solution for 15 min, rinsed 3 times with sterilized distilled water, and then incubated in glass jars containing 1% agar for germination. Germinated seedlings were transplanted to 100 g of peat substrate (containing 100 mL MMN medium with or without Zn ($ZnCl_2$, 1 or 0 mg/mL)) in a glass jar (95×73 mm^2). Five aseptic tomato seedlings were inoculated with each DESF. Growth was then allowed to proceed for 42 days in a growth chamber (22 °C, 65% RH, and 16 h of light with a maximum illumination of 5,000 lx). To determine the growth responses of the plants, the seedlings were carefully removed from the jar after incubation.

Evaluation of Zn concentrations in tomato

Evaluation of Zn concentrations in the seedlings was performed following the method described by Yang et al. (2015). Each plant sample was washed thoroughly with tap water and rinsed five times with deionized water to remove surface dust and soil. The cleaned samples were then dried at 80 °C in an oven for 48 h until a constant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_389400

weight was achieved. Afterward, the samples were crushed using a microphyte disintegrator.

The concentrations of Zn in the plant samples were determined using the method described by Allen (1989). Samples were completely digested in concentrated HNO_3 (16 moL/L) and $HClO_4$ (12 moL/L) at a ratio of 4:1 (v/v). The digestion tubes were removed from the digestion block to cool. After the solution had cleared, it was filtered through AdvanTec No. 1 filter paper and transferred quantitatively into a 10-mL volumetric flask by addition of distilled water. Metal concentrations were determined by flame atomic absorption spectrometry (FAAS).

Statistical analyses

Statistical Package for the Social Sciences (version 12.0) (Illinois, USA) for Windows was used for statistical analysis. Means of 3 or 5 separate experiments ± standard deviations ($n = 3$ or 5) were calculated from the collected data. Tukey's multiple range test at the $p \leq 0.05$ significance level was used to analyze differences between treatments.

Results

Molecular identification of six DSEFs

The data matrix used to construct the neighbor-joining tree was comprised of 18 taxa and 704 aligned characters (including gaps/missing data) (*Fig. 1*). Based on the results of the phylogenetic analysis, the internal transcribed spacer (ITS) sequences of RrtHH10 clustered with those of *Phialocephala*, forming a cluster with 100% bootstrap support. RrtHH10 shared the closest sequence identity with *Phialocephala fortinii* (GQ302683). The ITS sequences of CoLG3 were similar to those of CkDB2 and clustered with those of *Wiesneriomyces laurinus* (KR822217; KP057801), forming a cluster with 100% bootstrap support. The ITS sequences of RhYM6 were clustered with those of Herpotrichiellaceae sp. (KJ471529) and Eurotiomycetes sp. (KM520020), forming a cluster with 98% bootstrap support. The ITS sequences of MoAL5 were clustered with those of *Cladophialophora*, forming a cluster with 95% bootstrap support. MoAL5 shared the closest sequence identity with *Cladophialophora chaetospira* (EU035406). The ITS sequences of CkDB5 were clustered with those of *Scolecobasidium*, forming a cluster with 99% bootstrap support. CkDB5 shared the closest sequence identity with *Scolecobasidium humicola* (AY265334).

Screening of Zn-resistant DSEFs

After 14 days of incubation, the samples were harvested and dried at 70 °C until a constant weight was achieved (*Table 1*). In treatments without Zn, all six DSEFs survived; in contrast, only strains CkDB5 and RrtHH10 survived in treatments with Zn.

In treatments without Zn (*Table 1*), strain CkDB2 showed the highest dry weight of 74.0 ± 6.4 mg. By comparison, the dry weights of MoAL5, RrtHH10, RhYM6, CoLG3, and CkDB5 were 65.4 ± 5.7, 59.8 ± 6.3, 57.7 ± 4.9, 44.7 ± 1.9, and 39.2 ± 3.2 mg, respectively.

In treatments with Zn (*Table 1*), only strains CkDB5 and RrtHH10 survived; the dry weights of these strains were 28.8 ± 2.8 and 29.5 ± 1.2 mg, respectively.

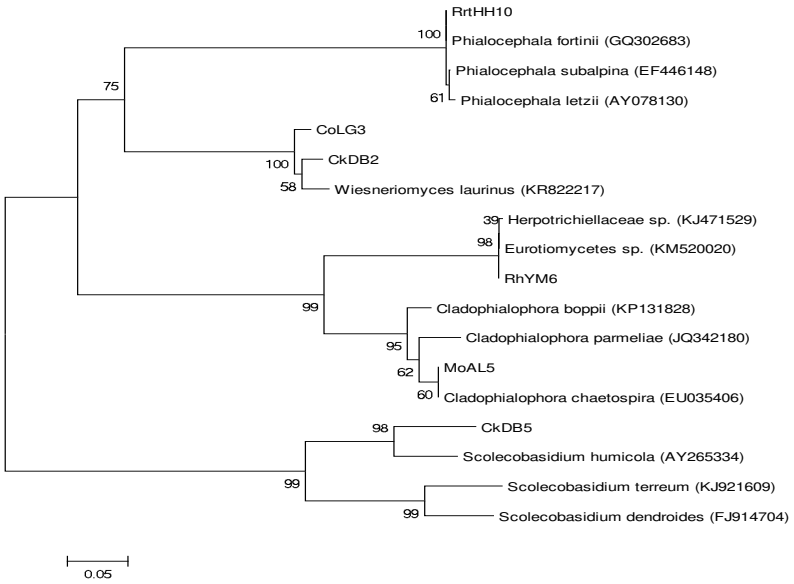

Figure 1. *The neighbor-joining phylogenetic tree of the six strains of interest. The tree was obtained using the maximum composite likelihood model for pairwise distance measurements based on ITS sequences. Numbers on branches indicate values generated from 1,000 bootstrap replica*

Table 1. *Dry weights of six DSEFs in MMN medium with and without Zn*

Treatment (strain)	Dry weight (mg)	
	Zn-free	Zn
CoLG3	44.7 ± 1.9^{b}	-
CkDB2	74.0 ± 6.4^{a}	-
CkDB5	39.2 ± 3.2^{b}	28.8 ± 2.8^{a}
MoAL5	65.4 ± 5.7^{ab}	-
RhYM6	57.7 ± 4.9^{ab}	-
RrtHH10	59.8 ± 6.3^{ab}	29.5 ± 1.2^{a}

All values represent the means ± standard deviations of three replicate cultures. Values in the same column with different letters indicate a difference at the 5% significance level

Evaluation of Zn tolerance range

Strains CkDB5 and RrtHH10 produced varying dry weights in media with different Zn concentrations after 14 days of incubation (*Table 2*).

Strain CkDB5 showed significantly different dry weights under different Zn concentrations (*Table 2*). The highest dry weight value in 0 mg/mL is 28.4 ± 1.8 mg, compared to 0.4 mg/mL (22.1 ± 4.2 mg), 0.8 mg/mL (19.1 ± 3.9 mg), 1.2 mg/mL (16.9 ± 1.9 mg), 1.6 mg/mL (16.0 ± 2.5 mg), 2.0 mg/mL (4.9 ± 0.6 mg) and 2.4 mg/mL (0 mg).

Strain RrtHH10 also showed significantly different dry weights under different Zn concentrations (*Table 2*). The highest dry weight value in 0 mg/mL is 53.4 ± 8.1 mg, compared to 0.4 mg/mL (42.4 ± 16.0 mg), 0.8 mg/mL (34.9 ± 6.2 mg), 1.2 mg/mL (11.5 ± 1.7 mg), 1.6 mg/mL (7.7 ± 1.9 mg), 2.0 mg/mL (5.9 ± 2.3 mg) and 2.4 mg/mL (0 mg).

Table 2. *Dry weights of strains CkDB5 and RrtHH10 in MMN medium with different Zn concentrations*

Zn concentrations (mg/mL)	Dry weight (mg)	
	CkDB5	**RrtHH10**
0	28.4 ± 1.8^{a}	53.4 ± 8.1^{a}
0.4	22.1 ± 4.2^{ab}	42.4 ± 16.0^{a}
0.8	19.1 ± 3.9^{b}	34.9 ± 6.2^{a}
1.2	16.9 ± 1.9^{b}	11.5 ± 1.7^{b}
1.6	16.0 ± 2.5^{b}	7.7 ± 1.9^{b}
2.0	4.9 ± 0.6^{c}	5.9 ± 2.3^{b}
2.4	0^{d}	0^{c}

All values represent the means ± standard deviations of three replicate cultures. Values in the same column with different letters indicate a difference at the 5% significance level

Morphological changes of the DSEFs under different Zn concentrations

The mycelial morphology of strains CkDB5 and RrtHH10 were observed under a light microscope after cultivation in MMN medium with different Zn concentrations for 14 days. Strains CkDB5 (*Fig. 2A–C*) and RrtHH10 (*Fig. 2D–F*) showed notable morphological changes in the presence of different Zn concentrations.

Growth response

After 42 days of incubation, all treated tomato seedlings (with/without Zn) had survived (*Fig. 3*), and the fresh weights of all treatments showed significant differences ($p < 0.05$) (*Table 3*).

Figure 3. *Morphology of tomato seedlings after incubation for 42 days. A. Plants inoculated with CkDB5 without Zn. B. Plants inoculated with CkDB5 with Zn. C. Plants inoculated with RrtHH10 without Zn. D. Plants inoculated with RrtHH10 with Zn. E. Controls without Zn. F. Controls with Zn*

In treatments without Zn (*Table 3*), plants inoculated with CkDB5 generated the highest fresh weights of 229.2 ± 5.1 mg compared to plants inoculated with RrtHH10 (81.5 ± 3.3 mg) and the control (54.7 ± 3.4 mg).

In treatments with Zn (*Table 3*), plants inoculated with CkDB5 also showed the highest fresh weights, 174.4 ± 11.4 mg, compared to plants inoculated with RrtHH10 (104.3 ± 11.2 mg) and the control (49.7 ± 4.0 mg).

Table 3. *Biomasses of tomato seedlings grown for 42 days in different treatments*

Treatment (mg mL^{-1})	Fresh weight (mg)		
	CkDB5-inoculation	RrtHH10-inoculation	Control
0	229.2 ± 5.1^{aA}	81.5 ± 3.3^{bB}	54.7 ± 3.4^{aC}
1	174.4 ± 11.4^{bA}	104.3 ± 11.2^{aB}	49.7 ± 4.0^{aC}

All values represent the means ± standard deviations of five replicate cultures. Values in the same row with different lowercase letters are significantly different at 5% significant level. Values in the same column with different capital letters are significantly different at 5% significant level

Evaluation of Zn concentrations in tomato

At harvest, the Zn concentrations of all treatments were determined by FAAS. The Zn concentrations of all treatments with Zn showed significant differences compared to all treatments without Zn ($p < 0.05$) (*Table 4*).

In treatments without Zn (*Table 4*), plants inoculated with CkDB5 showed the highest Zn concentration (92.99 ± 0.5 μg/g) compared to the control (56.4 ± 4.5 μg/g) and plants inoculated with RrtHH10 (0 μg/g).

In treatments with Zn (*Table 4*), plants inoculated with RrtHH10 demonstrated the highest Zn concentration ($1{,}083.03 \pm 13.0$ μg/g) compared to plants inoculated with CkDB5 (912.83 ± 6.2 μg/g) and the control (279.09 ± 6.3 μg/g).

Table 4. *Zn concentrations of tomato seedlings grown for 42 days in different treatments*

Treatment (mg mL^{-1})	Zn concentration (μg/g)		
	CkDB5-inoculation	RrtHH10-inoculation	Control
0	92.99 ± 0.5^{bA}	0^{bC}	56.4 ± 4.5^{bB}
1	912.83 ± 6.2^{aB}	1083.03 ± 13.0^{aA}	279.09 ± 6.3^{aC}

All values represent the means ± standard deviations of five replicate cultures. Values in the same row with different lowercase letters are significantly different at 5% significant level. Values in the same column with different capital letters are significantly different at 5% significant level

Discussion

In our laboratory, six isolates were shown to be DSEFs, which are known to facilitate the growth of host plants. The six isolates belonged to five taxa (*Fig. 1*); CoLG3 and CkDB2 belonged to *W. laurinus*, RrtHH10 belonged to *P. fortinii*, CkDB5 belonged to *S. humicola*, RhYM6 belonged to Herpotrichiellaceae, and MoAL5 belonged to *C. chaetospira*.

All six DSEFs that were cultivated in treatments without Zn survived after incubation for 14 days, but only strains CkDB5 and RrtHH10 survived in treatments with Zn (*Table 1*). Although strains CkDB5 and RrtHH10 did not show significant growth in MMN medium without Zn, they unexpectedly survived in MMN medium with Zn. Therefore, strains CkDB5 and RrtHH10 were selected for further study (*Table 1*).

The sensitivity of strains CkDB5 and RrtHH10 to Zn was determined based on MIC and EC_{50}. Following the different Zn concentrations in MMN medium for evaluation of Zn tolerance range (*Table 2*), strain CkDB5 had shown significant differences at a lower Zn concentration (0.8 mg/mL), while strain RrtHH10 showed significant differences at a higher Zn concentration (1.2 mg/mL). The MIC of CkDB5 was over 2.0 mg/mL, and its ME_{50} was over 1.6 mg/ml. The MIC of RrtHH10 was over 2.0 mg/mL, and its ME_{50}

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_389400

was over 0.8 mg/mL. Strain CkDB5 showed the same Zn resistance as the fungal endophyte H93 (EU797525) (ME_{50} = 1.5 mg/mL) (Zhang et al., 2008). Therefore, strain CkDB5 could belong to a group of highly tolerant fungi based on the studies by Wainwright and Gadd (1997) and Zhang et al. (2008). The mycelial morphology of the strains was twisted and looped with increasing Zn concentrations (*Fig. 2*). Ban et al. (2012) and Zhang et al. (2008) reported similar results.

Although all treated tomato seedlings (with/without Zn) survived 42 days of incubation (*Fig. 3; Table 3*), the fresh weights of plants inoculated with CkDB5 and RrtHH10 were significantly higher than those of the control. The fresh weight of plants inoculated with CkDB5 without Zn (229.2 ± 5.1 mg) was significantly higher than that of plants inoculated with CkDB5 with Zn (174.4 ± 11.4 mg). Compared to the fresh weight of the control (54.7 ± 3.4 mg), the fresh weight of plants inoculated with CkDB5 without Zn was 4 times higher (229.2 ± 5.1 mg). Compared to the fresh weight of the control (54.7 ± 3.4 mg), the fresh weight of plants inoculated with RrtHH10 without Zn was only 1.6 times higher (81.5 ± 3.3 mg). DSEFs can enhance the growth of their host plant (Fernando and Currah, 1996; Jumpponen et al., 1998; Shivanna et al., 1994). While strain CkDB5 could increase the biomass of *C. kanehirae* cuttings by 200% (Lin, 2016), the same strain increased the biomass of inoculated tomatoes by up to 400% in this study (*Table 3*).

Of the six treatments (*Table 4*) studied, the Zn concentration of plants inoculated with RrtHH10 with Zn was 1,000 times higher than that of plants without Zn. The Zn concentration of plants inoculated with CkDB5 with Zn was 10 times higher than that of plants without Zn. The Zn concentration of the control with Zn was 5 times higher than that of plants without Zn.

Based on our results, only strains CkDB5 and RrtHH10 were Zn-resistant. While CkDB5 and RrtHH10 presented identical MIC values (*Table 2*), the former indicated higher ME_{50} values than the latter (*Table 2*). With or without Zn, CkDB5 could promote the growth response of tomato (*Table 3*). Ban et al. (2012) indicated that DSEFs are typical root endophytes, and they believed that potential effects of DSEFs on host plants should be considered. DSEFs can affect the heavy-metal uptake of their host plants and enhance the tolerance of these plants to heavy metal stress. DSEFs have also been shown to promote the growth response of their host plants (Gadd, 2007; Lin, 2016; Selosse et al., 2004). These fungi have been observed to transport absorbed nutrients to host plants to support their growth in harsh habitats (Deram et al., 2008; Likar and Regvar, 2009; Zhang et al., 2013).

Conclusion

Molecular analysis revealed that the six DSEFs studied in this work could be divided into five clusters; strain CoLG3 and CkDB2 were classified as *W. laurinus*, while strain RrtHH10 was classified as *P. fortinii*. Strain MoAL5 was classified as *C. chaetospira*, while strain RhYM6 was classified as Herpotrichiellaceae or Eurotiomycetes. Finally, strain CkDB5 was classified as *S. humicola*. These strains may be new species in the world or new species in the fungal flora of Taiwan. Of these six DSEFs, only strains CkDB5 and RrtHH10 were Zn-resistant and could promote the growth response of *S. lycopersicum*. Of the two endophytes, strain CkDB5 was more tolerant to Zn and showed better growth responses. CkDB5 is not only Zn-resistant, but it is also a promoter of tomato growth.

Abstract. This research was carried out in 2018 in order to determine the hay yields, forage qualities botanical compositions and range conditions of 5 different natural rangelands located at different altitudes the Chuy Region, Kyrgyzstan. In the rangelands, the ratio of plant coverage was 96.0-98.0%, the ratio of grasses, legumes, other plant families in the plant covered area was 24.5–48.1%, 4.7–24.0%, 36.2–63.8%, respectively. In the rangelands, the rate of decreaser, increaser and invader species was 37.0%, 7.3% and 55.7%, respectively. The average dry matter yield (DMY) of all five ranges was 2904.6 kg ha^{-1}, crude protein (CP) was 10.6%, acid detergent fiber (ADF) and neutral detergent fiber (NDF) compositions were 39.1%, 57.1%, respectively. The crude protein yield (CPY) was 307.8 kg ha^{-1}, digestible dry matter yield (DDMY) was 1699.1 kg ha^{-1}, and relative feed value (RFV) was 95.3. The rangeland yield increased with altitude. One of the rangelands was in the moderate condition and the others were in poor range condition. According to research results, extensive research targeting appropriate range improvement strategies for each individual rangeland with unique soil and topographic conditions is recommended in order to select among the top seeding, seeding or natural seeding, weed control, grazing methods alone or combined with other range improvement strategies.
Keywords: *Central Asia, range, yield, quality, range condition*

Introduction

Rangelands are one of the cheapest sources of roughage for animals. In addition to providing the basis for sustainable animal production, rangelands form a functional environment by maintaining the soil.

Plant communities in rangelands are formed as a result of lengthy processes with the combined effects of soil, topography, and climatic factors. Therefore, the vegetation of each rangeland is unique. All plant communities, regardless of their location, evolve over time due to changes in environmental conditions. This process is called plant succession and the change may be in the number of species that make up the vegetation, the ratio of each species in the botanical composition or the rate of vegetation covering the soil. The direction of this change could either be in a more desirable and productive direction or in an undesirable and less productive direction (Blanchet et al., 2003). Plant communities, like other living communities, are in a continuous dynamism.

The rangelands in the Central Asian countries such as Kyrgyzstan, Kazakhstan, Tajikistan, Turkmenistan, and Uzbekistan are the land where the world's largest nomadic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_401416

stockbreeding is carried out. Rangelands account for 65% of the total surface area of these 5 Central Asian countries. These rangelands are the most important feed source for people with low income nomadic livestock (Blench and Sommer, 1999).

Kyrgyzstan is a mountainous country and people live on agriculture and animal husbandry. 86% of the total agricultural area consists of mountain rangelands and animal husbandry is based on rangelands. About 6.8 million hectares of Kyrgyzstan rangelands were reported to be in the process of deterioration, 3.0 million hectares have been under the weed occupation, and 1.7 million hectares has been reported to be degraded by overgrazing (Nishanov, 2015). Large degradation in Kyrgyzstan rangelands in the past 25 years due to overgrazing, inadequate research on this subject, the need for determination of conditions of the rangelands, and the need for developing sustainable improvement strategies of rangelands were expressed. According to the results of research carried out in the rangelands in different regions of Narin, presence of a number of taxa including *Artemisia dracunculus*, *Lappula sp*., *Galium verum*, *Dracocephalum integrifolium*, *Ranunculus sp*., *Onopordum acanthium*, *Draba nemorosa* were reported (Eddy, 2016). Rosales and Livinets (2017) stated that the rangelands were over-grazed by nomads in Kyrgyzstan during the independence period, grass yield and quality in rangelands is reduced, there is a serious lack of management in rangelands, there is not enough statistical information about the degradation of rangelands, overgrazing causes degradation in rangelands, the degradation of rangelands should be determined and improved, and there is lack of enough statistical information about the state of rangelands.

About 9.3 million hectares of the Kyrgyzstan territory is composed of grass prairies and due to the mismanagement of the rangelands, vegetation, yield potential and quality have decreased. This situation adversely affects the livestock and economy of the country and causes the destruction of land and water resources (Mirzabaev et al., 2016). In order to solve these problems, rangelands which have a decreased yield and quality should be rehabilitated, and high-quality feed producing potential should be reinstated. However, in order to be successful in rangeland improvement, the knowledge of the vegetation structure of the rangeland is a prerequisite. Rangeland research conducted in different parts of Turkey revealed that the area covered with plants in rangelands vary greatly. Plant cover percentages of the rangelands s were reported as 53.0%-66.0% by Erkun (1971), as 34.0% by Erkun (1972), as 14.0-37.0% by Ozmen (1977), as 17.0% by Gokkus (1984), as 78.5% by Cinar (2001), as 82.0% by Uslu (2005), as 71.9%-95.0% by Sen (2010), as 68.9-95.9% by Inal et al. (2011), as 84.4-99.0% by Cinar et al. (2014), as 83.3% by Ispirli et al. (2016), as 93.6% by Uzun et al. (2016). A great majority of the plants that are present and produce biomass of rangelands could not benefit animals as they are thorny species and weeds (Cinar et al., 2015).

This research was carried out to investigate the vegetation characteristics of natural rangelands in 5 different altitudes in the Chuy region, where 1/10 of Kyrgyzstan's rangelands is located, and to obtain information that can be used as a basis for improving rangelands in similar eco-geographic regions.

Materials and Methods

Materials

The vegetation studies were carried out between 1 June - 8 August 2018 in Tokbay (42°47'N, 74°25'E, elevation 810-945 m.), Kaskasu (42°40'N, 74°31'E, elevation 1540-1648 m.), Alaarca (42°35'N, 74°28'E, elevation 1750-1930 m.), Tamir (42°39'N,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_401416

74°39'E, elevation 1910-1950 m) and Chungurchak (42°38'N, 74°36'E, elevation 2090-2210 m) rangelands in different altitudes in Kyrgyzstan's Chuy region (*Figure 1*, *Figure 2*).

Table 1 shows the aspect, slope, distance to settlement, altitude and grazing intensity values of the rangelands whose vegetation were studied.

The closest meteorological station to the rangeland areas where the survey was conducted was in Bishkek. In Bishkek, total rainfall is 427 mm, average temperature is 10.4°C and the highest temperatures are recorded in July and the lowest temperatures are documented in January (Anonymous, 2019).

Figure 1. *The map of study area*

Methods

A modified wheel point method with loop for the vegetation survey was applied (Anonymous, 1962; Koc and Cakal, 2004) (*Figure 2*). Loop measurements were carried out in 3 different sections (in blocks) which were very homogeneous in terms of vegetation and soil in each range. The measurements were taken from four lines of 20 m extending in 4 directions in each block from a point considered as central. A total of 1200 loops were measured in each range, 100 in each 20 m line and 400 in each block. The ratio of plant covered area (%), botanical composition based on the percentage in the plant covered area (%) of the rangelands examined were determined according to the methods described by Gokkus et al. (2000).

Decreaser, increaser, and invader species expressing the responses of plant species to grazing were determined according to Anonymous (2008).

The quality scores of the species found in the rangelands were determined according to Bakır (1987) and degree of quality for each rangeland was estimated with the help of the following equation by Gokkus et al. (2000) (*Eq.1*) where the ratio of plant species in the botanical composition according to the coverage area and quality scores were used.

$$PQD: (\Sigma RxKP)/100 \qquad \text{(Eq.1)}$$

where:
PQD: Range quality degree,
R: The rate of the species in the botanical composition,
QS: Quality score of the species.

Figure 2. *Point wheel method used in vegetation study and vegetation surveyed rangeland*

Table 1. *Aspect, altitude, slope, area, longitude and latitude values for the rangelands whose vegetation were studied*

Range	Aspect	Slope (°)	Distance to Settlement (km)	Altitude (m.)	Grazing Intensity
Tokbay	Base	0-5	0-1	810-945	Heavy
Kaskasu	West	5-15	0-1	1540-1648	Moderate
Alaarca	South-North	30-40	10-15	1750-1930	Light
Tatır	West	15-25	3	1910-1950	Moderate
Chungurchak	East-West	0-30	10	2090-2210	Moderate

Plant identification in vegetation studies were conducted according to Edgecombe (1964), Garms et al. (1968), Davis (1970), Polunin and Huxley (1974), Huxley and Taylor (1977), Weymer (1981), Demiri (1983), Oztan and Okatan (1985) and Anonymous (2005, 2008, 2015). Life spans, families, and respons to grazing were determined according to Anonymous (2008, 2019).

The vegetation in the 70x70 cm dimension quadrats from the 5th, 10th, 15th m of each loop of the three plots were cut with scissors from soil level. The plant species that were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_401416

harvested from each quadrat were divided into groups as grasses, legumes and other plant families. Plant samples of each group were dried for 24 hours in a drier at 65ºC until the samples reach a constant weight. Then, each of the three plant groups were separately weighed and the sum of the dry weights was recorded as dry matter yield. After the average of dry matter yield values were determined for 12 quadrats taken from each plot and were converted to dry matter yield per hectare.

After drying and weighing the plant samples, nitrogen content was determined by Kjeldahl method by combining the samples belonging to 12 quadrats of each group. The determined nitrogen content was multiplied by 6.25 conversion coefficient and crude protein % values were estimated in each plant sample of the plant groups (Anonymous, 1995). The average crude protein contents of the plant specimens were determined by summing the figures obtained by increaser the ratios of the plant groups in the botanical composition in each plot by the crude protein ratio values.

NDF and ADF contents of the dried hay samples were analyzed using ANKOM 220 Fiber Analyzer and according to the methods described by Ankom (2009). In the calculation of CP, ADF and NDF contents of plant samples in each plot, the ratios of plant groups in botanical composition based on the weight in each plot were multiplied with the CP, ADF and NDF and the sum of the obtained values were recorded as CP, ADF and NDF ratio of plant samples from the plot.

CPY, DDMY, dry matter intake (DMI), digestible dry matter (DDM) and RFV were estimated according to the following equations (*Eq.2, Eq.3, Eq.4*) adapted from Sheaffer et al. (1995):

$$DMI = 120/(NDF\%) \text{ dry matter basis} \quad \text{(Eq.2)}$$

$$DDM = 88.9 - (0.779 \times ADF\% \text{ dry matter basis}) \quad \text{(Eq.3)}$$

$$RFV = (DDM\% \times DMI)/1.29 \quad \text{(Eq.4)}$$

$$CPY = CP\% \times DMY \quad \text{(Eq.5)}$$

Statistical Analyses

Considering the data gathered in a randomized complete block design, ANOVA analyses were performed for plant-covered area, botanical composition, DMY, CP, ADF, NDF, CPY, DDMY, RFV variables using MSTAT-C statistical package program (Steel and Torrie, 1960). Angle transformation was applied to data on the plant cover percentage and percentages of plant groups in the botanical composition before conducting analyses of variance (Tekindal, 1998). Duncan multiple comparison test was used for mean separations (Yurtsever, 1984).

Results and Discussion

Botanical Composition

The species, their families, life spans, types of response to grazing, coverage rates, percentages in botanical composition and some other vegetation characteristics of the five natural rangelands examined in the research are given in *Table 2* and *Table 3*.

24 species belonging to 22 genera of 10 families in Tokbay rangeland, 18 species belonging to 16 genera in 11 families in Alaarca rangeland, 21 species belonging to 20 genera of 9 families in Kaskasu rangeland, 19 species belonging to 17 genera of 9 families in Chungurchak rangeland, 23 species belonging to 22 genera of 13 families in Tatır rangeland were identified (*Table 2, Table 3*). It was determined that the number of species varied in the range of 19-24, while the highest number of species was in the Tokbay rangeland, and the lowest was in the Alaarca rangeland. The most common species in the rangelands were from the grasses (Poaceae) followed by legumes (Fabaceae) and chamomile (Asteraceae) (*Table 2*).

Table 3. *Vegetation Characteristics of Rangelands Examined*

Range	Number of Families	Number of Genera	Number of Species	Coverage rate (%)	Botanical Composition		
					Grasses (%)	Legumes (%)	Other Families (%)
Tokbay	10	22	24	97.0	41.2 b*	22.0 a	36.8 c

Mean	10.4	19.4	21.0	97.0	35.5	15.6	48.9

* The mean values indicated by different letters in the same column are significantly different ($P \leq 0.05$) based on Duncan test

According to the life cycle, 15 species of Tokbay range were perennial and 9 of them were annual, 20 of species of Kaskasu range were perennial and one of them were annual, 16 species of Alaarca range were perennial and 2 of them were annual, all of 19 of species in Chungurchak range were perennial, and 21 of the species in the Tamir range were perennial and 2 were identified as annual species.

Depending on their responses to grazing, 3 of the species identified in Tokbay rangeland were decreaser, 1 was increaser, and 20 were invader. Among the species identified in Kaskasu rangeland 6 were decreaser, 3 were increaser, and 12 were invader. In Alaarca rangeland, 4 of the identified species were decreaser, one was increaser, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_401416

13 were invader. In Chungurchak rangeland, 6 of the species were decreaser, 2 were increaser, and 11 were invader. In Tatır rangeland, 5 were decreaser, 1 was increaser, and 17 were found to be invader species.

Medicago minima (20.3%) in Tokbay rangeland, *Dactylis glomerata* (16.7%) in Alaarca rangeland, *Lolium perenne* (15.7%) in Kaskasu rangeland, *Dactylis glomerata* (23.7) in Tatır rangeland, and *Dactylis glomerata* (18.0%) in Chungurchak rangeland were the species with high coverage rates (*Table 2*).

The number of species in similar studies conducted in natural rangelands was reported by Bakır (1970) as 82, by Erkun (1972) as 121, by Koc and Gokkus (1994) as 152, by Cinar (2001) as 77, by Sen (2010) as 111, by Inal et al. (2011) as 37, by Cinar et al. (2014) as 41, by Gur and Altin (2015) as 149-177, and by Cinar et al. (2019) reported as 8-22. The differences in the number of species among the reports can be explained by differences in grazing pressure (Bakir, 1970; Altin et al., 2011).

The ratio of plant-covered area for the rangelands investigated here were similar to the ones reported by Cinar et al. (2014) in Hatay Kirikhan and by Inal et al. (2011) Çukurova lowland rangelands. Nontheless, the values determined in this research are much higher than the ratio of plant coverage reported by Erkun (1971), Ozmen (1977), Tukel (1981), and Buyukburc (1983) in Central Anatolian rangelands, by Gokkus (1984), Koc and Gokkus (1994) in the Eastern Anatolian rangelands, and those reported by Seydosoglu et al. (2019) in Batman Kozluk. The discrepancy among results can be attributed to the difference between the vegetation measurement methods, as well as the difference between the soil, climate, precipitation, grazing pressure and grazing animals.

As seen in *Table 3*, the highest and lowest number of species were determined in Tokbay and Alaarca rangelands, respectively. Coverage ratios of the plants ranged from 96.0% to 98.0% in the rangelands examined and this variation among rangelands was not significant.

In the rangelands examined, the ratio of grasses in the plant covered area ranged between 24.5% and 48.1% and this difference was significant. It was determined that range with the highest rate of grasses (48.1%) was Chungurchak and the lowest rate of grasses (24.5%) was Alaarca. The rate of legumes ranged between 4.7-24.0% and this variation was also significant. The rangeland with the highest legume composition (24.0%) was Kaskasu and the lowest one (4.7%) was the rangeland in Tatır. The ratio of other family species in the plant covered area ranged between 36.2-63.8% and was significantly different among rangelands. The rangeland with the highest percentage (63.8%) of other family group was one in Alaarca. The finding that Poaceae were more abundant in the Chungurchak rangeland in comparison to the others may be explained by that it is farther away from settlement areas in comparison to the other rangelands and moderate grazed (*Table 1, Table 3*).

Total percentage of *Geranium molle*, *Achillea millefolium*, *Taraxacum officinalis* species in the botanical composition of the rangeland in Alaarca was calculated as 24.8% while the total percentage of *Origanum vulgare*, *Geranium collinum*, *Achillea millefolium* in botanical composition of the rangeland in Tatır was 35.9%. Since the 3 species found in both rangelands were from other plant families, it can be concluded that the ratios of other plant families in Alaarca and Tamir were higher in the botanical composition compared to the covering area of other plant families. However, the reason for the high number of species in other plant families in these rangelands is the early and heavy grazing.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_401416

In similar studies conducted in natural rangelands, the rate of grasses in the area covered with plants was determined by Erkun (1972) as 56.0%, by Gokkus (1984) as 57.0%, by Cinar et al. (2014) as 54.0%, by Cinar et al. (2019) as 54.0%, and by Seydosoglu et al. (2019) as 25.4%. The rate of grasses determined in this research is lower than that of reported by Seydosoglu et al. (2019). This may be due to the different ecological conditions and grazing pressures of the rangelands.

In the previous research carried out in the rangelands, the rate of legumes in botanical composition was determined by Erkun (1972) as 8.0%, by Gokkus (1984) as 7.8%, by Uslu (2005) as 17.8%, by Sen (2010) as 15.0%, by Cinar et al. (2014) as 15.5%, by Cinar et al. (2019) as 22.0%, and by Seydosoglu et al. (2019) as 36.8%. The composition of legume in this research was similar to the one in Sen (2010), Cinar et al. (2014), Cinar et al. (2019) but deviated from other studies. The differences among the rangelands could be attributed to the climate and grazing pressure differences.

The average rate of other family plants in botanical composition in the rangelands examined in the research is consistent with the findings of Erkun (1972) and Sen (2010), and deviates from the composition reported in Cinar (2001), Uslu (2005) and Cinar et al. (2014). It can be concluded that the differences in ecological conditions and grazing pressure between the rangelands contributed to the observed difference in botanicak composition.

It was determined that the majority of the species found in the rangelands with the exception of the rangeland in the Tokbay range were perennial (87.3-100.0%), the number of annual species in the Tokbay rangeland and their percentage in the botanic composition are 9 and 49.4%, respectively (*Table 4*).

Table 4. *Number and percentage (%) of species in each range based on the life span*

Range	Annual		Perennial	
	Number of Species	Botanical Composition Ratio (%)	Number of Species	Botanical Composition Ratio(%)
Tokbay	9	49.4	15	50.6
Kaskasu	1	0.3	20	99.7
Alaarca	2	12.7	16	87.3
Tatır	2	2.3	21	97.7
Chungurchak	-	-	19	100.0

While the range of Tokbay is located immediately adjacent to a settlement, the distance of the rangelands other than the rangeland. The high number of annual species in Tokbay rangeland can be explained as heavy and uncontrolled grazing due to its close proximity to the settlement (*Table 1*).

Plant species in rangelands are classified according to their response to grazing as decreaser, increaser, and invader (Altin et al., 2011). The most sensitive to grazing and high-quality species are decreaser species and their rates in the rangelands examined were 29.4-51.0%, having a lower quality compared to the decreaser species, the proportion of increaser species ranged from 1.0% to 15.7%. With the withdrawing of decreaser and increaser species increases the proportion of the invader species, and they had a rate of 37.3- 69.6% (*Table 5*). As the average of the five rangelands examined, the proportion of the decreaser species was 37.0%, the proportion of increaser species was 7.3% and that of invader species was 55.7%. The high amount of decreaser species in the Chungurchak rangeland where these were the most abundant may be explained by the it is grazed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_401416

moderately due to its distance to settlement areas, while the low amount of these species in the Tokbay rangeland where these were the least abundant may be explained by that it is grazed heavily due to its proximity to settlement areas (*Table 1*). With heavy grazing, the decreaser species decrease and increaser species increase in a rangeland in time, and in the case of continuation of heavy grazing, the increaser species also decrease, but invader species increase (Bakir, 1987; Altin et al., 2011).

The high rate of invader species in the plant-covered area indicates that rangelands were grazed early, heavily, and over the capacity for many years, and were not utilized in accordance with proper grazing management (Altin et al., 2011).

Table 5. *Botanical compositions of the rangelands based on the plant groups with different responses to grazing according to the degree of effect in the examined rangelands*

Range	Decreaser	Increaser	Invader
Tokbay	29.4	1.0	69.6
Kaskasu	40.5	15.7	43.8
Alaarca	32.7	2.0	65.3
Tatır	31.4	6.1	62.5
Chungurchak	51.0	11.7	37.3
Mean	37.0	7.3	55.7

The average coverage proportions of the decreaser and increaser species determined in the present research were higher than the proportions reported by Cinar et al. (2014) in the Kirikhan rangelands of Hatay, and those reported by Cinar et al. (2019) in the high plateaus of Adana; however, the proportions were lower than those reported by Gur and Altin (2015) in Tekirdag and by Seydosoglu et al. (2019) in Batman. Proportion of invader species were lower than those reported by Seydosoglu et al. (2019), and higher than those reported by Cinar et al. (2019) and Gur and Altin (2015). This difference might be due to the difference in the climate and grazing pressure (Gokkus, 1991).

The excess of invasive species is an indication that rangelands are not managed in accordance with the appropriate range utilization techniques (Holeckek et al., 2004). Decreaser species are the most delicious species preferred by animals in the first place. As a result of early and heavy grazing in the rangelands, initially decreaser species disappear from the rangelands, and if the grazing pressure continues, the increaser species withdraw from the environment and invader species occupy the rangeland vegetation area (Gokkus, 1991; Altin et al., 2011). In terms of animal nutrition, low quality annual grasses and legumes are classified as invader species (Gokkus, 1991). 58.1% of the rangeland areas examined were covered with invasive species. This is an indication of early and heavy grazing (Cinar et al., 2019).

Hay Yield and Forage Quality

The data related to herbage yield and herbage quality in the rangelands examined in the current research are listed in *Table 6.*

As shown in *Table 6*, DMY varied between 2053.0 and 3690.0 kg ha^{-1}, CPY between 221.7 and 417.0 kg ha^{-1}, DDMY between 118.7 and 216.2 kg ha^{-1}, RFV between 94.5 and 96.7. Differences among rangelands in DMY and DDMY were statistically significant. The highest DMY, CPY and DDMY were found in Chungurchak rangeland, the lowest DMY, CPY, and DDMY were determined in Tokbay rangeland.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_401416

The highest yield in the Chungurcak rangeland is the distance of this its to the settlement, grazing density, and the decreasing species are higher than other pastures. In Tokbay pasture, it can be explained as low yield, close to settlement, heavy grazing and very low rate of reducing species (*Table 1*, *Table 5*). DDMY was generally calculated as high in pastures with high yields. This is an expected result.

Among the various studies carried out in rangelands, Sen (2010) reported DMY of 850-1720 kg ha^{-1}, the proportion of CP of 17.2%, CPY of 230 kg ha^{-1}. Cinar et al. (2015) reported DMY of 830 kg ha^{-1}, CP of 11.0%, of CPY of 90 kg ha^{-1}, ADF composition of 33.4%, NDF composition of 49.4%, and DDMY of 630 kg ha^{-1}. DMY was reported by Cacan and Basbag (2016) as 1440 kg ha^{-1} and by Seydosoglu et al. (2019) as 2980 kg ha^{-1}. Ozaslan Parlak et al. (2015) reported DMY as 900-3330 kg ha^{-1}, the proportion of CP as 11.0%, ADF composition as 30.2%, and NDF composition as 47.5%. Polat et al. (2018) noted the DMY as 1840 kg ha^{-1}, CP content as 7.5%, CPY as 130 kg ha^{-1}. Surmen and Kara (2018) estimated the DMY as 1630, CP content as 6.1%, CPY as 150 kg ha^{-1}, ADF composition as 39.5%, NDF composition as 60.3%, and the RFV as 91.4. According to the results obtained from the current research, DMY was similar to the value reported by Ozaslan Parlak et al. (2015), the rate of CP was closer to Cinar et al. (2015), and ADF and NDF composition values were in agreement with Surmen and Kara (2018). Ozaslan Parlak et al. (2015) stated that CP content above 7.5% is acceptable for livestock. In general, it can be concluded that DMY, CPY, and DDMY increased as the altitude increased. There was no coherence with the aforementioned studies in terms of other investigated variables. The reason for this may be the difference in the ratio of species found in the botanical composition in rangelands, climatic conditions, soil variables, precipitation patterns, and grazing pressures.

Table 6. *DMY, CP, ADF, NDF, CPY, DDMY and RFV in investigated rangelands*

Range	DMY (kg ha^{-1})	CP (%)	ADF (%)	NDF (%)	CPY (kg ha^{-1})	DDMY (kg ha^{-1})	RFV
Tokbay	2053.0 c*	10.8	39.9	56.3	221.7 c	1187.0 d	95.5
Kaskasu	2354.0 c	10.4	39.4	56.4	244.8 c	1370.0 c	96.7

Tatır	3431.0 ab	10.2	38.5	57.9	350.0 a	2021.0 a	94.6
Chungurchak	3690.0 a	11.3	38.9	57.2	417.0 a	2162.0 a	95.3
Mean	2904.6	10.6	39.1	57.1	307.8	1699.1	95.3

* The mean values indicated by different letters in the same column are significantly different ($P \leq 0.05$) based on Duncan test

Range Condition

The range quality scores calculated using botanical composition ratios and quality scores of plant species found in each rangeland ranged from 3.6 to 5.1. Chungurchak rangeland was found to be moderate and other rangelands were classified as poor. quality scores and range condition of the five rangelands examined are shown in *Table 7*.

The low range quality in the examined rangelands might can be attributed to disappearance of high-quality species due to uncontrolled, early, and heavy grazing for many years that have led spread of lower quality species (Koc, 1995; Cinar et al., 2014). Similarly, range statue ranged between very poor and poor were reported in Kilis rangelands (Sen, 2010), in the Kırıkhan rangelands of Hatay (Cinar et al., 2014), and in the higher parts of Adana (Cinar et al., 2019).

Chungurchak	5.1	Moderate

Conclusions

This research was carried out in order to determine the hay yield, forage quality, botanical composition and range condition in different natural rangelands (Tokbay, Kaskasu, Alaarca, Tatır, Chungurchak) located in different altitudes in Chuy Region, Kyrgyzstan. In the vegetation research, average of 21 species belonging to 19.4 genera from 10.4 families were identified. In these rangelands, the ratio of plant coverage was 96.0-98.0%, the ratio of grasses in the plant covered area was 24.5–48.1%, the proportion of legumes was 4.7–22.0%, and the proportion of other family plants ranged from 36.2-63.8%. In the rangelands, the rate of decreaser species was 37.0%, the rate of increaser species was 7.3% and the rate of invader species was 55.7%. The average dry matter yield of range was 2904.6 kg ha^{-1}, crude protein was 10.6%, ADF and NDF compositions were 39.1%, 57.1%, respectively. The crude protein yield was 307.8 kg ha^{-1}, digestible dry matter yield was 1699.1 kg ha^{-1}, and relative feed value was 95.3.

We can say that rangelands are different in aspect, slope, distance to settlement and grazing pressure.

It has been determined that approximately half of the rangelands are other family species, more than half are perennial species, and more than half are invasive species. We can say that the grazing pressure decreases as the pastures move away from the settlement area, the yield increases as the altitude rises, and grazing without control. One of the rangelands was in the moderate condition and the others were in poor range condition.

In the rangelands investigation and in similar ecological conditions, it is necessary that increase hay yield and forage quality to regulate grazing, minimize invasive species and weed rate and increase the decreasing species.

For this purpose, investigated rangelands and with similar ecological contiditons is recommended to make and implement new projects for pasture control, fertilization, over-seeding and grazing.

Abstract. In this research, we aimed to determine the effects of nitrogen fertilization on forage yield and forage quality of annual ryegrass (*Lolium multiflorum* L.) in Kazova, Tokat/Turkey conditions (the Central Black Sea Climate Zone) in 2014/2015 and 2015/2016 growing years. The experiment consisted of four replications in randomized complete block design to test effect of seven nitrogen rates (0, 50, 100, 150, 200, 250, 300 kg ha^{-1}) on plant height (PH), fresh forage yield (FFY), dry matter yield (DMY), crude protein ratio (CP), crude protein yield (CPY), Acid Detergent Fiber (ADF) ratio, Neutral Detergent Fiber (NDF) ratio, digestible dry matter ratio (DDM), digestible dry matter yield (DDMY), and relative feed value (RFV). The results revealed that the highest plant height (86.7 cm) was at the 200 kg ha^{-1} of nitrogen rate, highest fresh forage yield (48360 kg ha^{-1}), dry matter yield (13325 kg ha^{-1}), crude protein yield (1870 kg ha^{-1}) and digestible dry matter yield (8340 kg ha^{-1}) was obtained at the 250 kg ha^{-1} of nitrogen rate, and the highest digestible dry matter rate (62.72%) was determined at the 150 kg ha^{-1} nitrogen rate. Thus, 250 kg ha^{-1} nitrogen rate was the optimal dose for high forage yield and increasing nitrogen doses did not affect the ADF and NDF rates. Nevertheless, application of 300 kg ha^{-1} of nitrogen decreased yield but increased crude protein yield. Therefore, a nitrogen fertilization rate of 250 kg ha^{-1} is recommended for high forage yield of annual ryegrass (*Lolium multiflorum* L.) in the Central Black Sea Climate Zone or similar climatic conditions.
Keywords: *ADF, NDF, DMY, DDMY, RFV*

Introduction

Cost of animal derived food and food products are high in Turkey. One of the most important reasons for this is the insufficient production of high quality roughage. In order to meet the high quality roughage requirement in Turkey, it is necessary to improve the meadow pastures, increase the forage crop production areas, introduce other cheap and alternative roughage resources to animal production systems, and transfer the quality roughage production techniques to the producers (Serin and Tan, 2001).

Forage crop cultivation is one of the strategies to meet the high quality roughage need of the country's livestock. Forage legumes are the source of protein and forage grasses are the source of carbohydrates in animal diet. The annual forage grass *Lolium*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_417432

multiflorum L. is one of the grasses with highest forage production potential and fertilizer use efficiency (Acıkgoz, 2001). The annual ryegrass is also known as annual ryegrass since it was initially cultivated in Italy as a annual forage crop.

Annual ryegrass, which is a grassy forage plant of Southern Europe origin, is a one-year species cultivated in the genera *Lolium* (Genckan, 1983). It is an important alternative source of roughage in cool and temperate climates, in areas where barley and oats from winter cool climate cereals are grown for feed production. Under normal conditions, green yields varying from 15000 to 25000 kg ha^{-1} per hectare and hay yields of 5000-8000 kg ha^{-1} can be obtained. In areas where water is sufficient, it is harvested 2-3 times, 40000-60000 kg ha^{-1} green, 7500-15000 kg ha^{-1} dry grass can be taken (Baytekin et al. 2009).

In general, the crop is harvested and fed to livestock freshly; however, it can also be utilized as hay or silage. Annual forage grass production in Turkey has increased in recent years owing to the government subsidies for forage crops. The cultivation area of 4.832 da and green grass production of 17.023 tons in 2014 has increased to a cultivation area 103.410 da and green grass production of 448.086 tons in 2019 (TUIK, 2019).

In order to achieve the expected yield and quality of forage crops, the plants should be fertilized with the appropriate combination and rate in the required period. In addition to yield, forage quality is also of great importance for animal health. Nitrogen, which is the most important nutrient for plants, constitutes the majority of dry matter. In addition, nitrogen is incorporated to proteins, chlorophyll, enzymes, and vitamins in plants. Nitrogen is the most commonly used nutrient in grasses. Appropriate amounts of nitrogenous fertilizers increase the protein content in grasses, but the use of excess nitrogen in plants also leads to the accumulation of nitrate and alkaloids. A positive response was reported in annual ryegrass with the application of nitrogen fertilizers (Colak, 2015; Ozdemir et al., 2019).

Different results have been obtained in studies on fertilizer use on annual ryegrass. Celen (1991) reported that the highest yields were achieved at 100 and 150 kg ha^{-1} nitrogen (N) application in Bornova, İzmir/Turkey conditions. Seker (1992) realized highest dry matter and crude protein yields 200 kg ha^{-1} N and the highest crude protein ratio at the rate of 250 kg ha^{-1} N application rate in trials in Erzurum/Turkey. Parlak et al. (2007) indicated the highest fresh forage yield (11630 kg ha^{-1}), dry matter (3840 kg ha^{-1}) and crude protein yield (800 kg ha^{-1}) at 200 kg ha^{-1} N application in Ankara/Turkey. In a study carried out in Serbia, Simic et al. (2009) reported that the highest dry matter yield varied between years and achieved in N application rates of 50-150 kg ha^{-1}. Kesiktas (2010) reported the highest dry matter yield at the application of 100 to 150 kg ha^{-1} of N and the highest crude protein ratio at the 150 kg ha^{-1} N applications in Karaman/Turkey conditions. Pavinato et al. (2014) reported that the increase in the N rate increased dry matter and crude protein yield and the best results were attained from the dose of 120 kg ha^{-1} of N in Brazil. Colak (2015) declared 80 kg ha^{-1} of N being sufficient to achieve high yield in Ankara and Ozdemir et al. (2019) reported that 500 kg ha^{-1} of N was suitable for high yield and high quality product of annual forage grass in in a study conducted in Bursa/Turkey.

Annual ryegrass, high growth rate and nitrogen absorption in fertilization due to the ability to (Ozkul et al., 2012) is an alternative forage crops can be obtained high yield. Turkey and Turkey's Central Black Sea region is a plant that has the potential to close the fodder deficit in the region.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_417432

The purpose of the study, Turkey's Central Black Sea Region in the efficiency and high level of quality forage in closing the deficit will be an alternative forage crops in one annual ryegrass (*Lolium multiflorum* L.) to determine the appropriate nitrogen levels.

Materials and Method

Materials

The experimental trial was established in the Research and Application Center of Faculty of Agriculture located at Tasliciftlik Campus of Gaziosmanpasa University in Tokat Turkey for two years, 2014-2015 and 2015-2016 growing seasons. Trial area was 598 m above the sea level, at the 40°19'58.17 North latitude and 36°28'05 East longitude (*Figure 1*).

Figure 1. *Geographic location of the field trial*

Long term average rainfall, temperature, and relative humidity records of the research place was gathered compared to the temperature (°C), monthly total rainfall (mm) and monthly average relative humidity (%) of the breeding periods in which the experiment was conducted. The average temperatures of breeding periods (2014-2015, 2015-2016) (13.6, 12.0°C) in which the experiment was carried out were higher than the average long-term temperature (11.7°C), and total rainfall in the first breeding period (419.4 mm) is lower than the long year average (428.5 mm) and higher in the second breeding period (463.4 mm) than long year average. In addition, the relative humidity in the in the first breeding period (57.0%) is lower than the long year average (59.6%) and higher in the second breeding period (63.7%) than long year average (Anonymous, 2017). According to this, it can be concluded that the years in which the experiment was conducted were hotter and rainfall and humidity also different than the long-term averages (*Table 1*).

Chemical analyses of soil samples taken from 0-20 and 20-40 cm depths in the research area were carried out in Gaziosmanpasa University, Faculty of Agriculture, Department of Soil Science. According to the analysis results, the soil of the trial area was found to be poor in terms of organic matter, potassium, and lime, and it was clayey alkaline (Kacar, 2016).

In the research, Caramba cultivar (*Lolium multiflorum* cv. Caramba) was used and seven doses of nitrogen (0, 50, 100, 150, 200, 250, 300 kg ha^{-1}) were evaluated.

LYA: Long Year Average

Method

The experiment consisted of four replications in randomized complete block design (RCBD) with seven plots in each replication. Each plot consisted of 6 rows with 5 m length and 20 cm row spacing. Plants were seeded at 2-3 cm planting depth in 1st year on 16 October 2014 and 2nd year on 12 October 2015. In the experiment, the plot sizes were determined as 1.2x5 m = 6 m^2 (Avcioglu and Geren, 1996).

Sowing was based on 30 kg ha^{-1} seed amount (Acikgoz, 2001). Seeds weighed for each row were planted by hand in rows opened by marker. About ¼ of the predetermined nitrogen rate was applied after planting, another ¼ was applied during the tillering, ¼ was applied after the first harvest, and last ¼ was applied after the second harvest (Kesiktas, 2010). TSP (Triple Super Phosphate) was used as phosphorus fertilizer and urea was used as nitrogen fertilizer in the experiment. Pure 50 kg ha^{-1} phosphorus was applied to each parcel in planting (Kusvuran and Tansi, 2005). In both years, plots were harvested three times and irrigation was performed after the harvests.

The general view of the trial parcels is shown in *Figure 2*.

Figure 2. *General views from trial parcels in different periods*

The height of the 10 plants randomly selected from each plot were measured from the soil surface to the highest point of the plant and the plot based plant height was determined by taking the mean of the measured plants. The plots were harvested during

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_417432

the beginning of heading (10% heading). One row from the edges of each plot, top and bottom 0.5 m was mowed and removed, the remaining area was harvested. The fresh biomass obtained from each plot was weighed and converted to the fresh forage yield per ha (Anonymous, 2001). A randomly selected 500 g fresh forage sample was dried to a constant weight at 60ºC and dry weights ratios were determined based on dried samples (Sleugh et al., 2000). Samples of 5 g from the dried herbages were dried further for 24 hours in the oven set at 105ºC, cooled in a desiccator, and subsequently weighed on sensitive a balance to determine the dry matter ratios. Dry matter yields were calculated based on the obtained dry matter ratio. Some of the samples dried at 60ºC were ground and nitrogen was determined in the grass samples by Kjeldahl method. Determined nitrogen values were multiplied by 6.25 conversion coefficient to determine crude protein contents (%) of the of samples (Tan, 1995). In the experiment, ADF (Acid Detergent Fiber) and NDF (Neutral Detergent Fiber) analyses were performed, according to Van Soest et al. (1991) using the ANKOM 200/220 device.

Digestible dry matter ratio, ADF composition, relative feed value (RFV), dry matter consumption values were calculated using formulas (*Eq.1, Eq.2, Eq.3*) provided by Sheaffer et al. (1995).

$$\text{Digestible Dry Matter (DDM)} = 88.9 - (0.779 \times \%\ \text{ADF}) \quad \text{(Eq.1)}$$

$$\text{Dry Matter Intake (DMI)} = 120 / (\%\ \text{NDF}) \quad \text{(Eq.2)}$$

$$\text{Relative Feed Value} = (\%\text{DDM} \times \%\text{DMI})/1.29 \quad \text{(Eq.3)}$$

The digestible dry matter yield was obtained by multiplying the dry matter yield with the digestible dry matter ratio and the crude protein yield was obtained by multiplying the crude protein ratios and the dry matter yield.

The variance analysis (ANOVA) of the data was performed in the first year, second year and combined randomized block experiment design in MSTATC statistical program. Mean separations of significant traits were conducted using Duncan's multiple comparison test (Duzgunes et al., 1987).

Results and Discussion

The table of the variance analysis of the combined data is as follows (*Table 2*).

Table 2. *Results of analysis of variance and mean squares of the traits determined*

	DF	PH	FFY	DMY	CP	CPY	ADF	NDF	DDM	DDMY	RFV

According to the variance analysis, combined data of two years made a significant statistical difference in nitrogen applications, plant height, fresh forage yield, dry matter

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_417432

yield, crude protein yield, ADF, NDF, DDM, crude protein yield, DDMY and RFV. Nitrogen applications were found to be statistically significant in dry matter yield, crude protein yield, ADF, DDM, DDMY between years. Nitrogen x year interaction was not statistically significant in any parameter.

Plant Height (cm)

According to the ANOVA results, the nitrogen rate has a significant effect on plant height values of the first year and two-year average. However, nitrogen rates did not affect plant height of annual ryegrass in the second year. The average plant height values determined in the plots with different nitrogen rates are shown in *Table 3*.

Although the average plant height in the second year was higher than the first year, it was found that year effect was not statistically significant. In the first year and two-year averages, plant height was significantly higher in the plots where nitrogen was applied compare to the control group. Nitrogen dose applied to annual ryegrass increased the plant height (*Table 3*). This increase can be attributed to the vegetative growth stimulating effect of nitrogen fertilizers in plants (Kun, 1994; Gokmen et al., 2001).

Table 3. *Average plant height values (cm) of annual ryegrass based on nitrogen fertilizer rates*

Nitrogen (kg ha^{-1})	Years		
	2015	**2016**	**Mean**
0	76.9 b**	82.1	79.5 b
50	83.2 a	84.3	83.7 a
100	83.0 a	85.3	84.1 a
150	83.8 a	85.7	84.8 a
200	86.6 a	86.8	86.7 a
250	84.8 a	85.5	85.2 a
300	83.0 a	84.4	83.7 a
Mean	83.1	84.9	

** Values within the same columns followed by different letters are significantly different based on Duncan's test at $P < 0.01$

The average plant height of annual ryegrass was reported to be 60-90 cm by Erkun (1954), 65.7-68.6 cm by Kusvuran and Tansi (2005), 48.4 cm by Demiroglu et al. (2007), 64.5 cm by Kesiktas (2010), 88.4 cm by Cinar et al. (2011), 50.1-68.3 cm by Colak and Sancak (2017). The plant height measurement in the present study was closer to the values reported in the study of Cinar et al. (2011) and deviated from the other studies. This may be due to the variations in ecological conditions, cultivation techniques and the cultivars tested.

Fresh Forage Yield (kg ha^{-1})

Difference in the nitrogen rate had a significant effect on fresh forage yield of annual ryegrass in both years and in the mean of the two years. The average fresh forage yield values based on the nitrogen rates are given in *Table 4*.

As shown in *Table 4*, fresh forage yield ranged from 32330 kg ha^{-1} to 46150 kg ha^{-1} in the first year, from 40420 kg ha^{-1} to 50570 kg ha^{-1} in the second year, and from 36375 kg ha^{-1} to 48360 kg ha^{-1} in the two-year average depending on the fertilizer rate applied. In the first year, second year and two-year average, the highest fresh forage yield was obtained from the application of nitrogen rate of 250 kg ha^{-1}. However, fresh

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_417432

forage yield obtained from the nitrogen rates between 50-200 kg ha^{-1} in the first year, from the nitrogen rates of 150-200 kg ha^{-1} in the second year, and from the nitrogen rates between 150-200 kg ha^{-1} at the two-year averages were not significantly different from that of the nitrogen rate of 250 kg ha^{-1}. In both years separately and on a two-year average, the nitrogen rate of 300 kg ha^{-1} decreased fresh forage weight.

Table 4. *Fresh forage yield values (kg ha^{-1}) of annual ryegrass based on nitrogen fertilizer rates*

Nitrogen (kg ha^{-1})	Years		
	2015	**2016**	**Mean**
0	32330 b**	40420 d	36375 d
50	41150 a	44520 bcd	42835 bc
100	38510 ab	42670 bcd	40590 cd
150	43790 a	45790 abc	44790 abc
200	45930 a	47760 ab	46845 ab
250	46150 a	50570 a	48360 a
300	39660 ab	42230 cd	40945 cd
Mean	41074	44851	

** Values within the same columns followed by different small letters are significantly different based on Duncan's test at $P < 0.01$

The fresh forage yield of the annual ryegrass was reported to be 5500 kg ha^{-1} with the application of 150 kg ha^{-1} nitrogen (Alvim and Moojen, 1984), 13500.0 kg ha^{-1} with 55 kg ha^{-1} nitrogen application (Kallenbach et al., 2003), 11630 kg ha^{-1} with 200 kg ha^{-1} nitrogen application (Bright et al., 2006), 15430 kg ha^{-1} with 65 kg ha^{-1} nitrogen application (Piskin, 2007), 32450 kg ha^{-1} with 200 kg ha^{-1} nitrogen application (Kusvuran and Tansi, 2005), 19270, 19320, 19320 kg ha^{-1} with 40, 80, 120 kg ha^{-1} of nitrogen dose applications, respectively (Colak and Sancak, 2017).

When compared with the abovementioned previous research, it is evident that both fresh forage yield values and nitrogen rates vary greatly. This discrepancy may be due to differences in the nature of the studies, ecology, nitrogen rate, and the cultivar tested.

Dry Matter Yield (kg ha^{-1})

According to the ANOVA results for dry matter yield values, different nitrogen fertilizer rates had a significant effect on dry matter yield in the first year, second year, and two-year average. Average dry matter yield values in respect to nitrogen rates are given in *Table 5.*

Depending on the fertilizer rates applied, dry matter yield ranged from 8590 kg ha^{-1} to 12410 kg ha^{-1} in the first year, 11340 kg ha^{-1} to 14240 kg ha^{-1} in the second year, and 9965 kg ha^{-1} to 13325 kg ha^{-1} when means were averaged over two years. The highest dry matter yield in the first year, second year and two-year average was obtained from the application of 250 kg ha^{-1} nitrogen rate. Dry matter yield decreased at 300 kg ha^{-1} nitrogen rate for each of the two years and on average. Dry matter yield in the second year was significantly higher than that in the first year (*Table 4*). The reason for the higher average dry matter yield in the second year is higher rainfall in the second year (*Table 1*).

In general, dry matter yield results were parallel to fresh forage yield (*Table 4*) as expected. The earlier research revealed that dry matter yield of annual ryegrass was 9600 kg ha^{-1} when 350 kg ha^{-1} nitrogen fertilizer is applied (Corainville et al., 1973),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_417432

was 8760 kg ha^{-1} with 90 kg ha^{-1} nitrogen application (Bartholomew and Williams, 1978), was 2020 kg ha^{-1} with 55 kg ha^{-1} nitrogen application (Piskin, 2007). In the research reported here, the highest dry matter yield was obtained with the application of 250 kg ha^{-1} pure nitrogen. There is a discrepancy between our results and the previous results listed above. Different ecological conditions, variation in the rate of fertilizer, management differences and the difference in cultivar may have led the discrepancy among reported results.

Table 5. *Average dry matter yield values (kg ha^{-1}) of annual ryegrass based on nitrogen fertilizer rates*

Nitrogen (kg ha^{-1})	Years		
	2015	**2016**	**Mean**

Crude Protein Ratio (%)

ANOVA results for crude protein ratio based on different nitrogen rates revealed that nitrogen rates had a significant effect on the crude protein ratio in the first year, second year and on the two-year averages. Average crude protein ratios determined according to nitrogen rates are provided in *Table 6*.

The ratio of crude protein, one of the most important forage quality parameter, increased in parallel to the increase in the nitrogen rate in annual ryegrass. The highest crude protein content was obtained from 300 kg ha^{-1} nitrogen rate in both trial years and in two-year average. It has been stated by many researchers that nitrogen increases the crude protein content of annual grasses (Colak, 2015).

In the previous research, the highest crude protein ratio was reported at 200 and 250 kg ha^{-1} nitrogen application in Kusvuran and Tansi (2005), at 150 kg ha^{-1} nitrogen application in Simic et al. (2009) and Kesiktas (2010), at 470 kg ha^{-1} nitrogen application in Kusvuran (2011), and at 200 kg ha^{-1} nitrogen application in Colak (2015). When the results obtained here are compared with the abovementioned studies, no concordance is observed. Different ecological conditions, variation in the rate of fertilizer, management differences along with the difference in tested cultivars may have led this difference.

Crude Protein Yield (kg ha^{-1})

One way ANOVA results discerned that the crude protein yield significantly differ with the various fertilizer rates in the first year, second year, and two-year average. Average crude protein yields determined according to nitrogen rates are listed in *Table 7*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_417432

** Values within the same columns followed by different small letters are significantly different based on Duncan's test at $P < 0.01$.
$^{+}$ Values within the same row followed by different capital letters are significantly different based on Duncan's test at $P < 0.05$

The crude protein yield was calculated by multiplying the crude protein ratio and dry matter yield and the highest crude protein yield was obtained at the nitrogen rate of 250 kg ha^{-1} in the first year, in the second year and in two-year average. In general, the crude protein yields of the plots with high crude protein content and dry matter yield were high as expected (*Table 5*).

Crude protein yield of annual ryegrass was reported as 1200 kg ha^{-1} by Alvim and Moojen (1984), as 1290 kg ha^{-1} by Basbug (1990), as 470 kg ha^{-1} by Karakurt and Ekiz (1991), as 1150 kg ha^{-1} by Kusvuran and Tansi (2005), as 800 kg ha^{-1} by Bright et al. (2007), as 920 kg ha^{-1} by Kesiktas (2010), as 820 kg ha^{-1} by Kusvuran et al. (2014), and as 680 kg ha^{-1} by Colak and Sancak (2017). The results obtained in this study do not comply with the results listed above. It can be concluded that the difference in crude protein yields is not surprised as the trials were carried out in regions with different ecological characteristics, distinctive applications were performed, and different cultivars were tested.

ADF Concentration (%)

According to the one way ANOVA results, ADF concentration was not affected by the nitrogen fertilizer rate in the first year and in the second year. Nonetheless, nitrogen fertilizer application rates had a significant effect on two-year average ADF

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_417432

concentration values. The average ADF concentration values determined according to the nitrogen rates are given in *Table 8*.

According to the two-year averages, the ADF content was significantly higher at nitrogen rates of 50 kg ha^{-1} and 100 kg ha^{-1} compared to 150 kg ha^{-1} nitrogen application rate. However, the ADF concentrations at 0, 200, 250, and 300 kg ha^{-1} nitrogen rates were not different from both higher or lower concentrations of 50, 100 or 150 kg ha^{-1} doses. The mean ADF concentration in the first year was significantly higher than in the second year (*Table 8*). This may be due to the fact that the second falling rainfall and relative humidity are higher than the first year (*Table 1*).

Table 8. *Average ADF concentration (%) values of annual ryegrass based on nitrogen fertilizer rates*

Nitrogen (kg ha^{-1})	Years		
	2015	**2016**	**Mean**
0	33.64	33.65	33.64 ab*
50	34.72	34.66	34.69 a
100	34.62	34.81	34.71 a
150	33.86	33.33	33.59 b
200	35.95	33.72	34.65 ab
250	34.36	33.31	33.83 ab
300	34.15	33.40	33.78 ab
Mean	34.42 A+	33.84 B	

* Values within the same columns followed by different small letters are significantly different based on Duncan's test at $P < 0.05$.

+ Values within the same row followed by different capital letters are significantly different based on Duncan's test at $P < 0.05$

ADF concentrations of the annual ryegrass reported by Caddel and Allen (1997) were 31.0-35.0%, by Meeske et al. (2009) were 31.4%-32.3, by Kusvuran et al. (2014) was 37.4%, by Colak and Sancak (2017) were 31.1-32.1%, and by Ozdemir et al. (2019) were 30.5-34.2. The results obtained in this study are in agreement with Caddel and Allen (1997) and Ozdemir et al. (2019) but not with other studies. The difference can be attributed to the change in the cellulose and lignin contents of the cultivars along with the different ecological conditions and harvest regimen.

NDF Concentration (%)

According to the ANOVA results of NDF concentrations based on different nitrogen rates, the first year and the second year nitrogen rates did not affect the NDF concentrations. Nevertheless, nitrogen rates had a significant effect on the two-year average NDF concentrations in annual ryegrass (*Table 9*).

According to the two-year averages, the NDF composition of the herbage at 200 kg ha^{-1} nitrogen rate was significantly higher than that of the control and 250 to 300 kg ha^{-1} nitrogen rates (*Table 9*).

Van Soest (1985) stated that in order to ensure optimum milk yield in dairy cattle, NDF composition should be 36%. Yavuz (2005) affirmed that the amount of feed digested by the animal decreased with the increase in NDF ratio and the increase in NDF ratio in roughage caused a decrease of 1-2% of milk yield. Thus, it can be concluded that due to the high NDF composition, annual ryegrass alone is not suitable for feeding dairy cattle.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_417432

NDF composition in annual ryegrass was reported to be in the range of 47.7-54.7% by Viviani Rossi et al. (1994), was in the range of 40-46% according to Caddel and Allen (1997), was in the range of 42.2-50.6% in Teutsch and Smith (2001), was 47% in Meeske (2009), was 58.7% in Kusvuran and Tansi (2005), was 59.6% in Simsek (2015), and was in the range of 56.01-54.14% in Colak (2015). The results obtained in the current research did not show compliance with Caddel and Allen (1997), Meeske (2009), Kusvuran et al. (2014), Simsek (2015): however, they were in agreement with the Viviani Rossi et al. (1994), Teutsch and Smith (2001) and Colak (2015). It can be concluded that the differences in NDF composition can be attributed to the fact that the trials were carried out in regions with different ecological characteristics, with distinctive applications, and different cultivars.

Table 9. *Average NDF concentrations (%) of annual ryegrass based on nitrogen fertilizer rates*

Nitrogen (kg ha^{-1})	Years		
	2015	**2016**	**Mean**
0	54.85	51.35	53.10 b*
50	55.23	55.02	55.12 ab
100	55.40	54.34	54.87 ab
150	55.43	54.47	54.95 ab
200	56.38	56.45	56.42 a
250	54.23	53.39	53.81 b

Mean	54.97	54.13	

* Values within the same columns followed by different small letters are significantly different based on Duncan's test at $P < 0.05$

Digestible Dry Matter Ratio (%)

One way ANOVA analyses targeting the effect of nitrogen rate on digestible dry matter ratio revealed that different nitrogen rate did not lead a significant difference in the digestible dry matter ratios in the first and in the second years whereas a significant difference was observed among the nitrogen rates for the analysis of values averaged over two years (*Table 10*).

As indicated in *Table 10*, the average digestible dry matter ratio varied between 61.85% and 62.72% for the two-year averages depending on the nitrogen rates applied. The highest DDM ratio was found at 150 kg ha^{-1} nitrogen dose and the lowest was at 100 kg ha^{-1} nitrogen dose. The mean DDM ratio in the second year was significantly higher than the one in the first year. As expected, the rate of digestible dry matter, which was negatively correlated with the ADF composition of the herbage, was higher in the nitrogen dose with low ADF and higher in the year with the low ADF composition (*Table 8*).

Digestible Dry Matter Yield (kg ha^{-1})

Nitrogen rate significantly affected digestible dry matter yield in the first year, in the second year, in average over the two years (*Table 11*).

The digestible dry matter yield increased in annual ryegrass in parallel to nitrogen application rate. In the first year, the digestible dry matter yield at 250 kg ha^{-1} nitrogen rate was significantly higher than the those of rates other than 150 and 200 kg ha^{-1}. In the second year, the digestible dry matter yield at 250 kg ha^{-1} nitrogen rate was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_417432

significantly higher than those in rates other than 200 kg ha^{-1}. In the two-year average values, the digestible dry matter yield at 250 kg ha^{-1} nitrogen rate was significantly higher than in all other nitrogen rates (*Table 11*).

Digestible dry matter yield is a variable that depends on digestible dry matter content and dry matter yield. Therefore, digestible dry matter yield was high when both digestible dry matter ratio and dry matter yield were high (*Table 5, Table 10*).

Table 10. *Digestible dry matter ratios (%) of annual ryegrass based on nitrogen fertilizer rates*

Nitrogen (kg ha^{-1})	Years		
	2015	**2016**	**Mean**

Relative Feed Value (RFV)

According to the ANOVA results, nitrogen rates did not significantly affect the relative feed value in the first year. Nonetheless, relative feed values of the second year and two-year averages indicated that nitrogen rates had a significant effect on relative feed values in annual ryegrass (*Table 12*).

In the second year of the study and at the two-year averages, the lowest RFV was obtained from 200 kg ha^{-1} nitrogen application. The relative feed value is calculated using the ADF and NDF ratios and has a negative correlation with the ADF and NDF ratios. Therefore, a high relative feed value is expected at low ADF and NDF composition values.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_417432

Colak and Sancak (2017) reported RFV of 111.2 in annual ryegrass at 240 kg ha^{-1} nitrogen rate in a study conducted in Ankara. Kusvuran et al. (2014) reported RFV of 94.0 in annual ryegrass. RFV obtained from the present study is lower than the values reported in Colak and Sancak (2017) and higher than those reported in Kusvuran et al. (2014).

Caddel and Allen (1997) reported the relative feed value of completely headed wheat as lower than 77. Schroeder (2004) stated that the relative feed value decreases as the harvest time delayed, and Linn and Martin (1999) argued that the relative feed value of forage for high-milk yield dairy cows should be at least 124. The RFV obtained from the current study is below the stated value. RFV is a value obtained from ADF and NDF values. It is inversely proportional to ADF and NDF, and low RFV is obtained from high ADF and NDF values.

Table 12. *The average RFV of annual ryegrass based on nitrogen fertilizer rates*

Nitrogen (kg ha^{-1})	Years

Mean	105.1	107.6	

** Values within the same columns followed by different small letters are significantly different based on Duncan's test at $P < 0.01$

Conclusions

Forage crops produced in Turkey are not enough for animals. Therefore, meat and milk production is low. Annual ryegrass is a high yield and high quality alternative fodder plant due to its high growth rate and ability to absorb nitrogen. Annual ryegrass, fertilizer is a forage plant with high yield. The production of forage crops may increase with the determination of suitable fertilizer feeds. Meat and milk production can be increased by increasing forage crop production.

In this research, we aimed to determine the optimum rate of nitrogen fertilization to achieve high yield and high quality forage from annual ryegrass (*Lolium multiflorum* L.) in the Central Black Sea Climate Zone in Turkey. According to the results of the research, we conclude that (i) it is possible to obtain high yield and high forage quality with nitrogen fertilization under the conditions of Central Black Sea Climate Zone, (ii) application of 250 kg ha^{-1} nitrogen rate is appropriate for high yield, (iii) increasing nitrogen doses do not affect the ADF and NDF rates, and (iv) yield decreases with 300 kg ha^{-1} nitrogen application rate but the crude protein yield increases. For the annual ryegrass, 250 kg ha^{-1} nitrogen rate is recommended to achieve high yield in the Central Black Sea Climate Zone in Turkey and possibly in similar ecological conditions.

(Received 7th Sep 2019; accepted 14th Nov 2019)

Abstract. Water deficit is one of the main environmental constraints affecting the yield of winter wheat. We quantified the effect of water stress on the grain yield of winter wheat in northern China, by using meta-analysis method. Database was obtained through 1921 experimental observations derived from 53 research articles of the 2000 to 2017 period. The results showed that the grain yield was significantly affected by the water and latitude. Grain yield and number of spikes (ha^{-1}) increased with the total water from 1001 m^3 ha^{-1} to 4000 m^3 ha^{-1}. However, grain yield and number of spikes did not increase further at higher rates (>4000 m^3 ha^{-1}). The grain yield, number of spikes and thousand grain weight were higher at a total water of 1-1000 m^3 ha^{-1}, than those at 1001-2000 m^3 ha^{-1}. Water stress had no significant effect on grain number per ear. The grain yield first increased with the latitude to a maximum of 36-37° and then decreased with increasing latitude (>37°). In conclusion, the maximum yield of winter wheat was attained at 36-37° latitude and 3001-4000 m^3 ha^{-1} total water.

Introduction

Water is essential for ensuring agricultural productivity. As a result of global warming, water shortages are becoming a major problem affecting the sustainable production of global crops (Sauer et al., 2010; Cai et al., 2011). Studies have shown that the frequency and intensity of droughts will be increased in future, which may lead to severe declines in future crop yield (Dai, 2012; Daryanto et al., 2016). The wheat (*Triticum aestivum* L.) which is the second largest cereal crop in the world is very susceptible to water stress (Reyer et al., 2013). Under water stress, plants tend to close leaf stomata to reduce transpiration loss, which adversely affects its physiological processes and nutrient uptake finally leading to the decreased yield (Rossini et al., 2013; Zhang et al., 2017a). The yield components (spike number, grain number, and grain weight) directly affect the formation of wheat yield. Moderate drought can affect grain weight, and severe water shortage will lead to an obvious decrease in the spikelets and grain numbers (Giunta et al., 1993). Moderate water stress occurred at a certain stage of wheat, after re-watering could make a positive effect on the growth and developments of wheat and its yield compensation. Therefore, it is not always necessary to maintain sufficient water throughout the growing period of wheat, which may cause excessive vegetative growth and lower the economic coefficient. Moreover, due to the uneven distribution of water resources in region and time in China, and the traditional irrigation rate is always excessive which is 1~1.5 times than the demand of crops, the problem of low water efficiency seriously restricts China's agricultural development (Du et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_433446

2010; Wei et al., 2018). Therefore, how to scientifically use water, how to improve water use efficiency, and how to formulate effective water-saving agricultural practices are major issues that needs to be urgently solved in current years.

The degree of water stress of wheat in different regions is different, and the influence of temperature on it can't be ignored. Temperature is critical for controlling winter wheat growth and yield (Asseng et al., 2011; Farhangfar et al., 2015). Water stress is expected to increase in the future, and water stress may reduce crop yields in many parts of the world (Qin et al., 2018). Increased temperature shortens the duration of the wheat growing season, resulting in a decline in yield, and Temperature differences in different regions also indicate differences in latitude. Latitude is an important geographic factor that significantly affects temperature, sunshine hours and crop growth (Liu et al., 2013b). However, under different degrees of water stress, the variation of wheat yield with latitude remains to be studied. Therefore, this paper studied the variation of wheat yield under different degrees of water stress, and hoped that the results could improve our quantitative understanding of the impact of water stress on wheat yield in China.

Meta-analysis can quantitatively synthesize existing test data, systematically analyze the combined effects and influencing factors of specific measures, and determine the general trends in many independent experiments (Hedges et al., 1999). At present, most of the experiments on wheat water stress focus on the scale of individual test sites, and the results are not consistent due to differences in factors such as climate, soil and planting system. Therefore, present study was designed to study the effect of water stress and latitude on the yield and yield components of winter wheat in northern China based on the meta-analysis method.

Materials and methods

Data collection and classification

Various English (Web of Science, Google Scholar, Science Direct, Wiley online library, Springer) and Chinese (CNKI) databases were searched by using keywords: wheat, yield, water stress, water deficiency, China and their combinations. The articles related with water stress on winter wheat in China from 2000-2017 were collected and screened on the basis of the following criteria: (1) area was located in northern China and year and latitude and longitude of the test site was clearly mentioned; (2) the test plot was a field whereas pot experiments were not included; (3) the experimental study had a water stress treatment and also a well-watered control; (4) only the water stress as treatment along with control, and yield data were collected in the multi-factor study, whereas, other treatments were routinely processed in the local field. As a result of screening, 53 research articles containing 486 sets of data and 1921 test observations were obtained (*Fig. 1*). The distribution of study site was shown in (*Fig. 2*).

The sum of the irrigation rate and rainfall during the growth period of wheat (if test areas have no canopy to protect from rainfall) was taken as the total water, in order to investigate the effect of different the total water on winter wheat yield the collected data were classified into 5 irrigation ranges (*Table 1*). The treatment with no external irrigation and rainfall was taken as the control in study (total water is 0). Latitude of each test site was divided into four categories as: 34-35°, 35-36°, 36-37°, >37°, and 34-35° was taken as the control. Moreover, as only one experimental site having latitude <34° was obtained, which is not enough for meta-analysis, so this latitude was excluded (Red sites in *Fig. 2*).

Study site

The study site is located at 34°-39° north latitude and 103°-121° east longitude, in the Loess Plateau and the North China Plain (*Fig. 2*). It is dry in winter and has four distinct seasons and the coldest is in January, the precipitation is 400-800 mm and is concentrated in July and August and it belongs to monsoon climate of medium latitudes and temperate continental climate. The soil is mainly cinnamon soil and loessial soil. The cinnamon soil has a neutral to slightly alkaline reaction, the middle and lower parts have the accumulation of clay particle and calcium. The loessial soil is soft soil and organic matter content is low, has strong calcareous reaction and good water permeability and cultivability.

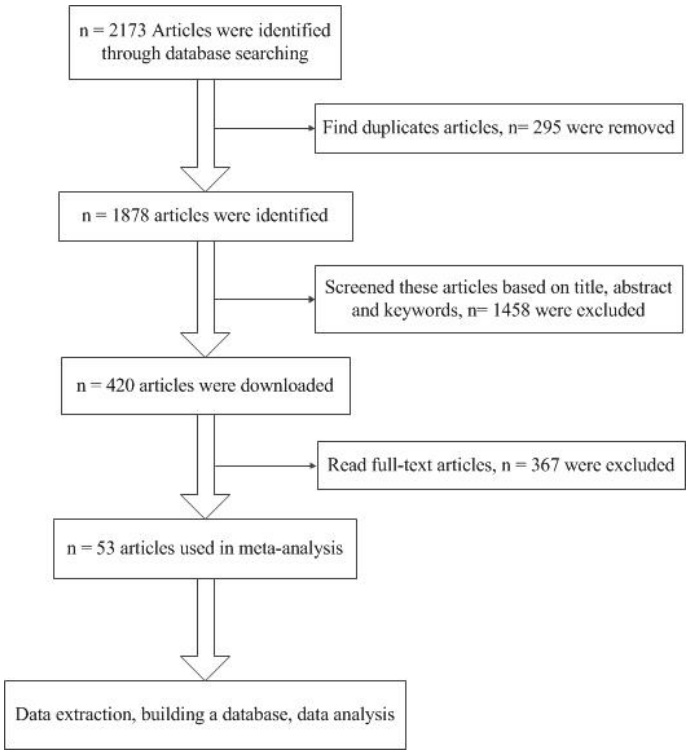

Figure 1. *Flowchart of the process of building the database and meta-analysis*

Data processing

Data analysis was performed using the integrated analysis method described by Hedges and Olkin (Hedges and Olkin, 1985). The effect size of water stress on GY, SN, GN and GW was evaluated by standardized mean difference (SMD), which is the relative value of the overlap between the two sets of data, and reflects the difference and representativeness between each other:

$$g = \frac{(\overline{X}_E - \overline{X}_C)}{S_{within}}\left(1 - \frac{3}{4(N_C + N_E - 2) - 1}\right) \quad \text{(Eq.1)}$$

$$S_{within} = \sqrt{\frac{(N_E - 1)(S_E)^2 + (N_C - 1)(S_C)^2}{N_E + N_C - 2}} \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_433446

$$V_g = (\frac{N_C + N_E}{N_C N_E} + \frac{d^2}{2(N_C + N_E)})(1 - \frac{3}{4(N_C + N_E - 2) - 1})^2 \quad \text{(Eq.3)}$$

where $\overline{X}_E$ and $\overline{X}_C$ are the average values of the treatment and the control group, g is standardized mean difference; N_E and N_C are the number of samples for the treatment and control groups; V_g is the variance of the independence study; S_E and S_C were the standard deviations of all comparisons between treatment and control, respectively, and S_{within} was the composite standard deviation within each study group. When studies do not report standard deviation, the missing standard deviation values were estimated by calculating the average coefficient of variation between each data set.

The combined effects and confidence intervals were calculated as follows:

$$W = \frac{1}{V_g} \quad \text{(Eq.4)}$$

$$M = \frac{\sum_{i=1}^{k} W_i g_i}{\sum_{i=1}^{k} W_i} \quad \text{(Eq.5)}$$

$$V_M = \frac{1}{\sum_{i=1}^{k} W_i} \quad \text{(Eq.6)}$$

$$SE_M = \sqrt{V_M} \quad \text{(Eq.7)}$$

$$LL_M = M - 1.96 * SE_M, \quad UL_M = M + 1.96 * SE_M \quad \text{(Eq.8)}$$

In the equation, W is the weight of each independent study; M is the weighted mean; VM is the variance of the combined effect; SE_M is the standard error of the combined effect; LL_M and UL_M are the upper and lower limits of the 95% confidence interval.

The relevant indicators in study were continuous variables, and the standardized mean difference after the integrated analysis represented the effect of different total water on wheat yield under water stress. Variables GY, SN, TGW and GN under different total water were calculated by the fixed- or random-effects model using software Revman (version 5.3, The Cochrane Collaboration, 2014). In this study, the inverse variance and the standardized mean difference were used as the effect size of the statistical measures and the meta-analysis, respectively. Random-effect model was used for moderate to high heterogeneity (X^2 > 50% and a chi-square P-value < 0.05) (Smithers et al., 2008). The heterogeneity test of the data in this paper reached a significant level (P_Q<0.05), so a random effects model was used. The difference between total water and the control was measured by the number of samples and the standard deviation. Confidence interval was finally generated by the effect size. If the 95% confidence interval size for a variable didn't cover 0, it indicated that irrigation treatment had a significant effect on yield compared to control. Engauge digitizer was used to extract data such as histograms in paper.

Results

Heterogeneity test analysis

The obtained data was analyzed by heterogeneity test and the results are shown in (*Table 2*). Results showed that the P-values of the meta-analysis of GY, SN and TGW were all less than 0.05, which indicated the data were statistically significant and can be used for further meta-analysis. However, the meta-analysis P-value for GN was greater than 0.05, which mean it was not statistically significant. All P-value of heterogeneity test were greater than 0.05 and I^2 was less than 50%, indicating that there was no significant heterogeneity in each group of data.

GY: grain yield; SN: spike number per hectare; TGW: thousand grain weight; GN: grain number per ear; W1, W2, W3, W4 and W5 were total water

Response of wheat yield to water stress

A meta-analysis of winter wheat yield in northern China showed that GY was affected by different total water (*Fig. 3*). The 95% confidence interval of GY effect size did not overlap with 0 indicating that the total water had a significant positive effect on GY. GY increased gradually with increasing the total water from W2 to W4. The GY reached the maximum at W4 and was decreased at W5. The GY at W1 was slightly higher than W2. The average increase of GY at W4 was 148% relative to control.

Response of wheat yield components to water stress

The results indicated the SN and TGW were significantly affected by total water (*Fig. 4*). The SN and TGW at W1 were higher than W2, and SN was increased by increasing total water from W2 to W4. The SN at W4 was 39.7% higher than control. The TGW was highest at W3, which was 79.7% higher than control. The 95% confidence interval of GN effect size contains 0, which indicate that different total water have no significant effect on GN.

Effect of latitude on winter wheat yield

It can be seen that winter wheat yield under different total water responded differently at different latitudes (*Fig. 5*). The GY at total water of W0, W2, W3 and W4 was significantly positive effect by increasing the latitudes (35-36°, 36-37°, and >37) as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_433446

compared to 34-35° (control). At W0, W2, W3 and W4, the grain yield was first increased with increasing the latitude and then decreased with the highest GY was recorded at 36-37° latitude. However, at latitudes of 35-36° and > 37°, the GY of W5 (total water >4000 m^3 ha^{-1}) has a negative impact, as compared to 34-35° (control). The effect of latitude 36-37° was non-significant on GY at W5.

Discussion

Water plays a pivotal role in nutrient availability and other physiological processes, and a major determinant of crop yield (Adu et al., 2018). It is well known that differences in water stress can lead to differences in yield. In this study, the grain yield, spikelet numbers and thousand grains weight of winter wheat were decreased with the decrease of the total water. Previous reports have shown that wheat yield decreased with increasing the degree of water stress (Zhang et al., 2016; Jin et al., 2018). Plants responds to water stress by closing the stomatal pores in order to reduce transpiration losses, resulting in insufficient photosynthesis, reduction in crop growth, biomass accumulation and yield (Guerfel et al., 2009; Mäkinen et al., 2018). Studies have shown that spikelet numbers, grain number and thousand grains weight were directly related to wheat yield and reduced under drought stress (Shamsuddin, 1987; Kiliç and Yağbasanlar, 2010). Moderate drought affects post-anthesis biomass production and transport of photosynthetic products to kernels, thereby affecting grain weight and reducing grain yield (Liu et al., 2016). Therefore, the yield was decreased with decreasing the total water from W4 (3001-4000 m^3 ha^{-1}) to W2 (1001-2000 m^3 ha^{-1}). However, the effect values of grain yield, spikelet numbers and thousand grains weight at W1 (1-1000 m^3 ha^{-1}, severe water stress) were greater than W2 (1001-2000 m^3 ha^{-1}). It may be due to the reason that drought triggers the antioxidant activity in plants and up-regulated the function of photosynthesis organs, improve leaf chlorophyll and Rubisco content through improved leaf water potential and improved photoprotection (Crafts-Brandner and Law, 2000; Abid et al., 2016). The increase in yield under W1 as compared to W2 may be related to the amount of nitrogen applied and the efficiency of nitrogen use. Proper nitrogen supply can increase cell number and volume, increase leaf photosynthetic rate and WUE, and mitigate the effects of drought stress. At low tissue water potential, nitrogen reduced the effects of drought stress on grain yield by maintaining metabolic activity, increasing leaf water potential, membrane stability index, and antioxidant activity (Zhang et al., 2007; Abid et al., 2016). Nitrogen use efficiency is generally increased in crops under water stress and higher nitrogen

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_433446

application rates increases crop drought resistance (Zhang et al., 2017b). Therefore, suitable application of water and nitrogen could enhance material accumulation, improve photosynthetic capacity, and promote grain formation. Although the data of normal nitrogen application in each experiment were extracted from this study, however, it is still impossible to rule out the effect of different nitrogen application rates on the results.

In addition, root distribution (> 0.8 m) of wheat in deep soils is critical for nutrient and water uptake, affecting wheat growth and grain yield (Dai et al., 2014; Xu et al., 2016). On the one hand, the response of wheat root system to water shortage is reduced redundancy of top root growth and increased growth of deeper roots (Song et al., 2009; White and Kirkegaard, 2010), thereby enhancing the ability of roots to absorb nutrients and water (Kaisermann et al., 2017). Some microbial groups can increase plant drought tolerance by increasing root biomass and depth to absorb water and nitrogen from deep soils to maintain growth and maintain yield (Azarbad et al., 2018; Liu et al., 2018). Under the condition of water shortage, the water evapotranspiration was decreased in the aboveground part, and more photosynthetic products were stored in the root system to improve water use efficiency. Under drought stress, nitrogen deficiency leads to increased vertical root permeability, reduced top root length density, and increased roots in deeper soil, thereby affecting grain yield (Wang et al., 2014; Xu et al., 2016). Therefore, when the total water is W1, the wheat yield will increase slightly, which may be the result of the wheat itself coping with stress, enhancing photosynthesis, increasing water and nitrogen use efficiency, and increasing the growth of deep roots.

It is well known that wheat production increased with increasing irrigation rate within a certain range, but as irrigation reached a certain level, WUE and yield were decreased (Trout and Dejonge, 2017; Jin et al., 2018). This study showed that the grain yield, spikelet numbers and grain weight of winter wheat were decreased by increasing total water from W4 to W5. Studies have shown that excessive irrigation reduced wheat yield mainly because of leaching of root nitrate due to excessive irrigation, resulting in insufficient nitrogen supply, causing premature root senescence and inhibiting photosynthesis, thereby reducing water and nitrogen use efficiency (Agami et al., 2018). Similarly, in loamy silty soil, excessive water tends to cause hypoxia in the root zone of the crop, thereby damaging the roots and reducing yield (Mäkinen et al., 2018). In addition, excessive irrigation of wheat can easily lead to lodging, leaf rust or mildew, affecting normal wheat growth (Bennett, 1984; Roelfs et al., 1992).

Previous studies showed that drought stress significantly reduced spikelet numbers, grain numbers and grain weight of wheat, and reduction in grain numbers had the greatest direct impact on grain yield (Simane et al., 1993). However, in the present study, water stress had no significant effect on grain numbers. Wheat grain yield formation and grain number are genetically controlled but also affected by the environment (Wang et al., 2014). The drought resistance and yield potential of different varieties were different in the 53 collected studies. For example, water stress was applied during wheat microspore stage, and drought resistant wheat variety SYN604 was having more number of grains than Sundor which is drought resistant variety (Ji et al., 2010). In addition, the stage of differentiation of young spikes before flowering is the key period for the formation of GN, this period determines the number of fertile flowers in wheat spikelets, which determines GN. Studies have shown that during meiosis of pollen development in wheat, water stress blocks the relationship between pollen grains and tapetal layer during microspore stage, degenerates the filaments, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_433446

the pollen grains cannot accumulate starch, resulting in nutrient deficiency and affecting pollen development, leads to a decrease in GN (Saini et al., 1984; Cattivelli et al., 2008). Moreover, under severe water stress, the use of male sterile materials to study the effects of wheat microspores stage on GN found that GN were decreased by 16.4% (Ji et al., 2010), even under mild water stress, starch accumulation and sucrose transport in the ovary are also severely affected. It indicated that the development of ovary under water stress had a certain effect on GN. Some studies have shown that under water stress, the cell wall invertase viability of sucrose transport in wheat anthers is related to pollen sterility, which is characterized by decreased cell wall invertase viability, blocked sucrose transport, and a large accumulation of sucrose in anthers, causes changes in the metabolism of other soluble sugars leading to infertility (Dorion et al., 1996; Koonjul et al., 2005; Ji et al., 2010). It can be seen that the reason that the water stress has no significant effect on GN may be due to the combined effects of variety and water in this study.

Latitude is an important geographic factor which affects temperature and solar radiation, thus affecting the duration of crop growth and yield (Liu et al., 2010, 2013b). This study showed that under different irrigation rate (except >4000 m^3 ha^{-1}), with the increase of latitude, the yield was first increased and then decreased. The maximum yield was attained at 36-37°. Similarly, Li (2010) indicated that with the increase of latitude in Henan Province, the yield of different wheat varieties was increased first and then decreased. Due to the large latitude span of China's wheat growing areas, the temperature difference is large, and the effect of temperature changes on wheat yield is not negligible (Asseng et al., 2011). In this study, the yield at latitude 35-36° (except for >4000 m^3 ha^{-1}) was lower than 36-37°, which might be due attributed to the high temperature at low latitude and increasing temperature resulting in decrease of yield. There are significant changes in climatic variables at different altitudes, which in turn affect the development and yield of winter wheat (Xiao et al., 2008). Dryland wheat yield is highest at medium elevations with sufficient precipitation and mild temperatures. At high elevations, temperatures are too low to allow the crops to mature with fewer yields.

Higher temperatures shorten the wheat growing season, which leads to a shortening of the grain filling period and a decrease in wheat yield (Dias and Lidon, 2010; Xiao et al., 2010; Asseng et al., 2011). The decline in wheat yield with increasing temperature is mainly due to less spikelet numbers (Asseng et al., 2015). Elevated temperatures also increase evapotranspiration (Trnka et al., 2012; Liu et al., 2013a), reducing soil water content, increasing water stress, and thereby reducing wheat yield (Qin et al., 2018; Li et al., 2019). At high altitude, the wheat yield might be affected by various other interacting factors such as region, climate, variety, soil texture (Tapley et al., 2013; Daryanto et al., 2016; Zhang et al., 2017b).

Conclusion

The results from meta-analysis method showed that the grain yield, spikelet number and grain weight of winter wheat were significantly affected by the total water, whereas, effect of total water was not significant on grain number. Yield and yield components were not increased by increasing total water from W1 (1-1000 m^3 ha^{-1}) to W2 (1001-2000 m^3 ha^{-1}). Grain yield and spike numbers were increased by further increasing total water with maximum at W4 (3001-4000 m^3 ha^{-1}). At W4, grain yield

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_433446

and spike numbers were 148.5% and 39.7% higher as compared to control, indicating that W4 was optimal total water. Thousand grain weight was highest at W3 (2001-3000 m^3 ha^{-1}) with 79.7% increase as compared to control (total water is 0). Under different total water, grain yield was increased with increasing latitude from 35-36˚ to 36-37° and then decreases at latitude > 37˚, and the specific reasons for decline in yield at high latitude remain to be further studied.

Abstract. Evaluation and monitoring of forest structure, diversity, and biomass carbon dynamics are essential for effective forest biodiversity and carbon conservation. Using inventory data of 174 field plots with a size of 400 m^2, this study estimated the forest structure, species diversity, growing stock characteristics and biomass carbon of the South West Region of Guangxi Zhuang Autonomous Region of China. Our results showed that a total of 198 species belonging to 51 families, and 128 genera were found. The results of different diversity indices showed a greater species variation across the forest. Furthermore, different tree attributes were recorded for forest structure. In this regard, the mean tree height was 10.3 m, while the mean basal area was 5.94 m^2 ha^{-1}. The mean growing stock volume was 104.14 m^3 ha^{-1}, and the average biomass carbon was 110.36 Mg ha^{-1}. Among the dominant species, the maximum importance value index (14.81%) and basal area (17.3 ± 3.03 m^2 ha^{-1}) were recorded for *Pinus massoniana*. While the maximum growing stock volume (116.4 ± 20.2 m^3 ha^{-1}) and biomass carbon (114 ± 18.3 Mg ha^{-1}) were found in the *Styrax subniveus*. Our results also highlighted that the basal area is a strong predictor of growing stock volume and biomass carbon compared to diameter and height. Moreover, the correlation between biomass carbon and diversity indices indicated a weak positive correlation, which provided the insight that high-value carbon- diversity forest can be achieved.
Keywords: *forest structure, biomass carbon, Tree diversity and density, carbon sequestration, carbon-diversity relation, Guangxi region*

Introduction

Forests are the largest contributors to territorial ecosystems on Earth and play a significant role in providing economic benefits as well as ecological services (Eckert, 2012; Meng et al., 2014). Forests are integral components of the global carbon cycle that take up and release a substantial amount of carbon (Wang et al., 2018). The regulation of atmospheric carbon concentration through forest carbon stock has been identified as a major political target to mitigate global climate change (Grassi et al., 2017). Forest ecosystems play an important role in the global carbon cycle (Li et al., 2017). While the estimation of carbon from forests brings an important understanding of global warming (Sierra et al., 2007). Globally, forests particularly tropical and sub-tropical forests are the center of biodiversity and carbon storage (Sullivan et al., 2017). About 60% of terrestrial

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_447467

photosynthesis takes place in the tropical forest (Field et al., 1998; Liu et al., 2015). This region has been recognized as a significant hotspot for global carbon source and sink and biodiversity (Bazzaz, 1998).

Over the past two decades, there has been a strong emphasis on the role of biodiversity in ecosystem properties, processes, and services to enhance carbon sequestration and storage (Naeem et al., 2009). Climate change and habitat loss are the two major components for the loss of global biodiversity (Thomas et al., 2013). Similarly, changes in the land use of forests are leading to emission sources of carbon (Matthews et al., 2014). Therefore, different incentives such as United Nation (UN) REDD + have emerged for the protection and conservation of high carbon and diversity areas (Robbins, 2016). The protection of forests for carbon and biodiversity depends on the relationship between biomass carbon and tree diversity. The positive relationship between biomass carbon and tree diversity would indicate synergies whereas a negative relationship would indicate difficult tradeoffs (Meng et al., 2014). However, in case of the absence of any relationship, the optimal solutions are required towards an understanding of the distribution of biomass carbon and biodiversity (Thomas et al., 2013).

The forest structure determines the functions of a forest; therefore, forest structure provides the fundamental bases for the formulation of forest management regime aimed at specific objectives (Warfield, 2006). Forests structural attributes such as stem density, growing stock volume, stand basal area, diameter, and tree height are the important variables for the management of forests (Meng et al., 2016). In addition, forest structural diversity, i.e., species diversity, tree size diversity, and position diversity, is more important to inform forest management (Corona, 2016). A notable example is structured-based forest management. Additionally, many authors documented the positive relationship between carbon sequestration and structural diversity (Noumi et al., 2018). Therefore, quick acquisition of forest structural variables, structural diversity indices, and forest carbon stocking is urgent for sustainable forest management.

The methods used to derive forest attributes include the conventional method and remote sensing method. National or regional forest field inventories data are also used for the measurement of different forest stand variables. In China, there are three major types of forest inventories including the national forest inventory, the forest management planning inventory, and the forest design operational inventory, which are used to derive such precedent forest attributes (Lei et al., 2009). However, regardless of the type of forest inventories, it is labour-cost, time-consuming and expensive.

In China, the researchers mainly focused on the measurement of carbon stock in different forest types (Dixon et al., 1994; Fang et al., 2007; Zhang et al., 2013). Similarly, forest structure and structural diversity have been documented by various authors (Meng et al., 2016). However, there is a lack of integrated information regarding the forest structure, species composition and diversity, and carbon dynamics. Therefore, the objective of our study is first to derive the forest attributes, including forest variables and forest structural diversity indices based on conventional forest inventory plots, mainly focused to answer the following questions: (1) what is the forest structure and the species diversity?; (2) how the carbon is distributed among the different diameter classes, among the tree height, mean diameter and basal area, and which attribute shaped the biomass carbon strongly; (4) what is the relationship of species diversity and biomass carbon?; (5) what is the status of structural attributes and biomass carbon potential of dominant tree species?

Materials and methods

Study area

The field statistics were obtained from the Experimental Center for Subtropical Forestry of the Chinese Academy of Forestry of Southwest of the Guangxi Zhuang Autonomous Region of China. The study site is the tropical research center situated in Pingxiang City (Píngxiáng Shì). The latitude and longitude extend from 21°57′ N to the 22°16′ N, 106°41′ E to 109°59′ E, respectively (*Fig. 1*). The area lies in the southern subtropical warm and semi-humid monsoon climate that is characterized by dry and wet season with a total mean annual precipitation ranging from 1200 to 1500 mm and annual evaporation is 1261-1388 mm. The relative humidity is 80-84%, with an average annual air temperature of about 20.5-21.7 °C, and ranges from minimum to maximum about 13 to 28 °C. The landscape is characterized by low mountain elevation ranging from 250-800 m and a slope range from 25 to 30%. The dominant parent rocks are granite, purple sand shale, and sandstone. The soil for the forest is developed by granite bricks and mostly red and purple in color (Kang et al., 2006; Meng et al., 2014; Ming et al., 2014). The natural vegetation includes the subtropical forest with a mixture of evergreen and deciduous species (Bruelheide et al., 2011). This region is rich in species diversity and the area is generally mixed but the dominant species of the forest vegetation are *Cunninghamia lanceolata*, *Magnoliaceae glanca, Illicium verum, Pinus massoniana, Betula alnoides, Castanopsis hystrix,* and *Quercus griffithii, Erythrophleum fordii, Castanopsis hystrix,* which are hardwood and have high economic value for timber (Lu et al., 1999; Bruelheide et al., 2011; Tang et al., 2012; Zhu et al., 2013).

Research design and field inventory

For data collection, overall 174 sample plots were laid out in the forest. The size of each sample plot was 400 m^2. In each sample plot, the distance and bearing of each sample plot center were measured with each stem that was located within the radius of the circular plot, and each species was counted. The plant species were identified and their diameter at breast height (1.3 m from the above-ground) was recorded. On the basis of the size of the diameter, the classification was made. The values of stem density and relative stem density, basal area, and relative basal area and importance value index (IVI) were calculated for dominant plant species. The species diversity indices and height of the trees at the plot level were measured. From the height (m) and diameter (cm), the volume (m^3 ha^{-1}) of the tree was measured. The volume was converted into biomass (Mg ha^{-1}). From the biomass value, the carbon content was estimated using the Intergovernmental Panel on Climate Change IPCC (2007) (Change, 2007; Keenan et al., 2015) guidelines. Biomass was then summed across all the plots to obtain carbon stock (Mg ha^{-1}).

Data analysis

Based on the collected information at the plot level, the data was analyzed for the various structural attributes such as diameter, basal area, and density. The relative stem density, basal area, relative basal area, and the importance value index (IVI) were assessed using *Equations 1-3*.

$$\text{Relative density (RD)} = \frac{\text{Number of particular species}}{\text{Number of all species}} \times 100 \quad \text{(Eq.1)}$$

$$\text{Relative basal area (RB)} = \frac{\text{Basal area of a particular species}}{\text{Basal area of all species}} \times 100 \quad \text{(Eq.2)}$$

$$\text{Importance valur index (IVI)} = \frac{\text{RD} + \text{RB}}{2} \times 100 \quad \text{(Eq.3)}$$

In order to compute the data for the description of the diversity, different community indices such as Shannon Wiener Diversity Index (SHI), Pielou Diversity Index (PI), and Simpson Diversity Index (SII) were used through *Equations 4-7*. (Magurran, 2013; Naidu and Kumar, 2016).

$$\text{SHI} = -\sum_{i=1}^{n} pi \cdot \ln(pi) \quad \text{(Eq.4)}$$

$$\text{PI} = \frac{\text{SHI}}{\ln(\text{S})} \quad \text{(Eq.5)}$$

where SHI is the Shannon Wiener Diversity Index and S is the total number of species across all samples in a dataset.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_447467

$$SII = 1 - \sum_{i=1}^{n} pi^2 \quad \text{(Eq.6)}$$

Statistical Gini coefficient (GC) is one of the components of forest structure used for the distribution of tree diameter in a forest by the indicator of tree size variation (McElhinny et al., 2005). This was measured using *Equation 7:*

$$GC = \sum_{t=1}^{n} (2t - n - 1)\text{bat} / \sum_{t=1}^{n} ba(n-1) \quad \text{(Eq.7)}$$

where *ba* is a basal area for the tree in rink *t* (m^2 ha^{-1}), t is the rink from 1 to n number. Gini coefficient ranged from 0 to 1.

For biomass carbon estimation, we first calculated the volume of the tree (*Eq. 8*) then the volume was converted into biomass using the available regression models to estimate plant biomass (*Table 1*) (Wang et al., 2015; Du et al., 2015) The biomass was converted into carbon stock in the upper story vegetation using a conversion factor of 0.5 which indicates 50% of total plant biomass is equal to carbon stock (*Eq. 9*), this conversion factor has been used worldwide (Ahmad et al., 2019; Brown and Lugo, 1982; Xiao et al., 2003; Ahmad and Nizami, 2015).

$$Volume\ of\ tree = A \times H \times FF \quad \text{(Eq.8)}$$

$$\text{Biomass carbon} = \text{Total biomass} * 0.5 \quad \text{(Eq.9)}$$

Table 1. *Allometric regression models used to estimate biomass*

S. No	Species	Model
1	Eucalyptus	$W_T = 0.138D^{2.436}$
2	Quercus	$W_T = 0.174D^{2.39}$

Statistical analysis

R package vegan was used for the calculation of the diversity indices (Team, 2013; Muneer et al., 2019) The variation in tree diameter, tree height, stem density, basal area, and biomass and carbon stock in the respective diameter classes (class-1 (5-11 cm), class-2 (12-16 cm), class-3 (17-28)) were determined by analysis of variance (ANOVA) using Statistix 8, version 8.1). Regression models were developed to study the relationship of tree height, diameter, and basal area with volume and biomass carbon by using Origin 2018. The correlation between respective diversity indices and biomass carbon was carried out using different correlation analyses such as the linear regression, Pearson correlation, and Spearman rank correlation.

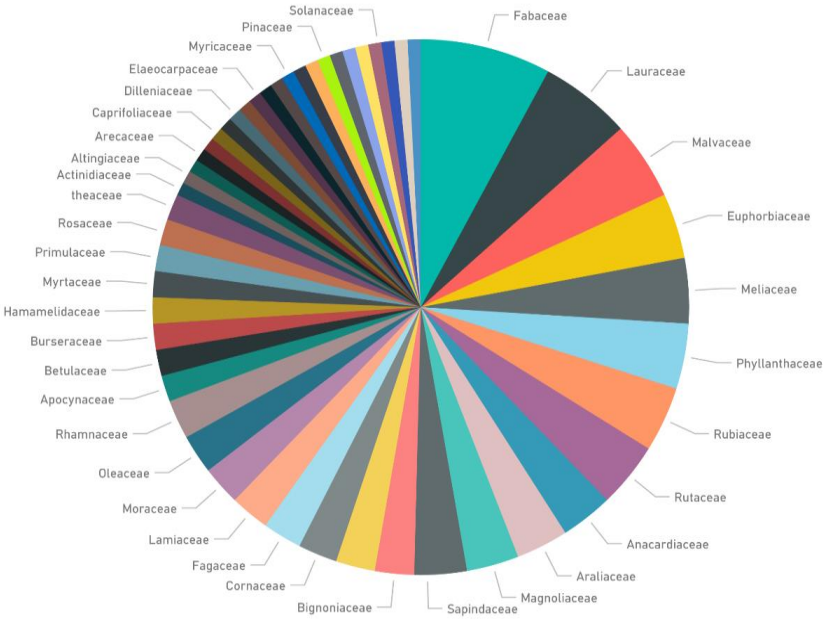
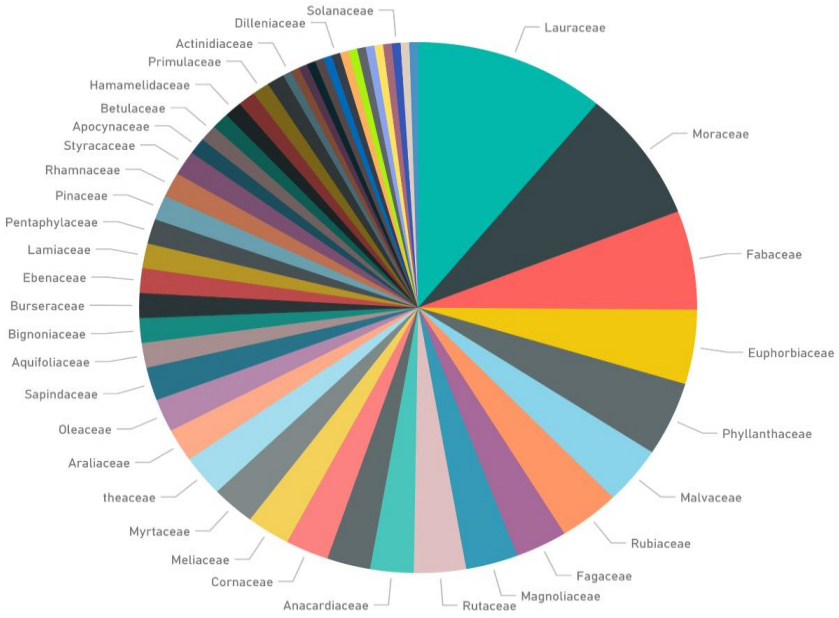
Results

Forest structure and species diversity

The results of the present study revealed that in this region 128 genera (*Fig. 2a*) and 198 species (*Fig. 2b*) belonging to 51 families were found. Among the 51 plant families, the highest number of genera i.e., 10, 7, 6, and 5 were found in *Fabaceae*, *Lauraceae*, *Malvaceae,* and *Rubiaceae* respectively. While the highest number of species were found in family Lauraceae, Moraceae and Fabaceae about 22, 16, and 12 respectively. Family Phyl*lanthaceae* and *Euphorbiaceae* each consisting of 5 genera and 9 species. In contrast, 16 families consisting of single genus and species.



(a) No. of the genus in respective families



(b) No. of species in respective families

Figure 2. *The relative contribution of the number of genera (a); and number of species (b) belonging to their respective families*

Regarding the species diversity at the plot level, it showed that SHI varied between 0 to 2.67 with a mean value of 1.034, while the SII varied between 0 and 1 with a mean value of 0.478. The PI value was found at the range of 0 and 1 with a mean value of 0.582 and the GC was in the range of 0 and 1 with a mean of 0.384 (*Fig. 3*). For more detail see *Appendix* (*Table A1*).

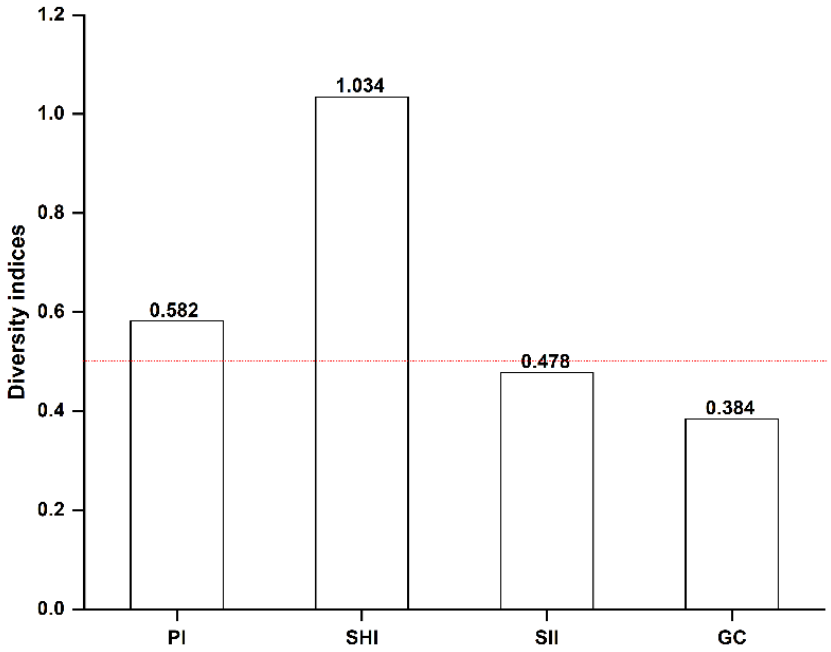

Figure 3. *Diversity indices for all sampling plots*

Growing stock characteristic and biomass carbon

This study revealed that in the tropical forest of Pingxing city, the average diameter varied significantly between the different diameter classes. The highest mean diameter was recorded in class-3, while the lowest was found in class-1. The significant higher value for the height was found for class-3 and the lowest was recorded in class-1. The average mean height was 10.3 ± 3.0 m. Mean density varied between 592.13 ± 280.24 to 955.70 ± 538.66 (trees ha^{-1}). A statistically lower stem density was recorded in the diameter class-1 compared to class-2 and class-3. While, the value of the basal area, stem volume, total tree biomass, and biomass carbon were recorded significantly higher in the class-3, while these were significantly lower in class-1 (*Table 2*).

The regression relationship of the basal area, diameter, and height with the volume and biomass carbon is presented in *Table 3* and *Figure 4*. The results of the analysis revealed that the basal area had a highly positive correlation with volume and biomass carbon. In contrast, a weak correlation was observed for diameter with volume and biomass carbon. Furthermore, the correlation of height with volume and biomass carbon was also found weak. These findings clearly explained that the basal area is the best predictor of growing stock and biomass carbon compared to stem diameter and tree height.

The relationship between diversity indices and biomass carbon is given in *Table 4*. It showed the positive but very weak correlation for all indices i.e., Pearson correlation, linear regression, and Spearman rank correlation.

Table 3. *Regression analysis between the basal area with volume and biomass carbon, diameter with volume, and biomass carbon and height with volume and biomass carbon*

Structural attributes, growing stock and biomass carbon of the dominant species

The results of various structural attributes, like stem density, basal area, relative stem density, relative basal area and importance value index (IVI) for individual dominant tree species (12) are given in *Table 5*. The results revealed that among the different dominant species, the highest stem density, basal area, relative stem density, relative basal area, and importance value index (IVI) were recorded for *Pinus massoniana.* Regarding growing stock characteristics, its maximum mean diameter was found for *Illicium verum* followed by *Styrax subniveus*, while the mean height was found the highest for *Styrax subniveus*, *Illicium verum.* The maximum growing stock volume and biomass carbon was observed for *Pinus massoniana* followed by *Manglietia hainanensis* (*Table 6*).

The results of the percentage distribution of different growing stock characteristics that include diameter, height, density, basal area, volume, and biomass carbon are given in *Table 7*. The results depicted that *Illicium verum* share a maximum percentage for diameter, while the highest percentage value for height was recorded for *Styrax subniveus*, for stem density, basal area, and biomass shared highest percentage value by *Pinus massoniana,* similarly, for volume the maximum percentage value was recorded for *Styrax subniveus*.

Discussion

The tropical forest that covers only 7-10% of the earth's land surface, is the hotspot for carbon storage and biodiversity (Bonan, 2008). and stores a significant part of global carbon and biodiversity (Poorter et al., 2015) In this study, we examined different structural attributes, species diversity and biomass carbon of the tropical forest in Guangxi Zhuang Autonomous Region of China. Our results reported a total of 198 species belonging to 51 families. Among the different families, family *Lauraceae* was the richest family with respect to the number of species followed by family *Moraceae* and *Phyllanthaceae*. The mean values of different diversity indices (*Fig. 2*) showed a greater variation in species across the forest. Similarly, at the plot level, the variation in the values of diversity indices pinpoints the diverse nature of the forest. The results of a number of species in this study are consistent with the results of the Dinghushan

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_447467

tropical forests of China (Ostertag et al., 2014). In comparison, our results fall in the acceptable range of species numbers (192-240) and families (46-50) reported from the tropical forest in different regions of Colombia, Sri Lanka and Thailand. However, our results represent a higher number of species and families with respect to the tropical forest of different region of Taiwan, Puerto Rico, Brazil, India, and USA, while a lower species and family numbers with respect to the tropical forest in different regions of Malaysia, Ecuador, Thailand, Cameroon, and the Republic of Cango (Ostertag et al., 2014). The average stem density in this study area varies from 50 to 2525 with a mean value of 812.17 ± 111.75, this value of stem density is greater from the reported value of the tropical forest of Mudumalai, India, but lower from the reported values across the tropical forest. The mean basal area (15.94 m^2 ha^{-1}) and biomass carbon (110.36 ± 31.70) of this study fall in the range of mean basal area and biomass carbon across the regions as reported in the previous study (Ostertag et al., 2014).

Stock is a key parameter for forest management as well in measuring biomass carbon of forest (Ahmad et al., 2019; Somogyi et al., 2008). Globally, national forestry inventories data are used for assessing forest growth. The FAO used national forest inventory data for global forestry statistics (FAO, 2010). In measuring forest growing stock and biomass carbon, tree height and diameter are the key components. Most of the volume tables are based on the height and diameter of a tree (Ahmad et al., 2019). But these tables represent the individual tree measurement. However, individual tree measurement is a time-consuming process that needs more financial and physical efforts. Therefore, there is a need for direct measurement of growing stock volume and biomass carbon. In this study, we test the scope of the tree height, diameter and basal area for the direct measurement of a tree growing stock volume and biomass carbon. The results that whether tree height, tree diameter, and basal area are in the best predictor of growing stock volume (GSV) and biomass carbon are presented in *Table 3*. The results in the table showed a strong positive correlation with the growing stock volume and biomass carbon with a coefficient of determination (R^2) value of 92 and 91, respectively. In the case of diameter, growing stock and biomass carbon relationship, there is a positive correlation, but the value of R^2 (0.40 and 0.38) represents a weak relationship compared to the basal area (*Fig. 3*) Similarly, height based growing stock volume and biomass carbon relationship also revealed a positive correlation, but not as strong as basal area based. These results clearly suggest that the basal area is the best predictor of growing stock volume and biomass carbon. Basal area is widely used in assessing forest growing stock and biomass carbon in the tropical wet and dry forest (Balderas Torres and Lovett, 2012).

Globally conservation measurements are emerging for forest biodiversity conservation with carbon management. The UN REED + policy helping in the establishment of safeguard areas with a high carbon stock and storage potential (Robbins, 2016). The potential of these safeguards areas for biodiversity and carbon conservation depends on the relationships between carbon and species diversity (Robbins, 2016). A positive correlation of species diversity indicates a potential interaction, while a negative would indicate “difficult trade-offs” (Gardner et al., 2012). Furthermore, the absence of any relationship would suggest different solutions for the establishment of safeguards areas (Thomas et al., 2013). Our present findings contrast with the reported positive diversity-biomass relationship (Cavanaugh et al., 2014). That tropical forests are positively but weekly correlated with species diversity in Asia. This presence of a weekly positive relationship indicates the driving mechanisms of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_447467

diversity-carbon relationships are scale-dependent or could be due to the environmental variations acting at a larger scale (Chisholm et al., 2013).

Conclusion

Assessing forest structural attributes, species diversity, growing stock characteristics, and biomass carbon is fundamental for effective forest carbon and biodiversity management. The results of the analysis of 174 field plots showed that the forest in the Guangxi region of China showed great variation in species diversity. The finding indicates that the forest vegetation had a large carbon mitigation potential. The basal area based growing stock and biomass carbon relationships highlighted that basal area is the best predictor for growing stock volume and biomass carbon compared to tree height and diameter. Thus, we suggest the use of the basal area for direct measurement of growing stock volume and biomass carbon to reduce both the financial and physical efforts. The positive but weak relationship of diversity indicates that a high carbon and biodiversity conservation forest can be achieved, that needs a further small scale and large-scale research. Our findings concluded that the forest of the Guangxi region, South China has not only a greater diversity but also has greater carbon mitigation potential.

(Received 7th Sep 2019; accepted 15th Nov 2019)

Abstract. Rice seedlings have a different response to drought stress intensity and duration, which reduces rice seedling growth and grain yield. In the year 2015, a greenhouse experiment was conducted to ascertain the effect of the relationship between drought stress intensity, duration, and drought resistance on rice seedling. Yangliangyou 6 ("super" rice variety) and Hanyou 113 (drought-resistance rice variety) were subjected to polyethylene glycol (PEG6000)-induced water stress. Drought stress intensities i.e. 10%, 15%, 20% and 25% PEG6000 with 4 d, 8 d or 12 d after emergence at 21 days was imposed, respectively. Control (0% PEG6000) was used for comparison. Drought dehydration factor (DDF) and root induction factor (RIF) increased with drought duration. In each drought stress duration, RIF, drought tolerance factor (DTF) and DDF were raised under moderate drought stress intensity (10-15% PEG6000), the advantage of DDF and DTF was shown at 12 d drought duration under severe drought stress intensity (20-25% PEG6000). Thus, drought stress intensity significantly negatively affected rice seedling growth compared with drought stress duration. Improvement in DDF and RIF enhanced rice seedling growth under moderate drought stress conditions, while severe drought stress positively stimulated DDF and DTF which resulted in improved rice seedling growth.
Keywords: *polyethylene glycol, drought tolerance, drought dehydration, root induction, dry mass*

Abbreviations: ARI: adversity resistance index; CDRF: comprehensive drought resistant factor; CK: control treatment (0% polyethylene glycol 6000 solution); Co: conductivity; DDF: drought dehydration factor; DM: dry mass; DTF: drought tolerance factor; HY113: Hanyou 113; LA: leaf area; LRL: longest root length; MLL: mean leaf length; MLW: mean leaf width; PEG: polyethylene glycol; Pro: proline; RDM: root dry matter; RIF: root induction factor; RN: root number; RV: root volume; RWC: relative water content; SDM: shoot dry matter; SH: seedling height; SS: soluble sugar; TDM: total dry matter; YLY6: Yangliangyou 6

Introduction

Rice (*Oryza sativa* L.) is the most important staple food crop for about 33% of people worldwide (Ye et al., 2013). Rice is grown under traditional flooding irrigation (Yang et al., 2008; Ye et al., 2013), but the shortage of water resources coupled with seasonal drought spell has limited rice production. Thus, stimulated the development of upland rice planting (Sun et al., 2012; Ye et al., 2013). Upland rice planting area has increased to 20 million ha worldwide and the planting area accounted for 12.7% of total rice planting area (Technology and Information Center of China Rice Research Institute, 2016). In China, due to limitations of hilly area, water shortage, suitable planting areas for upland rice were 5.3 million to 6.7 million ha (Technology and Information Center of China Rice Research

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_469486

Institute, 2016). But rice dry cultivation is still facing some challenges such as, variety selection, soil moisture conditions required for sowing and maintaining seedling growth. To overcome these challenges, it is important to improve planting technologies of upland rice to achieve optimistic resource utilization.

In current agricultural production systems, super rice variety (rice yield potential was about 10.5-12.0 t ha^{-1} and increased by 8-15% compared with ordinary hybrid and inbred varieties. This increment in yield was associated with more number per unit land area and large panicle size (Huang et al., 2011). Drought tolerance rice variety (the yield potential and good quality could be maintained under water-limited environments, as well as the capacity of water-saving or drought resistance (Luo et al., 2010)) were used in upland rice system to increase economic benefits. Upland rice is directly seeded by less water application which improved germination and emergence of rice seeds, and followed by no water application leading to seedling damage or death and consequently yields loss (Xu et al., 2017). Hence, it is necessary to define what modes of drought stress (different drought stress intensity and duration) had less effect on rice seedling during seedling stage. Also to identify drought tolerance of rice seedling growth in upland rice system. Rice dry cultivation mainly caused drought stress which impacted on rice seedling growth. Drought stress can induce various changes in morphological, metabolic and/or physiological functions and severely restrict both elongation and expansion of rice seedling (Kusaka et al., 2005). Drought stress also produced the reactive oxygen species (ROS), which could damage plant by lipid peroxidation, protein degradation, DNA fragmentation and ultimately cell death (Zhang et al., 2015). With increasing drought stress, shoot growth, root expansion and physiological function of rice seedling decreased (Pirdashti et al., 2003; Zheng et al., 2016). Increasing drought stress duration can restrain shoot growth of rice seedling and reducing yield and yield components (Asai et al., 2009; Duan et al., 2017). This indicated that drought stress intensity and duration had a negative effect on rice seedling growth. However, the effect of drought stress intensity coupled with duration on the rice seedling growth during seedling stage (after reviving stage) is lacking. Plants can avoid drought stress through two major mechanisms including drought dehydration and drought tolerance under drought stress conditions (Liu et al., 2003; Yue et al., 2006). Drought dehydration via using morphological plasticity of crops raised the water content of plant; drought tolerance indicated that crops could tolerate water loss and maintain certain metabolic or physiological processes such as, osmotic adjustment and antioxidant ability (Bandurska et al., 2003; Nazarli et al., 2014). Drought dehydration plays a crucial role in long-term drought duration, while drought tolerance had an obvious response to drought stress intensity (Yue et al., 2006; Farooq et al., 2009; Li et al., 2012). However, the relationship among the drought dehydration, tolerance, drought stress intensity and duration impact on rice seedling growth are poorly known.

Polyethylene glycol (PEG) is composed of a large molecular size and nontoxic in nature, therefore categorized as osmopriming reagents, which lowers the water potential without penetrating into seeds upon soaking (Chen and Arora, 2011; Zheng et al., 2016). Osmotic stress with PEG has been proposed to improve seed germination, early seedling vigor, antioxidant enzymes activity and eventually leading to increase stress tolerance in many crop plants (Chen and Arora, 2011). Seedlings death occurred at 8-12 d with water break after emergence under severe drought stress (Chen and Arora, 2011). Thus, in this study PEG was used to simulate drought stress in 12 d at water break after emergence (1) to investigate the morphology of shoot and root, anti-active substance

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_469486

and the accumulation in rice seedling under different drought stress intensity and duration; (2) to examine the relationship between drought stress intensity and duration as well as drought resistance impacted on rice seedling growth.

Materials and methods

Experiment site and design

A greenhouse experiment was conducted at Huazhong Agricultural University, Hubei Province, China (E114°29', N30°29') in the 2017 growing season. Two rice varieties were used, Hanyou 113 (HY113), having the ability of drought resistance and water-saving. It was bred by Shanghai Agricultural Biological Gene Center (Shanghai province, China); Yangliangyou 6 (YLY6, "super" hybrid rice), indica and two-line hybrid rice, which was bred by Lixiahe Regional Research of Agricultural Science (Jiangsu province, China). It is widely cultivated in the middle and lower reaches of Yangtze River. The initial seed moisture contents of HY113 and YLY6 were 10.8% and 11.0%, respectively. Rice seeds were sterilized with 25% prochloraz for 10 min. The seeds of YLY6 and HY113 were sown in culture solution (pH 5.0) at room temperature. The culture solution was a modified rice nutrient solution (nutrient solution scheme was provided by Internal Rice Research Institute) with the compositions (*Table 1*). The nutrient solution was renewed after 4 days. Three-week-old seedlings were transplanted to plastic buckets containing (250 mL, diameter 10 cm, height 15 cm) the same nutrient solution and renewed time. The room temperature and humidity were 25-30 °C and 80%, respectively. The natural light was used during the whole experiment.

Table 1. *Conventional nutrient solution*

Chemical compound	Formula weight	Concentration (g/L)
NH_4NO_3	80.04	22.8578
$NaH_2PO_4{\cdot}2H_2O$	156.01	10.072

$C_6H_7O_8{\cdot}H_2O$	210.14	14.875
$FeSO_4{\cdot}7H_2O$	278.02	4.9766
EDTA-$Na_2{\cdot}2H_2O$	372.24	6.665

PEG-6000 solution was used to induce osmotic stress on rice seedling (Chen and Arora, 2011; Zheng et al., 2016). Thirty treatments in each of eight replications (eight pots per replication and each pot comprised of one rice seedling) were used as follows: two varieties Yangliangyou 6 (YLY 6) and Hanyou 113 (HY113); five PEG-6000 solutions, i.e. 0%, 10%, 15%, 20% or 25% PEG-6000 (kg kg^{-1} (water)), the osmotic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_469486

potential in each solution respectively was maintained at 0 kPa, -10 kPa, -15 kPa, -20 kPa and -25 kPa, among these 0% PEG 6000 solution was used as control (CK); three drought duration with each PEG-6000 solutions to rice seedling were 4 d, 8 d and 12 d. In addition, 10%, 15% and 20-25% PEG-6000 concentration were regarded as mild, moderate and severe drought stress, respectively; and drought duration with 4 d, 8 d and 12 d were respectively referred to short-term, medium-term and long-term drought stress. Rice seedlings were watered with 0%, 10%, 15%, 20% or 25% PEG-6000 concentration at 5th days after seedlings transplanted to the plot.

Measurements

At 4 d, 8 d and 12 d after drought stress with two repetitions each treatment, seedlings were uprooted, washed, and placed into an insulated box to prevent deterioration. Rice seedlings, relative water content (RWC), soluble sugar (SS), proline content (Pro) and conductivity (Co) were assessed according to Basu et al. (2010).

Seedling morphological characteristics, dry mass and relative water content

Shoot length (SH), longest root length (LRL), mean leaf length (MLL) and mean leaf width (MLW) were measured with a ruler; leaf area (LA) were measured by LI-3100C (LI-COR Inc., Lincoln, NE, USA). Seedlings were dissected into roots and shoots to assess the fresh weight (FW), respectively.

The roots of each seedling were spread in a plastic tray contained deionized water and scanned using a flatbed scanner (300 dpi). Root images were analyzed using WinRhizo image analysis software (Regent Instruments, Quebec, Canada). The software was configured to measure root volume (RV, cm^3) and root number (RN).

After scanning the roots, the root and shoot of rice seedling were oven-dried at 80°C for 48 h, and shoot dry mass (SDM) and root dry mass (RDM) was weighed to obtain dry mass (DM). Adversity resistance index (ARI) was calculated by the formula (Wang et al., 2007):

$$ARI = (\frac{DM_{(T)}}{DM_{(CK)}}) \times DM_{(A)} \quad \text{(Eq.1)}$$

where $DM_{(T)}$ was the dry mass of each treatment except CK, $DM_{(CK)}$ was the dry mass in CK, $DM_{(A)}$ was the average value of dry mass in all treatments including CK.

RWC was calculated using the formula (Basu et al., 2010):

$$RWC = \frac{FW - DW}{FW} \quad \text{(Eq.2)}$$

where FW and DM respectively indicated the fresh weight and the dry mass of organs in rice seedling.

Soluble sugar, proline content and conductivity

Soluble sugar (SS) content was determined by Anthrone colorimetry (Zhang and Qu, 2003). A 1.0 ml aliquot of the supernatant of tissue extract (root or shoot) was added 1.5 mL distilled water, which was mixed with 1 ml of 9% phenol method, then

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_469486

homogenized in 5 mL of concentrated sulfuric acid. The mixture was at 25°C for 30 min. The absorption of chromophore was determined at 485 nm (Tecan-infinite M200, Switzerland).

Free proline content (Pro) of rice shoot and root were assayed according to the method (Bates et al., 1973). The samples were homogenized in 5 mL of 3% sulfo-salicylic acid and centrifuged at 6000 rpm for 10 min. The supernatant of 2 mL was heated with 2 mL of ninhydrin and 2 mL glacial acetic acid at 100°C for 1 h. The reaction was further extracted with 4 mL of toluene by vigorously vortexed for 30 s. The absorption of chromophore was determined at 520 nm.

To determine conductivity (Co), shoot or root materials (0.5 g) were washed with deionized water and placed in 20 ml deionized water tubes. The electrical conductivity of the solution was measured after 1 h of shaking at room temperature. Then samples were heated for 20 min and Co was measured. The Co measurements were performed (Li et al., 2013).

Statistical analysis

Analysis of variance (ANOVA), principal components analysis, correlation analysis and path analysis were performed using SPSS version 16.0 (SPSS Inc., Chicago, IL, USA) software. Differences between treatments were considered significant at $P < 0.01$ and $P < 0.05$ according to least significant difference (LSD) tests. Grey relational analysis was performed using DPS 7.5 (Zhejiang University, Hangzhou, China) software, gray correlation coefficient and grey incidence degrees were determined by the software. The value of the resolution ratio was 0.5. The figures were plotted using Sigma Plot software version 10.0 (Systat Software Inc., San Jose, CA, USA). Data represent means ± SD.

Results

The change of rice seedling morphological and physiological traits under drought stress intensity

The value of the SH and RN had significant ($P < 0.01$) difference in drought stress intensity (*Table 2)*, and reducing with the increasing PEG concentration, ARI raised and decreased later with increasing PEG concentration (*Table 3*). The high value ($P < 0.05$) of ARI for YLY6 were resulted in 15% PEG concentration level, AIR for HY113 in 10% PEG concentration level was significantly ($P < 0.05$) higher compared with others PEG concentrations. Both varieties had lower ($P < 0.05$) SH, MLL and MLW value when exposed to 20-25% PEG concentration. And SH, MLL and MLW showed no significant differences among 0%, 10% and 15% PEG concentration. While the RN and RV were resulted in higher values at 10% PEG concentration, while produced significantly lower values in 20-25% PEG concentration compared with 0%, 10% and 15% PEG levels. For both varieties, SS and Pro had higher value when subjected to 20-25% PEG concentration than other PEG concentration.

The vary of rice seedling morphological and physiological traits under drought stress processing duration

The SH, MLL, MLW, RN and RV were obviously influenced by drought stress duration (*Table 2*). Under both varieties, these parameters raised with the increase of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_469486

drought duration and greater ($P < 0.05$) value were resulted at 12 d drought duration compared with other drought duration (*Table 4*). While SH, RV and RN at 12 d maintained the maximum value ($P < 0.05$) compared to 4 d and 8 d drought duration. Pro content was significantly reduced during the 8-12 d drought duration; while SS at 12 d lowered ($P < 0.05$) than that in 4 d and 8 d drought duration.

The change of dry matter, leaf area, longest root length, conductivity and relative water content

Drought stress intensity and duration had significantly ($P < 0.01$) individual and interactive effects on the shoot and root dry mass and total dry mass (*Table 2*). For both varieties, the greater TDM (95.9-97.7) was exhibited at 12 d drought duration at 10% and 15% PEG concentration (*Fig. 1*); 15% PEG concentration induced greater SDM (70.1-77.3) during 12 d drought duration. A higher RDM (27.5-28.7) was formed during 10% PEG concentration at 12 d drought duration. A lower TDM, SDM and RDM (11.0-11.4) were produced under 20-25% PEG concentration during each drought duration.

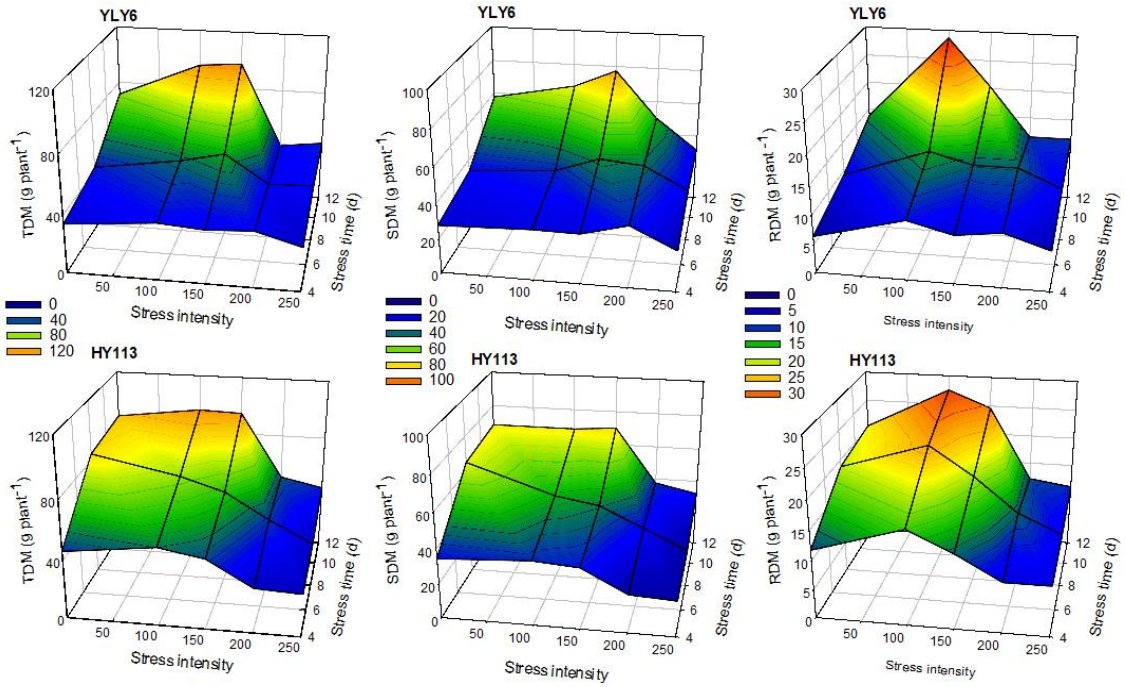

Figure 1. *The total dry matter (TDM, g plant^{-1}), shoot dry matter (SDM, g plant^{-1}), root dry matter (RDM, g plant^{-1}) in the coupling of drought stress intensity and stress duration under Yangliangyou 6 (YLY6) and Hanyou 113 (HY113)*

The individual and interactive effects of drought stress intensity and duration significantly ($P < 0.05$) changed the LA and LRL. The greatest LA (1.3-1.6) was observed for both varieties, respectively, at 12 d drought duration under 15% PEG level (*Fig. 2*). Both varieties had the greatest (10.7-13.1) LRL at 12 d processing duration with the 10% PEG concentration, while lowest (5.1-8.2) value resulted from 20% and 25% PEG concentration.

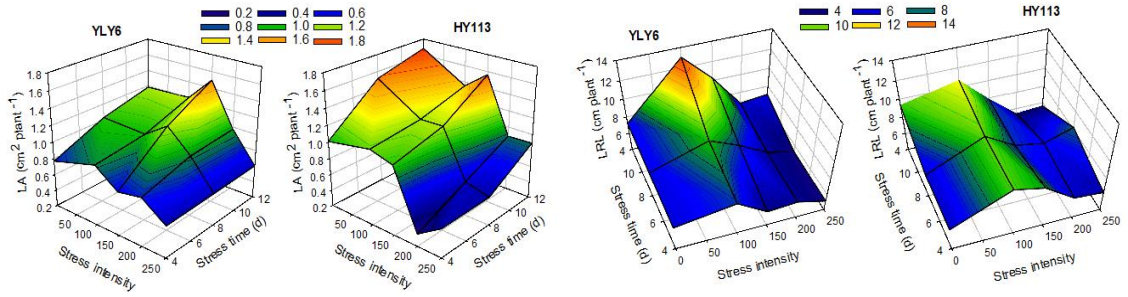

Figure 2. *The leaf area (LA, cm^2 $plant^{-1}$) and longest root length (LRL, cm $plant^{-1}$) in the coupling of drought stress intensity and stress duration under Yangliangyou 6 (YLY6) and Hanyou 113 (HY113)*

Drought stress intensity and duration had significant ($P < 0.05$) interactive effects on Co and RWC (*Table 2*). The Co showed peak (472.3) value at 8 d drought duration with 25% PEG concentration (*Fig. 3*), while the valley (17.5-72.9) appeared at 12 d drought duration within 0-15% PEG concentration. A lower value of RWC (0.71-0.78) resulted at 20% and 25% PEG concentration during each processing duration compared with other PEG concentrations.

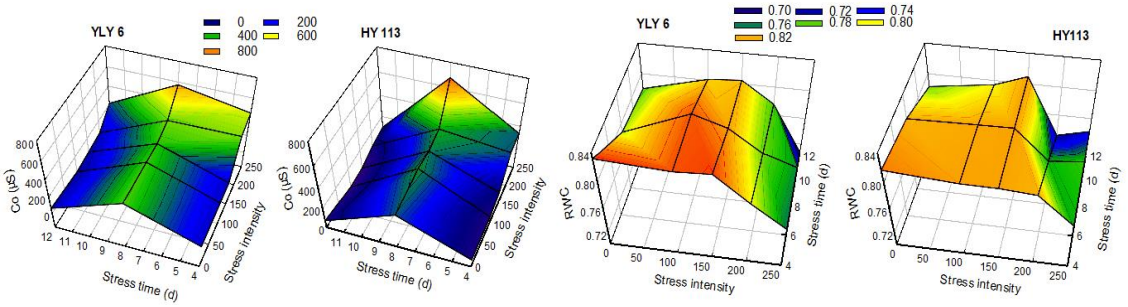

Figure 3. *The conductivity (Co, μS) and conductivity (Co, μS) in the coupling of drought stress intensity and stress duration under Yangliangyou 6 (YLY6) and Hanyou 113 (HY113)*

Table 2. *The shoot dry matter (SDM, g $plant^{-1}$), root dry matter (RDM, g $plant^{-1}$), adversity resistance index (ARI), relative water content (RWC), seedling height (SH, cm $plant^{-1}$), mean leaf length (MLL, cm $plant^{-1}$), mean leaf width (MLW, cm $plant^{-1}$), leaf area (LA, cm^2 $plant^{-1}$), longest root length (LRL, cm $plant^{-1}$), root number (RN, $plant^{-1}$), root volume (RV, cm^3 $plant^{-1}$), conductivity (Co, μS), soluble sugar (SS, %), proline (Pro, μg g^{-1}) and total dry matter (g $plant^{-1}$) of drought stress intensity and stress duration under Yangliangyou 6 (YLY6) and Hanyou 113 (HY113)*

	SDM	RDM	ARI	RWC	SH	MLL	MLW	LA	LRL	RN	RV	Co	SS	Pro	TDM

The principal component analysis of rice seedling morphological and physiological traits

The principal component analysis showed that RDM, SDM, SH, MLL, MLW, LA, RN and RV contributed to the first principal component (dehydration avoidance factor, DAF) (*Table 5*), while the LA was the major to the first principal component. ARI and RWC were summed up as the second principal component (comprehensive drought resistant factor, CDRF), RWC obviously supported on the factor. Co, SS and Pro were classified as the third principal component (drought tolerance factor, DTF), Co was leading component to the factor. In addition, RLR was called as fourth principal component (root induction factor, RIF).

Table 5. *The principal component analysis of the root dry matter (RDM, g plant^{-1}), shoot dry matter (SDM, g plant^{-1}), adversity resistance index (ARI), relative water content (RWC), seedling height (SH, cm plant^{-1}), mean leaf length (MLL, cm plant^{-1}), mean leaf width (MLW, cm plant^{-1}), leaf area (LA, cm^2 plant^{-1}), longest root length (LRL, cm plant^{-1}), root number (RN, plant^{-1}), root volume (RV, cm^3 plant^{-1}), conductivity (Co, μS), soluble sugar (SS, %), proline (Pro, μg g^{-1}) and total dry matter (g plant^{-1}) of drought stress intensity and stress duration under Yangliangyou 6 (YLY6) and Hanyou 113 (HY113)*

The relation and path analysis of principal component factors and dry matter accumulation

Correlation analysis explored that (*Fig. 4*), the TDM significantly ($P < 0.01$) positively related to LA, RWC, Co and LRL. The LA also significantly ($P < 0.01$) negatively correlated with Co, which indicated that dehydration avoidance factor, comprehensive drought resistant factor and drought tolerance factor related closely with biomass accumulation in rice seedling.

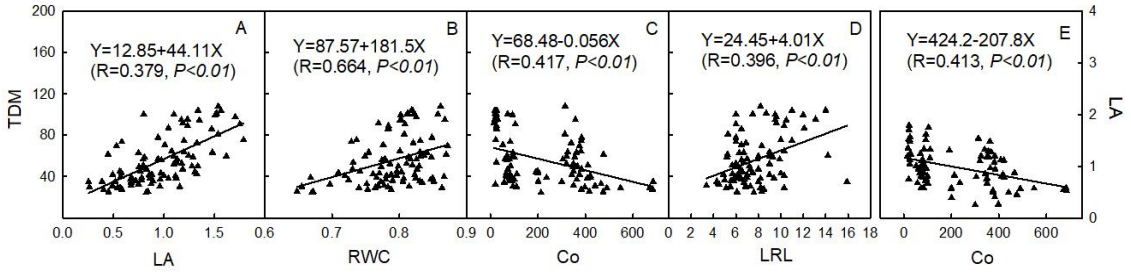

Figure 4. *Relationship (n = 90) for total dry matter (TDM, g plant^{-1}) with leaf area (LA, cm^2 plant^{-1}), total dry matter (TDM, g plant^{-1}) with relative water content (RWC), total dry matter (TDM, g plant^{-1}) with conductivity (Co, μS), total dry matter (TDM, g plant^{-1}) with longest root length (LRL, cm plant^{-1}) and leaf area (LA, cm^2 plant^{-1}) with conductivity (Co, μS) of stress intensity and stress duration under Yangliangyou 6 (YLY6) and Hanyou 113 (HY113)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_469486

Path analysis (*Table 6*) showed that LA, RWC, Co and LRL had greater direct effect on TDM in rice seedling, respectively, and Co had good indirect effect on TDM through LA. It showed that drought dehydration factor, comprehensive drought resistant factor and drought tolerance factor had great separate effect on rice seedling growth.

Table 6. *The path analysis (n = 90) for the direct or indirect effect on total dry matter (TDM, g plant^{-1}) by leaf area (LA, cm^2 plant^{-1}), relative water content (RWC), conductivity (Co, μS) and longest root length (LRL, cm plant^{-1}) of drought stress intensity and duration under Yangliangyou 6 (YLY6) and Hanyou 113 (HY113)*

The association analysis of principal component factors and dry matter accumulation

In two varieties, under 0%-4 d (stress intensity (SI)-stress duration (SD), 15%-4 d, 10%-4 d and 20%-4 d condition (*Table 7*), RWC as the key enabling factor on TDM, followed by LA significantly contributed to TDM under 0%-8 d, 10%-8 d, 10%-12 d, 20%-12 d and 25%-12 d condition. Co mainly supported TDM in 0%-8 d, 10%-8 d, 20%-8 d, 20%-12 d and 25%-8 d; Co lowered contribution to rice seedling in 10%-4 d, 15%-4 d, 20%-4 d and 25%-4 d. LRL was the main factor for TDM in 10%-4 d and 15%-8 d condition.

Table 7. *The association analysis of the leaf area (LA, cm^2 plant^{-1}), relative water content (RWC), conductivity (Co, μS) and longest root length (LRL, cm plant^{-1}) with total dry matter (TDM, g plant^{-1}) of stress intensity (SI) and stress duration (ST) under Yangliangyou 6 (YLY6) and Hanyou 113 (HY113)*

It is suggested that comprehensive drought resistant factor primarily supported seedling growth at 8-12 d stress duration at 10-15% PEG solution; under the coupling of the 20-25% PEG concentration and 12 d stress duration condition, drought dehydration factor mainly supported the seedling growth. Drought tolerance factor had an imperative role in seedling growth at 8-12 d stress duration under 15-20% PEG solution. The root induction factor was the major factor relating to seedling growth under 4 d drought stress duration with 10-15% PEG solution.

Discussion

Drought stress intensity had a great contribution to rice seedling growth compared with drought processing duration

Drought stress intensity and duration significantly alters rice seedling growth. In the present study, rice seedling growth showed a reducing trend in prolonged drought stress duration, while mild and moderate drought stress intensity (10-15% PEG concentration) enhanced rice seedling growth for all drought duration. In addition, shoot and root growth of rice seedling were more sensitive to drought stress intensity compared with drought duration, and root growth of rice seedling had a lower tolerance to drought stress intensity compared with the shoot of rice seedling.

Crop seedling growth slightly reduced with extending drought duration compared with control (Asai et al., 2009; Duan et al., 2017). As drought stress intensity increases, the root growth of seedling was decreased. Conversely, increases root physiological activity (root vigor and protective enzyme) (Sharma and Dubey, 2005; Ding et al., 2016). Rice shoot growth (biomass accumulation) was obviously reduced by lower leaf productivity (changed leaf morphology and gas exchange) under severe drought stress condition (Lu and Neumann, 1999). While moderate drought stress supported rice seedling growth because which motivated the compensatory capacity of the seedling (Sharma and Dubey, 2005; Yu et al., 2016). These data found that root and shoot of crop seedling were sensitive to drought stress while moderate drought stress had a positive effect on rice seedling growth.

In the present research, drought duration had less threaten to rice seedling growth compared to drought stress intensity, because rice seedling during long-term drought stress could counteract the adverse impact of moderate drought stress on rice seedling growth, or the compensatory capacity of rice seedling could be stimulated by long-term drought duration. Compared with the aerial part of rice seedling, root had a lower tolerance capacity to drought stress due to more sensitive to drought stress during rice seedling and was a source of drought stress signal. Thus, long-term drought duration or mild or moderate drought stress intensity had less effect on rice seedling growth. And to maintain root vigor was more benefit for rice seedling growth.

