Abstract. In Heilongjiang of China, the income of farmers affects the consumption of chemical agricultural products. This study simulated the relationships between chemical fertilizers, pesticides, agricultural film, and farmers' income growth for Heilongjiang (2005–2017) using Environmental Kuznets Curve (EKC) models. The results show that the total agricultural output value and the per capita income of farmers showed a decreasing trend, respectively. However, influenced by economic and policy factors, both chemical fertilizers and pesticides showed an N-shaped curve. The total agricultural output value and farmers' income growth in Heilongjiang had been at the "fast-growing" stage, with low environmental pollution according to the agricultural pollution level. Thus, the control of agricultural non-point source pollution has been quite effective, and as a result the agricultural environment improved significantly. The EKC models provided scientific evidence for estimating agricultural non-point source pollution load as well as their changeable trends for Heilongjiang from an economic perspective.
Keywords: *agricultural non-point pollution, chemical fertilizers, pesticides, per capita income of farmers, Heilongjiang*

Introduction

For a long time, China's grain output has increased greatly mainly as a result of the use of chemicals, such as fertilizers, pesticides and agricultural film. The input of chemical agricultural means has increased annually, and the scale has been expanding (*Fig. 1*). The low utilization rate of agricultural chemical means has led to the increasingly prominent problem of agricultural non-point source pollution, which has become a hot issue of social and public concern (Ongley et al., 2010; Huang et al., 2013; Li et al., 2014; Wang et al., 2019).

Grossman and Krueger (1995) introduced the EKC hypothesis, suggesting the existence of an inverse U-shaped relationship between pollutants and economy growth/income. It is reflected in the Environmental Kuznets Curve hypothesis which argues that as per capital income increases, environmental damages also rise to the maximum point at the beginning stage of economic development and eventually declines

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15511565

with the increase in income level (Barbier et al., 1996). The hypothesis is represented by an inverted U-shaped diagram that depicts the relationship between the level of environmental degradation and the economic growth (Grossman and Kruger, 1995).

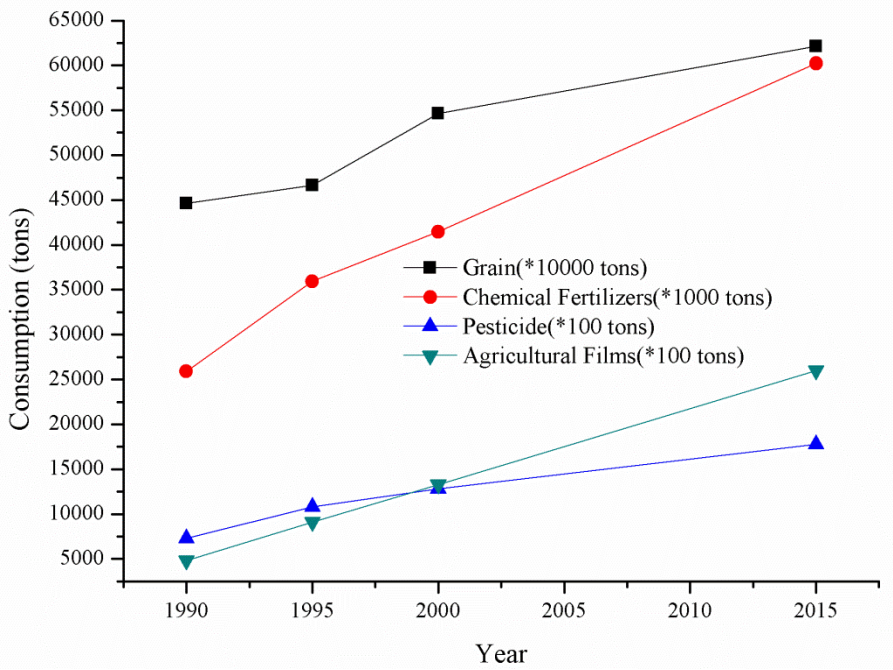

Figure 1. *The relation between grain growth and consumption of chemical agricultural production material in China. (Source: Department of Rural Socio-Economic Survey, National Bureau of Statistics)*

Empirical evidence on environmental risks in the US agricultural sector since 1970 supports the existence of increasing returns. Managi (2006) estimated the productivity of pesticide pollution abatement using refined empirical productivity measurement methods and explicitly control the level of technology. Their study showed the importance of including an environmental productivity variable in the EKC frame work. Jin et al. (2016) used time series data from 2000 to 2013 to verify the Environmental Kuznets Curve of pesticide use and economic growth in China, and to analyze the reasons for the increase of pesticide use in order to provide basis for the realization of pesticide reduction and sustainable agricultural development. Their results revealed that there is a significant inverted U-shaped curve relationship between pesticide use and per capita GDP and per capita gross agricultural output growth. That is, with economic growth, pesticide use increased first and then decreased. At present, China is still in the left half of the EKC curve, indicating that the use of pesticides is still in the rising stage (Zhang et al., 2019; Tzeremes, 2019). In order to achieve zero or even negative growth of pesticide use in China, it is necessary to formulate relevant policies for pesticide reduction and increase the promotion of advanced technology. Zhou et al. (2017) studied the provincial level data of 31 provinces (cities and districts) in China from 1993 to 2013, quantitatively analyzed the relationship between pesticide use and economic growth, and qualitatively explored the driving factors. The results show that there is a significant inverted U-shaped relationship between pesticide use and economic growth in China and other 24 provinces (cities and districts), except 7

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15511565

provinces (cities and districts). Among them, the use of pesticides in seven provinces (cities and districts) is still in the rising stage, and has not reached the peak; the use of pesticides in eight provinces (cities and districts) has reached the peak and showed a downward trend; the EKC curve of nine provinces (cities and districts) is in the "N" shape, and the use of pesticides is still in the rising stage.

The emission of non-point source pollutants from fertilizers in China shows an increasing trend (Shi et al., 2019). Mao et al. (2013) estimated the loss of phosphorus and nitrogen fertilizer in Ningxia irrigation area, and tested the relationship between agricultural non-point source pollution and farmers' per capita income. The results also supported the EKC hypothesis. Based on the provincial panel data from 1988 to 2016, Jie et al. (2018) examined the relationship between agricultural growth and non-point source pollution of fertilizers in China. On this basis, he used LMDI method to further investigate the internal causes of EKC formation. The results show that there is a significant "inverted U" EKC relationship between non-point source pollution of fertilizer and agricultural growth in China. The addition of space-time factors does not change the shape of EKC curve, but changes the time of inflection point. Wei et al. (2017) studied the effects of fertilizer input on water resources of Nanpanjiang River basin in Guizhou Province, taking fertilizer input and per capita income of rural residents in Guizhou Province from 2006 to 2015 as samples. Their results show that there is an Environmental Kuznets Curve between fertilizer input and environment, and the government and relevant departments should control the non-point source pollution caused by fertilizer input.

Shang et al. (2017) selected agricultural pollutants such as the intensity of agricultural film application as the evaluation index of agricultural non-point source pollution in Heilongjiang Province to verify the relationship between per capita agricultural output value and Environmental Kuznets Curve of agricultural non-point source pollution. Through research and analysis, the following conclusions are drawn: There is an EKC relationship between agricultural film and per capita agricultural output value in agricultural non-point source pollution sources in Heilongjiang Province, and the Environmental Kuznets Curve is inverted "N" type. On this basis, countermeasures and suggestions for non-point source pollution control in Heilongjiang Province are put forward. Combined with the first national census data of China, Dai et al. (2019) calculated agricultural non-point source pollution indexes based on the basic data of statistical yearbook. The results show that the overall trend of agricultural non-point source pollution is increasing yearly. From the EKC fitting curve test of agricultural non-point source pollution and per capita agricultural output value, it can be seen that the density of agricultural film use and per capita agricultural output value have a significant inverted u-shaped relationship. Combined with the results of empirical analysis, the paper puts forward some suggestions and measures to improve the situation of non-point source pollution in agriculture, increase agricultural economic growth and promote coordinated green development of agricultural environmental protection.

Materials and methods

Study area

Heilongjiang province (121°11′-135°05′E, 43°26′-53°33′N), located in the northeast of China, adjacent to Russia, is the world's famous major grain producing area (*Fig. 2*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15511565

It consists of thirteen municipalities and sixty-seven counties. The province covers a total area of 4.73×10^5 km^2, which accounts for 4.9% of China. Heilongjiang Province has been the main grain-producing area in China. In 2016, the cultivated land area was 1.24×10^7 ha, accounting for 7.5% of the whole country and 56.1% of the three northeastern provinces (Department of Rural Socio-economic Survey, National Bureau of Statistics, 2017). From the initial stage of the founding of the People's Republic of China, the annual output of grain has been increasing steadily reaching a breakthrough of 5×10^{10} kg in 2010. In 2018, the Province's total grain output reached 7.5×10^{10} kg, achieving a "15-years of bumper harvest "and ranking first in the country for eight consecutive years. In 2017, Heilongjiang's grain output accounted for 9.7% of the total national grain output and 51% of the three northeastern provinces (Department of Rural Socio-economic Survey, National Bureau of Statistics, 2018). Therefore, After the Sino-US Trade Dispute in 2018, the issue of agricultural resources and environmental security in Heilongjiang Province is of great significance in China.

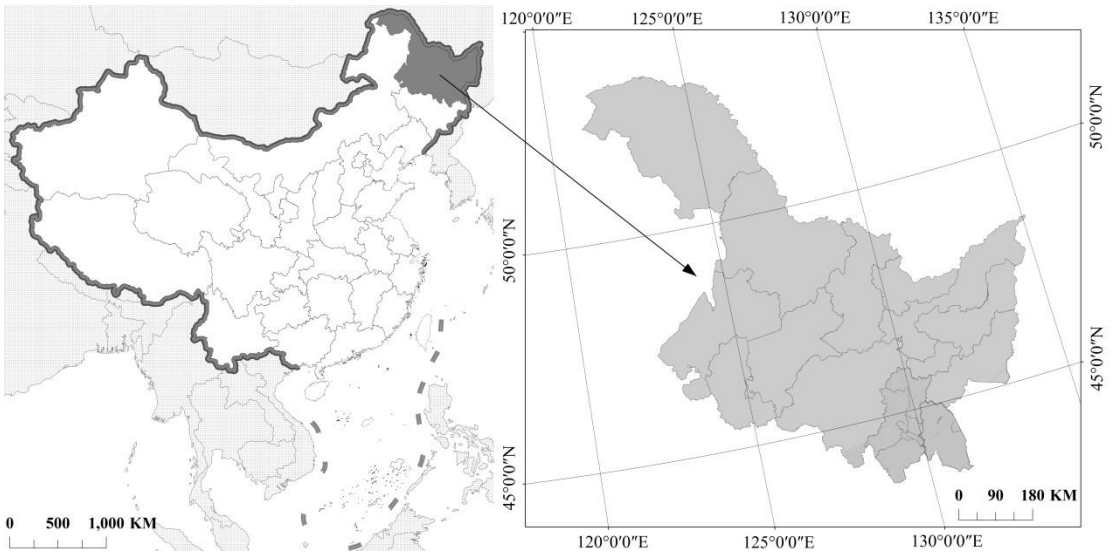

Figure 2. *Location sketch map of Heilongjiang Province*

Data and model

Data sources and processing

In order to analyze the relationship between farmers' income growth and agricultural non-point pollution in Heilongjiang, China, our empirical research used time series of consumption of chemical fertilizers, pesticides and agricultural films for the period 2005-2017 (*Table 1*). Data of farmers' income, consumption of chemical fertilizers, pesticides and agricultural films were obtained from the Heilongjiang Statistical Yearbook. The Data were processed using Excel 2016 and SPSS 20.

Model

On the basis of Environmental Kuznets Curve theory, the theoretical equation of the EKC between agricultural non-point pollution and farmers' income is

$$y = \beta_0 + \beta_1 X + \beta_2 X^2 + \beta_3 X^3 + \varepsilon$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15511565

where y is the environmental indicators, x is the per capita annual Net Income of farmers, β_0 is a constant, β_1, β_2 and β_3 is the estimated coefficient, ε is the error term.

Table 1. *Empirical research data in 2005-2017*

Year	Consumption of chemical fertilizers (10000 tons)	Consumption of pesticide (10000 tons)	Consumption of agricultural films (10000 tons)	Per capita annual net income of farmers (yuan)
2005	121.6	2.9	5.3	3221
2006	150.9	4.8	5.7	3552
2007	175.2	6	6.4	4132
2008	180.7	6.2	6.6	4856
2009	198.9	6.7	6.5	5207
2010	214.9	7.4	6.9	6211
2011	228.4	7.8	7.6	7591
2012	240.3	8.1	8.5	8604
2013	245	8.4	8.5	9634
2014	251.9	8.7	8.4	10453
2015	255.3	8.3	8.3	11095
2016	252.8	8.3	8.3	11832
2017	251.2	8.3	7.9	12665

The relationship between economic development and environment quality can be very complicated. From the above formula, we can draw seven relationships between environmental pollution and economic growth in the model.

1. If $\beta_1 > 0$, $\beta_2 = 0$, $\beta_3 = 0$, it shows that the relationship between economic growth and environmental pollution is a simple incremental one, which satisfies the first-order function relationship. The bigger the first-term coefficient is, the more serious the pollution will be with economic growth, as shown in the straight line *a* of *Figure 3*.

2. If $\beta_1 < 0$, $\beta_2 = 0$,$\beta_3 = 0$, it shows that the relationship between economic growth and environmental pollution is simple and decreasing, which satisfies the first-order function relationship, and the smaller the first-term coefficient, the better the environmental quality will be with the rapid economic growth, as shown in the straight line *b* below.

3. If $\beta_1 < 0$, $\beta_2 > 0$, $\beta_3 = 0$, it shows that the relationship between environmental quality and economic growth is a normal U-shaped relationship, which first improves and then deteriorates. Unlike the traditional inverted U-shaped Environmental Kuznets Curve (EKC), the environmental condition first improves and then deteriorates, as shown in *Figure 3c*.

4. If $\beta_1 > 0$, $\beta_2 < 0$, $\beta_3 = 0$, it shows that the relationship between environmental quality and economic growth is an inverted U-shaped relationship that deteriorates first and then improves. This is also a typical shape in international experience. The deterioration of environmental quality has a turning point, which is the highest or extreme point of environmental pollution, as shown in *Figure 3d*.

5. If $\beta_1 > 0$, $\beta_2 < 0$, $\beta_3 > 0$, it shows that the relationship between environmental pollution and economic growth is an N-type relationship, which first deteriorates, then

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15511565

improves, and finally deteriorates. The Environmental Kuznets Curve is shown in *Figure 3e*.

6. If $\beta_1 < 0$, $\beta_2 > 0$ and $\beta_3 < 0$, it shows that the relationship between environmental pollution and economic growth is an inverted N-type relationship, which first improves, then deteriorates, and then improves. The Environmental Kuznets Curve is shown in *Figure 3f*.

7. If $\beta_1 = 0$, $\beta_2 = 0$, $\beta_3 = 0$, it shows that there is no linear relationship between environmental pollution and economic growth, and there is no Environmental Kuznets Curve.

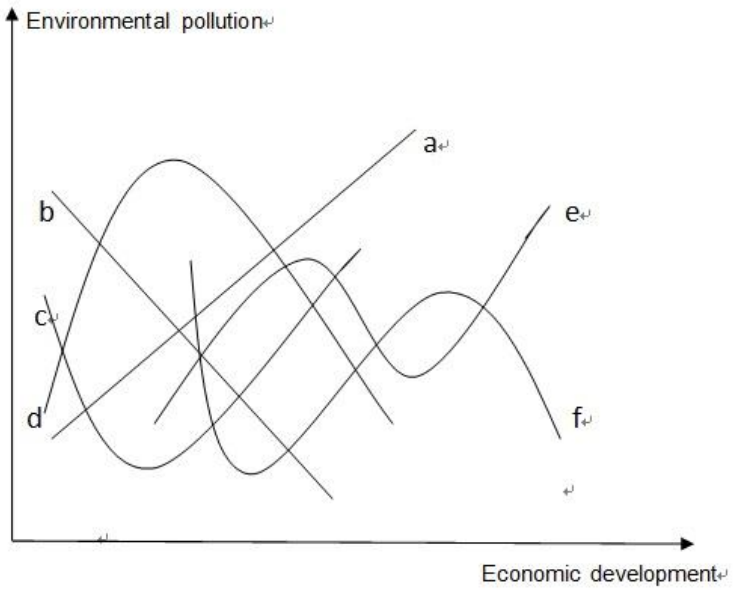

Figure 3. *Shape diagram of Environmental Kuznets Curve*

In this study, the per capita annual income of farmers was selected as the indicator which reflected the agricultural economic growth of Heilongjiang. Heilongjiang is a major agricultural province, agriculture is an important economic base. Therefore, the consumption of chemical fertilizers, pesticides and agricultural films was selected as the indicator which responded to pollution level of Heilongjiang.

With the help of SPSS software, income of farmers (as the horizontal axis) and agricultural production means (as the vertical axis) were fitted by linear, quadratic and cubic models. The results indicate that the cubic model can better reflect the relationship between consumption of chemical fertilizers, pesticides and income of farmers. The quadratic model can better reflect the fitting relationship between consumption of agricultural films and per capita income of farmers. For this reason, the relationship between income of farmers and agricultural environmental quality were fitted by the quadratic and cubic regression curve model (*Table 2*).

From the regression model of farmers' income of Heilongjiang with consumption of agricultural production means, it can be seen that the regression coefficient (R^2) of income with consumption of chemical fertilizer, pesticides and agricultural films was over 0.7. The fitting effect of per capita annual income of farmers and agricultural pollution index was ideal.

Table 2. *The analysis results of regression model*

Agricultural pollution index (Y)	Model summary					Regression equation
	R^2	F	$df1$	$df2$	Sig.	
Chemical fertilizers consumption	0.962	76.278	3	9	0.026	$Y = (1.728e-10)X^3 + (-5.360e-06)X^2 + 0.0545X - 9.889$
Pesticides consumption	0.891	24.643	3	9	0.036	$Y = (1.245e-11)X^3 + (-3.630e-07)X^2 + 0.003X - 4.357$
Agricultural films consumption	0.792	19.023	2	10	0.003	$Y = (-2.956e-08)X^2 + 0.001X + 3.250$

Results and analysis

Agricultural development of Heilongjiang

From 2005 to 2017, the economy of Heilongjiang has grown rapidly. The Gross Domestic Product (GDP) increased from 554.28 billion yuan to 1590.27 billion yuan, an increase of approximately threefold, with an average annual growth rate of 15.58%. In addition, the per capita GDP increased from 14516 yuan to 41916 yuan, a 2.89-fold increase, with an average annual growth rate of 15.73%, and the per capita income of farmers increased from 3221 yuan to 12665 yuan, increased by 3.93 times, with an average annual growth rate of 24.43%, which exceeded the growth rate of GDP and per capita GDP (*Fig. 4*).

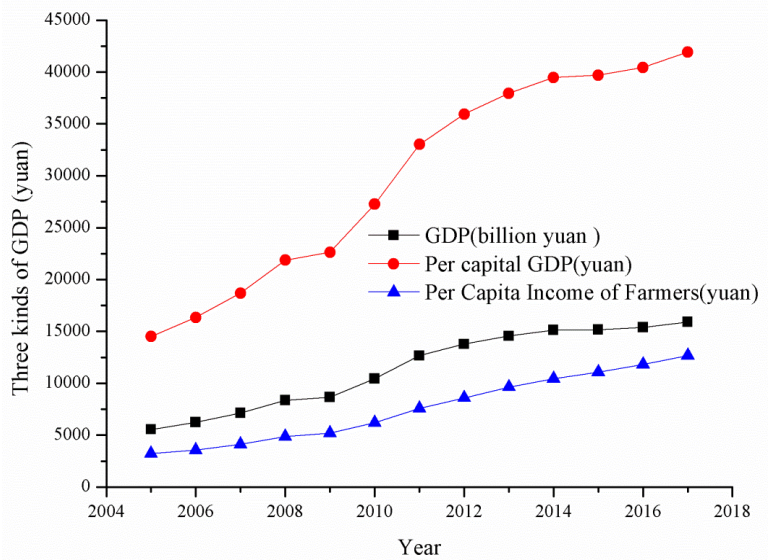

Figure 4. *The growth trend of GDP, per capita GDP and farmers' income in Heilongjiang during 2005~2017*

From 2005 to 2017, the growth rate of Heilongjiang's total agricultural output value is ahead of the whole country. China's agricultural output value increased 2.77 times, Heilongjiang's agricultural output value increased 4.32 times, and the growth rate exceeded China's agricultural output value by 1.56 times (*Fig. 5*). The average annual growth rate of China's total agricultural output value is 14.76%, while that of Heilongjiang Province is 27.63%, which is 1.87 times higher than the growth rate of China's total agricultural output value.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15511565

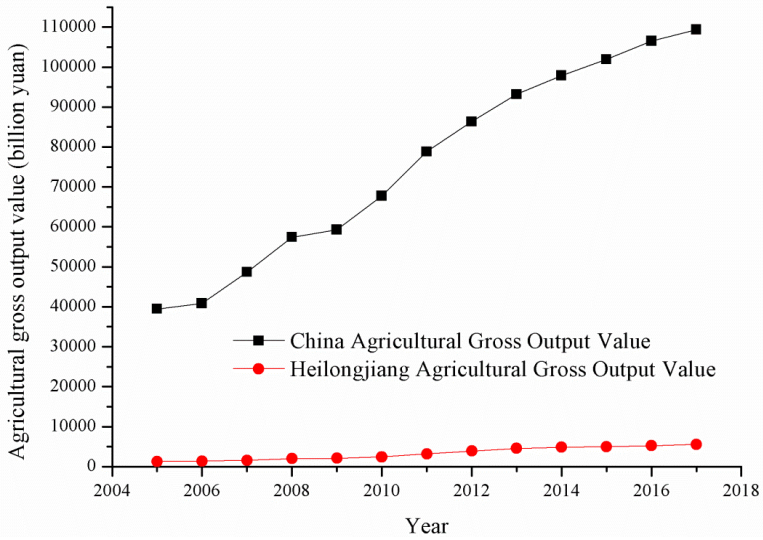

Figure 5. *The agricultural gross output value of China and Heilongjiang 2005~2017*

In the 13 years period (from 2005 to 2017), China's grain output has increased by 1.37 times, while Heilongjiang's grain output has increased by 2.06 times, and the grain growth rate is 1.5 times that of the whole country (*Fig. 6*). The average annual grain growth in China is 3.1%, compared with 8.8% in Heilongjiang, which is 2.84 times higher than that of the whole country. Heilongjiang accounted for 7.4% of the country's grain output in 2005, and increased to 11.2% in 2017.

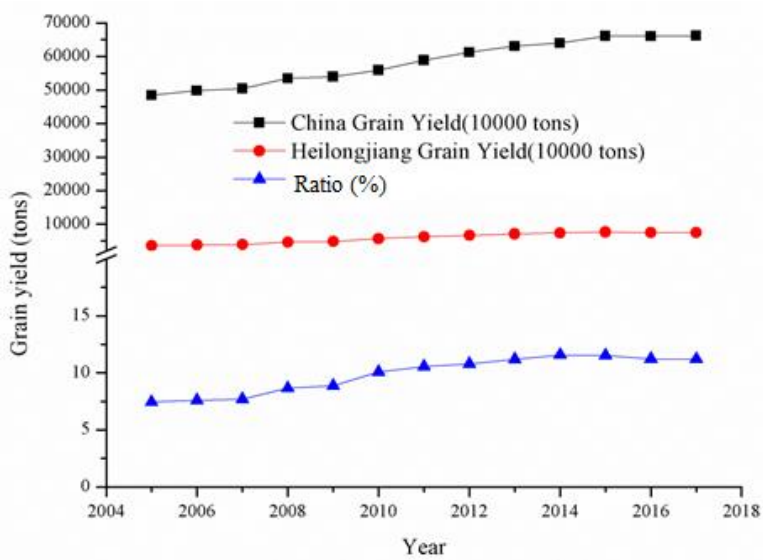

Figure 6. *The grain yield of China and Heilongjiang during 2005~2017*

In summary, the annual income growth rate of farmers exceeded the regional GDP and per capita GDP growth in Heilongjiang. The growth rate of Heilongjiang's total agricultural output value is obviously faster than that of the whole country. Heilongjiang is the most important major grain producing area in China, which is of great significance for ensuring national food security (Qi and Wu, 2017).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15511565

Agro-eco-environmental changes from 2005 to 2017 in Heilongjiang

With the growing demand of grain in China, the use of chemical fertilizers has also increased yearly. Until 2017, the intensity of fertilizer application in Heilongjiang Province was 170.10 kg/hm^2, which was 1.58 times higher than that in 2005, but still less than the world's recognized safety limit of 225 kg/hm^2 (Shi et al., 2016). The cubic model can better reflect the relationship between consumption of chemical fertilizers and income of farmers.

$$Y = (1.728e-10)X^3 + (-5.360e-06)X^2 + 0.0545X - 9.889 \quad \text{(Eq.1)}$$

As we can see, from the result of curve fitting, it is roughly "N" type, and the per capita income of farmers at inflection point was 9634 yuan (*Fig. 7*). Before the inflection point, the intensity of fertilizer application increased with the increase of income. When the inflection point approached, the growth rate decreased significantly. After the inflection point exceeded 12665 yuan, the intensity of fertilizer application increased significantly. The result was similar to that of Hebei, Jilin, Jiangsu, Jiangxi, Guangdong, Hainan, Sichuan, Yunnan, Shanxi, Gansu and other 10 provinces (Liu et al., 2009). The relationship of fertilizer consumption and agricultural economic growth matched the N-shape EKC in Heilongjiang province (Shang et al., 2017). Without control, the input of fertilizer will continue to increase. Generally speaking, there is an EKC relationship between fertilizer application intensity and per capita income of farmers, and it is on the left side of the EKC curve. It can be understood that agricultural economic growth brings farmers' income. On the other hand, the rising demand for grain in China promotes the development of grain production, and the application of fertilizer also increases. This is consistent with the conclusion of some scholars (Bruyn and Opschoor, 1997; Opschoor, 1997) that the N-shaped curve is caused by economic factors.

The cubic model can better reflect the relationship between consumption of chemical pesticides and income of farmers.

$$Y = (1.245e-11)X^3 + (-3.630e-07)X^2 + 0.003X - 4.357 \quad \text{(Eq.2)}$$

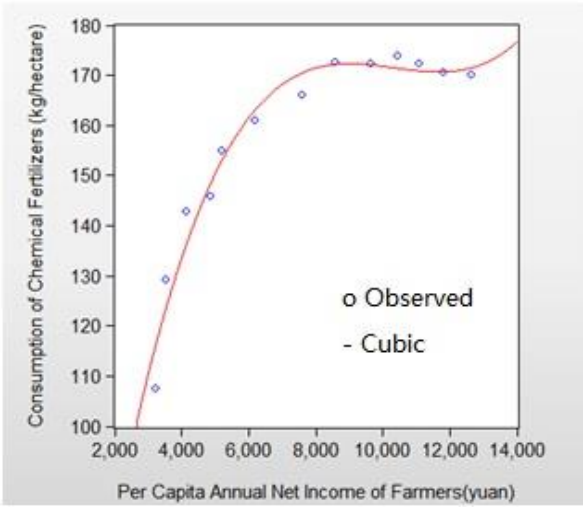

Figure 7. *The fitting curve of fertilizer consumption and per capita income of farmers in Heilongjiang during 2005~2017*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15511565

From the fitting income curve results of pesticides and farmers, it presented N-type EKC curve (*Fig. 8*), and the turning point was 7591 yuan per capita income of farmers. Before the turning point, the intensity of pesticide application increased with the increase of agricultural economy, and the growth rate of pesticide use decreased significantly near the turning point, while the intensity of pesticide application increased significantly after exceeding 11832 yuan. The intensity of pesticide application in Heilongjiang Province decreased with the increase of per capita agricultural income from 2014, because the overall planting structure of Heilongjiang Province has changed in recent years. There has been witnessed reduction of planting area of some cash crops and increase of planting area of Maize with lower pesticide consumption. This therefore has attributed reduction in the use of chemical herbicides. On the other hand, the production technology of pesticides has improved. Farmers are opting for the use of foliar spray hence the utilization rate of pesticides has been more efficiently Appeal causes led to the development of the right side of the EKC curve. Friedl and Getzner (2003) believed that the N-shaped curve is caused by policy factors. The application of pesticides in Heilongjiang validates this conclusion. There are about 232 million pesticide waste packages (bottles, bags and barrels) in Heilongjiang Province each year. The total weight of these packages is about 7,000 tons, and the residual pesticides in the packages are about 180 tons (Lin, 2017). The main causes of pesticide pollution in Heilongjiang Province is attributed to the weak awareness of environmental protection of farmers and safe use of pesticides; the lack of effective recovery methods and harmless treatment technology in the field of pesticides; and the lack of effective supervision mechanism for the use of pesticides.

The quadratic model can better reflect the fitting relationship between consumption of agricultural films and per capita income of farmers.

$$Y = (-2.956e-08)X^2 + 0.001X + 3.250 \quad \text{(Eq.3)}$$

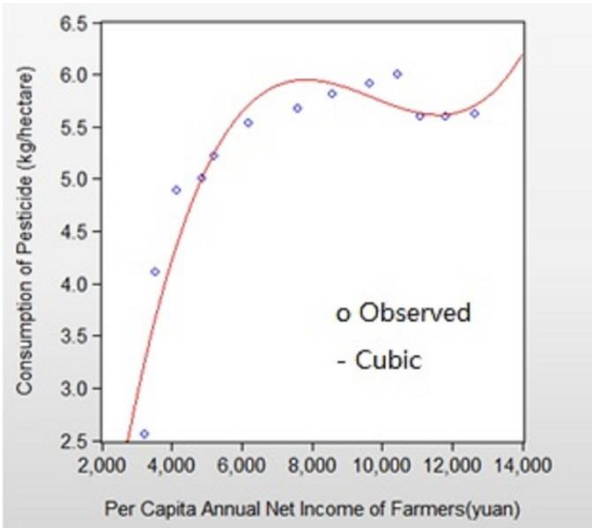

Figure 8. *The fitting curve of pesticide consumption and per capita income of farmers in Heilongjiang during 2005~2017*

According to the fitting curve results of agricultural film and income of farmers, it was a typical inverted U-shaped curve. The turning point of EKC occurred at 9634 yuan

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15511565

of per capita income of farmers. Before the turning point, the intensity of agricultural film application increased with agricultural economic growth, and then increased slowly when approaching the turning point. After exceeding 9634 yuan, the intensity of agricultural film application decreased sharply. As we can see from *Figure 9,* the agricultural film consumption showed a fluctuation from 2005 to 2017. The year 2012 was a turning point. Before 2012, the agricultural film consumption showed an increasing tendency, an increase of about 1.3 times, with an average annual growth rate of 20.29%. After 2012, the agricultural film consumption started to decrease gradually, with a decline of 12.23% in 2017 compared with 2012, which has confirmed the results of the EKC of agricultural film consumption and per capita income of farmers.

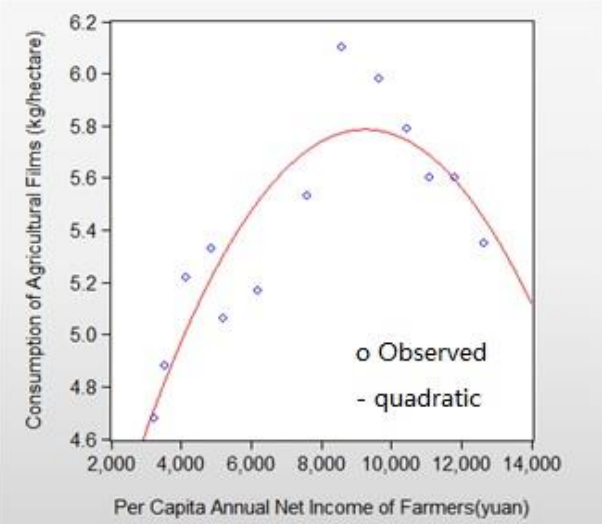

Figure 9. *The fitting curve of agricultural film consumption and per capita income of farmers in Heilongjiang during 2005~2017*

Control of agricultural non-point source pollution

A case study in north China showed that the amount of rural pollution source control reduced significantly, so as to protect and improve the environmental quality (Meng et al., 2014). In order to develop modern ecological agriculture, promote the transformation of China's grain base into a green granary and ensure food safety, Heilongjiang Province has implemented the "Three Reductions" of chemical fertilizers, chemical pesticides and chemical herbicides, and issued the "Opinions on the Implementation of the 'Three Reductions' of Agriculture in-depth". The opinions put forward that by 2020, the average application amount of chemical fertilizer per hectare should be reduced by more than 10%, the utilization rate of chemical fertilizer should be increased by 6.7%, the utilization rate of pesticides should be increased by 9%, and the use of herbicides should be reduced by more than 14,000 tons, or by 20%.

In controlling agricultural non-point source pollution, Heilongjiang Province has taken seven key measures.

Firstly, precise fertilization can be achieved by popularizing the technology of soil testing and formula fertilization and adjusting the structure of chemical fertilizer use.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15511565

Secondly, adhere to the combination of agriculture and animal husbandry, support large-scale aquaculture enterprises and large-scale farms, build fecal treatment facilities, encourage social capital to invest in the construction of organic fertilizer treatment plants, and promote harmless fermentation technology of livestock and poultry manure.

The third is to promote the technology of deep mechanical fertilization, water and fertilizer integration, foliar spraying and other effective fertilization techniques to reduce chemical fertilizer and improve fertilizer utilization rate.

The fourth is to demonstrate and popularize bio-pharmaceuticals and environmental protection agents, replacing low-activity pesticides and chemical additives with high-activity pesticides and environmental protection additives.

Fifth, to develop and improve the information management and prediction system of on-line monitoring of pests and diseases, establish a regional early warning and network management platform system above county level, and comprehensively enhance the ability of monitoring and early warning of major pests and diseases.

Sixth, through the national public welfare investment, the construction of centralized dispensing service stations, the precise allocation of pesticides, packaging and residual liquid recovery and treatment.

Lastly is to continue to implement subsidy policies for subsidy of subsistence land consolidation, so that all suitable cultivated land will be subsided once every three years to improve land output capacity.

In 2018, the provincial high standard demonstration area of "Three Reductions" in agriculture reached 2.7 million ha. Tieli City carried out the "three-reduction" agricultural action, reducing the application of chemical fertilizer by more than 30 kg/ha, pesticide by 5% and herbicide by 5%. Nenjiang County completed the "three-reduction" agricultural demonstration area of 300,000 ha in 2018, with the application of organic fertilizer and farm manure reaching 648,000 tons, with an average reduction of 18% in the three indicators.

Agricultural non-point source pollution control in Heilongjiang has achieved results. From *Figure 10,* it can be seen that the application intensity of fertilizer and pesticide in Heilongjiang reached the highest value in 2014 from 2005 to 2017, which was 173.75 kg/ha and 6.0 kg/ha respectively, and showed a decreasing trend yearly. The application intensity of agricultural film reached the highest value of 6.10 kg/ha in 2012, and then decreased afterwards.

Conclusion and suggestions

In summary, the relationship between agricultural environment and agricultural economic growth was harmonious in Heilongjiang. While maintaining 24.43% annual growth of farmers' income during the period from 2005 to 2017, Heilognjiang has managed to significantly reduce agricultural non-point source pollution. Analysis of a quadratic polynomial fit to the Environmental Kuznets Curve demonstrates that the environmental turning points for agricultural film consumption have occurred. This finding indicates that Heilongjiang has been at the stage of fast agricultural economic growth with low environmental pollution. Heilongjiang has established a green-oriented system forming a pattern of agricultural development that matches the carrying capacity of resources and environment and coordinates with the production of living ecology. Non-point source pollution in agriculture has been effectively controlled to achieve sustainable agricultural development.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15511565

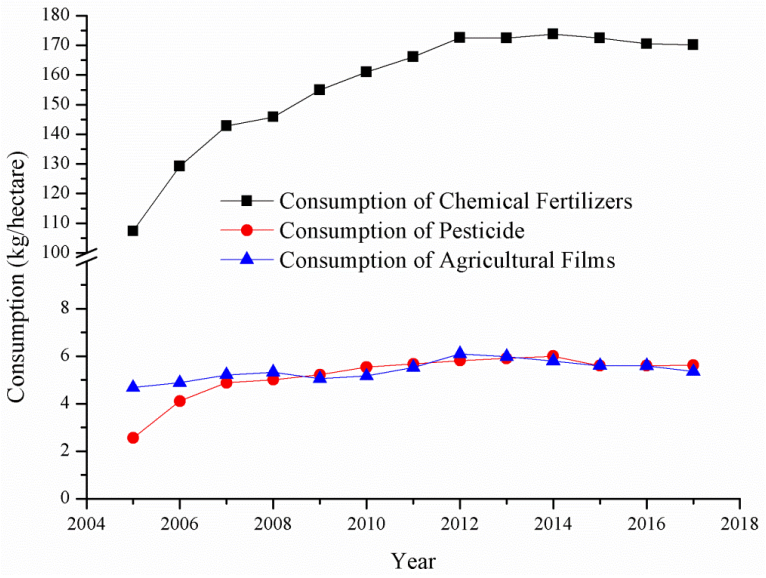

Figure 10. *Growth trend of agricultural non-point source pollution indicators in Heilongjiang during 2005~2017*

Although the quality of agricultural environment in Heilongjiang Province has been greatly improved, there are still many researches to be done in controlling agricultural comprehensive pollution and realizing ecological agriculture. In the future, the research work of increasing agricultural output value and controlling agricultural pollution will focus on three aspects.

First, give full play to regional comparative advantages and optimize the distribution structure of planting industry, in order to reduce the use of chemical fertilizers, pesticides and agricultural film. We should combine market demand orientation with farmers' traditional agriculture habits and accelerate the construction of a ternary planting structure featuring coordinated development of grain, economy and fodder. We will create an advantage zone for special agricultural products, and vigorously develop high value and high efficiency cash crops such as vegetables, fresh corn, edible fungi and potatoes with obvious supply advantages. As well as the special agricultural products such as selenium-rich ones, high green and organic food, and customized agricultural products. The corn industrial belt is mainly distributed in the cities of the first, second and third accumulative temperate zone in Songnen plain. The rice industrial belt is mainly distributed in the cities along the Nenjiang river, the Songhua river and the Sanjiang plain, as well as farms under the bureau of agricultural reclamation. The soybean industrial belt is mainly distributed in low limit of three accumulative temperate zones along the foothills of great and less Khingan mountains area and in the cities and farms under the bureau of agricultural reclamation in the fourth and fifth accumulative temperate zones. The belt is mainly distributed in arid and semi-arid areas such as Daqing, Qiqihar and Heihe. Potato industry belt is mainly distributed in Qiqihar, Harbin, Suihua, Heihe and other regions.

Secondly, to accelerate the open sharing and comprehensive utilization of large agricultural and rural data, in order to design and develop provincial-level agricultural Internet of Things (IoT) systems and related standards, and promote the application of Internet of Things technology. Through IoT, data sharing in the main business areas

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15511565

such as agricultural planting and production, agricultural machinery management, green food, soil testing and fertilization, plant protection, and agricultural products safety is realized, which effectively solves the problem of agricultural comprehensive pollution and continuously increases the income of farmers.

Lastly, we should coordinate the development of urban and rural integration, improve laws, regulations and policies related to non-point source pollution prevention and control in rural areas, such as straw burning and utilization, pollution prevention and control of agricultural film, pollution prevention and control of poultry and livestock breeding, and soil pollution prevention and control.

(Received 2nd Oct 2019; accepted 8th Jan 2020)

Abstract. Forest fires create an increasingly severe and negative impact on ecosystem services such as carbon storage, climate balancing and water supply as a result of global warming threatening our planet. One of the steps to fight forest fires is to perform a risk assessment. Forest fire risk assessment allows the identification of locations at high risk of forest fire and estimate its sphere of influence. In this way, it provides decision-making support to the fire-fighting organization. The purpose of this study was to conduct a forest fire risk assessment in forests located in Bucak Forest Enterprise in Turkey that is vulnerable to fire at the first degree. In the study, the weights of the criteria that lead to fire risk were computed with Analytic Hierarchy Process (AHP). The risk classes of the criteria were exported to the raster layer of the Geographical Information System (GIS). The results showed that 25% of forests in Bucak region were at high risk, while 32% were at medium fire risk. We believe that the approach adopted in this study may contribute to forest fire risk assessments and risk mapping of Mediterranean forest ecosystems that have similar climate, topographic structure and vegetation.
Keywords: *Mediterranean forests, fire risk factors, fire risk mapping, spatial analysis, fire sensitivity*

Introduction

Fire is an incident that leads to very severe changes in forest ecosystems (Naderpour et al., 2019). Forest fire poses a great danger to human life and environment (McKenzie et al., 2014; Garbolino et al., 2017). The European statistics demonstrate that 500 thousand hectares of forests are destroyed on average every year due to fire (EC, 2017). It is argued that the number of forest fires will increase in the future owing to climate change, changes in land use and forestry policies (González-De Vega et al., 2016; García-Llamas et al, 2019).

The Mediterranean forest ecosystems are resistant to fire (Pausas and Vallejo, 1999; Calvo et al., 2008); nevertheless, it is important to prevent fire before it reaches a dramatic point and fight against fire for social life and economy. We hope that forest fire risk assessments and organization of the efforts according to the risk levels identified will provide positive inputs for success in anti-forest fire efforts.

The forests located in the Mediterranean Region in the south of Turkey are vulnerable to fire; therefore, fire occurs very frequently in the forest ecosystems in this region. The statistics of the General Directorate for Forestry (GDF, 2019) reveal that on average more than 500 forest fire on average occur every year as a result of which more than 10000 hectares of forests are destroyed (*Figure 1*). As regards the causes of these fires, almost 90% of them are manmade (*Figure 2*).

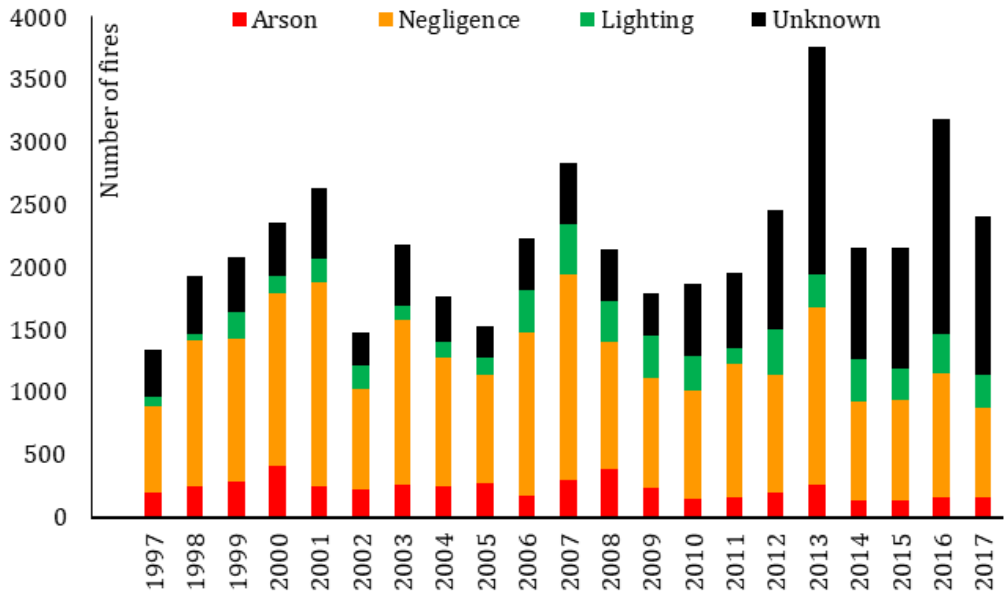

Figure 2. *The causes of forest fires in Turkey between years 1997-2017 (GDF, 2019)*

Forest lands are managed according to the decisions based on multiple criteria decision making (MCDM) methods. Particularly, decisions taken to prevent, fight and monitor forest fires are the most important ones. The location of fire lookout towers as well as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15671583

deployment area and number of first response teams are also decided with MCDM methods alone or MCDM in combination with GIS (Fisher and Keida, 1990; Korkmaz, 2004; Akay and Şakar, 2009; Akay and Şahin, 2019).

The objective of this study was to determine and map the fire risk zones of a forest ecosystem in Bucak Forest Enterprise in Turkey that is vulnerable to fire at the first degree. We are of the opinion that the best method to fight forest fires is to use the experts' knowledge, experience and predictions. In this context, the weights of the criteria for forest risk were determined with Analytic Hierarchy Process (AHP). GIS was also used as a support to determine the fire risk zones in the study area because one of the main goals of GIS is to support spatial decision making process (Simon, 1960). In this way, the spatial analysis of the criteria related to human behaviours, climate, vegetation and topography was conducted in GIS by using the risks computed for the study area with AHP. As a result, the "forest fire risk zones" of the forests in Bucak region were determined and mapped.

Multi-criteria decision making and AHP

Multi-criteria decision analysis is defined as a matrix to choose the best alternative from several potential candidates and in case of conflicting criteria to solve problems, which is called decision matrix. Various MCDM methods have been developed since 1960 for solving decision making problems (Malczewski and Rinner, 2015). What is important at this point is to determine which multiple-criteria decision-making method is the best to solve a certain multiple-criteria decision making problem (Guarini et al., 2018).

AHP is one of the most comprehensive methods of multi-criteria decision analysis, which is a digital approach (Kumar and Garg, 2017). It is a powerful and flexible decision-making theory to rank different features (Belhadi et al., 2017). AHP is a measurement theory based on pairwise comparison. In its comparisons, it uses absolute judgment scale to represent the measurement of a scale for a feature whereas the linguistic judgments related to the assessment of people are usually uncertain in real life and it is not realistic to represent them with exact values (Ishizaka and Nguyen, 2013). This method developed by Saaty (1980) is widely used to solve multiple-criteria decision making problems. It allows modelling in a hierarchical structure that describes the relationship between the main target of the criterion, sub-criteria and alternatives in solving a complex decision making problem. In another word, AHP is a method that synthesizes knowledge, experience, views and feelings of an individual (Kuruüzüm and Altan, 2001).

A priority vector is obtained in the pairwise comparison matrix. The priority vector is the "eigenvector" of the matrix. The decision priorities called as weights attributed to the qualitative features are determined in the form of eigenvector of the pairwise comparison matrix (Jain and Naq, 1996). The "relative importance" of the criteria is determined from the lowest ranking criteria to the highest criteria using the eigenvector. The stages of solving a multi-criteria decision making problem with AHP include the identification of the problem, observation of the system, creation of the hierarchical structure, control of consistency, determination of the priority values and conclusion (Saaty and Vargas, 2012).

GIS-based approach

GIS is a valuable tool that collects, processes and analyses spatial data with its structural and functional components and offers support to the decision-making process

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15671583

(Chang, 2016). While it is commonly used in disciplines examining spatial data, many users in forestry sector also prefer it. The GIS-based studies regarding the identification of forest fire risk zones showed that the interactive structure of GIS was a powerful source (Jaiswal et al., 2002; Yomralıoğlu, 2015). A formulation was developed to calculate the fire risk index values using vegetation type, proximity to settlements, proximity to roads and gradient variables. The variables were categorized according to their vulnerability to fire and every category was given a specific value (You et al., 2017). To determine the fire risk zones, the factors and sub-factors were determined using AHP, while spatial distribution of the risk categories were produced using GIS computation in proportion to the weights of these factors.

In Turkey, there are studies that have determined fire risk categories based on GIS (Sağlam et al., 2008; Küçük et al., 2017) and combined use of GIS and AHP (Güngöroğlu, 2017; Akbulak et al., 2018). AHP appears to be a method used for determining factors and their weights as regards fire risk. The determination of weights of main factors and sub-factors, determination of risk categories of the sub factors and setting values for those categories are all done by consulting an expert opinion. Besides using multi-criteria decision-making methods when determining these factors, the fire statistics observed for many years are also relevant. It is therefore possible to adapt the information from the relevant literature to the special characteristics of the field.

Materials and Methods

Study area

This study was conducted in Bucak Department of Forestry located in Western Mediterranean Region of Turkey with coordinates of 37°12'08" - 37°34'20" North latitude and 30°14'02" - 30°50'53" East longitude (*Figure 3*). As for the topographic structure of the region; the minimum, maximum and average altitudes are 72 m, 2317 m and 900 m, respectively. Average slope is 26%. In addition to the Mediterranean climate, continental climate can also be observed. In this region, the mean temperature was 15°C, the average maximum temperature was 21°C and the average minimum temperature was 9°C from 1932 to 2018. Summer is arid and warm (maximum temperature 43°C) and winter is cold and rainy (minimum temperature -14°C). The annual mean precipitation is 450 mm whereas it is 15 mm on average in summer. The relative mean humidity in summer is 40% and while the dominant wind direction is south (GDF, 2019; Worldclim, 2019).

The size of the field is 141,057 ha, and 71% is forestland. 38.64% of the forestland is unproductive with crown closure under 10%. In the region's forests, 73013 ha of land consist of coniferous species, while 19621 ha consist of deciduous species. Approximately 72% of the coniferous species consists of *Pinus brutia* Ten. and *Pinus nigra* Arnold which are relatively sensitive to fire.

Bucak Department of Forestry under Isparta Regional Directorate of Forestry is highly sensitive regarding forest fires. From 2008 to 2018 when the forest fires were investigated in the region, the highest number of fires was observed in this region with 0.9×10^{-3} per hectare. According to the same statistics, 85% of the forest fires in the region started during daytime, from 7:00 to 19:00 (IRDF, 2019). Within the fire-fighting organization, there are 4 lookout towers, 5 fire first response teams, 11 water trucks, 1 grader, 1 dozer and 10 fire pools.