Drought stress intensity and processing duration could impact on drought dehydration factor, comprehensive drought resistant factor, drought tolerance factor, root induction factor and the relationship among them

The impact of drought stress on rice seedling growth and development was not only related to the drought stress intensity and processing duration, but also corrected to drought resistance (drought dehydration and drought tolerance) of crops (Liu et al., 2003; Özdemir et al., 2004; Farooq et al., 2009). In the present research, drought

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_469486

dehydration, drought tolerance, comprehensive drought resistant and root induction factor increased when the plants were exposed to extending drought duration; moreover, drought dehydration, drought tolerance and comprehensive drought factor had greater value at moderate drought stress (15% PEG concentration) intensity within long term drought duration, while optimal root induction factor appeared at mild drought stress (10% PEG concentration) during medium and long term drought duration. And drought dehydration, comprehensive drought resistant, drought tolerance and root induction factors within each drought stress intensity, duration or their combination had a great independent effect.

Crops simultaneously had drought dehydration and tolerance ability (Liu et al., 2003; Chaves et al., 2003; Chang, 2008; Farooq et al., 2009). Drought tolerance or dehydration in crops showed a different size when crops faced a different drought stress intensity (Yu et al., 2016; Duan et al., 2017). Drought dehydration and drought tolerate ability had different ways to maintain the crops growth and avoid the much number water lose: short-term drought stress duration inspired the drought tolerance ability, while long-term drought stress duration easily induced the drought resistance (Yue et al., 2006; Farooq et al., 2009; Li et al., 2012). And these factors were respectively, controlled by a set of independent genetic characteristics, such as, root distribution (the longest root length) in the soil layer and leaf area was adjusted by related gene (Zhang et al., 2001; Yue et al., 2006; Du et al., 2018). In addition, under the assist of the compensation ability, mild and moderate drought stress intensity stimulated the formation of protection mechanisms in tissue cells to avoid the injury of tissue cells (Asai et al., 2009; Duan et al., 2017). With the raising stress duration, the generation of new cells replaced or eliminated which destroyed tissue cells or other matter in cells (Ming and Wang, 2002; Kottapalli et al., 2012). And the great activity or function of the new tissue cells raised the drought resistance ability supporting the rice seedling growth. Thus, drought dehydration played a crucial role in drought stress duration, while drought tolerance had an obvious response to drought stress intensity to support rice seedling growth. In addition, less alteration of seedling morphological traits, when seedling accumulated higher Pro and SS content, and rice seedling had low assimilate productivity during seedling stage. This indicated that the accumulated assimilates in seedling provided energy for the formation of the proteins and enzymes related to drought tolerance, while reducing the energy to support the morphogenesis of rice seedling, so that drought dehydration factor and drought tolerance factor showed an independent effect on rice seedling growth. And these factors had different acting time during drought stress.

Drought stress intensity and duration impacted on drought dehydration factor, comprehensive drought resistant factor, drought tolerance factor and root induction factor to adjust the rice seeding growth

In the present study, the rice seedling maintained the growth during drought stress, mainly supported by greater root induction, drought tolerance and drought dehydration factor at short-term, medium-term or long-term duration under mild drought stress intensity, respectively. The comprehensive drought resistant factor among all drought duration in moderate drought stress intensity, drought dehydration factor and drought tolerance factor at long-term processing time in severe stress intensity respectively played a crucial role in rice seedling growth.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_469486

The contribution of drought tolerance factor on rice seedling growth was mainly great physiological activity (polyphenols, flavonoids and antioxidant activity) under severe drought stress (Hussain et al., 2016, 2017). However, the formation of protective enzyme or cell activity was induced by environmental stress and reducing with increasing drought stress intensity (Manivannan et al., 2007; Samota et al., 2017). While Drought dehydration played a crucial role in long-term drought stress (Farooq et al., 2009; Li et al., 2012; Hussain et al., 2017). About RWC (comprehensive drought resistant factor) was considered to evaluate the response-ability of plant to drought stress (Farooq et al., 2009; Anjum et al., 2011), and the comprehensive drought resistant factor was supported by root or shoot physiological activity, decreasing water loss and enhancing physiological water use efficiency in rice seedling (Kaydan et al., 2008), but the comprehensive drought resistant factor also reduced with raising drought intensity (Nayyar et al., 2006; Anjum et al., 2011). Root induction factor including root distribution and the growth rate of root, rice root distribution in deep soil layer significantly related with drought stress and root growth rate was used to evaluate adaptability to stress environment, root growth and physiological activity (synthesis of protein) were stimulated by mild and moderate drought stress to increase water absorption (Farooq et al., 2009; Pérez et al., 2010). We concluded that drought tolerance factor and the comprehensive drought resistant factor reduced within severe drought stress, while root induction factor raised in mild and moderate drought stress, drought dehydration played a crucial role in long term drought stress. A greater drought tolerance showed under short-term drought stress; moreover, drought tolerance factor mainly improving drought resistance ability, the comprehensive drought resistant factor mainly raising the water use ability and root induction factor mainly promoting water absorption which all supported drought resistance ability during drought stress.

In the present study, the root is the first organ to contact with drought stress and is more sensitive to drought stress. This showed that root had an obvious change within a short time to face drought stress intensity. This improved root water absorption to support rice seedling growth in the short-term stress. Drought tolerance factor plays a key role in stress environment and mild drought stress had less effect on seedling growth. While mid drought stress coupled with medium-term drought duration could stimulate the drought tolerance factor by improving compensation ability to promote the drought tolerance ability of rice seedling. Under moderate drought stress, comprehensive drought resistant factor did not show a declining trend, it could be caused by great effect of the protection mechanism and drought dehydration factor, in each drought duration, respectively. This further directly supported rice seedling growth.

The drought dehydration factor and drought tolerance factor of rice seedling respectively including shoot or root morphological and physiologic traits. Drought dehydration factor and drought tolerance factor could take advantage during long term drought duration with severe drought stress, because the accumulation of carbohydrates, soluble proteins, some osmotic substances and the protective enzyme during a relatively long time improved water absorption or storage avoiding the destruction of free radicals to cells supporting rice seedling growth during severe drought stress. In addition, drought dehydration factor was supported by morphology of rice seedlings, such as root and leaf, which was the foundation of matter and energy to response or relieve drought stress of rice seedling. Hence, drought dehydration factor had a great contribution to rice seedling growth during a long-term drought stress condition.

Conclusion

Rice seedling growth in different drought stress intensity and duration was associated with their different stress resistant mode, including drought dehydration avoidance factor, comprehensive drought resistant factor, drought tolerance factor and root induction factor. Moreover, these factors have strong independent effect on seedling growth during different drought stress intensity and duration. The improved rice seedling growth was mainly associated with greater root induction factor, drought tolerance and drought dehydration factor at short, medium or long-term duration under mild drought stress intensity, respectively. While drought dehydration and drought tolerance factor at long-term processing duration under severe stress intensity played a crucial role to support the rice seedling growth. Thus, to focus on drought resistant traits under different drought environment are important way to evaluate rice seedling growth in rice dry cultivation systems.

At present, the breeding of drought-resistance rice variety uses the genetic advantage of rice varieties. In the future, genome, transcriptome, proteome, or metabolomics can be applied to study the interaction mechanism between the drought resistance ability (drought resistance, drought avoidance, drought dehydration and drought tolerance) and the environment (drought stress). It is of great significance to the future development of rice dry cultivation (reduce energy-saving production).

Abstract. The abundance and diversity of forest understory vegetation can be significantly impacted by forest management. Besides having a wide geographical distribution in Turkey, the Oriental beech (*Fagus orientalis* Lipsky) is also one of the economically important timber species of the country. The aim of this study is to compare the understory herb layer communities of mature and young beech stands which regenerated as a result of the shelterwood method. We studied understory plant species diversity and composition in 16 plots in old and young beech stands in Belgrad Forest near İstanbul, Turkey. We found no significant differences between the two stand types in understory plant diversity but understory species compositions in two stand types were found to be different. Our finding can be useful for forest management planning; by focusing on stand scale to achieve forest management conserving understory plant diversity in a forest.
Keywords: *Belgrad Forest, understory composition, indicator species, pure beech stands, stand age*

Introduction

Herb layer vegetation is an important component for biodiversity conservation efforts because it contains the majority of vascular plant species diversity and plays a significant role in forest ecosystem functioning (Augusto et al., 2003; Lorenz et al., 2006; Gilliam, 2007; Ellum, 2009). Maintenance of biological diversity during timber harvesting and successful regeneration of forest tree species has gained importance as an issue for sustainable forest management. Investigating the potential effects of silvicultural treatments on the future plant species diversity in forests is crucial for the improvement of effective management strategies to achieve sustainable forest ecosystems (Roberts and Gilliam, 1995; Lindenmayer and Franklin, 2002; Ellum, 2009; Yılmaz et al., 2018). Past and present human activities and natural disturbances are a major factor affecting the composition and diversity of plant species in a forest (Elliott et al., 1997; Stefańska-Krzaczek et al., 2019). Forest management practices lead to changes in species composition, age structure, and vertical stratification of tree layer and also indirectly affect understory microclimate, light availability, litter and soil properties in a forest. These forest understory conditions can also impact the diversity and composition of the herb layer (Paillet et al., 2011). Different forest management operations are applied throughout the life of the forest from regeneration to harvesting. Therefore, it is necessary to ascertain the impact of different silvicultural practices on understory plant composition and diversity (Hunter, 1999; Barbier et al., 2008; Durak, 2012).

Oriental beech is one of the major broadleaved forest trees in Turkey. Oriental beech forests cover 1 899 929 hectares and comprise about 8.5% of the forestland in Turkey (OGM, 2015). The oriental beech is commonly distributed in the northern region of Turkey and it is also scattered in western and southern parts of the country. This species can form pure stands; however, more frequently it mixes with broadleaved and conifer trees such as oak (*Quercus* sp.), hornbeam (*Carpinus betulus* L.), chestnut (*Castanea sativa* Mill.), fir (*Abies* sp.), Anatolian blackpine (*Pinus nigra* Arnold), Scots pine (*P. sylvestris* L.), oriental spruce (*Picea orientalis* (L.) Link.) between (30) 700-1300 (2000) m in Turkey (Yaltırık, 1982; Yılmaz, 2014).

The present study examined effects of shelterwood silvicultural method practices on herb layer composition and diversity in beech forests. Our main purpose was to investigate patterns in herb layer plant species diversity in response to two levels of stand age and structure. We compared mature and naturally regenerated young oriental beech stands with regards to stand structural features, understory richness and composition in Belgrad Forest to understand how the stand age and stand structure influences understory plant diversity.

Materials and methods

Study area

The study was conducted in the Belgrad Forest of İstanbul, 28°54′25″ - 28°56′37″ E, 41°13′00″ - 41°14′13″ N in Turkey (*Fig. 1*), a region with humid, mesothermal and maritime climate. Annual mean precipitation is about 1091 mm and annual mean temperature is about 12.8 °C (Özhan et al., 2010). Soils in the region are loamy clay and are developed mainly from carboniferous clay schists and neogene deposits (Balci et al., 1986). The forest covers 5900 ha, elevation ranges from about 45 to 230 m a.s.l.

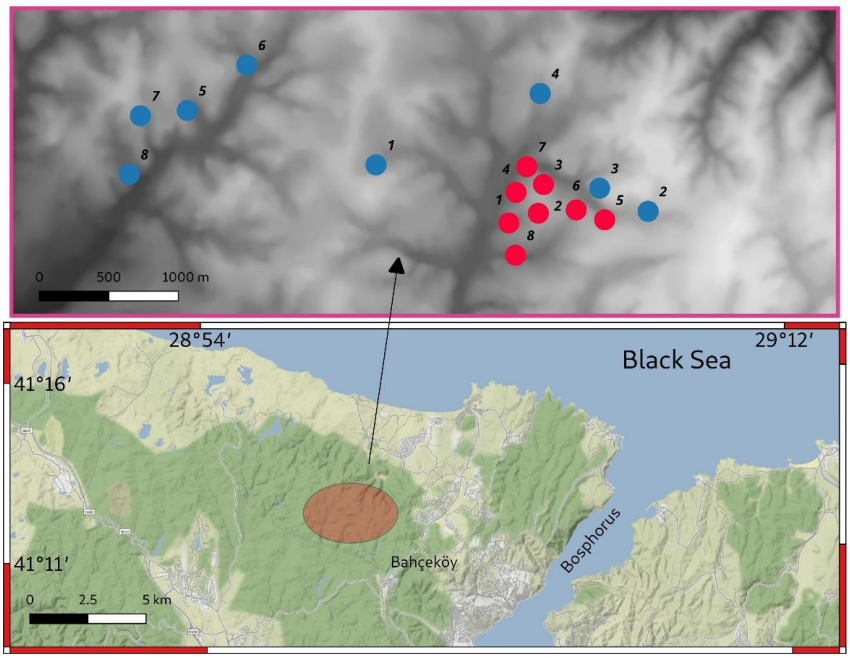

Figure 1. *The study area within the Belgrad Forest, İstanbul (bottom). The sampling plots of beech stands are represented by circles (top) which are color coded based on the stand's development stage (blue: mature beech stands, red: young beech stands)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_487498

The Belgrad Forest is an old preserved mixed deciduous forest ecosystem. The natural forest is composed of oak species (*Quercus petraea* (Mattushka) Liebl., *Quercus frainetto* Ten., *Q. cerris* L.), oriental beech (*Fagus orientalis*), chestnut *(Castanea sativa*) and European hornbeam (*Carpinus betulus*) with minor occurence of aspen (*Populus tremula* L.), common alder (*Alnus glutinosa* L.), field maple (*Acer campestre* L.) and field elm (*Ulmus minor* Mill.) (Yaltırık, 1966).

Pure oriental beech stands occupy the northwest and western slopes with an inclination of 10-40%, and are spread over the sandy loamy and loamy soils, the pH values of which vary from 4.4 to 5.8 in Belgrad Forest (Yaltırık et al., 1983). The beech stands in Belgrad Forest have been managed under the uniform shelterwood silvicultural method since 1959 (Saatçioğlu, 1970). Uniform shelterwood method used to regenerate an even age stand with multiple cuts to help shelter new establishment. Existing partial canopy which serves to modify understory conditions, create a favorable environment for reproduction, and provide a seed.

Vegetation data

A total of sixteen 20 m x 20 m permanent sample plots, 8 in naturally regenerated young beech stands (YB) and 8 mature beech stands (MB), were established in pure even aged beech forests in comparable site conditions in 2017. The sample plots were laid out in a homogenous and representative area located in each stand minimum 250 m far away each other to overcome spatial autocorrelation. Trees with a diameter at breast height (dbh) ≥ 8 cm, taken in two perpendicular directions, were measured. Tree density and basal area were estimated for each quadrat (*Table 1*).

Four 1 m × 1 m subplots were established at the corners of each plot to sample the herb layer. Vegetation surveys in each subplot were carried out during the main growing season (May-June) to avoid vegetation bias. All herb layer species were identified in whole plot area and cover of each species was estimated separately in four subplots with the ordinal scale of Braun Blanquet (1964). All herbaceous plants, ferns, seedling and saplings with a height of less than 50 cm were considered as herb layer. The nomenclature of vascular plants follows the Flora of Turkey (Davis, 1965-1980).

Statistical analysis

To investigate the interactions between stand development stage and herb layer, the data set was prepared and organized before performing statistical analysis. Community tables were created in two different data sets. Presence/absence data set (hereafter PADS) is the presence/absence of species in the 4 subplots (1 m × 1 m), and species identified in the each 20-m x 20-m permanent plot. Abundance data set (hereafter ADS) is the average abundance of species in the 4 subplots. A table indicating the development stage of the stands was produced as the environmental data set (hereafter EDS).

Diversity indices (richness, abundance, Shannon, Simpson) were calculated using the two data sets which were previously prepared and organized. The species richness was expressed as the number of herb-layer species for the PADS and was compared between successional stages of beech stands using species accumulation curves. The rank-abundance curves of ten most abundant plants was created from the ADS. Permutational multivariate analysis of variance (PERMANOVA) was used to compare the similarity of these two stand types (MB and YB). 'vegan' (Oksanen et al., 2019) and 'BiodiversityR' (Kind and Joe, 2005) packages of the R 3.0.1 (R Development Core Team, 2017) were used for the analysis.

As a measure of species diversity and dominance/abundance, accumulation curves (Kindt and Coe, 2005) were constructed. An indicator species analysis was executed to reveal the relationship between the herb layer species and the overstory composition (Dufrêne and Legendre, 1997) using the R package "indicspecies" (De Cáceres and Jansen, 2013).

Results and discussion

In this study, we were interested in comparing understory species composition and richness of two different succession stages of beech stands. Predicting the response of forest understory plants to disturbances caused by timber harvest or other silvicultural interventions is important to implement silvicultural practices focusing on the conservation of all components of forest ecosytems (Ellum, 2009). Results of the study clearly indicated that overstory structure and age shaped understory species composition in young and old even-aged beech forests.

Stand characteristics

Mean diameter at breast height and basal area of mature beech stands were 40.75 cm and 45.09 m^2/ha^{-1} while in young beech stands, they were 16.51 cm and 23.45 m^2/ha^{-1}, respectively (*Table 1*). The average number of trees was 306 in mature beech stands and 1025 in young beech stands. While the mean diameter of the breast height and the basal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_487498

area of mature beech stands are about twice as large as those of young beech stands, the number of trees in young stands is three times the amount in mature stands. According to these mean diameter values, the stands are in pole and mature development stage.

Diversity and abundance of understory herb layer

64 vascular plant species were identified in the understory of beech stands. 45 species occurred in young beech stands and 49 species were also found in mature stands (*Table 2*). All the species recorded were native in old beech stands but one non-native species was found in young beech stands (*Table A1* in the *Appendix*). Of the species recorded, while 19 species are unique to mature beech stands, 15 species are unique to young stands. Mean species richness was found same within the two stand types as 20.25. *Epimedium pubigerum* (DC.) C. Morren & Decne. was the most abundant species in all quadrats of young and mature beech stands (*Fig. 3*). İster and Gökbulak (2009) compared the species diversity of the herbaceous plants in the beech and oak stands in the same study area, and they identified 12 herbaceous plant species in 3 beech stands using transect sampling method.

Table 2. *Diversity indices of the mature and young beech stands (YB = young beech stands, MB = mature beech stands, PADS = 4 subplots plus whole plot area data, ADS = the average of 4 subplots data)*

		Richness (abundance)	**Mean richness**	**St. dev. of richness**	**Shannon index**	**Simpson index**
PADS	MB	49	20.25	4.30	3.66	0.969
	YB	45	20.25	3.33	3.51	0.964
ADS	MB	24 (339.83)	42.47	5.47	2.94	0.94
	YB	21 (343.50)	42.94	8.94	2.77	0.93

Kelemen et al. (2012) reported that in European beech forests species composition changed over time within the gaps but all species found before cutting were still present in the area after 8 years. Similarly, fir-beech forest in Slovenia Kutnar et al. (2015) detected a significant increase in species richness two years after logging. In our study, according to Simpson and Shannon-Wiener index, mature stands are more diverse than young stands in the two data sets (*Table 2*).

Accumulation curves of the understory species

The species richness of the understory plants of mature beech stands are higher than young ones (*Fig. 2*). The rarefaction curves revealed very consistent patterns across the two stand types. This suggested that herb layer richness became similar after 30-40 years of regeneration. The species richness was not affected significantly by shelterwood logging (Nagaike et al., 1999).

Rank abundance of the understory

When the 10 most common species on the herbaceous layer of young and mature stands are examined, it can be seen that 8 species are common in both stand types, but their rankings are different (*Fig. 3*). *Epimedium pubigerum* was the most common species in both stand types. *Smilax excelsa* L., *Ruscus hypoglossum* L. occurred in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_487498

young beech stand in the top 10 species but did not occur in mature beech stands. On the other hand, *Ornithogalum wiedemannii* Boiss. and *Carex sylvatica* Huds. were found in the top 10 species in the mature beech stands while they were not found in young beech stands (*Fig. 3*).

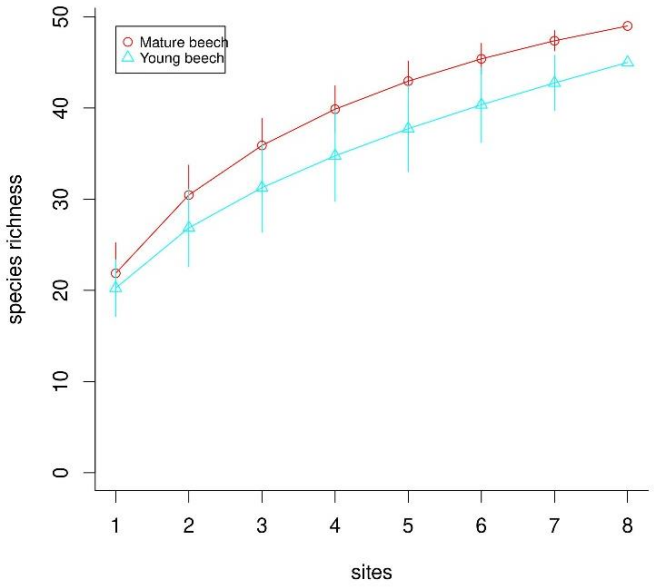

Figure 2. *Species accumulation of the herb layer of beech stands in the young and mature beech stands. Rarefaction curves present the relationship between number of samples and understory species richness in beech forest stands. The whiskers show standard deviation of species richness*

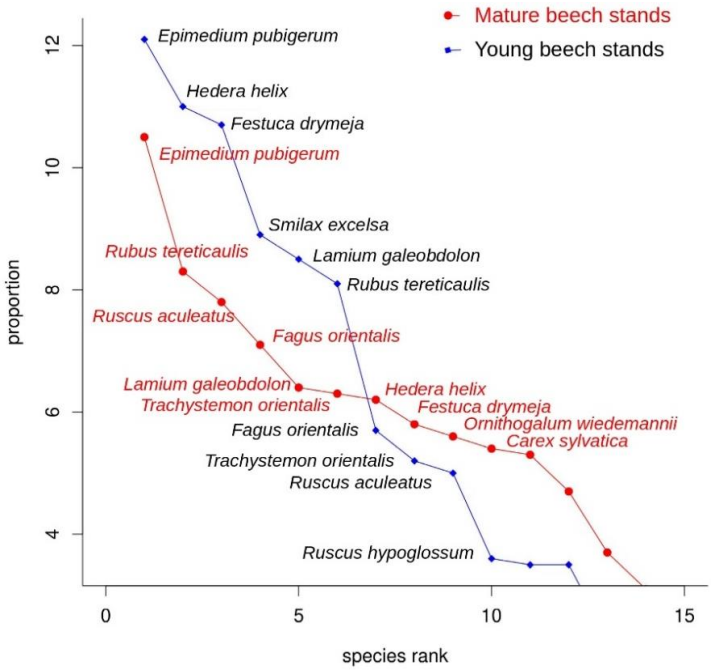

Figure 3. *The herb layer species ranked in order of decreasing fidelity with respect to the two beech stand types. The proportional abundances of the species were calculated for two stand type separately*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_487498

When we look at the diversity index values (*Table A2*) and accumulation curves graph of the two beech stand types (*Fig. 2*), the values of the old stands were determined to be higher.

Indicator species analysis

Only one indicator species was determined for each stand types by the multi-level pattern analysis (*Table 3*). This indicates that most of typical beech forest species were found in the herbaceous layer of both young and mature beech stands. The change in species composition during the successional stages is illustrated by the results of indicator species analysis. According to indicator species analysis, young beech stands were characterized by a shade plant species *Polystichum setiferum* (Forssk.) Moore ex Wyon. *Ornithogalum wiedemannii*, which is very seldom present in successionally younger stands, was detected as an indicator of old beech stands. These results indicate that young beech stands seem to reach stabile light condition and close canopy. According to Peet and Christensen (1988), however plant species and diversity decrease through substitution of natural succession in a forest but increase in steady-state phases of forest stand development.

Table 3. *The indicator herbaceous species of the beech stands*

Stand type	Indicator species	A	B	IndVal	p value
Mature beech	*Ornithogalum wiedemannii*	1.00	0.75	0.866	0.008**
Young beech	*Polystichum setiferum*	1.00	0.625	0.791	0.031*

The specificity (A), sensitivity (B), indicator value (IndVal) and significance (p value) are given. 'A' is the probability that the surveyed site belongs to the target site group, given that the species has been found. 'B' is the probability of finding the species in sites belonging to the site group. Significance codes: 0 '***' 0.001 '**' 0.01 '*' 0.05 '.' 0.1 ' ' 1

Similarity of herb layer composition in mature and young stands

According to the dissimilarity matrices, the community composition of the young and mature beech stands' herb layer was significantly different in terms of the compositional similarity (Bray-Curtis, $R^2_{ADONIS} = 0.16$, $P = 0.01$).

What causes the differences in composition and richness between these pure beech stands of two different successional stages? Since these areas are very close to each other, it is thought that there is not significant effect of climate and altitude factor. Previous studies have indicated the herb layer of beech stands various depending on the light conditions (Lysik, 2008). In a forest, understory light is closely dependent on the canopy structure and it is also considered the main limiting factor of understory plant richness and composition (Hill, 1979). Although understory plant species in a forest have different optimal light requirements, in beech forests, herb layer species are well adapted to low understory light conditions, or complete their life cycles before trees are completely foliated and therefore light would be less important for such species (Härdtle et al., 2003). The understory plant diversity in forests varies over time depending on stand structure. Namely, plant diversity increases rapidly in the years following the logging, then decreases when canopy closure occurs and increases slowly again depend on overstory tree density decreasing in overtime (Roberts and Gilliam, 1995; Ujházy et al., 2017).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_487498

The results of present study showed that successional stage was the main driver of understory herbaceous species composition in even aged beech forest and Aavik et al. (2009) reported similar results in boreonemoral forests. Herbaceous plants are less sensitive to shelterwood forestry than the other species groups in a forest (Brunet et al., 2010), and therefore the shelterwood system can be suggested as a suitable method for sustainable management of plant species diversity and composition of beech stands (Poorbabei and Poor-rostam, 2009).

Conclusions

Species composition of understory vegetation in oriental beech stands was related to management intensity. At the same time, our results indicate that natural regeneration in oriental beech forests using shelterwood systems did not cause significant differences in species richness but species composition may show differences over time in these forests. Forest managers should consider the actual and potential effects of their silvicultural practices on understory vegetation diversity and composition. Although there is a small difference in diversity index and rank abundance values, there is a significant difference between the community matrices of the two stand types and it shows that two stand types are different in understory plant species and compositions.

The results showed that species richness and coverage of vascular plants were related to overstory successional stage. The results suggest that stand age influences the herb layer composition in beech stands but 16 study plots do not allow broad generalization of our results. Therefore, further studies would be necessary to acquire more knowledge about change in species composition and diversity with stand development.

Acknowledgments. This study was supported by the Scientific Research Projects Coordination Unit of Istanbul University (Project Number FBA-2016-20319).

CHANGES IN GROWTH PARAMETERS, OIL YIELD, FATTY ACID COMPOSITION AND MINERAL CONTENT OF TWO SAFFLOWER (*CARTHAMUS TINCTORIUS* L.) GENOTYPES IN RESPONSE TO WATER STRESS

OZKAN, A.

Department of Gastronomy and Culinary Arts Faculty of Fine Arts, Gaziantep University, 27000 Gaziantep, Turkey
(e-mail: aozkan27@gmail.com)

(Received 9th Sep 2019; accepted 15th Nov 2019)

Abstract. The present study was designed to investigate the effects of water stress on growth and development parameters, oil yield coupled with their fatty acid composition as well as mineral content of two safflower genotypes including Remzibey-05 and Gokturk. Accordingly, significant differences regarding plant length, branch number per plant, capsule number per plant, capsule seed number, 1000-seed weight and seed yield per pot were assessed. However, first branch length did not exhibit significant differences between genotypes in response to the treatments. Furthermore, Oil yield was not significantly affected by severe water stress for Remzibey-05 even a 1.60% increase was observed under severe water stress but the yield was significantly increased by 2.37% in Gokturk. In terms of oil composition unsaturation degree, UFA/SFA significantly increased with stress for both genotypes. Concerning mineral content; Remzibey -05 genotype had the highest value of K and Na whereas Gokturk genotype had the highest values of Mg, Fe, Cu and Zn. Finally, the experimental groups were discriminated and identified using PCA and heatmap visualization.
Keywords: *fatty acid unsaturation degree, drought, Remzibey-05, Gokturk, water stress*

Introduction

Water stress resistance of crops is one of the great challenges for the world's agricultural systems. Water stress-induced loss in crop yield probably exceeds losses caused by other severe environmental constraints. Thereby, numerous researches in plants responses to water scarcity has been important interest for scientists for many years in order to develop, improve or explore drought-tolerant plant species or cultivars, genotypes within the same species for a sustainable agricultural production (Hamrouni et al., 2001; Turk et al., 2004; Al-Barrak, 2006; Bettaieb et al., 2009; Ozkan and Kulak, 2013; Zandalinas et al., 2018; Fahad et al., 2017; Shi et al., 2017; Ahmed et al., 2016; Ozkan, 2018; Rubin et al., 2017; Vurukonda et al., 2016; Pouri et al., 2019; Cetinkaya et al., 2016).

Water stress alters the biochemical synthesis pathways and subsequently production of primary and secondary metabolites is influenced. It is worthy to remark that industrially, medicinally or economically important metabolites may be accumulated beyond the decline in the growth and productivity of crops (Ozkan and Kulak, 2013; Hamrouni et al., 2001; Laribi et al., 2009). Of those, the variations in lipid content and its composition have been reported under varying irrigation degrees (Laribi et al., 2009; Bettaieb et al., 2010; Laribi et al., 2011; Ozkan and Kulak, 2013).

Safflower (*Carthamus tinctorius*) belonging to Asteraceae family is of the oldest cultivated oilseed crop but not common and not very popular when compared to other oil crops such as soybean, sunflower and peanut (Canavar et al., 2014; Bortolheiro and Silva, 2017). Of the oilseed crops, safflower has been well-documented to possess

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_499514

ability in moderate tolerance of environmental constraints but changes in oil yield and subsequently fatty acid composition have been reported, indicating that water constraints water deficient condition might cause increase protein and decrease oil contents of safflower (Nabipour et al., 2007; Amini et al., 2014; El Sabagh et al., 2019). Seed oil of safflower is well characterized with a large amount of saturated (palmitic and stearic) and unsaturated (oleic, linoleic and linolenic) fatty acids and composition. However, the percentage and content of the compounds and oil yield are particularly affected by water stress (Bortolheiro and Silva, 2017; Nabipour et al., 2007; Ashrafi and Razmjoo, 2010; Eslam, 2011; Amini et al., 2014; Ozkan and Kulak, 2013; Nazari et al., 2017). Since each species of the plants have been comprised of genotypes, cultivars, varieties, populations and chemotypes, many studies can be performed on the different genotypes of the same species. As well-known and documented that, plants have been adapted to environmental conditions through not only based their genetic inheritance and but also the primary and secondary metabolites inside. Through profiling the metabolite content, plants have been sorted as tolerant or sensitive. Along with the present study, two different safflower genotypes were used in order to determine their oil yield combined with fatty acid compositional profiling in response to water stress conditions. In addition to the oil and its composition, mineral content or accumulation of seed samples belonging to both genotypes were determined. Furthermore, growth and developmental parameters of genotypes were compared after subjection water stress and normal life span under irrigated conditions (control).

Materials and methods

Plant material and water deficit treatment

Experiments were performed under greenhouse conditions with pots including 2 kg soil mixture of 3:1:1 (soil-peat-perlite) at Gaziantep, Turkey. The experiments were carried out with three replicates corresponding 10 plants for each replicate. Each pot included one plant seedling. The effects of severe water stress (SWD) on safflower genotypes (Remzibey-05 and Gokturk) were investigated. The safflower genotypes are of the significant oil crops. The materials used herein are of the developed in Turkey. Herewith, the studies regarding adaptation of the genotypes in arid and semi-arid regions corresponding to the limited water sources are required. In this context, the genotypes were screened for their low water content tolerance corresponding to the oil yield coupled with their fatty acid composition in addition to basic agricultural parameters.

For the experimental processes, similar methods with Bettaieb et al. (2009) were followed. In brief, during the first 35 days of the study, plants were irrigated with tap water, and subsequently exposed to different water regimes: 100% (control group: C; 600 ml) 25% (severe water deficit group: SWD; 150 ml) of field capacity (FC). The properties of experimental soils were as follows: Potassium (297.75 ppm), organic matter (1.16%), salt (0.059) at a set pH (8.0). Experiments were conducted in a greenhouse with a 14-h photoperiod and performed between October 13, 2018 and July 26, 2019. Mean temperature was kept at 25 ± 2 °C during daytime and 14 ± 2 °C at nighttime, respectively, with a relative humidity of 70%. After harvest, seeds were airdried and stored at 4 °C until use for further analysis.

DOI: http://dx.doi.org/10.15666/aeer/1801_499514

Growth and yield parameter measurements

For each treatment, measurement of plant length, seed number per capsule, capsule number, 1000-seed weight, total weight per pot, and single plant yield were evaluated by harvest of six randomly selected plants from each experimental replicate (Ozkan and Kulak, 2013; Ozkan, 2018).

Oil extraction and fatty acid composition analysis

Oil extraction and then fatty acids of oil were determined according to our previous methods applied (Ozkan and Kulak, 2013; Ozkan, 2018). Briefly, oils were extracted from safflower seeds (each 2 g sample) with n-hexane for 4 h using a Soxhlet extraction apparatus. Subsequently, the solvent was evaporated under reduced pressure and temperature using a Rotary evaporator (Heidolph). 0.1 g of safflower oil was added to 2 ml n-heptanes into a screw-capped tube for esterification. The fatty acid analyses were conducted according to the official method COI/T.20/Doc.no.24 2001. 0.1 g of safflower oil was taken into screw-capped tube. 2 ml n-heptane was added and shaken. After 0.2 ml methanolic potassium hydroxide was added for esterification, tubes were vigorously shaken for 30 s after the vials were closed. The supernatant of the solution was taken followed after 1 h of incubation at room temperature. Then, the supernatant was put in 2 ml vials for injection.

Fatty acid composition profile determination

GC-FID analyses of fatty acids methyl esters were carried out on a Shimadzu gas chromatography (GC2010 series) equipped with a Supelco SP 2380 fused silica capillary column (100 m, 0.25 mm i.d., 0.2 μm film thickness). Helium was used as carrier gas, at a flow rate of 3 mL/min. The injection and detector temperature were 140 °C and 240 °C, respectively. The oven temperature was held isothermal at 140 °C for 5 min, then raised to 240 °C at 4 °C/min and held isothermal at 240 °C for 15 min. Injection volume of Diluted samples [1/100 (v/v) in n-heptanes] of 1.0 μL were injected automatically in the split mode (1/100). The identification of the constituents was based on comparison of the GC-retention times with those of available analytical standards (Larodan Fine chemicals, mixture of 37 components of fatty acids methyl esters). Peak area was used to obtain the percentage of individual fatty acid.

Sample preparation and measurement for mineral content

The harvested seed samples were cleaned, washed by de-ionized water, and dried. Pre-dried samples were de-moisturized at 70 °C for 48 h in an oven and ground for chemical analysis. 0.2 g of ground powdered seed samples were immediately placed into burning cup with 5 ml HNO_3 65% and 2 ml H_2O_2 30%. After the incineration process, the solution was cooled at room temperature for 45 min. The extracts were passed through a Whatman 42 filter paper. These filtrates were collected by de-ionized water in a 20 ml-polyethylene bottles and kept at 4 °C in laboratory for ICP-OES analysis. Each sample was analyzed in triplicate.

Statistical analysis

SPSS statistical program was used to determine statistical significance levels by employing the independent one-way ANOVA followed by Duncan multiple range test

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_499514

and the differences between individual means were considered to be statistically important at $p < 0.05$. Moreover, specifically for each genotype, control and stress group of plants were compared using independent t-test in order to determine to clarify their behaviour against stress. Also, the discrimination for experimental groups was done with the principal component analysis using SPSS software. Finally, heatmap was 209 constructed using ClustVis (https://biit.cs.ut.ee/clustvis/).

Results and discussion

Effect of water stress on plant growth and development parameters

Based on independent *t*-test, there were significant differences between plant length ($t = 2.274$; $p < 0.05$), capsule seed number ($t = 3.688$; $p < 0.01$), 1000-seed weight ($t = 2.333$; $p < 0.05$), seed yield per pot ($t = 5.231$; $p < 0.01$) for Remzibey-05 genotype in response to water stress. However, first branch length, branch number per plant and capsule number per plant did not exhibit significant differences between treatments ($p > 0.05$) (*Table 1*).

Table 1. *t-test analysis of growth and yield parameters of Remzibey-05 genotype exposed to water stress*

Growth and yield parameters	Control	SWD	t-statistic	p value
Plant length (cm)	37.50±6.02	29.33±6.41	2.274	0.046*
First branch length (cm)	18.50±6.29	17.33±5.57	0.340	0.741
Branch number per plant	4.83±1.33	3.83±1.17	1.384	0.197
Capsule number per plant	5.83±2.23	3.83±1.17	1.947	0.080~

**p < 0.01; *p < 0.05; ~p < 0.10; SWD: severe water deficit

Severe water stress significantly affected plant length ($t = 3.353$; $p < 0.01$), branch number per plant (t = 3.835; p < 0.01), capsule number per plant ($t = 4.715$; $p < 0.01$), capsule seed number (3.664; p < 0.01), seed yield per plant ($t = 8.871$; $p < 0.01$) in Gokturk genotype. However, first branch length ($t = 0.902$; $p > 0.05$) and 1000-seed weight ($t = 1.987$; $p > 0.05$) did not differ in Gokturk genotype in response to severe water stress (*Table 2*).

Table 2. *t-test analysis of growth and yield parameters of Gokturk genotype exposed to water stress*

Furthermore, independent t-test was performed in order to determine the differences between control and stress groups of genotypes. No differences were observed for the parameters of both genotypes in control groups (*Table 3*). Also, there were no significant differences-except capsule seed number between genotypes under severe stress conditions (*Table 4*).

Table 3. *t-test analysis of growth and yield parameters of both genotypes under irrigated conditions (control)*

Growth and yield parameters	Remzibey-05 control	Gokturk control	t-statistic	p value

**$p < 0.01$ ~$p < 0.10$; SWD: severe water deficit

One-way variance analysis reveals significant differences in terms of plant length ($F = 6.708$; $p < 0.01$), branch number per plant ($F = 3.750$; $p < 0.05$), capsule number per plant ($F = 5.719$; $p < 0.01$), capsule seed number ($F = 10.289$; $p < 0.01$), 1000-seed weight ($F = 3.413$; $p < 0.05$) and seed yield per pot ($F = 28.921$; $p < 0.01$). However, first branch length did not exhibit significant differences between genotypes in response to the treatments (*Table 5*).

In many and various studies regarding water stress and agronomical yield attributes interaction, stress conditions have been reported to exhibit inhibitory impacts on stem growth and plant height due to shrinkage in output changes in cellular water status of the plant. The effects of the water stress on the plant parts are variable for the examined parameters. The effects can be observed at certain developmental stages of the plant, a trait of the plant or genotypes of the same plant species (Prasad and Staggenborg, 2008).

Correlation analysis of growth and yield parameters of safflower

Table 6 presents the correlation analysis of plant length, first branch length, number of branches, capsule number, seed number, 1000-seed weight and seed yield in *Carthamus tinctorius* genotypes. Significant and positive relation was observed by 64.2% between plant height and first branch length ($r = 0.642$; $p < 0.01$). Also, 69.9% ratio between plant length and branch number was found to be significant with positive correlation ($r = 0.699$; $p < 0.01$). Plant length was also positively correlated with capsule number per plant by 80.4% ($r = 0.804$; $p < 0.01$). Plant length was furthermore positively correlated with seed yield per pot ($r = 0.782$; $p < 0.01$). moreover, significant and positive correlation coefficients between first branch length and capsule number per plant ($r = 0.417$; $p < 0.05$), first branch length and seed yield per pot ($r = 0.465$; $p < 0.05$), branch number per plant and capsule number per plant ($r = 0.900$; $p < 0.01$), branch number per plant and seed yield per pot ($r = 0.742$; $p < 0.01$), capsule seed number and seed yield per pot ($r = 0.790$; $p < 0.01$), capsule seed number and seed yield per pot ($r = 0.727$; $p < 0.01$) as well as 1000-seed weight and seed yield per pot ($r = 0.508$; $p < 0.05$) were observed. The remained coefficients were all positive but not significant. No negative correlations were found between investigated parameters (*Table 6*).

Table 6. *Correlation analysis of growth and yield parameters of safflower*

Effects of water stress on oil yield and fatty acid composition

Oil yield was not significantly affected with severe water stress in Remzibey-05 even a 1.60%increase was observed under severe water stress but the yield was significantly augmented by 2.37% in Gokturk. The non-significant changes in oil percentage could be attributed to stress timing at vegetation of the plant. In the current study, severe water stress was applied at the flowering. Nazari et al. (2017) also reported that drought stress at the flowering stage of some safflower did not influence seed oil percentages. In the studies performed on different genotypes of safflower, six different safflower lines were exposed to water stress and subsequently followed by rehydration. The oil yield increased from 24.18 ± 5.01 to 26.61 ± 6.21 (Bortolheiro and Silva, 2017). However, oil yield significantly decreased under water stress (Nabipour et al., 2007; Ashrafi and Razmjoo, 2010; Ensiye and Khorshid, 2010; Eslam, 2011; Amini et al., 2014). Ozkan and Kulak (2013) reported a non-significant slight increase in oil content of seeds of sesame seedlings exposed to severe water stress. Furthermore, drought stress did not cause significant changes in percentage of seed oil content of safflower species (Nazari et al., 2017).

After oil esterification, the fatty acid compounds in oil were identified using gas chromatography. Of the fatty acid compounds identified for both genotypes, oleic acid, linoleic acid, palmitic acid, stearic acid and behenic acid were of compounds with percentage over 1% (*Table 7*).

Their total percentage for treatments were 98.62% for Remzibey-05 control, 99.02% for Remzibey-05 SWD, 98.80% Gokturk control and 99.12% Gokturk SWD. The yield and percentage can change but the composition of the oil was not affected by severe water stress.

Of the compounds, palmitic acid percentage significantly decreased with severe water stress by 28.30% for Remzibey-05 and 15.61% in Gokturk genotype. No differences regarding percentage of the palmitic acid in control and SWD groups of both genotypes, respectively were found. The decline in palmitic acid under water stress was also reported (Ashrafi and Razmjoo, 2010; Petcu et al., 2001). However, Nazari et al. (2017) reported slight increases in palmitic percentages of for safflower species.

Stearic acid also exhibited similar manner with palmitic acid in both genotypes in response to severe water stress. Stearic acid decreased by 45.36% in Remzibey-05 and 26.66% in Gokturk genotypes. The decreases in percentage of stearic acid were documented (Ashrafi and Razmjoo, 2010). However, Laribi et al. (2009) noted an increase in palmitic acid (110%) and stearic acid (269%) and a decline in petroselinic acid (18.47%) in *Carum carvi* under severe water stress.

Oleic acid percentage significantly increased by 7.85% with severe water stress in Remzibey-05 but the percentage did not significantly vary with severe water stress in Gokturk genotype. Ashrafi and Razmjoo (2010) reported a decline in oleic acid percentage in different safflower genotypes but an increase was documented by Gao et al. (2009). In the study by Ozkan and Kulak (2013), two sesame genotypes were exposed to moderate and severe water stress, documenting that no significant changes in percentage of oleic acid in Cumhuriyet genotype were found while there was a slight but significant change Özberk genotype under severe water stress.

Linoleic acid percentage was not affected by severe water stress in Remzibey-05 genotype but increased by 1.80% in Gokturk under severe stress conditions. Linoleic acid percentage did not significantly vary in sesame (Cumhuriyet genotype) but increased with stress in sesame (Özberk genotype) (Ozkan and Kulak, 2013). Ashrafi

DOI: http://dx.doi.org/10.15666/aeer/1801_499514

and Razmjoo (2010) also reported a decline in percentage of linoleic acid in safflower genotypes.

Oleic acid and linoleic acid ratio increased in Remzibey-05 under severe water stress (ratio: 0.511 and 0.545 for control and SWD, respectively) but it decreased in Gokturk (0.554 and 0.545 for control and SWD, respectively). Laribi et al. (2009) reported decreases in oleic acid and linoleic acid ratio under severe water stress but an increased ratio of oleic acid/linoleic acid was reported (Talha and Osman, 1975).

Percentage of behenic acid increased by 10.64% and 17.19% in both genotypes in response to water stress Remzibey-05 and Gokturk, respectively. Behenic acid did not change in sesame seeds in response to water stress (Ozkan and Kulak, 2013; Ozkan, 2018).

Table 7. *Effects of water stress on oil yield and fatty acid composition of both safflower genotypes*

Fatty acid compounds	Remzibey-05 control	Remzibey-05 SWD	Change (%)	Gokturk control	Gokturk SWD	Change (%)
Myristic acid	.0762a	.0201b	-73.62%	.0460	.0314	-31.74%

Oilyield (%)	27.89	29.49	1.60	25.48b	27.85a	2.37%

SWD: Severe water deficit; Means for same genotypes with different superscripts (a-b) are significantly different according to Student t test ($\alpha = 0.05$)

Fatty acid unsaturation degree

Based on our experimental data (*Table 8*), lipids extracted from safflower seeds are dominated by C16 and C18 fatty acids which are common in higher plants (Rebey et al., 2017). Analysis of fatty acid composition indicated that safflower seeds in control plants of Remzibey-05 genotype were characterized by a high proportion of polyunsaturated fatty acids (PUFA) (58.68%) versus 30.10% of monounsaturated fatty acids (MUFA) and 10.87% of saturated fatty acids. SWD significantly decreased saturated fatty acids (SFA) whereas significantly increased MUFA, UFA and UFA/SFA. However, SWD did not elicit any significant changes in PUFA in Remzibey-05 genotype.

In control groups, safflower seeds in control plants of Gokturk genotype were characterized by a high proportion of polyunsaturated fatty acids (PUFA) (59.34%)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_499514

versus 32.96% of monounsaturated fatty acids (MUFA) and 7.36% of saturated fatty acids. SWD significantly decreased saturated fatty acids (SFA) whereas significantly increased PUFA, UFA and UFA/SFA. However, SWD did not elicit any significant changes in MUFA in Gokturk genotype.

Fatty acid unsaturation degree has been considered important in maintenance of membrane fluidity and providing optimal environment for proper membrane functions (Xu and Beardall, 1997; Rebey et al., 2017). In safflower seeds, under control and SWD, the unsaturated fatty acid (UFA) to saturated fatty acid (SFA) ratio was 8.17 and 11.54, respectively for genotype Remzibey-05. UFA/SFA was 12.55 (control) and 14.48 (SWD) for Gokturk genotype. Both genotypes exhibited similar manner regarding fatty acid unsaturation degree.

Table 8. *Fatty acid unsaturation degree of genotypes in response to water stress*

	Genotype: Remzibey-05			**Genotype: Gokturk**		
Fatty acid unsaturation degree	**Control**	**SWD**	**Change (%)**	**Control**	**SWD**	**Change (%)**
SFA	10.87a	7.96b	-26.77%	7.36a	6.46b	-12.23%
MUFA	30.10b	32.49a	7.94%	32.96	33.07	0.33%
PUFA	58.68	59.42	1.26%	59.34b	60.42a	1.82%
UFA	88.78b	91.90a	3.51%	92.31b	93.49a	1.28%
UFA/SFA	8.17b	11.54a	41.25%	12.55b	14.48a	15.38%

SWD: Severe water deficit; Means for same genotypes with different superscripts (a-b) are significantly different according to Student t test ($\alpha = 0.05$)

However, UFA/SFA was significantly decreased with rising water deficit levels, indicating that severe water stress causes a decline in the passive membrane permeability (Rebey et al., 2017) and coupling with an increase of cellular membrane rigidity (Monteiro de Paula et al., 1993). Herewith, plant might protect itself against possible accumulation oxidative stressors through modifying or re-structuring the membranes with less unsaturated fatty acids.

Correlations between major fatty acids and oil yield

Along with the present study, two correlation analyses for fatty acids were done (*Tables 9-10*). In the first correlation analysis (*Table 9*), all data obtained from both genotypes were pooled- not considering the experimental groups- and then correlated. According to the correlation coefficients, palmitic acid was positively correlated with stearic acid ($r = .955$; $p < 0.01$), oleic acid ($r = .882$; $p < 0.01$) but negatively correlated with behenic acid ($r = -.680$; $p < 0.05$). Stearic acid was positively correlated with oleic acid ($r = .938$; $p < 0.01$) but negatively correlated with linoleic acid ($r = -.917$; $p < 0.01$) and behenic acid ($r = -.650$; $p < 0.05$). Oleic acid was negatively correlated with linoleic acid ($r = -.0996$; $p < 0.01$).

According to the second correlation analysis done in order to determine whether correlation coefficients vary depending control and stress groups (*Table 10*), in control group, palmitic acid was positively and significantly correlated with linoleic acid ($r = .850$; $p < 0.05$) but in stress group, palmitic acid was again positively correlated but not significant. Also, palmitic acid was negatively and significantly correlated with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_499514

behenic acid (r = -.831; $p < 0.05$) but in stress groups, the coefficient was .060 and not significant. Oleic acid was positively and significantly correlated with behenic acid (r = .980; $p < 0.01$) in control group. However, the coefficient strongly shifted towards negative correlation from .980 to -.494. As expected, opposite changes were observed between linoleic acid and behenic acid from -.993 to .537 (*Table 10*).

Table 9. *Correlations between major fatty acids and oil yield in safflower seeds (n = 12)*

Effects of water stress on seed mineral content of safflower

The changes mineral contents in both genotypes with respect to the water stress treatments were statistically significant (*Table 11*). For Remzibey-05 genotype, K and Mg content significantly increased and as expectedly Na content significantly decreased. However, micro elements did not significantly differ as a response to severe water stress. For Gokturk genotype, K content significantly increased with severe stress. In similar to the Remzibey-05 genotype, there were decreases in Na content and increase in Mg content in Gokturk genotype. However, those changes were not statistically significant. Mg content diminished with drought (Grabaová and Martinková, 2001). Of the micro elements, Cu content significantly decreased with stress. The changes in content of micro elements were significant.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_499514

Any external stimuli-mediated internal changes in plant metabolism cause perturbations and pose impairments in mineral uptake and their translocation in the plants. Hu and Schmidhalter (2005) highlighted that the water stress induced- nutrient reductions might be attributed to the low transpiration ratio, decreased active transport and disrupted membrane permeability. In the former reports, K content decreased under drought conditions (Mahouachi, 2007). However, Ozkan and Kulak (2013) examined the K content in seeds of two genotypes of sesame, genotypes exhibited opposite behaviour of K accumulation in response to severe water stress. Arjenaki et al. (2012) reported the changes mineral elements of two wheat varieties contrasting drought stress, documenting that tolerant varieties had the highest value of K while sensitive variety had the highest value of Na. Along with the study, Remzibey-05 had the highest values of both K and Na in comparison with Gokturk. Furthermore, when evaluated the growth and yield, all parameters except 1000-seed weight favoured for Remzibey-05 genotype, which seems to be more tolerant against severe water stress.

Overall, it must be highlighted that the mineral uptake and sequential accumulation or partitioning of the minerals thought out the complex plant system are dependent many factors including species, genotypes, cultivars, age of the plant and then stress type and duration of the stress, timing of the stress (pre-flowering, flowering and post-flowering vegetative stage). Up to best knowledge and survey of the literature, the studies regarding with interaction of mineral uptake and following processes in response to water stress are scarce even though there are many studies focusing only the last accumulation and content of the status. Forthcoming studies are required to focus on the whole plant system response in terms of minerals and their fate after subjection to the water stress.

Principal components analysis (PCA) of genotypes

PCA is of the powerful statistical tools in discrimination of the samples based on identified components. Along with the study, two genotypes under two experimental groups with their fatty acid profiles were submitted to Principal Component Analysis. Accordingly, components extracted (*Table 12*), total variance explained (*Table 13*) and 2-D visualization of the experimental groups (*Fig. 1*) were obtained. Herewith, the first component (factor) explained 76.476% of total variances. The second and third components explained 18.965% and 45.596% of total variances respectively. Experimental groups were well-discriminated, clarified and identified using PCA,

DOI: http://dx.doi.org/10.15666/aeer/1801_499514

documenting that any external deviation from regular irrigation of the plants would cause changes in fatty acid metabolites with their percentage. Herein, genotype Remzibey-05 grown under control groups was quite differentiated from other groups (*Fig. 1*).

Table 12. *Components extracted based on fatty acid compounds corresponding to the their loadings*

Heatmap construction for genotypes for their fatty acid profile corresponding to control and stress conditions

According to the heatmap (*Fig. 2*), arachidic acid, myristic acid, stearic acid, palmitic acid and heneicosanoic acid were more pronounced under control conditions but SWD suppressed their content. SWD increased behenic acid, linoleic acid, cis-11-eicosanoic acid and palmitoleic acid in Remzibey-05 genotype.

SWD topped the percentage of linoleic acid, cis-10-heptadecanoic acid, lignoceric acid, linoleic acid, oleic acid, cis-11-eicasenoic acid and palmitoleic acid in comparison with the control group of Gokturk.

As seen in *Figure 2,* control and SWD experimental groups exhibited clear different behaviour corresponding to the fatty acid profiles, which were also coupled and supported with principal component analysis (*Fig. 1*).

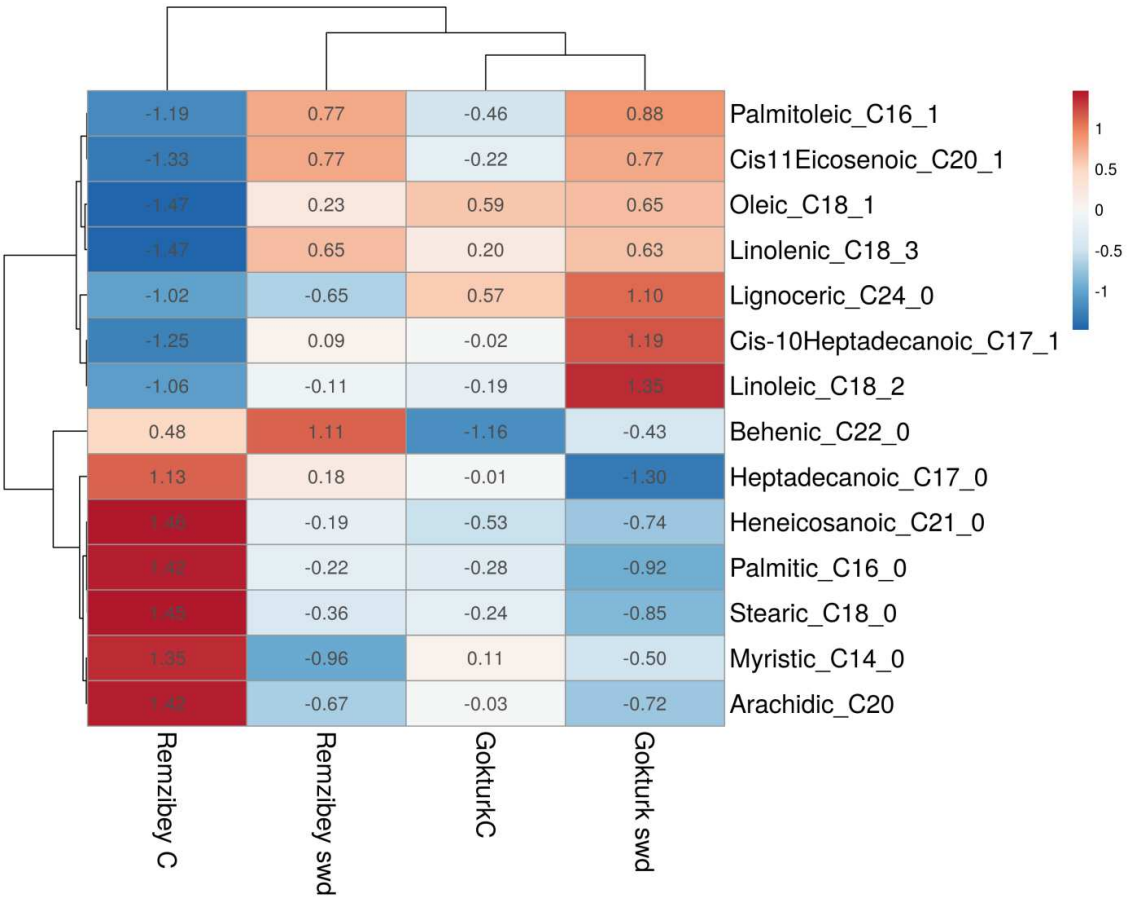

Figure 2. *Heatmap constructed for both genotypes concerned with fatty acid profile corresponding to control and stress groups*

Conclusion

The present study was designed to investigate the effects water stress on oil yield combined with their fatty acid profile and mineral contents of seeds of two safflower genotypes. The most important conclusions of this study are:

- Regarding growth and yield parameters under stress, Remzibey-05 genotype had higher values except 1000-seed weight but the values were not significant.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_499514

- Capsule number differences were reported to be significant under stress.
- Oil yield increased under stress conditions for both genotypes.
- UFA/SFA was significantly increased with stress for both genotypes.
- For Remzibey-05 genotype, K and Mg content significantly increased and as expectedly Na content significantly decreased. However, micro elements did not significantly differ as a response to severe water stress. For Gokturk genotype, K content significantly increased with severe stress.

Finally, genotypes exhibited similar behaviour regarding unsaturation degree of the oil, also increments in their oil yield.

For the forthcoming studies, field experiments regarding those genotypes should be performed since the present study was study was carried under controlled green house conditions. The study can be deemed as preliminary study to ascertain some basic properties of the two safflower genotypes under limited water sources. Moreover, more genotypes of the safflower can be screened for their performance and then a selection concerning high tolerant against low water content of soils for genotypes can be made.

Abstract. Immobilized microbial degradation technology has the advantages of simple solid-liquid separation, strong toxicity resistance, and low sludge yield. This study creatively added biochar to the immobilized microbial activated pellets and optimized the immobilization conditions for these pellets. This experiment also studied the removal efficiency of chemical oxygen demand (COD), total phosphorus (TP), ammonia nitrogen (NH_3-N) and total nitrogen (TN) for immobilized microbial pellets in the SBR (Sequencing Batch Reactor) with different dosages and hydraulic retention time (HRT). Results showed that the optimal conditions were reached when: the mass fraction of SA (sodium alginate) was 2%, the amount of PVA (polyvinyl alcohol) was 4%, and cross-linking time 24 h, the best biochar added was RS700. Mixed bacteria under the condition of the optimization system for immobilized pellets were added to the continuously running of SBR process, 20 mL bacteria suspension of immobilized pellets could be used to test the best dosage through the experiment monitoring. In a comprehensive consideration, the optimal HRT was 4 d, and the removal efficiency of COD, TP, NH_3-N and TN under the best dosage was reached at 76.79%, 56.50%, 67.60 % and 54.92% at 4 days, respectively. In the SBR process, the degradation efficiency of immobilized pellets for each pollutant COD, TP, NH_3-N and TN in the SBR conforms to the first-order kinetic model.
Keywords: *immobilized microbial pellets, SBR, first-order kinetic model, biochar, sewage treatment*

Introduction

The research on cold-resistant bacteria in China is relatively new, which has attracted extensive attention. It wasn't until the 1990s that people had a systematic understanding of the cold-resistant bacteria in the past century. The rate of contaminant biodegradation by cold-resistant bacteria at low temperature was also explored at that time (Tang et al., 2018). Psychrotolerant or psychrophilic microorganisms are extremophilic organisms, which can grow and reproduce at the temperatures ranging from -15℃ to +20℃. The cold-resistant microorganisms can grow from 0℃ to 40℃, and the optimal temperature is between 20℃ and 40℃. However, the psychrophilic microorganisms can grow from 0℃ to 20℃ and the optimal temperature is below 15℃. The environments they inhabit are ubiquitous on earth, as a large fraction of our planetary surface experiences temperatures below 15℃. Most psychrophiles are bacteria or archaea. They belong to *Arthrobacter sp.*, *Psychrobacter sp.*, members of the genera *Halomonas, Pseudomonas, Hyphomonas,* and *Sphingomonas* (Mei et al., 2016). Generally speaking, mixed bacteria refer to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_515529

mixed bacteria whose dominant strains are combined by measuring the functions of two or more microbial strains. It can be composed of different types of bacteria, such as fungi. It can also be a combination of different types of bacteria, such as bacteria and fungi. Also, it was found that the mixing of strains had better synergistic effect than that of a single strain.

Immobilized microbial degradation technology has been favored for its high density of bacteria, low yield of sludge, strong resistance to toxicity and continuous operation. Through immobilization, microorganisms are fixed on the carrier to maintain a highly dense and bioactive function and to proliferate to adsorb and degrade organic compounds in water under appropriate conditions (Rao and Viraraghavan, 2002; Hachicha et al., 2009). Immobilized microbial degradation technology also has the advantages of keeping the dominant bacteria of high processing efficiency, large amount of biomass, stable operation, easy solid–liquid separation, and low price, etc., which is of great research value in organic wastewater treatment. At present, immobilization technology has been widely used in the practical production of sewage treatment in all walks of life. For example, Liu et al. (2013) have studied the treatment of heavy oil wastewater from the Liaohe oil field of China by using the upper flow anaerobic sludge bed and the fixed biological aeration filter combined biological process. Zhao et al. (2010) used immobilized microorganism technology to treat red water through an aerobic biofilter, and the 2,4,6-nitrotoluene (TNT) was ultimately degraded. For an ideal immobilized microorganism technology, the selection of immobilized carrier is the most important in addition to establishing a highly efficient immobilized reactor and highly efficient and intensive microorganisms with strong resistance. It is of significant importance to find immobilized carriers with stable performance, good mass transfer, high intensity, long life span, and low price (Vázquez et al., 2006). The common carriers for immobilization include natural materials and synthesized materials. There is no doubt that the former has the advantages of lower cost, easy to obtain, and no complicated experimental preparation at earlier stage, which can be widely used in production (Shen and Duvnjak, 2005). In recent years, some agricultural byproducts, such as rice husk, pine bark, peanut shell, sawdust and cork biomass have been used in different kinds of wastewater treatment (He et al., 2019). Straw is the biomass material rich in cellulose, lignin, and other natural polymers (Marshall and Johns, 1996; Gundogdu et al., 2009). Its molecular chains is distributed with a large number of active groups such as hydroxyl and carboxyl groups, which has good complexation, adsorption, and flocculation effects on contaminants in water. At the same time, carboxyl, sulfonic acid group, amino, imino, acylamino, and other groups are good for cell adhesion and proliferation (Van Wyk, 1997; Argun et al., 2009).

Compared with traditional or conventional treatments Sequencing Batch Reactor (SBR) is an easily obtainable, on timescale, highly operational, flexible technology for newer and varied pollutants (Kulkarni, 2013; Dutta and Sarkar, 2015; Popple et al., 2016). The SBR systems have many advantages of lower operational cost, less bulking and higher flexibility to combine nitrification and denitrification phases into one reactor (Lim et al., 2011) with good removal efficiency for nitrogen, phosphorus and chemical oxygen demand (Ding et al., 2011; Popple et al., 2016; Khan et al., 2019; Showkat and Najar, 2019). Microbial degradation plays a dominant role in the removal of soluble/colloidal biodegradable organics in wastewater (Nguyen, 2000; Chen et al., 2017). However, the sewage treatment efficiency of SBR in northern China is rather

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_515529

low in winter. This is because microbial activity is decreases as the water temperature decreases, and the biological activity of SBR might decrease under winter conditions. Thereby the pollutant removal efficiency and, more importantly, the efficacy of this contaminant removal technique might be affected by seasonal changes (Tang et al., 2018).

In this study, it creatively added rice straw biochar to the sodium alginate and agar, and finally formed immobilized microbial pellets concluded mixed bacteria. The removal efficiencies of chemical oxygen demand (COD), total phosphorus (TP), ammonianitrogen (NH_3-N) and total nitrogen (TN) were measured to test the biotreatment performance of immobilized microbial pellets in the SBR system. The objectives of this study were to: i) prepare and introduce immobilized microbial pellets and optimize the immobilization conditions for immobilized pellets. ii) determine the removal efficiencies of chemical oxygen demand (COD), total phosphorus (TP), ammonianitrogen (NH_3-N) and total nitrogen (TN) with immobilized microbial pellets in the SBR. iii) evaluate the effects of different dosages and hydraulic retention time (HRT) with immobilized microbial pellets in the SBR. iii) provide a modelling tool to simulate and evaluate the pollutant removal efficiency of the immobilized microbial pellets. The results of this study provide a theoretical foundation and scientific support for the use of SBR in wastewater treatment, and may have great significance in solving the increasingly severe water pollution problem in China.

Materials and methods

Enrichment culture, separation, screening, and identification of the mixed Psychrotrophic bacteria species

The strains including three types of bacteria, used in the experiment, were isolated from the soil samples collected from the constructed wetlands in the Nansihu Lake in Shandong Province, China. Under cold-temperature conditions (6(±2)°C), Strain 1 was composed of a Gram-positive translucent circular ivory colony, with a moist surface, and regular edge. Strain 4 was a Gram-negative opaque round milky colony with a moist surface, and irregular edge. Strain 5 was a Gram-positive translucent yellow colony with a moist surface and irregular edges. Strains 1, 4 and 5 were all spherical with no flagella. After the strains 1, 4, and 5 were cultured, total DNA was extracted and used as a template. Using Primers 8f (5'AGAGTTTGATCCTGGCTCAG3') 20bp and 1492r (5'GGTTACCTTGTTACGACT-T3') and after cloning and purification, the PCR product was then carried out by Shanghai Biological Engineering Co, Ltd. The 16S rDNA specific sequence of strain 1 was 1498bp (GenBank acceptance number: KR083014), the 16S rDNA specific sequence of strain 4 was 1489bp (GenBank acceptance number: KR083015), and the rDNA specific sequence of strain 5 was 1469bp (GenBank acceptance number: KR083016), after the three strain sequences were analyzed, strain 1 was named Psychrobacter TM-1, strain 4 was named Sphingobacterium TM-2, and strain 5 was named Pseudomonas TM-3. Tang et al. (2018) had produced the phylogenetic tree in our previous research.

The process was repeated three times so that the remaining nutrients could be removed. Finally, the absorbance of the solution was adjusted to 1.2 using normal saline. The bacterial solutions were then mixed together at a volume ratio of 1:1:1 and were placed at 6℃ for later use.

Biochar preparation

The rice straw was collected from Nanquan Village, Qufu Country, Jining City, Shandong Province, China. 20 g of crushed feedstocks were covered with a fitted lid and pyrolyzed under oxygen-limited conditions in a muffle furnace. The pyrolysis temperature was heated from room temperature to different temperatures (300, 500 and 700°C) for 3 h, naturally cooled to room temperature, sealed and bottled for use. After treatment with 300 ml of 1 mol/L hydrochloric acid for 4 h, the ash substances such as calcium carbonate were removed, and then filtered, washed with distilled water until the washing liquid was neutral, and oven dried at 80°C for 24 h. The entire carbonized product was ground and sieved through a 60-mesh screen, transferred into a plastic bag. The biochar were denoted as RS300, RS500, RS700 (RS stands for rice straw, the number represents carbonization temperature), respectively.

Pellets with immobilized microbials

Biochar powder, sodium alginate, microbial liquid and polyvinyl alcohol (PVA) was used to prepare the immobilized microbial activated pellets. The preparation process for pellets is presented in *Figure 1*.

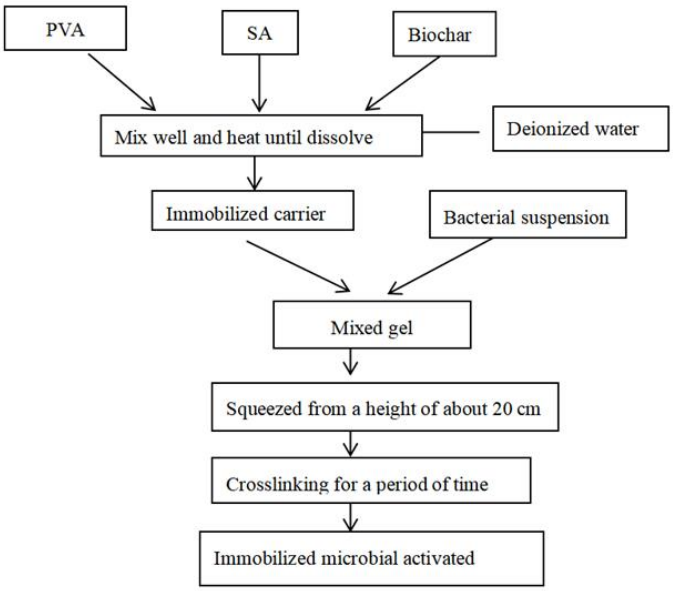

Figure 1. *The preparation process of immobilized pellets*

Add 4 g polyvinyl alcohol (PVA) to 100 mL deionized water in a beaker, heat it in water bath at 50-60°C until it is evenly dissolved. Then add 2 g alginic acid sodium (SA) and 0.4 g biochar as gelling agent after stirring and cooling to room temperature, 20 mL of the previously treated bacterial suspension was added and mixed well. The crosslinking agents were made by boronic acid, anhydrous calcium chloride and water at pH 6.5. The mixed gel was dripped to the crosslinking agent by a syringe and squeezed slightly from a height of about 20 cm. And the shape of pellets was naturally spherical, smooth and elastic. To obtain immobilized microbial activated pellets whose particle size 5.0 mm, it was placed at 6-8℃ in the freezer for the cross-linking for 0, 8, 16, 24, 36, and 48 h, respectively (Fu et al., 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_515529

The optimization conditions are set as follows using one-variable-at-a-time approach, various immobilization parameters were optimized by maintaining all factors at a constant level, except the variable under study. To determine the optimum addition amount of PVA, various concentrations of 0%, 2%, 3%, 4% and 5% (w/v) were added to prepare the pellets, respectively, when the amount of SA is fixed at 2%. Similarly, the addition amount of SA was 0%, 0.5%, 1%, 2%, 3%, and 4% (w/v), respectively, when the PVA was 4%. The cross-linking time was set to 0 h, 8 h, 16 h, 24 h and 36 h under the remaining conditions have not changed. For the effect of biochars at different temperature in the study, add RS300, RS500, RS700 0.4 g to the system, and the rest of the conditions were unchanged, immobilized pellets without biochar were added as blank controls at the same time, and triplicate for each experiment (Bisht et al., 2013).

Sequencing Batch Reactor (SBR)

The reactor is made of plexiglass and has a cylindrical shape with a bottom diameter of 15 cm, a column height of 25 cm, a volume of about 3 L, and an effective volume of 2 L. The experimental device was operated by mechanical agitation, and an aerator was placed at the bottom for aeration to control the DO concentration in the reactor during the aeration phase. The schematic diagram of the SBR is shown in *Figure 2*, and the operating cycle is shown in *Table 1*.

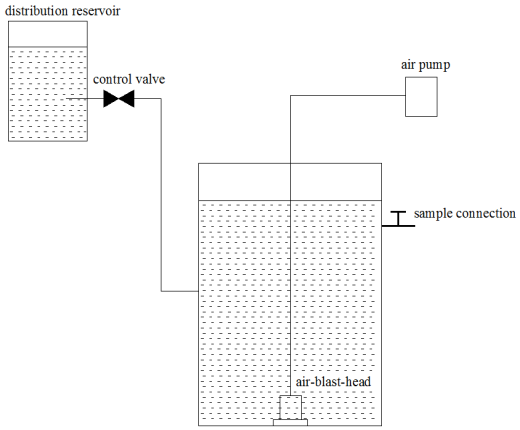

Figure 2. *The test installation diagram of SBR (Sequencing Batch Reactor, SBR)*

Table 1. *Experimental device operating cycle of SBR (Sequencing Batch Reactor, SBR)*

Number	Inflow (min)	Stirring (h)	Aeration (h)	Still standing (min)	Effluent (min)
1	2	0	0	55	3
2	2	1	2	55	3
3	2	1	4	55	3
4	2	1	6	55	3
5	2	1	8	55	3

In the simulated wastewater, glucose is used as carbon source, ammonium chloride as nitrogen source, and sodium dihydrogen phosphate as phosphorus source, and appropriate amount of trace elements are added to make C: N: P = 100:5:1. The initial values of COD, total nitrogen, total phosphorus and ammonia nitrogen are about 1000, 50, 10, 15 $mg \cdot ml^{-1}$ and pH =7.0, respectively.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_515529

Batch experiment

The pellets with immobilized microbials were introduced into SBR to verify the contaminants removing ability in engineering application, while exploring the ability to remove contaminants in different conditions and the effects of dose-up and HRT on the ability to remove contaminants. Each reactor was filled with 2.0 L wastewater and added different dosages and types of pellets with immobilized microbial under different conditions. As a control, the other reactor was not added pellets. Then, placed the two reactions in 6±2℃ constant temperature incubator for five days. Samples were taken from the reactor to determine the concentration of COD, TP, NH3-N and TN in the influent and effluent per 6 h. Triplicate of each set of experiments.

Analytical method and statistical analysis

The removal efficiencies of COD, TP, NH_3-N and TN were measured to test the biotreatment performance of immobilized microbial pellets in the SBR system. COD was determined by potassium dichromate oxidation method, TP was determined by ammonium molybdate spectrophotometry, NH_3-N was determined by phenol disulfonic acid spectrophotometry, and TN was determined by Peroxide of potassium sulfate - ultraviolet spectro- photometry. The specific operation steps for the determination of each index are detailed in Waterand Wastewater monitoring analysis method. 4th Edition. Beijing: China Environmental Science Press, 2002, in Chinese. Optical density of bacteria suspension was measured at 600 nm using a double beam spectrophotometer (UV-T9, Puxi, Beijing), pH was measured with a pH meter (ZD-2, Leici). The data were processed with the excel software and plotted with Origin 8.6.

Discussion and results

Optimization of immobilization conditions

PVA with resistance to microbial decomposition characteristics such as good mechanical strength, which makes it suitable as immobilized microorganism carrier. *Figure 3a* represents the effect of immobilized pellets with different PVA addition on COD, TP, NH_3-N and TN removal. Immobilized pellets after joining PVA mold faster, and with the increase of the amount of PVA, the pellets present ascendant trend on the COD and NH_3-N removal efficiency, but the removal efficiency of TP and TN decreased first, then increased slightly and then decreased. As shown in *Figure 4*, although the removal efficiency of TP reached the maximum without adding PVA (PVA(w/v) = 0%), considering that the mechanical strength of the pellets was too low at this time and had a certain viscosity, and the mechanical strength and molding speed were improved after adding PVA. When the PVA content was 4%, the removal efficiency of COD TP, NH_3-N and TN reached 50.57%, 58.41%, 48.95%, and 46.43%, respectively. The above conclusions indicated that the immobilized pellet with 4% PVA concentration was the most appropriate.

Calcium salt of SA is often used for embedding and fixation of microbial cells, and SA has a great impact on mechanical strength and mass transfer effect of immobilized pellets. The immobilized pellets without SA are difficult to form due to insufficient mechanical strength. After the addition of SA, the molding became easier, but when the SA concentration reached 3%, the molding became difficult due to the increased viscosity. As can be seen from *Figure 3b*, it can be seen that 2% SA concentration is the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_515529

best choice for the preparation of immobilized microbial pellets, and the removal efficiency of COD, TP, NH_3-N and TN reaches 47.25%, 46.06%, 47.68% and 40.94%, respectively.

The results of the best concentration of PVA and SV in immobilized microorganism carrier were similar to Ali et al.'s research (2015), which was use 6% (w/v) PVA and 2% (w/v) SA as the most appropriate mixture gel concentration in anammox biomass for meeting the criterion of rapid and successful start-up of anammox process.

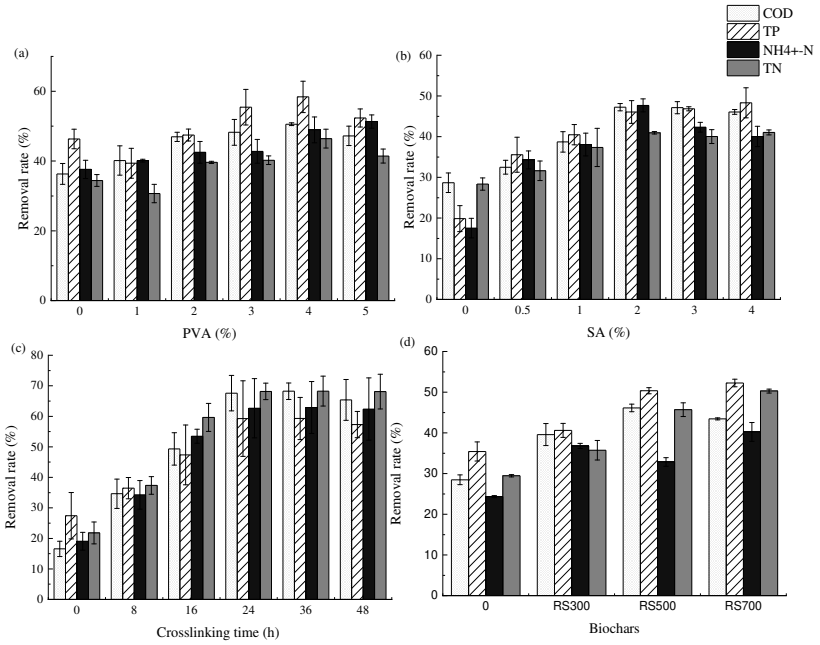

Figure 3. *The removal efficiency of COD (chemical oxygen demand, COD), TP (total phosphorus, TP), NH3-N (ammonianitrogen, NH3-N) and TN (total nitrogen, TN) for different immobilized pellets, as (a), (b), (c) and (d) shows the effect of PVA (polyvinyl alcohol, PVA), SA (alginic acid sodium, SA), crosslinking time and biochars type on the SBR (Sequencing Batch Reactor, SBR)*

a, b,

Figure 4. *The picture of immobilized pellets ((a) shows pellets without biochar, (b) shows pellets added RS700)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_515529

In order to explore the effect of immobilized microbial pellets prepared with different immobilization time, COD, TP, NH_3-N and TN concentrations in simulated wastewater were monitored. It can be seen that with the increase of crosslinking time, the removal efficiency of COD, TP, NH_3-N and TN of microbial immobilized pellets gradually increased. As can be seen from *Figure 3c*, the removal efficiency of COD, TP, and NH_3-N reaches the maximum at 24 h (91.41%, 79.08%, 47.68% and 84.51%, respectively). The removal rate of TN is relatively high, which reached 96.03%. Thus the optimal immobilization time for microbial immobilized pellets is 24 h, which was faster than Zhu et al.'s study (2009). In that research, the nitrite concentrations almost did not change from 39 hours to 49 hours at PVA-SA immobilized gel beads system because the ammonium was almost completely removed before 39 hours. As is shown in *Figure 3c*, the removal efficiency of NH_3-N was lower than Zhu et al.'s study (2009), which may because of the reaction temperature and initial concentration.

To explore the removal rate of COD, TP, NH_3-N and TN effects of immobilized pellets added biochar with different temperature, immobilized microbes pellets were added rice straw biochar 300℃ (RS300), 500℃ (RS500), 700℃ (RS700) 0.4 g, respectively, at the same time immobilized pellet without biochar was used as a control. It can be seen from *Figure 3d* that the removal efficiency of COD, TP, NH_3-N and TN were significantly improved after the addition of biochar RS700, which were achieved 99.42%, 98.24%, 94.23% and 99.01%, respectively. The mechanical strength was relatively stable. Meanwhile, the experimental data showed that the removal efficiency of COD, TP, NH_3-N and TN were RS700> RS500> RS300> 0. Removing of COD, TP, NH_3-N and TN from water onto biochar occurs due to its high surface area and microporosity (Lou et al., 2011). The differences of removal efficiency results between RS700, RS500, RS300 were due to that biochars produced at > 400℃ are more effective for organic contaminant sorption because of their high surface area and micropore development (Ahmad et al., 2012, 2014).

Effect of different dosages and HRT on Sequencing Batch Reactor (SBR)

To explore the effect of different dosages of immobilized microbe pellets on sewage treatment, the SBR reactor runs continuously for 5 days. The results showed an excellent sewage treatment efficiency of immobilized pellets added RS700. As shown in *Figure 5*, the removal efficiency of COD, TP, NH_3-N and TN increased with the dose (0-30 mL).

Actually, when the dosage of mixed bacterial solutions was increased from 0 mL to 10 mL, the removal efficiency of sewage in SBR was significantly improved. When the dosage was increased from 10 mL to 30 mL, the purification efficiency was improved; but, the improvement was not significant. Apparently, each sewage index has the best removal efficiency when the bacteria dosage is 30 mL, but the cost was too high to make it feasible. As can be seen from *Figure 5*, when the mixed bacterial liquid additive amount was 20 mL, within hydraulic retention time 5 d and water temperature 6 to 8℃, the removal efficiency of each index in SBR was gradually increased, eventually the removal rate of COD, TP, NH_3-N and TN reached 80.89%, 59.80%, 77.60% and 58.28%, respectively. From the perspective of operation cost and the efficaciousness of sewage treatment, 20 ml should be selected as the best dosage of the mixed bacterial solutions for the SBR.

HRT usually plays a key role in the removal of pollutants in water, and explores the best HRT is one of the steps necessary to conduct an SBR experiment (Hamjinda et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_515529

2017). In order to evaluate the effect of immobilized pellets with different HRT on sewage treatment, the SBR system was kept at 6 to 8℃ when the dosage was 20 mL. It can be seen in *Figure 6* that the removal efficiency of each index changes with HRT. As the HRT increased from 0 to 3 day, the removal efficiencies of COD, TP, NH_3-N and TN improved significantly. When HRT is increased from 3 days to 5 days, purification efficiency was improved. However, the improvement was not obvious. Considering the operating costs and experimental operation, 4 days should be selected as the best HRT for the SBR. When the HRT was 4 days, the removal rate of COD, TP, NH_3-N and TN for the pellets reached 79.32%, 59.31%, 72.35%, and 87.14%, respectively.

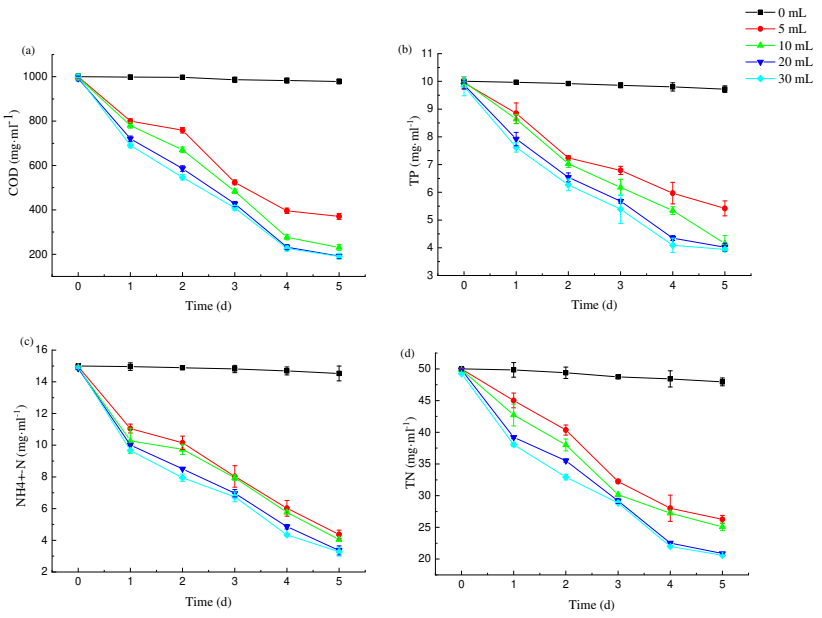

Figure 5. *The concentration of COD (chemical oxygen demand, COD), TP (total phosphorus, TP), NH_3-N (ammonianitrogen, NH3-N) and TN (total nitrogen, TN) changes with dosages in the SBR(as figure (a), (b), (c) and (d) shows the change of removal rate of COD, TP, NH3-N and TN with the increase of dosage)*

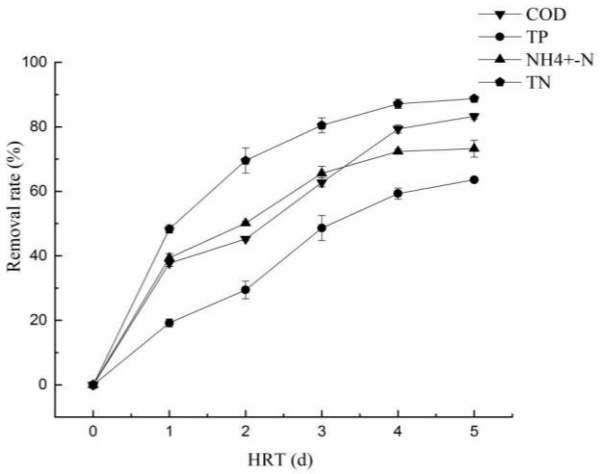

Figure 6. *The concentration of COD (chemical oxygen demand, COD), TP (total phosphorus, TP), NH3-N (ammonianitrogen, NH3-N) and TN (total nitrogen, TN) changes with hydraulic retention time (HRT) in the SBR (Sequencing Batch Reactor, SBR)*

Wastewater treatment dynamics equation

Kinetic research could optimize the technology and methods of biochemical processes. In fact, the patterns of microbial degradation could be predicted by modeling kinetic degradation models and modern techniques to simulate degradation(Jou et al., 2008). Kinetic model was used to describe an aerobic granular sludge reactor, fed with a defined influent, capable of simultaneously removing COD, nitrogen and phosphate in one sequencing batch reactor (SBR). The model could describe the experimental data from the SBR sufficiently. Thus, the effect of process parameters on the nutrient removal rates could be reliably evaluated (Chung and Rittmann, 2007). In the SBR system, the degradation efficiency of immobilized microbial pellets to pollutants in sewage can be simulated by first-order kinetic equation:

$$\ln \frac{C_e}{C_0} = -k_v t \qquad \text{(Eq.1)}$$

$$k_v = \frac{-1}{t} \ln(\frac{C_0}{C_e}) \qquad \text{(Eq.2)}$$

where k_v is the contaminant volume removal rate constant, d^{-1}; Ce and C_0 are the influent and effluent concentration, $mg \cdot ml^{-1}$; t is the hydraulic retention time, d.

According to the above kinetic model, the average effluent concentration of each contaminant in the SBR system was denoted as C_e, and the average influent concentration was denoted as C_0. ln (C_0 / C_e) was taken as the ordinate, and t (time) as the abscissa. The ln (C_0 / C_e) of different dosage of bacteria and different hydraulic retention time (dosage of bacteria is 20 mL) are taken as ordinate in the *Figure 7*, *Figure 8*, respectively.

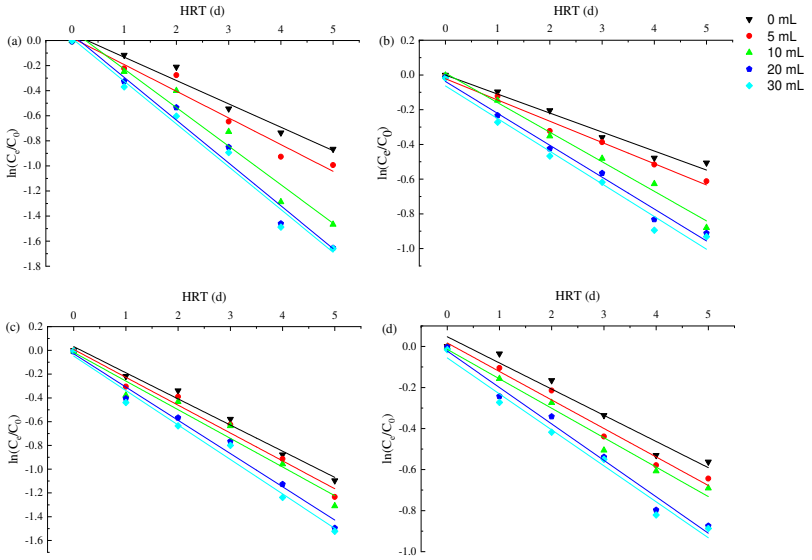

Figure 7. *First-order degradation of organic matter with different dosage of immobilized pellets added RS700 in the SBR (Sequencing Batch Reactor, SBR) units operated under 6 ~8℃, and (a), (b), (c), (d) represent the time curves of COD (chemical oxygen demand, COD), TP (total phosphorus, TP), NH3-N (ammonianitrogen, NH3-N) and TN (total nitrogen, TN)*

By monitoring the SBR operation system, the degradation efficiency of pollutants was improved under conditions of different amount of bacteria and different hydraulic residence time. As *Figure 7* and *Figure 8* showed that the removal kinetics of contaminants in the SBR conforms to the first-order kinetic model. The volume degradation rate k_v represents the treatment efficiency of the contaminants. Mixed Psychotropic bacterial flora had a noticeably high disposal rate for pollutants at a HRT of 4 days. Furthermore, the degradation rates of COD, TP, NH_3-N and TN significantly increased as the dosage of bacteria was increased. The R^2 of each k_v reached 0.78, 0.95, 0.98, 0.91. Similarly, Tang et al. (2018) added a mixed of *Psychrotrophic* bacteria

DOI: http://dx.doi.org/10.15666/aeer/1801_515529

strains in an integrated vertical-flow constructed wetland at a temperature of (6 ± 1)°C, which had a high disposal rate for pollutants at a HRT of 5 days and the degradation rates of COD, NH_3–N, NO_2^- −N, NO_3^- −N, TN and TP significantly increased as the dosage of bacteria was increased.

Conclusions

1) For immobilized microbe pellets, the optimal optimization conditions were reached when: the mass fraction of SA was 2%, the amount of PVA was 4%, and cross-linking time 24 h, the best biochar added was RS700. The results of the immobilization experiment provide a methodological support for improving the sewage treatment effect under low temperature conditions.

2) Mixed bacteria under the condition of optimization system for immobilized pellets was added to the continuous running of SBR process, 20 mL bacteria suspension of immobilized pellets could use to test the best dosage through the experiment monitoring. Under the optimal addition condition, the longer the HRT in the SBR process, the better the treatment effect would be. In a comprehensive consideration, the optimal HRT was 4 d, and the removal efficiency of COD, TP, NH_3-N and TN under the best dosage was reached at 76.79%, 56.50%, 67.60% and 54.92% at 4 days, respectively.

3) In the SBR process, the degradation efficiency of immobilized pellets for each pollutant COD, TP, NH_3-N and TN in the SBR conforms to the first-order kinetic model.

4) The results of this study provide a theoretical foundation and scientific support for the use of SBR in wastewater treatment, and may have great significance in solving the increasingly severe water pollution problem in China. In future research, the selection of microbial species and the optimization of immobilization conditions should be carried out for different types of sewage. At the same time, new materials should be considered as additives to promote the study of microbial activity.

Abstract. The current condition of waste management in Dhaka is a clear manifestation of poor sanitation in less developed nations. The city has been experiencing waste dumping on a daily basis. The aim of this research is to minimize waste, eliminate water contamination as well as greenhouse gas (GHG) emission by producing electricity from waste. An experiment was performed on a collection of wastewater samples and it was found that high level of water contamination is brought by extensive waste water contamination. The study found that wastewater from Dhaka city contained a diverse array of chemicals including toxic and non-toxic heavy metals, nitrates, phosphates, sodium ($Na^{+)}$, potassium (K^+), sodium sulphate (SO_4^{2-}), Calcium (Ca^{2+}), chloride (Cl^-) and harmful polyaromatic hydrocarbons. A multivariate analysis was applied and the level of contamination was detected to exceed the World Health Organization (WHO) permissible limit in all areas. Software simulation was also used in data analysis. The study found that 90% waste collection rate and High tech solid waste incinerator plan could produce 262.125 MW electricity per day and potentially reduce 2.375 million tons GHG emission in total per year.
Keywords: *water quality, green energy, water contamination, organic waste, and wastewater evacuation*

Introduction and literature

Dhaka is the capital of Bangladesh. The city is surrounded by four main rivers along with their many small cannels. Apart from these water masses there are several inland lakes and lowland inside the city. The source of water for these water masses is rain and seasonal rivers. The city population is estimated to be around 19 million hence the city is considered as one of the most highly populated towns on Earth. Moreover, the city is known to produce tremendous amount of solid wastes on a daily basis. Rising waste volumes together with the increasing complexity of waste treatment have become not only a major and growing public health but also environmental concerns. Due to the population growth, changing lifestyle and spending sequence of individuals, the amount of waste production is ever growing. The eminence as well as the composition of wastes are varying radically. Water pollution is not only impacting water organisms alone but also damages the natural biodiversity.

From the map (*Fig. 1*) we can see rivers around Dhaka City. These water-bodies are highly polluted and have reached alarming levels of pollution that is both economic and health concerns to inhabitants, mainly to the less endowed in the city. Generally, consumption of water originated from several of sources such as rivers, lakes and ponds and ground water. These waters are contaminated with arsenic (As), a toxic metalloid.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_531548

Arsenic exists in inorganic form (As^{3+} and As^{5+}) in aquatic system and poses a large public health threat when combined with methyl and dimethyl arsenic composites from natural systems including, anthropogenic as well as ecological sources (Chatterji, Arlosoroff and Guha, 2017; Cordonet al., 2018; Cui et al., 2018; Ijumulana et al., 2016). Comparative studies have shown that arsenic in water causes health risks such as generating non cancer effects, hypertension, cardiovascular diseases and diabetes (Tripathee et al., 2016; Khuhawar et al., 2019; Kumar et al., 2015; Song et al., 2016; Ijumulana et al., 2016). Inorganic arsenicals which fall in group I carcinogens create a high health risk which claims about 60–100 million people in India and Bangladesh after being found in drinking water as major contaminant from river, canal and lake (Huang et al., 2016; Antoniadis et al., 2017; Bettoschi et al., 2018). UNICEF has reported high awareness in Arsenic contamination in various parts in the country (Mehrotra et al., 2016; Ur Rehman et al., 2018).

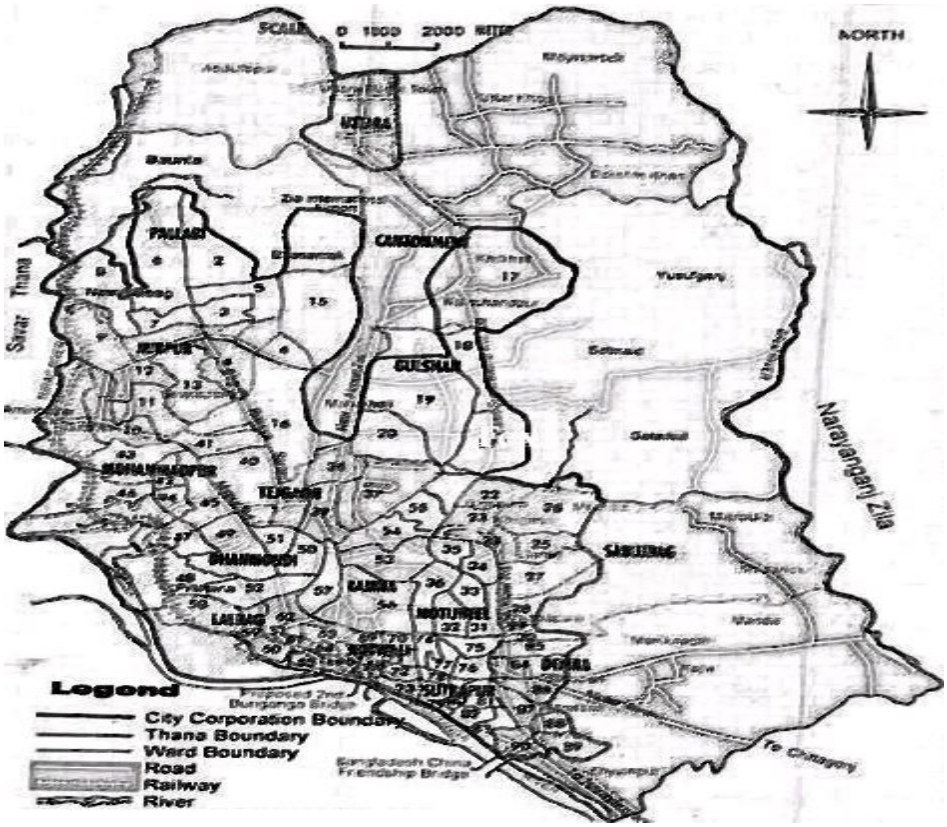

Figure 1. *Dhaka City location map*

This arsenic contamination happened due to household solid wastes, wastes from small industries and tannery effluents with multifarious features. The wastes are also linked with high level of organic pollutants mainly made up of chemicals as well as significant amounts of inorganic components which are toxic together which cause inhibitory effects on biological system (Ouyang et al., 2018 and Mohammadi et al., 2015). The water sources are polluted with more than 138 different pollutants. In addition, inhabitants are also throwing wastes directly and indirectly into the rivers. The biggest sources are Hazaribagh tannery wastes; water containing COD and the toxic stench wafting throughout the whole area is almost suffocating. Based on the current

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_531548

statistics lack of waste management in the city is turning out to be the main cause of water pollution. During the rainy season wastes and wastewater production is 100% higher than in the dry season.

The main supply of water in the city is (83%) ground water and surface water (17%). The peripheral rivers have undergone major pollution due to indiscriminate discharge of domestic and industrial wastes (*Figs. 2–5*). As a result, surface and ground waters are highly contaminated by different types of chemicals and microbes. Some other identified contaminants are residual chlorine, coliform and faecal coliform. According to Dhaka Water Supply and Sewerage Authority (DWASA, 2013), the city experiences high concentrations of E. coli in the ground water in the downtown area while water supply is also contaminated.

Figure 2. *Waste mixing with rain water at primary collection area*

Figure 3. *Bank of the river final dumping site*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_531548

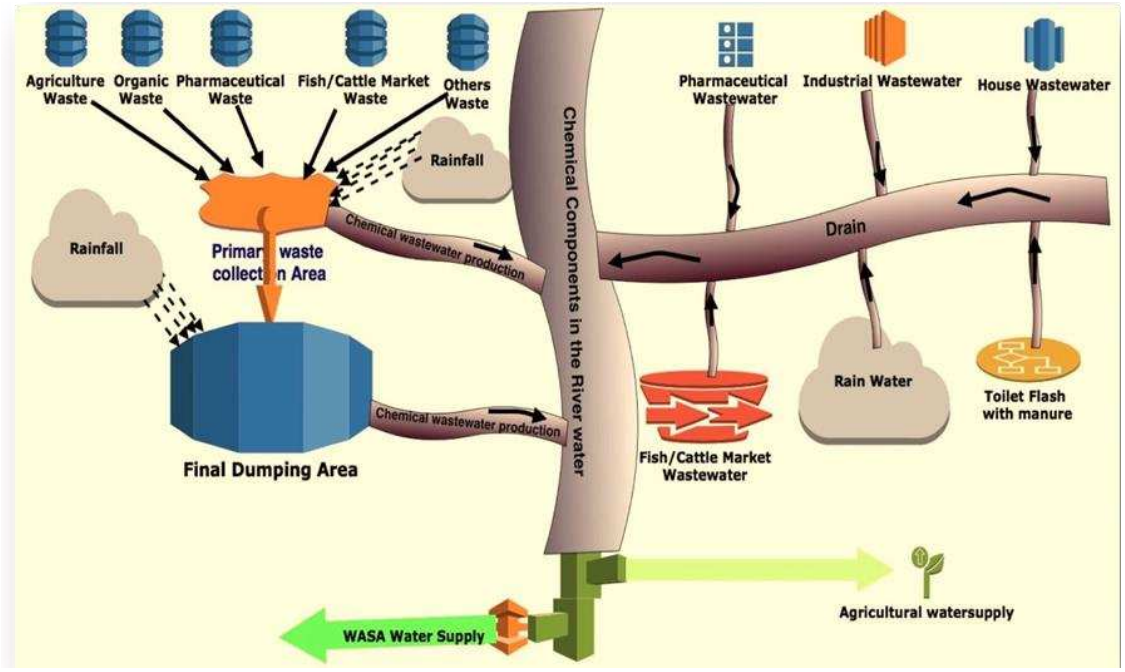

Figure 4. *Waste water generation process*

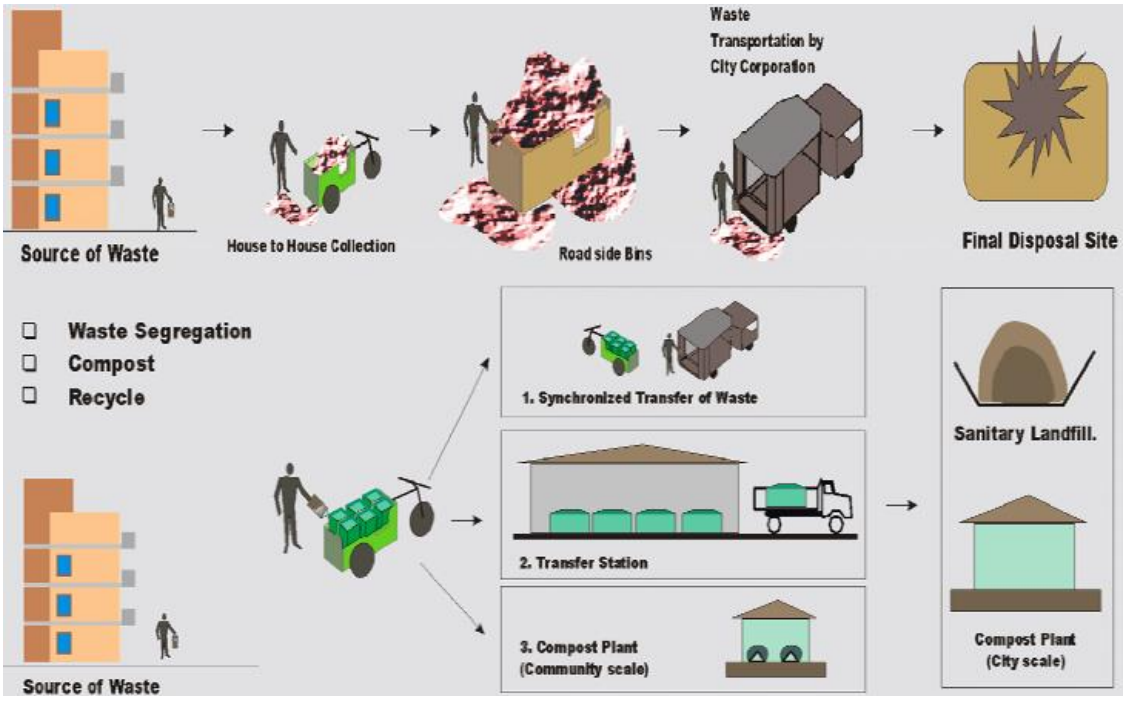

Figure 5. *Traditional waste management system in Dhaka City*

The fact that untreated industrial wastes are playing a critical role in the degradation of the environment, it is yet to receive international recognition. The poor in the city are highly affected by the pollution based on the current report. The city watershed has reduced by more than 30% over the past decade (Ana and Nandini, 2009). Ground water level is rapidly declining 3 m/yr (DWASA, 2013) due to a large-scale abstraction.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_531548

Therefore, ground water is no longer a viable option for water supply and the surface water will be the only option for water sources within the next half-century. To address the tremendous water pollution problem, specialists ought to independently collect as well as treat wastes in order to save the surface and the ground waters.

Currently there is no government agency which has carried out research concerning this on-going environmental issue. There is a great need for arsenic assessment study in the area to establish the level of waste and water pollution in the city of Dhaka (Bangladesh) as well as to assess the level of pollution and the main cause of pollution. The paper also sought to determine water quality parameter such as temperature, pH as well as other parameters in the water sources. In this outline, the objectives of the study were the followings: to show how wastes are converted to wastewater and mix with the water body (*Figure 4)*; to use a high tech advance waste management system in Dhaka City and to show GHG emission load reduction in order to save the valuable water resources.

Materials and methods

Study area

The study was conducted in Dhaka City. Dhaka is situated at 23°42'58"N 90°23'46"E on the eastern bank of the Buriganga River as shown in *Figure 1*.

Water sampling and analysis

Primary data was collected through sampling method and later on analysed independently based on the water sample origin. Water samples were collected from Buriganga River, Balu River, Turag River and in Tongi Canal around Dhaka City. Wastewater from tannery examined in the study was sourced from various sites such as Hazaribagh. Over 200 larger tanneries as well as other small ones collectively made up the largest fraction of wastewaters in the city. Grab samples collected from different drain tanneries were assessed to determine the conventional characterization of the raw tannery wastewater in the area. The recommended analyses were carried out in pair in accordance with required standard methods (Clessceri et al., 1998). More than 256 water samples from various sources were taken independently and from separate sampling points within Buriganga River, Balu River, Turag River and in Tongi Canal at Dhaka City. Of all collected water samples more than 153 were taken from > 15 m depth while the same number were taken from surface water. Van Dorn plastic bottles were used to gather samples. The collected water samples were stored in plastic bottles that were previously soaked in 10% nitric acid. During the study period, the researcher assessed water temperature, its pH as well as the concentration of dissolved solids using various instruments such as thermometer, pH meter respectively. The samples which were previously collected were then stored in an ice box, and transported to the lab in the same day to avoid delay.

A dilution of 1000 mg recommended standard solutions were sourced from internationally certified lab to be used as a control in the study of the various metals. In order to prevent contamination of the samples, all the glassware and plastic containers were treated with 5M HNO_3 and rinsed with distilled water and completely with ultrapure water. The physicochemical levels were established using recommended techniques (Tamasi and Cini, 2004; APHA, 1998). Moreover, methyl-orange was used to assess the level of alkalinity in the sample waters. EDTA was used to measure Calcium concentration in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_531548

samples using of complexometric titration (Eaton et al., 1995). In respect to analysis of arsenic as well as other metals water samples were pre-concentrated different zones (Arain et al., 2007; AOAC, 1995). Saturation indices were measured using speciation-modeling to determine the equilibrium condition of the minerals in the samples (USGS, 2007).

Filtered samples of aliquot were measured by evaporation method to estimate the amount of dissolved solid in the water samples. Both Sodium (Na) and Potassium (K) were determined using flame-photometer while Calcium (Ca) and Magnesium (Mg) were examined by complexometric titration technique using Na_2 EDTA as titrant. Other cations such as Fe^{2+}, Fe^{3+} , Mn^{2+}, Cu^{2+}, Zn^{2+}, B^{3-}, together with anions such as Cl^-, NO_3^--N, SO_4^{2-}-S, HCO_3^-, and CO_3^{2-} were examined based on recommended procedures. Qualitative test was done to detect the presence or absence of Arsenic (As). Irrigated water quality parameters viz. SAR, SSP, and H_T were used to classify the suitability of waters, along with pH, EC, and TDS.

For both quality assurance and control (QA/QC), data were examined based on the recommended method (Zacheus and Martikainen, 1997). Flame atomic absorption spectrophotometer technique was used to examine sodium, iron, and potassium within given limits of 0.02 g LOD. Consequently, sulphate concentration together with chloride, as well as nitrate concentrations were assessed using LOD 1.2, 1.4, 1.5 and 2.7 g, in that order. For the purpose of validation of ions, the researcher carried out ionic balance test (Lopez et al., 1999) as

$$Ion\ balance\ percent = \left\{\frac{\sum_{cations} - \sum_{anions}}{\sum_{cations} + \sum_{anions}}\right\} \times 100 \qquad \text{(Eq.1)}$$

On average the ion balance was around 1.18% with two outliers of around 1.8% and −3.1% were determined, the mean of the ion balance was around 0.6% (*Table 1*). The parameters of SAR, SSP, and H_T were measured from the analyzed data using the following formula:

$$SAR = \frac{[Na^+]}{\left\{\frac{([Ca^{2+}] + [Mg^{2+}])}{2}\right\}^{\frac{1}{2}}} \qquad \text{(Eq.2)}$$

$$SSP = \frac{Soluble\ Na\ concentration\ (meL^{-1})}{Total\ cation\ concentration\ (meL^{-1})} \times 100 \qquad \text{(Eq.3)}$$

$$H_T(mgL^{-1}) = 2.5 \times Ca^{2+} + 4.1 \times Mg^{2+} \qquad \text{(Eq.4)}$$

Correlation coefficient analysis was done for all possible combinations within the quality parameter.

Waste sample analysis

Primary and secondary data were used for this study purpose. Secondary data was collected through various books, reports, journals and articles, such as JAICA, Ministry of Environment and Forest (MOEF), Dhaka City Corporation (DCC) reports and different waste management plants in Japan. Data collection methods included document/literature review, semi-structured interviews, checklists and observation.

A semi-structured interview refers to a gathering in which the interviewer asks open-ended questions and allows for a discussion with the interviewee. There is no formalized process which is used while asking or answering the questions. In most cases, the interviewer asks the general questions which lead to further short questions within the discussion.

A checklist structures an individual's evaluation or observation of performance or even an artifact. They use simple criteria which can be labelled as present or absent and provide space for the observer to comment. Checklist can also be used to evaluate a database or structure out a peer observation and guide well while collecting data from a sample of the population.

The measure of combined dissolved solids in waters were determined by evaporating the filtrate of filtered samples. Sodium and Potassium levels were obtained by flame-photometer where else Calcium and Magnesium were obtained through complexometric titration using Na_2EDTA as reference sample titrant. Cations like Cu^{2+}, Zn^{2+}, and anions like Cl^-, NO_3^--N, SO_4^{2-}-S, HCO_3^-, and CO_3^{2-} were measured through photometry. The presence or absence of Arsenic (As) metal was determined using qualitative test.

The cation levels were obtained by atomic spectrophotometry by mechanism of flame absorption for potassium, sodium and iron while for the other cations hydride generation was used in their spectrophotometry. Anion concentrations were obtained through ion chromatography (Metrohm 838) and validated then calculated using *Equation 1.*

Lastly, observation involved direct or indirect viewing of object whether aware or unaware if it is being observed. In observation, the researcher may choose to collect data through a set of time periods or progressive observation throughout the project.

To properly investigate on waste generation (*Fig. 4*) and disposal system (*Fig. 2,3 & 5*), some areas were selected as sampling areas, such as Hazaribagh located at 23.734722°N, 90.369444°E with a total area of around 3.58 km^2; Gabtoli situated at 24°53'N 89° 27'E; Uttara on the other hand is situated at 23° 52'N 90°24.3'E; Dholpur (23.71674°N 90.4323178°E) and Mirpur located at 23.809309°N 90.360928°E. Stratified random sampling technique was used for public opinion survey on some attributes, such as waste generation (*Fig. 4*), waste dumping (*Fig. 2,&3*), and waste safety. The analysis was done using Urban Co-benefits Evaluation Tools and statistical tools, like Microsoft Excel used to perform calculation, visualization and analysis of data and information. It aids researchers to structure and process data through utilization of rows, columns and a combination of different formulas.

The method was to determine whether the current waste management process (*Fig. 5*) was being done as per legislation, the frequency in which environmental harm occurs and its significance. These measures were put in place to verify environmental damages (*Fig. 3*) and the optimal usage of water, energy and natural resources. In the project we have done the software simulation by classifying the wastes where combustible and non-combustible items are separated from the beginning. Step by step waste generation (*Fig. 4*), collection separation processes were done. Only the combustible wastes are simulated by the software. Hopefully, some medical wastes were also included in this system because in Dhaka City all

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_531548

wastes are dumped in the open pit and one dumping site. The aim was to answer the questions of this study which were: (1) how wastes convert to a wastewater stream, (2) chemical pollutants confirmation, (3) greenhouse gases production by conventional waste management procedure, and (4) a solution for saving surface water and GHG reduction

Total energy in MSW

Total energy in MSW was determined by its composition and moisture content. The MSW was reported to produce 95 m^3 of methane gas per tonne with an efficiency of 80% and energy production of $12.98 \cdot 10^5$ KWh/year (Kumar et al., 2009). The energy content of waste was measured by bomb calorimeter which entailed total combustion of the sample and then gauging the heat rise in surrounding water bath (Masters and Ela, 2013). This temperature value obtained is mainly higher in industries which manufacture products such as paper, metal and plastics. Khan et al. (1919) formulated formulas that determine temperature in food and paper industries. This formula was expressed in the equation below:

$$\mathrm{HHV}\left(\frac{\mathrm{kJ}}{\mathrm{kg}}\right) = 53.5(\mathrm{f} + 3.6\mathrm{cp}) + 372\mathrm{plr} \qquad \text{(Eq.5)}$$

where f is food, cp is paper and cardboard, and plr is plastic. However, some amount of HHV energy is lost through vaporization of the moisture.

Results

The results for the study were as follows:

Test results (water sample)

The tests were carried out in water samples in two depths; groundwater water and surface water. The ground water samples were classified depending on the mode they are found. Pump samples (PS, $n = 113$) were obtained at a depth range of 15.85 to 33.5 m and deep-tube well samples (DTS, $n = 40$) were obtained at a depth variation up to 120 m depth as shown in *Table 1a*. Surface water samples were classified into two categories, namely river samples (RS, $n = 33$) and municipal samples (MS, $n = 120$), depending on the place the samples were obtained from. Physical and chemical analysis of all samples were done.

The pH and EC of all samples were measured and their range obtained. The pH range for PS was 7.1-9.0 while for DTS was 7.9-8.1. The EC range for groundwater samples were 0.49–4.56 mS cm^{-1} for PS and 1.09–1.10 mS cm^{-1} for DTS. Alkalinity ranged from 178–1360 mg for both groundwater samples. The pH range for RS was 7.1-7.9 while that of MS was 7.0-8.6 where else the EC values ranged from 0.40–2.67 mS cm^{-1} and 0.40–3.71 mS cm^{-1}, respectively. Alkalinity in both samples of surface water ranged from 118–479 mg. The composition of major ion was almost similar in both categories of surface water.

Groundwater had significant Fe concentration ranging from 0.1 to 4.01 mg while surface water the level ranged much below the WHO recommendable range except at sampling point RS3. Arsenic concentration was more in the groundwater

compared to surface water with ground water registering the highest level of 108 g compared to 50.1 g for surface water.

Simulation results

The simulation result is shown in *Figures 6–8*. *Figure 6* shows almost 49% for landfill and open burning is almost 12%. *Figures 7* and *8* show that greenhouse gas emission is extremely high level in conventional approach.

Discussion

The pH of all samples was nearly above the acceptable level of World Health Organization (WHO) with high level of EC and alkalinity in samples which were obtained at deep points ($p > 0.05$). This variation in the levels of pH and alkalinity in groundwater samples compared to surface water samples was due to excess dissolution of organic and inorganic compounds which sediment at the ground of the water as thousands of tonnes of wastes are produced during the wet season (*Fig. 2*). Due to lack of proper treatment, wastes are terminated to the final dumping areas (*Fig. 3*) or open pits in main streets or close to the city emitting GHG gases which are dissolved in water by rainwater or seasonal water creating more anions in the surface of the water (*Fig. 2*), and finally the wastewaters are flowing into the rivers (*Fig. 3*). In the study the large concentration of cations and anions were due to more solubility of GHG gases emitted upon the burning of large quantities of waste production within the city. There was similar concentration of major ion in both municipal treated water samples and river surface water due to even distribution of ions in the water at a similar depth. There was a relative range in levels of different cations and anions. Sulphate ($SO4^{2-}$) ions ranged from 109–1519 mg, chloride Cl^- ions ranging from 63 to 718 mg, while Sodium ions (Na^+) ranged from 139 to 946 mg. Calcium ions ranged from 6.3 to 299 mg. The levels of concentration of different cations and anions depended on the nature of waste being dumped openly in the pit and their solubility levels in water (*Fig. 3*).

This 3R approach in stimulant results is very good (*Fig. 5*). However, this approach has its limitation, it can cover only small amount of wastes per day. To tackle huge amount of wastes (12-15 thousand tons/day) that produced in Dhaka City, it is not an ideal approach. In this situation, we are proposing an advanced technology for waste management system that could cover all the wastes in Dhaka City.

Proposed technology

Waste life cycle

After reviewing the waste disposal system and 3R approach (*Fig. 5*) in Dhaka City, we propose a design for waste life cycle to achieve our final goal. *Figure 9* shows the

proposed life cycle for solid wastes where waste-classification is started at sources (Burnable, non-burnable, recyclable, organic particularly kitchen wastes) and each of the waste will be treated accordingly.

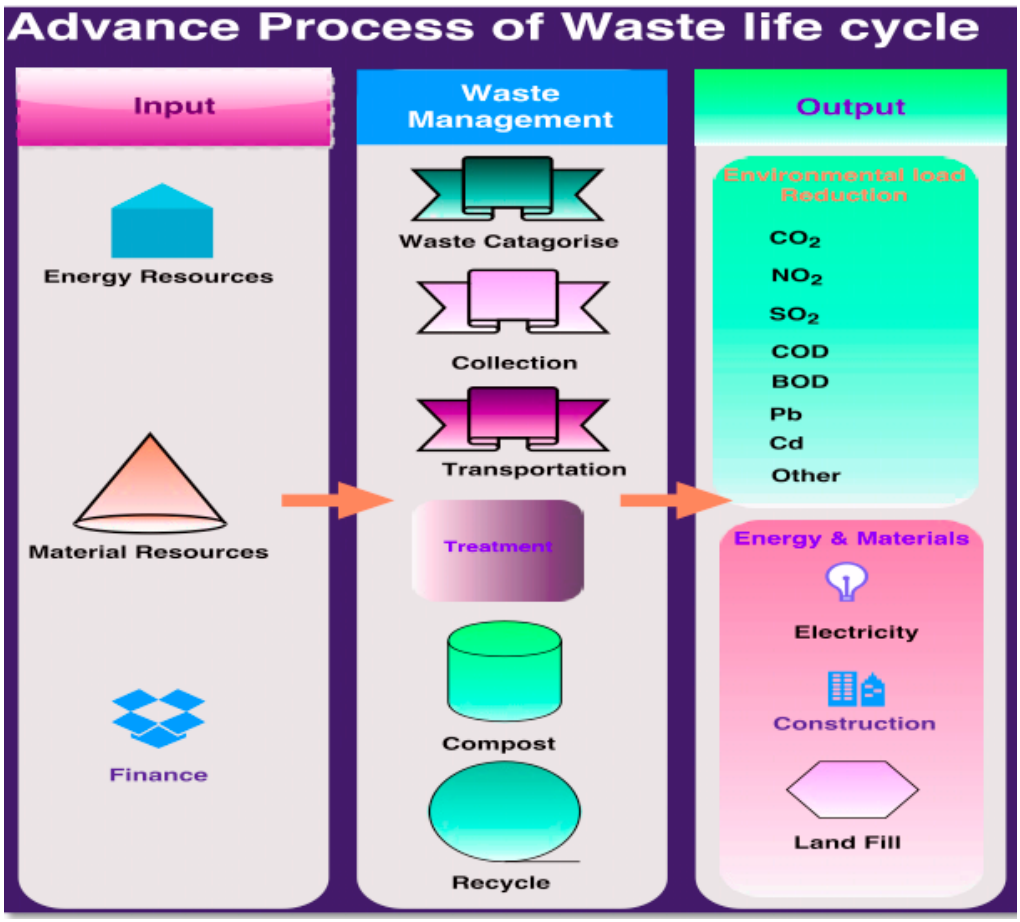

Figure 9. *Proposed system*

Proposed treatment plant

Figure 10 depicts incineration structure where burnable wastes are burned at 500 to 600 °C to keep valuable aluminium and un-oxidised ferrous metal that can be recovered by recycling. Non-combustible materials and sand are discharged from the bottom of the furnace through the non-combustible discharge conveyor. There are two types of separators here. If there are any ferrous metals contained in the non-combustible these are recovered with a magnetic separator, and the aluminium is recovered with an aluminium separator. The sand is stored in the sand storage tank.

Second stage is ash melting. The ash melting furnace has higher temperature because the gas is combusted while being circulated at the relatively high temperature at 1300 to 1400 °C (Kurahama Sanitary Facilities Association, Japan). This high temperature melts the ash contained in the gas, turning it into the slag, while greatly decreasing the amount of generated dioxins. The bottom of the ash-melting furnace is a discharge system for slag. Slag scraper conveyor is keeping and cooling slag by circulating cool water. This water is cooled by the water cooler and recycled for slag cooling system. Finally, slag is crushed by the slag crusher and stored in the slag storage yard.

DOI: http://dx.doi.org/10.15666/aeer/1801_531548

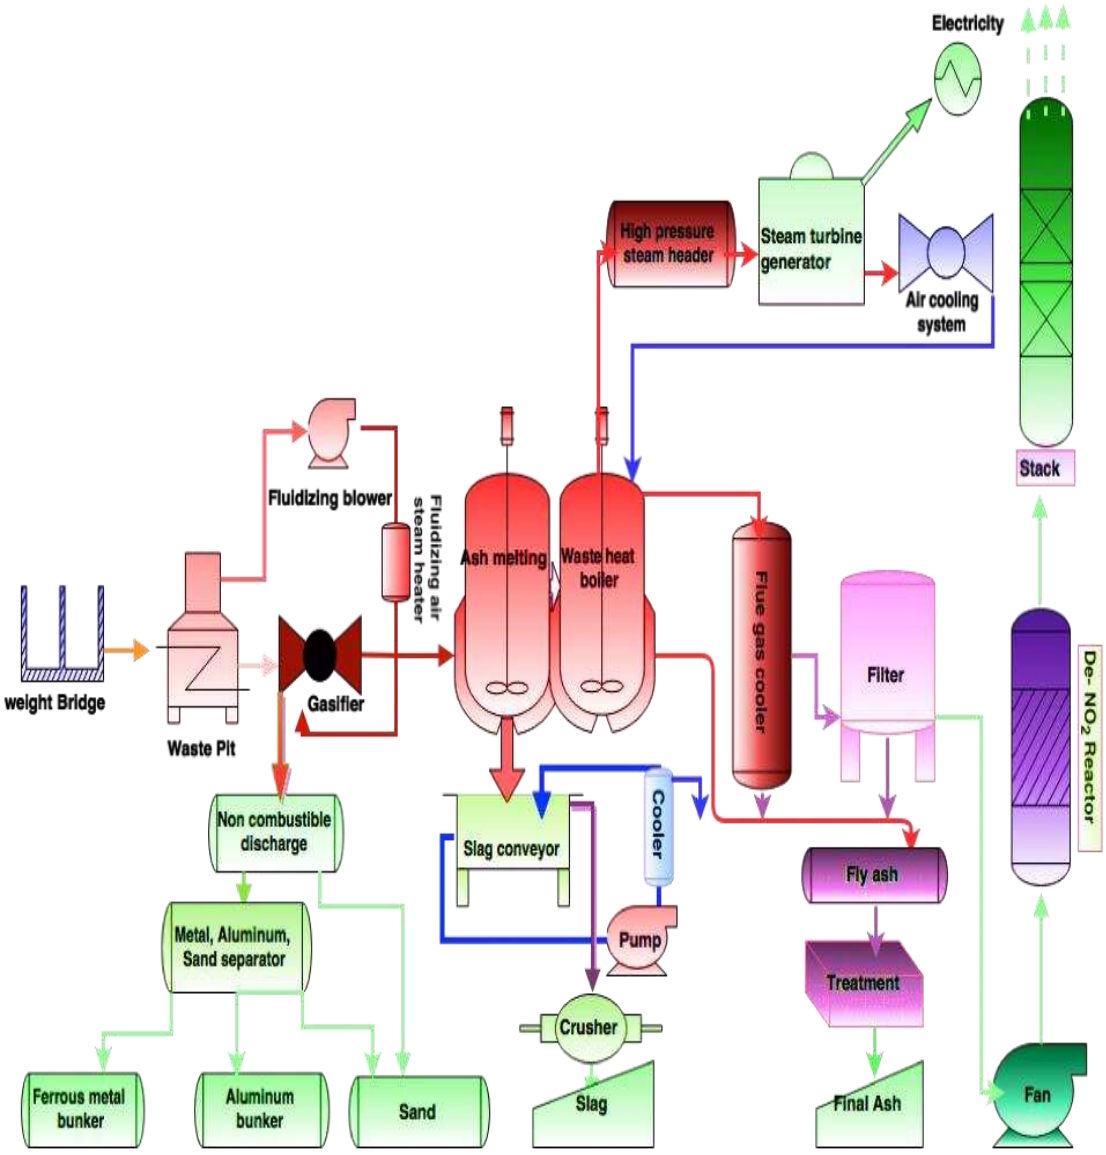

Figure 10. *Advance waste treatment plant*

The ash melting furnace and the waste heat boiler are directly connected to a heat boiler which has a high-pressure steam header that uses steam to generate power. The power generated is used to power the facilities and surplus sold. The steam is also used to provide hot water. The heat boiler discharges fly ash with flue gas at the bottom where the gas is taken back to the cooler while the ash is moved to a fly ash silo. This fly ash silo is also receiving ash from bag filter. Finally, fly ashes are treated by the treatment facility and sent to the hopper.

The gas is then cooled in water and filtered through filter bags made of fabrics to remove dust then reheated and passed through De-NO_2 reactor which removes nitrogen oxides contained in the gas as they react with ammonia through a catalytic reaction. Finally, it will discharge to the atmosphere by the stack. If we can implement this plant, our simulation result showed that GHG emission would be the same as of Kuraham waste management plant (Kurahama Sanitary Facilities Association, Japan). Thus, we can control environmental standard.

Proposed treatment plant's simulation result

Compared to the conventional waste treatment process, the High Tech system reduced the production of pollutants; particularly GHG is a million tonnes lower (180 to 0.03 thousand tonnes) as shown in *Figure 11* and *Table 2*.

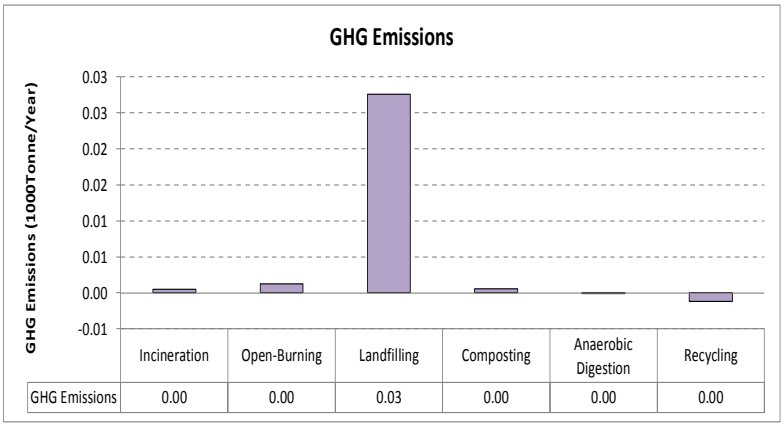

Figure 11. *Advance waste treatment plant gas emission*

Conclusion

The research concluded that the level of arsenic in different samples was higher than the acceptable level expected by WHO. The higher levels were mainly found in the ground water compared to the surface water were mainly due to waste dumping factors including the nature of waste, solubility that influence pH level, and concentration of different cations and anions. This High Tech waste treatment plant can potentially

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_531548

reduce totally 2.4 million tons GHG per year. The plant can also produce 256.125 MW electricity daily. Thus, the system is self-sustainable and environmental friendly. It will reduce polluted wastewater effluents from flowing into the water bodies and GHG emission in the environment significantly. Further research is required to identify how electricity can be generated. Moreover, the study was conducted in a developing country. To enable generalization of the findings, the study suggests a similar research to be conducted concerning under-developed and developed nations.

Abstract. This study discusses the development of mistletoe (*Viscum album* L.) and its economic impacts on natural afforestation and regeneration areas. In this context, a total of 16 sample areas were determined in Scots pine natural regeneration and afforestation areas with resembling habitat characteristics. The occurrence status of mistletoe in Scots pine (*Pinus sylvestris* L.) individuals in these areas was determined according to stem, branch and corolla parts and morphological age determination was also conducted for the plants. Additionally, the relationship between diameter and length increase of healthy individuals, and ones affected by mistletoe were modelled with simple linear regression analysis. Besides, the tree asset values of the stands were calculated by estimating maintenance and afforestation costs at the working sites, and economic loss potential was determined through the targeted forest product revenue. Study results have revealed that natural regeneration sites are less exposed to mistletoe damage than afforestation sites. While the mistletoe exposure was found to be 27% in the study areas, it was determined that there was a potential revenue loss of 21% concerning the target economic revenue as well as additional labour and afforestation costs.
Keywords: *forest cultivation, mistletoe, revenue loss, parasitic plant*

Introduction

Mistletoe is an evergreen hemiparasite plant which has chlorophyll to be able to make photosynthesis and can live in the branches and trunks of trees (Yüksel et al., 2005). There are 36 genus and 1400 species of mistletoe which have been identified throughout the world. Mistletoes spread generally in temperate and tropical zones. The parasitism characteristic of mistletoe was revealed first in 305 BC. and was described for the first time by the Greek botanist Theophrastus (Janssen, 2001; Zuber, 2004). Mistletoe is part of the Santatales order of Viscaceae (Loranthaceae) family. It has three subspecies as *V. album* ssp. *album*: observed in all trees, *V. album* ssp. *austriacum*: frequently in pine species, *V. album* ssp. *abietis* in firs (Bilgili et al., 2014). Mistletoes are observed in almost all Scots pine forests spreading in Turkey (Eroğlu and Başkaya, 1995; Zuber, 2004).

Mistletoe seeds are consumed fondly by the nectar birds. The mistletoe seeds stick firmly to the branches thanks to their adhesive covering and fibres on their outer surfaces (Frochot and Salle, 1980). Often the first contamination is observed in old trees and large branches. The reason for this is explained by that birds arrive at the top of tall trees (Yüksel et al., 2005). Mistletoe seeds which sprout on individuals express themselves through the bark with the radicles. Absorbent aerial roots growing from the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_549559

radicles penetrate into the cortex and advance to the cambium of the host individual. Lateral roots advancing down and up occur from roots which reached cambium (Glatzel, 1983; Tennakoon and Pate, 1996; Anonymous, 1998). These radicles form 1-2 radicles each year, but they do not exhibit an active grow into the wood. However, they show growth as each annual ring thickness and passively enter into the wood (Yüksel et al., 2005). The mistletoe disturbs the normal growth by using the host plant's mineral nutrients via their absorbent roots, thus weakening the host plant and often it results in the loss of vital functions. Besides, they create swelling in the branches they occupy and prevent the use of these parts (Popp and Richter, 1998; Zuber, 2004; Yüksel et al., 2005). It has been reported that the anatomic parameter values of individuals with mistletoe contamination vary between 19-82% (Göl et al., 2018). It is known that the volume and quality of timber to be obtained from logs are also affected by natural and ecological conditions (Mutanen and Toppinen, 2007; Malinen et al., 2015; Merganič et al., 2016; Gejdoš et al., 2019). It is also reported that biotic and abiotic pests have important effects on this issue (Fidan et al., 2016; Yaşar et al., 2016).

It is recommended that cleansing the mistletoe contaminated trunk parts by scraping and preventing any contact of these parts with sunlight and air are among recommended precautions. In the case that the mistletoe is observed on the branches, it is recommended that these branches are cut and removed (Yüksel et al., 2005). It is found that mistletoe affects the industrial use of the tree as well as economic losses because of the maintenance works which would be conducted. In addition, anomalies in the wood-based products introduced to the market adversely affect the demand of consumers (Öztürk, 2010).

In this study, it is aimed to determine the effect of mistletoe on the increase and growth, thus to determine the economic loss it causes by investigating Scots pine afforestation and natural regeneration areas in terms of mistletoe exposure.

Materials and methods

Materials

Research was conducted in Gumushane province of Turkey. Natural rejuvenation and afforestation areas within the borders of Gümüşhane Forest Management Directorate were selected as the study area. The working area is between 40° 32' and 40° 14' northern latitudes and 39° 56' and 40° 20' east longitudes (*Fig. 1*). In this context, the attention has been paid to work in areas where there are no significant elevation differences, slope and habitat differences in order to better deliver the differences between natural regeneration areas and afforestation areas. The average elevation of the study area has been measured as 1690 m in natural regeneration areas and as 1710 m in afforestation areas.

Sampling areas were determined as a result of the investigations for natural regeneration areas and afforestation areas which do not have slope, elevation and serious elevation differences under the same habitat conditions, by using the current stand map (*Fig. 2*).

Eight sample areas have been determined in the 162 numbered natural regeneration area which is 16.9 ha, 8 sample areas have been determined in the 207 numbered afforestation area which is 26.8 ha, and in total 16 sample areas have been determined. These areas have been determined as 100 m² in Çsa natural regeneration areas which are in "a" age and as 200 m² in Çsab afforestation areas, which are in "ab" age, as stated in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_549559

the management plans. The difference of the sample size of the selected area was due to the different size of the area of natural regeneration and afforestation. The stands of the selected sample areas have been transformed into Google Earth image by digitizing the existing stand maps with the help of Netcad program. Field works were carried out in April and May 2018.

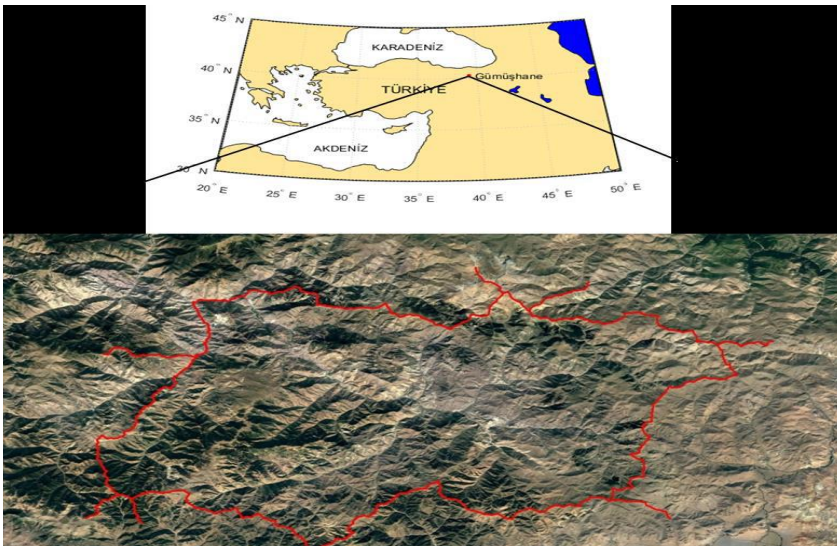

Figure 1. *General location of the research area*

Figure 2. *Sample areas of the research area*

Methods

Diameter and length measurements were conducted for each tree in the sampling areas. On the other hand, the mistletoe age was determined with the morphological age determination method for individuals in the sampling areas. The diameter of the trees

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_549559

was measured as d_{130} diameter by using a calliper. The length of the trees was measured with the help of SILVA CM 10152025 LA DP slope and length measuring compass. In this study, each tree has been divided into three parts as trunk, branch and canopy and mistletoe contamination conditions were determined in all trees that were analyzed. In this study, the power of mistletoe infection was evaluated on the basis of contamination on the top, branch and trunk of the tree, the age of exposure of the trees to the infection and the age of the mistletoe detected. The parameters of the infected and non-infected trees were evaluated together in order to analyze the effects of mistletoe on the development of individuals.

In order to determine the relationship of mistletoe contamination in the sampling areas with the diameter and length, t-test application was carried out with the help of the SPSS program. T-test, which is used to determine the differences between the variances of 2 independent variables, was utilized in order to identify whether or not there is a difference between the determined natural regeneration areas and afforestation areas for mistletoe contamination. In addition, one-way variance analysis and Tukey HSD Post-Hoc test were applied for identification of the difference in the sample areas in terms of contamination status.

Simple linear regression analysis was conducted to form the growth models of healthy individuals and individuals where mistletoe was observed. The tree assets cost value of the research area was determined primarily, in order to determine the economic value losses that might arise because of the mistletoe observed in natural regeneration and afforestation areas (Türker, 2013). In this context, afforestation costs, land value, annual administration costs, interest rates and economic revenue obtained as a result of the previous maintenance interference were determined. On the other hand, the economic damage of Forestry Managements (FM) from 1 m³ Scots pine wood product has been determined by assuming that mistletoe spread has stopped. While calculating this loss, the product classes which Gümüşhane FM can obtain in the future and today have been taken into consideration.

Tree assets cost value (TACV) was calculated with *Equation 1* (Türker, 2013).

$$ASMD = (c + B + V) * 1.0P^{m} - (B + V) - (D_{a} * 1.0P^{m-a} + ...) \qquad \text{(Eq.1)}$$

c: cost of afforestation, B: land value, V: annual administration costs, P^{m}: interest rate, P^{m-a}: the revenue received with the inference maintenance conducted before.

Results and discussion

In the natural regeneration and afforestation areas, 330 Scots pine individuals were examined in the 16 sample areas.

It was determined that 19 of 203 individuals were determined to be exposed to mistletoe in the natural regeneration area and 60 of 127 individuals were determined in the afforestation area (*Table 1*).

Afforestation areas were identified to be exposed to more mistletoe damage than natural regeneration areas. On the other hand, the mistletoe was found out to be the most effective on the trunks of the individuals, the least damage occurred on the top parts (*Fig. 3*). Age measurement was neglected due to the evaluation that the ages of the individuals in the sample areas where the study was conducted were approximately the same.

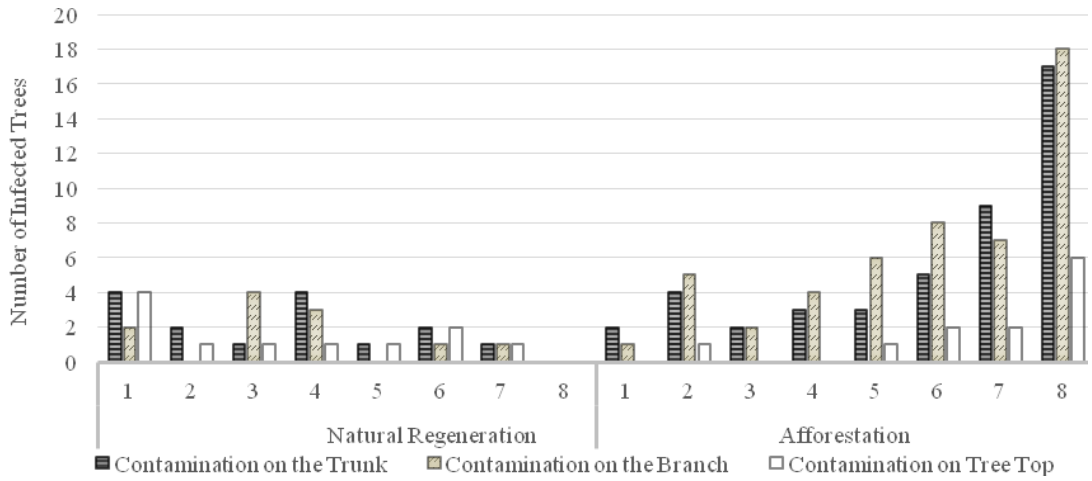

Figure 3. *Contamination status of mistletoe damage to trunk parts*

In the evaluations conducted, it is determined that the mistletoe occurs especially in the trunk parts, which is valid for both natural regeneration and afforestation areas. On the other hand, it was found out that the contamination to the top of the individuals in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_549559

the natural regeneration areas has occurred earlier and close to the time of the occurrence in the trunk. In afforestation areas, it was found that the contamination to the top of the trees occurred approximately 3 years after the contamination to the trunk (*Fig. 4*). As a result of the morphological age measurement, the average mistletoe age detected in the trunks was detected as 6 in the natural regeneration area, the average mistletoe age was detected as 4 in the branches and the average mistletoe age was detected as 4 in the canopy. In the afforestation areas, the mistletoe age was observed as 7 in the trunk, the mistletoe age was observed as 6 in the branch and the mistletoe age was observed as 3 in the canopy. As a result of the field study conducted, mistletoe contamination was detected in 15 sampling areas and no mistletoe was observed in only 1 area.

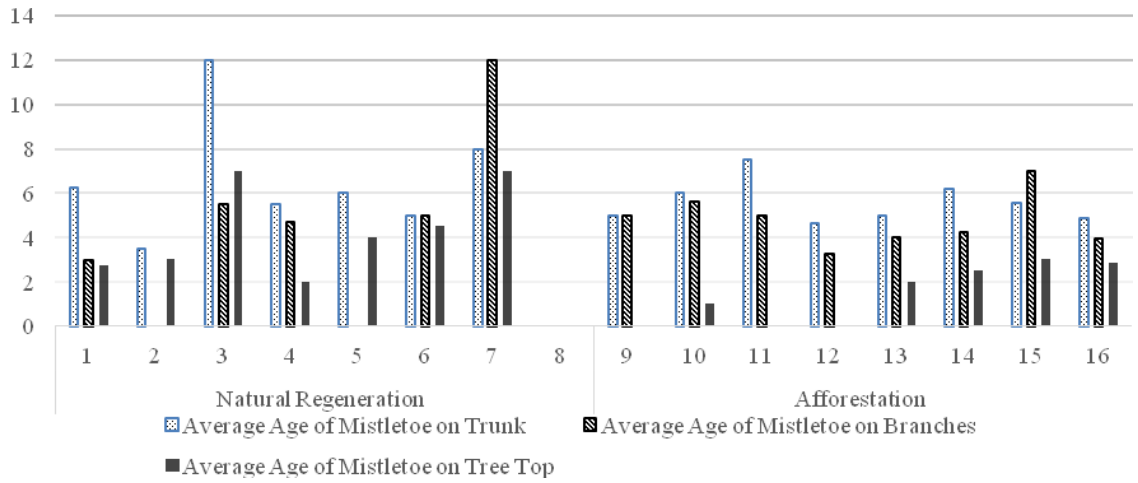

Figure 4. *Mistletoe age status in the sample areas*

As a result of the Single Sample T-Test we carried, it was found that the mistletoe exposure has increased as the d_{130} diameter and length of the individuals increased in the study areas. It can be said that the difference in question arose from the fact that mistletoe can receive more water and mineral nutrients from individuals with good diameter increase and thus show better development. Eroğlu and Başkaya (1995) have proved that mistletoe leads to an increase in the loss with 16-55% in the Scots pine individuals. It has been revealed in previous studies that mistletoe gets completely deteriorated of its closure as a result of fire, grazing and irregular exploitation and that it has affected negatively the stand increase by 8.5-16.5% in Sürmene-Çamburnu Scots pine forests (Sönmez, 2014). Sekendiz (1984) states that the annual increase loss of individuals will be 20% in the situations where the mistletoe is dense. Therefore, the processing of low diameter logs from these trees will decrease productivity and increase processing costs (Rast, 1974; Luppold and Bumgardner, 2019).

Conducted analyses showed that mistletoe exposure has occurred at a higher level in long individuals (*Fig. 5*). This difference can be said to be due to the fact that mistletoe can get more water and mineral nutrients from individuals with good length increase and thus enable better development. In a previous study, mistletoe was found to negatively affect the development of scots pine by 47% (Sönmez, 2014). Çatal and Carus (2011) found in a different study they carried out that the adverse impact of mistletoe is in the range of 26-63%. Similarly, Kanat et al. (2010) reported that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_549559

mistletoe negatively affected 22% increase in diameter in larch. Besides, Eroğlu (1993) has shown that the chemical structure of wood is deteriorated in scots pine individuals, where mistletoe contamination is observed, and therefore its usage properties are affected by this situation. According to Eroğlu and Başkaya (1995), while the rate of trees that dried in these forests was 1-2% per year ten years ago, it increased to 3.5% in recent years.

On the other hand, it is determined that mistletoe spread occurs more densely in afforestation areas than natural regeneration areas. All together statistically significant ($p < 0.05$) differences were identified between these areas in terms of mistletoe contamination (*Fig. 5*). The reason for this situation can be said to be that the afforestation areas are close to the old stands where mistletoe spread is observed, and the maintenance works conducted in these areas decrease the closeness. On the other hand, the presence of dense mistletoe which is detected especially in seed trees in natural regeneration areas has been observed to affect the young scots pine individuals living nearby.

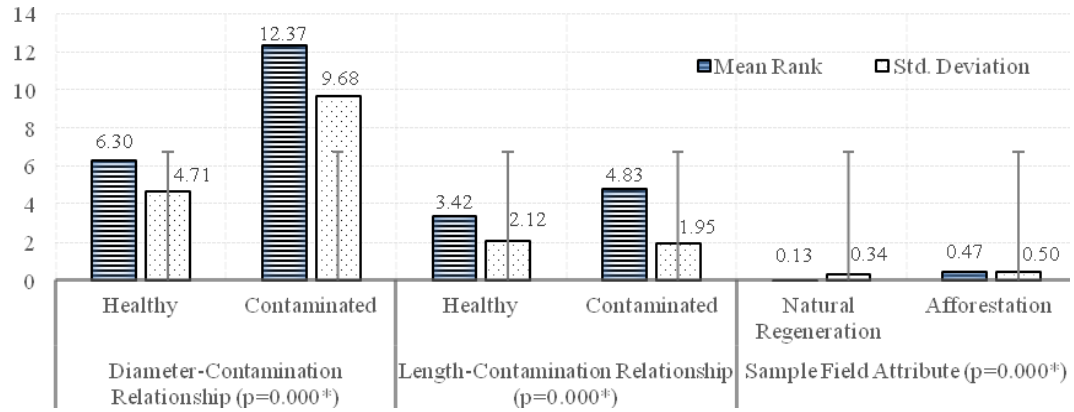

Figure 5. *Statistical comparisons concerning mistletoe contamination*

The results of the statistically significant differences between the sampling areas are given in *Table 2* in terms of mistletoe exposure. According to this, only difference were found between the sample areas 4 and 8 in natural regeneration sample areas. In the afforestation sample areas, the differences were identified between field 9, field 15 and 16. On the other hand, the differences were determined between all-natural regeneration and afforestation sample areas except for areas 1 and 4. *Table 2* shows the differences between the natural rejuvenation sample sites with (○), the differences between the afforestation sample sites with (●) and the differences between the two sites with (◐).

The findings concerning simple linear regression analysis conducted on healthy and mistletoe contaminated individuals in natural regeneration areas and afforestation areas are given in *Table 3*. In the study conducted on healthy and mistletoe contaminated individuals, the length was chosen as a variable depending on diameter and growth model equation, which reveals length values of individuals with respect to diameter, was developed (*Table 3; Eqs. 2* and *3*).

The obtained growth model revealed that mistletoe has an ever-increasing negative effect on the development of individuals. It has been emphasized in previous studies that the scots pine individuals in natural regeneration and afforestation areas lose their vital functions because of the mistletoe pest (Yüksel et al., 2005).

DOI: http://dx.doi.org/10.15666/aeer/1801_549559

It is thought that the maintenance interferences which the Scots pines exposed to mistletoe undergo until they lose their vital functions may cause a serious cost burden to the FMs. It was calculated that the annual maintenance cost covering the parameters such as identification and marking of the future trees, determination of the individuals to be cut off from the field and removal of these individuals from the field, labour costs and transportation expenses have been estimated as 78.81 $/ha. It has been determined that the land value is 78.81 $/ha and the annual land expenses are 12.26 $/ha from the records of Gümüşhane Forest Management Directorate.

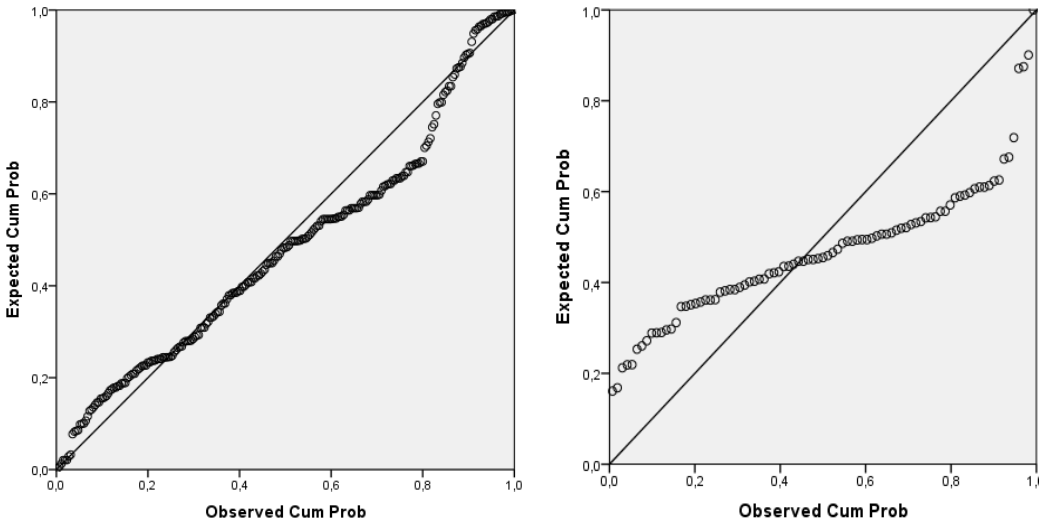

Figure 6. *Statistical comparisons concerning mistletoe contamination*

The products occurred in the maintenance of healthy individuals with d_{130} chest diameters of more than 8 cm are offered for sale in forest depots or ramps at a cost value. The products formed during the maintenance processes of the individuals with mistletoe contamination are put upon to the market as firewood regardless of the product class. The absence of any enterprises producing paper, fibre and particle boards in the region can be said to increase the revenue loss of FMs in the products where mistletoe contamination is observed.

It is understood that the afforestation and natural regeneration areas will lose the economic value of the individuals in the areas to a great extent before reaching the targeted administration period due to the mistletoe damage. Therefore, the necessity of reforestation of these areas emerges. Gümüşhane Forest Management Directorate, the unit responsible for the study area of this research, reported that the cost of reforestation in these areas is 874.29 $/ha and the cost of regeneration is 524.58 $/ha.

In the tree assets cost estimations we conducted (TACV), it was determined that 10 years ago 338.38 $ product was obtained from the area and that the stands were at the end of the 1st year class, meaning 20 years old, by making use of the management plans. As a result of the analysis, the TACV was identified to be approximately 1224.86 $. Besides, it was found that mistletoe caused approximately 21% loss from each targeted 1 m³ forest product revenue in the study areas where the average contamination was found as 27% (*Table 4*). In the determination of this damage, the cost of firewood was taken into consideration for all targeted forest product varieties.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_549559

Table 4. *The damage detected in the target forest products*

Product type	Price ($/m³)	Economic damage ($/m³)	Economic damage rate (%)
Log	27.32	5.85	21
Mine pole	23.06	4.79	21
Pole	20.22	3.64	18
Paper firewood	18.80	4.08	22
Average	22.35	4.59	21

Conclusions

The results of this study have proved that mistletoe can be effective in both natural regeneration and afforestation areas. The average contamination rate was determined as 27%. On the other hand, it is understood that mistletoe has an average revenue loss potential of 21% for the target forest products for the research areas. However, in the case that a decrease in revenue loss and forest products in the desired quality are wanted, additional costs must be endured.

According to the results of the study, mistletoe is more effective in afforestation areas when compared with natural regeneration areas in terms of distribution. Seed trees where mistletoe has occurred in the natural regeneration areas have an important effect on the increase of mistletoe spread in these areas.

At the same time, mistletoe occurrence negatively affects length and diameter growth in individuals. Therefore, it is seen that mistletoe causes quality and quantity loss in terms of forest products in natural regeneration and afforestation areas.

In future research, it will be useful to consider the effect of mistletoe on natural rejuvenation and afforestation sites on the basis of different tree species.

Abstract. Plants use the enzymatic and non-enzymatic antioxidant defense mechanisms to avoid and/or tolerate environmental stresses. As a useful element in plants, silicon plays an important role in activating these defense systems and thus in improving plant resistance to environmental stresses. The present research studied the effect of silicon on important antioxidants including Super Oxide Dismutase (SOD) and Catalase (CAT) and also on glucomannan, mannose, and aloin in *Aloe vera*. 60 Aloe vera plant of *Aloe barbadensis* Mill variety were taken. After applying the fertilizer treatments during cold stress treatment, 30 pots were placed at 25 °C (control) and 30 pots at 4 °C (stress), and then fertilizer side-treatments were applied. During their growth, the plants were treated with various silicon concentrations (500, 1000, 1500, and 2000 mg/l). Ninety days after they were planted, 30 of the plants were separated and exposed to cold stress at 4 °C for seven days. After applying the cold stress treatment, leaf samples were taken and analyzed simultaneously from treated and untreated plants. Results of ANOVA showed that cold stress and silicon treatments had significant effects on SOD, CAT, glucomannan, mannose, and aloin. Application of cold stress increased SOD and CAT activities and reduced glucomannan, mannose, and aloin concentrations. Increases in silicon concentration improved both enzymatic antioxidant activity and concentrations of soluble sugars and of aloin in *Aloe vera*. These results indicate that silicon plays a key role in enhancing plant defense systems against cold stress. Therefore, application of silicon fertilizers is of great importance in reducing losses caused by climatic stresses and in achieving the goals of sustainable agriculture.
Keywords: *antioxidant, aloe vera, silicon, plant resistance, sustainable agriculture*

Introduction

Among the various biotic stresses, cold stress or low temperature (LT) is one of the common important climatic factors that limit plant growth and yield (Adam and Murthy, 2014). It has been estimated that more than 15 percent of global agricultural products are lost annually due to frost damage (Zou et al., 2007). This type of stress also occurs repeatedly in Iran every year and inflicts heavy losses on farmers and orchard owners (Talebi, 2013). Considering the ever-growing human population and the purpose of developing sustainable agriculture and food security, enhancement of plant resistance to environmental stresses becomes important (Liang et al., 2015).

Plants continuously respond to changes in their surrounding environment and develop various efficient mechanisms to adapt themselves in the best possible way to various stresses in order to survive. Use of enzymatic and non-enzymatic antioxidant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_561575

systems is among the important strategies that plants employ to avoid and/or tolerate environmental stresses (Jung, 2004). In recent years, many advances have been made in understanding the mechanisms and processes involved in defensive adaptation to abiotic stresses in various plant species (Adam and Murthy, 2014). When faced with stresses, reactive oxygen species (ROS_s) such as superoxide anions (O^{2-}), hydroxyl radicals (OH), and hydrogen peroxide (H_2O_2) are excessively produced in plants. This increases cellular antioxidant potential that causes oxidative damages in plants (Ali and Alqurainy, 2006). Production of ROSs at times of stress is a natural metabolic process that happens in cells of all aerobic organisms (Alsher et al., 1997) and plays a very important role in activating the defensive system against biotic and abiotic stresses (Bafana et al., 2011). Due to the limitations in the quantities of $NADP^+$, one of the sites where ROSs may form is in the electron transfer chain. Induction of ROSs starts the processes of Lipid Per Oxidation (LPO) and also degradation of protein, pigments, and other cellular compounds (Allen, 1995; Balakhnina et al., 2010; Halliwell, 1984). Therefore, plants have efficient antioxidant defense systems to detoxify these ROSs and reduce damages that they cause (Gill and Tuteja, 2010). These defense systems consist of molecular antioxidants and antioxidant enzymes that degrade ROSs (Larson,1988). The enzymatic antioxidant system includes several efficient enzymes such as SOD and CAT, guaiacol peroxidase, ascorbate peroxidase, and glutathione reductase (Asada, 2006; Gunes et al., 2007b). The first enzyme to detoxify these reactive oxygen species in plants is SOD that converts superoxide into H_2O_2 and O_2 and protects cells against the oxidative stress resulting from superoxide. Nevertheless, H_2O_2 is also toxic to cells and is detoxified into water and oxygen by CAT (Zhu et al., 2010). Plant's ability to activate its defense mechanism against oxidative degradation is a key link in its mechanism of tolerance to unfavorable environmental conditions. Any change in the activity level of one or more antioxidant enzymes influences plant resistance to stressful factors (Bennicelli et al., 2005).

In addition to using the enzymatic antioxidant defense system, plants react to stress by accumulating compatible solutes such asproline (Gzik, 1997), glycinebetaine (Mansour, 1998), carbohydrates (Balibrea et al., 1997), and polyol (Kumar and Bandhu, 2005). One of the common features of compatible solutes is that they can accumulate to high levels without interfering with natural biochemical reactions (Zhang et al., 2004). In fact, they are hydrophilic and can replace water on the surface of proteins, protein complexes or membranes without disrupting their structure and function (Bohnert and Shen, 1999). These compounds can reduce the inhibitory effects of high concentrations of ions on the activities of the enzymes through fixation of proteins, protein complexes, or membranes under environmental stresses (Bohnert and Shen, 1999; Ashraf and Foolad, 2007). Moreover, compatible solutes may act as absorbers of reactive oxygen species (Seckin et al., 2009; An and Liang, 2013). As a non-toxic and protective osmolyte in higher plants, proline is usually involved in tolerance to salinity (Flowers et al., 1986).

Aloe vera and its derivatives

Aloe vera is a succulent plant species of the genus Aloe. An evergreen perennial, it is a stemless or very short-stemmed plant. The leaves are thick and fleshy. The margin of the leaf is serrated and has small white teeth. It has a variety species. A. vera is considered to be native to Africa. Different species of *Aloe vera* spread widely in North Africa as well as hot mountains in Africa, Madagascar, and Jordon. Some African native *Aloe vera* species are very similar to the treen (Royal Botanical Garden, 2014).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_561575

As a medicinal plant, *Aloe vera* plant is widely used in the medicinal, cosmetics and health sectors. *Aloe vera* plant contains chemical compounds and strong complexes, vitamins, enzymes, minerals, sugars, lignin, saponin, amino acids, and fats. Due to its many properties in the treatment of various diseases, *Aloe vera* has a worldwide reputation as a magic or multi-use plant. Some properties of *Aloe vera* plant include: gastric and duodenal ulcer treatment, ileus treatment, laxative, glucose and cholesterol regulator, kidney stones treatment, improving liver function, hemorrhoid treatment, reducing anemia, treatment of migraines, weight loss, reducing heartburn and brash, anti-stress, providing essential amino acids for the body, eczema treatment, fungicide, fast antipyretic, hair tonic, arthritis treatment, etc (Shelton, 1991).

Aloe vera requires high temperatures, light soil, and intense sunlight for growth and reproduction. Excessive accumulation of water around the root is a limiting factor in the growth of *Aloe vera*, which can result in root rot and attack of pathogenic fungi to the root of the plant (Royal Botanical Garden, 2014). The low temperature, especially the temperature that causes the plant's gel to freeze, can disrupt all the meristem activities of the plant, and thereby prevent it from survival. High salinity is another limiting factor in plant growth.

In the green leaf area of the *Aloe vera*, 20 species of anthraquinone, which is a phenolic compound, are found. Aloin and emodin are two well-known anthraquinones in Aloe vera. In addition to being known as a strong antibacterial and antiviral, these two compounds can prolong cell life and prevent live cell death. These two compounds contribute to destroy cancer cells, heal wounds, and strengthen the immune system. Two types of aloin, i.e. barbaloin and nataloin, with nitric acid under thermal condition and with fumingic acid under cold condition, produce oxalic acid, aloetic acid, and chrismatic acid.

Considering the importance and great properties of the *Aloe vera* plant and its cultivation at a very broad level, it is obvious that in order to have a healthy plant containing large quantities of white chemicals, the plant should provide with proper nutrition through supplying all nutrients and water needs as well as suitable temperature conditions. According to the plant nutrition science, it can be achieved the maximum plant growth as well as the best possible quality of the elements by providing maximum nutrients with appropriate concentrations, adjusting the pH of the food solution, the proper ratio of minerals to organic elements in the plant nutrition. With a proper nutrition, it can maximize the concentrations of the resulted elements from the plant, which will result in cost savings and increased yield per unit area. Maximum production quality and plant growth can be achieved by using chemical and organic codes.

References review

Many studies have shown that not only does silicon improve plant growth and yield (Ahmed et al., 2011; Balakhninaet al., 2012; Guneset al., 2007a; Ma et al., 2004; Savant et al., 1997; Hattori et al., 2005) but it also plays a key role in activating the enzymatic and non-enzymatic defense mechanisms of plants against biotic and abiotic stresses (Richmond and Sussman, 2003; Ma and Yamaji, 2006; Liang et al., 2007; Kim et al., 2011; Van Bockhaven et al., 2013). Molecular and biochemical mechanisms of silicon in relation to increases in plant resistance to stress are not well-known and require further research (Sivanesan and Park, 2014). Therefore, the present research intended to study the effect of silicon on some of the important antioxidant enzymes and phytochemical compounds in *Aloe vera*.

Murillo-Amador et al. (2014) investigated the effect of salinity on minerals and various chemicals found in *Aloe vera*. They investigated the effect of various concentrations of sodium chloride on proline concentration, phosphor-phenyl carboxylate enzyme in parenchyma and chlorophyll. They concluded that when salinity increased, the concentrations of proline and pepase enzyme increased in both parenchyma and chlorophyll. However, with increasing salinity, total protein concentration increased in parenchyma but decreased in chlorophyll.

Materials and methods

The greenhouse location

The experiment was carried out in No. 256, the greenhouse townhouse, in the Hashtgerd region located West of Alborz province in the Iran. Hashtgerd is located in the central part of Savojbolagh.

Hydroponic greenhouse

The greenhouse is of Dutch type with two layer coating of UV and anti-fog, and has a gas-fired heating system, fan cooling system, and side and ceiling valves. The greenhouse is equipped with an automatic temperature and humidity control system. The moisture and temperature data are measured by sensors and thermometers and instantaneously transmitted to the central processing system of the greenhouse. If the greenhouse humidity exceeds the limit, the processing center will immediately order the automatic opening of the side and ceiling valves, with the help of control switches. When the moisture content reaches the optimum level, the valves closing command is again given. In the case of insufficient moisture, the fog system automatically adjusts the moisture content. In the case of temperature sensors, if the temperature exceeds the programmed limit, the fan and pad system start until the desired temperature reaches. If the greenhouse temperature is lower than the desired temperature, the greenhouse processing unit will order turning on the heating system (gas-fired heaters). All information sent to the processing center is evaluated and, given the temperature and humidity requirements, the operating instructions are executed by the micro-switches. The irrigation system consists of two 5000-L reservoir tanks, a pumping system including pump and its related connections, as well as transmission lines and a nutritional solution collection system that is spaced 50 cm from each other. The whole greenhouse floor is concreted, sloped, and drained. The hydroponic greenhouse is of closed type, and nutritional solution is collected into the reservoir after watering the pots and restored to the system.

At first, 60 pots were placed in greenhouses 1 and 2 (30 pots per greenhouse). It should be noted that the greenhouses were divided into two equal parts of five 500 m by polyethylene coating.

A completely randomized factorial design including 2 temperature treatments, 2 silica fertilizer treatments, 5 silica surface treatments, each with three replications, and a total of 60 plots, were designed and implemented.

Aloe vera cultivation

60 Aloe vera plant of *Aloe barbadensis* Mill variety were taken. After applying the fertilizer treatments during cold stress treatment, 30 pots were placed at 25 °C (control) and 30 pots at 4 °C (stress), and then fertilizer side-treatments were applied.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_561575

Irrigation time

Each pot is irrigated for half an hour with two drippers with a flow rate of 4 L/h. Three irrigation were determined along with two hydroponic nutritional solutions at 10 am and 17 pm.

Sampling

Step 1: Before the temperature was reduced, sampling from the second leaves was performed in order to investigate and compare the effect of temperatures of 25 °C and 4 °C in greenhouse No. 2. According to standard condition, the samples were sent to the Standard Reference Laboratory of Iran to perform measurement tests of SOD, CAT, glucomannan, mannose, and aloin.

Step 2, after applying cold stress: According to the previous research (Liang et al., 2008), the activity of SOD and catalase increased and reached the maximum level in rape and wheat after 7 and 4 days of cold stress, respectively. Nayyar and Walia (2003) studied the 14-day seedlings under cold stress. They observed that reducing temperature to 4 °C increased the ion permeation, while adaptation to a low temperature of 10 °C for 6 days reduced the production of hydrogen peroxide LTS.

In order to compare the effect of reducing temperature in the greenhouse No. 2 after 7 days, sampling was carried out and the samples were sent to the Laboratory of National Genetic Bank Center (Standard Reference Laboratory, Iran), according to standard conditions. The comparison of fertilizer treatments means as well as the fertilizer treatment and temperature interaction are specified in *Table 3*. Temperatures of 25 °C and 4 °C correspond to before and after applying the cold stress, respectively (Control = 25 °C, cold stress = 4 °C). The zero concentration of silica (ppm = 0) is related to the control treatment, where no fertilizer treatment was applied.

Nutritional solution

At the first of the season, the temperatures of the both greenhouses were set at 25 °C. Then the pots were irrigated with water containing nutritional solution. Irrigation with water containing nutritional solution was performed daily, at 10 am and 17 pm, for 30 min. The nutritional solution used for the plant growth was modified Hoagland hormone in a hydroponic culture system (*Table 1*).

Table 1. *The morning and evening nutritional solution*

Morning nutritional solution	Evening nutritional solution
N (235 ppm)	Ca (14 ppm)
P (73 ppm)	K (65 ppm)
K (110 ppm)	Fe (1.8 ppm)
Mg (22 ppm)	
Zn (1.36 ppm)	
B (1.1 ppm)	
Mn (2.4 ppm)	

One month after planting *Aloe vera* in pots and using nutritional solutions in morning and evening, fertilizer treatments were applied to the pots every Monday. To this end,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_561575

after morning irrigation, some fertilizer was mixed with 20 ml of distilled water and added to the pots by hand. The numbering of the pots is done in a complete random manner. The zero concentration of silica was considered as control treatment. One month after treatments were applied, the temperature of greenhouse No. 2 was set at 4 °C, and this greenhouse was exposed to cold stress. After reducing temperature, fertilizer treatments were applied to the both greenhouses.

Planting Aloe vera and applying silicon fertilizer treatments

An experiment was conducted in the greenhouse town of Hashtgerd in Karaj on 60 (*Aloe barbadensis* Miller) plants with the average height of 15 cm and each with at least three leaves. They were planted in 18*14.7 cm polyethylene pots filled with a perlite and coco peat mix in a hydroponic system. The pots were automatically irrigated and fed with a standard nutrient solution once in the morning and another time in the afternoon. In addition, they were treated once a week with various levels of silicon (0 [in the control], and 500, 1000, 1500, and 2000 ppm) using potassium silicate and silicic acid.

Applying cold stress

The average temperature of the greenhouse was first set at 25 °C. After the plants were grown under normal conditions for three months, 30 of the pots were exposed to cold stress at 4 °C for seven days. 3. Sampling and measuring phytochemical and medicinal properties of Aloe vera

Following the cold stress, the second leaf of every plant was simultaneously removed and the samples were transferred to the lab in ice bags. The leaves were washed with distilled water, their surfaces were dried, and activities of the antioxidant enzymes (including SOD and CAT) and of the compatible solutes (including mannose, glucomannan, as well as aloin [as a medicinal compound]) were evaluated as follows.

Measuring activities of the antioxidant enzymes

To prepare enzymatic extracts (Sairamet al., 2002), 0.5 g of the frozen leaf sample was turned in to a homogeneous powder in a mortar with 10 ml of cold 0.1 M phosphate buffer (pH = 7.8) containing 0.5 mmol EDTA. The homogenized powder was transferred to centrifuge tubes and then centrifuged at 13000 rpm for 30 min at 4 °C. Using a spectrophotometer at 25 °C, enzymatic measurement of the supernatant was carried out with three replications.

SOD activity was measured based on the ability to prevent photo reduction of Nitro BlueTetrazolium (NBT) chloride using the method introduced by Giannopolitis and Ries (1977). Three mL of reaction solution containing 13 mmol of methionine, 75 µmol of NBT chloride, 2 µmol of riboflavin, 50 mmol phosphate buffer, and 50 µl of the extracted enzyme was exposed to two 15-Watt fluorescent light bulbs (with light intensity of 1000 lux) for 10 min at a distance of 20 cm. The reaction began when light was turned on and ended when it was turned off. The reaction solution was then covered with a black cloth until absorbance was measured. Absorbance was read at 560 nm using a model BT 600 spectrophotometer. One unit of SOD activity was considered to be the amount of the enzyme that could prevent photo reduction of NBT (ρ-nitro blue tetrazolium chloride) by 50 percent (Liang et al., 2008).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_561575

CAT activity was determined according to Chance and Maehly (1955). The CAT reaction solution containing 15 mmol of H_2O_2, 50 mmol of phosphate buffer, and 100 µl of the extracted enzyme were used. The reaction began by adding the enzyme and, after 1 min, reduction in H_2O_2 absorbance at 240 nm in 1 min was recorded. In this method, one unit of CAT activity was considered to be the amount of the enzyme that could oxidize one mmol of H_2O_2 in 1 min.

Measuring compatible solutes

The method introduced by Dubois et al. (1956), which is based on acidic hydrolysis of soluble sugars and production of furfural that generates a colored complex with phenol, was used to measure mannose. The leaf sample (0.2 g) was ground and homogenized in 4 ml of 25 mM sodium phosphate buffer (pH = 6.8). The reaction solution was prepared by pouring 0.5 ml of the extracted sugar solution, 0.5 ml of 5% phenol, and 2.5 ml of pure sulfuric acid in a test tube. The reaction began with the addition of the sulfuric acid. It was an exothermic reaction andproducedan orange color. After the solution cooled, absorbance was read at 490 nm using the spectrophotometer. The standard curve was drawn using various concentrations of mannose from 0 to 20 µg/ml.

To measure glucomannan, the method introduced by Eberendu et al. (2005) was used. This method is based on measuring changes in the Congo red indicator made by the presence of glucomannan in the reaction. The leaf sample (40 mg) was transferred to each conical polypropylene tube, 20 ml of distilled water was added to the tube and it was shaken at 200 rpm for 4 h. Forty ml of the Congo red indicator (sodium 4,4_-diphenyl-. 2,2_diazo-bis-1-naphtlamino-4-sulfonate) was then poured into the tube, the tube was left at room temperature for 20 minutes, and absorbance was read at 540 m. Standard solutions containing *Aloe vera* polysaccharides were prepared using the Waller et al. (1978) method. After the standard curve was drawn, glucomannan content was read in mg/L.

Measuring aloin

To measure aloin concentration in the green skin of *Aloe vera* leaves, the spectrophotometric method was used (Ellaithy et al., 1984). One gram of the green leaf tissue was ground and homogenized by liquid nitrogen in a crucible, 10 ml of methanol extraction solvent was added, and the solution was kept in a refrigerator at 4 °C for 24 h. The solution containing aloin was then centrifuged at 10,000 rpm for 10 min. The supernatant was passed through 0.45 µm filter paper, 2 mL of the magnesium acetate was added, and light absorption intensity was read at 262 nm.

Statistical analysis of the data

The factorial experiment with two factors (silicon at five concentration levels and temperature at the two levels of normal and low temperature) was carried out using a completely randomized design with three replications and the data was analyzed employing SAS. Before performing ANOVA, normality of the data was tested using the Kolmogorov-Smirnov (K-S) test.

Results

Results of ANOVA indicate that the effects of silicon and cold stress on levels of enzyme activity and on phytochemicals including SOD, CAT, glucomannan, mannose, and aloin, were significant at the 0.01 level ($P < 0.01$). The mutual effects of silicon and cold stress were also significant at the 0.01 level (*Table 2*).

Table 2. *Results of ANOVA related to biochemical properties*

Source of variance	df	SOD (Umg^{-1} of protein)	CAT (Umg^{-1} of protein)	Glucomannan (mg L^{-1})	Mannose (mg L^{-1})	Aloin (%)

The symbols *, **, and ns mean significance at P < 0:05 and P < 0.01 levels and not significant, respectively, and the numbers in the table are means of squares of the effects

The highest level of SOD activity (34.86 μmol/min) belonged to the 2000 ppm silicon concentration and the lowest (27.68 μmol/min) to the control (no silicon concentration). SOD activity at silicon concentrations of 500, 1000, 1500, and 2000 ppm increased by 17.3, 20.5, 23.4, and 25.9 percent, respectively, compared to the control (*Table 3*). The higher level of CAT activity was also observed in the treatments with high silicon concentrations (1500 and 2000 ppm) and the lowest in the control. CAT activity at silicon concentration of 2000 ppm (2.37 μmol/min) was about 37% higher than that of the control (1.72 μmol/min).

Table 3. *Comparison of the means of the main effects on antioxidant activities*

Source of variation	Treatment	SOD (Umg^{-1} of protein)	CAT (Umg^{-1} of protein)	Glucomannan (mg L^{-1})	Mannose (mg L^{-1})	Aloin (%)
Temperature	Control (25 °C)	27.81 b	1.97 b	0.35 a	0.75b	11.10 a
	Cold Stress (4 °C)	37.22 a	2.14 a	0.31 b	1.95a	4.29b
Concentration	0 ppm	27.68 b	1.72 b	0.31 c	1.28 c	7.44b
	500 ppm	32.49 a	1.99 ab	0.33 b	1.32 bc	7.58 bc

	1500 ppm	32.18 a	2.36 a	0.33 ab	1.36 b	7.83 ab
	2000 ppm	34.86 a	2.37 a	0.34 a	1.45 a	7.97 a

Means with similar Latin letters are not significantly different

Comparison of the means of the phytochemicals including glucomannan and mannose in *Aloe vera* indicated that cold stress was an influential factor on them so that their mean concentration in samples exposed to cold stress was significantly lower. These results suggest stoppage or reduction of plant metabolic processes. The average contents of glucomannan and mannose in plants not treated with cold stress were about 13 and 15 percent greater, respectively, compared to those that were exposed to cold stress. The aloin content in plants not exposed to cold stress was higher, compared to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_561575

plants that were treated with cold stress; however, the difference was not statistically significant.

Investigating the interaction between temperature and concentration of silicon on the activities of antioxidants (*Table 4*) indicates that at 25 °C or control temperature, increasing the concentration of silicon results in the increase in the activities of CAT and SOD enzymes as well as the concentrations of glucomannan, mannose, and aloin, and there is an ascending trend. This suggests that silicon has increased the activities of antioxidant enzymes in the plant by improving the nutritional value of *Aloe vera* plant under normal condition. Under stress temperature or at 4 °C, the activities of SOD and CAT enzymes increased with the different levels of silicon fertilizer treatments, and there was a significant difference when compared with control group. The highest and lowest values of SOD activity was related to 2000 ppm and 1000 pp, respectively. There were no significant differences between 500 ppm and 1000 ppm silicon treatments. That is, both have the same effect on SOD enzyme activity. The highest increase of CAT enzyme activity was due to 2000 ppm fertilizer treatment, which has a significant difference with the control group. Under cold stress or at 4 °C, the SOD enzyme activity increased by about 37%, using 2000 ppm silicon fertilizer treatment, compared with fertilizer treatment at 25 °C, indicating the effect of the temperature of 4 °C on the sudden increase of SOD activity at this temperature (the interaction between Si and stress temperature).

Investigating the interaction between control temperature and silicon concentration as well as stress temperature or 4 °C and silicon concentration on the CAT enzyme activity indicates that CAT activity increased under the stress temperature by 11% more than control temperature. This indicates the effect of the stress temperature and the concentration of silicon on the increase of activity of CAT antioxidant enzyme, which in turn shows the effect of Si on this enzyme. These two suggest the stimulation of the defense system and the increase in the activity of antioxidant enzymes. Investigating the interactions between temperature and concentration of silicon on the concentration of aloin indicates that temperature has a significant effect on the concentration of aloin. As the temperature decreases, the aloin concentration decreases, and when the temperature increases, the aloin concentration increases under the influence of the concentration of silicon.

Table 4. *Comparison of the interaction effects on antioxidant activities*

Temperature	Si Concentration	CAT (Umg^{-1} of protein)	SOD (Umg^{-1} of protein)	Aloin (%)	Mannose (%)	Glucomannan (%)
Control	0 ppm	25.51d *	1.84c	0.38 c	1.71c	10.73 b
	500 ppm	27.19cd	1.91b	0.39 b	0.75c	10.95 b
	1000 ppm	27.89cd	1.92b	0.41ab	0.74c	11.1ab
	1500 ppm	28.18c	1.96b	0.41ab	0.76c	11.28 a
	2000 ppm	29.31c	2.24ab	0.43 a	0.78c	11.55 a
Cold Stress	0 ppm	28.86c	1.59c	0.24 d	0.85b	4.16 c
	500 ppm	37.79b	2.06b	0.24 d	0.89b	4.21 c
	1000 ppm	38.87b	2.22ab	0.25 d	0.92ab	4.31 c
	1500 ppm	40.18a	2.35ab	0.25 d	0.96a	4.38 c
	2000 ppm	40.41a	2.50a	0.25 d	2.13 a	4.40 c

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_561575

Investigating the interactions between temperature and concentration of silicon on mannose indicates that the concentration of mannose has increased due to temperature reduction and increase in the concentration of silicon fertilizer. Investigating the trends of glucomannan changes suggests that the temperature reduction has resulted in the decrease of glucomannan concentration. That is, the concentration of glucomannan decreased under stress condition. At 25 °C, the concentration of glucomannan is increasing due to the increase in silicon concentration. At 4 °C, the increase in consumed level of silicon leads no significant difference in glucomannan concentration. Perhaps one of the reasons is that glucomannan is converted into simpler sugars to be consumed and moderating the cold stress at 4 °C.

Discussion

In order to investigate the effect of stress temperature (4 °C) on CAT, SOD, mannose, glucomannan, and aloin components as phytochemical and medicinal parameters of *Aloe vera* plant, as well as comparing it with optimum growth or control temperature (25 °C), and also studying the effect of type of the fertilizer, two type of silica fertilizer, i.e. salicylic acid and potassium silicate, with five levels of fertilizer treatments including 0, 500, 1000, 1500, and 2000 ppm for 60 potted *Aloe vera* plants under hydroponics cultivation were used. The temperatures of 4 °C and 25 °C were selected as stress and control or optimal conditions for plant growth, respectively. Different concentrations or treatment levels were tested for both plants exposed to 4 °C and 25 °C. Therefore, the interaction between temperature and silica treatment levels can be investigated. The results show that the concentrations of CAT and SOD increased due to cold stress and silica fertilizer treatment, when compared to 25 °C. Increasing SOD activity at 4 °C directly related to increase in silica concentration. That is, at 4 °C, with increasing silica concentration, the activity of SOD increased, and its most activity was in the concentration of 2000 ppm, which was 34.86 Vmg^{-1} of protein.

At 25 °C, application of fertilizer treatment could increase the SOD concentration in the plant, which has an activity of 27.81 Vmg^{-1} of protein. The examination of these two values indicates that the stress temperature (4 °C) triggered the plant's defense system and could increase the SOD concentration by about 6.99 units, when compared to 25 °C. This increase is about 25.13%.

Comparison of the means showed that the highest SOD and CAT activities were those of the cold stress treatment. Many studies have indicated that there is a direct relationship between antioxidant enzyme activity and plant resistance to cold stress (Javadian et al., 2010; Luo et al., 2011; Radyuk et al., 2009). Mean SOD activity in samples exposed to cold stress was 33.8 percent higher than that of the samples not exposed to cold stress. CAT was also influenced by cold stress, and its mean activity in samples exposed to cold stress was about 8.6% higher than that of the samples not treated with cold stress. These results indicated plant defense mechanism against cold stress.

Comparison of the means of various silicon concentrations revealed that there were significant differences between the control and the treatments. However, the differences between the various levels of silicon concentrations were not significant. This suggests that presence of silicon, even at low amounts, plays a significant role in improving and activating plant antioxidant defense system.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_561575

The results show the positive effect of silicon in the process of antioxidant synthesis. Comparison of the means of glucomannan, mannose, and aloin contents at various silicon concentrations showed that there was a direct relationship between silicon concentration and the contents of the phytochemicals so that their lowest contents were observed in the control treatment and the highest at silicon concentration of 2000 ppm.

As shown in the ANOVA table, the application of the 7-day cold treatment significantly affected antioxidant activity levels probably because of the positive effects that silicon had in the mechanism of inducing resistance in plants against the cold stress (Ma and Yamaji, 2006; Kim et al., 2011). Interaction effects of temperature and silicon concentration showed that the highest levels of antioxidant enzyme activity were observed at silicon concentrations of 1500 and 2000 ppm and the lowest in the control (no silicon application). In a similar study, Zhu et al. (2006) stated that silicon increased plant resistance against cold and frost.

The greater SOD and CAT contents were observed at high silicon concentrations, which indicated the role silicon played in the activities of these antioxidants. In a similar study, Gunes et al. (2008) reported that, depending on plant type and variety, silicon influenced the levels of antioxidant enzyme activity, especially those of SOD and CAT. They stated that plants increased their antioxidant activities under stress conditions to be able to neutralize or minimize the stress. They noticed that applying the silicon treatment enhanced plant defense system through increasing antioxidant synthesis and, hence, modified the destructive effects resulting from the stress. Liang et al. (2008) reported that silicon application under cold stress down to -5 °C increased SOD activity in wheat. They demonstrated that SOD activity increased and reached its highest level following cold storage treatment for four days. Fahimirad et al. (2013) noticed that SOD activity reached its highest level after applying cold stress for 7 days in colza.

Plants usually respond by accumulating compatible solutes such as soluble sugars, carbohydrates, and polyol. Study of the trend of changes in the phytochemicals glucomannan, mannose, and aloin caused by cold stress and by concentrations of applied silicon shows that they had their highest concentrations when silicon was applied at 2000 ppm. These results are consistent with those of other studies. For example, Duan et al. (2013) reported that silicon improved *Dendrobiumn moniliforme* resistance against cold stress by increasing free proline, soluble sugars, and soluble protein contents and by decreasing Malone Dialdehyde (MDA) content.

Yin et al. (2013) also reported that applying silicon to sorghum under salt stress could considerably increase the levels of soluble sugars such as sucrose and fructose. Other researchers reported the contradictory results that silicon application decreased the contents of compatible solutes such as proline in various plants (Soylemezoglu et al., 2009; Lee et al., 2010; Tuna et al., 2008; Gunes et al., 2007a). Some researchers consider proline accumulation in plant organs a sign of damages inflicted by stresses and, therefore, reduction in proline content resulting from silicon application can be attributed to the reduction in the damage caused by stresses. Kumar et al. (2010) noticed that pea cultivars resistant to cold had greater contents of proline and ascorbic acid and higher levels of SOD and CAT activities. In general, silicon can enhance the conditions for production of antioxidants and other plant materials, and protect plants against wilting caused by cold stress, through influencing their qualitative and quantitative characteristics including photosynthesis and respiration.

Moreover, the protective role of silicon in plants may also be due to accumulation of polysilicic acids inside cells. There are reports that show silicon can enhance plant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_561575

defense mechanisms through other processes such as accumulation of lignin, phenol compounds and phytoalexins (Epstein, 1999). Results of the present research indicate that increases in anthraquinone and aloin concentrations may be due to accumulation of lignin and phenolic compounds when silicon is applied. At the temperature of 255 °C, suitable photosynthetic conditions were prepared for the plants to produce higher quantities of aloin phenolic materials. Silicon influenced aloin concentration by affecting photosynthetic performance of *Aloe vera* and through inducing deposition of materials inside cells. At the temperature of 45 °C, silicon was able to increase the aloin content of plants compared to the control through stimulating the defense system of the plants and by increasing their photosynthetic ability.

Conclusions

Cold stress increased antioxidant enzymes and reduced metabolic activities of Aloevera. As an agent activating enzymatic and non-enzymatic defense system, silicon plays a key role in inducing plan resistance against cold stress. Applying silicon fertilizer augmented activities of SOD and CAT, enhanced contents of compatible solutes such as glucomannan and mannose, and also increased aloin concentration in Aloevera. The findings of the present research show the importance of applying silicon fertilizers in increasing plant resistance, in reducing damages caused by cold stress, and consequently, in achieving sustainable agricultural production.

Considering the effect of Si on the induction of plant defense system against the environmental stress, it is suggested that the effects of elements such as cobalt (K) on the activity of oxidative enzymes under cold and saline stresses would be tested. The effect of Si as spraying on the growth factors and antioxidant components of the plant in order to accelerate the absorption of the element and to reduce the stress of cold and drought stresses under sudden stresses can also be investigated.

(Received 16th Sep 2018; accepted 21st Jan 2020)

Abstract. The experiment was conducted to determine the lethal and sub-lethal concentrations of arsenic (As) in European carp (*Cyprinus carpio* L.) at College of Veterinary Sciences, BZU, Bahadur sub Campus Layyah Pakistan. The experimental fish were kept in aquarium and exposed to 5, 10, 15, 20, 25, 30 and 35 mg/L concentrations of As in laboratory. One group was considered to be the control where fish were not exposed to As. In each concentration, 10 fish were kept for a 96-h exposure period. There were five replications in each group. Dead fish were removed regularly from each test aquarium. Collected data of mortality were analyzed by using the Probit analysis in order to determine the 96-h LC_{50} of As on *Cyprinus carpio* with $P \leq 0.05$ probability level. Hepatosomatic index (HSI), gonadosomatic index (GSI) and intestinalsomatic index (ISI) were calculated based on weight of the body and weight of the respective organ of *Cyprinus carpio* fish. Results indicated that 96-h LC_{50} value of As in *Cyprinus carpio* was 25 mg L^{-1}. Sub lethal concentrations were 5.0, 2.5, 1.65 and 1.25 mg L^{-1}that were determined by taking 1/5th, 1/10th, 1/15th and 1/20th of LC_{50}. Likewise, increasing concentration of As significantly enhanced the value of HSI and reduced the value of GSI and ISI of *Cyprinus carpio* species. This study concluded that 25 mg L^{-1} As was found to be 50% lethal concentration for *Cyprinus carpio* species.
Keywords: acute toxicity, hepatosomatic, gonadosomatic, intestinalsomatic, LC_{50}

Introduction

Heavy metals are serious environmental pollutants effecting human beings differential injuriousness and aquatic organisms due to their high toxicity (Yang et al., 2014; Javed, 2015). To perform various physiological functions vital metals are required by the living organisms but beyond definite concentrations they may become hazardous to the organisms due to generation of free radicals leading to oxidative stress (Merciai et al., 2014). The important factors influencing the differential injuriousness of metallic ions are metal specific, including the mode of action and the solubility of the metal along with the physicochemical properties of the test medium (Naz and Javed, 2012; Gupta and Karthikeyan, 2016).

In different region of the world many types of contaminants are spread such as arsenic (As) (Flora et al., 2005; Shrivastava et al., 2015). Naturally As is present in the water in different chemical species and different oxidation states. The As known as a toxic trace element. The arsenite (AsO_3^{3-}) or arsenate (AsO_4^{-3}) are inorganic forms of this heavy metal and commonly its abundant forms are inorganic in the nature (Akter et al., 2005; Pedlar et al., 2002). The effect of As is more prominent when it interfere in accumulation, concentration, excretion and the gastrointestinal tract, skin, kidney and liver. As disturbs the biochemical, haematological and most important ion-regulatory factors of organisms and mainly fish present in the aquatic media, and variations of previous factors can be beneficial in environmental bio-monitoring from the contamination of As (Lavanya et al., 2011). For evaluating the effects of environmental pollution on aquatic ecosystems fish are choice of an organism (Gaim et al., 2015). As-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_577586

contaminated food by a fish intake through their gills, skin, and they are continuously exposed to it. Fishes are good indicators of As toxicity, they have long sentinels and used for biomonitoring of aquatic life and contaminants that is present im the water (Tisler and Zagorc-Koncan, 2002). Lethal toxicity of toxicant can be tested through the determination of LC_{50} value which is the most reliable for assessing the adverse effect on fish (Kumari et al., 2017). To make or establish the biomarkers of exposure fishes have good power of models as to study the toxicogenomics fishes are perfect organisms to work (Das et al., 2012). To reduce the hazardous forms of As in aquatic life fishes are best as they have different mechanisms for biotransformation (Bears et al., 2006). When the concentration of As increases in an aquatic ecosystem, than it affects various physiological systems like growth, reproduction, immune function, gene expression, histopathology and enzyme activities in the body of fish (Datta et al., 2009). It will negative for the health of humans if As-contaminated fish intake by the humans (Kar et al., 2011). The As involved in a series of molecular events like iron homeostasis, oxidative stress, carcinogenesis and lipid metabolism disorder (Xu et al., 2013). The As contamination is linked with the formation of Reactive oxygen species (ROS) causes severe injury and damage to the biological systems of organisms that is result of the As contamination (Patlolla and Tchounwou, 2005). The bioindicator of contaminant exposure is basically known as hepatosomatic index (HSI) (Sadekarpawar and Parikh, 2013). The changing in size of liver hypertrophy (an increase in size) and hyperplasia (an increase in number) is the result of detoxification of As contamination (Solé et al., 2010). The Study evaluate the relative liver size of fishes from contaminated places and disturbed locations also utilize the HSI, that expresses liver size in the form of percentage of the total body weight (Sadekarpawar and Parikh, 2013). Structural information and more functional like health and gonadal maturation status is supply by gonadosomatic index (GSI) which is also a bioindicator. The majority of the species go through the reproductive cycle and, commonly, difference in the gonadal size is observed in the cycle (Sadekarpawar and Parikh, 2013). The gonadal weight of the body in percentage used for defining the reproductive maturity and replies of environmental dynamics (e.g., seasonal changes) similarly, the exogenous stress also (e.g., exposition to contaminants). The gonad alterations like reduction of GSI and morphological changes are caused by the result of several environmental pollutants it is significative evidence (Sakamoto et al., 2003). Keeping in view the present issues connecting to freshwater fisheries in Pakistan the current research work was carried out to determine the lethal and sub lethal concentration of As to *C. carpio* that will help in the expansion of proper strategies for sustainable conservation of the fish.

Materials and methods

European carp (*Cyprinus carpio* L.) 400 fish (10 ± 0.5 cm length and 60 ± 5 g weight) were collected from fish nursery Karor Lali Ehsan Layyah Pakistan, acclimatized in aquaria for 15 days under laboratory conditions at College of Veterinary Sciences, BZU, Bahadur sub Campus Layyah Pakistan. The aquaria were continuously aerated through stone diffusers connected to a mechanical air compressor. Water temperature was 25 ± 2 °C and pH was maintained between 6.6 and 7.5. The fish were fed twice daily alternately with egg, goat liver and raw brine shrimp pellets. The experimental fish were exposed to different concentrations of arsenic *viz*: 5, 10, 15, 20, 25, 30 and 35 mg/L. One group was considered as a control where fish were not exposed to As. The 10 fish for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_577586

each concentration of As test were used. In the experimental aquaria water was replaced daily with fresh treatment of As. Five replicates for each concentration of arsenic was arranged under Complete Randomized Design (CRD). The experimental treatments were 0 (control), 5.0, 10.0, 15.0, 20.0, 25.0, 30.0 and 35.0 mg/L arsenic. Following parameters were studies during the course of study.

Determination of LC_{50} arsenic concentration

Ten fish samples were transferred to each aquarium and exposed to different concentrations of As (5, 10, 15, 20, 25, 30 and 35 mg/L) from sodium arsenite ($NaAsO_2$) was used as arsenic source. In all cases, control groups of fish were maintained. This trial was carried out for a period of 96 h LC_{50}. The mortality of the fish was recorded at 96 h of exposure. The effect of each concentration was tested at least in duplicate to verify reproducibility. The data were obtained in course of the investigation was analyzed statistically to see whether there is any influence of different treatments concentrations on the mortality of fish.

Sub-lethal concentration of arsenic

The concentrations of arsenic *viz*: 5, 10, 15, 20, 25, 30 and 35 mg/L were maintained in each treatment. Control group of fish was maintained without application of As. Sub lethal concentrations were determined by taking $1/5^{th}$, $1/10^{th}$, $1/15^{th}$ and $1/20^{th}$ of LC_{50} (Abdel-Hameid, 2009).

Length and weight

Samples of fish were removed from the aquaria of respective treatments. All samples were washed with distilled water, and transferred to the laboratory. Length of the fish was measured with the help of measuring tap and weight was noted with electronic balance (Digital Bench Scale - QM7264, Electric Burst Australia Pty Ltd).

Somatic indices

After the period of exposure fishes were removed and washed with freshwater. Control as well as treated groups were anesthetized by immersion in 50 mg/L tricaine methane sulphonate solution for 5–10 min before they were killed by decapitation and weighed; blood was allowed to drain and dissected to take out organs. Hence the liver, gonads and intestines weight was taken for the Hepatosomatic index (HSI), Gonadosomatic index (GSI) and Intestinal somatic index (ISI). The indices were calculated according to the following formula Parmeswaran (1974):

$$HSI = (\text{Liver weight (g)} / \text{Fish weight (g)}) \times 100 \quad \text{(Eq.1)}$$

$$GSI = (\text{Gonad weight (g)} / \text{Fish weight (g)}) \times 100 \quad \text{(Eq.2)}$$

$$ISI = (\text{Intestines weight (g)} / \text{Fish weight (g)}) \times 100 \quad \text{(Eq.3)}$$

Statistical analysis

The statistical analysis of this work was done using STATISTIX 8.1. The data of this work was presented as means ± standard deviation. Pair wise comparison was done

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_577586

between control and experimental groups by employing Duncan multiple variance test to resolve the statistical significance of the difference between the groups (Pipkin, 1984).

Results

Analyzed data reveal that mortality of *C. carpio* was increased by increasing the concentration of As. The 50% mortality was recorded at 25 mg L^{-1} As concentration while it caused 60% and 80% mortality at 30 and 35 mg L^{-1} respectively (Table 1). Whereas; other As concentrations 5, 10, 15 and 20 mg L^{-1} caused the 10, 30 and 40% morality in *C. carpio* (Table 1). These lethal concentrations of As to tested fish species was determined by the mean value of 96 h LC_{50} and with 95% confidence interval significant $P < 0.05$. The other concentrations of As were observed below the concentration of 25 mg L^{-1}. The upper and lower 95% confidence limits. Thus, As rated as highly toxic to *C. carpio*. Non-significant mortality was observed in control and 5 mg L^{-1} during the experimental periods (Table 1).

Table 1. *Effect of different concentration of arsenic on mortality of Cyprinus carpio*

Arsenic conc. (mg L^{-1})	Log conc.	Number of fish alive out of fifty	Mortality %	Probit kill
0.0 (control)	--	50	0	--
5.0	0.70	50	0	--
10.0	1.00	45	10	3.73
15.0	1.18	35	30	4.48
20.0	1.30	35	30	4.48
25.0	1.40	25	50	5.00
30.0	1.40	20	60	5.25
35.0	1.48	10	80	5.84

The various concentrations of As showed significant difference in mean length and weight of *C. carpio*. Significantly higher mean length and weight was gained in control group and that differences were not statistically significant where As was applied at the rate 5 and 10 mg L^{-1} respectively (*Fig. 1*). After that there was gradual decrease in mean length and weight with increasing the concentration of As (*Figs. 1* and *2*). Results indicated that value of HSI decreased significantly with increasing the level of As concentrations. Highest value of HSI was recorded in control treatment where As was not applied which was not statistically significant with lowest concentration (5 mg L^{-1}) of As (*Fig. 3*). It was found that there is gradual decrease in the value of HSI. Whereas; lowest value of HSI was measured at the highest concentration of As (*Fig. 3*). The GSI value showed significant difference among all As concentration. Significantly higher value of GSI was recorded in the control treatment that there were not statistically significant at 5 and 10 mg L^{-1} respectively (*Fig. 4*). After that there was gradual decrease in the value of GSI with increasing the concentration of As. In addition, lowest value of GSI was observed in the group where As was applied 35 mg L^{-1} while differences were not statistically significant to the group 7^{th} where As was applied 30 mg L^{-1}(*Fig. 4*). The value of ISI significantly decreased in fish subjected to As levels. Higher value of ISI was determined in the fish in control group that there were no significant differences where

fish was exposed to As level of 5 and 10 mg L^{-1} respectively. After that there was gradual decrease in the value of ISI with increasing the concentration of As (*Fig. 5*). In addition, lowest value of ISI was observed at 35.0 mg L^{-1} As concentration which was not statistically different to 30 mg $^{-}$L As concentration (*Fig. 5*).

Discussion

Instant and delayed toxic effects that occur in fish are the results of lethal toxicity. This delayed effect results in discoloration of skin and death of fish occurs ultimately (Abdullah and Javed, 2006). For 96-h LC_{50} determination, species-specific factor like fish sensitivity towards particular metals is important. In current study, the mortality of *Cyprinus carpio* increased gradually with increasing the level of As (*Fig. 6*). Pandey et al. (2005) reported the acute toxicity caused by arsenic in *Dicentrarchus labrax* based on dosage. Morcillo et al. (2015) reported mercuric chloride and malathion toxicity at 96-h time dependent dose in *Channa puctatus*. The results of our experiment showed that 25 mg L^{-1} was found to be 96-h LC_{50} and lethal concentrations of As for *C. carpio*. This indicates the mortality rate which increased with the increase in concentration for a particular time with regular mode of toxicant action at dangerous level due to As

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_577586

accumulation ultimately leading to fish death (Reddy et al., 2016). Over the gills fish, a mucus film formed when oxygen culminates hence damage occurs by respiratory epithelium causing mortality. (Das and Sahu, 2005) because gills tissues are main target organ of the fish imposed to As. As exposure to fish cause clogging of gills resulting in breathing anxiety because As damages directly the blood vessels and collapse them in gills (Mondal and Samanta, 2015). Kovendan et al. (2013) determined the 32 mg L^{-1} Arsenic tri-oxide to the adults' fish *C. carpio.* In another study, 24.5 mg L^{-1} was found to be 96-h LC_{50} and above that are lethal concentrations of As to *Ctenopharyn godonidella* (Kousar and Javed, 2014).

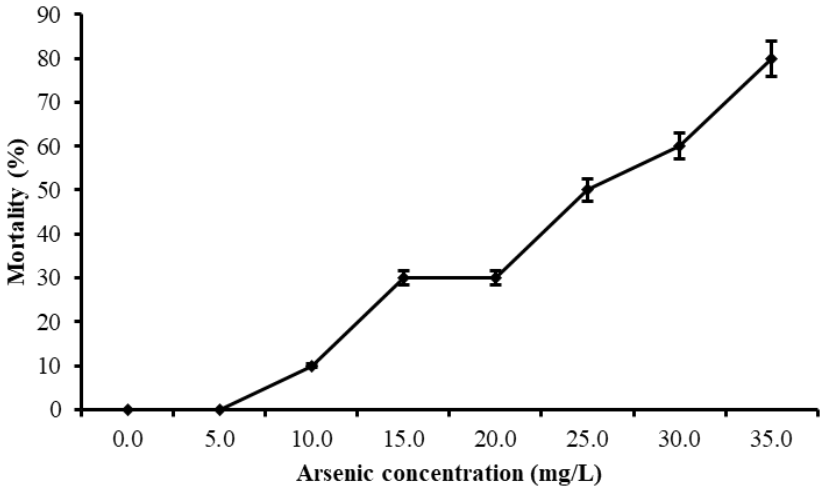

Figure 6. *Graphical estimation of 96-h LC_{50} of arsenic against the Cyprinus carpio*

The decreased in mean length and weight due to As exposure in fish can be explained by direct metabolic impacts study or by food chain destitution, both of these actions decreases the fish growth (Eastwood and Couture, 2002). Moreover; higher concentrations of As can change muscle fiber size that ultimately reduced the weight and length of fish (D'Amico et al., 2014). In another study, Begum et al. (2013) exposed fish with As from dose of 7 and 20 mg/L in *H. fossilis* and concluded that muscles bundles started to degenerate when As is exposed.

Current study indicated that value of hepato-somatic indices increased significantly with increasing the level of As concentrations. Changes in HSI may be considered as a good indicator generally of the tested population of fish (Bolger and Connolly, 1989). HIS increases with the increase in arsenic concentration due to hepatocytes or hyperplasia (Crunkhornet al., 2004). These researches not only favours previous findings about arsenic toxicity but also leads to the suggestion about changes in the liver of *C. batrachus* by sub lethal toxicity of As. (Lu et al., 2001; Chen et al., 2004). Hepatomegaly, reported earlier about fishes by many pollutants (Pait and Nelson, 2003; Barseet al., 2006; Abdel-Hameid, 2007; Datta et al., 2007). In our current study, the value of GSI decreased with increasing concentration of arsenic for *Cyprinus carpio*. These results are in line with the findings of Yamaguchi et al. (2007) about catfish (*Pangasianodon hypophthalamus*) exposed to metal water contamination. They reported that As when exposed to the fish, spermatogonia necrosis and sertoli cells vacillation occurs. This study records the ISI value reduction when As exposed. This result is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_577586

almost same who worked to check effects by other pollutants (Abdel-Hameid, 2007; Abdel-Tawwab et al., 2007). It may result in appetite loss and body weight reduction. Many research findings use ISI values as indicator to check physiological responses and changes by less feeding (Abdel-Tawwabet al., 2006, 2007; Abdel-Hameide, 2007).

Conclusion

Exposure of *Cyprinus carpio* to various concentration of As induced the harmful effect. Results indicated that 96-h LC_{50} values of As for *Cyprinus carpio* was 25 mg L^{-1}. Sub lethal concentrations were determined by taking $1/5^{th}$, $1/10^{th}$, $1/15^{th}$ and $1/20^{th}$ of LC_{50} that were found to be 5.0, 2.5, 1.65 and 1.25 mg L^{-1}. Likewise, increasing concentration of As significantly enhanced the value of HSI and reduced the value of GSI and ISI of *Cyprinus carpio* species.

Abstract. This study has been conducted in Bayramiç District of Çanakkale Province in 2017 aiming to determine the seasonal performance of single and mixed sowing of perennial grass with some cool seasoned Gramineae species. Integra of *Lolium perenne*, Rebel XLR of *Festuca arundinacea*, Dumas1 of *F. ovina*, J-5 of *F. rubra commutata*, Redskin of *F. rubra rubra*, Samantha of *F. rubra trichophylla* and Miracle of *Poa pratensis* were used as the experimental subjects of this study. Total biomass production and grass quality attributes were investigated based on the number of species in mixtures and seasons. Fresh and dry biomass values significantly varied correlating to the seasons. The highest biomass productions were observed in spring and autumn. The highest values for grass quality, color, width, and coverage were observed in autumn. Single-sown *L. perenne* plots had superior attributes as compared to the mixed-sown plots. But grass color had darker green tones with the increasing number of species in mixtures. Present findings revealed that single-sowings yielded better grasslands than that of mixed-sowings and better structures were observed in autumn and spring as compared in summer. To establish quality grasslands in similar ecologies, *L. perenne* should be preferred and 2-3 species should be incorporated into the mixtures.
Keywords: *L. perenne, mixed sowing, cool season, grass performance, grass color*

Introduction

Just depending on increasing world population and developing industries, majority of the population is concentrated at city centers. People are in need of parks and recreation spots to meet their yearnings and devotion to nature (Avcıoğlu, 1997; Oral and Açıkgöz, 2002). Increasing urbanization in Turkey also increased people's interest in green zones. Lawns constitute the highest green zones of urban life. These zones are commonly established with the aid of architectural techniques as green covers for visual and esthetic purposes. They appeal to the eye and offer mental comfort, thus constitute a resting place for people (Avcıoğlu, 1997). Besides, lawns are natural oxygen depots of the cities, thus they purify city air and regulate precipitation regimes (Oral and Açıkgöz, 2002). Such green zones are also significant in mitigation the impact of climate change through absorbing sunrays and in reduction of pollution through absorbing environmental dust particles (Avcıoğlu, 1997). Maintenance of football pitches over which various sport activities are performed is a quite troublesome and difficult job requiring expertise. To establish high-quality long-lasting grasslands with attractive color, well cover ratio and rate, fast regeneration rates, resistant to pests, diseases and negative conditions and requiring less maintenance and mowing, the grass species to be used, their characteristics and adaptation capacities to the places they used should

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_587596

throughly be investigated and appropriate ones should be selected meticulously (Avcıoğlu, 1997). Grasslands are green spots composed of plant species covering the entire ground surface with a uniform appearance and able to be continuously mowed. According to data of the World Health Organization (WHO), the amount of green spots per capita should be at least 9 m^2. While such an area is around 8-12 m^2 in EU countries, it is only 2 m^2 in Turkey. The amount of green spots open to public in metropolitan cities of New York, Paris, London, Rio de Janeiro and İstanbul was respectively reported as 14%, 9.4%, 38.4%, 29% and 1.5% (Sözen et al., 1991; Önder and Polat, 2012).

In this study, the plant species of Lolium, Festuca and Poa, Lolium perenne, F. ovina, F. rubra commutata, F. rubra rubra, F. rubra trichophylla and Poa pratensis plant species of the genus Lolium, Festuca and Poa have been used in the studies that was carried out in order to create grass areas in the ecology of Mediterranean countries. It was aimed to determine the performance and quality characteristics of different grass using single as well as mix-cropping systems.

Materials and methods

Experiments were conducted in Bayramiç town of Çanakkale province in the year 2017 (*Fig. 1;* see also photos in the *Appendix*). While the long-term annual precipitation of the experimental site was 647.5 mm, the annual precipitation of the experimental year was 656.5 mm. While the months November, December and January had the highest precipitation, the months July, August and September had the least precipitation. The average monthly temperature has been recorded as 16.2 °C until the study was conducted and the average monthly temperature decreased to16.1 °C in 2017. While the months June, July and August were the hottest months, the months December, January and February were the coldest months. Experimental soils were clay-loam in texture. Soils were non-saline (EC 0.85 mS/cm), slightly alkaline (pH 7.85), slightly limey (0.8%), poor in organic matter (0.78%), sufficient in available phosphorus (10.81 mg kg^{-1}) and potassium (329.75 mg kg^{-1}).

In the research; double, triple, quartet, fivefold, sixfold and septet mixtures of Lolium perenne Integra (LP) single and Festuca arundinacea Rebel XLR (FA), F. ovina Dumas1 (FO), F. rubra commutata J-5 (FRC), F. rubra rubra Redskin (FRR), F. rubra trichophylla Samantha (FRT) and Poa pratensis's Miracle (PP) varieties have been applied (*Table 1*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_587596

Experiments were conducted over 114 plots (1 m x 2 m = 2 m^2) in randomized blocks design with 3 replications. Sowing norm in the shape of seed/m^2. Plots were 20 cm apart and blocks were 40 cm apart from each other. Before sowing, nitrogen (N), phosphorus (P_2O_5) and potassium (K_2O) were applied to soils as composed fertilizer (15.15.15) as to have 10 g/m^2 on 19.10.2015. Ammonium sulphate was also applied to each plot on 02.05.2016 and 17.10.2016 as to have 5 g/m^2 N. Green and dry biomass along with grass quality according to Sills and Carrow (1983), Mehall et al., (1983) and Avcıoğlu (1997), grass color, width and coating ratios have been determined according to Spangenberg et al. (1986), Wenher et al. (1988), Goatley et al. (1994) and Avcıoğlu (1997). Resultant data were subjected to statistical analyses in accordance with randomized blocks split plots experimental design. Means were compared with Duncan's multiple comparison test (Düzgüneş et al., 1987).

Results

Fresh and dry biomass

While fresh biomass of grasslands significantly varied with the seasons, effects of number of species in mixtures and number of species x season interactions did not have significant effects on fresh biomass values. The highest fresh biomass (459.0 g/m^2) was obtained from spring and the least fresh biomass (314.9 g/m^2) was obtained from summer season. Based on the number of species in mixtures, fresh biomass values varied between 347.4–427.9 g/m^2. Despite the insignificant differences between them, single-sown and senary mixtures of *L. perenne* had slightly greater fresh biomass quantities (*Table 2*).

Table 2. *Number of species in the mixture and green mass amounts of grass area according to season (g/m^2)*

Number of species	Spring	Summer	Autumn	Mean
1	504.7	318.8	450.8	424.7
2	424.7	341.4	371.7	379.3

Mean	459.0 a	314.9 c	388.8 b	-
Significance	$P_{number\ of\ species} = 0.1795$, $P_{season} = 0.0001$, $P_{number\ of\ species*season} = 0.9586$			

While the dry biomass of single-sown and mixtures of *L. perenne* did not significantly vary relative to the number subject of species in mixtures, but significant differences were observed between the dry biomass values of the seasons. Based on number of species in mixtures, dry biomass values varied between 97.3–110.9 g/m^2. On the other hand, while the highest dry biomass values were observed in spring (112.6 g/m^2) and autumn (111.9 g/m^2), plants had less dry biomass in summer (87.0 g/m^2) (*Table 3*).

Grass quality

In order to determine the quality values of pre-harvest quality in each plot that applied by Sills and Carrow (1983) and Mehall et al. (1983), and the quality values were also determined according to the scale of 1-9 (1: worst, 9: best) with regard to the uniformity, frequency and cleanliness of the grass that described by Avcıoğlu (1997). While number of species in *L. perenne* mixtures and seasons had significant effects on grass quality, the effects of interactions were not found to be significant. The best quality (with a score of 9.0 points) was achieved in autumn and the poorest quality (with a score of 7.4 points) was observed in spring. Slight decreases were observed in quality scores with the increasing number of species in mixtures (*Table 4*).

Table 4. *Grass quality based on number of species in mixtures and seasons*

Number of species	Spring	Summer	Autumn	Mean
1	7.7	8.3	9.0	8.3 a
2	7.5	8.1	9.0	8.2 ab
3	7.5	8.1	8.9	8.2 ab
4	7.2	8.1	9.0	8.1 b
5	7.2	7.1	9.0	8.1 b
6	7.4	8.2	8.8	8.1 b
7	7.0	8.1	9.0	8.0 b
Mean	7.4 c	8.1 b	9.0 a	-
Significance	$P_{number\ of\ species} = 0.0310$, $P_{season} = 0.0001$, $P_{number\ of\ species*season} = 0.0705$			

Grass color

In each plot, the color of the grass was determined in the period in which the harvesting was not done in order to determine the color of the plot periodically applied by Spangenberg et al. (1986); Wenher et al. (1988) and Goatley et al. (1994), and the color of the grass has also been determined according to the harvesting scale of 1-9 (1: yellow, 9: dark green) as indicated by Avcıoğlu (1997). Grass color

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_587596

significantly varied with number of species in mixtures, seasons and their interactions. The best grass color (7.34) was observed in autumn and it was followed by summer (6.30) and spring (3.68). Increasing number of species in mixtures improved grass color (*Table 5*).

Table 5. *Grass color based on number of species in mixtures and seasons*

Number of species	Spring	Summer	Autumn	Mean

Significance	$P_{number\ of\ species} = 0.0021$, $P_{season} = 0.0001$, $P_{number\ of\ species*season} = 0.0001$			

Grass width

While number of species had significant effects on grass width, the effects of seasons and interactions were not found to be significant. Grass widths decreased with increasing number of species in mixtures. The highest grass width (3.98 mm) was obtained from single-sown *L. perenne* plots. Based on seasons, grass widths varied between 3.34-390 mm (*Table 6*).

Table 6. *Grass width based on number of species in mixtures and seasons (mm)*

Number of species	Spring	Summer	Autumn	Mean

Significance	$P_{numbe\ of\ species} = 0.0001$, $P_{season} = 0.1744$, $P_{numbe\ of\ species*season} = 0.9999$			

Grass coverage

Grass coverage was significantly greater in autumn (8.96) than in the other seasons. The lowest coverage (8.29) was observed in summer. Number of species in mixtures did not yield significant variations in grass coverage and the values varied between 8.46–8.68 (*Table 7*).

Discussion

The species used in formation of grasslands are cool season species. Cool season species exhibit their best growth and development in spring (Miller, 1984). Plants then exhibit regrowth in autumn with cooling weathers (Altın et al., 2011). Since hot weathers of summer put plants into stress, expected growth is not achieved even with evaporative cooling and fertilizations (Gökkuş, 1989). Therefore, in grasslands established with cool season species, the greatest biomass is observed in spring and autumn.

The best quality of single-sown *L. perenne* plots was attributed to genetic characteristics and this plant being well-adapted to grasslands. Since cool season species exhibit their best growth and development in spring and autumn, they are expected to have greater quality scores in these seasons. But, cold weather of winter and spring of the experimental year recessed plant growth and development. Such a case then yielded greater quality scores in summer instead of spring. Regrowth in autumn again increased the quality scores of grasslands.

Color is the primary quality attribute for grasslands. It is an indicator of agronomic and physiological characteristics and also plays a great role in visually (Kroon and Knops, 1991; Williems et al., 1993). Grassland color is directly related to chlorophyll content of graminae species (Açıkgöz, 1994; Avcıoğlu, 1997). Besides chloroplasts, color is also dependent on plant nitrogen, iron, and manganese uptake from the soil and plant water content. Therefore, each graminae species has its specific color tone (Beard, 1973; Açıkgöz, 1994; Avcıoğlu, 1997). Seasonal changes in color characteristics of grasslands continuously increased from spring to autumn. This is because single-sown and mixture grasses exhibited slow growth and development in spring, spent the summer in dormant nature and exhibited the most significant portion of growth and development in autumn. Therefore, the highest color scores were achieved in autumn (Açıkgöz, 1994).

The highest grass width of single-sown plots was attributed to less competition of single-sown plots for water and nutrients than the mixed-sown plots. Single-sown plants had greater plant widths as compared to plant heights. In competitive environments, plants generally have longer, but weaker stems.

Heat requirements of the plants were effective in coverage levels. Since experimented grass species were cool season species, coverage levels were also greater

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_587596

in cool seasons (autumn and spring). These plants generally get into dormant season in summers (Altın et al., 2011), thus they have low coverage levels in summers.

Conclusions

In this study, carried out in Çanakkale province, seasonal (spring, summer and autumn) performance of single-sown *Lolium perenne* and mixtures with *Festuca arundinacea, F. ovina*, *F. rubra commutata*, *F. rubra rubra*, *F. rubra trichophylla* and *Poa pratensis* have been investigated. Present findings revealed increasing fresh and dry biomass in spring and autumn and decreasing values in summer. Grass quality was ordered as autumn > summer > spring and the highest values were observed in single-sown plots. Grass colors increased with increasing number of species in mixtures. Grass quality did not change significantly with the seasons. The darkest grass color was observed in autumn. While grass widths did not change significantly with the seasons, but decreased with increasing number of species in mixtures. The highest grass coverage was attained in autumn. It was concluded based on present findings that single-sown *L. perenne* plots yielded the highest biomass values and quality attributes.

(Received 3rd Apr 2019; accepted 12th Dec 2019)

Abstract. The excessive application of potassium (K) fertilizer over the last 30 years has resulted in considerable resource waste and environmental risk. In order to economize and protect the environment, China launched a soil testing and fertilizer recommendation project from 2005 to 2015. A total of 1370 on-farm experiments were conducted concerning maize fields in Jilin Province Northeast China, also called the golden maize (*Zea mays* L.) belt, over the past ten years to evaluate the effects of the implemented project and to provide farmers with an improved fertilizer recommendation system. The results showed that the average yield of maize with K0 treatment was 9000 kg ha^{-1}. Its maximum yield (Max.yield) and increased yield (IY k) after application of K fertilizer averaged at 10200 kg ha^{-1} and 1100 kg ha^{-1}, respectively. Significant variability was evident in K0 yield and Max.yield over the years. Maize hybrids and different soil types had significant differences in IY yield. Meanwhile, IY k can either increase or decrease depending on K0 yield, which suggest that a suitable K fertilizer can improve the yield, whereas excessive fertilizing would have no obvious effect on the yield. In addition, the yield was found to be affected by environment, maize hybrids, soil types, and K fertilizer rate.
Keywords: *increasing yield, soil fertility, hybrids, soil types, fertilizer use efficiency*

Introduction

Alongside developing modern hybrids and improving agronomic management, fertilizer use is recognized in China as one of the key methods for increasing yield. Indeed, the effects of nitrogen (N) and phosphorus (P) fertilizers on corn production have been extensively studied; however, the effect of potassium (K) fertilizer has not been given much attention. As one of the three major plant macronutrients, potassium has multiple functions in the activation of cellular enzymes; the synthesis of proteins, starch, cellulose, and vitamins; the development of resistance to abiotic and biotic stresses; the improvement of N and P fertilizer use efficiency; and the enhancement of productivity and quality of agricultural produce (Ogundijo et al., 2017; Chen et al., 2012a; Epstein and Bloom, 2005). Neglect of the importance of potassium coupled with high input of inorganic N and P fertilizers to meet the continually increasing demand for food has resulted in their low use efficiency, as well as N:P:K imbalance in plant and soil systems leading to severe eutrophication (Tian et al., 2017; Zhang et al., 2011). Potassium deficiency is a nationwide phenomenon, with approximately 43% of soils requiring additional potassium (Zoerb et al., 2013). However, excessive application of potassium fertilizer, which could persist in the soil for years after application, is also a documented occurrence (Xie, 2000; Tenkorang and Lowenberg-DeBoer, 2009).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_597607

Therefore, determining the appropriate potassium input is crucial to the achievement of high yield and high efficiency.

China produced 155 Mt of maize (*Zea mays* L.) in 2007 (National Bureau of Statistics of China, 2007; Wang et al., 2007), which made the country the second largest producer of maize worldwide (Zhang et al., 2011). In 2017, the yield of maize increased to 259 Mt (National Bureau of Statistics of China, 2011). The increase of yield was apparent in Northeast China, particularly in Jilin Province, which increased from 18 Mt in 2007 to 32.5 Mt in 2017 (National Bureau of Statistics of China, 2017). The recent long-term application of K fertilizer may be one of the reasons for this improvement.

Several studies have demonstrated that long-term potassium fertilizer application can maintain crop productivity and soil quality (Wang et al., 2007), and that K efficiency and partial balance condition can affect crop yield (Zhang et al., 2011). However, studies on the relationship between corn yield and the long-term application of potassium fertilizer in Northeast China are scarce. In 2005, China launched a nationwide soil testing and fertilizer recommendation project to mitigate excessive and unbalanced fertilizer application. Hereby, we just chose the data in Jilin Province as analysis sample due to large amount of data in whole project, the objective of this study was to examine the ten-year experiment of "soil testing and fertilizer recommendation" in Northeast China from 2005 to 2015 and to determine (1) the relationship between corn yield and potassium fertilizer in K deficient and K excessive conditions, and (2) whether the amount of recommended K rate (RKR) was optimized by the K fertilizer to satisfy the K requirement of corn.

Materials and methods

The study area was located in Jilin province in Northeast China with between 40° and 47° N latitude and between 121° and 131° E longitude in the east of Eurasian continent in the middle latitude, which is not only one of the three black soil regions in the world, but also one of three golden corn belts in the world. The climate in the study area is warm-temperate, sub-humid, continental monsoon with cold winters and hot summers. Annual precipitation ranges from 500 mm to 800 mm, with 60 to 70% of the rainfall occurring in the summer. No irrigation was supplied during the corn-growing season. There are more than 30 counties in nine cities in Jilin province with 187400 km^2. The soil types primarily included Haplic Luvisol, Albic Luvisol, Haplic Phaeozem, Cambisol, Haplic Kastanozem, Calcaric Arenosol, Haplic Chernozeme, and Luvic Phaeozem (http://en.wikipedia.org/wiki/FAO_soil_classification; Gong et al., 1999).

Experimental design

A total of 1370 on-farm experiments on corn production were chose from 2005 to 2015 in 55 counties of Jilin Province (*Fig. 1*). All experimental fields received four K treatments without replication: No K control (K0), RKR, 50% RKR, and 150% RKR. RKR was determined according to the recommendations of an agronomist based on the estimated soil fertility and the target yield (1.1 times the average yield for the past five years, which varied by field). RKR values in different farm fields were different because of diverse soil condition and environmental variables.

The experiments were conducted on a continuous corn system, and new experimental sites were selected every year. Generally, one-third of N and the total K and P fertilizers

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_597607

were applied at pre-sowing, and the remaining two-thirds of N fertilizer was applied as top-dressing at around the six-leaf stage.

The plot size was approximately 40 m^2 (4 m × 10 m). Based on soil N and P levels, all plots received sufficient amounts of urea (185 kg to 250 kg N ha^{-1}) and triple superphosphate (60 kg to 120 kg P_2O_5 ha^{-1}) at pre-sowing. No organic manure was applied. All experiments were managed according to the same practices of each individual producer except for implementing the treatments and obtaining crop and soil samples, which were conducted by the researchers. A total of 71 maize hybrids were used in the experimental sites, which belong to four typical variety series in Jilin province, such as Zhengdan, Jidan, Xianyu, and Nongda，and these were individually selected by the farmers. Moreover, all hybrids had high yield potential. The corn was planted in the beginning of May and was harvested by the end of September. Weeds were controlled with herbicide after seedling, and no obvious water or pest stress was observed during the corn-growing seasons (the data in disaster such as flood, pest disaster, extreme drought in some trial sites and incomplete data have been eliminated). The plant population was about 55000 with 60 cm row spacing, which is typical in Jilin Province.

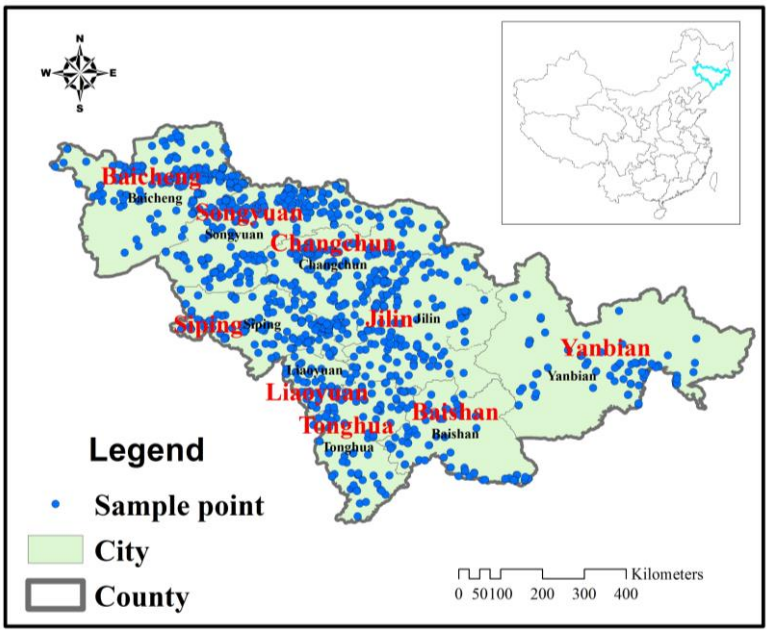

Figure 1. *Sample point information map*

Sampling and laboratory procedures

At least three samples of 20 cm soil layer were obtained from each field for all of the plots. The samples were air-dried, sieved, and used to measure the exchanged-K (Van Reeuwijk, 1992). For each experiment, gain yield at maturity was assessed by hand on a 2.5 m × 8 m section of each plot, and the value was adjusted to 14% moisture.

Data analysis

All experimental data were analyzed with correlation analysis method by using software SAS. Single factor analysis was employed to compare the mean yields of K

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_597607

treatments based on the least significant difference (LSD) at a 0.05 level of probability. Given the data complication, data on four common soil types (Albic soils, Chernozem, Aeolian sand, and Phaeozem) in Northeast China and four typical hybrids (Zhengdan, Jidan, Xianyu, and Nongda) in farmer fields across all treatments in the 1370 fields were selected and analyzed. The product of the dimension model and the years degrees of freedom (df = 10), hybrids (df = 3), and soil type (df = 3) was used to assess the overall variability of the increased yield (IY k), the yield with N0 treatment, and the maximum yield (Max.yield).

Maximum grain yield was defined as the highest mean yield of all K treatments for each field. Increased yield for applied K fertilizer (IY k) was defined as the difference between Max.yield and the yield of the K0 treatment for each experiment. The agronomic K efficiency (AEK) and K partial factor productivity (PFPK) were calculated based on *Equations 1* and *2* (Ladha et al., 2005). AEK is the yield increase per unit of K applied, and PFPK is the most significant index for farmers because it integrates the usage efficiency of both indigenous and applied K resources.

$$AEK = (YK - Y0) / K \quad \text{(Eq.1)}$$

$$PFPK = YK / K \quad \text{(Eq.2)}$$

where YK and Y0 represent the grain yield in K application plots and K0 plots, respectively, and K is K from the applied fertilizer.

Results

Yield, increasing yield, AEK and PFPK with different K treatments

In this study, soil organic matter, TN, TP, and PH in the top 20 cm soil profile averaged at 17.4 ± 19.6 g kg^{-1}, 1.4 ± 1.3 g kg^{-1}, 0.8 ± 0.4 g kg^{-1}, and 6.7 ± 1.0, respectively. These values are typical for rainfed corn production in Northeast China. The grain yield for the K0 treatment across all of the 1370 experiment fields averaged at 9.0 Mg ha^{-1} and varied from 2.1 Mg ha^{-1} to 17.9 Mg ha^{-1} (*Table 1*). Increasing yield rate resulting from K fertilizer input was 5.6%, 10.0%, and 8.9% for 50% RKR, RKR and 150% RKR, respectively. So it can be seen that the K fertilizer is one of important factors to increase yield. Reasonable K fertilizer rate can reach the best effect of increasing yield comparing to less or excessive K fertilizer application. The RKR across 1370 experiment fields was 72 ± 7.5 K_2O kg ha^{-1} and varied from 19.5 K_2O kg ha^{-1} to 180 K_2O kg ha^{-1}. The grain yield of RKR averaged at 9.9 Mg ha^{-1} and varied from 2.1 to 17.0 Mg ha^{-1}. AEK and PFPK for RKR averaged at 12.2 and 138.9 kg kg^{-1}, respectively (*Table 2*). Compared with RKR, the addition of more K beyond RKR (+50%) did not increase yields, but reduced AEK and PFPK. Treatments below RNR (-50%) resulted in a 0.4 Mg ha^{-1} yield loss. Therefore, RKR is a reasonable range to attain maximum grain yield.

Effect of years, hybrids and soil types on K fertilizer and yield

Year factor significantly affected the variation in Max.yield and K0 yield resulting from environmental factors such as rainfall, temperature, and insect pests (*Table 1*; P = 0.01). Max.yield among different years varied from 8.9 Mg ha^{-1} to 10.6 Mg ha^{-1}. The mean Max.yield in 2008 was 10.4 Mg ha^{-1}, which was caused by suitable rainfall

DOI: http://dx.doi.org/10.15666/aeer/1801_597607

and sunlight. The yield decreased in 2007 and 2009 because of drought. In addition, the yield decreased in 2010 because of the flood in certain parts of Jilin Province.

Q: quantile

Moreover, the different hybrids had extremely significant differences in Max.yield, K0 yield, and IY. Among the four typical maize (*Zea mays* L.) hybrids in Jilin Province, the Zhengdan hybrid has the highest K0 yield, which displayed higher tolerant ability of poor soil. However, the Xianyu hybrid has the highest Max.yield and IY, which indicate stronger sensitivity to potassium nutrition. The AE of the hybrid can be reflected by the following order: Xianyu > Jidan > Nongda > Zhengdan. The Xianyu hybrid exhibits high increased yield regardless of the environment. For example, in 2008 and 2007, the Xianyu hybrid had absolutely high IY, which exhibited better increasing potential (data did not show).

The yield from four typical soil types in Jilin Province had extremely significant differences in K0 treatment and Max.yield. The yield from Aeolian sand was the lowest,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_597607

whereas that from Phaeozem soils was the highest (*Fig. 2*). No difference in IY was observed. Optimum fertilizer rate was calculated via linear-regression analysis using SAS software. Results showed that the optimum fertilizer rate in Albic soils and Chernozem soils was generally higher than that in Aeolian sands. In an ideal environment, optimum K fertilizer rate in Albic soils, Phaeozem, Chernozem, and Aeolian sand soils was 63.2, 82.2, 58, and 51.6 kg/ha, respectively. The optimum yield calculated by SAS software was similar to the average yield, which indicated that RKR was a rational range.

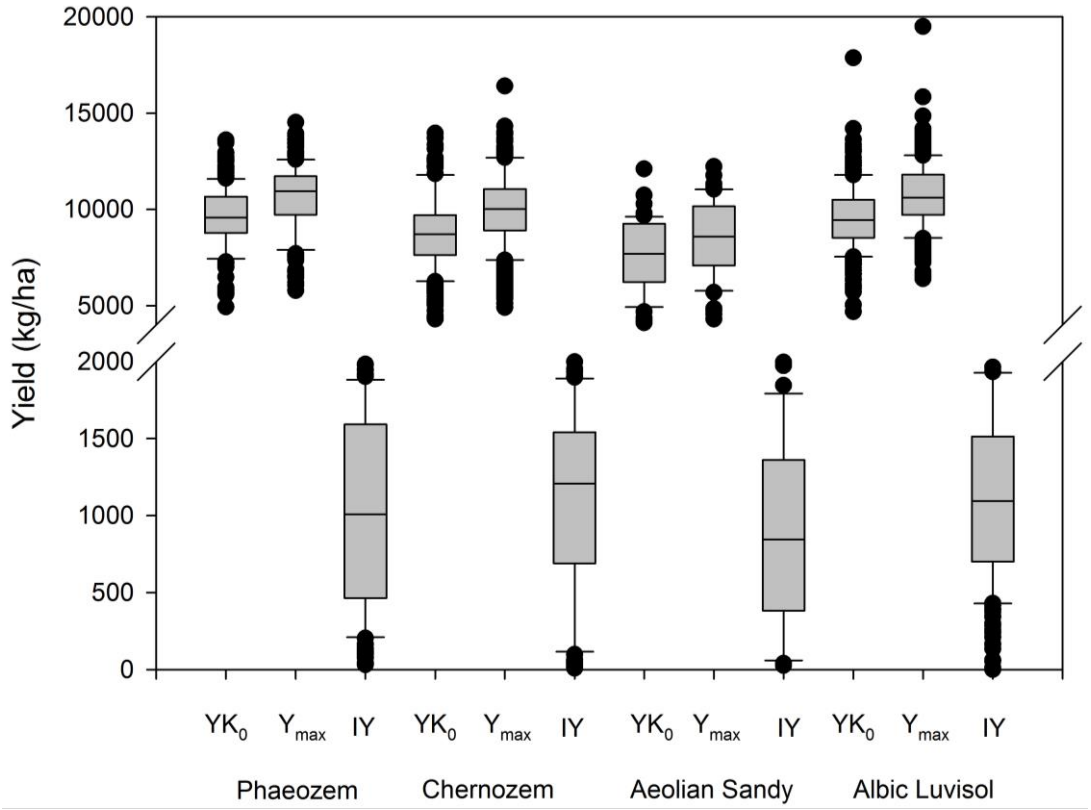

Figure 2. *Averaged yield per hectare of 4 kinds of soil types in 2005-2010 in test fields. YK_0 means yield with K0 treatment; Y_{max} means the maximum yield with K treatment; IY means increasing yield. The upper and lower limits of each box represent 25% and 75% values, the horizontal solid lines inside the box indicate mean values, respectively*

The relationships among Max yield, increasing yield and K0 yield

A close relationship was found between Max.yield and yield of K0 treatment across all fields (R2 = 0.87; *Fig. 3A*). The maximum grain yield increased as the yield of K0 treatment was increased. According to statistics, the rate of corn yield of RKR with respect to Max.yield is 52%. The rate of corn yield of 150% RKR with respect to Max.yield is 42% in all fields. These results indicated that a sufficient amount of K fertilizer was applied, which resulted in high yield. However, compared with the RKR yield, the average yield of RKR was higher than the yield of 150% RKR, and agronomic efficiency of RKR was significantly higher than that of 150% RKR, which indicated that RKR was the suitable amount of fertilizer that must be applied in Northeast China.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_597607

IY k has correlation with increasing yield of K0 treatment (R2 = 0.1; *Fig. 3B*). When the grain yield of K0 treatment is smaller than 8.0 Mg ha^{-1}, IY k increases with the yield of K0 treatment. However, when the grain yield of K0 treatment is greater than 8.0 Mg ha^{-1}, IY k decreases with the yield of K0 treatment. This phenomenon shows that a suitable amount of K fertilizer can improve the grain yield in the soil with K deficiency. However, the increase in yield caused by the application of K fertilizer in soils of middle and high yield is not significant. Moreover, when the corn grain yield is extremely high (greater than 12.0 Mg ha^{-1}), certain IY k were still higher (*Fig. 3B*). This finding partly indicated that the soils of certain plots were more fertile, which resulted in high yield, and the addition of K fertilizer input improved the soil fertility balance, which resulted in higher yield.

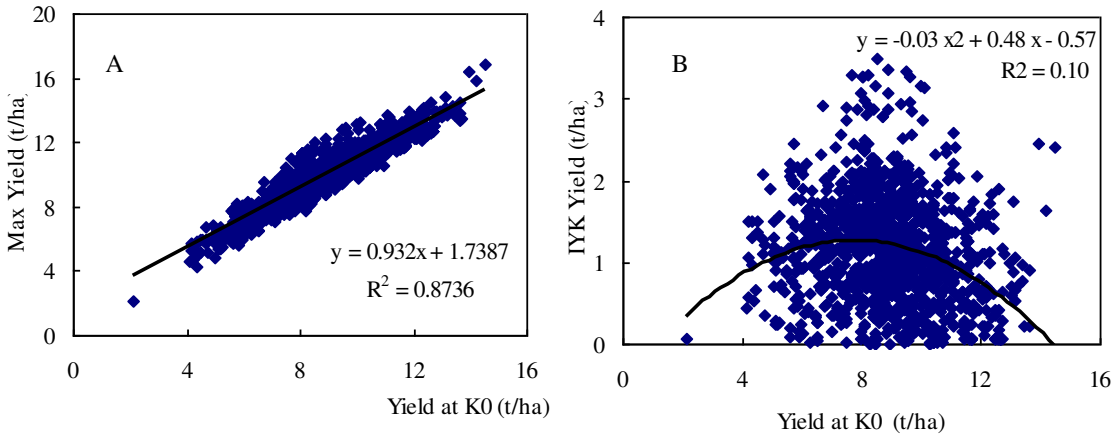

***Figure 3. A** Relationship between maximum yield (Max.yield) and grain yield at K0 treatments across all 1370 fields. **B** Relationship between increase yield (IYk) to applied K fertilizer and grain yield at K0 treatments across all 1370 fields*

The percentage of IYk (*Fig. 4*) in maximum yield (IY k/Max.yield) decreased with increasing yield for K0 treatments, which suggested a conflict between improving usage efficiency and further increasing the yields (Gao et al., 2012).

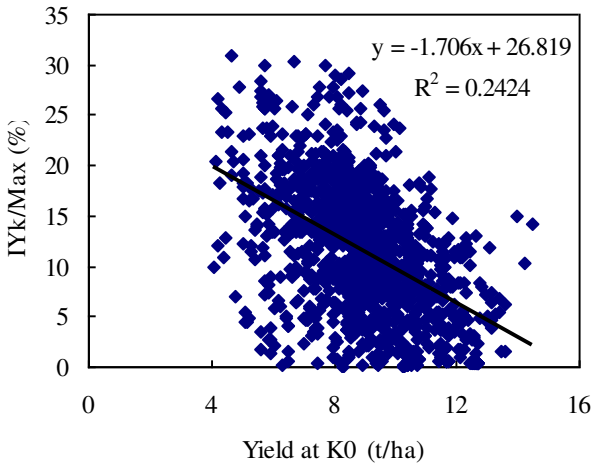

***Figure 4.** Relationship between the percentage of IYk in maximum yield (IY k/Max.yield) and grain yield at K0 treatments across all 1370 fields*

Discussion

Yield, increasing yield, AEK and PFPK

Jilin Province in Northeast China is one of the three gold corn belts of the world. The province is the most significant maize-producing regions in China. As the population continues to grow, the amount of farmland has decreased in recent years. Therefore, adding yield per unit to increase maize production has been the focus of several studies in China. From the Chinese Revolution until today, maize yield per hectare has gone through several stages of rapid development with the emergence of maize hybrid varieties, fertilizer application, and management technology improvement (Ren et al., 2010). From 2005 to the 2011, the averaged yield per hectare is from 3.2 Mg ha^{-1} to 7.5 Mg ha^{-1} because of the implementation of the soil testing and fertilizer recommendation project and the high-yield, high-efficiency management in Jilin Province (National Bureau of Statistics of China 2007; National Bureau of Statistics of China 2011), however the averaged K fertilization rate applied (K_2O) is from 38.4 kg ha^{-1} to 42.1 kg ha^{-1} due to decreased maize planting areas and increased potassium fertilizer emphasis, which is obviously lower than national maize averaged 82kg ha^{-1} (Li et al., 2010). Averaged agronomical efficiency (AE) and partial factor productivity from applied fertilizer (PFP) of potassium in 2005-2015 in Jilin province is 17.3 kg kg^{-1} and 32.7 kg kg^{-1} which is obviously higher than average level in China (Li et al., 2010). Compared with averaged yield per hectare in USA in 2005 9.3 Mg ha^{-1} and higher potassium use efficiency (Zhang et al., 2008), yield and fertilizer use efficiency in China were still lower mainly by three factors. First is farmer experience unconscious fertilization, farmers yet applied old notion of more input, then more output. Second is ignorant of mix application of organic and inorganic fertilizer, and of macro element and microelement fertilizer. Last is low level of mechanization.

Effect of year, hybrids and soil types on K fertilizer and yield

According to above historical data, three factors affect the yield per unit of maize and potassium fertilizer rate. First is environmental condition such as temperature, sunlight, and rainfall. The suitable climate for maize growth consists of four distinct seasons, with abundant sunshine and rain at the same time (Li et al., 2001; Zheng and Dong, 2000), temperature and rainfall have significant correlation with maize yield (Peng et al., 2008; Drury and Tan, 1995). Moreover, moisture content in soil has obvious interaction with potassium fertilizer efficiency. Potassium in soil transport mainly by diffusion, and the water in soil was strongly affected diffusion condition. So it should be pay attention to apply potassium fertilizer in dry years, and decrease potassium fertilizer rate in higher rainfall years (Ortas, 2018; Shen et al., 2008).

Second, the development of hybrids affected yield and potassium fertilizer rate. China popularized breeding and corn hybridization during the 1960s, and yield per unit was increased by 2.5 times (Sun, 2010). The yields of different maize hybrids had obvious differences under the same conditions (Chen et al., 2012b). Dissimilar tolerance of such hybrids to drought or herbicide resulted in significant yield variability (Weber and Golebiowska, 2010; Vasal, 2000). The assessment of yield stability is a significant issue for maize cultivar evaluation and recommendation (Liu et al., 2011). Therefore, summarizing the requirements of selected maize hybrids is necessary in selecting high-yield and stable-yield hybrids based on local climate conditions observed in previous years. And the characteristics of absorb potassium of different hybrids existed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_597607

significant changed. The abilities of absorb potassium of different hybrids in soils and in fertilizer had difference, the divergence of potassium content in each stage can reach 0.9-1.6 times, so the hybrids of long-term and large quantities of absorbing potassium should apply base potassium fertilizer and top-dressing fertilizer (Wang et al., 2004).

Finally, soil types are crucial to improve yield and potassium use efficiency. Crop yield response was controlled by a complex interaction that varied annually with soil textural characteristics (Tolk et al., 1999). Soil textural affects water supply, ventilation, fertilizer supply, heat preservation and basic fertility of soil, also influenced soil physics, mechanics of machinery and a series of other characteristics. The yield per unit affected by climate and soils is close to real yield potential in the agreeable hybrids and management technology. Different soil types have different rational potassium rate and fertilization styles due to high spatial variability in soil K content, the forms and availability to plants of soil K, i.e. potential K-supplying capacity, were related to mineralogy in different soil types (Darunsontaya et al., 2012). In Jilin province available potassium contents of Phaeozem Soils and Chernozem Soils are higher and slow-available potassium contents are relatively richer, the potential of potassium supply are huge; available potassium of Albic Soils is middle, the potential of potassium supply is limited, so it should be replenish proper potassium fertilizer; and available potassium and potential of potassium supply of Aeolian Sand Soils are lower, so it is necessary to increase potassium fertilizer and split application (Wang, 1998).

The relationships among Max yield, increasing yield and K0 yield

Soil fertility determined Max yield, increasing yield and K0 yield of maize. The higher the soil fertility is, the higher K0 yield and Max yield are and the lower the potential of increasing yield is. Increasing yield has significant negative correlation with the available potassium content of soil (Wang et al., 2004). So identifying and quantifying soil fertility variation and subsequently determining the optimal fertilization levels associated with different management styles are necessary to implement nutrient management (Tabu et al., 2006). Rational fertilization improved fertilizer use efficiency, protected the environment, and maintained soil fertility for creating suitable soils. Therefore, modeling and calculating the optimal fertilization in different soils and different climate conditions based on experimental data analysis from previous years can guide farmers in the process of scientific fertilization.

Conclusion

The challenge of meeting food demand with less pollution on the environment in China in the next 50 years can be overcome by increasing usage efficiency simultaneously (Gao et al., 2012). The effect of “soil testing and fertilizer recommendation” project in China from 2005 to 2015 was remarkable. The results from Jilin province with 1370 field trials showed that the average yield of maize with K0 treatment was 9000 kg ha^{-1}. Its maximum yield (Max.yield) and increased yield (IY k) after application of K fertilizer averaged at 10200 kg ha^{-1} and 1100 kg ha^{-1}, respectively. Significant variability was evident in K0 yield and Max.yield over the years. Maize hybrids and different soil types had significant differences in IY yield. Meanwhile, IY can either increase or decrease depending on K0 yield, which suggest that a suitable K fertilizer can improve the yield, whereas excessive K fertilizing would have no obvious effect on the yield. In addition, the yield was found to be affected by environment,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_597607

maize hybrids, soil types, and K fertilizer rate. Therefore, the research of precision K fertilizer application on different soils type and different maize hybrids in different climate condition should be carried out in the future, which will be of epoch-making significance for high-yield and high-efficiency of spring maize in Jilin province, in Northeast China.

Abstract. Agriculture has become an important source of greenhouse gas emissions. This paper calculates the agricultural GHGs emissions of 30 provinces in China from 1997 to 2016, and analyzes the emission intensity of GDP of carbon dioxide, methane and nitrous oxide by club convergence. After using the DEA CCR model to divide the club, the absolute β-convergence analysis method is used to verify the emission trends of various greenhouse gases. The results showed that the carbon dioxide emission intensity showed obvious absolute β convergence in all three clubs. Methane and nitrous oxide only have absolute β convergence in one of the clubs, respectively, and there is divergence in other clubs. Since the emission trends of the three greenhouse gases in the clubs are different, the formulation of reasonable reduction target allocation plan should be more detailed and targeted, and more stringent emission reduction targets should be set for provinces with high GHGs intensity of GDP in order to reduce it rapidly.
Keywords: *greenhouse gases, agriculture, convergence carbon dioxide, methane, nitrous oxide, emission reduction, climate policy*

Introduction

China is a large agricultural country and the earliest origin of crop and farming culture. Since the 1980s, the annual growth rate of Chinese agriculture has been at the forefront of the world. In 1978-2008, agricultural growth increased by an average annual growth rate of 4.6%. At the same time, agriculture has become a significant source of greenhouse gases. SAIN (China-UK Sustainable Agriculture Innovation Network, www.sainonline.org) reported that Chinese agriculture-related GHGs emissions accounted for 17%-20% of the total GHGs in the atmosphere, a ratio above the world average. In order to realize China's emission reduction commitments at the World Climate Conference in Paris, agricultural GHGs emission reduction has become the direction and inevitable trend of agricultural development in the future.

Carbon dioxide, methane and nitrous oxide are the most GHGs emitted in agricultural activities, and they are hot spots of research. Agricultural CO_2 flux is mainly derived from the combustion of fossil fuels, the respiration of plant roots and decomposition of organic matter. Agriculture is the source and sink of CO_2 (Zhang and Liang, 2011). Lal (2004) pointed out that global agricultural carbon sinks were down to 50% to 66% in history. Norse (2012) put forward that in the process of agricultural production of CO_2 mainly by agricultural, agricultural machinery, agricultural irrigation and agricultural straw burning. Lelieveld et al. (1998) showed that biological processes produce about 70% of agricultural CH_4. Yang et al. (2003) advised that the main sources of agricultural CH_4 were rice fields, wetlands, sediments, intestinal fermentation, and animal manure treatment. Li et al. (2009) used GAINS model to predict the N_2O emissions of Chinese

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_609624

agriculture. The results showed that the emissions would reach about 2 million t in 2030, an increase of 31% compared with 2000. Agricultural N_2O emission mainly comes from agricultural land, fertilizer application and animal manure management.

It can be seen that agricultural GHGs has been a hot issue in research, and its emissions should not be underestimated. So it has far-reaching significance for the accounting of China's agricultural GHGs emissions and emission intensity.

Regional convergence was proposed in the middle of the 20th century, and the empirical research was based on the Solow growth model. The results of the study within the neoclassical framework show that backward areas present a "catch-up effect" relative to advanced areas. In 1986, Baumol (1986) first proposed the hypothesis of regional convergence. Barro and Salaimartin (Barro and Salaimartin, 1992; Barro and Mankiw, 1995; Salaimartin, 1996) put forward the theory of σ convergence and β convergence.

Since regional convergence theory can give policy implications, some scholars have used this theory to study greenhouse gas emissions, but most of the research does not involve agricultural greenhouse gas emissions. Huang (2013) used the spatio-temporal dynamic convergence model to analyze the per capita carbon dioxide emissions of Chinese cities from 1985 to 2008. Hao (2015) studied the carbon dioxide emission intensity of 29 provinces in China from 1995 to 2011, and proved that there was absolute β convergence. Yang (2016) estimates total factor productivity from the perspective of whether there are environmental constraints, and examines the impact of carbon dioxide emissions on economic convergence in China's provinces. Robalino-Lopez (2016) studied the per capita carbon dioxide emissions of 10 South American countries from 1980 to 2010, and analyzed the convergence process of the per capita carbon dioxide emissions of these countries. Zang (2018) analyzed the per capita carbon dioxide emission convergence of 201 countries from 2003 to 2015, and calculated that the global per capita carbon emission convergence rate was less than 1% per year. Kouretas (2018) studied the convergence of energy consumption and carbon dioxide emission intensity in 23 European countries from 1970 to 2010 with the method of distribution dynamics, and the results showed that there was no convergence. Yu (2018) conducted a convergent analysis on the carbon intensity of China's industrial sector from 1995 to 2015, showing the existence of the condition convergent. The club convergence has also been used to study the issue of greenhouse gas emissions. The study of Jobert (2010) confirmed the convergence of European per capita carbon dioxide emissions. Based on China's provincial carbon intensity data from 1995 to 2011, Wang (2014) found that there was a significant divergence in carbon intensity at the national level by using logt test. Burnet (2016) studies the convergence of carbon dioxide emissions related to energy consumption across U.S. states between 1960 and 2010, forming a convergence club and two divergence groups. Apergis (2017) analyzed the carbon dioxide emissions of various states, and found empirically that there was no overall convergence of carbon dioxide emissions per capita in the United States. Liu (2018) studied the per capita emissions of industrial pollutants in 285 prefecture-level cities in China from 2003 to 2015, aiming to reveal the impact of industrial transfer on the formation of convergence clubs.

In this paper, the accounting of agricultural GHGs emissions and emission intensity is to understand the current situation of agricultural GHGs emissions in China more clearly. Because each club has a steady-state value of its emission intensity, the emission reduction share can be divided according to the decline rate of emission intensity. Therefore, the convergence analysis of agricultural GHGs emission intensity aims to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_609624

provide a reference for the Chinese government to define the reduction target allocation plan.

Methods

China's agricultural greenhouse gas emissions accounting

China's agricultural GHGs accounting method refers to the means recommended by IPCC (www.ipcc.ch), Min (2012) research results and the Provincial GHGs Inventory Compilation Guide. Carbon dioxide is calculated mainly from the use of fossil fuels in agricultural production. Methane comes from rice paddies, ruminant intestinal fermentation and animal waste treatment. Nitrous oxide emissions calculated in this paper also mainly come from three parts, namely, crop soil background, fertilizer application and animal manure management. Then, this paper uses the GWP value recommended by IPCC to derive the agricultural GHGs emissions in China.

Club convergence analysis

Convergence is not a black or white issue; it presents a trend of narrowing the gap. In this paper, the intensity of agricultural greenhouse gas emissions in China is mainly verified by club convergence.

According to the energy value theory, for CCR model, the input factors include chemical energy, mechanical power energy, thermal energy and bio-energy input in agricultural production. The output factor is greenhouse gas emissions. The rate of intra-club convergence is calculated according to the absolute β convergence regression equation.

$$\frac{1}{t-t_0}\ln\frac{x_{t,i}}{x_{0,i}} = \alpha - \frac{1-e^{-\beta(t-t_0)}}{t-t_0}\ln x_{0,i} + \varepsilon_{t,i} \quad \text{(Eq.1)}$$

where $x_{t,i}$ and $x_{0,i}$ represent the intensity of agricultural GHGs emissions in the initial and final stages of the i-th province, t represents the t-year, t_0 represents the initial, β represents the convergence rate, α represents the intercept term, and $\varepsilon_{i,t}$ represents the error term. When there is a positive β value, it indicates that there is absolute β convergence in the intensity of agricultural greenhouse gas emissions in the club; conversely.

Data

The basic agricultural data are collected from the Statistical Yearbook of China, Husbandry/Energy/Agriculture Statistical Yearbook of China. The specific data are shown in *Table 1*.

Results and discussion

Results of agricultural GHGs flux accounting in China

The agricultural greenhouse gas emissions in China from 1997 to 2016 are shown in *Figure 1a*. GHGs emissions of CO_2 equivalent are on the rise. In 1997, the flux was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_609624

952.7404 Tg CO_2 e, and in 2016, it was 1031.5290 Tg CO_2 e, with an average annual growth rate of 0.42%.

Table 1. *Data sources*

The relevant data	Source
Acreage of crops; the number of various animals; China's agricultural GDP	Statistical Yearbook of China
The number of livestock service number	Husbandry Statistical Yearbook of China
Agricultural employment data	Statistical Yearbooks of various provinces in China
The physical quantity of energy used in agricultural production	Energy Statistical Yearbook of China
Nitrogen fertilizer, phosphate fertilizer, potash fertilizer, compound fertilizer, pesticide, plastic film data	Agriculture Statistical Yearbook of China

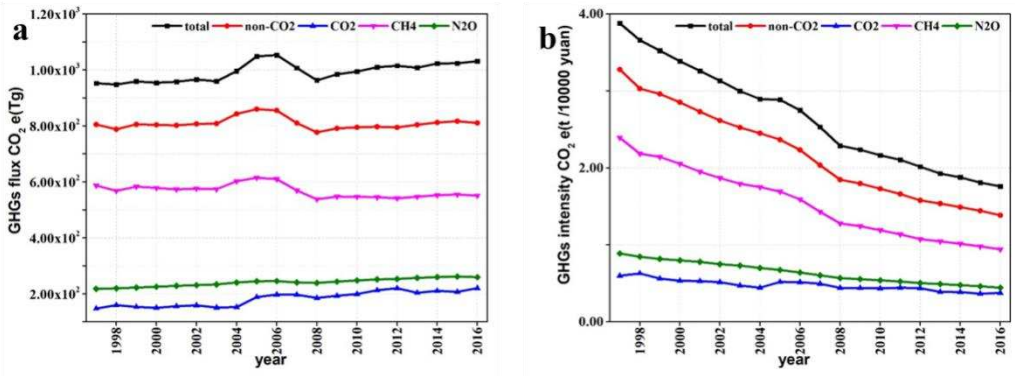

Figure 1. *The agricultural GHGs flux in China from 1997 to 2016*

Although agricultural GHGs flux in China shows an upward trend, the intensity of GDP declines obviously, almost linear (*Fig. 1b*). In 1997, the intensity was 3.8801 t/10,000 yuan (about 2.6744 kg/dollar), in 2016, 1.7621 t/10,000 yuan (about 1.2146 kg/dollar), the average annual decline rate was 4.24%.

Club convergence of agricultural GHGs intensity of GDP in China

According to the CCR model of DEA, the total factor energy efficiency of each province from 1997 to 2016 is calculated, and the average value is counted, and the club is divided according to the average value of total factor energy efficiency. Because the object of the study is 30 provinces, in order to ensure that the number of data substituted into the convergence model and the number of club members are relatively average, the corresponding critical value is taken to divide the clubs. Since the output in the CCR model (agricultural GHGs flux of CO_2 equivalent) is an undesired output, the lower efficiency value indicates that the situation of the region is more optimistic.

Club convergence of CO_2 intensity of GDP in China

Agricultural carbon dioxide flux and emission intensity distribution are shown in *Figure 2*. Agricultural carbon dioxide flux show a certain geographical difference, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_609624

north is higher than the south, the middle and east are higher than the west. In particular, the provinces that gather in the Inner Mongolia-Guangdong axis have the largest flux. The distribution of CO_2 intensity of GDP is also geographically different. The provinces with high intensity are concentrated in the northwest, and the intensity decreases from northwest to southeast.

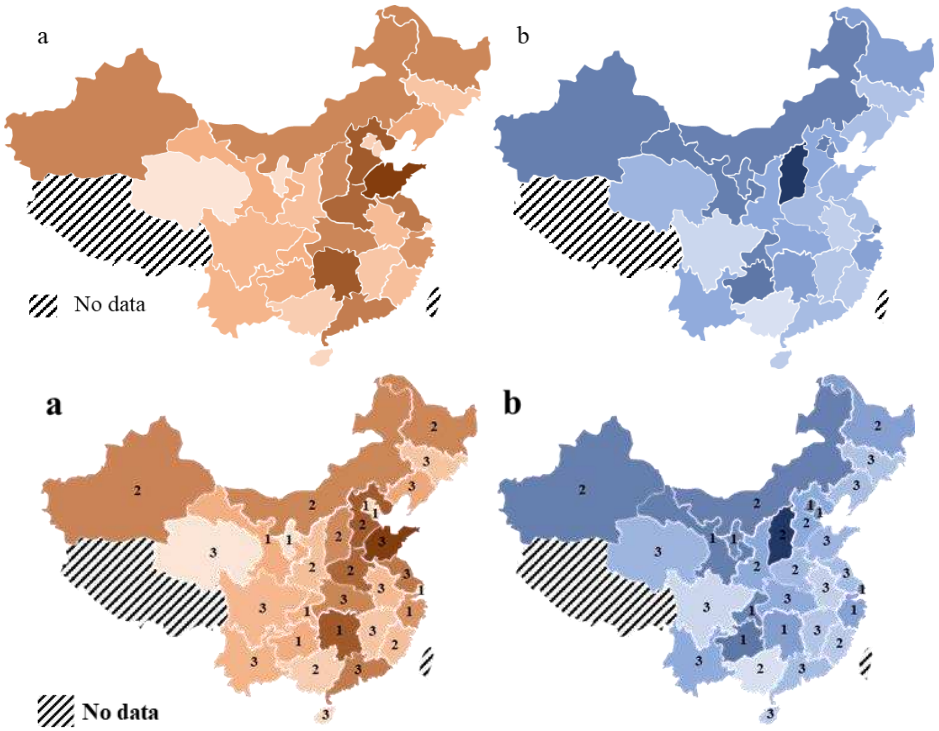

Figure 2. a *Annual average flux of agricultural CO_2 from 1997 to 2016.* ***b*** *Annual average CO_2 intensity of GDP from 1997 to 2016. (Note: The color of each patch represents the size of its flux/intensity, where the darker the color, the greater the flux/intensity. The numbers 1, 2, and 3 indicate which club the area belongs to)*

For the total factor energy efficiency of agricultural CO_2 emission, a threshold of 0.78 and 0.90 will be set for each of the three national clubs (as shown in *Fig. 3*).

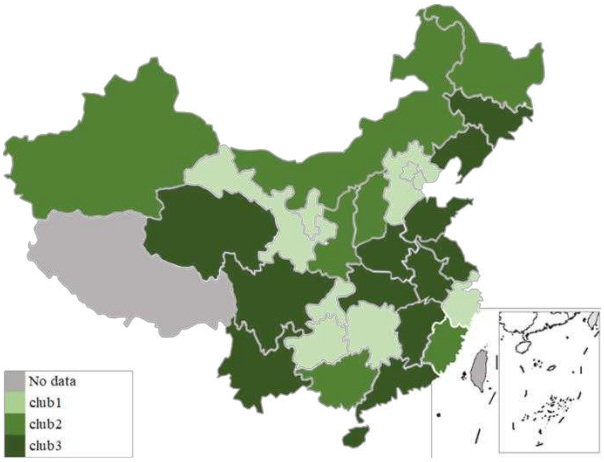

Figure 3. *Club distribution of agricultural carbon dioxide intensity of GDP*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_609624

In the past 20 years, agricultural carbon dioxide flux of club 1 accounted for about 24.26% of the national agricultural carbon dioxide flux, and the proportion is decreasing year by year (*Fig. 4a*). The agricultural CO_2 intensity of GDP was higher than other clubs, but the intensity declined at a higher rate, especially in Chongqing. As shown in *Figure 4b*, the strength of club 1 shows a downward trend, which also provides the possibility of verification of convergence. According to *Equation 1,* the calculation can obtain a positive β value, that is, within club 1, there is a significant absolute β convergence of agricultural CO_2 intensity, and the convergence rate is 15.55%. The existence of this convergence phenomenon indicates that the difference in the emission intensity of the club members will gradually disappear, and the intensity will eventually reach the same stable value. In order to achieve the development of low carbon in agriculture quickly, the club 1 should follow the pattern of the convergence of members' CO_2 intensity when designing reasonable reduction target allocation plan. Chongqing, Guizhou and Ningxia, where the emission intensity declines rapidly, should undertake heavier burden.

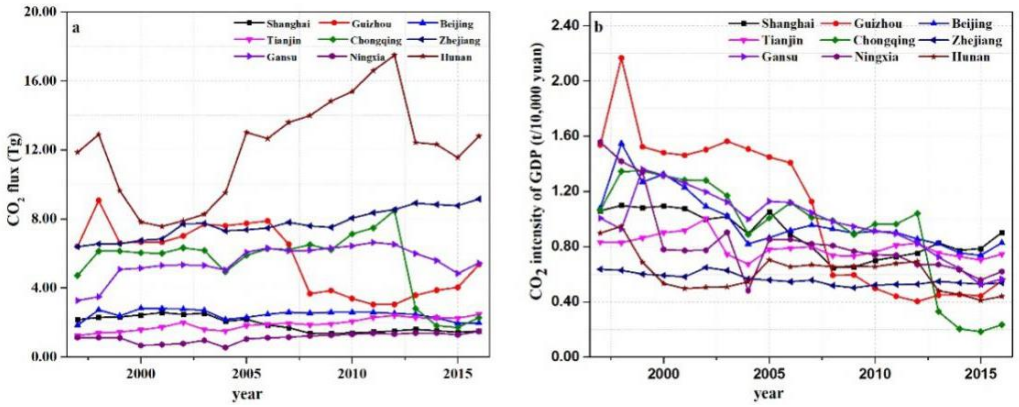

Figure 4. a *Agricultural CO_2 flux in club 1.* ***b*** *Agricultural CO_2 intensity of GDP in club 1*

From 1997 to 2016, the agricultural carbon dioxide flux of club 2 increased almost linearly (*Fig. 5a*). For the intensity of carbon dioxide, the reductions in Shanxi, Shaanxi and Henan are more obvious, and the intensity in Guangxi and Inner Mongolia is on the rise (*Fig. 5b*).

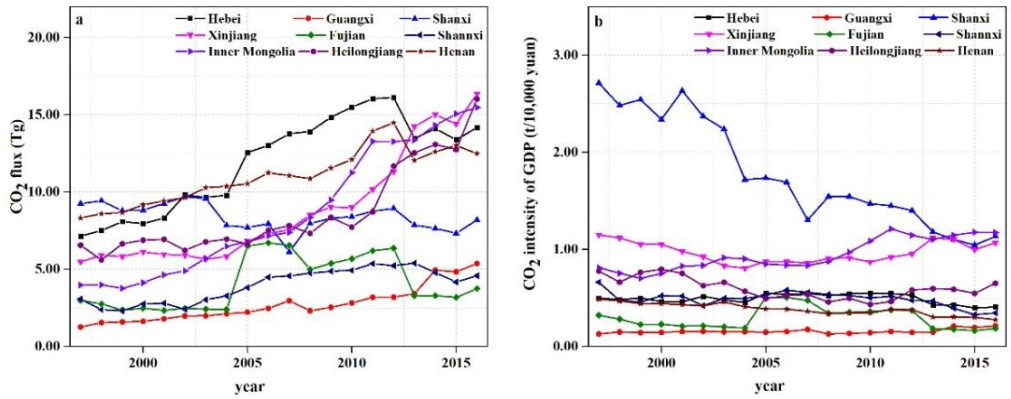

Figure 5. a *Agricultural CO_2 flux in club 2.* ***b*** *Agricultural CO_2 intensity of GDP in club 2*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_609624

The absolute β convergence rate of CO_2 intensity of club 2 is 1.69%. Members of club 2 are mostly energy-rich provinces. However, good resource endowments have made these places a rough way of using energy. At the same time, the economic development model of "energy dominates the economy" does not meet the requirements of sustainable development. Due to the special geographical and climatic conditions, Fujian and Guangxi have created distinctive subtropical agricultural farming methods, but the penetration rate of modern agricultural production methods is still low. Because of the absolute β convergence, reduction allocation plan of club 2 should abide by the convergence model. Considering the rate of decline in emission intensity, Shaanxi and Shanxi should bear more emission reduction tasks. At the present stage, it is impossible to completely abandon coal, and the clean and intensive use of coal is a strategic choice.

The CO_2 emission of club 3 is shown in the *Figure 6*. Club 3 is the group with the lowest carbon dioxide emission efficiency of agriculture. Its agricultural carbon dioxide flux accounts for 39.02% of the nation, and the ratio is decreasing. After calculation, the CO_2 intensity of GDP of club 3 satisfies the absolute β convergence condition, and the convergence rate is 5.08%. Except for Qinghai, Sichuan, Yunnan and Hubei, members of club 3 are mostly in the eastern coastal or offshore areas. At the same time, Guangdong and Jiangxi have the largest decline in emission intensity, so they should take more responsibility for cutting CO_2 emissions. As the members of this club are at the forefront of low-carbon development, it is a big problem to break the efficiency bottleneck.

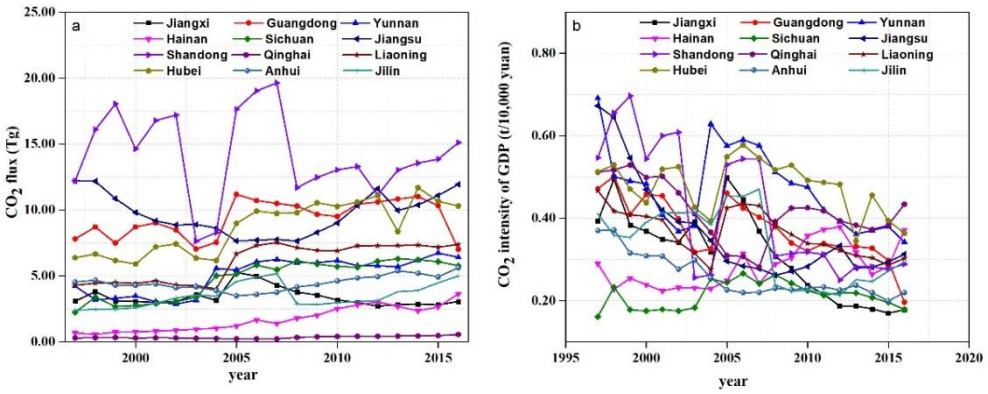

Figure 6. a *Agricultural CO_2 flux in club 3.* ***b*** *Agricultural CO_2 intensity of GDP in club 3*

The club convergence test results of agricultural CO_2 intensity is shown in *Table 2*. The decline of China's agricultural CO_2 emission intensity shows the increase of agricultural energy efficiency. However, according to the efficiency value calculated by DEA, it shows that each region has certain emission reduction potential. In other words, from club1 to club3, the potential to reduce emissions is decreasing in turn. The key to CO_2 emission reduction in China's agriculture is to adjust the structure of agricultural energy utilization and realize the clean utilization of coal.

Club convergence of CH_4 intensity of GDP in China

The flux of methane from agricultural production is diverging from the two provinces of Shaanxi and Shanxi, and the flux is increasing (*Fig. 7a*). This is mainly because the animal husbandry and planting industry in Shaanxi and Shanxi provinces

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_609624

are not developed. The CH_4 intensity of GDP in the Bohai Rim region is the lowest. The intensity in the north and south of the region is increasing (*Fig. 7b*).

Table 2. *Club convergence test results of agricultural carbon dioxide intensity*

The average energy efficiency value calculated based on CCR model, with threshold values of 0.25 and 0.45, the state is divided into three clubs. The distribution map is shown in *Figure 8*.

For club 1, please see *Figure 9*. In club 1, CH_4 emission intensity shows a downward trend, but there is no obvious convergence effect. Using *Equation 1,* a negative *β* value is calculated. This is caused by large differences in the agricultural industrial structure

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_609624

of each member. Therefore, the formulation of reduction plan should fully consider the imbalance of the emission intensity of club members. As the prime rice producing area in China, club 1 plays a significant role in China's food security. For large rice planting provinces, the focus of emission reduction should be on the rice planting season. Qinghai and Hainan should increase agricultural input, improve agricultural technology and develop leisure agriculture. As for Shanghai, with its current urban orientation, the development of primary industry has a low cost performance, and it should focus on the development of other high-tech industries.

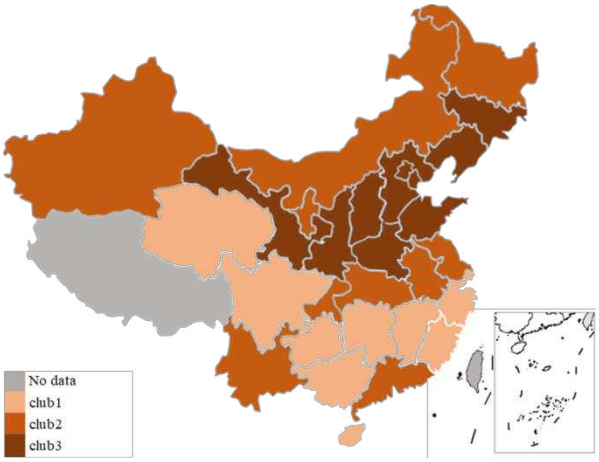

Figure 8. *Club distribution of agricultural methane intensity of GDP*

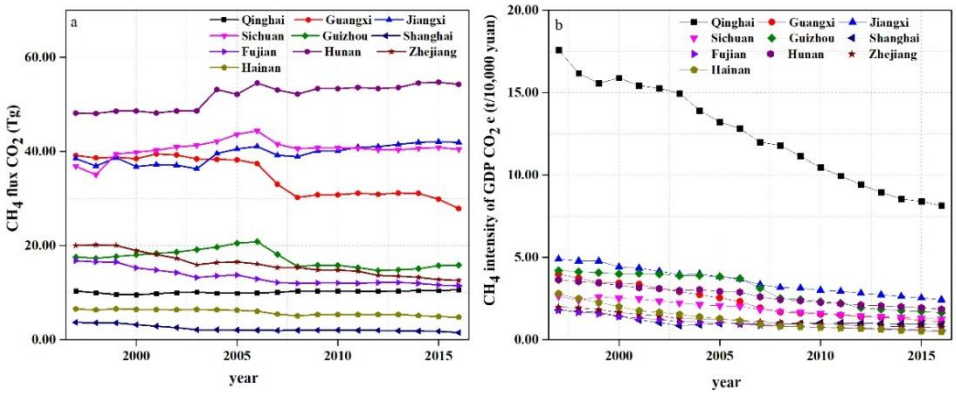

Figure 9. a *Agricultural CH_4 flux in club 1.* ***b*** *Agricultural CH_4 intensity of GDP in club 1*

Club 2 consists of seven major rice-growing provinces and three major livestock provinces. The club's agricultural CH_4 flux is slightly less than club 1 (*Fig. 10a*), accounting for 39.00% of the total, mainly from rice fields and animal husbandry. The intensity of members in the club showed a downward trend (*Fig. 10b*), and the gap between the maximum and minimum emission intensity in 2016 is less than the difference in 1997. However, the narrowing of the two extremes does not indicate the overall convergence of emission intensity. After calculation, a negative β value is obtained, that is, there is no absolute β convergence. The formulation of the target allocation project of club 2 should focus on two points, namely, animal husbandry and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_609624

rice field. Only by considering these two points can we create the optimal emission reduction effect.

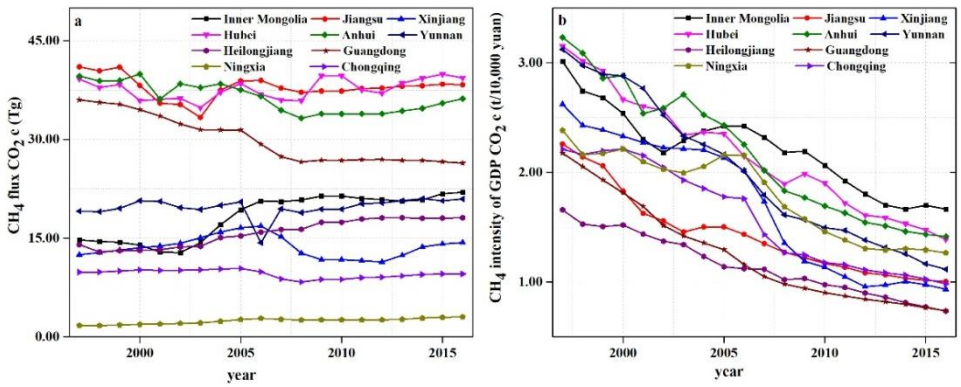

Figure 10. a *Agricultural CH_4 flux in club 2.* ***b*** *Agricultural CH_4 intensity of GDP in club 2*

Club 3 is the group with the lowest CH_4 emission efficiency in agriculture, and with the lowest methane emissions, the lowest methane intensity. It can be seen from *Figure 11b* that there is a clear downward trend of methane emission intensity. This is also verified on the model. After calculation, a positive β value is obtained, indicating that the rate of absolute β convergence is 2.19%. Similar agricultural bases and development patterns are the dominant factors of the convergence. Shanxi, Henan, Gansu, and Shaanxi, which have the highest rate of decline in emission intensity, should be allocated a larger share of CH_4 reduction. These regions have greater reduction potential than those with lower reduction rates such as Beijing and Liaoning.

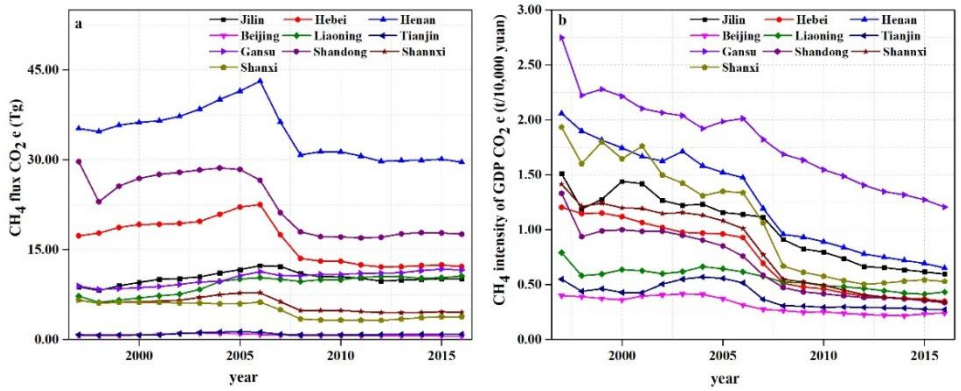

Figure 11. a *Agricultural CH_4 flux in club 3.* ***b*** *Agricultural CH_4 intensity of GDP in club 3*

CH_4 clubs are classified similarly to CO_2, with the most efficient club 1 having the greatest potential to reduce emissions. The main source of CH_4 is agriculture. CH_4 emission reduction mainly lies in paddy fields and animal husbandry, so emission reduction policy formulation should pay attention to the mid-term sunning of paddy fields and fertilizer management. At the same time, the management of pastoral areas is particularly important. The number of grassland should be used to determine the number of livestock breeding, so as to avoid the ecological dead cycle of vulnerable

DOI: http://dx.doi.org/10.15666/aeer/1801_609624

areas like Qinghai. In addition, the club convergence test results of agricultural CH_4 intensity is given in *Table 3*.

Club convergence of N_2O intensity of GDP in China

Agricultural nitrous oxide flux is mainly concentrated in the developed provinces of the planting industry, and the overall emissions in the east are greater than those in the west (*Fig. 12a*). The nitrous oxide intensity of GDP shows a different distribution pattern. The emission intensity in the west is greater than that in the east, showing a decreasing law from west to east, which is mainly caused by the fact that the agricultural output value in the east is much higher than that in the west (*Fig. 12b*).

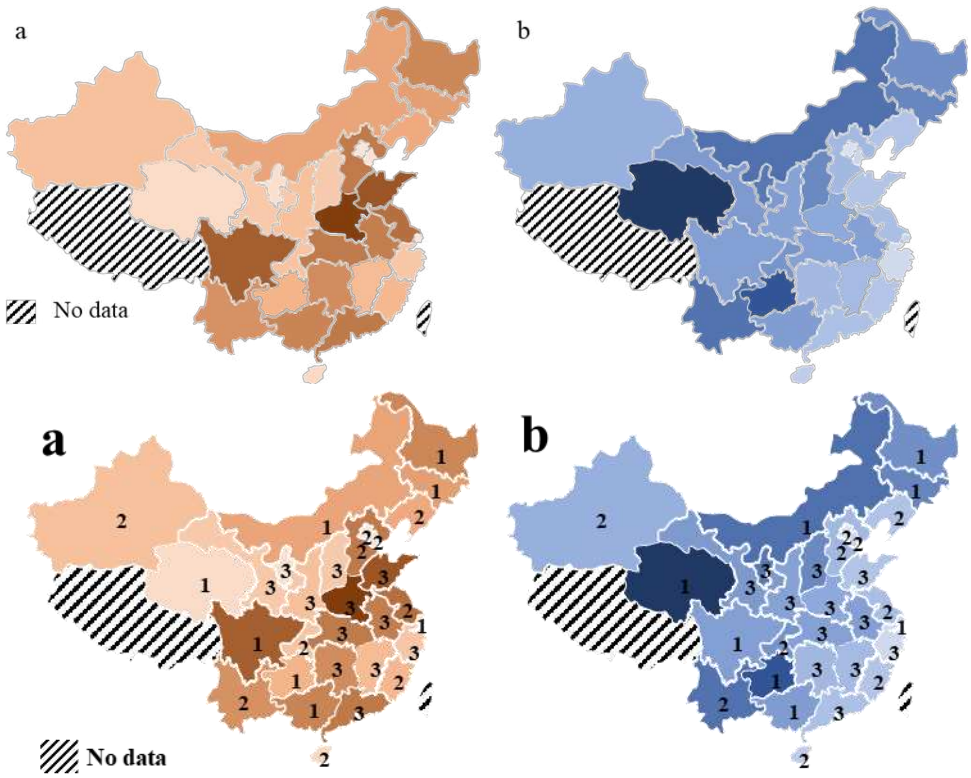

Figure 12. a *Annual average flux of agricultural N_2O from 1997 to 2016.* ***b*** *Annual average N_2O intensity of GDP from 1997 to 2016. The numbers 1, 2, and 3 indicate which club the area belongs to*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_609624

For nitrous oxide, the club is divided in the same way. The energy efficiency values are divided into three intervals with 0.70 and 0.90 as the two critical values. This resulted in 3 clubs as shown in *Figure 13*.

Figure 13. *Club distribution of agricultural nitrous oxide intensity of GDP*

The contradiction between people and land in the southwestern provinces of club 1 has intensified. In club 1, except for Shanghai, the agricultural N_2O flux of all members shows an increasing trend (*Fig. 14a*). According to *Equation 1,* a positive β value is calculated, which indicates that the absolute β convergence rate of the first club is 1.02%, that corresponds to *Figure 14b*. Agricultural N_2O reduction policy of the club should be formulated in accordance with the convergence model. Qinghai should undertake more emission reduction tasks and should reduce Shanghai's emission reduction pressure.

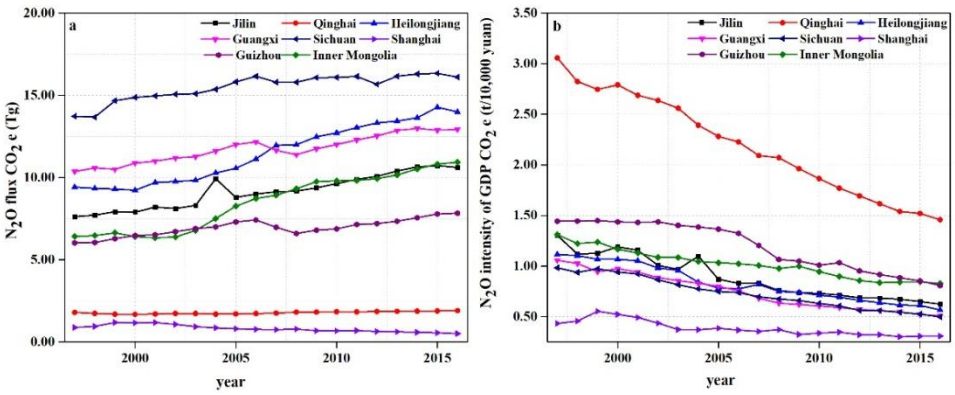

Figure 14. a *Agricultural N_2O flux in club 1.* ***b*** *Agricultural N_2O intensity of GDP in club 1*

The agricultural production of nitrous oxide flux is similar to club 1, but its emission intensity is only half of club 1 (*Fig. 15b*), which is mainly due to the fact that agricultural GDP of club 2 is much higher than club 1. There is no absolute β convergence in club 2, which indicates that the N_2O intensity of the members of the club will gradually increase, and its reduction target should be formulated according to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_609624

the divergent model. That is, each member's emission reduction policy has different emphasis.

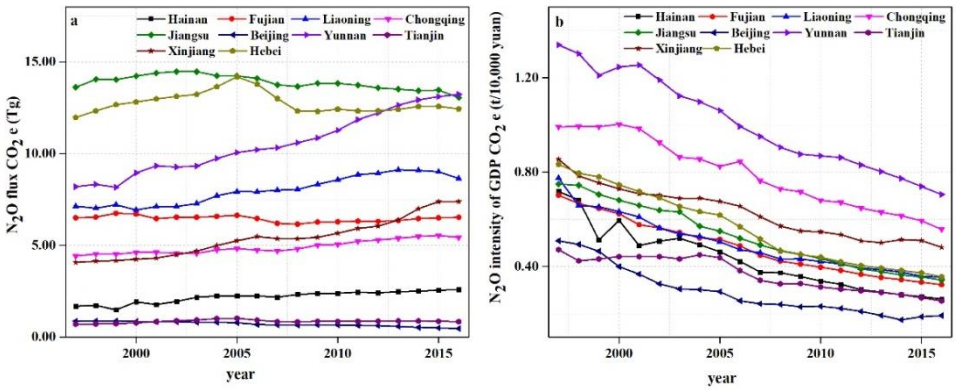

Figure 15. a *Agricultural N_2O flux in club 2.* ***b*** *Agricultural N_2O intensity of GDP in club 2*

Club 3 has the maximum number of members and the largest N_2O flux (*Fig. 16a*). Although flux has declined in 2005-2008, the overall trend is increasing. The intensity of N_2O of GDP within the club has decreased year by year and the gap has gradually constringed (*Fig. 16b*). A positive β value is calculated, and the β value is 0.17%, but the value of R^2 is only 0.0083, that is, the credibility of absolute β convergence is low. However, from *Figure 16b*, the narrowing of the difference in emission intensity seems to confirm the existence of the catch-up effect in the club.

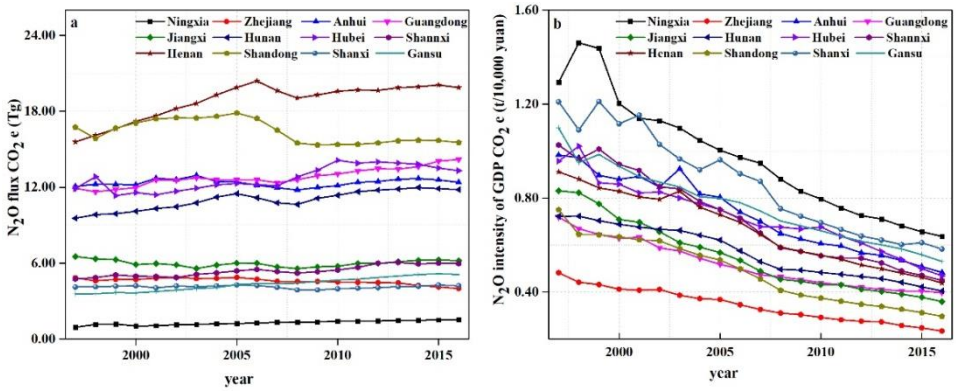

Figure 16. a *Agricultural N_2O flux in club 3.* ***b*** *Agricultural N_2O intensity of GDP in club 3*

Club 3 includes some crucial food production provinces, such as Shandong, Henan, Hunan, etc. The club plays an important role in ensuring Chinese food security. The SAIN another report pointed out that the excessive use of nitrogen fertilizer in cultivated wheat in Shaanxi reached 100%, and the excessive application of nitrogen fertilizer in the land where tomatoes were grown in Shandong reached 80-200%. According to the results of this study, club 3 has a huge potential for N_2O emission reduction in fertilizer. Club 3 has many plains and abundant labor force, so it is necessary to deepen the agricultural industrial chain and promote the urbanization process.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_609624

The club convergence test results of agricultural N_2O intensity is listed in *Table 4.* Agricultural N_2O mainly comes from planting industry. Based on the fact that China is a country with a large population, in order to feed more people on limited land, the agricultural input will be greatly increased, which will lead to the increase of N_2O emissions. However, the increase of economic benefits brought by the increase of input is limited. Therefore, this agricultural economy dominated by large input is not the optimal agricultural development path and is not conducive to emission reduction. In order to reduce the emission of N_2O, it is necessary to control the amount of nitrogen fertilizer and plant nitrogen-fixing crops with high economic benefits.

Conclusion

GHGs reduction can bring co-benefits for air quality and human health (West et al., 2013), and has become the mainstream trend of economic development in various countries. The exploration of agricultural low-carbon development is a key area for scholars from all over the world.

The results of the club analysis show that the intensity of carbon dioxide in agriculture is in club convergence, and the absolute β convergence rate of club 1 is 15.55%, club 2 is 1.69%, and club 3 is 5.08%. Therefore, the emission reduction policy of carbon dioxide should be formulated according to the convergence model within the club. The two greenhouse gases, methane and nitrous oxide, only have convergence in one club. The methane emission intensity only converges at club 3, and the absolute β convergence rate is 2.19%. The nitrous oxide emission intensity only converges in club 1, and the absolute β convergence rate is 1.02%. Therefore, the emission reduction mode of these two gases should not only consider the convergence characteristics in the club, but also follow the divergence mode in the other two clubs.

The treatment of agricultural waste of resources, low level of mechanization of agriculture, agricultural pollution, and agricultural product safety are all issues that need to be addressed in the development of low-carbon agriculture (Peng and Liang, 2016). In view of the characteristics of China's agriculture, in order to achieve the development of low-carbon agriculture, it is necessary to improve the utilization efficiency of fossil fuels, explore more adaptable rice varieties and planting patterns, and promote more scientific animal farming techniques and nitrogen fertilizer application models. In particular, reducing the excessive use of nitrogen fertilizer will bring additional benefits, such as improving water quality, reducing soil acidification, enhancing air quality, increasing farmers' income, and improving the purchasing power

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_609624

of the rural economy (Zhang et al., 2013). At the same time, agriculture as an important carbon sink, its role in greenhouse gas emission reduction can not be ignored, which will be gradually advanced in future research.

Abstract. Groundwater quality in the Basin of Dhamar (Yemen) has been studied using geographic information system (GIS), principal component analysis (PCA) and correlation technique. A geographic information system is a tool for mapping and analyzing spatial data and is also used to retrieve groundwater quality information. For this study 26 wells were selected, for each well thirteen physicochemical parameters were analyzed including electrical conductivity, Calcium (Ca^{2+}), Magnesium (Mg^{2+}), Sodium (Na^{+}), potassium (K^{+}), bicarbonate (HCO_3^{-}), Chloride (Cl^{-}), Sulphate (SO_4^{2-}), Nitrate (NO_3^{-}), Iron (Fe^{2+}), Fluoride (F^{-}) and Total Hardness (TH). The collected groundwater was evaluated for its suitability for both drinking and irrigation purposes. Correlation and PCA have been utilized to analyze the parameters. Cartographic maps of the study area have been generated using multivariate statistical tools and GIS approach Inverse Distance Weighting (IDW) for all the above parameters. The created maps can be used to visualize, analyze, and understand the relationship among all locations. Most of the wells are found to be within the permissible limit except one well and this is due to the anthropogenic pollution received by human activities. Correlation and principal component analysis can help in selecting the most significant parameters to determine the status of water quality. The tools available in the GIS environment supported the study in the integration of data with very different data structures, i..e. point, 2D and 3D, towards spatial modeling of processes relevant to the assessment of groundwater resources.
Keywords: *ground water quality, PCA, IDW, piper diagram, Yemen*

Introduction

Water is a source of life for life. This substance must be preserved from all influences: modern civilization, industrialization, urbanization, and an increase of the population (Kot et al., 2000; Rafiullah et al., 2012). The groundwater contamination in an urban environment is due to the infiltration of domestic untreated wastewater into the natural receiving environment, accentuated by favorable hydrogeological conditions (Ayad and Kahoul, 2016). Around the world, pressure on water resources and particularly on groundwater resources is on the rise, mainly due to increasing demand.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_625644

The captured water may contain elements that may have adverse health effects, such as pathogenic microorganisms, unwanted substances or even toxic substances (Hartemann, 2000; Patil et al., 2012). Determining the quality of groundwater is important in deciding whether water is safe to drink, agriculture or industry. Water quality is a concept that refers to the chemical, biological and physical characteristics of water. The quality of the water required is determined by the purpose for which the water is to be used (domestic, urban, agricultural or industrial). Evaluation of water for uses is based on the characteristics of the water in relation to the quality required. In relation to drinking water, the required quality is defined by "standards" which define concentrations of constituents so that they have no adverse effect on the health of the consumer during the lifetime of consumption (Bakraji and Karajo, 1999).

Yemen is one of the countries most threatened by lack of water, it is already facing a serious water crisis: the annual consumption per individual is mediocre (135 m^3) compared to that recorded in the Middle East and North Africa (1250 m^3). Many cities face a serious water shortage, the prospect of sustainability of water resources, the main source of concern is the ever-increasing demand for water in water supply and irrigated groundwater agriculture in the same well field area (Glass, 2010; Whiting et al., 2011).

The aims of this study are to evaluate the groundwater quality of the Dhamar basin and its purposes for drinking and irrigation using GIS, correlation, and PCA, the second is to understand the variations in water quality in this reservoir.

Materials and Method

Study area

The governorate of Dhamar is situated in the middle of central highlands of Yemen with an area of 7.586 km^2 and 2700 m above sea level, it is divided into 12 administrative districts and 314 sub-districts (*Figure 1*). Dhamar has located 100 km to the south of Sana'a and north of Ibb city and west of Al-Beidha. Dhamar city is the capital of the governorate and it is situated on the main road that connects Sana'a with several other governorates. Dhamar basin is one of the largest water basins in Yemeni governorates and the most depletion one with over 6000 wells lastly reported in 2009 (Al-Aizari et al., 2017).

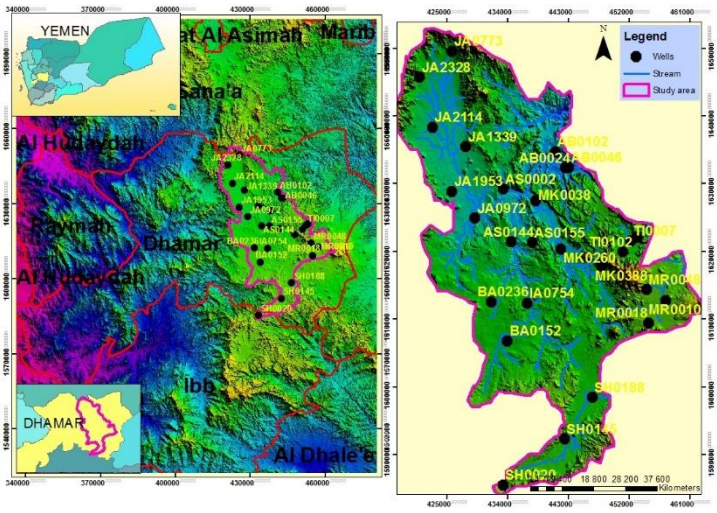

Figure 1. *Study area and samples location*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_625644

The climate of the study area is semi-arid. The annual rainfall is 407.8 mm, the maximum rainfall was 148.2 mm in June and the minimum was 88.2 mm in January during the period from 1999-2016. While the average monthly temperature varied from 21.4ºC in December -27.7°C in June for the same period (Al-Aizari et al., 2017). The geology of the study area comprises Quaternary alluvium, Tertry, Quaternary volcanic formations. Rhyolites, tuffs and ignimbrite ash-flow with occasional granite intrusions. The available hydrology data show that the main aquifers in Dhamar are Tertiary, Volcanic and Quaternary deposits. Groundwater subtraction through pumping wells in Quaternary deposits is more than Tertiary Volcanic. The outputs of this research are are identifying the productive aquifers and dominant fissure in the north-northeast of the study region (Geukens, 1966; Chiesa, 1983; Overstreet et al., 1985; Al-Kohlani, 2009).

Data sampling

A total of 27 well representing the Dhamar basin were selected in our study *Table 1*,14 groundwater samples were collected from each well in May 2009. These data have not been published earlier. The survey was carried out as part of a national program to monitor groundwater resources at a large number of locations nationwide. Since 2009 similar surveys have been carried out at other locations, which are not relevant for this study since samples were taken in different aquifers. It is not a common practice of this Government Department to publish the data they collect in response to governmental regulations. The samples were collected after pumping for 10 minutes, clean and dry polyethylene bottles are used for sample collection. The samples are tagged and stored in a refrigerator before the analysis (Girard, 1975). All samples were transported at temperature 4°C in portable coolers to the general agricultural research laboratory at Dahmer where the analyzes are carried out. Physio-chemical parameters were carried out EC, (Ca^{2+}), (Mg^{2+}), (Na^{+}), (K^{+}), (HCO_3^{-}), (Cl^{-}), (SO_4^{2-}), (NO_2^{-}), (Fe_2^{+}), (F^{-}) and (TH) and then compared with the guidelines admitted by the World Health Organization (WHO, 2003; Al-Asbahi, 2005).

Chemical analysis

EC is measured in the field using conductivity meter (Medium Conductivity Session CEL/850 (HACH). PH is measured by pH-422. Ca^{2+} and Mg^{2+} are estimated titrimetrically using 0.02 N EDTA. HCO_3^- and Cl^- are estimated by H_2SO_4 and $AgNO_3$ titration (0.02 N), respectively. Na^+ and K^+ are measured by using a Flame photometer (PFP 7). F-, Fe^{2+}, and NO_2- are measured by the portable data logging spectrophotometer HACH DR/2400. This standard method is suggested by the American Public Health Association (WHO, 2003; APHA, 2005) (*Table 2*).

Table 2. *Average physiochemical analyses for the grounds water and compared with YEMEN standards, WHO and Irrigation*

Variable	Unit	Minimum	Maximum	Mean	STDEV	Yemen Standard	WHO Guideline
EC	µs/cm	312.7	1915.8	524	323.6	750-2000	1000-1500

TH	mg/l	40	680	149.6	122.1	100-500	500

Geo-statistical analysis

Statistical analysis was carried out using statistical package for social sciences (Minitab17). The physicochemical analysis for all the samples was analyzed by Pearson's correlation coefficient and principal component analysis. The PCA adopted in this paper is based on normalized and standardized data and exploits the correlation matrix between groundwater quality parameters rather than the covariance matrix (Sabnavis and Patangay, 1998; Van den Brink and Ter Braak, 1999; Singh et al., 2004; Joshi et al., 2009; Khatoon et al., 2013; Chaubey and Patil, 2015).

Interpolation methods fall into two categories, namely: the deterministic method and geostatistical method (Chen and Liu, 2012). Deterministic interpolation methods create surfaces from measured points, based on either the extent of similarity or the degree of smoothing. For instance, Inverse Distance Weighting (IDW), radial basis functions and splines function. The geostatistical interpolation methods such as Kriging method (Davis and Ierapetritou, 2007; Elhag and Bahrawi, 2017) can describe spatial patterns and interpolate the value of a primary variable at unmeasured locations, and quantify the uncertainty or error of estimated surface (Elhag, 2016a).

IDW assumes that the attribute value of unmeasured points is the weighted average of known values of the neighborhood. IDW will use the measured values surrounding the unmeasured locations to predict the values of the unmeasured ones. Those measured values closest to the prediction location will have more influence on the predicted value than those farther away. Thus, IDW assumes that each measured point has a local influence that diminishes with distance. It weights the points closer to the prediction location greater than

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_625644

those far away. Maps layout are generated used ARCGIS 13 and AquaChem 2014 (Elhag, 2016a,b; Elhag and Bahrawi, 2016).

Sodium Adsorption Ratio

Sodium adsorption ratio (SAR) a formula used to evaluate salinity hazard and whether the water quality of the Groundwater Suitable or not acceptability for irrigation uses Lesch and Suarez (2009) (*Table 3*). SAR is calculated from the Na^+, Ca^{++}, and Mg^+ using the following equation.

$$SAR = Na/ [(Ca + Mg)/2]^{1/2} \quad \text{(Eq.1)}$$

where Na^+, Ca^{++}, and Mg^{++} are the concentrations expressed in milli-equivalents per litre (meq/L).

Table 3. *Irrigational Water Classification*

SAR (epm)	Classification
<10	Excellent
10-18	good
18-26	Permissible
>26	Unsuitable

It depend on the distribution of SAR as described in *Table 3* and *Figure 2* indicating that all wells suitable for irrigation. In relation to the hazardous effects of sodium adsorption ratio, the irrigation water quality rating is given in *Table 3*.

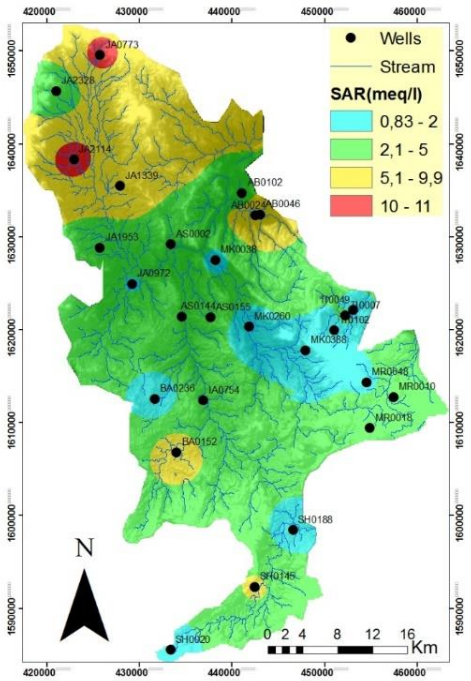

Figure 2. *Distribution of SAR*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_625644

Result and Discussions

The physicochemical analysis of 27 well and evaluating suitability for drinking water and irrigation purposes are summarized in *Table 2*.

The tested physiochemical parameters of the designated water wells in accordance with Yemen Maximum Allowable Unit (MAU) and compared to the World Health Organization (WHO) are cross-referenced in *Table 2*. The range of variation in Yemen standards is quite wide which makes it more difficult to have a fair judge. Generally, one one hand, the tested variables are within or slightly above the MAU. On the other hand, the tested variables are poorly recorded according to WHO.

EC in the collected samples is ranged from 312.7 to 1915.8 µs/cm with an average value of 524± 323.6. The map shows that the values of EC are within the permissible level except for some areas, mainly (well no. IA0754), in which the EC recorded 1915.8 µs/cm. Therefore, it exceeds the WHO permissible level but it still within the level of Yemen standard as in *Table 2*. The high value of EC in that location is due to contamination from the effluent of wastewater treatment plans (WWTP) as this well located in Mawaheb village. The cartographic map showing the distribution of EC is given in *Figure 3*. The EC showed strong correlation with Cl^- and SO_4^{2-} (r = 0.94, 0.93, respectively) and good correlation between with Ca^{2+} Mg^{2+}, Na^+ and TH (r = 0.76, 0.8, 0.52 and 0.84, respectively).