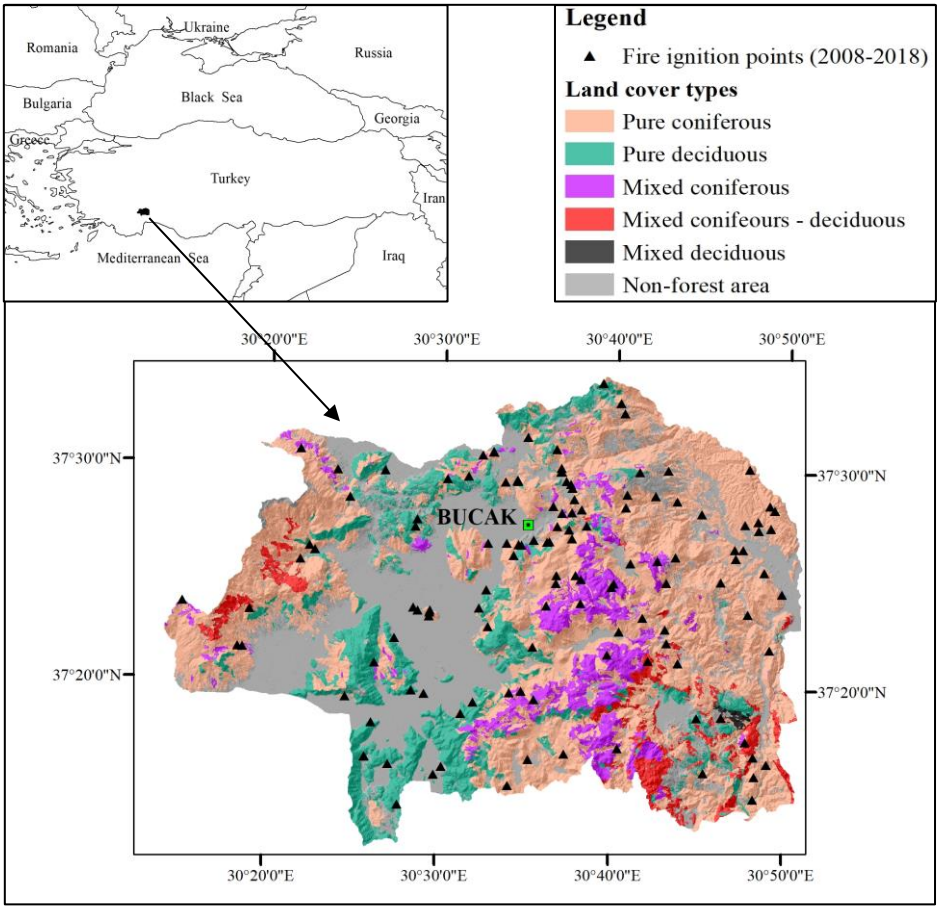

Figure 3. *Spatial location of the study area*

Dataset

Shuttle Radar Topography Mission (SRTM; version 3) data was used to create digital elevation model of the study field. This data was downloaded from https://gdex.cr.usgs.gov/gdex/ at a resolution of 1 arc-second (30 meters) from a global dataset (USGS, 2019). Altitude, slope and aspect maps were produced from the digital elevation data. Forest management plan maps for the years 2007 to 2017 of Bucak Forest State Enterprise were geographically categorized in ArcGIS environment into vegetation type, stand development period, crown closure, cultivated areas and settlements. Digital vector data of power lines and roads were provided by GIS department of Isparta Regional Directorate of Forestry. Climate data from 1970 to 2000 was obtained from http://worldclim.org/. In this platform where global climate data are presented, raster data with a resolution of approximately 1 km × 1 km was used. ArcGIS (version 10.2.2) software was used for GIS applications.

Methods

Computing the criteria weights using AHP

In the first stage of AHP, the decision problem was structured hierarchically. In the second step of AHP, pairwise comparisons and the option matrix were established. The pairwise comparison is an innate human ability and focuses on the relationship between

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15671583

pairwise data groups, thereby significantly reducing the complexity of decision-making (Saaty and Saaty, 2019). Pairwise comparison method consists of three steps: a) Forming the pairwise comparison matrix in all steps of the hierarchy, b) Computing the weights for each hierarchy, c) Determining the consistency index.

Hierarchically structuring the decision problem:

- Determining the criteria: Criteria are determined by expert opinion, relevant data sources and experiences of forest fire experts (Criteria and their definitions are shown in *Table 1*).
- The hierarchical structure of the decision problem was created (Saaty and Vargas, 2012).
- For pairwise comparisons to be evaluated by decision-makers to determine the criteria weights, pairwise comparison tables were formed (Saaty and Saaty, 2019).
- In pairwise comparisons, experts perform comparisons using the fundamental scale (Saaty, 1990).

Decisions are made by agreement based on two comparison scales or the geometric mean method can be used in the event of three different scales (Van den Honert and Lootsma, 1996; Bolloju, 2001).

Table 1. *Criteria and definitions*

Criteria	Sub-criteria	Definition
K_1: Human behaviour	K_{11}: Proximity to settlements	Settlements in and around the forest
	K_{12}: Proximity to the road network	Roads in and around the forest
	K_{13}: Proximity to the cultivated areas	Cultivated areas in and around the forest
	K_{14}: Proximity to the power lines	Power lines in and around the forest
K_2: Structural characteristics of forests	K_{21}: Vegetation type	Fire sensitivity of tree species
	K_{22}: Age of stand development	Forest texture which is sensitive to fire
	K_{23}: Crown closure	Shading rate of forest trees
K_3: Topographic structure of forests	K_{31}: Altitude	Elevations of the forest
	K_{32}: Slope	Forest slope
	K_{33}: Aspect	Dominant aspect of forest areas
K_4: Climate data	K_{41}: Mean temperature of warmest quarter	Mean temperature during fire season
	K_{42}: Precipitation of warmest quarter	Precipitation during fire season
	K_{43}: Mean wind speed of warmest quarter	Mean wind speed during fire season

After determining the criteria and completing pairwise comparisons, the comparison matrices of criteria and sub criteria are formed. By evaluating the comparison matrices, weights of criteria are computed. Consistency tests were applied to check the reliability of the matrices. In order to check the consistency of the matrix, consistency index and consistency rate are calculated (Saaty, 1980). The consistency index (CI) of the comparison matrix is calculated with the following formulation:

$$CI = \frac{\lambda_{max} - n}{n - 1} \quad \text{(Eq.1)}$$

where CI is consistency index, λ_{max} is the largest eigenvalue, n is the number of criteria compare.

The consistency rate (CR) is calculated with the following formulation:

$$CR = \frac{\mathrm{CI}}{RI} \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15671583

where, CI is consistency index, RI is random index which depends on the number of criteria being compared. For example, for n = 2, 3, 4, and 5, RI = 0.00, 0.52, 0.89 and 1.11, respectively. CR <0.10 indicates a reasonable consistency level for pairwise comparisons. CR ≥0.10, however, indicates that the values in the pairwise comparison matrix should be reviewed and revise (Saaty, 1980).

GIS-based evaluation and mapping

The relevant literature for determining the risk categories of the sub criteria used to identify the fire risk zones was reviewed (Jaiswal et al., 2002; Sağlam et al., 2008; You et al., 2017). Jaiswal et al. (2002) developed a formulation for fire risk index, which is also suitable for the field's conditions. The special conditions of the field require customisation of the variables related to the fire risk values. For example, variables of latitude and vegetation differ considerably. The risk values of vegetation cover were listed by examining the fire sensitivity status of the target stands, which were distributed in the region. After defining the risk values for all stand types in the geographic database, the stands with the same risk values were combined and clustered.

The most fire sensitive tree species in the region were red pine and black pine stands (Neyişçi et al., 1996). The highest risk values were assigned to these stands. The variables of the distance between the road and the power lines and the distance between the settlements and the cultivated areas were determined according to the approach described by You et al. (2017) and values proposed by Şentürk (2018). Additionally, the distribution of 130 fire exit points in the zones which were produced at intervals of 0-25 m, 25-50 m, 50-100 m and 100 m farther from the road, power lines, settlements and cultivated areas were also evaluated. The climate data was calculated according to the approach proposed by You et al. (2017).

Raster layers were prepared and categorized according to the classes in *Table 2*. These raster layers were multiplied by their own criteria weight using the "raster calculator" available at ArcGIS software and fire risk values were achieved. These values were categorized (Jenks and Caspall, 1971) and fire risk zones were mapped.

Results and Discussion

Forming of the comparison matrices of criteria and sub criteria in AHP

The criteria indicated in *Table 1* were evaluated by the experts according to the AHP comparison scale specified in *Table 3* and the comparison scheme in *Table 2*. Comparison matrix of the criteria was formed (*Table 3*).

Similarly, the same steps were applied for the sub criteria and as a result, the comparison matrices of the sub criteria of the K_1, K_2, K_3, K_4 criteria were calculated (*Tables 4-7*).

Evaluation of comparison matrices

To normalize the pairwise comparisons of the criteria,

- All columns are summed up (*Table 3*).
- Each column element in *Table 3* is divided into column sum (*Table 8*).
- Total rows are calculated (*Table 8*).
- Average of row sum (w) is found (*Table 8*).

Table 2. *Variables and risk values to be used in the calculation and mapping of fire risk*

Structural characteristics of forests

Criterion	Class	Risk	Value
Vegetation type	*Pinus brutia* and *P. nigra* stands	Very high	1.0
	Pinus brutia / *P. nigra* – coniferous mixed stands	High	0.7
	Other pure coniferous stands	Moderate	0.5
	Coniferous- deciduous mixed stands	Low	0.3
	Deciduous stands	Very low	0.1
Age of stand development	Young forest	Very high	1.0
	Medium age forest	High	0.7
	Old-growth forest	Moderate	0.5
	Mature forest	Low	0.3
Crown closure	%10-%40	Very high	1.0
	%40-%70	High	0.7
	>%70	Moderate	0.5
	<%10 coniferous –deciduous mixed stands	Low	0.3
	<%10 deciduous mixed stands	Very low	0.1

Human behavior

Criterion	Class	Risk	Value
Proximity to settlements (meter)	0-25	Very high	1.0
	25-50	High	0.7
	50-75	Moderate	0.5
	75-100	Low	0.3
	>100	Very low	0.1
Proximity to the road network (meter)	0-25	Very high	1.0
	25-50	High	0.7
	50-75	Moderate	0.5
	75-100	Low	0.3
	>100	Very low	0.1
Proximity to the cultivated areas (meter)	0-25	Very high	1.0
	25-50	High	0.7
	50-75	Moderate	0.5
	75-100	Low	0.3
	>100	Very low	0.1
Proximity to the power lines (meter)	0-25	Very high	1.0
	25-50	High	0.7
	50-75	Moderate	0.5
	75-100	Low	0.3
	>100	Very low	0.1

Topographic structure of forests

Criterion	Class	Risk	Value
Altitude (meter)	<700	Moderate	0.5
	700-1000	Very high	1.0
	1000-1300	High	0.7
	1300-1600	Low	0.3
	>1600	Very low	0.1
Slope (%)	1-15	Moderate Very	0.5
	15-30	high	1.0
	30-40	High	0.7
	40-50	Low	0.3
	>50	Very low	0.1
Aspect	Sunny (S,SW)	Very high	1.0
	Semi sunny (W,SE)	High	0.7
	Flat	Moderate	0.5
	Semi shady (NW,E)	Low	0.3
	Shady (N,NE)	Very low	0.1

Climate data

Criterion	Class	Risk	Value
Mean temperature of warmest quarter (°C)	>24	Very high	1.0
	22-24	High	0.7
	21-22	Moderate	0.5
	20-21	Low	0.3
	>20	Very low	0.1
Mean wind speed of warmest quarter (meter second^{-1})	>2.1	Very high	1.0
	2.0-2.1	High	0.7
	1.95-2.0	Moderate	0.5
	1.90-1.95	Low	0.3
	>1.90	Very low	0.1

Criterion	Class	Risk	Value
Precipitation of warmest quarter (millimeter)	<40	Very high	1.0
	40-50	High	0.7
	50-60	Moderate	0.5
	60-70	Low	0.3
	>70	Very low	0.1

w: the matrix's eigenvector

"w" in the last column of *Table 8* is the matrix's eigenvector and gives the weight of the criteria by percentage (%). It is necessary to calculate the consistency of the comparison matrix of the criteria. For a comparison matrix to be consistent, the maximum eigenvalue (λ max) must be equal to the dimensions of the matrix (*Table 9*). Consistency rate greater than 10% shows that some evaluations are contradictory in the comparisons (Partovi and Hopton, 1994).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15671583

Table 9. *Calculation of the consistency of the comparison matrix of criteria*

	K_1	K_2	K_3	K_4	w	v	v/w
K_1	1	3	5	7	0.564618	2.353746	4.168741
K_2	0.333	1	3	5	0.269109	1.106382	4.111278
K_3	0.200	0.333	1	1	0.091055	0.368810	4.050408
K_4	0.143	0.200	1	1	0.075218	0.300835	3.999510

w: the matrix's eigenvector, v: column vector

The previously calculated column vector (eigenvector/priority vector) is obtained by multiplying each row of the comparison criterion. The calculated column vector (v) is divided by the corresponding elements of the column vector (w) to obtain v/w values. The arithmetic mean of the v/w column vector gives the largest eigenvalue (λ max = 4.082484).

$$\text{Consistency Indicator} = (\lambda \text{ max-n})/\text{n-1} = (4.082484\text{-}4)/4\text{-}1 = 0.27495$$

$$\text{Consistency Ratio} = \text{Consistency Indicator} / \text{Random index}$$

Random Index for matrices with sizes of 1 to 15, in the table of random index, n = 4 is 0.89 (Saaty, 1990). According to this;

$$\text{Consistency Ratio} = 0.027495 / 0.9 = 0.03055$$

Since the consistency ratio is <0.1, the matrix can be considered consistent. For the other comparison matrices, the same steps were taken, and the criteria weights and consistency of the criteria were calculated and shown in *Table 10*.

Table 10. *Consistency ratios and weights of criteria and sub-criteria*

CR	Criteria	Weights	CR	Sub-criteria	Local weight	Overall weight
0.03	Human behaviour	0.5646	0.058	Proximity to settlements	0.1993	0.1125

CR: consistency ratio

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15671583

Pairwise comparison method is frequently use to estimate the weights of the criteria in the GIS-based multiple-criteria decision-making applications (Malczewski and Rinner, 2015). This method has been tested and applied in land suitability analyses (Stoms et al., 2002; Hamzeh et al., 2016; Bozdağ et al., 2016), environmental impact assessment studies (Bojórquez-Tapia et al., 2002; Rikhtegar et al, 2014) and natural resource management (Hessburg et al., 2013).

In this study, it was concluded that the contribution of human behaviour to fire risk was over 50% (*Table 10*). In a study conducted by You et al. (2017), the weight of human activities used to calculate fire risk was found to be the first one among other factors. It is also known that proximity to the road increases the risk of fire. Şentürk (2018) examined the relationship between the locations of forest fire starting points and the roads in Istanbul and found that 427 (~ 65%) of the 660 fire starting points were located at 0-100 meters from the road. Although climate seems to have a primary effect, it is proposed that it is important to know the proximity of forests to roads and settlements (Sağlam et al., 2008; Wu et al., 2014).

The mapping of fire risk zones

All geographic layers of the sub criteria in the GIS database were recorded as raster data, and the risk classifications shown in *Table 2* were identified. Thus, the spatial distribution of the risk zones belonging to 13 sub criteria was mapped (*Figure 4*). The criteria and weights determined by AHP were formulated with the help of ArcGIS software's spatial analysis tool and applied to the related geographical layers. The resulting fire risk map was created by using ArcGIS and is presented in *Figure 5*.

When the spatial distribution of fire risk zones is examined, it is understood that only 0.49% of forest lands in the field was ranked as very high risk (*Table 11*). Given that the ratio of the areas with medium and high fire risk is close to 60% in total, it is possible to suggest that the fire risk of forestlands in the region is relatively high.

The risk assessment conducted for the study area can possible used for the Mediterranean forest ecosystems that have similar forest cover, climate and topographic features. However, it should also be remembered that risk value may change as climate and forest cover change (Jaiswal et al., 2002; Sağlam et al., 2008; Neyişçi, 2009; Küçük et al., 2017). Moreover, we suggest that risk assessment can be performed and risk zones can be mapped for any forest ecosystem if the approach and methodology developed in this study are applied.

In terms of forest fire risks, coniferous species that account for about 80% of the forests in the field are at higher risk than broad-leaved species. However, it should not be overlooked that broad-leaved forests are also susceptible to fire in the dry season (Kodandapani et al., 2009).

In this study, human behaviour was found to has the highest weight for fire risk. The importance of human behaviours for fire risk has been reported by several studies (Vadrevu et al., 2009; Eskandari and Chuvieco, 2015; Eskandari, 2017). Proximity to forest roads, which is one of the sub-criteria of human behaviours has the highest weight in terms of fire risk (You et al., 2017; Şentürk, 2018). Other researchers also confirmed that vegetation composition (Sağlam et al., 2008; Chuvieco et al., 2012; You et al., 2017), topographic structure (Vadrevu et al., 2009; Çoban and Özdamar, 2014; Eskandari, 2017) and climate (Zumbrunnen et al., 2011; Eskandari, 2017) were important criteria for fire risk.

Conclusion

The nature has the power to find ways to compensate the damage caused by horrible catastrophes. Mediterranean forest ecosystems also have the power to cope with fire. Despite that, measures should be taken to fight forest fires as they threaten human life and lead to devastating economic loses, which may in turn lead to extremely dangerous consequence. In addition to several natural variables such as climate, topography, bedrock, vegetation cover, human factor also is also a dominant and adverse factors as regards forest fire. Therefore, it is ideal to manage so many processes from setting forestry

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15671583

policies to fight forest fires to planning land use, preserving the structural features of the natural forests, establishing forests suitable for the relevant degraded area and under extreme conditions, ensuring social and cultural development and in this way raising environmental awareness. One of the crucial elements of fight against forest fire is to create fire risk maps. In this way, fire risk zones may provide decision support in planning the fire-fighting organization. Areas at higher fire risk and thus areas where fire may potentially spread and grow can be determined and necessary measures can be taken.

In this study, the fire risk zones of first-degree fire sensitive Mediterranean forest ecosystems in Bucak were identified and mapped. In the total forestland in the study area, 0.5% of the forests were at a very high fire risk, 25% were at high risk, while 32% were at medium risk. This shows that around 60% of the forestlands are at medium and high forest fire risk. Accordingly, we can say that it is important that forest authority should take measures to prevent forest fires during fire season in this region and raise awareness of people through media and other means of communication. In addition, forest fire reports should contain accurate and detailed information about fire ignition point location and records of all events from the beginning to the end of the fire. We recommend that fire risk maps should be compared with the real fire records and fire risk assessment should be keep up to date.

Abstract. In the rice paddy ecosystem, application of nitrogen fertilizer and straw to soil methanogenic bacteria provides abundant methanogenic substrates, which significantly influences methane (CH_4) emission from paddy fields. The effects of nitrogen fertilizer and straw returning on CH_4 emissions in rice paddy fields were studied during a two year of the field experiment in Chao lake basin, China. The experiment consisted of 4 treatments: Control (CK), Traditional fertilizer (CT), Optimized fertilizer (CO) and CO with straw-return (CO + SR). The cumulative effects of straw-returning practices on greenhouse gas emission in a rice-wheat rotation system were determined, along with an estimation of CH_4 in a rice growing season. According to our results, The CH_4 emission fluxes from paddy field showed three different peak trends; Compared to CK, CT, CO, and CO + SR increased seasonal CH_4 emission by 36.6%, 45.8% and 42.0% in 2013 and by 42.0%, 48.5% and 80.1% in 2014, respectively. Anaerobic decomposition of wheat straw accelerates the decline of soil redox potential (Eh) after flooding, thereby providing suitable environmental conditions for the growth of methanogens and promoting CH_4 production in the subsequent rice season. The CH_4 emission fluxes of CK, CT, CO, and CO + SR were significantly correlated with soil temperatures at 5 cm depth. Therefore, our findings show that application rates of nitrogen fertilizer and straw returning to a paddy field could significantly affect the CH_4 emissions in China.
Keywords: *CH_4 flux, rice paddy, chemical fertilizer, straw application, nitrogen use efficiency*

Introduction

Since the industrial revolution, concentrations of atmospheric carbon dioxide (CO_2), methane (CH_4) and nitrous oxide (N_2O) have been increasing year after year; thus, global climate change caused by greenhouse gas emissions has become a common concern in the international community (Lubbers et al., 2013; Hussain et al., 2015; Xuejun and Fusuo, 2011; Shakoor et al., 2018). CH_4 is the smallest hydrocarbon and is a potent greenhouse gas (IPCC, 2013). It is mainly produced through the decomposition of organic waste and is also one of the main causes of global warming (Zhang et al., 2015b). Although its atmospheric concentration is much lower than that of CO_2, the rate of its emission is increasing at a much higher rate. The greenhouse effect of CH_4 is 27 times larger than that of CO_2, and its current contribution to the rate of global warming is about 15% (Liu et al., 2015; Hofmann et al., 2016).

The main sources of CH_4 in the atmosphere are natural wetlands, paddy fields, termites, ruminants, fossil fuel production processes, waste disposal and shallow water lakes (Karakurt et al., 2011; Musenze et al., 2014). It is estimated that 40 to 52% of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15851600

yearly CH_4 emissions are from soil, and farmlands are an important source of greenhouse gas emissions from soil ecosystems (Montzka et al., 2011; Linquist et al., 2012). Paddy fields are the main source of farmland soil CH_4 emissions. Globally, the total yearly amount of CH_4 emissions from paddy fields is between 35 and 150 Tg, which accounts for about 12% of global CH_4 emissions (Le Mer and Roger, 2001; Hofmann et al., 2016). Rice is one of the most important cereal crops in China, and its planting area accounts for 17.8% of the world total. CH_4 emitted from paddy fields accounts for 17.9% of the total CH_4 emissions in China, and is the second largest source after livestock farming (Yan et al., 2009; Hoben et al., 2011). Therefore, the studies on CH_4 emission characteristics are of great significance for the reduction of CH_4 emissions from paddy fields.

There are many factors affecting CH_4 emissions from farmland, which can be summarized into three categories: climatic factors such as temperature, precipitation, solar radiation intensity, and atmospheric CO_2 concentration (Walter et al., 2001); soil factors, such as soil organic matter and oxide content, texture, pH value (Wagner et al., 2005); Human factors include water management, application of organic manure and fertilizer amounts, types and dosage (Zou et al., 2005; Mohanty et al., 2017). Straw-return is one of the most important measures for improvement of farmland ecological environment. It improves soil structure, increases soil organic matter content and promotes a virtuous circle of ecosystem health (Lou et al., 2011; Nyamadzawo et al., 2015; Wang et al., 2017). In the rice paddy ecosystem, the use of straw provides a rich substrate for soil methanogenic bacteria, which significantly promotes CH_4 emissions from rice paddies (Ma et al., 2009; Qin et al., 2016; Koga and Tajima, 2011). The choice of straw type (Wassmann et al., 2000), adjustment of the application pattern (Zhu et al., 2014) and application time (Zhang et al., 2015a) maintain soil fertility while reducing CH_4 emissions to a certain extent. Bao et al. (2016) demonstrate that addition of nitrate influences transcriptional and functionally active methanogens, and can alleviate CH_4 production associated with a straw amendment in paddy soil incubations; this could occur through competition for common substrates between nitrate-utilizing organisms and methanogens (Shakoor et al., 2016). Hu et al. (2016) indicated that returning wheat straw prior to rice transplantation significantly increased seasonal CH_4 emissions during both the rice seasons and wheat seasons, compared to no straw-return. At the same time, annual CH_4 emissions were lower under ditch-buried wheat straw-return than that under wheat straw returned with rotary tillage and plowing. Zhang et al. (2015c) determined that compared with straw removal, straw-return significantly increased annual CH_4 emissions by 35.0%, annual GWP by 32.0%, and annual GHGI by 31.1%.

As a typical traditional agricultural region of China, the Chao Lake Basin has problems with excessive fertilizer application, low fertilizer utilization rates, and serious agricultural non-point source pollution. Beyond that, Chaohu's agriculture had not implemented continuous straw-return before 2013. Therefore, there are no systematic studies on the effect of straw-return on production, oxidation, and emission of CH_4 in the subsequent rice cropping season. To define the contribution of straw-return and fertilization practices on CH_4 emissions, this experiment was designed to test plots with and without the application of wheat straw. The CH_4 emission flux was observed in situ throughout the following rice season; the CH_4 production potential and soil oxidation potential of paddy soils were studied to explore the effect of wheat straw application on CH_4 production, oxidation, and emission during the subsequent rice season.

Materials and methods

Experimental site

The field experiments were performed on the rice crop from a rice-wheat rotation system at the Chaohu Experiment Station of Anhui Agriculture University, Hefei, China between June 2013 and October 2014 (117° 40' E, 31° 39' N, altitude 17 m). The research site is situated in the north subtropical humid monsoon climate zone and it is within the Chao lake water regulation zone, which makes it suitable for the growth of crops (*Fig. 1*).

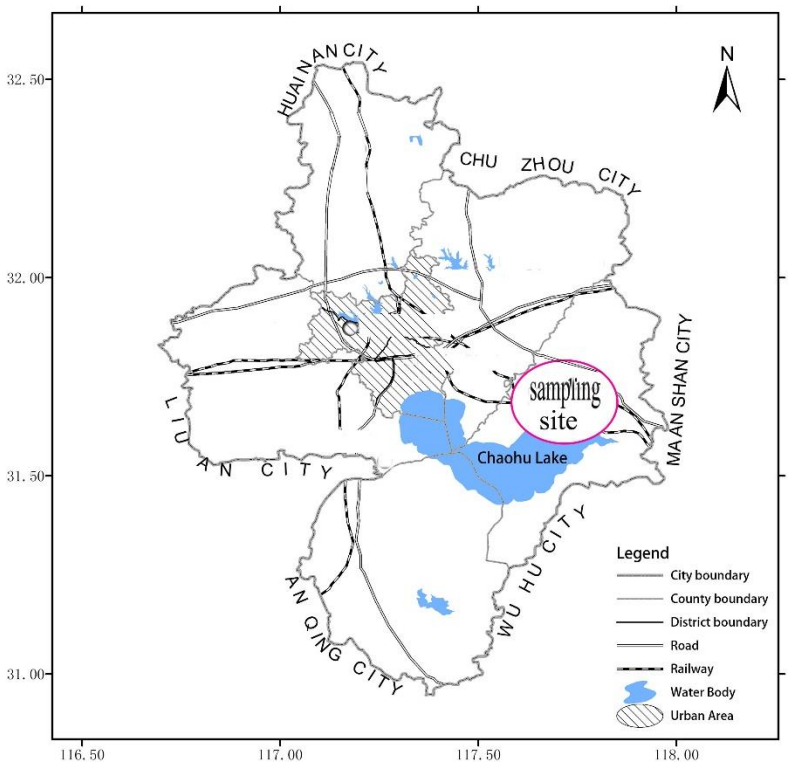

Figure 1. *Localization of the study area in Chaohu, China. (ArcGIS, ArcMap 10.2 version; http://www.esri.com/arcgis/about-arcgis; http://desktop.arcgis.com/en/arcmap/)*

The subtropical monsoon climate prevailed in the area with mean annual temperature and precipitation of 16.8 °C and 1358.3 mm, respectively. From 1986 to 2005, the mean seasonal temperature was 16.29 °C, which was similar to our findings (Shi et al., 2008). The soil type at the monitoring site is clay loamy soil with maximum water holding capacity. The specific physical and chemical properties of soil (0-10 cm) were: pH (H_2O) 6.18; Organic matter 23.64 g kg^{-1}; Total nitrogen 1.30 g kg^{-1}; clay content (particle size < 0.01 mm) 490 g kg^{-1}, respectively.

Treatment design and field management

The two phases of experiments included effects of different fertilization techniques and tillage patterns. The experiment consisted of 4 treatments, and each treatment was repeated 3 times; each experimental plot was 30 m^2, and the field was randomly sectored. Four treatments were adopted as follows:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15851600

1. Control treatment (CK): no fertilization during the rice season.
2. Traditional treatment (CT): traditional fertilization during the rice season.
3. Optimized fertilization (CO): fertilization optimized for maximum local economic output.
4. Optimized fertilization with straw-return (CO + SR): all straw produced in the wheat season is returned to the field and an additional 2 kg of the decomposing agent is applied per acre in conjunction with a 20% reduction in application of the optimized fertilizer amount.

Fertilizer application methods were application after sowing, rice base fertilizer application after seedling transplantation, and two top-dressing applications during the tillering and heading stages. The total amount of applied fertilizer and the amount of applied nitrogen for each stage are shown in *Table 1*.

Table 1. *Fertilization scheme of 2013 and 2014 rice season. (kg/hm^2)*

	Treatments	Total amount of the fertilizer			Base fertilizer			Tillering fertilizer	Panicle fertilizer	
		N	P_2O_5	K_2O	N	P_2O_5	K_2O	N	N	K_2O
Rice season	CK	0	0	0	0	0	0	0	0	0
	CT	180	67.5	67.5	67.5	67.5	67.5	67.5	45	0
	CO	225	67.5	120	90	67.5	84	90	45	36
	CO + SR	180	54	96	72	54	67.2	72	36	28.8

Management of all the fields was maintained at the same times, and in accordance with local routine management practices. During the rice growing period, irrigation was needed between 4 and 5 times. Fields were irrigated to a depth of 6-7 cm, 1 to 2 days prior to fertilizer application and at the end of the land sunning period. The amount of irrigation water was 822.7 mm. The rice crop was planted in May and harvested in early October. Rice plants were transplanted to the main field at a density of 20 hills per m^2 on May 25/26 and harvested on October 10/11 for the entire experimental period. The rice paddy field was regularly weeded to ensure the healthy growth of rice under normal conditions. Data was gathered for the individual cropping periods, which were June 13^{th,} 2013 – September 27^{th,} 2013 and June 21^{st,} 2014 – October 10th 2014, respectively (*Table 2*).

Tilling fertilizer	Jun 28	Jul 8
Panicle initiation fertilizer	Jul 27	Aug 5
Harvest	Sept 27	Oct 10

Gas sampling and measurements

A static closed chamber was constructed with polyester material, and was used to measure the CH_4 fluxes (Chadwicka, 2014; Roche et al., 2016) and the sample box was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15851600

made of 5 mm thick transparent organic glass. The sampling box was divided into upper and lower layers. In 2013, the box height was 1.2 m, and the dimensions of each layer were 0.5 m × 0.5 m × 0.6 m with an area of 0.25 m^2. In 2014, the height of the box is 1.0 m, and the dimensions of each layer were 0.5 m × 0.5 m × 0.5 m with an area of 0.25 m^2 (0.5 m × 0.5 m). A single-layer static box was used during the early growth stage, and a two-layer static box was used later when plants were higher than 0.6 m. The chamber was equipped with a thermometer on the top to measure the internal temperature. When taking samples, the chamber was placed into the base of the tank above. CH_4 gas samples were taken between 8:00 am and 11:00 am from the paddy fields, and 60 mL of the gas sample was extracted with a syringe 0, 10, 20, and 30-min interval after closing the chamber, respectively. At the same time, air temperature surface soil temperature and soil Eh at depths of 0, 5 and 10 cm were also measured. Daily precipitation and temperature were monitored with an automatic meteorological station approximately 500 m from the experimental plots.

Gas samples were collected from the first day of rice cultivation, and once every seven days thereafter. Samples were collected more frequently during the fertilization and land sunning periods. In the rice season, the conventional sampling frequency was every 3 to 5 days, but sampling was occasionally delayed in the event of precipitation. From 1 to 9 days after fertilization, data were collected every two days. In addition, sample analysis frequency increased during the land sunning period.

Data processing and statistical analysis

The samples were analyzed within 24 h. Gas chromatography (GC) was performed on a 450-GC system (Bruker Daltonics Inc., U.S.A.). CH_4 was detected by a flame ionization detector, and the emission flux was calculated using the following formula: $F = \rho \times V / A \times dc / dt \times 273 / T$, where F is the emission flux in units of $mg.m^{-2}.h^{-1}$ for CH_4, ρ is the density of CH_4 under standard conditions (0.714 $kg.m^{-3}$ for CH_4), V is the effective volume of the sampling chamber (m^3), A is the area covered by the sampling chamber (m^2), dc/dt is the change of CH_4 concentration ($\mu L.L^{-1}.h^{-1}$) in the sampling chamber per unit of time (positive value: gas emission; negative value: gas absorption), T is the temperature inside the chamber (K) and 273/T is the temperature impact factor. CH_4 emissions were calculated using a trapezoidal method according to the following formula: $Q = (F1 + F2) \times (t2-t1)/2\times24$, where Q is the total emission amount of CH_4 ($mg.m^{-2}$) and F1 and F2 are the corresponding emission fluxes at days t1 and t2. The temperature inside the chamber was measured simultaneously for the standardized correction of the volume of gas. Soil Eh was measured using a FJA-6 automated oxidation-reduction potential (ORP) analyzer (Nanjing Chuan-Di Instrument & Equipment CO., LTD. Nanjing, China).

All statistical analyses were performed using SPSS 17.0 (SPSS, Inc., USA) and EXCEL 2010 for Windows. Average fluxes and standard deviations of CH_4 were calculated based on data from triplicate plots. Differences in seasonal CH_4 emissions and grain yields between treatments were analyzed with two-way analysis of variance (ANOVA) and least significant difference (LSD) test. To determine correlation, Pearson's correlation test was applied at 5% level of significance. The map of study site was generated by using ArcGIS software (ArcMap 10.2 version; https://www.esri.com/en-us/arcgis/about-arcgis/overview). Finally, Origin 8.0 (Origin Lab Corporation, USA) was employed for figure preparation.

Results

Environmental conditions and crop productions

Chao Lake has a subtropical moist monsoon climate, and this region is dominated by both westerly circulation and subtropical circulation. Annual mean air temperatures were 15.8 °C and 16.3 °C for the 2013–2014 and 2014–2015 cropping years, respectively (*Fig. 2*). The respective annual precipitation values were 1065.6 mm and 1077.4 mm for the cropping years of 2013–2014 and 2014–2015, respectively (*Fig. 2*). The magnitudes and seasonal patterns of soil temperatures correlated with air temperatures during the two experimental years.

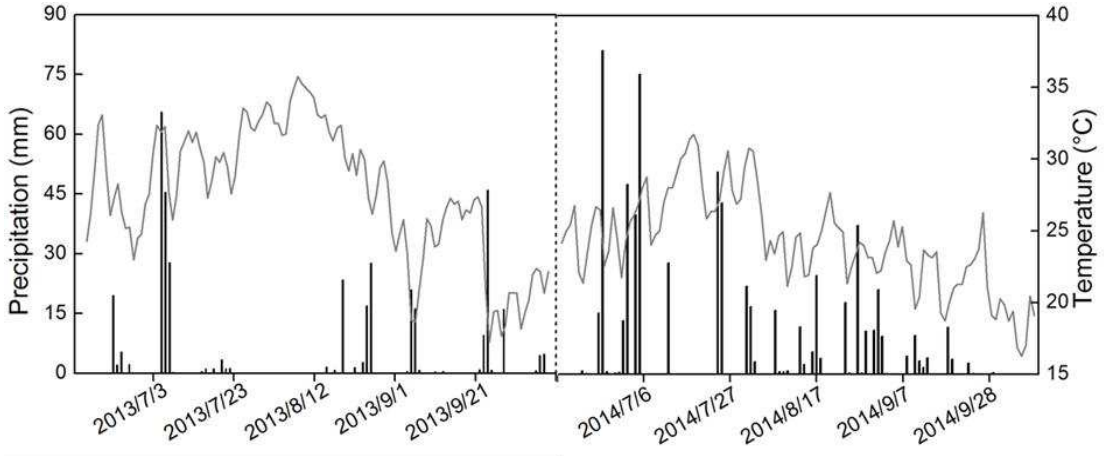

Figure 2. *Daily precipitation and mean air temperatures during the three rice growing seasons from 2013 to 2014*

CH_4 emissions during the rice-growing season

CH_4 emissions not only correlated with the influencing factors of substrate, environment, and fertilization but were also highly correlated with rice growth stage. Over the whole rice seasons from 2013 to 2014, the variable seasonal pattern of CH_4 emissions from rice paddies consisted of "three peaks", as shown in *Figure 3*.

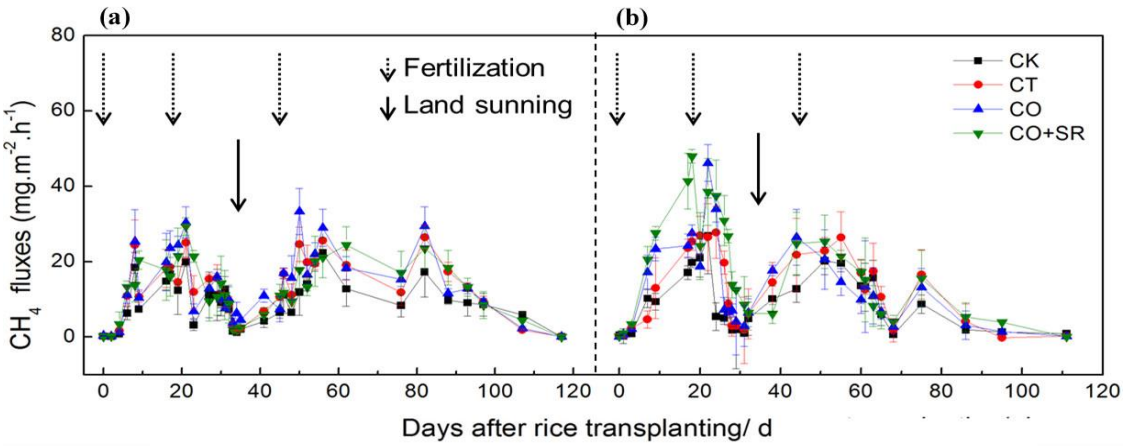

Figure 3. *Variation in methane emissions during the rice growing seasons of (a) 2013 and (b) 2014. The vertical bars represent standard errors of the means (n = 3)*

Due to the dry farming system in non-rice growing years, the soil environment had shifted to a state of oxidation; thus, CH_4 emissions did not appear during the early rice transplantation or with the latter fertilizer application. After a period of flooding, the soil state gradually shifted to a reducing environment, which directly resulted in gradual decreases in soil Eh and gradual increases in CH_4 emissions.

The first CH_4 emission peak appeared on the 22nd day after transplanting under the combined effects of fertilizer, substrate, and environmental factors. The order of CH_4 emission fluxes under each treatment were CO > CO + SR > CT > CK in 2013, and CO + SR > CO > CT > CK in 2014. During the drying of paddy fields in the sunshine (Days 23-31 in 2013 and days 27-35 in 2014), there were reductions in CH_4 production from methanogens, and the activity of methane-oxidizing bacteria was increased; thus, the CH_4 emissions from rice fields were very low during this period. After the re-flooding, the CH_4 emission flux of CK, CT, CO, and CO + SR increased slowly. With the application of panicle fertilizer on the 45th day, CH_4 emissions reached a high level and attained its second peak between days 50 and 55 both in 2013 and 2014. After 5 days of drying the paddy fields in the sunshine, the CH_4 emission flux decreased to a low level, but there were still measurable amounts of CH_4 emissions, and sixth-day observations showed a recovery of CH_4 emission fluxes. This may have been due to precipitation during the latter stages of drying. Even after the disappearance of field water, the soil retained a certain amount of moisture, and the added rainfall also contributed to the CH_4 emission flux recovery. The third CH_4 emission peak appeared during the blooming stage. The peak of CH_4 emissions was higher from CT, CO and CO + SR relative to CK, which was because the CK treatment lacked fertilizer; thus, the CT, CO, and CO + SR emission peaks were mainly caused by the input of nitrogen fertilizer.

Annual CH_4 emissions and global warming potential

The different fertilization treatments of the Chao Lake Basin experimental plots resulted in differential CH_4 emission fluxes (*Fig. 4*).

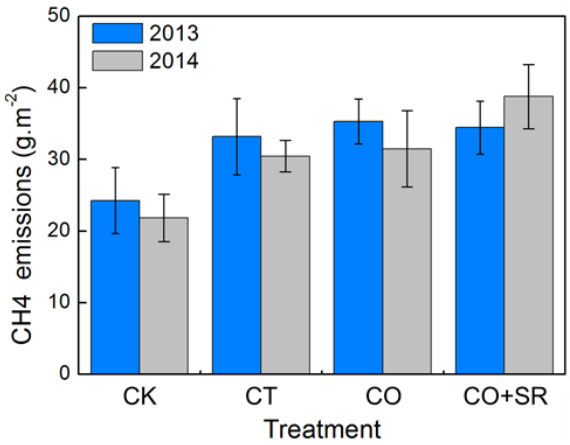

Figure 4. *CH_4 emissions under different fertilizer practices throughout the experimental period in 2013 and 2014. The vertical bars indicate standard errors of three replicates*

The total seasonal CH_4 emissions from all fertilization treatments were higher than the total CH_4 emissions from the CK treatment, indicating that application of chemical

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15851600

nitrogen fertilizer could increase CH_4 emissions from single-cropping paddy fields. Different fertilization and straw-return practices had different effects on the seasonal CH_4 emission accumulations; the seasonal CH_4 emission accumulation was calculated and significant differences were determined ($P < 0.05$) by LSD analysis of significant differences (*Table 3*). During the entire 2013 rice growth period, the total CH_4 emissions in CO treatments were the highest. The total CH_4 emitted was 35.3 ± 3.3 gm^{-2} (*Table 3*), which indicated that there was a certain relationship between CH_4 emission and the applied amounts of chemical nitrogen fertilizer. Compared with the CK treatment, CH_4 emissions from the CT, CO, and CO + SR treatments were increased by 36.6%, 45.8% and 42.0%, respectively. Although the optimized fertilization treatment CH_4 emission was 3.8% higher than that of the Optimized fertilization plus straw-return treatment, the difference in CH_4 emissions was not significant. During the entire 2014 rice growing period, the total CH_4 emitted from the CO + SR treatment was the highest and amounted to 38.8 ± 4.5 g m^{-2} (*Table 3*).

Table 3. *Average annual yields and emissions of CH_4 expressed as CO_2-equivalents for the rice growing seasons in 2013 and 2014*

Year	Treatment	CH_4 emission ($g \cdot m^{-2}$)	Rice yield ($kg \cdot hm^{-2}$)	Total E-CO_2 ($kgCO_2 \cdot hm^{-2}$)
2013	CK	24.3 ± 4.6a	5888.9 ± 146.9b	6063.6
	CT	33.2 ± 5.4a	7250.0 ± 127.3ab	8292.3
	CO	35.3 ± 3.3b	7611.1 ± 111.1a	8826.7
	CO + SR	34.5 ± 3.7b	7333.3 ± 364.3b	8613.7
2014	CK	21.8 ± 3.4c	5966.7 ± 135.6c	5456.6
	CT	30.4 ± 2.2b	8376.7 ± 189.6b	7612.5
	CO	31.5 ± 5.3a	8670.3 ± 111.1a	7870.5
	CO + SR	38.8 ± 4.5a	8273.4 ± 140.1a	9690.3

Data in the first two columns are expressed as Means ± SD; different letters within the same column denote significant differences in variable means among treatments over the 2013-2014 seasons based on the LSD multiple-range test ($P < 0.05$).

Compared with the CK treatment, the CT, CO, CO + SR treatments had increases in CH_4 emissions of 42.0%, 48.5%, and 80.1%, respectively. The maximum CH_4 fluxes were different between the two the rice growing season. The CH_4 emissions in 2014 from CK, CT and CO treatments showed a similar pattern as those of 2013, but were all lower than those in 2013; this was probably due to the inter-annual climate, rice growth conditions and other variability's, which led to differences in CH_4emission flux. There was a significant increase inCH_4 emission in the treatment of straw returning to the field in 2013 and 2014. The cumulative 2013 CH_4 emitted from straw-return was 1.42 times that of CK treatment, which increased to 1.80 in 2014; this indicated that straw-return increased the CH_4 emissions in Chao Lake rice paddies.

Effects of soil Eh during the rice-growing season on CH_4 emissions

Since methanogenesis requires substrates and extreme reducing conditions, sufficient methane-producing substrates and a suitable methanogenic growth environment are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15851600

prerequisites for CH_4 production. During the early stage of rice growth, soil Eh was still high (*Fig. 5*), which hindered CH_4 production in the soil, resulting in almost no CH_4 production after the first two treatments (*Fig. 3*). During the first four days after transplanting, CH_4 fluxes remained at 0 mg m^{-2} h^{-1} and began to increase rapidly for 8 days starting on day 6 to reach the first peak. These changes correlated well with increases in soil Eh. In the middle stage of rice growth, the soil Eh had decreased levels suitable for methanogenesis, and there was un-degraded straw remaining from the straw-return CO + SR treatment; this provided a rich methanogenic substrate and appropriate environment for CH_4 production, thereby promoting the production of CH_4 in paddy fields.

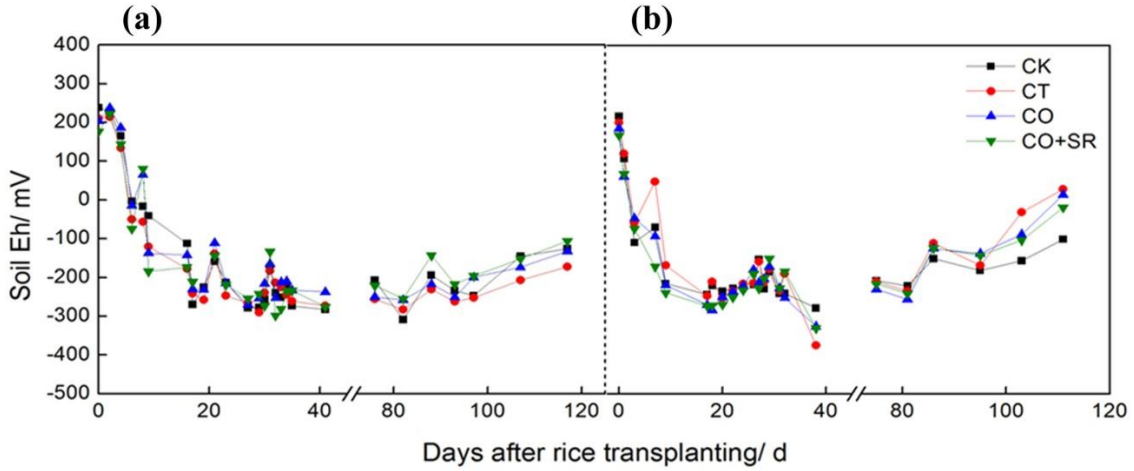

Figure 5. *Seasonal dynamic of soil Eh during the rice growing seasons of (a) 2013 and (b) 2014*

During the first four days after transplanting, CH_4 fluxes remained at 0 mg m^{-2} h^{-1} and began to increase rapidly for 8 days starting on day 6 to reach the first peak. These changes correlated well with increases in soil Eh. In the middle stage of rice growth, the soil Eh had decreased levels suitable for methanogenesis, and there was un-degraded straw remaining from the straw-return CO + SR treatment; this provided a rich methanogenic substrate and appropriate environment for CH_4 production, thereby promoting the production of CH_4 in paddy fields. The CH_4 production potential of the two treatments increased markedly from 35 to 66 days after transplanting. During the later stage of rice growth, soil Eh was not the limiting factor for CH_4 production. With the consumption of straw, CH_4 production potential gradually decreased and eventually stabilized. The straw mulch did not decompose because of the absence of straw organic matter supplement until the soil Eh decreased to levels suited for CH_4 production. The correlation between CH_4 emission flux and soil Eh is shown in *Table 4*.

Table 4. *Correlations of the variations in CH_4 emission flux with soil Eh*

Treatment	CK	CT	CO	CO + SR
E_h	-0.536	-0.652*	-0.571*	-0.736**

Effects of temperature on CH_4 emissions during the rice-growing season

Temperature affects both CH_4 production and emission, and the CH_4 emission flux from paddy field closely correlates with air and soil temperature. Correlation analysis was performed for CH_4 emission flux and surface temperatures at depths of 5 and 10 cm during the sampling period, and the correlation coefficients are shown in *Table 5*.

Table 5. *The correlation of the variations of the CH_4 emission flux with soil temperature*

Treatment	Soil surface temperature	5 cm depth temperature	10 cm depth temperature
CK	0.074	0.320*	0.169
CT	0.128	0.308*	0.116
CO	0.290*	0.335**	0.135
CO + SR	0.270*	0.312*	0.196

*Significantly correlated at the P > 0.05 level (bilateral); **significantly correlated at the P > 0.01 level (bilateral)

CH_4 emission fluxes were significantly correlated with soil temperatures at 5 cm depth ($P < 0.05$) for all treatments and with surface temperatures (0 cm depth) for the CO and CO + SR treatments; the land surface temperatures failed to correlate with CH_4 emission fluxes for CK and CT, whereas temperatures at a depth of 10 cm failed to correlate with CH_4 emission fluxes for any treatments. A large number of studies have shown that CH_4 emissions from rice fields are affected by many factors, such as soil properties, rice growth, tillage measures and climatic factors. Under the conditions of continuous flooding and with an adequate supply of organic matter, soil Eh was non-limiting and changes of CH_4 emission fluxes were mainly affected by the factors such as soil temperature. Compared with the surface temperatures and soil temperatures at a depth of 10 cm, CH_4 fluxes were more closely related to soil temperature at 5 cm depth; this may be because the soil CH_4 activity mainly occurred in 0 ~ 5 cm soil layer and decreased significantly thereafter. In addition, straw mulching had a significant effect on the surface temperature, which could increase the soil temperature at 5 cm to a certain extent, thus promoting the activity of methane-producing bacteria.

Relationship between CH_4 flux and soil temperature at 5 cm depth

The soil temperature at 5 cm depth was the main environmental factor affecting the CH_4 flux in paddy fields, and the regression equation was obtained by regression analysis between the CH_4 flux and the corresponding of 5 cm soil temperature values: CK: $Y = -17.30573 + 0.84321X$ ($R^2 = 0.14732$, $P < 0.05$); CT: $Y = -24.27339 + 1.19103X$ ($R^2 = 0.16676$, $P < 0.01$); CO: $Y = -28.48551 + 1.35211X$ ($R^2 = 0.17485$, $P < 0.05$); CO + SR: $Y = -24.55386 + 1.17238X$ ($R^2 = 0.14732$, $P < 0.05$), where x is the temperature and y is the CH_4 emission flux (*Fig. 6*). According to the equation, CH_4 emission fluxes were positively correlated with temperature, and the methanogenic activity of the 0~5 cm soil layer was higher than that of deeper soils.

Discussion

Numerous latest studies have shown that application of nitrogen fertilizer positively correlates with CH_4 emissions from agricultural soils (Parkin and Hatfield, 2013;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15851600

Halvorson et al., 2014). CH_4 emission fluxes from rice cropping fields ranged between 35.3 and 38.8 g m^{-2} over the experimental period, which agreed with results from previous studies (25.9 gm^{-2} to 41.9 gm^{-2}) conducted in different regions (Ku et al., 2017; Aulakh et al., 2001; Hu et al., 2016). In a terrestrial environment, there are numerous factors affecting CH_4 emissions such as denitrification, nitrification, chemodenitrification, heterotrophic nitrification, codenitrification and oxidation of ammonia; these processes are directly affected by the application of nitrogen fertilizer in the soil (Shurpali et al., 2016; Zhang et al., 2016; Luo et al., 2016; Shakoor et al., 2016). The results of this study also support this conclusion. In the same way, we analyzed the effects of nitrogen application on CH_4 emissions and emission peaks during the rice cropping seasons. In this study, the CK control treatment did not use nitrogen fertilizer application, and both its seasonal and annual CH_4 accumulated emissions were significantly lower than the other fertilization treatments. Seasonal CH_4 emissions fluxes observed by Ku et al. (2017) averaged a very low 15 gm^{-2} with nitrogen fertilizer applied at 150 kg ha^{-1}. Similarly, with reduced nitrogen fertilizer application to different agricultural fields (Molodovskaya et al., 2011; Ussiri et al., 2009; Deng et al., 2015), lower CH_4 emissions fluxes were reported. This study found that increasing the application of nitrogen fertilizer could promote CH_4 emission from soil into the atmospheric environment. This study confirmed that the straw returning significantly affected the CH_4 emission in the soil, whereas reduced application of nitrogen fertilizer can decrease CH_4 emissions. In 2014 rice growing period, the total CH_4 emitted from the CO + SR treatment was the highest among all the treatments and amounted to 38.8 gm^{-2} (*Table 3*). Similarly, previous studies also reported that the application of straw retuning can significantly increase CH_4 emissions (Wang et al., 2017, 2016, 2015).