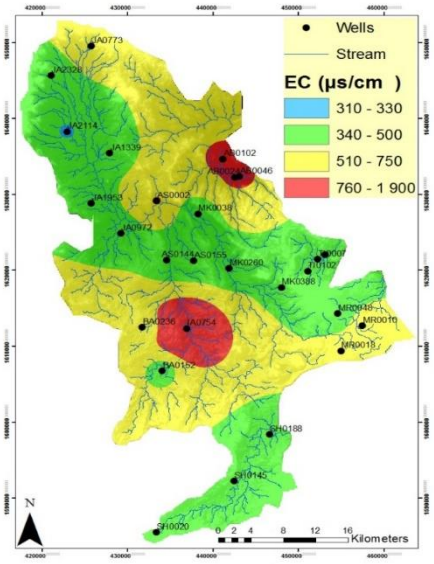

Figure 3. *Distribution of EC*

pH is considered as an important ecological factor that provides information on the types of geochemical equilibrium and solubility. From the thematic map (*Figure 4*), the pH is ranged from 5.8 to 9.2 so it is within the slandered of Yemen and WHO. The results show that three wells are basic and three well are acidic. The basic wells are Abisiyah (well no. ABS46, pH = 9.2), Balasan (well no. BB56, pH = 9.2) and Jahran (well no. QJB511, pH = 8.9). The three acidic wells are 6.3, 5.8 and 6.1 for the intervening area (well no. IA0754 pH = 6.3), Maram (well no. MR0018, pH = 5.8) and Jahran (well no. JA1953, pH = 6.1). pH showed negative correlation with all of parameters except Na^+ Cl^- and Fe^{2+} (r = 0.020, 00 and 0.34, respectively).

DOI: http://dx.doi.org/10.15666/aeer/1801_625644

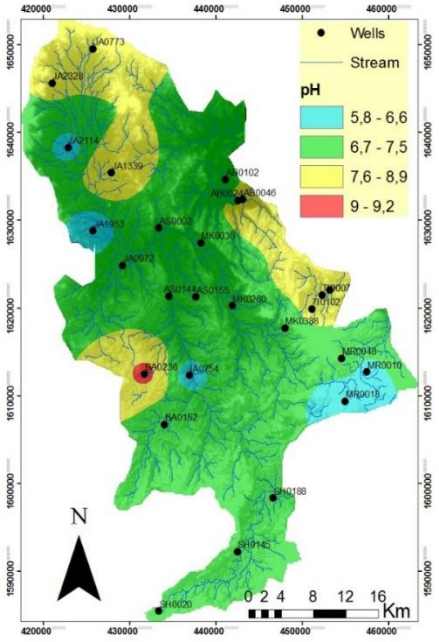

Figure 4. *Distribution of pH*

Na^+ varies from 14.6 to190 mg/l with an average value of 87.28 ± 51.88. The high concentration of sodium in water makes it unsatisfactory for use in irrigation purposes. The concentration of sodium in all samples are found to be within the permissible level of WHO and Yemen Standers *Table 2*. However, in well no AB0046, the concentration of sodium found to be near to the permissible level which is 190 mg/l. Na^+ has good correlation with Cl^- and SO_4^{2-} (r = 0.60, 0.53), demonstrated in *Figure 5*.

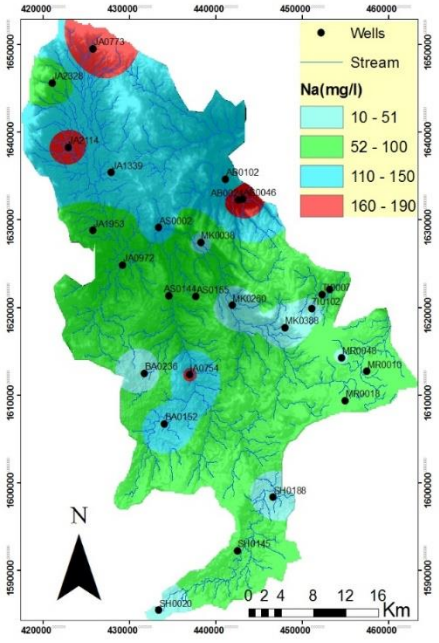

Figure 5. *Distribution of Na*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_625644

The concentration of K^+ various from 0.8 to 10.7 mg/l with an average value of 4.27 ± 2.59. The concentration of potassium in all samples is found to be within the permissible level (*Table 2*). K^+ has good correlation with F^-, (r = 0.53), demonstrated in *Figure 6*.

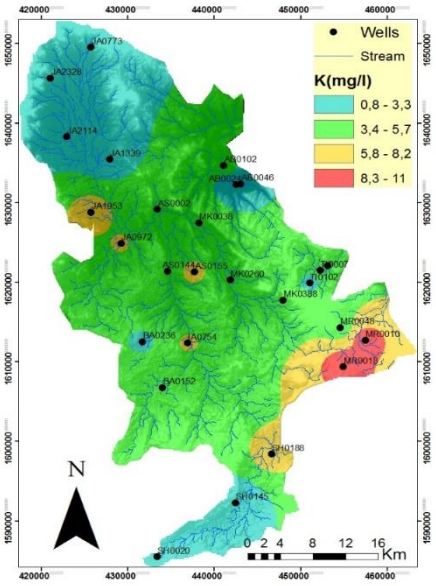

Figure 6. *Distribution of K*

The Mg^{2+} values range from 2.4 to 43.6 mg/l with an average value of 7.7 ± 7.71, the presence of Mg^{2+} in water generally does not have any health hazards to humans. The concentrations of Mg^{2+} in all samples are found to be within the permissible level in *Table 2* and *Figure 7*. Mg^{2+} is strong correlated with TH (r = 0.98) and with Ca^{2+} with Mg^{2+}, Cl^- and SO_4^{2-} (r = 0.81, 0.59 and 0.64), while it is good correlated with Cl^- and SO_4^{2-} (r= 0.78, 0.76) respectively.

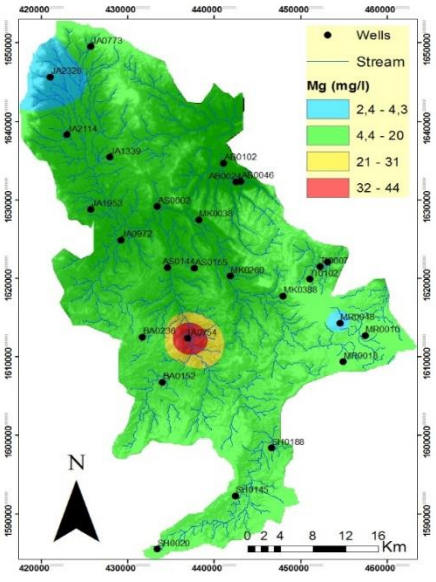

Figure 7. *Distribution of Mg*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_625644

Ca^{2+} ranges from 8 to 200 mg/l with an average value of 48.94 ± 37.88. the presence of Ca^{2+} in water does not have health hazards to humans. Ca^{2+} values are within the permissible level in all samples except in the intervening area (well no. IA0754). This may be attributed to pollution by wastewater (*Figure 8*). Ca^{2+} shows strong correlation with TH, (r = 0.98) and good correlation with Mg^{2+}, Cl^{-} and SO_4^{2-} (r =0.81, 0.59 and 0.64) respectively.

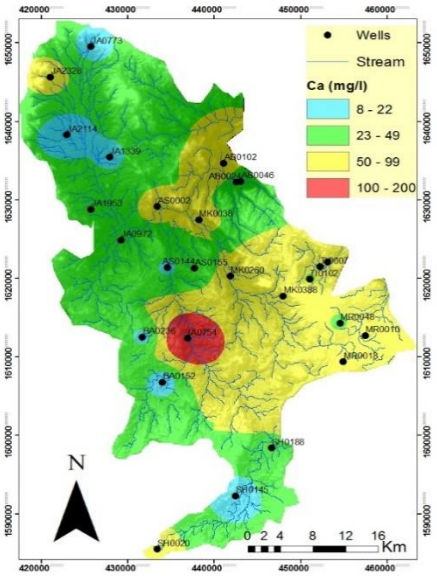

Figure 8. *Distribution of Ca*

SO_4^{2-} values various from 20-320 mg/l with an average value of 58.5 ± 64.5. The concentration of sulfate in all locations are within the permissible limit except the intervening area (well no. IA0754) where the sulfate value 320 mg/l. The SO_4^{2-} was has a good correlation between SO_4^{2-} with TH (r = 0.98) as is illustrated in *Figure 9*.

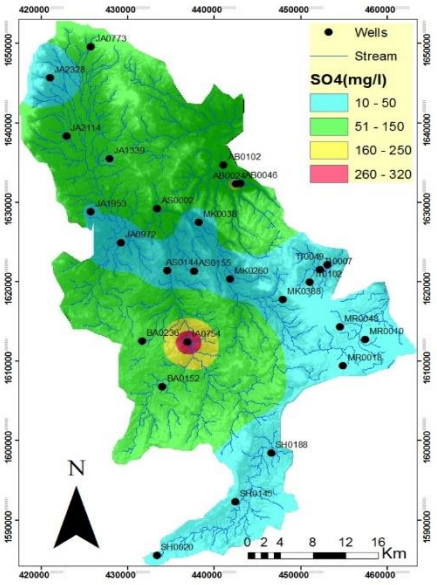

Figure 9. *Distribution of SO4--*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_625644

The HCO_3^- varies from 97.6 to 463.6 mg/l with an average value of 227.7 ± 83.1. The concentration of bicarbonate in all samples are found to be within the permissible limit (*Figure 10*). The HCO_3^- has strong correlation with SO_4^{2-} (r = 0.98).

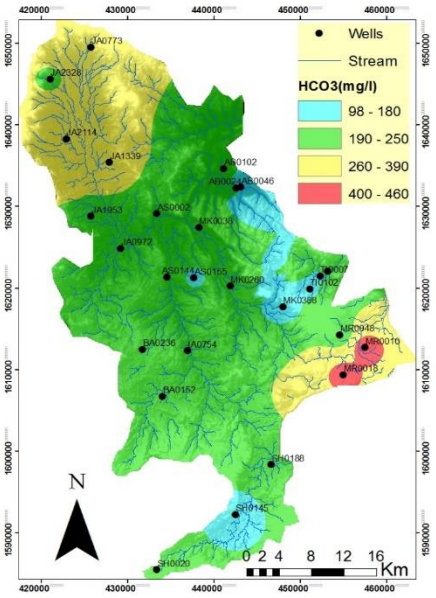

Figure 10. *Distribution of HCO_3^-*

WHO reported that atmosphere, legumes, plant debris, and animal excreta are the main source of water nitrate, alongside with the domestic water, sewage, septic tanks. Anionic and solubility of NO_3^{--} can also affect the concentration of NO_3^{--} in groundwater. In Yamen NO_3^{--} varies from 0.01 to 0.453 mg/l with an average value of 227.7 ± 83.1. The concentrations of nitrates in all samples are found to be within the permissible limit (*Table 2*), and its distribution in *Figure11*.

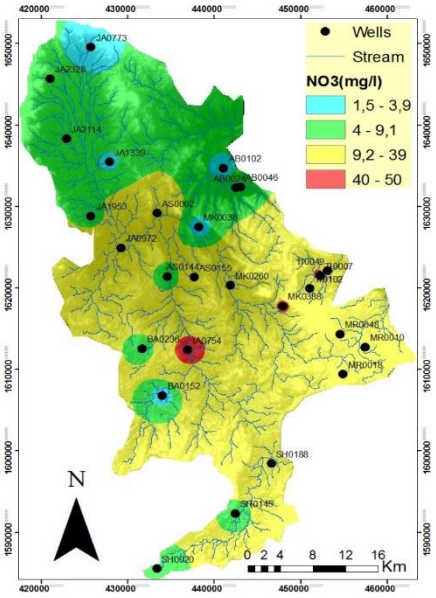

Figure 11. *Distribution of NO_3^{--}*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_625644

The F^- values various from 0 to 0.09 mg/l with an average value of 0.01556 ± 0.0268. Fluoride concentration is within the permissible level in all locations. Fluoride above permissible level may cause mottled enamel of teeth and skeleton deformity. The cartographic map of F^- is given in *Table 2* and demonstrated in *Figure 12*.

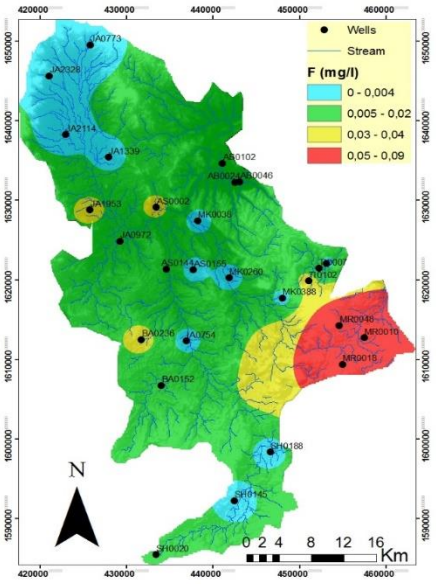

Figure 12. *Distribution of F*

Fe^{2+} concentration are varied from 0 to 1.07 mg/l with an average value of 0.2122 ± 0.2409. From the cartographic map (*Figure 13*), iron exceeded the permissible level in some wells Tinnan (TI0102), Tinnan (TI0007), Sherah (SH0188), and Jahran (JA1339). In the case of Tinnan (TI0102) and Jahran (JA1339) this may be attributed to strains of oxides and hydroxides on laundry, sanitary and plumbing textures. At concentration above 0.5 mg/l, iron cause an unpleasant taste (*Table 2*).

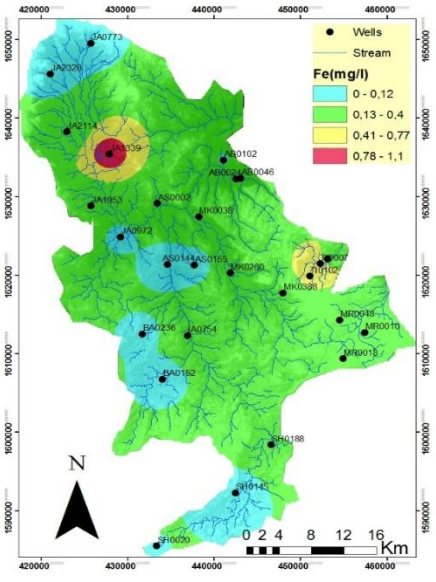

Figure 13. *Distribution of* Fe^{2+}

The TH values range from 40 to 680 mg/l with an average value of 149.6 ± 122.1 (*Figure 14*). All samples are within the permissible values as in *Table 1* except well no. IA0754 has a comparatively high TH value of 680 mg/l.

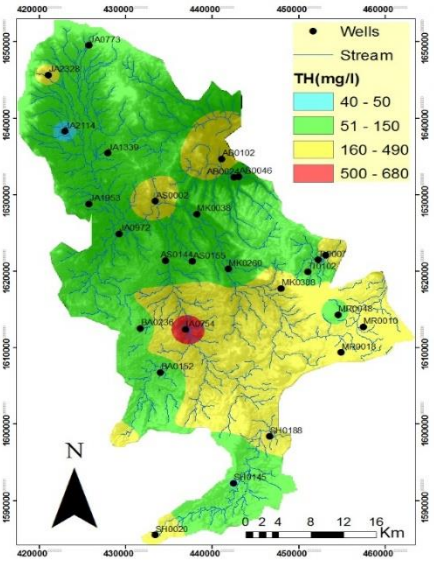

Figure 14. *Distribution of TH*

Cl^- is an important indicator of the contamination of groundwater by wastewater. The Cl^- values range from 29 to 335 mg/l with an average value of 70.9 ± 65.7. The permissible limit of Cl^- in drinking water for WHO guideline is 250 mg/l, while it is 600 mg/l for Yemeni Standards. The concentrations of Cl^- are within the permissible limit in all locations, except the intervening area (well no. IA0754) where the chloride value is 335 mg/l. The reason for high chloride in that well is due to the contamination of groundwater from effluent as discussed earlier. The cartographic map of Ca^{2+} is given in *Figure 15*. The Cl^- has a strong correlation with SO_4^{2-} (r = 0.98).

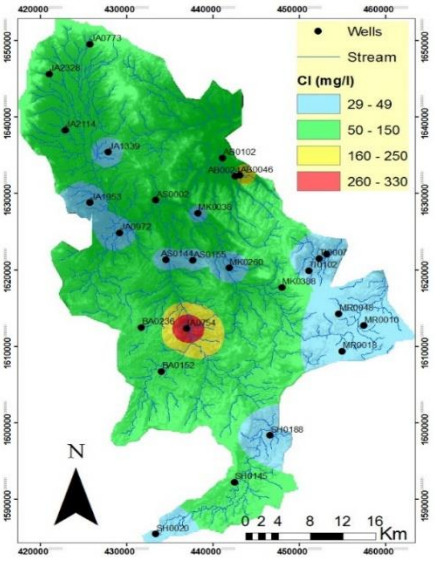

Figure 15. *Distribution of Cl^-*

Correlation analysis a widely used between variable, the correlation between two variables is the simple correlation that indicates the sufficiency of one variable to predict the other one (Sedgwick, 2012). This coefficient s used to determine the correlation between variables when the dependent (x) is only influenced by the independent (y) and vice versa (Benesty et al., 2009). *Table 4* displayed the values of the correlation coefficients between the parameters. Strong correlations r> 0.9 and good r = 0.5-0.9.

Table 4. *Correlation matrix of all studied parameters*

Principal Component Analysis

The principal component analysis is a multidimensional statistical method that can be used in the interpretation of a data matrix. This method, by looking for the reference directions of elongation of a multidimensional point cloud (eigenvalues), summarizes the information by projecting the point cloud on its preferential directions (factorial axes). Factors are linear combinations of the starting variables. Each variable contributing to the factor intervenes with a coefficient called "eigenvector" (Sabnavis and Patangay, 1998; Bahrawi et al., 2016; Elhag, 2016b).

Principal component analysis (PCA) for the groundwater allows determining its chemical characteristics, and their overall variations (factors). We select only the first two factors as they express 63.473% of the total variance. The analysis of the variables shows in *Tables 5, 6* and *Figures 16, 17*. The Factor 1 expresses 42.748% of the total factors and wells that correlated with the variables, these variables are conductivity, sodium, nitrates, chloride, calcium, sulfate, magnesium and Total hardens. While factor 2 expresses 20.725% of the total factors, these variables include bicarbonates, iron, fluoride, and potassium (*Figures 18 and 19*).

A piper diagram is a graphical representation of the chemistry of water samples. The cations and anions are shown by separate ternary plots. The apexes of the cation plot are calcium, magnesium, and sodium plus potassium cations. The piper diagram was preferred because of its accuracy in the identification of the water samples and the dominant component in the water chemistry (Piper, 1944; Elhag et al., 2019). Generally, the samples are showing different constituents of water as shown in *Table 7* and *Figure 20*. This indicates that the source's groundwater of these wells is different. The differences in compositions of the water are attributed to that the geology of the Dhamar area is generally volcanic and basaltic rock. However, some areas such as Jahran are having alluvial deposits.

Groundwater is different wells of Abisiyah is a mixture of Na^+, Ca^-, Cl^- $SO4^-$ and HCO_3^-. The geological nature of this area is basaltic rocks. Generally, the groundwater aquifers of basaltic rocks have Na^- Ca^- HCO_3 composition and any change of this water are due to contamination from human activities or heavy exploitation. The high concentration of Cl and SO_4 without any natural sources indicate human contamination. However, the concentrations of Cl and SO_4 are within the permissible limit of WHO and standard Yamen illustrated in *Figure 21*.

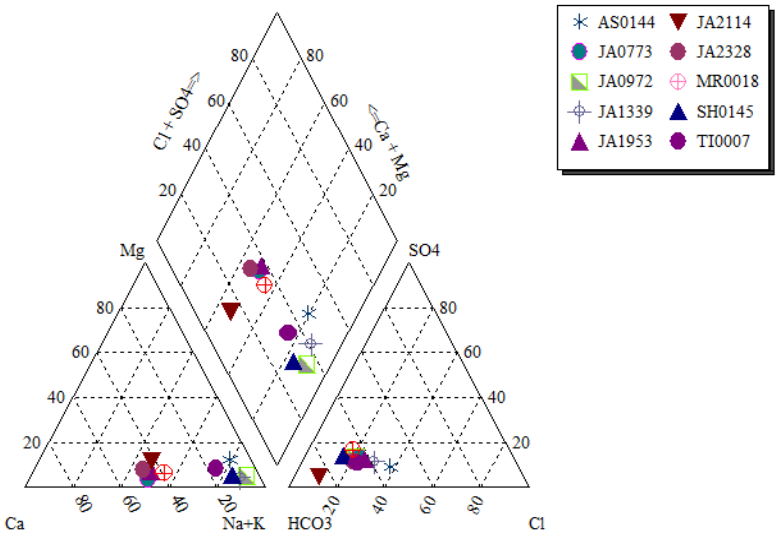

Figure 21. *Piper diagram of volcanic aquifer*

Predominantly, the water quality parameters used in the current research are varied based on the utilized sample in each rationing. Therefore, the categorization of different quality parameters using principal component analysis will help to examine the indices discrepancies (Yilmaz et al., 2018).

The dynamicity of the water quality monitoring process added further complications to designating mineral-affected wells in a systematic uniform perspective. The use of different quality parameters based on implementing different combinations and/or water samples in the form of water quality parameters evidenced to be more efficient to overcome wells' dynamicity problems (Elhag, 2016b; Bahrawi and Elhag, 2019; Elhag et al., 2019).

Earth is a forceful system that has been affected by natural and anthropological influences. One of the most substantial anthropogenic consequences on the earth are Land Use/Land Cover changes of (LULC) which take place over the earth surface. (Elhag, 2016c, Allam et al., 2019).

The water resources of the coastal region of the Gharb are susceptible to the pollution caused by the emergent industry and urbanization expansion. Certainly, the global economy growth, population density, and infrastructure developments stressed water quality and quantity (Elhag and Bahrawi 2014, Aremu, M. O. et al., 2017, Darwesh et al., 2019).

Conclusion

Geographic Information System (GIS), correlation and Principal Component Analysis have been found to be a highly useful technique towards water quality management. The results of this study provide some information that can be useful with respect to groundwater studies. Salinity values are an acceptable level, in spite of the strong water abstraction from the wells in Dhamar plain except for the well no IA0754 that its salinity recorded 1900 μS/cm that is due to contamination from the effluent of wastewater treatment plans (WWTP) as this well located in Mawaheb village. The average salinity values are 524 μS/cm at 25°C. About 99% of the wells are classified as suitable for drinking water, and only 1% of total wells exceed the Yemeni standard for drinking water with respect to the Iron element. All wells are suitable for irrigation purposes. The low TDS was found in the groundwater of the Dhamar area because groundwater drains in igneous rocks (acidic rock), which release a low concentration of major elements. The lower concentrations of Cl^- and SO_4^{--} are due to an artificial source of pollution by human activities. Generally, groundwater quality is good in Dhamar plain. The presence of nitrates shows that the pollutant penetrates freely from the surface and that because of the hydrodynamic characteristics of the aquifers. The results of the good analysis of Dhamar plain indicates that the type of groundwater is Na-Ca-Cl/ $SO^{4-}HCO^{3-}$ and $Ca^-Na^-HCO_3^-Cl$, to mixed nature. The study recommended that modeling of groundwater quality in response to growing exploitation, particularly for irrigation. Irrigation leads to the percolation of water with higher salinity, thus potentially harmful for the long term sustainability of groundwater resources. Monitoring should be done more frequently and continuously to ensure timely detection of anomalies.

Abstract. Thermal power plants are facilities that convert the chemical energy of solid, liquid and gas fuels respectively into thermal, mechanical and electric energy. The presumption of establishing a fossil fuel plant on this fertile area is putting the security of the agricultural products of the area at risk. A face to face survey was carried out with the 90 of the farmers living close to the planned area for the establishment of the fossil fuel plant in Suluova county of Amasya province. According to the survey results 43% of the farmers stated that fossil fuel plant is a necessity but it should be established far away from the agricultural estates whereas 30% of them think that these kind of fuel plants should not be established on any account and 27% of them expressed no opinion about the issue. A total of 60% of the farmers think that the agricultural consequences of the planned fossil fuel plant are not considered adequately; and 73% of the farmers think that a presumed fossil fuel plant in the area will negatively affect the yield and the quality of the agricultural products and 56% say that the agricultural estates will be negatively affected by it. Majority of the farmers stated that they would try to prevent the establishment of the plant even if they knew they would not succeed.
Keywords: *farmer, agriculture, thermal power plant, Amasya, pollution*

Introduction

Thermal power plants are the plants that convert the thermal energy of solid, liquid and gaseous fossil fuels into electrical energy. In this context, there are coal power plants, fuel-oil power plants and natural gas power plants. On the other hand, the plants that produce electricity from biomass are considered as thermal power plants (Chamber of Mechanical Engineers, 2017). It is stated that thermal power plants are preferred to produce electricity because of their advantages like being established with low costs and rapid feasibility and making use of the low-quality coal (Karaca et al., 2005).

As of late 2016, electricity production was 273,387 GWh, and 184,889 GWh of it was produced by thermal power plants in Turkey, 67,268 GWh was produced from hydroelectric plants, and 21,230 GWh from other renewable energy sources. In the same period, the rate of the electricity that was produced by thermal power plants to total electricity generation was 67.6%. Coal-originated power plants ranked the first in this rate with a share of 33.74%, followed by natural gas + LNG-based power plants with a rate of 32.1%, and followed by hydraulic power plants with 24.6%. As of the end

of 2016, it was of great importance that the share of electricity produced in wind power plants increased in total production from 3.4% to 5.7% (*Table 1*).

Table 1. *Distribution of electricity production of Turkey according to energy sources (GWh) (Ministry of Energy and Natural Sources, 2018)*

Primary energy source		2014		2015		2016	
		Production (GWh)	**Share (%)**	**Production (GWh)**	**Share (%)**	**Production (GWh)**	**Share (%)**

According to the data provided by Energy Market Regulatory Authority (EMRA), the domestic coal-fired power plants that are in operation in Turkey with production license are 34 in number; and one of them works on asphaltite, one on hard coal and the other is a lignite-fired power plant. There are also 6 power plants that are still under construction. The total installed capacity of the domestic coal, lignite and asphaltite-fired power plants was 9,842 MW at the end of 2016. A total of 38,460,314,490 kWh electricity was produced in lignite-fired power plants in 2016 in terms of capacity in production (*Table 2*).

The number of the plants in operation that have production license in Turkey with imported Coal is 10. There are also 7 other plants that are still under construction. The total established power of thermal power plants that run on imported coal is 7,571.4 MWe. A total of 53,777,704,022 kWh electricity was produced in 2016 in imported coal and hard coal-fired power plants. Although the number of natural gas-fired power plants that have production license is 326 in Turkey, those that are active are 252 in number. A total of 104 of these have over 10 MW capacity. The total established capacity of natural gas-fired thermal power plants was 22,156 MW as of the end of 2016. The total production of natural gas-fired power plants was 87,797,441,063 kWh in 2016 (EMRA, 2018).

The very fine ash particles, which are drawn upwards by the gases in chimneys because of the combustion in thermal power plants are considered to be important waste materials. It was reported that millions of ash, cinder and particles produced as waste by coal that is burnt in the power plants are stored at a certain height over a land of thousands of hectares and cause intense ash emission on forests, marquis, agricultural areas and residential areas (Pacyna, 1987).

Domestic coal	Seyitömer Thermal Power Plant	Kütahya- Merkez	600.00	600.00
Domestic coal	Kangal Thermal Power Plant	Sivas- Kangal	457.00	457.00
Domestic coal	Tufanbeyli Thermal Power Plant	Adana -Tufanbeyli	450.00	450.00
Domestic coal	Yeniköy Thermal Power Plant	Muğla -Milas	420.00	420.00
Domestic asphaltite	Silopi Thermal Power Plant	Şırnak-Silopi	405.00	405.00

Numerous studies were carried out in the literature on thermal power plants. The importance of thermal power plants, environmental effects and their effects on the chemical properties of soil and microbial activity have been focused on in these studies (Adriano et al., 1980; Bunzl et al., 1983; Mejsrik and Suacha, 1988; Karaca, 1997; Onacak, 1999; Baba et al., 2003; Karaca et al., 2005; Deniz, 2010; Özcan et al., 2014).

In the present study, the awareness levels, judgments and attitudes of the farmers that continue agricultural activities in Suluova County in Amasya province where a thermal power is intended to be built were examined. Suluova County is a green plain that has fertile soils. The county is one of the locomotive regions of the city in terms of economic production with the factory that processes sugar beet, with four mine quarries, with onion and wheat cultivation, and with animal husbandry because the area is also suitable for agricultural production. Gürmin Enerji Madencilik Sanayi ve Tic. Inc. intends to build a thermal power plant within the boundaries of Merzifon and Suluova in the region with a total established capacity of 450 MW. The company made the application for the project in 2013, and EMRA approved the project. However, the objections on the power plant that would be established in the region where there was agricultural production, and the lack of the viewpoints of relevant institutions which failed to submit their investigation results at the 2nd Examining and Evaluation Commission meeting caused that the Environmental Impact Assessment (EIA) process were ceased on August 25, 2016. During the 13 months as of this date, the Ministry of Environment and Urbanization decided to terminate the EIA process when there were no revised reports and when the company did not present any data. This result was not revealed at the questionnaire stage of our study (April, 2016).

Materials and methods

The main material of the present study consisted of the data that were obtained with face-to-face interviews that were conducted with the farmers who lived in the villages of Suluova County of Amasya Province. In addition, the data that were provided by Energy Market Regulatory Authority and the Ministry of Energy and Natural Sources were also made use of. The study was conducted in 4 villages. In selecting the villages, the reactions to the thermal power plant that was intended to be established in the region were taken into consideration, and the farmers were selected with the Purposeful Sampling Method to represent the region. A total of 90 questionnaires were conducted with the farmers who lived in these 4 villages. The questionnaire was carried out in March and April 2016.

The findings that were obtained in the study are presented in the study in tables after calculating the percentages. The 5-Point Likert Scale was employed in designing the questions on the judgments of the farmers, and the average scores were calculated.

Results and discussion

Information on the enterprises and farmers who participated in the questionnaire are given in *Table 3*.

Table 3. *Some information on the farmers and enterprises that were included in the study*

Average age	46

The average age of the farmers who participated in the study was 46. It was observed that farmers were mostly secondary graduates (31.11%), and high school graduates (48.89%). The income level of the farmers was determined to be 1020,21 $. A total of 77% of the income sources of the enterprises that were included in the study came from agriculture, and 20% from free trade; and 88% of the farmers had property lands. In addition, they were also tenants at a rate of 85%. When the products that were grown in the enterprises were examined, it was seen that dry onion was grown at the highest rate with a rate of 31.11%, followed by sugar beet (26.67%) and wheat (16.67%).

The farmers were asked if they had heard the name "thermal power plant" before. It was determined that approximately 96% of the farmers knew thermal power plants (*Table 4*). Especially in recent years, they had intense discussions about thermal power plants. Despite this, 4% of the farmers stated that they did not hear the name "thermal power plant" before.

Table 4. *Had the farmers heard of the name "thermal power plant" before?*

	Rate (%)
Yes	95.56
No	4.44
Total	100.00

The farmers who had heard the name "thermal power plant" and who were considered to have information on thermal power plants were asked about the establishment of the thermal power plants in their region. The results on this are given in *Table 5*. A total of 42.53% of the farmers had the same idea, which argued that thermal power plants must be established in our country; however, the place selection must be done very well. The rate of the farmers who thought that the energy that had to be produced with other means was 30%. The rate of those who had no clear idea on this subject was 24%.

Table 5. *Opinions of the farmers on establishing thermal power plants in our country*

	Rate (%)
Establishing thermal power plants is compulsory, they must definitely be established	3.45
They must definitely be established, but place selection must be made more accurately	42.53
They must definitely not be established; other ways must be found to produce energy	29.89
I do not have a clear idea about this	24.14
Total	100.00

On the other hand, more than half of the farmers who participated in the questionnaire (51.72%) claimed that it was completely wrong to establish Thermal Power Plant in the region that was close to their living area where they performed their agricultural activities. The rate of the farmers who thought that the establishment of the power plant in the region was the right decision remained as 1%. The rate of the farmers who did not have any ideas on this subject was 24.14% (*Table 6*).

The farmers thought that the agricultural effects of the thermal power plant that would be established in the Suluova region were not considered fully, and the necessary

DOI: http://dx.doi.org/10.15666/aeer/1801_645654

sensitivity was not considered (*Table 7*). As a matter of fact, the EIA process was terminated due to objections and the lack of the opinions of the relevant institutions.

Table 6. *Opinions of the farmers on the thermal power plant that was intended to be established in Suluova*

	Rate (%)
The establishment of the power plant in the region is suitable, this is a righteous decision	1.15
This could not have been established in this region, but this is not a very wrong decision	22.99
The power plant must definitely not be established in this region, this is a completely wrong decision	51.72
I have no idea	24.14
Total	100.00

Table 7. *The opinions of the farmers on the sensitivity in place selection of the thermal power plant that was intended to be established in Suluova*

	Rate (%)
Yes, the place selection was very sensitive	3.45
No, the place selection was not very sensitive at all	59.77
I do not have any idea	36.78
Total	100.00

The opinions of the farmers on the negative impacts of the thermal power plant were examined and scored with a 5-point Likert scale. The farmers were asked to respond to the questions on the negative impacts as “very high-5”; “high-4”; “moderate-3”; “very low-2”; “none-1”. The average scores were calculated by considering the answers of each farmer according to the score next to each answer. In this way, the common decisions of all the farmers who participated in the questionnaire were determined. The findings on this subject are given in *Table 8*.

Table 8. *The opinions of the farmers on negative effects of the thermal power plant on their villages (%)*

Negative effects on…	**Very high (5)**	**High (4)**	**Moderate (3)**	**Very low (2)**	**None (1)**	**Ave. score**
the human health	45.35	44.19	6.98	3.49	0.00	4.31
the natural vegetation	27.91	47.67	19.77	3.49	1.16	3.98
the other creatures living in the region	36.05	44.19	15.12	3.49	1.16	4.10
the fertility of agricultural products	36.05	48.84	11.63	3.49	0.00	4.17
the quality of agricultural products	38.37	47.67	11.63	2.33	0.00	4.22
the image of the agricultural products	11.63	53.49	19.77	9.30	5.81	3.56
the air of the village	13.95	43.02	19.77	10.47	12.79	3.35
the environmental beauty of the village	17.44	44.19	24.42	11.63	2.33	3.63
the agricultural soils	32.56	48.84	13.95	2.33	2.33	4.07

As it may be seen in *Table 8,* the farmers thought that the thermal power plant will have negative impacts on human health, natural vegetation, the fertility of the agricultural

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_645654

products, the quality and appearance of the agricultural products, the air and environmental beauty of the village and on agricultural lands at a high rate. As a matter of fact, in many previous studies, it was stated that the environmental pollution elements that stemmed from the thermal power plant were air, soil and water pollution (Goncaoğlu et al., 2000). In one of the studies conducted on Afşin-Elbistan Thermal Power Plant, the effects of the ash caused by the power plant on the agricultural fields were examined, and it was determined that this caused the accumulation of heavy metals in the plants (Kahraman, 2011). It was determined that toxic dusts that contained CO_2, NO and SO_2 in the composition of the emissions coming from Afsin-Elbistan Thermal Power Plant chimneys caused burns in the leaves of the plants, and in this way, the leaves dried and eventually the trees dried (Özcan et al., 2014). Again, many researchers found that the emissions coming from thermal power plants had high heavy metal contents in the dominant wind directions, and that pollutant gases like Sulfur Dioxide (SO_2), Carbon Dioxide (CO_2) and Nitrogen Oxide (NOx) had negative impacts on some tree species (Aydemir, 2008; Karaca et al., 2007; Deniz, 2010).

In the present study, the judgments of the farmers were determined with more detailed questions depending on the features and negative effects of thermal power plants. The findings on this subject are given in *Table 9*.

Table 9. *Judgments of the farmers on the characteristics of the thermal power plants (%)*

Thermal power plants	I definitely agree (5)	I agree (4)	I do not have any idea (3)	I do not agree (2)	I definitely do not agree (1)	Ave. score
…may cause various diseases depending on the fuel types used in them	55.81	40.70	0.00	2.33	1.16	4.48

…they do not affect agricultural production very negatively in the region	0.00	6.98	26.74	20.93	45.35	1.95

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_645654

The judgment to which the farmers highly agreed at a high rate (56%) was that various diseases emerged in humans depending on the fuels used in thermal power plants. In actual fact, the concern of the farmers on this subject was not unreasonable. Because in previous studies conducted in Turkey, it was determined that 20% of the health problems that could be attributed to exposure to particulate matter were caused by the burning of the coal in the thermal power plants (Gacal, 2017). The presence of gases SO2, CO_2, NOx in the waste gas that was released from coal thermal power plants may be taken in either by inhalation, directly or indirectly, through nutrients and water. It was stated that when people were exposed to an intense amount of these gases, the nervous system was affected, lung and respiratory problems were experienced, and cognitive development was affected negatively in children (Peden, 1997; Rusnak et al., 1997; Gacal, 2017). Secondly, the judgment to which the farmers highly agreed at a high rate (53%) was that the reason that these power plants caused loss of fertility in the products that were grown in the regions where thermal power plants were located. This was followed by the judgment that these plants caused soil pollution, soil desertification and product quality disorders with a participation rate of 47.67%. The farmers also approved "other" thermal power plant responses (average score: 1.95) that their thermal power plant would not have negative effects on agricultural production. In brief, the judgments of the farmers on the features of thermal power plants generally concentrated on damaging the soil, plants and human health. In many studies that were conducted on this subject support the judgments of farmers (Goncaoğlu et al., 2000; Aydemir, 2008; Karaca et al., 2007; Deniz, 2010; Kahraman, 2011; Özcan et al., 2014).

Conclusion and recommendations

It was shown in many previous studies that thermal power plants caused air pollution, water pollution and soil pollution and these impurities had negative effects on the living and agricultural products. Of course, the fuel used in thermal power plants was considered to be mostly coal, and the resulting damage caused by the gases that were produced in this process.

In the present study, how the thermal power plants were perceived by farmers was investigated with the sample case of the Suluova Region where the power plant was planned to be established. In the study, the majority of the farmers stated that it was important to establish thermal power plants to meet the energy needs of the country; however, the place of the establishment for these thermal power plants must be selected better. On the other hand, the farmers were also very concerned about the negative impacts of the thermal power plants on human health, agricultural lands and products, the vegetation cover, and all other living things. For this reason, the farmers who participated in the study wanted to stop the establishment of the thermal power plant in question. As a matter of fact, following the questionnaire stage of our study, the EIA process of the thermal power plant, which was planned to be established in the region by Gürmin Enerji Madencilik Sanayi ve Tic. Inc., was terminated with the justification that there were several shortcomings. Although it changes every year, the share of the thermal power plants in electricity production of Turkey is about 70%. It seems that the dominance of the thermal power plants in producing electricity with domestic sources will continue for a long time in Turkey which is dependent to external sources in terms of energy raw material. In this sense, the benefits of the thermal power plants must also be brought to the forefront. Especially the benefits like using domestic coal, the fact that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_645654

coal may be transported to all areas for installation, the resulting steam and water allowing low-cost electricity production may be considered. In this sense, increasing the efficiency of the existing thermal power plants, minimizing the damage that is given to the environment, providing maximum occupational health and work safety, prioritizing the use of domestic coal and biomass instead of the imported ones, and ensuring the establishment of thermal power plants with environmentally-friendly technologies are important.

(Received 22nd May 2019; accepted 25th Oct 2019)

Abstract. Citrus is an important fruit produced in the Pakistan. The peel and waste of citrus after juice extraction is mostly wasted which contain important antioxidants and polyphenols. In current study citrus waste after juice extraction was utilized in the production of broiler meat as a feed ingredient, which have positive effects on antioxidant level of the meat. Chicken breast nuggets were prepared from that meat resulting in positive effect on Thiobarbituric acid reactive substances (TBARS) and 2,2-diphenyl-1-picrylhydrazy (DDPH) activity of the nuggets. The pH of the nuggets reduced as the citrus waste supplementation in the feed of the broilers increased, color L* and b* values of the nuggets were reduced, and color a* value was increased as the citrus waste supplementation in the feed of the broilers increased. Texture and water holding capacity of the nuggets have significant effect due to interaction effect of storage and treatments.
Keywords: *color, meat, nuggets, nutrition, storage, texture, water activity*

Introduction

Chicken meat and its products are used worldwide due to many nutritionally important components which are good for human health i.e., low lipid contents and higher amount of polyunsaturated fatty acids, which are higher than that in any red meat (Jittrepotch et al., 2006). The major cause of deterioration of chicken meat and meat product is oxidation, especially autoxidation because of higher amount of polyunsaturated fatty acids in the meat of chicken which caused in the quality deterioration and off flavor, which can lead to serious health problems (Mohamed et al., 2008). Lipid oxidation in the meat causes undesirable changes by oxidizing fats enzymatically and non-enzymatically. Autoxidation is a chain reaction and causes the meat to deteriorate (Cheng, 2016). The control or minimizing the effect of oxidation is of greater interest for food industry. Oxidation of fats in the meat can be controlled by many strategies including animal dietary supplementation, processing, special packaging and use of antioxidants (Amaral et al., 2018). Because of oxidation problems in meat and meat products the trend of using synthetic antioxidants in broiler meat and meat products is increasing and possibility of toxicity of synthetic antioxidants is a concern for consumers using these products (Prasetyo et al., 2008).

The antioxidant potential of broiler meat and its meat products can be enhanced by feeding broilers with natural antioxidants in feed like alpha-tocopheryl acetate and alphalipoic acid (Sohaib et al., 2012). Alpha tocopherol acetate is effective antioxidant in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_655665

breaking of chain reactions of the oxidation of fats in foods (Miller et al., 2005). Arshad et al. (2011) working on vitamin E supplementation in feed of broiler meat observed that vitamin E as a source of natural antioxidant is effective in reducing oxidation of meat and meat products more than the control treatments. Kumar and Tanwar (2010) added ground mustard in the chicken meat nuggets and found that the treatments having mustard have greater potential of antioxidants and TBARS value of the treatments, with ground mustard have enhanced antioxidant potential as compared to treatment which were made without ground mustard. Citrus waste as a feed for different animals have studied and proven effective in enhancing antioxidant levels of animals and cost of production also reduced as citrus waste substituted the costly ingredients of feed.

Agricultural wastes including fruit wastes i.e. banana peel, citrus rind etc. are biodegradable and polluting agents for environment if not recycled and reused. But research has explored the importance of this waste material as source of nutrients for plants, animals and birds. Hence, fruit wastes are processed and utilized not only as supplements in food commodities but also as source of nutrients for plants (Arshad et al., 2018).

In the current study the broiler meat was produced using citrus waste supplementation as a feed ingredient. Meat produced from the citrus supplemented waste was incorporated in nuggets and observed for antioxidant and quality profile with objectives to enhance antioxidant profile of chicken meat products and to observe effect of natural antioxidants from broiler meat on storage properties of the nuggets.

Material and methods

The broiler birds of genus *Gallus Domesticus* were reared with experimental feed in the Research Farm of Institute of Animal Nutrition in University of Agriculture Faisalabad, Pakistan. Total of 225 birds were used in the study with 15 birds in each treatment. There were three replications of each treatment. The feed of broiler was made with the addition of citrus waste at five different proportions of citrus waste i.e., 0%, 2.5%, 5%, 7.5% and 10% using substitutional method and are indicated as MN_0, $MN_{2.5}$, MN_5, $MN_{7.5}$, and MN_{10}, respectively. The birds were reared for 42 days with standard conditions of food, water, and other environmental conditions. The temperature at the farm was maintained as 25-30°C with regular supply of water. Lightning was provided for at least 12 hours a day. After 42 days, birds were slaughtered and the breast meat of the broiler of different treatments was used for the preparation of meat nuggets.

Formulation for broiler meat nuggets

Five treatments of nuggets made with different chicken meat were fed on citrus supplemented feed having citrus waste level as 0%, 2.5%, 5%, 7.5% and 10%. The ingredients for preparation of nuggets were weighed and mixed according to the recipe (*Table 1*). The meat was washed with tap water, deboned manually and minced using electric mincer (MG 100). The broiler meat and onions were mixed in a meat mixer for five minutes, and then all other ingredients were added according to recipe and mixed using meat mixer to provide a uniform blend. The mixture was extended in a thin layer (10 mm thickness) and shaped into discs of 30 mm diameter (50±1 g/piece) to form a nugget. The nuggets were dipped in plain flour and bread crumbs separately and baked at 180ºC till attaining the desire color and texture. The nuggets were also stored at -20ºC for further analysis for different parameters at 0, 15 and 30 days of the storage.

DOI: http://dx.doi.org/10.15666/aeer/1801_655665

Table 1. *Recipe of the nuggets prepared from the broiler's breast meat fed on the feed with addition of citrus waste*

Sr. No	Name of the ingredient	Quantity used
1	Chicken boneless	500g
2	Egg	01
3	Black pepper	12g
4	Garlic paste	15g
5	Onion	150g
6	Plain flour	120g
7	Bread crumbs	70g
8	Salt	15g

Quality analysis of nuggets

Color of the Nuggets was determined with the method described by El-Gasim and Al-Wesali (2000) using hunter lab color measurement device in AARI Faisalabad. The pH of the nuggets prepared with chicken meat was determined as described by Sallam et al. (2004). Water activity of meat nuggets was measured following the method of El-Gasim and Al-Wesali (2000) using combination of a ventilated humidity and temperature probe. The humidity and temperature probe automatically showed the water activity value when it was placed on the meat samples. Water holding capacity of broiler meat nuggets was determined according to the method of Qiao et al. (2001). The nuggets samples were placed in 11 cm diameter filter paper between Plexiglas plates and pressed at 2000 psi pressure for 1 minute. The water holding capacity was measured using formula as indicated in *Eq. 1*.

$$\text{Water Holding capacity} = \frac{100\times\ (\text{total juice area} - \text{meat film area}) \times \text{water/squire inch filter paper}}{\text{Total moisture (mg) of original sample (sample weight in (mg)} \times \%\text{moisture)}} \text{(Eq.1)}$$

Thiobarbituric acid reactive substances (TBARS) assay was measured following the method of Asghar et al. (1989). The per-oxidative reaction was initiated by adding ferrous sulphate and hydrogen peroxide to the nuggets samples held in a water bath at 37°C. One mL sample prepared in buffer solution (0.1 M KCl: 0.05 M NaOH; 0.13 M Lactic acid) with pH 5.3–5.4 was withdrawn at 30 min intervals for a period of 120 min and mixed to a same volume of solution of Thiobarbituric acid (0.4%), trichloroacetic acid (10%), and hydrochloric acid (0.25 N). The mixture was heated in a boiling water bath for 15 min and then cooled. After centrifugation, absorbance of supernatant was measured at 532 nm. The extent of samples lipid peroxidation was calculated using the formula as indicated in *Eq. 2*.

$$\text{n} - \text{ Moles of Malondialdehydes} = \frac{(\text{sample absorbance} - \text{blank}) \times \text{Total sample volume}}{0.00156 \times 1000\ (\text{per mL})} \text{(Eq.2)}$$

The DPPH radical scavenging activity of broiler meat nuggets was determined following the method of Jung et al. (2010). The antioxidant activity of meat muscles fractions estimated by measuring scavenging abilities to DPPH stable radicals. A sample of 125 µL was mixed with 0.0012 M DPPH solution followed by the addition of 95% MeOH up to final volume of 4 mL. The absorbance of the resulting solution and the blank was recorded after 30 min at room temperature. The disappearance of DPPH was noted

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_655665

using spectrophotometer (CESIL CE7200, England) at 515 nm. Inhibition of free radicals by DPPH in percent (%) was calculated using formula as presented in *Eq. 3*.

$$\text{Inhibition (\%)} = [100 \times (\text{A blank} - \text{A sample}) \div \text{A blank} \quad \text{(Eq.3)}$$

Statistical analysis

The data obtained from treatments and replications were subjected to statistical analysis using statistical program SAS version 9.0 to determine the level of significance by two-way factorial ANOVA and Least Significant Different test as described by Steel et al. (1997).

Result and discussion

TBRAS of the nuggets

TBARS is the standard to evaluate oxidation of meat and meat products. The higher value of TBARS shows that product is towards the oxidation. *Figure 1a* shows that the TBARS of chicken meat nuggets was significantly influence due to interaction effect of effect of treatment and storage. TBARS value of the nuggets reduced in the treatments (MN_{10}) of the nuggets which was prepared from the meat of the broilers that were fed on the feed with the higher levels of citrus supplemented feed and higher values of the TBARS were observed in the control treatment (MN_0) at storage of 30 days. However, the TBARS value of the nuggets increased with the storage time but this increase was minimum in the treatment which was made from the chicken meat which have higher antioxidants from the citrus waste. Sohaib et al. (2013) observed the quality of the nuggets which was made from the chicken meat that were fed on the feed with alpha lipoic acid and alpha tocopherol was higher as compared to the control treatment. He observed that the TBARS value of the nuggets was high in the control treatment and low on the treatment which were prepared from the meat which have higher level of alpha lipoic acid and alpha tocopherol. Divya and Singh (2013) investigated addition of bitter melon extract as a source of natural antioxidant in the chicken meat nuggets. It was observed that addition of bitter melon in the chicken nuggets at 1% level improved the antioxidant properties via TBARS of the nuggets and the nugget controlled more lipid oxidation with bitter guard as a source of antioxidant. Mishra et al. (2015) observed increased in the TBARS value of the dehydrated chicken meat balls stored at ambient temperature for 45 days and also decrease in the TBARS value was observed when treated meat with rice flour was used.

DPPH activity

The data for DPPH activity of the nuggets prepared with the broiler breast meat fed on the natural antioxidants from the citrus waste is presented in the *Figure 1b* and *Figure 1c*, that shows nuggets have significant effects for DPPH activity due to treatments and storage life.

The mean values showed that maximum DPPH activity of nuggets was observed in MN_{10}, which was prepared from meat of broilers that were fed on 10% citrus supplemented feed while minimum DPPH activity value was observed in MN_0, the meat of that treatment was taken from the broilers group which were fed on control feed. This

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_655665

difference in the DPPH activity of different treatment is correlated with the amount of citrus waste used in the feed of broiler, as citrus waste is a rich source of phenolic substances like flavonoids which possess antioxidant activity and the natural antioxidants in the meat of the broilers raised DPPH activity. The DPPH activity of nuggets reduced during storage because of the loss in the polyphenolic contents of the meat.

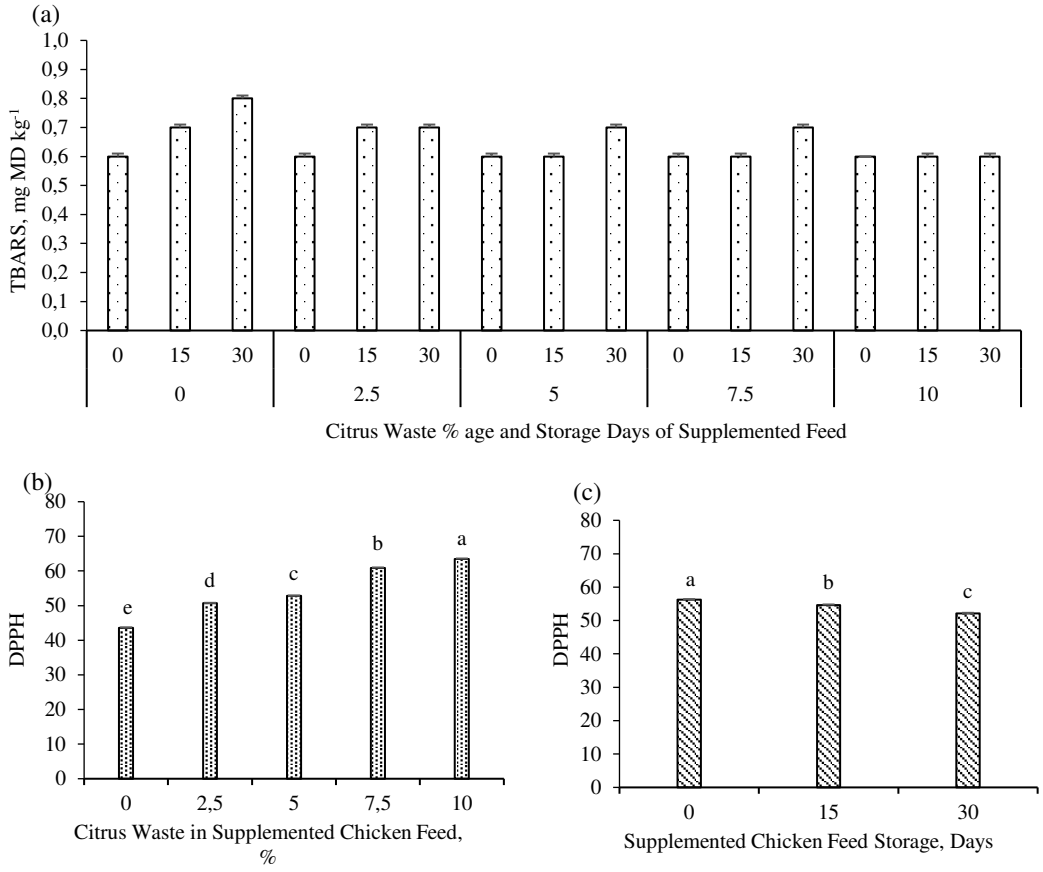

Figure 1. *Interaction effect of citrus waste supplementation and storage on TBARS (a) and individual effect of citrus waste supplementation (b) and storage (b) on chicken meat nuggets*

O'Sullivan et al. (2004) added different level of tocopherol acetate (vitamin E), rosemary (0.10%), sage (0.10%) and tea catechins (0.01%) in the feed of the broilers and concluded that nuggets made from the breast meat of broilers fed on the vitamin E alone have better antioxidant activities as measured by DPPH activity. Maliluan et al. (2013) added rice bran instead of wheat flour by substitution method in the formulation of the chicken nuggets and observed that antioxidant activity of the nuggets enhanced when rice bran was added in the nuggets however the sensory qualities of the nuggets decreased by adding rice bran.

pH of nuggets

The data for pH of the nuggets prepared with the broiler breast meat fed on the natural antioxidants from the citrus waste is presented in the *Figure 2*, that shows that the nuggets have significant effects for treatments and storage life. pH value of the nuggets showed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_655665

that maximum value of the pH was observed in the treatment which was made from the broiler meat which were fed on the control feed. Increased in the concentration of citrus waste in the feed of broiler decreased the pH of nuggets made from the broiler meat. pH value of nuggets increases as the storage period proceeded. Banerjee et al. (2012) prepared goat meat nuggets with broccoli powder extract as an antioxidant and observed decline in the pH of the nuggets when broccoli powder extract was used at the concentration of 2%. Yadav and Sanyal (1999) reported that pH of the nuggets was increased when antioxidants were added in the nuggets and pH also increased with storage.

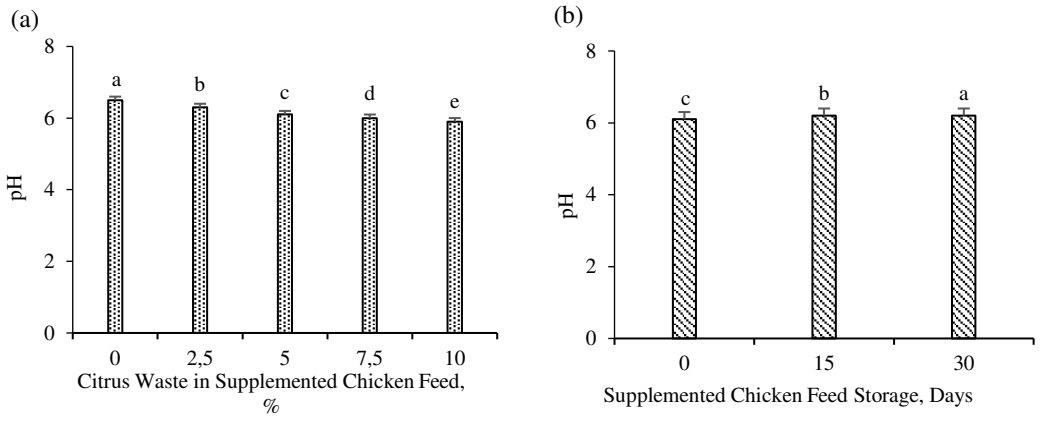

Figure 2. *Effect of citrus waste supplementation (a) and storage (b) on pH of chicken meat nuggets*

Color of nuggets

Color L value of nuggets*

The data for the color L* value of the nuggets is presented in the *Figure 3a*, which shows that the significant effects for the color L* value of the nuggets for treatments and storage was observed. The highest mean value (67.24) for color L* of nuggets was observed for treatment prepared with the meat of broilers fed on treatment plan MN_0 (control) which reduced significantly and lowest value of the color L* value of the nuggets was observed for the treatments of nugget prepared from meat of broilers fed on 10% citrus waste supplemented feed (MN_{10}). It is evident from the results that increase in level of citrus waste supplementation in feed increase the natural compound deposition in meat leading to a reduced of color L* value of nuggets. Decreasing trend for color L* value of the broiler meat nugget from zero-day interval to 30 days' interval was observed.

Bosale et al. (2011) evaluated functional chicken nuggets for quality and sensory parameters. They also observed decrease in the color value of the nuggets when ground carrot and mashed sweet potatoes were used as a functional ingredient in the chicken nuggets, which support current investigations. Naveena et al. (2008) observed decline in color for broiler nuggets when they were stored at freezing temperature and color of the nuggets changed from red to brown which was due to the formation of metmyoglobin in broiler meat. O'Sullivan et al. (2004) found increase in the color L* value of the chicken nuggets during storage when the meat of the broiler was used which was fed on Rosemary (0.10%) as a natural antioxidant in the feed.

DOI: http://dx.doi.org/10.15666/aeer/1801_655665

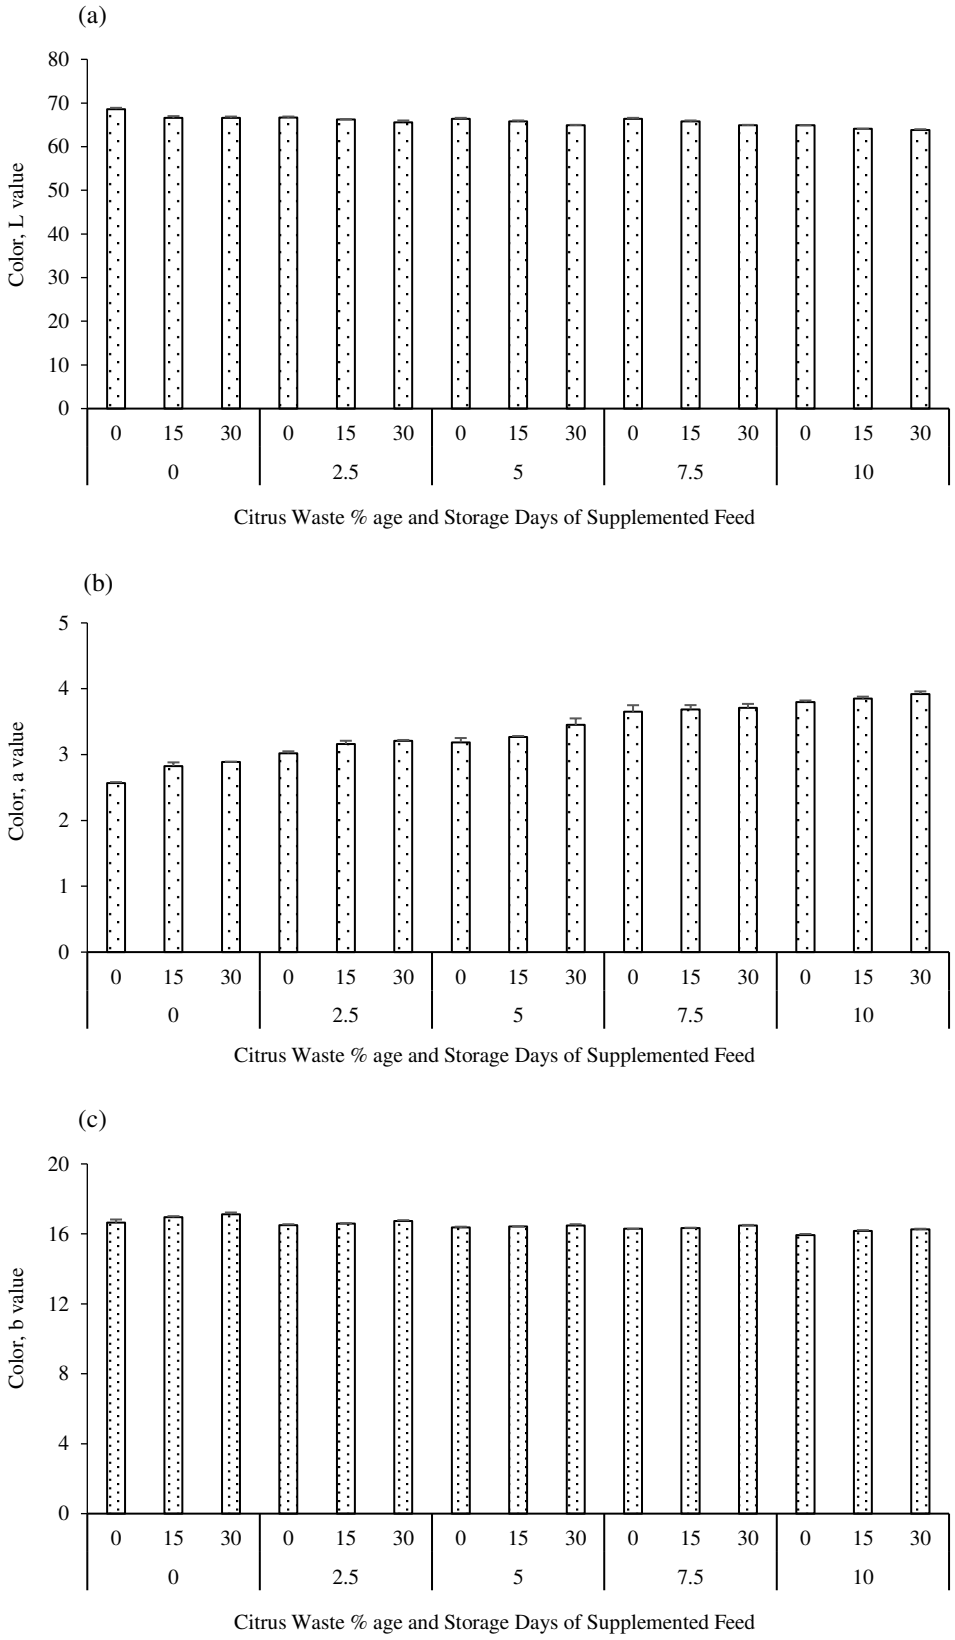

Figure 3. *Interaction effect of citrus waste supplementation and storage on Color L value(a), a value (b) and b value (c) of chicken meat nuggets*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_655665

Color a value (redness) of nuggets*

The data for the color a* value of the nuggets is presented in the *Figure 3b*, which shows significant effects for treatments and storage of the nuggets prepared from the broiler breast meat fed on the citrus waste supplemented feed. Maximum mean value for color a* of nuggets was observed for MN_{10} which was prepared with the meat of the broilers which were fed on maximum citrus waste contents (10%) whereas minimum mean value for color a* values of nuggets was observed for MN_0 which was prepared with the meat of the broilers which were fed on control feed (0% citrus waste). Similarly, potential variation was observed when the nuggets were stored for 30days under freezing conditions. Hunter a* values of chicken nuggets containing natural antioxidants in the feed of the broiler was also found increase by O'Sullivan et al. (2004) in their studies, which support findings of the current studies. Verma et al. (2013) in their studies observed increase in the color a* value of the sheep meat nuggets when they added guava powder in the nuggets.

Color b value (yellowness) of color of nuggets*

The data for the color b* value of the nuggets is presented in the *Figure 3c*, which shows significant effects for treatments and storage of the nuggets prepared from the broiler breast meat fed on the citrus waste supplemented feed. Maximum mean value for color b* of nuggets was observed for MN_0, the meat of which treatments was used from broilers that were reared on control feed (0% citrus waste in feed), whereas minimum value for b* values of color of nuggets was observed under MN_{10}, the meat of which treatments was used from birds that were reared on feed with maximum citrus waste contents (10% citrus waste in feed). The color b* value of the nuggets also increased as the storage period proceeded from 0 day to 30 days. Chandralekha et al. (2012) reported that chicken meat balls incorporated with pomegranate rind powder extract as a source of natural antioxidant, secured significantly higher color value than all other treatments but the color value decreased during storage. Similar results have been reported by Kala et al. (2007) in refrigerated chicken patties who observed increased in the color b* value.

Texture (shear force) and water holding capacity of the nuggets

The data for texture of the nuggets prepared with the broiler breast meat fed on the natural antioxidants from the citrus waste is presented in the *Figure 4a and 4b*, which shows that the nuggets have significant effects for treatments and storage life. Maximum value for texture of the nuggets was observed after 30^{th} days of storage whereas minimum value for texture of nuggets was observed after 0 days' interval. Texture values for nuggets increased from 0 day to 30 days of the storage. The results of current investigations are in line with the studies of Ruiz-Ramirez et al. (2005) who concluded that texture become harder as the storage period of the nuggets proceeded. Moran et al. (2012) reported lower values for shear force in groups of the nuggets in which antioxidant was used as compared to the control groups.

The data for the water holding capacity of nuggets is presented in the *Figure 4c*, which shows significant interaction effect of treatments and storage on water holding capacity of nuggets prepared from the broiler breast meat fed on the citrus waste supplemented feed. The highest value of water holding capacity of nuggets was observed in MN_{10} (nuggets prepared from the breast meat of the broilers which were fed on 10% citrus waste supplemented feed) at 10 days of storage period while lowest was observed for MN_0

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_655665

(nuggets prepared from the breast meat of the broilers which were fed on control feed) at 0 days of storage. Water holding capacity of the nuggets increased as the storage time proceeded from 0 day to 30 days. Kikki et al. (2014) reported similar results in their studies, they worked on development of functional chicken nuggets with the addition of fermented bamboo shoots, beet root and cabbage. They observed that nuggets with the cabbage incorporation possesses higher score for water holding capacity. Golsuch and Alvarado (2010) observed increased in the water holding capacity of the broiler normal and pale breast fillet, when used different marinating techniques. However, Arun et al. (2008) working on the effects of full fat soy paste and textural soy protein on the quality and shelf life of the goat meat nuggets on freeze storage observed non-significant effects on the water holding capacity of the nuggets.

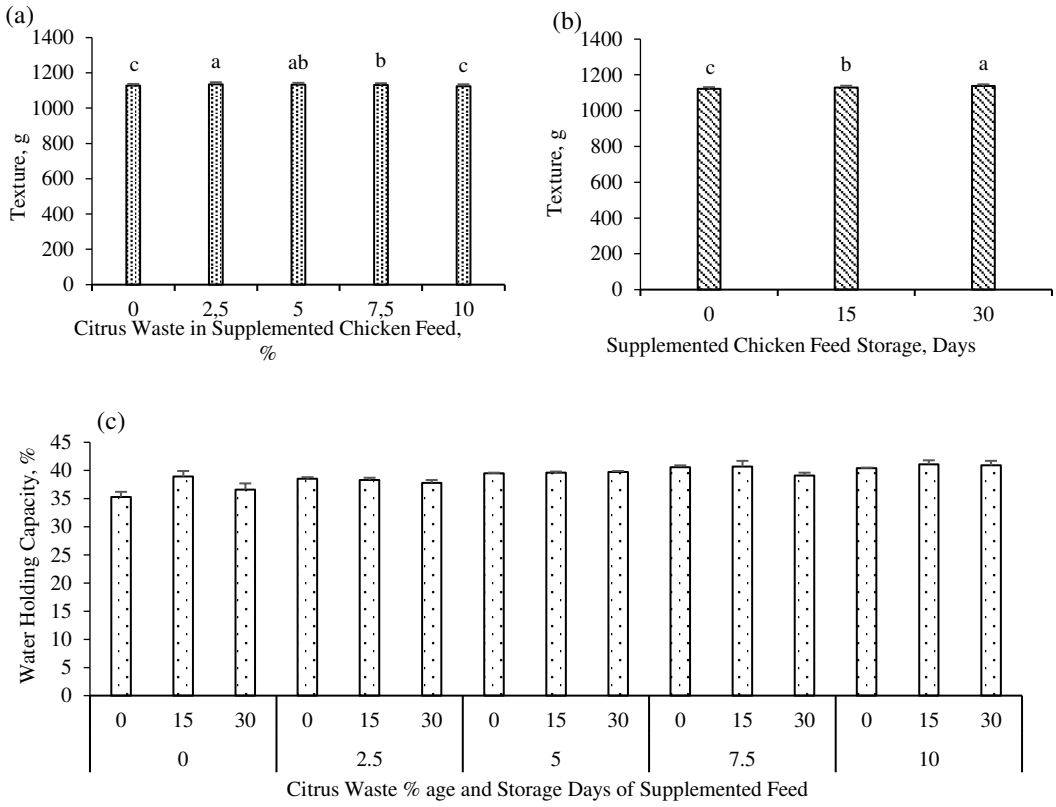

Figure 4. *Individual effect of citrus waste treatment (a) and storage (b) on texture and interaction effect of treatment and storage on water holding capacity (c) of chicken meat nuggets*

Conclusion

In the current findings citrus waste after juice extraction is used in the broiler meat production, the meat was further utilized in the nuggets preparation. The results showed positive effects on quality and the antioxidant profile of the nuggets. The citrus waste is normally wasted and in this study it is utilized for meat production. The study may be effective for the industry of food processing. Further studies might be conducted to increase utilization of citrus waste for different food products under different environmental conditions where different varieties of both citrus and the broiler chicken

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_655665

can be tried for manufacturing of meat, eggs, and meat products. In this way the citrus waste may be properly utilized for the benefits of human being as it is good source of natural antioxidants that is usually wasted after juice extraction.

(Received 29th May 2019; accepted 25th Nov 2019)

Abstract. The management of industrial solid waste demands the establishment of suitable management systems. Such systems must take into consideration multiple factors that allow selecting the most adequate treatment techniques among the ones available. The selection of these techniques is a complex process that not only depends on factors inherent to the treatment or the waste itself, but also on other factors. For this reason, this study analyses the influence of location on the management of an industrial solid waste such as LD sludge. Firstly, we used a methodology developed in a previous part of this study, that can identify six treatment solutions, then, a set of environmental, regulatory and socioeconomic indicators are chosen. Going a step further in this investigation, proves through the application of the methodology in five different locations, that environmental characteristics influence the final treatment solution for the same waste. According to this, two sets of groups can be identified for the best treatment solution: one in which the highest score is 1 A Ceramization and another in which the final result is 1 B Vitrification.
Keywords: *sludge, analytical hierarchy process, management methodology, system of indicators, industrial facilities*

Introduction

Over the course of history, and as the population has grown, the needs and level of comfort for individuals have increased exponentially, resulting in an excessive generation of waste parallel to the generation of goods. This lack of social conscience that until recently was undeniable, dumping this waste in an uncontrolled manner and causing serious economic, social and environmental problems, has been giving way to the emergence of a new social conscience.

The problem of environmental pollution has its origin in the fast urbanization and industrialization produced in the last few decades. Although the amount of waste produced in cities is worrying, the generation of waste at the industrial level is even more so. In spite of being more varied and numerous, they are more dangerous and, as a consequence, more difficult to control, causing serious problems in the operations of their use and subsequent disposal. This, in combination with greater social awareness, makes the need to develop new management methods and procedures becoming more and more evident. However, just as important as their development is the way they are applied and adapted to the constantly changing technological and social environment. One-way to go a step further and make the most of these management systems, is to incorporate specific tools that allow the influence of certain external agents to be measured.

Therefore, the industrial solid waste management (ISWM) is a complex issue that industrial companies around the world must tackle on a daily basis. All of them must try

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_667681

to use the best techniques available to treat the waste material and establish the most suitable management and treatment systems.

In many cases, the selection of the most suitable treatment or set of treatments is a complex issue, due to the need to bear in mind a considerable amount of factors (technical, economic, social...). Obviously, the special characteristics of the industrial waste are often crucial, though the environmental conditions of the area where the waste is generated are also decisive.

In the managing of industrial solid waste (ISW) or any type or waste, not only should be taken into account, to study which treatment is the best according to the characteristics of the waste, if not that the process is much more complex. In addition, the performance produced should be analysed according to the environmental characteristics of the site or location where it is to be managed. Based on the measurement of this performance, it could be decided which environment is best to treat the waste.

Based on this hypothesis, it might appear that the research currently being carried out on this particular subject could be countless, but this is not the case. Since many of the existing works only study the optimal location of the industrial facilities to reduce its impact from the beginning using decision support systems (Arán et al., 2008) or multi-criteria decision making techniques (Çebi and Otay, 2015) including Analytic Hierarchy Processes (Kauko, 2006; Dey and Ramcharan, 2008; Srdjevic et al., 2007; Akıncı et al., 2013). Other researches use bi-level programming models (Wu and Yang, 2018) or analyse (Chen et al., 2014) or compare (Glatte, 2015) different models.

Some authors study the optimal location of the treatment plants using multi-criteria approaches, taking into account technical, economic and environmental aspects (Önüt and Soner, 2008; Wibowo and Grandhi, 2017; Wójcik et al., 2014; Kyriakis et al., 2017; Samah et al., 2017; Ulubeyli et al., 2017). For this purpose, different techniques and methodologies are used, including Analytic Hierarchy Processes (Önüt and Soner, 2008; Milutinović et al., 2014; Samah et al., 2017), programming models (Vaillancourt and Waaub, 2002; Haastrup et al., 1998; Paul et al., 2018), or fuzzy systems (Carniel and Schneider, 2017; Abdulhasan et al., 2019). Other select the most appropriate treatments for waste at a given location (Achillas et al., 2010; Xu et al., 2014; Nouri et al., 2018) or a comparison between two locations (Milutinović et al., 2016; Inglezakis et al., 2018).

Thus, the work here presented pursues two goals:

- Check that the environmental conditions of a location can modify the most suitable treatment for a specific industrial waste.
- Verify that the previously developed methodology by the authors (Fernández et al., 2014) is capable of providing the best solution in several geographical locations with different physical, environmental and social conditions where the waste material is generated.

Materials and methods

Methodology for the ISWM

As described above, the methodology for the selection of the most suitable solution for the waste material that has been used, is the one defended by Fernández et al. (2014)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_667681

This methodology has a series of characteristics that makes it the most suitable for the study of the treatment of industrial solid waste:

- First, its adaptability to any type of waste, either solid or semisolid.
- It can be applied to any type of environment by adjusting the location conditions of the installation where the management process is taken place (climate, soil, closeness to populated areas or green areas, etc.).
- It is a flexible methodology that can consider different criteria or environmental indicators.
- It is user-friendly, since the decision process guides and helps users through the different options.
- It is easy to update, by including new treatment methods, changes derived from evolution in technology or social and economic conditions.

All these characteristics allow the methodology to continue evolution and thus be able to comply with the future lines contemplated in the first part of the study developed in Spain (Fernández et al., 2014). For its application, the methodology is structured in four stages, defined in *Figure 1*.

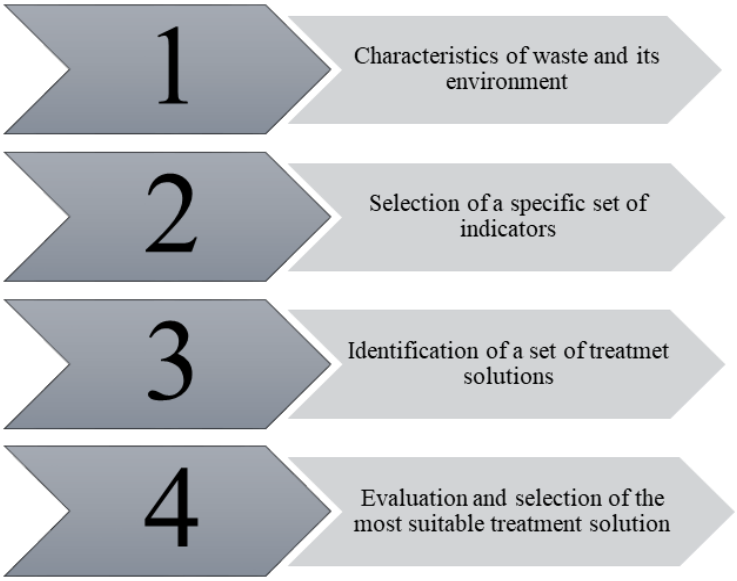

Figure 1. *Methodology development diagram*

The first thing to learn is the characteristics of the waste to be treated and the environment where the treatment will be developed. All this information is then collected in files or sheets, one with the characteristics of the waste material and the other with those of the environment, the first classifies the waste material according to information related to its identification, and the second collects information on the location where the treatment system will be set and its conditions.

The second stage involves the selection of a specific set of indicators for each case of application, the result of particularizing a system of general indicators.

For this purpose, the general Environmental Indicator System (EIS) for any area of the company, will be specific to waste management by configuring a System of Environmental Indicators for Solid Waste Management (SEISWAM) that will be the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_667681

means of subsequent evaluation of the possible treatment solutions applicable to this waste. The characteristics of the indicators are described in the "Indicator sheet".

In the third stage, the treatment solutions are identified thanks to an "alternative selection chart" (Fernández et al., 2014), which presents the necessary process for the treatment of a solid waste from its generation to its disposal, elimination or reuse, and functions as a decision aid system. This identification is carried out taking into account the characteristics of the waste "Waste sheet" and the set of available techniques, "Process sheet", which collects the main data of interest of each technique and waste to which is applicable. Each of these solutions can consists of more than one treatment process.

The last stage of the methodology presents the results of the study and allows us to select the most suitable solution among all the possible solutions previously identified in the previous stage. For this purpose, the selected set of indicators is available, which evaluates each of the available solutions. This evaluation is performed through the application of the Analytical Hierarchy Process (AHP), developed by Tomas Saaty in 1980 (Saaty, 1980).

Case study

Next, the application of this methodology to a particular case is described, where the goal is to search the optimal treatment solution for the same industrial waste in different locations worldwide.

Waste product studied

LD converter sludge is the waste material resulting from the wet processing of gas in the steel-making process in the Basic Oxigen Furnace (BOF) converter or LD converter, named after the Austrian towns Linz and Donawitz where this system was first developed. This waste material involves a serious concern due to the vast amount generated, around 27 kg of LD sludge per ton of hot metal. Its physical and chemical components allow different alternatives or possibilities of treatment. On the other hand, it has a percentage of recoverable material, its metal part, which makes it a reusable product both for the steelmaking and other types of industries (*Table 1*).

Selection of locations

In order to develop this study, 5 populations close to steel mills have been selected, where the LD slag is obtained and which have different physical, environmental and social environment conditions.

Among the possible locations, areas with different climate conditions have been selected, according to the climate classification developed by Köppen. This procedure is based on empirical observations (Köppen, 1900) to establish a climate classification system that uses monthly temperatures and rainfalls to define the limits of the different types of climate worldwide. This classification was revised and updated afterwards (Köppen and Geiger, 1930, 1936; Stern et al., 2000; Peel et al., 2007) and it is widely used worldwide by meteorologists and geologists (Chen and Chen, 2013; Feng et al., 2014), apart from being the base of multiple scientific studies (Pražnikar, 2017; Almorox and Quej, 2015; Yoo and Rohli, 2016).

According to these premises, the populations of Avilés (Spain), Lázaro Cárdenas (Mexico), Tubarao (Brazil), Newcastle (South Africa) and Beijing (China) were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_667681

selected for the study. The climatological conditions of these locations are displayed in *Table 2*. In the case of Spain, the data have been obtained from the State Meteorological Agency (AEMET, 2017) and the data of the rest of the locations have been collected from the WMO repository, World Meteorological Organization (WMO, 2017), from the official website of the NOAA, National Oceanic and Atmospheric Administration, which belongs to the USA Government.

[1]Chemical Abstract Service Register Number (American Chemical Society)

The town of Avilés is located in the North East coast of Spain, with mild temperatures in all seasons, with and average temperature of 13.5 °C, high relative humidity (78%) and frequent rain. On the contrary, Newcastle (South Africa) has a drier climate, with lower relative humidity (59%) but higher average temperatures (21.9 °C) and less rainfall. On the other hand, Lázaro Cárdenas, a town located near the Pacific Coast of Mexico, has a tropical rainforest climate, where winters are cold but the average annual rainfall is still high all year around. The average rainfall level is 1278 mm and temperatures are high, with an average temperature of 27 °C and a high relative humidity. The humidity of the Brazilian city of Tubarao (61%) is lower than the case of Mexico, while the temperatures are also high (26.4 °C), with a lower rainfall level than in the previous case (1,003 mm), although relatively similar to the town of Avilés.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_667681

In Beijing, the weather conditions are quite similar to those of the city of Newcastle in South Africa, although it is colder, (11.8 °C) and drier (47%), and the level of rainfall is a bit higher (577 mm) than that of the Chinese capital.

When selecting these populations, apart from the different climate characteristics, the type of location has also been taken into account, that is, if it is an industrial or rural area and if it is near or not to population centres or natural reserves. In this sense, Avilés, Newcastle and Beijing are considered as populations located in industrial areas, against Tubarao and Lázaro Cárdenas, which are closer to rural areas with small population centres and close to areas considered as natural heritage.

Selection of a specific set of indicators

The indicators system has been established as one of the most useful tools for monitoring the process information flows, which provide us with techniques to evaluate their efficiency.

The so-called SEISWAM was developed at the same time as the methodology used in this paper (Fernández et al., 2014) and it is based on the following two former systems:

- The first one is based on a system of indicators in which the principles of ISO 14031 standard are specified (ISO International Organization for Standardization), the European eco-management and audit scheme contained in the EMAS Regulation (Comision Europea, 2003; DOUE, 2009), extended with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_667681

the present classification in the report issued by the Public Society of Environmental Management of Basque Government IHOBE (IHOBE, 1999).

- The second one is the GRI system (Global Reporting Initiative), which is the main international standard for the drafting of Sustainability and Corporate Social Responsibility Reports (CSR) (GRI, 2005).

The indicators system is specialized in the management of industrial solid waste by using a selection chart to define the methodology of waste management. This gives a more complex system called SEISWAM, which is comprised of hundreds of indicators.

Among these indicators, the most representative ones in terms of measuring the impacts of inputs and outputs processes were selected resulting eleven (*Table 3*). These indicators collect globally the different environmental impacts (environmental indicators), socioeconomic impacts (financial behaviour indicators) and those affecting the management process according to the set of treatments that waste endures (environment indicators).

Table 3. *Indicators considered*

Number	Indicator name
1	Specific energy consumption
2	Specific water consumption
3	Specific consumption of chemical agents
4	Volume of liquid effluents
5	Volume of gas emissions
6	Total share of profitable solid
7	Operational costs of environmental protection
8	Average rainfall of the area where the installation is located
9	Wind speed in relation to the average in the area where the installation is located
10	Proportion of natural heritage affected
11	Proximity to local populations

Of these eleven indicators, the first seven are dependent on the characteristics of the waste material and measure the environmental, social, economic impacts of the waste management process. Essentially, it has been decided to select those that directly and easily quantify the inputs and outputs in the flowchart, to compare the results obtained with those of the first part of the study carried out by Fernández et al. (2014). For instance, the indicator 'Specific water consumption' has been selected over other possible ones like 'Rate of type of water", because the latter does not evaluate all the water in the whole process, but only of those processes that work with a certain type of water. The same happens with indicators concerning chemical agents, effluents and gas emissions.

The selection of the indicator 'Operating costs of environmental protection' incorporates the economic impact from the viewpoint of environmental protection related to the operations performed in the waste management facility. This is not the case in other possible suitable indicators such as 'Environmental aid granted by the Government' in which, besides taking into account mainly economic factors, there is no reference whatsoever to the management process.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_667681

Regarding the quantification of the system outputs, in the case of the indicator 'Total share of profitable solid', this more global indicator has been chosen rather than 'Total amount of profitable solid with respect to energy consumption', in which the usable solids are quantified, but only taking into account the input of energy to the process.

Regarding the indicators corresponding to the environmental conditions that affect the treatment processes, it has been selected the ones referring to the climate characteristics of the area most liable to affect the waste treatment system, such as rainfall and speed. Regarding the living conditions, the most representative indicators of this level have been chosen, such as the 'natural heritage affected' and the 'Proximity to local populations' without going into details about the classification or type of soil (rural or urban).

Set of treatment solutions

By the 'alternative selection chart' (Fernández et al., 2014) the different treatment solutions are identified, obtaining six possible treatment alternatives:

- Alternative 1 A. Ceramization
- Alternative 1 B. Vitrification
- Alternative 2.1 A. External manager of hazardous solids
- Alternative 2.2 A. Phytoremediation
- Alternative 2.2 B. Bioremediation
- Alternative 2.2 C. On site vitrification

Each of these alternatives is comprised of a set of treatments that start when the waste enters the facility and ends when the final product is obtained. To summarize, they are identified only with the name of the last valorization treatment applied to the waste. The treatments that constitute each alternative are described below.

In the alternative selection chart, the waste material goes through a series of initial considerations such as its categorization as a non-radioactive, hazardous and valuable slag, according to its initial classification. Afterwards, the sludge is dried to be submitted to a magnetic separation process. As a result, the solid magnetic fraction is usable while the non-magnetic part goes back into the decision process. This non-magnetic solid could be recovered (alternative 1) or not (alternative 2). If the recovery of such fraction is chosen, it would be possible to apply the treatments of ceramization (Alternative 1 A. Ceramization) or vitrification (Alternative 1 B. Vitrification). In the case of not choosing to recover the waste material (alternative 2), it must be determined if it is legally disposable or not. In this particular case, it would not be disposable, since, according to the legislation and the initial characterization, this waste material contains a series of toxic components that surpass the legal thresholds. Therefore, at this point, there are two options. The first one would be not treating the waste internally but carrying it instead to an External manager of hazardous solids (Alternative 2.1 A). The second one would be treating the waste internally, with these different treatment possibilities: Phytorremediation (Alternative 2.2 A. Phytoremediation), Bioremediation (Alternative 2.2 B. Bioremediation) or onsite vitrification (Alternative 2.2 C. On site vitrification).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_667681

Results

The five proposed locations are assessed using the eleven selected indicators that constitute the decision criteria of the AHP method (Fernández et al., 2014), which corresponds to the last stage of the methodology, *Evaluation of alternatives*, giving the results of the study. This way, the influence of weather conditions is opposed to the proximity to population areas, industrial zones, rural areas, nature reserves, etc. in the treatment processes. In this stage, the environmental impacts are taken into account when assessing the indicators. Therefore, each management solution will have a different score.

In the calculation of the judgment matrix by paired comparison of the treatment alternatives for each of the criteria or indicators related to the environment, the weights of each of these criteria vary depending on each location. For instance:

- In damp and rainy locations, landfill treatments produce more leachates than in drier climates. As a consequence, in Avilés or Lázaro Cárdenas, a higher quantity of liquid effluents and alternatives such as 2.2 A Phytoremediation and 2.2 B Bioremediation would be generated and, therefore, they receive a worse assessment than others such as 1A Ceramization. On the contrary, Newcastle and Beijing have a lower amount of effluents and the alternatives 2.2 Phytorremediation and 2.2 B Bioremediation obtain a better assessment.
- In locations with high wind speed, gas pollution moves to other nearby areas such as population centres or natural parks. In these cases, the criteria or indicators 'Affected natural heritage' or 'Operational costs of environmental protection', become negative factors or criteria when assessing certain treatments. This would be the case of towns such as Avilés or Tubarao, where the scores of valorization processes such as ceramization or vitrification are lower than those corresponding to landfill or shipping to an external manager of hazardous solids.

Taking into account this calculation and the weights of indicators according to the area where the treatment facility is located, the following scores are obtained in *Table 4*.

Table 4. *Hierarchical analysis method solutions in different locations*

Alternatives	Alternative priority vector				
	Avilés Industrial	**Lázaro Cárdenas Rural**	**Tubarao Rural**	**Newcastle Industrial**	**Beijing Industrial**
1 A Ceramization	**0.2635**	**0.2705**	**0.2602**	0.1857	0.1857
1 B Vitrification	0.2429	0.2516	0.2459	**0.1923**	**0.1937**
2.1 External manager of hazardous solids	0.2386	0.2381	0.2371	0.1801	0.1788
2.2 A Phytoremediation	0.0794	0.0882	0.0803	0.1776	0.1853
2.2 B Bioremediation	0.0692	0.0702	0.0703	0.1378	0.1393
2.2 C On site vitrification	0.1063	0.0814	0.1062	0.1265	0.1173

It can be noticed that the best-valued treatment alternative in each location, that is, the one with the highest value or score, vary in the different sites. The alternative 1A. Ceramization is the preferred option in the first three locations (Avilés, Lázaro Cárdenas and Tubarao) while in the other two (Newcastle and Beijing) the highest score is for alternative 1B Vitrification.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_667681

In all cases, a better assessment is given to the alternatives that end with the waste valorization (ceramization and vitrification) compared to those of final treatment (landfill, - phytoremediation and bioremediation - and external manager).

Discussion

According to the solution proposed by the methodology as the most suitable one, two sets of groups can be identified: one in which the highest score is 1 A Ceramization and another in which the final result is 1 B Vitrification.

In order to describe in a better way what is observed in *Table 4,* the distribution of two localities is shown in *Figure 2,* Lázaro Cárdenas belonging to the first site and Beijing belonging to the second, in the first case, the scores appear more concentrated in the treatment processes and external manager, while in the second the scores are similar.

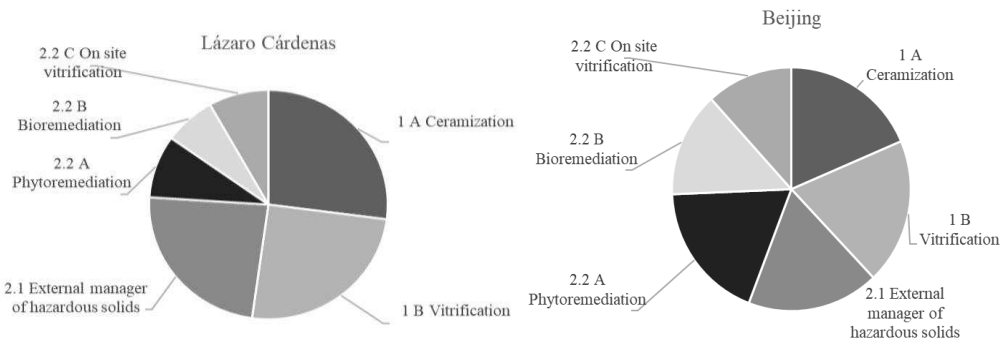

Figure 2. *Priorities of treatment alternatives according to location*

The scores given by the experts to the different treatment alternatives in the comparative analysis, depending on the selected criteria or indicators, vary due to the following causes:

1. Leachates can appear in damp and rainy climates so, as a consequence, the landfill treatment alternatives (phytoremediation and bioremediation) have poorer scores. This is what occurs in the first three locations (Avilés, Lázaro y Tubarao), for having more rainfall than the other two (Newcastle and Beijing).
2. On the other hand, the landfill treatment alternatives obtain higher scores for the good results obtained by these techniques in climates with less rainfall, as in the case of Newcastle. According to different studies (Sharma and Pandey, 2014; Liphadzi et al., 2005) the plants and microorganisms used in these areas (Yadav and Hassanizadeh, 2011; Hejazi et al., 2003) develop their activity effectively by clearing the soil of heavy metals due to favorable weather conditions.
3. Gas emissions occurring near rural areas where the natural habitat is more diverse, such as Lázaro Cárdenas and Tubarao, generate more environmental impact than in industrial areas, which favours the scoring of alternatives that include landfilling, such as 2.2 A Phytoremediation, 2.2 B Bioremediation, diminishing the scoring of the alternatives that do not include it, such as 1 B Vitrification and 2.1 A External manager. These impacts also occur in Aviles,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_667681

but since it has an industrial environment, the natural and rural heritage is less affected, so landfill scores do not rise as much as in rural locations.

4. Wind speed is similar in all studied locations, although the highest wind speed corresponds to Avilés. In this area, emissions in the form of leaks that can break into the atmosphere are more likely to be dragged to further area, thus extending the range of pollution. This makes the valorization processes more expensive than those of landfilling or manager dispatching. On the contrary, the opposite case occurs in the rest of the locations where the wind speeds are softer.

In the first analysis, the operability of the methodology was proved (Fernández et al., 2014), a locality with specific environmental conditions was chosen and the scores of the treatment alternatives were calculated, being the highest alternative 1A ceramization.

In this research, in which the type of waste and the evaluation criteria are the same, besides demonstrating the characteristics of the methodology described in the materials and methods section; adaptability, applicability, flexibility, user-friendly, easy to update; the treatment solutions obtained in each of the five locations have been compared, it can be observed that the changes in the environmental conditions of the site established at the beginning of the analysis differ significantly, therefore the evaluation of the indicators changes and, consequently, the results vary.

Conclusions

This study has implemented the methodology by Fernández et al. (2014) in order to select the most suitable treatment alternative to the same waste in five different locations. The results obtained show that the best solution may vary when environmental conditions are significantly changed.

In the case studied, the treatment of LD sludge, when analyzing the influence of the climatic and environmental conditions of the location in the different treatment processes, the following results were obtained:

A high-level rainfall constrains the suitability of the landfill treatments, since in this context there is a higher-level generation of leachates.

- The gas emissions produced at the output of some treatments (vitrification or ceramization), combined with the wind conditions may have a negative impact in rural locations or other places, as for instance natural reserves or protected areas. This makes these treatments less suitable. On the contrary, if these conditions are in industrial areas or its proximity, it has a less negative impact.
- In the case of the developed methodological process, a series of inherent characteristics of the methodology are reviewed and checked:
- Its applicability and flexibility, allow the use of the most suitable criteria or environmental indicators in each case, more or less according to the number of criteria of study required for each case.
- Its simple upgrading. This makes it easier to add new waste treatment techniques to the valorization decisions or treatment requirements included in the alternative selection chart.

DOI: http://dx.doi.org/10.15666/aeer/1801_667681

Within the future lines of research in this study, the analysis developed can be perfectly extended to other similar facilities located in other cities under different climatic and environmental conditions, being able to obtain a different solution in a changing environment.

The same methodology can be applied in other industrial sectors (glass, textiles, mining, etc.) that generate other types of waste (liquid effluents, wastewater and gaseous emissions) and as a result with different treatments to those described above, allowing to personalize the system of general indicators and develop an alternative selection diagram similar to that exposed.

In the same way, another series of criteria can be incorporated into the study, either parameters related to the social or economic conditions of the environment, or other factors that could have a critical role in the security of the waste storage and other outputs, using the extensive system of indicators that includes the methodology or incorporating new indicators if necessary.

Finally, a software could be developed to support this methodology, allowing for each of the treatment alternatives, the quantitative determination of effluent outputs, energy consumption, chemical agents, etc.

Abstract. This study aimed to develop a vigor test method that can be applied in the seed storage and ecological restoration of Aging chive (*Allium senescens* L). The impact weight of each temperature on germination was described with a sine curve equation. The closer the temperature was to 18.9 °C, the faster the germination was, and temperatures below 8.0 °C and above 29.7 °C negated the temperature accumulation effect. A verification and validation test confirmed the 'impact weight on germination' to be reasonable because it exhibited a hump-shaped relationship with the time to reach 85% germination among the temperature treatments. Furthermore, the time to reach 25, 50 and 75% germination and the change in germination with time did not differ between the actual and predicted values. The hourly accumulated value of 'impact weight on germination' was taken as the temperature score (TS), and the temperature requirement for vigorous germination was 294TS. The temperature requirement was applied to hourly temperature data from Geumsan, Korea, from 1999-2018, and the average date of vigorous seed germination was May 3. Increasing temperature elevation advanced the predicted germination date. Based on the earliest predicted date, germination will advance rapidly. If the temperature is elevated by 2.5 °C, the germination date will advance markedly to November 23.
Keywords: *Allium senescens L., German garlic, germination, seed vault, wild plant*

Introduction

The Baekdudaegan Global Seed Vault (BGSV) of the National Baekdudaegan Arboretum was established to preserve and safely store seeds of wild plants collected worldwide. A seed vault is a center for permanent storage, in contrast to a seed bank, which allows seeds to be deposited and removed easily. The permanent storage of seeds conserves biodiversity and allows restoration to prevent extinction, which could occur in response to climate change and natural disasters, among other events. Because seeds are the core of ecological restoration (Broadhurst et al., 2015), the BGSV could serve as a potential material supplier for a wide range of species restoration and ecosystem reconstruction activities as it includes seeds from wild plant species.

Seed viability is one of the most important factors for the permanent storage of seeds and ecological restoration (Marcos-Filho, 2015). Storing seeds confirmed to have high vitality by a vigor test not only increases their storability but also affects the efficiency of the seed vault. Moreover, a vigor test provides information that can be used to restore the germination of seeds stabilized for storage, which is a key factor in the restoration of natural habitats (van der Valk et al., 1999).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_683695

To achieve ecological restoration using seeds, information on germination characteristics and the environment of the target site should be taken into account. Since the selection of species for restoration gives priority to native species, vigor test results for the species and environmental information at the target site are especially important for determining the success or failure of the restoration.

The species used in this study, Aging chive (*Allium senescens* L.), is a perennial herb of the *Liliaceae* family with thicker leaves than other members of this family (Oh et al., 2012). Because of its very strong scent, its aromatic components and chemical composition have been studied (Chung and Lee, 2001; Chung, 2010). For example, methanol extracts of this species were found to suppress reactive oxygen species (ROS) production and lipid accumulation and consequently inhibit adipogenesis (Choi and Kim, 2014). Despite the studies on this species, it is classified as a rare plant in Korea and is in danger of extinction (Korea National Arboretum, 1997).

Thus, this study aimed to develop a vigor test method for *A. senescens*, an endangered species, that can be flexibly applied during seed storage and ecological restoration. Furthermore, germination timing was inferred using temporal temperature data from seed collection sites, and the variability of this trait in response to climate change was predicted. We intend to incorporate these results into the BGSV database (DB) of wild species seeds.

Materials and methods

Seed information and experimental conditions

Seeds of *A. senescens* collected from the Chungcheongnam-do Forest Environment Research Institute, Korea, in 2018 were used in this study (N36.4336, E127.3721). The collected seeds were stored at -20 °C before the experiment started. Nonempty and healthy seeds were selected for experiments using a soft X-ray test (EMT-F70, Softex Co., Ltd, Japan). The seed germination rate was measured using a thermal gradient plate (TGP, ONSOL Corp., Suwon, Korea). The TGP consisted of 60 compartments with individually controlled day and night temperature conditions. The day and night lengths were both fixed at 12 h. The day and night temperatures included 10- and 6-step gradational conditions with 3 °C intervals from 7 to 34 °C and 6 °C intervals from 5 to 35 °C, respectively. In total, 60 temperature combinations were implemented. The germination rate was observed until 22 days after sowing (DAS) (3 weeks). Over 40 seeds and 4 repeats were allocated per temperature condition, including temperatures below the experimental conditions for verification and validation.

Species-specific seed vigor test

Temperature data measured every hour were used in this study. Therefore, the day and night temperatures of each temperature condition were accumulated for 12 h per day. In the first step of the species-specific seed vigor test (SSVT), the effect of day and night temperatures on seed germination was evaluated by two-way analysis of variance (ANOVA). In the second step, the relationships between temperature and the germination rate were analyzed. Temperatures affecting or not affecting germination were distinguished by correlation analysis between the germination rate and cumulative hours at each temperature, and the directions of their effects, i.e., whether they were positive or negative, were investigated. In addition, to examine the effects of temperature on germination, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_683695

standardized regression coefficient of each temperature condition was obtained by multiple linear regression analysis. In the third step of the SSVT, the cumulative score was calculated for each temperature. The largest standardized regression coefficient obtained in the previous step was set to 1, and the remaining values were converted into the ratios of the largest value. Therefore, the standardized regression coefficients, namely, the relative weights of the cumulative temperature effects on germination, were converted to a range with a maximum of 1. Nonlinear regression analysis was performed with the converted values, and the simplest equation, specifically, the one with statistical significance and an R^2 value greater than 0.9, was selected. The simplest form was selected for addition to the DB of seed vaults and seed banks. In the last (fourth) step, the temperature requirement for vigorous germination of *A. senescens* seeds was evaluated as the cumulative temperature score (TS) defined by the selected equation when the germination rate reached 85%. A germination rate of 85% is the standard rate used to evaluate seed vitality, as suggested by the Royal Botanic Gardens, Kew (Newton et al., 2009).

Verification and validation of the SSVT

For verification and validation of the SSVT, we simplified the temperature conditions irrespective of day or night. All compartments of the TGP were set at 20 °C until the first three DAS. Then, 7 gradational temperatures separated by 5 °C intervals from 5 to 35 °C were applied in accordance with each treatment. After 9 DAS, the temperature of all treatments was reset at 20 °C. Therefore, the temperature sets supplied to each treatment until 3 DAS, during 3-9 DAS and after 9 DAS were 20-5-20, 20-10-20, 20-15-20, 20-20-20, 20-25-20, 20-30-20 and 20-35-20 °C. These temperature sets were used to test the canceling effects of temperature accumulation and impact weight ratios on germination.

Verification and validation were performed from two main viewpoints. The first viewpoint was the property of 'impact weight on germination' being given to each temperature. To this end, the time it took to reach an 85% germination rate was compared with the 'impact weight on germination'. The second was the accuracy of this property in predicting the temperature requirement of *A. senescens*. To this end, differences between the actual and predicted times required to reach germination rates of 25, 50 and 75% were evaluated. In addition, the predicted germination rates were compared with the actual values according to the elapsed time.

Regional temperature data and simulation of climate change

Hourly temperature data of the sampling area were collected. According to the Korea Biodiversity Information System (Korea National Arboretum, 2019), seeds of *A. senescens* are generally sown in late October and germinate in the spring of the following year. Thus, in this study, it was assumed that the seeds were sown in late October, and the temperature accumulation started on November 1. The temperature accumulation pattern was investigated by applying the equation developed as part of the SSVT to the hourly temperature data from 1999 to 2018 in Geumsan, Korea (N36.1056, E127.4817; Altitude 173 m). In addition, the time required to achieve vigorous seed germination was considered the time when the temperature requirement of *A. senescens* was fulfilled. To simulate climate change, the elevated temperature method applied by Park et al. (2018) was used. Temperature increases of 0.5 to 6.0 °C with a 0.5 °C interval were applied to the temperature data from 1999 to 2018.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_683695

Statistical analysis

For statistical analyses, SPSS 21 (SPSS Inc., Chicago, IL, USA) and the 'fRegression' package of the R program were used.

Results

Species-specific seed vigor test

In the first step of the SSVT, the effects of day and night temperatures on the germination rate were investigated by two-way ANOVA (*Table 1*). The germination rates were not influenced by day temperature, night temperature or their combination until 3 DAS because they remained at 0% during that period. In contrast, day temperature, night temperature and their combination began to elicit changes in germination rates 6 DAS. Thus, since the supplied temperatures affected the germination rate, regardless of whether they were supplied during day or night, the following steps of the SSVT focused on temperature itself without the separation of day and night.

Table 1. *The p-values obtained from two-way ANOVA of the effects of day and night temperatures on the germination rate. The durations of both day and night were 12 h*

Days after sowing	Temperature			*N*
	Day	Night	Day * Night

In the second step, the relationship between the germination rate and temperature was investigated. In the correlation analysis results (*Table 2*), 29 °C was not related to the germination rate, but the remaining temperatures had an effect on the germination rate. Temperatures in the range of 10-28 °C increased the germination rate, but the low and high temperatures of 5, 7, 31, 34, and 35 °C reduced the germination rate by increasing the cumulative hours under those conditions. In the next step, the relative effect weights of temperatures except 29 °C on the germination rate were investigated by multiple regression analysis (*Table 2*). The standardized regression coefficient of each temperature indicates the relative weight of its effect on the germination rate. Based on the results, 19 °C had the largest effect weight, and the farther away the temperature was from 19 °C, the smaller the effect weight became. Additionally, the standardized coefficient of each temperature was converted to a ratio relative to 19 °C and combined with the effect direction, i.e., whether the effect on the germination rate was positive or negative, which was derived by correlation analysis.

Table 2. *Correlation and multiple regression analyses between germination rates and the cumulative hours within the supplied temperatures. Correlation analysis was performed for all supplied temperatures. Temperatures confirmed to be not significant in the correlation analysis were not included in the multiple regression analysis. 'Impact weight ratio' was converted based on the largest absolute value of the standardized regression coefficients, specifically, that of 19 °C*

Temperature (°C)	Correlation analysis	Multiple regression analysis	
	Correlation coefficient	Absolute value of the standardized regression coefficient	Impact weight ratio
5	-0.106**	0.092**	-0.22
7	-0.038**	0.116**	-0.27
10	0.043**	0.190**	0.45
11	0.107**	0.094**	0.22
13	0.103**	0.245**	0.58
16	0.194**	0.331**	0.78
17	0.473**	0.416**	0.99
19	0.293**	0.421**	1.00
22	0.258**	0.390**	0.92
23	0.420**	0.369**	0.88
25	0.124**	0.265**	0.63
28	0.080**	0.225**	0.53
29	-0.001ns	-	0.00
31	-0.053**	0.101**	-0.24
34	-0.079**	0.077**	-0.18
35	-0.156**	0.137**	-0.32

Nonlinear regression analysis of these converted values was performed to estimate the effect of temperature, including the non-supplied temperature, on the germination rate (*Fig. 1*). When the temperatures with a 0.1 °C interval were substituted into the derived equation, the impact weight on germination was the highest for 18.9 °C and declined gradually for increasingly distant temperatures. The impact weights of 8.0 and 29.7 °C on germination were both 0.00, which indicated that those temperatures had no influence on the germination rate, and their contiguous temperatures also had little influence. In addition, temperatures below 8.0 °C and above 29.7 °C negated the temperature accumulation for germination because they were given a negative germination impact weight. These relationships between temperature and germination were consistent with the results of the analysis of the actual supplied temperatures (shown in *Table 2*).

Temperature requirement for vigorous germination based on the SSVT

The temperature requirement for vigorous seed germination of *A. senescens* was calculated by linear regression analysis between the germination rate and TS (*Fig. 2*). The TS was the hourly accumulated 'impact weight on germination'. The temperature requirement of *A. senescens* was 294TS because the germination rate was above 85% when the TS was higher than 294.

DOI: http://dx.doi.org/10.15666/aeer/1801_683695

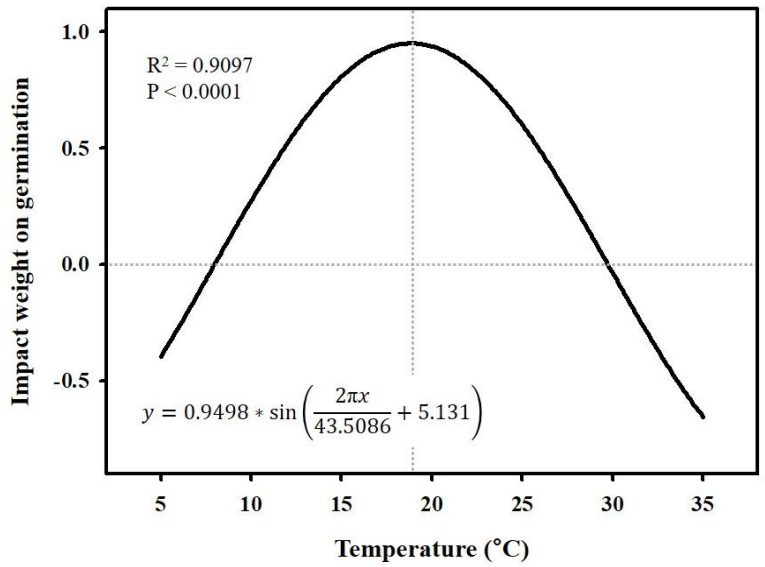

Figure 1. *Regression curve of the impact weight on germination according to temperature. The curve was derived from the standardized regression coefficient ratios*

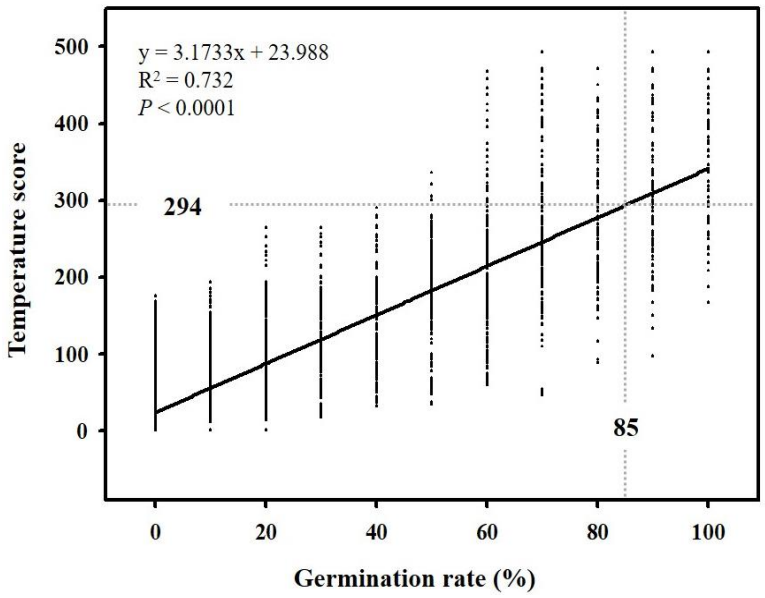

Figure 2. *Linear regression analysis between the temperature score (TS) and germination rate. The TS is the accumulated value of the hourly temperature data according to the equation in Figure 1. A germination rate of 85% was the criterion used to evaluate seed vitality, as suggested by the Royal Botanic Gardens, Kew (Newton et al., 2009)*

Verification and validation of the SSVT

A new germination test was performed to assess the validity of 'impact weight on germination' and the SSVT equation. To this end, the time required to reach an 85% germination rate in each temperature treatment was investigated (*Fig. 3A*). Since a higher 'impact weight on germination' induced earlier fulfillment of the temperature requirement, the time to reach 85% germination exhibited a hump-shaped relationship

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_683695

with 'impact weight on germination'. Germination in the 20 °C treatment, which was given the highest 'impact weight on germination', reached 85% at the earliest time, 15 DAS. The farther the temperature was from 20 °C, the more delayed the time to reach 85% germination became (in inverse proportion to the 'impact weight on germination'). This pattern was especially pronounced in the 5, 30 and 35 °C treatments, which had negative 'impact weight on germination' values: the times to reach 85% germination were over 20 DAS and noticeably delayed compared to those of the other treatments. Thus, the 'impact weight on germination' metric and the equation established as part of the SSVT for comparing temperature treatments were effective.

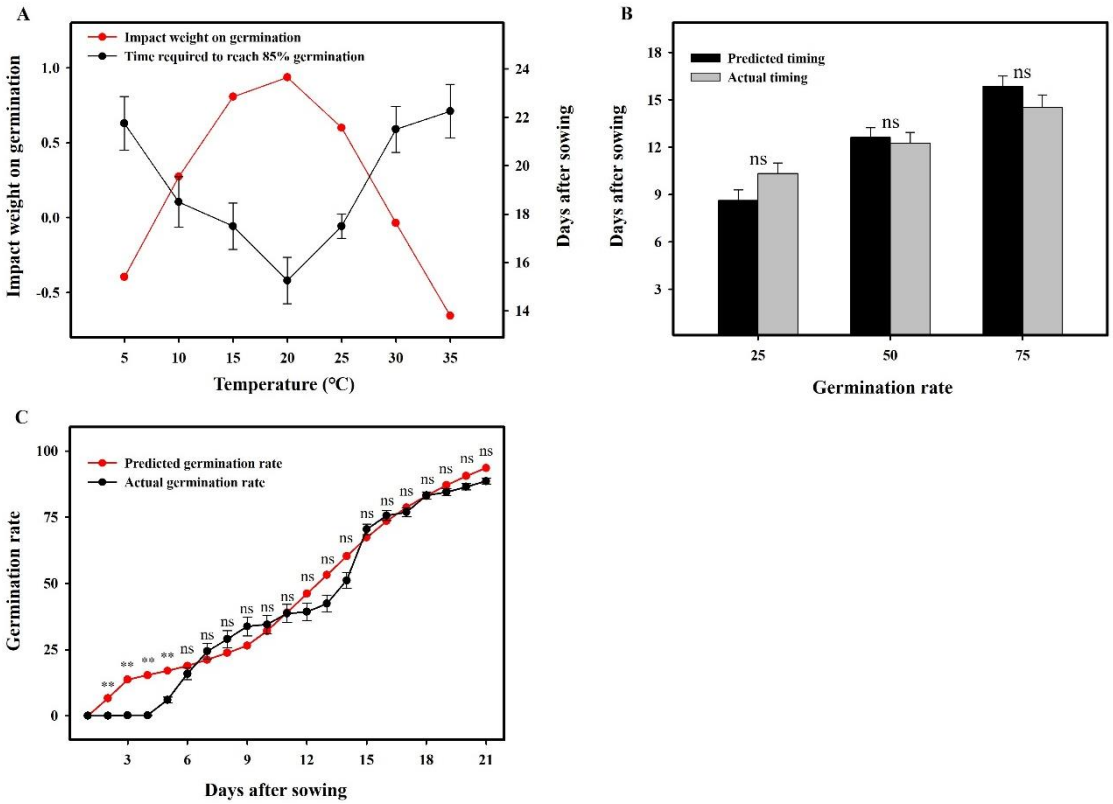

Figure 3. *Verification and validation of the species-specific seed vigor test. (A) Impact weight on germination and the time required to reach 85% germination by temperature. In the germination test used for verification, temperatures on the X-axis were supplied to each treatment 3-9 days after sowing (DAS), and 20 °C was supplied before 3 and after 9 DAS. (B) The predicted and actual times required to reach 25, 50 and 75% germination. (C) The predicted and actual germination rates with increasing DAS*

The adequacy of these methods for predicting the germination rate was also tested, which included validation of whether the temperature requirement of *A. senescens* for vigorous seed germination was correctly calculated. The predicted times to reach 25, 50 and 75% germination calculated by the regression between the TS and germination rate were compared to the actual measured times (*Fig. 3B*). The actual and predicted times to reach 25% germination were 10.3 and 8.6 DAS, respectively, differing by approximately 2 days. Discrepancies between the predicted and actual times were lowest at a 50% germination rate (0.4 days) and 75% germination rate (approximately

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_683695

1 day). Consequently, the actual and predicted times to reach 25, 50 and 75% germination rates exhibited no significant differences, even though the largest discrepancy between them was approximately 2 days.

The predicted and actual changes in the germination rate with the elapse of DAS were also compared (*Fig. 3C*). The predicted germination rates until 5 DAS were higher than the actual values because the predicted germination rates estimated by linear regression increased from the beginning, while actual germination did not start until 3-4 DAS. Overall, the predicted and actual germination rate changes over time did not differ, except during the period before 5 DAS, even though the actual values fluctuated compared to the stable predicted line. The mean value of the difference between the predicted and actual values over the whole period was 5.4%, and the mean error after 6 DAS decreased to 4.2%. Thus, prediction of the germination rate by the SSVT equation and the temperature requirement of *A. senescens* was reliable with no significant error.

Regional adaptation under climate change

The temperature requirement and SSVT equation of *A. senescens* were applied to hourly temperature data from Geumsan, Chungcheongnam-do, in the 2017-2018 season (*Fig. 4*). Seeds sown in late October 2017 did not receive sufficient temperature accumulation for germination, namely, a TS, until March 10 of the following year (a period of more than 4 months). Since the mean temperature during the period was -0.3 °C, the nonaccumulation of the TS was likely due to the negating effect of the low-temperature part of the SSVT equation. As a result, seeds sown in late October 2017 began to undergo temperature accumulation on March 10 of the following year. On April 30, 2018, the accumulated TS reached 294TS, which indicated the time of vigorous seed germination. These results supported the 'sowing in October and germination in spring of the following year' specification in the Korea Biodiversity Information System (Korea National Arboretum, 2019).

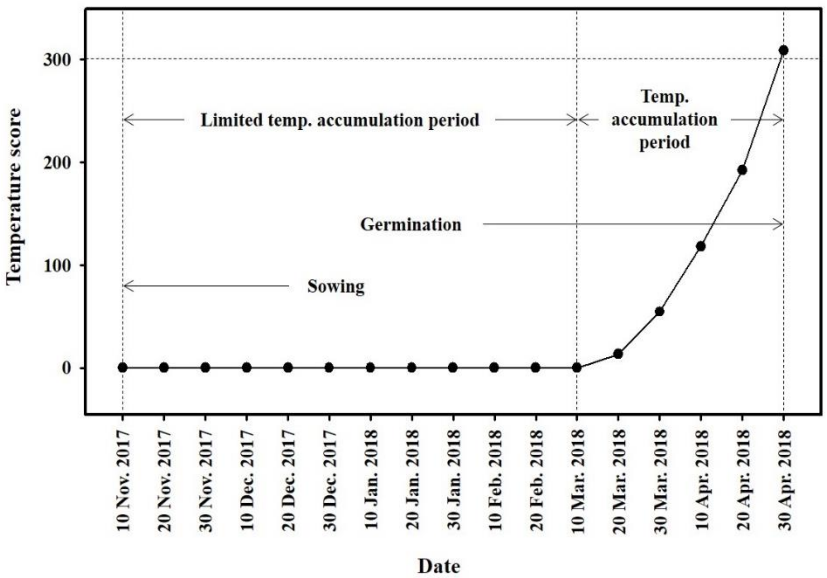

Figure 4. *Temperature score accumulation patterns of Allium senescens L. seeds during the 2017-2018 season in Geumsan, Korea. It was assumed that seeds were sown in late October based on the Korea Biodiversity Information System (Korea National Arboretum, 2019)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_683695

The effect of climate change was estimated by hourly temperature data collected from 1999-2018 (*Table 3*). The mean date of germination in 1999-2018 was May 3, and the earliest date was April 23. The more elevated the temperature was, the more the predicted date of germination advanced. If the temperature was elevated by 6.0 °C, the germination date was predicted to be more than one and a half months earlier than at present. Based on the predicted earliest date, that germination date would move forward much more rapidly. The germination date, which is April 23 at present, gradually advanced with elevated temperature until the temperature was elevated by 2.0 °C. If the temperature was elevated by 2.5 °C, the germination date was predicted to be markedly advanced to November 23. These results indicate that seeds sown in October would germinate within one month in the same year without going through winter if the temperature was elevated by 2.5 °C or more.

Table 3. *Predicted germination date of Allium senescens L. according to temperature elevation. The temperature elevations were applied to the hourly temperature data from Geumsan, Korea, collected in 1999-2018 by the method of Park et al. (2018)*

Temperature elevation (°C)	Predicted germination date	
	Mean date	Earliest date

3.5	1 Apr. ± 10.9	19 Nov.
4.0	30 Mar. ± 10.7	19 Nov.
4.5	28 Mar. ± 10.6	18 Nov.
5.0	26 Mar. ± 10.5	18 Nov.
5.5	17 Mar. ± 12.0	17 Nov.
6.0	15 Mar. ± 11.8	17 Nov.

Discussion

Temperature is a dominant factor among the diverse environmental factors that affect the rate and velocity of germination (Bellairs and Bell, 1990; Cony and Trione, 1996). Since the rate and velocity of germination vary among not only species but also genotypes of the same species, many studies investigating the effect of temperature on germination have been performed on individual species or genotypes (Acharya et al., 1983). For example, in rapeseed (*Brassica napus* L.), cold-resistant varieties maintained high germination rates under low-temperature conditions, but the germination rates of cold-sensitive varieties were markedly reduced (Luo et al., 2018).

Base temperature (T_b) is an important factor in the relationship between seed germination and temperature. T_b is the lowest temperature threshold affecting seed germination, and the process of germination is controlled by the accumulation of temperature above T_b (Batlla and Benech-Arnold, 2015). Various models have been developed to investigate T_b (Dahal et al., 1990; Steinmaus et al., 2000; Tan et al., 2017),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_683695

and T_b can be set differently because calculation methods differ among models (Luo et al., 2018). These results suggest that the selection of a suitable model is required and that model fitting for the target species must be performed. The process examined in this study might be another useful method for investigating T_b. In the present study, the temperature corresponding to T_b was 8.0 °C, and germination was accelerated by the accumulation of temperature above 8.0 °C. In contrast, temperatures above 30 °C did not accelerate germination, which suggested that another T_b, representing the highest temperature threshold, was also required. The investigation of the upper and lower limits of T_b would enable the selection of effective temperatures for germination, which could be set to 8-30 °C.

The investigation of temperatures below T_b is also important. Seed germination is an essential stage that affects the maintenance of populations and regional adaptation for ecological restoration (Qiu et al., 2010). In actual field conditions, temperatures below T_b are common, in contrast to the constant or stable temperatures above T_b that are supplied in growth chambers. If T_b is applied at a lower threshold, then the temperatures below T_b are meaningless. In this study, in contrast, temperatures below T_b negated the effect of temperature accumulation on germination. These negating effects on temperature accumulation could be utilized during seed storage. When the accumulation of effective temperature leads to germination activation, the negating effect on temperature accumulation could be used to reverse the activated state back to the stable state. Many studies have reported that low temperatures limit the metabolic processes required for germination by controlling lipid and protein mobilization and enzyme activities (Nykiforuk and Johnson-Flanagan, 1994; Hoppe and Theimer, 1997).

In addition, the existence of optimal conditions for the acceleration of germination suggested that changes in the germination rate and velocity vary among temperature levels, even in the effective range (Luo et al., 2018). This variability in germination behavior among temperatures suggests that the timing of sowing must be flexible to accommodate the thermal conditions of the target area (King et al., 1986; Russo et al., 2010). In other words, the effect of ecological restoration could be maximized by sowing seeds at the optimal time, thereby minimizing the number of days to germination. The tool predicting germination in this study was ‘temperature requirement’, which was expressed as the TS. The TS represented the influence of a temperature regime on germination, and the ‘temperature requirement’ was the hourly accumulated value of the TS to a specific criterion. In this study, the TS accumulation criterion was 85%, which was chosen to add vigorous germination information to the seed storage DB. However, the germination rate criterion can be adjusted to calculate the temperature requirement. The objectives of this study were somewhat contradictory: to determine how to stabilize seeds for long-term storage and how to activate germination for restoration when needed.

Seed vigor information is only a small part of the seed storage DB, which includes diverse information, such as the weight and size of seeds, collection site and timing, and donating country or institution. Thus, we tried to input information that was simple but useful and diverse into the seed storage DB. The ‘impact weight on germination’ equation and ‘temperature requirement’ derived by the SSVT were entered into only two boxes in a small section of the seed storage DB. However, these conditions provide various types of information, such as the optimal and effective temperature ranges accelerating germination, the conditions that negate effective temperature accumulation and the time required to reach the ideal germination rate. Furthermore, this

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_683695

formularization and quantification of the relationship between germination and temperature can be utilized in various ways. The estimation of the climate change effect performed in this study is only one example. Preferentially, ecosystem destruction and extinction should no longer occur. We anticipate that the results of this study on germination temperature and climate change effect estimation will be utilized as fundamental information in the preparation of stored seeds for restoration.

Conclusion

In this study, the effective or positive temperature range for germination of *A. senescens* was set, and the impact weight on germination by temperature levels was evaluated. Furthermore, the temperatures that negated the temperature accumulation for germination were verified. Since the SSVT equation was compared to the actual temperature data in the field, it was possible to predict the changes in germination timing. In general, temperate plants need to accumulate low-temperature effects to break their dormancy, and germination would begin only under this condition. Concretely, it was reported that seeds of *A. senescens* need a chilling period longer than 427 h at temperatures below 5 °C (Suh et al., 2005). Thus, it could be regarded that the changes in germination timing resulting from increased temperatures would occur for only the stored seeds in the low temperature range, as observed in this study. Self-sown seeds in the field may be more seriously affected by climate change than the seeds stored at low temperatures during certain periods. The period for vernalization by low-temperature accumulation required for dormancy release would be shortened due to the elevated temperature. If the chilling requirements of *A. senescens* are not fulfilled, the germination of seeds would become virtually impossible. These facts suggest that both temperature conditions for vernalization and germination must be considered together to more precisely predict the effects of climate change. In fact, the results of studies that examined both the chilling required for dormancy release and the temperature accumulation to germination are being reported on not only the seeds but also the buds of temperate plants (Park and Park, 2019).

Meanwhile, this study had modeling limitations that were aimed at seed storage and ecological restoration at the same time. If seed storage is then aim, further studies on actual storage conditions below 5 °C, which were examined in this study, should be performed. In contrast, if the final objective is ecological restoration, detailed habitat conditions such as soil characteristics and incline direction should also be considered.

Acknowledgements. We are very grateful to the Chungcheongnam-do Forest Environment Research Institute for providing seeds. This work was supported by a National Research Foundation of Korea (NRF) grant funded by the Korean government (MSIT) (No. NRF-2017R1D1A1B03034615).

Abstract. Puszcza Zielonka Landscape Park (PZLP), located in western Poland is an area under the constant pressure of urbanization processes occurring in the zone of influence of the Poznań urban agglomeration. The park was established in 1993. The protected area is surrounded by built-up areas, which interrupt the continuity of wildlife corridors. The park and its buffer zone are located in six communes, which have their own spatial policies. The aim of the article was to determine changes in the trends, scale and rate of investments in the park and its buffer zone, expressed by changes in the land cover and use, which have taken place since the establishment of the park. These changes were considered important factors affecting the state of protected natural values and defining the effectiveness of protective instruments. The study included an analysis of the spatial policy of the communes expressed in Study of the Conditions and Directions of the Spatial Management (SCDSM) and its compliance with the Park protection trends indicated in the Protection Plan. The analyses were carried out with GIS tools. The results showed conflicts between the intended changes in land development expressed by local governments and the park protection objectives.

Introduction

According to the Nature Conservation Act (2004), a landscape park is a largescale form of nature conservation created for natural, historical, cultural and scenic values so as to preserve and popularise them with respect to sustainable development. 131 landscape parks have been established in Poland. They occupy a total area of about 2.61 million ha, i.e. 8.3% of the area of Poland and 2% of the protected area system. So far 13 landscape parks have been established in Greater Poland (Wielkopolska). They occupy a total area of 179,870.60 ha. A landscape park is a form of protection of natural and scenic values which does not involve restrictive protective provisions. Business activities are allowed in landscape parks and their buffer zones. They are only partly limited by specific regulations. This is in line with the concept of active protection, but simultaneously, it may cause different conflicts and threats. The continuous loss of

DOI: http://dx.doi.org/10.15666/aeer/1801_697712

biodiversity and unfavourable changes in the natural environment, which are globally observed, are mostly caused by human activities such as intensive agricultural production, urbanization and infrastructure development, which lead to overexploitation of natural resources and degradation of the environment. These problems also affect particularly valuable areas, including protected areas. The need to combine the objectives of nature conservation and environment protection with the objectives resulting from the need for socioeconomic development and the needs of local communities is a significant challenge all over the world (Dimitrakopoulos et al., 2010; Bicknell et al., 2017; Lopez-Bao et al., 2017; Weaver and Lawton, 2017; Atmis, 2018).

Urbanization is thought to be the second (after agricultural production) most unfavourable factor exerting pressure on natural ecosystems, but it has the most degrading and the longest-lasting effects (Treby and Castley, 2016). It may cause the loss, fragmentation or isolation of valuable ecosystems (including forests) (Bradshaw, 2012) and the declineing ecological stability (Muchová and Tárníková, 2018) the loss of open spaces (including agricultural areas) as well as increased environmental pollution, especially water (Maheshwari and Bristow, 2016), air and soil (Zhang, 2016). It may also limit biodiversity, threatening numerous species of plants and animals (Hamer and McDonnell, 2008; Border et al., 2017). The dynamic development of cities increases the urbanisation pressure exerted on protected areas (McDonald et al., 2009).

Changes induced by urbanization and manifested by the development of buildings in Puszcza Zielonka Landscape Park, located in Greater Poland (Wielkopolska) near the city of Poznań and, above all, in its buffer zone were the subject of research presented in this article. These changes are considered a significant factor affecting the state of protected natural values and determining the effectiveness of protective instruments, especially those related with spatial planning. The aim of the original research was to determine changes in the trends, scale and rate of investments in the park and its buffer zone, expressed by changes in the land cover and use, which have taken place since the establishment of the park. The study included an analysis of the spatial policy of the communes expressed in Study of the Conditions and Directions of the Spatial Management of a Commune (hereinafter SCDSM) and its compliance with the Park protection trends indicated in the Protection Plan.

Study area and methods

Puszcza Zielonka Landscape Park, established in 1993, hereinafter referred to as PZLP, is located about 30 km northeast of the city of Poznań (*Fig. 1*). There is about 120.4 km^2 of protected area, which is mostly covered by forests. There are a few villages and hamlets located within the boundaries of PZLP (Kamińsko, Pławno, Tuczno, Zielonka, Głęboczek, Łopuchówko, Gać, Dzwonowo, Dąbrówka Kościelna). Apart from buildings, there are some small meadows, wastelands and cultivated lands in these places. The terrain also includes numerous ribbon lakes, which make the park particularly attractive to tourists. There are often recreational buildings near the lakes. They are mostly concentrated on Lake Kołatkowskie and Lake Tuczno in the village of Tuczno, and on Lake Miejskie in the village of Kamińsko.

The park is surrounded by a buffer zone, which occupies an area of about 97.8 km^2. The buffer zone terrain mostly includes arable lands, enclosures and suburban single-family buildings. The biggest settlements located in the PZLP buffer zone are: Kicin, Owińska, Bolechówko, Rakownia and Boduszewo.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_697712

The park area is located in the communes of Czerwonak, Skoki, Murowana Goślina, Kiszkowo, and Pobiedziska (part of the buffer zone is also located in the commune of Swarzędz) and in the counties of Poznań, Wągrowiec and Gniezno. The largest part of PZLP is located in the commune of Murowana Goślina and occupies an area of nearly 6,200 ha. The smallest part of the park is located in the commune of Kiszkowo, with about 360 ha of protected areas. More than a half of the buffer zone area is located in the communes of Czerwonak and Pobiedziska (2,870 ha and 2,500 ha, respectively). The smallest part of the buffer zone area is in the commune of Skoki – 870 ha (the author's calculation).

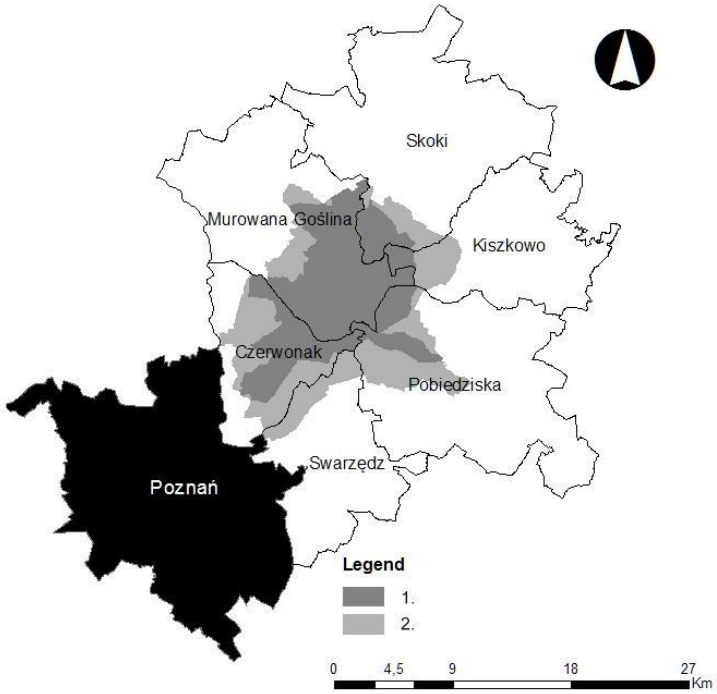

Figure 1. *The administrative location of Puszcza Zielonka Landscape Park with its buffer zone: 1. Puszcza Zielonka Landscape Park, 2. The buffer zone of Puszcza Zielonka Landscape Park*

The ArcGIS 10.5.1 version was used to investigate changes in the terrain occupied by the park and buffer zone. The rate and scale of transformations was observed at three chosen momens: first – in the past (1989); second – the current state (2017) and third – in the future, showing the changes predicted on the basis of planning documents. The first interval refers to the period before 1993, when the park was established. Data for this period were obtained by the digitalization of archival topographic maps scaled 1:25,000, which were imported by the WMS service. The maps were made between 1962 and 1989. Presented maps and data show distribution of the different land use types. We assumed a small scale of changes that took place at that time due to investment limitations before the transformation of the political system in Poland in 1989. The second time interval covers the changes which have taken place since the park was established and which were registered on the basis of current (2017) orthophoto maps (geoportal.gov.pl). Presented data and maps show distribution of the different land use types in about 2017 year. Next, the Study of the Conditions and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_697712

Directions of the Spatial Management of individual communes located in the Park and its buffer zone were studied to make a forecast of possible changes in the land cover and use. Local Spatial Management Plans were not taken into account due to the fact that these documents covered only a small part of the area under study.

As there were different thematic layers in the SCDSM of individual communes, it was necessary to simplify the provisions in them and adapt them to the terrain typology assumed in this article so as to identify and make a synthetic record of changes. The following 9 types of land cover were distinguished: (1) forests, (2) trees (mid-field afforestations, wastelands overgrown with trees, lanes of trees along watercourses), (3) surface waters, (4) meadows and pastures, (5) arable land, (6) permanent crops, (7) residential, recreational and service buildings, (8) storage and industrial areas, (9) roads. Then, the area was measured according to the aforementioned typology, allowing for the assumed research periods. The rate of dynamics of variation in the land cover was calculated according to the following formula developed by the authors (Gałecka-Drozda et al., 2019), where the data for 1989 were assumed as the starting point (*Eq. 1*).

$$R_{dvlc} = \left(\frac{Ca\ or\ Fa}{Ia} * 100\%\right) - 100\% \quad \text{(Eq.1)}$$

where:
Rdvlc – the rate of dynamics of variation in the land cover [%];
Ca – the current area [ha] (data from 2017);
Fa – the forecast area [ha] (based on Studies of Conditions and Directions of the Spatial Menagement);
Ia – the input area [ha] (areas used as reference for other periods under analysis, data from 1989).

The results of investigations made at the three time intervals were presented in a standardised graphic form, which enabled a comparison of changes in the land cover and use during the entire research period. Changes in the park and its buffer zone were analysed separately. The research also included a comparative analysis of the spatial policies in individual communes based on the provisions included in SCDSM. Next, the provisions were compared with the recommendations included in the PZLP Protection Plan.

Content of Puszcza Zielonka Landscape Park Protection Plan

Following Art. 19 Para. 6 of the Nature Conservation Act of 16 April 2004 and in order to stop unfavourable processes occurring in PZLP the Park authorities prepared the Park Protection Plan (Puszcza Zielonka Landscape Park Protection Plan, 2005). 8 functional and landscape zones were identified in PZLP and its buffer zone. Orders and prohibitions regarding the conservation of resources were formulated for 5 zones, located within the Park. Recommendations concerning the economic use and space management were made for 3 zones located in the buffer zone.

Tasks, orders and prohibitions were formulated within the zones. Their aim was to conserve nature and protect landscape, allowing for sustainable development, without complete exclusion of business activity from the PZLP area. Recommendations related to the functioning of the zones should be transferred to the planning documents of municipalities in the Park. The protection plan included 37 arrangements concerning the elimination or limitation of external threats, which were included in the study of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_697712

conditions and directions of the spatial management in communes, local spatial management plans and the voivodeship spatial development plan. Most provisions in the Park Protection Plan concern the limitation of urbanization pressure in PZLP and its buffer zone, for example by leaving undeveloped strips of land along the forest border and lake shores, by avoiding the scattering of buildings and locating them in areas without the infrastructure, by not separating new building plots in particularly valuable areas, including river valleys.

Results

Analysis of spatial policy of communes based on Study of the Conditions and Directions of the Spatial Management

The SCDSM of the communes located in PZLP and its buffer zone include declarations to protect the values due to which the park was established. However, the main goals of the spatial policy of communes are not always consistent with the objectives of PZLP protection, although all the SCDSM that were made after the Park Protection Plan refer to these documents. The functional and spatial zones and recommendations for them were transferred directly from the Park Protection Plan to the SCDSMof Murowana Goślina, Skoki and Swarzędz. The plans also include provisions which are beneficial to the Park protection. These provisions recommend the concentration rather than dispersion of buildings (Study of the Conditions and Directions of the Spatial Management of the Commune of Pobiedziska, 2011; Study of the Conditions and Directions of the Spatial Management of the Commune of Kiszkowo, 2012; Study of the Conditions and Directions of the Spatial Management of the Commune of Murowana Goślina, 2012), their location in places with adequate infrastructure (Study of the Conditions and Directions of the Spatial Management of the Commune of Pobiedziska, 2011), the will to inhibit space and environment degradation caused by uncontrolled development of holiday and residential buildings (Study of the Conditions and Directions of the Spatial Management of the Commune of Murowana Goślina, 2012). However, this did not prevent the provisions which allowed enlargement of built-up areas in the Park and the buffer zone. These areas became larger in all of the aforementioned communes, but to a different extent. In some communes the enlargement of built-up areas written in the SCDSM was moderate in relation to the areas belonging to the Park, whereas intensive building development was planned in areas of lower natural and scenic value, e.g. in the communes of Skoki, Swarzędz, and Czerwonak (including the repealed SCDSM of the Spatial Management (2010)).

During the period under study the commune of Czerwonak used the SCDSMadopted in 2000 and 2010 (Study of the Conditions and Directions of the Spatial Management of the Commune of Czerwonak, 2000, 2010). However, the sentence passed by the Provincial Administrative Court in Poznań in 2014 annulled the resolution concerning the newer variant of the document with more beneficial provisions referring to the protection of natural values in PZLP (Study of the Conditions and Directions of the Spatial Management of the Commune of Czerwonak, 2000, 2010).

Analysis of changes in land cover in Park and its buffer zone

At present more than 85% of the Puszcza Zielonka Landscape Park area is covered by forests (*Table 1*).

* initial state – areas used as reference for other periods under analysis

Meadows, pastures and arable lands cover about 5% of the Park area. The share of built-up areas is small – 1.35% of the Park area, i.e. 162.5 ha. The comparison of the current state with the state before 1989 revealed slight changes. The forest area

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_697712

increased by over 200 ha (less than 2% of the total PZLP area), whereas the farmland area decreased (the area of meadows and pastures decreased by about 130 ha, whereas the area of plantations decreased by about 150 ha). At the same time, the built-up area increased by 68 ha (from 0.8% to 1.35% of the total area of the Park).

As results from the SCDSM of the communes belonging to the Park, the forest area will increase slightly, i.e. by about 16 ha, whereas the total farmland area may decrease by about 240 ha. The built-up area will increase by 221.4 ha (from 1.35% to 3.19% of the total PZLP area). The area of new buildings will significantly exceed the area that is currently occupied by buildings (*Fig. 2*). The areas of new investments are concentrated in Dąbrówka Kościelna (the commune of Kiszkowo) and in Tuczno (the commune of Pobiedziska). The areas of other building investments are scattered around the existing villages and hamlets in the Park.

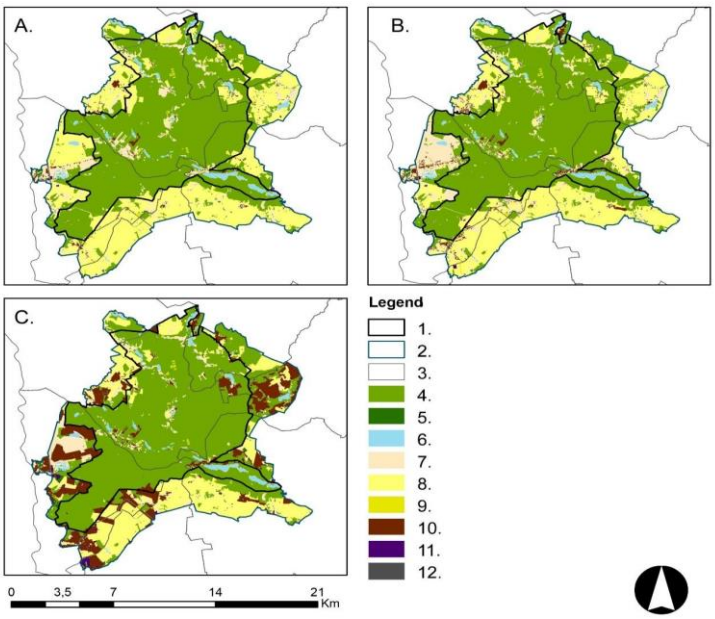

Figure 2. *Changes in the land cover of Puszcza Zielonka Landscape Park and its buffer zone (A. Before 1989, B. Current state 2017; C. Forecast based on the Study of the Conditions and Directions of the Spatial Management; 1. Puszcza Zielonka Landscape Park, 2. Puszcza Zielonka Landscape Park buffer zone, 3. Commune boundaries, 4. Forests, 5. Trees, 6. Surface waters, 7. Meadows and pastures, 8. Arable land, 9. Permanent crops, 10. Residential, recreational and service buildings, 11. Storage and industrial areas, 12. roads)*

At present the Park buffer zone is agricultural, as plantations, meadows and pastures occupy almost 70% of the area. The share of forests amounts to 25%. Built-up areas occupy about. 430 ha, i.e. about 4.4% of the land cover. Since the end of the 1980s the area of arable land has decreased by almost 1,300 ha. It was mostly transformed into meadows and pastures, the area of which has increased by almost 790 ha. These changes resulted from the progressive fallowing of arable land, which is a common phenomenon in areas under high investment pressure. The forest cover in the buffer zone has increased by nearly 260 ha (from about 22% to 25% of the total area). The share of built-up areas has increased by more than two times (by 230 ha, from 2% to 4.4% of the total area). According to the SCDSM, the area occupied by residential, recreational and service buildings may increase. It may ultimately cover 25% of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_697712

buffer zone, having increased by almost six times (by 2,026.23 ha). New building investments are planned in farmlands. The share of farmlands may decrease from 50.5% to 37.5% of the total buffer zone area, whereas the share of meadows and pastures may decrease from 17.5% to 9%.

Residential, recreational and service development was the main focus of the analysis of changes in the use of space in the Park and its buffer zone in individual communes (*Table 2*). The greatest changes were observed or forecasted in these types of land cover. Differences in the farmland area were also significant, but they were closely related to changes in built-up areas, so they were not described in detail.

* initial state – areas used as reference for other periods under analysis

The distribution of changes in the land cover (mostly the enlargement of developed areas) in individual communes in PZLP and its buffer zone was uneven. Since the late 1980s the most buildings have appeared in the communes of Poznań County: Murowana Goślina (increase by 30 ha), Pobiedziska (increase by 26.5 ha) and Czerwonak (increase by 8 ha). The analysis of changes in relation to the area of communes located in the Park shows that they were the least favourable in Pobiedziska, where 1.74% of the commune area belonging to the park was occupied by new buildings. In the communes of Murowana Goślina and Czerwonak the areas belonging to the park and occupied by new buildings amounted to 0.49% and 0.28%, respectively.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_697712

In the commune of Kiszkowo the areas with investments increased only by 3 ha. There was no change in the commune of Skoki. The increase in built-up areas in particular communes was correlated with their location in relation to Poznań. The changes were the smallest in the communes which were the most distant from the city limits.

According to the SCDSM, the biggest changes in built-up areas located in the Park can be expected in the commune of Kiszkowo, where the area of new investments may increase by nearly 100 ha, i.e. by about 45% of all newly built-up areas in PZLP. It is a very high increase because the area occupied by the Park in this commune is the smallest (almost a third of this area may be developed). According to the SCDSM of the Commune of Kiszkowo, large areas will be used for housing development and some areas will be used for tourist and recreational development. The development area in the commune of Czerwonak may increase by almost 70 ha (in comparison with Kiszkowo it is a slight increase, i.e. a fortieth of the commune area located in the Park). Also, according to the SCDSM of this commune, large areas were allocated for the development of 'tourist services' (understood as tourist and recreational services), but only some of them can be used for building development, including recreational buildings. The potential increase in the area of investments in the Park located in the communes of Murowana Goślina and Pobiedziska is very similar, i.e. over 21 ha. However, as far as the area of communes located in PZLP is concerned, the situation is much better in the commune of Murowana Goślina, where new developments may occupy 1/285 of the commune area belonging to the Park, whereas in the commune of Pobiedziska it will be a 1/17 of the Park area. The smallest increase in the area of new developments can be expected in the commune of Skoki, i.e. about 8.5 ha, which is 1/127 of the Park area. (*Fig. 2*).

The distribution of changes in individual communes in the Park buffer zone was different than in PZLP. Between 1989 and 2017 the largest amount of new developments was observed in the commune of Czerwonak (more than 100 ha), which was under the greatest influence of Poznań, and in the commune of Murowana Goślina (about 43 ha). In both communes it was an increase of about 3.7% of the area located in the buffer zone. In the commune of Skoki the increase amounted to about 3% (the area of new developments increased by 26 ha). Surprisingly, during the period under analysis the smallest amount of building developments in the Park buffer zone was observed in the commune of Swarzędz (only 3 ha), which is also strongly influenced by Poznań. The analysis of SCDSMof the commune showed that the potential areas of building developments were planned at other locations.

The greatest changes in the area of building developments in the Park buffer zone are forecasted in the commune of Czerwonak, where according to the SCDSM, almost 1,000 ha of new investments can be expected, which amounts to more than 48% of all new development areas in PZLP and nearly a third of the commune area in the Park buffer zone. In view of the Park protection aims, the provisions of the SCDSM of the Commune of Kiszkowo are the least favourable, where the increase in the area of new buildings concerns almost half of this area (about 540 ha). The potential increase in building development areas in the communes of Murowana Goślina, Pobiedziska and Swarzędz is very similar and amounts to 142, 163 and 160 ha, respectively. The Park buffer zone located in the communes of Murowana Goślina and Swarzędz occupies about a seventh of their areas, whereas in the commune of Pobiedziska it is a fifteenth of the area. The increase in development areas was the smallest in the buffer zone

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_697712

located in the commune of Skoki (similar to that for the PZLP area) and amounted to 65 ha, i.e. about a thirteenth of the commune area being the buffer zone of the Park.

Discussion

The rapid global urban development decreases the distance between urban and protected areas. McDonald et al. (2009) proved that in many regions it was shorter than 50 km, so urban areas may significantly affect protected areas. Intensified urbanization is also noticeable in PZLP and the Park buffer zone, which are located closest to the city limits of Poznań. Agricultural landscape still prevails in the northeast of the Park buffer zone. On the other hand, urbanization is the strongest in the southern and western parts of the Park buffer zone, where it is manifested by progressive increase in built-up areas, as compared with the time when the Park was established, and its further development, as provided in the SCDSM.

The administrative conditions of the Park and its buffer zone do not favour the protection of natural and scenic values. This space is managed by six communes which implement their own spatial policies with different assumptions. Although they undertake many joint activities in the fields of tourism and water and wastewater management and they cooperate within the Puszcza Zielonka Intercommunal Union, but the planning activities of individual communes are not coordinated. In practice, the declared intentions to protect natural values turn out to be in opposition to specific provisions of SCDSM of these communes. In consequence, it may increase urbanization in the Park and its buffer zone, even in the zones that were designated in the Park Protection Plan for protection against urbanization pressure. From the point of view of the goals of PZLP protection, the commune of Murowana Goślina as well as the communes of Skoki, Pobiedziska and Czerwonak have the most favourable spatial policies concerning construction areas. The scale of the growth of new buildings in the commune of Kiszkowo is incomparable with other communes and it is inconsistent with the assumptions of PZLP protection.

On the other hand, the most favourable spatial policy of protection of the Park buffer zone is led by the communes of Pobiedziska, Skoki, Swarzędz and Murowana Goślina. According to the SCDSM, the largest increase in new building developments can be expected in the communes of Kiszkowo and Czerwonak. Geldmann et al. (2015) stressed the importance of monitoring the management of protected areas. The assessment of the effectiveness of protective activities enables evaluation of the strengths and weaknesses of this process and helps to improve it. It also applies to conservation activities implemented at the lowest communal level of spatial planning in Poland.

The creation of buffer zones is a commonly used method to protect valuable natural areas. Studies conducted by Lima and Ranieri (2018) in Brazil showed that protection plans usually set recommendations rather than detailed rules for the use of buffer zone resources. Apart from that, individual SCDSM were inconsistent as regards spatial development in buffer zones around protected areas. The results of this study indicate that the use of a buffer zone as an effective strategy of management of protected areas requires detailed arrangements between the managements of protected areas and local governments responsible for land use planning. Otherwise, the establishment of a buffer zone can only be a symbolic action, without any practical influence on the preservation of values and the functioning of the protected area.

DOI: http://dx.doi.org/10.15666/aeer/1801_697712

The author's original research led to the conclusion that the presence of the PZLP buffer zone did not always isolate the Park from unfavourable spatial phenomena because the spatial policies of individual communes located in PZLP and its buffer zone were not always consistent with the Park protection goals. It is particularly worrying that according to the SCDSM, the commune governments have allocated such a large area of protected land for building developments. Different approaches of the communes to the spatial policy concerning valuable natural areas might indicate that not all local governments are aware of the significance of the existing values and the consequences of their loss. It is beneficial for the Park protection that according to the Studies of the Conditions and Directions of the Spatial Management (e.g. of Czerwonak (2010), Swarzędz (2011), Skoki (2010)), the local governments have allocated urbanized zones or strips for building developments outside the protected area and its buffer zone, in other parts of the communes. A similar solution was used in SCDSM of the commune of Pobiedziska (2011). However, a significant increase in housing and recreational investments in the Park and its buffer zone shows that the commune authorities have not been consistent in the implementation of this goal. Urbanization pressure is a commonly observed phenomenon also in other protected area in Poland (Wycichowska, 2008; Warczewska and Mastalarska-Cetera, 2011; Krajewski, 2014). Grochowska (2015) noted in Walbrzych Sudets Landscape Park the dispersion of buildings beyond shaped settlement systems and investment pressure directed at the most attractive landscapes and the expansion of summer construction, which is a result of improperly conducted municipal spatial policy.

As results from the SCDSM of Czerwonak, the situation is not good for the Park protection. In 2010, the authorities attempted to adopt a new Study. However, the sentence passed by the Provincial Administrative Court in Poznań in 2014 annulled the resolution of the Commune Council. In the new version of the document, the area of building developments was smaller than in the previous version, especially in the 'Forest Strip' and 'Open Landscape Strip', which covered the area of PZLP and its buffer zone. In contrast to the previous version of the SCDSM, according to the new version, one of the landowners was deprived of the right to build up plots in the village of Annowo, so he decided to go to court. The aforementioned areas were found to have natural and scenic values and were to be protected as the Annowo Meadows Protected Landscape Area. The sentence passed by the Provincial Administrative Court in Poznań in 2013 annulled also the resolution of the Commune Council in the matter of Annowo Meadows Protected Landscape Area creation, passed in 2008 (Environmental Protection Plan, 2013).

It is important not only to protect the Park area, but also to develop its connections with neighbouring valuable natural and protected areas such as: Promno Landscape Park, Natura 2000 areas (the Mała Wełna River Valley near Kiszkowo PLB300006, Biedrusko PLH300001, Kiszkowo Ponds PLH30_27, Biedrusko PLH300001), Biedrusko Protected Landscape Area, Lednica Landscape Park. The development of an ecological network combining valuable habitats into a system and preventing their fragmentation is considered to be one of the essential and most effective ways to protect biodiversity and preserve the stability of ecosystems (Closset-Kopp et al., 2016; Gonzalez et al., 2017; Fardila et al., 2017; Yang et al., 2017; Fletcher et al., 2018). One of the trends in nature conservation is to develop large-scale spatial systems consisting of protected areas, which are supplemented and connected by surrounding areas (Shwartz et al., 2017). The isolation of protected areas from their surroundings by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_697712

building developments, which may destroy the existing links with neighbouring valuable natural areas and prevent the creation of such links in the future, is a negative effect of the urbanization of the areas surrounding PZLP (*Fig. 3*).

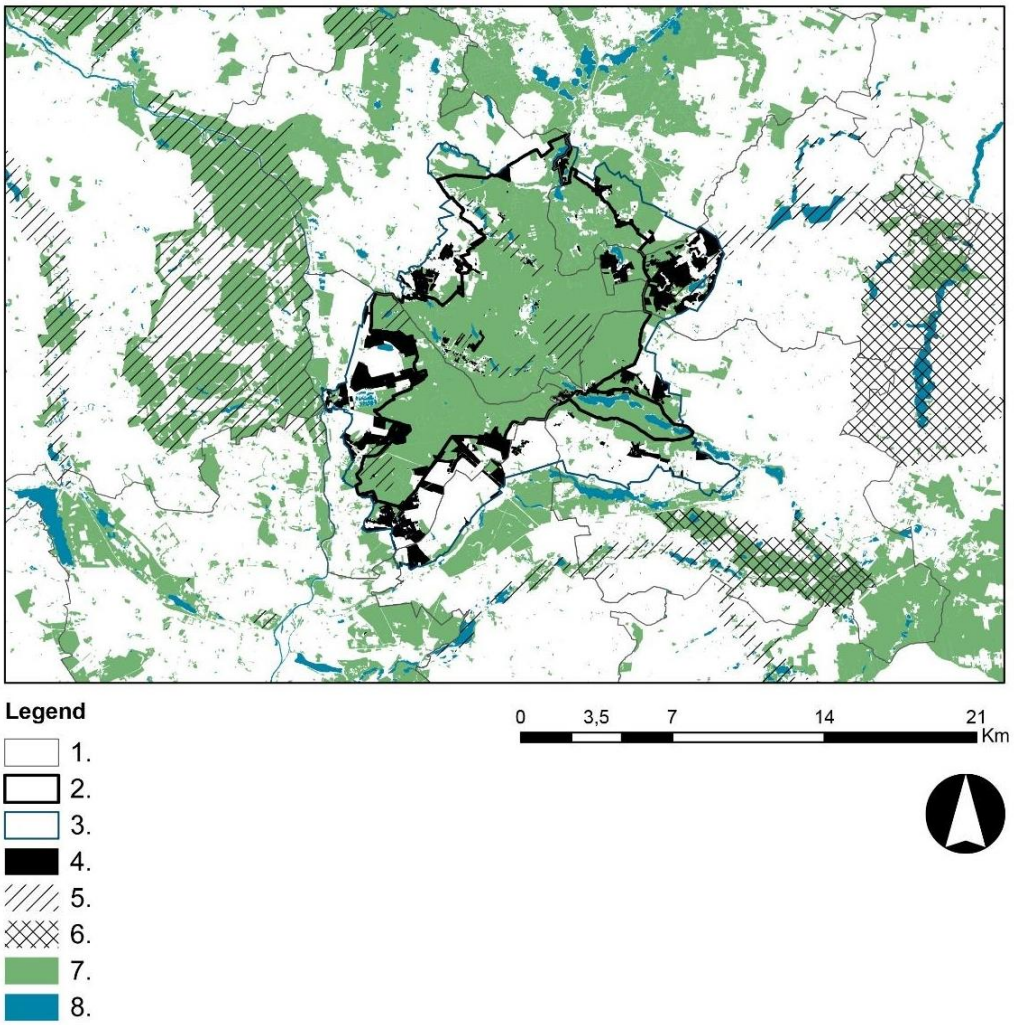

Figure 3. *Areas for building developments in the Study of the Conditions and Directions of the Spatial Management of the communes vs. natural and protected areas in the surroundings of Puszcza Zielonka Landscape Park and its buffer zone (1. Commune boundaries, 2. Puszcza Zielonka Landscape Park, 3. Buffer zone, 4. Building development areas in the Park and its buffer zone according to the Study of the Conditions and Directions of the Spatial Management of the communes, 5. Natura 2000 areas, 6. Landscape parks, 7. Forests, 8. Open waters)*

The problem particularly concerns the Park buffer zone, because it is subject to stronger urbanization pressure. As Xun et al. (2017) indicated, there is also an urgent need to protect or restore natural habitats located beyond directly protected areas so as to maintain the functional connection of habitat networks. In the past researchers indicated the problem of destruction of natural connections in PZLP by building developments, which enclosed forests with a ring (Raszka, 2010). Spatial planning tools give a possibility to create ecological networks (Szulczewska, 2004). However, as results from the research, not all communes are able and willing to use these tools. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_697712

problem of destruction of the continuity of valuable natural areas by building developments is most likely to affect the southwestern part of the Park buffer zone, which has links with the Warta River valley and the protected area on the other riverbank within the Biedrusko range. It is also likely to affect the eastern part, where Promno Landscape Park and Natura 2000 areas in the Wełna River valley are located near the Park buffer zone (*Fig. 3*).

Conclusions

Since the 1990s there have been changes in the land cover in Puszcza Zielonka Landscape Park. The forest area has increased slightly, the farmland area has decreased, and the share of built-up areas has increased. At the same time, there have been changes in the PZLP buffer zone. The area of arable land has decreased, the area of meadows, pastures and forests has increased whereas there has been a significant, more than a double increase in built-up areas. The observed changes show that this area is under the pressure of urbanization.

In the last twenty years there have been irregular changes in the land cover caused by the separation of new construction sites in individual communes located in PZLP and its buffer zone. Since the late 1990s the most buildings have appeared in the communes located in Poznań County due to the influence of the big city on the scale and rate of urbanization processes.

The analysis of the Studies of the Conditions and Directions of the Spatial Management of the communes located in the Park and its buffer zone showed the continuation of current spatial development trends, i.e. a slight increase in the forest area and an intensive growth of built-up areas at the expense of farmland. These changes are irregularly distributed around the area of six communes located in the Park and its buffer zone. It shows that individual local governments have different approaches to natural and spatial resources in their spatial policies.

The so-far collected materials suggest that further investigation into the pressure of urbanisation processes on protected areas is needed. Therefore, extending the research to other protected areas is recommended. Another prospect for further research is also to investigate the influence of local planning documents over landscape protection. Monitoring changes in the use of protected areas is also an important task for the future. Following existing trends in spatial development gives the opportunity to correct municipal spatial policy before it leads to irreversible losses of environmental and landscape resources. It would also be useful to follow trends in spatial development of the larger number of protected areas.

(Received 16th Jun 2019; accepted 16th Oct 2019)

Abstract. Citrus is one of the most promising fruit crops of Pakistan owing to its delicious taste and excellent aroma. Kinnow being a promising variety has a significant importance in the global market. Pakistan is facing a drastic reduction in Kinnow mandarin quality due to improper postharvest management and hence severe losses regarding quality and shelf life which might be up to 40%. The aim of this study was to find some alternative botanical product against chemical (fomesa) wax and fungicide to extend the shelf life of Kinnow mandarin. Fruits were treated with fomesa wax, 30% coconut oil, 60% aloe vera extract and Thiabendazole (TBZ) with standardized doses and stored at 5°C for 90 days. It was observed that 30% coconut oil performed almost at par to commercial wax and better than all other treatments. The fruits treated with 30% coconut oil showed minimum weight loss (11.70%), fruit rot (5.83%), maximum juice weight (42 g), biochemical parameters such as total soluble solids (10.90°Brix), titratable acidity (1.09%), ascorbic acid contents (40 mg 100 g^{-1}), total sugars (16%), maximum total antioxidants (70% inhibition) and maximum enzymatic activity [catalase (18.10U mg^{-1} protein), peroxidase (0.79U mg^{-1} protein) and superoxide dismutase (133.93 U mg^{-1} protein)] of Kinnow fruits which were stored up to 90 days. It was concluded from the present study that pre storage treatment of 30% coconut oil was the most effective to reduce decay losses and maintain the fruit quality during 90 days storage.
Keywords: *wax & fungicide, postharvest losses, coconut oil*

Introduction

Citrus is ranked first among fruit crops, consisting almost 40% of fruits being grown in Pakistan, and enlists the country amongst top 15 producers of the world. The Kinnow is the extensively cultivated variety of citrus fruit and a common name of mandarin (*Citrus reticulate* L.) in Pakistan. The Kinnow grown in this region is a result of cross between King *Citrus nobilis* and *Citrus deliciosa* of Riverside California and is the principal citrus commercial cultivar. In Pakistan, Kinnow mandarin occupies imperative position among fruits (Siddique and Garnevska, 2018). In Pakistan, Kinnow export increased tremendously 2017-18 and touched a record of 370,000 tons compared to the previous year (Trade Development Authority of Pakistan, 2018).

Main Kinnow growing areas of Pakistan are Sargodha, Faisalabad, Bhalwal, Toba Tek Singh, Mandi Bahauddin and Sahiwal. Sargodha share 95% from total production of citrus in country (GOP, 2015). Kinnow is a good source of vitamin C, carbohydrates (fructose, glucose and sucrose), also having significant magnesium and calcium quantity. Similarly, Citrus fruits also have significant amount of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_713729

phytochemicals (monoterpenes, limonoids and flavonoids, carotenoids) which help to reduce the chance of cardiovascular diseases, cancer and cataracts (Arowora et al., 2013; Singh et al., 2018).

In Pakistan, Kinnow export increased tremendously 2017-18 and touched a record of 370,000 tons compared to the previous year (Trade Development Authority of Pakistan, 2018).

Postharvest losses ranges from 23-38% and sometimes up to 40% while 5-10% in developed countries containing Brazil, Australia, Spain, USA, Israel and Italy (FAOSTAT, 2017). These losses caused due to absence of suitable pre and post-harvest management practices, restricted cold chain services, inadequate packing houses and usually sluggish marketing system consequently low return to processor, farmer and trader (FAO, 2006). Kinnow need the proper management system to retain its good quality because there is a risk of deterioration of Kinnow after its harvesting in case of inappropriate management.

Among the various approaches applied to enhance the shelf life substitute of efficient cost technology, utilization of edible coating (wax, oil, extracts) to fruit has attained a considerable attention worldwide in these days (Tietel et al., 2010). For the formulation of comestible films and coatings, different kinds of materials are practiced having very indispensable features (Sindhu and Singhrot, 2016).

Effects of different treatments including commercial wax, herbal extracts (Fan et al., 2009; Romanazzi, 2010) essential oils, edible oils, Chitosan (Xu et al., 2007; Obenland et al., 2008; Paolo and Marisol, 2008) and fungicide has been studied to sustain quality of the fruit covering and increase shelf-life of citrus (Kinnow) fruits. Bisen et al. (2008) illustrated that increased kagzi lime's firmness and decreased fruit weight losses could be ensured with the optimum application of mustard oil. Though, short studies have been done regarding use of different edible oil base coatings to increase the storage life of the Kinnow fruit. In recent times, aloe vera gel based edible coating trend has been increasing for the preservation of different fruits and vegetables (Valverde et al., 2005; Chauhan et al., 2014; Hassanpour, 2015). This tasteless natural product eco-friendly substitute to artificial preservative and delays, respiration rate and reduce proliferation of microorganisms in fruits (Castillo et al., 2010; Garcia et al., 2013; Sogvar et al., 2016). Application of coconut oil, castor oil and sesame oil as postharvest covering of fruits cause reduction in moisture and weight loss of fruits (Creel et al., 2006; Ali et al., 2010).

A number of plants have recognized and classified by Grainge et al. (1984) which possess fungicidal and growth regulating properties, as well as some plants such as neem, lantana and melia. Moreover, neem leaves, fruits and bark have enormous pharmacological properties like anti-ulcer, anti-fungal, anti-bacterial, and pesticide (Biswas et al., 2002).

Aloe vera is a natural product having no taste which is safe and also environment friendly as the alternate for the synthetic preservative. It is used in numerous cases as prevention tool to manage fruit decay as its gel based edible coatings used to avert the respiration rate, delay oxidative browning, moisture loss and firmness. Owing to presence of numerous complex ingredients (enzymes, amino acid, phenolic compounds, salicylic acid, and glycoproteins) it is considered as a beneficial plant (Serrano et al., 2006). These ingredients possess the antifungal properties (Nidiry et al., 2011). Hence *Aloe vera* reduces the proliferation of various insects, pests and microorganisms in fruits (Castillo et al., 2010).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_713729

In Pakistan the use of fungicide is very common to control postharvest diseases but unfortunately, the application of non-chemical techniques is being ignored which can prevent the harmful consequences for human health. The use of chemicals has been discouraged to control the losses of fruits worldwide as there is emergence of concepts regarding food safety in the postharvest supply chain. The import of food commodities with chemical residues has been banned by numerous countries (Khalid et al., 2012).

The National standards fixed maximum residual limit (MRL) on fruits' exports which exceeds this limit would be rejected by importers (Pesticide Action Network, 2012). Industry is facing the challenge to maintain the quality of fruit with minimum chemical residues. The plant extract and organic nature mineral oil is the best alternate to control the pre and postharvest disease for the fruits across the world.

Commercial waxes are usually expensive which are being used in food industry so, there is need to introduce low-cost and effective eco-friendly bio product like oil and plant extracts which are edible and have no residual effect on human health. In view of contemporary scenario high priced wax, fungicide and to reduce postharvest losses, this current investigation was planned with this objective to ascertain the best local plant extract and oil to sustain the quality and storage life of Kinnow fruits.

Materials and methods

The current study was planned to assess the effectiveness of different coatings like oil, plant extracts, commercial wax and fungicide to increase the consumption period of Kinnow and all the experimentations were carried out at Postgraduate Pomology Laboratory (PPL) in University of Agriculture Faisalabad (UAF) Pakistan during 2015-2016. Physiologically matured Kinnow fruits were picked from Experimental Fruit Orchard, located in UAF. The fruits were brought to PPL and were graded to get rid of unhealthy or bruised ones. The fruits were cleaned up in tap water and dried under fan. All treatments (coating materials and storage day intervals) were evaluated under factorial CRD (Completely randomized design).

Plant extracts, oil were compared with commercial wax and fungicide. T_0: Control T_1: Fomesa wax, T_2: 30% Coconut oil, T_3: 60% Aloe vera extract (Best dose) and T_4: Thiabendazole (TBZ) Commercial Fungicide. 20 fruits of Kinnow were used and each treatment was replicated four time. These plant extract were simply treated by dipping method. Treated Kinnow fruits were placed in cold storage at 5˚C and 85% RH for the time period of 90 days and quality parameters were studied up to 3 months (by keeping equal intervals of 15 days).

Physical and physiological characteristics

Fruits samples were weighed before storage and consecutive intervals of 15 days until the end of whole storage. The fruit parameters were calculated by using following formulas.

$$Fruit\ rot\ (\%) = \frac{Spoiled\ fruits\ x\ 100}{Total\ fruits} \quad \text{(Eq.1)}$$

$$Weight\ loss\ (\%) = \frac{Initial\ weight\ of\ fruit - final\ weight\ of\ fruit\ x\ 100}{Initial\ weight\ of\ fruit} \quad \text{(Eq.2)}$$

Peel weight (g)

The peel weight was measured using digital weight balance after peeling off fruit. Peel weight was denoted as in g.

$$Juice\ contents\ (\%) = \frac{Average\ juice\ weight\ x\ 100}{Average\ fruit\ weight} \quad \text{(Eq.3)}$$

Physiochemical characteristics

Total soluble solids (°Brix)

Total Soluble solid was measured by a digital device named refractometer (RX 5000, Atago, Japan).

Titratable acidity (%)

$$TA\ (\%) = \frac{0.1\ N\ NaOH\ x\ 0.0064\ x\ 100\ ml\ juice\ used}{ml\ juice\ used} \quad \text{(Eq.4)}$$

Ascorbic acid

Juice contents regarding ascorbic acid were found following the procedure as described by AOAC (2000). A known quantity of juice (10 ml) was poured into 100 ml volumetric flask and final volume was prepared by adding 0.4% oxalic acid solution. 5 ml filtrated aliquot was taken from the volume, and titrated against 2, 6-dicholorophenolindophenol until the end point (light pink color).

$$Ascorbic\ acid\ (mg\ 100\ g^{-1}) = \frac{1\ x\ R1\ x\ V\ x\ 100}{R\ x\ W\ x\ V1} \quad \text{(Eq.5)}$$

Total phenolic and total antioxidants

The results regarding total Phenolic (mg GAE $100g^{-1}$) were recorded using spectrophotometer at wavelength of 765 nm and 517 nm, respectively (Ainsworth and Gillespie, 2007).

Enzymes assay

Frozen juice was used to estimate the enzymatic activities of POD, CAT an SOD after homogenization using phosphate buffer. The enzyme extracts were prepared and readings were recorded at spectrophotometer at specific wavelengths. The activity of enzyme was demonstrated as **U mg^{-1} protein** (Liu et al., 2011).

Statistical analysis

The recorded data were subjected to statistical analysis of variance using two way ANOVA to examine the overall significant data, whereas the (LSD) least significant difference test ($P \leq 0.05$) was performed for the comparison of means (treatments and storage periods) (Steel et al., 1997).

Results

Physical and physiological characteristics

Weight loss (%)

The weight of Kinnow fruit was gradually decreased during cold storage. The statistically evaluated data indicated significant results. The Kinnow fruits stored without any treatment indicated the highest weight loss than fomesa wax and 30% coconut oil treated fruits which showed 2.99 and 2.90-fold lower weight losses respectively. The interactive effects of different coatings and storage period showed higher weight loss (31.80%) in control treatment followed by fruit treated with TBZ, 60% aloe vera extract, 30% coconut oil and fomesa wax where weight losses were 13.10%, 12.55%, 11.70%, and 11.40%, respectively. The interaction suggested that during 15-90 days interval control treatments had a continuous reduction in fruit weight, but treated fruits showed less decrease during first 60 days and during 75-90 days fast reduction occurred in fruit weight. Among all treatments Kinnow fruits treated with 30% coconut oil extract exhibited lower weight loss up to 90 days (*Figure 1*).

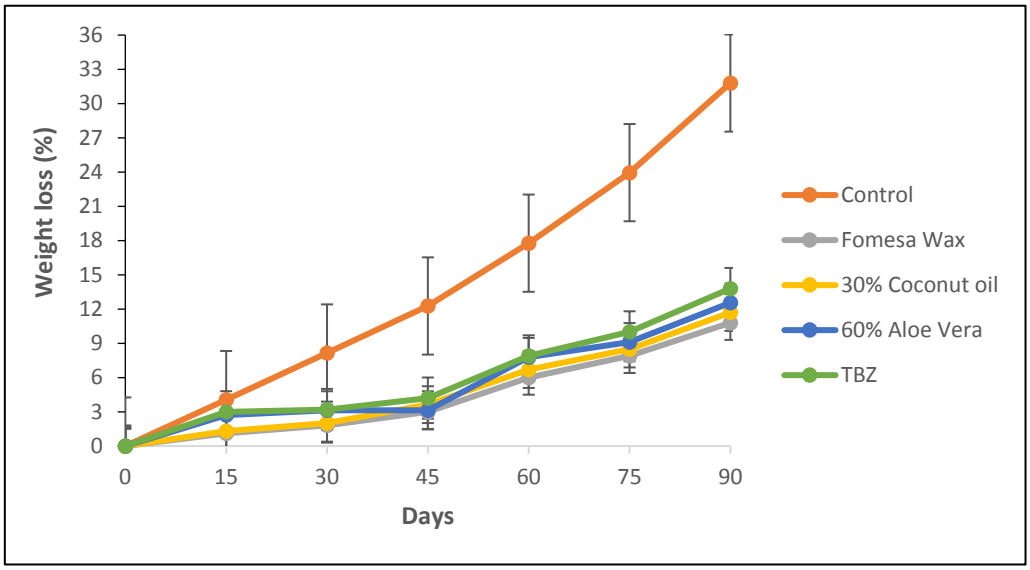

Figure 1. *Effects of different coating treatments on weight loss (%) of 'Kinnow' fruit stored at 5°C. LSD value ($p \leq 0.05$) for treatments = 0.21, storage days =0.25 and interaction = 0.56*

Fruit rot (%)

Fruit rot of Kinnow mandarin fruit was progressively increased during storage period. The data depicted that Interactive effect of all treatments and storage days have significant impact on treatment means. The prestorage treatment of TBZ and 60% aloe vera showed lowest fruit rot (0.93% and 1.16%) than untreated fruit respectively over 90 days storage period. The Kinnow treated with TBZ and 60% aloe vera extract showed minor fruit rot which was statistically at par. The fruit rot was minimum (0.79%) when Kinnow were examined after 15 days of storage where fruit rot percentage was the highest i.e. (9.09%) when Kinnow were tested after 90 days. The interactive effects showed substantial results, the fruit rot (29.20%) was maximum in control treatment when assessed after 90 days storage followed by fruit treated with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_713729

30% coconut oil and fomesa wax, where fruit rot were 5.83%, 5.23%, 2.83% and 2.35%, respectively. Control treatments had swift increase in fruit rot (%) after 45 days while TBZ and 60% aloe vera extract coating treatment which were at par showed minimum decay even during 75-90 days. It was interesting to analyze that TBZ and 60% aloe vera extract treated fruit showed almost 0% decay during initial 30 days while untreated fruits had 6.25% fruit rot during the same period (*Figure 2*).

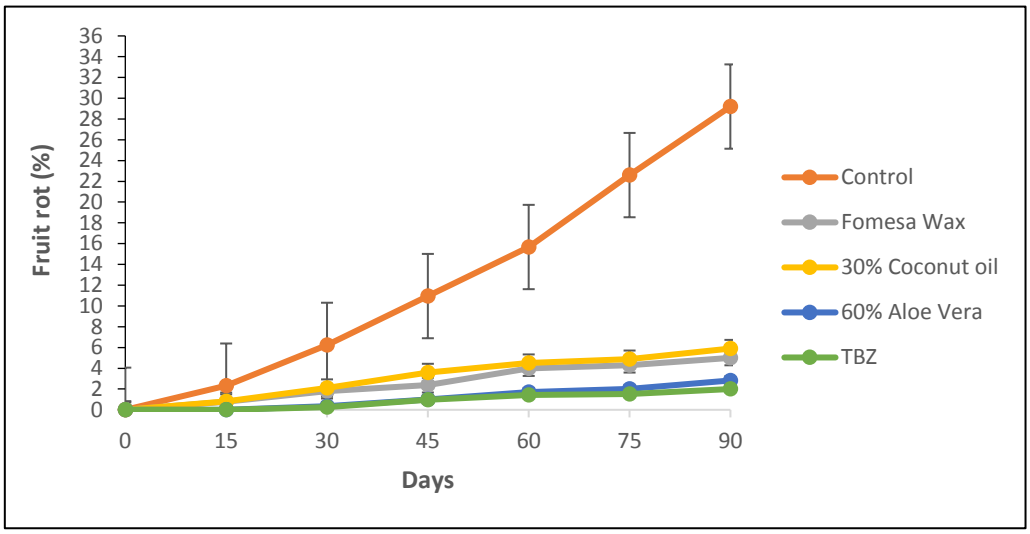

Figure 2. *Effects of different coating treatments on fruit rot (%) of 'Kinnow' fruit stored at 5°C. LSD value ($p \leq 0.05$) for treatments = 0.44, storage days = 0.52 and interaction = 1.17*

Peel weight (g)

Peel weight of Kinnow fruit was reduced due to loss of moisture, in this experimental study. The highest peel weight was maintained about 1.18 and 1.17-fold by fomesa wax and 30% coconut oil treated fruit than control respectively during prolonge storage. The peel weights were 1.18, 1.32 and 1.53-fold higher over 45, 60 and 90 days storage period, respectively. A reverse relation in weight of peel and storage time was noted as the storage progressed. Kinnow fruits treated with fomesa wax held higher peel weight from 0-45 days while fomesa wax and 30% coconut oil showed parallel results to limit weight reduction from peel of fruits. (*Figure 3*).

Juice contents (%)

It was noted that due to increased metabolic activities juice weight of Kinnow was steadily decreased in current study. The statistically investigated data depicted highly significant results among treatments, storage days and their interactions. Among different treatments Kinnow fruits treated with fomesa wax and 30% coconut oil revealed significantly 1.17 and 1.17-fold higher juice weight respectively after 90 days of cold storage. The application of coconut oil was effective to maintain the juice weight during storage period. A positive linear trend was observed for juice weight up to 0-45 days of storage when fruits were treated with 30% coconut oil and fomesa wax. However, an application 30% coconut oil and fomesa wax proved to be at par with each other, similarly a sever negative linear trend was observed in untreated Kinnow fruits for peel weight when observed during 15-90 days. The interactive effects showed highly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_713729

significant results, during storage period of 30, 45, 60 and 90 days, juice weights were 1.09, 1.15, 1.22 and 1.51-fold higher in fruits treated with 30% coconut oil than control fruit respectively (*Figure 4*).

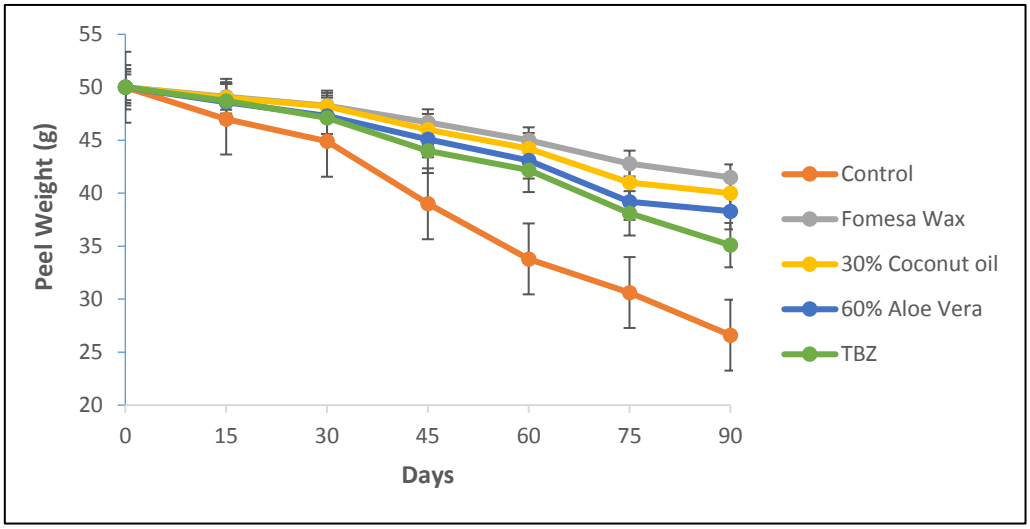

Figure 3. *Effects of different coating treatments on peel weight (g) of 'Kinnow' fruit stored at 5°C. LSD value ($p \leq 0.05$) for treatments = 0.23, storage days = 0.28 and interaction = 0.62*

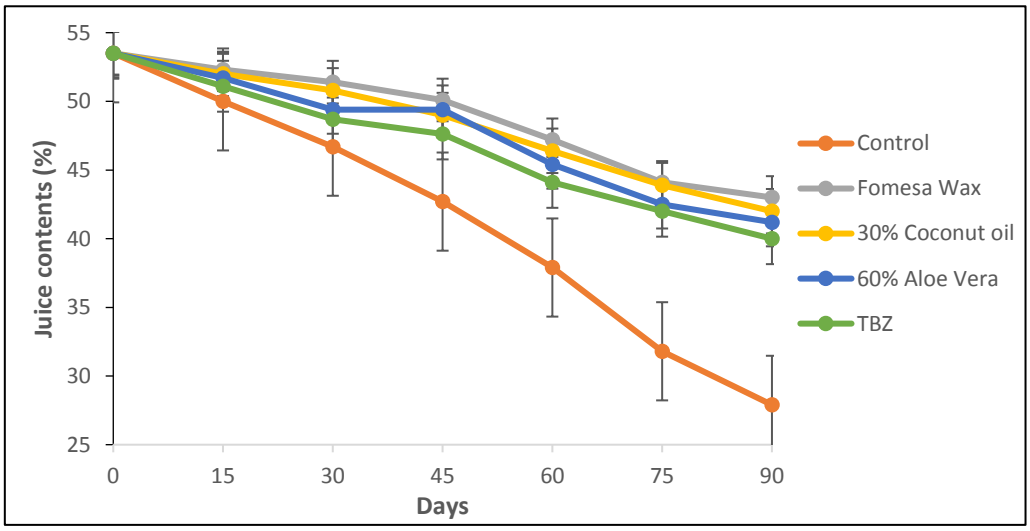

Figure 4. *Effects of different coating treatments on juice contents (%) of Kinnow mandarin stored at 5°C. LSD value ($p \leq 0.05$) for treatments = 0.27, storage days =0.32 and interaction = 0.73*

Bio-chemical characteristics

Total soluble solids (°Brix)

The rapid increase in total soluble solid was found in control treatment than treated fruit. The Kinnow mandarin fruits treated with fomesa wax and 30% coconut oil exhibited the lower total soluble solid contents (1.12 and 1.11-fold) as matched to the untreated fruits respectively during whole storage time. The soluble solid contents were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_713729

minimum (9.25°Brix) when Kinnow were tested after 15 days of storage where soluble solid contents were highest i.e. 11.44°Brix when Kinnow were analyzed after 90 days of storage. The results showed that coconut oil has positive impact on the TSS of fruits. No sever turn in total soluble solid was observed up to 45 days of storage, however, a blunt increase in TSS during 60-90 days was recorded. Furthermore, commercial wax performed at par to 30% coconut oil and helpful to maintain the soluble solid contents. After 30 and 90 days cold storage, total soluble solid contents were 1.06 and 1.11-fold in 30% coconut oil treated fruit than control respectively (*Figure 5*).

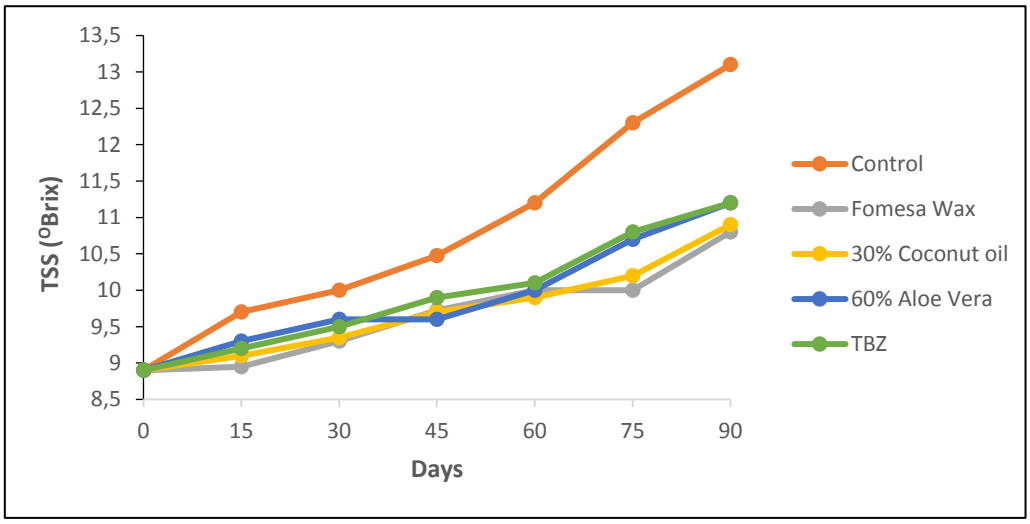

Figure 5. *Effects of different coating treatments on TSS (°Brix) of Kinnow fruit stored at 5°C. LSD value ($p \leq 0.05$) for treatments = 0.17, storage days = 0.20 and interaction = 0.45*

Titratable acidity (%)

Among the treatments, fomesa wax and 30% coconut oil treated fruit resulted in 1.21-fold higher titratable acidity than control during 90 days storage. Interactive effects exhibited that control treatments had an instant drop in TA after 45 days of storage, while, application of 30% coconut oil proved to be mandatory for sustaining the TA up to 60-90 days of storage. The interaction exhibited highest TA was observed in the treatments with fomesa wax (1.10) followed by the treatments of 30% coconut oil (1.09), 60% aloe vera extract (1.01), TBZ (0.98) and control treatment (0.68) respectively after 90 days of storage. 30% coconut oil treated fruit exhibited higher (1.17, 1.24, 1.32 and 1.60-fold) titratable acidity in Kinnow fruits during storage (30, 45, 60 and 90 days) period respectively, than untreated fruit. It was found that titratable acidity of fruits was inversely proportional with prolong storage period (*Figure 6*).

Vitamin C (mg 100 g^{-1})

The statistically investigated data showed highly significant results among treatments, storage days and their relation. The prestorage application of fomesa wax and 30% coconut oil indicated around 1.22 and 1.21-fold higher ascorbic acid contents in Kinnow fruit than untreated fruit respectively. However, a gradual decreasing trend was noted after 15 days in control treatment while commercial wax and 30% coconut oil treated fruit had greater drop during 75-90 days. It was noted that highest vitamin C

DOI: http://dx.doi.org/10.15666/aeer/1801_713729

contents were observed in fruits treated with fomesa wax (40.60 mg 100 g^{-1}) followed by the treatments of 30% coconut oil (40.13 mg 100 g^{-1}), 60% aloe vera extract (38.70 mg 100 g^{-1}), TBZ (38.15 mg 100 g^{-1}) and control treatment (21.38 mg 100 g^{-1}) after 90 days of respectively. During storage period of 30, 60 and 90 days 30% coconut oil treated fruit exhibited 1.02, 1.33 and 1.87-fold higher than control fruit respectively (*Table 1*).

Total phenolic contents (mg GAE 100 g^{-1})

The statistically examined data indicated highly significant results in treatments, storage days and their relation. Increase in TPC activity was more distinct in coconut and oil and fomesa wax than control fruits. After 90 days mean total phenolic contents value was 1.11-fold higher in fruits treated with 30% coconut oil than untreated fruits. The interactive effects of treatments and storage days untreated fruits showed a continuous decrease in TPC from 30-90. Results revealed that fomesa wax treated fruits

30% coconut oil treated fruits showed 1.10, 1.21 and 1.76-fold higher after 30, 45 and 90 days of cold storage than untreated fruits. Interaction showed that highest antioxidant activity (70.92) was observed in fomesa wax followed by the treatment of 30% coconut oil (70.0), 60% aloe vera extract (68.25%), TBZ (67.55) and control

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_713729

treatment (39.75%) respectively after 90 day storage period. 30% coconut oil and and commercial wax showed parallel results in stored fruits. The interactive effects revealed that antioxidant potential of fruit increased up to 0-30 days but reduced gradually up to 90 days. Moreover; 30% coconut oil was more useful to maintain antioxidant activities for long time period (*Table 3*).

Catalase (U mg^{-1} protein)

The data pertaining to CAT enzyme activity of Kinnow fruits illustrated statistically significant outcomes in treatments, storage days and their interactions. The control treatment exhibited the lowest catalase activity as compared to the Kinnow fruit treated with fomesa wax and 30% coconut oil having highest (1.31 and 1.30-fold) catalase activity respectively during storage. Interaction of treatment and storage time revealed falling trend in catalase enzyme activity with prolonged storage but also reduced after 30-60 days depending on treatments. Maximum catalase activity (18.70) was observed in fomesa wax treated fruits followed by treatments of 30% coconut oil (18.10), aloe vera extract 60% (17.23), TBZ (17.0) and control treatment (9.03) respectively after 90 days of storage period. Kinnow fruits treated with fomesa wax showed increase up to 45 days however 30% coconut oil also performed at par to maintain catalase activity on the other hand control treatment initially start decline (*Figure 7*).

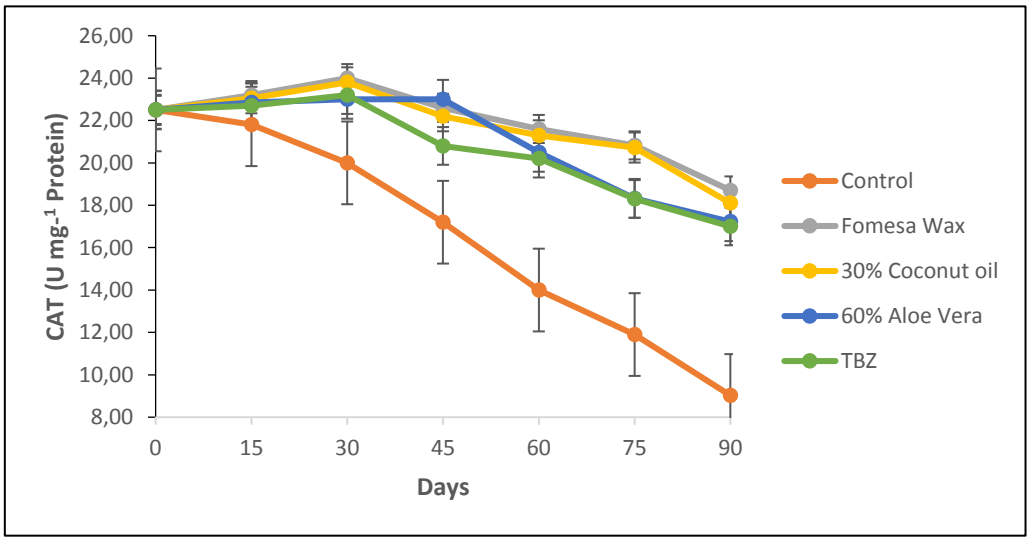

Figure 7. *Effects of different coating treatments on catalase (U mg^{-1} protein) of Kinnow fruit stored at 5°C. LSD value ($p \leq 0.05$) for treatments = 0.27, storage days =0.31 and interaction = 0.71*

Peroxidase (U mg^{-1} protein)

The data regarding to POD enzyme activity of Kinnow fruits illustrated statistically non-significant results but their interactions for treatments and storage days was significant. The highest peroxidase enzyme activity (1.16-fold) was observed and Kinnow treated with fomesa wax and 30% coconut oil having highest (21.92) peroxidase enzyme activity followed by fruit treated with 30% coconut oil as compared to untreated fruit during storage. 30% coconut oil treated fruit showed 1.18, 1.23 and 1.46-fold higher POD enzyme activity after 45, 60 and 90 days of storage than control fruits (*Figure 8*).

DOI: http://dx.doi.org/10.15666/aeer/1801_713729

Superoxide dismutase (U mg^{-1} protein)

The data related to SOD enzyme activity of Kinnow fruits demonstrated significant outcomes in treatments, storage time and their relation. The activity of SOD enzyme was increased to its peak when fruit treated with coconut oil than control fruit during entire storage. The Kinnow fruits dipped in fomesa wax and 30% coconut oil exhibited 1.08 and 1.07-fold higher SOD activity than untreated fruit during cold storage. It was noted that higher SOD enzyme activity was observed in fomesa wax treated fruits (1.15-fold) and 30% coconut oil (1.14-fold) as compared to untreated fruit after 90 days. High value of SOD activity (117.50) was observed in fomesa wax treated fruits after 15 days of storage period. 30% coconut oil and fomesa wax indicated almost at par to maintain SOD activity during storage (*Figure 9*).

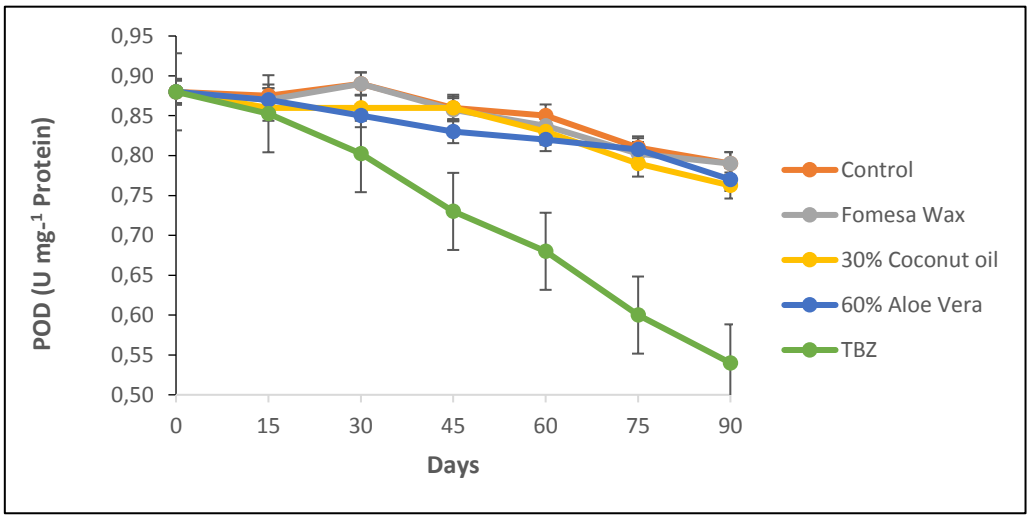

Figure 8. *Effects of different coating treatments on peroxidase (U mg^{-1} protein) of Kinnow stored at 5°C. LSD value ($p \leq 0.05$) for treatments = 0.01, storage days =0.02 and interaction=0.04*

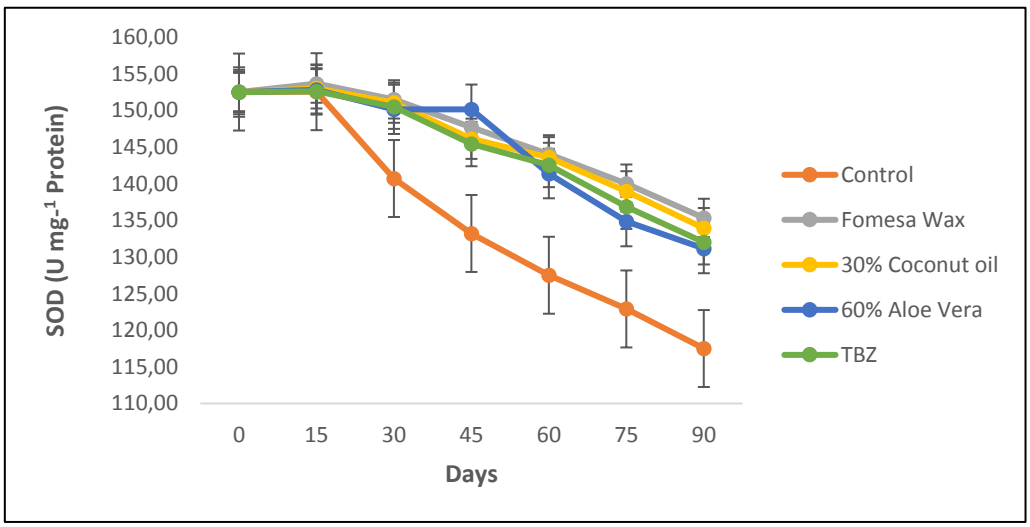

Figure 9. *Effects of different coating treatments on superoxide dismutase (U mg^{-1} protein) of Kinnow fruit stored at 5°C. LSD value ($p \leq 0.05$) for treatments = 0.64, storage days = 0.75 and interaction = 1.68*

Discussion

It is quite obvious from the results of the study that among all the treatment applied to Kinnow mandarin for the extension of storage life 30% coconut oil proved to be the best during 90 days of the storage. This is clear as fruit is living entity after the harvest and various physiological processes especially the respiration and transpiration are going on which utilizes the substrate present in the fruit so the fruit losses its weight because of these processes. Similar results of increasing physiological loss in weight during storage has also been reported in Grapes (Shiri et al., 2011), Jujube fruits (Xing et al., 2015; Shahi et al., 2015), and Mango (Carrillo et al., 2000; Gill et al., 2015). The results of current study for weight loss was in similar with the findings of Albanese et al. (2007) who explained that coating treatment slow down the weight loss. The coated fruits showed a positive action of prestorage treatment which slow down transpiration, because these coatings create a layer on citrus fruit surface that inhibit the evaporation. Likewise, in another study conducted by Krasniewska et al. (2014) it was found that the coatings of pullulan on apple and pepper decreased the weight loss in these fruits.

Coatings of fomesa wax and 30% coconut oil inhibited the agents of moisture particularly and due to this minimum decay loss happened. Yadav et al. (2010) described the reason of decay loss which was due to wax coating's interaction effect as moisture inhibitor as well as microbial inhibitor in their point of view. Similar results were found in Asian pear when observed by Mahajan et al. (2013). On the other hand, Gautam et al. (2003) reported the same results in mango, Ahmad et al. (2005) and Yadav et al. (2010) in Kinnow mandarin reported minimum decay loss during the period of storage by applying wax on these fruits.

Results concerning about TSS in this research showed that fruits treated with 30% coconut oil had lower total soluble solids as comparing them to control treatment. Increased TSS in control was due to solute accumulated in vacuoles of cells and starch gets hydrolyzed in to sugars. The increase in TSS up to 15 days may be attributed due to the hydrolysis of acid and deposition of polysaccharide as reported earlier by Omayma et al. (2010). Probable reason in reduction of TSS in 30% coconut oil treated fruit was due to the conversion of polysaccharides in to disaccharides and monosaccharaides means less hydrolysis of starch into sugars.

The higher titratable acidity in the commercial wax (fomesa wax) and 30% coconut oil treated Kinnow fruits could be because of least consumption of acids in the process of respiration during storage. The decrease in acidity in control treatment was probably due to the utilization of citric acid by the microbes as a source of carbon and O_2 collected inside caused acidosis after dissolving and developing carbonic acid (Carrillo et al., 1995). The coatings facilitated in better maintenance of titratable acidity than control fruits, which could be because of the positive role of coatings in delaying the process of ripening in fruits (El-Anany et al., 2009). Patriaca et al. (2005) indicated that coatings were effective in retention the titratable acidity of Kinnow.

Generally, vitamin C contents of fruits decreasing during storage. However, the 30% coconut oil and fomesa wax treated fruits showed higher contents of vitamin C as compared to control after 90 days storage. During the period of storage, the ascorbic acid was degraded which decreased the vitamin C. Similarly, Lee and Kader (2000) proposed that leaching in thermal breakdown and surrounding water became the reason of vitamin C loss. There were similar results shown by Sonkar et al. (2009) in Kinnow, Ahmad et al. (2005) in Kinnow, Deka et al. (2006) in mandarin. These studies indicated that there were maximum contents of Vitamin C in the fruits which were coated with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_713729

wax. Dehydro ascorbic acid is formulated as a result of moderate oxidation of vitamin C, as it is a fact that vitamin C is quite vulnerable to oxidative deterioration.

Shahid and Abbasi (2011) reported that there was maximum vitamin C in fresh fruit before ripening and after that due to the ascorbic acid oxidase action it was decreased. Generally, a major part of ascorbic acid transformed into juice and oxidized. The present study indicated that fruits treated with 30% coconut oil showed similar results as commercial wax had higher total phenolic contents of the Kinnow fruits in contrast to untreated fruits.

Paolo and Marisol (2008) in their research revealed that during storage, the total phenolic contents increased and vitamin C reduced. Consequently, phenolic compounds synthesis becomes the reason of increase in antioxidant activity during the period of storage of Kinnow fruit. They reported the reduction in phenol content of control and Kinnow coated with herbal extract, essential oil and commercial wax during the period of storage, these findings are a sequence of the results of Lim et al. (2006) who conducted research on fruit of citrus. During the period of storage, polyphenol oxidase enzymes' oxidative activity is related with the decrease in total phenols contents which makes the phenol to quinones compound. During the initial days, a sudden increase in the phenolic contents was observed it is due to the fact that due to reduction in temperature activation and generation of certain phenolic contents happened, as a result of above phenomenon dehydration of Kinnow occurred which further increased the juice phenolics (Silva et al., 2013). After a definite time period the phenolics decreased because antioxidant activity decrease which is sign of minimum resistance of fruits against the attack of pathogen.

The increase in activity of antioxidant enzymatic at early stages may because of environmental stress which increases the ROS level at protein, which finally modifies the cellular homeostasis (Suzuki and Mittler, 2006). Antioxidant activity's foresaid results demonstrated that Kinnow fruit which was coated with the wax and coconut oil with 30% encourage the scavenging capacity. Fruits of coated Kinnow which were stored at temperature of 4ºC showed reduction in antioxidant activity after 90 days because of rigorous reduction in phenolics and ascorbic acid through biosynthesis. Hassanpour et al. (2015) reported the dependency of antioxidant activity upon flavonoids, anthocyanins, total phenols and ascorbic acid. They also supported the current results on antioxidant activity.

Conclusion

It was concluded that 30% coconut oil performed best among all the treatments. The fruits treated with 30% coconut oil showed minimum weight loss, fruit rot, maximum juice weight, biochemical parameters like total soluble solids, titratable acidity, ascorbic acid contents, total sugar, maximum total antioxidants and maximum enzymatic activity (CAT, POD and SOD) of Kinnow mandarin fruits which were stored up to 90 days. It was also evaluated that 60% aloe vera extract proved valuable for long term storage of Kinnow mandarin and to control the storage rot because it performed almost at par to commercial fungicide. Hence botanical extracts can improve the storage life of Kinnow mandarin so it can be recommended to overcome the storage issues of Kinnow fruits. Finally, it was obvious from experiment that prestorage treatment of 30% coconut oil was most effective to reduce decay losses and maintain the fruit quality during 90 days storage.

Future recommendations

There is a need to explore the penetration level of these treatments molecular level studies are also required to check the efficacy and accuracy. Effects of these prestorage applications on bio profile of phenolics and antioxidants, flavonoids should be checked to find a best treatment in terms of international standards.

Abstract. The study aimed to examine the effect of the decomposition of macrophyte materials on the release potential of heavy metals (Zn, Cu, Pb and Cd) from the lake sediment to the overlying water. A laboratory experiment was carried out with a common macrophyte species (*Carex cinerascens* Kukenth) to examine the effects of macrophyte decomposition on the release of heavy metals (Cu, Zn, Cd, Pb) from the sediment. Fresh aboveground parts of the macrophyte were added to the sediment and the treated sediment was subsequently subjected to a permanent flood condition. Dissolved organic carbon (DOC), pH and heavy metal concentrations of the overlying water were measured during the 135-day experiment. In most cases, the rate at which heavy metals were released form the sediments was reduced after the addition of macrophyte biomass. The greater the amount of the macrophyte amendment, the greater the decrease in heavy metals released from the sediment. There is no significant correlation between the DOC concentration in the overlying water and the four heavy metals released from sediments. The addition of macrophyte biomass can reduce the heavy metals release from sediments.
Keywords: *dissolved organic carbon, Carex cinerascens Kukenth, metal mobility*

Introduction

By acting as a sink of organic matter, wetland sediments generally play a fundamental role in determining the concentration of nutrients in waters (Yuan et al., 2011; Dittrich et al., 2013). However, sediments usually suffer severe levels of heavy metal pollution – up to hundreds of parts per million (Yin, 2011). There are several reports that wetland sediments are heavily contaminated with heavy metals (Kouba et al., 2010; Yuan et al., 2011; Schaller et al., 2013). This results in an enhanced environmental risk for associated ecosystems and organisms, especially as the heavy metals may be at concentrations that are toxic to many species (Nriagu and Pacyna, 1988).

Sediment can become remobilized and release metals into the water column; therefore, sediments area potential source of contamination in wetland environments (Hafeznezami et al., 2012). Some studies have demonstrated that sediments can be a significant source of metal emissions (Chon et al., 2012; Schaller et al., 2013). The sediments most significant for binding metals are thought to be organic matter and Fe and Mn oxyhydroxides. Recent studies have demonstrated that organic matter in lake sediments can interact with heavy metals to form organometal complexes, and thus can significantly affect various aspects of heavy metals such as form, distribution, biotoxicity, migration and transformation (Yamashita and Jaffe, 2008; Guo et al., 2012).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_731745

In freshwater environments, organic matter is a ubiquitous, naturally occurring, heterogeneous mixture of organic compounds formed from the degradation of lignin-rich plant materials and the decay of dead organic biomass. Based on filtration, the organic matter fraction that passes through a 0.45-μm membrane is known as the dissolved organic matter (DOM), of which ≥50% by mass is carbon. The concentration of DOM is widely variable in freshwater and commonly reported in mg C L^{-1}, as dissolved organic carbon (DOC) (Al-Reasi et al., 2013).

Organic matter in sediments is highly influenced by the primary production in lake ecosystems (Noges et al., 1999). After decaying, the detritus from macrophytes and algal biomass settles into sediments and will eventually be decomposed by the microbial community (Han et al., 2015). Microbial decay of organic matter in sediments is accompanied by the release of DOC into the water (Schaller et al., 2008). DOC is known to complex heavy metals and remains mobile (Sachs et al., 2007; Zhao et al., 2009). Ashworth and Alloway (2008) showed that the solubility of the heavy metals copper (Cu), nickel (Ni), and lead (Pb)in soil have a strong positive relationship to the solubility of organic matter. Soil DOM may increase aqueous heavy metal concentrations by forming metal-DOM aqueous complexes, as demonstrated by Wang and Mulligan (2009). However, Ranville et al. (2007) showed that high DOC levels had no effect on uranium remobilization when the pH was above 7. Moreover, there are observations that vegetated water bodies and related organic sediments have a higher capacity to immobilize the mobile metals (Dienemann et al., 2006; Ross and Dudel, 2008). Plant litter can provide a metal sink if, during decomposition, metals are bound to the litter by passive sorption on the organic surfaces or by accumulation by microbial colonizers of the litter (Du Laing et al., 2006, 2007; Guo et al., 2006). Accordingly, strong positive correlations have been found between metal concentrations in the sediment and organic matter concentrations in the upper sediment layer of the Scheldt marshes (Du Laing et al., 2007). As a result, the DOC produced during plant decomposition could enhance the mobility of heavy metals in the sediment or soil, but the plant materials could also provide a metal sink. It is unclear which process is dominant.

Therefore, a laboratory experiment was conducted to examine the effect of the decomposition of macrophyte materials (*Carex cinerascens* Kukenth) on the release potential of heavy metals (Zn, Cu, Pb and Cd) from the lake sediment to the overlying water.

Material and methods

The wetland plant selection and collection

Carex cinerascens is a good forage grass, and is distributed in Northeast, Northwest, North, East, Central and southwest alpine area of China. It grows on the lake, riverside or marshland.

On April 5th, 2016, the aboveground biomass of *C. cinerascens* was sampled from Xicha Lake located in Gongqingcheng city of Jiangxi province in China. The aboveground parts were harvested and thoroughly washed with deionized water. After allowing most of the water to drip off, the fresh macrophytes were chopped into approximate one-centimetre sections. Chopped plant parts were mixed in order to equalize any differences in the composition of various plant organs, the variability in their decomposition rates, and the resultant activity of microbial decomposers.

The wetland sediment collection and treatment

Surface sediment samples (0-10 cm) were collected from Xicha Lake located in Gongqingcheng city in December 2014 during the dry season. Upon return to the laboratory, the sediment was air dried and sieved through a 2-mm mesh nylon sieve. Heavy metals were added to the sediment in the form of $CuSO_4 \cdot 5H_2O$, $ZnCl_2$, $CdSO_4 \cdot 8/3H_2O$ and $Pb(NO_3)_2$. The sediment was increased artificially to reach final values of 394 $mg \cdot kg^{-1}$ of Cu, 775 $mg \cdot kg^{-1}$ of Zn, 7 $mg \cdot kg^{-1}$ of Cd and 352 $mg \cdot kg^{-1}$ of Pb for the low levels of heavy metal contamination (LS), and 691 $mg \cdot kg^{-1}$ of Cu, 1445 $mg \cdot kg^{-1}$ of Zn, 12 $mg \cdot kg^{-1}$ of Cd and 596 $mg \cdot kg^{-1}$ of Pb for the high levels of heavy metal contamination (HS). The sediment was then placed in a plastic bucket and watered well. After 16 months, the sediment was sieved through a 2 mm mesh nylon sieve and was subjected to laboratory-scale incubation experiments. *Table 1* reports selected characteristics of the sediment used in the experiment.

Table 1. *Physical and chemical properties of the two levels of heavy metal contamination*

Parameters	Cu	Zn	Cd	Pb	Ca	Mg	TC	pH
	mg kg^{-1}						%	
LS	394	775	7	352	4911	4269	0.46	5.50
HS	691	1445	12	596	5186	4597	0.48	5.54

LS and HS represent the low and high levels of heavy metal contamination in the sediment, respectively

The overlying water used in the experiment

On April 5th, 2016, water was collected from Xicha Lake located in Gongqingcheng city, where the water quality is relatively good. After being transported to the laboratory, the collected lake water was filtered immediately through a 0.45-μm membrane and stored at 4°C for the experiment. The pH of the lake water was 6.94. The concentrations of Cu, Zn, Cd, Pb, Ca and Mg in the lake water were 0.656 μgL^{-1}, 4.980 μgL^{-1}, 0.533 μgL^{-1}, 0.385 μgL^{-1}, 27461 μgL^{-1} and 3038 μgL^{-1}, respectively.

Experimental conditions and design

To investigate the effects of the decomposition of the aboveground parts of *C. cinerascens* in flooding season on the release of heavy metals from the sediment, two levels of macrophyte biomass additions were used in the experiment. One level is 17 g of fresh weight, which represents the macrophyte biomass in the spring in the field, and the other is 7 g fresh weight. For the experiment with sediments, there were six treatments: LS+water, LS+7 g macrophyte+water, LS+17 g macrophyte+water, HS+water, HS+7 g macrophyte+water, and HS+17 g macrophyte+water. In addition, two treatments without sediments were included: 7 g macrophyte+water and, 17 g macrophyte+water. In total, eight treatments were conducted with each treatment performed in triplicate. The sediment+water and sediment+macrophyte+water treatments were used to test the effect of plant decomposition on the release of heavy metals from the sediments. The macrophyte+water treatment was used to determine the amount of heavy metal release from the plant itself to the overlying water.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_731745

The release experiments were performed in 2.0-L glass beakers 13.3 cm in diameter and 19.3 cm in height, and the beakers were side-wrapped in black plastic to avoid light exposure. First, 300 g of air-dried sediment were put into the bottom of the vessel, and mixed with increasing amounts of chopped fresh plant weight. Finally, 1.5 L of filtered lake water was added into each beaker. All experiments were conducted at the laboratory with no temperature control from April 5th to August 18th, 2016, and the incubation lasted 135 days. During the experimental period, water samples were taken (after 1, 4, 11, 18, 32, 90 and 135 days) from each vessel with a pipette at a depth of 5 cm above the sediment-water interface for the heavy metal and DOC analysis, and then the pH of the overlying water was determined. Before the first day of the sampling, the evaporated water was added and after the sampling, 20 ml of deionized water was added to supplement the sampling water. For heavy metal analysis, the 10-ml sample was centrifuged immediately after sampling and acidified with HNO_3. For the determination of dissolved organic carbon (DOC), 10 ml of water was sampled using PE (polyethylene) vessels, filtered using 0.45-μm cellulose-acetate filters and immediately measured.

Analytical methods

The element concentrations were analysed at the analytical laboratory of the Beijing Research Institute of Uranium Geology, which is registered to the China National Accreditation Service for Conformity Assessment and the China Metrology Accreditation system, using an inductively coupled plasma mass spectrometer (Perkin-Elmer Elan DRC-e, American). The DOC of the water samples was determined using a TOC analyser (Tekmar Torch, American). Carbon content in the sediment samples was measured with an element analyser (ElementarVario Macro Cube, Germany). The pH of the overlying water was determined using a pH meter (Leici PHSJ-3F, Shanghai) and the pH of the sediment was also determined by a pH meter according to the Standard of the Ministry of Agriculture of the People's Republic of China (NY/T 1377-2007).

Statistical analysis

The percent decrease of the concentration of metal *X* in overlying water at time *t* after addition of macrophytes (PD_t) was calculated according to the following formula:

$$PD_t(\%) = \frac{X_{t0}(mgL^{-1}) - X_{tp}(mgL^{-1})}{X_{t0}(mgL^{-1})} \times 100 \qquad \text{(Eq.1)}$$

where PD_t is the decreased percentage of metal *X* concentration in the overlying water after the addition of the macrophyte; X_{t0} is the metal *X* concentration in the overlying water with no addition of the macrophyte at time *t*; and X_{tp} is the metal *X* concentration in the overlying water after addition of the macrophyte at time *t*. $PD_t<0$ indicates a net increase of metal *'X'* released from the sediment by the decaying plant, while $PD_t>0$ indicates a net decrease of metal *'X'* released by the decaying plant.

For each heavy metal pollution level, differences in the measured parameters among three treatments were tested by a one-way analysis of variance (ANOVA) followed by Tukey's post hoc analysis when appropriate. A correlation analysis (Pearson's correlation coefficients) was used to test the relationships between DOC and heavy metal concentration during the 135-day period. Differences in the percentage decrease of the heavy metal concentration in overlying water after the macrophyte biomass

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_731745

addition, between the earlier stage of the experiment (treatments for 1 day, 4 days and 11 days) and the later stage (treatments for 18 days, 32 days, 90 days and 135 days), were tested with a paired samples test. All statistical analyses were performed using the SPSS 11.5 software package.

Results

Dynamic changes in pH and DOC concentration in overlying water

The pH of the overlying water was significantly decreased by the macrophyte addition on the first day and then increased by the macrophyte addition (*Fig. 1*). However, there were no significant differences in pH between the sediment+water+7 g macrophyte treatment and the sediment+water+17 g macrophyte treatments ($p>0.05$). And there were no significant differences in pH between the two treatments with low and high concentrations of heavy metals in sediments ($p>0.05$) and the pH values shown in *Fig. 1* were the average of the treatments with low and high concentrations of heavy metal in sediments.

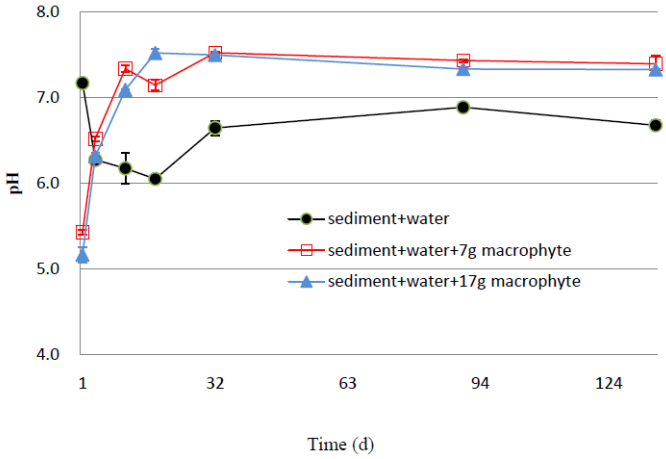

Figure 1. *Change in pH value of overlying water during the C. cinerascens amendment. The pH values shown in the figure were the average of the treatments with low and high concentrations of heavy metal in sediments*

The DOC concentrations of the overlying water in the treatments with macrophyte biomass amendments increased remarkably, and showed similar variation during the 135-day decomposition process (*Fig. 2*). For the treatments with low and high levels of heavy metal contamination in sediments, the DOC concentrations in treatments with the macrophyte addition increased with time and peaked around day 4 and day 11, and then decreased or remained relatively stable. In addition, the mean DOC concentrations followed the order: sediment+water+17 g macrophyte>sediment+water+7 g macrophyte >sediment+water (*Fig. 2a,b*). Within the treatments with the same amount of macrophyte biomass addition, there were no significant differences in DOC concentrations between the two treatments with low and high concentrations of heavy metal in sediments ($p>0.05$). DOC concentrations ranged from 0.47-5.05 mgL^{-1} in the sediment treatments, 1.5-21.27 mgL^{-1} in the sediment+water+7 g macrophyte treatment and 0.65-50.82 mgL^{-1} in the sediment+water+17 g macrophyte treatments.

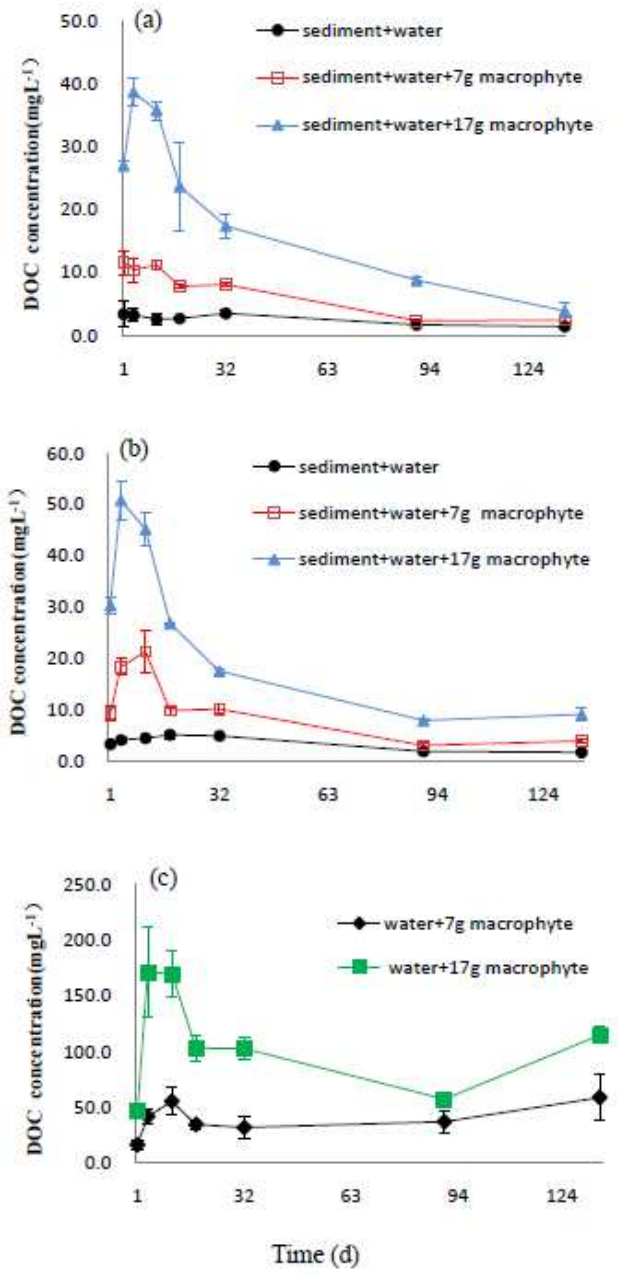

Figure 2. *Change in DOC concentrations in overlying water during the C. cinerascens amendment. (a) The treatments with low concentrations of heavy metal in sediments; (b)the treatments with high concentrations of heavy metal in sediments; (c) the treatments without sediments, as a function of time after flooding. Error bars indicate standard deviations*

However, DOC concentrations in the water+macrophyte treatment were significantly higher than in the sediment+water+macrophyte treatments with the same amount of macrophyte biomass added ($p<0.05$). DOC concentrations in the water+7 g macrophyte treatments ranged from 15.93-58.49 mgL^{-1} and from 45.83-171.75 mgL^{-1} in the water+17 g macrophyte treatment. However, for the water+macrophyte treatments, DOC concentrations increased during the first few days, then declined, and increased at a later stage.

The effect of macrophyte addition on the release of heavy metals from sediments

Dynamic changes in heavy metal concentration of the overlying water

For the water+macrophyte treatments, the concentrations of four heavy metals in the water body were very low, at several parts per billion. Thus, the effect of heavy metals released by the macrophyte itself into the overlying water is negligible in the sediment+water+macrophyte treatment (*Fig. 3c, Fig. 4c, Fig. 5c, and Fig. 6c*).

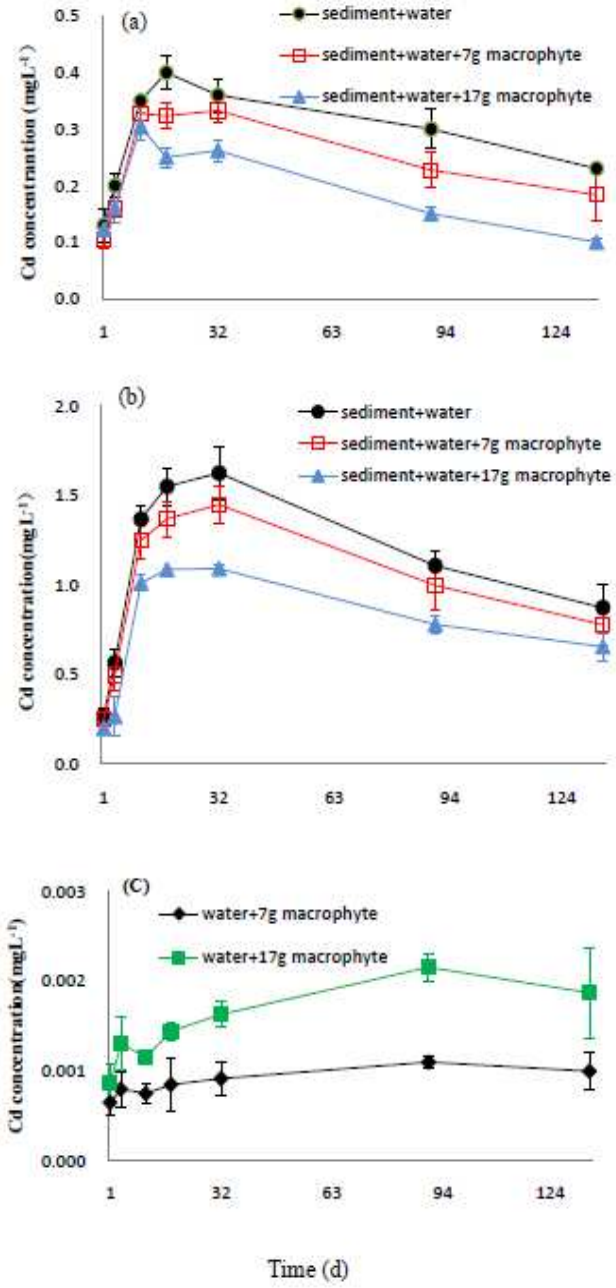

Figure 3. *Changes in Cd concentrations in overlying water during the C. cinerascens amendment. (a)The treatments with low concentrations of heavy metal in sediments;(b) the treatments with high concentrations of heavy metal in sediments; (c) the treatments without sediments, as a function of time after flooding. Error bars indicate standard deviations*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_731745

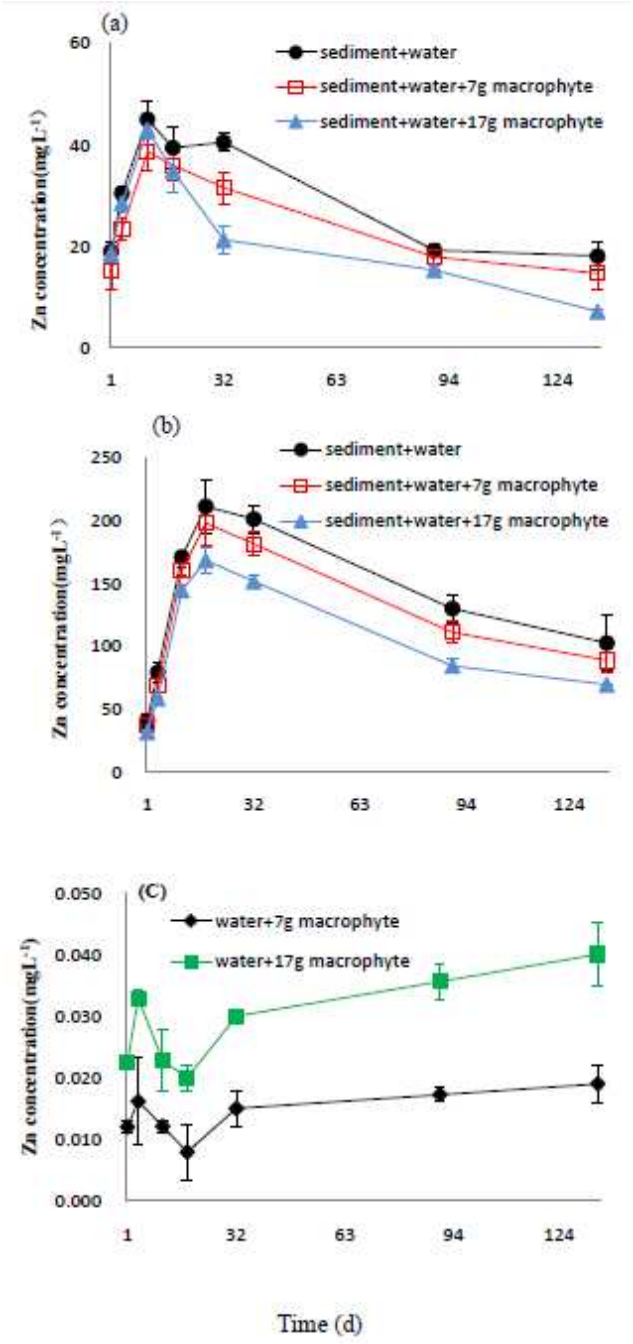

Figure 4. *Changes in Zn concentrations in overlying water during the C. cinerascens amendment. (a)The treatments with low concentrations of heavy metal in sediments;(b) the treatments with high concentrations of heavy metal in sediments; (c) the treatments without sediments, as a function of time after flooding. Error bars indicate standard deviations*

The release of four kinds of heavy metals in the sediments was not the same, as a function of time after flooding. However, in general, in the later stage of the experiment, the mean concentrations of Cd, Zn, Cu and Pb in the overlying water followed the order: sediment+water > sediment+water+7 g macrophyte > sediment+water+17 g macrophyte.

For both levels of heavy metal contamination in the sediment, Cd and Zn concentrations in the overlying water first increased with time and then decreased. In general, the effect of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_731745

the macrophyte addition on the release of heavy metals from sediment was not obvious in the early stage of the experiment, but in the later stage, the macrophyte addition could significantly reduce the release of heavy metals from sediment to the overlying water ($p<0.05$). In general, the mean Cd and Zn concentrations in the overlying water followed the order: sediment+water > sediment+water+7 g macrophyte > sediment+water+17 g macrophyte (*Fig. 3a,b and Fig. 4a,b*).

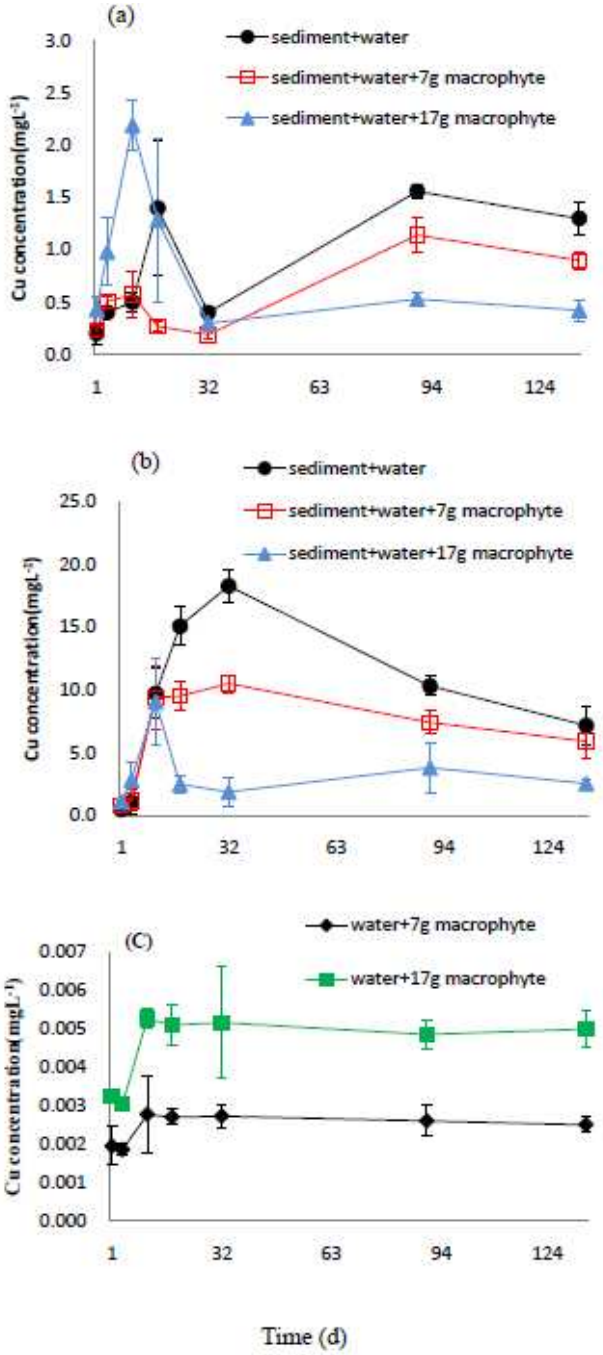

Figure 5. *Changes in Cu concentrations in overlying water during the C. cinerascens amendment. (a) The treatments with low concentrations of heavy metal in sediments; (b) the treatments with high concentrations of heavy metal in sediments; (c) the treatments without sediments, as a function of time after flooding. Error bars indicate standard deviations*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_731745

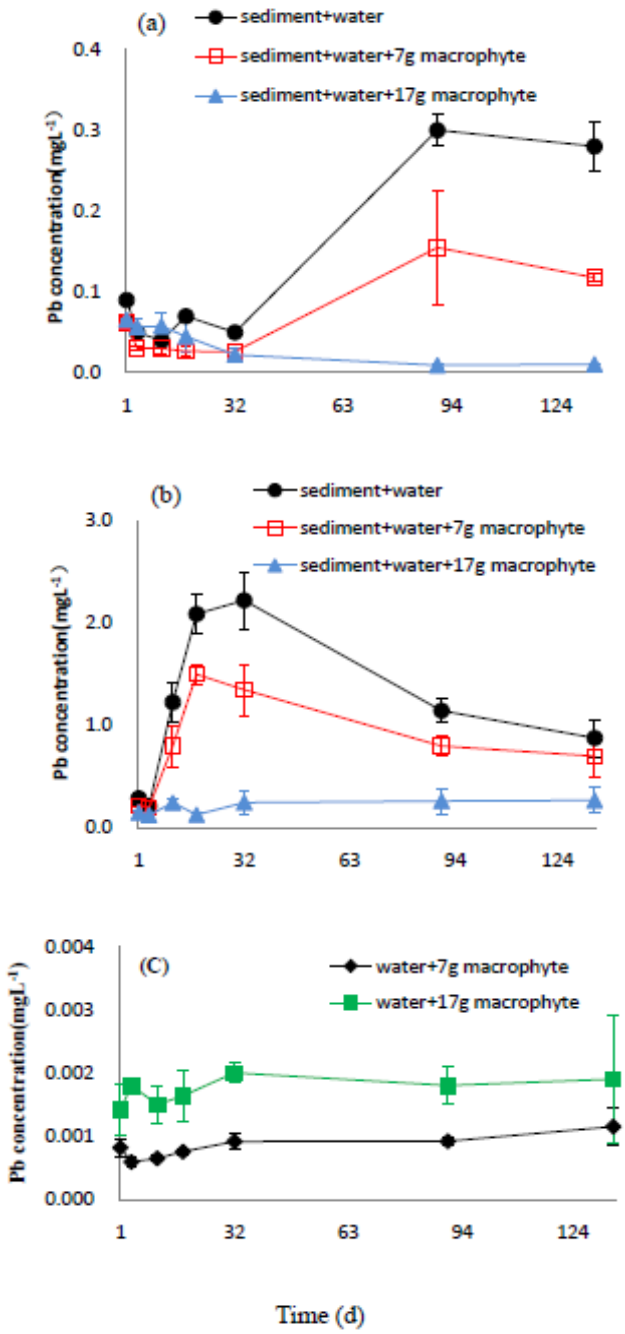

Figure 6. *Changes in Pb concentrations in overlying water during the C. cinerascens amendment. (a) The treatments with low concentrations of heavy metal in sediments; (b) the treatments with high concentrations of heavy metal in sediments; (c) the treatments without sediments, as a function of time after flooding. Error bars indicate standard deviations*

The release of Cu and Pb were slightly different from Cd and Zn, as a function of time after flooding. At low levels of heavy metal sediment contamination, both the Cu and Pb concentrations in the overlying water began to increase after 32 days, and the macrophyte addition significantly reduced the metal concentrations in the overlying water ($p<0.05$). At high levels of heavy metal contamination, the Cu and Pb

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_731745

concentrations in the overlying water first increased, then decreased and tended to be stable. At the two levels of heavy metal sediment contamination, the mean Cu and Pb concentrations in the later stage of the experiment followed the order: sediment+water> sediment+water+7 g macrophyte > sediment+water+17 g macrophyte *(Fig. 5a,b and Fig. 6a,b*). Moreover, the heavy metal concentration in the overlying water was significantly lower in the treatments with 17 g macrophyte addition than without macrophyte addition ($p<0.05$).

The decreased heavy metal concentrations in overlying water after the plant biomass addition to the sediment

To investigate the effect of the macrophyte biomass addition on the release of heavy metals from the sediments, $PD_t(\%)$was calculated according to *Eq. (1)*, and the results are shown in *Table 2*. It was found that the $PD_t(\%)$ values of Cd and Zn were all greater than zero. With low levels of heavy metal contamination in sediments, the Cd and Zn concentrations in the overlying water were decreased 6%-20% and 7%-23%, respectively, with the7 g macrophyte biomass addition, and 6%-57% and 2-60%, respectively, with the 17 g macrophyte biomass addition.

Table 2. *The decreased percentage of heavy metal concentration in overlying water after addition of plant biomass*

Treatment	1d	4d	11d	18d	32d	90d	135d
Cd							
LS+water+7g macrophyte	19	21	6	19	8	24	20
LS+water+17g macrophyte	6	20	13	38	27	50	57
HS+water+7g macrophyte	8	12	9	12	11	10	11
HS+water+7g macrophyte	26	53	26	30	33	30	25
Zn							
LS+water+7g macrophyte	20	23	14	9	22	7	19
LS+water+17g macrophyte	2	7	5	12	48	20	60
HS+water+7g macrophyte	10	13	6	6	10	14	13
HS+water+7g macrophyte	23	26	15	20	25	35	32
Cu							
LS+water+7g macrophyte	-18	-28	-14	81	53	27	31
LS+water+17g macrophyte	-115	-145	-338	8	26	66	68
HS+water+7g macrophyte	-65	-12	3	37	43	28	18
HS+water+7g macrophyte	-128	-163	7	84	90	63	65
Pb							
LS+water+7g macrophyte	31	39	24	62	48	48	58
LS+water+17g macrophyte	27	-13	-45	36	55	97	96
HS+water+7g macrophyte	24	6	35	28	39	30	20
HS+water+7g macrophyte	48	42	80	94	89	77	69

With high levels of heavy metal contamination in sediments, the Cd and Zn concentrations in the overlying water were decreased 8%-12% and 6%-14%, respectively, with the 7 g macrophyte biomass addition, and 26%-53% and 15%-35%, respectively, with the 17 g macrophyte biomass addition. The $PD_t(\%)$ values of Cu and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_731745

Pb were all greater than zero in the late stage of the experiment. At low levels of heavy metal contamination in sediments, the Cu and Pb concentrations in the overlying water were decreased 27%-81% and 7%-23%, respectively, with the 7 g macrophyte biomass addition, and 6%-57% and 2%-60%, respectively, with the 17 g macrophyte biomass addition. The PD_t(%) values of Cu were less than 0 in the early stage, indicating that the addition of the macrophyte biomass promoted Cu release, but in the later stage of the experiment, the macrophyte biomass addition significantly reduced the release of Cu, reaching a maximum of 90%. For Pb, the addition of the macrophyte biomass reduced the release of Pb by up to 97%. The macrophyte additions have greater decreasing effects on the release of Pb and Cu than on the release of Cd and Zn.

There were no significant differences in the percentage of Cd and Zn concentrations in the overlying water in the macrophyte biomass addition treatments between the earlier stage and the later stage of the experiment ($p>0.05$). The decreased concentrations of Cu and Pb in the overlying water of the macrophyte biomass addition treatment in the later stages of the experiment were significantly higher than in the earlier stages of the experiment ($p<0.01$ and $p<0.05$, respectively).

Correlation between DOC and heavy metal release to the overlying water

The DOC concentration in the overlying water was tested for correlations with heavy metal concentrations in order to determine the share of metals bound directly to the DOC. With low levels of heavy metal contamination in sediments, DOC had a significantly negative correlation with Pb concentration (R^2=-0.284, $p<0.01$). No correlations between DOC concentration and Cd, Zn and Cu concentrations were observed. With high levels of heavy metal contamination in sediments, DOC had a significantly negative correlation with the Cd and Pb concentrations (R^2=-0.266 and -0.443, respectively, $p<0.01$). No correlation between the DOC concentration and the Zn and Cu concentrations was observed.

Discussion

DOC is released during plant litter decomposition, when soluble polymeric organic substances are released into the water in the form of dissolved carbon (Bonanomi et al., 2014). The ability of DOC to bind metals during transport through water or soil and to form stable, aqueous complexes with copper, nickel, zinc and other ions has been shown in numerous works (Li and Shuman, 1997; Refaey et al., 2017). However, in this study, there were no significant positive correlations between the DOC concentration in the overlying water and the four heavy metals released from sediments. Some results also report that total dissolved metal concentrations (Cd, Zn, Cu, Pb, Co, Mn, Ni) generally did not show any significant or systematic correlation with DOC concentrations in river waters of Texas, and concluded that natural organic matter complexation was generally not a major process controlling trace metal concentrations (Jiann et al., 2013). Our results are also in accordance with other studies revealing an impact of invertebrate shredders on metal (calcium, manganese, iron, copper, zinc, arsenic, lead) fixation/remobilization with no influence on the DOC level (Schaller et al., 2010, 2013).

The releases of Cd, Zn, Cu and Pb from sediments were not identically affected by the fresh macrophyte biomass amendments. In most cases, the greater the amount of the plant biomass amendment, the greater the decrease in heavy metals released from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_731745

sediment to the overlying water. It was demonstrated that in the process of plant litters decomposition, metals are combined with litters through passive adsorption on organic surfaces or accumulated by microbial colonizers of the litter. And then plant litters can be places for metal sink (Du Laing et al., 2006, 2007; Guo et al., 2006). Therefore, studies have shown a strong positive correlation between the concentration of metal in the sediment and the concentration of organic matter in the upper sediment layer of the Scheldt marshes (Du Laing et al., 2007). The negative correlation and lack of correlation between the formation of DOC and the release of heavy metals in this study may be attributed to the fact that heavy metals were strongly bound to solid biomass and other colloids fixed on larger fractions but neither attached nor adsorbed the DOC (Schaller et al., 2010).

Conclusion

This study aimed to investigate the effects of the decomposition of macrophyte materials on heavy metals released from the lake sediment to the overlying water. In conclusion, wetland macrophytes could reduce the release of heavy metals from sediments to the overlying water. The release of heavy metals was not affected by DOC and the plant material may act as a metal sink.

The control of plant harvest or the stimulation of plant biomass production could be considered as management techniques to reduce the mobility of heavy metals in wetland ecosystems. Nevertheless, it is important to note that besides DOC and pH, the effects of decomposing plant materials on environmental conditions, such as electrolytic conductivity, dissolved oxygen and decomposition rate, are not considered in this study. Moreover, more investigations are necessary to understand the mechanisms and the fate of immobilized heavy metals after further decomposition.

Abstract. The gas production effect of two kinds of straws mixed with pig manure via anaerobic fermentation under two sets of temperatures 32℃ and 52℃ has been studied in this experiment. In the process, sunflower and corn straw were used as raw materials with activated sludge as inoculum in a batch anaerobic fermentation reactor. The results showed that the average methane content of sunflower straw reached 62.55% at 37℃, which was 20.41% higher than that of sunflower straw at 52℃.The cumulative methanogenic yield of corn stalks was higher than that of sunflower stalks at different temperatures. The cumulative methane production of corn stalks was the highest at 52℃, and 67.99 L of methane was produced in 54 days. The cumulative methane production of sunflower stalks was the lowest at 52℃, and the methane production was 34.09 L in 53 days. The results showed that corn stalks produce more methane than sunflower stalks and are more suitable for high temperature anaerobic fermentation. On the other hand, sunflower stalks were found suitable for medium temperature fermentation.

Introduction

The People's Republic of China as a large agricultural country has abundant straw resources. In 2017, the country's collectible straw production from the main crops reached 900 million tons (Liu et al., 2018). This production included the straw from corn (*Zea mays* L., Fam.: Poaceae) and sunflower (*Helianthes annuus* L., Fam.: Asteraceae). The amount was nearly more than 1/3 of the total straw production of China. In China, reasonable conversion of straw to available energy is crucial field of research (Du et al., 2015). At present, a large amount of straw in China is not being effectively utilized, resulting in wastage of resources and pollution to the environment due to indiscriminate burning (Fan et al., 2018). The anaerobic fermentation technology is an effective means to ensure the utilization of straw resources and the technology can sufficiently solve the problem of straw waste management and generate renewable energy such as methane gas to alleviate the energy shortage in China (Duan et al., 2016). The effort will promote

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_747756

the sustainable development of the society and improve the economy and ecological condition of the environment (Wan et al., 2010; Jha et al., 2011; Sun, 2016).

Studies related to the methane production by straw is affected by a number of factors. Among which temperature is an important factor affecting anaerobic fermentation (Brown et al., 2012; Huang et al., 2018). It plays an important role in microbial growth rate, enzyme activity, biochemical reaction rate, etc. Generally, the anaerobic fermentation temperature is divided into three gradients: low temperature, medium temperature and high temperature (Liu et al., 2008; Yin et al., 2014). Juan et al. (2018) found that the methane production efficiency of corn straw increased with increasing temperature. During anaerobic fermentation at high temperature like 55℃, the total organic load (TS) was 100 g/L. The yield of TS in the corn straw unit was 44.68% higher than that under the anaerobic digestion at 45℃, which was 64.08% higher than 35℃. Studies by Pang et al. (2018) and others showed that the cumulative methane production of anaerobic fermentation of cow manure and straw at 35℃ was 91.84 L, which was 20% higher than that at 25℃ and 30℃. Contreras et al. (2012) explored the potential for methane production in rice straw and rice at 37℃ and 55℃. It was found that the biogas production at high temperature was 0.43 $m^3 \cdot kg/vs$, which was 0.09 $m^3 \cdot kg/vs$ higher than that under medium temperature. It was confirmed that the high-temperature fermentation of rice straw was better.

In the present research, studies on the effects of temperature on anaerobic fermentation of different types of straw have been reported (Gu et al., 2016). Some previous studies have shown different types of gas production by using different compositions of straw. However, there exists very few studies on the effect of temperature and on the potentiality of anaerobic fermentation of sunflower straw and its anaerobicity. In order to fill up the gap between theoretical research and the application of the technology in practice, the concept of present research has been developed. In this research, using batch anaerobic fermentation reactor, the effect of gas production changes by sunflower and corn straw at 37℃ and 52℃ has been compared during the research, the changes of various parameters while the anaerobic fermentation of two straws were in operation have also been studied. So, the aim of the present research is to maximize the utilization of straw anaerobic fermentation, improve the resource utilization of sunflower straw and corn straw and to provide data support for straw anaerobic fermentation technology.

Materials and Methods

Experiments

The corn straw for the present study was collected from the Shenbei New District of Shenyang City, Liaoning Province, China. The whole corn was harvested and after separating the grains of the cobs, the straws were air dried and crushed. The crushed biomass of the straw was passed through a 20-mesh sieve. The source and treatment of sunflower straw were the same as those applied for the corn straw. Fresh pig manure was collected from Shenbei New District, Shenyang City, Liaoning Province. The inoculum used for the experiment was the biogas slurry collected after carrying out in vitro anaerobic fermentation. Fresh pig manure (mass ratio 1:10) was added before the experiment which was carried out at medium (37℃) and high temperature (52℃) for 15

Main devices

A controllable constant temperature fermentation unit was used for carrying out the tests involved in the present investigation. The experimental protocol has been presented in *Fig. 1*.

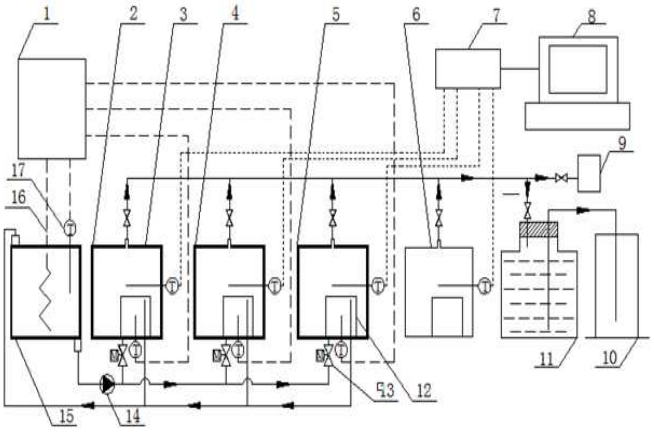

Figure 1. *Schematic diagram of controllable constant- temperature fermenting equipment 1. Temperature controller 2. Insulation layer 3. Fermentation cylinder 4. Fermentation cylinder 5. Fermentation cylinder 6. Fermentation cylinder 7. Data collecting instrument 8. Computer 9. Biogas analyzer 10. Water storage tank 11. Gas storage tank 12. Internal water tank 13. Solenoid valve 14. Hot water pump 15. Constant temperature water tank 16. Heating wire 17. Temperature sensor*

The device is mainly composed of a heating water tank, a temperature controller, a cylindrical 304 stainless steel fermenter with an effective volume of 10 L (with a height to diameter ratio of 1:1) and a gas collecting device. The fermenter of the device is insulated from the environment and the temperature of the fermenter is adjusted. The flow rate of the circulating heating water tank is precisely controlled, and the temperature is measured with a Pt100 platinum resistance temperature detecting device with an accuracy of ±0.1℃.

Other instruments used for determining various other experimental parameters were: TDL-5-A centrifuge (Shanghai Anting Scientific Instrument Factory); GZX-9240MBE digital display blast drying oven (Shanghai Boxun Industrial Co., Ltd.); UV-9200 UV-visible spectrophotometer (Beijing Ruili Analytical Instruments Co., Ltd.); Biogas check

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_747756

biogas analyzer (Geotech, UK); JSM5600LV scanning electron microscope (JEOL, Japan) and D/MAX-2004 powder X-ray diffractometer (Nippon Science).

Anaerobic digestion test design

The mass ratio of corn and sunflower stalk and pig manure was 1:2 and the amount of biogas slury inoculation was 30% of the mass. The corn straw group contained: straw, pig manure, acclimated biogas slurry at the rate of 0.30 kg, 0.59 kg and 1.70 kg, respectively. On the other hand, sunflower straw group contained: 0.30 kg, 0.58 kg and 1.69 kg as straw, pig manure and acclimated biogas slurry, respectively after feeding, 6.0 kg distilled water was added.

The fermenter has a volume of about 6 L, and the temperature is controlled at 52 ± 1℃ and 37±1℃, respectively. The reaction tank is shaken 3 times per day, and the digestion process is continued until no gas is produced. The test run cycle was fixed for 54 d. The pH value, gas composition and gas production of the fermentation broth were measured every 5 days, and indicators like the chemical oxygen demand (COD), volatile fatty acids (VFAs) and ammonia nitrogen (NH_4^+-N) of the fermentation broth were measured at intervals of 4 days. After the fermentation, the corn straw residue is separated, and the weight after drying was taken and recorded.

Analysis methods

The total solids (TS) and volatile solids (VS) of corn straw, sunflower straw, pig manure and biogas slurry inoculum samples were measured according to the standard methods (APHA, 1998). The biogas components were measured using a Biogas Check. The pH value was measured using an Oriol PHS3C portable pH meter. VFAs and COD determination is based on Liu et al. (2013), using spectrophotometry and potassium dichromate method respectively. While phenol sodium hypochlorite colorimetry method was used to determine NH_4^+-N concentration. The measurement of alkalinity was carried out using an acid-base indicator titration method.

Neutral detergent fiber (NDF), acid detergent fiber (ADF) and acid detergent lignin (ADL) measurements were done via Paradigm analysis. Cellulose (CL) and hemicellulose (HC) quality scores were done after ADF-ADL and NDF-ADF. The structural analysis were carried out using scanning electron microscope (SEM) as well as X-ray diffraction (XRD).

Results and Discussion

Gas production changes of corn straw and sunflower straw under anaerobic fermentation at different temperatures

It can be seen from *Figs. 2-3* that the gas production amount is significantly different depending upon the temperature and straw varieties. During the 54 d fermentation period, the gas yield of corn straw reached the peak at 11.72 L/d on the 42nd day at 52℃. At this temperature, the sunflower straw reached the highest daily gas production at 4.94 L/d on the 44th day. At 37℃, the gas yield of corn straw reached the peak at 4.83 L/d on the 51st day, while the peak gas yield of sunflower straw appeared at 47 d, which was 5.92 L/d. In contrast, the peak gas production time during high temperature fermentation at 52℃ was earlier than that at 37℃. In addition, the cumulative gas production of corn straw at 52℃ was 140.31 L while the cumulative gas production of sunflower straw was 80.68 L.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_747756

On the other hand, the cumulative gas production of corn straw at 37℃ was 92.46 L and the peak gas yield of sunflower straw was 67.55 L. Cumulative total biogas production in the present investigation followed an order: 52℃ corn straw>37℃ corn straw>52℃ sunflower straw>37℃ sunflower straw. The cumulative gas production of corn straw and sunflower straw at 52℃ is higher than the cumulative gas production at 37℃, indicating that the bioactivity of the bacteria is stronger under high temperature. During which, the decomposition efficiency of cellulose, hemicellulose and other substances is higher and the metabolic rate of microbial cells is accelerated. The anaerobic fermentation efficiency is improved. In addition, the cumulative gas production of corn straw was higher than that of sunflower straw. The daily gas production of sunflower straw during the late stage decreased to the initial stage of the reaction, indicating that the content of cellulose and other substances in sunflower straw was lower than that of corn straw. Insufficient accumulation leads to a decrease in gas production efficiency and a decrease in gas production during the later stages of methanogen production.

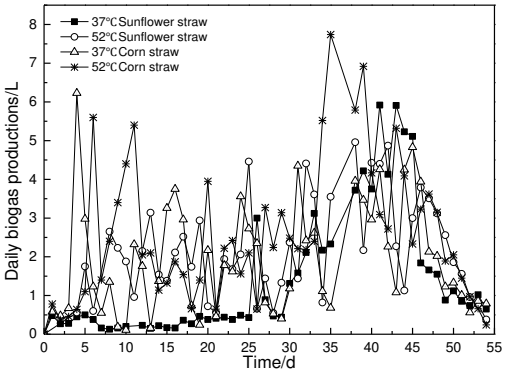

Figure 2. *Daily biogas production trends of corn straw and sunflower straw at different temperatures*

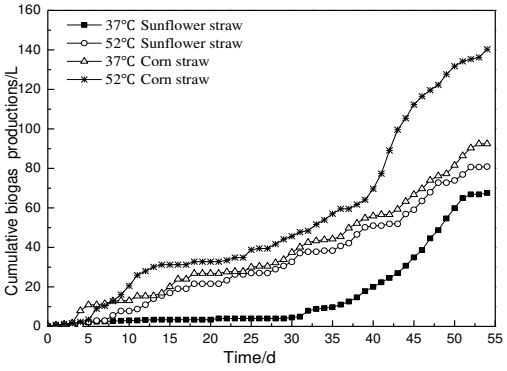

Figure 3. *Cumulative biogas production trends of corn straw and sunflower straw at different temperatures*

Anaerobic fermentation pH and fatty acid changes of corn straw and sunflower straw at different temperatures

Because, acid-producing bacteria have a wide range of pH adaptation and methane producing bacteria are sensitive to pH changes, pH plays a great role in the anaerobic digestion processes.

During the 54-day fermentation period, the pH of each group can be roughly divided into three stages: “stable-decline-fast rise”. The overall pH of the fermentation was between 6.5 and 7.9, indicating that the self-regulating pH inside the fermentation can maintain a stable fluctuation range (Zhou et al., 2014). Since the added activated sludge itself is weakly alkaline, the pH gradually rises during the initial stage of the reaction. During the period of 18 d-30 d, the pH value may decrease. It may be that the hydrolysis and acidification of the acetogenic bacteria decomposes the available materials in the straw and converts them into volatile fatty acids. At this time, the ammonia nitrogen content of the alkalinity in the fermentation system is insufficient, and the methanogens are still insufficiently adapted to the environment. A large amount of fatty acids accumulate, leading to a drop in pH (Fang et al., 2017). From 35 d to 47 d in the later stage of the experiment, as the reaction continued, the methanogens gradually adapted to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_747756

the environment. As a result the activity of the strains increased and began to reproduce, consuming large amounts of fatty acids and producing ammonia nitrogen. The pH level rose again. As seen from figures (*Fig. 4 and Fig.5*) there is an opposite trend of change of pH and VFAs in anaerobic fermentation. During the mid-stage pH drop, the fatty acid concentration was at a higher value; while the pH value increased at the late stage of fermentation, the concentration of volatile fatty acids began to decrease rapidly.

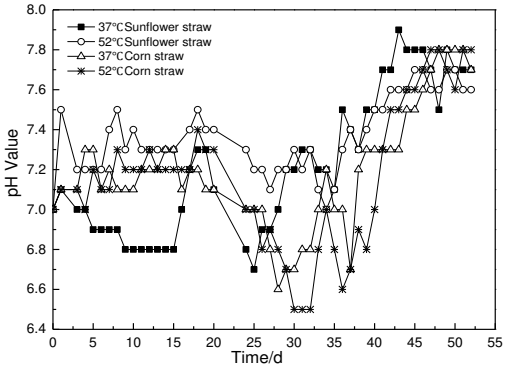

Figure 4. *Change trend of pH value of corn straw and sunflower straw under different temperatures*

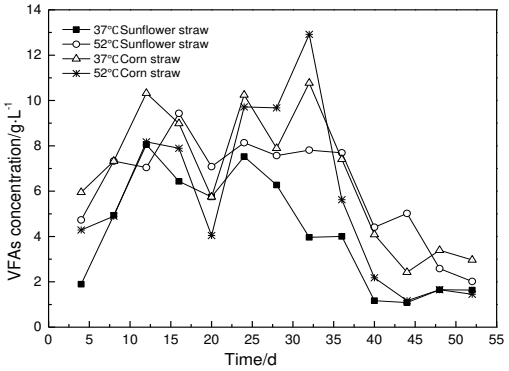

Figure 5. *Change trend of volatile fatty acids concentration of corn straw and sunflower straw under different temperatures*

Volatile fatty acids are important intermediary compounds for reflecting microbial metabolism during anaerobic fermentation of straw (Xu et al., 2016).

At 37℃, sunflower straw reaches almost in the acidification and gas-free stage within 30 days before the middle temperature anaerobic digestion. However, the average concentration of VFAs was the lowest at this stage, and the theoretical inhibition intensity was the lowest, but the cumulative gas production was the lowest. The analysis showed that the sunflower stalks were under medium temperature conditions. The volatile acid produced had the highest propionic acid content, while propionic acid had the most obvious inhibitory effect on methanogens, which led to the inhibition of gas production in the first and middle stages. The average concentration of VFAs in corn straw at 37℃ was higher than 52℃. Although, the average content of methane in corn straw at 52℃ and 37℃ was not much different, only 2.8% higher, but the cumulative yield of corn straw methane at 52℃ was much higher than that of sunflower straw. The results showed that different temperatures had different effects on the methanogenesis of sunflower straw and corn straw. At 37℃, the methane production increased rapidly and the average methane content was the highest. The analysis showed that the methanogens used acetic acid, the acetic acid content decreased, and the acetic acid was resistant to propionic acid. Oxygen digestion has the strongest inhibitory effect. The decrease in acetic acid content leads to an increase in the degradation ability of propionic acid, and the gas production efficiency of methanogens increases. The content of VFAs decreased at the beginning of 52℃ corn straw for 30 days. At the same time, the methane production grew rapidly and the average methane content was higher than 37℃, indicating that corn straw was more suitable for 52℃ high temperature anaerobic fermentation.

Ammonia nitrogen concentration changes in corn straw and sunflower straw under anaerobic fermentation at different temperatures

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_747756

The change of ammonia nitrogen concentration is an important parameter for the stability of the reaction fermentation system. It can be seen from *Fig. 6* that the average ammonia nitrogen value of sunflower straw is 1.19 g/L at 37℃ and 1.87 g/L at 52℃ and the average ammonia nitrogen value of corn straw at 37℃ is 1.85 g/L and at 52℃, it is 1.98. g/L. At 37℃, the ammonia nitrogen concentration and pH of the sunflower straw fermentation were lower than other groups. It may be that at 37℃ sunflower straw has higher activity of acid-producing bacteria at this stage, while the methanogen has not adapted to the environment, resulting in low ammonia nitrogen concentration. On the 40th day of fermentation, the daily methane production of sunflower straw increased significantly at 37℃. It is known from *Figure 4* that the pH increased rapidly. At this stage, the ammonia nitrogen concentration decreased rapidly and the volatile fatty acid reached the lowest value (Lin et al., 2011). It indicated that low concentration of ammonia nitrogen can promote the proliferation and division of methanogens and increase the yield of methane, which is consistent with the experimental study of Shun et al. (2018).

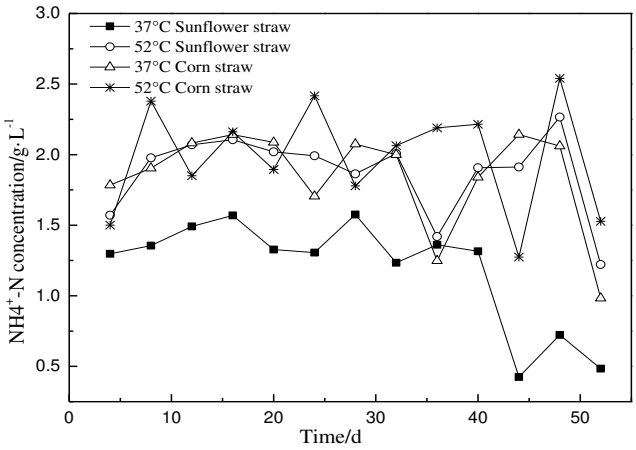

Figure 6. *Change trend of ammonia nitrogen concentration of corn straw and sunflower straw under different temperatures*

The average concentration of ammonia nitrogen in high temperature anaerobic fermentation of corn straw and sunflower straw was higher than that of medium temperature anaerobic fermentation. In the appropriate temperature range, as the temperature increases, the activity of the strain gradually increases resulting an increasing rate of ammonia nitrogen.

Anaerobic methanogenesis of corn straw and sunflower straw at different temperatures

It can be seen from *Figs. 7-8* that the methane production in the middle and early days before the reaction is low, and in the late, rate rises rapidly, The peak value appears between 42 d and 51 d, and the gas production fluctuates greatly, indicating that the experimental fermentation factors are excessive. At the temperature of 52℃, the methanogenic rate of corn stalks increased rapidly from 40 d to44 d. It was found that a large amount of methanogenic precursors such as acetic acid, formic acid, ethanol and CO_2 were formed in the middle and early stages of corn stalks at the same temperature. Methanogens can be utilized, and gas production increases, leading to peak values. The peak daily methane production of sunflower straw at 37℃ and sunflower straw at 52℃

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_747756

was 47 d and 44 d, respectively. The peaks of daily methane production at 37℃ and 52℃ of corn straw were 51 d and 42 d, respectively. It can be seen that as the temperature increases, the peak value of the daily methane gas conversion is advanced. However, there is no such rule in methane production. From *Table 2*, the highest content of methane in corn stalks at 52℃ is 73.7%, while the highest methane content in corn stalks at 37℃ is 70.9%. However, sunflower straw and corn stalks showed an opposite trend. The maximum content of methane from sunflower straw at 37℃ was 78.37%, while the same at 52℃ was only 58.70%. It can be speculated that the cumulative methane production of corn stalks increases with increasing temperature within a certain temperature range. The accumulated methane production of sunflower straw at 37℃ was higher than 52℃. The result showed that 37℃ was closer to the optimum temperature of sunflower straw anaerobic fermentation. While the activity of methanogen was inhibited at 52℃, and the methane production decreased.

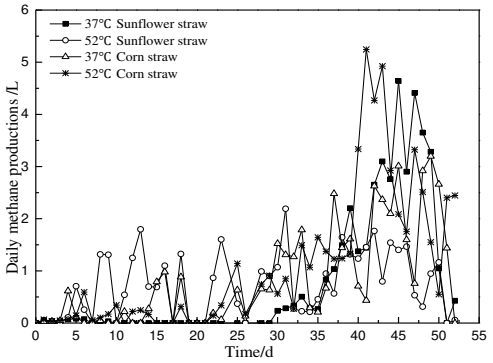

Figure 7. *Daily methane production of corn straw and sunflower straw under different temperatures*

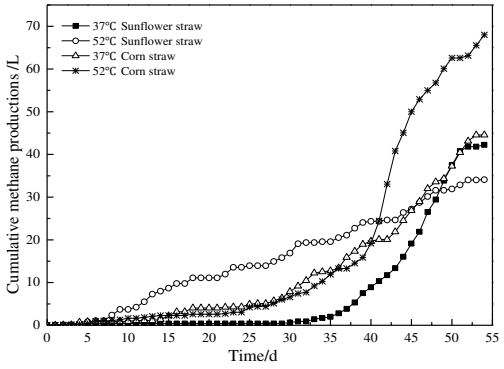

Figure 8. *Cumulative methane production of corn straw and sunflower straw under different temperatures*

Table 2. *Biogas production and methane production changes*

Grouping	Sunflower straw at 37℃	Sunflower straw at 52℃	Corn straw at 37℃	Corn straw at 52℃
Daily biogas productions/L	1.25	1.49	1.71	2.59
TS biogas productions/L·kg^{-1}TS	141.35	169.27	193.53	293.69
VS biogas productions/L·kg^{-1}VS	175.06	209.64	266.59	404.55
TS methane productions/L·kg^{-1}TS	88.41	71.33	93.28	142.32
VS methane productions/L·kg^{-1}VS	109.45	88.34	128.49	196.05
Average methane content%	62.55	42.14	48.20	48.46
Maximum methane content%	78.37	58.70	70.90	73.70

Conclusions

From the present investigation, experiments show that temperature has a significant effect on the gas production characteristics of combined sunflower straw and corn straw anaerobic fermentation.

In the 100-day fermentation test, the cumulative methane production of corn stalk at 52°C was 77.99 L, which was 128.77% higher than that of anaerobic fermentation of sunflower straw at the same temperature. When the fermentation temperature was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_747756

maintained at 37°C, the cumulative production of methane from sunflower straw The lowest amount, only 34.09 L. However, the average content of methane in sunflower straw at the fermentation temperature of 37°C was 62.55%, which was higher than the average content of corn stalks at 37 degrees Celsius and sunflower stalks at 52 degrees Celsius by 14.35% and 20.41%. In general, in order to improve the methane yield of anaerobic fermentation of straw, corn straw is more suitable for anaerobic fermentation at high temperature (52℃). Unlike corn straw, sunflower straw is more suitable for anaerobic fermentation at medium temperature (37℃).

The methane production characteristics of straw and pig manure under medium and high temperature anaerobic fermentation conditions were studied. It was proved that corn stalk and pig manure could effectively improve the C/N ratio of materials and improve anaerobic digestion efficiency, and synergistically in anaerobic fermentation.

There is no research on low temperature (<15°C). The winter temperature in northern China is low, and the anaerobic mixing of straw and pig manure at low temperature is studied. Fermentation has high value for the utilization of biomass resources.

Abstracts. Carbon isotope composition of the tissue of several mollusc species gathered from the Huaxi river, in China, a typical karst river, was analysed to determine their potential food sources. The results showed that $\delta^{13}C_{tissues}$ values of gastropod species *Cipangopaludina chinensis* are about 3‰ heavier than the values of bivalve species *Corbicula fluminea* and *Anodonta woodiana*, which indicates the different food and nutrition sources between species. According to the $\delta^{13}C$ values of mollusc's tissues and the potential food, bivalve species *C. fluminea* and *A. woodiana* mainly assimilate phytoplankton and terrestrial plant detritus as food, while gastropod species *C. chinensis* also utilize sediment organic matter as a food source excluding the phytoplankton and terrestrial plant detritus. Moreover, the preferential food selection behavior and varied metabolic intensity between different ages and individuals may lead to some variation of $\delta^{13}C_{tissues}$ values of *C. fluminea*. This study will be helpful in defining the role of molluscs in the energy flow of the karst river ecosystem, and to protect and manage those molluscs' resources.

Keywords: *nutrition, Corbicula fluminea, Anodonta woodiana, phytoplankton, terrestrial plant detritus*

Introduction

Molluscs, such as bivalves, and gastropods are important large benthic animals in river ecosystems, and they usually play an important role in the ecosystem through feeding and nutrient excretion activities as they often dominate the macrobenthic community (Boltovskoy et al., 1995; Nichols and Garling, 2000; Xu and Yang, 2007; Atkinson et al., 2010). Meanwhile, molluscs usually are important economic fishery resources. It is therefore essential to study the diet of those animals for better understanding the role of molluscs in carbon and nitrogen cycling in the freshwater ecosystems, and for the better management of molluscs resources (Paulet et al., 2006; Fukumoria et al., 2008).

There are several ways to better understand the diet of organisms, including direct observation of feeding behavior, gut contents analysis, and stable isotopes analysis of the soft tissues of organisms and the potential food sources (Raikow and Hamilton, 2001). Direct observation of the feeding behavior of bivalves are very complicated and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_757768

involved the measurement of filtering rates or examination of filtering morphology (Kryger and Riisgard, 1988; Ward et al., 1993; Silverman et al., 1997). Gut content analyses may be misleading because the method cannot distinguish ingested material that is not assimilated (Miura and Yamashiro, 1990; Raikow and Hamilton, 2001). In contrast to these conventional methods, stable isotope analysis has been used successfully in many studies of spatial and temporal variations in potential diets of invertebrates (DeNiro and Epstein, 1978; Stephenson and Lyon, 1982; Fry and Sherr, 1984; Zanden and Rasmussen, 1990; Kang et al., 1999; Cai et al., 2001; Kasai et al., 2006; Paulet et al., 2006; Fukumoria et al., 2008; Schlacher and Connolly, 2014; Graniero et al., 2016; Ishikawa et al., 2017; Zhao et al., 2019). The stable isotope techniques are based on the assumption that the isotopic composition of an organism is linked to its diet, such as it is generally accepted that the $\delta^{13}C$ value of an organism reflects the $\delta^{13}C$ value of its diet, with little (~1‰) or no change (DeNiro and Epstein, 1978; Fry and Sherr, 1984).

In this study we analyzed the stable carbon isotope composition of several molluscs tissues in the Huaxi river, China, which is a typical karst river, to determine what carbon sources were being used by those molluscs and to define the role of molluscs in the energy flow of the karst river ecosystem, which will be very helpful to protect and better manage the molluscs resources.

Materials and Methods

On August 10, 2007, a number of animals, bivalve species *Corbicula fluminea*, *Anodonta woodiana* and gastropod species *Cipangopaludina chinensis* were collected from Huaxi river, Guiyang city, China, which is a typical karst region (*Fig. 1*). The animals were brought back to the laboratory and the shell height was accurately measured using a caliper, the tissue is quickly removed with a scalpel. According to the size of shell height, *C. fluminea* tissue samples were divided into 6 groups (*Table 1*), and there were two kind of tissue samples in each group, one included individual tissue samples, and the other was a mixture of several animal tissue samples with the similar shell height (about 10 to 15 animals mixed together). Three individual tissue samples both of *A. woodiana* and *C. chinensis* were selected to determine the composition of organic carbon isotopes.

Tissues were dried in an oven at 60℃ for 24 hours, 5 drops of 2% hydrochloric acid was added to remove the inorganic carbonate (some *C. fluminea* mixed samples were not treated with hydrochloric acid) (*Table 1*). After acid treatment, *C. fluminea*, *A. woodiana* and *C. chinensis* tissue samples were dried again in an oven, and then ground into powder with a mortar and pestle, about 0.1 mg samples were placed in the tin cup, then wrapped the tin cup into cubes and no samples leakage was ensured. $\delta^{13}C_{tissues}$ are determined using EA-IRMS (Euro EA-3000) at the state key laboratory of

environmental geochemistry, CAS, China, IAEA C-3 cellulose (-24.91‰, PDB) was used for calibration, and the determination accuracy was 0.05‰.

Descriptive statistics and correlation analysis were used for data statistics, and SPSS13.0 software was used for data analysis.

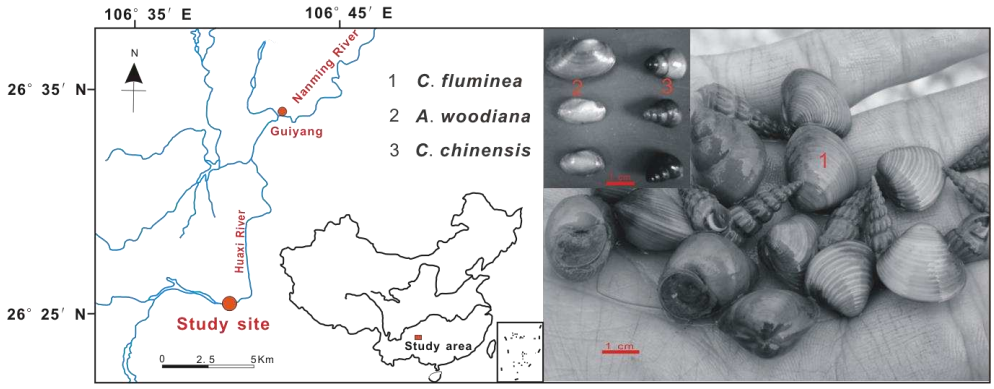

Figure 1. *Sampling locations and images of C. fluminea, A. woodiana and C. chinensis*

Table 1. *Different group of C. fluminea tissue samples*

Group	Shell height (mm)	Individual sample	Mixed sample	
1	4.0～ 5.9	1-1	1-2	-
2	6.0～ 7.9	2-1	2-2	-
3	12.0～13.9	3-1	3-2	3-3*
4	15.0～16.9	4-1	4-2	4-3*
5	17.0～19.9	5-1	5-2	5-3*
6	20.0～22.9	6-1	6-2	6-3*

*the samples were not treated with hydrochloric acid

Results

$\delta^{13}C_{tissues}$ values of C. fluminea

From group 1 to group 6, $\delta^{13}C_{tissues}$ values of *C. fluminea* individual samples were -28.49‰, -28.67‰, -28.96‰, -29.00‰, -29.02‰ and -28.42‰, respectively, while δ13Ctissues values of mixed samples were -28.31‰, -28.60‰, -28.89‰, -28.93‰, -28.95‰ and -28.33‰, respectively. The results showed that there is no significant difference of $\delta^{13}C_{tissues}$ values between the individual samples and mixed samples in the same group (R^2= 0.98, n=6) (*Fig. 2*), which may indicate that animals with similar shell height (similar age) assimilate similar food and nutrition. However, in the different groups (different ages), $\delta^{13}C_{tissues}$ values of *C. fluminea* showed some variation, the biggest amplitudes of variation are 0.60‰ and 0.65‰ for individual samples and mixed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_757768

samples, respectively, this variation may indicate that *C. fluminea* has certain changes of food resources or different preferable choices of food and nutrition during the growth process.

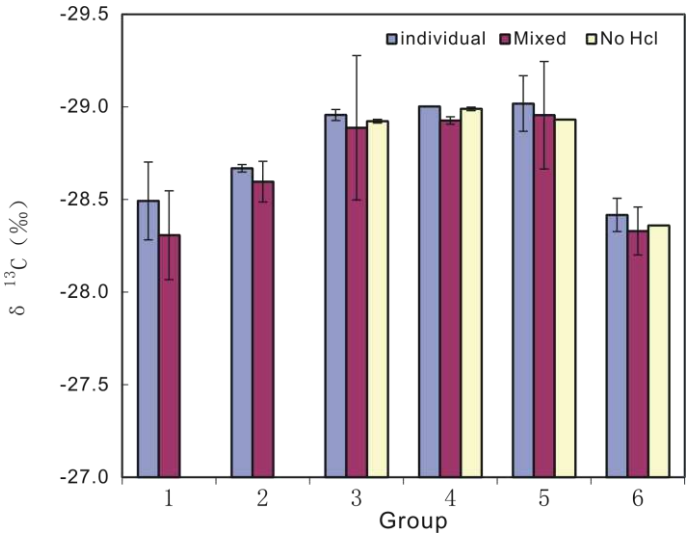

Figure 2. *$\delta^{13}C_{tissues}$ values of C. fluminea samples (The vertical line is the standard deviation)*

Effect of sample treatment on $\delta^{13}C_{tissues}$ values of C. fluminea

From *Fig. 2*, $\delta^{13}C_{tissues}$ values of *C. fluminea* did not show significant differences between samples that were treated by hydrochloric acid and those with no-hydrochloric acid treatment, this result may indicate that inorganic carbonate in *C. fluminea* tissue samples are very low, and have little impact on the analysis of $\delta^{13}C_{tissues}$ values, so it seems unnecessary to treat *C. fluminea* tissues with hydrochloric acid before isotope analysis. While some studies found that the acid treatments can change both $\delta^{13}C_{tissues}$ and $\delta^{15}N_{tissues}$ values, specially the $\delta^{13}C_{tissues}$ because of the removal of the isotopically heavier inorganic carbonate (Schlacher and Connolly, 2014). Zhao et al. (2019) also reported that the acid-treated mussel's periostracum showed lower $\delta^{13}C$ values compared to those in untreated specimens, the offsets ranging from 0.35 to 5.13‰, which show a statistically significant difference in $\delta^{13}C$ values. Since it is impossible to determine the amount of inorganic carbonate in advance, and mechanical removal is unfeasible, acid treatment is needed in carbonate-rich sample.

$\delta^{13}C_{tissues}$ values between different species

$\delta^{13}C_{tissues}$ values of three *A. woodiana* samples were -28.92‰, -29.00‰ and -29.04‰, respectively (*Fig. 3a*), which are highly consistent with the $\delta^{13}C_{tissues}$ values of *Anodonta spp* (-28.7±0.8‰) in Congjiang county, Guizhou province (Zhang et al., 2010). Considering that Congjiang county is very close to Huaxi river area, and are both belong to typical southwest karst regions of China, and have the same geological

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_757768

bedrock, vegetation types and soil types, this being consistent of $\delta^{13}C_{tissues}$ indicate that the carbon isotopes of molluscs tissues can really record the host environmental information.

$\delta^{13}C_{tissues}$ values of three *C. chinensis* samples were -26.27‰, -26.05‰ and -26.34‰, respectively (*Fig. 3a*). Comparation to *C. fluminea* and *A. woodiana* is also shown in *Fig. 3a*. $\delta^{13}C$ tissue values of *C. fluminea* and *A. woodiana* are very close to each other, while *C. chinensis* are about 3‰ heavier than bivalve species, this may indicate that both bivalve species *C. fluminea* and *A. woodiana* are relatively consistent in their food and nutrition sources, and are significantly different from gastropod species *C. chinensis.* This is also consistent with the previous study result, which found that $\delta^{13}C_{tissues}$ values of gastropod species are usually more positive than those of bivalves (*Fig. 3b*) (Cai et al., 2001).

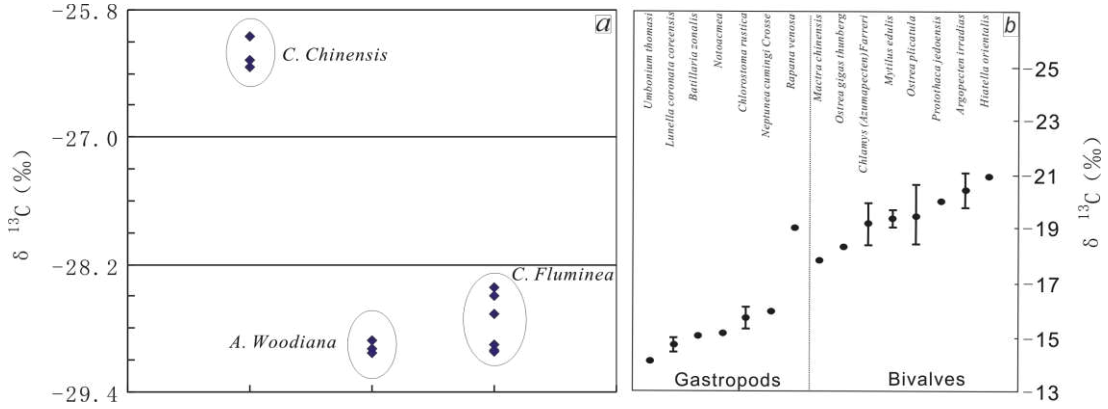

Figure 3. *$\delta^{13}C_{tissues}$ values of molluscs (a: $\delta^{13}C_{tissues}$ values of C. fluminea, A. woodiana and C. chinensis in this study; b: $\delta^{13}C_{tissues}$ values of several gastropods and bivalves species from Cai et al., 2001)*

Discussion

$\delta^{13}C_{tissues}$ values of C. fluminea between different groups

In the different groups (different ages), $\delta^{13}C_{tissues}$ values of *C. fluminea* show some variation both in individual samples and mixed samples, and the biggest amplitude of variation are 0.60‰ and 0.65‰ for individual samples and mixed samples, respectively. This variation of $\delta^{13}C_{tissues}$ values between different groups may indicate that *C. fluminea* has certain changes of food or different preferable choices of food during the growth process.

Studies have proved that bivalves have selective feeding characteristics at different ages, such as prefering different kinds of food or different sizes of particles in the same food (Ward and Shumway, 2004). They believed that filtering mollusc has two feeding mechanisms: (1) those that utilize mucous nets or strings (external to or within the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_757768

mantle cavity) to collect material, which known as hydrodynamic effect or passive feeding, and (2) those that rely on ciliated structures (proboscides, ctenidia) for particle collection, transport and processing, also known as mucilage ciliation effect or active feeding. There are also a few bivalves that rely on both of these mechanisms for particle collection (Ward and Shumway, 2004).

Ward and Shumway (2004) also found that the small size mollusc prefers to let the food flows through the main gill filaments directly into the back of the ventricle, along the back cilia swing into the lip, which known as hydrodynamic effect or passive feeding. The larger size of mollusc has strong active feeding ability, let the food flows enters the ventral edge of the gill under the action of the whole gill system, and enters the labial valve along the abdominal food delivery groove, also known as mucilage ciliation. Different ways of eating lead to absorb different or different sizes of food and nutrients, which can lead to differences in $\delta^{13}C_{tissues}$ values. Shumway et al. (1990) also found that the bivalve feeding behavior was related to the size of the food particles, and even related to the mucus action and chemical receptors of mollusc, which vary among individuals. Moreover, study on the scallop *Pecten maximus* in the field showed that tissue carbon isotopic composition can be also influenced by metabolic activity of the organism (Lorrain et al., 2002). Paulet et al. (2006) found that difference of $\delta^{13}C_{tissues}$ values between scallops and oysters could be due to differences in tissue growth rates between species. So the variation of $\delta^{13}C_{tissues}$ values of *C. fluminea* between different groups in this study may be caused by several reasons, such as the selective feeding characteristics and varied metabolic intensity at different ages.

$\delta^{13}C_{tissues}$ values between different species: a tool to determine the food sources

Gastropods are usually thought to be deposit-feeding, and food sources are mainly fluvial suspended material and sediment organic matter, while bivalves are defined as filter-feeding (Graney et al., 1984; Lorrain et al., 2002; Gillikin et al., 2006) and obtains suspended particles, such as plankton from the water through filtration by holding its inhalant siphon above the sediment surface (Britton and Morton, 1982; Kasai and Nakata, 2005; Kasai et al., 2006). While some studies found that filter-feeding alone cannot balance bivalve's energy budgets, the deposit feeding is also a significant source of nutrition for bivalve, especially in food-limiting situations (Aldridge and McMahon, 1978; Boltovskoy et al., 1995). For example, Hakenkamp and Palmer (1999) found that although *C. fluminea* is already known to be an important filterer of phytoplankton and seston from the water column, it has also been shown that it collects food within the stream through pedal-feeding, using cilia on the foot to collect subsurface organic matter. Moreover, Raikow and Hamilton (2001) found that potential food sources for bivalves also included epipsammon (detritus and possibly algae mixed with sand). An energy budget for the fingernail clam *Sphaerium striatinum* was reported by Hornbach et al. (1984), who estimated that 35% of its energy was derived from suspension feeding and the rest possibly from deposit feeding.

DOI: http://dx.doi.org/10.15666/aeer/1801_757768

Determining the exact sources of food used by mollusc species can be difficult because of the heterogeneity of materials in suspension at any given time (Atkinson et al., 2010) and the co-existence of filter-feeding and deposit-feeding (McMahon and Bogan, 2001). However, from all the previous studies, we can still conclude that the main food sources of molluscs are POM (paticle organic matter) and SOM (sediment organic matter). Both the POM and SOM pool are a mixture of different sources of carbon, each with an often distinct $\delta^{13}C$ value, the POM pool are mainly including phytoplankton, terrestrial plant detritus and soil organic carbon, the SOM pool are mainly including benthic algae, bacteria and sediment organic matter (Langdon and Newell, 1990; Cranford and Grant, 1990; Kang et al., 1999; Nichols and Garling, 2000).

$\delta^{13}C$ of phytoplankton

Although it is well established that the carbon isotope fractionation between phytoplankton and DIC is variable (Rau et al., 1992; Hinga et al., 1994), a value between 18‰ and 22‰ is often used as an estimate (Cai et al., 1988; Hellings et al., 1999). Therefore, similar to Fry (2002) and Gillkin et al. (2006), an average value of 20‰ is used in this study ($\delta^{13}C_{DIC-20}$) to represent $\delta^{13}C$ of phytoplankton. $\delta^{13}C_{DIC}$ of Huaxi river range from -9.58‰ to -3.60‰, with an average of -7.15‰ (Yan et al., 2009), so $\delta^{13}C_{DIC-20}$ range from -29.58‰ ～ -23.60‰, with an average of -27.15‰. $\delta^{13}C_{DIC-20}$ of Huaxi river are consistent to the typical values of freshwater phytoplankton, which is between -24‰ and -42‰ (Zanden and Rasmussen, 1999), and also consistent to $\delta^{13}C$ of Guizhou freshwater phytoplankton, which ranges from -35.03‰ to -22.97‰ (Li, 2009).

$\delta^{13}C$ of terrestrial plant detritus

Du et al. (2014) measured the $\delta^{13}C$ of common local plant species grown in Wangjiazhai catchments, a typical karst desertification area in Qingzhen City, which is very close to Huaxi river, $\delta^{13}C$ of plants ranged from -30.7‰～-26.5‰, with an average value of -28.1‰. Since the $\delta^{13}C$ value remains the same when a plant dies and becomes detritus (Smith and Epstein, 1971; Haines, 1977), so -30.7‰～-26.5‰, with an average value of -28.1‰ was used to represent the $\delta^{13}C$ of terrestrial plant detritus in this study.

$\delta^{13}C$ of sediment organic matter

Zhao et al. (2012) studied the geochemical characteristics in sediments in a small watershed of central Guizhou province, the results demonstrated that fluvial sediment are mainly derived from chemical weathering and soil physical erosion in the basin. The main soil types in Guizhou province were calcareous soil and yellow soil, and studies showed that the $\delta^{13}C$ values of calcareous soil and yellow soil were between -22.9‰ ~-21.5‰ and -25.6‰ ~-22.4‰ respectively (Li et al., 2012). The main soil type in Huaxi river area is yellow soil, so -25.6‰ ~-22.4‰ was used in this study.

DOI: http://dx.doi.org/10.15666/aeer/1801_757768

Fig. 4 shows the $\delta^{13}C_{tissue}$ values of mollusks that were analyzed in this study and their potential main food sources. According to the *Fig. 4*, we can conclude that bivalve species *C. fluminea* and *A. woodiana* main food sources are phytoplankton and terrestrial plant detritus. Phytoplankton as a main food source for bivalves was proved by many studies (Ogilvie et al., 2000; Gillikin et al., 2006), while some research studies also found that terrestrial plant detritus contribution in bivalve diet is important during the periods when abundance of phytoplankton is too low to satisfy bivalve energy needs (Cranford and Grant, 1990; Langdon and Newell, 1990). Kasai et al. (2005) also found that the contribution of terrestrial organic matter is significantly important for the corbicula diet, although the contribution gradually changes among sampling sites. However, it's more complicated for gastropod species, according to the $\delta^{13}C_{tissues}$ values, besides of the phytoplankton and terrestrial plant detritus, *C. chinensis* must also assimilate sediment organic matter as food sources, which have a significantly heavier carbon isotope composition.

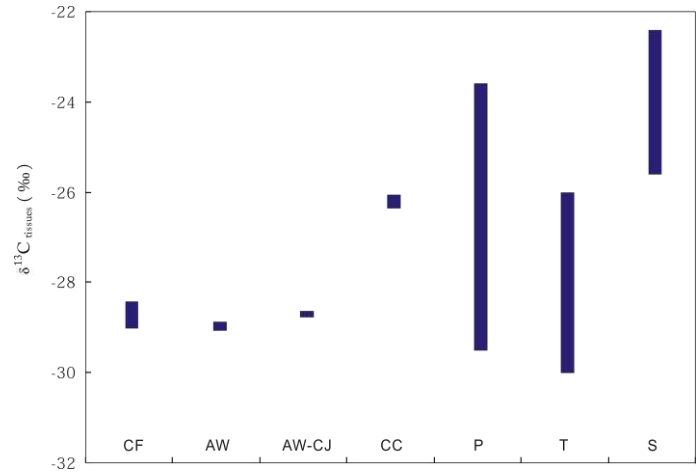

Figure 4. *$\delta^{13}C$ values of molluscs and potential food sources (CF is C. flminea; AW is A. woodiana; CC is C. chinensis; AW-CJ is Anodonta spp from Congjiang county; P, T, S are phytoplankton, terrestrial plant detritus and sediment organic matter, respectively)*

The relative abundance of multiple food sources in the diet of organisms can be quantified using a classical isotope mixing model, which is related to the $\delta^{13}C$ values of each food resource (Gannes et al., 1997; Raikow and Hamilton, 2001). As we did not have stable isotope values of some molluscs potential food sources in the Huaxi river, such as benthic algae, bacteria, we cannot quantitatively evaluate the mollusks' diet. However, this study still further illustrates the values of stable carbon isotope of mollusk's tissues as a tool in tracing organic carbon flow and recycle through a typical karst river ecosystem.

DOI: http://dx.doi.org/10.15666/aeer/1801_757768

Conclusion

$\delta^{13}C_{tissues}$ values of bivalve species *C. fluminea* and *A. woodiana* are very close to each other, while *C. chinensis* are about 3‰ heavier than bivalve species, which indicate the different food and nutrition sources between species.

Comparing the $\delta^{13}C$ values of molluscs tissues and the potential food, bivalve species, *C. fluminea* and *A. woodiana* mainly assimilate phytoplankton and terrestrial plant detritus as food, while gastropod species *C. chinensis* also use sediment organic matter as a food source besides the phytoplankton and terrestrial plant detritus.

$\delta^{13}C_{tissues}$ values of *C. fluminea* between different sizes showed some variation, which may be caused by several reasons, such as the selective feeding characteristics and variational metabolic intensity at different ages.

Acknowledgements. We express our gratitude to Dr Zhu Zhengjie for laboratory assistance and isotope measurement. Abstract. Cotton crop is grown in China, Brazil, Pakistan, India and in the USA. It is a major global resource in textile production. Phosphorus has major role in the growth and yield of plants facilitating higher crop production. Phosphorous is involved in plant growth and opening of flower bud while low nitrogen and magnesium absorption inhibits plant growth. Higher input cost of fertilizers and numerous other yield limiting factors are major problems for farmers. To mitigate the problem, present study was carried out at the Central Cotton Research Institute (CCRI), Multan, Pakistan. The experimental treatments comprised of three cultivars viz. V_1 = MNH - 886, V_2 = CIM - 616 and V_3 = FH-LALAZAR and seven levels of Phosphorous viz. To = Zero kg ha^{-1}, T_1 = 50 kg ha^{-1}, T_2 = 50 kg ha^{-1} + foliar (2% TSP solution), T_3 = 75 kg ha^{-1}, T_4 = 75 kg ha^{-1} + foliar (2% solution of Triple super phosphate), T_5 = 100 kg ha^{-1} + seed application (5% solution of triple super phosphate), T_6 = 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution). Different genotypes significantly differed in various growth, yield and quality attributes. In this regard, the cultivar FH- Lalazar produced the highest plant height (152.50 cm), lint yield (50.58 kg ha^{-1}), seed cotton harvest (27%), ginning out turn (0.02%), crop growth rate (4.79 kg ha^{-1}), fiber uniformity (45.50), fiber strength (30.16 tppsi) and micronair (4.72 µg/inch). CIM-616 showed the maximum number of bolls/plant (28.91), leaf area index (0.65 kg ha^{-1}), boll weight (2.98 g), and staple length (20.19 mm). In conclusion, cultivar FH-LZ using 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution) produced higher yield, ginning out turn, seed cotton harvest, crop growth rate and fiber uniformity with lower input cost and attained the maximum output with higher crop production.
Keywords: *yields, transgenic cotton, fiber quality, foliar application, phosphorous concentration*

Introduction

Cotton is a commercial crop for its excellent quality as fiber and oil so it is grown in whole regions of the world (Zhang et al., 2012). Lately, cotton has been grown in a region of 2907 thousand hectares while the ranks of production is 13.2 million bales (Govt. of Pakistan, 2018). During flowering and boll opening stage the continuous rain may possibly cause the reduction of pollination phenomenon and ultimately minimize fiber quality. Therefore, heavy rainfall causes flower buds and young bolls to fall during flowering (Gaikwad, 2018).

Nutritional quality of crops can be enhanced and may vary depending upon the soil conditions as well as genetic make-up of genotypes (Zhang et al., 2012; Ahmad et al., 2019). However, optimum dose of macro-nutrients as well as micronutrients and their proper application maximized crop production (Vance et al., 2003). Reduction of phosphorous availability resulted in minimizing the cotton plant growth. Reduction of phosphorus causes the minimization of different traits i.e. reduced flowering, imbalanced pollination, boll weight and boll size. Moreover, low phosphorus in cotton crop inhibits

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_769781

dark green leaves and flower bud necrosis. Lower phosphorous availability in cotton crop also affects the development of flower buds and also minimized the absorption of nitrogen resulting in inhibited cell growth and their expansion (Dohary et al., 2004).

Phosphorous is taken up by the roots. So among all of this many factors which affect the cotton response to phosphorous the most is the type of soil. The acute amount of phosphorous is a main issue of actual concentration of phosphorous, which is provided at the time of cotton growth (Crozier et al., 2004). Numerous traits i.e. early phosphorous accumulation and lint yield positively respond to phosphorous in calcareous soils (Bronson et al., 2003). However, the reduction of phosphorous may possibly minimize the nitrogen level. Due to the indeterminate type of growth and deep-growing root system of cotton crop phosphorous concentration availability is low (Zhou et al., 2011).

Several nutrients were applied through foliar spray to leaves that may prevent their senescence and decline in photosynthesis allowing photosynthesis and carbon fixation to be prolonged thus increasing the yield of cotton (Bronson et al., 2001). Those resistant cultivars were selected that had greater capability to tolerate unfavorable conditions including nutritional stress which results in higher yield of crop (Zambrosi et al., 2012). The efficiency of phosphorus cultivars having the ability to grow well and produce the maximum yield in soil with the minimum phosphorous (Fageria et al., 2010). Thus, effiicnet application of phosphorus was recorded in several agronomic crops. (Zambrosi et al., 2012; Fageria and Moraes, 2013).

Foliar application and seed treatments are successfully used in application of several nutrients especially phosphorus. Among all the nutrient application methods, foliar application is considered as one of the most suitable method and it is also helpful for proper use of nutrients in plants (Girma et al., 2007). Furthermore, combination of foliar application and seed treatment results in efficient use of phosphorus to plants and ultimately enhanced cotton production. Application of phosphorus to all other agronomic crops is very common; however, its use in cotton is very limited. Therefore, current study is more helpful for cotton growers to enhance production through foliar application of phosphorus (Verma et al., 2018). The optimum dose of phosphorus and its timely application drastically enhance cotton crop production all over the globe (Araújo et al., 2012). So, the purpose of this current study was to demonstrate the optimum application of phosphorus for various cotton cultivars.

Materials and methods

Experimental details

Current study was conducted in the research farm of Central Cotton Research Institute (CCRI) Multan, Pakistan to mitigate various cultivars of cotton with various foliar application of phosphorus during 2015-2016. The soil at the Research Farm was silt loam and its organic content was 0.86%, Nitrogen concentration was 0.09%, Phosphorous concentration was 12.5 ppm, Sand was 16%, Silt was 57%, Clay was 27%. Experimental treatments comprised of three cotton cultivars viz. V_1 = MNH - 886, V_2 = CIM - 616 and V_3 = FH-LALAZAR and seven phosphorus levels viz. To = Zero, T_1 = 50 kg ha^{-1}, T_2 = 50 kg ha^{-1} + foliar (2%TSPsolution), T_3 = 75 kgha^{-1}, T_4 = 75 kg ha^{-1} + application of foliar (2% solution of triple super phosphate),T_5 = 100 kg ha^{-1} + seed application (5%solution of triple super phosphate), T_6 = 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution). One meter area was marked from the center of the plot from where sampling for various parameters

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_769781

was done. CCRI lies at a latitude of 30°, and at a longitude of 71°, the altitude is 125 in the cotton belt of Punjab. After the preparation of seed bed the sowing was carried out with cotton Rabi drill on the 28th May, 2015 and on the 31st May, 2016 respectively. Net plot size was 6.1 m × 9.0 m = 54.9 m^2 with a sowing rate of 110 g/plot. Randomized Complete Block Design (RCBD) was applied along three replications. Urea fertilizers (36 kg ha^{-1}) were applied as per standard rule according to crop requirement, and seven phosphorous levels were used and TSP as a source were also applied. Whole of phosphorous according to treatments done on sowing time and application of nitrogen done on three intervals as per standard roles at both years. Pendimethaline (herbicide) was applied at the rate of 82.5 g ha^{-1} to control weeds. For the chewing and sucking insect pest different products such as Nitenpyren, Diafenthoran, Triazophos were applied and Leuforan Irrigation was performed as crop needed. Harvesting was done from 05-11-2015 and 13-11-2016 and picking interval was two weeks.

Observations

Agronomic traits

Five plants were randomly chosen from every plot and the height of the plant was observed with a measuring tape in between about the base of the plant to the terminal bud. Same plants were used to measure no. of bolls/plant. One hundred fully opened bolls were selected for picking to get a hundred boll weight. Yield of cotton was calculated after picking by same plot, after this the bolls were weighed to get the yield (kg ha^{-1}). Ginning out turn (%) was calculated by the following formula: mass of cotton lint/mass of seed cotton x 100 (Baloch et al., 2014).

Allometry traits

Leaf area of each plant was measured with a leaf area meter (CI-203, LCi Bio Scientific, USA). Leaf area index (LAI) was calculated according to the method of Hunt (1978) using the following formula: LAI = Leaf Area/Ground Area Leaf. Area duration was recorded simultaneously by LAI_1 and LAI_2 with leaf area indices at times T_1 and T_2 and LAD (days) = $(LAI_1 + LAI_2) \times (T_2-T_1)/2$ (Hassan et al., 2016). Crop growth rate was measured by collecting weighed samples of 10, 30, 60 g of green leaves, stalks and bolls collected by same treatment at various stages of plant growth, which then were dried in the oven at 80 °C. Crop growth rate was calculated by using the formula of Hunt (1978).

Quality traits

Quality traits, cotton seed were ginned in an electrically powered ginning machine to separate lint from seed followed by cleaning of those samples. Each sample was acclimatized at an optimum temperature of 20 °C with 65 % relative humidity level in an air conditioned chamber. The level of humidity was measured by a humidifier (HIV-900) at the humidity level of 8.5% Tisarum et al. (2019). Fiber strength is calculated by breaking the fibers held between clamp jaws. It is mentioned as g/tex, which is the force used to break bundle (Apel and Hirt2004)

Data analysis

Data was analyzed by using Statistix 8.1 (Tallahassee Florida, USA) on computer. The means of treatment were separately analyzed by LSD @ 5% level of probability.

Pearson's correlation was constructed through software XLSTAT, 2017(Anjum et al., 2018; Ahmad and Anjum, 2018). Whereas economic analysis was performed as determined by Ahmad et al. (2016). Climatic data of experimental site was evaluated as described (Pakistan Metrological Department, 2016).

Results

Different cotton cultivars and yield related traits were significantly differed in the current study. Significantly higher plant height (60.03 inch) was recorded from Cultivar FH-Lalazar and the lowest height of plant (57.74 inch) was measured from MNH-886. The treatment 100 kg ha^{-1} + seed application (5% solution of triple super phosphate) (61.02 inch), under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution) resulted in a significantly higher plant height (61.93 inch), while the minimum plant height was calculated from control (56.38 inch). Cultivars and phosphorus levels interaction showing significantly higher plant height (61.81 inch) was recorded from FH-LZ with 75 kg ha^{-1} + foliar (2% TSP solution), followed by the plant height (63.38) from FH-LZ with100 kg ha^{-1} + seed treatment (5% TSP solution), followed by the plant height (64.17 inch) from FH-LZ under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution), while the minimum (55.24 inch) was recorded from MNH-886 with Zero kg ha^{-1} (*Table 1*). The higher the no. of bolls/plant (28.91) recorded from CIM-616, the lower the no. of bolls/plant (24.50) occurred from cultivar MNH-886. From treatment 100 kg ha^{-1} + seed solution (5% solution of triple super phosphate) (29.11) under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution) higher no. of bolls/plant were found (29.65), the minimum in no. of bolls/plant was found in control (23.77). Regarding the level of phosphorous and cultivars interaction the highest no. of bolls/plant (35.33) occurred from CIM-612 under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution), followed by (33.33) from CIM-612 with 100 kg ha^{-1} + seed treatment (5% TSP solution). So the minimum no. of bolls/plant (22.00) was present in MNH-886 with control (*Table 1*).