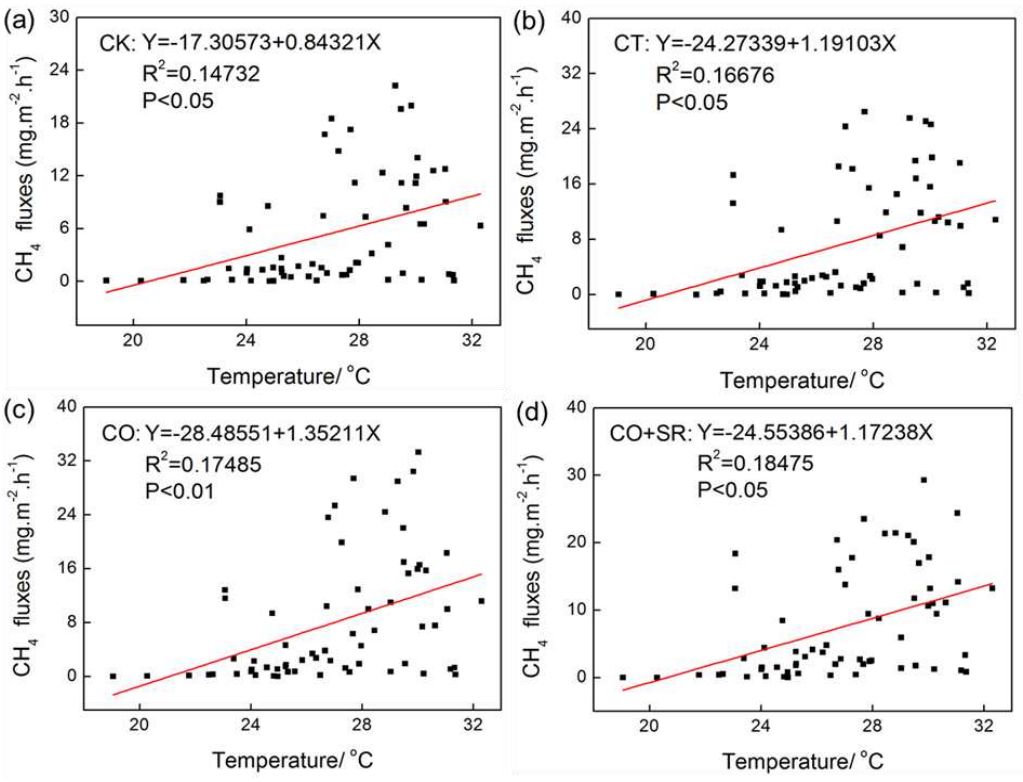

Figure 6. *Relationship between methane fluxes and soil temperatures of the 5 cm soil layer, (a) CK, (b) CT, (c) CO, (d) CO + SR*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_15851600

Generally, CH_4 is emitted during soil denitrification and nitrification processes (Shakoor et al., 2016; Smith et al., 1997), which are highly related to soil temperature (Smith et al., 1997; Sun et al., 2016; Aulakh et al., 2001); thus, soil temperature can greatly influence CH_4 emissions. Increased emissions of CH_4 as soil temperature increased from 25 °C to 30 °C showed that production of CH_4 was sensitive to soil temperature (Liu et al., 2017). In this study, the average soil temperature was 15.6 °C with a range of -3.1 °C to 34.5 °C. Maximum CH_4 emissions were observed at 27.5 °C, which was similar to results from recent studies (Maljanen et al., 2017; Liu et al., 2017). Gaihre et al. (2013) also studied that higher temperature could responsible for elevated of CH_4 emission, which was further increased by the application of straw returning.

Soil Eh is a key factor of CH_4 emission from paddy fields and it does not only affect methanogens activities but also involved in gas transformation through the aerenchyma (Le Mer and Roger, 2001). At a lower value of soil Eh, methanogens activities and formation of aerenchyma were increased (Kludze et al., 1993). Significant emissions of CH_4 occur once soil Eh is < -100 mV (Hou et al., 2016; Gaihre et al., 2013). So, the emission of CH_4 is negatively correlated to soil Eh. In our findings, the value of soil Eh was very high during the early stage of rice growth (*Fig. 5*), which delayed CH_4 production and emissions, which was similar to previous recent studies (Charles et al., 2017; Xu et al., 2017; Gaihre et al., 2013; Wang et al., 2017).

Conclusions

The experimental results of two - year farmland in Chao lake single-cropping rice fields showed that: CH_4 emission pattern from rice field consisted of “three peaks”, which appeared before land sunning and after the re-flooding period; the seasonal variation pattern was consistent. CH_4 seasonal emissions were lowest under the CK treatment for both years and were highest under the CO treatment during 2013 and the CO + SR treatment in 2014. The CO + SR treatment may have produced less CH_4 in 2013 due to a large number of stalks initially returned to the field, resulting in an excessive C/N ratio which inhibited soil respiration and affected microbial activities. A year later, the physical and chemical properties of the land had reached a balance, which could better reflect the effect of straw return on CH_4 emissions. The CO + SR treatment increased the total CH_4 emissions by 42.0% and 80.1% in 2013 and 2014, respectively. There was a significant correlation between CH_4 emissions from CO + SR treatment and soil temperatures at depths of 0 and 5 cm, but not at 10 cm. In addition, there was a significant negative correlation between CH_4 emissions and soil E_h. We estimated total CH_4 emissions from the rice growing periods of the two years, and emissions of the different treatments were CO + SR > CO > CT > CK. Straw return to soil can improve soil fertility, increase rice yield, but also increases the CH_4 emissions from rice fields. Therefore, it is necessary to consider the problem of straw returning from no-tillage paddy fields to effectively realize the carbon sequestration potential and reduce the emission of greenhouse gases.

Abstract. We detected presence of 23 types of organochlorine pesticides (OCPs) in 21 mixed samples obtained along the banks of Dawen River in China by gas chromatography. we analyzed the spatial distribution of OC residues, potential source, and the ecological and health risks. The results show that OCPs were detected in all the 21 sampling sites, and 86.6% of the 23 types of OCPs had a detection rate above 90%. Furthermore, the analysis of the single-factor pollution index shows that 14% of the sampling sites were mildly polluted, whereas 4.8% had medium-level pollution. Analysis of the Nemerow's multi-factor index shows that 9.5% of the sampling sites were mildly polluted. We found that Dawenkou Town and Wenyang Town are severely polluted, whereas Ciyao Town and Jiangji Town are less polluted by arcgis12.0 spatial analysis. Compared to other regions in China, the HCHs content is at a low level but DDTs at a high level in the study area. Assessment of health risks of OCP residues shows that the carcinogenic risk and the non-carcinogenic risk caused by exposure to OCPs is negligible. OCPs are primarily obtained from previous residues and recent use of lindane.
Keywords: *OCPs residues, DDT, HCHs, health risks*

Introduction

Chlorine in organic compounds is referred to as organochlorine. Organochlorine pesticides (OCPs), a type of persistent organic pollutants, have been drawn considerable research attention because of the pollution and environmental harm they have caused. Once OCPs enter the soil, the soil is contaminated, and because OCPs are hard to decompose and accumulate, they will enter the human body through the food chain and cause intoxication. OCPs are harmful to both the ecological system and human health, resulting in nervous system disorders, cancer, reproductive abnormalities, and congenital defects (Chen et al., 2017), Although the Chinese government banned OCPs in the 1980s, studies in recent years have revealed that HCHs and DDTs were still found in the soil and water in many regions across China (An et al., 2005; Cheng, 2014; Cui et al., 2014; Cheng et al., 2018; Cui et al., 2012, 2014; Chen et al., 2011; Dai et al., 2012).

Dawen River watershed, which is famous for high and stable crop yields, has been included in the ecological restoration program of the Mount Tai area in Shandong province of China. As an important part of the urban environment, the suburban soil has significant influence over the quality of the environment and ecological functions of a city. Note that OCPs residues in soil will affect the safety of crops and may cause food scarcity in cities and threaten human health (Cui et al., 2014).

DOI: http://dx.doi.org/10.15666/aeer/1801_159172

Using the topsoil in Wenyang Field as the research object, we performed pollution analysis, health risk analysis, and ecological risk analysis to identify the pollution condition and potential risks in Wenyang Field. We believe this study will provide effective solutions for soil restoration and provide a scientific basis for sustainable soil utilization and the protection of human health.

Materials and methods

Study area description

Wenyang Field (*Fig. 1*), the fertile land along the banks of Dawen River in its middle and lower reaches in china, was selected as the research area. Wenyang Field has a flat terrain and covers an area of 14 km^2. Feicheng City, Ningyang County, and Daiyue District located in Wenyang Field. It is subject to the warm temperate continental monsoon climate with high temperature coinciding with high precipitation, which facilitates the growth of crops. The major soil types of soil in this area include cinnamon soil and brown soil. The soil layer is thick and the soil is fertile. Dawen River, the largest branch of Yellow River in its lower reach, flows through Wenyang Field, while the underground water level is three to four meters deep. These natural conditions provide Wenyang Field with abundant water and fertile soil. As an important crop-yielding area in Taiwan, Wenyang Field is known as the "bread basket of Mount Tai" and supplies over 10,000 tons of corns and wheat to China; it is also rich in mineral resources such as gypsum and halite.

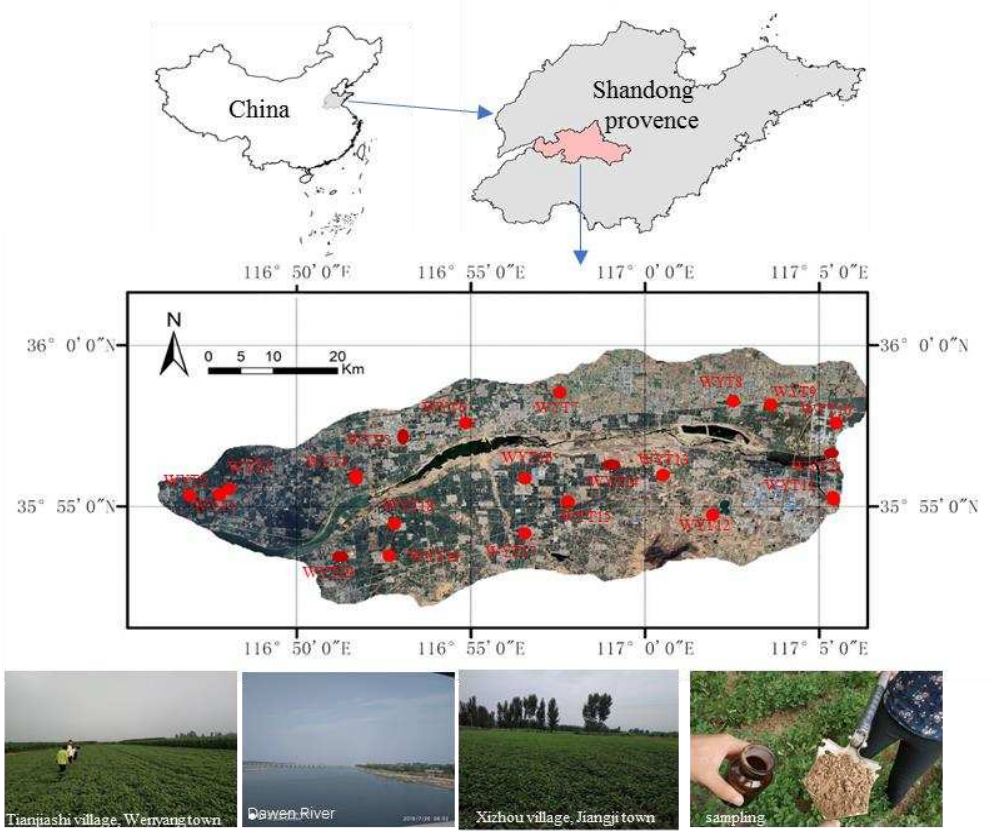

Figure 1. *Location of study area, distribution of sampling site sand sampling photos in Dawen River Basin in China*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_159172

Sample collection

The sampling points are located at 21 locations on both sides of the Dawen River (*Table 1, Fig. 1*). Preliminary surveys of the Dawen River watershed were conducted using GPS, and 21 mixed soil samples were collected according to "Technical Guidelines for Environmental Site Investigation" (HJ25.1-2014) in July 2018. Five-point sampling method was used to collect the samples, 5 samples are collected at each location to be mixed into one sample. and the sampling depth was from 0 to 20 cm. Details of specific sampling point locations and vegetation. The 200 g soil was sealed in brown wild-mouth bottles (250 ml) after being collected and stored in lab freezers at 4 °C. To test the physical and chemical indicators of the soil, a soil sample of 1 kg was collected and packed in the sampling bag. The collected soil samples were transported to the Lunan Institute of Geo-engineering Investigation of Shandong for additional tests.

In this paper, SPSS 12.0 software is used for data statistical analysis, and arcgis12.0 Kriging difference method is used for spatial analysis (Ma et al. 2015).

Methods

The samples were tested at the Nunan Institute of Geo-engineering Investigation of Shandong and 23 types of OC compounds were analyzed. The GC-ECD method was used to detect OCPs in the soil. The detection and testing tools included the Agilent 7890B-5977B mass spectrometer, the Thermo ASE 350 pressurized fluid extractor, the SUPELCO VISIPREP 24^{TM} DL solid-phase extraction device, and the HP-5

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_159172

chromatographic column. The reagents used included 20 types of standard mixtures of OC solvents, and the testing procedure was as follows. The samples were dried and grinded before being screened through a 250-μm sieve (No. 60 sieve). The sample was mixed with diatomaceous earth (1 g) and the mixture was added to the extraction cell (22 ml) before pressurized fluid extraction was conducted according to the HJ783-2016 standards. After extraction, n-hexane was used to wash the tube wall of the concentrator exposed during the nitrogen blowing process to concentrate n-hexane to 1 ml. The eluent was then transferred to the column and 2 ml of n-hexane was used to wash the concentrator several times, and then all the eluent was transferred into the column (if desulfurization was required, the solvent would be sunk in copper sheets for ~5 min). The eluents were collected and concentrated before the internal standard was added for testing. When drawing the curves, five sample bottles of 1.5 ml were used to prepare solvents of five different concentrations by mixing the OCPs standard intermediate solution, the substitute intermediate solution, internal standard intermediate solution, and n-hexane solution extracted by the pipette. The mass concentrations of OCPs and substitutes for the five solvents were 20, 50, 100, 200 and 500 ng/ml, and the internal standard mass concentration was 20.0 ng/ml.

Results

Characteristics of OCPs residues

Table 2 shows the conditions of OCPs residues in the soil of Wenyang Field in china. The total content of OCPs residues (ΣOCPs) is between *nd* and 197.01 ng/g. The detection rate of OCPs in the 21 sampling sites in Wenyang Field reached 100%, and 23 types of OCPs were detected. The most prevalent OCPs detected in the soil of Wenyang Field measured by the average content are DDTs (53.84 ng/g), endrin aldehyde (18.47 ng/g), and heptachlor epoxide (17.07 ng/g).

HCHs

The detection rate of HCHs (such as α-, β-, γ-, and δ-HCH) is 100% with the residue content between 1.58 and 15.95 ng/g (average of 4.23 ng/g). The largest content of HCHs was observed at WYT10 (near the glass manufacturing plant), while the content of HCHs in the topsoil of Wenyang Field was far below 100 ng/g, which is the threshold value for agricultural land pollution as stipulated in "Soil Environment Quality Standard" (GB15618-2018). The content of HCHs in the topsoil of Wenyang Field is below that at Jining in Shandong (5.73 ng/g) (Pang et al., 2009), Henan province (12.55 ng/g) (Cheng et al., 2018), Baotou (8.37 ng/g) (Meng et al., 2017a), Inner Mongolia (8.63 ng/g) (Meng et al., 2017b), Changchun (10.95 ng/g) (Xiao, 2017), and Yangtze River Delta (7.73 ng/g) (Shi et al., 2016); however, the content of HCHs is above that in Shanghai (2.19 ng/g) (Cheng et al., 2018). This comparison indicates that the HCHs pollution in the soil of Wenyang Field is still at a low level. The HCH isomers have different physical, chemical, and toxic properties; furthermore, in terms of the dichlorination and degradation rate, γ-HCH > α-HCH > δ-HCH > β-HCH. However, the results of this study show that the detection rate of β-HCH is the highest, and β-HCH > γ-HCH > α-HCH > δ-HCH in terms of the average residue of HCHs. According to *Figure 2a,* which shows the distribution of HCHs content, the HCH content is high in Wenkou Town and Ciyao Town but relatively low in the western area.

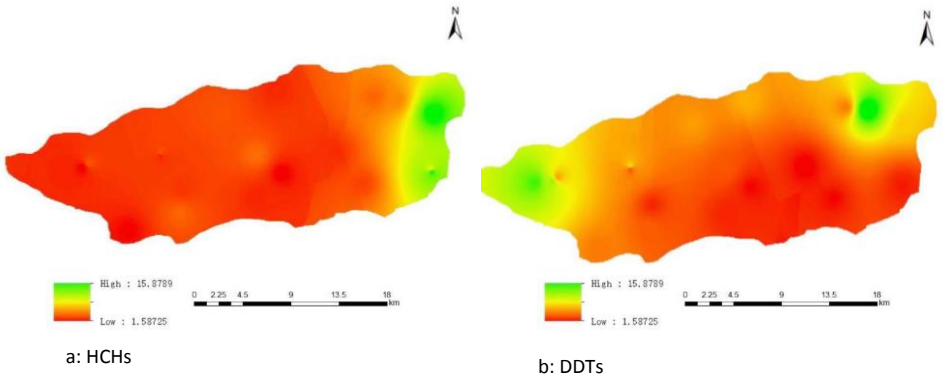

Figure 2. *Distribution of HCHs and DDTs content in Dawen River Basin in China*

DDTs

The detection rate of DDTs, including DD, DDE, and DDT, is 100% in the study area, and the residue content is between 8.4 and 197.01 ng/g (average of 53.84 ng/g).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_159172

The highest content occurs at WYT9 (a celery-growing field). Note that the residue content of DDTs is higher than that of HCHs, and HCHs and DDTs have the same variable coefficient of 0.93. The average content of DDTs in the topsoil of Wenyang Field is 51% of the average content of all organic pollutants. The DDTs content in the topsoil of some sampling sites is already > 100 ng/g, which is the threshold value for agricultural land pollution risks stipulated in "Soil Environment Quality Standard" (GB15618-2018). Note that the content of DDTs in the topsoil of Wenyang Field is higher than that at Jining (17 ng/g) (Pang et al., 2009), Shanghai (13.15 ng/g) (Jiang et al., 2010), Henan (8.97 ng/g) (Cheng et al., 2018), Baotou (9.51 ng/g) (Meng et al., 2017a), Inner Mongolia (9.71 ng/g) (Meng et al., 2017b) and Yangtze River Delta (Shi Lei et al., 2016); however, it is below that at Yantai (160 ng/g) (Dai et al., 2012) and Songhuajiang in Jilin (92 ng/g) (Liu et al., 2013). The comparison indicates that the DDT pollution in the soil of Wenyang Field is at a high level. The four derivatives of DDTs by average content are ranked as follows: p,p′-DDT > p,p′-DDE > p,p′-DDD > o,p′-DDT, and the content of p,p′-DDT is the highest. *Figure 2b* shows that the content of DDTs is high in Anjiazhuang Town and Dawenkou Town, but relatively low in Jiangji Town and Ciyao Town.

Discussion

OCPs pollution analysis

Single-factor pollution index analysis

The single-factor index method (Chen et al., 2011; Wu, 2012) and the equation $P_i = C_i/S_i$ were used to calculate the single-factor pollution index P_i of the pollutant i:

$$p_i = \frac{C_i}{S_i} \quad \text{(Eq.1)}$$

Figure 3 shows the calculation results, and the single-factor pollution index of HCHs is generally seen to be lesser than that of DDTs. The curve for DDTs in *Figure 3* shows sharp fluctuation, which indicates the pollution level of DDTs varies considerably from one region to another. While 14% of sampling sites showed mild pollution, Xiaohou Village showed the highest single-factor pollution index of ~1.9; hence, it is considered under medium-level pollution. *Figure 4* shows that the level of pollution is high in Dawen Town and Wenyang Town, but relatively low in Ciyao Town and Jiangji Town.

Nemerow's pollution index analysis

According to the Nemerow's pollution index method, we used the equation to calculate the composite soil pollution index P_N:

$$P_N = \sqrt{\frac{P_i^2 + P_{i(max)}^2}{2}} \quad \text{(Eq.2)}$$

Figure 5 shows the calculation results in which 9.5% of sampling sites are mildly polluted with the highest index in Xiaohou Village. As shown *in Figure 6,* the pollution level in Dawenkou Town and Wenyang Town is high, but it is relatively low in Ciyao Town and Jiangji Town.

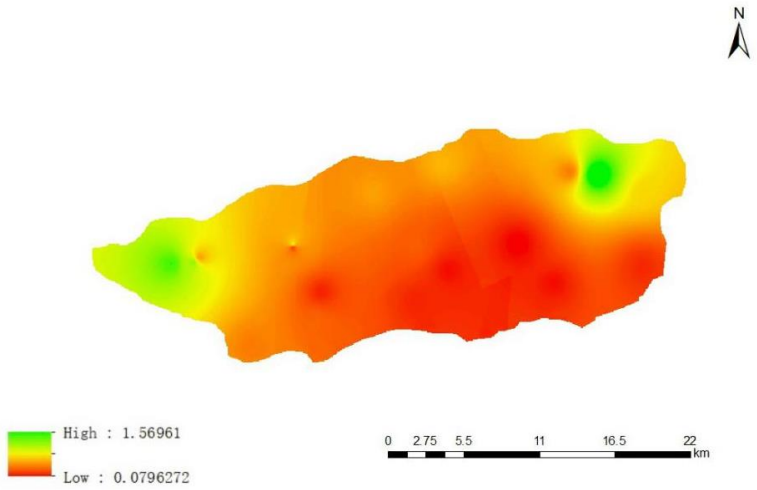

Figure 6. *Interpolation of Nemerow's pollution index in Dawen River Basin in China*

Assessment of ecological risks of OCPs

We assessed the ecological risks of OCPs according to the concept of adverse biological effects proposed (Long et al., 1995). Effect range low (ERL) and effect range median (ERM), proposed in the study by Long et al., are used as threshold values to identify the level of ecological risks of pollutants. If the value of a pollutant is lesser than ERL, it has no obvious biological toxicity and the ecological risk is < 10%; if the value falls between ERL and ERM, the pollutant has potential toxic effects; and if the value is higher than ERM, it is biologically toxic and its ecological risk is > 75% (Zhu et al., 2012; Lin et al., 2011).

The data obtained in tests in this study are compared with ERL and ERM. Note that in 20 of the 21 samples, i.e., ~95.24% of samples, the value of p,p'-DDT is higher than ERM, which indicates that it has a very high level of ecological risk. Among the 21 samples, the value of p,p'-DDE is lower than ERL in nine samples; however, the value of p,p'-DDE in the other 12 is between ERL and ERM, i.e., 42.86% and 57.14% of samples, respectively, which indicates that p,p'-DDE has a relatively high level of ecological risk. Note that in 16 of the 21 samples, i.e., 76.19% of samples, the value of p,p'-DDD is lower than ERL. Thus, the ecological risks posed by OCPs in the soil of Wenyang Field needs to be examined.

Assessment of ecological risks of DDTs is based on studies (Jongbloed et al., 1996). By designing a simplified food web, Jongbloed et al. identified the threshold content of DDTs in soil, which would cause secondary poisoning: 10 μg/kg for soil worms, 11 μg/kg for birds, and 190 μg/kg for mammals (Jongbloed et al., 1996). In most of the sampling sites, the content of DDT in soil is higher than the maximum allowable content of DDTs residues for soil worms and birds; therefore, the ecological risk they pose to soil worms and birds is high. However, the content of DDTs in most of the sampling sites is below the maximum allowable content of DDTs residues for mammals; therefore, the ecological risk DDTs pose to mammals is relatively low.

Assessment of health risks of OCPs

Human health risk research is an important content of organic pollution research, and the risk can be used as an important basis for the next soil use. Most of them use the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_159172

health risk model recommended by the EPA of the United States for evaluation, and the results show that the health risk in most regions is relatively small (Liu et al., 2017; Zhang, 2016; Cheng, 2014).

Based on the health risk assessment model proposed by United States Environmental Protection Agency (USEPA), this study assesses the human health risks of OCPs residues in soil. The human body can be exposed to OCPs in soil via three channels: ingestion through the mouth, dermal contact, and inhaling of dust or volatile gases. The parameters for calculating the average daily dosage are determined from the guiding documents issued by USEPA (USEPA,1997, 2002, 2010) and the studies by Niu, et al. (Niu et al., 2013). The equations to calculate the average daily dosage (ADD, mg/kg^{-1} day^{-1}) of OCPs that the human body is exposed to by the three pathways are listed as *Equations 3–5* (USEPA, 1996):

$$\mathrm{ADD}_{ingest} = \frac{\mathrm{C}_{soil} \times \mathrm{IngR} \times \mathrm{EF} \times \mathrm{ED}}{\mathrm{PEF} \times \mathrm{BW} \times \mathrm{AT}} \times CF \quad \text{(Eq.3)}$$

$$\mathrm{ADD}_{dermal} = \frac{\mathrm{C}_{soil} \times \mathrm{SA} \times \mathrm{AF} \times \mathrm{ABS} \times \mathrm{EF} \times \mathrm{ED}}{\mathrm{BW} \times \mathrm{AT}} \times CF \quad \text{(Eq.4)}$$

$$ADD_{inhale} = \frac{\mathrm{C}_{soil} \times \mathrm{InhR} \times \mathrm{EF} \times \mathrm{ED}}{\mathrm{PEF} \times \mathrm{BW} \times \mathrm{AT}} \quad \text{(Eq.5)}$$

Using the hazard index (HI) method, this study evaluates the non-carcinogenic risk of OCPs; moreover, by dividing the reference daily dosage from each exposure channel (ADD_{ing}, ADD_{dermal}, and ADD_{inh}) by the actual daily dosage from each channel, this study calculates the hazard quotient (HQ) of each channel of exposure (Zhang Jingjing.2016). By multiplying the life average daily dosage (LADD) and the cancer slope factor (SF), this study calculates the carcinogenic risk (Risk). The calculation equations are as follows (*Eqs. 6–9*) (USEPA, 2002):

$$HQ = \frac{\mathrm{ADD}}{\mathrm{RFD}} \quad \text{(Eq.6)}$$

$$\mathrm{HI} = \sum HQ_i \quad \text{(Eq.7)}$$

$$Risk_i = LADD \times SF_i \quad \text{(Eq.8)}$$

$$\mathrm{Risk} = \sum Risk_i \quad \text{(Eq.9)}$$

HI means the overall non-carcinogenic risk of exposure to OCPs via all three channels. When *HI* or *HQ* is < 1, the risk is considered low or negligible; however, when *HI* or *HQ* is > 1, it is considered that there are non-carcinogenic risks. *Risk* refers to the level of carcinogenic risk, i.e., the probability of developing cancer. *SF* refers to the cancer slope factor, which indicates the maximum possibility of developing cancer associated with exposure to a certain dosage of a pollutant. When Risk is < 10^{-6}, the risk of cancer is considered very low; when *Risk* is between 10^{-6} and 10^{-4}, the risk of cancer is considered low; and when *Risk* is > 10^{-1}, the risk of cancer is considered high (Niu et al., 2013). The reference dosage and carcinogenic slope factor for each channel are obtained from the Supplemental Guidance for Developing Soil Screening Levels for Superfund Sites issued by USEPA in 2010 (USEPA, 2010).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_159172

According to the calculation results, both among children and adults, the three exposure channels are ranked as follows by the dosage of OCPs that enter the human body: ingestion through the month > the dosage from inhaling > the dosage from dermal contact. Ingestion is the major channel of exposure to OCPs. By ranking the detected daily dosage of OCPs, the dosage in children from all these three channels is higher than that in adults. In terms of the dosage of exposure, leading to non-carcinogenic risks, the different types of OCPs are ranked as follows: DDT, HCHs, p,p′-DDE, β-HCH, p,p′-DDD, γ-HCH, α-HCH. *Table 3* shows the average daily dosages of these OCPs.

Table 3. *Average daily exposure of three pathways (mg·kg^{-1} day^{-1})*

	ADD$_{ing}$	**ADD$_{dermal}$**	**ADD$_{inh}$**	**ADD$_{ing}$**	**ADD$_{dermal}$**	**ADD$_{inh}$**
DDTs	5.26E-08	1.47E-08	2.32E-08	2.25E-08	8.99E-09	2.19E-08
HCHs	4.64E-09	1.30E-09	2.04E-09	1.99E-09	7.93E-10	1.94E-09
p,p'-DDE	4.21E-09	1.18E-09	1.86E-09	1.80E-09	7.19E-10	1.76E-09
β-HCH	2.39E-09	6.69E-10	1.05E-09	1.02E-09	4.08E-10	9.97E-10
p,p'-DDD	2.23E-09	6.25E-10	9.85E-10	9.57E-10	3.82E-10	9.33E-10
γ-HCH	1.08E-09	3.02E-10	4.76E-10	4.62E-10	1.84E-10	4.50E-10
α-HCH	8.36E-10	2.34E-10	3.69E-10	3.58E-10	1.43E-10	3.49E-10

According to equations and relevant parameters of the three channels, the different types of OCPs are ranked as DDTs > HCHs > α-HCH > β-HCH > p, p′-DDE > p,p′-DDD > γ-HCH in terms of the carcinogenic risk they incur. The carcinogenic risk associated with exposure to OCPs through all the three channels among children is higher than that among adults. As shown by the calculation result, the value of carcinogenic risks associated with exposure to OCPs through different channels is far below 10^{-6}, which indicates that the carcinogenic risk of OCPs in the topsoil of Wenyang Field is small and negligible; hence, it will not pose a threat to human health.

According to certain parameters and calculation of the equations, both among children and adults, the value of non-carcinogenic risk associated with exposure to OCPs via the ingestion channel is higher than that through the dermal contact channel. Note that the value of non-carcinogenic risk associated with exposure to OCPs through the inhaling channel has not been obtained because of the lack of corresponding parameters. In terms of the non-carcinogenic risk associated with exposure through the channels of ingestion and dermal contact, the different types of OCPs are ranked as DDTs > HCHs > β-HCH > γ-HCH > α-HCH. The non-carcinogenic risk (represented by HI) of each type of OCPs is far below 1, which indicates that the non-carcinogenic risk posed by OCPs in the topsoil of Wenyang Field is small and almost negligible.

Pollution source analysis

DDTs have two biodegradation mechanisms in soil, i.e. either DDT is degraded to DDD through reductive dichlorination in anaerobic conditions or it is degraded to DDE through dehydrochlorination in aerobiotic conditions. Note that DDD and DDE are less toxic than DDT, and DDE is very stable. Generally, in the soil contaminated by DDTs, the ratio of (DDE + DDD)/DDT will exceed 1, which indicates that the DDTs have not been used for a long time and that there is no new source of DDT pollution (Cui et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_159172

2014). Thus, the ratio of (DDE + DDD)/DDT can be used to identify whether DDTs are used in the study area. In this study, the ratio (*Table 4*) of the 21 sampling sites is below 1(0-0.6), which means DDTs are used recently. If the ratio of (p,p'-DDT + o,p'-DDT)/DDTs is below 0.5, it indicates that the DDT pesticides are used long ago and there is no new source of pollution. The calculated ratio (*Table 4*) in the 21 sampling sites is above 0.5(0.6-1.0), which means that it has not been long since usage of DDTs in most areas of the Dawen River watershed, and DDTs are recently used in the 21 sampling sites (Cui et al., 2014). These two ratios lead to the same conclusion that it has not been long since DDTs are used in the topsoil of the Dawen River watershed.

Table 4. *Proportions of DDTs for source identification in surface soil of the study area (ng g^{-1})*

HCHs pollution is mainly caused by the usage of HCHs and lindane. In China, after HCHs were banned, lindane has been extensively used in agricultural production; therefore, the components of HCH isomers have been used as indicators for environmental pollution (USEPA, 2010). The components of HCHs include α-HCH (55%–60%), β-HCH (5%–14%), γ-HCH (12%–16%), δ-HCH (6%–8%), ε-HCH (2%–9%), heptachlorocyclohexane (4%), and octochlorocyclohexane (0.6%). In lindane, the content of γ-HCH is > 90%. Among the four HCH isomers, β-HCH is the easily absorbed by the soil but is the most difficult to be degraded by microorganisms in the soil. In the natural environment, α-HCH and γ-HCH can be converted to β-HCH. The average percentage of α-HCH, β-HCH, γ-HCH, and δ-HCH detected in this study is 9%,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_159172

26.33%, 11.90%, and 3.6% of the average content of HCH. Previously, studies have shown that the ratio of α-HCH/γ-HCH can be used to analyze the source of HCHs. In particular, when the ratio is < 1, HCHs are mainly derived from the usage of lindane; when the ratio is near 0, it indicates that lindane has been used recently (Cui et al., 2014); when the ratio of HCH/γ-HCH falls between 3.44 and 5.00, the source of HCHs may be industrial production; and when the ratio exceeds 5.00, the HCHs may be the previous use of HCHs or biodegradation reactions (Cui et al., 2014). The results (*Table 5*) show that 33% of the sampling sites have a ratio that approaches 0 (α-HCH/γ-HCH is below 0.4) and 57% of the sampling sites have a ratio below 1(0.2-1.0), which indicates that lindane has been recently used in some areas around Wenyang Field. Most areas have no recent use of lindane.

Conclusion

Using gas chromatography, we detected the content of OCPs in 21 topsoil samples of Wenyang Field and analyzed the residue characteristics, health risks, ecological risks, and potential sources of OCPs. We obtained the following results. First, the major components of the 23 types of OC pollutants are DDTs (6.76–222.76 ng/g), endrin aldehyde, heptachlor epoxide, and HCHs (1.22–17.34 ng/g). Note that the detection rates of HCHs and DDTs in the topsoil of the study area can reach 100%. As shown by the map of distribution of OCPs, the pollution level is high in Dawenkou Town and Wenyang Town, while the pollution is relatively low in Ciyao Town and Jiangji Town. Second, when analyzing the ecological risks of OCPs, it is revealed that OCPs pose high ecological risk to soil worms and birds but pose no obvious threats to mammals. Third, the analysis of health risks of OCPs shows that the carcinogenic risk associated with exposure to OCPs through different channels is below 10^{-6}, which indicates that the carcinogenic risk of OCPs in the soil of Wenyang Field is small and negligible. Note that the value of non-carcinogenic risk (represented by hazard index) of each type of OCPs is far below 1, which indicates that the non-carcinogenic risk associated with exposure to OCPs in the soil of Wenyang Field is small and almost negligible. Fourth, the analysis of the sources of OCPs in the study area reveals that OCPs are mainly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_159172

derived from residues of OCPs used previously and because of the recent use of lindane. To conclude, the development of biological agents that can clean the soil is important reduction in the usage of pesticides and fertilizers should be encouraged.

Follow-up research can be carried out, (1) A total of 21 samples were collected on the north and south of Dawen River this time, and the number of samples can be increased in the later. (2) Some organic pollutions, such as DDTs and HCHs, are hard to be degraded. In addition to the influence of natural and cultural environment, we can take samples and test in the same place several years later to see whether the pollution concentration will change significantly with time.(3) we can increase humanistic survey to know the changes of frequency, brand and efficacy of pesticides used by local farmers in recent years, Deeply understand the source of organic pollution.

(Received 3rd Oct 2019; accepted 8th Jan 2020)

Abstract. This study was carried out to investigate the effects of different substrates (barley+straw and barley+dry olive pulp) on the feed value of barley plants produced in a hydroponic system. In addition, germination of barley was tested in experiment 2 for silage quality. For this purpose, barley was harvested on the 7th day of the experiment. Nutrient contents of plant samples were determined. Dry matter content of the fodders increased significantly with the addition of straw ($P<0.01$), while the ash, ADF and NDF contents significantly increased ($P<0.01$) with the addition of dry olive pulp (prina) ratio. In trial 2, the addition of straw and dry olive pulp increased the dry matter content of the silage while the straw increased the pH of silage ($P<0.01$). The contribution of dry olive pulp increased total ash, ADF and NDF values in silage. Protein levels did not differ in either trials ($P>0.05$). The results revealed that the use of straw is useful in preventing the negative effect of excess water in germination environment. In addition, relative feed value (RFV) and digestible dry matter (DDM) criteria of feeds were quite satisfactory. Nutrient content and other quality criteria of feed indicated that hydroponic barley is a favorable silage material with base materials, though wheat straw was superior to dry olive pulp.
Keywords: *olive pulp, hydroponic farming, germination, animal feed, straw*

Introduction

Supply of quality fresh green feed is one of the major challenges for animal breeders in hot summer months. Traditional fresh green forage production requires land, labor and a significant amount of water. Hydroponic feed production technique converts an energy feed such as barley grain into a green feed and requires less soil, water and labor, and enables production at any time of the year. In addition, the fresh forage produced in hydroponic systems are claimed to have high digestibility (Chung et al., 1989; Islam and Jalal, 2016). Hydroponic systems, unlike other production systems, are based on the reuse of water; thus, consumes 87% less water for the same amount of feed production (Al-Karaki and Al-Moani, 2011). Corn is less preferred because it does not germinate as easily as barley. Wheat and rye are not preferred compared to barley because wheat is consumed as human food. Rye seeds are very small, an efficient germination cannot be achieved in one week and is more suitable for grazing on pasture. Rye grass is not also preferred because it is not a plant that is consumed as grain like barley. This production model is suitable and economical for some annual plants consumed as grain. Barley is most commonly used cheap source in hydroponic systems and can be obtained easily. The harvest is very easy and practical, so it is possible to harvest every day of the year and there is no need for stocking.

Studies conducted on the hydroponic feed production revealed no loss of dry matter or no significant changes in nutrient content (Peer and Leeson, 1985). In contrast, some reports indicated that high humidity in hydroponic fodder adversely affects the feed consumption of animals and excessive moisture causes mold problems in hydroponic production. Therefore, Tudor et al. (2003) recommended the addition of straw during consumption to decrease the moisture and increase dry matter content.

Total of 4500 tons of olive was produced in Sanliurfa province, Turkey in 2016 (TUIK, 2016). Olive pulp is a major byproduct and environmental pollutant of oil extraction process and approximately 70-80% of processed olives turns into olive pulp which corresponds to 3500 tons per year. Olive pulp consists of shell, seed and crushed fruit and can be utilized as a germination medium due to the high nutrient contents. Sansoucy (1985) reported that olive pulp may contain as high as 75 to 80% dry matter, 3 to 5% crude ash, 35 to 50% crude cellulose, 5 to 10% crude protein and 8 to 15% crude oil as dry matter basis (Sansoucy, 1985).

Moisture content of hydroponic feed can be reduced, and nutrient losses can be minimized using agricultural wastes such as straw or dry olive pulp in hydroponic plant production Dry olive pulp can also provide some nutrients to the germination environment. This study was aimed to cope with high moisture problem in soilless barley production and to reduce nutrient losses in germinated barley by using olive pulp and straw.

Material and Method

The experiment was conducted during April 2014 at the Faculty of Agriculture, Harran University, Turkey. The study consisted of two different germination experiments in controlled room conditions under natural lighting at temperatures varying between 16 and 35ºC throughout the experiments.

Experiment 1

The seeds of barley (*Hordeum vulgare* L.), with 88% dry matter and 11% crude protein used as the material in the experiments were purchased from a local grain market and kept in a cold environment (4ºC) to ensure the germination (*vernalization*) a day before the start of the experiment. The barley used was the local *Ayhan* variety of malting barley in this study. The germination system was adapted from the system applied by Al-Karaki and Al-Hashimi (2012). Germination experiment was conducted in aluminum trays with the dimensions of 19 × 9 × 3 cm. The first experiment comprised only of the germination of barley and the second experiment was on quality of silage prepared by the germinated barley.

The barley grains, which were kept in the cold for one day, were washed and filtered to remove dust and dirt. In this way, seeds were thoroughly cleaned and disinfected. Barley grains were kept in water for one day to soften the seeds; thus, facilitated the germination. The soften seeds were scattered on trays for the germination.

The effect of three different treatments on germination of barley seeds was investigated. The treatments were control (C, only barley), wheat straw (WB) and dry olive pulp (PB). In control treatment, barley seeds were placed in the trays without any supportive material. Barley seeds were covered with wheat straw in WB and with dry olive pulp in PB treatments. WB and PB were taken up to cover the barley seeds and approximately 15 g for straw and 50 g for dry olive pulp. The aim of experiment 1 was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16011610

to investigate the germination power and the effects of wheat straw and dry olive pulp on nutritional value of germinated barley. Wet weight of barley was used to determine the amount of seeds to be sown. Accordingly, 60 g of wet barley seeds were weighed into 0.017 m^2 trays and left for germination. The amount of seeds corresponded to 3550 g wet barley per m^2, which was equivalent to 1000 g dry barley grain per m^2 (*Fig. 1*).

Figure 1. *Barley germination patterns in hydroponics (top right: with dry olive pulp (PB); top left: with wheat straw (WB) and bottom: barley (Control; C))*

The seeds were carefully placed into floor of the germination trays up to a height corresponding to finger thickness and covered the whole floor of the trays. Seeds were covered by straw and dry olive pulp to reduce the moisture in hydroponic feed. The trays were placed close to the windows for natural lighting throughout the germination. Temperature and humidity of the environment were recorded during the germination. The temperature varied between 16 and 35ºC and humidity ranged from 20 to 66% during the trial. Since water accumulation in the system causes the formation of mold, excess water had to be drained. Therefore, the trays were placed with 1-2% inclination to discharge the excess water. Plants were watered twice a day (morning and afternoon) during the germination process, avoiding over watering and providing good drainage. Irrigation was continued until the water covered all the seeds.

Dense green cover and matted/entangled root accumulation in the tray were the criteria of germination success. The experiment 1 was terminated after 7 days, and the trays were weighed on the morning of 8th day. The biomass harvested in each treatment was measured and green fodder yield was determined. After the germination, straw and dry olive pulp was removed. Plant yield/seed ratio, grass yield, crude protein ratio, protein yield, plant height and root structure were determined. Fresh and dry weights of harvested plants were recorded. Plant samples was dried to a constant weight in an oven at 55°C for two 48 hours. The dried samples were ground to pass through 1 mm sieve for crude protein ratio and protein yield analysis.

DOI: http://dx.doi.org/10.15666/aeer/1801_16011610

Experiment 2

Barley seedlings of C, WB and PB treatments were harvested on day 7 and silage of each treatment was prepared in air tight nylon bags to determine quality traits of silages (*Fig. 2*). Silage bags were kept for 60 days, and the bags were opened, and samples were analyzed for quality traits. The pH, color, odor and appearance of silage samples were determined, and dry mater contents were measured. Dry matter yield, crude ash, acid detergent fiber (ADF), neutral detergent fiber (NDF) and protein contents were analyzed in air dried silage samples. The NDF and ADF contents were determined by ANKOM-200 fiber analyzer using the method of Van Soest et al. (1991). Nitrogen content was analyzed by Kjeldahl method. Flieg score was calculated using the relationship between pH of silage and dry matter content. There is a high correlation between the silo feed and quality calculated according to following equation (Kara et al., 2009).

$$Flieg\ score := 205 + (2 * silage\ dry\ matter, \%) - 40 * pH\ of\ silage\ feed \quad \text{(Eq.1)}$$

Figure 2. *Making silage of germinated hydroponic product in nylon bags*

Estimating the Relative Feed Value, Digestible Dry Matter and Dry Matter Intake

Relative Feed Value (RFV) is an index that estimates the digestible dry matter (DDM) of samples from the ADF and calculates the dry matter intake (DMI) potential (as a percentage of body weight, BW) from NDF. The index is then calculated as DDM multiplied by DMI and divided by 1.29 (Stallings, 2006).

$$Digestible\ Dry\ Matter\ (DDM) = 88.9 - (0.779 * \%\ ADF) \quad \text{(Eq.2)}$$

$$Dry\ matter\ intake\ (DMI)(\%\ of\ BW) = 120/(\%NDF) \quad \text{(Eq.3)}$$

$$Relative\ feed\ value\ (RFV) = (DDM * DMI)/1.29 \quad \text{(Eq.4)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16011610

Statistical Analysis

The data were analyzed by one-way analysis of variance (ANOVA) test according to the randomized plot design with three treatments (SPSS, 2003). Experiment 1 and 2 were evaluated under 3 different groups by drying in trial 1 and silage in trial 2. Each experiment was analyzed separately; each treatment (C, WB and PB) had three replications. However, RFV, DDM and DMI values of the experiment 1 and 2 were analyzed together. Thus, the effects of different treatments (such as silage application) on feed value were assessed together.

Results

The images of green parts and root formation one week after the germination were shown in *Fig. 3*. Yield and some characteristics of germinated barley in experiment 1 were presented in *Table 1*. Forage yield barley with different hydroponic medium treatments ranged from 1056 to 1315 g m^{-2} and the highest green yield was obtained in WB treatment (P<0.01).

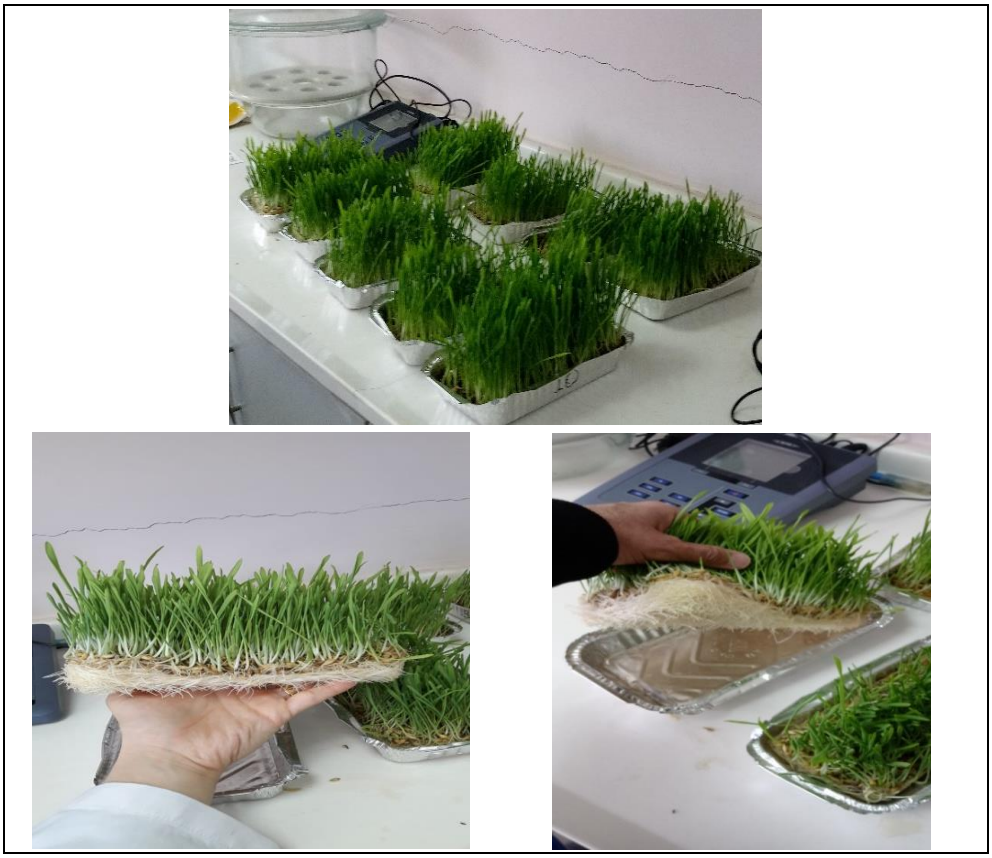

Figure 3. *Green parts and root formation of barley plants one week after the germination*

Mean dry matter content in WB treatment was significantly (P<0.01) higher than that in C and PB treatments. Total ash, ADF and NDF in PB treatment were higher than those in C and WB (P<0.01). Dry matter yield, total N and crude protein content were not significantly different among different treatments (*Table 1*).

Some characteristics of barley silage produced in hydroponic system with different cover materials in experiment 2 were presented in *Table 2*. Mean pH value and dry matter content of silage were higher in WB treatment than that in C and PB treatments (P<0.01). ADF and NDF content of silage samples were significantly higher (P<0.01) in PB treatment than that in C and WB treatments. Total N and crude protein content of silage samples were not significantly different among different treatments (*Table 2*).

The RFV values of both experiments were analyzed together in experiment 1 and 2 to assess the overall effect of cover materials and feed value of silage. The lowest DMI, DDM and RFV values were obtained in the PB treatments (P<0.01), while the highest values of RFV and DMI were observed in the WB treatments.

Discussion

In contrast to Fazaeli et al. (2012) and Kılıç (2016) who stated that dry matter content of the hydroponic green feed does not substantially change compared to the grain form of the same feed (88%), the results showed that dry matter production was significantly improved in a short period of time (7 days). This is one of the important outcomes of our study. Although the cover materials were removed after the germination, dry matter content (90 and 96%, respectively) in WB and PB treatments was higher than that in control (barley-only) treatment (89.8%). The improvement in dry matter content was even more pronounced in the PB treatment. The highest dry matter yield was obtained in straw supported hydroponic barley; however, no significant change was observed in dry matter yield of control and PB treatments. The results revealed that contribution of straw cover on germination and subsequent growth of barley as indicated by the dry matter yield was greater compared to that of olive pulp.

Straw-supported hydroponic forage production improved the efficiency of water use. The productivity was higher in WB treatment compared to control and PB treatments. This result could be attributed to the high level of dry matter content in WB treatment

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16011610

which absorbed higher water and provided a more suitable environment for germination. The results showed that straw can be an important cover material to eliminate the mold problem caused by high humidity in hydroponic forage production.

Crude protein content of fodder in all treatments was similar that could be related to the removal of straw cover material from the medium after the germination, and low protein content of olive pulp. Although the cover materials were removed from the environment after the germination, some of the dry olive pulp may have remained in the environment as dust or thinner form. Total ash, ADF and NDF contents in PB treatment were higher compared to the control. This could be ascribed by the high level of ash, ADF and NDF contents in dry olive pulp. Therefore, total ash content of dry olive pulp caused an increase in ash level of hydroponic barley fodder.

Plant height and root development were not significantly different among the treatments. The highest plant height during the 7-day of germination period was 12 cm. The results showed that the cover materials did not affect the growth rate, however, they could suppress the excess moisture occurring in the hydroponic environment. Gunasekaran et al. (2018) used plastic trays with cover materials to germinate barley seeds in hydroponic barley cultivation. Like the results on growth rate reported in our study, Gunasekaran et al. (2018) stated that the cover material did not affect the growth rate. However, they found that paddy husk and bagasse provided the highest forage yield. The researchers placed the cover materials on the floor of trays and stated that the entangled structure between the roots and the base material caused the waste of feed. However, the cover materials were used to cover the barley seeds in the trays (*Fig. 1*); thus, matted structure problem between the roots and the cover material was not observed in our study.

The study did not focus on measuring seed density per square meter. However, the seeding rate used was about 1000 g m^{-2} which resulted in a certain amount of dry yield increase and no fungal contamination. Naik et al. (2015) reported that high seed density increased the chances of microbial contamination in the root mat, which in turn affected the growth of the sprouts. The fodder yield obtained from 1000 g dry seed m^{-2} density for 7 days was 1315 g. Al-Karaki and Al-Hashimi (2012) used 400 g m^{-2} seeding rate for barley and obtained 1122 g dry yield m^{-2} for 8 days not 7 days.

The pH value and dry matter content in WB treatment were significantly increased during silage making, and this was quite favorable for silage quality (*Table 2*). The results revealed that the use of straw cover material during germination caused drier germination environment which had an effect on pH increase. The changes ADF and NDF contents were significantly important and related to the use of dry olive pulp as the cover material. The cell wall components of dry olive pulp increased the cell wall of the silage produced in PB treatments. The ash content of barley silages was increased in PB treatments during silage due to the high ash content of dry olive pulp (*Table 2*). The cell wall deposition, such as the percentage of NDF and ADF probably, increased the ash content of silage in PB treatment. Reasonable silages in terms of Flieg score were produced in WB and PB treatments due to the contribution of straw or dry olive pulp to ambient pH and dry matter level.

The highest RFV and DMI values were observed in the WB treatments where straw was used as the cover material (*Table 3*). The animal consumption of some fodders may negatively be affected due to the high moisture content of the fodders. Therefore, Fazaeli et al. (2012) and Tudor et al. (2003) suggested adding some hay to decrease the moisture and raise the dry matter contents of fodder. Mean DMI value of green feed in WB

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16011610

treatment was higher in our study. The RFV value is used generally to compare similar forages for the consumption and digestion (Wettstein et al., 2000). The RFV values were found as "Prime" for all fodders according to the Quality Grading Standard assigned by the Hay Market Task Force of American Forage and Grassland Council. Since DDM value is affected from ADF content of feeds, higher DDM value in WB treatments can also be attributed to the lower ADF content (Robinson, 2005).

Table 3. *The RFV, DDM and DMI values of samples from Experiment 1 and 2*

Parameters of feed evaluation	Samples							
	Experiment 1			Experiment 2				
	C	WB	PB	CS	WB	PB	SEM	Sig.
DDM, [%]	$77.4^{c\,\beta}$	76.0^{bc}	65.7^{a}	75.3^{bc}	74.6^{b}	64.8^{a}	0.7	0.01
DMI, [% BW]	3.0^{b}	3.5^{c}	2.5^{a}	3.5^{c}	3.6^{c}	2.9^{b}	0.1	0.01
RFV	178.5^{c}	209.1^{d}	128.0^{a}	202.2^{d}	206.3^{d}	147.1^{b}	4.4	0.01

RFV: Relative feed value, DDM: Digestible dry matter (%of body weight), DMI: Dry matter intake (%of body weight, C: Control (only barley germination), WB: barley covered with wheat straw, PB: barley covered with dry olive pulp, $^{\beta}$: Means followed by different letters are significantly different by each other at $P<0.05$ level of significance

Conclusion

Feed analysis showed that dry matter protein content of the barley fodder produced in hydroponic system increased; however, the protein value did not significantly differ from the barley grain seeds as a percent of dry matter. The results concluded that barley is a good grain for fodder and silage production under hydroponic conditions. In addition, the green and silage feed values obtained are satisfactory and better-quality hydroponics can be produced in the germination environments supported by cover materials (straw and dry olive pulp). The results revealed that wheat straw was more effective than dry olive pulp which had no significant effect on all parameters compared to control in experiment 1 and 2. This production model is suitable for some annual plants consumed as grain and it is not a suitable production method for plants with very small seed. On the other hand, since this type of production is not effective and economical for perennial plants, it would be useful to conduct studies on some other annual forage plants.

Abstract. Myrtle is known to be an important aromatic and medicinal plant species. Myrtle plant is consumed mainly as spice having several uses in the perfumery, food and pharmaceutical industries. It is also widely used for ornamental purposes such as fencing, roadsides, and green cutting. Plant tissue culture techniques are an essential tool to micropropagate for the plant producer. TIS (Temporary immersion systems) is an alternative plant tissue culture technique for micropropagation mechanism in plant species. A new culture vessel named PlantForm TIS bioreactor has been recently developed. In the present study, we aimed to evaluate and compare a new type of TIS bioreactors with agar media for myrtle. MS (Murashige and Skoog) medium supplemented with 1 mg l^{-1} BAP (benzylaminopurine) was used for multiplication, with 1 mg l^{-1} IBA (indole-3-butyric acid) for rooting. Two different immersion times (4 h and 8 h) were compared with the solid agar medium. Plantlets growing in PlantForm systems performed better than those in the solid medium. All data recorded at micropropagation and rooting treatments were much more successful. In conclusion, PlantForm TIS bioreactor presents a valid alternative to traditional in vitro micropropagation and rooting systems, resulting in a reduction of cost, labor, and time for the mass propagation.
Keywords: *benzylaminopurine, micropropagation, PlantForm, plant tissue culture, bioreactor*

Introduction

Myrtus communis L., commonly named myrtle, a valuable medicinal and aromatic species (Wannes et al., 2010; Dahmoune et al., 2015). Myrtle is known to be a member of the Myrtaceae family, which contains 3,000 species naturally growing in tropical and subtropical regions. Myrtle is mostly consumed as spice having several practices in the food, pharmaceutical, and industries (Sumbul et al., 2011; Casaburi et al., 2015). Myrtle plant could also be used as ornamental purposes such as fencing, roadsides, and green cutting (Shekafandeh, 2007; Danial, 2009). Myrtle broadly grows in 500-600 m altitude, most notably in pine forests and riversides in the Taurus Mountains of Turkey (Aydın and Özcan, 2007). Myrtle has several genotypes with yellowish-white or bluish-black colored fruits (Şan et al., 2015).

Many different biotechnological methods could be performed to fruit crops to get better ones during plant breeding strategies. One of the critical applications of biotechnology is known to be plant tissue culture in fruit science. Plant tissue culture techniques include several processes of clonal propagation and micropropagation. Known technologies in plant biotechnology have been expanded to contain virus elimination, somatic embryogenesis, organogenesis, production of haploid plants and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16111620

somatic hybridization as well as bioreactors (Idowu, 2009; Donmez et al., 2016). Bioreactors containing liquid media for micropropagation and rooting started to become more popular thanks to the low production costs (Paek et al., 2001) and the ease of scaling-up (Preil, 1991). Several bioreactor systems have been published (membrane raft system, nutrient mist bioreactor, and temporary immersion bioreactor) (Akita and Takayama, 1994). Among these systems, temporary immersion bioreactor has become more popular. TIS is simple to use and gives mass production rate with minimum physiological disorders (Afreen, 2008).

In practice, TIS wetting the entire culture or plant tissue used as explant with a nutrient medium, and then draining away of the excess nutrient medium under gravity consequently, the plant material has access to air defined as temporary immersion system. TIS usually involves two different cycles; one of them is a wetting, and the other is the drying cycle occurring periodically (Afreen, 2008). Various temporary immersion systems have been developed like RITA, RALM, PLANTIMA, SETIS as well as PlantForm. The RITA system has been found to increase root development in *Hevea brasiliensis* (Etienne et al., 1997). The bioreactor RALM (Biorreatores RALM, Ralm Industria e Comercio ltda., Brazil) is a TIS, operating on the Twin-Flask principle. The SETIS system (Vervit, Belgium, distributed by Duchefa Biochemie, The Netherlands) operates similarly as the Ebb-and-Flow TIS system. PLANTIMA (A-Tech Bioscientific Co., Ltd., Taiwan) is a small volume TIS, operated on the RITA principle and has been used for plantlet propagation (Yan et al., 2010, 2011). Box-in-Bag is a disposable TIS, operating on the principle of the Ebb-and-Flow TIS. The WAVE bioreactor is a mechanical rocking platform that uses disposable pre-sterilized cultivation bags (Eibl and Eibl, 2006, 2008; Eibl et al., 2009; Georgiev et al., 2014).

An immersion cycle consists of the frequency and duration of immersion. It means immersion should be applied with a planned time and frequency. Immersion cycles directly affect the plant micropropagation by influencing water and nutrient uptake and in addition to that hyperhydricity of the cultured plant tissue (Albarran et al., 2005).

Liquid-based systems have been known to be much more suitable to automation and, consequently, appropriate for the reducing of costs and labor, as a liquid medium could be changed readily during scaling-up, and the cleaning of boxes is simplified compared to agar-based systems (Preil, 1991).

The present study is the first report for myrtle micropropagation with TIS. We aimed to determine the effects of the traditional tissue culture method and PlantForm Temporary Immersion System at in vitro propagation and rooting on Myrtle.

Materials and methods

Plant material

Myrtle, *Myrtus communis* L., genotype was used for in vitro micropropagation and rooting both PlantForm temporary immersion system and traditional solid medium. Plant material was obtained from a commercial seedling company in Adana, Turkey.

Surface sterilization

Shoot tips of Myrtle plants were cut from donor plants and washed firstly under running tap water about 10 min and then the plant material plunged in 70% ethanol for 2 min, and dipped in 10% solution of sodium hypochlorite (commercial bleach solution

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16111620

with 4.5% active chlorine, v/v, NaOCl; Domestos®) together with 1–2 drops of Tween-20 for 20 min afterward, the plant material was washed three-four times with sterile distilled water.

Multiplication medium

MS (Murashige and Skoog, 1962) medium were used for multiplication. MS supplemented with 1 mg l^{-1} BAP (benzylaminopurine), 30 g l^{-1} sucrose, 8 g l^{-1} agar, pH 5.8 were prepared and autoclaved at 121 °C for 15 min. Shoot tips of myrtle were cultured and propagated on MS medium, and incubated in a growth chamber at 25 ± 2 °C under cool white fluorescent light at 16 h photoperiod condition. Plants were propagated until we have enough plant material to experiment with PlantForm system (*Fig. 1*) and solid medium at the same time.

Micropropagation on PlantForm and solid medium

MS medium supplemented with 1 mg l^{-1} BAP, 30 g l^{-1} sucrose with 8 g l^{-1} agar (all Sigma-Aldrich, St. Louis, USA) were prepared in magentas [(9 plantlets/magenta) (76.20 x 76.20 x 10.16 mm)] for solid medium, without agar for PlantForm bioreactor system [120 plantlets/box (180 x 150 x 150 mm)]. pH of media was adjusted to 5.8 and autoclaved at 121 °C for 15 min. The plantlets that developed were subcultured onto fresh MS media in Magenta and PlantForm boxes for three times in every six weeks. Two different immersion time were performed in PlantForm bioreactor system: 15 min/4 h and 15 min/8 h. The air was renewed for 15 min/4 h with a pumping system adjusted by an automatic timer for the regulation of aeration and medium supply to the plant material in the temporary immersion system for both treatments. At the end of the three subculture, micropropagation rate, average plant length (cm), number of leaves, fresh weight (g) and dry weight (g) were recorded.

Rooting medium

Shoots coming from micropropagation were moved to MS medium supplemented with the same components with multiplication medium except for BAP. For rooting 1 mg l^{-1} IBA were used. The cultures were maintained incubated in a growth chamber at 25 °C under cool white fluorescent light at 16 h photoperiod condition. Six weeks later rooting rate, numbers of roots, fresh weight (g), dry weight (g), length of roots, and plants (cm) were recorded.

The plants were weighed on a precision balance and this was recorded as fresh weight. The plants that fresh weight was determined were weighed after being kept in 70 °C drying-oven for 3 days and the results were recorded as dry weight. Plant and root lengths were measured with a ruler.

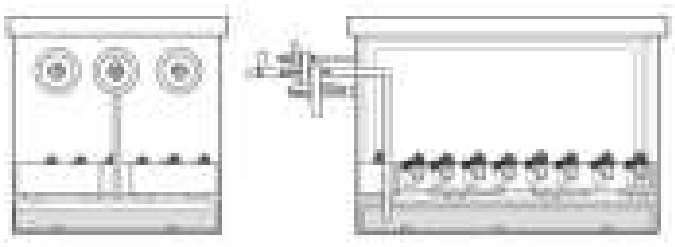

Figure 1. *PlantForm TIS bioreactor system (the size is 180 x 150 x 150 mm)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16111620

Acclimatization

Plantlets well-developed in PlantForm bioreactor and magenta boxes were removed and roots of the plant material were gently washed under running tap water and plunged in a liquid including 50% (w/v) of a 2.5 g l^{-1} fungicide (Captan 50WP, Fruit&Ornamental, NY, USA) for 10-15 s and afterward moved to plastic pots (7 cm × 7 cm width and length) including autoclaved peat (Klasmann, KTS-1) and perlite (1:1, v/v). Then, myrtle plants were replaced in a controlled greenhouse under natural light at 95-98% relative humidity and 22-24 °C.

Data analysis

All studies were performed according to a completely randomized design. Experiments were repeated twice with three replicates. Micropropagation rate was calculated as the number of shoots having after culture/total number of plants. The rooting rate was calculated by dividing the number of rooted plants by the number of total plantlets in rooting assays. All quantitative data calculated as percentage value were subjected to arcsine transformation before variance analysis. All data were expressed as means, and analysis of variance was performed. Means detected the statistically different were separated by least significant difference test (LSD) to evaluate differences among PlantForm 4h-8h immersion time and solid medium in Myrtle. Statistical analysis was performed by using JMP® software (SAS Institute, Cary, NC) ver. 8.00.

Results and discussion

Micropropagation on PlantForm and solid medium

The effects of PlantForm TIS bioreactor for myrtle were evaluated and compared with the traditional solid medium. Plantlets growing in PlantForm system were better than the solid medium. All data recorded at micropropagation treatments are much more successful. Micropropagation rate (%), plant length (cm), number of leaves, fresh weight (g) and dry weight (g) coming from PlantForm 4 h and 8 h immersion time and solid medium were presented *Table 1*. Micropropagation rate was detected statistically significant and calculated as 11.40 (PlantForm 8 h immersion), 8.55 (PlantForm 4 h immersion), and 6.25 (Solid medium). Similarly, there were important differences in plant length. The average plant length (cm) was detected only 3.12 cm in solid medium. However, plantlets coming from PlantForm 8 h immersion time 8.80 cm, PlantForm 4 h immersion time 7.95 cm. When compared to PlantForm 8 h, PlantForm 4 h immersion and solid medium, PlantForm systems were effective in plant mass. The mean fresh weight is 1.00, 0.59, and 0.17 g, and dry weight is 0.26, 0.11, 0.02 g, the number of leaves is 66.70, 51.85, and 38.80, respectively. Apparent differences between the agar medium and PlantForm were shown in *Figure 2*.

Rooting medium

The effects of PlantForm TIS bioreactor for rooting in myrtle were evaluated and compared with the traditional solid medium. Plantlets coming from PlantForm and Solid micropropagation media were transferred to rooting media. Rooting rate was calculated as 100% for PlantForm system in different two immersion time, but in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16111620

solid medium, only 70% of plantlets were rooted. The roots were initiated in the media about after 10-15 days of inoculation. All data recorded at rooting treatments are much more successful similar to micropropagation data. Plant length (cm), root length, number of the root, fresh weight (g), and dry weight (g) at PlantForm 4 h and 8 h immersion time, and solid medium were presented *Table 2*. Plant length was calculated the highest in PlantForm 8 h immersion (15.10 cm), the lowest in solid medium (4.59 cm). The results of root length were also similar to plant length. The most successful treatment was detected PlantForm 8 h immersion time with 8.10 cm. It is only 1.45 cm in solid medium. It is about 6 times more in PlantForm system than a solid medium. PlantForm system (8 h immersion) was much more effective in root mass when compared to PlantForm 8 h, PlantForm 4 h immersion time and solid medium. The mean fresh weight is 1.54, 0.59, and 0.44 g, and dry weight is 0.068, 0.660, 0.018 g, the number of roots is 5.40, 4.10, and 2.01, respectively.

Acclimatization

Plantlets with shoots and roots from PlantForm bioreactor and magenta boxes were transferred to plastic pots. Plants were successfully acclimatized in a greenhouse. There were no statistical differences among the treatments on survival. However, plants from PlantForm bioreactor systems showed better performance on survival (*Fig. 2F*).

TIS bioreactors are an alternative in vitro micropropagation mechanism for plant species. There are several different TIS systems; Gravity Immersion Bioreactors (BIG), Temporary Immersion Bioreactors (BIT®), Recipient for Automated Temporary Immersion (RITA®). However, these bioreactors are either too small or too heavy to handle with a small interior bottom, which often leads to disorders of cultures due to high density (Welander et al., 2007). In order to solve the problems of TIS, a new culture vessel named PlantForm TIS bioreactor has been recently produced (Welander et al., 2014). Since the first report of a liquid culture in TIS of about 30 years ago, numerous prototypes have been developed. Among these, PlantForm, a recently-developed TIS device, allowing periodic medium immersion and independent ventilation of containers (Lambardi et al., 2015). Immersion frequency could affect micropropagation and rooting in TIS cultures. Therefore, it is a critical issue to adjust optimum immersion time. The effect of immersion frequency (6, 8 and 12 h) for in vitro propagation of *Gerbera jamesonii* were investigated by Frómeta et al. (2017) in BIT system. They reported that immersion every 8 h with additional ventilation produced more shoots with better morphology than the control. However, when shoots were immersed every 6 h, shoots had higher fresh and dry weight. In the present study, we applied two different immersion time (4 h and 8 h) for myrtle. It was observed the better result in both micropropagation and rooting at 8 h immersion time. Damiano et al. (2007) investigated that growth performances of *Rubus fruticosus, Arbutus unedo* and *M. communis* plants by using a TIS composed of two glass bottles connected with a silicone tube; one of the bottles was used to contain explants which layed on glass beads. Immersion time was adjusted to 120 min/day. They compared to those in solid and stationary liquid conditions and, determined much higher multiplication rates in the TIS: *Rubus fruticosus* (x9.3), *M. communis* (x8.4), *Arbutus unedo* (x3.6). We also had a higher multiplication rate from PlantForm TIS for myrtle. Here, we detect a better multiplication rate in myrtle; it is high because PlantForm was positively affected the development of plants. Another reason could be the immersion time. Multiplication rate is higher in the 8 h immersion time than 4 h.

In different plant species, several TIS were used and tested. Ramírez-Mosqueda and Iglesias-Andreu (2016) compared BIT, BIG and RITA systems for multiplication and rooting of *Vanilla planifolia*. They found that a higher number of shoots/explant were observed in the multiplication phase in BIT systems (18.06 shoots/explant), followed by RITA (12.77) and BIG (6.83). In the rooting phase, a higher number of longer roots were obtained in BIT compared with BIG and RITA. It is clear that different systems could show conflicting results in the same genotype. PlantForm, in our study, gave high

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16111620

positive results for micropropagation and rooting on myrtle. The success of PlantForm also was reported by Lambardi et al. (2015). Its performance with ornamental (*Carex oshimensis* 'Evergreen' and *Chrysanthemum morifolium*) and fruit species (*Ficus carica* and *Ribes rubrum*) is critically analyzed. The results confirmed the convenience of the PlantForm-based TIS for the proliferation of high-quality shoot clusters; moreover, with some species, the system stimulated the contemporary proliferation and rooting of shoots, which can be maintained in proliferation or directly transferred to the acclimatization phase. In another study, the effectiveness of the PlantForm bioreactor in micropropagation of myrtle and olive was examined through measurements of biomass production during the subcultured period in comparison to semi-solid medium culture. The results showed that both species are well adapted to growth in the bioreactor, with survival rates and quality of the crops higher than those obtained under standard culture conditions. Furthermore, the case of myrtle shoot cultures demonstrated the possibility to reduce the concentration of macro and micronutrients in the liquid medium without compromising the growth rates (Benelli et al., 2014).

Temporary immersion bioreactor system could also use for obtaining somatic embryos. Albarran et al. (2005) obtained somatic embryos in *Coffea arabica* L. using a temporary immersion bioreactor system. They optimized the immersion cycles to increased production and quality of embryos. Researches revealed that increasing the frequency of short immersions (1 min immersion every 24, 12 and 4 h) affected embryo production (480, 2,094 and 3,081 embryos/1-l bioreactor, respectively) and improved quality (60, 79 and 85% of torpedo-shaped embryos, respectively).

In tissue culture, cytokinins and auxins are remarkable medium contents in detecting the developmental pathways of the plant cells. Cytokinins induce adventitious bud formation in cultures (Rajbhar et al., 2016). Auxins play significant roles in the growth and differentiation of cultured cells and tissues (Alexandrova et al., 1996; Bohidar et al., 2008; Ngomuo et al., 2013). There are some reports that different cytokinins and auxins were used and compared for myrtle micropropagation and rooting in agar media. Rezaee and Kamali (2014) investigated the effect of different media and different plant growth regulations and the concentration of shoot proliferation in myrtle. The results indicated that between, MS and WPM, media, WPM showed better results rather than MS. In shoot proliferation stage were used BA at levels of 0, 0.5, 1, 2, 3, 4, 5 and 6 mg l^{-1} and IBA at levels of 0 and 0.1 mg l^{-1}, then three traits containing: leaf number, shoot length and shoot proliferation were examined. The best result was obtained by using of modified WPM medium with BA in 4 and IBA in 0.1 mg l^{-1}. In the present study, we also used 1 mg l^{-1} BAP, and we had positive results on the multiplication rate. Different auxins can be used for rooting of plants in in vitro cultures. Auxins such as NAA, IBA, IAA routinely use for plant rooting in vitro cultures. Scarpa et al. (2000) evaluated the influence of two IAA concentrations (0.5 mg l^{-1} and 1 mg l^{-1}) and different medium to induce root induction of Myrtle. Researchers found that the best rooting results (61%) were obtained with O13 medium containing 1 mg l^{-1} IAA. Hatzilazarou et al. (2001) investigated the rooting capability of two myrtle clones, with large (clone A) and small (clone B) leaves. Shoots transferred to WPM medium containing several concentrations (0, 0.5, 1 or 2 μM) of IBA, IAA or NAA in rooting assays. According to this study, the best rooting was achieved with the application of 0.5 μM IBA (96% rooting) and 1 μM IAA (100% rooting) for clone A and B, respectively. Ruffoni et al. (2010) determined that IAA and IBA at 0.5 mg/L increased the rooting percentage and evidenced a difference in the shape and length of the roots in myrtle plant. Aka Kacar et al. (2017)

DOI: http://dx.doi.org/10.15666/aeer/1801_16111620

investigated the effects of different IBA (0, 1, 2, 4 mg l^{-1}) and activated charcoal (AC) (0, 0.5, 1, 2 g l^{-1}) concentrations on myrtle rooting in in vitro conditions. They used agar MS medium for rooting and reported that the best combination was detected 2 mg l^{-1} IBA without AC in terms of rooting rate. Similarly, root length, root number, and plant length were recorded less than PlantForm vessels of our study. In the present study, we used IBA for rooting, and it was successful for rooting both in PlantForm and agar media. However, there were apparent differences among the treatments in term of the rooting data. Plants coming from PlantForm were much more at high quality.

Conclusion

In conclusion, the PlantForm TIS bioreactor represents a valid alternative to conventional systems in vitro micropropagation and rooting, resulting in a reduction of cost, labor, and time for the mass propagation. Comparative investigations between semi-solid medium and bioreactor culture revealed that shoot proliferation and growth were more efficient in the temporary immersion bioreactor system.

Abstract. The Olifants River System and its catchment have been exposed to prolonged and cumulative ecosystem stress as a result of human settlements, mining, agricultural and industrial activities. The Blyde River is known to supply the Olifants River with water of good quality and quantity. However, theintensive farming and human settlements in the catchment could threaten the river. The aim of the study was to assess the water quality of the Blyde River in South Africa using aquatic macroinvertebrates as bioindicators. Seven sites along the river were selected for sampling. The family composition, based on abundance and diversity was evaluated in relation to environmental variables. The results of some measured physicochemical parameters revealed that water quality of the Blyde River is not significantly altered and the presence of ecologically sensitive macroinvertebrates was an indication of good water quality as this benthic fauna was well represented in all seasons and most parts of the river. The study therefore has indicated that the river was inhabited by a healthy macroinvertebrate community suggesting that the water is still of good quality.
Keywords: *anthropogenic activities, bioassessment, environmental factors, spatial distribution, water pollution*

Introduction

Many river systems have been subjected to a range of disturbances due to the fastgrowing human population and increasing human activities, and leading to water quality degradation (Jun et al., 2016; Ferreira et al., 2017; Santos et al., 2017; Niba and Sakwe, 2018). The effluents from activities such as, industries, mining, agriculture, domestic and urban development contain various pollutants, which often end up in water bodies and may affect the ecological status of the river (Dalu and Froneman, 2016; Hunt et al., 2017).

Benthic macroinvertebrates respond differentially to biotic and abiotic factors in their environment and therefore, the structure of macroinvertebrates has long been used as bio-indicators to assess the water quality of water bodies (Li et al., 2010; Wolmarans et al., 2014; Jun et al., 2016). Benthic macroinvertebrates are the most common faunal assemblages for bio-assessment and provide more reliable assessment of long-term ecological changes in the quality of aquatic systems compared to its rapidly changing physicochemical characteristics. Their multiple life stages, sedentary nature, and varying tolerance levels to environmental stressors render them useful in assessing temporal and spatial changes within an aquatic ecosystem (Rosenberg and Resh, 1993). However, specific preferences for certain ranges of abiotic and biotic characteristics, mean that changes in these factors often create large differences in benthic community structure even over small spatial scales (Grönroos and Heino, 2012). Different groups of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16211635

macroinvertebrates have different environmental requirements and respond to changes in environmental factors, such as temperature, dissolved oxygen, conductivity and salinity (Külköylüoğlu, 2004; Grab, 2014; Masese et al., 2014). Thus, the degree of tolerance of these factors vary among different organisms, and information gathered from such studies reflect the quality of water in the river.

The Olifants River System provides water for industrial, mining, agricultural and domestic uses (Machete et al., 2004). Along the Olifants River, pollution arising from intensive and subsistence agriculture practices in all the sub-catchment and the numerous point- and non-point-sources (diffuse), including mining and industrial pollution in the Upper Olifants catchment area contain complex mixtures of chemicals, many of which may have deleterious effects on aquatic systems. Due to these various activities in its catchment, the river has become one of the most polluted rivers in South Africa (Grobler et al., 1994; Addo-Bediako et al., 2018). Many of the impoundments and tributaries of the Olifants River System are said to be contaminated with heavy metals, inorganic nutrients such as, sulphates and nitrates from agricultural areas, mine drainages and wastewater treatment (WWT) plant (Oberholster et al., 2013). The Blyde River is an important tributary of the Olifants River (Ashton et al., 2001). It is known for its continuous flow and good water quality (Raven, 2004). However, the recent human activities in the catchment may be impacting the quality of the water and the biota e.g. macroinvertebrates. Thus, the study assessed the water quality of the Blyde River using aquatic macroinvertebrate communities. The objectives of this study were: (i) to describe the spatial distribution and assemblage structures of macroinvertebrates; (ii) to determine major environmental variables that affect their distribution. We hypothesize that: environmental conditions play important role in the distribution and abundance of aquatic macroinvertebrates.

Materials and methods

Study area

The Blyde River rises on the western slopes of the Drakensberg Mountains (Mpumalanga) and flows northwards to join the Olifants River in Limpopo Province, South Africa (Raven, 2004). The catchment is approximately 2000 km^2 in size. The mean annual precipitation is about 1000 mm and it is considerably higher than the other sub-catchment areas in the Olifants River Basin (Raven, 2004). Seven sampling sites were selected along the river (*Fig. 1*). S1 (24°30’59.46”S 30°47’56.14”E), S2 (24°30’14.42”S 30°50’08.49”E). S3 (24°25’52.45”S 30°50’03.59”E), S4 (24°24’19.03”S 30°47’54.19”E), S5 (24°19’30.90”S 30°49’52.00”S), S6 (24°23’04.94”S 30°48’22.09”E) and S7 (24°15’30.38”S 30°50’13.22”E). The sites represent four different groups of land use; domestic (S1 & S2), agriculture (S3 & S5), industrial (S4) and nature reserves (S6 & S7).

Physicochemical parameters

This study was conducted in winter (July) and spring (October) of 2017, summer (January) and autumn (April) of 2018. Seasonal water samples were collected in 1000 ml polyethylene bottles (acid pre-treated) and stored at 4°C prior to analysis. Seasonal environmental variables, such as pH, water temperature, dissolved oxygen, (DO), total dissolved solids (TDS) and electrical conductivity were recorded at the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16211635

sampling sites using a YSI Model 554 Data logger, for the characterization of each sample point. Water current (flow velocity) was measured using a portable flowmeter Model 2000 (Marsh McBirney, Maryland, US). Channel width and water depth were measured using a tape measure and graduated measuring rod, respectively. Laboratory analysis was conducted to determine the nutrients (NH_4, NO_2, NO_3 and PO_4), turbidity, sulphates using a spectrophotometer (Merck Pharo 100 Spectroquant™) with Merck cell test kits in the Biodiversity Water Laboratory, University of Limpopo.

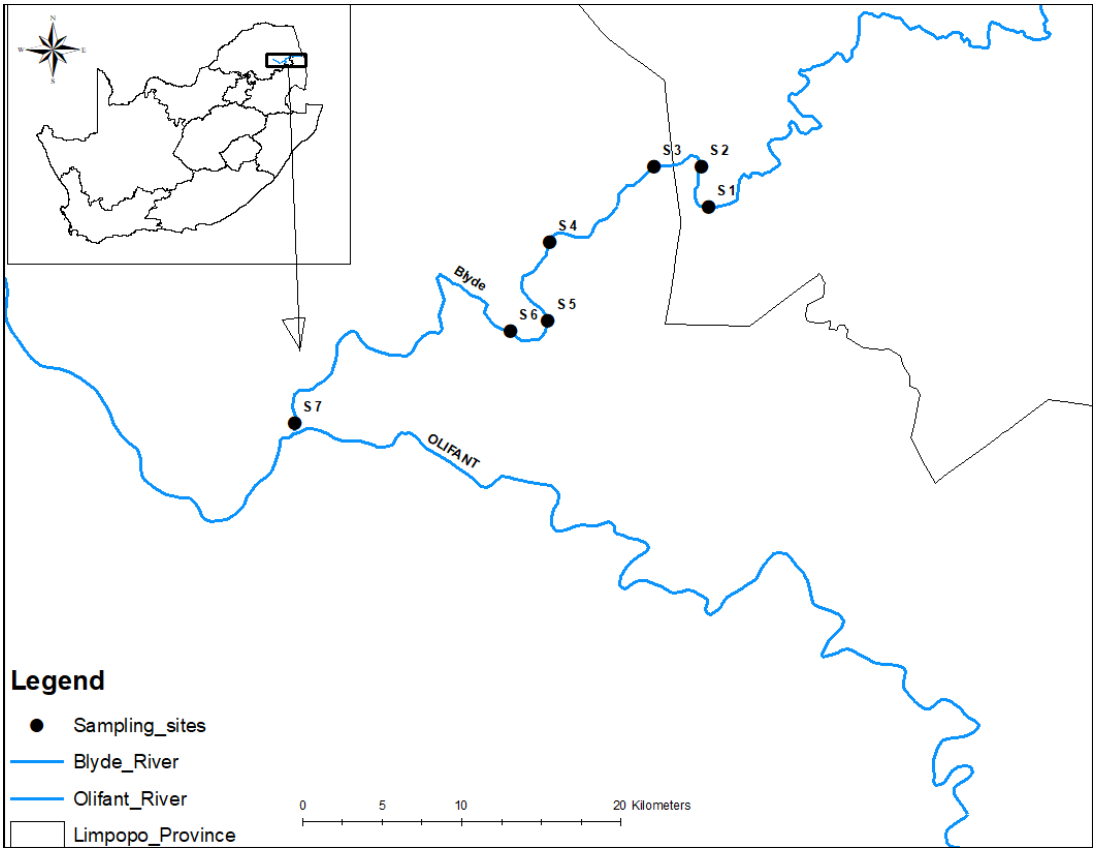

Figure 1. *Map of the study area, showing the locations of the seven sampling sites of the Blyde River*

Sampling of macroinvertebrates

Seasonal benthic macroinvertebrate samples were collected at seven sites (S1, S2, S3, S4, S5, S6 and S7) of the river. The samples were collected within a 100-m stretch of the study sites, with substrata of biotypes consisting mainly of mud, sand, gravel or stones. Samples were collected using a 30 cm by 30 cm sampling net with a 500 µm mesh size. Benthic macroinvertebrates were collected using the kick sampling method described by Dickens and Graham (2002), whereby the substrate was disturbed by kicking for a period of 5 min to free macroinvertebrates. The samples were collected per site from all aquatic habitats (i.e. riffles, pools and vegetated margins). For the vegetation biotopes, macroinvertebrates were sampled by scraping the net back and forth through vegetation (approximately 2 m). The macroinvertebrates were then separated from organic and mineral matter, counted, after identification to the family

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16211635

level using Gerber and Gabriel's field guide manual (2002)), and released back into the river. Where specimens could not be identified in the field, the samples were preserved in 70% ethanol and transported to the University of Limpopo's Biodiversity laboratory for further identification, with an aid of a stereomicroscope (Leica EZ4) and a magnifying glass. The South African Scoring System (SASS 5) were further used to classify the macroinvertebrates collected into three groups, namely tolerant (scores 1–5), moderately tolerant (scores 6–10) and sensitive (scores 11–15) to pollution (Dickens and Graham, 2002).

Statistical analysis

The mean and standard deviation of the respective water variables were calculated. Data were first tested for normality and homogeneity of variance using the Kolmogorov- Smirnoff and Levene's tests respectively. The analysis of variance (ANOVA) was performed to determine whether there were significant differences among the different sites and seasons (winter, spring, summer and autumn) in water variables. Canonical correspondence analysis (CCA) was used to relate macroinvertebrate assemblages to environmental variables and to identify which environmental variables could best differentiate them (Jun et al., 2016). Monte Carlo simulations were carried out to verify whether the variables exerted a significant effect ($p < 0.05$) on macroinvertebrate distributions. Taxa abundance data were transformed to log (x + 1) in both analyses to down-weight the effects of dominant taxa. Square-root-transformation was used for the environmental parameters and were transformed to log (x + 1) except pH. CCA were conducted using CANOCO version 5.1 software (ter Braak and Šmilauer, 2002). Spearman correlation coefficients between macroinvertebrates and environmental variables were calculated to assist interpretation of changes in community profile using STATISTICA software (StatSoft, Inc., version 10, Tulsa, OK, USA).

Results

Physicochemical parameters

The physicochemical parameters of the water are summarised in *Table 1*. The lowest mean temperature (22.3 °C) was recorded at Site 1 and the highest mean temperature at S7 (24.90 °C). The highest mean dissolved oxygen (DO) was recorded at S2 (11.85 mg/l) and the lowest was recorded at S5 (8.70 mg/l). The pH was slightly alkaline at all sites and showed little variation. The pH ranged from 8.3 at S5 to 8.7 at S1. The lowest mean EC (270.85 mS/m) was recorded at S1 and the highest (442.20 mS/m) was recorded at S5, while the lowest mean TDS (132.9 mg/l) was recorded at S1 and the highest (252.80 mg/l) was recorded at S7. The mean salinity ranged from 0.25‰ at S1 to 0.49‰ at S7. There was a very strong positive correlation between pH and DO ($r = 0.92$, $p < 0.05$). There were no significant differences in the above physicochemical parameters among the sites and seasons ($p > 0.05$), except seasonal variation in temperature and salinity ($p < 0.05$). However, S3 and S5 had the highest TDS and EC values but low DO values. Whilst S1, S2 and S6 exhibited low TDS and EC values but high DO values. Turbidity levels were within the recommended values. The nutrients levels were generally low except ortho-phosphate.

Macroinvertebrates

A total of 19 832 individuals belonging to 11 orders and 36 families were collected at the various sampling sites and seasons. The total number of specimens collected per site for the seasons ranged from 1 053 at S3 to 6 876 at S5 (*Table 2a*). The highest number of families (32) was found at S6 and the lowest (23) was found at S7. The dominant taxa were Hydropsychidae (3 683), followed by Caenidae (2 519), Baetidae (2 483), Simuliidae (2 218), Chironomidae (1 499), Elmidae (1 160) and Corbiculidae (1 079). S1 was dominated by generalist Caenidae, sensitive Hydropsychidae and Baetidae, S2 by generalist Caenidae, sensitive Baetidae and Hydropsychidae, S3 by sensitive Hydropsychidae, Baetidae and Heptageniidae, S4 by sensitive Baetidae, Hydropsychida and Hydropsychidae, S5 by sensitive Hydropsychidae and tolerant Chironomidae and Simuliidae, S6 by tolerant Simuliidae, sensitive Hydropsychidae and generalist Caenidae, and S7 by tolerant Thiaridae, sensitive Hydropsychidae and sensitive Baetidae. The highest macroinvertebrate diversity (32 families) was recorded at S6 and the lowest (23 families) was recorded at S7. S7 had low diversity but high numbers of certain taxa e.g. Thiaridae. Taxa richness ranged between 24 during summer and 33 in spring (*Table 2b*). Taxa richness differed among seasons ($p < 0.05$). The lowest number of individual macroinvertebrates were recorded during summer and the highest during winter, about ten times higher than that of summer.

Cluster analysis produced three main clusters of sites based on macroinvertebrate taxa (*Fig. 2a*). The first cluster was S5, the second was S6, and the third was a cluster of S1, S2, S3, S4 and S7. Spearman correlation was used to show the relationships among the sites (*Table 3*). The correlation yielded positive correlations among all the sites with respect to the macroinvertebrate families. The strongest correlations were between S1 and S2 ($r = 0.813$), S3 and S4 ($r = 0.812$), and the weakest correlation was between S1 and S5 ($r = 0.431$). Furthermore, even the seasonal variation across the sites rarely indicated any variation (*Fig. 2b*).

b

Figure 2. a *Cluster analysis based on macroinvertebrates taxa collected at seven sampling sites along the Blyde River.* ***b*** *Seasonal macroinvertebrates distribution across the seven of the Blyde River (W = winter, Sp = spring, Su = summer and A = autumn)*

The number of tolerant families ranged from 10 at S7 to 13 at S6, while the number of moderately tolerant families ranged from 11 at S1 and S7 to 15 at S2 and S3, and the sensitive families ranged from two at S7 to five at S6 (*Fig. 3*). There were more numbers of tolerant, moderate tolerant and sensitive families collected in winter and spring (low flow seasons) than in summer and autumn (high flow seasons). The highest numbers of families were recorded in spring (32), followed by winter (27), autumn (25) and then summer (22). Thus, 12 more families were collected in the low-flow season than in the high-flow season. More than 7 tolerant families, 2 moderate tolerant families and 3 sensitive families were recorded at low-flow than high-flow seasons.

The Canonical correspondence analysis (CCA) showed a correlation between some of the taxa and environmental variables (*Fig. 4*). The families Aeshnidae, Caenidae, Chlorocyphidae, Leptoceridae, Platycnemididae, Protoneuridae and Psephenidae were associated with high pH and dissolved oxygen. The TDS, temperature, salinity and electrical conductivity, affected the families Coenagrionidae, Corbiculidae, Chironomidae, Physidae and Tricorythidae. The taxa-environment correlations for first and second axes were 0.99, and the cumulative percentage variance of taxa-environment relation for first and second axes combination was 65.5% (*Table 4*).

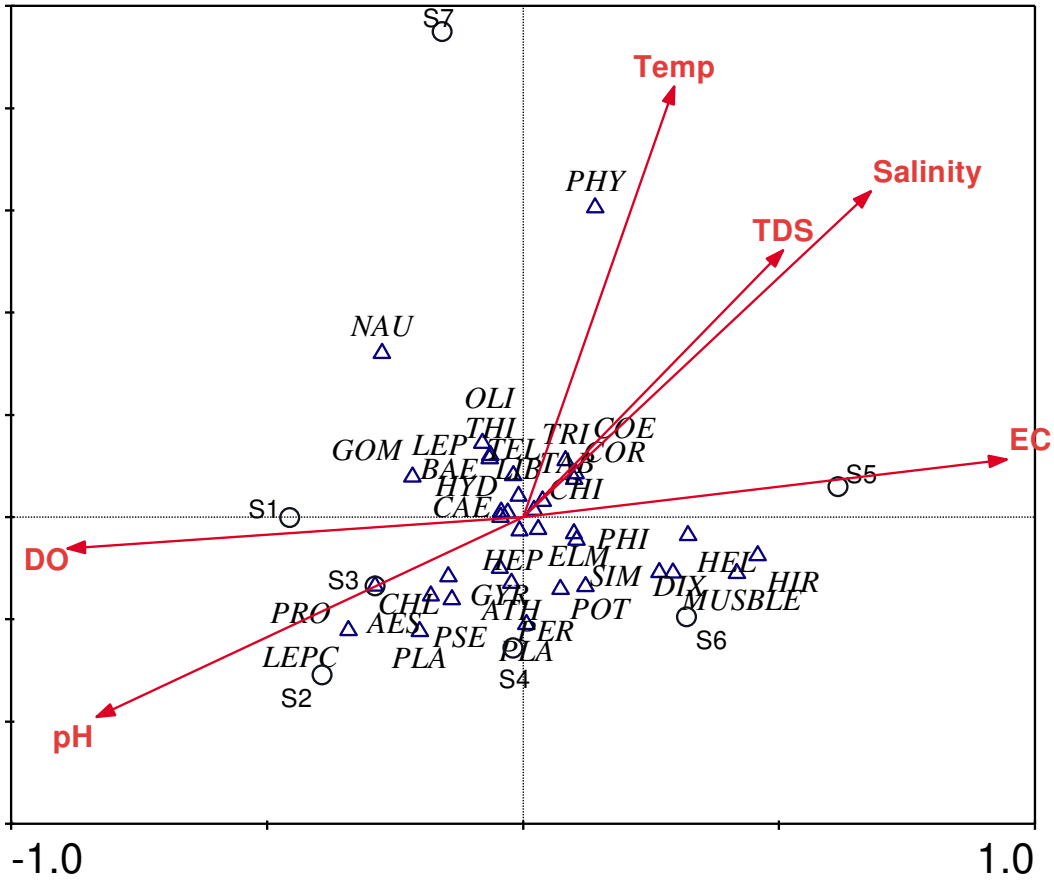

Figure 4. *Canonical correspondence analysis (CCA) ordination of the macroinvertebrates collected at the sampling sites (arrows indicate environmental variables; circles denote sites; triangles denote family code names)*

Discussion

Physicochemical parameters

The physicochemical parameters showed relatively little changes across sites and seasons. There was a strong positive correlation between pH and DO, and could be due to the fact that both pH and DO are affected by algal photosynthesis, respiration, temperature and oxidative decomposition of organic matter (Zang et al., 2011). Rivers in less disturbed areas are frequently characterised by low conductivity, turbidity and silt load, hence good water quality. In the Blyde River, the sites generally had moderate temperatures, TDS and conductivity values. However, TDS, salinity and sulphate were relatively high at S7 (the confluence of the Blyde and Olifants rivers), and could be due to increased runoff from human activities along the river to downstream or from the Olifants River. The DO levels were high throughout the sampling periods and the sites, with the highest level recorded in winter, as dissolved oxygen is temperature dependent. Nutrients levels were not too high despite the intensive agricultural activities in the catchment (DWAF, 1996; de Villiers and Thiart, 2007).

Macroinvertebrates

The macroinvertebrate assemblages in the Blyde River were rich in Ephemeroptera, Diptera and Trichoptera (*Table 2a*), and this trend is in support of other studies in both temperate and tropical rivers and streams (Al-Shami et al., 2013a, b; Jun et al., 2016). Taxa diversity is said to be variable in rivers in response to disturbance, suitable habitat availability and resource availability. Higher diversity is an indication of equal or close to equal opportunity of co-existence (Olomukoro and Ezemonye, 2007). A decreased diversity with corresponding increased abundance of few taxa is an indication of community disturbance and imbalance (Morphin-Kani and Murugesan, 2014). The low number of sensitive families at S7 and high numbers of tolerant species, could be due to poor water quality from the Olifants River. Furthermore, the low number of taxa at S3 could be due to the high-water current throughout the sampling period, resulting in less favourable conditions for many macroinvertebrates to survive in such an environment.

The high number of individuals and families of Ephemeroptera could be due to high oxygen concentration and fast flowing waters (Jun et al., 2016; Rasifudi et al., 2018). The presence of these taxa at all the sites indicates a high level of water quality at most parts of the river (Griffin et al., 2015). In addition, the high number of individuals from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16211635

the family Hydropsychidae (Tricoptera), at all the sites could further confirm the good quality of the water. The presence of sensitive taxa is an indication of good habitat structure and good water quality (Lopez-Doval et al., 2010; Matlou et al., 2017). The cluster analysis shows only three main groupings, an indication that the conditions of most of the sites are similar. This is confirmed by the Spearman correlation which shows positive relationship among all the sampling sites, with high correlation among the third cluster group (S1, S2, S3, S4 and S7). The seasonal macroinvertebrate distribution among the sites rarely showed any variation (*Fig. 2b*). While seasonality can be a driven force of river community dynamics, its effect is regulated by the likelihood of its recurrence (Tonkin et al., 2017). The lack of seasonality effect is an indication of the relative lack of a significant variability in environmental conditions of the river. The high number of macroinvertebrates recorded at S5 from different tolerant groups such as, Hydropsychidae, Simuliidae, Chironomidae and Elmidae could be attributed to good biotope diversity (higher habitat heterogeneity), as this site was characterised by bedrock, sand, areas of high current, pools and sparse vegetation. Furthermore, the high abundance of Simuliidae at S5 could be due to the presence of the Weir above the sampling site. High presence of Simuliidae has been reported below many impoundments, and their abundance is linked to reservoir outflows (Boon, 1998; Marchetti et al., 2014; Rasifudi et al., 2018).

There was seasonal variation in the composition of macroinvertebrates in the Blyde River. The high number of taxa and abundance during winter could be due to relatively good water quality as a result of less discharge from the catchment. During raining season, which usually starts in spring through to autumn in the area of the study, the river receives a lot of discharge from the catchment which may destroy the microhabitat of the macroinvertebrates. Furthermore, high flows which normally occur in raining season are known to affect aquatic macroinvertebrates both directly and indirectly through changes to habitat. Substrates of macroinvertebrats can be moved down-stream (Piniewki et al., 2017).

Most taxa sampled clumped at the centre of the CCA ordination plot, suggesting that no particular measured environmental variable defined the taxa distribution (Niba and Sakwe, 2018). It also confirms the fact that the conditions at most of the sites are similar and therefore may support similar macroinvertebrate communities. The taxa-environmental correlation for both axes 1 and 2 was 0.99, which indicates high predictive power of the selected environmental variables. Many of the pollution intolerant taxa could live in areas with high DO and pH and many of the pollution tolerant taxa could group in areas with high EC, TDS, salinity and temperature. Thus, interactions of macroinvertebrate communities may be influenced by abiotic factors in the environment (Florencio et al., 2013; Heino, 2013).

Conclusion

Despite the active agricultural activities in the Blyde River catchment, the aquatic community was indicative of good water quality. The high diversity and the presence of high abundance of sensitive taxa confirm the good quality or/and habitat heterogeneity of most parts of the river. However, the water from the Olifants River might have affected the quality of the water at S7 (the confluence of the Blyde and the Olifants River), hence the distribution of the macroinvertebrate communities was characterised by high number of pollutant taxa, Mollusca, especially Thiaridae. Seasonal variation of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16211635

the distribution of macroinvertebrates was also observed. The results suggest that currently the human activities along the Blyde River has little impact on the integrity of the river system. Though the current activities may not pose a threat to the water quality and benthic macroinvertebrates in the river, further monitoring is necessary due to increasing human activities in the catchment of the river. The study revealed that combination of physicochemical and biological measures in water quality assessment provides positive and promising results as they show sensitivity to environmental changes hence, aquatic macroinvertebrates are good biological indicators of pollution.

Abstract. Detailed and reliable information about the suitable distribution of species provides important knowledge for species protection management. The objectives of the study were to predict and analyze the potential distribution, driving factors and niche parameters of *Anabasis aphylla* under different scenarios. We combined the distribution data of *A. aphylla*, maximum entropy model and ArcGIS to predict the potential distribution of the plant in northwestern China under Paleoclimate, current and future (RCP4.5 2050 and RCP4.5 2070) climatic scenarios. The results showed the highly suitable distribution areas of *A. aphylla* were mainly concentrated in the southern margin of the Junggar Basin and the west side of the Tarim Basin. The primary environmental variable limit for the distribution of *A. aphylla* was precipitation seasonality. Precipitation and temperature have an important influence on the distribution of *A. aphylla*. According to the prediction of Palaeoclimate scenario, unsuitable areas of *A. aphylla* under the current, 2050 and 2070 climatic scenarios all increased, while the barely suitable areas of *A. aphylla* decreased. This study provides an important theoretical basis for the management, protection and restoration of *A. aphylla*.
Keywords: *Anabasis aphylla, AUC, environmental variables, ecological niche, suitable area*

Introduction

The study of the relationship between plant geographical distribution, climate and the prediction of plant spatial distribution pattern, is not only a research hots pot of traditional plant ecology and biogeography, but also an important research field of global ecology and global geography (Wang and Ni, 2009). Climate change research has noted that due to the increasing of CO_2 concentration in the earth's atmosphere, the global average temperature has increased over the past 100 years (Houghton et al., 2001). Climate change affected many ecosystems and biotas worldwide, it may accelerate the loss of biodiversity (Parmesan, 2006) and threaten the current distribution of species in the future (Araújo et al., 2011). In recent years, climate change and human activities have had a strong impact on the distribution of plant species in the arid northwest. Therefore, it is very necessary to study the future dynamics of vegetation in arid regions, which can provide better guidance for ecological protection and restoration in the arid regions of northwest China.

Anabasis aphylla is a chenopodiaceous shrub with high capabilities to endure salt-alkali, resist drought and prevent sand drift. It is also a constructive species for desert soil and plays a vital role in maintaining ecological stability and preventing natural disasters like desertification (Chu et al., 2014). Zhang et al. (2003) found that in areas with high groundwater level, easy to accumulate water and high salt content, *A. aphylla* occupied an absolute advantage. There were few studies on the correlation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16371648

between the geographical distribution and environmental variables in a large area of *A. aphylla*. Jiang (2003) predicted the potential geographical distribution of *Anabasis* plants, and indicated that the distribution of *Anabasis* plants in China was concentrated in the arid regions of northwest. Based on 19 environmental variables and Maxent (maximum entropy model), Wang (2018) studied the distribution center of *Anabasis* plants in China, and found that these plants have higher adaptability to the arid and semi-arid climate than the warm temperate continental arid climate. All of these studies can provide a reference for the research in this paper. In china, *A. aphylla* is mainly distributed in northwest region, in diluvial fans, lowlands among dunes, in the Gobi desert and on hillsides (Chu et al., 2014). However, due to the influence of agricultural development, oil exploitation, harsh environmental conditions and other activities, the habitat of *A. aphylla* populations in Xinjiang was severely fragmented. All of this caused the self-renewal ability of *A. aphylla* population was poor, and most of the areas were in a recession trend (Chu et al., 2014). Therefore, it is of great practical significance for the management and protection of the plant to study the potential distribution range and spatial distribution pattern of *A. aphylla* under climate change scenarios.