The maximum boll weight (2.98 g) was measured from CIM-616, the lowest (1.21 g) from MNH-886. Concerning the phosphorus applications, the treatment 75 kg ha^{-1} (2.26 g), 75 kg ha^{-1} + foliar (2% TSP solution), (2.27 g), 100 kg ha^{-1} + application of seed treatment (5% TSP solution) (2.29 g) under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution) (2.45 g) increased boll weight, and a decrease of boll weight was measured from control (1.60 g). Regarding the levels of phosphorous and cultivars maximum weight of boll (3.20 g) was calculated from CIM-616 by50 kg ha^{-1}, followed by (3.22 g) from CIM-616 with 50 kg ha^{-1} + foliar (2% TSP solution), followed by (3.30 g) from CIM-616 with 75 kg ha^{-1}, followed by (3.32 g) from CIM-616 with 75 kg ha^{-1} + foliar (2%TSPsolution), followed by (3.30 g) from CIM-616 with 100 kg ha^{-1} + seed treatment (5%TSPsolution) and (3.32 g) from CIM - 616 under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution) (*Table 1*). The highest cotton yield was found from FH-Lalazar (2809.3 kg ha^{-1}), while the lowest was (1905.6 kg ha^{-1}) from MNH-886. Level of application 75 kg ha^{-1} (2638.00 kg ha^{-1}), 75 kg ha^{-1} + foliar (2% TSP solution), (2651.00 kg ha^{-1}), 100 kg ha^{-1} + seed treatment (5% TSP solution) (2763.9 kg ha^{-1}), under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super

DOI: http://dx.doi.org/10.15666/aeer/1801_769781

phosphate, and foliar application of a 2% solution) (2769.9 kg ha^{-1}) showed statistically higher yield of cotton, the minimum cotton yield (1941.1 kg ha^{-1})was determined from control, and 50 kg ha^{-1} (2002.3 kg ha^{-1}) and 50 kg ha^{-1} + foliar (2% TSP solution) (2004.3 kg ha^{-1}). Cultivars with levels of phosphorus interaction gave the highest cotton yield (3776.3 kg ha^{-1}) measured from FH-Lalazar with 75 kg ha^{-1},(3976.3 kg ha^{-1}) from cultivar FH-LZ with75 kg ha^{-1} + foliar (2% TSP solution), followed by (3844.00 kg ha^{-1}) from cultivar FH-Lalazar with100 kg ha^{-1} + seed treatment (5% TSP solution) and (4044.0 kg ha^{-1}) from FH-LZ under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution)·, while lower cotton yield (1561.7 kg ha^{-1}) was measured from FH-LZ with Zero kg ha^{-1} (*Table 1*).

Cultivar FH-Lalazar (50.58 kg ha^{-1}) gave the highest lint yield, the lowest yield of lint was measured (37.33 kg ha^{-1}) from cultivar MNH-886. The treatment 50 kg ha^{-1} (44.00), 50 kg ha^{-1} + foliar (2% TSP solution)(2004.3 kg ha^{-1}). (44.55), 75 kg ha^{-1} (44.88), 75 kg ha^{-1} + foliar (2% TSP solution) (45.00), 100 kg ha^{-1} + seed application (5% solution of triple super phosphate) (45.55) under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution) (45.89 kg ha^{-1}) resulted in statistically higher lint yield, the minimum lint yield was (40.00 kg ha^{-1}) obtained from control (*Table 2*). FH-Lalazar (0.76 kg ha^{-1}) showed statistically higher biological yield, the lowest biological yield was determined from two cultivars MNH-886 (0.69 kg ha^{-1}) and CIM-616 (0.67 kg ha^{-1}). Treatment 100 kg ha^{-1} + seed treatment (5% TSP solution) (0.83 kg ha^{-1}) under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution) (0.92 kg ha^{-1}) showed statistically higher biological

DOI: http://dx.doi.org/10.15666/aeer/1801_769781

yield, the minimum biological yield (0.57 kg ha^{-1}) was obtained from control (*Table 2*). Higher seed cotton harvest (27%) was calculated from FH-LZ, while the minimum seed cotton harvest (19.00%) from MNH-886. The treatment 75 kg ha^{-1}(26.00%), 75 kg ha^{-1} + foliar (2% TSP solution) (27.00%), 100 kg ha^{-1} + seed application (5% solution of triple super phosphate) (27.00%) under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution). (27.00%) yielded statistically higher seed cotton harvest, the lowest seed cotton harvest was measured from control Zero kg ha^{-1} (19.00%), 50 kg ha^{-1}(20.00%), 50 kg ha^{-1} + foliar (2% TSP solution) (20.00%) (*Table 2*). FH-Lalazar (0.02%) showed statistically maximum ginning out turn, the lowest ginning out turn was found in two cultivars MNH-886 (0.019%) and CIM-616 (0.018%). Regarding the treatment under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution).(0.019%) higher ginning out turn was measured, lower ginning out turn was found from control Zero kg ha^{-1} (0.011%), 50 kg ha^{-1} (0.012%). Concerning cultivars and phosphorus levels interaction the highest ginning out turn (0.028 %) was recorded from FH-Lalazar with Zero kg ha^{-1}, the lowest got (0.016%) was found from CIM-616 with Zero kg ha^{-1} (*Table 2*).

Higher leaf area index (0.65 m^2/m^2) was found from CIM-616, lower leaf area index (0.49 m^2/m^2) was measured from MNH-886. Treatment under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution) (0.67 kg h^{-1}) resulted the statistically maximum leaf area index, the lowest (0.51 m^2/m^2) was determined from control (*Table 3*). Cultivar FH-Lalazar (4.79 g m^{-2} day^{-1}) gave maximum crop growth rate, the minimum was found from cultivar MNH-

886 (4.15 g m^{-2} day^{-1}). Concerning cultivars and phosphorus levels interaction higher crop growth rate (5.12 g m^{-2} day^{-1}) was measured from FH-Lalazar under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution). While the minimum (4.03 g m^{-2} day^{-1}) was calculated from cultivar MNH-886 with Zero g m^{-2} day^{-1} (*Table 3*). Maximum leaf area duration was calculated from FH-Lalazar (659.7), while the lowest was in MNH-886 (381.9) (*Table 3*). The highest phosphorus concentration was recorded in 100 + seed treatment (591.2) and 100 + seed + foliar (597.2). The highest phosphorus concentration was in two cultivars i.e. MNH-886 (40.08%) and FH-LZ (45.50%). Further detail regarding the phosphorus concentration is shown (*Table 3*).

So due to all of this, cultivar CIM-616 (47.00), FH-Lalazar (45.50) showed statistically higher fiber uniformity. Treatment 75 kg ha^{-1} (45.77), 75 kg ha^{-1} + foliar (2% TSP solution) (45.99), 100 kg ha^{-1} + seed application (5% solution of triple super phosphate) (47.55) under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution) (48.34) resulted the statistically maximum fiber uniformity, the minimum fiber uniformity was determined from control (*Table 4*). Cultivar CIM-616 (20.19 mm) showed maximum staple length, and cultivar MNH-886 (14.83 mm) the minimum. So, the application of level of phosphorus, treatment 75 kg ha^{-1} + foliar (2% TSP solution) (91.88 mm) 100 kg ha^{-1} + application of seed treatment (5% TSP solution)(20.44 mm) under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution).(21.00 mm) gave maximum staple length, so minimum staple length was calculated from control (15.22 mm) and 50 kg ha^{-1} (16.33 mm) (*Table 4*). FH-LZ

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_769781

exhibited the highest fiber strength (30.16 tppsi) while the minimum fiber strength was determined (23.08 tppsi) from MNH-886. The treatment under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution) (28.00 tppsi) showed statistically higher fiber strength, lower fiber strength (24.33 tppsi) was recorded from control (*Table 4*). Cultivar FH-LZ showed the highest micronair (4.72 µg/inch), the minimum was found from cultivar MNH-886 (4.14). Application of treatment 100 kg ha^{-1} + seed treatment (5% TSP solution) (4.68 µg/inch) under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution). (4.75 µg/inch), 75 kg ha^{-1} (4.45 µg/inch), 75 kg ha^{-1} + foliar (2%TSPsolution) (4.51 µg/inch) resulted statistically higher micronair, lower was recorded from control (4.27 µg/inch), 50 kg ha^{-1} (4.34 µg/inch), 50 kg ha^{-1} + 5%foliar (2%TSPsolution) (4.40 µg/inch). Regarding phosphorus levels and cultivars interaction the highest micronair was measured from FH-Lalazar with 100 kg ha^{-1} + seed treatment (5% TSP solution) (5.06) from cultivar CIM-616 under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution) (5.08 µg/inch) (*Table 4*).

Pearson's correlation of various cotton traits cultivars showed that plant height shared a direct significant correlation with all other studied traits i.e. no. of bolls/plant, boll weight, yield of cotton, lint yield, biological yield, seed cotton harvest, got, LAI, CGR, LAD, phosphorus concentration, fiber uniformity, staple length, fiber strength and micronair. Moreover, it has been studied that seed cotton harvest trait gave non-significant correlation with lint yield. Similarly, leaf area duration gave non-significant correlation with lint yield among all the studied traits (*Table 5*). Correlation matrix is an

DOI: http://dx.doi.org/10.15666/aeer/1801_769781

important tool for the evaluation of trait association with each other (Anjum et al., 2018). Economic analysis of cost benefit ratio presented that maximum output can be attained with low input cost. And the highest benefit cost ratio was found 1.73 while the lowest was 1.27 during 2015, therefore in 2016 the highest was 1.81 and the lowest was 1.34 (*Table 6*). Eco-metrological data had long term effects on benefit cost ratio and net returns, therefore all these parameters must be calculated (*Table 7*).

Discussion

Different parameters such as structure of plants, production of total dry mater and economic yield become used to evaluate useful doses of fertilizer. When the main node stem was enhanced then it would be mainly obligate for height of plant, no. of bolls/plant and boll weight. Cultivar MNH-147 gave the highest height of plant and no. of bolls/plant in comparison to CIM-240. The reason was due to the growth habit of cultivar MNH-147 because it is more indeterminate as compared to CIM-240 (Malik et al., 2006). The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_769781

performance of cultivars may varied under different concentrations of phosphorus (Ramya and Hebsur, 2018). Phosphorous is an essential nutrient, the effect was stagnant to cotton crop, enhancing no. of flowers (Russell, 2001). Yield of cotton and lint significant were enhanced through application of phosphorus which is excellent trait for higher production. It has been noted that phosphorus affects photosynthesis so as essential commodities, while these commodities are the main factors affecting the yield of cotton. Phosphorous fertilizer is the main component to give power for plant growth and enhance weight of boll in cotton. Biological yield is equivalent to the above ground biomass. It is cumulative concerning both plant weight and root weight. Biological yield plays an imperative role in the increase of cotton production. Biological yield affected different parameters viz, environment, soil, and other plant factors. Results of the current experiment demonstrated the highest biological yield (Ramya and Hebsur, 2018). Biological yield was found highest when the spacing of plants was increased (Al-Dalain et al., 2012). Leaf area index is a main parameter for crop growth. It also describes raw materials produced by total radiation to plant for the initiation of leaf. There would be different ranges of leaf area index in young cotton plant. The cotton plant has ability to capture all of solar radiation when leaf area index reached the range of 3 (Zhou et al., 2011). Crop growth rate would be measured on different strategies such as that maximum calculated from NIAB-846 lower doses of nitrogen (50 kg ha^{-1}), the best crop growth rate on next cultivars, CIM-496, NIAB-824, demonstrated with increase of nitrogen doses of 100, 150 kg nitrogen per hectare simultaneously. While the reduction of CGR was observed with high stress treatments such as moisture stress and stages of vegetative growth (Hassan et al., 2016). Dry matter production of a crop is dependent on leaf area duration. Alkaline soils gave the highest yield when different relationship occurred between leaf area duration, yield and biomass. When there was no competition of weed, it was observed that leaf area duration gave the highest (136.85 days) in plots after transplantation so the reduction occurred due to the increase of competition. Reductions of LAD was observed in plots with competition of barnyard grass throughout the crop growth season. (Chen et al., 2018; Verma et al., 2018).

Many researcher papers demonstrated that phosphorous gave response to cotton crop such as that (Magare et al., 2018; Rosace et al., 2018). Khan et al., (2014) demonstrated FU gave a positive response for Ginning out turn and value of micronair. Positive response of fiber uniformity was found on yield of cotton for fiber strength whereas negative response demonstrated for mean length and upper half mean length. Fiber uniformity, staple length, fiber strength and micronair are excellent traits to enhance the potential of textile industry. All these traits were probably enhanced with phosphorus application.

Cotton growers have many difficulties due to enhanced commodities. So, increase of inputs cost resulting in decrease of output/ profit.. Improper fertilizer is a main source to increase the production cost. Most of all growers of cotton use nitrogen fertilizer; while 85% of growers use phosphorous fertilizer for higher rate of production (Miao et al., 2018). Fertilizer cost is a major problem and has the 2nd largest commodity value and accounts for 22% of total cost production (Makhdum et al., 2001). Phosphorous is a main nutrient but overall in cotton crop the efficiency of phosphorous is low because farmer could not facilitate phosphorous fertilizer in all soil type. Due to all of this various research studies on cotton which responds to phosphorus positively and economically were conducted (Miao et al., 2018). Results demonstrated that phosphorus is a main nutrient for cotton crop for the highest yield of cotton compared to nitrogen. So, phosphorus provides positive response for better production of cotton in Punjab.

Conclusion

It is concluded that decreased amount of phosphorus demonstrated in decreased yield of cotton along with its related traits. However, cultivar FH-LZ along with phosphorous level under 100 kg ha^{-1} phosphorous (with seed application of a 5% solution of triple super phosphate, and foliar application of a 2% solution) demonstrated the highest values and excellent performance for many yield traits.

Therefore, it is recommended that farmers and researchers of the vicinity may use exogenous phosphorus to get the highest yield and excellent quality of fiber of cotton crop.

(Received 3rd Jul 2019; accepted 14th Nov 2019)

Abstract. In developing countries like Pakistan, leading CO_2 emission source is deforestation of temperate forests, which must be estimated precisely for resilient climate policy. This research evaluates temporal deforestation, above and below ground carbon stock, biomass estimation potential of vegetation indices derived from Sentinel-2 imagery, carbon emission from deforestation and carbon sequestration potential. Forest inventory data was collected and used in allometric equations, to calculate aboveground biomass and carbon stock. The temporal deforestation rate was estimated using LANDSAT 7 & 8 (2000-2015) data. Biomass was predicted using the most optimal VI by developing linear regression model. The carbon emission from deforestation was estimated using activity data and emission factor. Above ground biomass and carbon stock estimated for the study area were 148.79 t/ha and 69.93 t/ha with mean CO_2 equivalent value of 322.5 t/ha. The estimated forest cover change using Landsat satellite data (2000-2015) was about 16.88% with 2.51% annual deforestation rate. Relationship between red-edge VIs and AGB were the best and reduced saturation problem. Carbon loss in fifteen years were about 6.96 Mt CO_2 e. The carbon sequestration capacity for the study area was 82.07 t/ha ± 13 t/ha. This research methodology is cost effective, helps in sustainable forest management and reduces carbon losses.
Keywords: *activity data, carbon losses, climate change, GIS, REDD+, remote sensing, sequestration potential*

Introduction

In sequestration of carbon forests play a significant role and act as a natural carbon sink to mitigate climate change. There is about 33% area of the world covered with forests which accounts for 80% aggregate over ground earthbound carbon and 40% below canopy carbon (Noble et al., 2000). The rate of carbon storage in the world's forests is estimated to be about 4.1 $GtCyr^{-1}$ from 2000 to 2007 (Stinson et al., 2011). The significant contribution of greenhouse gas emission is due to forest fire, degradation, fossil fuel burning, and deforestation. The Greenhouse gas emission can be reduced through sustainable management, conservation, restoring forest and increment in forest trees (Noble et al., 2000). While conservation of forest not only act to be the source of carbon but also gives a more extensive scope of services and products to people, and it also has natural, financial, social, ecological and environmental benefits. The carbon density in the forest is higher than in other type of environments and hence has a role in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_783815

decreasing atmospheric carbon emissions (Stinson et al., 2011). According to IPCC, outflow of carbon dioxide from a change in land use is about 10% of the outflows that are from human-made activities. As deforestation, degradation and erosion occur it leads to an increase in carbon emission and a decrease in sequestration (Dube et al., 2012). About 50.8% of coniferous wood comprises of carbon and herbs, woody plants in forest act as essential storage of carbon (Thomas and Martin, 2012). There is a significant role of forest in global climate change as about 17.4% of yearly CO_2 discharge are due to degradation and deforestation of forests (Egenhofer, 2007). Forests located at high-latitude in the northern hemisphere act as major sinks of carbon and play a leading part in reducing emissions of carbon in the global carbon cycle (Schimel et al., 2000; Valentini et al., 2000). Therefore, countries having more risk of deforestation and degradation should increase the protected areas as an effort for the conservation of their forest environmental services (Jackson and Baker, 2010; Lippke et al., 2003). Of the 3984 million ha worldwide forest area it is estimated that about 13.25% of the areas are protected forests (Keenan et al., 2015).

According to IPCC, a baseline must be created for the assessment of carbon stock, and it needs a mapping of vegetation biomass arrangement from local to worldwide scale (Dobbs et al., 2014; Pan et al., 2011). To counterbalance carbon release at less expense and obtain sustainable forest management REDD+ has promoted interest at international level (Caparros et al., 2011; Neilson et al., 2006). The primary aim of REDD+ is to make motivators for decreasing discharges from degradation and deforestation and enhancement of carbon stock through improvement, sustainable forest management and conservation in the developing countries (Balderas Torres and Skutsch, 2012). According to the strategy of UNFCCC on REDD+ release of carbon from the forests will be ascertained and the compensation will be given to developing countries in favor of a decrease in carbon emission. In order to receive the compensation, they should indicate that in the forest they increased carbon storage rate and due to degradation and deforestation national carbon release rate are decreased (increasing carbon sequestration) (Le Toan et al., 2011; Sessa and Dolman, 2008). Then an arrangement of "national forest reference emission level/reference levels (REL/RL) (or sub-national REL/RLs as an interval measure) and safeguards" should be set up and then by those results financing should be given (Brown, 2002; Lu, 2006).

Pakistan has a forest cover of 4.55 million hectares (5.1%). Most of the forest in the country is located in the northern part which is generally natural and coniferous. These forests can be categorized as moist temperate, dry temperate, sub-tropical chir pine and sub-alpine forests. These types comprise about 54% of the area of forests. Forest/tree cover stretches out over a region of 1.51 million ha (except alpine pasture), which makes about 20.3% of total land area of Khyber Pakhtunkhwa province. In Khyber Pakhtunkhwa, the natural forests comprise of sub-tropical chir pine forests having *Pinus roxberghii* (Chir pine), and *Quercus* spp. The dry and moist temperate forests have dominant species of *Pinus wallichiana* (Blue pine), *Picea smithiana* (Spruce) and *Cedrus deodara* (Deodar) as well as several broad-leaved species such as *Acer caesium* (Maple), *Aesculus indica* (Horse chestnut), *Juglans regia* (Walnut) and *Prunus padus* (Bird cherry).

It is estimated that over 1 million hectares of forests are lost in Pakistan between 1990 and 2015 (FAO, 2014), which is about 25% of its natural forests with the average deforestation rate of 42,200 ha per year. The above ground and below ground biomass are reduced due to deforestation at an annual rate of 2.2%, totaling over 100 million tons CO_2

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_783815

e; from 330 million tons of CO_2 in 1990 to 213 million tons of CO_2 in 2010 (WorldBank, 2015). Deforestation is mainly driven by increasing demand of forest product such as fuelwood, fodder, and timber, outstripping the supply of these products, population expansion, grazing, land use change and illegal harvesting (FCPF, 2013). Coniferous forest area has been rapidly declining due to the high value of conifer timber. Government forests have been transferred to the non-forestry and commercial purpose such as infrastructure development, agriculture, defense, and tourism in recent decades (WorldBank, 2015). In Pakistan coniferous forests are considered to be the most important species for preservation due to their high carbon stock, the presence of peatlands, and longer maturity age (Karki et al., 2014). Deforestation and land-use change are identified as major sources of emissions. Forestry and land use change contribute approximately 3% to Pakistan's total GHG emissions (around 9 $MtCO_2$ e in 2008) (Aslam et al., 2011). Net emissions are forecast to rise from 10,000 $GgCO_2$ e in 2011 to 13,000 $GgCO_2$ in 2020 and 15,000 $GgCO_2$ e in 2030 (PAEC-ASAD: Athar, 2009).

Pakistan commenced REDD+ activities in 2010 and it is a UN-REDD partner country. In 2012 REDD+ Preparedness Phase (R-PP) for Pakistan was initiated by the Worldwide Fund for Nature Pakistan (WWF-Pakistan), the International Center for Integrated Mountain Development (ICIMOD), and the Climate Change Ministry. For REDD+ guidance has been recommended by the United Nation Framework Convention on Climate Change using RS and ground-based carbon measurement for carbon, biomass estimation, GHG emissions and change in forest area due to deforestation and degradation. Subsequently, there is an absence of data for the appraisals of reasonable REDD+ action regions. Furthermore, tools have been developed since the 1990s to identify which zones are the most vulnerable to deforestation and ultimately releasing carbon (Päivinen et al., 2001; Piao et al., 2005). However, less data availability can be a barrier in their use in developing countries (Angelsen, 2009; Sitoe et al., 2014). The decrease in carbon emission must be surveyed in order to create installments for REDD+ activity at the national or sub-national level. This incorporates the evaluation of the two factors, i.e., activity data (a change which occurred in a particular period in a forest area) and emission factor (change occurred in carbon stock of forest). Both of these factors must be assessed through the nations taking part in REDD+ through the usage of authentic MRV systems (Plugge et al., 2013). Field data and RS gives us a proficient answer to observe the condition and changes of forest carbon stock (Melville et al., 2015; Tomppo et al., 2008).

The conventional field inventory methods of forest carbon stock inventory are considered more accurate. The field technique can be further divided into two methods, i.e., destructive and non-destructive methods. The destructive method is also called harvest method (Gibbs et al., 2007). In this method the trees in a study area are all felled in the destructive method then their parts like a tree trunk, leaves, and branches are weighed and then after oven drying the weight of these components are recorded again. When biomass estimation is done without tree felling then it is called the non-destructive method, and it can be used for threatened and protected species (Montes et al., 2000), the above-ground biomass can also be evaluated from volume tables using DBH (Diameter at breast height) and trees height as a reference variable. These two parameters, i.e., height and DBH can be easily obtained and then using the allometric model tree biomass can be determined (Picard et al., 2012). However, it presents various challenges including limited to small scale survey, expensive, and time-consuming methods.

To estimate above ground biomass studies have been conducted using optical satellite images of medium-resolution (Fernández-Manso et al., 2014; Gizachew et al., 2016; Lu et al., 2002; Muukkonen and Heiskanen, 2005). For estimation of biomass VIs were derived in these studies from optical images (Landsat, ASTER) because there is correlation between AGB assessed from field data and VIs. Major problems in estimation of above ground biomass is low spatial resolution and saturation problem in the satellite imageries (Lu, 2005). Sentinel-2 satellite which is recently launched have high spatial, spectral and temporal resolution and also have new red-edge spectral band for vegetation monitoring which will further increase the accuracy of AGB estimation (Delegido et al., 2011).

Two components restrict carbon sequestration potential, i.e., carbon cannot be retained by the forests forever, and as growth occurs in the forest, a saturated state will be attained which is called as the carbon carrying capacity (CCC) (Keith et al., 2009). It means that carbon sequestration of forests has a maximum point of confinement (Odum) known as carbon sequestration potential (CSP) (Keith et al., 2009). On the other hand, degradation and deforestation conservation of all the forests is not possible. Hence for reciprocation between fulfilling forest products demands of humans and saving carbon sink capacity of forests attention should be given to those forests having high Carbon Carrying Capacity (CCC) and Carbon Sequestration Potential (CSP). Carbon density is decided by two variables which are the age of the forest (Pregitzer and Euskirchen, 2004) and climate (precipitation, temperature, etc.). Forests having old growth contain higher biomass and can represent the carbon carrying capacity of biomes (Keith et al., 2009). Assessment of Carbon Sequestration Potential (CSP) is challenging as old-growth forest data is not available (Cramer et al., 2001).

Geographic information systems (GIS) and Remote sensing (RS) techniques can effectively evaluate and analyze forest carbon stock at a regional and global scale. However, RS cannot directly measure carbon stock and need ground-based traditional field survey techniques. The RS techniques have been reported to be more accurate and useful where forest carbon densities are low, i.e., in temperate forest condition and young stand. However, the RS techniques are not very accurate in the tropical forest which are the most carbon-rich due to saturation of the remote sensing signals (Rosenqvist et al., 2003). Furthermore, since most of the remote sensing sensors are optical (visible and near-infrared bands) in nature; therefore, their use is limited due to higher cloud cover. To overcome this issue active remote sensing techniques like LIDAR are now becoming a prominent approach (Asner, 2001).

Currently, Very High-Resolution Satellite (VHRS) optical imagery, i.e., Quick bird, Geo-eye, are being used for the extraction of forest inventory parameters (Baral, 2011). Phua et al. (2014) found a strong positive correlation between forest inventory data such as DBH and Height and Satellite-based crown area data. SPOT, Landsat and ASTER imagery have been used for the estimation of AGB through the extraction of Vegetation Indices (VIs) from imagery and then through statistical techniques their relationship assessment with AGB. According to Silleos et al. (2006), optical satellite imagery sun-view angle, atmospheric effects, and soil-back ground can be reduced by VIs. Few studies (Fernández-Manso et al., 2014; Gizachew et al., 2016; Lu et al., 2002; Muukkonen and Heiskanen, 2005) reported on relationship between forest biomass and VIs derived from Sentinal-2 imagery. Hence, more research is needed on abilities of VIs which are obtained from optical satellite images of medium-resolution for forest biomass evaluation, specifically in Sentinel-2 satellite image which is recently launched.

DOI: http://dx.doi.org/10.15666/aeer/1801_783815

Most of the studies discussed have assessed forest biomass/carbon stock using remote sensing techniques. This study estimates above and below ground carbon stock, temporal deforestation, potential of several type of vegetation indices from sentinel-2 imagery in estimation of biomass, carbon emission from deforestation and carbon sequestration potential using forest inventory and remote sensing data for sustainable management of forests.

Major objectives of the study were:

- Generating land cover maps for the assessment of temporal deforestation.
- Estimating above and below ground biomass/carbon stock from forest inventory data.
- Potential of Several type of vegetation indices from sentinel-2 imagery in the estimation of biomass.
- Producing and validating biomass maps by developing regression model between forest inventory and remotely sensed data.
- Quantifying carbon losses from land use change using forest inventory and remote sensing data.
- To assess the carbon sequestration potential of study area.

Materials and methods

Study area

Battagram (latitude 34.41 N and longitude 73.1 E), a district of Khyber-Pakhtunkhwa (KP) province of Pakistan was selected as a study area (*Fig. 1*). Its total area is about 1507 km^2. The district terrain is mountainous in nature with an altitude above 4000 m covered with thick forest. There are four ranges in Battagram district namely Hillan, Battagram, Allai, and Pashto range. It includes forests, rangeland, alpine pasture, and agriculture. The average temperature of the district is 18.5 °C with an average annual precipitation of 1218 mm during winter, snowfall used to be heavy on the northern part at higher altitudes of the mountainous regions.

The Battagram forests can be characterized as Himalayan moist temperate forest and Sub-alpine temperate regions. The legal status of most of the forest found is Guzara forest (community-owned forests).

The underlying rock in the area consists of gneissose – schist, gneiss, granitoid-schist and mica-schist. Shales occur in chir zone. Metamorphic and plutonic igneous rocks are also found. Low grade metamorphic rocks like (i) Graphite Schist, (ii) Recrys-talline limestone, (iii) Amphibole Schist (iv) Quart-mica Schist (v) Green Schist are exposed in the southern and the south-western part of the area.

Methods

Sample plots were laid out using stratified cluster sampling technique in the study area for the collection of forest inventory data. The forest inventory data was collected in June 2016 on tree diameter and height parameters and used in the allometric equations for the estimation of biomass. About 11 different vegetation indices (VIs) were derived from Sentinel-2 imagery to establish a relationship between VIs, and above ground biomass (AGB). For linear regression model development best VI was used in order to predict biomass. To assess the land use/landcover satellites Landsat-7 and Landsat-8 imagery data were used. Carbon emissions were estimated by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_783815

multiplying the emission factor with activity data. Activity data and emission factor were calculated from remotely sensed images and forest inventory data respectively. Finally, carbon sequestration potential was assessed from carbon carrying capacity (CCC) and carbon density. The complete methodology flow chart is given in *Figure 2*.

Data collection/field procedure

A total of fifty-five (55) plots were sampled using a stratified cluster sampling technique in the study area. Circular plots of radius 17.84 m were taken with a plot to plot distance of 200 m. Before final data processing field measurements errors were corrected (McRoberts et al., 2010) as accuracy and results of inventory is affected by these errors (Molto et al., 2013). Sample plots shape and size were taken according to UNFCCC guidelines. For carbon inventory trees having DBH $\geq$ 5 cm were measured (Nizami, 2012). Plot measurement includes information about GPS coordinates, aspect, elevation, forest type, species, diameter at breast height (DBH), crown cover and tree height. The DBH was measured at 1.3 meters above the ground from collar point of trees on the uphill side and according to field measurement standard while tree height was measured by Haga Altimeter. The plot to plot navigation was done by Sunnto Compass, and within plot distance and plot to plot, the distance was measured using measuring tape (Nizami, 2012). Defected trees such as a buttressed tree, forked trees, and trees having butt log damaged by fire were also measured. All the field data was recorded in departmental field inventory forms and further transferred to Microsoft Excel sheets for the calculation of biomass and carbon stocks.

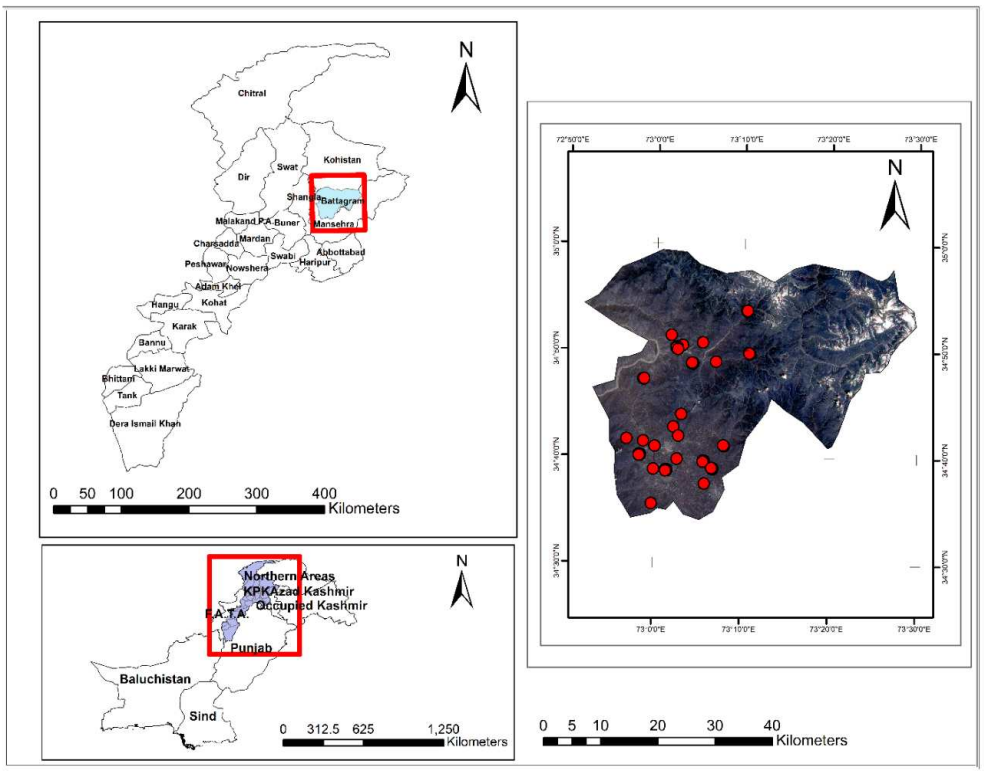

Figure 1. *Study area map is showing its location, sentinel-2 imagery of study area and forest inventory sample plots analyzed in the study area using stratified cluster sampling according to national forest inventory and field surveying manual and UNFCCC guidelines with a plot to plot distance of 200 m*

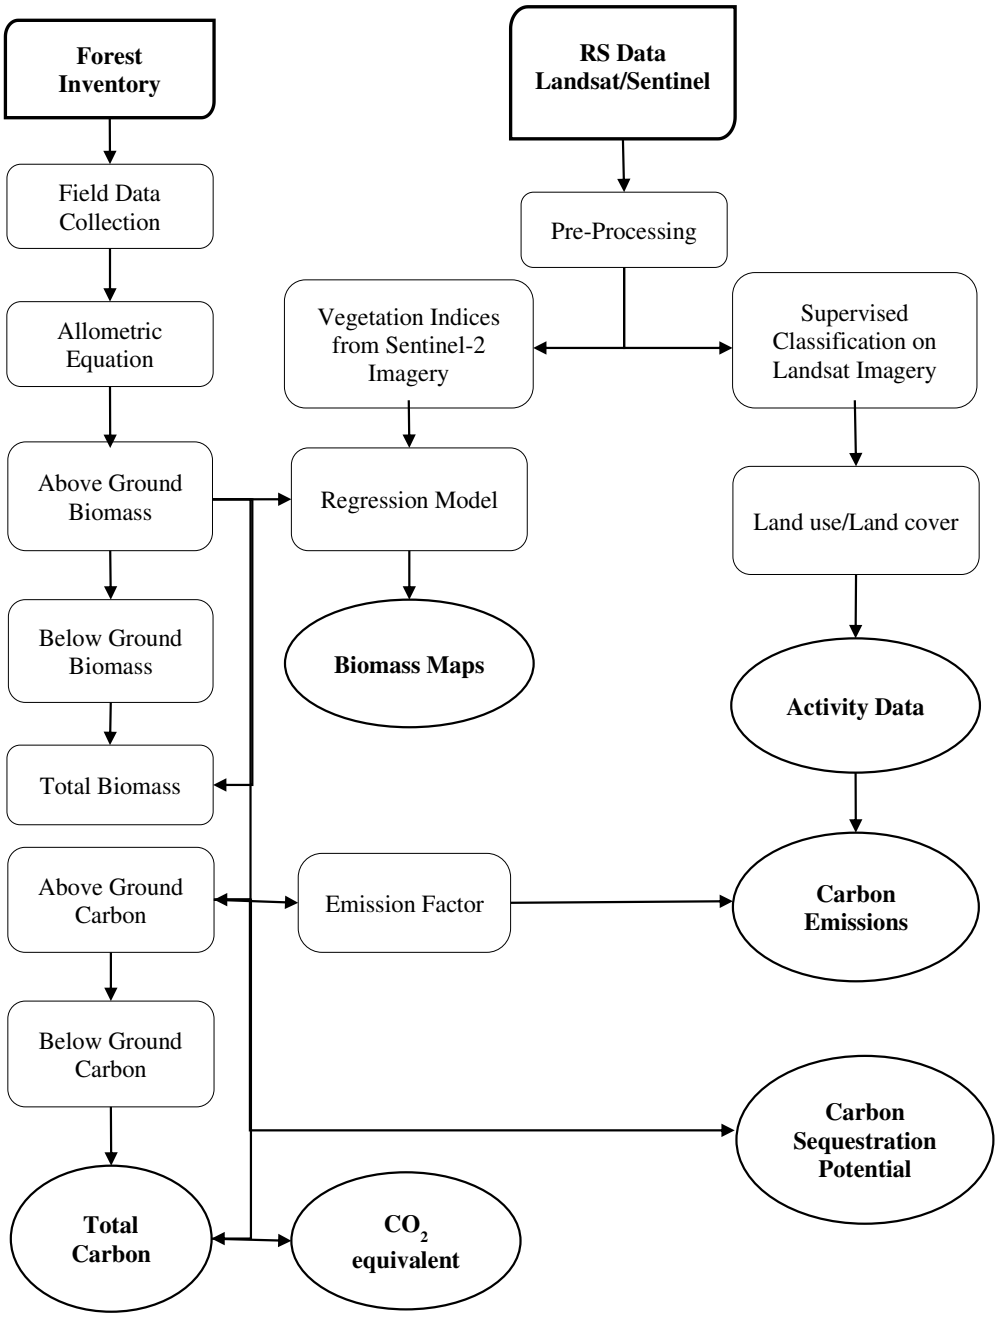

Figure 2. *Workflow of the research method and data types used*

Calculation of above/below ground biomass and carbon stock

The AGB can be computed by two methods: (i) Biomass expansion method and (ii) use of Allometric equations. In Biomass expansion factor method first volume is calculated with field measurements such as height, DBH, and Form factors and then the volume is multiplied with wood density and BEF (Biomass Expansion Factor) in order to get final biomass (Nizami, 2012). It is multiplied with wood density because there is a relationship between biomass and density of wood, i.e. the higher the density, the higher the biomass. While it is multiplied with BEF because we have calculated the volume of stem only while the biomass is also stored in branches so we cannot measure

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_783815

the volume of each branch of tree, therefore, we multiply it with a fixed value of BEF for each species. For calculation of AGB allometric equations were used by using forest stands parameters such as trees height and Diameter at breast height (DBH). Allometric equations are the regression equations between forest attributes used for the estimation of tree height, biomass or other growth attributes (Chave et al., 2005; Gao et al., 2016; Shi and Liu, 2017). Hence with the use of field measurements such as diameter and height, we can assess biomass (Gao et al., 2015). The height represents primary growth while the secondary growth is represented by the diameter of trees. The allometric equations (*Table A1* in the *Appendix*) which were used in this research were formulated by Ali (Ali, 2015). These allometric equations are different for different species; it means that these are species specific. These allometric equations are acceptable for all bioclimatic conditions and forest types. The above ground biomass (AGB) in kgs per plot was then converted into per hectare by multiplying AGB of the plot with 10 as the size of our plot was one-tenth of a hectare. Then divided with 1000 in order to obtain AGB in tons. Finally, in order to obtain AGC (Above Ground Carbon stock), the biomass in tons was multiplied with 0.47, a conversion factor formulated by IPCC (*Eq. 1;* IPCC, 2006). According to the conversion factor, about one half of total dry biomass is carbon stock for given species. For assessment of BGB (below ground biomass) and BGC (below ground carbon stocks) the AGB (above ground biomass) and AGC (above ground carbon) were multiplied with a conversion factor of 0.26 (Ali et al., 2018; IPCC, 2006; Ravindranath and Ostwald, 2008). For the estimation of total carbon stocks above ground carbon and below ground carbon were added and converted into CO_2 equivalent by multiplying total carbon stocks with a 3.66 factor. While 3.66 is a ratio of molecular mass to the atomic mass of carbon.

$$C=AGB\times CF \quad \text{(Eq.1)}$$

where C is Carbon stock, AGB is above ground biomass and CF is Conversion factor (0.47).

Satellite data

To generate biomass map the cloud-free (≤10%) Sentinel-2 image data (orthorectified imagery with projection system of UTM/WGS84), of July 2016 was downloaded (http://www.earthexplorer.usgs.gov). Because of high spatial resolution (10 m) of imagery as compare to other open source satellite products it was considered acceptable for research. The Spectral resolution of Sentinel-2 imagery is high with Red, Blue, Green, and NIR bands; hence it is considered suitable for vegetation studies. For monitoring vegetation, it additionally accompanies three red-edge spectral bands.

Using ENVI software Sentinel-2 optical imagery was preprocessed for radiometric correction in order to improve image quality. The radiometric correction primary purpose was to reduce sun angle and atmospheric effects (Baillarin et al., 2012). In QGIS software semi-automatic classification plugin was used for the transformation of imagery from radiance to surface reflectance through the application of Dark Object Subtraction (DOS). The DOS method works by removing in every band the darkest pixel which will be affected by scattering in the atmosphere (Chavez Jr, 1988). This method does not need ground truth data as it is image based and is easy to apply (Chavez, 1996). The shortwave infrared band and red-edge band with a spatial resolution of 20 m were resampled into a 10 m spatial resolution using resampling tool in ArcMap.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_783815

Computation of VIs was done through various spectral bands combination having 10 m and 20 m spatial resolution hence to make all bands of same spatial resolution (10 m) resampling was performed. The imagery was clipped using the study area shapefile.

Deriving vegetation indices

Several vegetation indices have been reported in the literature for the derivation of biomass. In this study, three categories of vegetation indices were considered for the derivation of biomass, which includes: Broadband VIs, Canopy Water Content Indices, and Narrow Red Edge band VIs (*Table A2*). In broadband category, the sensitivity of vegetation indices is very high to canopy leaf area. The vegetation indices in the broadband category are sensitive to the canopy leaf area.

The Canopy Water Content Indices use the near-infrared spectral band and shortwave infrared (SWIR) spectral band. To study water content in the vegetation it is used. Through this VIs health of vegetation can be assessed as healthier vegetation have more carbon storage capacity as compared to trees having water stress. The Narrow Red Edge band vegetation indices use the near infra band. However, it does not utilize the red band rather it uses red-edge spectral band (690-740 nm). To study biophysical characters of vegetation these are mainly used (Mutanga and Skidmore, 2004b). These VIs show the vegetation photosynthesis in more detail than broadband indices. It overcomes the signal saturation issue of broadband indices which is due to high canopy density.

In this study twenty-five (25) different vegetation indices selected from the three broad categories were derived from high spectral and spatial resolution Sentinel-2 image of July 2016. Out of twenty-five indices, only eleven (11) vegetation indices were selected on the basis of their performance, i.e. having significant R-square value between the forty-five (45) field surveyed plots biomass and derived vegetation indices. However, only one vegetation index was selected on the basis of lowest root mean square error (RMSE) with the lowest p-value and high significant R-square value. A linear regression model was developed between the selected vegetation index and field surveyed biomass of the forty-five plots. The linear regression model was used in the ArcGIS software raster calculator to generate biomass map for the entire study area.

Validation of biomass map

The biomass map was validated using the remaining ten (10) plot data. Since out of fifty-five plot data only forty-five plots data were used to generate the linear regression model the rest of ten plot data was kept for validation of the biomass map. The biomass values were extracted from the thematic biomass maps for the 10 sites and compared with the field surveyed generated biomass data using the correlation coefficient, P-value and RMSE statistics. Model accuracy was assessed by the following formula (*Eq. 2*):

$$RMSE=\sqrt{\frac{\sum_{i=1}^{n}(y_i-\hat{y})^2}{n}} \quad \text{(Eq.2)}$$

where "Y_i" is Measured value of biomass, "$\hat{Y}$" is Estimated value of biomass and "n" is Number of samples.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_783815

Activity data

Activity data (forest change/deforestation) was assessed in the study area from the year 2000 to 2015 using the Landsat-7 and Landsat-8 satellite Data (http://www.earthexplorer.usgs.gov). The temporal satellite data was preprocessed in ERDAS IMAGINE software and supervised classification algorithm was applied for the assessment of land cover classes and to find the change in forest cover which had occurred in the last fifteen years. A thematic map was obtained of seven major land use classes, i.e. forest, glacier and snow, water, barren land, settlement, shrub and grassland, and agriculture. The forest in the study area was extracted, and forest change thematic map was derived by subtracting forest area of the thematic map of 2015 from the forest area of the thematic map of 2000 and finally the deforested areas were obtained. *Equation 3* (Sader and Joyce, 1988) was used to assess the average annual deforestation rate in the study area.

$$\text{Annual Rate (\% per year)} = \left(\frac{((Y_1 - Y_2)\times 100)}{(Y_1 \times N)}\right) \quad \text{(Eq.3)}$$

where "Y_1" is the total area of forest on the initial date, i.e. 2000, "Y_2" is the total area of the forest on the final date, i.e. 2015 and "N" is the number of years in a particular period, i.e. 15 years.

Carbon emission estimation

To estimate carbon emission the activity data and emission factor were multiplied (*Eq. 4;* Plugge et al., 2013).

$$CE = AD \times EF \quad \text{(Eq.4)}$$

where "CE" is Carbon Emissions, "AD" is Activity Data (Change in forest cover) and "EF" is Emission Factor which can be calculated using *Equation 5* (REDD+, 2006).

$$EF = [(AGC2000 - AGC2015)\times 3.66] \quad \text{(Eq.5)}$$

where "EF" is Emission Factor, "AGC2000" is Above ground carbon for the year 2000, and "AGC2015". The Above ground carbon for the year 2015 while "3.66" or "44/12" is a conversion factor. This conversion factor is the ratio of molecular mass to the atomic mass of carbon.

Carbon sequestration potential

The storage capacity of carbon increases rapidly as the forest is in the developmental stage and hence forest act as a carbon sink. While the old forest (80-100 years age) carbon stock increases very slowly and exchange of carbon among the atmosphere and the forests reaches to a balanced state therefore forests reach to a stage of carbon neutrality (Zhou et al., 2002) and this old-growth forest could be taken as Carbon Carrying Capacity (CCC) reference of those forests having climatic condition similar to these old-growth forests. Assessment of Carbon Sequestration Potential (CSP) is challenging as old-growth forest data is not available (Cramer et al., 2001).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_783815

Carbon Sequestration Potential of a particular forest type can be evaluated through the difference between carbon density of the current forest and old-growth forest as shown in *Equation 6* (Hudiburg et al., 2009; Liu et al., 2011; Smithwick et al., 2002).

$$CSP=CCC-CD \quad \text{(Eq.6)}$$

where CSP is Carbon Sequestration Potential, CCC is Carbon Carrying Capacity, and CD is Carbon Density.

Results

Landuse landcover change detection

The Landsat temporal (year 2000 and 2015) satellite data was classified into seven major classes (Glacier and snow, Water, Barren land, Settlement, Shrub and Grassland, Agriculture and Forest) (*Fig. 3*). Landsat-7 (ETM+) and Landsat-8 (OLI) data were used for generating LULC maps for the year 2000 and 2015. Over the fifteen years even though there was no significant change was found in the settlement (0.3%), but a major decreasing change was observed in the forest (-16.9%) and barren land (-7.7%) while an increasing change was recorded in the agriculture (12.2%). The data suggest that, since there was no significant change was found in the settlement most of the forest land was used for agricultural purposes while the major cause of deforestation could be illegal logging.

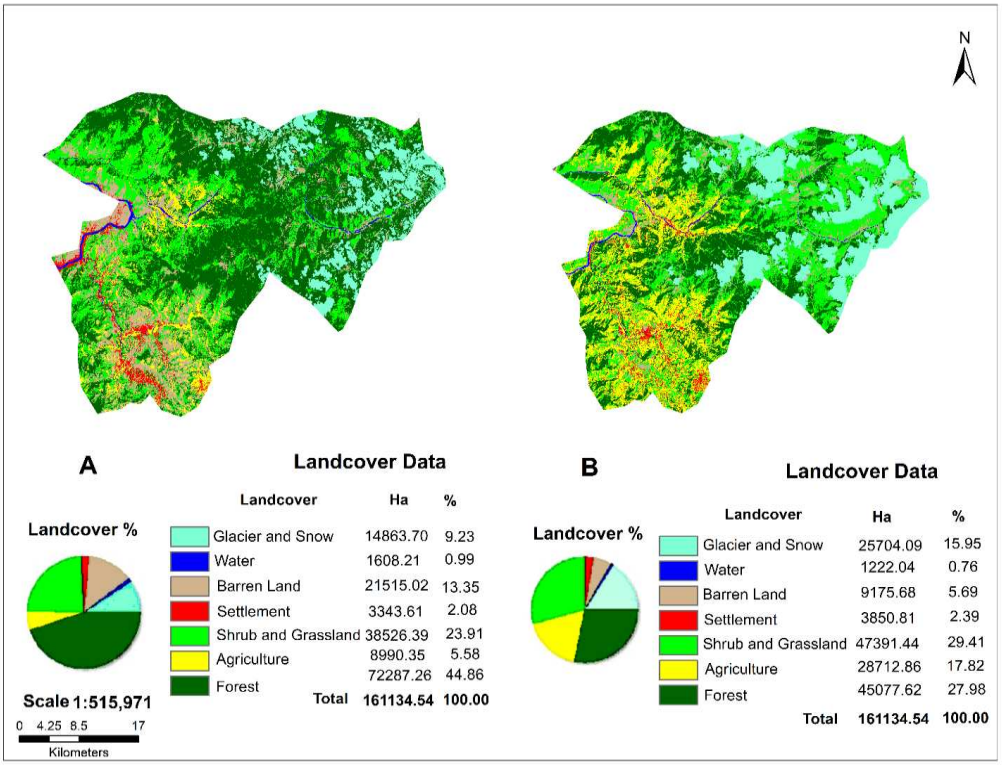

Figure 3. *Study area Land cover/use map for the year 2000 (A) derived from Landsat-7 (ETM+) and Study area Land cover/use map for the year 2015 (B) derived from Landsat-8 (OLI/TIRS) using supervised classification and maximum likelihood algorithm in ERDAS Imagine 2015*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_783815

Figure 4 shows the extracted forest land cover area from the land cover/land use map. In 2000 forest area was 72287.26 ha (44.86% of the total study area), which decreased to 45077.62 ha (27.98% of the study area) in 2015. It indicates a 27209.64 ha (-16.88%) loss with an annual deforestation rate of 2.51%, i.e. 1814.41 ha deforestation per year which is quite alarming. In order to decrease carbon emissions, forest conservation and sustainable forest management practices are required as the deforestation rate is very high in the study area. For agricultural purpose, natural forests are cleared hence disturbing the ecology of the area. Factors like illegal logging, wood harvesting for construction and fuel wood are the major reasons for deforestation. Moreover, the legal status of the forests in our study area is guzara forest which means it has community rights and all acts in guzara forests are allowed until and unless prohibited by the government, therefore, it is not protected or conserved like reserved forests.

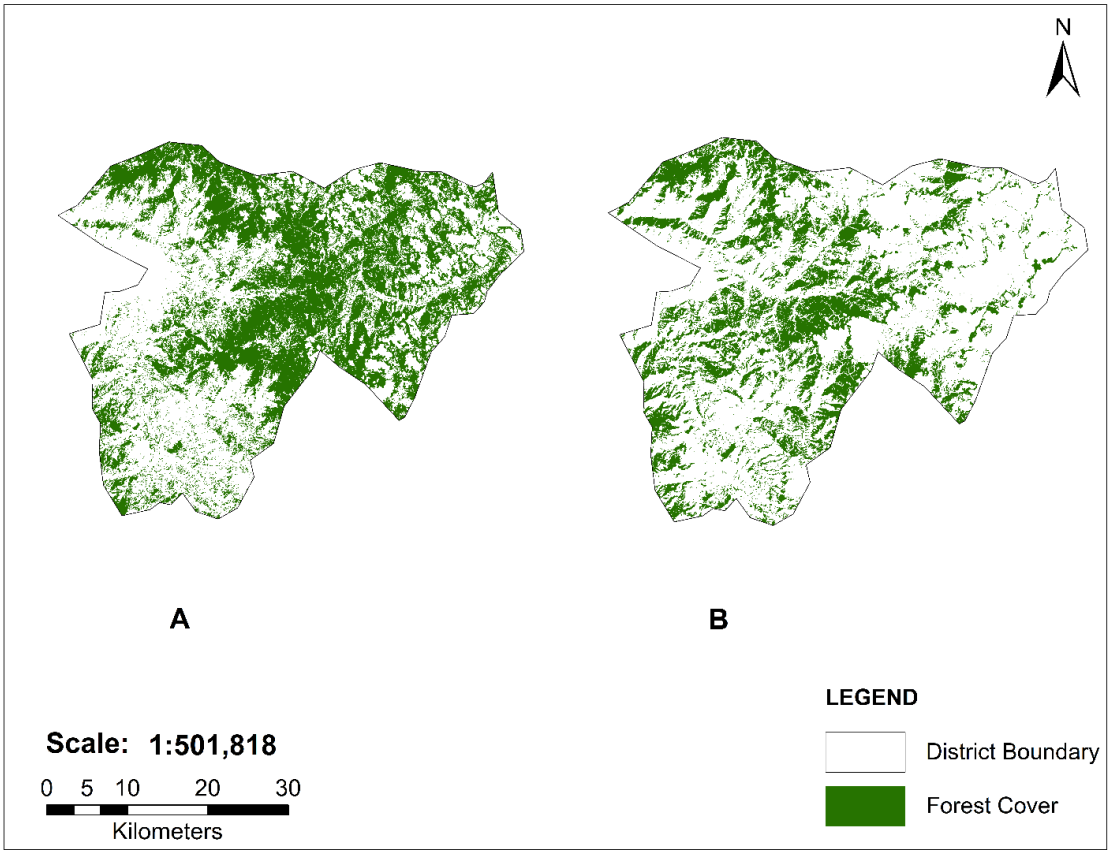

Figure 4. *Study area forest cover map for the year 2000 (A) extracted from land use/cover map of 2000 and study area forest cover map for the year 2015 (B) extracted from land use/cover map of 2015 using conversion tool from raster to polygon and then dissolve tool in ArcMap 10.5.1*

Validation of land use land cover map

LULC maps were validated using user's accuracy, producer's accuracy, kappa statistics and overall classification accuracy. 49 points were distributed randomly on each year imagery having seven classes. For each class there were seven points. Reference

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_783815

points and results of classification were compared from which error matrices created and with the help of these error matrices producer's users and overall accuracy of the classification was assessed. Overall classification accuracy ranges from 80.44% -86.24 while overall kappa statistics ranges from 0.7621-0.8422. Accuracy results for each class can be seen in *Table 1* which are in acceptable range. Accuracy of the year 2000 imagery is less because of the less spatial resolution imagery availability at Google Earth on our study area so it was difficult to discriminate between various classes.

Table 1. *Accuracy assessment results of LULC map*

Years	Accuracy/classes	Glacier/snow	Water	Barren land	Settlement	Shrub and grassland	Agriculture	Forest
2000	Producer's accuracy (%)	71.54	90.54	68.77	65.31	89.23	74.19	86.79
	User's accuracy (%)	69.14	95.13	73.15	71.73	88.71	75.97	89.25
	Overall classification accuracy (%) 80.44				Overall kappa statistics = 0.7621			
2015	Producer's accuracy (%)	89.35	91.95	78.26	83.47	67.59	87.50	89.97
	User's accuracy (%)	87.73	97.79	81.35	85.71	79.53	77.59	93.97
	Overall classification accuracy (%) 86.24				Overall kappa statistics = 0.8422			

Biomass and carbon stock

The major forest tree species found in the study area were Pinus wallichiana (Kail), Pinus roxberghii (Chir pine), Picea smithiana (Spruce), Abies pindrow (Fir), Cedrus deodara (Deodar) as well as some broadleaved species. *Table 2* shows descriptive statistics of biomass, carbon stock and CO2 e (carbon dioxide equivalent) calculated from the field survey data collected from the 55 plots in the study area while *Table A3* shows Biomass, Carbon Stock and CO2 e estimated per plot in the study area. The above ground biomass (AGB) ranged from 279.59 t/ha to 46.45 t/ha with a mean of 148.79 t/ha (±40.77). The above ground carbon (AGC) ranged from 131.41 t/ha to 21.83 t/ha with a mean of 69.93 t/ha (±19.16). The denser the forest, the higher the value of biomass and carbon stock were. The CO_2 e ranged from 606 t/ha to 100 t/ha with a mean of 322 t/ha (±88.36). Total AGB in the study area was 6.7 Mt, and total BGB (below ground biomass) was 1.74 Mt while the total Biomass (AGB + BGB) was 8.45 Mt. Similarly, the total AGC in the study area was 3.15 Mt and total BGC (below ground carbon) was 0.82 Mt while the total Carbon (AGC + BGC) was 3.97 Mt. Finally, the total CO_2 e in the study area was 14.53 Mt. According to Ahmad et al. (2014), the mean AGB and AGC in coniferous forests of Dir were found to be 258.98 t/ha and 129.49 t/ha, respectively. According to IPCC the range of AGB in the temperate forest is about 220 to 295 t/ha (IPCC, 2006). While according to Gairola et al. (2011), in the moist temperate forest of India the AGB ranges from 215.5-468.2 t/ha and AGC from 107.8-234.1 t/ha (Gairola et al., 2011). Similarly, Whittaker and Niering estimated AGB value in fir temperate forest which was 360-440 t/ha (Whittaker and Niering, 1975). The forest in our study area falls in the category of "Guzara Forest," and in guzara forest all the act are allowed until and unless prohibited by the government. Hence these are not reserved forests, the human interference and social pressure are more in these forests as compared to the reserved forest, as these have community rights. Therefore, more disturbance has been observed in these forests.

Relationship between biomass and vegetation indices

Evaluating several vegetation indices is helpful when vegetation canopies are not uniform in terms of species which leads to complexity and variation in groundcover. Factors such as topography, background soil reflectance and variation in internal canopy signal scattering could interfere with final vegetation signal since in different ranges of biomass and groundcover different indices are more sensitive (Huete, 1988). In this regard twenty-five (25) vegetation indices were calculated and tested concerning its relationship with the biomass. *Figure 5* shows eleven (11) vegetation indices which had a significant ($p \leq 0.01$) correlation with biomass. In comparison, narrowband red-edge vegetation indices performed better than the other types of indices. In the narrowband vegetation indices, RERVI had the highest R-square ($r^2 = 0.68$; $p \leq 0.01$) while the NDII which is canopy water content VI had the lowest R-square ($r^2 = 0.16$; $p \leq 0.005$).

Correlation between broadband vegetation indices and biomass

Figure B1 (see *Appendix*) shows scatter plot graphs depicting relationships between biomass and various broadband vegetation indices. The R-square values of EVI, GNDVI, NDVI, SAVI, SQSR, and TSAVI were 0.29, 0.33, 0.28, 0.28, 0.21, and 0.29, respectively. The coefficients of the linear models between biomass and broadband vegetation indices were significant ($p \leq 0.01$). Since most of these indices (broadband VIs) use NIR and Red bands, therefore, sensor saturation issues were encountered especially in areas where there was dense and mature vegetation (Lu et al., 2012; Wang et al., 2016).

Relationship between biomass and canopy water vegetation indices

Figure B2 shows relationships between biomass and two canopy water indices, i.e. Normalized Difference Infrared Index (NDII) and Normalized Difference Water Index (NDWI). Significant relationships were found between biomass vs. NDII ($R^2 = 0.16$, $p \leq 0.01$) and NDWI ($R^2 = 0.21$, $p \leq 0.01$). However, there R-square values were mostly lower comparatively than the broadband vegetation indices since these indices use mostly the shortwave infrared bands of the sentinel sensor i.e. band 12 ($\lambda = 1610$ nm) and band 13 ($\lambda = 2190$ nm) which are more sensitive to water in the green vegetation than to the chlorophyll content.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_783815

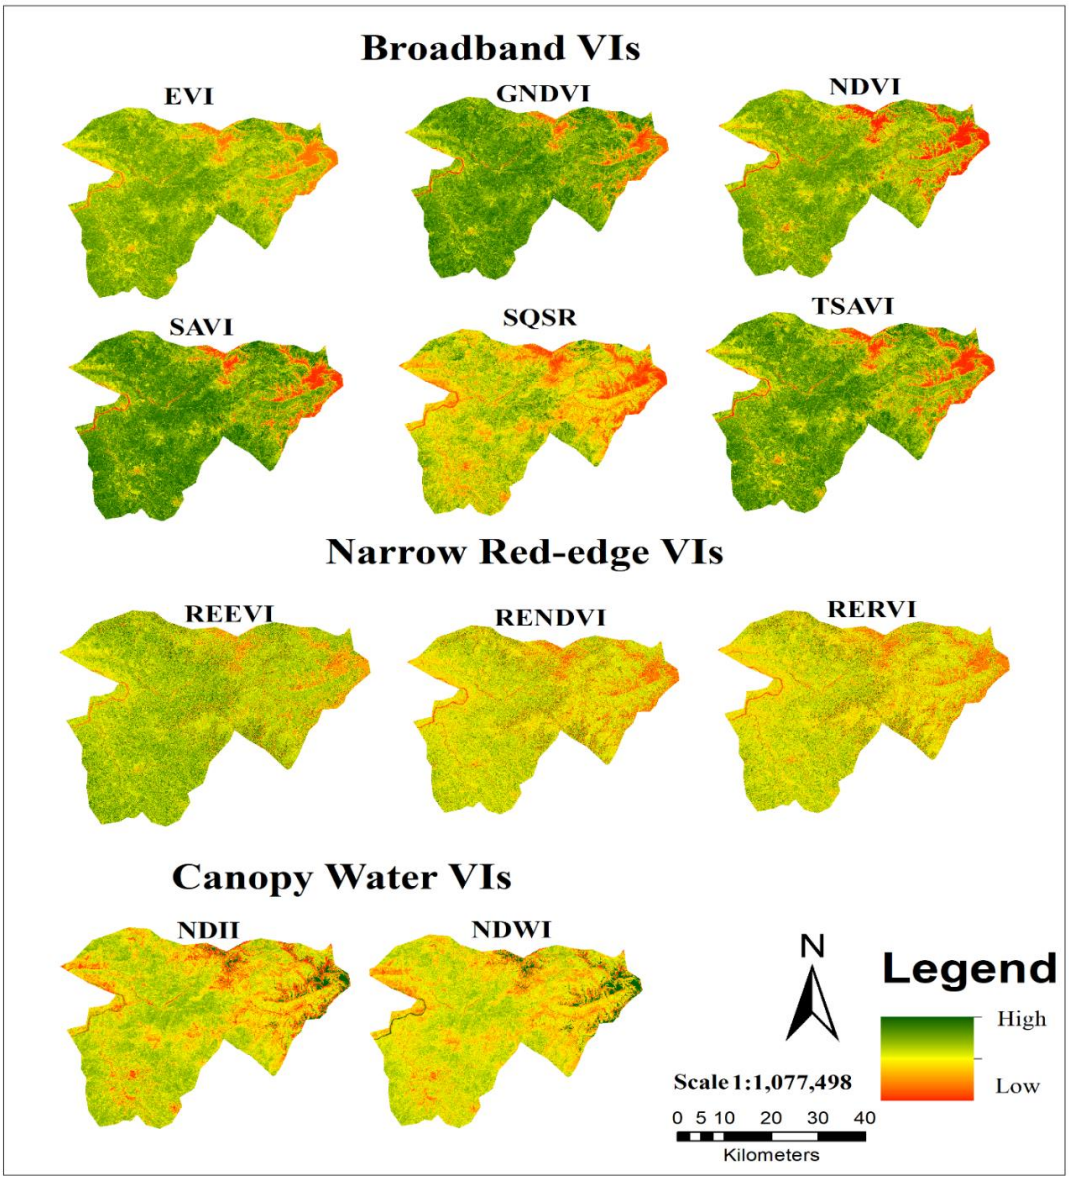

Figure 5. *Broadband vegetation indices, narrow red-edge and canopy water vegetation indices derived from Sentinel-2 satellite imagery using their equations and distinct bands combination in ArcMap*

Relationship between biomass and narrow red-edge indices

Using red-edge spectral bands VIs were calculated and saturation effects is decreased. Comparatively the red band ($\lambda = 665$ nm) is known to have high absorptivity/sensitivity compared to the red-edge band ($\lambda = 740$ nm). However, the red-edge band remains to be sensitive to chlorophyll but to a moderate extent which reduces the saturation effects (Gitelson et al., 1996). *Figure B3* shows relationships between biomass and red-edge vegetation indices, i.e. Red-edge Normalized Difference Vegetation Index (RENDVI), Red-edge Enhanced Vegetation Index (RE-EVI), and Red-edge Ratio Vegetation Index (RERVI). Due to narrow red-edge band, VIs saturation effect is reduced and the relationship of these indices with biomass was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_783815

highly significant, and yielded higher R-square values. Higher relationships of biomass were found with RE-EVI, RE-NDVI and RERVI ($R^2 = 0.67$, $p \leq 0.01$).

It can be deduced from the results of this study that red-edge bands are very useful in dense and mature forests where saturation has been reported to be a regular issue when using the red band in calculating the indices.

Mapping spatial distribution of biomass

Figure 6 shows spatial variability of predicted biomass using the forty-five (45) field surveyed data out of the fifty-five (55) total plot data. The remaining ten (10) biomass data was used for validation of the final biomass map. The best vegetation index was selected from the various indices which had the highest correlation coefficient and the lowest RMSE with field survey biomass data. A linear regression model was developed between RERVI and field surveyed 45 biomass data. The regression model was used in ArcMap's raster calculator tool to generate the final study area biomass map.

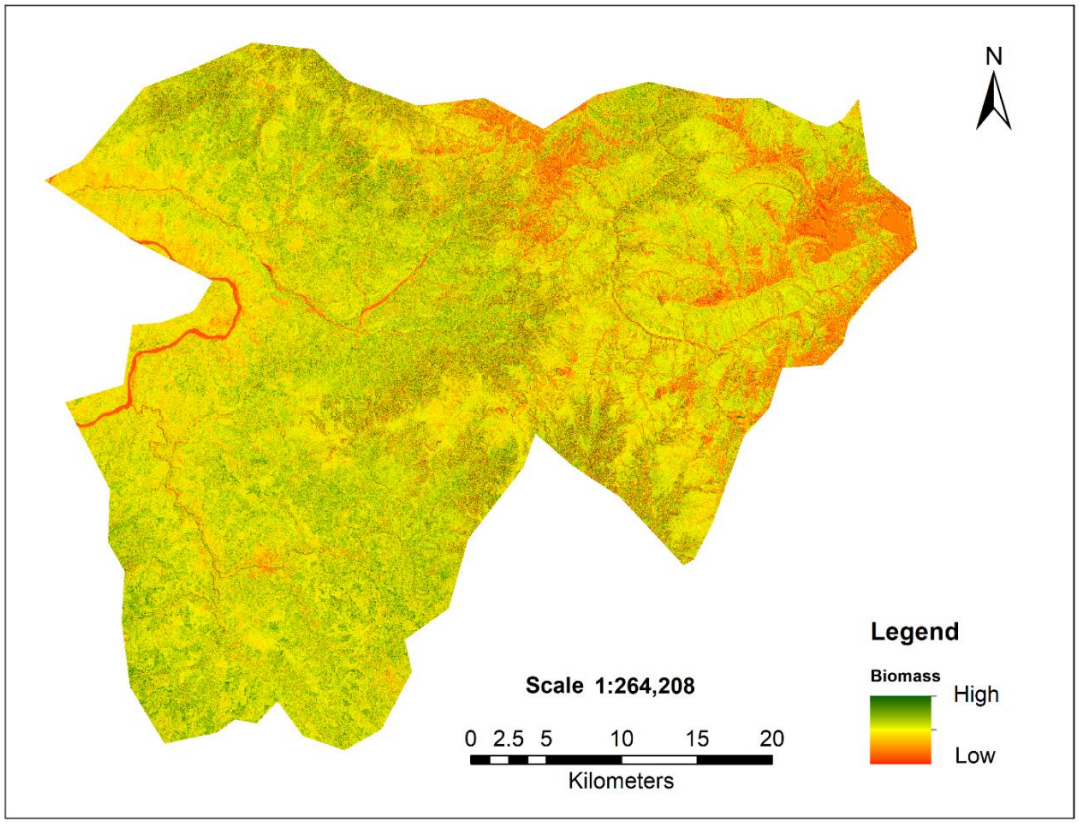

Figure 6. *Study area biomass map derived from Sentinel-2 imagery best vegetation index (having high R-square, Low RMSE, and P-value less than 0.01) using its regression equation in ArcMap raster calculator from the best vegetation index (Red-edge Ratio Vegetation Index (RERVI)*

Accuracy of biomass map

To evaluate how well the predicted biomass corresponds to the actual on-ground biomass, the remaining ten (10) ground surveyed data points were overlaid on the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_783815

predicted biomass map and data was extracted for statistical comparison. A significant ($p \leq 0.01$) R-square = 0.67 with an RMSE = 35.23 t/ha was found between the observed and predicted biomass which validates the final biomass map.

Calculation of carbon emissions

Emission factor determined was equal to 255.94 tCO_2 e/ha, and in fifteen years carbon emissions were about 6.96 Mt CO_2 e.

$$\text{Emission Factor} = 69.93 \times 3.66$$

$$\text{Emission Factor} = 255.94\ tCO_2\ e/ha$$

Activity data means a change in forest cover as we have already calculated the change in forest cover from 2000-2015 through remote sensing.

$$\text{Activity data} = 27209.64\ ha$$

By putting these values in the equation we get:

$$CE = AD \times EF$$

$$CE = 27209.64 \times 255.94$$

$$CE = 6964138.66\ t\ CO_2\ e$$

$$CE = 6.96\ Mt\ CO_2\ e$$

Carbon sequestration potential

For our study area, which is a temperate forest, the C sequestration potential was calculated using the following formula:

$$\text{Carbon Sequestration Potential (CSP)} = \text{Carbon Carrying Capacity (CCC)} - \text{Carbon Density (CD)}$$

$$CSP = (152 \pm 13)^{*} - (69.93) = 82.07 \pm 13\ t/ha$$

(Divide this value by the age of forest)

$$CSP = 82.07 \pm 13\ t/ha \div 100\ years = 0.82 \pm 0.13\ t/ha/year$$

(When forest age is assumed to be 100 years at maturity)

*This is a generic value of carbon carrying capacity (CCC) for the moist temperate forests (Yingchun et al., 2012).

The carbon sequestration potential estimated for the study area was 82.07 t/ha ± 13 t/ha. Hence the temperate forest possesses carbon sequestration potential up to 82.07 t/ha ± 13 t/ha. If we assume the rotation age of the forest to be hundred (100) years then the carbon sequestration potential will be 0.82 ± 0.13 t/ha/year. It means that the forest can sequestrate about 0.82 ± 0.13 tons of carbon per hectare in a year.

DOI: http://dx.doi.org/10.15666/aeer/1801_783815

Discussion

Our study finding suggests that during the last fifteen-year deforestation had occurred at an alarming rate. The forested area has been mainly converted into agricultural land for food production. Subsequently, the CO_2 e emission rate is comparatively very high during the reporting period. Since the study area falls within the "Guzara forest" (forest with community rights) which mandate the resident's rights to the forest wood for fuel and construction purpose. The deforestation rate could be reduced to a sustainable level and carbon sequestration potential can be enhanced by providing residents with alternative sources of energy and building construction material as well as through sustainable forest management practices. The REDD+ incentive should be extended to locals for carbon crediting and reforestation of the deforested area. Furthermore, our finding suggests that the narrowband red-edge vegetation indices (RE-EVI, RENDVI and RERVI) performed better in the estimation of forest biomass as compared to broadband vegetation indices (EVI, GNDVI, NDVI, SAVI, SQSR and TSAVI) and canopy water vegetation indices (NDII and NDWI). Among the narrowband red-edge vegetation indices, RERVI performed the best in biomass estimation. Image of vegetation indices shows us less saturation in narrow band red-edge indices as compared to canopy water content and broad band VIs.

Landuse landcover change detection

Activity data means change occurred in the forest area. For land use change the Landsat-7 and Landsat-8 data was used. Data was downloaded from USGS earthexplorer website (Earthexplorer.usgs.gov) of June month for the year 2000 and for the month of September for 2015. These months images were downloaded because the vegetation is mostly visible having less cloud and snow cover. In erdas imagine 2015 supervised classification algorithm was applied for the assessment of land cover classes and to find change in the forest cover which had occurred in the last fifteen years. Landsat had a coarse resolution so it is difficult to correctly classify various land cover classes so for this purpose we connected the erdas imagine with google earth pro so when we go to the particular area on satellite imagery the google earth automatically goes to that place on that particular date and hence it is easy to classify various land features then. Spectral signatures were taken for particular classes and more than five hundred signatures were taken for single class using maximum likelihood algorithm, supervised classification was applied and thematic map of seven major classes was obtained (Glacier and Snow, Water, Barren Land, Settlement, Shrub and Grassland, Agriculture, Forest). After classification manual correction were done using recode option in Erdas imagine then mean filter was applied and finally accuracy assessment was done. Major decreasing change was observed in the forest (-16.9%) and barren land (-7.7%) while agricultural area was increased (12.2%). There was no significant change in settlement (0.3%) so the major cause of deforestation could be illegal logging. The annual deforestation rate was 2.51%.

Above ground biomass/carbon stock estimation

Above ground biomass was estimated in field through forest inventory (DBH and Height) and using allometric equations. Mean AGB of 148.79 t/ha was obtained which was then converted to carbon stock through a conversion factor and the mean value of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_783815

above ground carbon stock obtained was 69.93 t/ha. From sentinel-2 imagery several type of VIs indices were calculated and finally to assess the relationship between AGB and vegetation indices linear regression model was developed. Thus, the forest biomass was calculated by both methods (field inventory and remote sensing) and biomass map was validated from the field data.

Correlation between AGB and VIs

Relationship between AGB and VIs was assessed using linear regression model. In this study three categories of vegetation indices; broad band, canopy water content and narrow red-edge band VIs were used. These categories of indices were assessed in our study area as these have effect on assessment of above ground biomass performance and accuracy. Four different types of bands were used in the computation of these vegetation indices consisting of Red, Near Infrared (NIR), Short Wave Infrared (SWIR) and Red-edge bands.

Correlation between AGB and broadband VIs

Broadband VIs and AGB had weak relationship. The VIs includes EVI, GNDVI, NDVI, SAVI, SQSR and TSAVI. Our results of broadband VIs are similar to that of Mcmorrow et al. (Foody et al., 2001), according to which relationship between biomass and NDVI is poor. Using Landsat TM derived NDVI AGB was estimated by Mganga and Lyaruu (2015) in Mgaraganza and Kitwe forest areas of Tanzania. From the results we see in both areas r^2 of 0.22 and 0.23. Nugroho (2006) assessed the relationship between VIs and AGB, r^2 value was 0.21 for EVI and 0.14 for NDVI. The main reason of less accuracy was saturation problem.

There are two main reasons of saturation, one is crops maturity (Mutanga and Skidmore, 2004a; Wang et al., 2016) while the other is due to complex forest structure (Lu et al., 2016; Sinha et al., 2016). Due to saturation VIs cannot sense increase in biomass and it occurs when the area is covered fully by leaves or vegetation fully covers the land. So the indices values do not change while the biomass continues to increase. According to Wang (Wang et al., 2016) saturation occurs due to the reason that Vegetation indices are computed using NIR and red spectral band (680nm). So electromagnetic spectrum radiations are absorbed by the red band and it does not increase continuously with increase in canopy cover due to the reason that when canopy closure is at 100% the amount of red energy absorbed reaches to peak. Besides this, due to multiple scattering the reflectance of NIR increases when canopy reaches 100% (Thenkabail et al., 2000). Therefore, in broad band indices ratio (EVI, SAVI, NDVI) an inequality is being caused because of increase in NIR band and decrease in red absorption band hence results are poor in the assessment of biomass (Mutanga and Skidmore, 2004a).

Correlation between AGB and canopy water content VIs

Relationship of AGB and canopy water content index was very weak with an r^2 of 0.16 for NDII and 0.22 for NDWI. Using SWIR bands canopy water content VIs computation was done (Lu et al., 2016). As canopy cover increases the water content also increases in leaf. Less research has been conducted on biomass estimation from canopy water content VIs.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_783815

Correlation between AGB and narrow red-edge VIs

Using band 6 of Sentinel-2 image which is a red-egde band of 740 nm wavelength and NIR band narrow red-edge VIs were calculated. Relationship between AGB and red edge VIs is the highest. The r^2 0.68 of RERVI was the highest. Narrow red-edge Vegetation Indices outperform the other two categories. Because the red-edge spectral band is between NIR and red region which is a high cholophyll absorption and reflectance area. Therefore, the variations in leaf properties and chlorphyll highly affect the red-edge spectral bands (Slonecker et al., 2009). The red-edge and NIR (700 nm to 1300 nm) part of reflectance is higher (about 60%) while red region (500 to 700 nm) reflects less than 30% (Gitelson and Merzlyak, 1997). Several studies (Chen et al., 2007b; Zhao et al., 2007) were conducted to compare the performance of VIs (NDVI, EVI, SR) using NIR and red bands with red-edge bands. From the results we can see that relationship of red-edge indices were better as it improves the r^2 significantly than that of red band. Relationship between VIs derived from World-View 2 was assessed by Winmore (2012) for carbon stock estimation in the forests of south Africa. In this study mutual comparison of standard vegetation indices (NDVI, SAVI, SR) and red-edge indices (NDVI-RE, SAVI-RE and SR-RE) was conducted through simple linear regression. From the results it was concluded that using red-edge band the r^2 increased which concludes that carbon stock estimation accuracy was improved by red-edge band. According Mutanga et al. (2012) RENDVI performed better having an r^2 of 0.67 in comparison with standard NDVI having r^2 of 0.39. In these studies, the Standard NDVI performance were a bit high than those of our results because of medium spatial resolution (10 m) of sentinel-2 imagery than that of World-View-2 images (2 m) as we know from previous studies that on performance of VIs spatial resolution have an influence on the estimation of biomass (Gara et al., 2017). Besides this saturation problem is less in simple forest structure than that of complex forest structure.

Mapping spatial distribution of biomass

The biomass map shows a denser forest biomass in the northwestern and low in the northeastern quadrant of the study area so more dissimilarities are observed in the northeastern side of the study area due to less forest cover resulting in significant variation in the biomass (Chi et al., 2015). The lowest biomass could be due to the highest altitude of the study area as above 3500 m elevation there are subalpine and alpine pastures, so the biomass was found to be the lowest. Using remotely sensed optical data for biomass mapping have specific limitation such as if we use it in open tree canopy cover and near snow then it underestimates the biomass in both cases (Karlson et al., 2015). Also in the assessment of vegetation cover from optical data, there are more chances of neglecting little trees (Karlson et al., 2014). The openness in the forest maybe due to high anthropogenic activities related to illegal logging etc.

The overall spatial variability in the biomass could be due to different species occurrence, i.e. Pinus roxberghii (chir pine), Pinus wallichiana (Kail), Pinus gerardiana (Chilghoza), Abies pindrow (Fir), Picea smithiana (Spruce), Cedrus deodara (Deodar) and Quercus spp (Oak) in the study area. This could result in the variation of the final biomass while the biomass in coniferous species will be higher than that of broadleaved species because of its high wood density, volume, and age. Biomass also depends on the age of tree species; therefore, the younger trees have lower biomass while the mature trees have higher biomass. Northern aspect is cool and has more moisture and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_783815

vegetation cover; therefore, biomass could also be high on the northern aspect while the southern aspect is warmer having less moisture and vegetation cover, therefore, resulting in low biomass. The denser the vegetation and crown cover are the higher the biomass will be (Du et al., 2014).

Calculation of carbon emission

The historical forest inventory data was not available with the local forest department. Therefore, we assumed the year 2000 carbon stock data to be the same as carbon stock of 2015 (69.93) to calculate the carbon emission.

In our case, the forest acts as a source of carbon not sink. Forests are not protected according to forests policy, and forest law enforcement is also very weak due to which illegal logging and wood harvesting occur. Emissions of CO_2 results increased due to land-use change because of deforestation which is a major cause of climate change. According to Houghton (2003), on a global scale, the deforestation contributes about 156 Pg of carbon emitted to the atmosphere from 1850 to 2005 and 12% to 15% of total emissions of GHG. Our results suggest 6.96 $MtCO_2$ e contributed to the atmosphere from our study area during the 15 years (2000-2015). Since due to deforestation carbon is not only lost to the atmosphere but the mechanism of CO_2 absorption by trees is also eliminated (Rokityanskiy et al., 2007). Degradation and deforestation may be due to disease, flood, fire, and storm, (natural causes) while it may also be due to illegal wood harvesting, expansion of agriculture, government policies, development of infrastructure, poverty, as well as the cultural attitude that changed towards the forest (Keenan et al., 2015).

Carbon sequestration potential

To mitigate the atmospheric CO_2 effectively, one has to quantify the C sequestration potential of all C pools including a forest in order to best estimate its contribution. For example, when the forest is in the developmental stage, then the C storage capacity could be manifold, and it will act as a sink of C while the old forest (80-100 years age) stores carbon very slowly. So for reducing carbon emission, we should attain carbon carrying capacity and decrease human disturbance in our forests. The forest sequestration potential can be enhanced through afforestation, reforestation activities, reducing the anthropogenic activities as well using sustainable forest management practices.

Remote sensing applicability for REDD+ implementation

In third world countries where check and balance systems of monitoring are not adhered to fulfill the requirements of the international obligations, the RS techniques can play a critical and decisive role in successful forest activities monitoring and implementation of the REDD+ system at local and national spatial scales. The remote sensing technique for monitoring and implementation seems to be the best, cost-effective and accurate method for the assessment of carbon stock, biomass, and carbon emission. From our results, the VIs derived from Sentinel-2 are implicit for the assessment of carbon stock and the biomass as well. Besides this, the Sentinel-2 imagery is multi-spectral having 13-bands consisting of SWIR and Red-edge spectral bands and is freely available. As compared to other medium resolution satellite imageries it has 10 m spatial resolution which is high. The availability of Red-edge

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_783815

band reduces the saturation problem. The method adopted in this study is feasible and could be applied on a larger spatial scale, i.e. at the regional and national level. For the assessment of forest cover change and carbon emission estimation Landsat open source and historic data increase its importance. Hence this study will serve REDD+ in its objective of sustainable forest management and reducing CO_2 emissions.

Study limitation and recommendation for future research

In Sentinel-2 satellite imagery, not all the spectral bands are of the same resolution, i.e. some of the bands are of 10 m resolution while others are of 20 m. In order to make all the bands of the same resolution (10 m), we had to resample the data due to which the accuracy of estimation of biomass from VIs might have been affected as some of the spectral information might be lost due to resampling. Use of high-resolution optical data both for the assessment of deforestation, degradation as well as biomass and carbon stock can further increase the accuracy of the results.

In the future, research is required on the integration of optical and RADAR data since optical data do not take into account the below canopy vegetation which could result in an underestimation of above ground biomass. This issue can be resolved by incorporating the RADAR data that could also reduce sensor saturation in optical-sensor images. Launching of additional advanced satellite sensors are required which are specifically designed for terrestrial carbon stock monitoring and particularly that of spaceborne LiDAR sensor. Hence LiDAR data use can further increase the accuracy.

Use of historical ground data can improve our understanding of carbon emission estimation. For a better insight of variation in carbon stock of forest ecosystem and carbon emissions, spatiotemporal analysis of carbon fluxes studies needs to be carried out. Furthermore, carbon sequestration potential can be assessed with better accuracy, if climatic variables (precipitation, temperature) and old-growth forest data are available (Cramer et al., 2001).

Farm forestry, agroforestry practices and technologies of clean energy should help in the reduction of carbon emissions. For sustainable forest management and climate change, clean development mechanism as well as UN REDD+ program could be helpful.

Conclusions

From this study, we conclude that forest land is decreased at an alarming rate because of increase in agricultural land, shrub/grassland and urban areas and about 16.88% of forest area is lost in fifteen years. The annual deforestation rate is 2.51% and due to deforestation carbon emissions were about 6.96 Mt CO_2 e in fifteen years. Natural forests are cleared for agricultural purpose due to which the ecology of the region is disturbed. To decrease carbon emissions, the deforestation and degradation must be lessened through conservation of forest and sustainable management of the forest. AGB and carbon stock in the study area were 148.79 t/ha and 69.93 t/ha. VIs derived from sentinel-2 imagery have the potential in the estimation of biomass. Saturation problem leads to poor estimation of AGB in canopy water content and broadband Vis. However, red-edge band reduces the saturation problem and thus it is more appropriate. Therefore, in future red-edge VIs should be used for biomass estimation instead of broadband VIs. Spatial distribution of biomass was mapped from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_783815

the best VI and validated with the ground data which is much important in order to know management, disturbance and carbon fluxes in the forest. Carbon sequestration potential was 82.07 t/ha ± 13 t/ha.

For better forest management, remote sensing and GIS should also be applied with ground forestry operations and in the estimation of biomass, carbon stock and carbon emissions the use of remotely sensed data such as Vegetation Indices. This can decrease labor force. The ground data can be applied on a large scale, i.e. at regional and national level through remote sensing. From the study, we can see that biomass and carbon stock can be estimated with better accuracy from vegetation indices derived from sentinel-2 imagery as compared to other sensors because of its high spatial resolution (10 m) as well as spectral bands for vegetation study.

The areas which are inaccessible and ground survey is difficult to be performed so this method is more suitable for biomass and carbon stock estimation. Hence this method seems to be the most cost-effective, best and most accurate for the assessment of biomass, carbon stock, change in forest cover and carbon emissions. This study will serve REDD+ in its objective of sustainable forest management and lessening emission of CO_2 in the atmosphere.

APPENDIX A

Table A1. *List of allometric equations for major species*

Species	Model	Allometric equation
General (coniferous)	$M=a(\rho\times D^2\ H)^b$	$AGB=0.1645\times(\rho\times D^2\times H)^{0.8586}$
Pinus roxberghii (chir pine)	$M=a(D^2\times H)^b$	$AGB=0.0224\times(D^2\times H)^{0.9767}$
Cedrus deodara (Deodar)	$M=a(D^2\times H)^b$	$AGB=0.1779\times(D^2\times H)^{0.8103}$
Pinus Wallichiana (Kail)	$M=a(D^2\times H)^b$	$AGB=0.0631\times(D^2\times H)^{0.8798}$
Pinus gerardiana (Chilghoza)	$M=a\times D^b$	$AGB=0.0253\times D^{2.6077}$
Abies Pindrow (Fir)	$M=a(D^2\times H)^b$	$AGB=0.0954\times(D^2\times H)^{0.8114}$
Picea smithiana (Spruce)	$M=a(D^2\times H)^b$	$AGB=0.0843\times(D^2\times H)^{0.8472}$
Quercus ilex (Oak)	$M=a(D^2\times H)^b$	$AGB=0.8277\times(D^2\times H)^{0.6655}$

Table A2. *Description and formula of the categories of various vegetation indices*

Vegetation index	Formula	Sentinel-2 bands	Reference
Broadband VIs			
EVI – Enhanced VI	$EVI2 = 2.5 \times \frac{NIR - Red}{NIR + 2.4Red + 1}$	Whereas NIR is spectral band 8, while the red is spectral band 4	Jiang et al., 2008
GNDVI – Green Normalized Difference VI	$GNDVI = \frac{NIR - Green}{NIR + Green}$	Where NIR is spectral band 8 while Green is spectral band 3	Gitelson et al., 1996
NDVI – Normalized Difference VI	$NDVI = \frac{NIR - Red}{NIR + Red}$	Where NIR is spectral band 8, while the red is spectral band 4	Rouse Jr et al., 1974
SAVI – Soil Adjusted VI	$SAVI = \frac{NIR - Red}{NIR + Red + L} \times (1 + L)$	Whereas NIR is spectral band 8 and Red is Spectral band 4	Huete, 1988
SQSR – Square Root Simple Ratio	$SQSR = \sqrt{\frac{NIR}{Red}}$	Whereas NIR is spectral band 8 and RED is spectral band 4	Itkonen, 2012
TSAVI – Transformed Soil Adjusted VI	$TSAVI = \frac{a\,(NIR - aR - b)}{[a(NIR - b) + 0.08\,(1 + a^2)]}$	Where NIR spectral band 8 and Red is Spectral band 4	Baret and Guyot, 1991
Canopy Water Content Indices			
NDII – Normalized Difference Infrared Index	$NDII = \frac{NIR - SWIR}{NIR + SWIR}$	Where: NIR is spectral band 8, while the shortwave infrared (SWIR) is spectral band 13	Hunt et al., 2012
NDWI – Normalized Difference Water Index	$NDWI = \frac{NIR - SWIR}{NIR + SWIR}$	Where: NIR is spectral band 8, while shortwave infrared (SWIR) is spectral band 12	Gao, 1996
Narrow Red Edge Band VIs			
RE-EVI – Re-Edge Enhanced VI	$RE_{EVI} = 2.5 \times \frac{NIR - RE}{NIR + 2.4RE + 1}$	Where: NIR is spectral band 8, While the red-edge is spectral band 6	Abdel-Rahman et al., 2017
RENDVI – Red-Edge Normalized Difference VI	$RENDVI = \frac{NIR - red}{NIR + red}$	Where: NIR is spectral band 8, while the red-edge spectral band 6	Chen et al., 2007a
RERVI – Red Edge Ratio Vegetation Index	$RERVI = \frac{NIR}{RE}$	Where: NIR is spectral band 8, while the red-edge is spectral band 6	Cao et al., 2016

(Received 9th Jul 2019; accepted 15th Nov 2019)

Abstract. The structural patterns and the seasonal dynamics of fishery species were studied in the Bohai Sea, based on fishery-independent data surveyed in each season sampling stations. A total of 88 fishery species belonging to 64 families were recorded, in detail 43 fishes, 29 crustaceans, 12 molluscas, three echinoderms and one species of scyphozoan. Among them, 21 species commonly found throughout the study period defined as 'common' species, and eight species those were the highest contributors defined as 'dominant' species (based on SIMPER analysis, their cumulative contribution was more than 70%). Maximum abundance was recorded in the summer season while species number was higher in both summer and autumn season. Among the community parameters, species richness (3.79), diversity (2.31) and Simpson indices (0.88) peaked in the autumn season whereas species evenness (0.95) was in the winter. However, species diversity, evenness, and Simpson indices were lower in the summer season (0.57, 0.18 and 0.18, respectively) while species richness was in the winter (1.65). Multivariate PCoA analysis revealed that there was a significant seasonal variation in fisheries assemblages. Furthermore, ANOSIM (Global $R = 0.467$, $P = 0.01$) indicated a distinct community structure of fishery species between the four seasons. Thus, this result suggests that fisheries assemblages might be influenced by the seasonal dynamics of the ecological condition of the Bohai Sea.

Keywords: *fisheries assemblages, multivariate analyses, community parameters, seasonal patterns, trawl survey data*

Introduction

The Bohai Sea, a semi-enclosed inland sea is a unique waterbody that houses rich marine and coastal biological resources (i.e., fishes/shellfishes; oil, gas, and minerals; estuaries; tidal flats; seagrass beds) as well as a great potentiality for mariculture and tourism purpose in the northeastern China (Zhang et al., 2002; Song and Duan, 2018). However, the rapid human

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_817837

settlement and industrial development that was triggered from 1985 along the coast of Bohai Sea accelerated the degradation in estuarine and marine ecosystems by altering hydro-pedological properties (i.e., water and sediments qualities) over the decades (Liu et al., 2011; Gao et al., 2014; Li et al., 2016). Besides, the changing climate variabilities such as temperature (*T*), salinity (*S*), and biogenic elements altered the Bohai Sea ecosystems which significantly influenced the living biotic communities (Lin et al., 2001; Yu et al., 2009). The variations of species in the communities are closely interrelated with the ecological conditions of water masses. Over the recent decades, anthropogenic activities mainly linked to urbanization and industrialization have a notable effect on the species diversity of the primary producers and benthos communities which may have triggered off the declining trend of fishery populations in the Bohai Sea (Hu et al., 2011; Liu et al., 2011).

Several studies have been focused on the characteristics of fish and fishery dynamics of the Bohai Sea (Chen et al., 1997; Tang et al., 2003; Jin, 2004; Shan et al., 2012, 2016; Zhang et al., 2012). Investigations have been reported that fishery stock status in the Bohai Sea experienced declining trends (Liu et al., 1990; Zhang et al., 2006; Zhou et al., 2013). Moreover, the Bohai Sea has been considered one of the most exploited fishing ground in the world (Wu et al., 2017; Liu et al., 2017). As a result, species abundance, diversity, and trophic structure had significantly shrunk in this ecosystem (Deng and Jin, 2001; Jin, 2004; Zhang and Tang, 2004; Shan et al., 2012). Spatio-temporal shifts of dominant species from large-size of high economic value to short-lived, low-trophic-level, low economic value and changes of ecosystem structure and functioning on the decadal-scale have been documented (Shan et al., 2013, 2016; Rahman et al., 2019).

The present study accounts the Bohai Sea as a major fishery center in China in view, and evaluated a one-year fishery-independent data (i.e., a pair of trawlers) to analyze the community patterns and dynamics of the fishery species. The specific aims of the research were (a) to document the taxonomic composition and species distribution patterns of fishery species, and (b) to illustrate the community patterns and the seasonal dynamics of fishery species during the study period.

Materials and methods

Study area

The Bohai Sea (37°07`~41°N and 117°35`~121°10`E) is a semi-enclosed marginal sea of the northwestern Pacific Ocean on the northern coast of China. It extends for about 450 km from north to south and about 350 km from east to west, where the Bohai Strait is used as a junction to the Yellow Sea between Shandong and Liaodong Peninsulas (*Fig. 1*). It has an area of 77,000 km^2, which includes Bohai, Laizhou, and Liaodong Bays. The water depth varies at 10-20 m in the continental shelf where maximal water depth of 70 m is recorded in the northern part of Bohai Strait. The hydrographic conditions have greatly influenced by many factors such as river discharges, wind–tide–thermohaline circulation, stratification during summer, and vertical and horizontal mixing of nutrients in winter that support higher primary productivity (Ning et al., 2010).

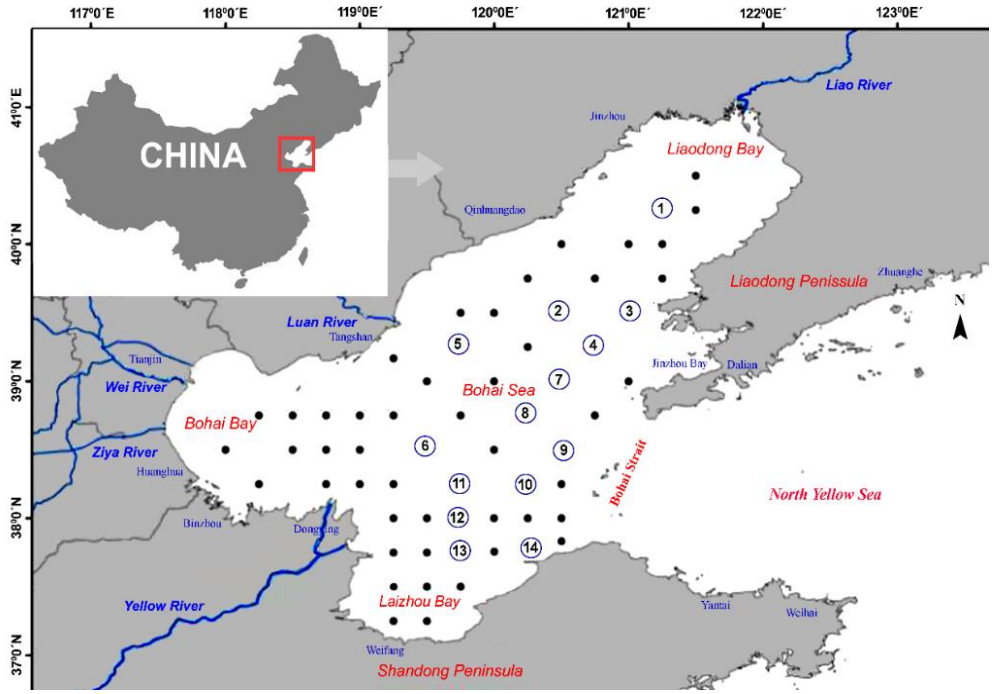

Figure 1. *Geographical locations of sampling points in the Bohai Sea, China*

Data source

Data were collected from a pair trawler (i.e., the capability was 200 horsepower; the distance between wings was 22.6 m, headline height was between 5 m and 6 m, cod mesh size was 2 cm, and circumference was 30.6 m.) survey carried out by the Yellow Sea Fisheries Research Institute. The surveyed sampling stations were designed on a fixed station grid of 0.5°N × 0.5°E. The hauls were lowered for sampling during the daytime, the duration at least 15 minutes to 60 minutes and an average hauling speed of 5.09 km/h. The average sampling depth was 23.18 meters (*Table 1*). All data were then standardized to a one-hour trawl duration for consistency. The survey period divided into four seasons namely as winter (January), spring (May), summer (August), and autumn (November) season. Samples were collected from the fixed 70 sampling stations. Among them, 14 stations were surveyed in each season. We selected these common sampling stations for analysis among the seasons.

Collected fishery specimens at each station were sorted firstly family and order level, then to species level, or the lowest possible taxon level. Subsequently, total abundance/individual abundance and species composition were recorded. The abundance of the species was expressed as the number of individual species catch per haul (ind./haul), and the composition of the species was expressed as a percentage of the total number of species recorded (%).

14	37°75′ N	120°25′ E	Laizhou Bay	14.93	4.82

Data analysis

Diversity patterns of fishery species were summarized by frequently used diversity measuring indices such as Shannon-Wiener Index (H') (Shannon & Weaver) (*Eq. 1*), species evenness (J') (Pielou) (*Eq. 2*), species richness (d) (Margalef) (*Eq. 3*) and Simpson index (1-λ′) (Simpson) (*Eq. 4*), these four indices were measured using the following formulas:

$$H' = \sum_{i=1}^{S} P_{i(lnP_i)} \quad \text{(Eq.1)}$$

$$J' = H'/lnS \quad \text{(Eq.2)}$$

$$d = (S-1)/lnN \quad \text{(Eq.3)}$$

$$1 - \lambda' = 1 - SUM\left(N_i * (N_i - 1)\right)/\left(N * (N-1)\right) \quad \text{(Eq.4)}$$

where, H'= observed diversity index; P_i= proportion of the total count arising from the ith species; S= total number of species; and N= the total number of individuals.

Both multivariate and univariate analyses were conducted for summarizing seasonal variation in fishery dynamics and their seasonal patterns of community structure using PRIMER v7.0.13 and IBMSPSS v.22. The patterns of species distribution between the four seasons were analyzed by shade plotting analysis from average standardized species abundance data. The species whose presence was available in all four seasons were defined as 'common species' in the community. The contribution of each species to the average Bray-Curtis similarity among the 14 trawls stations was calculated using SIMPER (similarity percentage analysis) program. Based on the SIMPER analysis, those

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_817837

species have a cumulative contribution of more than 70% in the total communities were defined as 'dominant species'. Both the dominant and common species identified as an important species in the fishery communities (Zhu and Tang, 2002; Shan et al., 2016). The significant differences of the fisheries community structure among the seasons were tested using ANOSIM (analysis of similarity) (Anderson et al., 2008; Clarke and Gorley, 2015). The seasonal variations in fishery assemblages were analyzed by coordination of the submodule of PCoA (Principal coordinates analysis) of PREMANOVA + of Bray–Curtis similarities from square root transformed species abundance data (Anderson et al., 2008; Clarke and Gorley, 2015).

A simple Pearson correlation matrix was performed to identify an existing correlation among the dominant species of fishery communities using IBMSPSS v.22, and data were log-transformed before analysis.

Results

Taxonomic composition and species distribution

A total of 88 species belonging to 64 families were identified. These fishery samples included 43 fish species belonging to 28 families, 29 crustacean species belonging to 21 families, 12 mollusca species belonging to 11 families, three echinoderm species belonging to three families and one species of scyphozoan. The list of identified fishery species including their seasonal distribution, average abundance, frequency of occurrence was summarized in *Table 2*. Among the species, 21 species were reported common in terms of their presence in all four seasons, and eight species were found to be dominant with their higher contribution in the communities.

Based on the species distribution patterns, 19 species were present in three seasons, 18 species were present in two seasons, and 30 species were distributed only in one season (*Fig. 2*).

In terms of dominance (result from SIMPER analysis >70%), six species belonged to crustaceans (*Alpheus japonicas*, 15.34%; *Oratosquilla oratoria*, 11.57%; *Palaemon gravieri*, 10.57%; *Crangon affinis*, 8.85%; *Acetes chinensis*, 7.53%; *Leptochela gracilis*, 7.19%) and others were one fish species (*Engraulis japonicas*, 6.30%) and one cephalopod species (*Loligo japonica*, 8.51%) (*Table 2* and *Fig. 2*).

In terms of species belonging to family, the maximum number of species were recorded under the family of Gobiidae with seven species (*Amblychaeturichthys hexanema*, *Chaeturichthys stigmatias*, *Cryptocentrus filifer*, *Favonigobius gymnauchen*, *Ctenotrypauchen chinensis*, *Synechogobius hasta*, and *Odontamblyopus rubicundus*), followed by the family of Engraulidae with five species (*Coilia mystus*, *Engraulis japonicas*, *Setipinna taty*, *Thrissa kammalensis,* and *Thrissa mystax*) and the Penaeidae with four species (*Fenneropenaeus chinensis, Marsupenaeus japonicas, Metapenaeopsis dalei* and *Trachypenaeus curvirostris*) (*Table 2*).

According to the frequency of occurrence of the dominant species, *Acetes chinensis*, *Palaemon gravieri,* and *Alpheus japonicas* were accounting for 62.64%, 46.06%, and 32.62%, respectively in the winter season (January) while *Crangon affinis* and *Oratosquilla oratoria* were accounting for 85.18% and 60.08%, respectively in the spring season (May). In the summer season (August) *Engraulis japonicus*, *Loligo japonica*, *Palaemon gravieri,* and *Oratosquilla oratoria* were accounting for 93.25%, 76.82%, 62.12%, and 39.92%, respectively whereas *Alpheus japonicas*, *Leptochela gracilis* and *Palaemon gravieri* were accounting for 46.65%, 86.55%, 37.88%, respectively in the autumn season (November) (*Table 2* and *Fig. 2*).

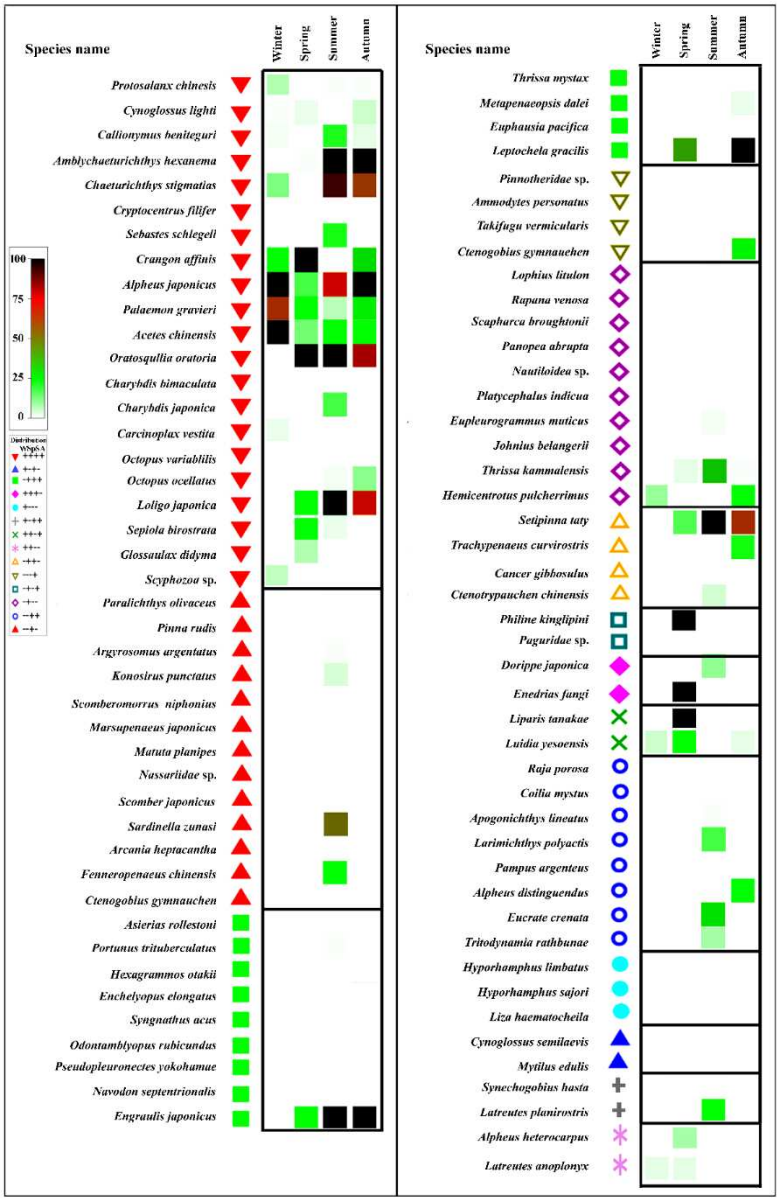

Figure 2. *Shade plot showing the seasonal distribution pattern of fishery species in terms of their relative abundance during the study period in the Bohai Sea*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_817837

Seasonal variation in fishery dynamics

In terms of abundance of dominant species per haul, the individual abundance found to be higher in the summer and lower in the winter (*Fig. 3a*). As to relative abundance, three species of crustaceans were predominant in the winter (*Alpheus japonicas*, *Acetes chinensis* and *Palaemon gravieri*); two species in the spring (*Crangos affinis* and *Oratosquilla oratoria*); two species in the summer (*Engraulis japonicus* and *Oratosquilla oratoria*); and two species in the autumn season (*Leptochela gracilis* and *Alpheus japonicus*) (*Fig. 3b*).

Based on species occurrence, the maximum species occurred in summer and autumn, whereas the minimum was in winter (*Fig. 4a*). For example, of these 88 species, 24 were occurred in summer and autumn, while only seven species were in winter. In terms of total abundance, the highest abundance recorded in summer, while the lowest was in winter (*Fig. 4b*).

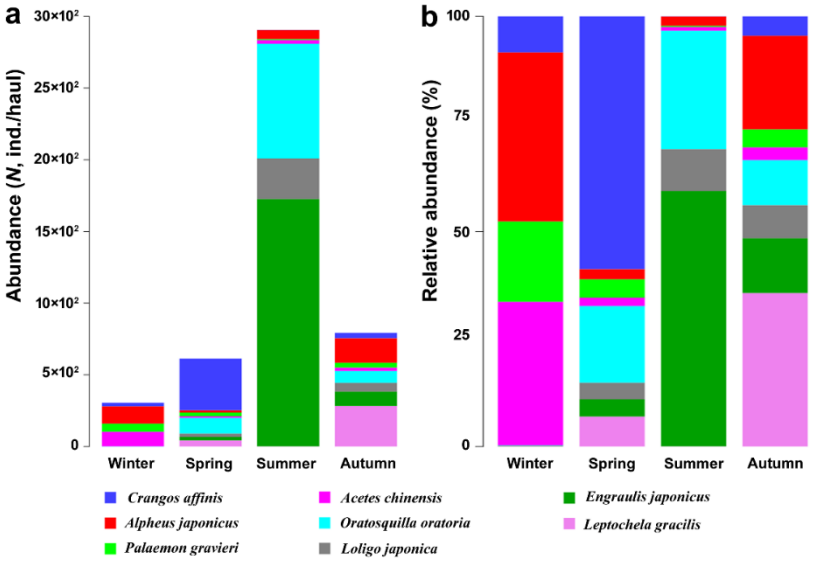

Figure 3. *Variation in abundance and relative abundance of dominant species of fishery species during the study period in the Bohai Sea*

The analysis of similarity (ANOSIM) revealed that there was a significant difference in fishery community structure between the four seasons (Global, R = 0.467, $P < 0.001$). Based on SIMPER analysis, seven typical species (*Crangon affinis, Enedrias fangi, Oratosquilla oratoria, Acetes chinensis, Alpheus japonicas, Liparis tanakae* and *Philine kinglipini*) driven 93.34% average dissimilarities between winter and spring seasons. Similarly, six species (*Engraulis japonicas, Oratosquilla oratoria, Loligo japonica, Alpheus japonicas, Acetes chinensis* and *Chaeturichthys stigmatias*) in winter and spring seasons (97.33%); eight species (*Leptochela gracilis, Alpheus japonicas, Acetes chinensis, Amblychaeturichthys hexanema, Engraulis japonicas, Setipinna taty, Palaemon gravieri,* and *Crangon affinis*) in winter and autumn seasons (90.37%); seven species (*Engraulis japonicas, Oratosquilla oratoria, Loligo japonica, Crangon affinis, Amblychaeturichthys hexanema, Setipinna taty* and *Enedrias fangi*) in spring and summer seasons (95.07); nine species (*Leptochela gracilis, Crangon affinis,*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_817837

Enedrias fangi, Amblychaeturichthys hexanema, Oratosquilla oratoria, Liparis tanakae, Philine kinglipini, Alpheus japonicas and *Engraulis japonicus*) in spring and autumn seasons (89.81%); and six species (*Engraulis japonicas, Oratosquilla oratoria, Loligo japonica, Amblychaeturichthys hexanema, Leptochela gracilis,* and *Setipinna taty*) in summer and autumn seasons (92.29%) (*Table 3*).

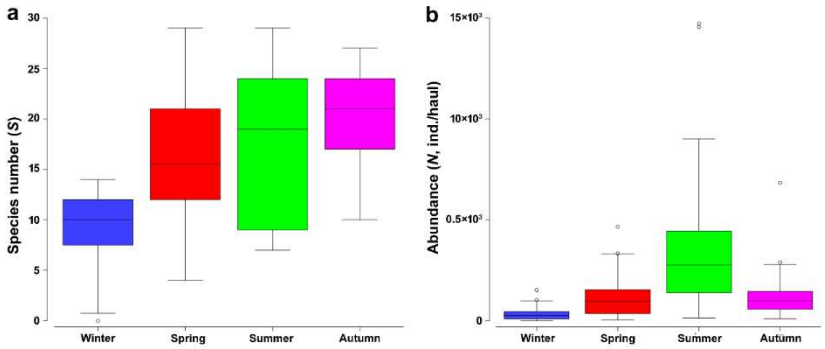

Figure 4. *Seasonal variation in species number (a) and total abundance (b) in the fishery species during the study period in the Bohai Sea*

Seasonal variation in diversity pattern of fishery species

Among the community parameters, the species richness showed increasing trend from winter to autumn season, with a higher value in the autumn and lower in winter while species evenness showed opposite that decreased from winter to summer, then again increased in autumn season with a value higher in winter and lower in summer season (*Fig. 5a,b*). The species diversity (H') and Simpson index (1-λ′) showed similar seasonal patterns and both indices values were higher in autumn and lower in the summer season (*Fig. 5c,d*).

In terms of fishery diversity status, there was a clear temporal variation revealed in the Bohai Sea during the study period (*Fig. 5*). For example, the highest value of species richness (3.79) was found in the autumn season whereas it was the lowest (1.65) in the winter with an average of 2.80±0.59. The species evenness was found to be maximum (0.95) in the winter season and minimum (0.18) in the summer season with an average of 0.63±0.17. The maximum species diversity index was (2.31) recorded in autumn season and minimum (0.57) was in summer season with an average of 1.82±0.44 while Simpson index was found to be similar with diversity that was the highest (0.88) in autumn season and the lowest (0.18) in summer season with an average of 0.73±0.18 (*Fig. 5*).

Patterns of community structural of fishery species

Principal analysis of coordinates (PCoA) summarized the seasonal structural variations in the fishery species. The first canonical axis (PCoA1) separated the samples in winter and spring (on the left) from those in summer and autumn (on the right), while the second canonical axis (PCoA2) discriminated the samples in winter and summer (upper) from those at the others two seasons spring and autumn (lower) (*Fig. 6a*).

Ave. Diss., average dissimilarity; Cont., contribution

Vector overlay of Pearson correlations of eight dominant species revealed that vectors of four species (*Engraulis japonicas*, *Oratosquilla oratoria*, *Loligo japonica* and *Leptochela gracilis*) pointed towards the sample clouds in summer season (upper right), three species (*Alpheus japonicas*, *Acetes chinensis* and *Palaemon gravieri*) of crustacean towards that in winter season (upper left), and one species (*Crangos affinis*) toward in spring season (lower left) (*Fig. 6b*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_817837

A simple Pearson correlation among the eight dominant species was summarized in *Table 4* showed a significant correlation during the study period. Among these eight species, only four species showed significant correlations. For example, *Palaemon gravieri* showed a positively significant correlation with *Alpheus japonicus* (r=0.427**, P<0.01) whereas *Loligo japonica* correlated with *Oratosquilla oratoria* (r=0.517**, P<0.01) (*Table 4*).

Discussion

The Bohai Sea is considered as an important fishery ground (i.e., spawning, nursing, and fishing) in northern China and the fishery resources have a dynamic nature (Chen et al., 1997; Deng and Jin, 2001). For instance, this shallow water mass used as an important migratory route for many marine species from the Yellow Sea (Liu, 1990). However, the increasing pressure of anthropogenic activities and climate variabilities have already altered the Bohai Sea ecosystem (Lin et al., 2001; Ning et al., 2010; Guo et al., 2013; Liu and Zhang, 2013; Pelling et al., 2013). Investigations have documented that change in climatic conditions and overfishing are the main drivers for fast-paced structural change in the marine ecosystem (Planque et al., 2010; Aschan et al., 2013; Rocha et al., 2015). In this study, we evaluated the characteristics of community structure and dynamics of fishery species in the Bohai Sea.

The Bohai Sea ecosystem is mainly composed of warm water and warm-temperate species. Previous research based on the ecotypes features (i.e., warm-water, warm-temperate, and cold-temperate species), a total of 97 fish species were reported over six decades where a rapid shifting of dominant species occurred (Shan et al., 2016). After 1982, both in the spring and summer season, the species of that ecotype decreased. In an earlier study in the Yellow River estuary of Laizhou Bay in the Bohai Sea, reported that 77 fish species were accounted for where eight pelagic fishes catch contributed more than 10% in every sampling year (Shan et al., 2013). The species composition changed during the survey periods in the Yellow River estuary. Another survey results in the Yellow and

Bohai Seas, reported a total of 126 species comprising 102 fishes, 17 crustaceans, five cephalopods and two medusas where *Acetes chinensis* was the most dominant in terms of biomass (Chen et al., 1997). Thirty-two crustacean species were enlisted, among them only single species *Crangon affinis* was the dominant species both in Yellow and Bohai Seas during the spring season (Wu et al., 2012). In our study results, *Crangon affinis* was found to be the dominant species which is consisted of previous research results. In addition, our present study found that major dominant species were belonging to crustacean group (*Alpheus japonicas*, 15.34%; *Oratosquilla oratoria*, 11.57%; *Palaemon gravieri,* 10.57%; *Crangon affinis,* 8.85%; *Acetes chinensis,* 7.53%; *Leptochela gracilis,* 7.19%) which clearly indicated the dominant fishery species shift in this ecosystem. The small-sized, pelagic fishes (*Engraulis japonicas*, 6.30%), and crustaceans' species prevailed in the Bohai Sea ecosystem were also reported (Xu and Jin, 2005; Wang et al., 2010; Li et al., 2013).

Based on species richness and total abundance, the maximum was recorded in the summer season. In addition, abundance of eight dominant species also showed similar community variation, thus might be due to variation in ecological conditions among the seasons. Several studies have stated that environmental factors (e.g., temperature, transparency, salinity, dissolved oxygen, nutrients, and water pH) can significantly influence the ecological condition of water in both temporal and spatial scales. Therefore, this ecological condition may shape the fishery species in the Bohai Sea ecosystem (Lin et al., 2001; Jin et al., 2013; Shan et al., 2016). The present study found that there was a significant seasonal shift of dominant fishery species which might be due to fluctuation of water parameters (e.g., temperature) over the decades (Jin 2004; Shan et al., 2016). Many studies showed that recent climate-change-induced variabilities negatively affected the pelagic fishery productivity (Jin et al., 2003; Stige et al., 2006; Perry et al., 2010). The changes in variabilities impede the supply of primary productivity and breakdown the interaction of the trophic levels. So the resultant of this lower food supply can affect the fishery recruitment patterns and dynamics by limiting species migration and shifting keystone species (Zhu and Tang, 2002; Ning et al., 2010) (*Table 5*).

Diversity indices are widely used in the representation of the homogeneity and heterogeneity of ecosystem status, such as existing fishery status on species levels (Shan et al., 2010a, 2011, 2013; Chen et al., 2018). Generally, higher indices values indicate a better environment/ecological quality status and represent a stable ecosystem condition (Chen et al., 1997; Shan et al., 2010b). In the present study we found, species richness, Simpson indices, and diversity were higher in the autumn season which indicated that the ecological condition of water was relatively favorable for fishery species in this season compared to the other three seasons. This variation might be occurred due to the fluctuation of water temperature in the Bohai Sea (Xia and Xiong, 2013). Besides, several anthropogenic stresses (e.g., both municipal/land-based pollution, beerier of natural water flow, coastal reclamation activities) have significant negative effects on fishery species composition and distribution (Zhao and Kong, 2000; Cui et al., 2005; Shan et al., 2013; Yan et al., 2013). In addition, changing of the ecological condition due to algal blooms in winter have a significant negative impact on fishery species was reported in elsewhere

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_817837

which is consistent with the present study findings that fishery stock turns over in autumn season just after winter season (Wang et al., 2006; Tang et al., 2010). Thus, the findings of the present study suggest that the community patterns and dynamics structure of fishery species have closed interactions with climate and water ecological conditions in the Bohai Sea.

Multivariate analysis is a more useful tool than univariate analysis for summarizing the interaction of biotic communities with abiotic factors (Anderson et al., 2008; Clark and Gorley, 2015; Chen et al., 2018). Based on these strategies in the present study, PCoA (principal coordinates analysis) and ANOSIM (analysis of similarity) demonstrated that there was an apparent significant seasonal variation in community patterns and dynamics of fishery species in the Bohai Sea ecosystem. This variation is mainly driven by eight dominant species and their mutual interactions (*Table 4*) with typical species (*Table 3*).

Conclusion

The shallow Bohai Sea ecosystem is used as a unique ground for spawning, feeding, and nursery for many commercial as well as ecological fishery species. The structural patterns and community dynamics of the fishery species in the Bohai Sea are complex and have complicated linked with multiple factors (e.g., pollution, overfishing, climate change, and water ecology). In our present study used a pair trawl survey data to observe the seasonal variation in community patterns and structural dynamics fishery species especially, their abundance, composition, distribution and dominant shift in the Bohai Sea. The community parameters mainly, species richness, diversity, and Simpson indices were higher in the autumn. Multivariate analyses revealed a significant seasonal variation in the fishery community structure patterns and structural dynamics. Our results suggest that ecological conditions may shape the community structure of fishery species in the Bohai

Sea. Although this study didn't include environmental and climate data, however, such results are important for fisheries assessment and maintaining sustainable fisheries management initiative. Moreover, further studies on the fishery community patterns based on climate and environmental observations are needed to verify this outcome.

Acknowledgments. The first author would like to express appreciation to the Chinese Scholarship Council (CSC) for sponsorship during his doctoral degree (CSC No. 2016GXY026). This work supported by the National Basic Research Program of China (No. 2015CB453303). The first author is very thankful and indebted to lab mates from both the Yellow Sea Fisheries Research Institute, Chinese Academy of Fishery Sciences and Laboratory of Fish Population Dynamics, Ocean University of China.

PLUVIO-THERMAL CONDITIONS PERTAINING TO VEGETATION OF KEY CROPS IN SOUTHEASTERN POLAND 1901-2010

ZIERNICKA-WOJTASZEK, A.

(Received 9th Jul 2019; accepted 16th Oct 2019)

Abstract. The aim of this article is to analyze the variability of current climate changes, as well as favorable and unfavorable trends in weather conditions for key crops in south-eastern Poland in the April-October period (1901-2010). The climate variability was analyzed for four time slices (climate normals): 1901-1930, 1931-1960, 1961-1990, and 1981-2010. The aforementioned slices include natural dry and wet cycles as well as cool and warm periods. Numerous weather bulletins and written accounts were used in this study, as well as mean area temperature values and precipitation totals. The data, especially from the last 30 years, implies that key crops will be less susceptible to heat related stress during spring months whilst becoming more susceptible to the precipitation deficit stress in the summer months (due to increased evaporation and the lack of a clear precipitation trend). The article also proves that climate analyses based on mean values recorded over an extended period of time are useful for characterizing current climate conditions in a historical context, but can neither be applied for forecasting purposes nor put to practical use.
Keywords: *the Subcarpathian voivodeship, plant vegetation, climate change, pluvio-thermal conditions, global warming*

Introduction

Due to natural climate variability, the characteristics that apply to resources, qualities and climatic hazards in a given region are assessed usually over a period of 30 years (climate normal recommended by the World Meteorological Organization). The World Meteorological Organization and its predecessor (the International Meteorological Organization) have initiated and coordinated the establishment of climate normals for its member states. This process started with the period 1901-1930 and continues today, with updates being made every 30 years such as 1931-1960, 1961-1990 (Arguez and Vose, 2011). This principle is not contradicted by long-term analyses of climate data as well as analyses of individual cases of extreme weather events that occur worldwide.

Owing to the clearly visible warming trend that has been observed in recent years and the intensifying process of global warming (Solomon et al., 2007; Milly et al., 2008) the idea to characterize current or future climate conditions by means of 30 year normals, is being questioned more and more often (Livezey et al., 2007). In the existing situation, in order to make the climate statistics more accurate, it becomes necessary to update climate normals not every 30 years, but every 10 years. For instance, instead of making 1991-2020 the next normal, the 1971-2000, and recently even 1981-2010 are being used. In order to obtain a broader temporal perspective, emission scenarios are elaborated by the IPCC (i.e. 2000 scenario), which are subsequently used by climate modelling centers as an integral component for predicting Earth's climate variability.

Natural climate variability and contemporary climate change affect certain aspects of the environment and human economic activity. In agriculture they lead to fluctuations of meteorological conditions during the vegetation period, which result in crop variability (Křen, 1995; Motha and Baier, 2005). In the past, variable weather conditions which often led to extreme events caused numerous crop failures. Long time ago scholars drew up chronicles of natural hazards that affected the Polish nation. The work of Bujak (1976) which analyzes periods: 1450 to 1700 and 1772-1848 for the Polish region of Galicia is worth mentioning at this point. A successful continuation of this trend in research, from the point of view of economic history, is presented in the study entitled *The History of the Climate of Galicia in the years 1848-1913* (Wnęk, 1999). The subtitle of this study is: *The Impact of Meteorological Phenomena on the Socio-economic Development of Galicia*. The author's decision to put meteorological phenomena first, indicates that such phenomena are far more destructive than other types of natural hazards. What is important, is that this study is based on instrumental data and emphasizes the climate's role in the nineteenth century society. It also shows the impact of the climate on plant production, price variations, and the mortality rate in Galicia.

The continuation of this trend in research is presented in the work of Zawora, who devised a calendar of meteorological conditions of the vegetation of crops in southeastern Poland in the years 1901-1990 (Zawora, 1993). The author of this study assigned intervals which are favorable or unfavorable in terms of excessive or insufficient precipitation, too high or too low temperatures and a combination of such elements, to each month of the vegetation period. This was possible thanks to the accounts provided by agricultural correspondents, who described the state of crops for each month of the vegetation period. The author treated this particular study as material for further climatic and agroclimatic studies. He did not carry out a periodization in the entire 90-year period either in terms of climatic or meteorological conditions of the vegetation of key crops. The presented study constitutes not only a continuation of studies by a 20-year extension period, (1991-2010) which is characterized by clear warming, but also provides a new viewpoint on climate conditions in this particular period and its impact on the meteorological conditions of vegetation. More recent research by other authors aim at being studies on the adaptation to climate extremes of some crop plant varieties, European varieties of wheat in particular (Mäkinen et al., 2018a,b; Kahiluoto et al., 2019). The forecasted climate, and environmental changes emphasise the need for plant breeding strategies which ensure both: a significant increase in crop potentials, and a resistance to extreme weather phenomena, such as heatwaves, late occurring frosts, and droughts (Stratonovitch and Semenov, 2015). It is noteworthy, that moderate climate areas with adequate conditions for vine cultivation are increasing (Machar et al., 2017).

The aim of this article, which simultaneously provides a new viewpoint on the studied period (110 years), is to present the frequency of both favorable and unfavorable meteorological conditions for key crops in the productive cycle in southeastern Poland. This analysis takes into account three different aspects: climate variability in selected time slices (1901-1930, 1931-1960, 1961-1990, 1971-2000 and 1981-2010), periods of wet-dry and warm-cool cycles, and, finally, an emphasis on the last 30 years, which are marked by a clearly increasing temperature trend (Kożuchowski and Żmudzka, 2001; IPCC, 2007; Żmudzka, 2009).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_839848

The authors propose two scientific hypotheses which can be phrased as follows: 1. The practical usability of climate studies, which are primarily based on standard values, can be limited by the periodicity of meteorological phenomena. 2. The progressing global warming, during its initial phase, leads to the improvement of the meteorological conditions of vegetation, whilst in the next stage (especially recent years), leads to the increasing frequency of dry periods despite the lack of clear trends regarding precipitation totals.

Materials and methods

The principle materials used in this study featured agriculture correspondent bulletins about the state of cultivation (qualifying levels 1-5), as well as other reports pertaining to the meteorological conditions of the vegetation of key crops. It should be noted that the crops have not been divided into cultivated plants' categories such as: winter crops, spring crops, root crops and productive grassland. The majority of the above-mentioned bulletins and reports were drawn up at the end of each month, and were successively published over a longer period of time in a wide variety of statistical, agrometeorological, and agricultural journals (Biuletyn Agrometeorologiczny, Biuletyn Państwowej Służby Hydrologiczno-Meteorologicznej, Doświadczalnictwo Rolnicze, Gazeta Rolnicza, Kwartalnik Statystyczny, Miesięcznik Statystyczny, Miesięczny Przegląd Agrometeorologiczny, Rolnik, System Monitoringu Suszy Rolniczej w Polsce (SMSR), Tygodnik Rolniczy, Wiadomości Korespondenta Rolnego GUS, Wiadomości Meteorologiczne PIM). In their original form, they focused on the four main plant groups: winter crops, spring crops, root crops and productive grassland, which clearly differed in terms of both thermal and pluvial requirements. The relationships between the aforementioned groups of plants were standardized having in mind the methodological rule, which can be expressed in the following way: climate variability during individual vegetation periods is superior to the requirements of specific cultivate plants.

The climate data were gathered throughout a 110-year period (1901-2010) which was analyzed during the vegetation period only i.e. April-October. Accounts pertaining to the state of crops were assembled at the end of each month, hence every year 7 reports were drawn up. The bulletins always pertained to administrative units. However, it should be noted that administrative divisions were changed 6 times during the studied period. Therefore, the authors of this article tried to modify the reports about cultivation state so that they fit into the current area of the Subcarpathian voivodeship which was implemented on January 1, 1999. The studied area can be assigned to temperate-transient climate type, which is influenced by oceanic air masses and an increasing continental impact (Obrębska-Starklowa, 1977; Cebulak, 1992). In terms of the lie of the land, this area includes lowlands (the Sandomierz Basin), foothills and mountains (the Central and Eastern Beskid). The geographic coordinates of the extreme points are: 50°49′ – 49°00′N, and 21°09′ – 23°33′E (*Fig. 1*).

According to correspondents' accounts which pertain to the state of the crops at the end of each month, the pluvio-thermal conditions were labeled either as favorable or unfavorable. Among the unfavourable conditions, there are: too low temperature, very low precipitation, excessive precipitation, too low temperature combined with excessive precipitation, very low temperature and precipitation, and finally very high temperature combined with insufficient precipitation. The classification of favorable and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_839848

unfavorable pluvio-thermal conditions was based exclusively on the correspondents' accounts rather than on temperature or precipitation values (Zawora, 1993).

Apart from the calendar pertaining to meteorological conditions of vegetation of key crops, the authors also devised a pluvio-thermal calendar for the studied period (1901-2010), valid for vegetation period (April-October). They were mean area values for the studied area coming from 7 weather stations with long time observation stretches, taking into account the appropriate corrections resulting from the differences in the values of the meteorological elements, between the values from several weather stations, and from several dozens weather stations evenly distributed throughout the area. The homogeneity of the data was verified on the basis of two methods: difference stability (for temperature) and quotient stability (for precipitation).

Figure 1. *Area of investigations*

The principle research method featured the comparison of the frequency of favorable and unfavorable pluvio-thermal conditions which pertain to the vegetation of key crops during the following climate normals: 1901-1930, 1931-1960, 1961-1990 and 1981-2010. The authors also carried out a comparison of the meteorological conditions and their changes over a longer period of time (such as 1901-1941 and 1942-1964). A detailed analysis of these changes and trends was included with reference to the last three decades (1981-2010), which is simultaneously the current climate normal, and a period of an intensified air temperature increase worldwide.

Results

In the period 1901-1930 favorable meteorological conditions for vegetation occurred with a 46% frequency. In the beginning of the vegetation period (April) such conditions were observed every three years. The primary limiting factors were very cold temperatures (20%), frequently combined with excessive precipitation (20%). Meteorological conditions during the vegetation period improved in the subsequent months, however they deteriorated again in September and October. In May, an important limiting factor were the dry conditions (23%), while in July - excessive precipitation (17%) often combined with very cold temperatures. In the remaining months one of the most unfavorable factors for the vegetation of plants was excessive precipitation (*Table 1*).

DOI: http://dx.doi.org/10.15666/aeer/1801_839848

The characteristics of the 1901-1930 period reveal that it was cold and wet compared to the subsequent 1931-1960 period. The temperature mean during the vegetation period was 12.7ºC and the precipitation total equaled 532 mm (1901-1930). The subsequent 30-year period was warmer and dryer. The vegetation period temperature mean reached 13.3ºC and the precipitation total dropped to 496 mm. This gradually improved the vegetation of key crops. Also the frequency of months with favorable pluvio-thermal conditions increased from 46 to 53%. The percentage of very cold temperatures during April and May decreased by nearly half in the second 30-year period. In the month of June very cold temperatures were not observed during the 1931-1960 period. In general, the frequency of occurrence of dry months increased during the vegetation period from 15 to 20%. In contrast, the frequency of excessive precipitation decreased from 16 to 12%, and cases of excessive precipitation combined with too low temperature decreased by half (12 to 6%, *Tables 1 and 2*).

Table 1. *The frequency of occurrence of favorable and unfavorable pluvio-thermal conditions for the vegetation of key crops in southeastern Poland in the period 1901-1930 (%)*

Meteorological conditions of vegetation	Month							
	IV	V	VI	VII	VIII	IX	X	IV-X
Favorable thermal and pluvial conditions	33	50	47	50	63	43	33	46

Insufficient precipitation	7	23	10	13	7	27	20	15
Excessive precipitation	7	-	3	17	23	27	37	16
Too low temperatures and excessive precipitation	20	13	13	17	7	3	7	12
Too low temperatures and insufficient precipitation	7	7	10	-	-	-	-	3
Too high temperatures and insufficient precipitation	6	-	7	3	-	-	3	3

Table 2. *The frequency of occurrence of favorable and unfavorable pluvio-thermal conditions for the vegetation of key crops in southeastern Poland in the period 1931-1960 (%)*

Meteorological conditions of vegetation	Month							
	IV	V	VI	VII	VIII	IX	X	IV-X
Favorable thermal and pluvial conditions	53	37	74	60	44	64	40	53
Too low temperature	10	3	-	-	-	-	-	2
Insufficient precipitation	7	17	17	23	30	23	23	20
Excessive precipitation	-	-	3	10	23	7	37	12
Too low temperatures and excessive precipitation	17	17	3	-	3	3	-	6
Too low temperatures and insufficient precipitation	3	10	3	-	-	-	-	2
Too high temperatures and insufficient precipitation	10	16	-	7	-	3	-	5

The period 1961-1990 with a mean temperature of 13.0ºC is ranked between the first and second period. The precipitation total during the 1961-1990 period was 509 mm and was only 13 mm higher than during the previous period and 23 mm lower than during the 1901-1930 period. It should be noted, that the 1971-1980 decade was quite cold and wet. The meteorological conditions of vegetation deteriorated slightly compared with the previous 30-year period. Favorable meteorological conditions were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_839848

observed during 50% of the time from April to October. In general, the frequency of occurrence of unfavorable conditions during the 1961-1990 period was intermediate compared to the cold and wet 1901-1930 period, and, the warm and dryer 1931-1960 period. Only the frequency of occurrence of cold months was similar to the 1901-1930 period. Specifically, April was not as cool as during the 1901-1930 period, whilst the frequency of very cold temperatures was observed from April until July. One of the features of this period is the lowest occurrence of very dry and extremely hot months compared to individual decades in the years 1901-1960 (*Tables 1-3*).

Table 3. *The frequency of occurrence of favorable and unfavorable pluvio-thermal conditions for the vegetation of key crops in southeastern Poland in the period 1961-1990 (%)*

Meteorological conditions of vegetation	Month							
	IV	V	VI	VII	VIII	IX	X	IV-X
Favorable thermal and pluvial conditions	38	53	54	56	57	50	43	50
Too low temperature	13	7	7	7	-	-	-	5

Too low temperatures and excessive precipitation	13	17	20	17	3	-	-	10
Too low temperatures and insufficient precipitation	10	7	3	-	3	-	-	3
Too high temperatures and insufficient precipitation	3	-	3	-	-	-	-	1

As noted at the beginning of this article, after 1961-1990, climate normals are changed every 10 years so they include for example periods: 1971-2000 and 1981-2010. The climate normal 1971-2000 should be omitted since it includes 20 years that overlap with each of the two above-mentioned periods. On the other hand, we should thoroughly analyze the recent 1981-2010 normal, since the last three decades were marked by an increasing warming occurring worldwide. In this particular period, the vegetation period temperature mean was highest 13.7°C, whilst precipitation totals were identical as in the 1961-1990 period (509 mm). A further improvement of meteorological conditions was observed during the vegetation period, and this fact was confirmed by a 57% monthly increase in favorable conditions. This of course is the highest frequency among all the analyzed 30-year periods. On the other hand, the frequency of cold months decreased, especially in April and May. The frequency of occurrence of relatively dry months increased, especially in the case of dry months combined with extremely high temperatures. It should be emphasized, that the frequency of dry months with very high temperatures increased dramatically. During the previous 30-year periods, such months occurred sporadically, whilst in the 1981-2010 period they occurred in every month of the vegetation period. They occurred with most intensity during the summer months (10% frequency, *Table 4*).

A very interesting aspect can be seen when we examine the evolution of meteorological conditions of vegetation in the period 1981-2010. As a rule, the closer we get to the end of the vegetation period, the more it turns out that the frequency of favorable meteorological conditions gradually decreases in the subsequent 30-year periods (57, 55, 53%, respectively). This is caused by the increasing frequency of dry periods, especially ones that are due to the increasing number of dry periods and, especially, to the occurrence of extreme temperature events (*Table 5*).

Table 5. *A comparison of the frequency of occurrence of favorable and unfavorable pluvio-thermal conditions during the vegetation of key crops in southeastern Poland in the periods: 1981-2010, 1991-2010 and 2001-2010 (%)*

Meteorological conditions of vegetation	Period		
	1981-2010	1991-2010	2001-2010
Favorable thermal and pluvial conditions	57	55	53
Too low temperature	3	2	1
Insufficient precipitation	16	14	14
Excessive precipitation	13	17	19
Too low temperatures and excessive precipitation	4	3	-
Too low temperatures and insufficient precipitation	1	-	-
Too high temperatures and insufficient precipitation	6	9	13

The comparison of the frequency of occurrence of favorable and unfavorable pluvio-thermal conditions of vegetation of key crops in the period 1901-1980 (before rapid warming) and 1981-2010 (rapid warming phase), indicates that the frequency varies at the significance level $\alpha = 0{,}1\%$ in the months April, May and July and at the significance level 1% in August. In June and September, the differences are not statistically significant.

Discussion

The analysis of the frequency of occurrence of favorable pluvio-thermal conditions enables us to calculate mean optimal temperature values and precipitation totals for the relevant months, as well as to designate optimal value intervals. The difference between mean values of meteorological components and their optimal values constitutes both deficits and surpluses in terms of precipitation totals and temperature. The second problem that can be solved here, (in other words: the second methodological approach) is the calculation of the aforementioned deficits and surpluses by employing natural climate cycles (occurrence of dry-wet or warm-cool conditions). The idea behind such type of analysis can be explained by the example mentioned below.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_839848

During the post-war period a study was published, commissioned by the Main Spatial Planning Office, concerning the deficits and surpluses of atmospheric precipitation in individual Polish voivodeships (Hohendorf, 1948). The study period was 40 years long (1890-1930). Precipitation surpluses during the vegetation period in the former Rzeszów voivodeship equaled: for grains (103 mm), for beetroot (65 mm), for potatoes (93 mm), whilst for grassland there was a deficit equaled to 52 mm. If we assume an equal area for all of the aforementioned crops, this gives us an average surplus of 52 mm. Based on the analysis of data presented in the above-mentioned publication, the authors of this article suggest that the mean precipitation deficit for all studied crops in the period 1901-1941 (with optimal precipitation equal to 538 mm and 488 mm) could be estimated at about 50 mm. Therefore, this is the same order of magnitude as in Hohendorf's work, which, by the way, was conducted in a similar time period and in an area of about the same size.

If Hohendorf's research results had been used as indications for the planned irrigation projects, then the practical usage of this study comprised the post war years, which were marked by increasing levels of agrotechnics. In addition, this period was clearly marked by dry conditions (1941-1964). The precipitation total in the Rzeszów voivodeship equaled 455 mm, but the optimal precipitation increased due to the increasing temperature and the increasing level of agrotechnics (507 mm). As a result, the precipitation deficit during the vegetation period dropped to 52 mm. It should be noted, that during this period irrigation should have been employed instead of dehydration.

In this particular case, we are dealing with an adequate study assessment from a *post factum* perspective. This is due to the fact that a natural climate variability occurred after the study period, and we can expect possible consequences of these changes. Natural climate fluctuations also do not appear in elaborations that consist of data collected over long periods of time, as in the case of the aforementioned calendar of the meteorological conditions of key crops in southeastern Poland (Zawora, 1993). At present, when the anthropogenic factor of global warming is extensively mentioned in scientific studies, an assumption is made, that the analyses which pertain to present climate conditions need to be supplemented by basic climate forecasts (Górski, 2007; Górski and Kozyra, 2011).

There exist numerous scientific studies which present future visions of climate and selected causes of changes based on different climate change scenarios (IPCC, 2012, 2014a,b, 2018). The construction of such concepts is associated with a large degree of uncertainty, because each climate scenario is based on the fact that greenhouse gas emissions will increase depending on three factors: demographic development, implemented technology and assumed world economic development. At the same time, there is a large number of climate characteristics available, such as climate atlases that are based on past data, which are frequently out of date. This article attempts to eliminate such flaws, as well as present a description of contemporary agroclimate with reference to changes that have taken place since the beginnings of the twentieth century.

This study comprises simplifications, generalizations and shortcomings that can be supplemented in subsequent phases of this project. We can mention here such future suggestions as: the inclusion of the winter season, a variability analysis pertaining to yields of individual crop types (taking into account changing level of agrotechnics), the inclusion of meteorological conditions during field works, soil diversity, regional diversity of a given phenomenon. Conversely, a similar study or research could be carried out for individual physiographic regions or administrative units throughout Poland.

Conclusions

1. Large natural climate variability, periodicity and climatic fluctuations enable us to claim that 30-year climate normals are not always a relevant period for climate characteristics in terms of performed and projected climate irrigation projects as well as adaptation activities in terms of unfavorable meteorological conditions and future climate change. Better results are obtained when we include natural periods of temperature and precipitation variability.

2. Progressing global warming has generally improved meteorological conditions of vegetation of major crops. The frequency of occurrence of favorable months has increased from 46% (1901-1930) to 57% in 1981-2010. The amelioration of meteorological conditions is mainly due to a decrease in the frequency of cool months and cool and wet months in the beginning of the vegetation period.

3. The last 30-year period (1981-2010), which is simultaneously the new obligatory climate normal as well as a period with a clear increase in temperature (with lack of precipitation trend) is marked by a gradual decrease in favorable conditions for vegetation and a simultaneous increase in unfavorable conditions caused by the increased frequency of excessive precipitation and dry periods (caused mainly by occurrence of extremely high temperatures).

(Received 10th Jul 2019; accepted 11th Dec 2019)

Abstract. The experiment was conducted to investigate the effect of priming treatments on the physiological parameters of naturally aged onion (*Allium cepa* L.) seed, six seed priming treatments viz., Control, Hydro priming followed by dry dressing with Thiram (2 g/kg), Hydration with GA_3 (50 ppm), Hydration with KNO_3 (0.5% solution), Hydration with KH_2PO_4 (0.5% solution), and Biofertilizer (*Azotobacter*) were analyzed to identify the most suitable priming treatment. The standard seed germination, seedling length, seedling dry weight, seed vigour index-I & II and viability test (Tz test), decreased significantly, while electrical conductivity increased with the advancement of the ageing period. The field parameters viz., seedling emergence index and seedling establishment also decreased significantly with the natural ageing of seeds. The seed quality improvement through seed priming was noticed more in marginal seed lot, i.e., one-year-old seed lot. Among various priming treatments, hydration with GA3 @ 50 PPM followed by biofertilizer, (*Azotobacter*) performed best in enhancing all seed vigour and viability characteristics and lowering the electrical conductivity of naturally aged onion seeds. In conclusion, the present study revealed that onion seed loses its viability rapidly under ambient storage conditions. Therefore, seed priming with GA_3 @ 50 ppm and biofertilizer, (*Azotobacter*) can be used effectively to enhance its vigour and viability. These priming treatments can aid to improve the quality of seed stored for one year, thus ensuring good plant stands from the stored seed of a poor storer crop.
Keywords: *onion, GA_3, Azotobacter, germination, viability, seedling emergence index*

Introduction

Onion (*Allium cepa* L.) is a bulb crop of worldwide importance. India ranks first in the cultivated area with 1.31 million ha but ranks second in terms of total production (22.42 million tons) after China (FAO, 2017). Most crucial input for improving the yield is the use of good quality seeds. However, onion seeds exhibit some poor attributes like inferior longevity and storability, which ultimately result in rapid loss of viability (Khan et al., 2004). Furthermore, low-quality seeds result in low and asynchronous germination and high numbers of abnormal seedlings under stress conditions in early spring planting (Borowski and Michalek, 2006). Ultimately, quality of onion seed is dependent on several factors, some of which are surrounding environment during plant growth and seed development, location of seeds on plant, time of seed harvest, seed harvesting techniques, storage conditions and seed treatment before sowing. In the case of onions, where seed size is small, and seed establishment is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_849862

poor, seed priming is the most promising method to improve seed establishment. Seed priming is a pre-sowing, controlled hydration treatment where physiological and biochemical activities are stimulated in the seed, but radicle protrusion is prevented (Khan, 1992). Bosland and Votara (2000) were of the view that priming leads to enhanced and uniform germination. Moreover, primed onion and leek seeds maintained viability after one year when stored at 10 °C (Drew et al., 1997). Similar results have been reported in the case of tomato, asparagus and canola (Argerich et al., 1989; Owen and Pill, 1994; Basra et al., 2003). Many researchers have studied effect of seed priming on enhancement of germination, morphological characters, yield, etc. (Thejeshwini et al., 2019; Muruli et al., 2016; Saranya, 2017; Patil and Manjare, 2013; Arin et al., 2011; Selvarani and Umarani, 2011; Nego et al., 2015).

Seed priming (pre-sowing hydration treatments of seeds) is widely used for enabling better crop establishment (Taylor et al., 1998). Priming is a process in which seeds are imbibed in either water or osmotic solution or a combination of solid matrix carrier and water in specific proportions followed by drying before radicle emergence. In several studies, an increase in the nuclear DNA contents of radicle meristem cells from the G1 to the S or G2 phases of the cell cycle was noticed. The recorded effects of priming treatments on the storability of seeds are contradictory. The advancement of the germination process during priming continuously consumes stored substances and consequently may shorten seed longevity. However, the repair of DNA damage will increase longevity (Osborne, 1983). The results obtained so far are few, limited, contrasting because of the variability of the response to treatments of cultivars and even seed lots (Bradford, 1986) which require a careful choice of the compounds to proper standardization of the seed priming method and methodology for individual crops is the most critical determinant of success of the seed priming treatment.

In storage, the viability and vigour of the seeds not only vary from genera to genera and variety to variety, but is also regulated by many physicochemical factors like moisture content, atmospheric relative humidity, temperature, initial seed quality, physical and chemical composition of seed, gaseous exchange, storage structure, packaging materials etc. (Doijode, 1988). It will be of immense use to seed industry and farming community that how best the seeds can be stored by treating the seeds with chemicals and inert matter at relatively low cost under ambient storage and refrigerated conditions, with minimum quantitative and qualitative losses. As the quality, seed plays an important role in obtaining higher returns, as it is expected to perform well under any given environmental conditions.

Keeping in view the above facts, the present study was conducted with the objective of determining the most appropriate seed priming treatment and its physiological effects in differentially aged onion seeds.

Materials and methods

Experimental layout

The freshly harvested seed of three onion cultivars viz., Hisar-2 (V1), Hisar Onion-3 (V2) and Hisar Onion-4 (V3) were brought to the laboratory and stored in cloth bags under room temperature conditions (27 ± 1 °C, relative humidity (RH) 54 ± 3%) with seed moisture 7-8%. The seed lots of each of the three varieties were stored under ambient conditions in the laboratory of Seed Science and Technology, Haryana Agricultural University), Hisar, India This seed was used for further studies according

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_849862

to different years of natural seed ageing. These varieties were selected based on their extensive cultivation and popularity among Haryana farmers. Details of the experimental material are provided in *Table 1*.

Table 1. *Differentially aged seedlot during the two years of study*

Year of study	Lots	Year of production	Age of seed lot/seed age
2013	A	2013	Fresh
	B	2012	1 years old
	C	2011	2 years old
2014	A	2014	Fresh
	B	2013	1 year old
	C	2012	2 years old
	D	2011	3 years old

Treatments

Six seed priming treatments were compared with untreated control. The treatments are detailed in *Table 2*.

Table 2. *Details of priming treatments under study*

Hydro-priming followed by dry dressing with Thiram (2 g/kg)	Hydration with distilled water and followed by dry dressing of seeds by thiram fungicides (2 g/kg seed)
Hydration with GA_3 (50 ppm)	50 mg of gibberellic acid (GA_3) was dissolved in 2 L of water to make solution of concentration of 50 ppm. One to three drops of acetone were also added as GA_3 cannot dissolve in distilled water
Hydration with KNO_3 (0.5% solution)	5 g of potassium nitrate ($KN0_3$) was dissolved in 1 L of distilled water
Hydration with KH_2PO_4 (0.5% solution)	5 g of potassium dihydrogen phosphate (KH_2PO_4) was dissolved in 1 L of distilled water
Biofertilizer (*Azotobacter*)	Seeds were first treated with 2% jaggary solution and then with *Azotobacter* strain HT-57. The strain was taken from the biofertilizers unit of CCS HAU, Hisar

The seed of each lot was soaked in a sufficient amount of solution for 16 h in each treatment. Then the seed was dried in the shade at 20 °C to attain the initial seed weight to maintain original or near to safe moisture content.

Observations

Germination and seed viability determination

Germination assays were determined according to the procedure described by International rules for seed testing (ISTA, 2015) by placing seeds in Petri plates for germination at 20-22 °C and 90 ± 2% RH (100 sterilized seeds per Petri plate in four replicates) in a germination chamber. Germination (%) was scored at radicle growth of 2 mm, or more and counting of normal and abnormal seedlings was started on the 5th day

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_849862

and continued up to the 20th day (final count) followed by calculation of germination percentage. After the germination test, seedling length, dry seedling weight and seed vigour index were measured and calculated as per the standard procedure. Seedling length (cm) was measured from 20 randomly selected healthy seedlings at the time of final count of germination. These selected seedlings were then kept in a hot air oven at 60 °C for 48 h for the recording of seedling dry weight (mg). Based on the seed germination, seedling length and seedling dry weight data, seed vigour index-I (SV-I) and seed vigour index-II (SVI-II) were calculated (Abdul Baki and Anderson, 1972). To evaluate the viability, 25 seeds were soaked in 50 ml water and kept in the incubator at 30 ± 1 °C (in three replicates) for 24 h. After incubation, seeds were cut longitudinally and maintained in 1% staining solution of 2,3,5-triphenyl tetrazolium chloride (TTC) for 4 h at 38 ± 1 °C under dark conditions (Moore, 1973). During the staining period, only viable part of the seed is converted into red colour due to the formation of triphenyl formazon from TTC solution.

Electrical conductivity test (EC)

The electrical conductivity of seed leachates was measured for seeds of different age. Fifty seeds were soaked in 75 ml deionised water and incubated at 25 °C for 24 h. Seed leachates were collected, and conductivity (dS/cm/seed) was recorded by using digital conductivity meter (Model 304, Systronics, Ahmedabad, India) along with deionised water as a control (Dadlani and Aggarwal, 1987).

Field parameters

Seedling emergence index (SEI)

The number of seedlings emerged under field conditions were counted daily from 1st day to 20th day, and the seedling emergence index was calculated as described by (Maguire, 1962).

$$\text{SEI} = \frac{\text{No. of seedlings emerged on the first day}}{\text{Day of the first count (1st)}} + \cdots + \frac{\text{No. of seedlings emerged on last day}}{\text{Day of the last count (20th)}}$$

Seedling establishment (%)

Seedling establishment was estimated under field conditions by including the total number of seedlings after emergence or when there was no further addition to the total emergence.

Statistical analyses

The statistical analysis was carried out for each observed character under the study using MS-Excel and SPSS Statistics 20. The means of the treatments were compared using Duncan's Multiple Range Test (DMRT). Besides, the linear regressions were determined with the help of data analysis tool pack in MS Excel.

Experimental results

Results of the study showed that the effect of priming, seed age and their interaction were significant at $p < 0.05$ for all the seed quality parameters studied. Therefore, the seed lots of different ages were analysed separately for all the parameters. The

laboratory parameters study was laid in completely randomized design CRD (*Table 3*), and field parameters were laid in randomized block design RBD (*Table 4*). During the second year of study, an additional seed lot of three-year-old seed was also studied.

Seed priming has significant influence ($p < 0.05$) on the different traits of onion seed. Among the different seed priming treatments, hydration with GA_3 (50 ppm) was most effective in enhancing different traits followed by treatment with biofertilizer *Azotobacter*. Other treatments in declining order of seed quality are, hydro priming followed by dry dressing with Thiram (2 g/kg), hydration with KH_2PO_4 (0.5%) and hydration with KNO_3 (0.5%). Priming of seeds with various treatments was found competent to improve the quality in fresh and marginal seed lots. Out of the differentially aged seed lots, fresh seed performed the best, and the seed quality tends to decline with the ageing of the seed. Fresh seed lot was characterized by a high number of germinating seeds, exceeding 80% even in unprimed seed (*Table 5*). GA_3 emerged as the most effective priming treatment as it registered 11.23% increase in germination over control. After a year of storage, germination under different priming treatments dropped by 12.45 (*Azotobacter*), 13.11 (GA_3), 17.55 (Thiram), 20.1 (KH_2PO_4) and 20.45% (KNO_3), while unprimed seed recorded a reduction of 21.45%. A decline in germination in all the treatments was above 40% after three years of storage when compared with germination after two years of storage. The decrease in germination after three years of storage was below 10%. A similar trend was observed in the case of seed viability, where there was a steep decline after one year of storage (*Table 5*).

Seed priming with GA_3 in fresh seed was the best combination followed by priming with Thiram. More than 70.71% GA_3 primed seed was viable in the one-year-old seed lot. Viability of seed was below 25% in the primed and non-primed seed of two and three-year-old seed lot. A gradual decline in seedling length (cm) and seedling dry weight (mg) was observed in all the priming treatments with the progression of storage period (*Table 6*). In all of the aged seed lots, priming with GA_3 improved both seedling characteristics over other priming treatments in differentially aged seed lots. Seed vigour index- I (SVI-I) was highest in GA_3 primed seed in case of fresh, one year old and three-year-old seed lots (*Table 7*). While SVI-I was highest in Thiram primed seed that has been stored for two years.

On the other hand, seed vigour index- II (SVI-II) was highest in *Azotobacter* primed two-year-old seed (*Table 7*). GA_3 priming recorded highest SVI-II in other aged seed lots. Electrical conductivity (EC) of GA_3 primed seed was lowest among the all priming treatments in the four seed lots studied (*Table 8*). This was followed by priming treatments of *Azotobacter* and Thiram, while the oldest aged seed had the highest EC values. The field parameters, i.e., seedling emergence index (SEI) and seedling establishment (SE) were also high in the fresh and one-year-old seed lot and followed a

Based on the effectiveness for enhancement of germination, vigour and storage potential, the best priming treatment is GA_3 @ 50 ppm followed by Biofertilizer *Aztobacter*. While the least effective treatment was KNO_3. Priming of the seeds with various treatments was found competent to improve the seed quality in fresh as well as marginal (one-year-old) and sub-marginal (two-year-old) seed age. No doubt performance of fresh seed was found better over all the other lots but, the improvement was comparatively more in marginal seed age, i.e., one-year-old seed lot (Lot1) because in this lot seed germination achieved up to 70% as per Indian minimum seed certification standards (IMSCS) standards.

Linear regression analysis revealed that germination and SE exhibited significant positive relationship ($p < 0.05$) in one-year-old seed lot, where germination explained 81% variation in SE (*Fig. 1*). Successful SE depends on several factors and ability of seeds to germinate is one of them. Present studies reveal that higher germination capacity under laboratory conditions is quite apparent through better establishment of seedlings under field conditions. These two parameters had a high positive correlation ($r = 0.90$), which indicates that priming in the one-year-old seed can result in good performance in field conditions. Similarly, both the vigour indices, i.e., SVI-I ($p < 0.01$) and SVI-II ($p < 0.05$) also had a positive association with SEI in one-year-old seed lot. SVI-I and SVI-II explained 89 and 73% variation in SEI, respectively (*Fig. 2*). Correlation of SVI-I and SVI-II with SEI had high positive values of 0.94 and 0.85, respectively. Vigour indices are based on germination, seedling length and seedling dry weight, and high values of these indices indicate fast-growing seedlings with good quality characteristics which are ultimately reflected in SEI. Fast-growing and healthy seedlings (which are a basis for vigour indices) lead to the higher values of SEI. Overall, it could be said that priming of onion seed stored for one year has good performance under heterogeneous field conditions leading to a good plant stand.

Discussion

Seed priming was identified to improve the germination and seedling establishment in some of the critical field crops like soybean, wheat, maize, sunflower and sugarbeet (Singh, 1995; Khajeh-Hosseini et al., 2003; Sdeghian and Yavari, 2004). The improved performance and quality of seed after is due to several processes like DNA repair, activation of enzymes and endosperm weakening in primed seeds (Osborne, 1983; Dell'Aquilla et al., 1998; Moosavi et al., 2009). Also, priming enhances antioxidant activity in the seeds, which results in reduced lipid peroxidation, improves seed quality (Hsu et al., 2003; Chiu et al., 2006). Davison and Bray (1991) have observed some changes in the protein pattern in the primed seeds. Vigorous crops grown from primed seeds were able to capture more nitrogen than plants grown from non-primed seeds, thus utilising nitrogen before leaching or volatilization losses (Byrum and Copland, 1995). Ramadevi and Gopalkrishan (2001) are of the view that enhanced hydration of all seed parts leading to reduced damage to the embryonic axis could be the reason behind the increased speed of emergence and seedling establishment. Toxic effect of potassium salts on the germinating seeds is the reason behind KNO_3 being the least effective treatment. Toxic effect of KCL has been reported by some workers where it has a negative effect on germinating embryos which leads to a reduction in germination and seedling death (Giri and Schillinger, 2003; Yari et al., 2011).

Gibberellic Acid (GA_3) is an essential growth regulator, which aids in breaking seed dormancy, promoting germination, internodal length, growth of hypocotyl and cell division in the cambial zone and enlargement of leaf size. GA_3 degrades cells surrounding the radicle by stimulating hydrolytic enzymes, which ultimately speeds germination (Rood et al., 1990). GA_3 also plays a vital role in the mobilization of endosperm reserves during germination of seeds (Weiss and Ori, 2007). During the germination process, GA_3 is released from an embryo, which activates genes responsible for alpha-amylase mRNA transcription (Taiz and Zeiger, 1991). Exogenous application of GA_3 might lead to activation of such genes in seeds, thus improving germination. Increased vigour characteristics elevated peroxide scavenging enzymes activities and decline in lipid peroxidation some of the possible reasons behind enhanced seed germination. Higher metabolic activity in primed seeds causes efficient food mobilization during early hours of germination, which leads to increased shoot and root lengths (Brar et al., 2019).

Consequently, it results in higher seedling dry weight (Bailly et al., 2002; Jett et al., 1996). Priming of fresh and aged onion seed with GA_3 (50 ppm) resulted in favourbale impact on the germination ability and seed vigour. Also the aged seed was more responsive to priming as compared to the fresh seed (Muruli et al., 2016). Yarnia et al. (2012) determined the effect of hormonal treatments i.e., IAA, GA_3 and kinetin on germination and seedling growth of onion. Of these priming treatments GA_3 and IAA led to improved attributes such as germination, seedling length, root length, seedling dry weight etc. Helaly et al. (2016) also reported highest germination, seed yield and weight of thousand seeds in GA_3 (1000 ppm) primed onion seeds. In case of shallots also GA_3 priming significantly enhances the germination, speed of germination, seedling vigour and rate of seedling emergence (Agung and Diara, 2017).

GA_3 priming was followed by bio-priming with *Azotobacter,* which is known to promote plant growth through indole-3-acetic acid (IAA) production and nitrogen fixation (Hafeez et al., 2004). *Azotobacter* inoculations are known to produce GA_3, IAA and cytokinins (Barea and Brown, 1974), which enhances seedling development and plant growth (Brown, 1982). Bacteria produce plant growth regulators which alter morphology and metabolism of the plant, yields more extended root systems and improves absorption of water and minerals (Bashan et al., 2004; Lai et al., 2008; Fibach-Paldi et al., 2012). *Azotobacter* enhances germination in rice and cotton by the synthesis of growth promoters and antifungal antibiotic production, which ensure seed safety during germination (Shende et al., 1977). Inoculation with *Azotobacter* increases shoot, and root length in maize and sorghum and pre-soaking of seed improves germination and seedling establishment (Ahmed et al., 1998). Bio-agents are also more effective as compared to synthetic chemicals as they improve seed quality characteristics while providing tolerance to other toxic agents. Brar et al. (2015) reported improved seed quality characteristics in tomato with the supply of biofertilizers like *Azotobacter*. Treatment with biofertilizers also enhanced the seed yield and improved the fertility status of the soil by nitrogen fixation.

Lower EC for primed seed may be due to improved plasma membrane structure as a result of slow hydration in the priming treatments (McDonald, 1980). Kumar (2004) reported that onion seeds treated with GA_3 recorded the maximum decline in seed leachates in comparison to control. Improvement of germination at high levels of ageing was not achieved through priming as the irreversible damage could not be repaired (Butler et al., 2009). During the programmed cell death (PCD), catalase rate and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_849862

sensitivity reduce, which indicates that the ageing causes PCD and subsequent the reduction of seed viability.

Conclusion

It is concluded that the standard germination, vigour indices and EC tests could be used as reliable predictors of seed quality because of easiness, quickness and accuracy in their execution. Further, various seed priming treatments can be used for enhancing seed quality of marginal seed lot. GA_3 (50 ppm) was found to be best priming treatment for improving the seed quality followed by biofertilizer (*Azotobacter*), hydro priming and dry dressing with Thiram (2 g/kg), KH 2 PO 4 (0.5%) and KNO 3 (0.5%), respectively. Overall, the priming technology was found useful and beneficial for enhancing the physiological, biochemical and storage potential of onion seed**.** Indeed, in the case of these onion varieties, we recommend the priming treatment for getting a bumper harvest.

Abstract. Trend analysis of streamflow and its linkages to rainfall can facilitate the development of water resource management plans for watersheds. The present study focuses on trends in observed streamflow of the lower Tamiraparani river sub-basin in Tamilnadu, India using Mann – Kendall test and Sen's slope estimator for a period of 30 years. From this analysis, both the annual streamflow, annual rainfall increased very marginally at the rate of 0.1799 m^3/s/year and 4.3741 mm/year, respectively. Similarly, in the northeast monsoon period, both the rainfall and streamflow were increased very minimally during the analysis period. However, the observations made during the southwest monsoon showed declining trends for most of the rainfall stations and no significant trend was observed for streamflow. The calculated Spearman's Rho correlation factor (ρ) between rainfall and streamflow showed weak correlation during summer (0.26) and very strong correlation during northeast monsoon (0.83), strong correlation during southwest monsoon (0.53) and moderate correlation during winter (0.40). From this analysis, using Mann – Kendal test and Spearman's correlation it implies that other than precipitation and temperature, urbanization, watershed and ecological development of the catchment area could have also influenced the trends of streamflow.
Keywords: *climate variables, climate change, hydrological environment, Mann – Kendal, Sen's slope*

Introduction

Water is a vital element for both natural and artificial environments and it is provided by the rivers of the country offering life generating fuel to ecology (Islam and Sikder, 2012). Rainfall serves as one among the major sources of flow in the rivers while others include melting of glaciers, base flow from groundwater, return flow from agricultural areas etc. (Raghunath, 2006). Streamflow assessment plays a vital role in guiding the decision makers for better planning and providing accurate information towards the future research. Due to the climate change and anthropogenic activities, most rivers are altering their streamflows on a global scale and present rivers are under severe threats (Gautam and Acharya, 2012). So, it is vital to analyse the changing phenomenon of various climatic variables mainly rainfall and temperature. The work by Jayadas and Ambujam (2019) studied the trend patterns of rainfall in lower Vellar sub-basin in Tamil Nadu which indicated that there has been an early onset of monsoon in the last three decades. Jain and Kumar (2012) reviewed about the trend analysis of rainfall and temperature of many studies and explained about the estimation procedure of trend analysis and magnitude of trend by Mann – Kendal and Sen's slope estimator.

Mann – Kendal test is one of the best methods for rainfall and temperature trend analysis to study the impacts of climate change and Mann – Kendal test can be used as the best water management tool for proper watershed protection (Nouri, 2017). Palaniswami and Muthiah (2018) analysed the trends in annual, seasonal maximum and minimum temperature in the Vellar river basin in Tamilnadu and found out that there is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_863878

a significantly increasing trend in the basin. Punyawardena and Premalal (2013) using the Mann – Kendal test in central Sri Lanka observed that there was increasing trend patterns in the very heavy rainfall data series. Chakraborty et al. (2013) observed there was decreasing trends in both annual and seasonal rainfall in the Seonath river basin and they estimated the decreased rainfall as -13.8mm/year for Bodala river basin and 0.1 mm/year in sigma station using Sen's slope estimator test. Chand et al. (2019) analysed the temperature trends in the river basin in Nepal and they observed that there were the highest warming trends in the summer season followed by winter, pre monsoon and post monsoon. It is well understood that globally there is an increasing pattern of trends in temperature and decreasing patterns in rainfall. In addition to this, the work done by Panda et al. (2013) on streamflow trends in the Mahanadi river basin, India, estimated that there was a declining rate of 3388 x 106/decade in the river which suggested the possible environmental measures for the protection of the river basin. Various research works (Yadav et al., 2014; Ahmad et al., 2015; Javari, 2017; John and Brema, 2018) highlighted the importance of Mann – Kendal and Sen's slope estimator to detect the trend and Magnitude of trends and outlined the effectiveness of the statistical tests in finding out the trend of rainfall, temperature and streamflow in several areas worldwide. Hydro-climatic conditions assessment at a larger regional scale may lead to the loss of the spatial information of the particular variable. Therefore, it is logical to analyse hydro climatic variables at a small scale rather than at larger scale. So the objective of the study is framed to analyse the trend patterns in the measured stream flow and rainfall at the sub-basin level. Also, to investigate the correlation of upstream catchment rainfall over the streamflow of the lower Tamiraparani sub-basin which is one among the sub-basins of perennial Tamiraparani River basin in India.

Materials and Methods

Study area

The lower Tamiraparani sub-basin is one among the seven sub-basins of Tamiraparani river basin in Tamilnadu, India as shown in *Fig. 1*. The lower Tamiraparani sub-basin lies between geographic coordinates N. lat 8º26'53.14" to 9º12'00" and E. long 77º29'19.91" to 78º07'52.31". The entire sub-basin covers an area of about 1891.64 km^2. Tamiraparani River originates from Agastya malai on the Western Ghats of India, at an altitude of about 2000 m. River Tamiraparani has a number of tributaries named Servalar, Manimuttar, Gadananadhi, Pachaiyar and Chittar. The river flows towards north east initially and towards east in the middle and at the end it confluences with Bay of Bengal near Palaya Kayal as shown in *Fig. 2*. All the sub-basins along with Lower Tamiraparani basin lies within the tropical monsoon zone. Among all the basins, lower Tamiraparani sub-basin has the highest concentration of population, about 45 percent of the entire basin population lives here. It covers almost 37 percent of the total command area of the entire basin (Report on Micro level Reappraisal study of Tamiraparani River basin, 2015). Based on the hydro meteorological features of the basin, the entire year is divided into two periods 1) Monsoon period from June to December and 2) Non-monsoon period spanning from January to May. The monsoon period of the sub-basin is further sub-divided into southwest monsoon period from June to September and northeast monsoon period from October to December. Similarly, the non-monsoon period is further sub-divided into winter period from January and February and summer period from March to May. For

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_863878

the rainfall trend analysis, Point rainfall from rain gauges maintained by PWD were used. There are totally 16 rain gauge stations available, out of these 13 rain gauge stations located upstream to the stream gauge station were considered for the analysis. As these stations influence the streamflow measured in the lower Tamiraparani sub-basin, the rainfall data from these stations were considered based on availability and reliability as shown in *Fig. 2*. As per the PWD appraisal report, the maximum annual rainfall is 1237.2 mm and the minimum annual rainfall is 236.30 mm in the study area. There is a gauge station named Murappanadu in the lower Tamiraparani sub-basin to measure the streamflow variations in the river. In the entire river basin, there are a total of two weather stations to measure temperature, relative humidity, wind speed and solar radiation.

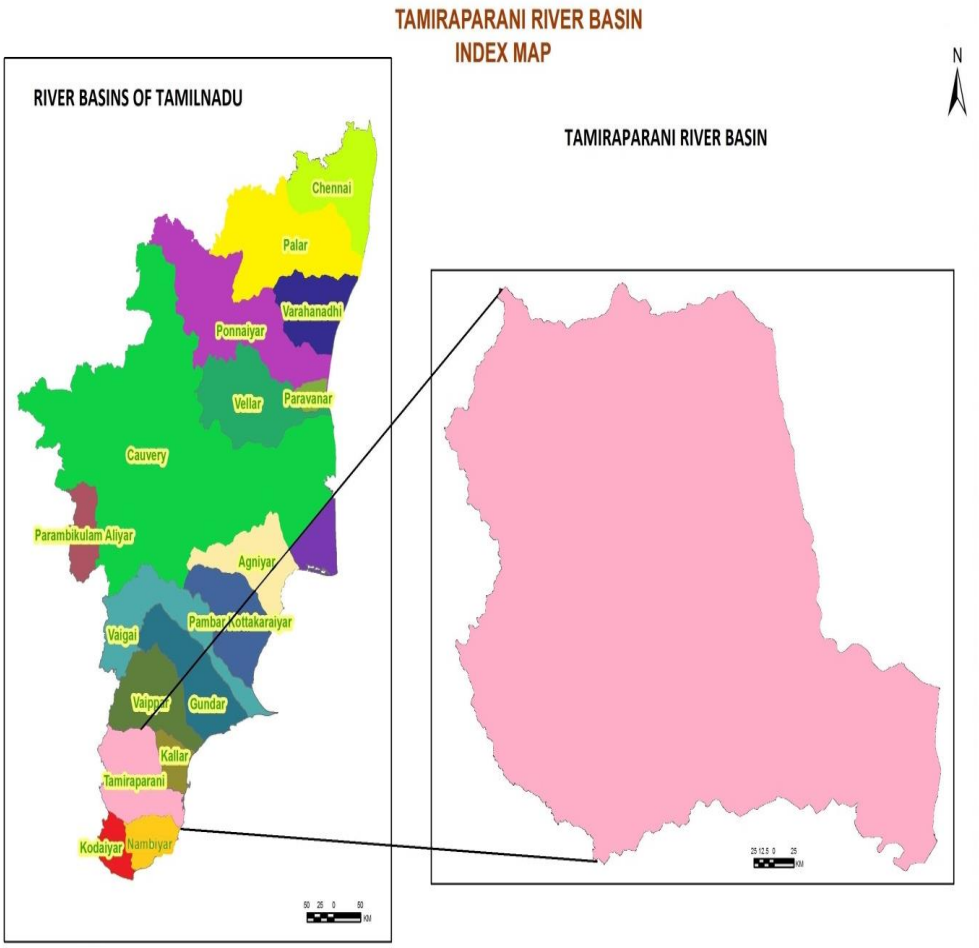

Figure 1. *Index Map of Tamiraparani River basin*

Data set

Streamflow data of the river were collected from the gauging station named Murappanadu as shown in *Fig. 2*, which is maintained by the Central Water Commission, Government of India. This is the nodal department in India to observe, calculate, quality check and archive all the hydrologic data of the river. All the meteorological parameters such as rainfall, wind speed and humidity and solar radiation were collected from the Institute of Water Studies, Public Works Department, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_863878

Tamil Nadu. Due to the insufficient availability of the observed temperature data, the temperature data was extracted from the gridded data collected from the Indian Meteorological department at the resolution of 1°*1°. The duration of the data sample collected was from 01-Jan-1985 to 31-Dec-2015. For the proper assessment of all climate change observations and to compare the spatial distribution of trend of streamflow and rainfall, it is normally necessary to have the sample duration of a minimum of 30 years of data. For the study, lower Tamiraparani river sub-basin is delineated using 30 m resolution ASTER data in ArcGIS 10.3. The total area of the sub-basin is estimated to be 1891.64 km^2. For the rainfall trend analysis, annual and seasonal rainfall from all influencing rain gauge stations contributing the streamflow in the study area from upper and middle reaches considered for the study as depicted in *Fig. 2*. The location details and period of data records of influencing and non-influencing rain gauges considered are given in *Table 1*.

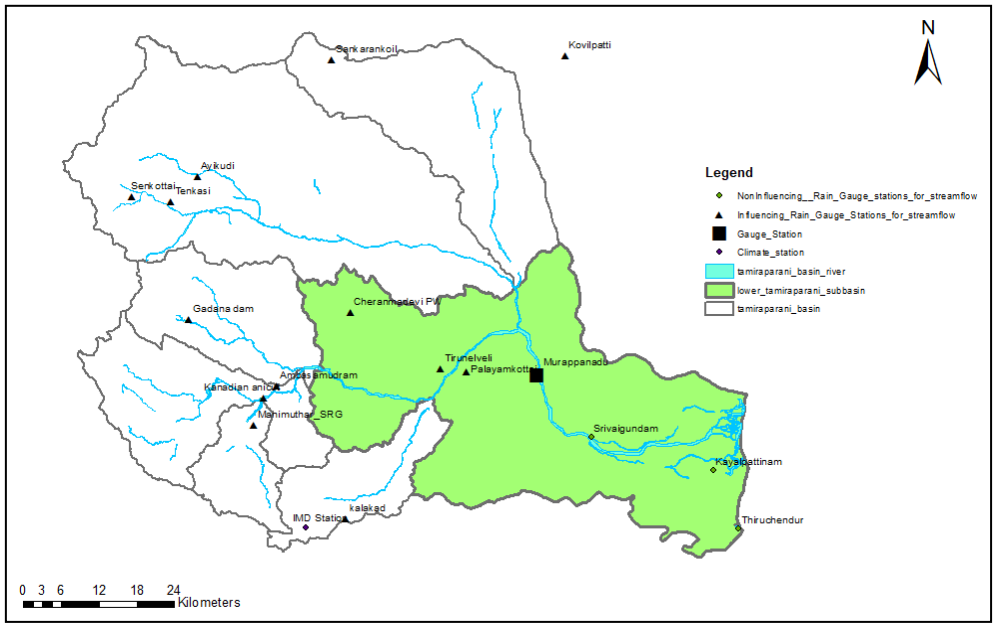

Figure 2. *Geographical distribution of major stream network, streamflow gauging station and the influencing and non-influencing Rain gauge stations for streamflow of gauging station of Lower Tamiraparani sub-basin*

Analysis of data

The following indicators were estimated and subjected to trend analysis.

- Inter - annual monthly mean streamflow which was calculated by estimating the monthly mean streamflow values for the same month of all the years.
- Annual mean streamflow which was estimated by taking the mean streamflow values for all the months of the gauging station.
- Seasonal mean streamflow, which was calculated by taking the mean of monthly streamflow values for summer, winter, northeast monsoon and southwest monsoon separately.
- Monthly maximum and minimum streamflows which were calculated by considering the maximum and minimum streamflow values recorded in a month for the gauging station.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_863878

- Monthly and annual rainfall for all the rain gauges at the upstream of gauging station.
- Weighted annual, seasonal and monthly average rainfall for the rain gauges at upstream of the gauging station.
- Annual and seasonal maximum and minimum mean temperature for the weather station.

Theissen polygon method is one of the normally used methods in computing average rainfall for all hydrological studies. Through this theissen polygon method in the ArcGIS environment, the weights of each rain gauge stations were calculated with respect to the entire basin area and the annual and seasonal rainfall of the rain gauges which is at the upstream side of the gauge station was calculated.

Table 1. *Geographical Coordinates and period of data records of the Rain Gauge stations*

*Non-influencing rain gauge stations to the stream flow

Statistical analysis

While analyzing the trends in the data series, the monotonic trends of all the hydro – climatic data series was tested using non parametric Mann – Kendall test using XLSTAT program. Initially all the time series data of the study were tested for lag one autocorrelation. If the time series data did not show any auto correlation, then Mann – Kendall test was adopted for the trend analysis. If auto correlation was detected in the time series data then modified Mann – Kendall as suggested by Hamed-Rao using XLSTAT program should be used since Mann – Kendall test did not account for the serial auto correlation existing in the hydro –climatic series (Abeysingha et al., 2014). Then in order to compare the spatio-temporal variability between the rainfall and stream flow over the basin, the standardized anomaly was calculated for the time series data of both rainfall and streamflow. The standardized anomaly is calculated by subtracting the mean value of the data series from each observation and then divides the following with the standard deviation of the series.

Mann – Kendall test

Monotonic trend analysis for rainfall, temperature and streamflow have been effectively done with non-parametric Mann – Kendall test in the studies (Mondal et al., 2012; Sharif et al., 2013; Silva et al., 2015). Mann – Kendall test is a statistical method which is being used for studying the variations of spatial regions and temporal trends of hydro climatic series. Mann – Kendall test had been formulated by Mann (1945) as non-parametric test for trend detection and the test statistic distribution had been given by Kendall (1955) for testing non-linear trend and turning point. Mann – Kendall test is a two tailed test. The test statistics S is calculated by

$$S = \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} sgn(X_j - X_i), \quad \text{(Eq.1)}$$

$$sgn(X_j - X_i) \begin{cases} 1 \; if (X_j - X_i) > 0 \\ 0 \; if (X_j - X_i) = 0 \\ -1 \; if (X_j - X_i) < 0 \end{cases} \quad \text{(Eq.2)}$$

$$\sigma^2 = \frac{1}{18}\left[n(n-1)(2n+5) - \sum_{p}^{q} t_p(t_p - 1)(2t_p + 5)\right], \quad \text{(Eq.3)}$$

$$Z = \begin{cases} \frac{S-1}{\sigma} \; if \; S > 0, \\ 0 \quad if \; S = 0, \\ \frac{S+1}{\sigma} \; if \; S < 0. \end{cases} \quad \text{(Eq.4)}$$

In the above equations Xi and Xj are the time series observations, n is the length of time series, tp is the number of ties for pth value and q is the number of tied values. The test hypothesis for Mann – Kendall analysis of trend is as follows:

- H_o: There is no trend in the series.
- H_a: There is a trend in the series.

Positive Z values indicate an increasing trend in the hydrologic time series and negative Z values indicate a decreasing trend. The statistic Z has a normal distribution. For testing the increasing or decreasing trend at α level of significance Ho was rejected if $|Z|>Z(1-\alpha/2)$, where $Z(1-\alpha/2)$ was obtained from the standard normal cumulative distribution.

Sen's Slope estimator test

Many research studies (Jayawardene et al., 2015; Samo et al., 2017; Gedefaw et al., 2018) estimated the magnitude of changing trends of the meteorological parameters well using Sen's slope estimator test. This test calculates both the slope and intercept using Sen's method (Sen, 1968). Initially a set of linear slope is calculated using

$$T_i = \frac{X_j - X_k}{j - k} \; For \; i = 1,2,3 \ldots .N \quad \text{(Eq.5)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_863878

where, X_j and X_k are considered as data value at time j and k (j>k), respectively. The median of these N values of Ti is represented as Sen's estimator of slope which is given as:

$$Q_i = \begin{cases} \frac{T_{N+1}}{2} \; N \; is \; odd \\ \frac{1}{2}\left(\frac{T_N}{2} + \frac{T_{N+1}}{2}\right) \; N \; is \; even \end{cases} \quad \text{(Eq.6)}$$

Positive value of Q_i indicates upward or increasing trend and a negative value of Q_i represents a presence of downward or decreasing trend in the time series of the data. Using the median based non-parametric slope estimator method suggested by Theil-Sen method (Theil, 1950). The magnitude of the trend is calculated using *Equation 7*

$$\beta = median \frac{x_j - x_k}{j-k} \ldots \forall \ldots k < j \quad \text{(Eq.7)}$$

where X_j and X_k are the consecutive data values of series in year j and k, and β is the magnitude of the trend slope of data values.

Spearman's Rho correlation

Then non-parametric Spearman's Rho correlation coefficient (ρ) was used to test the relation between rainfall and streamflow. The Spearman's rank-order correlation is considered as the non-parametric method of the Pearson product-moment correlation. Spearman's Rho correlation coefficient, (ρ, also signified by *r*s) estimates the strength and path of connotation between two ranked variables. Normally the co-efficient of Spearman's Rho correlation is calculated to determine the dependency rate of dependent variable which is streamflow in the river to the independent variable rainfall.

Results and Discussions

Rainfall and stream flow behaviour of the lower Tamiraparani sub-basin

To study the overall behaviour of the stream flow and rainfall of the influencing rain gauges, mean monthly stream flow and rainfall, annual streamflow and annual rainfall for the basin was calculated for the period of 30 years. Through the analysis, it was observed that both the maximum streamflow and maximum rainfall were observed during the month of November for most of the years. This indicates that almost all the rainfall occurring during November contributes to the streamflow of the river. In the lower Tamiraparani sub-basin bimodal rainfall pattern was observed, similar pattern was also observed in the streamflow of the river. The observed anomaly between the catchment rainfall and streamflow is depicted in *Fig. 3*. Both the annual mean streamflow and theissen weighted catchment rainfall of the basin showed no significant trends at both 5% and 10% level of significance as depicted in *Table 2*. The calculated Spearman's Rho correlation coefficient between two parameters showed that annual stream flow and annual rainfall have a very strong positive correlation existing between each other. The work observed in the river basin of Sri Lanka suggested that positive correlation between the annual rainfall and streamflow implied that annual mean streamflow of the river is mainly contributed by the catchment rainfall (Abeysingha et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_863878

al., 2017). So in the lower Tamiraparani sub-basin the value of (ρ =0.72) implied that streamflow is mainly contributed by the annual catchment rainfall from all influencing rain gauges from upper reaches of the gauge station. The results are in well agreement with the study by Sharannya et al. (2018), which also observed that changes in annual streamflow is directly correlated to the changes in annual rainfall for past and present scenarios.

Trends in seasonal streamflow and seasonal rainfall

Monotonic trends in streamflow and rainfall for the observed four seasons were analysed for the sub-basin and the Sen's slope estimator for all the seasons was calculated and given in *Table 3 and 4*. The calculated Sen's slope estimator for all the influencing rain gauges for all the seasons depicted that almost more than 50% of the influencing rain gauges showed no significant trends as depicted in *Table 2*. Most of the major river basins in northern India showed decreasing trends in the streamflow due to the decreasing of trends in rainfall and due to the anthropogenic activities in the basin level (Jain et al., 2017). However, the sub-basin level analysis of the study of the lower Tamiraparani showed marginally increasing trends in streamflow for all the seasons. While for the calculated weighted average seasonal rainfall, both the winter and southwest monsoon periods showed minimally declining trends, which is only of about 0.7477 mm/year and 1.1091 mm/year as depicted in *Table 4*. The observed rainfall trends during the southwest monsoon and winter periods showed a decreasing trend in the last 30 years of the study area, which is well linked with the trend analysis in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_863878

other major Indian river basin (Sharma and Singh, 2019). The calculated Spearman's rho correlation coefficient (ρ = 0.53) between the rainfall and streamflow in the southwest monsoon showed well correlation and during winter (ρ = 0.40) showed moderate correlation between the parameters as depicted in *Table 5*. In spite of the declining trends in the rainfall, minimal increase in streamflow implies that streamflow in lower Tamiraparani basin is not fully influenced by the rainfall during the periods instead partially influenced by others like anthropogenic activities which includes agricultural return flow, release water from hydro-electric power plant and rainfall in the upper hilly areas.

These observations were following the same pattern in the study of trend assessment (Nune et al., 2013) between the rainfall and stream flow in Himayat Sagar catchment in southern India in which they observed a change in stream flow without significant change in rainfall, and then they endorsed the changes in stream flow trends to anthropogenic influences in the particular catchment. The observed trends for the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_863878

northeast monsoon for both streamflow and the rainfall showed minimal increase at a rate of 0.3337 m^3/sec and 3.6938 mm/year but very strong positive correlation exists between the rainfall and stream flow ($\rho = 0.82$) during that period. The variation of the stream flow during North East Monson in the catchment is mainly attributed to the rainfall as evident by the significant positive correlation. The similar increasing trend pattern in the northeast monsoon rainfall was also observed in Amaravathi river basin one of the main river basins in Tamilnadu (Sridhar et al., 2017).

The observed trends between rainfall and stream flow during summer periods showed no significant trends which is of about 1.1291 mm/year and 0.0976 m^3/sec and also there was weak correlation ($\rho = 0.26$) between the rainfall and stream flow which implies that influence of rainfall to the streamflow is very minimum during the summer periods. Vidhya and Arulkumar (2017) predicted that there will be increase in streamflow up to the period of 2040 due to climate changes and decrease in streamflow will be observed with the combined effects of streamflow and climate changes which is well correlated with the present study with observed increasing trends in streamflow with the act of climate change. Then the observed decrease in the summer monsoon rainfall implied the weakening of westerlies in lower troposphere and formation of easterly jet stream in the upper troposphere as mentioned in the study for the Indian region (Naidu et al., 2009). In order to compare the spatio-temporal variability of the seasonal rainfall and streamflow, standardized anomaly was calculated and given in *Fig. 4a-d* for all the seasons.

Trends in monthly mean streamflow

To study the monthly behaviour of streamflow in the river, trends using Mann – Kendall test and Sen's slope were analysed for inter-annual monthly mean streamflow values as depicted in *Table 6*. Inter-annual monthly mean streamflow showed significantly positive trends for some of the months as quoted in the work carried out in the Gomati river basin which is the perennial river in Northern India (Abeysingha et al., 2016). The trend patterns of Tamiraparani streamflow also followed the same significantly increasing trends at 5% and 10% level of significance for the months of February, March, May, September, November and December. The significantly increasing trends of the following months September, November and December showed the influence of northeast monsoon rainfall to the streamflow in the sub-basin. For the months of February, March and May, the significantly increasing trends are due to the influence of climate change in the upper reaches of the sub-basin.

Trends in monthly rainfall of the influencing rain gauge stations

Monotonic trends for the inter-annual mean monthly rainfall for all the influencing stations of the streamflow in the sub-basin were analysed and it is shown in *Table 7*. From the results, mixed trend was observed for all the months for all the rain gauges for the lower Tamiraparani sub-basin but none were significant. For all the influencing rain gauges, no significant trends were observed for some of the months. During the month of February which is the winter season, very minimum change rate of rainfall was observed for all the rain gauges studied. In the study analysed by Arthi et al. (2014) no significant trends were observed for the weekly and monthly rainfall in the Coimbatore district of Tamilnadu. The similar pattern of no significant trend was also observed in the present study for the monthly rainfall pattern in all rain gauges of the sub-basin which covers the Tirunelveli and Thoothukudi districts of Tamilnadu.

Trends in temperature

Table 8 showed the trends in annual, seasonal maximum and minimum temperature of the entire sub-basin for the study period. Annual temperature has increasing trends for both the maximum and minimum temperature. The results are well in agreement with the studies (Khavse et al., 2015; Ozgur et al., 2017), which analysed the long-term

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_863878

temperature trends for the periods of 100 years in the study and they identified increasing trends in annual temperature and decreasing trends in the monthly temperature. Zarenistanak (2014) analysed the trend patterns of temperature in Iran and they found non-significant trends in rainfall and significant trends in the temperature during summer and they observed that maximum temperature was more stable than minimum and mean temperature very precisely. The similar pattern was also observed in the present study with the stable increasing trends at a rate of 0.01°C/year in the maximum temperature while the minimum temperature showed no stable trends. In the seasonal analysis, both the seasonal maximum and minimum temperature showed no significant trends for all the seasons except southwest monsoon and winter season. During the northeast monsoon period, both maximum and minimum temperature showed marginal increase during the analysis. The summer period of the study area showed decrease in summer temperature at a minimal rate of -0.0049°C and -0.0062°C for both maximum and minimum temperature, respectively. However, in the southwest monsoon and winter, significantly increasing trend for maximum temperature is observed. Even a small change in the temperature can affect the agricultural patterns in the area largely (Sharma and Chaudhary, 2014). Since this sub-basin covers the majority of agricultural land use patterns, it is advisable to take appropriate measures to protect the crop yield by reducing the drying tendency especially during the southwest monsoon period and winter periods.

Conclusions and Recommendations

The analysis on the annual, seasonal and mean monthly streamflow observed at the Murappanadu gauge station for the period of 30 years, which is in the lower Tamiraparani sub-basin showed that there is less drying tendency of the downstream catchments of the entire Tamiraparani river basin. The annual rainfall contributed mainly to the annual streamflow as evident by the positive correlation. The observed rainfall trends during the Southwest monsoon and winter periods showed a nominally declining trend in the last 30 years of the study area and slightly increasing trends during northeast and summer season. The present study mainly concluded that variation of streamflow in the basin is partly attributed by the rainfall during southwest monsoon and the variation of streamflow during the Northeast monsoon is mainly attributed by the rainfall during the analysis period with the calculated correlation coefficient. Since the study area lies in the downstream side of river, the marginal increase in the streamflow with the decrease in rainfall during the southwest monsoon and winter indicates that other factors such as anthropogenic activities and other exogenous and ecological changes may contribute to changes in streamflow in the downstream areas. Decrease in rainfall and increase in temperature during these periods suggests that proper management measures ought to be adopted to avoid the detrimental effects of drying tendency of the area to provide proper agricultural production and ecosystem sustainability in the future. These sub-basin level seasonal observations from the present study are thus helpful in developing the holistic water management planning within the sub – basin particularly during the southwest monsoon and winter by taking the managemental practices at different spatial scales based on the needs, which may be useful to conserve the water to meet the demands in the drying trends by increasing water use efficiency of the river water in various sectors of the hydrological environment. From those observations, it is further recommended to carry out detailed analysis of rainfall, temperature and streamflow with the higher temporal resolution to develop a very precise relation among all the parameters. The decreased rainfall trends with increased trend in the temperature during southwest monsoon and winter season create a critical need to perform more detailed analysis to study the impacts on groundwater and surface water resources. Furthermore, this work can also be extended to study the impacts of projected land uses and future climatic projections over the streamflow to develop suitable policy and plans to maintain sustainability in available natural resources.

Abstract. While the contribution of stable tomato cultivars to ecological balance and environmental preservation has been recognized, two tomato cultivars have developed methods for tissue culture. For two tomato cultivars *Solanum lycopersicum* and *Solanum pimpinellifolium*, the regeneration capacity of two types of explants (cotyledons and stem node segments) was compared. Explants were cultured on five different regeneration media (½ MS and BAP) for stem node and MS for callus induction with a combination of 6-benzylaminopurine (BAP) and α- naphthaleneacetic acid (NAA). It was found that ability to regenerate was substantially dependent on both the cultivars and the type of explant. Stem nodes, followed by cotyledons, were the best explants to induce shoot regeneration. It was noticed that the best formulation of the medium for this regeneration from cotyledon explants used was MS with 1 mg/L BAP and MS+1BAP+0.25 NAA mg/L for callus induction in *S. pimpinellifolium* and for stem node explant the best formulation used was ½ MS and 7 mg/L BAP in *S. lycopersicum* was observed. All these data raised the possibility that to preserve and propagate wide hybrids of tomato materials *in vitro*, the regeneration ability of two explants was compared in *Solanum lycopersicum* and *S. pimpinellifolium*.
Keywords: *tomato, explants, benzyloaminopurine (BAP), α-naphthylacetic acid (NAA), stem node*

Introduction

Tomato (*Solanum lycopersicum*, 2n=2x=24), is an economically important crop worldwide. Moreover, this vegetable appears as a model plant for the introgression of agronomically crucial genes into the genome of dicotyledonous crop plants (Bhatia et al., 2004). The introduction of qualitative traits into commercial tomato cultivars is substantial, the aim being to ameliorate their nutritional value, productivity, abiotic stress resistance and application in molecular farming (Gerszberg et al., 2015). These crop species exhibited

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_879888

extraordinary nutritional value that's why it is considered to be preventive food (Raiola et al., 2014).

Recently, this crop has gained huge popularity due to its anti-cancer and antioxidant characteristic (Khuong et al., 2013). Elaboration of the aforementioned system is essential for positive results in a broad range of techniques, including micro propagation, mutation selection, somatic hybridization or germplasm preservation of the ecological balance (Benson, 2000).

Numerous studies pointed out that the process of tomato regeneration via the organogenesis pathway is influenced by various elements, including media composition, environmental conditions, genotype, explant origin and its age (Ishag et al., 2009; Rashid and Bal, 2010; Zhang et al., 2012; Wayase and Shitole, 2014). So far, several procedures were developed concerning *in vitro* tomato plants regeneration from diverse explants through organogenesis and tomato transformation (Gerszberg et al., 2015).

These findings pointed out the intractability of *S. lycopersicum* explants (fragmentary or even complete incapability to react to *in vitro* culture impulses) (Bhatia et al., 2004). Consequently, the improvement of a suitable recovery system exploiting tissue culture techniques of *S. lycopersicum* plants has a great potential if we consider the fact that various genotypes differ in regards to their morphogenic potential.

Traditional methods for tomato breeding can be expensive and tedious due to the time and facilities required by each breeding generation and to the problems with the selection of suitable standards for cultivating (Gerszberg et al., 2015). Therefore, as an alternative, the creation of effective regeneration protocols is an essential step for exploiting of tissue or cell culture for genetic amelioration.

Tomato *in vitro* culture has been used successfully in various biotechnological applications including clonal propagation of high-value commercial cultivars, virus-free plants, and genetic transformation (Hanus-Fajerska, 2005; Li et al., 2011; Yarra et al., 2012; Namitha and Pradeep, 2013).

The current research was focused on the impact of different media formulations on the regeneration of two tomato inbred lines of *S. lycopersicum* and *S. pimpinellifolium.* We used two inbred lines for *in vitro* culture to establish the best system of tissue culture in tomato, to conserve F_1 plants from wide hybridization for the balance of ecology.

Materials and methods

Plant materials

The present research work was conducted at Department of Horticulture, Faculty of Agricultural Sciences and Technology, Bahauddin Zakariya University Multan, Pakistan. Two different inbred lines of *Solanum lycopersicum c*v. Micro-Tom (2n = 24) and *S. pimpinellifolium* line WVa700 (2n = 24) were used as a plant material in this study. The seeds of these varieties were surface sterilized with 70% (v / v) ethanol for 1 minute; subsequently they were dipped in a commercial bleach solution comprising 5.5% (w / v) of sodium hypochlorite for 10 minutes accompanied by 5 times rinsed with sterilized distilled water (3 minutes for each).

Culture conditions

The seeds were placed in a sterilized glass jar containing MS medium and then transferred to the growth room under controlled conditions at a temperature of 25±1°C

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_879888

under 16 hours of photoperiod light intensity (1500 lux) and relative humidity (60-70%). Sterilized seeds were placed in jars on the seed germination medium. Four seeds were inoculated in each jar. The culture was then incubated in the incubation room until seed germination. It was observed that seeds began to grow in the dark and were later transferred to light.

The explants, both cotyledon and stem node, were taken from sterile seedlings (young seedlings) and placed on two media types: MS with different concentrations of benzylaminopurine (BAP i.e. cytokinin) and α- naphthaleneacetic acid (NAA i.e. auxin) for callus induction and ½ MS and BAP with different concentrations for stem node induction respectively to conserve F_1 plants as shown in (*Table 1* and *Table 2*). Experiment was repeated three times, with a total of 150 explants (50 explants per replicate).

Table 1. *Composition of culture media used for stem node induction and plant regeneration of Solanum lycopersicum and Solanum pimpinellifolium*

Medium	Composition
MS_1	without plant growth regulators
MS_2	½ MS + 1 mg/L BAP
MS_3	½ MS + 3 mg/L BAP
MS_4	½ MS + 5 mg/L BAP
MS_5	½ MS+ 7 mg/L BAP

MS= Murashige and Skoog medium, BAP= benzyloaminopurine

Table 2. *Composition of culture media used for callus induction and plant regeneration of Solanum lycopersicum and Solanum pimpinellifolium*

Medium	Composition
MS_1	without phytohormones
MS_2	1 mg/L BAP + 0.25 mg/L NAA
MS_3	1mg/L BAP + 0.50 mg/L NAA
MS_4	2mg/L BAP + 0.25 mg/L NAA
MS_5	2 mg/L BAP + 0.50 mg/L NAA

BAP= benzyloaminopurine, NAA= α- naphthaleneacetic acid

Experimental data for stem node induction and callus bud induction was collected after 15, 30 and 45 days, respectively. All the regeneration parameters (e.g. callus bud induction frequency and axillary bud frequency or growth features) were evaluated constantly. Explants of the two varieties were grown on 5 different media to evaluate their regeneration capacity.

Statistical analysis

The data collected was statistically analyzed following the analysis of the variance (ANOVA) technique and the mean differences were assessed by Duncan's Multiple Range Test (DMRT) using the statistical computer package program MSTATC (Gomez and Gomez, 1984).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_879888

Results

The purpose of this study was to investigate the performance of the two tomato explants, one explant (cotyledon) for callus induction and another explant (stem node) for axillary bud induction from two different cultivars i.e. inbred lines of *S. lycopersicum* cv. (Micro-Tom) (2n = 24) and *S. pimpinellifolium* line (WVa700) (2n = 24) were used as parents. The seed germination rate on MS media was 80% where 1.5% of the seeds were contaminated and the remainder was unable to grow. The impact of different levels and combinations of PGRs in both cultivars was noted in MS and ½ MS media for tomato explant for callus proliferation and stem node induction.

In the present experiment, the capability of two types of tomato explants (cotyledons and stem nodes) for the regeneration through indirect organogenesis was tested. Both explants cut from tomato seedlings (young seedlings) were cultured on various media: ½ MS+BAP (at different concentrations) for stem node and BAP (cytokinin), together with NAA (auxin) (at different concentrations) for cotyledon for the production of callus and multiple shoots (*Table 1* and *Table 2*).

Generally, callus induction was noticed in the aforementioned type of explant culture. Among the 5 media tested, no substantial variation was observed in the frequency of callus induction except *S.pimpinelifolium* at BAP, together with NAA (at different concentrations) for cotyledon for the production of callus but the highest callus bud induction frequency was noticed with the concentration of MS+ 1BAP+0.25 NAA (*Fig. 1*).

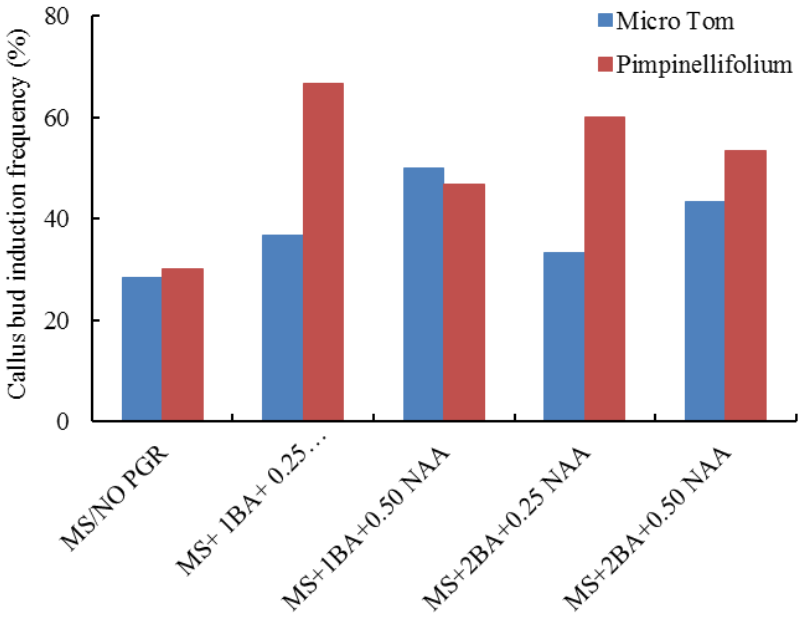

Figure 1. *Callus bud induction frequency of Solanum lycopersicum cv. Micro-Tom and S. pimpinellifolium line WVa700*

Callus formation began within ~12 days and shortly thereafter buds occurred. The origination of calli and shoots was noticed in the middle part of explants and on cut edges. In terms of morphology, the callus was fragile and characterized by a pale yellow or green color. In general, stem node explant showed high frequency of axillary bud regeneration in comparison to the callus originating from cotyledons because callus

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_879888

induction took a long time to regenerate while stem node usually took less time. Shoot regeneration frequency changed with medium composition, the variety and also with explant type.

Despite the fact the plant regeneration could be caused with BAP only, combining with NAA enhanced the frequency of plant regeneration significantly. Based on our results, MS with 1mg/L BAP and 0.25 mg/L NAA is the best formulation of the medium for regeneration from the cotyledon explants used in this research. The regeneration of plants from axillary buds or shoots has been shown to be the most generally applicable and reliable method of *in vitro* true-to-type propagation (*Fig. 2*).

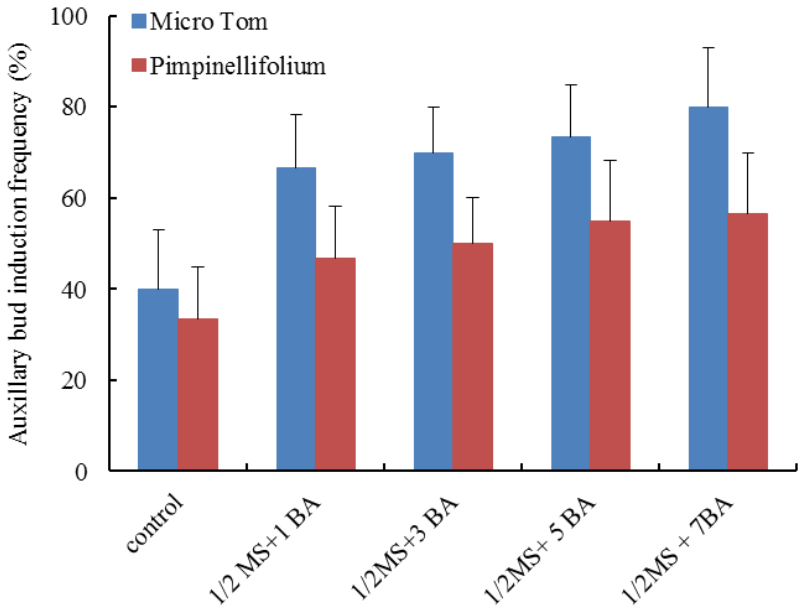

Figure 2. *Axillary bud formation percentage of Solanum lycopersicum cv. Micro-Tom and S. pimpinellifolium line WVa700*

We observed high regeneration axillary bud frequency from the stem node explants used in this study with the following concentrations ½ MS and 1BA, ½ MS and 3BA, ½ MS and 5BA and ½ MS and 7BA.

Our data showed the highest axillary bud regeneration frequency (80%) in *S. lycopersicum* (Micro-Tom) and (56.6%) in *S. pimpinelifolium* (WVa700). Moreover, by comparing two cultivars, highest germination rate was observed in Micro-Tom and lower in Pimpinellifolium (WVa700). It has therefore been noted that ½ MS and 7 mg/L BA in Micro-Tom are the best formulation of the medium used for this stem node explant regeneration (*S.lycopersicum*) (*Fig. 2*).

According to recent findings, in callus induction, *S. pimpinellifolium* (WVa700) showed high callus bud induction and multiple shoot regeneration as compared to *Solanum lycopersicum* (Micro-Tom) (*Fig. 1*) while in stem node induction, *Solanum lycopersicum* (Micro-Tom) showed high axillary bud regeneration frequency over *S.pimpinellifolium* (WVa700) (*Fig. 2* and *Fig. 3*).

Plants with a well-developed root system were moved to pots with a soil and perlite compound (3:1) and subsequently successfully acclimated and grown in a glasshouse. All *in vitro* plants were characterized by normal phenotypic appearance.

Discussion

The seeds of both cultivars *Solanum lycopersicum* and *S. pimpinellifolium* were germinated on plant growth regulator-free MS medium. Fifteen days after germination, seedlings were harvested for use as explant. The use of *in vitro* methods is useful for many cultivars and the individuals who rely on them. It has been noted that plant regeneration by *in vitro* technologies is usually associated with the existence of variability among regenerants (Duncan, 1996).

In our previous studies, phenotypic traits of parents and their hybrids in terms of plant height (6.866 cm for M_W and 5.966 cm for W_M) at 6 leaf stage, plant height (56.66 cm for M_W and 74.33 cm for W_M) at 8 leaf stage (70 days old leaf), fruit shape index (0.953 for M_W and 0.985 for W_M) and single fruit weight (3.622 g for M_W and 4.352 g for W_M) were observed at 6 leaf stage (45 days old leaf) respectively (*Fig. 4* and *Fig. 5*) (Raza et al., 2017). The present experiment was performed to conserve F_1 generation used in our previous studies by using *in vitro* technique.

Plant growth regulators (PGRs); have influenced the morphogenic response by modifying various physiological processes. In the case of tomato regeneration, a broad range of different phytohormones (e.g. BAP, zeatin, 2iP (isopentenyl adenine), KIN (Kinetin), IAA, NAA (α-Naphthaleneacetic acid) IBA (Indole-3-butyric acid), 2, 4-D (2, 4-Dichlorophenoxyacetic acid) at varying concentrations have been used so far (Koleva Gudeva and Dedejski, 2012; Jehan and Hassanein, 2013; Koul et al., 2014).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_879888

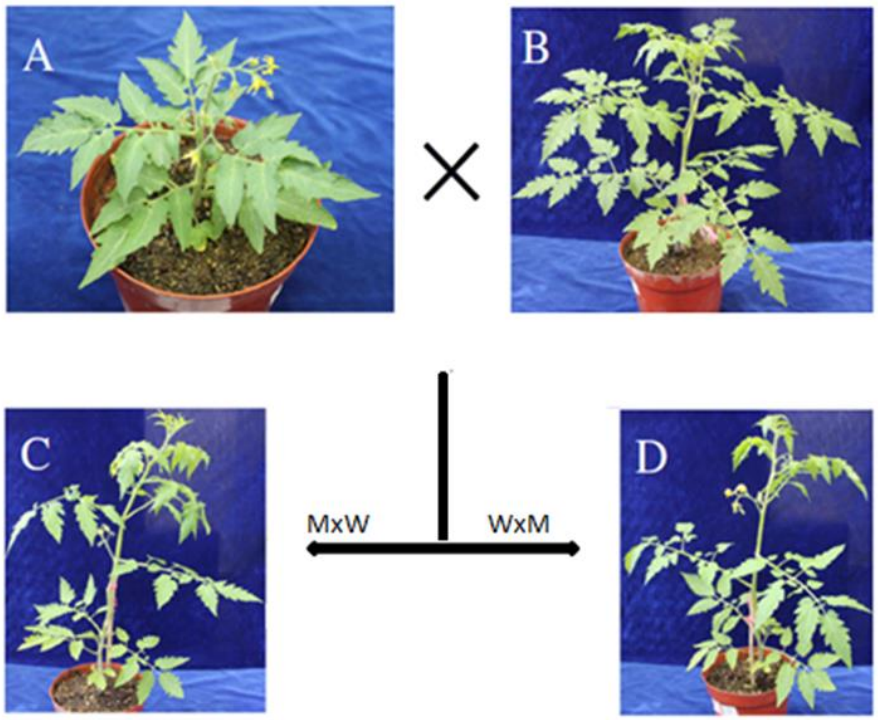

Figure 4. *Parents and their reciprocal hybrids,* ***A****. Solanum lycopersicum cv. Micro-Tom,* ***B.*** *S. pimpinellifolium line WVa700,* ***C.*** *Micro- Tom_WVa700 i.e. (Micro-Tom X WVa700)* ***D.*** *WVa700_Micro-Tom i.e. (WVa700 X Micro-Tom)*

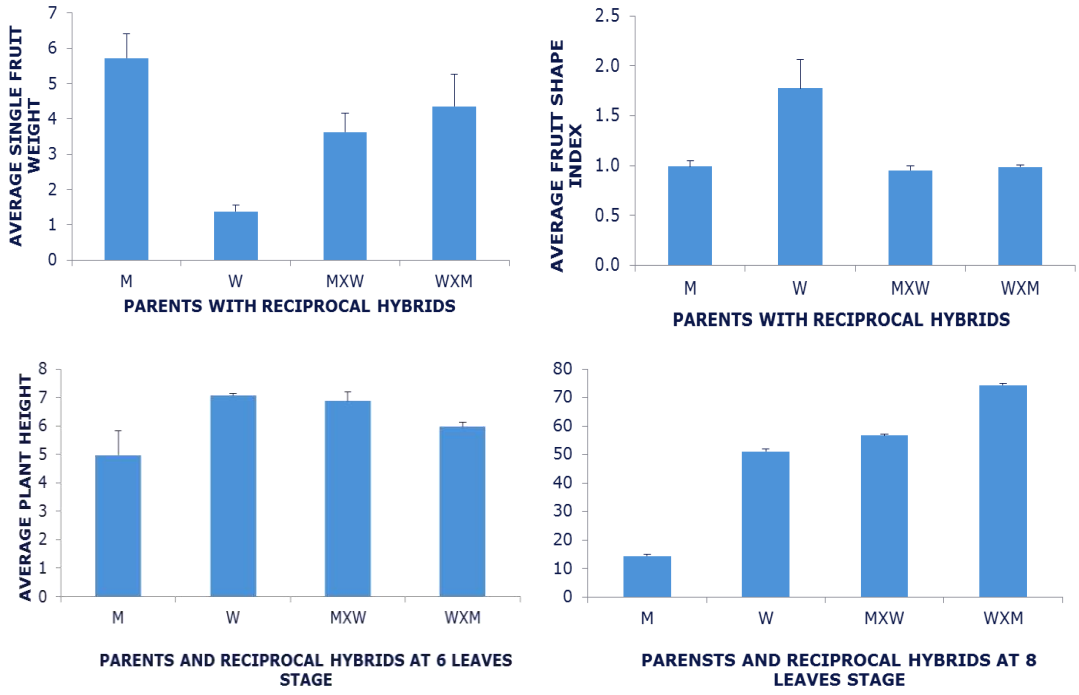

Figure 5. *Phenotypic traits of parents Solanum lycopersicum cv. Micro-Tom, S. pimpinellifolium line WVa700, and their reciprocal hybrids (Micro-Tom X WVa700) and (WVa700 X Micro-Tom)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_879888

Moreover, the nature and concentration of PGRs used in the medium proven to be dependent on the cultivar being cultured and especially on the auxin or cytokinins applied (Koleva Gudeva and Dedejski, 2012; Bahurupe et al., 2013; Jehan and Hassanein, 2013; Koul et al., 2014; Wayase and Shitole, 2014). Majority of *in vitro* methods depend on induction of the regeneration process exploiting different explants cultured *in vitro*. Various types of explants were used by others: seed-cut cotyledon, hypocotyl, leaf, stem sections, nods, internodes, pedicels, petioles, apical meristem, shoot apex/tip and inflorescences for organogenesis (Gerszberg et al., 2015).

A substantially higher range of BA (22.2 μM) was used for *Hedeoma multiflorum* micro propagation (Koroch et al., 1997). Slightly lower values were recorded for *S. lycopersicum* (Micro-tom) (*Fig. 1*). In many tree species, a range of auxin in combination with cytokinin played a vital role in multiple shoot regeneration (Vengadesan et al., 2002; Giri et al., 2004; Anis et al., 2011). Moreover, addition of low levels of auxin along with cytokinin is known to increase shoot numbers in many plant species like *Wrightia tinctoria* (Purohit et al., 1994).

Conclusion

The present study revealed an acceptable frequency of regeneration from two explants (cotyledons and stem node segments). Development of an effective *in vitro* regeneration protocol for crop species could be extremely beneficial in the process of cultivating and creating new varieties or in breeding lines in a relatively short period of time and for genetic improvement by exploiting biotechnology strategies. It is known that there are more than ten thousand tomato cultivars, and it is therefore impossible to establish a universal tomato regeneration protocol.

Hence, creating a tissue culture protocol for selected commercially important varieties is fully justified. This step should be preceded by wide screening of the above-mentioned varieties of morphogenic potential. Our study would provide novel valuable information about this very important issue. It can be concluded from the above findings that the regeneration protocol developed in this study is simple, reproducible and applicable.

Abstract. Estimating the soil content using near infrared (NIR) spectroscopy with an appropriate method of multivariate regression analysis, is a rapid and nondestructive testing technique with the virtue of high analysis speed and easy operation. Partial least squares (PLS) and least square support vector machine (LS-SVM) as the existing models widely used in other studies were improved and employed to develop an optimal regression model for the prediction of typical soil nutrient in Wuling mountain, Hunan Province, including total nitrogen, available phosphorus, and organic carbon. The performance of models established in this research was assessed by the coefficient of determination (R) and the root mean square error of calibration (RMSEC) and prediction (RMSEP). The result showed that the pre-processing method MSC+SG displayed the highest R values in PLS and LS-SVM models, which were 0.89 and 0.91, respectively. However, compared to the PLS model, LS-SVM displayed more desirable performance on the predictions. The RSMEC and RMSEP values of LS-SVM (4.84 and 4.75, respectively) were much better compared to PLS (6.15 and 6.58, respectively).
Keywords: *near infrared spectroscopy, chemometrics, soil nutrient analysis, prediction models, partial least squares*

Introduction

Soil nutrients are crucial for plant growth. The traditional analysis methods in laboratory restrict sample numbers due to the exhausting test time. Investigating the nutrient content in laboratory is time-consuming and demands considerable expenses. In the past decades, researches have been implemented to estimate the soil nutrient content from reflectance in the near infrared ranges (vis-NIR, 700-2500 nm) since spectrum data in the vis-NIR range has been proved to be reasonably accurate and fast in practical applications (Chung et al., 2015; Chen et al., 2017; Sampaio et al., 2018). With the development of chemometric methods and combination with NIR spectroscopy practices, these techniques have been

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_889899

extensively applied to estimate soil nutrient content, such as total nitrogen, available phosphorus, and organic carbon (Pandit et al., 2010; Kwon et al., 2014; Sudarno et al., 2017; Yu and He, 2017). Compared with traditional test methods, the NIR spectroscopy techniques are not only cost- and time-effective, but also non-destructive, and demand no chemical reagents during the measurement (Al-Harrasi et al., 2017; Genisheva et al., 2018). Ecological environment monitoring requires rapid investigation and response to the drastic change of soil properties. Therefore, NIR spectroscopy techniques as promising test methods used in ecological environment monitoring will be effectively monitoring the change of soil properties in certain areas.

Partial least squares (PLS) regression is a statistical method, associated with principal component regression (PCR) (Yang and Ying, 2011). However, it is not to find the hyperplane of the minimum variance between dependent and independent variables, but to find a linear regression model by projecting predictive variables and observational variables into a new space. Under one algorithm, PLS can combine multiple linear regression (MLR), principal component analysis (PCA) and correlation analysis between two groups of variables together (Suykens and Vandewalle, 1999; Stella et al., 2015). PLS is a regression modeling method of multiple dependent variables for multiple independent variables, which can solve many problems that cannot be solved by ordinary multiple regression. Support vector machine (SVM) is a new general learning method proposed by Vapnik et al. (1997) according to statistical theory. It is based on the VC dimension (Vapnik Chervonenks Dimension) theory of statistical theory and the structural risk minimization principle. It can solve small sample, nonlinear, high dimension and local minima better. Practical problems such as classification, function approximation and time series prediction have become one of the hotspots in machine learning. Least square support vector machine (LS-SVM) is an improvement of SVM. Contrasted to the standard SVM model, this method has obvious advantages: (1) using equality constraints rather than inequality constraints in standard SVM algorithm; (2) transforming quadratic programming problem into solving linear equations directly (Suykens and Vandewalle, 1999; Li et al., 2017).

In China, a large sum of farmland has been converted to forests under the policy of returning farmland to forests in the past two decades. A lot of studies focused on the effects of this policy on ecosystem processes. However, little concerns were cast on the influence on the change of soil content, especially in hilly erosion areas. Therefore, the object of this paper is to evaluate the performance of PLS and LS-SVM modeling techniques to predict the typical nutrient content in soil, including total nitrogen, available phosphorus, and organic carbon content of soil sampled in the hilly erosion area of Cili where is located in Wuling mountain area of Hunan Province.

Materials and Methods

Soil sampling and laboratory analysis

The sample sites where the soil samples collected were in Liangxi Village, Wuling mountains of West Hunan Province in China (E111°12′42.836″, N29°25′27.582″), about 7 km northwest of Cili County. The annual average temperature and precipitation in this location are 18.1°C and 1436 mm, respectively. The landscape mainly includes mountains, posts and plains, in which is dominated by red soil, and the layer of soil is more than 80 cm. The forest in the sample sites is a concentrated area of returning farmland to forest, due to its coverage rate in this area over 80%, and the vegetation types oriented at returning farmland to forests and secondary forests. In this area the soil parent rock is mainly sand shale, and the soil is primarily yellow-red soil and acid soil. *Pinus massoniana* forest, *Eucommia ulmoides* forest, *Citrus reticulata* and miscellaneous shrub forest are the dominant vegetation types in and around the sampled sites. All samples were taken randomly from 0-50 cm below the ground. In May 2018, the soil of this location was sampled in 29 different sites spanning mainly alongside the Li River, which was illustrated in *Fig. 1*. All soil samples of laboratory analysis were performed in accordance with Chinese Standards, including GB 9834, NY/T 1121.7, and HJ 615.

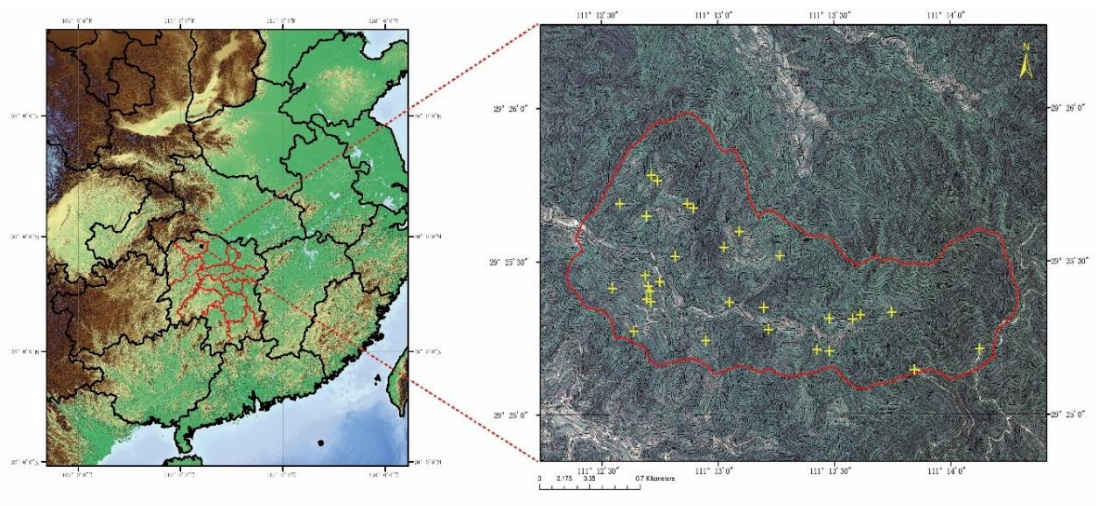

Figure 1. *The location of the sites sampled: Cili, Hunan Province*

Optical measurement

Vis-NIR spectra from 400 nm to 2500 nm, 2 nm/step with 1050 points was obtained by using Antaris II FT-NIR spectrometer (Thermo Fisher Scientific, the United States) charged with a sample cup. Every spectrum of all soil samples was collected with an average of 32 scans with 16 references scans before each sample.

DOI: http://dx.doi.org/10.15666/aeer/1801_889899

Spectral data pre-treatment

It is prone to scatter effects for NIR spectroscopy when the samples are solid. The scattering effects are primarily caused by the distribution of sample size. Therefore, data pre-processing was crucial to establish the best models. The pre-processing techniques applied in this paper were standard normal variate (SNV), multiplicative scatter correction (MSC), 1st derivative using the Savitsky-Golay (SG) routine with 7 points and a 3rd order polynomial fitted to the data. All pre-processing steps were performed in Unscrambler X 10.4 (CAMO Software Inc., USA).

Comparison of calibration algorithms

In order to predict the of the soil nutrients content from the NIR spectrum data demands the calibration of the NIR spectra and the laboratory analysis values of soil nutrients. In our research, PLS and LS-SVM were used and compared to construct models to predict soil nutrient content. The data of the matrices are comprised of NIR spectra that was dominated by X and the values of soil content including total nitrogen, available phosphorus, and organic carbon that dominated by the vector Y.

Partial least squares regression

PLS regression is applied widely and considered as one of the most common multivariate methods for the establishment of predictive models. Usually, multiple linear regression (MLR) is utilized to build prediction models with a lot of factors. However, once the factor number is getting too large, the model will be defined as over-fitting which means that the model fits the sampled data perfectly but fails to predict the new sample data well. Under such circumstances, there are many dominant factors, but there may be few latent factors that account for most of the variation in the response. The primary concept of PLS is to attempt to extract these latent factors, accounting for as much of the dominant factor variation as possible while constructing the perfect models to fit the responses well. Therefore, PLS is also called ‘‘projection to latent structure’’(Geladi and Kowalski, 1986; Tobias, 2017).

Least square support vector machine

LS-SVM is least squares version of SVM, which is a set of related supervised learning methods that analyze data and recognize patterns to be utilized for classification and prediction analysis. In these versions, the solution is obtained by solving a set of linear equations rather than a convex quadratic programming (QP) problem for classical SVMs (Suykens and Vandewalle, 1999). By this method, the improved LS-SVM avoids the complicated calculations of the classical SVMs. Also, it can also solve the problem of the multivariate calibration relatively fast and avoid over-fitting.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_889899

Evaluation of model performance

The quantitative models between NIR spectral data and soil content were built by PLS and LS-SVM, respectively. The modeling parameters were optimized and evaluated by the root mean square error of calibration (RMSEC) and prediction (RMSEP), and the coefficient of determination (R). RMSE and R are defined as follow (*Eq. 1* and *Eq. 2*).

$$RMSE=\sqrt{\frac{\sum_{i=1}^{n}(y_i-\hat{y}_i)^2}{n}} \quad \text{(Eq.1)}$$

The coefficient of determination is illustrated as below.

$$R=\sqrt{1-\frac{\sum_{i=1}^{n}(y_i-\hat{y}_i)^2}{\sum_{i=1}^{n}(y_i-\hat{y})^2}} \quad \text{(Eq.2)}$$

where n is the soil sample number in the validation test set, y_i and $\hat{y}_i$ are the experimental data measured by laboratory analysis and the predictive results of the model for the corresponding test sample i, respectively.

Results

Soil content

Table 1 summarizes the laboratory analysis values of total nitrogen, available phosphorus, and organic carbon of all 306 soil samples, which displays the calibration set and the validation set, respectively. The total nitrogen content for all the sets ranging from 50.88 mg·kg^{-1} to 648.93 mg·kg^{-1}, which has an average of 205.42 mg·kg^{-1}. The contents of available phosphorus and organic carbon for all sets are varying from 0.81 mg·kg^{-1} to 90.45 mg·kg^{-1} and 1.86 g·kg^{-1} to 25.44 g·kg^{-1}, respectively. The average values of these two contents are 0.15 mg·kg^{-1} and 13.72 g·kg^{-1} separately. The mean values in these sets of total nitrogen, available phosphorus, and organic carbon content are similar to each other, while the standard deviations are also close to each other. Therefore, it can be confident in the validation.

NIR spectrum of soil samples

The original NIR spectrum (10,000-4000 cm^{-1}) of soil samples are represented in *Fig. 2*. NIR spectra displayed different degrees of migration or drift that made pretreatment

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_889899

crucial for the establishment of prediction models with desirable performance. Moreover, the bands were broad and overlap, which made the spectrum difficult to interpret. Although the variables of the soil samples had quite a wide range of values, some useful information was represented in the vis-NIR region related to the total nitrogen, available phosphorus, and organic carbon of soil samples. There were mainly three absorption bands observed at 7083 cm^{-1}, 5205 cm^{-1} and 4532 cm^{-1}, among which 5205 cm^{-1} displayed the strongest absorption relevant with the combination of bending and stretching of hydroxyl group (O-H) of soil content (Cho et al., 1998; Cécillon et al., 2009; An et al., 2015). The absorption band observed at 7083 cm^{-1} was owing to the combination of C-H second overtone and the first overtone of O-H anti-symmetric stretching of soil (Cécillon et al., 2009; Viscarra Rossel and Hicks, 2015). The NIR spectrum of soil also displayed a major absorption band at 4532 cm^{-1}, due to the stretching and bending vibrations of C-H groups linked to organic carbon (Douglas et al., 2018).

Performance of PLS and LS-SVM models

Pre-processing methods are quite crucial for the accuracy of models. For PLS, the most optimum calibration was obtained by applying the pre-processing method with MSC combined with SG pretreatment (RMSEC=6.15 and R_c=0.89). The validation results of MSC+SG pretreatment was also the best of all (RMSEP=6.58 and R_p=0.90).

For the spectra analyzed by LS-SVM, the most optimum calibration was achieved by using the pre-processing method also with MSC combined with SG pretreatment for prediction of total nitrogen, available phosphorus, and organic carbon content (RMSEC=4.84 and R_c=0.91), which maintained the best validation results (RMSEP=4.75 and R_p=0.93). The optimum calibrated PLS and LS-SVM models were employed to conduct predictions for total nitrogen, available phosphorus, and organic carbon content that the results confirmed the desirable accuracy of these selected models in bold in *Table 2*.

Table 2. *Analysis of PLSR and LS-SVM models with selected pre-processing methods including SG, ANV+SG, MSC+SG and 1stD+SD*

Model types	Data pre-processing	Calibration set		Validation set	
		R_c	RMSEC	R_p	RMSEP
PLSR	None	0.78	8.55	0.76	8.01
	SG	0.84	7.21	0.86	7.45
	SNV+SG	0.86	7.02	0.84	6.89

	1stD+SG	0.86	4.97	0.87	4.87

The results emphasized in bold are selected models

Discussion

NIR spectra of solid samples is usually prone to scatter noise due to the uneven distribution of particle size of samples, for example soil samples (Casale and Simonetti, 2014; Acquah et al., 2015). To take full advantage of the spectra data re sample corded by NIR and to diminish the noise to the most extent, the data pre-processing methods are usually crucial to the establishment of the calibration model. The results of prediction are related to some uncertainties which mainly comprise environment conditions, measurement error, model selection and system settings. A simultaneous applications of data pre-processing methods and PLS models were applied to validate which model could

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_889899

be more accurate in the predictions of soil nutrients including total nitrogen, available phosphorus, and organic carbon content. A large number of computer runs were required in order to establish different models derived from analysis of NIR spectrum data corresponding to different pre-processing methods. It is crucial to enhance the predictive ability of the analysis of the NIR spectroscopy data, particularly for batch samples of more sophisticate systems (Suykens and Vandewalle, 1999).

In addition, it is obvious that the optimal smoothing mode should be chosen in order to implement the pretreatment optimization for the following establishment of the best prediction models. The performance of PLS and LS-SVM was different to some extent when SG smoothing and the pre-processing method (MSC, 1stD or SNV) was applied separately or combined, respectively. Spectra could be normalized by SNV when there were variations of the effective path length among samples. Moreover, this kind of path length could emerge especially when investigating powdered samples. In this study, the particle size, structure and color were varying among the soil samples.

SG filter is widely used in data flow smoothing and de-noising. It is known as a smoothing method based upon the local polynomial least squares fitting in time domain (Tobias, 2017). The most important merit of this method is that it can keep the shape and width of the signal unchanged while filtering out the noise. When smoothing filter is used to filter the signal, the low-frequency components of the signal are fitted and the high-frequency components are smoothed out. If the noise is at high frequency, then the result of filtering is to remove the noise. Otherwise, if the noise is at low frequency, then the result of filtering is to leave the noise (Geladi et al., 1985; Norgaard et al., 2000). MSC is a multivariate scattering correction technique, which can effectively eliminate the baseline shift and offset caused by scattering between samples and improve the signal-to-noise ratio of the original spectra. This pre-processing method can be regarded as a suitable way to smooth the spectroscopy data of samples with different structure and size. It could be concluded from *Table 2* that the data pre-processing method (MSC+SG) displayed the highest R values in PLS and LS-SVM models, which were 0.89 and 0.91, respectively. This step of pre-processing methods could eliminate the spectrum differences in the same series of samples caused by the inhomogeneity of particle size. However, model effect could be different when the pre-processing methods were applied separately or combined. The R_c values of PLS and LS-SVM models used SG pretreatment method separately were both lower than SG combined with SNV, MSC or 1stD. Therefore, the appropriate combination should be screened for the pre-processing optimization.

Comparing the performances of PLS and LS-SVM, LS-SVM displayed better prediction ability. For PLS and LS-SVM models, all variables from the soil sample spectrum were applied to the calibration of the models. The values of RSMEC and RMSEP of LS-SVM (4.84 and 4.75, respectively) were better compared to PLS (6.15 and 6.58, respectively). LS-SVM uses the least squares linear system as the loss function to replace it, so the inequality constraint is replaced by the equality constraint method, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_889899

the LS-SVM evolves into the solution of linear equations, which improves the speed of solution and the convergence precision of solution. Therefore, compared with PLS model, LS-SVM demonstrated more desirable ability of predictions on the content of soil nutrients.

Conclusions

Based on NIR spectroscopy and chemometrics, two quantitative prediction models of soil nutrients including total nitrogen, available phosphorus, and organic carbon were established, which were PLS and LS-SVM models. As the existing prediction models, these models were widely applied in other studies, which were improved and adopted in this study for the prediction of typical soil nutrient in Wuling mountain, Hunan Province, including total nitrogen, available phosphorus, and organic carbon. The results illustrated that these two models both had good predictive ability. The pre-processing methods could enhance the ability of prediction models. MSC+SG method displayed the highest R values in PLS and LS-SVM models, which were 0.89 and 0.91, respectively. However, compared with PLS model, LS-SVM displayed more desirable performance on the predictions. The values of RSMEC and RMSEP of LS-SVM (4.84 and 4.75, respectively) were much better compared to PLS (6.15 and 6.58, respectively). The proposed methods in this study demonstrated obvious superiority over traditional laboratory test. The results demonstrated that NIR spectroscopy combined with chemometric technique is a rapid, low cost and reliable method for the analysis of soil content in the soil monitoring and improvement along the area of Wuling mountain. Further studies will be performed to validate the model in another place located in Hunan Province. In addition, more predictive models will be developed for practical applications in future.

(Received 13th Jul 2019; accepted 25th Nov 2019)

Abstract. Orthogonal and single factor experiments were used to investigate the remediation effect of single and compound washing on Pb contaminated soil from a typical non-ferrous metal smelter. The optimal washing conditions and speciation distribution of Pb were determined. The obtained removal efficiency of Pb from the soil is 68.35%, which could be remedied to less than "risk intervention values (Pb < 2500 mg·kg^{-1}) for soil contamination of the development land" in soil environmental quality standard China (GB36600-2018) when the compound ratio of HCl & Rhamnolipid is 1:1, the ratio of liquid-solid is 10:1 and the washing time is 1080 min. The removal efficiency of Pb are significantly higher when using compound eluents compared to single eluents, such as HCl, EDTA, oxalic acid and rhamnolipid. Moreover, compound eluents can effectively remove active Pb from soil, which greatly reduces their bioavailability and environmental risk.
Keywords: *heavy metal pollution, soil washing, rhamnolipid, speciation distribution, kinetic analysis*

Introduction

Global industrialization is accelerating at a continuous rate. The development of the non-ferrous metal mining, smelting and processing industry in particular has led to the severe degradation of soils due to heavy metal pollution, and such contamination incidents have also attracted much attention (Park et al., 2002; Li et al., 2013; de Andrade Lima and Bernardez, 2017). Many experimental remediation technologies for heavy metal contaminated soils, such as soil exchange, solidification and stabilization, vitrification, and phytoremediation microbial remediation, have been developed (Dermont et al., 2008; Voglar and Leštan, 2011; Reza et al., 2015). However, they are difficult to implement in practical remediation projects of heavy metal contaminated soil due to their limitations, characteristics, secondary pollution, cost end effect on contaminated soil (Moutsatsou et al., 2006; Chen et al., 2017).

Soil contaminated by heavy metals in non-ferrous metal smelters is characterized by its high pollution intensity, complex forms, and is often accompanied by other heavy metals, which brings great challenges to its remediation (Bacon and Dinev, 2005; Burges et al., 2017). However, chemical washing has a promising application prospect as it is highly efficient, low cost, and has a short cycle (Abumaizar and Smith, 1999; de Andrade Lima and Bernardez,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_901912

2017). The type of eluent is the key to the repair effect, and the mechanism and removal capacity of different types of eluents vary. Common eluents include: inorganic eluents, artificial chelating agents, natural organic acid, biological surfactant and compound eluents (Dermont et al., 2008). For example, inorganic eluents can quickly and effectively remove heavy metals from the soil, and is low cost, but may damage the soil structure and biology. Artificial chelating agents can effectively remove heavy metals by self-chelating, but they are not easily biodegradable, and therefore cause secondary soil pollution. The costs of biological surfactants are often too high, which limits their engineering applications (Chen et al., 2017). Compound washing can not only improve the removal efficiency of pollutants, but also avoids secondary pollution and high cost associated with a single eluent through the synergistic solubilization of compound reagents.

In this paper, Pb contaminated soil from typical non-ferrous metal smelter was selected as the research object, and remedial target is to satisfy with the requirement of the "Risk control standard for soil contamination of development land" in soil environmental quality standard China (GB36600-2018). Hydrochloric Acid (HCl), Oxalic Acid, Ethylene Diamine Tetraacetic Acid (EDTA) and Rhamnolipid were selected as eluents, and oscillating washing experiments were carried out on the contaminated soil by single and compound washing. The optimal combination of eluents and conditions of washing were determined, and the washing kineties and washing mechanism were explored to establish the theoretical basis and technical support for the actual remediation project of heavy metal contaminated soil in non-ferrous metal smelters.

Materials and methods

Soil samples collection and preservation

Soil samples were collected from the surface layer (0-100 cm) of a typical non-ferrous metal smelter in Yunnan, China (103.329, 26.455). Remove the impurities, such as stones and plant roots, and air-dry naturally in the absence of light. After crushing, they are fully mixed and evenly stored in plastic bags. Subsequently, soil samples are screened according to the specific requirements of the experiment. Some of the soil samples were screened with 100 meshes for the determination of soil physical and chemical properties and heavy metals. Another part of the soil samples was screened with 20 meshes for washing experiments. The basic characteristics and test methods of the soil sample are shown in *Table 1* and *Fig. 1*.

Figure 1. *Soil samples collection and preservation*

Experimental equipment

Inductively Coupled Plasma Optical Emission Spectrometer (ICP-OES-5100, Agilent Technologies), Thermostatic oscillator (THZ-82, Guohua electric appliance Co., Ltd., China), Ultraviolet spectrophotometer (Cary 4000, Agilent Technologies), electronic balance (CP-214, Ohaus instrument), High speed tabletop refrigerated centrifuge (LXJ-Ⅱ B, Shanghai anting scientific instrument, China), Microwave digestion instrument (Mars-6, CEM Corporation) were used in the experiment. All experimental water is deionized water.

Method of washing experiment

The washing experiment conditions of single eluents are shown in *Table 2* according to the principle of an orthogonal experiment (Cui et al., 2007; Zhao et al., 2013; Zuo et al., 2016).

Table 2. *Orthogonal experiment conditions for single eluents*

Levels	HCl (M)	Oxalic acid (M)	EDTA (M)	Rhamnolipid (%)	Liquid-solid ratio	Washing time (min)
1	0.1	0.1	0.01	0.25	5:1	60
2	0.5	0.2	0.05	0.5	8:1	180
3	1.0	0.5	0.1	1.0	10:1	480
4	2.0	1.0	0.2	2.0	15:1	900

A single factor experiment was used for compound washing, and the basic specific experimental methods were carried out in the following order: (1) Determination of the optimum compound ratio: HCl was compounded with EDTA and Rhamnolipid (2%), respectively. The compound ratios were set as 3:1, 2:1, 1:1, 1:2, and 1:3. The liquid-solid ratio was 8:1, and the washing time was 480 min; (2) Determination of optimal liquid-solid ratio: The compound ratio of HCl & EDTA was 1:1, the compound ratio of HCl & Rhamnolipid was 1:2, and the washing time was 480 min. The liquid-solid ratio gradients were set to 3:1 5:1, 8:1, 10:1, 15:1, and 20:1; (3) Determination of the optimum washing time: The compound ratio of HCl & EDTA was selected for 1: 1, and liquid-solid ratio for 10: 1. The compound ratio of HCl & Rhamnolipid as 1: 2, and liquid-solid ratio for 15: 1. The washing times for the two compound eluents were set at 60, 180, 300, 480, 720, 1080, 1440, and 2160 min.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_901912

Soil samples of 3.00 g were weighed and packed into 100 mL centrifugal tubes. The eluents were added according to the experimental methods to oscillate for a given time at 210 RPM at room temperature, centrifuged at 5000 RPM for 6 min, and the supernatant was filtered with a 0.45 μm filter membrane. The contents of Pb were determined by ICP-OES.

All data were averaged by three groups of parallel experiments.

Determination method

In order to determine the distribution of heavy metal speciation in the soil before and after washing, the continuous extraction method of modified BCR was selected for the determination of Pb speciation in the soil (Tessier et al., 1979; Ashraf et al., 2012): (1) *Acid extractable*: add 40 mL of 0.1 M CH_3COOH to 1.00 g of soil samples, shaken at 210 RPM for 16 h at (22±5)°C, and centrifuged at 3000 RPM for 20 min; (2) *Reducible*: 40 mL of 0.5 M $NH_2OH{\cdot}HCl$ was added to the residue, and shaken at (22±5)°C for 16 h, centrifuged at 3000 RPM for 20 min; (3) *Oxidizable*: 10 mL of H_2O_2 was added to the residue at room temperature for 1 h, and 10 mL of H_2O_2 was added again at (85±2)℃ and maintained for 1 h, evaporated to near dryness, then 50 mL of 1 M CH_3COONH_4 was added, shaken at (22±5)°C for 16 h, and centrifuged at 3000 RPM for 20 min; (4) *Residual*: residual residue of 0.10 g was weighted and 10 mL HNO_3, 1 mL $HClO_4$ and 1 mL HF were added. The residue was microwaved until clear and transparent.

The content of various forms of Pb was determined by ICP-OES.

Methods of data processing and analysis

In this study, the ratio of heavy metal content in washing solution to original heavy metal content in contaminated soil was used to calculate the removal rate of Pb; and the results of washing were analyzed by Origin 2017.

Method of washing kinetics

In order to better understand the process of Pb washing in soil, three different models, Elovich equation, Two-constant equation, First-order equation, were selected to analyze and evaluate the washing kinetics data by least squares regression.

Elovich equation (*Eq.1*) contains a series of reactions including solute diffusion and surface activation in the liquid phase. Two-constant equation (*Eq.2*) is applicable to the dynamic system process with relatively complex reaction. First-order equation (*Eq.3*) reflects the relationship between reaction equilibrium concentration and reaction rate. Their expressions are as follows:

$$S = A + Blnt \quad \text{(Eq.1)}$$

$$lnS = A + Blnt \quad \text{(Eq.2)}$$

$$lnS = lnS_{max} + Bt \quad \text{(Eq.3)}$$

where, S ($mg{\cdot}kg^{-1}$) was the washing amount of Pb, S_{max} ($mg{\cdot}kg^{-1}$) was the total washing amount at equilibrium, A and B were both constants, and t (min) was the washing time. The determination coefficient (R^2) is used to judge the significance and merits of the model. The larger R^2 indicating that the higher the fitting degree, the better the model.

Results and discussion

Effect of single eluent washing conditions

The experiment results are shown in *Table 3~Table 6*.

Table 3 shows that the concentration of HCl is the key factor affecting the removal rate of Pb. The higher the concentration, the higher the removal efficiency of Pb in soil, with the highest removal rate of 39.22%. However, there was no significant change in the removal rate of Pb in soil when HCl exceeds 1.0 $mol \cdot L^{-1}$, and increasing HCl concentration leads to the destruction of soil structure and physic-chemical properties, and increases the cost of remediating the contaminated soil (Moutsatsou et al., 2006). The washing process of HCl is mainly the result of the interaction of H^+ promoting the dissolution of solid heavy metals and Cl^- complexation promoting the formation of metal ion complexes.

Table 3. *Orthogonal experiment and results of HCl washing*

Oxalic acid is a kind of natural organic acid eluent, which has the characteristics of extensive existence and easy biodegradation. It can be seen from *Table 4* that the oxalic acid has little effect on removing Pb from soil, only about 1%, regardless of the concentration of oxalic acid. The main reason is that oxalic acid is one of the dicarboxylic acids, and has few reaction sites, which provides limited acidity and concentration of oxalate ion, and provides fewer reaction sites. In addition, oxalate ion reacts with Pb released from soil to produce insoluble compound C_2O_4Pb, whose standard solubility product constant is 4.8×10^{-10} (Wei et al., 2016), which further inhibits the migration of metal ions to the aqueous phase, resulting in a poor washing effect.

It can be seen from *Table 5* that EDTA has a strong extraction efficiency for Pb in soil, and removal effect increases with the increase of EDTA concentration, up to 43.41%. This is due to its strong complexing ability and easy formation of 1:1 soluble complex with metals. The equilibrium constant of Pb-EDTA complex is 19.0 (Zhang et al., 2010; Qiao et al., 2017), which can further promote the desorption of Pb from the surface of soil

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_901912

particles and inhibit the re-adsorption of desorbed heavy metals. However, EDTA can easily cause secondary pollution to soil due to its own difficulty in degradation, and the instability of its chelates with heavy metals may bring potential environmental risks (Wei et al., 2016). Therefore, the optimal elution concentration of EDTA is 0.2 $mol \cdot L^{-1}$.

Rhamnolipid, an environmentally friendly anionic biological surfactant, can complexes with heavy metal ions by its own special hydroxyl and carboxyl structure, and can also reduce the surface tension of eluent and weaken the adhesion of heavy metal ions

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_901912

to soil (Nitschke et al., 2010). However, as shown in *Table 6*, rhamnolipid washing alone is less effective in removing Pb from contaminated soil, with a maximum efficiency of less than 2.0%. The reason is that rhamnolipid is a pH neutral substance and can only remove water-soluble heavy metal ions, which is consistent with the research results of Zhou et al. (Wen et al., 2009; Zhou et al., 2017). Therefore, it must be combined with other acid eluents in order to wash heavy metals in soil more efficiently and economically.

In addition, by comparing the magnitude of the Range (*R*) of orthogonal experiments, the influence degree of washing conditions for single eluents on the removal rate of Pb can be shown as follows: *Eluent Concentration* > *Liquid-Solid Ratio* > *Washing Time*.

In summary, there are great differences in the removal efficiency of heavy metals in soil by four kinds of single eluents. Among them, HCl and EDTA had better removal efficiency of Pb in soil, optimum washing conditions of HCl and EDTA were 1 $mol \cdot L^{-1}$, 0.2 $mol \cdot L^{-1}$, respectively; the liquid-solid ratios were 15:1 and 8:1; the washing time of both was 480 min; Oxalic acid is not suitable for remediation of contaminated soil in this site because of its poor washing effect; rhamnolipid needs to be combined with acid eluents in order to fully play its role.

Effect of compound eluent washing conditions

Compound eluents are optimized by compounding different types of single eluents, which mainly utilize the synergistic effect of different agents to further improve the removal efficiency of pollutants, and can avoid the secondary pollution and high cost of the single eluent. HCl was compounded with EDTA and rhamnolipid according to the orthogonal experimental results of single eluent, and the elution conditions were optimized by single factor experiments of compound washing.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_901912

Effect of the compound ratio of eluent on washing efficiency

It can be seen from *Fig. 2* that with the increase of the compound ratio of HCl & EDTA, the removal rate of Pb first increase and then decrease. The removal rates of Pb are the highest (up to 60.36%) when the ratio of HCl & EDTA is 1:1. However, for HCl & Rhamnolipid, the higher the compound ratio, the better the removal efficiency of heavy metals, but when the compound ratio exceeds 1:2, the removal rate does not change much. In addition, the removal rate of Pb by compound eluents were better than that by single eluents.

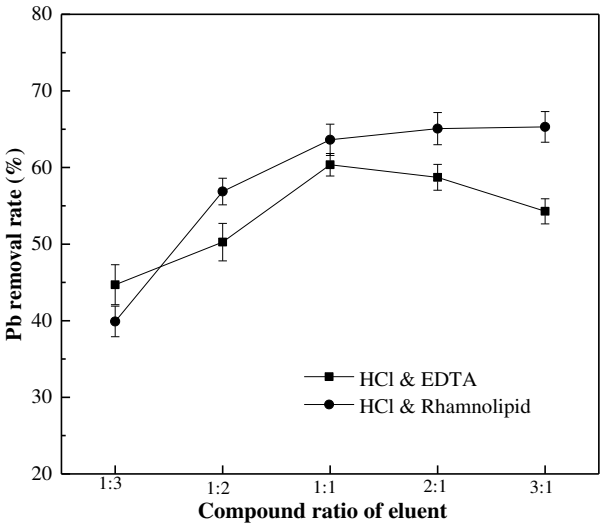

Figure 2. *Effect of compound ratio on Pb removal rate*

For HCl & EDTA combined elution, the elution mechanism is mainly as follows: (1) The acid solubility of H^+ and the complexation of Cl^- provided by HCl; (2) EDTA can not only reduce the surface tension of the eluent, but also form a stable complex Pb-EDTA with a coordination ratio of 1:1 with Pb; (3) the synergistic solubilization among different agents. However, for HCl & Rhamnolipid, besides (1) and (3), rhamnolipid is an anionic biosurfactant, which can not only reduce the surface tension of the eluent, but also form stable complexes with the special hydroxyl and carboxyl structures of the eluent and the Pb released from the soil.

Effect of liquid-solid ratio and washing time on washing efficiency

It can be concluded from *Fig. 3(a)* that with the increase of liquid-solid ratio, the removal rate of Pb in the soil of the two kinds of compound eluents are generally increasing; however, rate of removal increases slowly when it reaches a certain liquid-solid ratio. The essence of the increase of liquid-solid ratio is the increase of the amount of eluent, which leads to the increasing removal rate of heavy metals. The optimal liquid-solid ratio of both HCl & EDTA and HCl & Rhamnolipid was 10:1, according to the removal rate of Pb and the cost of remediation.

Washing time is a key factor that determines whether the eluent can interact adequately with the heavy metal pollutants in soil. Appropriate washing time can not only shorten the period of soil remediation, but also save costs. As can be seen from *Fig. 3(b)*, the longer the washing time, the higher the removal efficiency of the two kinds of compound

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_901912

eluents. However, when washing time exceeds a certain limit, the removal efficiency of heavy metals does not exhibit much change. Therefore, the washing time of HCl & EDTA was 720 min, while that of HCl & Rhamnolipid was 1080 min.

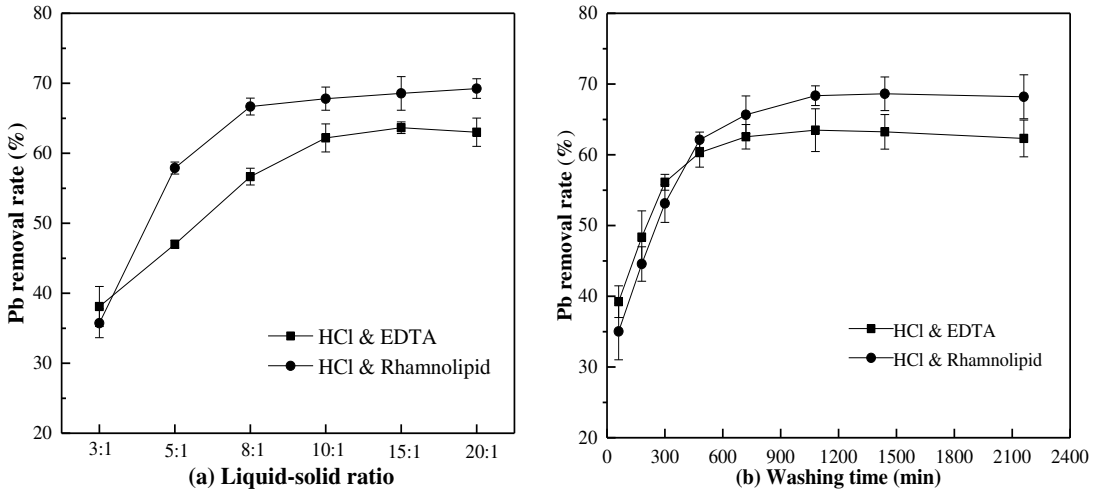

Figure 3. *Effect of liquid-solid ratio and washing time on washing efficiency*

Therefore, considering various factors of soil remediation, such as washing cost, secondary pollution, etc., HCl & Rhamnolipid compound washing effect is better, the optimum mixed ratio is 1:1, the liquid-solid ratio is 15:1, the washing time is 1080 min, and the removal rate of Pb in soil is 68.35%, which can be repaired to meet "risk intervention values (Pb content < 2500mg·kg^{-1}) for soil contamination of the development land" in soil environmental quality standard China (GB36600-2018).

Kinetics of compound washing

In order to better understand the process of Pb washing in soil, three different models, Elovich equation, Two-constant equation, First-order equation, were selected to analyze and evaluate the washing kinetics data by least squares regression, and the fitting results are shown in *Table 7*.

Table 7. *Fitting results of three different models*

Equation	**Elovich equation** $S = A + B\ln t$	**Two-constant equation** $\ln S = A + B\ln t$	**First-order equation** $\ln S = \ln Smax + Bt$
Fitting result	y = 10.391x - 6.3177	y = 0.2009x + 2.7916	y = 0.0003x + 3.8352
R^2	R^2 = 0.9339	R^2 = 0.9199	R^2 = 0.5468

By comparing R^2 of the three models, it can be seen that Elovich equation and Two-constant equation have a high fitting degree for the washing kinetics of heavy metal Pb in contaminated soil, while First-order equation is not suitable for describing the washing kinetics. Therefore, the washing desorption process of Pb in soil by HCl & Rhamnolipid is controlled by diffusion factors, and it is mainly a heterogeneous diffusion process.

DOI: http://dx.doi.org/10.15666/aeer/1801_901912

Speciation distribution of Pb before and after washing

The risks of heavy metal pollution to soil is directly related to their total concentration as well as their speciation distribution. In this study, we further compare the speciation changes of Pb in the soil before and after compound washing. The results are shown in *Table 8*.

Table 8. *Speciation distribution of Pb in soil before and after washing*

Pb speciation	Before washing		HCl & EDTA		HCl & Rhamnolipid	
	Content ($mg \cdot kg^{-1}$)	Percentage (%)	Content ($mg \cdot kg^{-1}$)	Percentage (%)	Content ($mg \cdot kg^{-1}$)	Percentage (%)
Acid extractable	1426.50	19.02	350.35	12.47	240.70	10.14
Reducible	2058.00	27.44	233.75	8.32	141.24	5.95
Oxidizable	1192.50	15.90	272.52	9.70	190.14	8.01
Residual	2823.00	37.64	1952.88	69.51	1801.67	75.9
Total	7500.00	100.00	2809.50	100.00	2373.75	100

Table 8 shows that Pb in contaminated soils of the smelter exists mainly in the form of Residual and Reducible, accounting for 37.64% and 27.44%, respectively, indicating that Pb forms a stable crystal structure with soil or firmly binds with clay minerals. After compound washing, the speciation distribution of Pb in soil changed greatly, and the concentration of all forms decreased significantly, indicating that the compound eluents of HCl & EDTA and HCl & Rhamnolipid could release Pb in various forms.

The Acid extractable is the most susceptible metal form to washing, and it is very sensitive to pH changes, and can be easily eluted when the pH is reduced. Therefore, the addition of HCl among the compound eluent greatly reduced the content of acid extractable Pb in the soil. Reducible mainly refers to heavy metals bound by Fe and Mn oxides in soil (Shen et al., 2007). The content of reducible Pb in soil also decreased significantly, which is mainly due to the high content of Fe and Mn in the soil polluted by this smelting site. A large amount of Fe and Mn are extracted at the same time in the process of composite washing, which leads to the decrease of Pb content in the form of Fe and Mn oxides in soil. The Oxidizable mainly refers to heavy metals bound by organic matter and sulfide in soil. The higher the content of organic matter in soil, the better the extraction of Oxidizable (i.e. organic matter bound) (Li et al., 1996). The content of organic matter in the soil used in this study is relatively high, so the content of Oxidizable Pb has also decreased significantly after complex washing. The properties of Residual are usually stable, and they usually exist in silicate, primary minerals and secondary minerals (Barona et al., 2001). The residual Pb in soil also decreases to some extent after complex washing, which may be due to the release of some residual Pb accompanied by silicate dispersion.

Conclusion

In this study, single and compound eluents were applied to washing remediate the soils with Pb contamination intensity of 7500 $mg \cdot kg^{-1}$ in an abandoned non-ferrous metal smelter in Yunnan China. The results showed that when the compound ratio of HCl (1 $mol \cdot L^{-1}$) & Rhamnolipid (2%) was 1:1, the liquid-solid ratio was 10:1, and the washing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_901912

time was 1080 min, the removal rate of Pb in the soil was 68.35%, which met "*Risk screening value for soil contamination of the development land*" (Pb < 2500 $mg \cdot kg^{-1}$) in "soil environmental quality standard China (GB36600-2018)". The washing desorption process of Pb in soil conforms to Elovich model and is mainly a heterogeneous diffusion process. In addition, from the distribution of Pb forms in soil, the main forms of Pb in the waste smelter soil are acid extractable and reducible. The active Pb was effectively removed, which greatly reduced the biological toxicity and environmental risk of the soil.

The heavy metals in the contaminated soil are eventually transferred to the washing waste liquid, so the recovery and treatment of the washing waste liquid should be further studied in the future. In addition, this study mainly simulated the ectopic washing process of contaminated soil, and the amount of soil used in the experiment was less. Therefore, the soil column washing experiment could be conducted by simulating the in-situ washing process in the future.

Abstract. Urban sprawl is a major factor that threatens the loss of arable landmass, and its evolving morphology has long interested numerous scholars. However, existing research on this study has not been concerned with the cases of ordinary cities, particularly their intra-urban land and urban sprawl. This study goes beyond mega-/super-cities and takes Zhuhai, an ordinary large city in China's Pearl River Delta (PRD) region, as a case. Through remote sensing and GIS technology, this research identifies the increasing built-up areas and its sub-typologies (infill, outlying and edge-expansion), distinguishes the reclamation area and the decreasing arable landmass and evaluates the rate of land-use inside its five districts from 1980 to 2015. The growth of urban areas and loss of arable landmass are uneven inside Zhuhai. The most uneven outlying and infill growth were observed from 1990 to 1995 and from 2013 to 2015, respectively. Edge-expansion is the least imbalanced typology and reached its minimum from 2010 to 2013. The extent of variability of the total urban sprawl generally accords with that of edge-expansion and imbalance of arable landmass loss that reached a peak from 2005 to 2008. However, policy, planning and other factors that matter in urban sprawl are also discussed.
Keywords: *land reclamation, arable land loss, variability, Landsat, ArcGIS*

Introduction

The term sprawl originated from the U.S. and its rapid suburbanisation (Leichenko and Solecki, 2014). However, the definition of urban sprawl varies among researchers and policymakers as this politically charged terminology lacks precision in the narrative of policy documents. In addition, the characteristics of sprawl differ from place to place (e.g. Sprawl in American cities is much less dense than that in Asian cities) (Shahraki, 2011; Hamidi and Ewing, 2014). Thus, contextualised case studies, especially from the global South, are needed to offer insights. In this research, we specifically deploy urban land sprawl denoting the adjacent sprawl of urban land, away from existing built-up area to undeveloped rural area. With the breakthrough of urban margins, this type of urban activity is often criticised for encroaching arable land, causing environmental degradation and undermining the natural landscape. Thus, sprawl represents an uncoordinated growth without thinking about the random effects, the additive urban growth that results in inefficient resource utilisation and ecological destruction (Bhatta et al., 2010). This unsustainability has already been revealed in fast-expanding cities. For instance, in India, under unprecedented urban sprawl, land use has changed rapidly in fringe towns and cities along the rapid transportation corridor (Theobald, 2001). Indicators used to identify urban

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_913927

sprawl include the loss of arable landmass and forest habitat and the increase of impervious surface.

Urban sprawl is a spatial process along with complex changes in land use (Bhatta et al., 2010). This process is influenced by urban policy and planning. Urban sprawl morphology and its spatiotemporal characteristics have attracted the attention of scholars. Old theories, such as concentric zones and sectors and multiple nuclei theories (Burgess, 1925; Hoyt, 1939; Harris and Ullman, 1945) are unable to capture long-term and multi-temporal sprawl patterns. Recent research has benefitted from the advancement of remote sensing. However, data assemblage and interpretation have always been an enormous task before quantifying land-use change (Batty, 2002; Herold et al., 2003; Peng et al., 2010; Xian et al., 2019). Moreover, researchers have focused on the sprawl patterns of cities (especially mega city-regions) across macro-scale regions, nations and even the world (Grainger, 1995; Li et al., 2004; Hamidi and Ewing, 2014; Scheuer et al., 2016; Li and Li, 2019; Aniekwe and Igu, 2019). For instance, Hamidi and Ewing (2014) have stated that the growth of infill increases the density of metropolitan areas (often in coastal areas). However, they have identified that the density of urbanised areas in the U.S. decreases with the increase of metropolitan sprawl between 2000 and 2010, leading to overuse of automobiles. In an up-to-date study exploring the spatiotemporal patterns of urban sprawl in China from 2006 to 2014 (Li and Li, 2019), the growth rates of built-up areas outweighing the population are most significant in the Western region, followed by the Eastern and Central regions and least significant in the Northeast. The rates of urban sprawl in mega and super cities are minimum, sometimes even negative. However, these rates are still notable in large and medium cities. The sprawl is also found related to population and economic growth. Nevertheless, the manner in which ordinary, large, medium and small cities sprawl, including the patterns and typologies in intra-urban sprawls, remains unclear. Do these cities sprawl with different patterns or rules? How does sprawl take place inside the city? What are the specific causes?

This current study aims to address the questions by giving special attention to the volume, structure and forms of land use (Long and Li, 2012). Furthermore, the trend, rates and variability of urban land sprawl in a non-mega-/super-city is examined. Zhuhai, located in the Southern coast China, is selected as the study area for two main reasons. Firstly, urban China is an interesting subject matter, exhibiting different sprawl patterns from the American model. These patterns are revealed in numerous up-to-date studies (Chen, 2016; You, 2016; Ding and Wang, 2018; Yang et al., 2018; Liu, 2020). Secondly, different from mega-/super-cities (according to the National Statistical Bureau, cities with permanent residents more than 10 million are megacities; between 5 and 10 million are super cities; between 1 and 5 million are large cities; between 500 hundred thousand and 1 million are medium cities and fewer than 500 hundred thousand are small cities), Zhuhai is a large city embracing a green environment and eco-city ideology. From a small county to a sizable metropolis, the specific trajectory and forms of sprawl can update existing understanding beyond economic star megacities, e.g. Shenzhen, Guangzhou, and Shanghai. However, in what patterns city grows is still unclear. Unravelling the spatiotemporal transition of land can provide a comprehensive picture and produce invaluable implications for the ongoing urban development in China. Using Zhuhai as a case, this research distinguishes and quantifies different land use (e.g., urban built-up area and arable land); evaluates the rate of land-use change to economic and population growth; measures the extent of sprawl variability and discusses how policy, planning and other factors matter in urban sprawl. Edge-expansion, outlying, and infilling as different sprawl typologies of built-up area are also computed (Budd, 1996; Liu et al., 2010; Shi et al., 2010).

Materials and methods

Area of research

Zhuhai, known as a city of hundred islands, has been reputed for its appeal, windy coastline, diverse tropical vegetation, green ambiance for liveability and stretched urban structure in Pearl River Delta (PRD) in China. Adjacent to Jiangmen, Zhongshan and Macau, Zhuhai is situated at the estuary of South Guangdong (*Fig. 1*). The city has Xiangzhou, Doumen, Jinwan districts under its jurisdiction. Gaoxin district, which are known as the city's High-tech Zone, and Hensqin vitalise local economic growth. Zhuhai is a typical fast-growing immigrant city evolving from a traditional Cantonese-speaking region of Guangdong province to a Mandarin-based area with a large influx of immigrants from inland provinces.

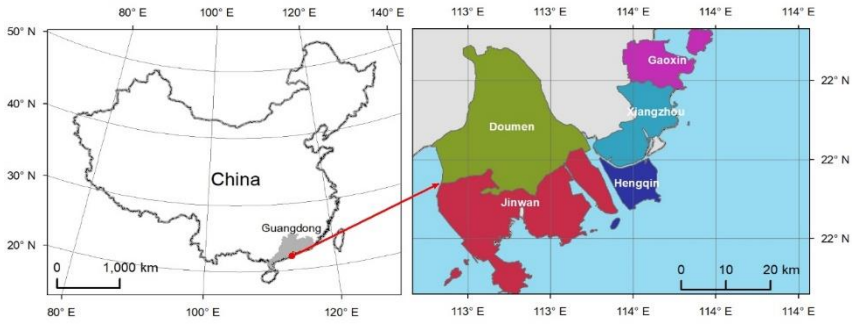

Figure 1. *Zhuhai's Location and its districts*

Data sources

Land cover and land-use change identification are essential for ecological environment analysis and planning. The information is commonly extracted from satellite images by using supervised classification methods, which require classified reference samples to train the classifier and subsequently classify unknown data (Qi et al., 2012). Given the availability of the data and pre-research on Zhuhai, remote sensing images spanning nine years from Landsat satellites are acquired from the United States Geological Survey, with a time span of 35 years (*Table 1*). Except for the earliest 1980 image provided by the Multispectral Scanner Sensor (MSS), which have 78 m coarse resolution, the rest of the images of the Thematic Maps (TM) and Operational Land Imager (OLI) all have 30 m resolution.

Table 1. *Dataset of landsat images*

Acquisition time	Satellite	Sensor	Resolution (m)
1980	Landsat-3	MSS	78
1990	Landsat-5	TM	30
1995	Landsat-6	TM	30
2000	Landsat-7	TM	30
2005	Landsat-5	TM	30
2008	Landsat-5	TM	30
2010	Landsat-7	TM	30
2013	Landsat-8	OLI	30
2015	Landsat-8	OLI	30

As the expansion rate became increasingly rapid, the later the periods, the shorter the time, such that the urban land change can be accurately captured

DOI: http://dx.doi.org/10.15666/aeer/1801_913927

Methods

Identifying land use types

Diverse methods are used to determine the different types of land use. In this research, support vector machines (SVMs) (Chang and Lin, 2011), which are one of the most widely used supervised classifiers, are used for Landsat image classification to extract land cover information. Radial basis function (RBF) is selected as the mapping kernel of SVM. A grid search strategy is used to derive the optimal parameters of the RBF kernel SVM (Chang and Lin, 2011). To collect ground truth data in assessing the accuracy of identifying urban sprawl features, fieldwork is conducted using high-resolution Google Earth images. Based on experience with multinomial distribution (Congalton and Green, 2009), a minimum of 50 samples are collected for each land cover class. Different categories of land use are identified. The built-up area is the main parameter quantifying urban sprawl (Shahraki, 2011). Reclamation is a special parameter to complement the understanding of coastal urban expansion. The built-up area is visually interpreted through the software of ArcMap and reviewed by qualified technicians (Akbari et al., 2003) as visual form performs better than spectral signal in distinguishing land use characteristics. Furthermore, visual form avoids misclassifications and guarantees preciseness.

Evaluating the rate of change

In assessing the growth of the economy and population relates with urban land sprawl, standardised sprawl efficiency of GDP ($LSGDP_s$) and permanent residents ($LSPE_s$) (calculating the growth rate of the GDP and the permanent resident population to that of urban built-up areas) is applied to each district in different periods. This article also calculates the annual loss rate of arable land, which partially transited to the increase of the built-up areas.

Measuring the extent of variability

The coefficient of variation (CV) is calculated to reveal the extent of variability in relation to the mean of land sprawl, arable land and forest loss within a city. The CV is defined as the ratio of the standard deviation to the mean value and is calculated as

$$(C \cdot V)_{ij} = \frac{S_{ij}}{\bar{X}_{ij}} \times 100\%,\ S_{ij} = \sqrt{\sum \left(\bar{G}_{ijk} - \bar{X}_{ij} \right)^2 / n} \qquad \text{(Eq.1)}$$

where $(C \cdot V)_{ij}$ is the variation score of sprawl/loss type j during time period i, $\bar{X}_{ij}$ and S_{ij} denote the sample mean and standard deviation of sprawl type j during time period i, and n represents the number of the sample. A larger value of CV signifies a greater level of dispersion around the mean. Conversely, a smaller value of CV entails a lower level of dispersion around the mean. This research also measures the CV of different typologies of land sprawl, which are calculated by the Landscape Expansion Index (LEI) (Liu et al., 2010; Xian et al., 2019). In LEI, different value intervals denote various sprawl typologies: newly built patches that spread from the boundary of existent areas are identified as edge-expansion (0–50). Enclave new patches detaching from the existent areas is categorised as outlying (0). Newly developed urban patch stuffing an existing land parcel is infill (50–100). The typologies further detail the sprawl trajectory of the case city.

Results

The general trend of urban land sprawl

The general change of urban land use is identified through visual interpretation based on Landsat data and presented in *Fig. 2*. The left vertical axes indicate data sets of forest, urban and arable land in square kilometers while the right vertical axes shows urban land per capita (with unit of km^2/person). Among the identified categories, arable land and forest land gradually decrease over time. Until 2015, almost 300 km^2 of arable land and 50 km^2 of forest land has been encroached, a substantial part of which has turned into urban built-up area. From 1980 to 2015, the proportion of Zhuhai's arable land to the total landmass dropped from 44.64% to 23.88%, with the urban built-up area expanding to 240.48 km^2. The urban built-up area has increased from 35.19 to 275.67 km^2, whereas the per capita area has fluctuated significantly, surging from 96.32 m^2 in 1980 to 168.53 m^2 in 1995; this area declined to 144.13 m^2 in 2000 and increased again to 169.73 m^2 in 2013 (*Figs. 2 and 3*).

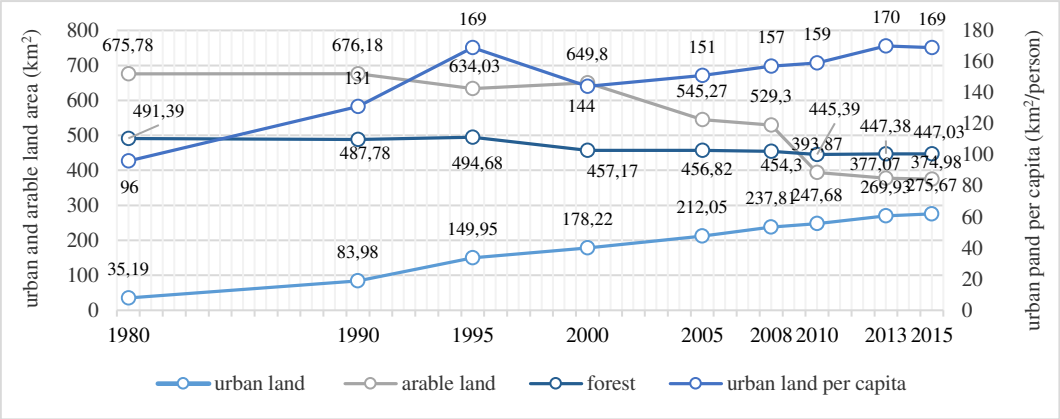

Figure 2. *Change of urban and arable land (per capita) in Zhuhai (1980–2015)*

The coastline in Zhuhai was reshaped from 1980 to 2015 (*Fig. 3*). From 1980 to 1990, artificial land reclaimed along the coastlines reached a peak of 108.4 km^2, which happened along the Western coast of Jinwan. From 1990 to 1995, reclamation projects decreased but remained considerable at 11.27 km^2 in areas scattered around Northeast Hengqin. From 1995 to 2000, Northwest Hengqin and the Western Coast of Jinwan witnessed visible reclamation. However, the amount reduced to 7.35 km^2. From 2000 to 2005, the reclamation mainly took place in South Jinwan and North Gaoxin and slightly increased to 8.12 km^2. Between 2005 and 2008, lands were reclaimed along the Southwest boast of Jinwan but shrank sharply to 1.45 km^2. From 2008 to 2010, three pieces of land up to 10.16 km^2 were reclaimed in South Jinwan and Northwest Hengqin. However, from 2010 to 2013, the reclamation area dropped to 8.96 km^2. From 2013 to 2015, these areas were reduced to 0.45 km^2, which all occurred in the Jinwan District.

The gains and loss rates of urban land sprawl

The intra-urban spatiotemporal patterns, the annual sprawl area of Zhuhai and the five districts are calculated (*Fig. 4*). Jinwan overwhelmingly expanded over 700 ha in 1990 and 1995, 270 ha in 2000 and 2005, 480 ha in 2005 and 2008, 250 ha in 2010 and 2013,

DOI: http://dx.doi.org/10.15666/aeer/1801_913927

followed by Xiangzhou, expanding 290 ha in 1980 and 1990, 340 ha in 1990 and 1995, 250 ha in 1995 and 2000. The least sprawled district is Hengqin with a less than 10 ha annual increase before 2010. The annual sprawl areas of Doumen and Gaoxin districts were among the average.

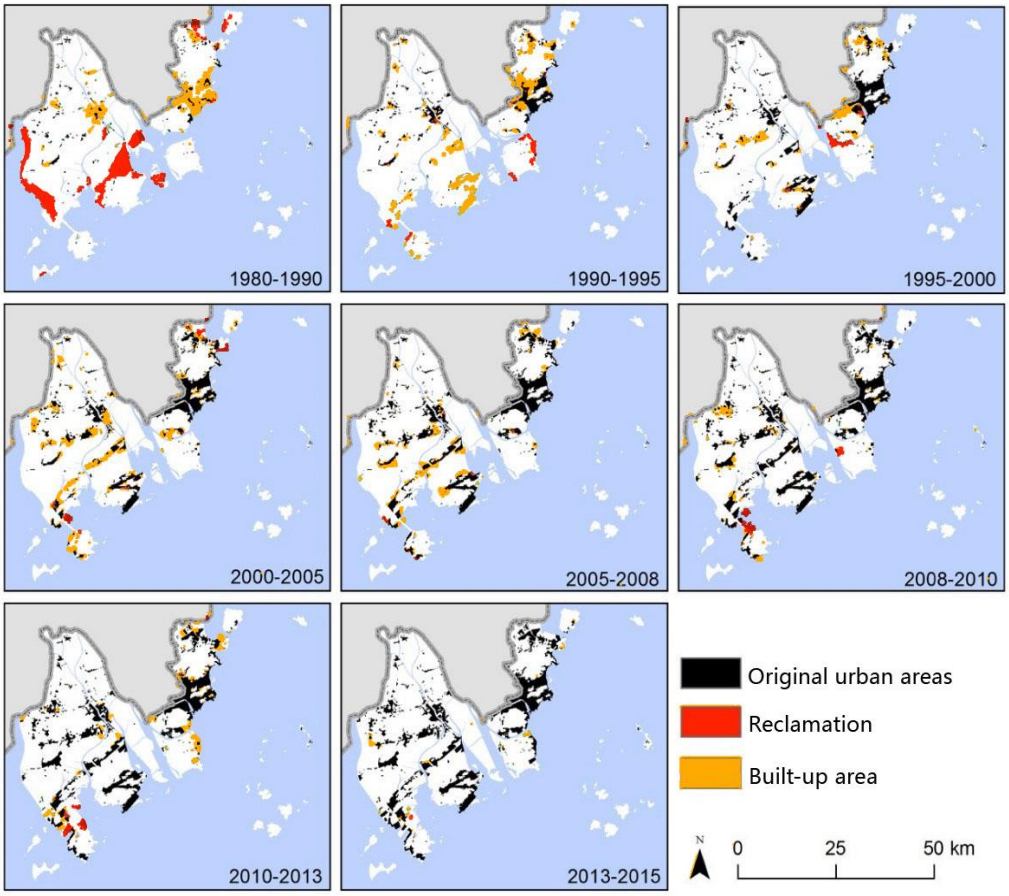

Figure 3. *Urban land sprawl and coastal land reclamation in Zhuhai (1980-2015)*

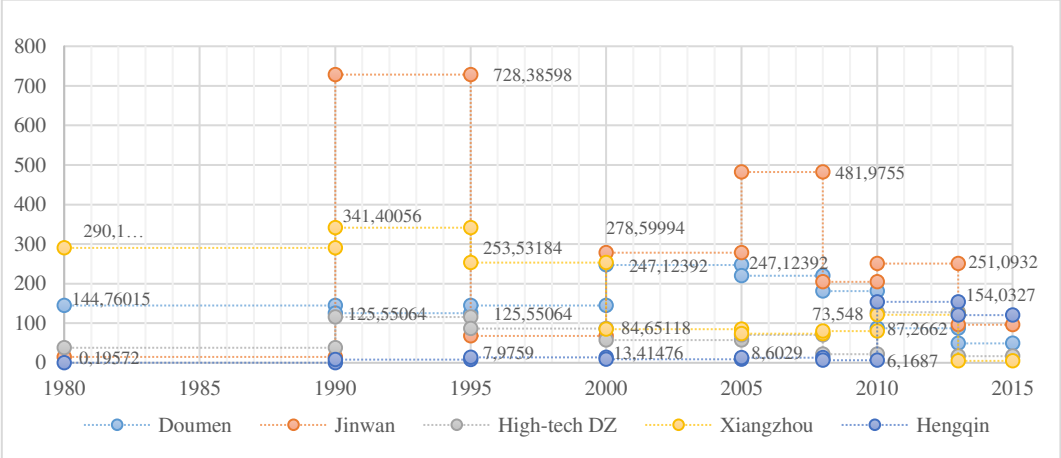

Figure 4. *Annual sprawl area of Zhuhai's five districts in eight periods (1980-2015) (unit: hectare)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_913927

$LSGDP_s$ was generally higher than $LSPE_s$ during 2008 and 2015. Xiangzhou's $LSGDP_s$ is highest in 2008-2010 (36.66) but declined thereafter (*Fig. 5*). Jinwan's $LSGDP_s$ declined first in 2010-2013 and increased again in 2013-2015. Doumen's $LSGDP_s$ was negative in 2008-2010 (-0.98) but had a significant increase throughout 2010-2013 (10.87) and 2013-2015 (13.86). All the districts' $LSPE_s$ decreased in 2010-2013 and increased in 2013-2015, but Xiangzhou's $LSPE_s$ in 2008-2010 (6.19) remains most significant and Jinwan's $LSPE_s$ is minimum in 2010-2013 (0.13).

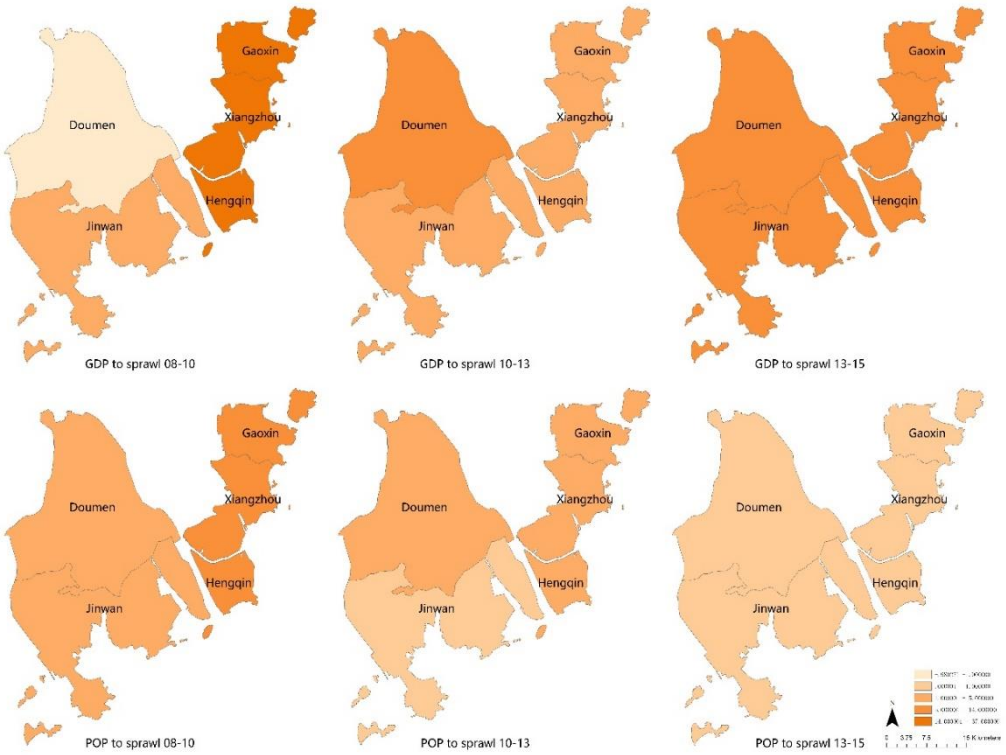

Figure 5. *Standard sprawl efficiency of GDP and permanent residents in Zhuhai's five districts (2008-2015)*

Loss rate of arable land is greater after 2000 than in previous years but varies across periods and districts (*Fig. 6*). In *Fig. 6*, the shallow the colour, the greater loss of the arable land. The most intensive loss of arable land occurred between 2000 and 2005, and 2010 and 2013, with each district losing more than 0.9% arable land except Gaoxin (2010-2013). Xiangzhou (1990–1995, -5.17%; 2008–2010, -11.38%; 2010–2013, -8.21%) and Gaoxin (1990–1995, -4.76%; 2008–2010, -21.73%) were the top districts that experienced intensive arable land decrease with over a 4.5% loss rate. Hengqin gained arable lands in 1980–1990 (7.48%) and 1990–1995 (60.42%). A similar increase was also observed in Gaoxin (1995–2000, 4.12%), Doumen (1995–2000, 2.23%) and Jinwan (1980–1990, 1990–1995, 1.08%).

Imbalance of urban land sprawl

From 1980 to 2015, the CV of arable land loss was higher and greater than forest loss (*Fig. 7*). However, both lands experienced three rounds of increase (1990–1995, 2005-2008, 2013–2015). The lowest value was in 2010 and 2013, with both CVs reaching

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_913927

zero, thus indicating a highly balanced loss of arable land and forest. The imbalance of arable loss reached a peak in 2005–2008, with a CV of 0.87 and forest loss in 1990–1995, with a CV of 0.76.

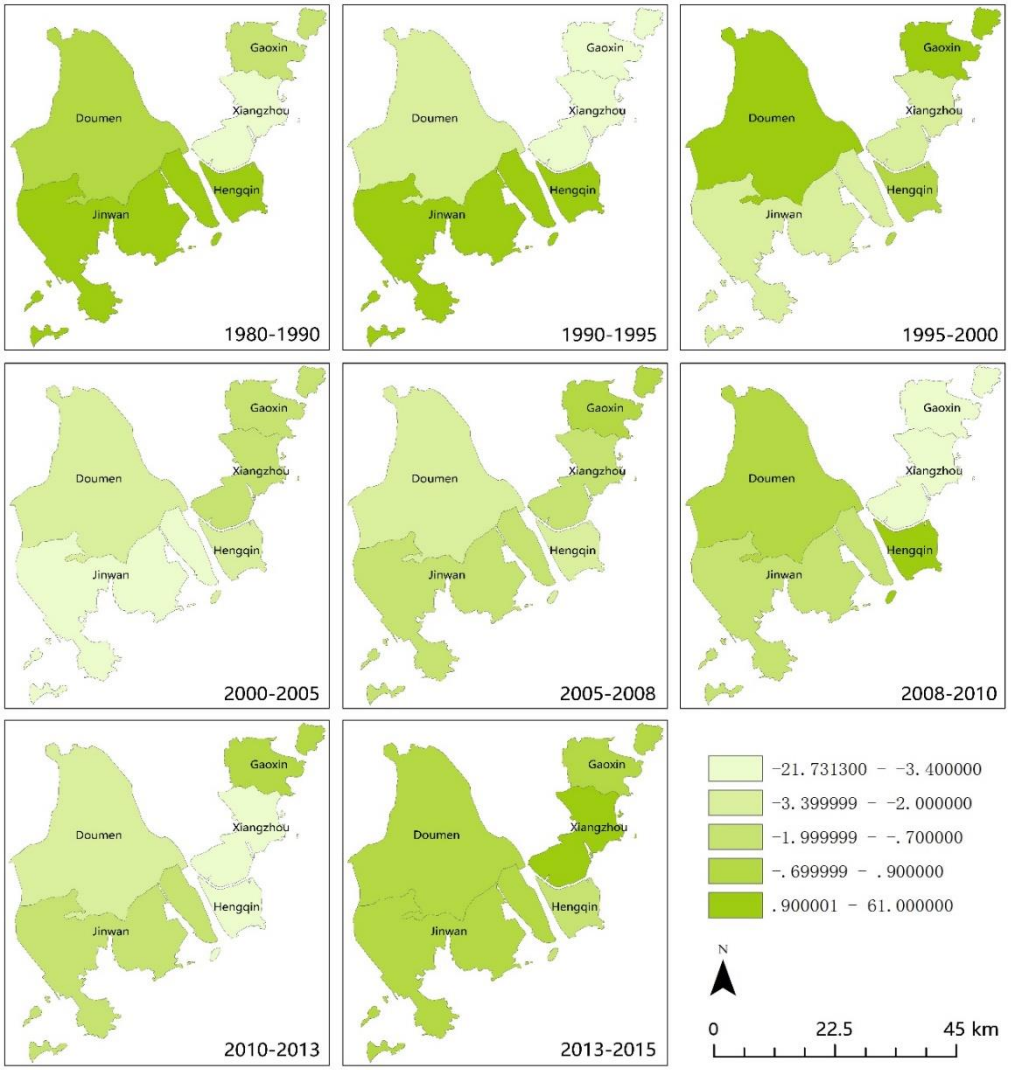

Figure 6. *Annual loss rate of arable land in Zhuhai's five districts (1980–2015)*

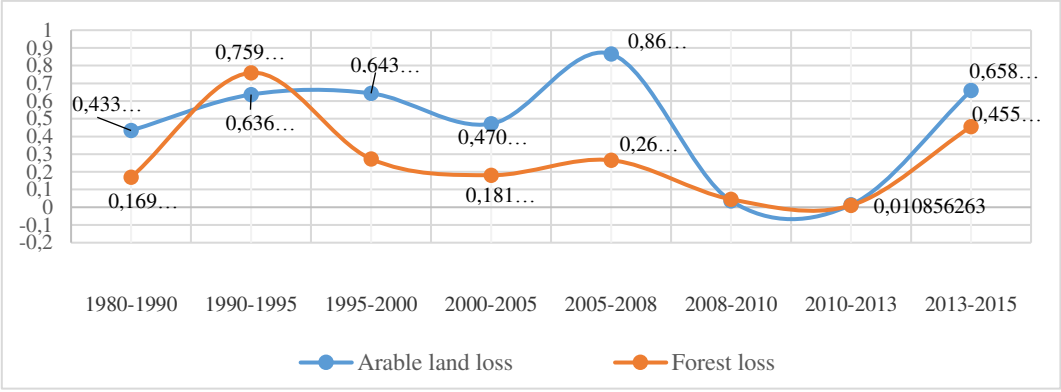

Figure 7. *The CV of arable land and forest loss throughout eight periods (1980-2015)*

To get a clearer picture of intra-urban sprawl patterns, sprawl typologies of eight periods in Zhuhai's five districts are explored (*Table 2*). Edge expansion has played a major role for 35 years and was mainly distributed across former centres of Doumen and Xiangzhou in the initial period. Outlying growth mainly took place in the Jinwan District and surpassed edge expansion in the early 1990s. Though much lesser than the other two types, infill growth was significant from 1995 to 2000, 2000 to 2005 and 2010 to 2013. In addition, this growth occasionally occurred in the Gaoxin District before 2005. Sprawl in Hengqin gained speed in 2010 with edge expansion and outlying growth representing the main types. Three typological sprawls stabilised from 1995 to 2010. Between 1995 and 2000, the growth amount decreased to 28.30 km^2 with the outlying growth suddenly dropping to 5.47 km^2 and hardly increasing in large numbers afterwards. Between 2000 and 2005, the sprawl area fairly reached 34.1 km^2 in which edge expansion and infill growth made up certain vacant spaces along Zhuhai Avenue. From 2005 to 2008, westward sprawl increased with edge sprawl continued completing the main transport corridor. The outlying growth and infill growth supplemented the sprawl but did not take the main role. The subsequent sprawl from 2010 to 2013 and from 2013 to 2015 experienced a downward trend. The edge expansion continued to drop, but the outlying growth became substantial, especially in Hengqin.

The imbalance of infill growth reached its peak (2013–2015) with a CV of 2.24 (*Fig. 8*). The CV of outlying growth fluctuated the most before 2010 and became the most uneven from 1990 to 1995 with a CV of 1.93 and from 2005 to 2008 with a CV of 1.46. Overall, edge expansion is the least imbalanced growth type and reached its minimum from 2010 to 2013 with a CV of 0.42. The extent of variability of total sprawl generally accords with that of edge expansion.

Discussion

Environmental policies/discourses regulating sprawl rates and typologies

The Zhuhai's remarkable growth and 35-year sprawl is only half of Guangzhou's growth (from 1978 to 2005) and less than 35% of Shenzhen's (from 1980 to 2010). Loss of arable land is particularly striking in Shenzhen, shrinking from 354.73 km^2 in 1979 to 39.77 km^2 in 2015 and decreasing to 88.8% in the same period (Li et al., 2004). Most of Shenzhen's arable land designated for vegetable use became polluted and surrounded by urban areas. The relatively smaller sprawl in Zhuhai is due to its pro-environmental policies/discourses. Zhuhai was prudent in the early 1980s, when numerous PRD cities prioritised industrialisation as their development strategy for economic growth. Balancing the economy and the environment was central to Zhuhai's early development pathway. Having labelled itself as a coastal garden city and favouring tourism as its key industry for development, Zhuhai did not jeopardise its ecological environment. Suppressing industrial development to retain the city's environmental quality and beautiful landscape affected Zhuhai's economy. This phenomenon was reflected not only in the smaller expansion area of its urban land but also in its slower economic growth than its counterparts, such as Shenzhen. Zhuhai's average GDP growth rate was only 20% of Shenzhen from 1979 to 1984. Similar to Shenzhen, Zhuhai put industrialisation as part of its agenda since 1984 to address the economic backwardness. Zhuhai's GDP began to accelerate, and more than 3,000 cooperative firms were set up. In this period, Zhuhai's urban growth ran into a fast track, and its urban construction land experienced an upsurge until the early 1990s. Similar to other cities in the PRD, Zhuhai's industrialisation had low technology and was labour-intensive, which led to environmental degradation. Manufacturing firms sprouted and contaminated the soil, water and air. Land reclamation between the 1980s and the early 1990s also reached its peak (*Fig. 3*). Most of the reclaimed land was used for agricultural purposes, such as paddy fields, fishponds and cropland, to support local industrial development. These early large-scale reclamation projects were approved by the Ministry of Water Resources, but none of them obtained a permit for ocean use from the State Oceanic Administration nor evaluated environmental and ecological effects. This scenario threatened local ecological sustainability. A series of environmental regulations, such as the Eight Prohibitions for Environmental Protection, legislated in 1992, were legitimised. This legislation proposed numerous

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_913927

prohibitions to improve the quality of the natural environment. For instance, buildings that exceeded 25 m above the hillside, less than 30 m approaching the riverbank or 50 m along the estuary bank were prohibited. Noise higher than 45 decibels was also forbidden to nurture a quiet and peaceful environment. Other regulations were made available to control pollution and carbon emission. This pro-environment mentality slowed Zhuhai's expansion rate. From 1995 to 2000, the expanded urban construction land area was 42.3%, and from 1990 to 1995, the outlying growth declined. In Zhuhai's pursuit of a garden city, the city followed the policies of Singapore, a world renowned model for learning environment-friendly initiatives such as vegetation planting (Orff, 2001). Adopting these practices were important to strengthen the role of Zhuhai as an ecologically sustainable pioneer in PRD. The idea of an eco-city protected urban landscapes and environments. It also transformed Zhuhai into a liveable garden city. Zhuhai's economy was overshadowed by Shenzhen and Guangzhou, but Zhuhai's pleasant environment showcased its achievements in eco-city building and were in favour of the city's long-term sustainability.

High-tech industrial development was integrated into Zhuhai's pro-environment strategy, in which eco-sustainability and urban growth became interdependent. Zhuhai was a fishing village with a weak technological foundation; it started to develop as a high-tech city in the early 1990s. The local government invested over one billion yuan to build Zhuhai University Town to attract science and technology talents. The college students and talents played a large role in Zhuhai's high-tech development, especially in the growth of industrial parks. Built in 1992, the Zhuhai National High-Tech Industrial Development Zone expanded in 1999, nurtured several high-tech firms and generated considerable output values. High-tech city development balanced economic growth and ecological sustainability. This development also played a positive role in the sustainable development of Zhuhai.

Ecological landscape steering sprawl balance and typologies

The ecological landscape of Zhuhai is significant to determine the typologies and (im)balance of urban land sprawl. Zhuhai's distinctive mountainous terrain fosters initial sprawl surrounding the boundary of mountains and hills. From 1980 to 1990, urban land around the Fenghuang and Banzhang mountains in the Xiangzhou District expanded prominently and was mainly characterised by edge expansion. In the Doumen District, areas along the Huangyang mountains were urbanised mostly with edge expansion as the main form supplemented by infill growth. Some sporadic expansion took place around other small hills, and the mountain-oriented expansion persisted until the early 2000s. Zhuhai grew in harmony with its natural surroundings and captured the idea of an eco-city. Thus, Zhuhai strategically selected eco-city as its development model. Unlike numerous Chinese cities, Zhuhai did not destroy mountains for expansion. Its sprawl is fast and rational. Given that Xiangzhou and Doumen county centres were naturally developed around green mountains, this type of infill growth also emerged occasionally in matured built-up areas. This scenario was particularly evident from 1990 to 2000.

The coastal landscape enriches Zhuhai's sprawl, and this land reclamation has lasted until today. Reclamation creates new land over oceans, riverbeds or lakebeds. As a key mechanism accommodating urban growth, reclamation is popular in many harbour cities (Ng, 2011). Zhuhai has been reclaiming land for years and remains keen on expanding over the waters. Most of the reclamation took has taken place in Jinwan District and Hengqin Island. Coastal reclamation in the first decade was tremendous, with 108.4 km^2

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_913927

area having been infilled. However, a considerable proportion of the reclamation was not for urban growth but for agricultural use, thus aligning with Zhuhai's policies for sustainability in its early reform period. These reclamation activities result from an integrated thinking toward ecology and socioeconomic development, maximising the benefits that can be brought to local development and minimising the damage to local sustainability. In the early 1990s, Hengqin was recognised as one of the four key development zones by the Guangdong provincial government, for which the land area almost doubled by reclamation. This change has propped up the upscaling of Hengqin as a national new area. In 2013, the State Council approved to reclaim an approximately 20-km^2 seaside land area in Jinwan, creating new land for competitive industrial development, such as a yacht base and for the aviation industry. In 2015, the adjustment of the Hengqin Ocean Functional and Reclamation Plan was approved, granting 27.9 km^2 more reclamation quotas in South Hengqin. This reclamation largely resolved the land resource constraints for free trade zone. Given the negative ecological impacts, the municipal government launched several rounds of environmental evaluation before project delivery to mitigate its adverse effects on nature. Harbour reclamation was part of Zhuhai's marine urban economic strategy. However, the cost and benefits of its reclamation are difficult to determine. Moreover, the ecological consequences of the reclamation also prompted substantial concerns from experts, scholars and officials. Large-scale reclamation is detrimental to sustainability in the long run and should best be practiced with caution in the future.

Geolocation is also influential. Similar to Shenzhen bordering Hong Kong, Zhuhai is close to Macau. However, Macau is not as competitive as Hong Kong; its tiny economic scale hardly benefits Zhuhai. This circumstance partly explains why Zhuhai did not follow Shenzhen's targeted strategy for industrialisation and why the city turned to eco-city development. Nevertheless, this difference did not prevent Zhuhai's cross-border land sprawl. From 1980 to 1990, Zhuhai started its urban land sprawl near Macau, mainly in the form of edge expansion supplemented by outlying growth. In all the increased 48.79 km^2 area in the first decade, more than 29 km^2 was in Xiangzhou District, which borders Macau. Land sprawl in Hengqin also benefitted from Zhuhai's cross-border location. In the early stage, Hengqin grew extremely slowly but cross-border vantage helped this area gain particular attention from the central government. In 2009, Hengqin was upgraded to a national new area, and its growth reached a peak of 4.62 km^2 from 2010 to 2013 and 2.41 km^2 in a short period between 2013 and 2015.

Conclusion

In deploying technical tools of remote sensing and GIS, this article investigates the general change of urban built-up area in the hinterlands and reclamation in the coast of Zhuhai, an ordinary large city in China's PRD region. It unravels spatiotemporal characteristics of urban land sprawl and discusses how the land of Zhuhai evolves under citywide pro-environment policies/discourses. The results corroborate that Zhuhai's urban land has expanded 1.06% annually for the past 35 years. Furthermore, the sudden growth of urban built-up area in total and per capita in 1995 (*Fig. 2*) was interpretable from local, regional, and national levels. At the local level, Zhuhai airport was officially built into navigation. As most advanced and modern airports at that time, Zhuhai airport not only racked up air passage between the city and other parts of China but also drove local construction profoundly. At the regional level, industrial investment from Hong

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_913927

Kong to PRD reached 25.2 billion HKD in 1995, leading to massive industrialisation in PRD. Regional urbanisation driven by this type of industrialisation has brought considerable growth opportunities for cities in PRD. At the national level, the number of cities experienced a surge from 193 in 1978 to 622 in 1994. With the huge influx of rural immigrants, urban population reached 343 million in 1994 and imposed an urgent demand for urban construction. The urban sprawl slowed down in the last five years of the 1990s and accelerated again in the 2000s with the construction of new towns in the Western part of the city. The rate slowed down from 2008 to 2010 but accelerated again from 2010 to 2013 with the promotion of Hengqin to a national new area in 2009. The findings of Zhuhai's three typologies of sprawl confirm the following information. Firstly, edge expansion has dominated each period and is prominent along the boundary of mountains and hills. Secondly, enclave development zones and new towns contribute to outlying growth. Thirdly, infill, as a supplement, mainly appears in well-developed city centres and is less common than the other two. The rate and intensity of three typologies have varied over time.

This study contributes to the understanding of urban sprawl in high density, rail transit-oriented area beyond the 'American model' and provides a view on a modest growing city. Different from U.S. metropolitan areas or China's mega-/super-cities where rates of outlying or expansion are less significant (than infill) or even negative (Hamidi and Ewing, 2014; Li and Li, 2019), Zhuhai's sprawl remains dominated by edge expansion with infill playing a negligible role. It also offers a clearer picture of urban land sprawl inside a city. The growth of urban built-up areas is uneven inside Zhuhai. Outlying was most uneven from 1990 to 1995 with a CV of 1.93 The unbalance of infill reached its peak recently (2013–2015) with a CV of 2.24. Edge expansion is the least unbalanced typology reaching the minimum of 0.42 CV from 2010 to 2013. The CV of arable land loss was higher and fluctuated greater than that of forest loss. The unbalance of arable land loss reached a peak from 2005 to 2008 with a CV of 0.87. In addition, extent of intra-urban land sprawl imbalance significantly fluctuates because local urban sprawl is sensitive to policy makings from local political leaders who are frequently reposted under China's floating cadre appointment system (He et al., 2018). Leaders of each tenure are likely to propose new potential areas, leading to great variability of urban sprawl inside the city. This city-level pattern is distinct from the macro-level one that regional differences (among the east, west, central, and northeast) have long been well-noted and that the backward west region has long sprawled more extensive than the developed east.

Furthermore, Zhuhai's growth amount is not as resplendent as that in star cities, such as Shenzhen and Guangzhou. From 1980 to 2015, the expanded urban area in Zhuhai was only one-third of that in Shenzhen and half of that in Guangzhou. This prudential growth has prevented Zhuhai's natural ambience from damage and has led the city to embrace a sustainable garden city ideology. Without sacrificing the environment, Zhuhai has gained several awards nationally and internationally for its ecological merits since 1997. Furthermore, its specific sprawl trajectory sheds some light on policy implications. Firstly, a pro-environment policy may reconcile contradictions between ecological environment and urban growth. It distinguishes cities with ecological merits from others. Secondly, environmental policy suppresses urban land growth to preserve high-quality environments for sustainable long-term development, thereby reaching a compromise between environmental sustainability and urban land growth. Thirdly, growth typology, despite circumstantial differences, conforms with environmental development in which natural mountains, rivers, and harbours are of utmost respected. Zhuhai did not stagnate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_913927

but developed at a slow pace, which brought the city's natural environment into play. This study argues to conduct more in-depth case studies to enrich the understanding of intra-urban sprawl patterns, especially those invisible land sprawl, in small to medium sized cities and relate local policy and politics with the interpretations of sprawl patterns. Future research can also benefit from quantifying conversion between urban built-up area and other land uses so that the sources of sprawl can be tracked and monitored.

Abstract. Injection of methanol as a thermodynamic inhibitor is a common approach in the petroleum industry. Due to the volatility and recovery process of methanol, it could be found in natural waters, sediments, soil, and so on. This study focused on adsorption and degradation behavior of methanol in produced water （PW） at northern Shaanxi oil and gas fields soil, China. Through dynamic tests, the results showed that the pH, gas condensate, salinity of PW and temperature have weak influences on methanol adsorption on the soil. Through the simulated degradation experiments, the chemical oxidation, photo and thermal degradation were found not to be the main mechanism of methanol degradation (MD) in nature. The methanol in some soil could not de degraded completely by Nitrate-reducing bacteria (NRB) in the soil within 60 days unless methanol content was less than 600 mg/L with NRB medium. The Griess detection verified that there were NRB in five soils. Even without the NRB medium, there are great differences in MD of the soils. If the concentration of methanol was more than 1000 mg/L, the MD efficiencies were obviously slowing down, nearly 0. The longer the gas development time of the study region, the stronger the MD ability of the region's soil.

Keywords: *methanol, adsorption, degradation, sandy soil, Nitrate-reducing bacteria (NRB)*

Introduction

In economic and safety hazards points of view, it is crucial to avoid the formation of clathrate hydrate of gases in oil and natural gas transportation/production systems (Muromachi, 2019). Injection of methanol as a thermodynamic inhibitor is a common approach in industry to shift the hydrate phase boundary to higher pressures/lower temperatures. Because of its high volatility, methanol is lost in the vapor phase, which lead its toxicity to the environment and human beings (Aziz et al., 2002). Although methanol in aqueous solution was generally treated by biological treatment and advanced oxidation processes (AOPs), in which the most

DOI: http://dx.doi.org/10.15666/aeer/1801_929942

commonly used approaches were the up flow anaerobic sludge bed (UASB), supercritical water oxidation (SCWO), bio-filtration and plasma degradation (Ma et al., 2009, 2013; Fujii et al., 2011; Barcón et al., 2012; Zhen et al., 2017; Wu et al., 2019), but few studies focused on adsorption and degradation behavior of the methanol in produced water (PW) in the soil. The northern Shaanxi oil and gas fields is located in Ordos plateau (Semi-arid region), China. The surface layer of the soil is the quaternary aeolian sandy soil or brown desert soil, among which aeolian sandy soil is in the majority. Because of the special soil composition, the methanol will show special adsorption and degradation behavior in the soil. Through temperature oscillation dynamic tests and the simulated degradation of methanol in the five kinds of typical soil, the behavior of adsorption and degradation have been discussed, which lead to a better understanding of the influence of methanol on the north Shaanxi gas field environment.