In previous studies, Species Distribution Models (SDMs) have been used to model the potential geographic distribution of species in areas where the known distribution of species is lacking (Stockwell and Peters, 1999), and have also been used to estimate species distribution patterns and propose conservation strategies (Ortega-Huerta and Peterson, 2004). There are many different SDMs to choose from when predicting the potential distribution of species. This study selected the maximum entropy model (Maxent) as a predictive tool, as recent studies have shown that this method has a stronger ability to distinguish between the suitable and unsuitable regions of the species than other model methods (Phillips et al., 2006; Hernandez et al., 2008; Ma et al., 2017). Maxent has been demonstrated to be a powerful function when modelling rare species with narrow ranges and available scarce presence only occurrence data (Phillips et al., 2006; Elith et al., 2006, 2015; Pearson et al., 2007; Wisz et al., 2008; Rebelo and Jones, 2010; Sardà-Palomera et al., 2012; Garcia et al., 2013; Marcer et al., 2013). The advantages of Maxent including (1) the input species data can be presence only data; (2) both continuous and categorical data can be used as input variables; (3) its prediction accuracy is always stable and reliable, even with incomplete data, small sample sizes and gaps; (4) a spatially explicit habitat suitability map can be directly produced; and (5) the importance of individual environmental variables can be evaluated using a built in jackknife test (Yi et al., 2016). Studies using the Maxent model to predict the extent of species in different areas are concentrated on rare or endangered plants (Wilson et al., 2011; Babar et al., 2012; Marcer et al., 2013; Yi et al., 2016), invasive plants (Padalia et al., 2014) and insects (Santos et al., 2017; Wang et al., 2017). Maxent also has been successfully applied to the potential distribution of desert plant species in arid regions. Wang and Ni (2009) predicted the potential geographical distribution of five *Caragana* species in temperate arid and semi-arid regions of northern China. Ma et al. (2010) predicted the potential distribution and pattern of *Gymnocarpos przewalskii* in the desert area of Northwest China.

This study is based on the new scenario of the Fifth Interval Panel on Climate Change (IPCC): climatic factor data obtained from the RCP (Representative concentration pathways) 4.5 (medium emission scenario). Combined with the distribution data of *A. aphylla*, Maxent model and ArcGIS tools were used to predict the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16371648

potential distribution, spatial pattern and changes of *A. aphylla* in northwestern China under Paleoclimate, current and future climatic scenarios. We aim to answer the following questions: (1) What is the distribution potential of *A. aphylla* in northwestern China under paleoclimate and current climate scenarios? (2) How will climate change affect the suitable distribution range and spatial pattern of *A. aphylla* in the future? (3) Which environmental factors and niche parameters that mainly restrict the distribution of *A. aphylla*?

Materials

Study area

In China, *A. aphylla* mainly distributed in the northwestern region. We attempted to find all possible habitats of *A. aphylla* in northwesten China, extending a certain distance to the surrounding area of the known geographical distribution of *A. aphylla* as the study area (31°09′ N-53°23′ N and 73°40′ E-126°04′ E). The specific geographical scope of the administrative division of this area mainly includes the whole territory of Xinjiang, Inner Mongolia, Qinghai and Gansu. A geographic base map of China was obtained from the National Fundamental Geographic Information System (http://nfgis.nsdi. gov.cn). Most of the study area is arid and semi-arid and has a typical continental climate. The climate is dry all year with strong evaporation. Specifically, the dryness is greater than 4 (Ma et al., 2010), and the evaporation is basically more than 1000 mm (Wei et al., 2003). The study area is characterized by complex topography, fragile ecosystems, and long-term disturbance by human activities.

Occurrence collection of A. aphylla

The occurrence locations of *A. aphylla* were collected from databases, including the including the 1:1000000 vegetation atlas of China, the Chinese Virtual Herbarium dataset (CVH, http://www.cvh.org.cn/), Plant Photo Bank of China dataset (http://plantphoto.cn), Global Biodiversity Information Facility dataset (GBIF, https://www.gbif.org/) and some related references (Xu, 2003; Liu and Yang, 2006). Based on the occurrence location *A. aphylla*, we conducted extensive field investigations in Xinjiang, Badan Jaran Desert in Inner Mongolia and Jiuquan in Gansu during the summer (June to September) of 2017 and 2018. Xinjiang is the most distributed area of *A. aphylla*, the surveyed areas included Bole, Changji, Kashi, Atushi, Karamay and Shihezi. We found those areas where previously distributed with *A. aphylla* due to disturbances and disruptions of human activity are now less distributed, such as Karamay, Bole and Fukang of Changji. The distribution of *A. aphylla* in the core area was patchy. After removing repetitive occurrences and updating the distribution of *A. aphylla,* we obtained 99 data records for constructing the models. With the help of ArcGIS 10.4, a distribution of *A. aphylla* map was developed (*Fig. 1*).

Environmental variables

The 19 bioclimatic variables and one biophysical variable (altitude) with a 30s (ca. 1 km) spatial resolution, downloaded from World Bioclimatic Database (http://www.worldclim.org). The current climate data (1961-1990) and Paleoclimate data for the Mid-Holocene (about 6000 years ago) were derived from CCSM4 (Collins et al., 2006). The future climate data for RCP4.5 for carbon dioxide for 2050

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16371648

(2041-2060 average climate) and 2070 (2061-2080 average climate) were included. Mid-Holocene is the most recent climate suitable period. Its radiation intensity and the increase of modern atmospheric CO_2 have similar warming effects on the climate, so the Mid-Holocene climate simulation is of great significance for the prediction of climate scenarios for future global warming (Joussaume et al., 1995). This data set describes annual trends in climate, seasonality, and extreme environmental conditions and is often used for the prediction of niche models.

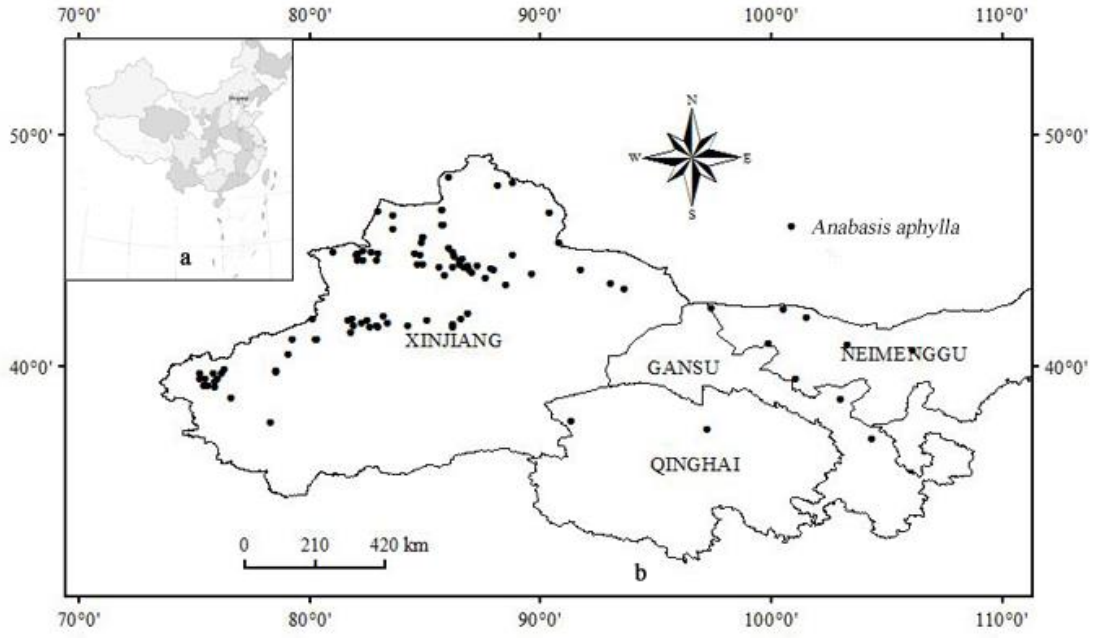

Figure 1. *Distribution of A. aphylla used in this study (a) Map of China; (b) Distribution of A. aphylla in northwestern China*

To avoid the collinearity between environmental variables, Maxent′ s jackknife was used to sort the 20 environmental variables according to their contribution rate. Environmental factors with a sum of 10 cumulative contribution rates >90% were selected for models (Wei et al., 2019), including 9 bioclimatic variables and altitude data (*Table 1*). These variables included annual mean temperature (bio1), isothermality (bio3, *Eq.1*), minimum temperature of coldest month (bio6), temperature annual range (bio7, *Eq.2*), annual precipitation (bio12), precipitation of wettest month (bio13), precipitation of seasonality (bio15), precipitation of driest quarter (bio17), precipitation of warmest quarter (bio18) and altitude.

$$\text{Isothermality}\,(\%) = (P2/P7)\times 100 \qquad \text{(Eq.1)}$$

$$\text{Temperature Annual Range}\,(^{\circ}\text{C}) = P5 - P6 \qquad \text{(Eq.2)}$$

where P2 is mean diurnal range; P5 is maximum temperature of warmest month; P6 is minimum temperature of coldest month; P7 is temperature annual range.

Species distribution modelling

This study used Maxent v3.3.3 software for analysis. We randomly selected 75% data for model training and 25% for model test. Selected the jackknife method in the environmental parameter settings, the remaining parameter settings selected the default parameters (Ma et al., 2017) and set 10 repetitions. The analysis results were output in logical format and ASCII type. For the 10 replicate results in different climate scenarios, used ArcGIS 10.4 to find the mean value as the final model result (Ma et al., 2017).

A Jackknife test was used to measure the variable importance in the model development, and receiver operating curve analysis (ROC) was used for model quality (Wang et al., 2017). The Jackknife test to examine the importance of individual variables for Maxent predictions. The receiver operating characteristic area under curve (AUC) method is a widely used procedure for comparing species distribution model performance of Maxent models (Lobo et al., 2010; Babar et al., 2012). The ROC plots the sensitivity values and the false positive fraction for all available probability thresholds (Manel et al., 2001). AUC provides a single measure of model performance independent of any particular choice of threshold. The AUC measures model performance ranging from 0 to 1. Accuracy classification for AUC is: 1>excellent>0.9>good>0.8>fair>0.7>poor>0.6>fail (Swets, 1988).

For display and further analysis, we imported the results of the Maxent models predicting the presence of *A. aphylla* (0-1 range) into Arc GIS 10.4. Five classes of potential habitats were regrouped (Yang et al., 2013): unsuitable habitat (0-0.2); barely suitable habitat (0.2-0.4); suitable habitat (0.4-0.6); highly suitable habitat (0.6-0.7); very highly suitable habitat (0.7-1.0). For each model, we calculated the areas of *A. aphylla* under different climatic scenarios.

DOI: http://dx.doi.org/10.15666/aeer/1801_16371648

Results

Model performance and variables' contribution

In this study, models predictive accuracy of *A. aphylla* habitat was assessed as a good level. Specifically, under the current and the RCP4.5 2050 period, the AUC values verified by the model results were 0.901. Under the Paleoclimate and the RCP4.5 2070 climate scenarios the value of AUC were 0.877 and 0.898, respectively. This indicated that the potential growth area and ecological suitability of *A. aphylla* modelled by this study were highly accurate and reliable.

Under different climatic scenarios, the environmental variables that contributed most to the construction of the potential distribution model of *A. aphylla* with the Maxent algorithm were Bio15 (31% of the variation), followed by bio13 (18.1% of the variation), bio12 (10% of the variation), bio6 (9.2% of the variation), bio1 (8.8% of the variation), bio18 (7.6% of the variation), bio17 (6.1% of the variation), bio7 (4.9% of the variation), bio3 (3.5% of the variation) and alt (0.9% of the variation) (*Table 1*, *Fig. 2*). The cumulative contributions of these factors reached values as high as 90.8%. *A. aphylla* is highly adaptable to low temperature environments (Peng et al., 2018). Our previous studies showed that the seeds of *A. aphylla* can germinate in early spring when the ground is moist due to melting snow (Peng et al., 2018). In the Junggar Basin with more *A. aphylla* distributed, the annual extreme maximum temperature can reach 42.9℃ (Chu et al., 2014). Therefore, *A. aphylla* has a strong adaptability to temperature.

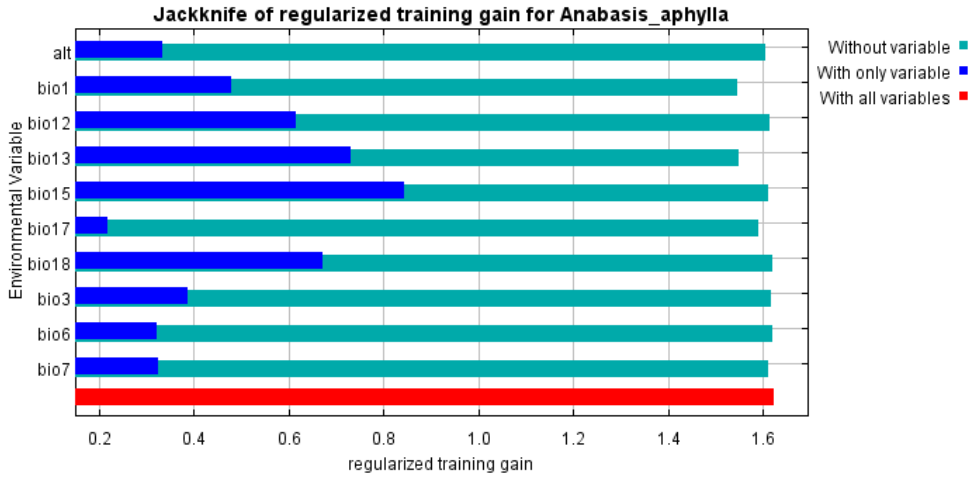

Figure 2. *Results of the jackknife test of variables' contribution in modelling A. aphylla's habitat distribution (The regularized training gain describes how much better the Maxent distribution fits the occurrence data compared to a uniform distribution. The dark blue bars indicate the gain from using each variable in isolation, the light blue bars indicate the gain lost by removing the single variable from the full model, and the red bar indicates the gain using all of the variables)*

Response curves

Response curves showed the quantitative relationship between environmental variables and the logistic probability of occurrence, which deepen our understanding of the ecological niche of species (Yi et al., 2016). This curves can provide useful

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16371648

information about the required environmental threshold (existence probability >0.4) for optimal growth of plant species. According to the response curve (*Fig. 3*), the probability of occurrence of *A. aphylla* decreases considerably in regions in which the precipitation of seasonality (bio15) is above 80% (*Fig. 3A*). The optimal growth annual precipitation of *A. aphylla* (bio12) was approximately 140 mm (*Fig. 3B*). The probability of occurrence of *A. aphylla* increases in areas with an annual mean temperature (bio1) between 5℃ and 13℃ (*Fig. 3C*).

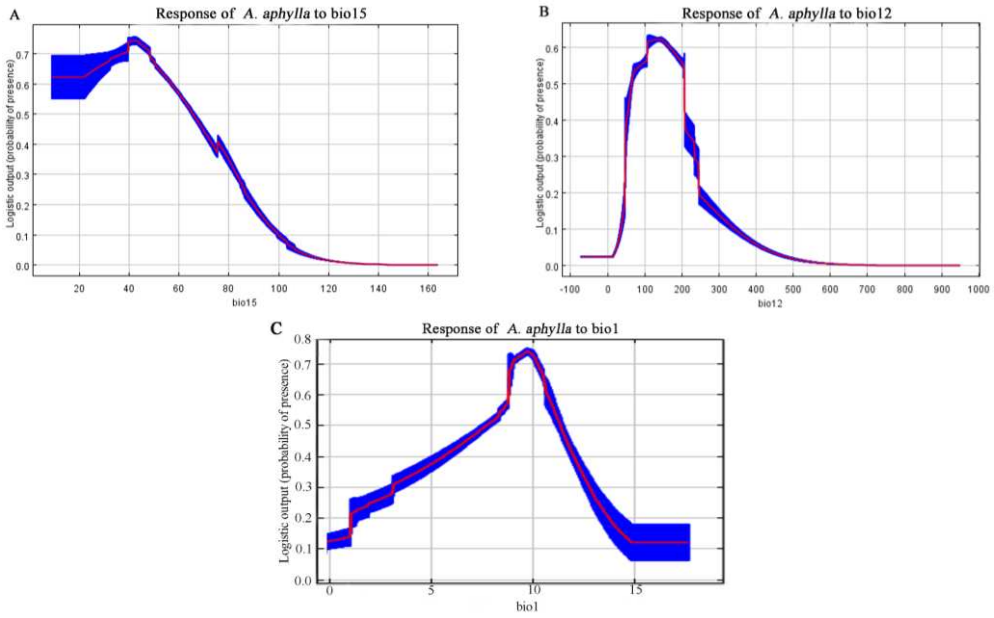

Figure 3. *Response curves of the main environmental variables in A. aphylla' s habitat distribution model* ***(A)*** *bio15: precipitation of seasonality (C of V);* ***(B)*** *bio12: annual precipitation (mm);* ***(C)*** *bio1: annual mean temperature (℃)*

Predicted geographical distribution of A. aphylla

According to the predicted geographical distribution under different climatic scenarios (*Fig. 4*), the highly and very highly suitable distribution areas of *A. aphylla* were mainly concentrated in Xinjiang, of which the southern margin of the Junggar Basin and the western side of Tarim Basin were the very highly suitable areas. As far as the Xinjiang region was concerned, the distribution of *A. aphylla* in northern was more than in southern. In addition, *A. aphylla* also had a suitable distribution in some areas of the Hexi Corridor. The suitable distribution value of *A. aphylla* in Inner Mongolia and Qinghai was low. In Inner Mongolia, the expansion of the Badain Jaran Desert area may be one of the reasons for the reduced distribution area of *A. aphylla*. Compared with the Palaeoclimate scenario, the suitable areas of *A. aphylla* in the central part of Qinghai were reduced under the current and RCP4.5 2050 climatic scenarios.

According to the prediction of Palaeoclimate scenario, the total unsuitable areas of *A. aphylla* under the current, 2050 and 2070 climatic scenarios were increased, while the barely suitable areas of *A. aphylla* decreased (*Table 2*). The reduction of barely suitable area was mainly concentrated in central Inner Mongolia (*Fig. 4*). Compared with the current climate scenario, the very highly suitable distribution area of *A. aphylla* will decrease by 10.5% and 13.9% respectively in 2050 and 2070 (*Table 2*).

Discussion

Based on the Maxent model and GIS tools, this study predicted the potential distribution of *A. aphylla* in northwestern China under Paleoclimate, current and future climatic scenarios (*Fig. 3*). The *A. aphylla's* distribution points used for models were derived from the Chinese Plant Image Database, Vegetation Atlas, GBIF, CHV and published articles, these covered all distribution of *A. aphylla* in China. According to the ROC curve, the potential distribution model prediction results of *A. aphylla* during different climatic backgrounds showed that AUC values were higher than 0.877, indicating that the model prediction results were accurate and credible.

Under the Palaeoclimate and current climatic scenarios, the highly suitable distribution area of *A. aphylla* was mainly along the southern margin of the Junggar Basin and the west side of the Tarim Basin. In addition, the fitness value was higher in some areas of the Hexi Corridor, but low in most areas of Inner Mongolia and Qinghai. The highly suitable distribution area of *A. aphylla* found in this study was consistent with the findings of Wang et al. (2018). *A. aphylla* has a sporadic distribution in the Hexi Corridor area, and fragmentation is more serious. This finding may be related to the increase in evaporation caused by climatic warming in the Hexi Corridor, which has

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16371648

led to aggravation of drought in this part of the region and increased desertification trends (Ren and Yang, 2008). Under climatic scenarios in the future, the total suitable areas of *A. aphylla* will be increased. As the global climate continues to warm because of the increase in CO_2, China's climate will accordingly change. According to the regional climatic model, annual precipitation in most parts of northwestern China will increase by more than 20% under a doubling of the CO_2 concentration, with Xinjiang and Hexi increasing the most, reaching 20%-50% (Gao et al., 2001). Climate change has different effects on the distribution patterns of different species. Some species are threatened by climate change and are endangered or even extinct; others will benefit from climate change (Ma et al., 2017). In this study, it was determined that *A. aphylla* belongs to the latter case according to the change in its distribution area. At large spatial scales, climatic factors are key factors limiting the plant's potential distribution (Ma et al., 2017). However, in addition to the influence of abiotic factors on the distribution range of plants, human activities, interactions between species and the limitation of groundwater level all affect the geographical distribution pattern of species and their relationship with climate (Wang and Ni, 2009).

The Maxent prediction results in this study showed that the suitable distribution area of *A. aphylla* was mainly along the southern margin of the Junggar Basin, the west side of the Tarim Basin and parts of the Hexi Corridor. *A. aphylla* often grows in gravel and saline soils in the desert at the front of diluvial fans, intermontane platforms and arid hillsides of low mountain (Chu et al., 2014); these areas were found to be more disturbed by human activities during the field investigation. Because of agricultural reclamation, oil exploitation and other human activities, the actual distribution of *A. aphylla* was mostly in patches with serious fragmentation. Particularly since the 1960s, the continuous increased population and the blind development of agricultural reclamation land resulted in a rapid expansion of desertification area. For example, along the southern margin of the Gurbantunggut Desert, the cultivated area increased from 818 km^2 to 5500 km^2, increasing the cultivated area nearly 7 times (Wei et al., 2003). Therefore, in view of the serious fragmentation caused by human activities, it is suggested to add *A. aphylla* to the list of endangered species for protection.

Conclusions

A. aphylla as one of the dominant species in the desert area of China, has strong drought tolerance. In this study, the highly and very highly suitable areas of *A. aphylla* were mainly concentrated in the southern margin of the Junggar Basin and the western side of Tarim Basin. The Maxent model's jackknife test of environmental variables showed that precipitation of seasonality (31%) contributed most to the model. The models obtained in this study indicated that climate change had different effects on different suitable distribution areas. By calculating the area of the very highly suitable of *A. aphylla*, it will decrease in the future climate scenarios (*Table 2*). Therefore, by modelling the potential suitable area of *A. aphylla* and studying its niche requirements, it is of great significance for its protection in the future.

In this study, the potential distribution prediction of *A. aphylla* was only based on environmental variables, without considering the influence of human factors and ecological niche overlap between different species. In the actual distribution, *A. aphylla* was distributed in patches in the core area due to the influence of land use. *Haloxylon ammodendron* and other *Anabasis* plants have similar ecological characteristics to *A.*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16371648

aphylla, so its geographical distribution is also affected by these plants. It is very necessary to study the geographical distribution of vegetation in combination with human disturbance and the overlap of niche between different species, so as to provide protection suggestions. Such as the establishment of core reserves. At the same time, *A. aphylla* is more affected by the topography in the distribution area. For example, it is separated by Tianshan mountain in Xinjiang and influenced by Hexi Corridor in Gansu. Due to the effects of reproductive isolation and environmental differences, genetic differentiation among populations of the same species distributed in different regions will occur (Guo, 2010). Therefore, it is of great significance to study the species evolution and genetic diversity of *A. aphylla.*

EVALUATION OF SOME FRUIT CHARACTERISTICS OF JUJUBE (*ZIZIPHUS JUJUBA* MILL) GENOTYPES IN MANISA, TURKEY

ACARSOY BILGIN, N.

Department of Horticulture, Faculty of Agriculture, Ege University, İzmir, Turkey
(Orcid ID: 0000-0002-5018-6347; e-mail: nihalacarsoy@yahoo.com)

(Received 4th Oct 2019; accepted 8th Jan 2020)

Abstract. Jujube fruits are widely consumed all over the world as food and herbal medicine due to their health benefits. It is known as a species with a wide variety of products. It can be found naturally throughout the world, including Turkey. Jujube is particularly popular nowadays for its high antioxidant activity and phenolic content. In this study conducted on 10 genotypes selected in Manisa/Demirci (Turkey) pomological, biochemical and organoleptic properties of fruit genotypes were investigated. The results stated, the characteristics examined differed according to genotypes. The highest TSS, phenol and antioxidant content were 45.34%, 322.39 mg GAE/g fw and 96.75 µmol TE/g fw, respectively. Some genotypes are thought to be beneficial for public health as well as for table use due to their phytochemical contents.
Keywords: *selection, pomological, biochemical, organoleptic, statistical*

Introduction

Jujube (*Ziziphus jujuba* Mill) is one of the temperate fruit species. This plant is resistant to extreme rain fall and is not affected by drought can survive at heights up to 1700 m above sea level (Ecevit et al., 2002). Jujube is widely grown in almost all over the world (Mukhtar et al., 2004; Gozlekci et al., 2015). In China, it has been cultivated in for many years. It is naturally found in Russia, India, Middle East, Anatolia, Southern Europe and North Africa. There are 6 genus including *Colletia, Frangula, Hovenia, Paliurus, Rhamnus, Ziziphus* and 25 species in the native flora of Turkey (Anşin and Özkan, 1997). Among them, *Ziziphus jujuba* and *Ziziphus mauritiana* are grown for fruits (İslam et al., 2006).

Jujube is usually growing home gardens and as a border tree in a field edge. It grows in Marmara, Western and Southern Anatolia in Turkey (Yücel, 2005). In this respect, Isparta, Hatay, Iskenderun, Antalya, Kayseri, Bursa, Çanakkale are important production centers (Karıncalı, 2003). Also besides, Çoruh Valley, Manisa/Demirci and Denizli/Çivril noteworthy. In this area, there is abundant natural flora and different species are observed (Yaşa, 2016).

In recent years, fruit species with high antioxidant activity, phenolic and vitamin contents are of great interest (Wojdylo et al., 2016). Thereby, jujube has a significant impact on human nutrition all over the world. Fruits are delicious and eaten as fresh, dried, candy, jam, juice, wine, syrup, tea bag sand compotes (Liu, 2006).

The bioactive components show large variations according to genotypes and growing, and ripening (Choi et al., 2011; Koley et al., 2016). Total phenol contents and antioxidant activity of jujube fruits were found to be high in previous study (Kamiloglu et al., 2009). They have significant levels of vitamin A, B, C and content many minerals (Wojdyloa et al., 2016). Accordingly, it is an excellent source of nutrients and phytochemicals and can also contribute to a healthy diet. In this way, it also has a protective feature against various diseases with its composition. Because of these properties, the fruit is well-known as a nourishing food also seeds; roots and leaves are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16491660

known as folk medicine (Mukhtar et al., 2004; Abdel-Zaher et al., 2005; Li et al., 2005). Additionally, fruits contain sugar, tannin and mucilage substances. For this reason, it is recommended that diabetics consume fruit directly. This further increases the importance of the product.

Determining genetic diversity is a prerequisite for conservation of genetic resources, due to the loss of many features of gene erosion. This is important for the sustainability of biodiversity. In this economically valuable species, breeders are researching their genetic resources (Ahmad et al., 2019; Dahlia et al., 2019; Sharif et al., 2019). In the development of new varieties, hybridization breeding takes place over a long period and is difficult. Thanks to the genetic diversity in nature, selection breeding is preferred. Morphological and molecular markers are used to determine genotypes in the population (Ahmad et al., 2019; Chen et al., 2019; Dahlia et al., 2019). As is known, morphological evaluation is easy and inexpensive (Zhang et al., 2015). In this way, breeders can identify elite genotypes by investigating plant, fruit and sensory characteristics (Uddin and Hussain, 2012; Godi and Joshi, 2016).

In Turkey, similarly to many other fruits, this species has a gene pool. The characteristics of jujube genotypes have been determined in different locations in our country but there is no standard variety. This will contribute to breeding programs which new genotypes with different characteristics will be developed. Considering these explanations in the current study, pomological, biochemical and organoleptic properties of 10 genotypes were identified in Manisa/Demirci location.

Materials and methods

In this study, 10 local jujube genotypes selected from Manisa/Demirci were used as material (*Fig. 1*). Sampling was performed to represent genetic diversity in the experimental area. In phenotypic observations, individuals with different fruit characteristics such as fruit size, color and taste were selected. For each genotype, 30 fruits were analyzed. Samples were collected during the commercial maturation period (September 2018).

Figure 1. *The location of the experimental area*

Fruit and stone weights of the harvested samples were determined, and average flesh/stone ratios were calculated. The fruit width and length were measured. Fruit ground colors were stated twice at the equatorial regions of both cheeks for five fruits

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16491660

with "CR300 model Minolta Colorimeter". The values of L*, a*, b* were measured and chrome (C*) and hue angle (h°) were determined based on these values (Karaçalı, 2012). TA values (%) were measured such that 5 ml of fruit juice was completed to 100 ml with distilled water and 0.1 N of NaOH was added to reach a pH of 8.00-8.10. TSS content in fruit juice was found by a digital refractometer (%), and the pH values were read by a pH meter (Karaçalı, 2012). Total phenol content and antioxidant activity were determined in the fruit samples prepared by Thaipong et al. (2006) method. Total phenol content was determined by the Folin-Ciocalteu method (Swain and Hillis, 1959). The results were expressed as mg gallic acid equivalent (GAE)/100 g fresh weight (FW). The FRAP method was used to determine the antioxidant activities. The results were given as Trolox equivalent (TE)/g dm (Benzie and Strain, 1996).

Jujube fruits were evaluated regarding flavor, texture and general acceptability by Meligaared et al. (1991) and Uddin and Hussain (2012). According to this, flavor: no taste (1), elaeagnus-apple (3), apple-pear (5), elaeagnus (7), apple (9); texture: soft (3), medium (5), hard (7) and acceptability: poor (1), fair (3), medium (5), good (7), very good (9) were evaluated with scale ranged from dislike (1) to like (9). At this stage, each genotype was tasted by 10 panelists.

Results were subjected to a variance analysis by using SPSS Statistics 20 statistical package program. Significant differences between averages were defined by Duncan test at the $P < 0.05$ significant level. The mean, minimum, maximum, and standard deviation values of the properties examined were determined. Moreover, the relationship among these values was revealed by conducting Pearson's correlation analysis. Differences or similarities of genotypes were evaluated according to their analyzed properties by applying PCA to the findings obtained. Moreover, cluster analysis (CA) was utilized to create a dendrogram showing similarities and differences between genotypes.

Results and discussion

Some pomological properties of 10 jujube genotypes are shown in *Table 1*. There was a statistically significant difference in fruit weight, flesh/stone ratio, fruit width and length among genotypes ($P \leq 0.05$). In terms of the investigated characteristics, genotype 10 was the first, followed by genotype 9. On the other hand, the values of genotype 8 were found to be low, in general. Differences in fruit weight (2.73 g to 24.33 g) caused a higher standard deviation. Thus, genotypes exhibited heterogeneity for this trait. The flesh/stone ratio ranged from 4.93 to 27.63. Similar to average fruit weight, higher standard deviation occurred. Minimum and maximum values of fruit width and length were determined as 17.55-34.83 and 18.64-37.48 mm, respectively. Jujube genotypes (*Ziziphus mauritiana*) with large fruits are reported to have a fruit weight range of 4 g (Gorh) to 36 g (Foladi) under the climatic conditions of Pakistan. The highest and lowest stone weight were found in the same genotype (Abbas et al., 2012). Confirming our results, fruit weight, width, and length were noticed as 23 g, 37 mm and 40 mm, respectively by Galindo et al. (2015). Furthermore, for three different jujube genotypes, Kavas and Dalkılıç (2015) explained the variation range of fruit weight (8.21-28.85 g), fruit width (24.02-37.35 mm) and fruit length (29.47-43.73 mm) in Kızılcaköy, Aydın. The change of data based on genotypes was also revealed in the earlier findings of Gao et al. (2012). These findings are synchronized with our study.

Table 1. *Pomological properties of jujube genotypes*

Genotypes number	Fruit weight (g)	Stone weight (g)	Flesh/stone ratio	Fruit width (mm)	Fruit length (mm)
1	5.37 c	0.78[a]	5.88 f	22.62 b	21.80 c
2	4.72 e	0.41	10.47 c	19.17 cd	19.88 def
3	5.03 d	0.76	5.62 g	19.92 c	20.45 cde
4	3.26 h	0.32	9.19 d	19.16 cd	18.64 f
5	4.31 f	0.64	5.74 fg	19.08 cd	19.22 ef
6	4.30 f	0.68	5.32 h	18.17 d	21.43 cd
7	3.59 g	0.43	7.35 e	17.55 d	18.95 ef
8	2.73 ı	0.46	4.93 ı	17.68 d	18.76 ef
9	7.16 b	0.55	12.00 b	23.76 b	25.68 b
10	24.33 a	0.85	27.63 a	34.83 a	37.48 a
Min.	2.73	0.32	4.93	17.55	18.64
Max.	24.33	0.85	27.63	34.83	37.48
Avg.	6.48	0.59	9.41	21.19	22.23
St. dev.	6.17	0.17	6.60	5.07	5.61

The differences in the means were determined by the Duncan test according to $P \leq 0.05$. [a]: Not significant

For all color variables, significant differences among genotypes occurred (*Table 2*). Generally, the highest values were obtained in genotype 6, except a* value. In genotype 5, the a* value, which expresses the red color, was the maximum. At the same time, it has a darker color owing to the L* value is low. Moreover, the hue value was found low. Thus, this genotype has come to the fore in terms of color. The b* (5.62) and h° (5.71) values identified a high level of variation. As compared with Galindo et al. (2015), it was seen that h° value was lower in our study. This emphasizes that the red color is dominant. In contrast to this research, Kavas and Dalkılıç (2015) did not find any difference in this matter. The color values were influenced by many factors such as genotype, harvest time, cultural practices, crop load, etc. (Wang et al., 2012; Gündüz and Saraçoğlu, 2014).

Biochemical properties (pH, TSS, TA, total phenol and antioxidant activity) significantly differed depending on genotypes (*Table 3*). No variation was observed in terms of pH and TA. The average value of pH was 5.11 and the TA value was 0.45%. Genotypes are similar in this respect. In this trial, minimum TSS content was found to be 19.20% while a maximum of 45.34%. The high standard deviation indicates a high variation in the population on account of phenol content and antioxidant activity. This diversity is desirable for plant breeders. Total phenol content and antioxidant activity were detected to be 239.90-322.39 mg GAE/g FW and 43.86-96.75 µmol TE/g FW, respectively. Jujube contains much higher TSS than many fruit species (Yao, 2013). While the TTS content of jujube fruits was determined as 24% (Abbas et al., 2012), 32% (Kavas and Dalkılıç, 2015), 19% (Koley et al., 2016), 30% (Gao et al., 2012) and 32% (Ecevit et al., 2008) in previous research, this value was found to be extremely high as 45.34% by ours. Godi and Joshi (2016) stated that the variation in TSS among the jujube genotype may vary mainly due to different harvest periods or genotype. As it is known, if the product load decreases, TSS and TA values increase but not the pH. Compared with the previous study (Galindo et al., 2015), TA content was found to be lower, pH was similar in our study. It is pointed out that jujube fruits are rich in total

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16491660

phenol contents and antioxidant activity (Yao, 2013). In Indian jujube commercial cultivars (*Z. mauritiana*), the range of total phenol was 172-328.6 mg GAE/100 g (Koley et al., 2016). Our findings are supported by this study. Many external factors may influence the change of the phenol content (Imamoglu, 2016). Although fruits such as strawberry (Zheng et al., 2007), grapes (İşçi et al., 2014), black mulberry (Özgen et al., 2009) contain high phenol, *Ziziphus* contains much more phenol than these fruit species. When compared to cherry and grapefruits with high antioxidant activity, jujube genotypes are superior in this respect (Çağlar and Demirci, 2017; Beyhan et al., 2018).

Results presented in *Table 4* display the organoleptic features of jujube genotypes. The difference between genotypes was statistically significant for flavor (1.00 to 9.00). The best flavor has been identified in genotypes 10 and 7, and there were also remarkable by texture. Considering general acceptability, genotypes 10 (9.00) and 8 (1.67) ranked first and last, respectively. The flavor of fruit was generally described as apple by Kavas and Dalkılıç (2015). It was reported that the product load and fruit flavor were not related to Grande de Albatera variety (Galindo et al., 2015). The variation observed in these characteristics was also demonstrated in 19 genotypes evaluated by Godi and Joshi (2016). In addition to fresh consumption, fruits are also evaluated in different forms such as gel, pickle, and jelly. For this purpose, sensory evaluations are also important (Uddin and Hussain, 2012).

Table 4. *Organoleptic evaluation of jujube genotypes*

St. dev.	2.49	1.53	2.60

The differences in the means were determined by the Duncan test according to $P \leq 0.05$. Flavor: no taste (1), elaeagnus-apple (3), apple-pear (5), elaeagnus (7), apple (9); Texture: soft (3), medium (5), hard (7); General acceptability: poor (1), fair (3), medium (5), good (7), very good (9)

The correlation coefficients between the features examined of jujube genotypes are seen in *Table 5*. Accordingly, the highest correlation was determined between fruit width and length ($r = 0.976$; $p < 0.01$). Further, fruit width and length showed a significantly positive and strong correlation to fruit weight ($r = 0.960$ and 0.968; $p < 0.01$), stone weight ($r = 0.591$ and 0.589; $p < 0.01$) and flesh/stone ratio ($r = 0.918$ and 0.923; $p < 0.01$). Fruit weight had a positive correlation with stone weight and flesh/stone ratio but a negative correlation with total acidity. L*, b*, h° and C* color of the fruit were also found to be correlated. As L* increased, b* ($r = 0.91$), h° ($r = 0.780$), C* ($r = 0.861$) and total acidity ($r = 0.592$) increased; however, pH ($r = -0.757$) and TSS ($r = -0.556$) decreased. Fruit a* value showed a positive correlation to h° value and TSS, but negative correlation to C* value. A positive correlation was observed between fruit b* color and total acidity, stone weight while pH negatively affected TSS. Fruit h° color had a positive and strong correlation with total acidity ($r = 0.659$) but weak correlation with stone weight ($r = 0.404$). Fruit C* value showed a positive correlation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16491660

to total acidity ($r = 0.392$; $p < 0.05$), but negative correlation to pH ($r = 0.754$; $p < 0.01$) and TSS ($r = 0.653$; $p < 0.01$). A negative correlation was observed between antioxidant activity and pH ($r = -0.474$; $p < 0.01$). Total phenol had a positive correlation with L* ($r = 0.407$; $p < 0.05$), b* ($r = 0.412$; $p < 0.05$), h° ($r = 0.468$; $p < 0.01$) and total acidity ($r = 0.431$; $p < 0.05$). From the other side, a negative correlation appeared between total phenol and pH ($r = -0.436$; $p < 0.05$). In jujube with an apple-like flavor; pH and flesh/stone ratio were higher, whereas h° value, total acidity and antioxidant activity decreased. In jujube with hard flesh; fruit weight, flesh/stone ratio, fruit width and length were higher, whereas color a* was lower than soft flesh. Fruit acceptability had a positive and strong correlation with fruit and stone weight, fruit width and length, flesh/stone ratio and texture while weak, and negative correlation with TSS. Positive correlation between phenolic content and antioxidant activity is mentioned (Gao et al., 2012; Imamoglu, 2016; Koley et al., 2016) however, a correlation was not found in our results. This is also confirmed by Li et al. (2005, 2007).

Principal component analysis (PCA) defined 88.850% of the genotypes with 18 properties and was explained by four principal components (*Table 6*). PC1, PC2, PC3 and PC4 accounted for 30.905%, 30.703%, 14.883% and 12.359% respectively of the variability. Consequently, PC1 constituted mainly fruit width, length, weight, acceptability, flesh/stone ratio and stone weight; PC2 included mainly ground color b*, L*, h°, C*, pH, antioxidant activity, and total acidity; PC3 show mainly ground color a*, texture and TSS; PC4 represents mainly flavor and total phenol.

Figure 2 shows biplot based on PCA for fruit quality traits in jujube genotypes in rotated space. PC1 explained fruit width, length, weight, acceptability, flesh/stone ratio, and stone weight. Positive values for PC2 indicated ground color b*, L*, h°, C*, antioxidant activity, and total acidity, while negative PC2 values display pH. Positive values for PC3 represent ground color a* and TSS, while negative PC3 values point out the texture. PCA was performed to study the correlation between fruit quality parameters (Koley et al., 2016).

Extraction method: principal component analysis. Rotation method: Varimax with Kaiser normalization

Clustering analysis (CA) was used to determine the degree of similarity of jujube genotypes, is shown in *Figure 3* as dendrograms. Thus, the genotypes were categorized under two main groups. 6th genotype formed a separate group from the others. The similarities or differences among the jujube genotypes examined with CA showed a correlation with those examined with PCA in terms of investigated characteristics.

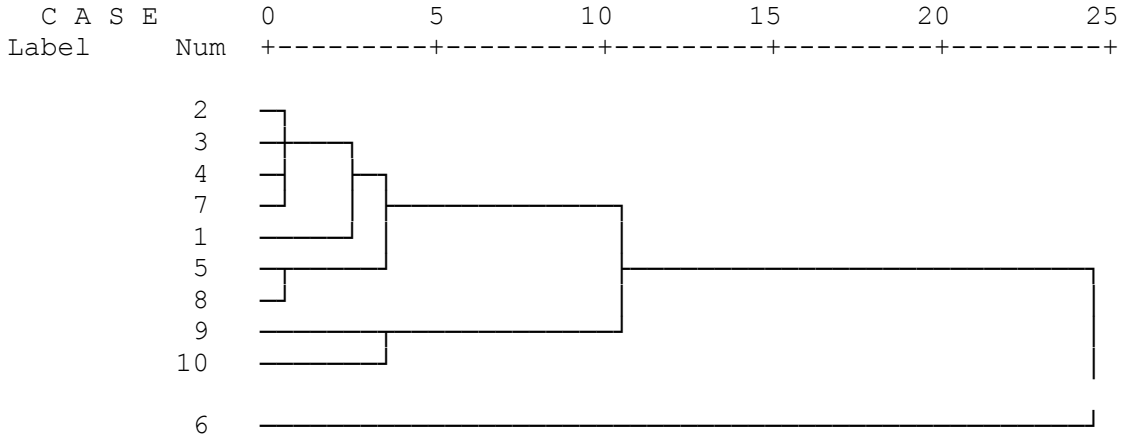

Figure 3. *Dendrogram of hierarchical cluster analysis obtained by Ward's clustering method*

Conclusion

This study was planned to evaluate some fruit characteristics of 10 jujube genotypes collected from the Demirci location in Turkey. In terms of TSS content, especially genotype 8 is very important and this value is also high in genotype 5. Besides, the fruits of these two genotypes are dark red, high phenol content, elaeagnus taste, and soft texture. Genotype 1 is prominent because of its rich antioxidant content. In this respect, it is a natural antioxidant source and can be considered as an alternative healthy food. On the other hand, genotype 6 is a different group from other genotypes due to its high phenol content and light color. Also, the fruits of genotype 10 are large and taste like apple and their acceptability is good. The jujubes mentioned above are suitable for table consumption. They seem to have a beneficial effect on folk medicine due to their phytochemical contents. The identified genotypes show variation under the same ecological conditions. In this context, they are valuable as a genetic resource. These genotypes are promising. In future studies, a patent may be granted for any genotypes. They can also be used as parents in breeding programs. Furthermore, molecular studies can be performed to determine the genetic relationship. For jujube, this study is essential because there is little information in Turkey. It is important to continue such studies in terms of evaluating the present population in nature and identifying genotypes for different purposes.

Abstract. The aim of the research conducted in 2013–2016 at Grabów, Mazowieckie Province, Poland was to compare the yield and nutritive value of a fodder after the renovation of sward and to assess the usefulness of certain legume-grass mixtures for undersowing. A two-factor experiment was established in which the first factor included 3 methods of renovating grassland: 1 - after ploughing; 2 - after the compact disc harrow; 3 - after destroying the old sward with herbicide, sowing with the slit seed drill for direct sowing (Moore type). The second factor was 3 legume-grass mixtures: Krasula, Cent 4 and original. Similar fodder dry matter yields and nutritive values. Along with the increasing percentage of legumes in the sward (under conditions of rainfall deficiency), the protein value of feed (PDI), protein yield and feed filling value (LFU) increased in subsequent years of use. A tendency to lower yields after sowing grassland sward with a mixture Cent 4, containing short-lived grass species (*Lolium perenne* L. and *Lolium multiflorum* Lam.), was observed. The mean nutritive value was suitable for use for meat cattle, dried dairy cows, while in the first year after undersowing, for good beef cattle, older heifers, marginally for dairy cows.
Keywords: *compact harrow, direct sowing, legume-grasses mixtures, ploughing, relative nutritional value*

Abbreviations: RSD, residual standard deviation; v%, coefficient of variation; NDF, neutral detergent fibre ($g \cdot kg^{-1}$); ADF, acid detergent fibre ($g \cdot kg^{-1}$); ADL, acid detergent lignin's ($g \cdot kg^{-1}$); UFL, feed unit for lactation; PDI, protein digested in small intestine ($g \cdot kg^{-1}$); LFU, value of the filling units for lactation; RFV, relative nutritional value

Introduction

Grassland is a source of low-cost and valuable roughage for grasslands animals, mainly ruminants. The high percentage of green forage and fodder processed from grasslands increases the profitability of milk and beef production, ensuring a stable income for farmers (Donnellan et al., 2012). Proper grassland management, productivity, and species and chemical composition play an important role in animal nutrition.

Worldwide, grassland produces food for about one billion people (De Vliegher et al., 2014). In Europe, they occupy about a third of the agricultural area (Lesschen et al., 2014) and are important not only for the production of animal feed and human food, but also for environmental functions which are now more important than economic functions. Grasslands have a positive impact on the natural environment, preventing soil erosion and carbon and nitrogen losses, constituting water reservoirs, maintaining the biodiversity of flora and fauna, increasing soil biological activity, limiting the effects of climate change (by collecting water), protecting nature, as well as providing biomass for energy purposes

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16611677

(Velthof et al., 2010; Zając et al., 2010; De Vliegher et al., 2014; Lesschen et al., 2014; Reinsch et al., 2018). In the recent 30 years, the grassland area has decreased, among other things, due to a decrease in the cattle population, deterioration in the quality of feed, and the introduction of protein concentrates and low-cost soya beans in animal feed, as well as the abandonment of certain grassland (De Vliegher et al., 2014).

In Europe there is a large regional variation in grassland productivity, where the highest productivity, of about 10 $t \cdot ha^{-1}$, is observed in the regions of north-western Spain, the Netherlands, western France, northern Germany, Ireland (Lesschen et al., 2014). In Poland, according to the Central Statistical Office (GUS) data, in 2017 the yields obtained on permanent meadows amounted to 5.42 $t \cdot ha^{-1}$, while on pastures they were even lower (GUS, 2018).

Decrease in yield levels, weed infestation of sward, and its simplified species composition, as well as errors in pratotechniques (i.e., improper use, inadequate fertilization, or one-sided fertilization with nitrogen only), appearance of grass species of low economic value in sward, lack of legumes, inadequate climatic conditions, and in particular, the shortage of precipitation, all lead to the degradation, as a result of which grasslands have to be renovated (Kulik, 2010; Terlikowski and Barszczewski, 2015). This can be carried out by different methods including: fertilization and rational use; reseeding of low-cut sward in a traditional way or with machines constructed for this purpose after mechanical, or chemical destruction of a part of the sward with a heavy harrow or a tiller and applying the method of full tillage after ploughing to completely destruct the old sward (Mocanu and Hermenean, 2009; Kulik, 2010; Zając et al., 2010; Elsaesser, 2012; Reheul et al., 2017). Renovation by full tillage after ploughing, consisting of ploughing up, inverting the furrow-slice and carrying out a set of pre-sowing tillage, is considered the most radical, unfavourable for the environment and costly type of renovation, because it destroys the soil structure. The aerated soil organic matter releases nitrogen and phosphorus and washes out in the form of soluble forms of these components (Kulik, 2010; Velthof et al., 2010; Zając et al., 2010; De Vliegher et al., 2014). McDonald et al. (2011a,b) showed higher mineralization and loss of N_2O and higher leaching of soluble carbon by 10-30% both in manure fertilization and manure-free fertilization after the application of herbicide for the renovation of grassland than after the ploughing and a full set of pre-sowing procedures. Grasslands retain more greenhouse gases than arable land, so their ploughing and conversion to arable land has more drastic environmental consequences. Fewer side effects accompany the renovation of grassland with less invasive methods such as: direct sowing, tillage using rotary tillers and undersowing (Mocanu and Hermemean, 2009; Kulik, 2010; Łyszczarz et al., 2010; Velthof et al., 2010; Zając et al., 2010; Golka et al., 2016). The rate of organic matter mineralization on permanent grassland. On mineral soil can be reduced by ploughing in autumn, and on organic soil - in spring. Studies by Reheul et al. (2017) and Reinsch et al. (2018) did not confirm the effect of the ploughing date (autumn, spring) on yields and N_2O emissions, as similar yields were obtained after ploughing in autumn and spring. According to these authors, N_2O emissions are affected by quality of fodder after grassland renovation (Rehel et al., 2017; Reinsch et al., 2018).

In literature, there are different opinions regarding the increase in the level of yield and the improvement of the feed quality after the renovation of greenery. Mocanu and Hermenean (2009), who renovated the sward by direct sowing with a special seed drill, achieved an increase in dry matter yield by 48.5% to 134% in of protein yield by 105-129% in relation to the control (degraded meadow). Kayser et al. (2018) believe that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16611677

all renovation techniques lead to an increased productivity and that the renewed sward should be used properly to maintain valuable grass and legume species. Łyszczarz et al. (2010), in turn, describe the re-degradation of sward already after about three years after renovation, when the yield of the renovated sward became equal to that obtained on meadows not fertilized for 20 years. The effects of the renovation are not always positive, as there is often no increase in yield and quality of the forage and no guarantee of a long-term renovation effect (Elsaesser, 2012).

It was decided to evaluate the effect of grassland renovation methods on the yield of dry matter and protein as well as the relative nutritional value of fodder in conventional conditions. The usefulness for reseeding of several legume-grass mixtures available on the Polish market was also checked.

Material and methods

Site, location, and climate

A two-factor field experiment was carried out at the Agricultural Experimental Station of the Institute of Soil Science and Plant Cultivation in Grabów, Mazowieckie Voivodeship (51°21′ N; 21°40′ E), Poland in the years of 2013–2016. It was established on according to FAO – WRB classification system 2014, Umbrisols and Phaeozems. It was characterized by a neutral reaction (pH in 1 M KCl 6.6) the available nutrient content of the soil was as follows (mg·100 g^{-1} soil): phosphorus 10.8 (average content), potassium 6.02 (low content) and magnesium 12.3 (high content).

Meteorological conditions

The field experiment was located in a temperate continental climate zone. Meteorological conditions during the study period were varied (*Fig. 1*). In Polish condition, for permanent meadows, optimal rainfall during the growing season is 420 mm, slightly larger are characterized by permanent pastures – 450 mm, rainfall distribution in individual months is also important (Grabarczyk, 1989). According to this author (Grabarczyk, 1989), optimal rainfall in meadows and pastures grasslands and average air temperature should be: in April - precipitation - 50 mm, average air temperature - 8°C; in May - rainfall of 65 mm (meadows) and 70 mm (pastures), air temperature - 13°C; in June - rainfall - 80 mm (meadows) and 90 mm (pastures), air temperature - 16°C; in July - rainfall 90 mm (meadows) and 100 mm, air temperature - 18°C; in August - precipitation is 80 mm of precipitation, air temperature - 17°C; in September - rainfall 55 mm (meadows) and 60 mm (pastures), air temperature 14°C. Optimal rainfall for grassland was recorded in May 2014 (120 mm precipitation), June 2013 (115 mm precipitation), July and August 2014 (100 mm and 80 mm, respectively) and in September 2015 (93,9 mm). In the remaining research period, and especially in 2016, the lack of rainfall was significant, therefore in the second and third years of use (2015 and 2016) the efficiency of thinned sward was estimated only in the first three shoots. The last revival of sward was grazed without prior crop evaluation or botanical mass analysis.