Material and Method

Soil Sample collection and pre-treatment

The five kinds of soil samples were collected from five different sites located in Northern Shaanxi gas field, respectively is Jingbian gas field (1#), Jingbian farmland (2#), Zizhou gas field (3#), Zizhou farmland (4#) and Wuding river (5#) in Mizhi county, Yunlin city. The map of study area were showed as in *Fig. 1*. The surface layer is the quaternary aeolian sandy soil or brown desert soil, among which aeolian sandy soil is in the majority (Ma et al., 2013). The sampling date was April to May, 2018. The sampling depth is 0 ~ 20 cm. After the soil sample is naturally dried, ground and sifted with a 2 mm sifter, then stored in five bottles at low temperature.

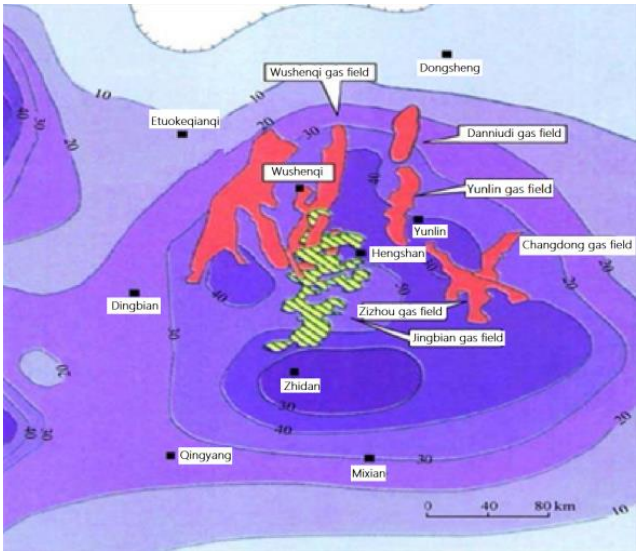

Figure 1. *The map of study area*

Measurement of soil parameters

The physiochemical analysis (pH, moisture, organic matter content and mass size distribution) of five samples was respectively refer to "Soil dry matter and moisture determination - gravimetric method" (HJ 613-2011), "Soil test part II: determination of pH" (NY/T 1121.1 – 2006), "Determination of forest soil organic matter and calculation

DOI: http://dx.doi.org/10.15666/aeer/1801_929942

of carbon - nitrogen ratio" (LY/T 1237 – 1999) and the Wu's method (Ghasemy et al., 2019).

Adsorption test

Adsorption of methanol in different soils

Due to the strong adsorption capacity of bentonite and activated carbon, these two materials were selected as the experimental reference in order to facilitate the study of the adsorption capacity of methanol in five soil samples. The seven samples were taken respectively in the experiment and 20.00 g were put into a 250 mL glass bottle, and 100 mL methanol concentration of 1000 mg/L solution with 10000 mg/L salinity and a certain amount of microbial inhibitors were added. Then, the sealed 250 mL bottle were settled in the thermostatic oscillator (TS-200B, Shanghai Tiancheng co. LTD) under the condition of 25℃ for 24 h, later transferred to the soil suspension in the centrifuge tube at 4000 r/min centrifuge for 10 min after taking centrifugal supernatant on 2 mL for methanol concentration. The concentrations of methanol was determined by gas chromatography (Agilent HP 6890). A packed column (Agilent Porapak N G3591-80036) was used. The retention time of methanol was 5.652 min (Ma et al., 2013). The adsorption capacity and samples site were compared, and 3# was selected as the representative for future research.

Adsorption equilibrium and isotherm of methanol in soil

In Adsorption equilibrium test, the 2 mL supernatant was samples after 0.5, 1, 2, 4, 6, 8, 10, 12, 24 h. In Adsorption isotherm test, the methanol concentration, respectively is 0, 20, 40, 60, 80, 100, 200, 500 and 1000 mg/L. Other test conditions are consistent with conditions detailed above.

Affecting factors of methanol adsorption in soil

The range of PW pH , temperature, gas condensate, salinity were according to the quality of gas PW from Northern Shaanxi gas field (The quality of gas PW from North Shaanxi gas field had analyzed by our lab in the past 10 years). Other test conditions are consistent with conditions detailed above.

Degradation behavior of Methanol in soils

Physicochemical factors on degradation of methanol in different simulation conditions

When the gas PW with methanol is treated and injected back into the stratum, it will directly or indirectly enter the soil environment because of evaporation and leakage. According to the possible factors affecting degradation of methanol in the possible environment, ammonium persulfate and hydrogen peroxide (used as oil-field chemicals), high temperature and pressure (reinjection into some formations), strong ultraviolet (direct splar radiation) were selected to make a series of simulation experiments to study the degradation degree of methanol in gas PW under different conditions. A temperature and pressure reactor (Parr 4578, Parr instrument company, USA) was used to stimulate the condition of reinjection formation (200℃ and 15 MPa). The 50 g core powder was added into the reactor, and the methanol equilibrium concentration after 12 hours adsorption in core powder was the baseline concentration for degradation. A UV light (80W, Xinbao Environmental Products Co., Ltd., CHN) was used to stimulate rapid splar

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_929942

radiation. The source of radiation was located 25 cm from samples and positioned horizontally. All solution is 1 L and 1000 mg/L methanol, and other experimental temperature is 25℃ unless it is specifically requested.

Stimulated degradation experiment in different soils

Nitrate reducing bacteria (NRB) are very common in nature, most of which are facultative. When methanol (CH_3OH) is used as the carbon source in wastewater treatment, the reaction formula for synthesis of exogenous denitrifying cells was shown in *Eq.1* (Ma and Wei, 2009).

$$NO_3^- + 1.08CH_3OH + 0.24H_2CO_3 \rightarrow 0.06C_5H_7NO_2 + 0.47N_2 + 1.68H_2O + CO_2 + OH^- \quad \text{(Eq.1)}$$

According to the above theory, if methanol is degraded by NRB in nature, the degradation rate would increase. Therefore, the difference between with or without the medium of NRB (M_{NRB}) was compared in different salinity water with different methanol concentration under 25℃ and the proportion of 1# soil to methanol (20%) after 60 days. *Table 1* is the composition of M_{NRB}.

Table 1. *The composition of M_{NRB}*

Composition	KH_2PO_4	$KHCO_3$	$MgSO_4$	$FeCl_3$	$CaCl_2$	CH_3COONa	$(NH_4)_2SO_4$	$NaNO_3$
Concentration (mg/L)	30	500	200	100	30	860	660	850

According above studies, the different soils was respectively soaked in the simulated water containing 200 ~ 2200 mg/L methanol (salinity: 100000 mg/L) for 120 d with the proportion of the soils to methanol (20%). In order to verify the effect of NRB, NRB was enriched, separated and screened form five soils samples, respectively. Two strains in every solid mediums plate were selected, which grow faster, colony moist, roundness, surface smooth, edge tidy, bulging and larger colonies. After many times of separation and purification, a strain was selected out of every two in the soil, which were 1S#, 2S#, 3S#, 4S# and 5S# strain. The five strains of bacteria were tested with Griess reagent (García-Robledo et al., 2014).

Each experiment was performed three times, and the average value is calculated by three parallel experiments.

Results and discussions

Physiochemical analysis results of five samples

The physiochemical analysis results of five samples were shown in *Table 2*. The minimum moisture of five soils was 0.30% (w/w) while the maximum is 1.45% (w/w). The pH values of the tested soil samples were all around 8.0 ~ 9.0, belonging to weakly alkaline soil. The organic content of the tested soil samples was also relatively small, among which the organic matter content of 4# was the highest, 0.655% (w/w) and that of 1# was the lowest, 0.266%(w/w). All soils are sandy soil, except 4# soil is loam sandy soil, which would lead that it was easy for the methanol to infiltrate into the groundwater through them.

Adsorption of methanol in different soils

The results of methanol adsorption capacity (MAC) in different soils are shown in *Fig. 2*. The MAC in the five tested soil samples was significantly different from that of activated carbon and bentonite. The largest adsorption capacity of activated carbon was up to 2.38 mg/g, that of bentonite took second place, reached about 1.37 mg/g, and those of five soils are between 0.45 mg/g and 0.60 mg/g. Among five soils, the soil from Zizhou had higher adsorption capacity than those of other soils. The reasons should be that the soil from Zizhou has higher organic content which lead to higher adsorption capacity. The experimental results are consistent with the characteristics of small activated carbon/bentonite particles, large specific surface area of particles and large adsorption capacity. Therefore, it can be concluded that the five soils have a certain adsorption capacity for methanol, but the adsorption amount is relatively small. All that also should lead that most of methanol could infiltrate into groundwater through them easily and not be degraded in the soils.

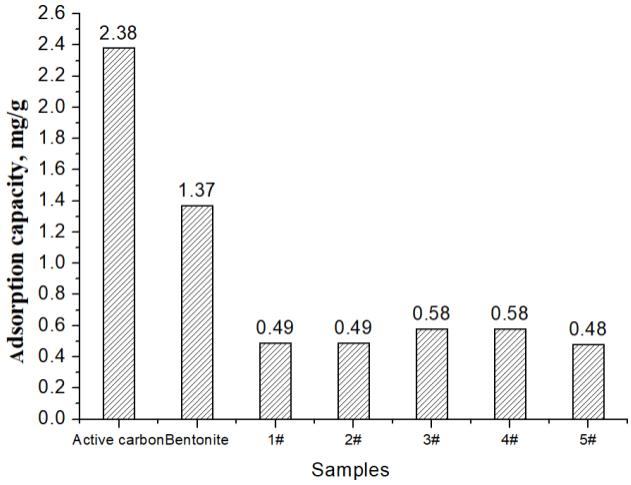

Figure 2. *MAC in different samples and soils*

Adsorption equilibrium and isotherm of methanol in soil

The adsorption equilibrium curve and isotherm curve of methanol in 3# soil respectively was shown in *Fig. 3* and *Fig. 4*.

From *Fig. 3*, when the adsorption time was less than 10 h, the adsorption capacity of methanol in the 3# soil increased rapidly, but when the adsorption time was more than

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_929942

10 h, the adsorption capacity tended to be stable, and the maximum adsorption amount was about 0.55 mg/g. This reason is that the opportunity for the soil to fully contact methanol increases with the gradual extension of time, and the amount of methanol adsorption in the soil increases. From *Fig. 4*, when the methanol concentration is samller than 200 mg/L, the adsorption capacity increases sharply with the increase of methanol concentration. When the methanol concentration is higher than 200 mg/L, the adsorption capacity tends to be balanced, about 0.5 mg/g, which indicated that the adsorption capacity of methanol in the soil had reached a saturated state.

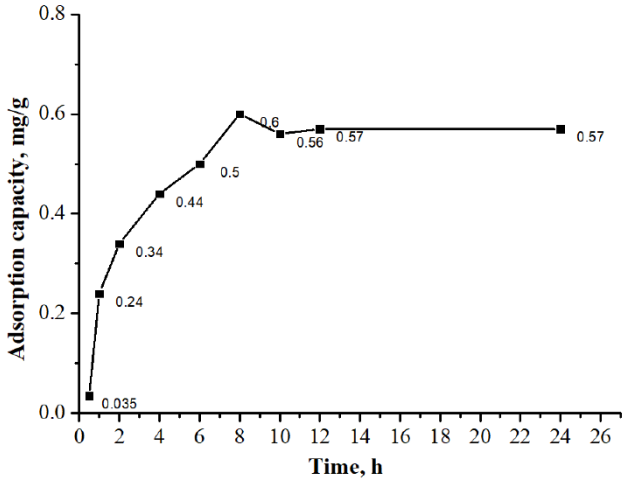

Figure 3. *Adsorption equilibrium curve of methanol in 3# soil*

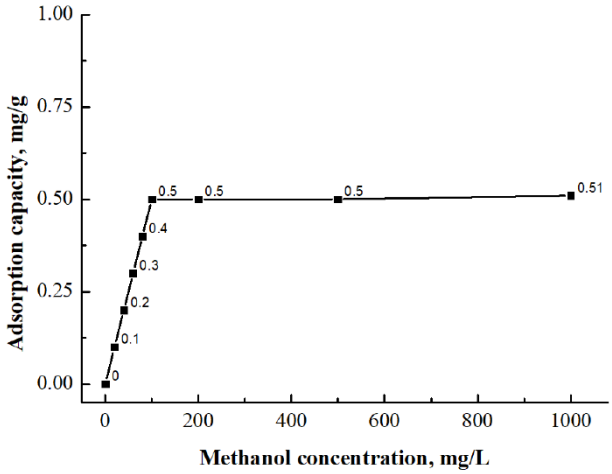

Figure 4. *Isotherm curve of methanol in 3# soil*

Affecting factors of methanol adsorption in soil

pH values

The influence of different pH values on the methanol adsorption amount (MAA) was shown in *Fig. 5*. As can be seen from *Fig. 5*, with the increase of pH value of solution, the MAAin soil gradually decreases from 0.458 mg/g to 0.007 mg/g. In the alkaline environment, the sediments and organic matter in the soil may undergo flocculation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_929942

changes, leading to the fact that methanol molecules cannot be uniformly adsorbed on the soil sediments and organic matter (Viotti et al., 2000). Lopez et al. (1996) believe that at low pH, strong hydrogen bonds are formed between organic pollutants and O, N, and H atoms in some materials in the soil, but they are completely different under alkaline conditions, and the resistance to hydrogen bond formation increases, leading to hydrogen bond dissociation. Some scholars also reached the conclusion that the adsorption amount of an organic compound in alkaline soil was low, while that in acidic soil was high (Ertli and Marton, 2004; Goh and Lim, 2004). With the increase of pH value, the increase of OH^{-1} content on the surface of soil particles leads to the increase of electrostatic repulsion force, the decrease of charge density on the surface of soil, and the decrease of adsorption force on the surface of soil particles. The pH value is an important factor affecting the variable charge, and the change of pH value has an important impact on the electrostatic adsorption of anions. With the decrease of pH value, the positive charge increases, and the amount of electrostatic adsorption of anions increases. In the case of pH > 7, even the variable charge soil with kaolinite and iron and aluminum oxides as the main colloidal substances has a relatively low electrostatic adsorption capacity of anions (Zhang, 2009).

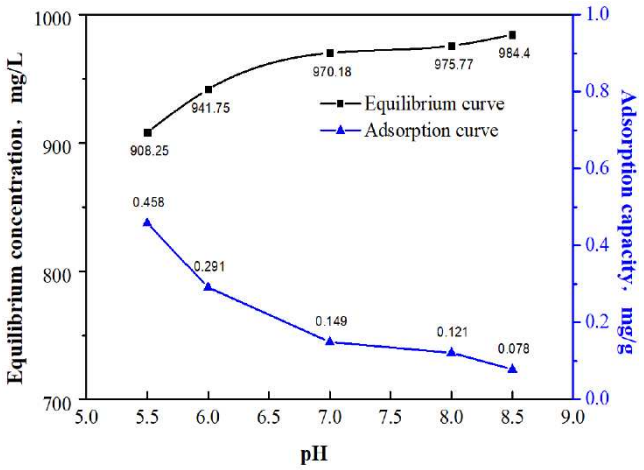

Figure 5. *Influence of different pH values on the MAA in 3# soil*

Salinity

The effects of water quality with different salinity on the adsorption of methanol in soil was shown in *Fig. 6*.

The MAA in soil increases from 0.373 mg/g to 0.487 mg/g with the increase of salinity in solution from 0 mg/L to 100000 mg/L. This was due to the adsorption coefficient (*Kp*) is defined as follows *Eq.2* (Pena et al., 2019):

$$K_p = \frac{\text{Adsorption capacity of organic compounds in the solid phase, mg/g}}{\text{dissolved amount of organic matter in aqueous solution, mg/L}} \quad \text{(Eq.2)}$$

From *Eq.2*, the *Kp* is related to the adsorption amount in solid phase and the solubility of organic matter in water phase. With the increase of salinity in soil solution, the solubility of organic matter in water decreases, which is mainly due to the influence of "salting out". Salting out, in which salts are added to an aqueous solution of a substance, results in a decrease in the solubility of the substance. In this experiment, the soil adsorption increased with the increase

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_929942

of salinity, indicating that methanol was affected by "salting out". Since "salting out" reduced the value in the denominator of the above equation, *Kp* value increased (Zhao et al., 2000). The lower the solubility, the higher the solid adsorption. The adsorption capacity is closely related to the hydrophilicity of the adsorbed substance. Although salinity cannot change the nature of the adsorbed substance in the soil, it does change its solubility. Therefore, it is basically the same as increasing its hydrophobic effect, so the solid phase adsorption increases. It can be seen from the above analysis that the adsorption of pollutants by salinity mainly affects the solubility of pollutants (Gennadiev et al., 2015).

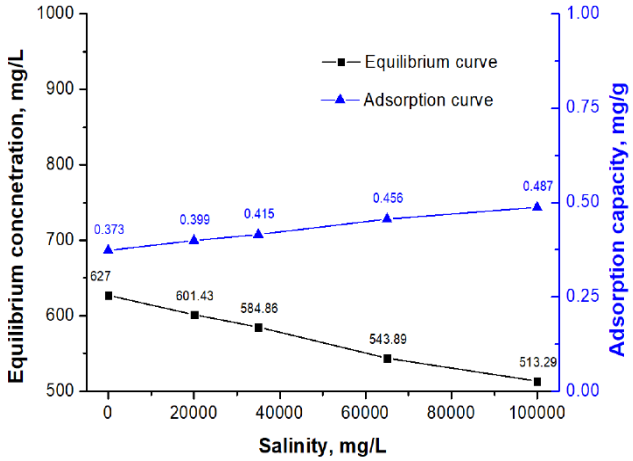

Figure 6. *Influence of different salinity on the methanol adsorption amount in 3# soil*

Condensate oil

The effect of condensate oil content on the methanol adsorption in soil was shown in *Fig. 7*.

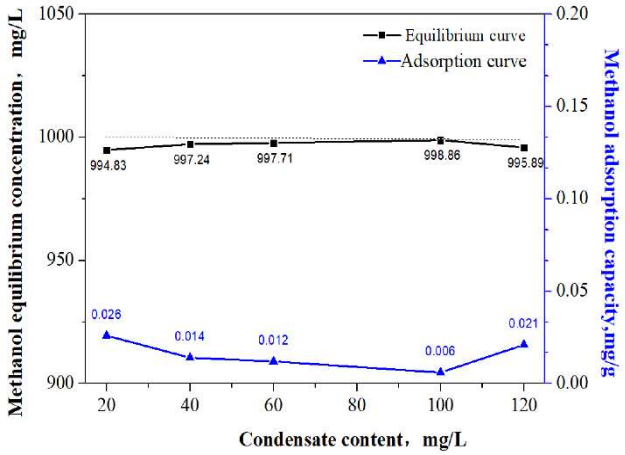

Figure 7. *Effect of condensate oil content on the methanol adsorption in 3# soil*

With the increase of the condensate concentration, the equilibrium concentration of methanol in the soil did not change much, between 994.83 mg/L and 995.89 mg/L, indicating that the condensate could not be adsorbed by the sediments or organic matters

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_929942

in the soil after entering the soil environment. Some scholars also found similar phenomena in soil-water system (Jonker et al., 2003, 2006). They called the minimum concentration of oil in sediments or soil in independent form as critical sperate phase concentration (CSPC), and pointed out that this concentration was related to organic matter content. Generally, the higher the organic matter content is, the higher the CSPC is, which is 11% (Khan et al., 2018) or 15% (Li et al., 2019) of the soil organic carbon content. The soil organic matter content of 3# sandy soil is 0.41%, which should be 1100 or 1500 mg/kg according to the theoretical value of CSPC in previous studies. The practical significance of CSPC is that when the condensate oil concentration in the soil is greater than this value, the condensate oil can exist in the soil in the form of free state (independent phase), as a "adsorbent" to enhance the overall adsorption (distribution) ability of the soil to other organic pollutants. When the value is less than that, the condensate oil is absorbed by the soil organic matter in the form of "adsorbent", which may compete with other organic pollutants for the adsorption position on the organic matter. In the study of Jonker et al. (2003, 2006) this competitive adsorption was more obvious.

Temperature

The influence of environmental temperature on the MAA in the soil was shown in *Fig. 8*. With the increase of temperature from 10 ℃ to 35℃ , the MAA in the soil also increases obviously (from 0.330 mg/g to 0.975 mg/g) when the temperature was below 35℃. When the temperature rises to 35℃, the adsorption curve begins to be smooth, methanol adsorption capacity is essentially unchanged. It indicates that the adsorption reaction rate of methanol in soil increases with the increase of temperature. When the adsorption capacity of methanol in soil reaches a balance, the MAA in soil does not increase, indicating that the adsorption of methanol in soil is an endothermic process. Li et al. (2019) believed that soil adsorption is a kind of biphasic adsorption, and mineral as a traditional solid adsorbent, organic matter as a distribution medium. As the temperature rises, water molecules are more affected by molecules than organics, and the relative adsorption competitiveness of organic matters increases, and the adsorption capacity on the mineral surface increases (Pena et al., 2019).

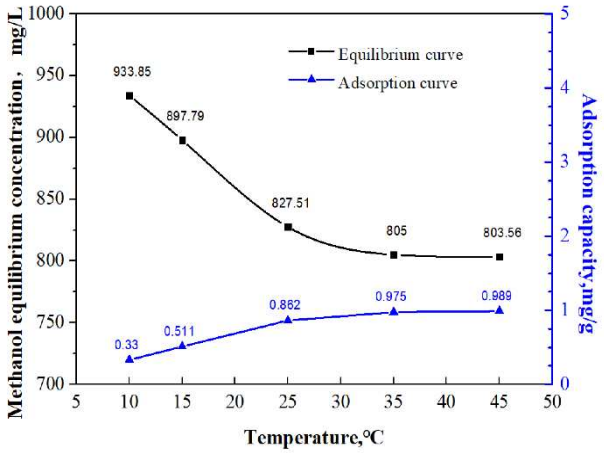

Figure 8. *Influence of environmental temperature on the MAA in 3# soil*

Degradation behavior of methanol in soils

Physicochemical factors on degradation of methanol in different simulation conditions

Degradation degree of methanol in different simulated extreme environment was shown in *Table 3*. The degradation efficiency (η) of methanol in extreme environment (200℃, 15 Mpa) after 30 days was only 10.18%. The *η* of strong ultraviolet radiation and the chemical oxidation were 23.94%, 21.69% and 11.84%, respectively. The radiation intensity and the concentration of chemical oxidant were usually more than their value in nature. The results showed that among the factors on degradation of organic matter in nature, the physicochemical factors, such as thermal degradation relying solely on temperature, chemical oxidation degradation and photo-degradation could not be found the main factors of methanol degradation (MD).

Table 3. *Degradation degree of methanol in different simulated environment*

Simulated extreme environment (200℃, 15 MPa)			**Strong ultraviolet radiation (Power: 80W)**			**Chemical oxidation (Reaction time: 30 min)**			
Reaction time (day)	Concentration (mg/L)	η (%)	Reaction time (h)	Concentration (mg/L)	η (%)	Reaction dosage (mg/L)		Concentration (mg/L)	η (%)

Nitrate reducing bacteria influence on methanol degradation

NRB influence on (MD) in 1# soil was shown in *Fig. 9*. Obviously, the ability to degrade methanol of 1# soil with M_{NRB} was much higher than that of 1# soil without M_{NRB}, up more than 50%, which indicated that NRB could significantly promoted the degradation methanol ability of the soil.

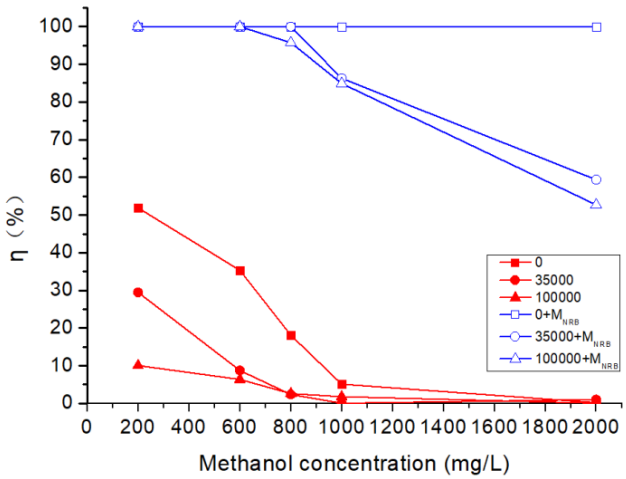

Figure 9. *NRB influence on MD in 1# soil (60 days)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_929942

In the presence of M_{NRB}, methanol concentration in fresh water was less than 2000 mg/L, the methanol can be completely degraded in 1# soil. In the absence of M_{NRB}, methanol cannot be completely degraded within the range of 200 ~ 2000 mg/L, the highest η was only 51.9% and the lowest one was 0.07%, nearly 0. In the presence or absence of M_{NRB}, the degradation rate began to decline when the salinity increased, and the degradation rate decreased significantly when the methanol concentration was more than 1000 mg/L. The reason should be that both salt and methanol have inhibitory effect on soil microorganisms and affect the biodegradation of methanol.

Methanol degradation in different soils

MD efficiency in different soils was shown in *Fig. 10*.

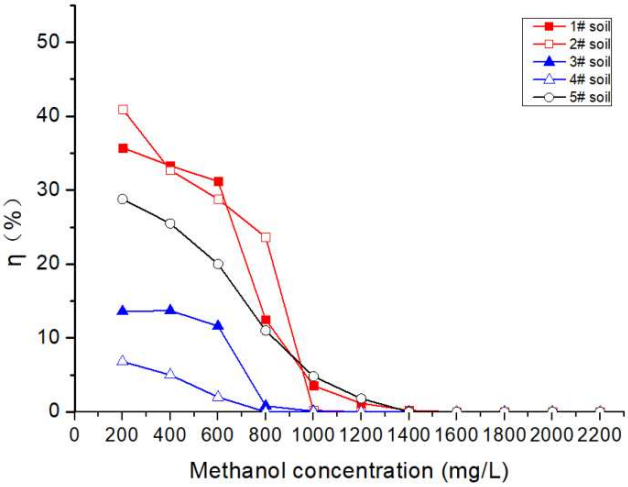

Figure 10. *Different MD in different soils (Salinity: 100000 mg/L, Without M_{NRB} and 120 days)*

When the salinity is 100000 mg/L in the absence of M_{NRB}, the degradation degree of methanol was obviously different when the initial concentrations were different. The highest η was 2# soil, 41.0%. The degradation rate decreased rapidly when the methanol concentration was greater than 1000 mg/L. The lowest one was nearly 0 when the methanol concentration is more than 1400 mg/L. There were great differences existing in degradation rate of different soil. The 1# and 2# soil from Jingbian had the best degradation ability of methanol, followed by the 5# from the Wuding river, the worst were that of 3# and 4# soils from Zizhou. The main reasons should be the Jingbian region had the longest history of developing gas, so it is the earliest blocks where the methanol was first used among the three regions. The microbes in Jiangbian surrounding soil has more superiority strains capable of degrading methanol. The 5# sediments was from Wuding river, so the microbial content in it was relatively high. Therefore, 3# soil and 4# soil had the lower degradation ability of methanol than other's.

The Griess detection result of five strains was showed in *Fig. 11*. Compared with the control, all the bacterial solutions immediately changed from colorless or pale yellow to red after the addition of Griess reagent, which indicated that all strains were NRB. Under the same culture conditions, the color of the reaction between strain 3S# and Griess reagent was lighter than that of other strains, while that of strains 1S# and 4S# was faster and darker. This may be related to the quantity of nitrate reductase and nitrite reductase

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_929942

produced by each strain. The higher the concentration of nitrate reductase and nitrite reductase in the bacterial solution, the deeper the color rendering, which indicated that the denitrification ability of each NRB is different (Ma and Wei, 2009). Compared with the degradation results, the denitrification ability of five NRB strains from five soils did not correspond to the MD capacity of five soils. The reason should be that the MD in the soil was not entirely dependent on NRB, but the NRB significantly promoted the degradation methanol ability of the soil.

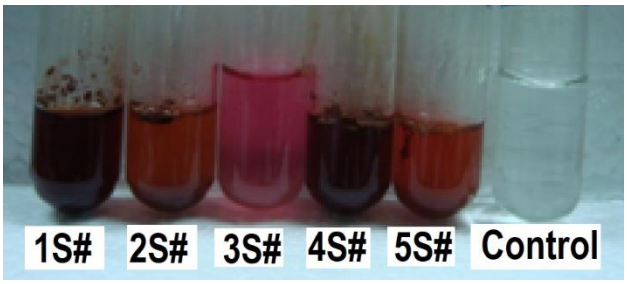

Figure 11. *Griess detection photo of five strains form five soils*

Conclusion

Five kinds of soils in the study region are sandy soil or loam sandy soil, and the MAA of them are relatively small, which would lead that the methanol to infiltrate into groundwater through them easily not be degraded in the soils. The pH, gas condensate, salinity of PW, temperature have the weak influences on methanol adsorption on the soil. Through the simulated degradation experiment of methanol, the chemical oxidation degradation, photo-degradation and thermal degradation are not the main mechanism of MD. But when the methanol comes into contact with the soil, the methanol in some soils could not de degraded completely by NRB in the soil within 60 days unless methanol content is less than 600 mg/L with NRB medium. The NRB significantly promoted the degradation methanol ability of the soil. Even without the NRB medium, there are large differences among the soils although five soils had the certain capability to degrade methanol. When the methanol content increase or the salinity of the water increased without M_{NRB}, the MD rate decreased. The Griess detection verified the there were NRB in five soil. The longer the gas developing time of the studying region, the stronger the methanol degrading ability of the region's soil. If the concentration was more than 1000 mg/L, the MD efficiencies were obviously slow after 120 days. Both salt and methanol have inhibitory effect on soil microorganisms and affect the biodegradation of methanol. The conclusion leaded to a better understanding of the influence of methanol on the north Shaanxi gas field environment, and suggested that the biodegradation of methanol in nature should be considered, especially NRB.

Abstract. Using aquatic plants to control nitrogen (N) and phosphorus (P) loads and restore eutrophic lakes has been put into practice since the 1980s. However, existing studies can hardly illustrate the law of N&P flow in water, aquatic plants and sediment during the growth of plants. In this study, three typical aquatic plants, two emerged plants and one submerged plant from Lake Gehu, China, were chosen to study the rule of N&P flow. The N&P contents and some related parameters in the water, sediment and plant samples were measured and the correlations between them were analyzed. The results show that the flow of N&P is generally controlled by the growth of plants, and N can flow directly between plants and sediment while P transfer is more significant in water and sediment. In emerged plants, 70-75% total nitrogen (TN) and over 50% total phosphorus (TP) is concentrated in leaves at early and medium stages of growth, and at the decline stage N&P transfer to roots. Results also show that reaping plants around August and purifying sediment after plants decay can make nutrient removal efficiency.
Keywords: *eutrophication, lakes restoration, nutrient removal, Lake Gehu, experimental study*

Introduction

Eutrophication has been a worldwide water pollution problem for decades. In the lower reaches of the Yangtze River basin, China, eutrophication has been affecting people's daily life. For example, algal bloom occured in Lake Taihu around the end of May and lasted for 2 months in 2007. It affected the nearby city Wuxi where more than 2 million people were short of drinking water (Guo, 2007). From 2011 to 2013, cyanobacteria have comprised over 99% of total phytoplankton biomass in Lake Chaohu during the whole summer which affected water supply for 7.6 million people (Zhang et al., 2015). Although the Chinese government has taken actions to restore the aquatic ecosystem, the annual surveys of water quality of lakes, from 2006 to 2016, show a high proportion of eutrophicated lakes at around 78%. In short, eutrophication is still a serious problem in China.

For a long time, phosphorus (P) has been considered as the elemental factor to stimulate excess growth of phytoplankton and further trigger algae bloom (Hilton et al., 2006). However, some experiment results show that only controlling P loads does not have a significant effect on eutrophic status. Meanwhile, nitrogen (N) was discovered as another essential factor that contributes to eutrophication process (Dodds, 2007). Also, it

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_943957

is now commonly accepted that reducing both N&P loads can reduce water nutrient level (Conley et al., 2009).

Using aquatic plants to control N&P loads and restore eutrophic lakes is widely recognized in ecology (Qiu et al., 2001; Xiao et al., 2009) since aquatic plants can absorb and assimilate nutrients, and also stimulate the microbial action of the rhizosphere (Hans, 1997). There are many studies on aquatic plants in eutrophic environment. Periphyton and phytoplankton together with macrophyte are indicators of a eutrophic environment (Hilton et al., 2006). Furthermore, the coexistence of snails and submerged plants can decrease concentrations of N&P in water (Mo et al., 2017), but various species of plants have different abilities of removing excess nutrients (Wen and Recknagel, 2002). However, aquatic plants growing environment is complex, it also contains water and sediment, which both have impact on nutrient loads. For example, physical and chemical properties of water can make enormous difference, like calcium phosphate (Ca-P) dissolved very easily at low pH while aluminium phosphate (Al-P) dissolved more easily at high pH (Smil, 2000); ferric ion (Fe^{3+}) will reduce to ferrous ion (Fe^{2+}) when water is anaerobic which can cause ferric phosphate (Fe-P) to dissolve (Liu et al., 2002). Hydraulic dynamics is also a significant factor of nutrient transfer, like the retention time of water (O'Hare et al., 2018) and flow velocity (Hilton et al., 2006). Besides, adsorption and desorption of sediment have essential effects in transferring N&P (Wang et al., 2018; Meghdadi, 2018) since mineral composition and some other sediment characteristics play key roles in this process (Smil, 2000). As indicated above, existing studies make good explanations on factors affecting N&P transferring, but lack showing the process of N&P flow in the whole aquatic environment system.

Although lake ecological restoration is carried out by cultivating aquatic plants, surveys revealed that the lake eutrophication in China hadn't been alleviated significantly in recent years (China water resources bulletin 2010-2016). The result does not meet expectations due to the lack of scientific management, which further indicates the importance of learning the rule of N&P flowing between water, aquatic plants and sediment. This will therefore serve as a guide to form a rational and systematic management of aquatic plants for effective restoration of eutrophic lakes. Furthermore, diversity of aquatic plants varies a lot with time and space (Rooney et al., 2011; Bolpagni et al., 2018). Such perspective can be reflected in Lake Gehu. From 1970 to 2007, the total aquatic plants coverage had a sharp decline (Xu et al., 2013). Since 2012, several types of emerged plants were cultivated in shallow areas (Wu et al., 2017). This means surveys of aquatic plants species should be conducted before learning the rule of N&P flowing in water, aquatic plants and sediment.

Hence, the present work has been undertaken with the following objectives: (1) Figuring out the changing processes of N&P concentration in water, aquatic plants and sediment during aquatic plants growth, respectively. (2) Learning the rule of N&P flowing in water-aquatic plants-sediment within a life cycle of aquatic plants. (3) Giving suggestions on using aquatic plants to restore eutrophic lakes.

Materials and Methods

Study area

This study is based on the background of Lake Gehu, China. The coordinates of the lake are 119°44'E-119°52'E and 31°28'N-31°44'N (*Fig. 1*). Lake Gehu, the main source of drinking water for nearby residents, is an important shallow lake in the south of Lake

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_943957

Taihu in Jiangsu province, China (*Fig. 1a*), which belongs to the Taihu basin. It is a typical shallow aquatic vegetation lake. The water storage area is 144.1 km^2 and the average water depth is 1.31 m. The lake has a moderate and humid climate and also has sufficient sunlight. And the annual mean temperature is around 16.7℃. It plays an essential role in protecting the water quality of Lake Taihu, forming the most important natural defense line for Lake Taihu (Xu et al., 2013). Around 16 rivers enter into it from west, while 15 others divert from south-east (*Fig. 1b*). Lake Gehu has been eutrophic for over a decade with a strong adverse influence on local freshwater supply, and aquaculture. Since 2009, the local government carried out many measures to restore Lake Gehu including aquatic plant restoration (Wu et al., 2017). However, the algal bloom still occurs in high frequency, especially in summer.

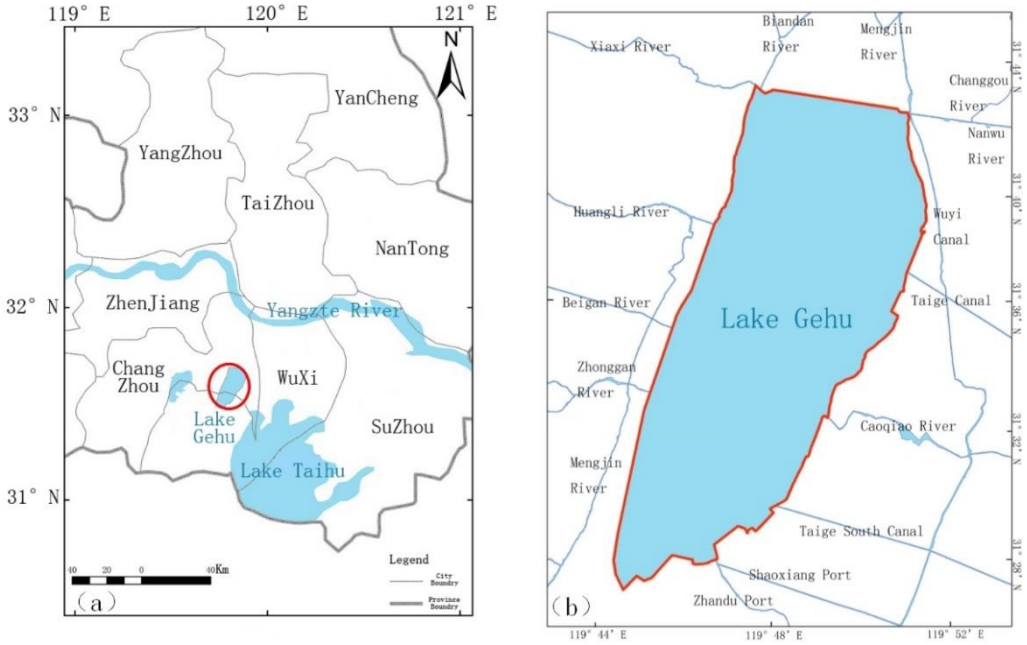

Figure 1. *Location (a) and River system (b) of Lake Gehu*

Experiment materials

Materials for experiments and relative value settings are based on the results of a field investigation, which are shown in the results section.

Aquatic plants: Two emerged plants *Phragmites australis* (*Ph.a.*), *Zizania latifolia* (*Z.l.*), and one submerged plant *Hydrilla verticillata* (*H.v.*) were collected at the same time from Lake Gehu, in the early of April when plants were at their initial stage of growth, for indoor cultivating experiment particularly.

Water: NH_4Cl and KH_2PO_4 were used to formulate experimental water. Initial N&P concentration were set at 2.0 mg/L and 0.2 mg/L, respectively.

Sediment: Experimental sediments were from areas around aquatic plants in Lake Gehu, to replicate the original growing environment for aquatic plants.

Indoor experiment

The indoor cultivating experiments were conducted in 70 L (0.5*0.35*0.4 m) cubic plastic containers. In each container, there were about 50 L water with initial N&P

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_943957

concentration, moderate sediment at bottom (around 0.12 m depth), and 500 g submerged plants or 5 emerged plants. The total water depth was around 0.3 m. Besides, control experiments (no plants) were also arranged. Each container had a duplicate (*Fig. 2*). All containers were settled together to ensure other environmental conditions unified. The experiment was conducted in a ventilated indoor area. The temperature was set at room temperature. The avarage temperture was around 20℃ while it reached 7-8℃ in December and was over 30℃ in July and August. The sunny weather contained 60% of experimental days, thus the sunlight was abundant. The initial pH and the dissovled oxgen content (DO) of the water were around 6.7 and 9 mg/L, repectively.

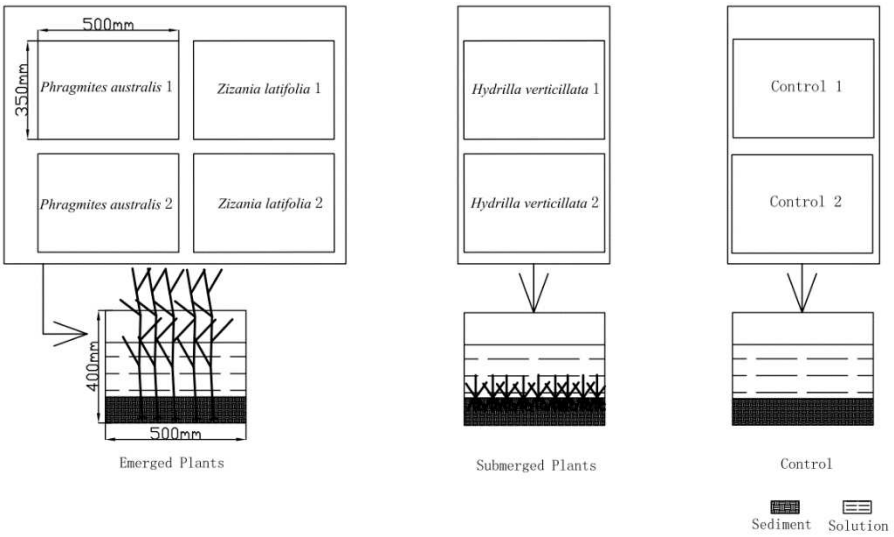

Figure 2. *Experiment arrangement. Phragmites australis and Zizania latifolia are emerged plants showed in the left, Hydrilla verticillata is the submerged plant showed in the middle and control groups with no plants are showed in the right. Each experimental container has a duplicate*

Sampling and analysis

The indoor cultivating experiment initiated from May and ended at the end of December 2016, covering a life cycle of aquatic plants. The frequency of taking plants and sediment samples was twice per month, around the 10th and the 20th of each month. Around 10 g plants samples and 50 g sediment samples were taken synchronously from every container every time. Emerged plant samples were separated into leaves, stems and roots, while submerged plant samples were analyzed as a whole since they were too small to separate. Samples were operated orderly by freeze-drying, grinding and sieving. Then total nitrogen concentration (TN) and total phosphorus concentration (TP) of samples were analyzed in a timely manner. TN of samples were analyzed by persulfate digestion (Smarta et al., 1983) while TP of samples were analyzed by SEDEX method (Ruttenberg, 1992). Analysis experiments of all parameters at different time were repeated 3 times. Around 200 ml water samples were taken from each container once a week. Samples were saved in fridge with the temperature around 5℃. Analysis experiments were conducted within 24 h after sampling. The following water parameters were analyzed: pH, dissolved oxygen content (DO), chemical oxygen demand (COD), TN, TP, ammonia nitrogen (NH_4^+-N) and nitrate nitrogen (NO_3^--N). pH and DO were recorded by a multi-parameter

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_943957

data logger (YSI 6820). Analysis experiments of other parameters were proceeded accroding to standard techniques (APHA, 1980; Valderrama, 1981; Jin and Tu, 1990). Analysis experiments of all parameters at different times were repeated 3 times.

Statistical analysis

First, parameters of water, aquatic plants and sediment samples were sorted by time, plant species and organs. Prior to statistical analysis, the normality of data sets was tested with Shapiro–Wilk test (Wang et al., 2012). Then, the T test was applied for statistical comparison of measured values among different times, plant species and organs for judge whether a detected trend was statistically significant or not. Last, parameters of water, aquatic plants and sediment samples were analyzed by Spearman correlation analysis (IBM statistic, version 22) to learn the flow progress of N&P in water-aquatic plants-sediment. A p-value of <0.05 was considered statistically significant.

Result

To obtain up-to-date distribution of aquatic plants and N&P loads in Lake Gehu, surveys were conducted in 2016. There are about 15 species of aquatic plants: 3 submerged macrophyte, 7 emerged plants, 3 floating plants and 2 floating-leaved macrophyte. Among these species, two emerged plants *Phragmites australis* (*Ph.a.*), *Zizania latifolia* (*Z.l.*), and one submerged plant *Hydrilla verticillata* (*H.v.*), have evidently high coverage, frequency and abundance which are critical parameters to calculate the Simpson index (Magurran, 1988). TN in water was 2.343 mg/L while TP was 0.245 mg/L. Both TN&TP reach the Ⅴ level (TN=2.0 mg/L; TP=0.2 mg/L) according to the Chinese environment quality standard (*Environment quality standard for surface water-GB 3838-2002*) which indicates that Lake Gehu is still highly eutrophicated.

N and P in plants

In the experiment, May, August and December repersent the germination, flourish growth and decay periods of aquatic plants. Values of TN&TP in plants in August are significantly higher than in May and December ($p<0.05$); There is a significant difference between emerged plants and submerged plants ($p<0.05$). A significant difference is also found between different organs of emerged plants ($p<0.05$). Changing trends of TN&TP in plants with time, organs and species are shown in *Figures 3 and 4* in detail.

Curves of TN&TP in two emergent plant leaves are unimodal in general, while peaks mainly lie between July and September (*Fig. 3*). No significant difference is observed for TN between two emerged plant leaves ($p=0.258$). The variation range starts from around 10 mg/g, gradually increases and reaches the maximum at 25 mg/g, and finally decreases to about 1 mg/g. TP of two emerged plants have similar start and end values, around 1.3 mg/g and 0.1 mg/g, respectively. However, the TP peak of *Ph.a.* reaches 2.5 mg/g while that of *Z.l.* is relatively lower at 1.8 mg/g. From May to October, leaves contained the most nutrient, with TP accounting for over 50% of total and TN accounting for nearly 70-75%. Values in leaves are significantly higher than in stems and roots ($p<0.05$). TN&TP in emerged plant stems both show a continuous downward trend with fluctuation, but value ranges are significantly different ($p<0.05$). In April and May, when peaks appeared, TN is around 10 mg/g while TP is around 1.5-1.8 mg/g. TN&TP then decrease to 1.0

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_943957

mg/g and 0.1 mg/g respectively at the end of experiment. Besides, in this two periods, TN&TP in stems and leaves are close (TN: p=0.637; TP: p=0.542). TN&TP in emerged plant roots are generally steady but fluctuate near the end of the experiment. TN&TP in *Ph.a.* roots are higher than those in *Z.l.*, although the difference is not significant (TN: p=0.071; TP: p=0.062). During May-September, TN&TP in roots account for less than 10% of total. However, in October-December, TP in roots is significantly higher than in stems and leaves ($p<0.05$), the proportion increase with over 50%. Changes of TN&TP in emerged plant leaves, stems and roots indicate that leaves absorb large amount of nutrient and act as the main organ to store nutrient at early and medium stages of plant growth. However, when plants decay, nutrient in roots increases while that in leaves and stems both decreases. Therefore, roots are the main organ to store nutrient when emerged plants decay. In conclusion, in emerged plants, nutrients are absorbed from outside and stored mainly in leaves at early and medium stages of growth but gradually transferred to roots when decay.

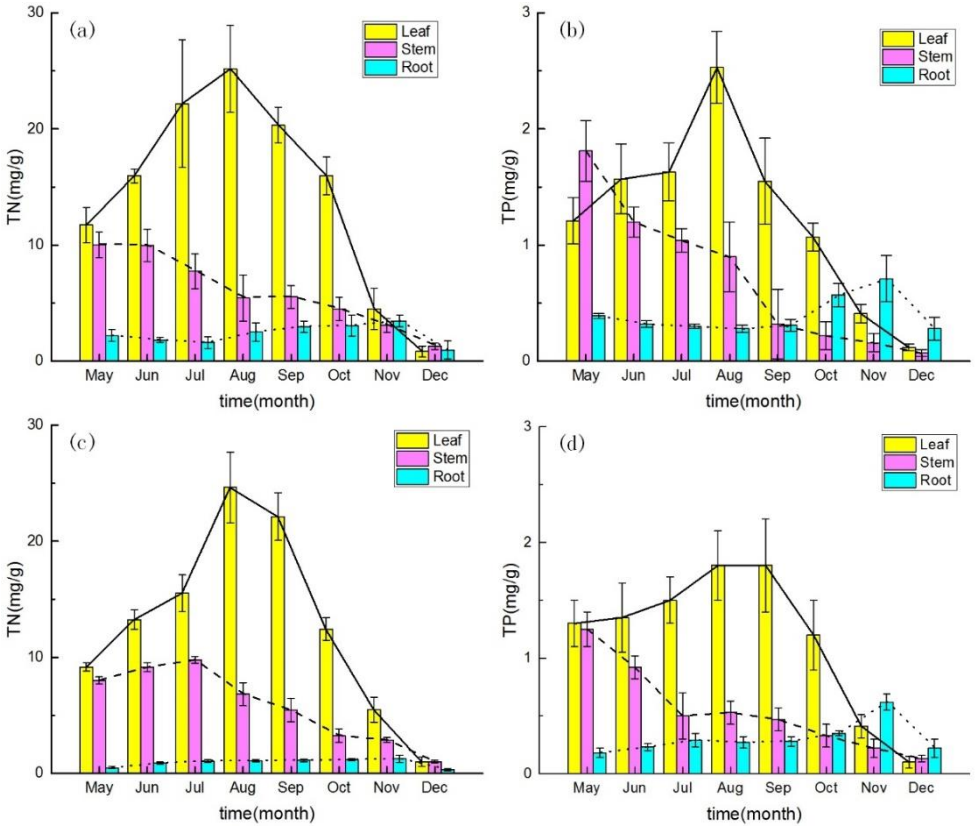

Figure 3. *Total nitrogen (TN) in Phragmites australis (Ph.a.) (a), Zizania latifolia (Z.l.) (b) and total phosphorus (TP) in Ph.a.(c), Z.l.(d). In total 4 samples are collected for each month, of which 2 samples are collected at the 10th of the month and the other 2 collected at the 20th of the month. The mean values for each month are presented by color bars and the standard deviations are presented by error bars*

Although curves of TN&TP in *H.v.* are both unimodal (*Fig. 4*), values of TN are significantly higher than TP ($p<0.05$). TN increases from around 15 mg/g to around 36 mg/g, then decreases to around 5 mg/g. While TP increases from around 3 mg/g to about 6 mg/g, then decreases to less than 1 mg/g. Peaks appear in July and August. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_943957

ratio of TN to TP of *H.v.* is around 5:1 to 7:1, and this ratio of *Ph.a.* and *Z.l.* is the most around 15:1. It indicates that the growing of *H.v.* is limited by N while the growing of *Ph.a.* and *Z.l.* is limited both by N and P (Tessier et al., 2003).

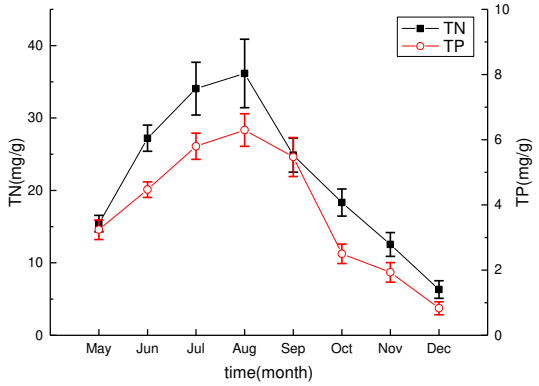

Figure 4. *Total nitrogen (TN) and total phosphorus (TP) in Hydrilla verticillata (H.v.). In total 4 samples are collected for each month, of which 2 samples are collected at the 10th of the month and the other 2 collected at the 20th of the month. The standard deviations are presented by error bars*

N and P in sediment

Values of TN&TP in sediments in May and December are significantly higher than in August ($p<0.05$). There is a significant difference between control groups (no plants) and plant groups ($p<0.05$). Changing trends of TN&TP in sediments with time are shown in *Figure 5* in detail.

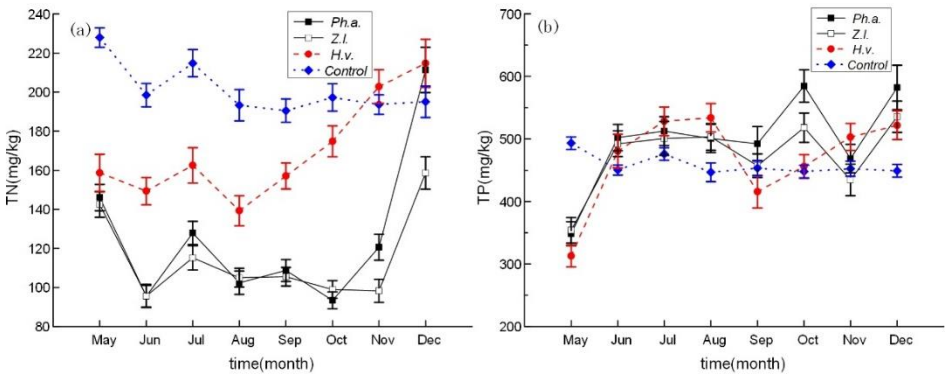

Figure 5. *Changing trends of total nitrogen (TN) (a) and total phosphorus (TP) (b) in sediment with time. 'Ph.a.', 'Z.l.' and 'H.v.' represent sediment samples from Phragmites australis groups, Zizania latifolia groups and Hydrilla verticillata groups, respectively. In total 4 samples are collected for each month, of which 2 samples are collected at the 10th of the month and the other 2 collected at the 20th of the month. The standard deviations are presented by error bars*

No significant difference is observed for the TN&TP in control groups sediment among different times (TN: $p=0.061$; TP: $p=0.057$), changing trends are basically in stable state with slight fluctuations (*Fig. 5*). TN ranged from 190.54 to 227.93 mg/kg,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_943957

while TP ranged from 446.72 to 453.27 mg/kg. TP decreased at the beginning because the concentration between water and sediment tended to equilibrate phosphorus concentration (EPC_0) (Zhou et al., 2005). Slight fluctuations might be caused by temperature variation. Changing trends of TN in the sediment of the container with emerged plants are similar (*Fig. 5a*). And variation ranges are close ($p=0.457$), 93.43-211.35 mg/kg. In the first two months, the value sharply decreased by 50.45 mg/kg ($p<0.05$), while in the last two months, it dramatically increased by 90.72 mg/kg ($p<0.05$). However, it was relatively stable around 93-125 mg/kg during other months. It indicates adsorption and desorption effects of sediments are not obvious when aquatic plants exist in the system. Changing trends of TP in three aquatic plants sediment are similar, rising first and then fluctuating (*Fig. 5b*). The value range is close ($p>0.05$). The minimum at the beginning was around 350.00 mg/kg, then the value increased by around 150.00 mg/kg during the first month. The maximum value appeared in the end, around 550 mg/kg.

Water parameters

All water parameters, except NH_4^+-N, show significant difference in May, August and December ($p<0.05$; NH_4^+-N: $p=0.242$). All water parameters, except NH_4^+-N, show significant difference between control groups (no plants) and plant groups ($p<0.05$; NH_4^+-N: $p=0.463$). However, to show the transforming of different forms of N in water, NH_4^+-N concentration was still contained in *Fig. 6*.

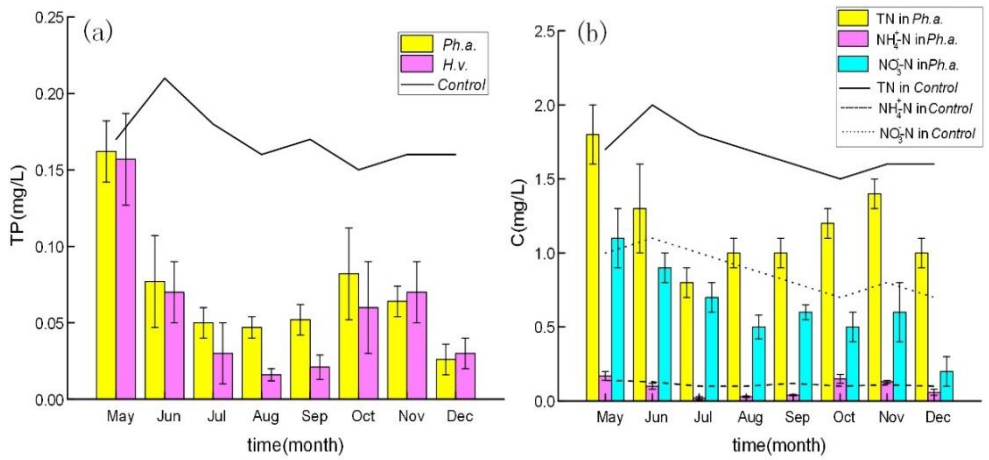

Figure 6. *Changing trends of total phosphorus (TP) (a) and three forms of nitrogen (N) (b) in water samples with time. 'Ph.a.' and 'H.v.' represent water samples from Phragmites australis groups and Hydrilla verticillata groups, respectively. 'TN', 'NH_4^+-N' and 'NO_3^--N' represent concentration of total nitrogen, ammonia nitrogen and nitrate nitrogen, respectively. In total 8 samples are collected for each month, of which 2 samples are collected every week. The mean values for each month are presented by color bars and the standard deviations are presented by error bars*

pH, DO and COD

pH, DO and COD in control groups show no signifcant difference with time ($p>0.05$). Control groups pH was between 8.0 and 8.5, water was alkalescence. DO fluctuated in 8.0-11.0 mg/L. COD was below 5.0 mg/L all the time and stayed at a relatively low level.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_943957

In general, water quality of control groups is good (*Table 1*). Values of these 3 water parameters in aquatic plants are close and no significant difference is found ($p>0.05$). pH decreased from 8.0 to around 6.5 first, and then increased to 8.0, so the water changed from alkaline to faintly acidic and resumed to alkaline. It might have a relation with concentrations of phosphate radical (PO_4^{3-}) and ammonium radical (NH_4^+). DO kept low level in aquatic plant groups, the avarage was below 2.0 mg/L. COD increased first then declined. These two parameters are both affected with plants biomass.

Table 1. *pH, dissolved oxygen (DO) and chemical oxygen demand (COD) in the water samples of aquatic plants and control groups*

Month	Control			*Ph.a.*			*Z.l.*			*H.v.*		
	pH	**DO**	**COD**	**pH**	**DO**	**COD**	**pH**	**DO**	**COD**	**pH**	**DO**	**COD**

Dec	8.2	8.0	2.5	7.6	2.0	6.0	7.4	1.4	5.5	7.7	0.5	6.6

The unit of DO and COD are both mg/L. 'Ph.a.', 'Z.l.' and 'H.v.' represent water samples from Phragmites australis groups, Zizania latifolia groups and Hydrilla verticillata groups, respectively. In total 8 samples are collected for each month, of which 2 samples are collected every week

N&P in water

Values of TN&TP in water have no significant difference in emerged plants (TN: $p=0.534$; TP: $p=0.730$). Also the changing trends are similar. Therefore, *Ph.c.* is selected as representative of emerged plants for plots (*Fig. 6*).

The TP in water of control groups ranged from 0.15 mg/L to 0.21 mg/L, with a continuously declining trend. Range of TN (NO_3^--N, NH_4^+-N) in water of control groups was 1.5-2.0 mg/L (0.7-1.1 mg/L, 0.10-0.14 mg/L). TN and NO_3^--N both declined with fluctuations, while NH_4^+-N maintained a steady state with slight fluctuations. This reflects the process of nutrient exchange between water and sediment forced by concentration gradient. The TP in water of plant groups decreased at the beginning and near the end of the experiment. The range of TN (NO_3^--N, NH_4^+-N) was 1.00-2.00 mg/L (0.20-1.10 mg/L, 0.03-0.17 mg/L), which were all lower than those in control groups ($p<0.05$). NH_4^+-N accounts for less than 10% of TN on average while NO_3^--N accounts for more than 50% of TN on average.

Comparing control groups and plant groups, it can be concluded that plants can stimulate nutrient flowing, and biochemical action is a more powerful force than concentration gradient. NO_3^--N is the main form of N existing in water and transform between NO_3^--N and NH_4^+-N are controlled by nitrification and denitrification (Reddy et al., 1990). From May to August TN&TP in water of emerged plants decreased by 0.800 mg/L and 0.115 mg/L, respectively while those of submerged plants decreased by 1.000 mg/L and 0.141 mg/L, respectively. Declines of TN&TP in water of submerged plants

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_943957

are greater than those of emerged plants ($p<0.05$). Submerged plants act better in removing N&P loads than emerged plants.

Correlation analysis

The experiment lasted 8 months (May-December). Plants and sediment samples were collected twice per month (at 10th and 20th), while water samples were collected 4 times per month (including 10th and 20th). Besides, each experimental container had a duplicate (*Fig. 2*). Thus, parameters of samples at 10th and 20th every month are used for spearman correlation analysis, and the number of samples were 32.

Correlations of TN, TP in plants and sediment are shown in *Table 2*. There is a significant negative correlation between TN in roots of emergent plants and TN in sediment. TN in submerged plants has a significant negative correlation with TN in sediment. TP in plants and sediment does not present strong correlation. It indicates that N flow mainly occurred between plants and sediment directly by biochemical action of roots.

Table 2. *Spearman's rank correlation coefficient of N&P between aquatic plants and sediments*

Ph.a.						
Sediment	**Leaf**		**Stem**		**Root**	
	TN	TP	TN	TP	TN	TP
TN	-0.692	-0.167	-0.095	-0.079	-0.903**	-0.733

Sediment	**Plants** TN			**Plants** TP		
TN	-0.833*			-0.810*		
TP	0.381			0.286		

'Ph.a.', 'Z.l.' and 'H.v.' represent samples from Phragmites australis groups, Zizania latifolia groups and Hydrilla verticillata groups, respectively. TP and TN represent for total nitrogen concentration and total phosphorus concentration, respectively. n=32 (number of samples). Statistical significance codes: * $p<0.05$; ** $p<0.001$

Correlations of TN&TP in plants and sediment with water parameters are shown in *Table 3*. There is no significant correlation in control groups. TN&TP in emerged plant leaves and submerged plants have a strong positive correlation with water COD. There is a significant negative correlation between TP in water and sediment. These suggest plant growth may increase the content of organic matters in water, which can be a hazard of aquatic plants restoring eutrophicated lakes. P flow mainly relies on water since it shows no strong correlation between plants and sediments but presents a significant negative correlation between water and sediments.

Discussion

Difference of nitrogen and phosphorus flow

The difference of N&P flow is that N transfers mainly between sediments and plants, while P needs water to realize cycling. P in water is diversified into the total particle phosphorus (TPP) and the total dissolved phosphorus (TDP). Large amount of TPP can transfer in a short time. Most of P release during the eluviation (Liu et al., 2018) is one phenomenon caused by this. It implies P flow is mainly a physical process. Biochemical actions of plants have minor effect on P flow (Smil, 2000). It can explain the strong correlation of P in sediment and water, also the conclusion of P flow relying on water. In addition, this conclusion applies to some natural catchments. For example, TPP is the main form of P in many rivers (Meybeck, 1982). N is identified as the organic nitrogen (ON) and the inorganic nitrogen (IN). The latter is the main form of N in water and sediment. IN can be known as NH_4^+-N, NO_3^--N, and NO_2^-N. But plants need to transform IN to ON to meet growing requirements. It indicates N flow is mainly through

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_943957

biochemical reaction, which is also concluded in other research (Rattray et al., 1991). For example, NO_3^--N can be transformed to NH_4^+-N through catalytic reduction by nitrate reductase (May et al., 2011); nitrification and denitrification, influenced by plants growth, can make mutual transformation of NH_4^+-N, NO_3^--N, and NO_2^--N (Reddy et al., 1990). Thus there is a significant negative correlation between N in plant roots and sediment, and N flow is mainly between plants and sediment rather than between sediment and water.

Emerged plants vs submerged plants

Emerged plant leaves and stems are usually above water surface, while roots and part of stems are under water surface. Therefore, emerged plants have properties of both land and aquatic plants. Their roots are the main organ absorbing nutrient from sediments, meanwhile they can get abundant sunlight. Thus they usually show large biomass. Besides, emerged plants can weaken hydraulic dynamics and prevent sediment suspended (Hans, 1997). Furthermore, it can reduce sediments desorption effects. To sum up, emerged plants have significant effects on N&P in sediment, which is also showed in the correlation analysis of this study. Submerged plants are usually entirely under water surface, so they have larger biomass within water than emerged plants. Large biomass is likely to make water turn to anaerobic state which will stimulate the release of N&P (Reddy et al., 1990; Liu et al., 2002). In this study, sharp decrease of TN&TP in *H.v.* during Aug.-Oct. (*Fig. 4*) verifies the conclusion mentioned above. The submerged plants have roots degraded due to the limitation of light intensity (Phillips et al., 1978; Jones et al., 1999), but their other parts all have the ability of absorbing water and nutrient. Thus submerged plants have strong connections with N&P in water. In natural lakes, commensalisms and competitions between emerged and submerged plants are ubiquitous, and it is worthy of consideration in further studies.

Some suggestions for aquatic plants restoration

According to *Fig. 6*, N&P in water show a sharp decline during plants growth, which indicates aquatic plants do have the ability of removing excess nutrient in water. Moreover, submerged plants act better than emerged plants in removing nutrient, so submerged plants are the superior choice in restoring eutrophicated lakes. And some studies, focusing on effects of submerged plants restoration, have already verified the practicability of this suggestion (Gao et al., 2017). However, the results also show aquatic plants can release a large amount of N&P when they decay. Therefore, it may cause a secondary pollution unless aquatic plants are reaped scientifically. For saving cost, it's essential to know the time and main plant organs to reap. Reaping the 3 aquatic plants around August and September is a proper timing. At this time around 70-75% TP and 80% TN of water can be removed according to *Fig. 6*. However, this value could be lower in lakes since hydrodynamics and some other conditions are not considered in this study. Besides, emerged plant leaves need to be reaped by times, since leaves fall easily in natural environment and the residue can release nutrient directly into sediment and water. Although emerged plant roots contain most nutrient when plants decay, it is not suggested to reap roots, because they are the key of plant regeneration and moderate residues are helpful to remove N (Gessner, 2000; Hernes et al., 2001). If controlling P loads is the main purpose, it is imperative to reap plants before P in plants reach the peak. The reason is the amount of P release is large within a short time when plants decay (Liu et al., 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_943957

On the other hand, if controlling N loads is the main purpose, reducing content of NO_3^--N by enhancing denitrification would be an effective action.

In *Fig. 6*, there is another low value occurring around November and December, because N&P are adsorbed by sediments after plants decay. Thus, purifying sediments at this time can remove around 90% N&P in water. Although this value could be lower in lakes where water and sediment interactions are strong, purifying sediment is still necessary to prevent sediment become the source of N&P. However, it is too costly to initiate a project specifically for such purpose. As a result, the purification can be combined and included within some other engineering projects like dredging and reclamation at the appropriate time. As this experimental study has simplified some complicated environmental conditions, further studies could be done to find more integrated solutions for restoring the highly eutrophicated lakes.

Conclusion

For increasing the efficiency of using aquatic plants to restore eutrophic lakes and learning the rule of N&P flow between water, aquatic plants and sediment, indoor experiments were conducted. The general process of N&P flow in the system is from water and sediments to plants, then back to water, and finally they are adsorbed by sediments. However, N flow is mainly between plants and sediment, while P flow is mainly between water and sediment. Generally, N flow is a biochemical process, while P flow is a physical process. N&P in emerged plants are stored in leaves at early and medium stages of growth (May-October) and transferred to roots at the decline stage (November-December). Submerged plants act better in removing excess nutrient in water, but harvesting them before N&P contents reaching peak is indispensable (August). Purifying sediments after plants decay (December) can be helpful to decrease N&P loads, which can be combined and included within some other engineering projects.

Competition and promotion exist between different species of aquatic plants in nature, which may reduce or improve effects of using aquatic plants to restore eutrophic lakes. Thus, learning competition and promotion between different aquatic plants species is a meaningful direction for further study.

Abstract. Microbial communities and substrate enzymes play a key role in constructed wetlands (CWs), therefore it's important to understand the diversity of microbial communities and activities of enzymes therein. In this study, System A (planting with *Pennisetum sinese Roxb*); System B (planting with *Pennisetum purpureum Schum.*); and System C (no plant) -- were set to investigate the variation of species richness, community equitability and substrate enzymes. It showed that Betaproteobacteria were most abundant in these three systems. The number of microorganisms species in system A, system B and system C were 60-90 cm > 30-60 cm > 0-30 cm, 60-90 cm > 0-30 cm > 30-60 cm and 30-60 cm > 60-90 cm > 0-30 cm, respectively. But urease, phosphatase and cellulose were all reduced with the increase of matrix depth. The results showed that the enzyme activity was not necessarily related to the number of microorganisms species, but enzyme activity could be related to the population of corresponding functional bacteria. In conclusion, Proteobacteria, Bacteroidetes, Firmicutes, Acidobacteria, Chloroflexi, Verrucomicrobia, Actinobacteria, TM7, Nitrospira, and OP11 were detected in these three constructed wetlands. However, there are still about 10% unknown bacteria at class level. The specific relationship between microorganisms, enzymes and wetland pollutant removal remains to be further studied in the future indicating that wetland microbial research has great potential in the future.
Keywords: *vertical flow constructed wetland, microbial communities, substrate enzymes, Pennisetum sinese Roxb, Pennisetum purpureum Schum*

Introduction

Constructed wetland (CW) is a prospective sewage purification technology (Kadlec and Knight, 1996; Cui et al., 2013). Compared with traditional sewage treatment methods, CW has the simple technology, relatively low operation and maintenance requirements (Zuritaa et al., 2009; Tang et al., 2017). CWs mainly include 2 types, which are surface flow CW and subsurface flow CW (IWA, 2000; Kadlec and Wallace, 2008; Vymazal and Kröpfelová, 2008). Vertical flow constructed wetland (VFCW) is a kind of subsurface flow wetland (Xu et al., 2015). In the last two decades, VFCW technology has become a popular choice for sewage treatment (Prochaska and Zouboulis, 2006; Abou-Elela et al., 2012), because it is high-efficiency not only for mitigation of biochemical oxygen demand and total suspendedsolids (Vymazal, 2009) but also for nitrification even in winter (Arias et al., 2005; Cooper, 2005; Prochaska et al., 2007). The VFCW with unsaturated flow has stronger oxygen carrying capacity than horizontal underground flow and is more effective for the mineralization of biodegradable organics (Kantawanichkul et al., 2009). As we all know, the main mechanism of CW sewage purification is the interaction of substrate, vegetation and microorganism through a series of biological, physicochemical reactions (Truu et al., 2009; Fu et al., 2013). Wetlands vegetation can affect enzyme activity and microbial

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_959971

species structure and diversity that in turn indirectly affect enzyme activity (Zhang et al., 2010). Therefore, it's important to see the activities of enzymes and diversity of microbial population in constructed wetland. Wang (2009) proposed that the number of microorganisms, bacterial diversity and dominant community in the wetland system are closely relevant to the removal of phosphorus, nitrogen and organic compounds. Zhang et al. (2010) wetlands contains a wide range of cellulose and glycosidase, protease, urease, phosphatase, phenol oxidase and other enzymes. In our preliminary study, based on the study of the microbial enzyme activity in the artificial wetland system, the urease activity in the root system of aquatic plants was considered as an important index of nitrogen purification (Cui et al., 2013). In this study, several important bacterial communities (Proteobacteria, Bacteroidetes, Chloroflexi, Nitrospira, and OP11 etc.) and activities of substrate enzymes related to C, N and P cycle was analyzed, employing Illumina high-throughput sequencing technology and zymological means. The objective of this study is to estimate the space distribution of bacterial community and enzyme activities in the VFCW system. It is expected to provide a theoretical basis for microbial regulation of VFCW.

Materials and methods

Construction of VFCW

Three vertical wetlands were established and maintained in the greenhouse facility of South China Agriculture University (SCAU) in Guangzhou city. Each system was structured at 200 cm x 100 cm x 130 cm (length x wide x height). These three systems were constructed as followed: System A planted with *Pennisetum sinese Roxb,* System B planted with *Pennisetum purpureum Schum*., and System C planted nothing. The sketch map of the CW systems was seen in *Figure 1*. The vegetation types of *Pennisetum sinese Roxb* and *Pennisetum purpureum Schum*. were transplanted into A, B system respectively, and the density is 10 plant/m^2.

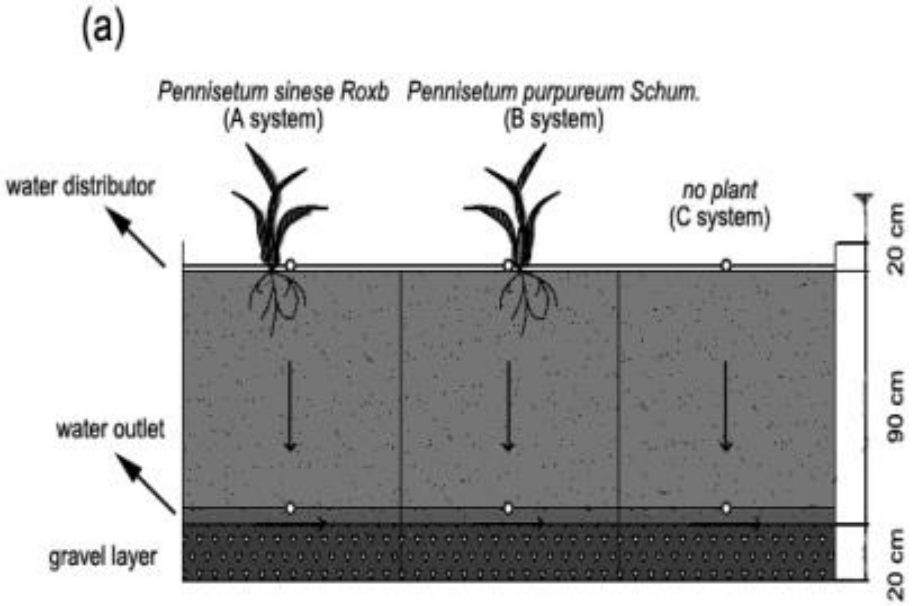

Figure 1. *The profile of wetland system*

DOI: http://dx.doi.org/10.15666/aeer/1801_959971

Synthetic sewage

The synthetic wastewater is prepared from 400 litres of tap water, 70 g milk powder, 60 g soluble starch, 18 g urea, 10 g $(NH_4)_2SO_4$, 6 g $MgSO_4$, 6 g KH_2PO_4, 60 g $NaHCO_3$, and 50 ml 1% $FeCl_3$. Water quality indicators were as follows: the average values of TN, TP and COD were 40 mg/L, 4 mg/L and 330 mg/L. The pH value was 6.39-6.7 and the DO value was 4-6.

Operation of constructed wetland

Each CW system was constructed in mid-March, then started to operate on 28th of March and at last ended on 26th of September. These three systems carried out at 20 cm/d hydraulic loading. The sewage was feeded on 28th of March, these three systems were irrigated continuously with sewage for 8 hours every day. On 11th of April, we collected the water from the outlet position and analyzed once a week. The water monitoring indexes include TN, TP and COD etc. The over ground part of system vegetations were reaped once a month. By the end of the trial, five substrate samples were collected individually from 0–30 cm layer, 30–60 cm layer and 60–90 cm layer in every constructed wetland. These five samples were blended to get one typical sample for each layer. The community structure and diversities were monitored, by using High-throughput Sequencing Techniques and the enzyme activities were measured by zymological methods. The basic information of soil samples are shown in *Table 1*.

Table 1. *Basic information of sample (DNA samples)*

Sample number	Constructed wetland	Depth(cm)	Code
1	A (planting with planting *Pennisetum sinese Roxb*)	0-30	A1
2	A (planting with planting *Pennisetum sinese Roxb*)	30-60	A2
3	A (planting with planting *Pennisetum sinese Roxb*)	60-90	A3
4	B (planting with *Pennisetum purpureum Schum.*)	0-30	B1
5	B (planting with *Pennisetum purpureum Schum.*)	30-60	B2
6	B (planting with *Pennisetum purpureum Schum.*)	60-90	B3
7	C(no plant)	0-30	C1
8	C(no plant)	30-60	C2
9	C(no plant)	60-90	C3

Note: A (1,2,3) indicates that the sampling depth in system A is 0-30 cm (top layer), 30-60 cm (middle layer), and 60-90 cm (bottom layer), respectively. B (1, 2, 3), C (1, 2, 3) were set in the same way

DNA extraction

DNA was extracted from matrix samples using the Power Soil DNA separation kit (Mobio Laboratories Inc., Carlsbad, CA, USA) in accordance with the manufacturer's protocol. The extraction quantity and quality of DNA were determined by spectrophotometry. The extracted DNA before further analysis is stored in - 80°C.

DOI: http://dx.doi.org/10.15666/aeer/1801_959971

PCR detection

The V3-V4 region (338F-806R) of 16S rRNA was amplified by PCR with the primers 338F (5'-ACTCCTACGGGAGGCAGCA-3') and 806R (5'-GGACTACHVGGGTWTCTAAT-3') (Wang et al., 2014; Lin et al., 2018).

These PCR reactions were proceed in a 30 ul reaction mixture, including 0.75 units Ex Taq DNA polymerase, 1× Ex Taq loading buffer, 0.2 mM dNTP mix, 0.2 μM of each primer, and 100 ng template DNA.

The amplification of each specimen was carried out in triplicate in an Eppendorf Master cycler PC.

94ºC	30 s	35 cycles
50ºC	1 min	
72ºC	1 min	
72ºC	10 min	

The PCR production was replicated and its concentration was monitored in a 2% agarose gel, Amplicons of all specimen were collected at the same ratio and the mixture was purified using the Gel Extraction Kit (E.Z.N.A.TM). Purified and mixed PCR products meet the requirements and were sequenced based on Illumina Miseq PE (paired end) 280bp.

Statistical analysis

Microbiological information analysis: the purified mixed PCR products were used for high throughput sequencing. Using Mothur (V.1.36.1) the original DNA sequence was filtered to remove chimeras and obtain the optimized sequence; According to 97% similarity, the optimized sequence is divided into Operational Taxonomic Units (OTU). Species taxonomy: A total of 6752 OTUs were obtained from 9 soil samples. Of the 6751 OTUs species in the sample, 5693 (84.3%) were at least accurate to phylum level and 5173 (76.6%) were at least to class level. Venn diagram analysis: It can be used to count the number of common or unique OTU in multiple samples, and can intuitively show the degree of similarity of OTU composition among environmental samples. water quality and soil enzymes were analyzed by EXCEL2007 and SPSS17.0. A one-way analysis of variance was conducted for constructed wetland: system A (planting *Pennisetum sinese Roxb*), system B (planting *Pennisetum purpureum Schum.*) and system C (no plant), to be detected the statistical significance of differences ($p < 0.05$) between means of treatments, and the Duncan test was performed.

Enzymes activities measured

Urease activity was measured by phenol-sodium hypochlorite method. The determination of urease activity in soil is based on the amount of ammonia produced after the enzymatic reaction with urea as the substrate, and can also be obtained by measuring the amount of unhydrolyzed urea. In this method, the urease liveness was analyzed by taking urea as the zymolyte, and the blue indophenol was produced by the reaction of the enzyme product ammonia with phenol-sodium hypochlorite. Phosphatase was measured by disodium phenyl phosphate method. In this method, the activity of the enzyme is expressed by the amount of phenol produced by hydrolyzing the substrate with phosphodisodium phosphate as the substrate under the action of phosphatase (Guan, 1986).

Results

Microbial community composition

At the phylum level, 26 phyla of bacterial, 523 genera were identified in this study. Among 9 substrate samples, Proteobacteria (averaging 55.1%) was the most abundant phyla, followed by (averaging 10.2%), unclassified (averaging 8.0%), Firmicutes (averaging 6.6%), Acidobacteria (averaging 5.3%), and Chloroflexi (averaging 4.7%). The other predominant phyla (>1%) were Verrucomicrobia (averaging 1.9%), Actinobacteria (averaging 1.8%), TM7 (averaging 1.6%), Nitrospira (averaging 1.4%), and OP11 (averaging 1.1%). Furthermore, their relative abundance of these predominant bacterial populations usually exhibits significant spatial variability in every system.

From *Figure 2(a)*, it showed that there was a large difference in bacterial flora among the three constructed wetlands. Proteobacteria was dominant in 9 studied samples. The spatial variation of the proportion of proteobacteria in VFCW has rarely been studied. In this experiment, the analysis on community of wetland microorganisms showed the advantage of proteobacteria in vertical flow to CW. However, a relatively high proportion of proteobacterial was found in the systems of planting with planting *Pennisetum sinese Roxb* and with *Pennisetum purpureum Schum.*, while the system with no plants showed a decrease. The abundance of the Chloroflexi in system A (planting with *Pennisetum sinese Roxb*) and B (planting with *Pennisetum purpureum Schum.*) was higher than that of system C (no plant). At the same time, the abundance of Chloroflexi phylum increased as the substrate depth deepen. Chloroflexi is a facultative anaerobic bacterium, which has been proved to be effective in eliminating chloride pollution in the environment. In this study, the results showed the following rule: The Nitrospira of the planting system was stronger than that not plant system, but decreased with the increase of substrate depth, Nitrospira on the top layer of system B is remarkably the highest (planting with *Pennisetum purpureum Schum.*), while the abundance of firmicutes, Bacteroidetes and OP11 in system C were higher than system A and system B.

At the class level, in total, 53 bacterial taxa were observed. Most predominant bacteria (>1%) were ascribed to Betaproteobacteria (averaging 24.1%), followed by Deltaproteobacteria (averaging 13.4%), Alphaproteobacteria (averaging 10.5%), Gammaproteobacteria (averaging 5.8%), Clostridia (averaging 4.8%), Bacteroidia (averaging 4.6%), Anaerolineae (averaging 4.2%), Actinobacteria (averaging 1.84%), Sphingobacteria (averaging 1.80%), Acidobacteria_Gp7 (averaging 1.63%), and Nitrospira (averaging 1.4%). Furthermore, the relative abundance of these groups indicates that the spatial variations of wetland systems are large.

Figure 2(b) showed that proteobacteria mainly was composed of Alpha-, Beta-, Delta- and Gammaproteobacteria. Betaproteobacteria was most richest in these three systems. The distribution of the Deltaproteobacteria showed the following trends: as the substrate depth increased, the Deltaproteobacteria abundance also increased, and this bacterium were the most abundant in system C (the abundance of C3 was up to 22.5%). Compared to Deltaproteobacteria, Alphaproteobacteria was adverse, and it was most abundant in top layer substrate of these 9 constructed wetlands, while the distribution rule is that the bacterial abundance decreased as substrate depth increased. It showed that the depth of substrate has a strong impact on microbial community structure.

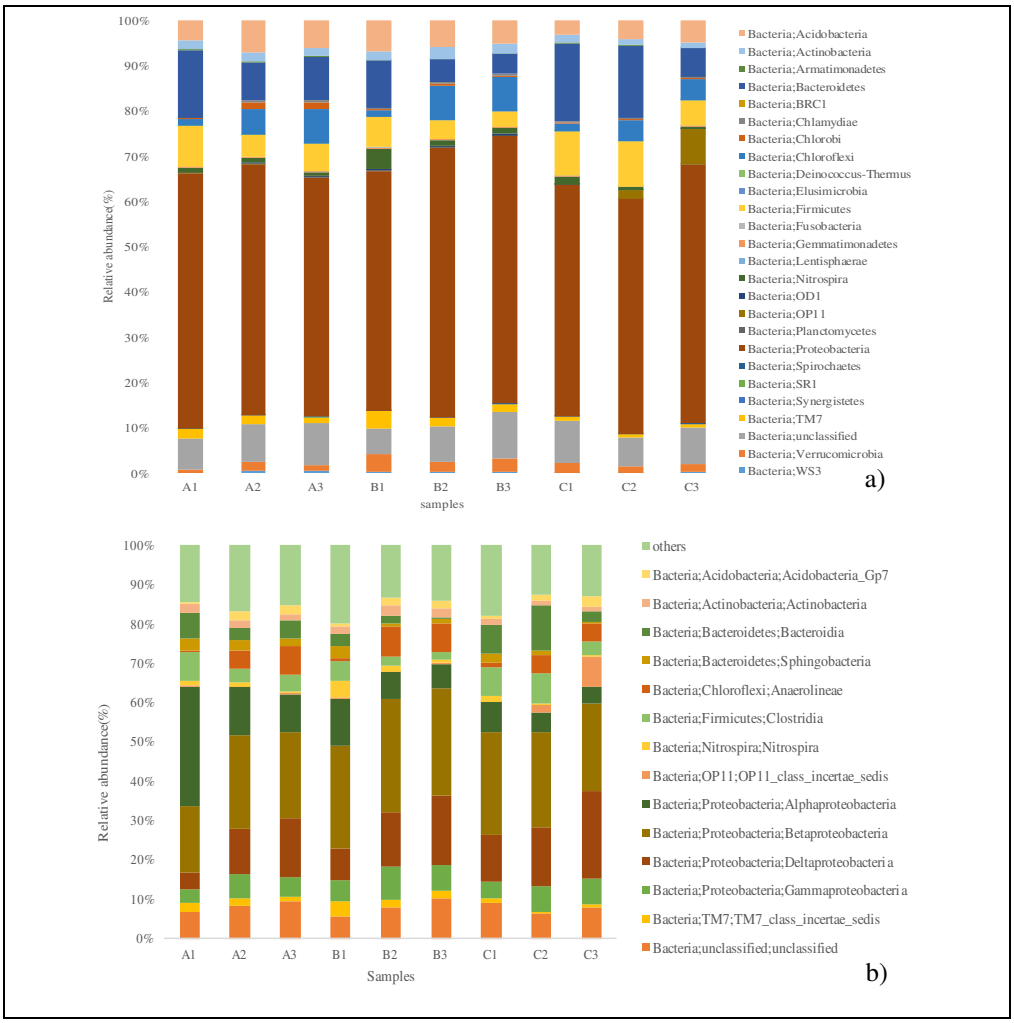

Figure 2. *Bacterial community composition in three vertical flow constructed wetland. a) Phylum-level distribution of bacteria; b) Class-level distribution of bacteria (Others include the bacteria class with the relative abundance less than 1% in each sample)*

Venn analysis

The common number of OTU (operational taxonomic units) among multiple samples can reflect the similarity and overlap of environmental samples. The statistical results are obtained in the form of Venn diagram. In general, 97% of OTU at similar levels was selected for analysis, and the number of OTU can also represent the number of bacterial species. From *Figure 3*, there were some results as followed: The number of bacterial species in system A, system B and system C were 60-90 cm > 30-60 cm > 0-30 cm, 60-90 cm > 0-30 cm > 30-60 cm and 30-60 cm > 60-90 cm > 0-30 cm, respectively.

Enzymes activities

Figure 4 illustrated that the changes of urease, phosphatase and cellulose are consistent, and they all reduced with the increase of matrix depth. The rule was shown as followed: 0-30 cm > 30-60 cm > 60-90 cm.This is consistent with previous research results. The comparison between this result and *Fig. 3* indicates that the number of microorganisms is not necessarily related to the enzyme activity.

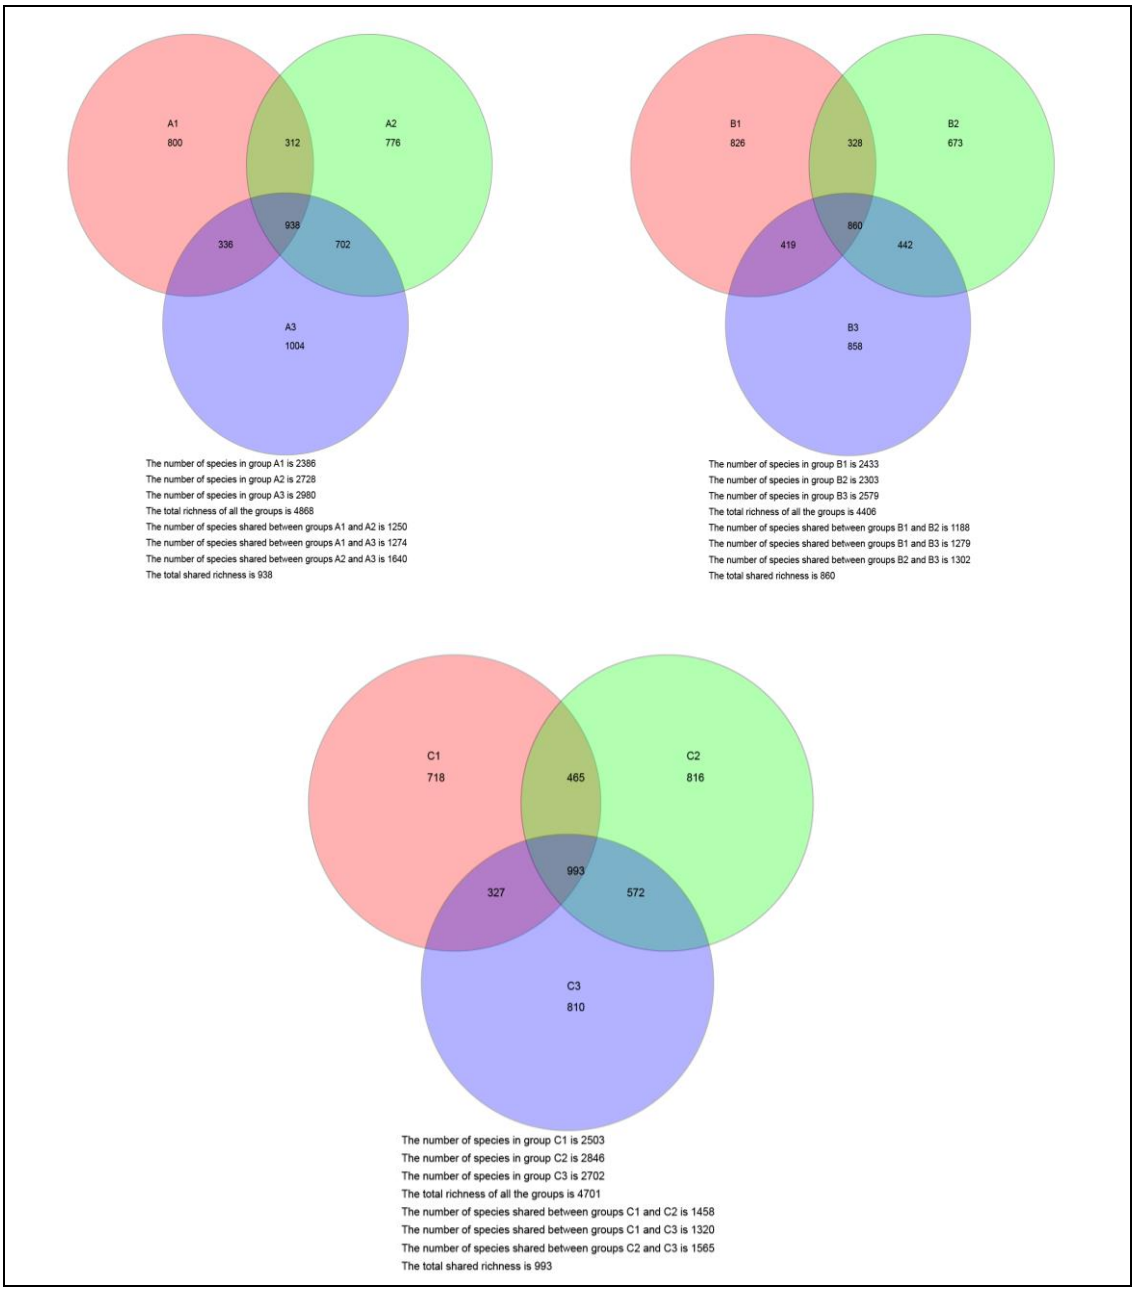

Figure 3. *Venn diagram*

Water quality change

Figure 5 illustrated that the changes of TN, TP and COD. The N removal efficiency in these three CW systems was about 50–70%. With the operation of the system, the removal rate of TP basically presents a downward trend. After August 15, the P removal efficiency patterns from the three CW systems were in the following order: B > A > C, and showed a significant difference in September 12 ($p = < 0.01$). The average removal efficiency of COD was higher than 85% and COD removal performed was satisfied.

Discussion

Microbial community in constructed wetland

Species diversity is a prerequisite for maintaining the normal function of an ecosystem (Ansola et al., 2014). The richness and diversity of bacterial communities make wetlands play an important ecological role in nutrient cycling, organic degradation, heavy metal morphological transformation and greenhouse gas emissions (Conrad, 1996). Among the 9 soil types of wetland plants in this study area, the abundance and diversity of soil bacterial communities are consistent: Proteobacteria was dominant in 9 studied samples. Proteobacteriagate is a kinds of bacterial community, in the study of many wetland bacteria have the highest relative abundance, such as the Yellow River delta wetland (Yu et al., 2012), China Hong Kong mangrove wetland (Jiang et al., 2013), the United States Olentangy river wetland (Ligi et al., 2014) and artificial wetland (Ansola et al., 2014), etc. The proteobacteria mainly was composed of Alpha-, Beta-, Delta- and Gammaproteobacteria. Betaproteobacteria was most richest in these three systems. Chloroflexi and Nitrospirae in system A and B are remarkably higher than system C, however, the abundance of firmicutes, Bacteroidetes and OP11 in system C were higher than system A and system B. These results proved that the presence of vegetation, types of vegetation all can affect the microbial community structure. The regulation of plant collocation could vary the microbial structure distribution, and eventually optimize the decontamination ability of the wetland system. The results can provide theoretical basis for the selection and matching of constructed wetland plants in the future.

Enzyme activity

The number of microorganisms in system A, system B and system C were 60-90 cm > 30-60 cm > 0-30 cm, 60-90 cm > 0-30 cm > 30-60 cm and 30-60 cm > 60-90 cm > 0-30 cm, respectively. But urease, phosphatase and cellulose were all reduced with the increase of matrix depth. The results showed that the enzyme activity was not necessarily related to the number of microorganisms. Guo (1997) found that the relationship among urease, phosphatase, cellulose activities and microbial biomass were as followed: Enzymes activities increased with the increase of microbial biomass. However, our research was not consistent with it, which may be related to the structure of the VFCW (Aon and Colaneri, 2011) or some function bacterial. Due to the special structure, the oxygen in the upper matrix of the VFCW was relatively sufficient, which was only conducive to the reproduction of aerobic microorganisms. In addition, the enzyme activity of rhizosphere in system A was different from that in system B. Both urease and phosphatase showed that the activity of planting *Pennisetum purpureum Schum.*'s enzyme was higher than that of planting *Pennisetum sinese Roxb*'s enzyme. Enzyme activity around rhizosphere can not only reflect the bacteria activities in plant root zone, but also reflect the effect of plant spices. Different plants have different influence on secretion of enzymes and microorganisms' growth. *Pennisetum sinese Roxb* and *Pennisetum purpureum Schum*. both have large biomass. Therefore, the rhizosphere microorganism quantity and activity are slightly higher. Consequently, *Pennisetum sinese Roxb* and *Pennisetum purpureum Schum.* should be the better vegetation choices for construct wetland to remove pollution.

Water quality changes

The high removal efficiency of TN and COD in this experiment might be attributed to the higher temperature in summer, resulting in higher microbial activities. Temperature indeed has a great effect on the nutrients removal efficiency of CWs (Fan et al., 2013). It could be related to some functional bacteria, for example the Nitrospira are known for their role in nitrite oxidation (Feng et al., 2013), and the proteobacteria often take advantage of ammonia gas produced by the decomposition of organic matter and may have participated in the biological reaction of various organic matters in nature or artificial systems (Madigan et al., 1997; Liao et al., 2013; Liu et al., 2014). It may indirectly explain the effective removal of TN and COD in these three VFCWs. In addition, a previous study also showed that proteobacterium was dominant in the large-scale CW purification and polluted river system (Wei et al., 2015).

Above all, the variation in microbial structure are most likely to reflect the impact of changes in microbial community of constructed wetland in the balance wetland ecosystem. In future studies, we must focus on the potential mechanisms driving community variation and elucidation of how these variations affect the microbial community function of constructed wetlands.

Conclusion

(1) There was no direct relationship between microbial species population and enzyme activity. Meanwhile, planting vegetation whether or not, vegetation type and substrate depth may have a great influence on the bacterial community and substrate enzyme in VFCW. This suggests that we could improve pollutant removal by planting different wetland plants and designing different substrate depths to regulate wetland microorganisms.

(2) Proteobacteria predominated in these three systems, which was mainly included Alpha-, Beta-, Delta- and Gammaproteobacteria, and among them Betaproteobacteria was most abundant. Enzyme activity is independent of microbial populations, but could be related to the populations of corresponding functional bacteria, for example Nitrospira may be related to urease. In future studies, we will further research the specific relationship between enzymes and microorganisms in wetland decontamination, and use genetic engineering to study the decontamination mechanism of microorganisms deeply.

(Received 13th Jul 2019; accepted 25th Nov 2019)

Abstract. A survey of seasonal variations in the distribution of nutrients along a standard section of the East China Sea was carried out between 1991 and 2015. Here, interannual variations of five key nutrients are analyzed and discussed in the context of possible controlling factors, with special attention given to seasonal variations recorded over the year 2015. Results indicate that concentrations of dissolved inorganic nitrogen (DIN), phosphate (DIP) and silicate (DSi) exhibit gradual increases over this period. Measured concentrations of DIN, DIP and DSi were 5.34–11.87 μmol/L, 0.31–0.53 μmol/L and 11.12-23.15 μmol/L, respectively. Since 1996, concentrations of DIN, DIP and DSi have increased significantly. The annual average concentration of DIN , DIP and DSi in the East China Sea were ~2 times greater in 2015 than in 1991, respectively. The N/P ratio exhibits an increasing trend followed by steady-state asymmetric M-type fluctuations. Conversely, the Si/N ratio is generally stable and exhibits an asymmetric W-type fluctuation. The distribution of nutrients in the East China Sea exhibits clear seasonal variations, with phosphate and inorganic nitrogen contents generally higher in autumn and winter than in spring and summer. Silicate content is higher in summer and winter than in autumn and spring. The main source of nutrients into the East China Sea is the Yangtze River plume, with the Taiwan Warm Current providing an additional, secondary source. The combined effects of the Yangtze River plume and the Taiwan Warm Current enforce a decreasing trend in nutrient concentrations from west to east.

Keywords: *inorganic nitrogen, phosphate, silicate, interannual change, seasonal variation*

Introduction

The East China Sea is bordered by the Yangtze River estuary in the west, the Pacific Ocean in the east, the Taiwan Strait in the south and the Yellow Sea in the north. The boundary between the East China Sea and the Yellow Sea is defined by the line between the northern end of the Yangtze River estuary and the southernmost point of Jeju Island. The eastern boundary of the East China Sea with the Pacific Ocean is defined by the Ryukyu Islands. The East China Sea is fed by more than 40 rivers exceeding 100 kilometers in length (Yanzgi et al., 1993; Chu et al., 2005). These rivers add nutrients to the East China Sea which, in turn, supports one of the most highly productive marine ecosystems in the world (Li and Dag, 2004). As a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_973985

result, the distribution and variations in nutrient concentrations in the East China Sea is a topic of great importance that has inspired numerous scientific investigations.

For example, Wang et al. (2008) studied the three-dimensional distribution and seasonal variation of nutrients in the East China Sea. Wang et al. (2019) then improved on these studies by incorporating a three-dimensional low-trophic ecosystem model that revaluated budgets of nutrients and biogenic particles (phytoplankton and detritus) in the East China Sea and found that export of biogenic particles through the Tsushima Strait is greater than that through the continental shelf break.

Based on surveys of nutrient concentrations along three sections in the East China Sea, Cao et al. (2014) compared profiles collected during the relatively wet period of 1989–2010 to more typical profiles along the same sections to identify long-term changes in the concentrations and distributions of inorganic nitrogen, active phosphate and silicate. To evaluate the contribution of each source of nutrients to the nutrient inventory and primary production over the continental shelf, Zhang et al. (2019) tracked the behavior of all of the state variables incorporated into a low-trophic ecosystem model. Using this technique, Zhang et al. (2019) discovered strong seasonal variations in the spatial distribution of nutrient sources attributable to seawater circulation, mixing, and stratification. The ecological effect of these nutrients is in turn affected by the level of nutrient limitation, light availability and water temperature at the locations of each of these sources (Zhang et al., 2019). Mi et al. (2011) used the survey data collected between April and August, 2011, to analyze and discuss the distribution of nutrients in the East China Sea and adjacent Yellow Sea over the spring and summer seasons, as well as various influencing factors. Based on survey data collected over four voyages conducted in the East China Sea (120°–128°E, 25°–33°N) over the spring, summer, autumn and winter of 2013, Ye et al. (2015) analyzed the spatiotemporal distribution and structure of nutrients in the East China Sea and discussed limitations to the growth of phytoplankton.

Excess nutrients can lead to pollution of water in the East China Sea. Moreover, the concentrations and distributions of these nutrients vary from year to year. Therefore, to promote the rational exploitation and utilization of the marine resources in the East China Sea it is important to generate accurate and timely understandings of the distribution, spatiotemporal variations and influencing factors of nutrients in the East China Sea.

In this study, we analyze the results of nutrient monitoring surveys conducted between 1991 and 2015 and evaluate interannual trends and variations in nutrient concentrations and distributions. Additional survey data collected from 30 stations in the East China Sea in the spring (May), summer (August), autumn (November) and winter (February) of 2015 to determine the distribution of nutrients in East China Sea and possible influencing factors are likewise discussed and analyzed. The goal of this study is to systematically investigate the distribution of nutrients in the East China Sea and to identify seasonal, interannual and long-term variations in the distributions of these nutrients over the past 25 years, thereby providing fundamental data by which to advance scientific study of the East China Sea and to promote rational development and utilization of marine resources in this region.

Materials and methods

Sample collection

Samples were collected during a series of four oceanographic research cruises conducted by the Ningbo Marine Environmental Monitoring Center along standard sections of the East China Sea (27–33°N, 121–128°E), China, between 1991 and 2015. The total of 30 survey stations are arranged into 3 oceanographic sections supplemented by four auxiliary stations. A map of the relevant survey stations is presented in *Fig. 1*.

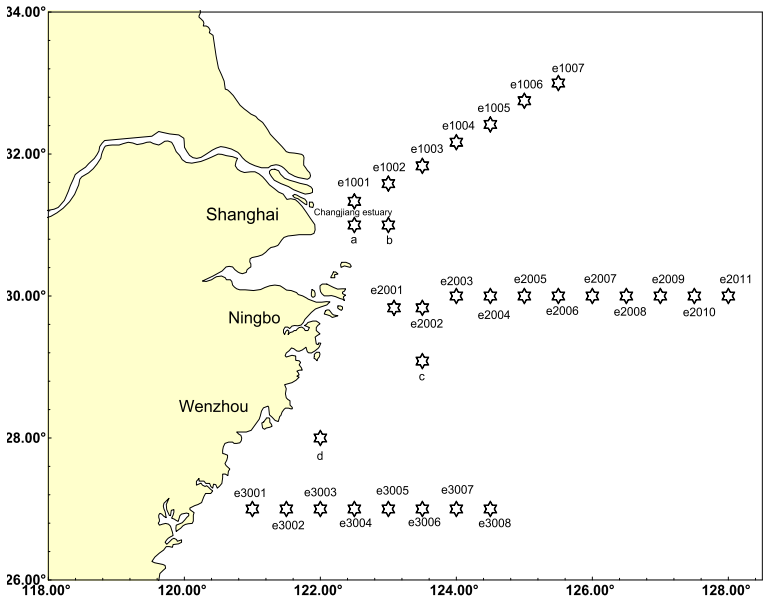

Figure 1. *Sampling sites in the East China Sea*

Sampling and analysis

Full water-depth sampling of seawater was conducted using a CTD self-capacitive sampler (Seabird, USA). Samples were filtered using a HCl acid-washed neutral pH cellulose acetate fiber filtration membrane (0.45 μm). After filtration, nutrient assays were conducted using the methods outlined in the fourth volume of the marine survey code (GB17378.4-2007): the investigation of the chemical elements in sea water (Xu et al., 2005). The analytical methods and detection limits for dissolved inorganic phosphate (DIP), nitrite (NO_2-N), nitrate (NO_3-N), ammonium salt (NH_4-N) and silicate (DSi) are presented in *Table 1*. Dissolved inorganic nitrogen is the sum of the nitrate, nitrite and ammonia nitrogen components (*i.e.*, DIN =NO_3-N+NO_2-N+NH_4-N). Data interpolations between sampling locations, statistical data processing and visualization were carried out using the Surfer software (Golden Software, USA).

Data processing

Long-term trends in nutrient concentrations were evaluated by performing a linear regression on monitoring results obtained in August and calculating the Pearson correlation coefficient, R. (*Eq. 1*)

This coefficient was defined as the correlation coefficient between the time series {X} and the integers {n}, i=1,2,3,...,n. In this study, n is the total span of years of the data. The coefficient was computed from the following equation:

$$R = \frac{\sum (x-\bar{x})\cdot(y-\bar{y})}{\sqrt{\sum (x-\bar{x})^2 \cdot \sum (y-\bar{y})^2}} \quad \text{(Eq.1)}$$

where y=(n+1)/2. Its significance level is determined from the Student's t-test. A positive (negative) value of *R* indicates that the time series {X} has a linear positive (negative) trend (Liu et al., 2005).

Results and discussion

Interannual variations in nutrient concentrations

Analyses of dissolved nutrient concentrations indicate that concentrations of DIN in the East China Sea gradually increased over the study period, from 5.34 μmol/L in 1991 to 11.87 μmol/L in 2015 (*Fig. 2*). Concentrations of DIP likewise gradually increased, from 0.31 μmol/L in 1991 to 0.49 μmol/L in 2015 (*Fig. 3*). Concentrations of DSi exhibit high levels of interannual variability (*Fig. 4*). However, with the exception of a large increase in 1999, the trend is generally increasing, from 11.12 μmol/L in 1991 to 23.15 μmol/L in 2015. Since 1996, the average concentration of DIN, DIP and DSi in the East China Sea have increased significantly. The annual average concentration of DIN in the East China Sea in 2015 was ~2 times greater than that measured in 1991, the annual average concentration of DIP increased ~1.6 times, and the annual average concentration of DSi increased ~2 times.

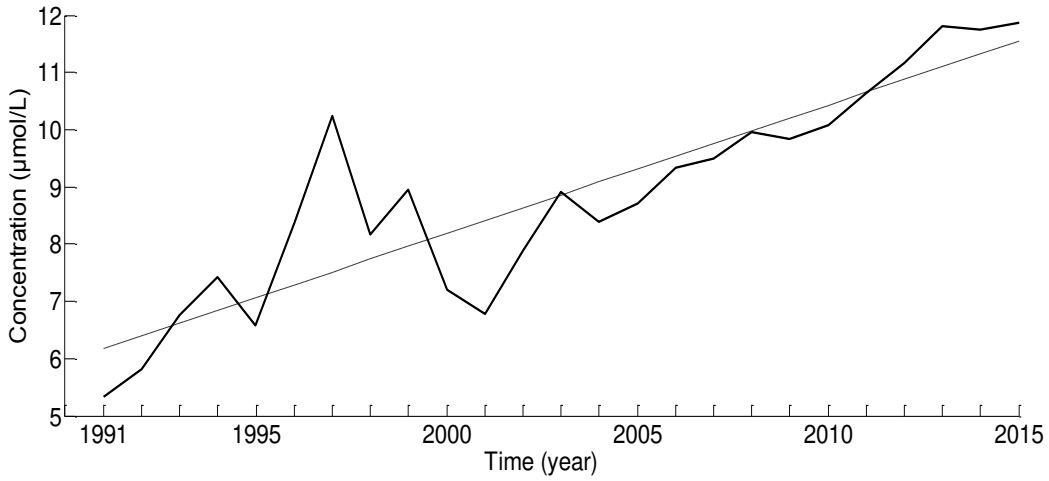

Figure 2. *Interannual variations and long-term trends in DIN concentrations in the East China Sea*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_973985

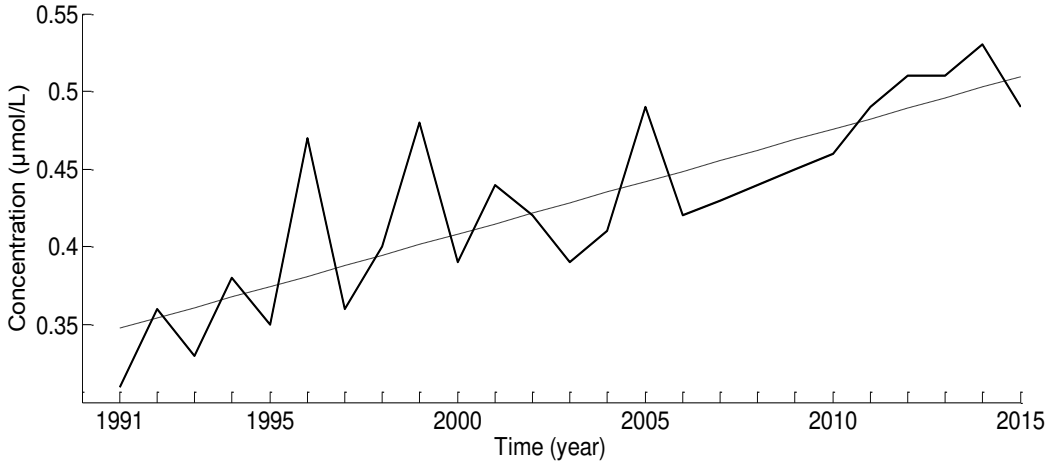

Figure 3. *Interannual variations and long-term trends in DIP concentrations in the East China Sea*

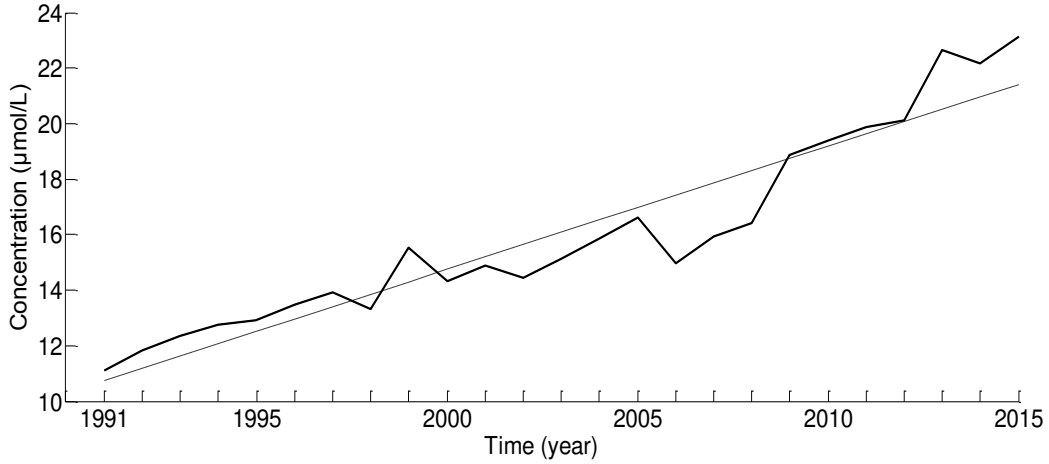

Figure 4. *Interannual variations and long-term trends in DSi concentrations in the East China Sea*

The nutrient content of samples collected at Datong Station on the Yangtze River exhibit a similar historical change to that of the East China Sea (Li et al., 2007), suggesting that annual variations in DIN and DIP in the East China Sea are synchronized with those of the Yangtze River estuary (Chen et al., 2011). As a result, we propose that the increase of DIN and DIP in the East China Sea is primarily attributable to runoff from the Yangtze River. Since 1996, the concentration of DIN and DIP in the East China Sea has increased significantly (Cao et al., 2014). Bing et al. (2019) analyzed velocity and nutrient data collected from satellite images and *in situ* measurements between 1993 and 2014 to study spatiotemporal variations in cross-shelf nutrient exchanges at the 200 m isobath. Average integrated nitrate transport (FQ) over this 22-year period is 22.0±12.4 kmol/s (Bing et al., 2019). Furthermore, the on- and off-shelf components of FQ are roughly twice that of FQ itself, such that variations in FQ over time are primarily determined by the on-shelf component (Bing et al., 2019).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_973985

While interannual variations in FQ are greater than seasonal variations, no persistent interannual signal was identified (Bing et al., 2019). Our results show that this increase is also in line with a longer term gradual trend, which would suggest that these increases in nutrient concentrations are caused by long-term environmental changes. For example, the development of agriculture and the establishment of chemical industrial facilities along the coast and along the Yangtze River would tend to increase the input of nutrients from land sources, including runoff from the Yangtze River. Acting in contrast to this trend, the expansion of sewage processing facilities would tend to decrease the amount of coastal industrial pollutants and related inorganic nutrient directly discharged into the sea. Processes within the ocean, such as physical dilution by oceanic seawater and the absorption of nutrients by marine phytoplankton would also serve to modify nutrient concentrations in the East China Sea (Luo, 2006).

As concentrations of DIN, DIP and DSi change, derivative ratios such as N/P and Si/N also change (Li et al., 2007). It is generally considered that the proportion of C: Si: N: P suitable for diatom growth is 106: 16: 16: 1 (Xia et al., 2007), and that changes in nutrient concentrations affect the cell size and community composition of phytoplankton (Pätsch et al., 1997; Egge et al., 1998). Between 1991 and 2015, the N/P ratio of nutrients in the East China Sea increased gradually and then stabilized after 2009, exhibiting an asymmetric M-type pattern (*Fig. 5*). The maximum and minimum values of N/P appeared in 1997 and 2001, respectively, and their values were 28.44 and 15.41. Between 1991 and 2009, the average Si/N ratio in the East China Sea exhibited an asymmetric W-type fluctuation (*Fig. 6*). The maximum and minimum values of Si/N appeared in 2001 and 1997, respectively, and their values were 2.20 and 1.36. After 2009, the Si/N ratio gradually stabilized between 1.80 and 1.95.

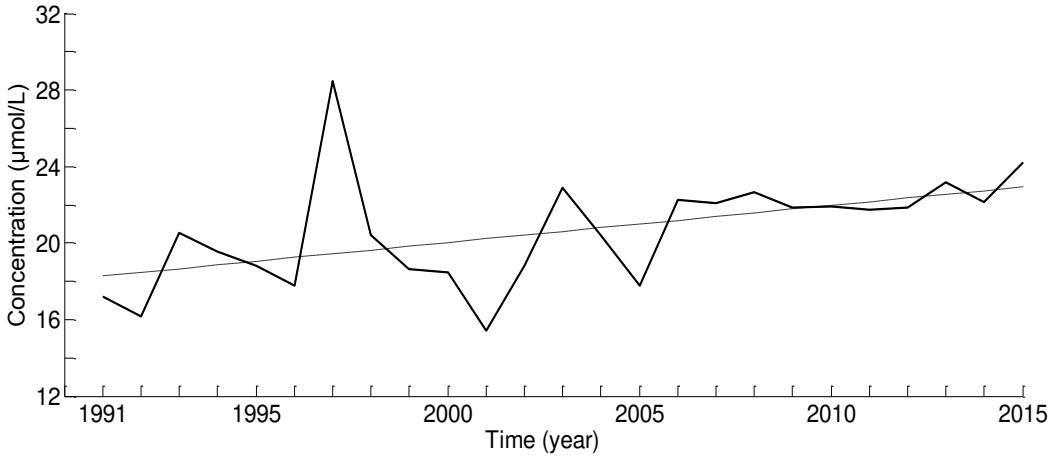

Figure 5. *Interannual variations and long-term trends in the N/P ratio in the East China Sea*

A large number of studies have shown that the value of N/P is closely related to the growth of phytoplankton (e.g., Chen et al., 2011). When plankton masses proliferate, although nitrogen and phosphorus are consumed in large quantities, inorganic nitrogen still maintains a high concentration. However, the proportion of N/P in the East China Sea was basically maintained at 21.93 ± 6.51. This ratio is only slightly higher than that reported by Redfield (1958) and is largely attributable to the high concentration of inorganic nitrogen.

DOI: http://dx.doi.org/10.15666/aeer/1801_973985

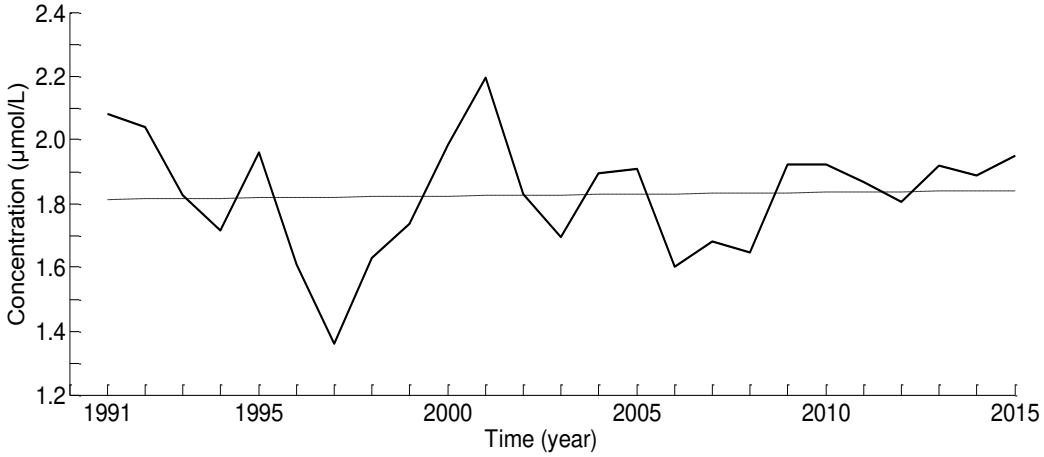

Figure 6. *Interannual variations and long-term trends in the Si/N ratio in the East China Sea*

The Si/N ratio in East China Sea is greater than 1. Therefore, DSi is not a limiting factor in the growth of diatoms. In recent years, changes in sediment transport have had a direct effect on the flux of dissolved silicate to the ocean (Humborg et al., 1997). However, our data show that despite high levels of interannual variation, the Si/N ratio of the East China Sea has been generally stable. Over the past twenty-five years, the N/P and Si/N ratios of seawater in the East China Sea show a trend of roundabout rise, and all tend to be stable. The interannual variation of nutrients in the East China Sea is becoming much more stable, which may be related to changes the runoff, sediment transport and the structure of N and P use in chemical fertilizers (Chen et al., 2011). This apparent stabilization is closely related to the relevant policies of the total pollution control of the marine environmental and the protection of the marine environment.

Distribution of nutrients in East China Sea District surface waters

Figure 7 shows the planar distribution of phosphate, inorganic nitrogen, and silicate in the surface waters based on samples collected during the four research cruises. It can be seen from the figure that high surface concentrations of phosphate, inorganic nitrogen, and silicate in the East China Sea in the spring (May), summer (August), autumn (November) and winter (February) of 2015 appear in the waters of the Yangtze River estuary, and expand to form dense isolines. As the importance of oceanic waters increases with distance offshore, surface concentrations of phosphate, inorganic nitrogen, silicate gradually decrease. Controlling for location, surface concentrations of phosphate are higher in winter and autumn than in summer and spring. This pattern may be related to the gradual growth of surface water phytoplankton in the in the spring and the associated large amount of phosphate absorption. Surface concentrations of inorganic nitrogen were likewise higher in winter and autumn than in spring and summer. Surface concentrations of inorganic nitrogen increased in autumn and reached the highest value in winter before decreasing in spring, and reaching the lowest value in summer. Concentrations of DIN may be affected by the expansion of runoff from the Yangtze River. Areas of high DIN concentrations are centered around the Yangtze River estuary, whereas DIN concentrations generally decrease with distance from the estuary. The main reason for this structure of nutrients is the segregations of surface

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_973985

waters from nutrient-rich deep waters over the summer and subsequent depletion of biogenic nutrients in surface waters (Ning et al., 1998). Surface concentrations of DSi are higher in summer and winter than in autumn and spring. The distribution of silicate in the waters of the Yangtze River estuary is basically the same as that of the Yangtze River, which extends as two tongues, one to the northeast and a second to the southeast, with a wide range of influence (Zhu et al., 2005).

Analysis of changes in nutrients

Changes in the distribution of nutrients in the East China Sea are closely related to seasonal variations in marine biological activities and internal biogeochemical nutrient cycling mechanisms. Nutrient concentrations are additionally controlled by complex circulation patterns in the East China Sea, which are strongly affected by seasonal variations in Yangtze River discharge and associated nutrient transport (Gao et al., 2004; Ye et al., 2017). Previous studies of nutrients in the East China Sea have indicated that the Kuroshio, Taiwan warm current, the Yellow Sea warm current and the Yangtze River estuary plume with its associated freshwater input greatly affect the distribution of nutrients and that substantial exchanges occur between these contrasting water masses (Wang et al., 2002; Chen et al., 2007).

The East China Sea is located in the East Asian monsoon region, which has exhibited a high rate of global environmental change. This leads to challenges in researching the dynamics of nutrient concentrations and related biogeochemical processes and marine ecosystems, which are strongly affected by complex monsoon-driven physical and chemical conditions (Liu et al., 2003). The outer sea area of the East China Sea is strongly influenced by the western side of the Taiwan warm current. Hence, contrasting concentrations of nutrients occur in the surface water and the bottom water. The invasion path of the Taiwan warm current into the East China Sea is characterized by a high level of nutrients in the bottom water (Wang et al., 2008). Nutrient concentrations in East China Sea surface water are primarily influenced by the input of freshwater from the Yangtze River, and high concentrations of nutrients occur in coastal surface waters of the Yangtze River estuary, as well as off the coasts of Zhejiang and Fujian provinces. Surface waters in the open ocean are greatly affected by the influence of the Kuroshio Current, where nutrient concentrations are generally low. Deeper waters are affected by the decomposition of organic matter, and nutrient concentrations generally increase with depth (Mi et al., 2012). The concentration of nitrate in the freshwater of the Yangtze River is high (the highest concentration is up to 100 μmol/L), but the concentration of phosphate is relatively low (Liu et al., 2008). As a result, the concentrations of nutrients in the sea area near the Yangtze River estuary is significantly larger than that of the middle and bottom layers. This further indicates that the main source of the nutrients into the East China Sea is the Yangtze River, and that phosphate concentrations in the East China Sea are primarily controlled by concentrations in the Yangtze River and the Taiwan warm current (Shi et al., 2003). Nutrient concentrations exhibit a decreasing trend from west to east or, alternatively, with distance offshore. The nutrient concentrations of DIN, DIP and DSi in the Kuroshio Subsurface Water and Kuroshio Intermediate Water are additionally quite high, indicating that these water masses, together with Changjiang Diluted Water (CDW), are probably important contributors to the nutrients inventories of the northeastern section of the East China Sea (Liu et al., 2017).

Conclusion

Based on the analysis of nutrient concentrations in seawater samples taken along standard oceanographic sections in the East China Sea for nearly 25 years, we conclude that concentrations of DIN, DIP and DSi exhibit a gradual increase characterized by interannual variability. Concentrations of DIP, DIN and DSi range from 5.34-11.87 μmol/L, 0.31–0.53 μmol/L and 11.12–23.15 μmol/L, respectively. From 1996, the concentrations of DIN, DIP and DSi increased significantly. In 2015, the annual average concentration of DIN in the East China Sea was ~2 times greater than in 1991, the annual average concentration of DIP was ~1.6 times greater, and the annual average DSi concentration was ~2 times greater. This increase in nutrient concentration primarily reflects increases in land-source emissions, physical dilution by ocean water and absorption of nutrients by phytoplankton. The N/P ratio of the East China Sea is generally stable and exhibits an asymmetric M-type fluctuation. The Si/N ratio is likewise generally stable and exhibits an asymmetric W-type fluctuation. This may be related to changes in runoff and sediment transport as well as changes in the N and P structure of chemical fertilizer over recent years. Certain policy changes, such as China's recent efforts to control China's total marine pollution and protect marine environments may also play a significant role.

The distribution of nutrients in the East China Sea exhibits clear seasonal variations. Concentrations of phosphate and inorganic nitrogen are higher in winter and autumn than that in summer and spring. Silicate concentrations are higher in summer and winter than in autumn and spring. The major source of nutrients into the East China Sea is the Yangtze River estuary plume. Consequently, nutrient concentrations decrease from west to east.

Despite the scale of this study, we advocate for the adoption of continued annual marine environmental monitoring, which will provide reliable data support for decision-making by China's marine environmental management departments. We additionally propose strengthening marine environmental monitoring and early warning systems and adherence to the strategy of sea and land pooling. Recognizing that data alone will not solve any environmental issues, we additionally advocate for the strengthening marine protection efforts and promoting these efforts through more widespread awareness and environmental education.

Abstract. Illumina high-throughput sequencing was applied to study the microbial community structure and seasonal variations in the mudflat sediments of Sansha Bay, China. Significant seasonal differences of microbial communities were observed, and pH, total P, total N, and organic carbon concentration were important factors affecting the microbial communities. A total of 52 bacterial phyla were detected in the sediments, dominated by *γ-Proteobacteria* (27.78%), *δ-Proteobacteria* (20.16%) and Bacteroidetes (10.58%). A total of 717 bacterial genera were detected, and among the top 100 genera with the highest abundances, 48 genera changed significantly (p <0.05) with seasons. The microbial community structure in summer was significantly different from others, and the environmental factors driving the changes were mainly temperature, organic carbon and total N concentration. The bacteria with higher abundances in summer were mainly attached bacteria, thermophilic bacteria, anaerobic bacteria, and those involved in carbon and nitrogen cycling, while in other seasons, those with higher abundances were mainly aerobic bacteria, which could adapt to low temperatures and are involved in the degradation of cellulose and chitosan. However, the physicochemical indexes didn't change significantly, which indicated that the bacterial communities are more sensitive and can serve as a good sentinel for environmental changes.
Keywords: *Illumina high-throughput sequencing, bacterial genetic diversity, seasonal changes, intertidal sediments, physiochemical characteristics, Sansha Bay*

Introduction

Traditionally, marine environmental quality is assessed by physical-chemical and biological indexes, such as dissolved oxygen (DO), chemical oxygen demand (COD), nitrogen (N), phosphorus (P), heavy metal, persistent pollutant, and so on (Arsad et al., 2012). However, such static indexes have difficulties characterizing the structure and function of the marine ecosystem (Viswanathan et al., 2010). At present, most of the biological indicators used to characterize ecosystem structure and function are large animals, plants or benthos (Cabana et al., 2013; Hannah, 2015; Wang et al., 2018), or some microscopically visible single-celled organisms, such as diatoms and cyanobacteria (Daby, 2006). Nevertheless, when the impact of the disturbance has caused obvious changes in these biological indicators, the time of early warning is long gone.

Microorganisms are one of the most important components of the intertidal zones of mudflat ecosystems, and are involved in nutrient cycling, energy flow, organic matter degradation, and pollutant removal. Microbial communities are sensitive to environmental variation, which makes them ideal biological indicators for environmental pollution and ecosystem changes (Sun et al., 2012). Total coliforms,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_9871000

fecal coliforms (*Escherichia coli*) and enterococci have been commonly used as indicators to assess the microbiological safety of water resources (Lage and Bondoso, 2011). Previous studies also showed that there was a positive and strong association of total phosphorous, total nitrogen, and ammonium-nitrogen contents with micro-eukaryotes and Gram-positive bacteria (Zhao et al., 2010), and several metals are also strongly associated with microbial community composition (Cao et al., 2006). Although microorganisms are more sensitive to environmental changes and are better indicators for environmental quality, they have not been adopted as environmental quality indexes yet due to our poor understanding of them and the difficulty of detection. The emergence of molecular biological technique, especially the high-throughput sequencing, has provided us important opportunity for fully and deeply understand environmental microbes because of the high data throughput (10^3–10^6 sequences per sample), high accuracy and low cost. This technique enables us to identify the dominant and rare populations within a community simultaneously, thus it could reveal a significantly greater level of microbial diversity than conventional molecular tools (Binladen et al., 2007; Caporaso and Gordon, 2011).

Sansha Bay is a typical enclosed bay, which is located on the southeastern coast of Ningde City, Fujian Province, and includes Dongwuyang, Guanjingyang, and Sanduao. The streams and rivers from the eight surrounding cities, with a basin area of 8,700 km^2, flow into this harbor, containing the domestic sewage of over 2 million people (Tang et al., 2018). In recent years, due to the high discharge of domestic sewage and industrial wastewater as well as the large inflow of residual breeding bait, the mudflat environment has been subjected to substantial pollution. The main goals of the study are to investigate the community structure and seasonal variations of organisms in mudflat sediments of Sansha Bay, and their relationship to physicochemical indexes. The results present here will provide microbial parameters for assessing the environment quality, and to lay a foundation for further illumination of the ecological functions of microorganisms in mudflat sediments.

Methods

Sample collection and physiochemical index analysis

The study was performed in the Northern Yantian port of Sansha Bay (*Fig. A1*). The total area was about 2.6 acre, at an east longitude from 119.7975 to 119.7986 and a northern latitude from 26.8411 to 30.8422. The study area was divided into four plots, and sediment samples of each plot were collected on 10 October, 2014 (autumn), 2 January, 2015 (winter), 6 April 2015 (spring), and 2 July 2015 (summer). The sediments of the surface layer (top 3-5 cm) were removed and about 200 g subsurface sediments from three different sites within the same plot were collected and mixed as one sample, resulting in a total of 16 samples in four batches. The samples were termed as Oct-P1 to Oct-P4, Jan-P1 to Jan-P4, Apr-P1 to Apr-P4, Jul-P1 to Jul-P4, according to sampling time and sampling plots.

All the 16 sediment samples were used for the determination of the physicochemical indices, 10 g sediments of each sample were freeze-dried in a lyophilizer (Labconco, Kansas City, MO, USA). The following parameters were analyzed, and each sample was measured twice. Total nitrogen (TN) was determined via the Kjeldahl method (Bradstreet, 1954) and total phosphorus (TP) via the ammonium molybdate spectrophotometric method (GB11894-89, China; Huang,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_9871000

2000). Organic matter contents (OrgC and OrgS) were determined via a Vario Max CNS analyzer (Elementar, Hanau, Germany). For the determination of pH, sediment and water were mixed at a ratio of 1:5 (W/V). Water temperature (Tm) was measured on the site.

DNA extraction, PCR amplification, and Illumina sequencing

For DNA extraction with the PowerSoil DNA Isolation Kit (MOBIO-Laboratories, USA), we used 0.25 g of the sediment samples. The V4 variable region in the bacterial 16S rRNA gene was amplified with the primer pair 515F (5'- GTG CCA GCM GCC GCG GTA A-3') and 806R (5'- GGA CTA CHV GGG TWT CTA AT-3'). The PCR products of the different samples were mixed with equimolar concentration and sent to the Majorbio Co. Ltd. (Shanghai) for paired-end sequencing through the Illumina Miseq platform.

Bioinformatic analysis

Post-processing of the Illumina sequence reads included quality control and clustering of the operational taxonomic unit (OTU) with 97% sequence identity. The QIIME was applied to collect the OTUs for sequence clustering, the chimeras were removed, and OTU abundance was defined. The RDP Bayesian classifier was applied to conduct taxonomic analyses on OUT-representative sequences with 97% similarity level; the classification was identified in the Silva database (Release128 http://www.arb-silva.de), and the community composition of each sample was analyzed at each classification level, including phylum, class, order, family, genus, and OTU.

Mothur software was used to analyze alpha diversity. Community diversity was estimated by Shannon (Magurran, 1988) and Simpson (Simpson, 1949) indices. The total number of species in each sample was estimated with Chao1 and Ace. Phylogenetic diversity (PD) whole tree was used to analyze the relationships among observed species. Sampling coverage was used to evaluate whether the sequencing quantity is enough.

Hierarchical clustering was analyzed by the unweighted pair group method with arithmetic (UPGMA). Student's *t*- test was used to test the significant difference of alpha diversity in different season, and one-way ANOVA was used to test the differences of physicochemical factors or bacterial communities at the phylum and genus levels. All statistical analyses were carried out using software SPSS 18.0 or stats packages in the R environment (version 3.2.2, http://www.r-project.org) (R Development Core Team, 2008).

Redundancy Analysis (RDA) was used to reveal the relationship between physicochemical factors and bacterial community composition (Wollenberg, 1977). Forward selection of physicochemical factors was performed by Monte Carlo test with 999 permutations. The Partial Mantel test was also applied to distinguish the relative contribution of time variables (Legendre et al., 2016). RDA was carried out using rda packages in R environment. The original sequence data obtained was submitted to the NCBI SRA database with the registration number PRJNA505598.

Results

Sequencing results and alpha diversity analysis

We obtained a total of 533,568 effective high-quality sequences, which were classified into 65,517 OTUs, with an average of 4,095 ± 346.52 OTUs in each sample. Sequence homogenization was conducted to obtain 30,000 sequences in each sample, followed by alpha diversity analysis; the results are shown in *Table 1*. The coverage of each sample was over 96%, indicating that most bacterial groups could be determined. However, the sequencing depth did not reach saturation, which indicates that the microflorae in the sediment of Sansha Bay was highly abundant. The Shannon index values ranged from 6.31 to 7.02, while the PD index varied between 179.61 and 242.73. The diversity index variations in each sample were not significantly different (p >0.05, *Table A1*) among the different seasons.

Beta diversity

According to the beta diversity distance matrix, hierarchical clustering analysis was conducted at different classification levels, and the UPGMA algorithm was used to construct the tree structure (*Fig. 1*). *Figure 1* shows that the clustering results were not stable at the phylum and class levels. However, from the order to the OTU level, except for sample Jan-P4, the other samples were clustered into four categories according to the sampling time; the most significant difference was observed between the summer sample and other samples, while the differences were lower among spring, autumn, and winter samples.

Microbial community structure and seasonal changes in mudflat sediments in Sansha Bay

Microbial community structure and dynamic changes at the phylum level

We detected a total of 52 bacterial phyla in the mudflat sediments of Sansha Bay (*Fig. 2*). The dominant microbial phylum was *Proteobacteria*, and the proportions of *γ-Proteobacteria*, *δ-Proteobacteria* and *α-Proteobacteria* in the total sequences were 27.78, 20.16 and 4.36%, respectively. The subdominant phylum *Bacteroidetes* accounted for 10.58% of the total sequences. The other abundant phyla were *Planctomycetes* (5.09%), *Chloroflexi* (4.95%), *Acidobacteria* (3.65%), *Nitrospirae* (2.38%), *Cyanobacteria* (2.10%), *Gemmatimonadetes* (1.94%), *Verrucomicrobia* (1.59%), and *Latescibacteria* (1.01%). The proportions of the other 42 bacterial phyla, including *Spirochaetae*, *Actinobacteria*, and *Ignavibacteriae*, were always below 1%.

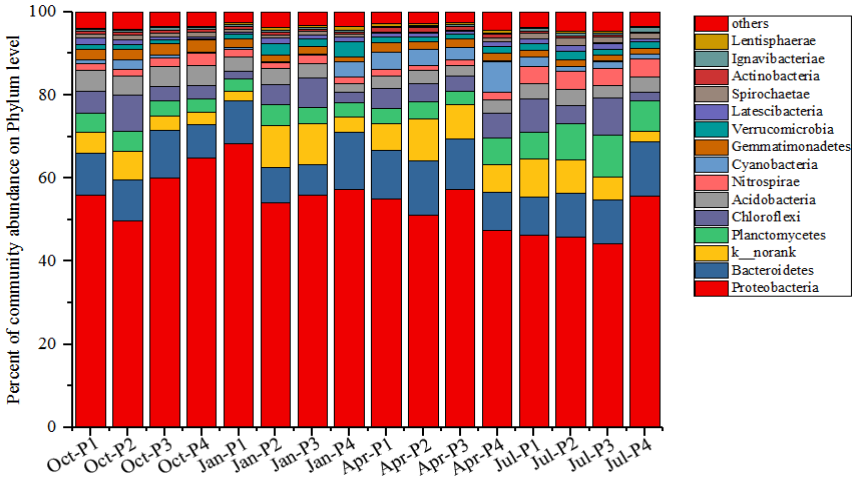

Figure 2. *Microbial communities in mudflat sediments of Sansha Bay, China, at the phylum level (Oct, Jan, Apr and Jul indicate sampling times; P1, P2, P3 and P4 represent four different sampling plots)*

Of the 52 bacterial phyla, 14 showed significant differences (p <0.05, *Table A2*) among the different sampling seasons. Compared with the other seasons, the abundances of nine phyla were significantly increased in summer, including *Planctomycetes*, *Nitrospirae*, *Spirochaetae*, *Ignavibacteriae*, *Hydrogenedentes*, *KSB3_Modulibacteria*, *Chlorobi*, *Tenericutes*, and *PAUC34f*. In contrast, the abundances of two phyla, *Actinobacteria* and *Armatimonadetes*, were significantly increased in winter.

Microbial community structure and dynamic changes at the genus level

A total of 717 bacterial genera were detected in the sediments of Sansha Bay. The dominant microbial genus that could be identified was *Desulfobulbus*, which occupied 4.97%. The subdominant genus were *Nitrospira* (2.34%) and *Sva0081_sediment_group* (1.73%). Most of the genera occupied less than 1%, including *Halioglobus*, *Draconibacterium*, *Deferrisoma*, *Spirochaeta*, *Urania-1B-19_marine_sediment_group*, *Haliea*, *Desulfatiglans*, *Aquibacter* and so on. In addition, unclassified genera also occupied a large proportion, such as c_*Gammaproteobacteria* (occupied 6.69%), f_*JTB255_marine_benthic_group* (6.22%) and o_*Gammaproteobacteria Incertae_Sedis* (4.32%), etc.

Among the top 100 genera with the highest abundances, 48 genera showed significant variations (p <0.05, *Table A3*). The clustering results of the heat map (*Fig. 3*) also indicated significant seasonal differences in the microbial community structures, with more significant differences between summer and other seasons and smaller differences among spring, autumn, and winter. Compared with the samples from the other seasons, in summer, 13 genera showed significantly higher abundances, including *Nitrospira*, f_*Flammeovirgaceae*, *Deferrisoma*, *Spirochaeta* and f_*Lentimicrobiaceae*, etc., while in winter, genera *Aquibacter*, *Kangiella*, *Lutibacter* and other 9 genera increased significantly. In autumn, 14 genera increased significantly, including *Haliea*, *Desulfatiglans*, *Sulfurovum*, *Robiginitalea*, and *Haliangium*, etc., while only *Halioglobus* and other 8 genera increased significantly in spring.

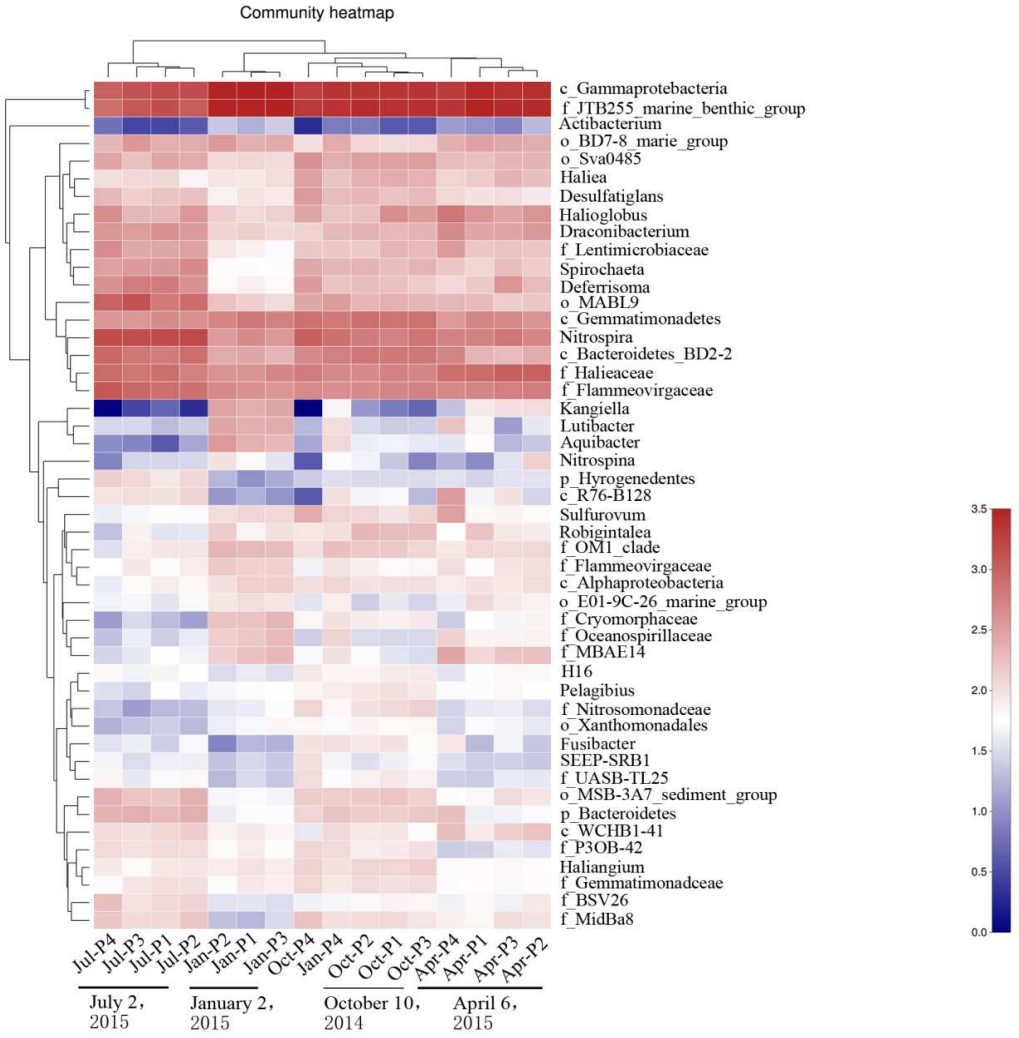

Figure 3. *Heatmap of the microbial communities in mudflat sediments of Sansha Bay, China, at the genus level. (Oct, Jan, Apr and Jul indicate sampling times; P1, P2, P3 and P4 represent four different sampling plots)*

Physicochemical indices of mudflat sediments in Sansha Bay and the relationships with microbial communities

The values of the physicochemical indices are shown in *Figure 4*. In the different sampling seasons, pH ranged from 8.37 to 8.59, with highest values in spring and lowest values in winter. Temperature varied between 12.61 and 30.06℃, with highest values in summer and lowest values in winter, and the difference between summer and winter had reached a significant level (p <0.05, *Table A4*). Furthermore, organic carbon, total nitrogen, and total phosphorus concentrations were also highest in summer, while the organic sulfur levels were lowest in summer and highest in winter. However, except for the temperature, all these differences among other physicochemical indices were not statistically significant.

At the genus level, the microbial communities were used as indicators for environmental changes applying redundancy analysis (RDA), and six physicochemical indices of the sediment, including TP, TN, OrgC, OrgS, Tm, and pH, were used as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_9871000

explanatory variables (*Fig. 5*). The RDA1 and RDA2 explained 76.48 and 3.74% of the total variance, respectively. At the genus level, the microbial community structure in summer differed most significantly from those of the other seasons, followed by the community structure in spring. In contrast, the communities in winter and autumn showed a higher similarity. TP, TN, OrgC, Tm, and pH were important factors affecting the microbial community structure and were correlated (p <0.05) or highly correlated (p <0.01) with microbial community structure (*Table A5*).

Discussion

Previous studies have indicated temperature is an important factor influencing microbial diversity in mudflat sediments (Hicks et al., 2018). The seasonal differences of microorganisms in mudflat sediments of Sansha Bay were significant, and the summer samples most significantly differed from the samples taken in the other seasons. This was consistent with the significantly higher water temperature in Sansha Bay at summer, indicating a highly significant correlation between temperature and microbial communities. Temperature was also an important factor affecting phytoplankton communities, and in a previous study, the phytoplankton density increased with increasing water temperatures (Wang et al., 2015). While, the higher phytoplankton density results in the release of higher amounts of dissolved organic matter, directly affecting the microbial community structure (Shabarova et al., 2017). Also it can be seen in *Fig. 5*, TN and OrgC were significantly correlated with the microbial community structure and had the highest impacts on microbial communities in summer.

In terms of microbial community composition, the abundance of *Planctomycetes* was significantly higher in summer, and most of them are attached bacteria (Caporaso and Gordon, 2011). The significant increase of such bacteria in summer might be related to the generally higher biomass levels in summer. Bacteria which were significantly increased in summer included those involved in nitrogen or carbon cycles, such as *Nitrospirae* and *Nitrospira*, which are important nitrite-oxidizing bacteria. The phylum *Spirochaetae* is mainly composed of anaerobic heterotrophic microorganisms, which are involved in lignocellulose degradation and nitrogen fixation (Chen et al., 2017a). *Chlorobi* is a strictly anaerobic photoautotrophic bacterium and able to fix CO_2. The higher input rates of N and P, the lower the relative abundance of *Chlorobi* (Ling et al., 2017). The phylum *Ignavibacteria* consists of strictly organotrophic, facultatively anaerobic bacteria which are divided from *Chlorobi*. They play an important role in the degradation of polycyclic aromatic hydrocarbons (PAHs) and in the removal or organic matter (Kadnikov et al., 2013). Some bacteria in *Hydrogenedent* are involved in key geochemical processes including sulfur, nitrogen, and carbon cycles and generally survive in dark and hypoxic sub-surface biospheres (Momper et al., 2018). Most of the genera with significantly increased abundances in summer are thermophilic microorganisms. For example, the optimum growth temperature of *Deferrisoma* is 50℃, while both *Nitrospira* and *Draconibacterium* can survive temperatures above 30℃, corresponding to the relatively high temperatures in summer (Du et al., 2015; Hoshino et al., 2016; Daims and Wagner, 2018).

The bacterial species with increased abundances in the other seasons were mainly aerobic bacteria and involved in the degradation of cellulose and chitosan. In winter, the abundance of *Actinobacteria*, which can adapt to lower temperatures, was significantly increased, and they played important roles in carbon cycling and the decomposition of cellulose and chitosan (Aparicio et al., 2018). *Armatimonadetes*, a group of aerobic oligotrophic soil bacteria with a wide distribution, was chemoautotrophic and involved in the degradation of photosynthetic biomass (Hu et al., 2014). Previous studies have found that *Armatimonadetes* might also be involved in hydrolysis-fermentation and the degradation of cellulose (Lee et al., 2014). The abundance of genera *Lutibacter* and *Aquibacter* in the family *Flavobacteriaceae* are also significantly increased in the winter. *Flavobacteriaceae* can degrade high-molecular-weight organic polymers, including cellulose, chitosan, and proteins (Wissuwa et al., 2017), while *Kangiella* can

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_9871000

use lignocellulose degrade by-products derived from it, facilitating the degradation of rhizome residues in sediments (Darjany et al., 2014). The increased abundances of these bacteria in winter might be related to the lower temperatures, decreased organic nutrient content, increased dissolved oxygen levels, as well as the relatively higher contents of animal and plant residues. *Gemmatimonadetes*, with a significantly higher abundance in autumn, are common soil bacteria and can adapt to low humidity levels; they are an indicator for semiarid ecosystems (Genderjahn et al., 2018); this corresponds to the decrease in relative humidity in autumn. *Halioglobus*, with a significantly increased abundance in spring samples, is a Gram-negative aerobic bacterium and can reduce nitrate into N_2 (Chen et al., 2017b).

Conclusion

The microbial community structure in the Sansha Bay sediments presented significant seasonal variations, with the most significant differences in summer. The environmental factors driving this microbial community variation were mainly temperature, but also organic carbon and total nitrogen concentrations. However, no significant differences were observed in physicochemical indexes among different seasons, this indicated that the bacterial communities are more sensitive and can serve as a good sentinel for environmental changes. The results present here provide microbial parameters for assessing the environment quality, and to lay a foundation for further illumination of the ecological functions of microorganisms in intertidal sediments. However, most of our discussions regarding the bacterial functions derived from previous studies, clearly a combination of the high throughput sequencing approach presented here and isolation and characterization of the indicator bacteria will both be required in the future to better understand microbial functionality. Furthermore, numerous microbial groups detected in this study were uncategorized or unidentified, and their physiological functions needed to be further investigated.

Table A4. *P values of physicochemical indices of mudflat sediments in Sansha Bay*

Estimators	P value (autumn-spring)	P value (autumn-winter)	P value (autumn-summer)	P value (spring-winter)	P value (spring-summer)	P value (summer-winter)
pH	0.0574	0.5801	0.0837	0.0571	0.1535	0.0840
OrgC	0.5801	0.1396	0.0500	0.1070	0.1007	0.0563
OrgS	0.4003	0.5565	0.1755	0.1318	0.5527	0.0534
TP	0.0503	0.0545	0.0572	0.5966	0.6832	0.5979
TN	0.5598	0.1488	0.0975	0.4626	0.0599	0.0513
Tm	0.0559	0.0594	0.0503	0.0519	0.0503	0.0212

TN, TP, OrgC and OrgS, Tm represent total nitrogen, total phosphorus, Organic carbon and sulfur contents, Water temperature, respectively

Table A5. *P values and envfit of Physicochemical indices in Sansha Bay*

Estimators	RDA1	RDA2	r^2	P value
pH	-0.1782	0.984	0.5437	0.004
OrgC	-0.9734	0.2292	0.6121	0.001
OrgS	0.7598	-0.6501	0.2965	0.097
TP	-0.5014	0.8652	0.4572	0.016
TN	-0.9868	-0.1622	0.6171	0.002
Tm	-0.9042	0.4272	0.8758	0.001

TN, TP, OrgC and OrgS, Tm represent total nitrogen, total phosphorus, Organic carbon and sulfur contents, Water temperature, respectively