The mixtures were sown under good humidity and thermal conditions, after heavy but uneven rainfall. Favourable conditions promoted the germination, initial growth and development of crops and weeds. In summer, weather conditions deteriorated during the sowing year. In 2014, the average monthly precipitation was above the long-term average

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16611677

for this period, with the highest storm precipitation in May (*Fig. 1*). In 2015, May, June and September, humidity conditions were conducive to the development of the sward. In the remaining period, the deficiency of precipitation and temperatures higher than the long-term average, resulted in poor regrowth, therefore only three sward harvests were carried out. The year of 2016 was the driest and warmest year compared to the other years, so the growth of the sward in this period was limited. As in the previous year, only 3 harvests were carried out, and the fourth sward regrowth was grazed upon by cows. Habitat and climate conditions determine the success of the renovation. Of special importance are humidity conditions in the year of sowing, not only during the procedure but also within a few days after sowing (Bélanger and Tremblay, 2010).

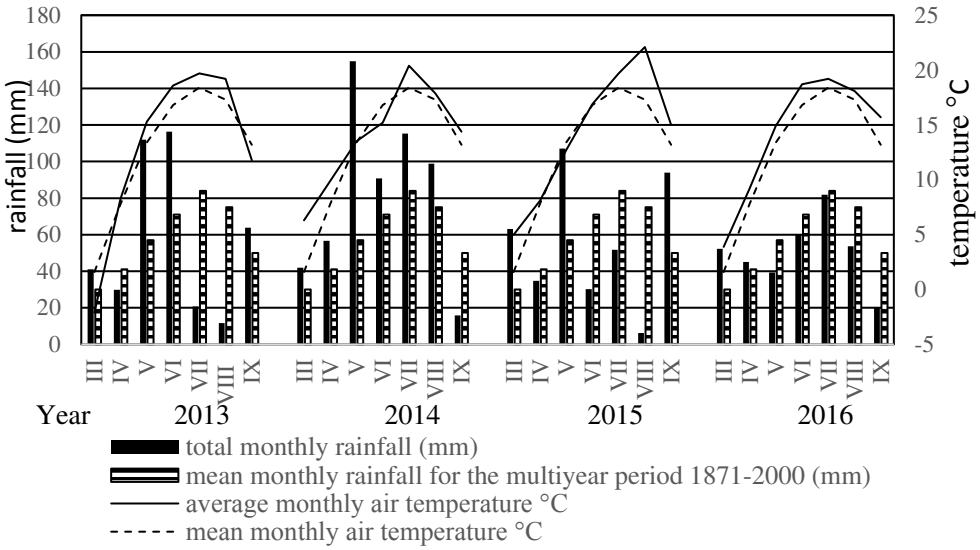

Figure 1. *Meteorological condition in the years 2013–2016 Grabów, Poland during the growing season*

Experimental treatments and design

Studies on the effect of grassland renovation on dry matter, protein yield, and nutritive value of the renovated sward were carried out in a two-factor experiment sown in the split-block system, in four replicates, on a gross area of 0.6 ha. The factors studied were three methods of renovating grassland:

1) ploughing and full tillage, plus sowing of legume-grass mixtures with a grain seed drill;

2) destruction of the sward with a compact disc harrow and sowing of seeds with a grain seed drill;

3) destruction of the old sward with a herbicide and sowing of seeds with a seed drill (Moore type). The second factor were three mixtures of legumes and grasses:

K - Krasula + 3.5 kg white clover (*Trifolium repens* L.) 'Romena' consisting of: perennial ryegrass (*Lolium perenne* L.) (25.7%), Italian ryegrass (*Lolium multiflorum* Lam.) (9.19%), meadow timothy (*Phleum pratense* L.) (13.79%), orchard grass (*Dactilis glomerata* L.) (9.19%), red fescue (*Festuca rubra* L.) (9.19%), tall fescue (*Festuca arundinacea* Schreb.) (9.19%), sheep's fescue (*Festuca ovina* L.) (4.59%), red clover (*Trifolium pratense* L.) (4.59%), lucerne (*Medicago sativa* L.) (4.59%), bent grass

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16611677

(*Agrostis alba* L.) (1.83%) + 3.5 kg·ha^{-1} white clover (*Trifolium repens* L.) ('Romena', 8.11%); seed sowing rate – 40 kg·ha^{-1}.

C - Cent 4 consisting of: perennial ryegrass (*Lolium perenne* L.) (40.0%), Italian ryegrass (*Lolium multiflorum* Lam.) (10.0%), tall fescue (*Festuca arundinacea* Schreb.) (15.0%), meadow fescue (*Festuca pratensis* Huds.) (5.0%), meadow timothy (*Phleum pratense* L.) (5.0%), meadow bluegrass (*Poa pratensis* L.) (5.0%), festulolium (*Festulolium braunii* (K. Richt.) A. Camus) (5.0%), lucerne (*Medicago sativa* L.) (10.0%) and white clover (*Trifolium repens* L.) (5.0% %); see sowing rate – 35 kg·ha^{-1}.

O - original mixtures consisting of: of white clover (*Trifolium repens* L.) 'Barda' (10.0%), hybrid lucerne (Medicago x varia Martyn Fl. Rust.) 'Radius' (20.0%), red clover (*Trifolium pratense* L.) 'Milena' (20.0%) (legumes accounting for 50.0% in total), perennial ryegrass (*Lolium perenne* L.) 'Artemis' (15.0%), orchard grass (*Dactilis glomerata* L.) 'Amila' (15.0%), meadow fescue (*Festuca pratensis* Huds.) 'Anturka' (10.0%), festulolium (*Festulolium braunii* (K. Richt.) A Camus) 'Agula' 10.0% in pure sowing; seed sowing rate - 23 kg·ha^{-1}.

In the spring of 2013, the necessary cultivation procedures were carried out on the grassland to be renovated in accordance with the experiment scheme. The ploughing was carried out to a depth of 30 cm (treatment 1). Under the conditions of the renovation, the top layer of soil was loosened to the depth of 5 cm with a compact disc harrow (treatment 2) by a simplified method. On the treatments with direct sowing, the development of degraded sward was inhibited with Roundup 360 SL at a dose of 6 l per hectare (treatment 3). Legume-grass mixtures were sown in the second decade of June. In the summer, the sward was mowed twice in order to inhibit the development of weeds. In October the whole area of the experiment was grazed upon by cows. A total of 6 cuts of sward for haylage were carried out during the study and 9 short term grazing's (2–3 days of grazing) of 79–85 productive cows, were carried out. In the sowing year, two swaths were made for the mechanical weeding of sward mixtures and one grazing of cows on the surface of the entire experiment (2013 year). In the first year of use (2014 year), the first and second regrowth of sward was cutting, while in the second and third year of use (2015 and 2016 year) only first sward regrowth was intended for silage. Cows were grazed on the remaining sward regrowth. During the period of field research in the years 2023-2016 no chemical protection of sward mixtures was carried out.

Pre-sowing and top dressing fertilization

Superphosphate (40% P_2O_5) in the amount of 60 kg ha^{-1} P_2O_5 and potassium salt (60% K_2O) in the dose of 60 kg ha^{-1} were used before the sowing.

In each year of full use, during the spring start of the mixture's growing season, it was fertilized with phosphorus – 80 kg ha^{-1} P_2O_5, potassium – 36 kg ha^{-1} P_2O_5 and nitrogen (ammonium nitrate) - 34 kg ha^{-1} N. After the first regrowth was harvested, the sward was fertilized with potassium - 60 kg ha^{-1} K_2O in the first year of use, 40 kg ha^{-1} K_2O in the following years, and with nitrogen 31 kg ha^{-1} N. In the second year of use, phosphorus in the dose of 40 kg ha^{-1} P_2O_5 was also applied. In all years of use, after the second and third harvest / grazing, the sward was fertilised with nitrogen in the amount of 31 kg ha^{-1} N.

Measurements

Green matter yield was determined on the basis of green forage samples taken from the area of 10 m^2 from each plot. During harvesting, two samples of green forage weighing 0.5 kg were taken to calculate the drying rate (%) and to perform a simplified

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16611677

botanical analysis of sward (grass of all species together, lucerne, white and red clover together, weeds). An analysis of the botanical composition of sward was carried out in each regrowth, and the percentage of a given plant fraction (lucerne; clover; grasses) in the total dry matter of the sample, was calculated.

Chemical analysis

The assessment of the chemical composition and feed value of the sward was carried out in an accredited IUNG-PIB laboratory in Puławy, Poland. Plant material from the first sward regrowth, in each of the 3 years of full use, was analysed. For chemical analyses, a sample of 0.5 kg of green fodder was taken from each plot. After drying, the plant material was combined into object tests and ground. Chemical analysis was carried out in some of the prepared plant material. The dry matter content of mixtures was determined by weight method according to test procedure PB 35.1 - first edition -10.05. 2013, total nitrogen - flow analysis (CFA) (PB 33.1- second edition -05.03.2014); while the contents of crude fibre and fibre fraction (Neutral Detergent Fibre -NDF; Acid Detergent Fibre - ADF; Acid Detergent Lignin's - ADL) - according to test procedure PB 51. 1 - second edition - 01.08.2013. The results of chemical analyses were used for the nutritional assessment of biomass according to the Linn and Martin (1989) based on the fibre fraction content. The evaluated classification parameter was relative feed value calculated on the basis of fibre fraction content according to the formula (*Eq. 1*) (Linn and Martin, 1989):

$$RFV = [DDM \times DMI]:1.29 \quad \text{(Eq.1)}$$

where,
DDM (dry matter digestibility in %) = $88.9 - 0.779 \times$ ADF,
DMI (dry matter intake in % body weight) = (DMI=120 : NDF),
NDF – neutral detergent fibre,
ADF – acid detergent fibre.

The relative feed value (RFV) obtained from the calculation was compared with feed quality classes and the ranges of RFV developed by Jeranyama and Garcia (2004) for cattle.

Statistical analysis

For comparison of dry matter yields and total protein yields in the first cut, the content of total protein, crude fibre in mixtures' dry matter, digestibility of organic mass, content of neutral and acid detergent fibre (NDF, ADF and ADL), as well as relative nutritional value, the analysis of variance was applied. Calculations were performed in the program Statistica (Stat Soft Inc., USA). The Tukey's test ($P \leq 0.05$) compared the mean values for the factors tested in the field experiment; the 1st factor – three methods of grassland renovation; the 2nd factor – three legume-grass mixtures.

Results and discussion

Botanical composition

In the sward renovated with the full tillage method after ploughing (1), after disc harrow (2) and after the application of herbicide and direct sowing (3), in all years of use, grasses dominated in spring regrowth (*Fig. 2*). Their percentage was varied and amounted

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16611677

to about 72% to 93% of the sward. The percentage of legumes in the sward increased in summer and autumn, and in the second and third year of use, there were more legumes than grasses in the sward. Among legumes, in the first two years of use of mixtures, there were more clovers (white clover and red clover in total) than lucerne in the sward. However, the situation changed due to a shortage of precipitation. In the third year of use, lucerne prevailed in the sward, as this plant tolerated the deepening drought, while part of clover and grass plants receded from the sward during this period.

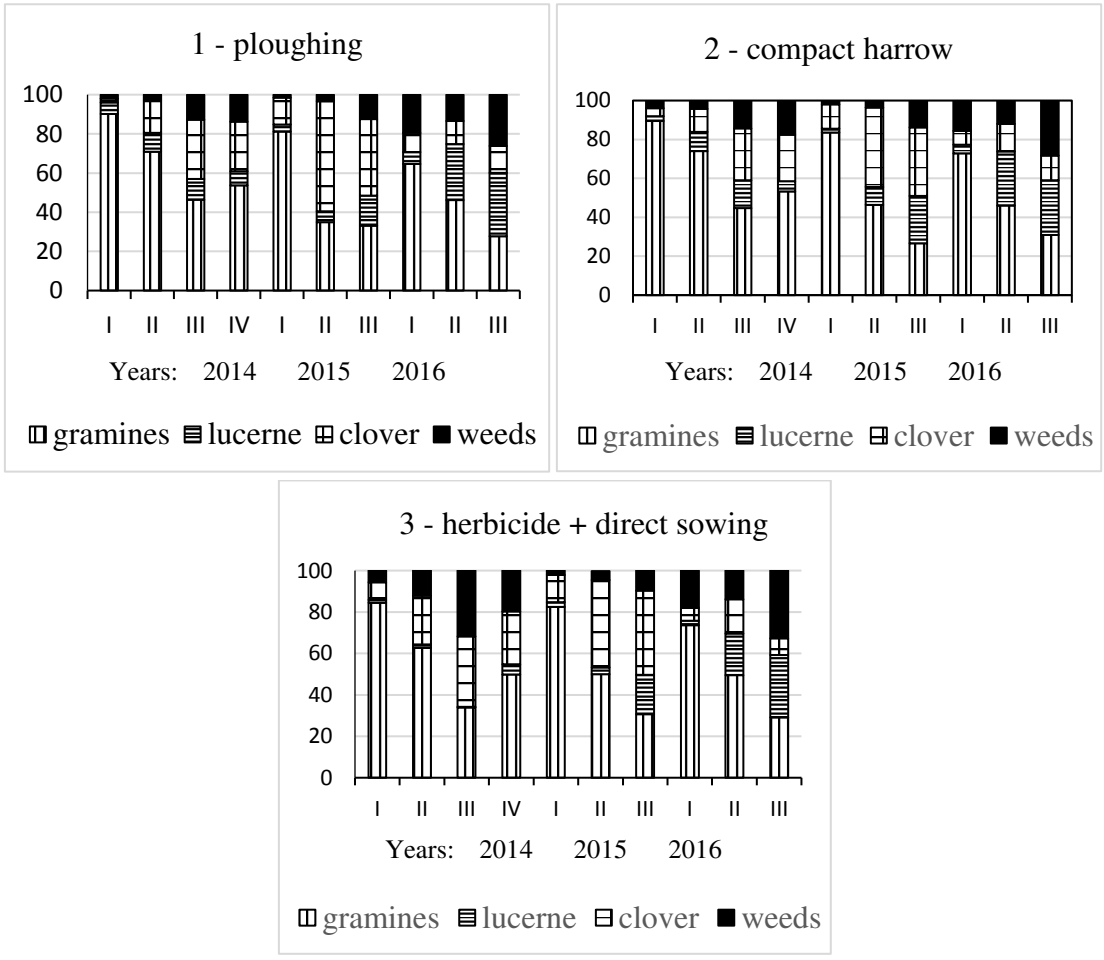

Figure 2. *Percentage of components in the dry matter yield of legume-grass mixtures depending on the method of sward renovation in 2014–2016 (%)*

Due to different sensitivity to drought, multi-species mixtures of legumes and grasses should be used for the renovation of grasslands as their varied development in subsequent years of use and different water needs may increase the sward longevity and success of this procedure (Łyszczarz et al., 2010; Isselstein and Kayser, 2015). Under non-precipitation conditions, weed infestation of the sward increased, especially in the second and third year of use (*Fig. 2*), being particularly high at the end of the third year of use. The sward weeded faster on the treatment with the use of herbicide to inhibit the development of sward and with direct sowing with a special slit seed drill (treatment 3). In this research treatment, part of the weeds was not completely destroyed by herbicide spraying and regenerated quite quickly. The same was true for the simplified tillage,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16611677

which involved moving the topsoil to a depth of 5 cm with a compact disc harrow (treatment 2), where some legumes and weeds with a deep root system (such as *Taraxacum officinale* Wep.) grew back quickly.

There were 18% of legumes (including red clover, lucerne and white clover) in the sown mixture Krasula seeds, 15% – in the mixture Cent 4 (lucerne, white clover), and 50% in the original mixture (white clover, hybrid clover and red clover). The percentage of components in the sward of mixtures changed dynamically in the years of use, and varied significantly from the species composition of seed mixtures (*Fig. 3*). In the spring of the first year of use, grasses dominated in the sward of the compared mixtures (from about 80% to 92% of the sward yield). However, already in the third growth of sward, their percentage was only about 40% of dry matter yield. In this period the percentage of clovers and weeds increased as well. In every year of use, in summer and autumn, when the lack of moisture in the soil was significant, legumes dominated in sward (especially in 2015 and 2016). In the second year (2015), these were clovers, while in the drier third year of use (2016) - lucerne. The weed infestation of the sward increased as well, with the highest weed infestation during the whole period of use being recorded for mixture Cent 4. At the end of the third year of use, weeds accounted for as much as 47% of the dry matter yield of this mixture. At that time, the sward of the original mixture was the least weeded (about 17% of weeds).

A small number of herbs and weeds in the sward (especially when used for grazing) is attractive for animals, as it improves the taste of the sward, and in the case of legumes, also the quality of feed, because the rate of decrease in the nutritive value of this group of plants is lower than that of grasses (Peyraude et al., 2009). Factors that make it possible to maintain biodiversity in the sward include proper use, proper fertilization, and grazing upon by a small number of animals, as well as proper selection of legume and grass species for mixtures (Klimek et al., 2007; De Vliegher et al., 2014; Głąb et al., 2016).

Dry matter production

During the three-year period of use, the method of renovation (full tillage after ploughing - treatment 1; surface soil disturbance to a depth of 5 cm with a compact disc harrow - treatment 2; sward spraying with herbicide and direct sowing - treatment 3) had no significant effect on dry matter yields (*Table 1*). In the years of use, no interaction was found between the factors investigated, i.e. the method of renovation of green use and mixtures used for renovation. The coefficient of variation (v%) indicates a small differentiation of dry matter yields in the first and second year of use of mixtures (2014 and 2015 years) and average yield changes in the third year of use of mixtures (2016 years; v% = 24.9).

The highest yields were harvested in the first year of use (from 10.65 to 11.21 t $ha^{-1)}$. In the following years, the yield decreased due to deteriorating humidity conditions and summer drought. The lowest yields (about 8.4 t ha^{-1}) were obtained in the second year of full use (2015), when the deficit of precipitation in relation to the long-term average was the highest (*Table 1*). Good pluviometric conditions before sowing and in the year following the renovation were conducive to the development and yield of the mixtures. Similar observations on this subject are presented by Bélanger and Tremblay (2010). Literature contains various contradictory information about the yields of the renovated sward. Terlikowski and Barszczewski (2015) and Golka et al. (2016), after the renovation, achieved improved yield and use value of sward. However, Velthof et al. (2010), Reheul et al. (2017), Grace et al. (2018) and Kayser et al. (2018) argue that renovation does not

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16611677

always lead to higher sward yields. Kulik (2010) considered the resowing performed directly into the old sward (without earlier inhibition of sward development) to be the most unreliable method of renovation in comparison with the use of herbicide or a tiller to limit the growth of the degraded sward. In turn, in the studies of Łyszczarz et al. (2010), the use of herbicide and disc harrow before resowing turned out to be the most effective method of renovation, while direct sowing into the sward with special seeders was completely unsuccessful.

The species composition of legume-grass mixtures used for resowing the sward had a significant impact on the yields only in the first year of use (2014) (*Table 1*). Statistical analysis showed that the original mixture (treatment A) produced significantly higher yields (about 12 t·ha^{-1}) in comparison of with mixture Cent 4 (9.90 t ha^{-1}). The original mixture (treatment A) consisted of 3 species of legumes: white clover (10%), hybrid lucerne (20%) and red clover (20%), while the mixture Cent 4 was composed of two species of legumes in smaller amounts: lucerne (10%) and white clover (5%). Earlier studies confirmed the effect of the percentage and species of legumes on the yield and quality of feed obtained from legume-grass mixtures (Elgersma and Søegaard, 2016, 2018). In other studies, the lack of common cocksfoot in the mixture used for sowing and the high proportion of perennial and Italian ryegrass were found to be the cause of low yields of dry matter, energy, and protein per unit area (Gaweł et al., 2018). Legumes from the mixtures enter into symbiosis with nitrogen-binding bacteria from the air, which in different amounts, depending on the species or even the cultivar of legume, is transferred to the grasses in the mixtures. Therefore, the longevity and frost resistance of this group of plants affects the quality of feed from the mixtures (Bélanger and Tremblay, 2010). In addition, the grasses absorb nitrogen from the soil by absorbing the biologically-bound nitrogen. Isselstein and Kayser (2015) recommend multispecies legume-grass mixtures for renovation of sward, but their opinion is not always confirmed in practice, as evidenced by similar yields of multispecies and simplified mixtures described by Grace et al. (2018).

In the second and third year of use (2015 and 2016), when humidity conditions deteriorated, the dry matter yield of the compared mixtures did not differ significantly, amounting to 7.91–8.86 t ha^{-1} (*Table 1*). In this period, the lowest yield was obtained from a mixture the Cent 4, in which perennial ryegrass and Italian ryegrass accounted for 50%,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16611677

while the common cocksfoot did not occur at all. This type of grass, according to our own research, determines the durability and productivity of sward after resowing (Gaweł, 2017; Gaweł et al., 2018) (*Table1*).

Organic components

In the period of three years of use, no significant differences were found in the concentration of total protein, crude fibre and organic matter digestibility in the sward renewed with comparable methods: full tillage after ploughing (treatment 1) and simplified tillage after surface soil disturbance to the depth of 5 cm (treatment 2), as well as after the inhibition of sward development with herbicide and direct sowing (treatment 3) (*Table 2*). Different results were obtained under ecological conditions, where the sward renovated using the simplified method after the compact harrow (treatment 2) had a higher content of total protein than the sward after ploughing (treatment 1) (Gaweł, 2017). There was no significant effect of the percentage and species of legumes in the sown mixtures on the abundance of the first cut in total protein. Vasiljević et al. (2011) describes seasonal changes and significant differences among cultivars of red clover in total protein concentration. In our own studies, the total protein content of sward increased in the third year of use, as legumes were better able to withstand the lack of moisture in the soil and their percentage in the sward was higher than that of grasses. In Mediterranean conditions, Mantino et al. (2016) also showed a positive correlation of the share of lucerne in the sward with the protein content in the dry matter of the mixtures and negative with the concentration of the neutral fibre fraction (NDF). Tremblay et al. (2015) believe that correctly selected species of legumes and grasses for mixtures offer an opportunity to balance energy and protein in feed.

Usage of the renovation of the grassland: 1* – ploughing, 2 - compact disc harrow, 3 – herbicide + direct sowing. Mixtures: K** – see *Figure 3*. Values in bold are statistically significant ($P \leq 0.05$)

In the second year of use, in the conditions of the renovation with the simplified method, after surface soil disturbance to the depth of 5 cm (treatment 2), the abundance of dry matter in fibre was significantly lower in comparison to the one obtained on the treatment with the renovation after ploughing (treatment 1) (*Table 2*). The species composition of mixtures used for resowing had no effect on the crude fibre content, which

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16611677

ranged from 276.67 to 346.00 g kg^{-1} dry matter. The method of renovation and species composition of mixtures for resowing of the sward did not significantly affect the digestibility of organic matter. A significant decrease in organic matter digestibility in the third year of use was probably due to high weed infestation and the predominance of legumes in the sward of mixtures (*Figs. 1 and 2*). It is known from the literature that legume plants are characterized by a high concentration of crude fibre, especially of lignin fraction (Montino et al., 2016; Elgersma and Søegaard, 2018).

The method of renovation and species composition of legume-grass mixtures had no significant effect on the content of neutral and acid fractions of fibre and lignin in dry matter (*Table 3*). Most often, the fibre content increased in the third year of use of sward. It is known from the literature about the high abundance of legumes (especially lucerne) in fibre fractions (Elgersma and Søegaard, 2016). According to Bélenger and Tremblay (2010), lucerne contains more neutral fibre fraction (NDF), and the organic matter digestibility of this species is lower than that of grasses. In addition to the age of the plants, weather conditions (warmth, good sunshine) also increase the concentration of fibre in the sward. This is confirmed by the Elgersma and Søegaard (2018) study, which showed that in dry years the contents of NDF and ADF in the dry matter of sward increased. Vasiljević et al. (2011) emphasize the importance of the development stage of plants at harvest time in the evaluation of feed quality.

Nutritive value

There was no effect of sward renovation method and species composition of mixtures used for resowing on the nutritive quality of feed (*Table 4*). Lack of significant differences in nutritive value may be associated with the analysis of chemical composition only in the first growth of sward. As Vasiljević et al. (2011) have shown, the abundance of sward in minerals increases during the growing season, while spring regrowth is characterized by a low concentration of nutrients, energy, and protein. The 3-year average economic and production analysis carried out in this experiment also did not show any influence of the examined factors on the content and net production of energy units and kilograms of total protein produced from one hectare (Gaweł et al., 2018).

UFL – feed unit for lactation, PDI – protein digested in small intestine, LFU – value of the filling units for lactation. Usage of the renovation of the grassland: 1* – ploughing, 2 - compact disc harrow, 3 – herbicide + direct sowing. Mixtures: K** – see Figure 3

The experiment calculated the value of filling units (LFU) to evaluate the ability of animals to consume roughage with the lowest possible consumption of concentrates (*Table 4*). The influence of the sward renovation method and the species composition of mixtures on this parameter of feed quality were not found. It is believed that the nutritive value is influenced by the proportion of legumes in sward, which age slower than grasses (Peyraud et al., 2009). Rook and Yarrow (2002) obtained a higher filling value in the case of legumes than in the case of grasses, despite the high content of lignin fractions in the dry matter of these plants.

Yield of total protein and relative nutritional value

The compared methods of grassland renovation and species composition of mixtures had no significant effect on the total protein yield in the first year of use from 370.4 to 578.1 kg ha^{-1}, and in the third year of use 716.3 to 773.8 kg ha^{-1} (*Table 5*). The observed increase in protein yield in the third year of use resulted from the high percentage of legumes in the sward of mixtures in this period (*Figs. 2 and 3*). Renovation of permanent grassland carried out in north-eastern Poland by direct resowing and full tillage showed an increase in protein yield by an average of 300 kg ha^{-1} in relation to the control (Terlikowski and Barszczewski, 2015). On the other hand, after renovation by direct sowing with a slit seed drill, Mocanu and Hermenean (2009) recorded an increase in protein yield by 105–129% in relation to the control.

In the three-year period of use, no significant influence of the method of renovation of grassland and species composition of mixtures on relative feed value (*Table 5*) was found. The best-quality relative nutritional value, of class III, was obtained in the first year of use of the mixtures, due to the achieved compartments value of 103.42-114.93. According to Jeranyama and Garcia (2004), quality grading tables, good beef cattle, older heifers and marginally, dairy cows may be consumers of this feed. In the following years of use, the obtained fodder was classified to the class IV quality, intended for feeding meat cattle or dried dairy cows.

Conclusions

1. The compared methods of renovation of grassland sward (full tillage method after ploughing - treatment 1); simplified tillage after surface soil disturbance to the depth of 5 cm with a compact disc harrow - treatment 2); destruction of degraded sward with herbicide and sowing of mixtures with Moore slit seed drill - treatment 3), gave similar production results, therefore all of them are considered useful in conditions of research for renovation of degraded grassland.

2. In the three-year period of use, characterized by a periodic precipitation deficiency, a tendency to weaker yields for the mixture Cent 4, with short-lived species of grasses, including perennial and Italian ryegrass, was recorded compared to the mixture Krasula and the original mixture.

3. Regardless of the method of renovation and species composition of mixtures used to renovate the sward, legumes withstood moisture deficiency better than grasses, and their percentage in the sward increased in subsequent years of use. Increasing percentage of legumes in the sward positively influenced the content of protein value (PDI), value of the filling units for lactation (LFU) and protein yield (kg ha^{-1}).

4. Good beef cattle, older heifers, and marginally, dairy cows can be fed with fodder obtained in the first year after the renovation of the sward because of range of the relative nutritive value achieved. In the following years, the relative nutritional value worsened, which is why the feed should be used to feed animals with lower nutritional requirements, i.e., meat cattle or dried dairy cows.

5. In the years characterized by rainfall deficiency, renovation of grassland can be carried out by the method of destruction of the sward with a compact disc harrow and sowing of seeds with a grain seed drill. Under these conditions, reseeding should be used, among others, for species that tolerate soil moisture deficiency, such as alfalfa and cocksfoot.

Abstract. Phylum Nematoda is one of the most abundant group of metazoans. Root-knot nematodes (*Meloidogyne* spp.) pose a risk to agricultural crops in the world. The *Meloidogyne* genus comprises about 100 species and their host range includes more than 3000 plant species. *Meloidogyne incognita* is one of the most predominant species of this genus damaging a variety of field crops and vegetables. It is very difficult for farmers to diagnose its symptoms due to similarities with nutritional deficiencies. However to overcome this issue, the literature review of researches on the identification, classification, life cycle, symptoms, economic impact and management strategies of *M. incognita* was planned. The literature review provides an overview and useful information regarding decisions about management of this nematode species in the future.
Keywords: *Nematoda, Metazoan, economic impact, management, deficiencies*

Introduction

Phylum "Nematoda" is an abundant collection of metazoan on earth (Ahmed et al., 2016; Kergunteuil et al., 2016). Nematodes are common, extensively distributed and well adaptable group of organism that directly impact economy due to massive losses to crops. Nematodes covered about 90% of all multicellular organisms (Çetintaş et al., 2017). Nematodes are usually rounded in cross-section, both ends tapering and elongated in shape. They are heterosexual and possess all systems of higher organisms excluding the circulatory or respiratory systems. They are parasites of animals, insects, humans, and plants. Some of them feed upon decaying matters, bacteria and on other micro-organisms.

Plant parasitic nematodes caused lesions in plants and produced secondary infection in them by facilitating other organisms such as fungus, bacteria and viruses (Smant et al., 2018). However, damage caused by nematodes is frequently not easy to differentiate from other reasons because of their microscopic size. They are usually live in soil, roots and in leaves and cause enormous threat to agriculture, about upto US $ 157 billion

annual losses (Youssef et al., 2013). Some of them are migratory in nature whereas others are sedentary (Kihika et al., 2017; Palomares-Rius et al., 2017).

The most destructive nematodes genera are *Heterodera*; *Meloidogyne*; *Rotylenchulus*; *Helicotylenchus*; *Tylenchorhynchus*; *Pratylenchus*; *Ditylenchus*; *Xiphinema*; *Longidorus*. Most of plant parasitic nematodes belong to order Tylenchida while *Xiphinema* and *Longidorus* belong to order Dorylaimida. They caused extensive losses to the crops because a number of them are vectors of some viruses (Lizanne and Pai, 2014).

Meloidogyne genus is one of the most destructive pathogen (Kamran et al., 2014; Xiang et al., 2017). They are economically important parasites and one of the most damaging pests of vegetables and others crops (Anwar and McKenry, 2010; Kamran et al., 2012; Castagnone-Sereno et al., 2013). They are cosmopolitan and recorded from Africa, Asia, Caribbean, Central, North and South America, Europe and Oceania. They are obligate parasites of woody plants, monocotyledonous and dicotyledonous herbaceous plants. This genus has approximately 100 species while four major species are *M. arenaria*; *M. hepla*; *M. incognita* and *M. javanica* (Hunt and Handoo, 2009; Lunt et al., 2014).

The major four species of Root-knot nematodes (RKN) are present in People's Republic of China but *M. incognita* is one of the most predominant (Dong et al., 2014). It has wide host range and cause dramatic yield loss in China (Naranjo and Ellsworth, 2001; Shun-xiang et al., 2001). It directly and indirectly damages the crop like toppling, loss of yield, poor quality, delay in maturity and also causes losses of economic importance etc. (Yan et al., 2011; Onkendi et al., 2014).

They have been controlled by synthetic chemicals but pose risks to soil environment, costly, highly toxic. Some of them are a carcinogenic agent, that's why most nematicide chemicals have been withdrawn from market for example methyl bromide, ethylene dibromide (EDB) and dibromochloropropane (Onkendi et al., 2014; Nicol et al., 2011). Nowadays scientists are mainly focused on crop rotation, plant resistance, bio-control and cultural practices to overcome this problematic issue (Chitwood, 2002). Bio-control is safe and eco-friendly in application compared to chemicals because it has no residual effects on food (Cetintas et al., 2018).

Identification of *Meloidogyne incognita*

For identification of *M. incognita* mostly morphological, molecular and isoenzymatic characters are used. Morphological study of perineal patterns of female has been most commonly used characcter for the identification. Whereas, sometimes morphological characters of different species overlap with each other that is why molecular identification is used for accurate diagnosis. Different methods have been employed for molecular identification like DNA Marker; ribosomal Large Subunits (LSU) D2/D3 expansion segments (Rius et al., 2007), Small Subunits (SSL) (Powers, 2004), Mitochondrial DNA (Xu et al., 2004; Jeyaprakash et al., 2006) , intergenic spacer (IGS) (Wishart et al., 2002), Random amplified polymorphic DNA (RAPD) (Adam et al., 2007), internal transcribe spacers (ITS) (Skantar et al., 2008) and Sequence-Characterized-Amplified Regions (SCAR) (Randig et al., 2002). Isoenzyme phenotyping is based upon relative mobility of enzymes extracted from mature females of *M. incognita* on gel electrophoresis (Cunha et al., 2018). Morphological, molecular and biochemical data should be combined to improve the determination and reliability of diagnosis.

Life cycle of *Meloidogyne incognita*

The life cycle of *M. incognita* consists of five different stages; egg, J2, J3, J4 and adults (*Figure 1*). The female present in plant roots laid eggs, that developed into J2 juveniles. Hatching of eggs are temperature driven usually without requiring any stimulus from plants (Karssen et al., 2013). J2 infecting host roots and complete further developmental stages on feeding sites however J3 and J4 juveniles have sedentary nature and J4 molt into female or male adult. After fertilization females remained in plant roots and produced egg masses. Usually females reproduce through mitotic parthenogenesis (Hussey and Janssen, 2002).

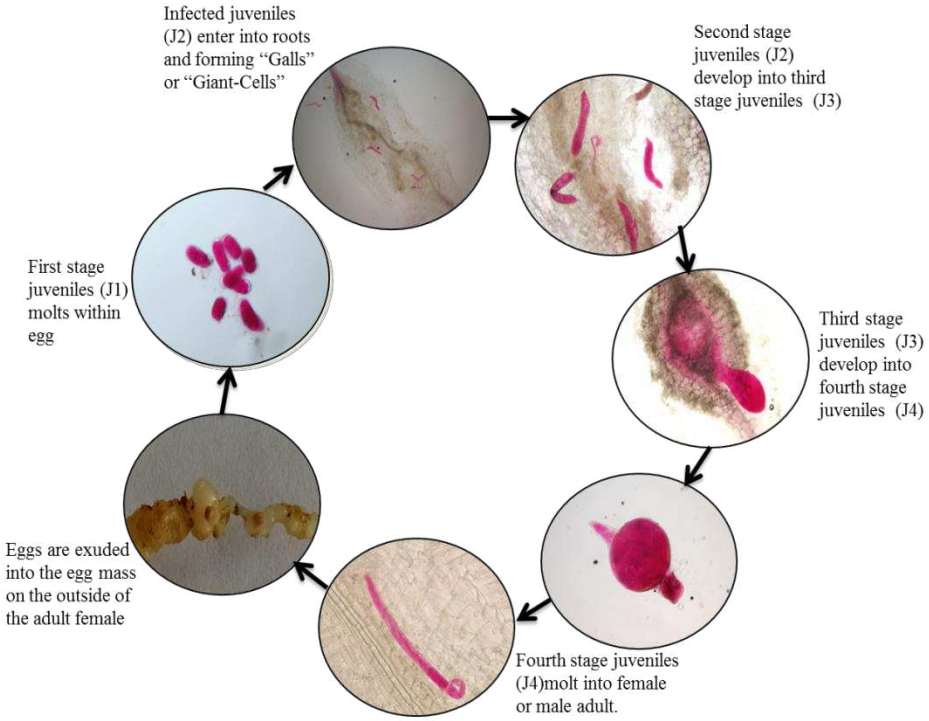

Figure 1. *Life cycle of Meloidogyne incognita*

Symptoms produced by *Meloidogyne incognita*

Plants infected by *M. incognita* showed nutritional deficiency i.e. yellowing of leaves, stunted growth, wilting and plant death (Priya et al., 2011). The farmers did not diagnose its damage due to similarities with nutritional deficiencies like chlorosis (Zeng et al., 2018; Ye et al., 2015). It developed the gall or swelling and cell expansion in roots of infected plant. Infected roots showed bushier and shorter length compared with healthy roots (Miyashita et al., 2014; Ma et al., 2013). The host range of root knot nematodes included more than 3000 plant species (Abdellatif et al., 2016). That's why it is difficult to find any common crop which was not parasitized by it (Castagnone-Sereno et al., 2013). They directly feed upon plants and cause the lesion in it which helps secondary pathogens such as pathogenic bacteria, fungus and viruses that cause secondary infections (Smant et al., 2018; Palomares-Rius et al., 2017).

Management strategies

The main objective of controlling *M. incognita* in soil is to secure crops from its attack to obtain maximum yield (Norshie et al., 2011). Different approaches have been implemented to control *M. incognita* such as chemical control, biological control, cultural control and use of resistant cultivars.

Chemical control

Nematicides are the most effective method to control the *Meloidogyne* spp. but they contain active components of Aldi-carb (Temik), methyl bromide and some other compounds which are prohibited. Chemical nematicides contain usually harmful agents which severely damage the ecosystem (Onkendi et al., 2014). Nematicides can reduced the high populations of root knot nematodes but unable to eliminate completely and accumulate in plant tissues (Sirias, 2011). Chemical nematicides are grouped into non-fumigant and fumigant and non-fumigant depend upon their volatility in soil. The first commerical non- fumigant active integredient was *O*-2,4-dichlorophenyl O,O-diethyl phosphorothioate (Taylor, 2003). A few non-fumigant nematicidal active integredients are ethoprop, fluazaindolizine, fluensulfone, fluopyram, oxamyl, spirotetramata and terbufos (Wram and Zasada, 2019; Hajihassani et al., 2019; Giannakou and Panopoulou, 2019). Chemical fumigant type nematicides are highly effective in controlling root-knot nematodes. Some common nematicidal active integredients of fumigants are allyl isothiocyanate, chloropicrin, dimethyl disulfide, metam potassium, metam sodium and 1,3 dichloropropene (1,3-D) (Desaeger et al., 2017; Sikora and Roberts, 2018). They are very toxic for animals and human beings because its residues may be present in food chain (Walters and Heil, 2007).

Biological control

Biological control is usually safer than chemical. Fungi belong to genera *Acremonium, Chaetomium, Paecilomyces* and *Trichoderma* have been known as antagonistic to plant parasitic nematodes (Govinden-Soulange and Levantard, 2008; Sharon et al., 2009). Colonization of these genera of fungus showed that seedling on cucumber was very low because they suppressed plant parasitic nematodes before penetration into host (Kiewnick and Sikora, 2006). Saprophytic fungi demonstrated to reduce rate of penetration of root knot nematodes in tomato roots (Dababat and Sikora, 2007). Obligate symbiotic arbiscular mycorrhizal fungi can alter the finding host behavior in *Meloidogyne* spp. (Reimann et al., 2008). Roots colonization by *Fusarium oxysporum* led to accumulation of root that showed repelling effect on *M. incognita* in tomato (Selim, 2010). Nonpathogenic *Fusarium* strains were capable in reducing *M. incognita* on tomato (Terra et al., 2018). Certain endophytes can be used as controlling nematodes (Zabalgogeazcoa, 2008). *Penicillium chrysogenum* is one of the most important fungi to control *M. incognita* (Yao et al., 2014). However level of inoculums can be reduced by seed treatment (Athman, 2006). (Dababat and Sikora, 2007) reported that systemic resistance against *M. incognita* was induced by changing chemical composition through nonpathogenic *Fusarium* Fo162. Arbuscular mycorrhizal (AM) fungi reduced severity of diseases in plants due to plant parasitic nematodes (Akköprü and Demir, 2005). Different mutualistic endophytes were used as antagonists against plant parasitic nematodes. Microorganisms such as fungi and rhizobacteria show

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16791690

efficiency to control *Meloidogyne* spp. (Vos et al., 2013). The endophytic bacteria reduce root-knot nematodes penetration in plants (Padgham and Sikora, 2007).

Cultural control

The use and development of resistant crop cultivars and the use of cleaning of farm implements, intercropping, clean planting materials and crop rotation showed influence on cultural practices (Briar et al., 2016). Heat solarization and treatment of the soil before cultivation of seed played role for controlling *Meloidogyne incognita* (Ioannou, 2000). Egg infectivity of *M. incognita* can be reduced through solarization of soil for 3 weeks (Nicol et al., 2011).

Resistant cultivars

Several studies are going on throughout the world to extend the crops with resistance against root knot nematodes (Norshie et al., 2011). Resistance gene Rmc-1 located on chromosome 11 of wild potato was found resistant against *Meloidogyne* spp. (Brown et al., 2006). In isogenic tomato cultivars resistance gene Mi-1.2 confers best for huge nematode pressure (200,000 eggs/plant) (Corbett et al., 2011). The Me and N genes from pepper and the Mi2 through Mi8 genes from *Lycopersicon* identified against root knot nematodes (Mitkowski and Abawi, 2003). Some crops have been rendered susceptible with entering resistance breaking *Meloidogyne* spp. (Brown et al., 2009; Kiewnick et al., 2009).

Mode of reduction of *Meloidogyne incognita*

Four possible mode of action can reduce the *M. incognita* (i) inhibition (ii) development of antagonistic microbiota (iii) altered or enhanced plant growth, nutrition and morphology (iv) induced resistance (Whipps, 2004). Resistance is a safer and economically more important method than other disease controlling strategies (cultural or chemical control) due to its environmental friendly nature and disease controlling potential (Ibrahim et al., 2016).

Induced resistance

Induced resistance can be defined as a development of defensive capacity of plant against broad-spectrum of pests and pathogens that are attained after appropriate stimulation. The resulting evaluated resistance due to inducer upon infection or disease by a pathogen or pest is called systemic acquired resistance (SAR) or induced systemic resistance (ISR) (Ramamoorthy et al., 2001). The resistance in Nematology can be defined as the ability of a plant to inhibit the reproduction of nematode species relative to reproduction on plant lacking such resistance. There is a great potential in managing *M. incognita* because it is economically highly effective (Starr and Roberts, 2004). At least two forms of induced resistance, induced systemic resistance (ISR) and Systemic acquired resistance (SAR) have similar phenomenon responses but involve different pathways (Vallad and Goodman, 2004). The downstream components are similar but upstream components are usually different, mainly involving the ethylene (Et) or jasmonic acid (JA) pathways for induced systemic resistance and Salicylic acid (SA) for systemic acquired resistance (Pieterse and Van Loon, 2007). Systemic acquired resistance is usually triggered by local infections and disease, provides long-lasting

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16791690

systemic resistance to successive pathogen or pest attack, and it is associated with PR genes activation and requires involvement of signaling molecules such as salicylic acid (Shoresh et al., 2010).

Induced resistance may be local or systemic. Local induced resistance response is local whereas systemic induced resistance is induced in a part of the plant that is separated spatially from the point of induction. When protection from disease is specific to a plant region which is treated with inducing agents is called local induced resistance. Whereas systemic induced resistance occurs when the plant is protected systemically due to the application of inducers to a single part of the plant. Induced systemic resistance is not neccessarily confined to roots only (Vos et al., 2012), its extension towards aerial parts of plant seems possible (Fritz et al., 2006). Plant immune system proposes two pathogen induced defense responses such as effector-triggered immunity (ETI) and pattern-triggered immunity (PTI) (Shukla et al., 2018).

Inducers

Plant resistance against nematodes could be successfully induced by the application of different biotic and abiotic inducers resulting in broad-spectrum responses (Nikoo et al., 2014). These agents involve jasmonic acid (JA) and salicylic acid (SA) as key signaling molecules (Pieterse et al., 2012). Induced disease resistance is the process of an active resistance which depends upon host's barriers, activated by abiotic or biotic agents called elicitors (Fatma et al., 2014).

Abiotic inducer

Chemical defense activators can efficiently protect the crops against pests and pathogens such as *M. incognita* but they are rarely used in practice due to various reasons such as chemical induced resistance slowing down the progression of disease rather than completely eliminating it (Walters and Heil, 2007). Whereas when these chemicals applied in higher concentration negative effects are imposed on seed, plant growth and vigor (van Hulten et al., 2006). Chemicals can adversly affect the plant growth promoting microorganisms (de Roman et al., 2011).

Biotic inducer

Microorganisms such as fungi and rhizobacteria are efficient to control *Meloidogyne* spp. (Vos et al., 2013). These microorganisms are able to induce resistance through activation of jasmonic acid, salicylic acid and ethylene pathways which promote the production of PR proteins, reactive oxygen species and phenolic compounds (Hao et al., 2012). Fungi have the potential to induce resistance against *M. incognita* (Mascarin and Junior, 2012). *Trichoderma harzianum* have the ability to increase enzymatic activities against root-knot nematodes (Naserinasab et al., 2011). It has been reported that *T. harzianum* induces resistance against *M. incognita* in tomato (Harman et al., 2004) adopts priming of JA and SA related defense responses according to the stages of nematode (de Medeirosa et al., 2015; Martínez-Medina et al., 2017). Non-pathogenic *Fusarium oxysporum* changed the chemical composition of root exudates so it reduced invasion and attraction of *M. incognita* and thus induced systemic resistance in plants (Dababat and Sikora, 2007). Induced systemic resistance by plant growth promoting rhizobacteria (PGPR) has been successfully achieved in large number of agricultural crops including cucumber, potato, Arabidopsis, tomato, chili, sugarcane, rice, mango

DOI: http://dx.doi.org/10.15666/aeer/1801_16791690

and carnation against broad-spectrum of pathogens including bacteria, viruses, fungi and nematodes etc. (Reddy, 2012; Alizadeh et al., 2013).

Seed coating

Seed coating with resistance biotic inducing agents efficiently protected the plants against pathogens and pests (Paudel et al., 2014; Worrall et al., 2012). It is a common technique to improve seed germination and conservation while protecting the emerging seedling against pathogens (Govinden-Soulange and Levantard, 2008). Fermentation liquid of *Penicillium chrysogenum* induced resistance to *M. incognita* in *Solanum lycopersicm* and *Cucumis sativus* (Yao et al., 2014; Sikandar et al., 2019).

Conclusion

It is concluded that *M. incognita* is a great risk to agriculture because its above ground symptoms are usually similar with nutrition deficiencies. Although, chemical control is effective they contain harmful agents that rigorously damage any ecosystem. However, biological control and induced resistance in crop plants are safer strategies because of their eco-friendly nature. Thus, it is recommended to adopt biological control strategies rather than utilizing synthetic chemical agents.

Abstract. Alacadağ, due its different vegetation composition, has been declared as Nature Protection Area in Antalya in Turkey. The special vegetation composition may sign that special lichen taxa can be found in the area. Therefore, the richness of the lichenized and lichenicolous fungi of the area was determined. According to results, a total of 125 taxa belonging to 9 orders, 27 families and 66 genera were identified. Three of these taxa are lichenicolous fungi living parasitically on lichens. Of these three, *Abrothallus welwitschii* Tul. ex Mont. is newly recorded from Turkey. In addition, lichenized fungi *Calicium pinicola* (Tibell) M. Prieto & Wedin, *Catapyrenium psoromoides* (Borrer) R. Sant., *Parmelia ernstiae* Feuerer & A. Thell., *Sticta limbata* (Sm.) Ach. were reported firstly in Turkey with this research. Of all determined taxa for the area and thirty-three taxa for Antalya Province are new. Fourteen taxa that had been known as specific to different geographical regions of Turkey before, were first record from Mediterranean region of the country. In addition, it is concluded that the species richness composition of Alacadağ Nature Protection Area showed low similarity to nearby compared areas. It was determined that many of these dissimilar taxa are only species that can live in good environmental conditions.
Keywords: *biodiversity, lichen, lichen systematic, systematic*

Introduction

Lichens are symbiotic association of fungi and algae and/or cyanobacteria (Hawksworth, 1991; Yuan et al., 2005; Tripp, 2017). This complex association makes it difficult to classify these organisms. However, photobiont partners have their own classifications. For this reason, the identification of "lichen species" is carried out by the classification of the fungus that can form lichen (lichenized fungi). In the world and Turkey, many studies on the classification of these interesting organisms have been done. In addition, parasitic fungi taxa on lichens (lichenicolous fungi) were also included in these studies. Feuerer and Hawksworth (2007) reported that a total of 18.882 lichenized and lichenicolous fungi were recorded worldwide. A book entitled "Türkiye Likenleri Listesi- A Checklist of the Lichens of Turkey" (John and Turk, 2017), based on previous studies, reported that totally 1898 taxa of lichenized and lichenicolous fungi had been determined in Turkey.

Lichens are highly diverse in protected areas without human intervention (Hilmo and Såstad, 2001; Gauslaa et al., 2007; Knapp et al., 2008). Therefore, protected areas are very valuable in terms of lichens. Protected areas in Turkey are divided into four statuses: national parks, nature parks, nature monuments and nature protection area

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16911706

(MPK, 1983). Nature protection areas are the least destructed of these areas by human intervention. Nature protection areas are defined as;

- A part of nature which contains rare examples of ecosystems.
- Species and natural phenomena that are rare.
- Endangered ecosystems which are important for science and education.
- Require absolute protection and are reserved for science use only and educational purposes (MPK, 1983).

Of the IUCN protected area categories (Dudley, 2008; Mitchell et al., 2018), the Absolute Nature Reserve and Wilderness category is equivalent to the Nature Protection Area (Eroğlu, 2014). Alacadağ Nature Protection Area is one of the rare areas that is located in Antalya Province in the Mediterranean Region of Anatolia. It is a special forest formed of more than 20 tree species that are rare, old and/or monumental. *Cedrus libani* A. Rich., *Pinus brutia* Ten., *Juniperus oxycedrus* L., *Quercus coccifera* L., *Fraxinus angustifolia* Wahl., *Acer platanoides* L., *Pistacia terebinthus* L., *Ostrya carpinifolia* Scop., *Fraxinus ornus* L., *Sorbus torminalis* (L.) Crantz. are some of these tree species. The vegetation composition of the area is even different than its near surroundings. Due to this feature, the area was declared a nature protection area in 01.10.1990. This special vegetation composition suggests that the area is rich in terms of lichen richness. Thus, the lichenized and lichenicolous fungi richness of the Alacadağ Nature Protection Area is found to be worth investigating and this formed the purpose of this study.

Materials and methods

Study area

Alacadağ Nature Protection Area is located in the Mediterranean Region of Anatolia at the western slopes of Alacadağ Mountain, with the Neighborhood of Alacadağ, District of Finike, Antalya Province Area which is 15 km away from the district of Finike and 128 km away from Antalya, between the coordinates: 36°21'31"N 30°02'14"E, 36°21'24"N 30°03'04"E - 36°23'27"N 30°03'04"E, 36°23'41"N 30°03'49"E The total area is 427 hectares and the altitude varies between 884 - 1809 m (*Figure 1*).

Collecting of samples

The lichen samples had been collected from all substrates in Alacadağ Nature Protection Area in 2016 and deposited in the private fungarium Dr. Özge Tufan-Çetin. 398 lichen samples were collected. Field studies were carried out in selected 8 random localities that have different vegetation cover types, topographic structure, micro-climate characteristics and altitudes (*Table 1, Figure 1, Figure 2, Figure 3*).

Identification of samples

Dried samples were examined by using a light microscope (Nikon Eclipse E100) for microscopic characters; and a stereoscopic zoom microscope (Nikon SMZ745T) for macroscopic characters. For identification of the species, the following literature has been used: Clauzade and Roux (1985), Wirth et al. (1995), Smith et al. (2009), Moberg (1977), Tucker and Thiers (1998), Ihlen and Wedin (2008), Arup et al. (2013), Otálora et al. (2014). When required, spot tests, UV tests and TLC has also been carried out. Index Fungorum (2018) website was used in order to update the names of lichens taxa.

Figure 3. *A view from Alacadağ Nature Protection Area (Nature Reserve) Finike-Antalya*

Data analysis

The lichen richness data obtained from Alacadağ Nature Protection Area and the data obtained from near and previously studied areas were compared. These areas are the Elmalı Cedar Research Forest and Termessos National Park. The data from Elmalı Cedar Research Forest with altitudes from 1300 to 1880, approximately 23 km away from Alacadağ, were recorded by Çobanoglu and Sevgi (2006). Data of Termessos

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16911706

National Park with altitudes from 360 to 1665 m, approximately 75 km away from Alacadağ, were determined by Tufan et al. (2005). The similarities of these three areas were calculated using Sorensen similarity index (Sørensen, 1948) with PAST 3.14. Since the richness of lichenicolous fungi had not been found in previous studies, these taxa were not included in the similarity assessment. In addition by Çobanoğlu and Sevgi (2006), the richness of epiphytic lichens had been investigated in the Elmalı Cedar Research Forest. Therefore, the similarity study for this area was applied only for epiphytic lichens.

Results

Results of taxa identification

This study is the first comprehensive study to determine the lichenized and the lichenicolous fungi species in the Alacadağ Nature Protection Area (Antalya-Finike). As a result of the field studies, 398 specimens collected and identified. A total of 125 taxa belonging to 9 orders, 27 families and 66 genera were determined with laboratory studies. They are listed in alphabetic order below. Taxa new for Turkey are marked by a plus (+) and taxa new for Antalya province are highlighted by an asterisk (*) in the list. In addition, lichenicolous fungi are indicated with a hash (#):

 # Abrothallus parmeliarum (Sommerf.) Arnold, Loc 3 on lichen on *Cedrus libani.*
+ # * *Abrothallus welwitschii* Tul. ex Mont, Loc 1 on lichen on *Acer* sp.
Acarospora cervina A.Massal., Loc 5 on calcareous rock.

Results of data analysis

The results obtained from this study and the results obtained from Elmalı Cedar Research Forest (Çobanoglu and Sevgi, 2006) and Termessos National Park (Tufan et al., 2005) were compared. In Elmalı Cedar Research Forest (Çobanoğlu and Sevgi, 2006), only the richness of epiphytic lichenized fungi had been investigated. Therefore, the similarity study for this area was applied only for epiphytic lichens. 54 epiphytic lichenized fungi taxa had been determined from Elmalı Cedar Research Forest and 77 epiphytic lichenized fungi taxa (without lichenicolous fungi) were identified in the Alacadağ Nature Protection Area. The epiphytic lichenized fungi taxa of the Elmalı Cedar Research Forest and the Alacadağ Nature Protection Area were found to be 0.4122% similar (27 common taxa) according to the Sorensen similarity index. 160 lichenized fungi taxa had been determined from Termessos National Park (Tufan et al., 2005). 39.007% similarity (55 common taxa) was determined between the lichenized fungi richness of Alacadağ Nature Protection Area and the lichenized fungi richness of Termessos National Park.

Discussion

Antalya, in Southern-west of Turkey, has been visited many times by lichen systematic researchers. A total of 402 lichenized and lichenicolous fungi taxa had been identified including the center city and districts of Antalya (Fellows, 1841; Pišút, 1970; Ayaşlıgil, 1987; Lumbsch, 1989; John, 1992, 1995, 1996, 2000, 2007; Zeybek et al., 1993; Vězda, 1996; Nimis and John, 1998; Schindler, 1998; Litterski and Otte, 2002; Meyer, 2002; Halda, 2003; Breuss and John, 2004; Çobanoğlu, 2005; Tufan et al., 2005; Schiefelbein, 2006; Mayrhofer and Sheard, 2007; Yavuz and Çobanoğlu, 2007; Pišút and Guttová, 2008; Kocakaya et al., 2009; Tufan-Cetin and Sümbül, 2011; Halici et al., 2012; Kocakaya et al., 2014; Özdemir Turk et al., 2015; Tufan-Çetin, 2015, 2019; Vondrák et al., 2016; John and Turk, 2017). In this study, 124 taxa belong to 9 orders, 27 families and 66 genera were determined. 33 of these were recorded for the first time in Antalya and the number of lichenized and lichenicolous fungi taxa of Antalya reach to 435.

Three of the taxa identified in the research area are lichenicolous fungi that live parasitically on lichens. A lichenicolous fungus species, *Abrothallus welwitschia*, is newly recorded for Turkey. *Abrotallus* is a genus that does not have a clear similarity to other genera of Ascomycetes and has many hypotheses about its phylogenetic relations (Pérez-Ortega et al., 2014). It is mostly composed of parasitic fungi living on lichens. World distirubition of *Abrothallus welwitschii* is Europe (France, England, Ireland, Spain, Portugal), New Zealand, Africa (Kenya), North America (America), South America (Chile). *Abrothallus welwitschii* mostly choses species belonging to the genus *Sticta* as host (Suija et al., 2015). In this study, this species was determined over *Sticta limbata*. *Stict limbata* was determined first time in Turkey from Alacadağ Nature Protection Area. Also *Stict limbata* is found in the Northern Hemisphere, South Africa, South America, Australia, New Zealand and East Asia (Japan, China, Korea) (Jayalal et al., 2014). Also the taxon in red list was categorized as "vulnerable" in Italy (Nascimbene et al., 2013). This species was reported living on mossy tree bark in the old forests by Smith et al. (2009). Similarly, in our research area, the species was identified from old *Cedrus libani* trees.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16911706

Calicium pinicola which had been defined as new combination with *Cyphelium pinicola* Tibell, Svensk Bot. Tidskr by Prieto et al. (2016), was reported as a new record for Turkey from this research area. This species which is located in Austria, Macedonia, USA (Obermayer, 1998) and the Swiss Alps (Nimis et al., 2018), is threatened with extinction in Switzerland (Bürgi-Meyer and Dietrich, 2011), categorized as "vulnerable" in Italy (Nascimbene et al., 2013).

Of the new records for Turkey *Catapyrenium psoromoides* is a species found in the Southwest of Asia Temperate, East Africa, Europe, New Zealand and North America. It is near threatened with extinction in Italy according to Nascimbene et al. (2013). The taxon lives on trees or on mosses (Breuss, 2002; Prieto et al., 2010). In our study, it was determined also over the moss.

Parmelia ernstia which has a wide distribution in Europe (Austria, Belgium, Bosnia and Herzegovina, Britain, Bulgaria, Czechia, Denmark, Estonia, France, Germany, Greece, Ireland, Lithuania, Luxembourg, Netherlands, Slovenia, Spain, Poland, Sweden), have been recorded from Turkey for the first time by this research. This species is also distributed in Algeria and Canary Islands in Africa (Kukwa et al., 2012). According to Kukwa et al. (2012) this species is rarely seen in coniferous deciduous trees. In Italy, *Parmelia ernstia* was identified from *Quercus* and *Pinus* species (Nimis and Martellos, 2017). Also in this study, the species was recorded on *Cedrus libani*.

In the Italian red list of epiphytic lichens *Calicium pinicola*, *Hypogymnia vittata*, *Sticta limbata* are categorized as "vulnerable" and *Catapyrenium psoromoides*; *Pannaria conoplea*; *Ricasolia amplissima* are classificated as "near threatened" (Nascimbene et al., 2013). The Alacadağ Nature Protection Area is home to these sensitive species.

Most of the new records for Antalya in this study, have limited distribution in Turkey. In *Figure 4*, Turkey distribution maps of some taxa are given. The maps were created using the information of John and Türk (2017). There are also maps showing the biogeographical regions and phytogeographical regions of Turkey in *Figure 4g and 4h*. *Arthonia didyma* (*Figure 4a*), *Arthonia medulla, Lecania cuprea, Lepraria umbricola, Mycobilimbia tetramera* (*Figure 4c*), *Ramalina calicaris, Ricasolia amplissima* (*Figure 4e*), that had been defined as specific to the Euro-Siberian Phytogeographical Region (P.R.) (Black Sea Biogeographical Region (B.R.)) of Turkey (John and Türk, 2017), have been found newly in Mediterranean Region of Turkey with this study. *Protoblastenia calva* that was defined only from Irano-Turanian P.R. (Anatolian B.R.) of Turkey have been found in our research area (John and Türk, 2017). Similiarly, *Bryoria nadvornikiana, Calicium trabinellum*, *Hypogymnia vittata* (*Figure 4b*), *Pannaria conoplea* (*Figure 4d*), *Ochrolechia tartarea*, *Xanthoria isidioidea* were known in both Euro-Siberian P.R. (Black Sea B.R.) and Iran-Turanian P.R. (Anatolia B.R.) of Turkey (John and Türk, 2017). With our study these taxa have been recorded in Turkey's Mediterranean B.R. (Mediterranean P.R.). In addition, *Cladonia parasitica* which was defined as a lichen of the Euro-Siberian P.R. (Black Sea B.R.) in Turkey, had been found before in the south of Anatolia (in Hatay) same as with our study (John and Türk, 2017). The reason for this species to be found in Hatay may be due to the fact that this region is an enclave of Euro-Siberian P.R. (Black Sea B.R.) (Atalay, 1986). The presence of this species also in the research area may show that the area has a special ecological structure. On the other hand, *Rinodina oleae* (*Figure 4f*), *Lathagrium auriforme, Lobaria pulmonaria* (*Figure 5*), *Ochrolechia parella, Rinodina pyrina* which

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16911706

are the new record taxa for Antalya, have a wide geographical distribution in Turkey and have been found in this research area.

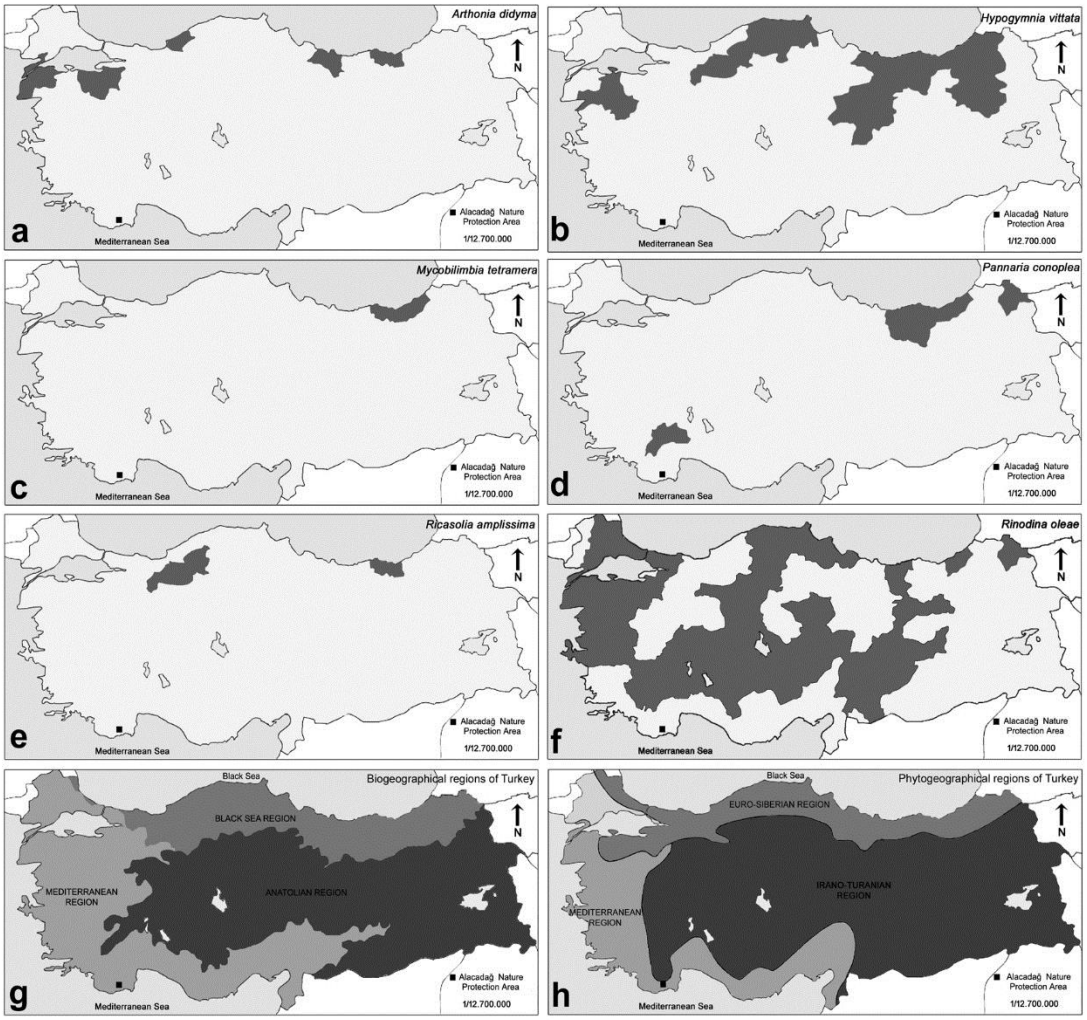

Figure 4. a-f. *Turkey distribution map of some lichen taxa from Alacadağ Nature Protection Area (a. Arthonia didyma, b. Hypogymnia vittata, c. Mycobilimbia tetramera, d. Pannaria conoplea, e. Ricasolia amplissima, f. Rinodina oleae)* ***g.*** *Biogeographical regions of Turkey* ***h.*** *Phytogeographical regions of Turkey*

When our richness data were compared with data of the nearby areas, with data of Termessos National Park, one of the compared area, 39.007% similarity rate were found. In addition, the epiphytic lichenized fungi richness data of the Alacadağ Nature Protection Area were found 0.4122% similarity with data of Elmalı Cedar Research Forest according to the Sorensen similarity index. However, according to Tufan-Çetin (2019), the richness of Termessos National Park is 55.52% (according to Sorensen similarity index) similar with the richness of Altınbeşik Cave National Park which is one of the protected areas of Antalya. In addition, Tufan-Çetin and Sumbul (2011) reported that Köprülü Canyon, another national park of Antalya, showed 58.29% similarity with Termessos National Park (according to Sorensen similarity index). According to these reference comparisons, it is concluded that the species richness

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_16911706

composition of Alacadağ Nature Protection Area showed low similarity to other areas. Futhermore, it was determined that many of dissimilar taxa (according to compared area) are only species that can live in good environmental conditions and in old forests *(Figure 6)* (Nimis and Martellos, 2017). Comparison area data dating back 13-14 years before may be the result of the better environmental quality than today. But the fact that these dissimilar taxa in the area can live in good environmental quality may indicate that the environmental change has not occurred in the area.

DOI: http://dx.doi.org/10.15666/aeer/1801_16911706

Conclusion

This study is the first comprehensive study to determine the lichenized and lichenicolous fungi taxa in the Alacadağ Nature Protection Area (Nature Reserve). Many taxa were newly recorded from Turkey, Turkey's Mediterranean region and Antalya Province with this study. Taxa that had been known as specific to different geographical regions of Turkey before, were firstly determined from the area. Furthermore, species richness composition of Alacadağ Nature Protection Area was found low similarity to other areas All these noteworthy species findings indicate a different species composition structure in the Alacadağ Nature Protection Area compared to the Mediterranean lichen composition. In fact, Alacadağ has been declared as nature protection area (Nature Reserve) due to its rich plant diversity. In this study, it was also determined that the area has a different ecological structure in terms of lichens like plant diversity.

Nowadays, on three sides of Alacadağ Nature Protection Area are surrounded by marble quarries (*Figure 1*). It is obligatory to protect the area, which is emphasized as having a special structure also in this study, from the pressure of marble quarries. It has been observed that the density of sensitive species (*Catapyrenium psoromoides, Calicium pinicola*, *Hypogymnia vittata*; *Sticta limbata, Pannaria conoplea*; *Ricasolia amplissima*) in the area decreases when it was approached the marble quarries. For this reason, the density of the species in the area should be examined with a further study.

Abstract. The evaluation of genotype × environment interaction (G×E) is an important component of the selection process in multi-environment trials. The objective of this study was to analyze the G×E interaction for seed yield (SY), germination rate (GR), thousand seed weight (TSW) and protein content (PC) of 18 sunflower parental lines through the application of AMMI analysis, as well as to identify suitable sunflower parental lines with both high performance and high stability. Highly significant differences for SY, GR, TSW and PC were found for main effects (genotypes, years). For all investigated traits G×E interaction was also highly significant, suggesting a different response of genotypes across testing environments. Highest SY was shown by genotypes G12, G14 and G17. Most stable lines for seed yield were G1, G2, G18 and G17. High stability in terms of GR showed the genotypes G3, G11 and G15, with average values higher than the general average. In the three-year experiment environment E3 was most stable for GR. Genotypes G2, G4, G5, G6 and G7 were stable for TSW. Similar average values and stability for TSW showed E2 and E3. The lines with the most stable reaction in the examined environmental conditions for PC were G7 and G10. The most stable environment for PC was E3.
Keywords: *AMMI analysis, germination rate, protein content, 1000 seed weight, seed yield*

Introduction

Sunflower (*Helianthus annuus* L.), with soybean (*Glycine max* (L.) Merr.) and rapeseed (*Brassica napus* L.), are some of the most important crops grown in the world and used as edible oil (Rauf et al., 2017; Kaya et al., 2019; Mahmood et al., 2019). It is arousing the interest of the producers, due to the possibility of using its oil as human food or as raw material for industrial purposes (Sabaghnia et al., 2016). High and stable yields are characteristics of greatest importance in commercial production. In the production of sunflower seed despite the yield, seed quality is very important. The primary goal of sunflower seed production is the production of genetically and physically pure seeds which are physiologically mature and healthy and have high germination rate as well as tolerance to agro-ecological stress (Miklič et al., 2011). Success in sunflower growing and production depends not only on the genetic potential of the genotype but also on environmental conditions (Denčić et al., 2011). Knowing how environmental factors impact plant growth and development would reduce the possibility of sustaining significant yield and seed quality losses (Marjanović-Jeromela et al., 2011). The use of genotype main effect plus genotype-by-environment interaction biplot analysis by plant breeders and other agricultural researchers has increased dramatically during the past decade for analyzing multi-environment trial data (Yan et al., 2007).

The researchers very often ignore interaction in the recommendation for growing some hybrids. As the interaction is present in agriculture, it is necessary to use

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17071719

corresponding statistical methods for the efficient evaluation of interaction (Ceretta and van Eeuwijk, 2008). The key question of adaptive selection is how to treat mutual relations between genotype and the environment. Basic aspects of this relation concern the assessment of adaptive capacity and stability of phenotypes in different environments and the assessment of the environment's suitability as a background for selection (Marinković et al., 2011).

In multi-environment trials, it is common to measure several response variables or attributes to determine the genotypes with the best characteristics. Thus, it is important to have techniques to analyze multivariate multi-environment trial data (García-Peña et al., 2016). AMMI (additive main effects and multiplicative interaction) model can be used to analyze multiple yield trials (Oliveira et al., 2014). It is one of the most often used model (Ceretta and van Eeuwijk, 2008). This hybrid statistical model incorporates both ANOVA for the additive component and PCA (principal component analysis) for the multiplicative component (Balalić et al., 2010). Since ANOVA and PCA are part of the AMMI model, this model is more suitable for characterizing the G×E interaction (Oliveira et al., 2006). The other advantage of AMMI analysis is to identify the presence of crossover GE Interaction (Kadhem, 2014). The magnitude of interaction shows the influence of environmental factors on adaptability and stability, which is a desired character only when it is connected with a yield above average (Yan and Hunt, 2003). AMMI model can provide an accurate estimation of the true performance potential of genotypes to determinate the effect of different environment (Musavi et al., 2016). Multi-environment trials (MET) are an important part of breeding programs in order to select superior genotypes for the specific region, as reported by Branković et al. (2012).

This study was conducted to give more accurate investigation about the performance of 18 different sunflower parental lines in order to identify those which are most promising for better exploitation. AMMI analysis will give information on stability and genotype by environment interaction for seed yield, germination rate, thousand seed weight and protein content of sunflower lines.

Materials and methods

Field experiments were conducted during three seasons on plots where seed production of sunflower parental lines was established. Ten of them were lines based on CMS (G1-G10) and eight of them were restorer lines (G11-G18). All examined genotypes represent parental components of the best-selling sunflower hybrids of the Institute of Field and Vegetable Crops, Novi Sad, Serbia.

The test environments are not typically environments for sunflower commercial production, since idea of successful sunflower seed production can be arranged only on locations where commercial sunflower is not producing (isolation and genetic purity of parental lines are one the most important factors for good seed production). Because of these facts (conditions), in many cases, the locations where the sunflower seed production (especially in cases of sunflower parental line seed production) are characterized by worse conditions (mainly refers to the quality of the soil and weather conditions). The average temperature and rainfall for both locations are presented in *Table 1*.

Plants were produced on two different soil types: pseudogley (location 1; pH is 5.9-6.5) and degraded chernozem (Location 2; pH 6.2-6.6); the soil is fertilized with 400 kg of complex fertilizer NPK (15:15:15) and 250 kg of KAN (27% N) given during crop cultivation.

The experiments were arranged in a randomized complete block design (RCBD) with three replications. The following parameters were studied:

Seed yield (SY): Upon maturity, 10 plants were picked manually, from different locations on the plot, and seed yield per plant was determined. By the application of previously determined plant density *(50.000 plants ha^{-1})*, obtained seed yield per plant was determined in kg ha^{-1} with 9% of moisture.

Samples from each replication were taken to laboratory and following parameters were studied:

Germination rate (G): Standard method. Examination of seed germination was repeated 4 times. Each time 100 seeds were used. Germination was determined after 10 days. Only naturally formed seeds were used for determination of this parameter. Germination was expressed in relative values (ISTA rules, 2014).

1000 seed weight (TSW): Examination of 1000 seed weight was repeated 4 times. Each time 100 seeds were used. The obtained value was applied to 1000 seed weight and was specified in grams.

Protein content (PC): Determined by standard Kjeldahl method with the help of VAP-50-Gerhardt apparatus. This parameter is also expressed in relative value.

Data were analyzed using two-way analysis of variance (ANOVA). The AMMI model was used to analyze the G × E interaction (Gauch, 1988). AMMI analysis of variance and AMMI1 biplot were done using GENSTAT computer program.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17071719

To analyze the G × E interaction, the AMMI model was used (Gauch, 1988). The AMMI statistical model is a combination of customary analysis of variance (ANOVA) and principal component analysis (PCA). The equation (*Eq. 1*) of this model is:

$$Y_{ge} = \mu + \alpha_g + \beta_e + \Sigma_n \lambda_n \gamma_{gn} \delta_{en} + \rho_{ge} + \varepsilon_{ger} \quad \text{(Eq.1)}$$

with Yge is the trait of genotype g in environment e; μ is the grand mean, αg is the genotypes deviation from grand mean and the environment deviation β_e, λn is the eigenvalue of PCA axis n; γ_{gn} and δen are the genotype and environment PCA scores for PCA axis n; ρge is the residual of AMMI model and ε_{ger} is the random error. AMMI uses ordinary ANOVA to analyze main effects and principal component to analyze the non-additive residual (interaction) left over by the ANOVA model. PCA decomposes the interaction into PCA axes 1 to N and residual remains if all axes are not used. If most of the G × E interaction sum of squares (SS) can be captured in the first N PCA axes, a reduced AMMI model, incorporating only the first N axes, can be used. The interaction between any genotype and environment can be estimated by multiplying the score of the interaction principal component axis (IPCA) of genotype by an environment IPCA score.

Results and discussion

Seed yield (SY)

Breeders are mainly concerned with crop yield and yield stability and this performance depends on the genetic yield potential; all those desirable genes that have been incorporated into a cultivar in the course of the breeding process (Marinković et al., 2011). According to these authors yield stability depends on the cultivar's capacity to react to environmental conditions.

On the basis of ANOVA, it can be seen that both main effects (G and Y) and interaction (G × Y) had a highly significant effect on SY. For SY, main effects and interaction were highly significant. SY was predominantly influenced by the genotype (81.62%). Year amounted to SY with 0.38%, and interaction with 18.00% (*Table 2*). This interaction (sums of squares) showed different performance of genotypes in the year of growing. According to Marinković et al. (2011), the results of the AMMI analysis of variance for the seed yield showed that both additive effects (genotype and environmental conditions) as well as their interaction had highly significant proportions in the total variance of the experiment.

The SY varied between 253.3 kg (G4) and 1415.9 kg (G12). The general mean germination rate of the trial was 664.07 kg (*Table 3*). Some of the genotypes had mean values over this average value. Concerning years (E) the highest mean value for SY was stated in E3 (696.4 kg), while the lowest in E2 (645.2 kg), as shown in *Table 3*. According to Sial and Ahmad (2000) high seed yield should not be the only criterion for stability of a genotype unless its high performance is established over the different environmental conditions. The AMMI1 graph for SY shows the difference between the lines (G) and the years (E) in the main effects and interaction. Most stable are lines G1, G2, G18 and G17 and they had also seed yield over average. There are some other stable lines, but with lowest seed yield concerning the average which was 664.7 kg/ha. E1 (the year 2013) was most stable because its value was nearest to the line of stability

DOI: http://dx.doi.org/10.15666/aeer/1801_17071719

and had seed yield on the average value. E3 (the year 2015) contributed most to G × E interaction, having value farthest away from stability axes (*Fig. 1*).

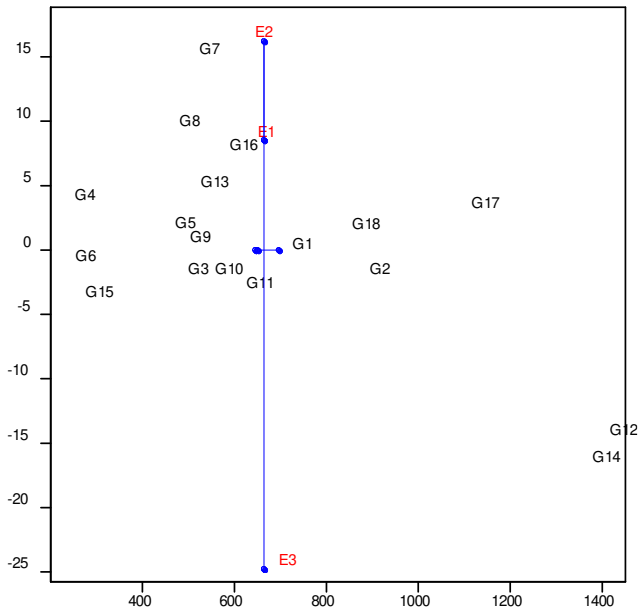

Figure 1. *AMMI 1 biplot of 18 sunflower lines over three growing environments for seed yield*

Germination rate (GR)

Understanding of G × E interaction in plant species is important because it has implications for economic yield and seed quality (Thangavel et al., 2011). The size of the genotype interaction × external environment (G × E) is the result of variation of uncontrolled factors, such as climate factors that are varying from year to year (Adugna and Labuschange, 2002). Germination seed under various environmental conditions and represents a critical component of the plant life cycle that is of eminent ecological and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17071719

agronomic importance (He et al., 2014). It has been observed that a change of temperature, photoperiod, or nutrient or drought stress, during seed development, maturation, and after dispersal, may strongly affect seed performance (Donohue, 2009). On the basis of ANOVA, it can be seen that both main effects (G and Y) and interaction (G × Y) had a highly significant effect on GR. From the main effects, genotype contributed mostly to the GR (37.21%), and then environment (12.36%). The interaction effect accounted for most of the sum of squares (50.43%) indicating the substantial effect of interaction on the GR performance of the eighteen sunflower genotypes evaluated in this study. Interaction showed that the performance of genotypes responded differently to variations in the year of growing (*Table 2*).

Table 3. *Average values for seed yield (SY) and germination rate (GR) and first IPCA (interaction principal component axis) in sunflower lines*

Genotype	SY (kg)	IPCA[1]	GR (%)	IPCA[1]

G17	1115.6	2.97	85.00	0.62
G18	856.0	1.38	87.78	-0.89
E1	650.6	8.54	85.44	-3.70
E2	645.2	16.22	89.37	2.58
E3	696.4	-24.76	86.80	1.12

It is very important that sunflower seed quality be maintained at a high level in different production conditions (Mrđa et al., 2012). The same finding was obtained by Pacheco et al. (2005), who reported that sunflower seed is greatly influenced by environmental factors, which most often results in high variability, both among different years in a single location and among different locations in a single year as well as among different locations and years. The GR varied between 80.22% (G2) and 92.00% (G16). The general mean germination rate of the trial was 87.2% (*Table 3*). Some of the genotypes had mean values over this average value. Concerning years (E) the highest mean value for GR was stated in E2 (89.37%), while the lowest in E1 (85.44%), as shown in *Table 3*. The same finding was obtained by Pacheco et al. (2005), who reported that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17071719

sunflower seed is greatly influenced by environmental factors, which most often results in high variability, both among different years in a single location and among different locations in a single year as well as among different locations and years.

AMMI is the best model in multi-environmental experiments. It provides an understanding of complex genotype by environment interactions (Gauch, 2006). AMMI1 biplot in our experiment showed that the sunflower genotypes were grouped on the basis of their reaction to environmental conditions which prevailed in the three-year period. From the AMMI1 biplot, it can be seen that it was a significant difference in GR for main effects (G, E) and for the interaction (G×E). Lower IPCA values for genotypes (lines) and environments (years) suggest lower interaction level and therefore higher stability (Gauch, 2006). The genotypes G3, G11 and G15, with mean values higher than the general average (87.2%) showed high stability for GR. Their position in relation to the abscissa indicates that it had similar GR in all environments. These genotypes contributed least to the G×E interaction, as they were closer to the center of origin of the axes. Genotypes G16 and G13, had the highest mean values for GR but had less stability. The genotypes farthest away from the graphic's origin contributed most to increase the G×E interaction for GR, such as G1, G2, G9 and G10 (*Fig. 2*).

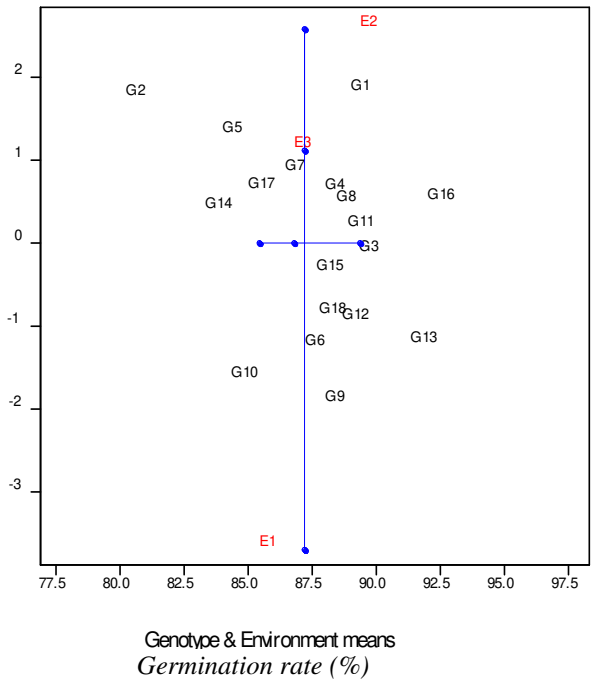

Figure 2. *AMMI 1 biplot of 18 sunflower lines over three growing environments for germination rate*

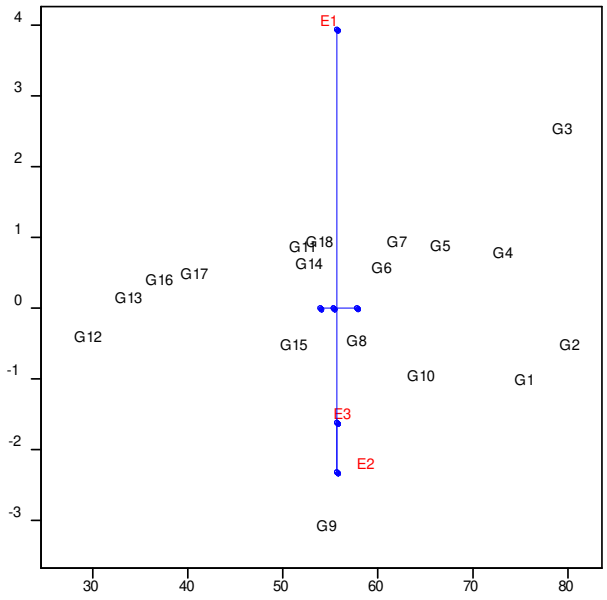
The lowest interaction effect was registered in E3, which was most stable in the three-year investigation. Genotypes with mean values on the average (G7) and over average (G4, G8) showed positive interaction with E3. G1 showed highest interaction effect on the positive side of IPCA. The highest interaction on the negative side of IPCA was evident in G9. Negative interaction with E2 had genotype G10, with mean values lower than average. G10 showed positive interaction with the first year of the experiment. Close positions on the graph of the lines G4, G8 and G11 suggest that they require similar environmental conditions which can be used in seed production. Similar

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17071719

associations can be found between genotypes G6, G12 and G18. Among the environments, the highest level of stability was found in the E3, while the positions E1 and E2 at the ends of the graph suggest that they can be marked as very unstable for the trait of germination rate. Opposite positions of the environments E1 and E2 suggest that these environments have very different growing conditions for the examined trait.

1000 seed weight (TSW)

It is very important that the sunflower hybrid seed, which is used for sowing, has a high value of thousand seed mass. Such seed conserve more food reserves and plants that develop from embryos grow faster, which is often very important in unfavorable agro-ecological conditions (Balalić et al., 2012). Considering the fact that there is a significant positive correlation between the mass of 1000 seeds and yield (Kaya et al., 2007), it is in interest to use hybrids with as high values of this trait. All sources of variation, main effects and interaction, for TSW were highly significant. TSW was predominantly influenced by the genotype (91.53%). Year amounted to TSW with 1.10%, and interaction with 7.41% (*Table 2*). The TSW varied from 28.3 g (G12) to 79.10 g (G2), with a mean average of 55.7 g. The environment with highest TSW was E2 (57.9 g), while the E1 had the lowest average of TSW (53.9 g) (*Table 4*). Based on experiment carried out under Iranian conditions, the mass of 1000 seeds ranged between 36.0 g and 50.0 g (Beg et al., 2007), while the values obtained by Nel (2001) during the two-year experiment in the conditions of South Africa ranged between 59.4 g 78.5 g. Based on a test of 13 hybrids during a four-year experiment in the conditions of central Italy, Laureti et al. (2007) obtained that the 1000 seeds average mass was 45.2 g. Values closer to the stability line (0) indicate stabile genotypes or stable years in relation to genotypes. Genotypes G2, G4, G5, G6 and G7 were stable for TSW because their values are nearest to the line of stability (*Fig. 3*).



Thousand seed weight (g)

G18	52.42	0.81	16.51	-0.59
E1	53.94	3.94	19.71	-2.67
E2	57.79	-2.32	18.54	1.74
E3	55.32	-1.62	17.71	0.92

They had also higher average values in relation to the general average (55.7 g). G3 showed high mean value for TSW, but it was unstable. The lines with the high levels of IPCA scores (*Table 4*) were G3, G9 and G12 which is in accordance with their positions on the graph. Genotypes G13 and G12 had very high stability for this trait, but the lowest mean values for TSW. Positive interaction for TSW was stated for G3, which had the highest value for this trait, but was very unstable. Genotypes G10, G8, G15 on the negative side of IPCA were in interaction with E2 and E3. E1 had the highest IPCA score and was highly unstable environment from the aspect of TSW. It had the highest positive interaction effect for TSW, and mean value on the average level. Environments E2 and E3 had similar mean values and stability. Values of all environments varied around the average TSW axis. Also, lines with similar IPCA results can be separated into specific groups such as lines G6, G7 and G5, also lines G14, G11 and G18 create another distinct association.

Protein content (PC)

The protein content ranges from 13-20% in sunflower. Majority of existing proteins in fully developed seeds have structural or metabolic roles. Besides these roles, proteins in seeds also serve to provide a store of amino acids needed for germination and early seedling growth (Shewry et al., 1995). Results of ANOVA indicated that the main

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17071719

effects and interaction were highly significant for PC. The influence of genotype on PC amounted to 55.82%, of the year to 9.26% and of interaction to 34.92% (*Table 2*). The values of the protein content were between 15.3% (G13) and 21.9% (G1). The general average value of the trial was 18.7%. The environment with the highest protein content was E1 (19.7%), while E3 (17.7%) has the lowest average value for this trait (*Table 4*).

From the aspect of protein content, the lines with the most stable reaction in the examined environmental conditions were G7 and G10. They had a PC over general average (18.7%) and were stable for this trait. High stability showed also G14, G15 and G13, but they had lowest mean values for PC. Genotype with the highest protein content was G1, but it was unstable. The environment with the lowest IPCA score for PC was E3. IPCA value of E2 was similar to E3 while the E1 had diametrically opposite reaction. It was the most unstable environment because it was furthest from the line of stability (0). G3 was in the positive interaction with E3. The most unstable environment was E1 because it was furthest from the line of stability (0). E2 had an average value on the general average. Specific groups of lines with similar IPCA scores such as G13, G15 and G14, also G2, G6, G8 and G9 can be marked out for they similar reaction to environmental conditions (*Fig. 4*).

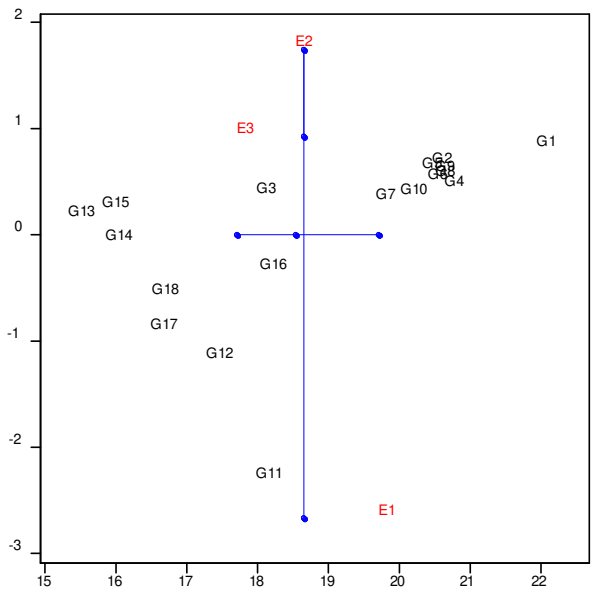

Figure 4. *AMMI 1 biplot of 18 sunflower lines over three growing environments for protein content*

An ideal genotype is defined as one that is the highest yielding across all test environments and is absolutely stable in performance, namely one that ranks the highest in all test environments (Yan et al., 2003; Pourdad and Moghaddam, 2013). Although such an ideal cultivar may not exist in reality, it can be used as a reference for cultivar evaluation. A genotype is more desirable if it is located closer to the ideal cultivar. Thus, using the ideal cultivar as the center, concentric circles were drawn to help visualize the distance between each genotype and the ideal cultivar (Yan, 2002; Pourdad and Moghaddam, 2013).

Conclusion

On the basis of the analyses of seed yield, germination rate, thousand seeds weight:

The AMMI ANOVA indicated that main effects (G, E) were highly significant for SY, GR, TSW and PC. G × E interaction also was highly significant for all investigated traits, suggesting a differential response of genotypes (lines) across testing environments (years).

Highest mean values for yield and stability had genotypes G12, G14 and G17. The genotypes G3, G11 and G15, with mean values higher than the general average showed high stability for GR. Environment E3 was most stable for GR in the three-year investigation. Genotypes G2, G4, G5, G6 and G7 were stable for TSW because their values were nearest to the line of stability. Environments E2 and E3 had similar mean values and stability for TSW. From the aspect of protein content, the lines with the most stable reaction in the examined environmental conditions were G7 and G10. For PC the environment E3 was most stable. The method successfully integrate the attributes measured in the multi-environment trial. The analysis helps the breeder make decisions in favor of moderate to high seed yield, 1000 seed weight and protein content with good seed germination to moderate sunflower hybrids in general or in selected environments. The combination of analysis of variance and principal component analysis in the AMMI model, along with the prediction assessment, is a valuable approach for understanding genotype × environment interaction.

Based on the obtained results we can conclude that sunflower lines G2, G12 and G14 developed at Institute of Field and Vegetable Crops Novi Sad are suitable for high yield production and all other observed parameters. Crossing this lines Institute created new hybrids NS FELIKS and NS KRUNA (both hybrids were registered in the EU and Serbia). The seeds of these hybrids Institute of Field and Vegetable Crops sales in the domestic and foreign markets. A further objective of this research will be observation of new created lines and their behavior in different years of production.

Abstract. Heavy metal pollution is a serious and widespread environmental problem that destroys microbial ecology. In this study, determination of copper and cadmium concentrations and heavy metal-resistant bacteria identification in water samples obtained from four sites at Seybouse River in Algeria were carried out. The minimum inhibition concentration (MIC) and minimum bactericidal concentration (MBC) were determined in culture media with 12.5-3600 µg/mL of cadmium and copper salts. Metallothionein (MT) production was evaluated by spectrophotometry methodology. Trace metal element concentrations determined in the water samples revealed spatial variations for Cu and Cd. A total of 12 copper- and cadmium-resistant bacteria (KZ1-KZ12) were isolated from surface water in Seybouse River. Five isolates KZ2, KZ5, KZ8, KZ10 and KZ11 showed high values of minimum inhibitory concentration (MIC = 3600 µg/mL) for each heavy metal. High MBC of the strain toward Cu and Cd was found to be >3600 µg/mL. The MT concentration in five best isolates which showed high resistances increased with increasing metal concentration (r = 0.936, p = 0.006). High levels of MT are detected in bacterial strains exposed to Cd (51.66-90.53 nmol MT/g bacterial biomass). These indicated that the isolates can be used efficiently in removal of heavy metals in contaminated sites.
Keywords: *cadmium, copper, MIC, MBC, protein-binding*

Introduction

Heavy metals are the main group of inorganic pollutants which are continuously accumulating in our environment (Manasi and Rajesh, 2016). In many developed and developing countries the heavy metal pollution has risen due to rapid industrialization, mining operations, discharge of industrial wastes, long term use of poor quality waters for irrigation and intensive agricultural practices (Rizvi et al., 2019). In recent years, heavy metal pollution in rivers, estuaries, and near-shore waters has become a serious problem (Li et al., 2015). At high concentrations, cadmium and copper which are major contaminants found in the environment, are extremely poisonous to human(s), animals, plants and microbes which can damage cell membranes, alter particularity of enzymes, destroy the structure of DNA, bind the vital protein and cause further discrepancies (Jaishankar et al., 2014; Marzan et al., 2017). In regards to bacteria cells, pollution by heavy metals affects every aspect of bacterial metabolism and activity, structural inconsistency of the cytoplasmic membrane, retardation of the onset of growth, extending the lag phase of cultures, various structural abnormalities, decrease in the respiratory activity and death of the cells are some of the predominant ones (Aljerf and Almasri, 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17211737

Selective pressures from metal containing environments have led to the development of resistance systems in microorganisms to virtually all toxic metals. Bacteria strains have an array of mechanisms to deal with elevated concentrations of heavy metals and are often precise for one or few metals. This is achieved in different ways either through biological, physical, or chemical systems which include precipitation, complexation, adsorption, transport, product excretion, pigments, polysaccharides, enzymes, and specific metal binding proteins (Gupta and Diwan, 2017; Mutiat et al., 2018). Cysteine rich metallothionein proteins play an important role in immobilization of toxic heavy metals within the bacterial cell; thereby protecting their enzyme catalyzed metabolic processes (Choudhary, 2019). The thiol groups of cysteine residues enable MTs to bind essential and non-essential metalswith high affinity (Li et al., 2015). Due to metal detoxification property bacteria possessing metallothioneins are considered an ideal tool for bioremediation of heavy metal contaminated environments (Choudhary, 2019). Moreover, MT has been used as a biomarker of metal exposure in several ecotoxicological investigations (Mikawska et al., 2018).

Being an industrial city, Guelma province (Northeast of Algeria) is facing pollution problems. Heavy metals discharged from industries and agricultural activities pose threat to human population, aquatic biodiversity as well as agricultural environment. There are multiple causes for the water contamination in the Seybouse River Basin, which has been identified as one of the polluted rivers in Guelma province (Guettaf et al., 2014; Talbi and Kachi, 2019). Currently, direct diversion of untreated waste water from municipal areas, industrial wastage and extensive agricultural practices are observed along the banks of the Seybouse River. Land degradation is becoming a serious problem in the area, and recent studies have shown that the waters of the Seybouse River contain a series of heavy metals (Belabed et al., 2017; Talbi and Kachi, 2019).

One of the best ways to remove heavy metals from the environment, which recently have attracted a lot of interest, is the use of microorganisms. The use of microorganisms not only low cost and safe for the environment, but also has a high yield and is readily available (Mohseni et al., 2014). So, the study of bacteria with different resistance mechanisms is urgent, in order to discover potential candidates for the bio-removal of contaminants of diverse origins from the environment (Giovanella et al., 2017).

In this context, the present study aims to evaluate the levels of contamination by copper and cadmium in the surface waters of Seybouse River Basin, to isolate copper-resistant and cadmium-resistant bacteria, to identify those bacteria and their ability to induce metallothionein as a fundamental research to ensure the basis of their resistance in order to use them for detoxification in further bioremediation studies.

Materials and Methods

Site description and sample collection

The study area is located in the Seybouse watershed (*Fig. 1*), which is situated in the extreme Northeast of Algeria with a surface of about 6,471 km^2 and has a population of 1.5 million. The river basin lies within the territories of Guelma province, El-Taref province (near Drean), and Annaba province. It is bordered in the north by the Mediterranean Sea, in the south by the Wilaya of Souk-Ahras, in the west by Edough Massif, Lake Fetzara, and in the east by Mafragh wadi (Louhi et al., 2012). Water of Seybouse River contributes in the irrigation of the plains of Guelma and Annaba provinces. The area is characterized by an annual average rainfall of 600 mm, a more or

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17211737

less cool winter and a hot dry summer (Guettaf et al., 2014). Water samples were collected from four sites (S1, S2, S3, S4) in the middle of the Seybouse Basin (Guelma province) (*Fig. 1*). The characteristics of the sampling sites are shown in *Table 1*.

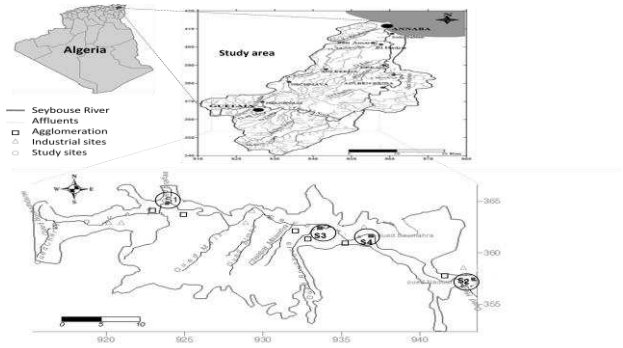

Figure 1. *Map of the four selected sampling sites in Seybouse River. S1: Bradaa wadi, S2: Nadhor wadi, S3: Boussora wadi, S4: Boumahra wadi*

Table 1. *Characterization of sampling sites at Seybouse River (Source: author'sdata)*

Sampling sites	Geographic coordinates	Pollution
Bradaa wadi (S1)	36.29376 N 7.26483 E	Agricultural activities
Nadhor wadi (S2)	36.25017 N 7.37485 E	Sewage effluents of canned tomato factory
Boussora wadi (S3)	36.28113 N 7.32064 E	Agricultural water discharges
Boumahra wadi (S4)	36.27427 N 7.31498 E	Sewage of marble factory

Twenty-four samples were collected from Seybouse River during two periods, March and April, 2019. At each sampling site, 500 mL water samples were collected for bacteriological analysis in sterile water sampling bottles (VWR, USA). Simultaneously, samples for trace metal elements (TME) were collected in 1.5 L decontaminated polyethylene bottles (VWR, USA). Water samples were acidified using 1% HNO_3 (REACH, Netherlands) to reach a pH lower than 2. Using a vacuum pump (MIDLAND, USA), 0.5% (v/v) was filtered with a membrane of 1.2 µm porosity (SARTORIUS, France) and then preserved at 0°C prior to TME analysis.

Environmental factor measurements

Water temperature (T), pH, salinity, dissolved oxygen (DO) and electrical conductivity (EC), were measured in situ at the time of sampling using a field multimeter (WTW Multi 340i, Germany). The concentrations of two trace metal elements (Cu and Cd) in the water were determined using an Inductively Coupled Plasma-Atomic Emission Spectroscopy (ICP-AES, Thermo Electron IRIS Intrepid II XSP, USA). The results were expressed in mg/L for water. All the measurements were performed in triplicate.

Screening and characterization of metal-resistant bacteria

Two metals (Cd^{2+} and Cu^{2+}) were selected for metal resistance screening based on a wide range of expected toxicities and their presence in water samples. Bacteria from the water samples were isolated using the spread plate technique. During routine culture

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17211737

and experimental procedures, bacterial cells were grown in liquid Luria Broth (LB) (pH 7.2–7.4) (KD Medical, Germany) in the presence of 100 µg/mL heavy metal and incubated at 37 °C with shaking at 150 rpm for 24 h (Xiaoyan et al., 2016). The metals were added as $CdCl_2 \cdot 2H_2O$ and $CuSO_4 \cdot 5H_2O$ (Merck, Germany). Control plates also prepared with LB media without including any heavy metal to make comparison. Individual distinct colonies were identified by their morphological and biochemical characteristics according to procedures described by Holt et al. (1994).

Minimum inhibitory concentration (MIC) and Minimal biocidal concentration (MBC)

The Minimal Inhibitory Concentration (MIC) for each metal-resistant bacterial isolate was determined using LB (KD Medical, Germany) containing different concentrations of one of the two heavy metals (Cd^{+2}, Cu^{+2}): 12.5, 25, 50, 100, 200, 400, 800, 1600, 3200 µg/mL. Metal salts ($CdCl_2$ and $CuSO_4$ $5H_2O$) were used to prepare 5 g/L stock solution. Each stock solution was filter-sterilized and used for preparation of the final concentrations. After standardization of the inoculums, 1 mL of the diluted inoculums was added to 1 mL of each metal concentration except for the sterility control, which contained only LB (Keevil, 2001). Subsequently, the tubes were incubated in an oven at 37 °C for 24 h. Microbial growth was considered as positive in the tubes that showed any increase in turbidity or growth at the bottom. The MIC was defined as the lowest dilution with negative growth. To determine the minimum bactericidal concentration (MBC), a 10 µL from those tubes, which did not show any visible growth in MIC assay, was cultured on LB agar (KD Medical, Germany) and incubated at 37 °C for 18 to 24 h. The lowest concentration of metal producing no growth was considered to be the minimum bactericidal concentration (MBC). When growth was observed with the highest concentration of the antibacterial, the MBC was considered as the highest dilution and was indicated by the sign "greater than (>)" (Keevil, 2001). Non-inoculated LB culture medium was used as the negative control and LB culture medium without the addition of metals as the positive control.

Extraction and estimation of metallothionein (MT)

Five best isolates (KZ2, KZ5, KZ8, KZ10 and KZ11) were selected based on degree of resistance to heavy metals. The metallothioneins (MTs) secreted by strains under heavy metal pressure were quantitatively assessed by the method of Murthy et al. (2011). The amounts of metallothionein in the samples were estimated using the GSH standard (Bio-tech, China), assuming that 1 mol of MT contains 20 mol of cysteine and were expressed in nmol/g bacterial biomass (Ana and Garcia-Vazquez, 2006). All experiments were performed in triplicate.

Data analysis

The data are expressed in mean values±standard deviation of the mean (SD). Statistical analysis of the data was performed using SPSS (Ver. 25.0, 2017), and the normal distribution was verified by applying the Kolmogorov–Smirnov, making it possible to choose parametric methods for the statistical analysis. Inter-site comparisons were performed using the analysis of variance (one-way ANOVA test). If significant difference between the mean values of the physicochemical parameters and TME concentrations in all studied sites was observed, Student-Newman-Keuils post hoc test

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17211737

was used to determine differences between study sites. Student's t-test was conducted to identify the significant differences between the MT variations. The correlation between MT levels and metal concentrations are evaluated by the Pearson correlation coefficient (r) (p<0.05).

Results

Environmental characterization

The variations of physicochemical parameters and TME (Cu, Cd) in water are given in *Table 2*. The thermal water revealed similar mean values in the four sites (p = 0.765). Regarding pH, the analytical data revealed that water in the four sites was alkaline. Salinity and conductivity results showed that the maximum mean values are registered at site S4 and the lowest mean values are recorded at site S1. The dissolved oxygen levels reveal different means between the four sites, the highest level were recorded at site S3. The concentrations of the heavy metals investigated were significantly different between the different sampling sites (ANOVA, Student-Newman-Keuilspost hoc test). The maximum metal concentrations were observed at Bradaa wadi and Boumahra wadi for Cu and Cd, respectively. The concentrations of copper in water were within the respective international and national recommended limits for natural water. For Cd, the concentrations were above the limit of detection (*Table 2*).

Screening and characterization of metal-resistant bacteria

Twelve metal-resistant bacteria were isolated from surface water in middle of Seybouse basin using a spread plate procedure, and were designated KZ1 to KZ12. Physiological and biochemical characterization of the bacterial strains was shown in *Table 3*. All of the bacteria were Gram-negative bacilli, smooth, sticky, non spore-forming and formed opaque colonies. Strain KZ5 produced a blue-green pigment that could be seen clearly in the liquid LB medium. This blue-green pigment, formed in the medium without Cd, was not present in the medium containing Cd, demonstrating that addition of Cd inhibits pigment formation (*Fig. 2*).

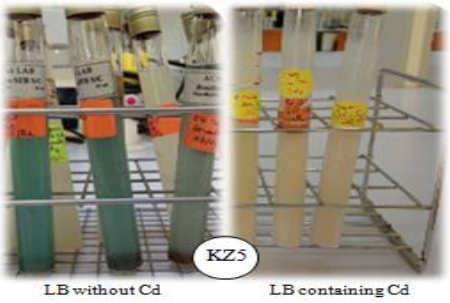

Figure 2. *Inhibition of bleu-green pigment production by the isolate KZ5 after exposure to cadmium*

Minimum inhibitory concentration (MIC) and Minimal biocidal concentration (MBC)

The order of MICs and MBCs for the majority of bacterial isolates was found to be Cu > Cd (*Table 4*). More than 40% of the strains possessed maximum tolerable concentration equal or higher than 800 µg/mL metal (*Fig. 3*). KZ2, KZ5, KZ8, KZ10 and KZ11 are resistant against Cu and Cd with the highest MIC and MBC (3600 µg/mL and > 3600 µg/mL, respectively). Cadmium tolerance was higher for *Pseudomonas aeruginosa* (KZ5) (MBC > 3600 µg/mL). Besides, *Aeromonas hydrophila* (KZ6) shows highest sensitivity to Cd as well as their resistance capacity against Cu are also lower compared to other bacteria. Comparison between all isolates to the same concentration of metal showed that the *p* values were significantly different ($p = 0.03$).

Table 4. *Minimum inhibitory concentration (MIC) and Minimal biocidal concentration (MBC) of copper and cadmium against bacteria isolated from surface water*

Bacterial isolates	Copper		Cadmium	
	MIC (µg/mL)	MBC (µg/mL)	MIC (µg/mL)	MBC (µg/mL)
KZ1	400	800	200	400
KZ2	3600	>3600	3600	3600
KZ3	800	1600	400	800
KZ4	800	1600	200	400

KZ10	3600	>3600	3600	3600
KZ11	3600	>3600	3600	3600
KZ12	800	1600	200	400

Extraction and estimation of metallothionein (MT)

Figure 4 shows the estimation of MT concentrations in the five best isolates (KZ2, KZ5, KZ8, KZ10 and KZ11). The MT concentration in the control (without metals) was zero whereas the levels of MT dosed are usually high at 1600 µg/mL metal compared to other metal concentrations. The MT level increased significantly ($r = 0.936$, $p = 0.006$)

DOI: http://dx.doi.org/10.15666/aeer/1801_17211737

in a metal concentrations. Results of this part revealed that Cd was the better inducer for MT than copper by the five isolates. The application of the Student's t-test for comparing the MT variation reveal a significant difference between MT concentration in the bacteria strains exposed to copper and MT content after exposure to cadmium ($p = 0.005$).

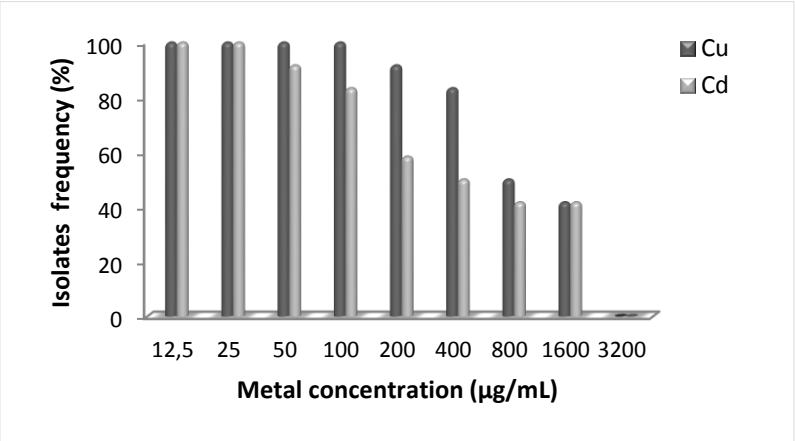

Figure 3. *Percentage of metal-resistant bacteria in relation to concentrations of heavy metals*

Discussion

Environmental characterization

The thermal water revealed similar mean values in the four sites and it depends clearly on climatic conditions (Benhalima et al., 2018). The recorded pH values demonstrated a slight water alkalinity and did not show a variation between the sites S1 and S2 (Student- Newman-Keuils test). The pH of most freshwater systems is dependent on the mineral content of the surrounding rocks, soils and contamination by agricultural, urban or industrial discharges, and often ranges from 6 to 8 (Aminot and Kérouel, 2004). Generally, the optimum pH for bacterial growth is between 6.5 and 7.5. Salinity values were slightly low in Bradaa wadi (S1) compared to the other sites; this would probably be related to the dilution phenomenon during wet periods. Cañedo-Argüelles et al. (2019) indicate that urbanization and agriculture are the main drivers of river and stream salinization. The increase in conductivity at Nadhor wadi (S2), Boussora wadi (S3) and Boumahra wadi (S4) may be due to its proximity to the intense anthropogenic activities in this part of the basin. The dissolved oxygen levels reveal different means between the four sites, the highest level were recorded at site S3. Dissolved Oxygen is essential for the survival of the aerobic organisms present in the waterbody. In addition, microorganisms such as bacteria use the dissolved oxygen to decompose the organic material at the bottom of the water, which contributes to the recycling of nutrients (Eljaiek-Urzola et al., 2019). The high concentrations of dissolved oxygen during the study period can be explained by phytoplankton flares that can cause a temporary endogenous oxygen supply in aquatic environmental (Aminot and Kérouel, 2004). The results obtained of temperature, pH and the dissolved oxygen correspond with the work performed in the northeastern surface water of Algeria (Guettaf et al., 2014; Chaoui et al., 2015).

Heavy metal pollution is a worldwide predicament which disturbs the environmental equilibrium by gaining entry into the ecosystem due to their small size and bioaccumulation tendency (Manasi and Rajesh, 2016).The measured TME in the water of the four sampling sites revealed that the two elements (Cu and Cd) are present. Copper concentrations in surface waters of surveyed wadis are not homogeneous (Student-Newman-Keuils test) but they do not exceed the international and national threshold values 2 mg/L (Zaigham et al., 2012; OJAR, 2014). The main source of Cu is telluric and would be related to the soil geology of this part of the Seybouse basin. In the study area, the importance of agricultural practices, traffic activities and municipal wastewater discharge is likely to increase transfers of Cu to surface waters. Jiang et al. (2017) indicate that copper distribution depends on the local dominance of farming and animal husbandry. In addition, Belabed et al. (2013) and Diop (2014) indicate that deterioration of sulfates (especially chalcopyrite and galenite) can increase sulfates and acidity justifying the presence of copper which increase is mainly related to the mining activity inducing trace metal mobilization. Also, DIOP (2014) indicate that copper are associated to sandy facieses directly exposed to waste discharges.

Concerning Cd, its concentration was recorded above the international and national permissible limit 0.005 mg/L (Zaigham et al., 2012; OJAR, 2014) in all the water samples. Metals in higher concentrations displace the essential nutritional minerals in the living systems and prove deleterious to them by disrupting the functioning of vital organs making it a global environmental concern (Manasi and Rajesh, 2016). The high levels of cadmium in study sites may be explained by the leaching of agriculture lands

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17211737

enriched with phosphate fertilizers and industrial liquid wastes. Huanga et al. (2019) indicated that agricultural materials (including mineral fertilizers, organic fertilizers, pesticides, plastic films, etc.) have been highlighted as a major source of Cd. Results of this study are in agreement with the studies of Louhi et al. (2012), Khaled-Khodja et al. (2016), Belabed et al. (2017) and Talbi and Kachi (2019), who reported that the level of heavy metals increasing in the Seybouse rivers due to discharge of industrial effluents, the sewage discharged by the localities and the intensive use of chemical fertilizers and pesticides in agriculture.

Screening and characterization of metal-resistant bacteria

Results revealed a predominance of Gram-negative bacteria; the strains were predominantly glucose fermentatives bacteria, which belonged to the *Enterobacteriaceae* family. There are obvious differences in the physiological and biochemical characteristics of the twelve bacteria. The strains were identified as *Escherichia coli, Citrobacter freundii, Chryseobacterium indologenes, Raoultella ornithinolytica, Pseudomonas aeruginosa, Aeromonas hydrophila*, *Acinetobacter baumannii, Klebsiella oxytoca, Pasteurella trehalosi, Proteus vulgaris, Salmonella* Typhimurium and *Shigella* spp.

Pseudomonas aeruginosa did not form a blue-green pigment after exposure to cadmium. Bacterial pigments are known to protect the cell against any photo oxidative damage caused due to the toxic metal ions. So, the lack of pigment production indicates a toxic concentration of Cd. It is already reported that at low metal concentrations, bacterial pigmentation is inhibited (Manasi and Rajesh, 2016).

Resistance in bacteria against these toxic metals reflects the threshold of environmental contamination and the direct or indirect exposure of these bacteria to the toxic compounds (Manasi and Rajesh, 2016). Bacteria have metal binding abilities and they are known to exhibit not only tolerance to metals but also their detoxification. There are many reports describing microbes, especially from enterobacteria and *Pseudomonas* genus, that are resistant to heavy metals. Niveshika et al. (2016) isolated Cd- and Cu-resistant strains of *Proteus vulgaris*, *Serratia* and *Pseudomonas* from water samples of Ganga River in India. Marzan et al. (2017) isolated Cd- resistant enterobacteria from tannery effluent in Chittagong city, Bangladesh. Türetken et al. (2019) isolated several metal-resistant bacterial strains from water samples collected from a Lake in Turkey.

Minimum inhibitory concentration (MIC) and minimal biocidal concentration (MBC)

The multi-metal resistance of the 12 bacterial strains of interest in liquid medium was tested by determining the minimal inhibitory concentrations (MIC) following a two-fold dilution technique approach. High MIC values indicate high tolerance of the bacterial isolate toward the metal and vice-versa.The results of growth pattern of bacterial isolates in presence of different of Cu and Cd concentration showed that all strains were multi-metal-resistant (Cu- and Cd-resistant). Several studies have shown the existence of multi-metal- resistant bacteria (Banerjee et al., 2015; Hoque and Fritscher, 2019; Türetken et al., 2019), and this is intimately related to the coresistance mechanism found in bacteria. Cai et al. (2019) demonstrated that flanked insert sequence elements on the heavy metal resistant genes suggested that horizontal gene transfer events may have resulted in multiple heavy metal resistance phenotypes and genotypes in bacterial strains.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17211737

Upon above experiments, the resistance level Cu > Cd showed for all bacterial isolates. This result may be explained by the fact that the toxicity of Cu is lower than Cd. At lower concentration, copper is an essential trace element participating in many vital biological processes but at high concentrations, it exerts inhibitory action on bacteria by blocking essential functional groups or modifiying. On the other hand, bacteria cells have evolved and now provide complex and efficient regulation mechanisms to neutralize toxic copper (Li et al., 2019). While, cadmium is highly toxic, it is non-essential heavy metal element for all organisms that can accumulate in cells, where it disturbs the function of some enzymes and directly attacks nuclear DNA in microorganisms (Abbas et al., 2017; Chellaiah, 2018).

The continued environmental heavy metal pollution enables bacteria to develop resistance against these substances (Türetken et al., 2019). To counteract copper intoxication, bacteria can express a wide range of efflux systems to maintain metal ion homeostasis. Other copper resistance systems found in Gram-negative bacteria, such as the periplasmic multi-copper oxidase (e.g., CueO from *E. coli*), that oxidizes Cu^{1+} to Cu^{2+} were detected (Alquethamy et al., 2019). For cadmium, three metal resistance mechanisms in bacteria have been revealed: Cd ions can be prevented from flowing into cells by the presence of polysaccharides, proteins and fats on their surfaces; Cd can be expelled through efflux pumps and it can be chelated by intracellular metallothionein (Qin et al., 2019). However, aside from these mechanisms Cd resistant genes are present in plasmid DNA of Enterobacteria (Vidhyaparkavi et al., 2017).

Among all cultures, cadmium tolerance was higher for *Pseudomonas aeruginosa*. *Pseudomonas aeruginosa* is ubiquitous in water ecosystems and showed high resistance to heavy metals (Chellaiah, 2018). Various studies have been published of different heavy metal resistant mechanisms found in the genus *Pseudomonas*, as well as reports of chromosome and plasmid-encoded genetic determinants for resistance to heavy metals (Wrightet al., 2019). Many researchers have reported that *P. aeruginosa* as Cd- and Cu-resistant bacteria were isolated from different environment regions (Chen et al., 2016; Chellaiah, 2018; Karimpour et al., 2018; Wright et al., 2019).

High MIC values against two types of heavy metals recorded for *Citrobacter freundii*, *Klebsiella oxytoca*, *Proteus vulgaris* and *Salmonella* Typhimurium can be explained by the fact that *Enterobacteriaceae* species are able to resist toxic metals, which are widely spread in the natural environment. High levels of metal ions represent a stress factor for Enterobacteria, which then enlarge their plasmids under stress conditions. However, under appropriate conditions, plasmids shrink and disappear and can adapt to the environment. Furthermore, the resistance of the *Enterobacteriaceae* members to heavy metal salts is also related to metal pollution in the environment (Çardak and Altug, 2014). Heavy metal resistance of *Enterobacteriaceae* was showed by many studies (Rafiq et al., 2017; Kyaing et al., 2019; Bhardwaj et al., 2018). Altimera et al. (2012) showed that bacteria were tolerant to copper with MIC value ranging from 3.1 to 4.7 mM. In Addition, Mathivanan and Rajaram (2014) studied that some cadmium tolerant bacteria able to tolerance up to 400 mg/L of Cd^{2+} which were isolated from the polluted coastal. Irawati et al. (2017) identified indigenous heavy metal tolerant bacteria from Kemisan River and the highest copper tolerant bacteria showed MIC value of 10 mM showing those isolates were used for further study of copper contamination control.

The *Aeromonas hydrophila* strain (KZ6) was the isolate showing the lowest metal-resistant capacity compared to other bacteria, which could be related to the toxic effect

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17211737

of metals on this bacterial cells. Moreover, microorganisms can interact with heavy metal via many mechanisms and different level of metal tolerant level might be due to different types of mechanisms such as bioaccumulation and biosorption processes within each isolates (Kyaing et al., 2019).

The reason why microbial populations differ so hugely in their ability to tolerate such deadly pollutants can be explain by the fact that such variable metal tolerance behavior occurring naturally among microbes towards various heavy metals could be due to (i) the differences in available macro and micro nutrient elements in growth media/water supporting bacterial growth (ii), variable genetic constituents of bacterial strains and (iii) the growth conditions/environmental variables affecting the bacterial growth (Rizvi et al., 2019).

Extraction and estimation of metallothionein (MT)

Considering the importance of MTs in metal detoxification, the five best isolates (KZ2, KZ5, KZ8, KZ10 and KZ11) were screened to see whether these strains were able to induce MTs production while growing in the presence of Cu and Cd. Indeed, the five strains exhibited greater production of MTs in the presence of both Cu and Cd, suggesting an obvious role of metals in MTs induction (*Fig. 2*). Maximum MT levels were recorded for *Pseudomonas aeruginosa* KZ5, *Proteus vulgaris* KZ10 and *Klebsiella oxytoca* KZ8 (77.13, 78.11 and 90.53 nmol MT/g bacterial biomass, respectively). The metallothioneins have been found in some limited *Procaryota*, including cyanobacteria, pseudomonads and mycobacteria (Genetyki et al., 2017). The first bacterial metallothionein SmtA was characterized in *Synechococcus* PCC 7942 function as sequester and detoxifies Cd^{2+} and Zn^{2+}. Later SmtA also is found in the *Anabaena* PCC 7120, *P. aeruginosa* and *Pseudomonas putida* (Malekzadeh and Shahpiri, 2017). Subsequently, proteins similar to SmtA were found in other cyanobacteria and *γ-proteobacteria*, such as the genus *Pseudomonas.* All those bacterial proteins similar to SmtA were included in BmtA (bacterial MTs) family (Gutiérrez et al., 2019). Furthermore, Gram-negative bacterial species such as *E. coli, Serratia liquefaciens, Klebsiella pneumoniae* was recognized on production of intracellular cadmium-binding proteins (Kumar et al., 2019). The bacterial MTs differ in terms of primary structure, the number and type of metal ions they bind, as well as with regard to their physiological functions. The expression of bacterial MTs is regulated by metals via metalosensors (Genetyki et al., 2017). MTs from *Enterobacteriaceae* seem to be involved in zinc and copper homeostasis, while in *Pseudomonas* they are linked to cadmium detoxification.

Results revealed that the MT level increased significantly in a metal concentration ($r = 0.936$, $p = 0.006$). Generally, the MT expression level is dose-dependent on heavy metals (Walker et al., 2014). In bacteria strains, intracellular sequestration of metals is mostly based on the presence of metallothionein which is involved in many cellular functions, particularly in the transport, storage and detoxification of metals (Chudobova et al., 2015). Therefore, an increased concentration of metallothionein can be important for homeostasis and detoxification of metals to acquire resistance to heavy metal in the bacterial strains isolated from surface water. Accordingly, the ability of bacteria isolates express metallothionein due to the expose of heavy metals compared to control (without metal) was tested. Numerous reports have shown that MTs play crucial roles in maintaining metal homeostasis and protect against heavy metal toxicity through intracellular sequestration (Chudobova et al., 2015). Mikowska et al. (2018) and Xu et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17211737

al. (2018) revealed that MTs are implicated in homeostasis of essential heavy metals such as copper, detoxification of noxious metal cations such as cadmium. Also, Abbas et al. (2017) indicate that the cadmium-resistant bacteria have also adopted the strategy to bind the cadmium with intracellular binding proteins (bacterial metallothioneins).

According to the literature, MT is predominantly a Cu-binding protein, but results of this part revealed that Cd was however, found, to be a superior inducer of MTs compared to Cu (p = 0.005).The strength of MT defense depends on several factors connected with the metal characteristics and organism attributes (Mikawska et al., 2018). Therefore, an increase in MT levels may reflect an elevated demand to detoxify Cd. Wang et al. (2014) reviewed the recent advances of characteristics, functions and applications of metallothionein and they demonstrated that Cd was the most potential for MTs induction among three metals (i.e., Cd, Cu, and Zn). Xu et al. (2018) demonstrate that metallothionein- like protein type 3 (CsMTL3) can improve metal tolerance, especially for Cd^{2+} ions and suggest that the composition and arrangement of N-terminal Cys residues are associated with binding capacity and preference for different metal ions. Similar to our research, habjanic et al. (2018) showed that a Gram-negative bacteria has a histidine-rich Mt with a disordered tail displays higher binding capacity for cadmium than other metal.

Conclusion

The results of the present study showed that the waters of Seybouse River are under the influences of heavy metal pollution (especially Cd). Eleven metal-resistant bacterial strains were isolated and identified from surface water in Seybouse basin. All of the strains were showed the resistance level Cu > Cd. The isolates *Citrobacter freundii*, *Pseudomonas aeruginosa*, *Klebsiella oxytoca*, *Proteus vulgaris* and *Salmonella* Typhimurium showed the high MIC values against Cd and Cu. These five isolates presented metallothionein induction as its mechanisms of metal resistance. It has been shown that Cd was found, to be a superior inducer of MTs compared to Cu.

The results obtained in this study, therefore, clearly establish the fact that MTs so generated by bacterial communities in stressed environments could be useful in efficiently detoxifying metal contaminated environments. Hence, the use of bacteria possessing this property of secreting MTs could be explored as a cost effective approach in bioremediation strategies. Further study of the effects of different supplements and conditions in their growth is needed to identify their efficiency as bioremediation agents, where optimization of pH, temperature, and incubation time can influence metal resistance capacity.

(Received 22nd Jul 2019; accepted 28th Nov 2019)

Abstract. This study was conducted to determine the relationships between woody plant species alpha diversity (α) and environmental factors in Dedegöl (Yenişarbademli) Mountain area. The research data obtained from 103 sampling plots after the land inventory study was used to calculate the diversity variables. The coverage area and habitat characteristics of woody plant species in each sampling plot were recorded during the field work. Clustering analysis (CLA) was used to group the sampling plots base on the vegetation data matrix. Correspondence Analysis (CA) and detrended correspondence analysis (DCA) from the ordination techniques were applied in the study to the vegetation matrix in order to determine the distribution degree of the sampling plots on the ordination axis. As a result of the CA applied, surface stoniness was found to be the environmental factor that had the highest correlation. In conclusion, surface stoniness was found to have an important impact on the vegetation distribution. Furthermore, canonical correspondence analysis (CCA) was applied at the final stage of the study. In conclusion, Shannon-Wiener was the most effective index to calculate the alpha species diversity while surface stoniness and elevation were the most explanatory variables for alpha species diversity in the study site.
Keywords: *biodiversity, forest ecosistems, habitat factors, Shannon-Wiener index, ordination methods*

Introduction

Biological diversity is the degree of variation in the living organisms in a specific ecosystem, biome or in the entire world, referring to the variability in the species, functions and structures among the living organisms. Forest ecosystems constitute the most important sources of biological diversity as they contain 2/3 of the world's ecosystems (Thompson et al., 2009).

Biological diversity is a very broad concept that covers genetic diversity, species diversity and ecosystem diversity (Hunter, 1996; Aertsen et al., 2010; Negiz, 2013).

Species diversity is one of the most important elements to determine the biological diversity in forest ecosystems. Studies on forest ecology mainly focus on plant species diversity (Özkan, 2006; Özkan and Süel, 2008; Negiz, 2013; Özkan, 2016; Negiz and Aygül, 2019).

Species diversity is divided into three categories of alpha diversity (α), beta diversity (β) and gamma (γ) diversity (Gülsoy and Özkan, 2008). Alpha diversity is determined for a specific area while beta diversity is the measure of diversity amog areas. Gamma

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_173183

diversity refers to the total diversity of the relevant ecosystem covering these areas (Whittaker, 1972; Zhao et al., 2005; Mareno et al., 2006; Hashemi, 2010).

High species diversity is very important for a forest ecosystem. Ecosystems, which have a rich species diversity, are more resilient against any kind of adverse impacts. In other words, it plays a key role in the sustainability of ecosystems (Negiz, 2013).

On the other hand, there are important relationships between species diversity and habitat characteristics in forest ecosystems. It is clear that the areas with high potential in terms of species diversity can be identified if such relationships are known (Linder, 2001; Özkan, 2006).

Our study site – Dedegöl Mountains – (Yenişarbademli) region has a very rich forest asset. However, the amount of forestlands, which were degraded by people, is close to that of the actual forestlands. Potential areas should be identified to establish new forests. Therefore, it is important to determine the biological diversity of the area. This study was conducted in order to determine the relationships between the alpha diversity of Dedegöl Mountain (Yenişarbademli) region having a very high plant species diversity in the Mediterranean region and the habitat characteristics.

Material and Methods

Study area

The study site is located in the Dedegöl (Yenişarbademli) Mountain areas in Turkey at 37°38'35″ north an 31°21'17″ east coordinates. The study site is situated in the Lakes Region of the Mediterranean Region, in the west of Beyşehir Lake, and the vast majority of the site is contained in Isparta- Yenişarbademli and Isparta-Konya provincial boundaries (*Fig. 1*). The elevation of the region varies from 820 m to 2992 m. The mean monthly temperature during many years is 10.7 degrees. The total mean annual precipitation is 727 mm.

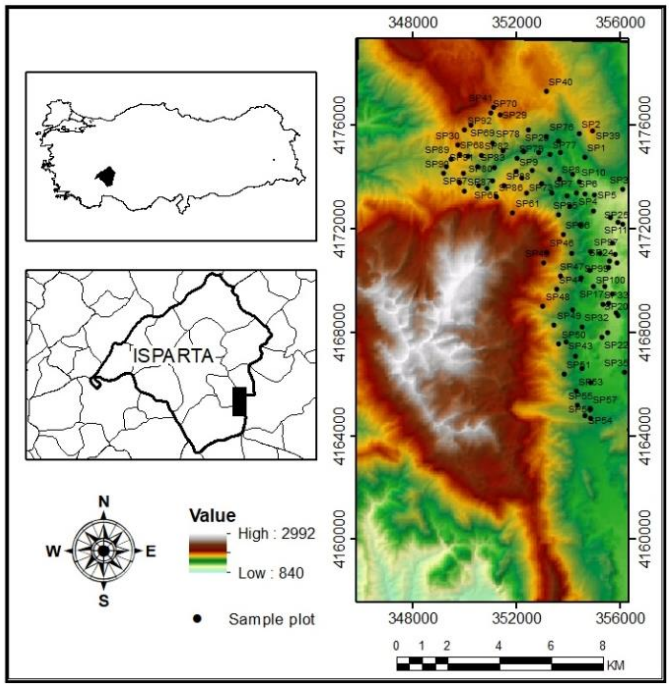

Figure 1. *Location Map of Dedegöl Mountain Region*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_173183

Sampling method

In this study, 103 sampling plots were used. Studies on sampling areas were carried out between April and September, which was the vegetation period in 2016-2017. The sampling plots were selected randomly at a size of 20 m x20 m. The woody plant species in the sampling plots were identified and recorded in the inventory cards according to the Braun-Blanquet method.

From the environmental variables; latitude, longitudes and elevation were determined with global position sistems (GPS), while slope was determined with abney level and aspect was determined with a compass and slope position was determined in 5 classes (Valley Floor: 1, Lower: 2, Intermediate: 3, Upper: 4, Ridge: 5). Surface stoniness was calculated as the mean percentage (%) of 20 different points in the lower sampling plots with an iron bar and recorded to be associated with the alpha diversity inputs. Obtained environmental variables and the codes given to them for use in statistical analysis are given in *Table 1*.

Table 1. *Environmental variables and their codes*

Codes	Environmental variables
LATITU	Latitude
LONGTI	Longitude
ELEVATION	Elevation
ASPECT	Aspect
ALTITUDE	Altitude
SLOPOS	Slope Position
SURSTON	Surface Stoniness

Data analysis

First, the environmental variables were determined for alpha diversity. During the office work, firstly the coverage area of woody plant species was digitalized according to the method propose by Fontaine et al. (2007) and Özkan (2009) to calculate the alpha diversity (r:0.01, +:0.02, 1:0.04, 2:0.15, 3:0.375, 4:0.625, 5:0.875).

The climate data was obtained from 19 different climate data downloaded from http://www.worldclim.org (*Table 2*). This data was downloaded at the world scale, and was then reduced to the scale of the study site and made available to be used in the study.

The environmental variables were obtained through the digital elevation model. First the slope and aspect maps were created with ArcGIS software, then the topographic position index (TPI), ruggedness index (EI), roughness index (PI) and shading index (GI) were created. Following these stages, different equations were used to calculate the values of the aspect compliance index (AC), temperature index (TI) and radiation index (RI).

The researchers have developed indexes to calculate the alpha species diversity such as Shannon- Wiener, Brillouin, Simpson, Margalef D and Berger- Parker (Shannon, 1948; Simpson, 1949; Berger and Parker, 1970; Clifford and Stephenson, 1975; Pielou, 1975; Özkan, 2016). Basic components analysis was applied with the help of SPSS software so as to decide which of these indexes should be used. In order to determine the relationships between the alpha values and environmental factors, spearman rank correlation analysis and regression analysis were applied with the help of SPSS software. Clustering analysis was performed according to the Ward's method through the Past program to divide the vegetation groups by using the woody plants identified in the sampling plots. The

DOI: http://dx.doi.org/10.15666/aeer/1801_173183

relationship analysis among the qualities was performed via the SPSS software in order to determine the indicator species of the groups which were divided with the clustering analysis. Ordination methods (DCA; CCA; CA) were used with the help of PC-ORD for more clear interpretation of the relationships between the woody vegetation identified in the sampling plots and the environmental factors.

BIO19	Precipitation of Coldest Quarter

Results and Discussion

The data obtained from 103 sampling plots were used. The species that had the highest presence in the study site were *Pinus nigra* (98.06%), *Cistus laurifolius* (57.28%), *Verbascum glomeratum* (57.28%).

As a result of the basic components analysis (BCA) performed to determine the representative diversity index out of the alpha diversity indexes; Taxa_S (0.937), Simpson_1-D (0.917), Shannon-Wiener index (0.950), Shannon-Wiener index were found to have the highest coefficient.

In many studies on biodiversity, usually Shannon-Wiener index was used to calculate the alpha diversity index while the results were consistent with that finding (Gorelick, 2006; Ohsawa and Nagaike, 2006; Liang et al., 2007; Gülsoy and Özkan, 2008; Negiz, 2013).

As a result of the basic components analysis (BCA) performed to reduce the climate variables or select the most suitable representative climate variables; two components with a variance greater than and variance contribution greater than 10% were found. The variance contribution of the first component was 83.3% while that of the second component was 12.7% and the rate of these two components in the total variance was 96%.

According to the Spearman rank correlation analysis that showed the relationships between the alpha species diversity and environmental factors; the alpha species diversity (Shannon_H) had a significantly positive correlation with BIO1 (r_s=0.269 and $p<0.01$), BIO2 (r_s=0.278 and $p<0.01$), BIO4 (r_s=0.273 and $p<0.01$) and BIO10 (r_s=0.274 and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_173183

$p<0.01$); BIO11 ($r_s=0.273$ and $p<0.01$); ALTITUDE ($r_s=0.292$ and $p<0.01$) and SURSTON ($r_s=0.359$ and $p<0.01$) while it had a negative relationship with BIO12 ($r_s= -0.360$ and $p<0.01$) and ELEVATION ($r_s= -0.220$ and $p<0.05$).

The alpha diversity values had positive correlations with several climate variables selected as the representative climate variables whereas it had a negative relationship with only annual precipitation (BIO12). As mentioned above, heavy snow and snow thickness at especially higher elevations in the region can be suggested as the most important reason for that. Another important aspect of the Spearman rank correlation analysis results was that the alpha diversity variables had a positive correlation with SURSTON while it had a negative relationship with ELEVATION. The positive correlation with surface stoniness can be explained by the fact that the areas with high surface stoniness were located in the south-eastern parts of the study site and thus the sunshine duration was longer in those area compared to the others.

According to the results of the multiple regression analysis performed to model the alpha diversity; R^2 value of the best model was 0.272 and its standard error was 0.348. That is, the model explained 27.2% of the variance and it is significant at the level of $p<0.01$. This model was constituted with SURSTON, ELEVATION, BIO5, TPI. The variance inflation factors of the model were lower than 5. Its tolerance values were closer to 1. The significance level of all variables including the model's constant was lower than 5%. Beta value indicates the significance of the variables in the model. In this context, ELEVATION was the most important variable.

The relationships with ELEVATION were negative as those in the Spearman rank correlation analysis. This shows that the alpha diversity was higher at lower elevations.

As a result of the clustering analysis performed according to the Ward's method; groups of 2 (T:-31.7211; A:0.05868; P:0), 3 (T:-29.3821; A:0.078724; P:0), 4 (T:-32.8804; A:0.107194; P:0) and 5 (T:-30.6251; A:0.68298; P:0) were used. In order to decide the most suitable group separation, MRPP analysis was conducted with PC-ORD program. According to the MRPP analysis; it was decided that the group of 4 had the most effective results in terms of T, A and P values.

A relationship analysis between qualities was performed to determine the indicator plant species of the groups. The analysis revealed that the most important indicator species in Group A were *Cistus laurifolius* and *Rosa canina*, while *Cistus laurifolius*, *Euphorbia* sp., *Juniperus excelsa*, *Laurus nobilis*, *Populus tremula* and *Thymus samius* were the most important indicator species in Group B. The most important indicator species of Group C were *Cistus laurifolius*, *Euphorbia* sp., *Juniperus oxycedrus* subsp. *oxycedrus*, *Rosa canina* and *Verbascum* sp. while *Sambucus ebulus* and *Abies cilicica subsp. isaurica* were the most important indicator species in Group D.

The results of the Spearman rank correlation analysis performed to investigate the relationships between the abovementioned groups and the alpha species diversity (Shannon_H). Group A (Correlation Coefficient: 0.358; Significance Level:0) and Group D (Correlation Coefficient: 0.281; Significance Level:0.004) had a positive relationship with the groups whereas Group C (Correlation Coefficient: -0.384; Significance Level:0) had a negative relationship with the groups.

In conclusion, the sampling plots in Group A were located at the intermediate elevations in the study site (1226-1694). *Rosa canina* and *Cistus laurifolius* that were the indicator species in Group A verify this finding. Group A had a higher alpha diversity than the other groups. This leads to the conclusion that the species diversity is higher at intermediate elevations in the study site. It was found that the species diversity decreased

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_173183

as the elevation increased in the study site. This can be explained by the fact that there were some snow-covered locations at high elevations in the study site with heavy snow for a long time (approximately 6 months a year). Many plant species in the region preferred low elevations due to the snow cover (Özkan, 2006; Özkan and Negiz, 2011).

The ranking and association analysis were conducted according to the ordination methods. First, the location of the vegetation communities on the axis was determined according to different ordination methods. Furthermore, the groups identified according to the clustering analysis were transferred to the ordination axis at this point to demonstrate the relationship between the groups and the distribution of vegetation communities. Finally, the environmental variables included in the data as the second matrix were associated with the ordination axis so that the vegetation-environment relationships on the axis were interpreted.

Correspondence Analysis (CA) was the first ranking-association analysis to have been applied in the study. The vegetation data matrix was evaluated with the correspondence analysis. The location of the sampling plots was identified on the ordination axis. 3 axis were obtained with this analysis, while Axis 1 (0.339; 7.72), Axis 2 (0.261; 5.93), Axis 3 (0.238; 5.43) were identified according to the Eigenvalue coefficient and variance explanation power of the axis. This indicates that Axis 1 had the highest Eigenvalue coefficient and variance explanation power. Therefore, it was decided to include only the Axis 1 in the analysis. The location of the sampling plots on Axis 1-2 is shown in *Fig. 2*.

The correlation coefficients of the relationships between the Axis 1-2 and plant species in the vegetation data matrix were found to be *Cirsium arvense* subsp. *vestitum* (0.519), *Euphorbia* sp. (0.664), *Populus tremula* (-0.564) and *Thymus samius* (0.550) while the plant species had the highest correlation with Axis 1.

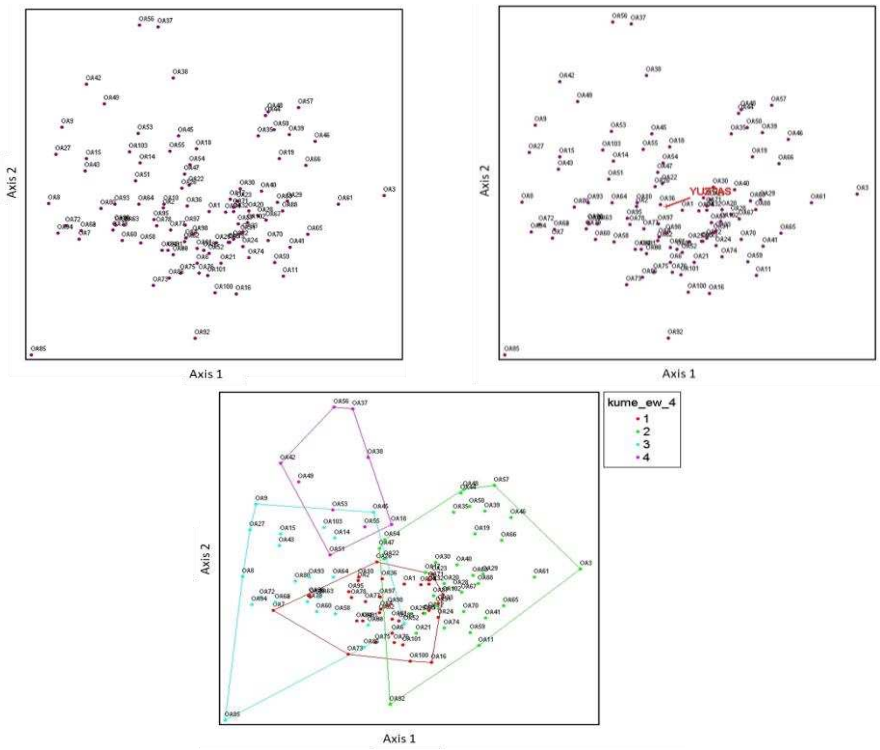

Figure 2. *Location of sampling plots on Axis 1-2 according to the correspondence analysis, location of environmental variables and Euclidean-Ward's 4 groups according to the clustering analysis*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_173183

As regards the correlation coefficients of the environmental variables according to the association between the axis and environmental data matrix; SURSTON (0.368) were found to be the environmental factor that had the highest correlation with the axis while it had a positive correlation with Axis 1. The location of the statistically significant environmental variables on the axis is shown in *Fig. 2*.

When the results relating to the vegetation data matrix and those of the environmental variables were interpreted together on Axis 1, it was understood to have a positive correlation with *Cirsium arvense* subsp. *vestitum, Euphorbia* sp., *Populus tremula*, *Thymus samius*.

At the next stage, the location of the groups identified at the Euclidean-Ward's 4 Groups separation stage in the clustering analysis according to the results of the grouping analyses was transferred to the Axis 1-2 identified in the correspondence analysis (*Fig. 2*).

The detrended correspondence analysis (DCA) was another ranking-association analysis applied in the study. With this analysis, 3 axis were identified, which were Axis 1 (0.339; 3.155), Axis 2 (0.234; 2.567) and Axis 3 (0.182; 2.193) according to their Eigenvalue coefficients and variance explanation power. Axis 2 had the highest Eigenvalue coefficient and variance explanation power. Therefore, it was decided to include only the Axis 1 in the analysis. The location of the sampling plots on Axis 1-2 is shown in *Fig. 3*.

The correlation coefficients of the relationships between Axis 1-2 and the plant species in the vegetation data matrix were found to be *Cirsium arvense* subsp. *vestitum* (0.531), *Euphorbia* sp. (0.678), *Juniperus excelsa* (0.508), *Populus tremula* (-0.562) and *Thymus samius* (0.552) while the plant species had the highest correlation with Axis 1.

As regards the correlation coefficients of the environmental variables according to the association between the axis and environmental data matrix; SURSTON (0.375) were found to be the environmental factor that had the highest correlation with the axis while it had a positive correlation with Axis 1. The location of the statistically significant environmental variables on the axis is shown in *Fig. 3*.

When the results relating to the vegetation data matrix and those of the environmental variables were interpreted together on Axis 1, it was understood that there was a positive correlation with *Cirsium arvense* subsp. *vestitum*, *Euphorbia* sp., *Juniperus excelsa*, *Populus tremula* and *Thymus samius*.

At the next stage, the location of the groups identified at the Euclidean-Ward's 4 Groups separation stage in the clustering analysis according to the results of the grouping analyses was transferred to the Axis 1-2 identified in the correspondence analysis (*Fig. 3*).

The canonical correspondence analysis (CCA) was another analysis applied in the study. With this analysis, 3 axes were identified, which were Axis 1 (0.179; 4.7), Axis 2 (0.151; 4), Axis 3 (0.118; 2.9) according to their Eigenvalue coefficients and variance explanation power. This indicates that Axis 1 had the highest Eigenvalue coefficient and variance explanation power. Therefore, it was decided to include only the Axis 1 in the analysis. The location of the sampling plots on Axis 1-2 is shown in *Fig. 4*.

The correlation coefficients of the relationships between Axis 1-2 and the plant species in the vegetation data matrix were found to be *Cistus laurifolius* (-0.557), *Cirsium arvense* subsp. *vestitum* (0.501), *Euphorbia* sp. (0.609), *Laurus nobilis* (0.540) and *Thymus samius* (0.549) while the plant species had the highest correlation with Axis 1.

As regards the correlation coefficients of the environmental variables according to the association between the axis and environmental data matrix; SURSTON (0.477) and BIO12 (0.393) were found to be the environmental factor that had the highest correlation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_173183

with the axis while they had a positive correlation with Axis 1. The location of the statistically significant environmental variables on the axis is shown in *Fig. 4*.

When the results relating to the vegetation data matrix and those of the environmental variables were interpreted together on Axis 1, it was understood that there was a positive correlation with *Cistus laurifolius*, *Cirsium arvense* subsp. *vestitum*, *Laurus nobilis*, *Thymus samius*, *Euphorbia* sp., SURSTON and BIO12.

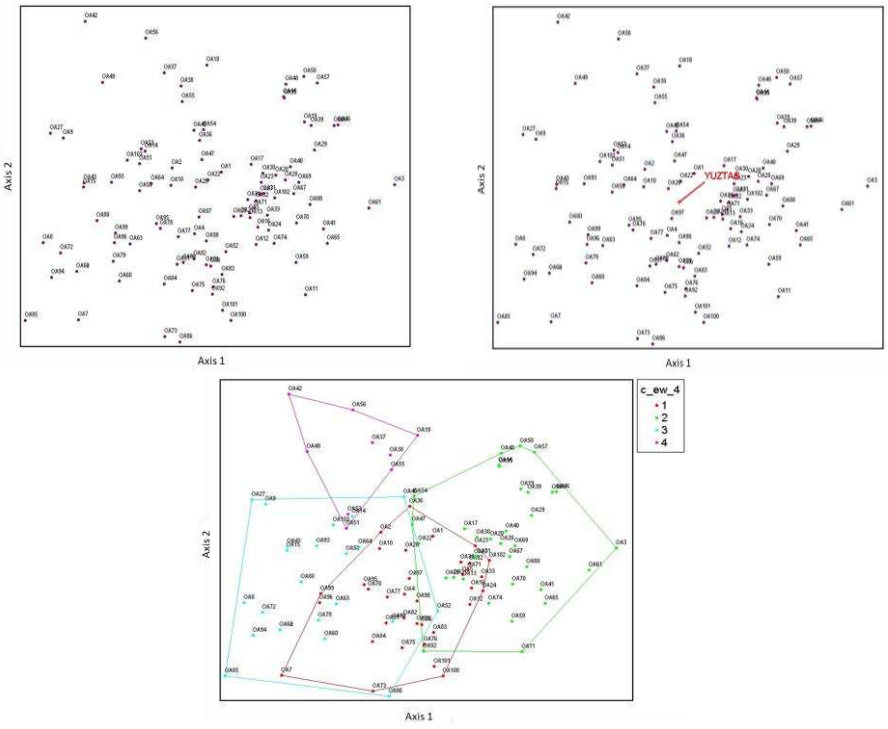

Figure 3. *Location of sampling plots on Axis 1-2 according to the detrended correspondence analysis, location of environmental variables and Euclidean-Ward's 4 groups according to the clustering analysis*

At the next stage, the location of the groups identified at the Euclidean-Ward's 4 Groups separation stage in the clustering analysis according to the results of the grouping analyses was transferred to the Axis 1-2 identified in the correspondence analysis (*Fig. 4*).

The relationships between the results of these analyses (ordination axis values of sampling plots) and habitat characteristics were tested with the Pearson correlation analysis. The results of the ordination analysis were similar concerning the statistical significance of the environmental variables. The structured groups were transferred to the graphical result of each ordination analysis and the conformity of the sampling plots with their respective groups was tested in their distribution in the ordination axis.

The results of DCA, one of the ordination methods applied, demonstrated that four groups identified in the clustering analysis were more clearly separated compared to the other ordination methods (CA, CCA) to explain the vegetation-environment relationships in Yenişarbademli.

DCA results also showed that SURSTON had the highest positive correlation with especially Axis 1 regarding the location of the sampling plots. Similarly, SURSTON was the environmental variable that had the strongest positive relationship also in RA and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_173183

CCA. Several studies conducted in the Mediterranean region found that elevation was the most important habitat factor that had an impact on the vegetation distribution (Fontaine et al., 2007; Özkan et al., 2009; Şentürk et al., 2013). The reason why SURSTON was found to be the most important variable in this study was that the areas with high surface stoniness were located in the southeast part of the study site as in the Spearman rank analysis and multiple regression analysis and thus the duration of sunlight in these areas was higher than the other locations.

As regards the CCA process, the relationships between the environmental variables demonstrate that SURSTON, BIO4, BIO12 had high relationships with one another. Therefore, the distribution of vegetation was denser especially in the southeast locations with high surface stoniness as the annual precipitation and seasonal temperature in the region increased.

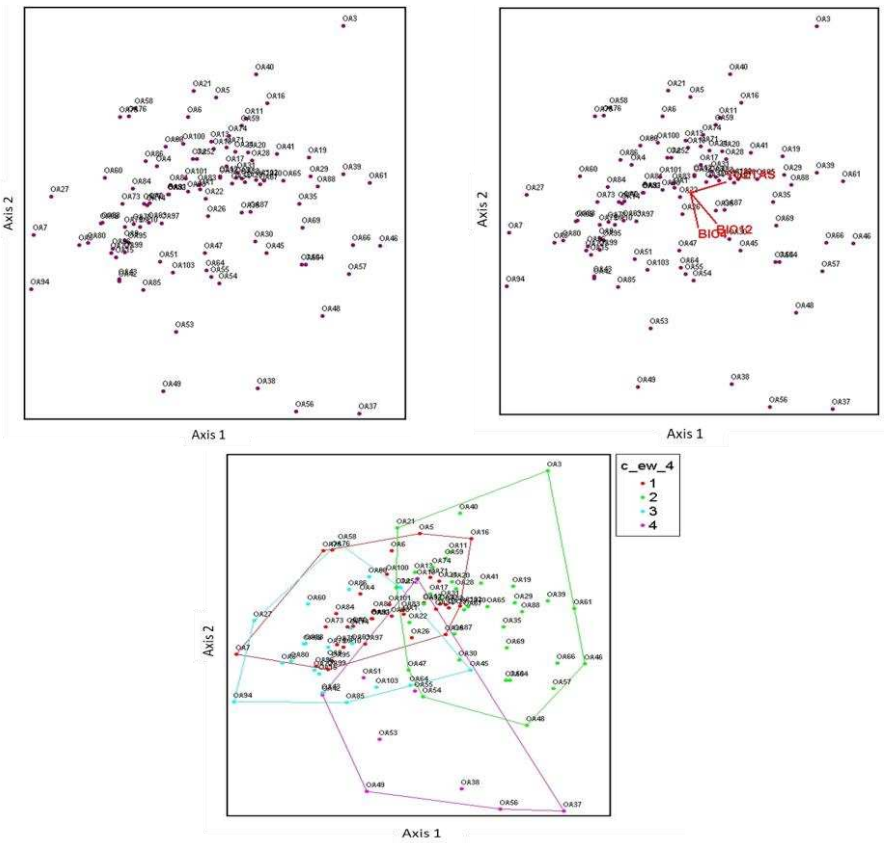

Figure 4. *Location of sampling plots on Axis 1-2 according to the canonical correspondence analysis, location of environmental variables and Euclidean-Ward's 4 groups according to the clustering analysis*

Conclusions

In summary, this study demonstrated that the sampling plots had a higher alpha diversity when the elevation variability was lower and surface stoniness variability was higher. It was also found that the distribution of vegetation was denser in areas where the seasonal temperature and annual precipitation were higher.

The study area was mountainous and carstic, which played a significant role in these findings. This information is also important to determine the areas with high potential for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_173183

the components of species diversity. The Lakes Region was one of the oldest settlements in Yenişarbademli while the ecosystem had been destroyed by people for a long time (Vanhaverbeke and Waelkens, 2003; Karaca, 2005; Özkan et al., 2010). Most of the forests have been degraded due to the destruction; therefore, it is important to understand/predict the potential of especially the destroyed areas with the help of the actual information.

(Received 13th Oct 2019; accepted 21st Jan 2020)

Abstract. Genetic diversity of 38 almond local genotypes was investigated using RADP and ISSR markers with the analysis of nut morphology. Samples were taken from five locations for this study, including Sharbazher, Mergapan, Qaradakh, Barznja, and Hawraman. Almond nuts width, length and thickness were studied and their mean values were observed to range between 16.18-27.21 mm, 24.18-41.07 mm and 11.49-16.81 mm, respectively. Polymorphic bands of mean values were 9.5 for random amplified polymorphic DNA (RAPD) and 8 for inter-simple sequence repeat (ISSR). The PIC values were recorded for RAPD primes to range between 0.77 to 0.97 and those for ISSR primers were also verified between 0.36 to 0.97. Based on Jaccard similarity coefficients, the genetic distances were recorded between 0.32 (B-G3 vs. B-G4) (M-G2 vs. M-G1) to 0.75 (H-G5 vs. Q-G1) and all genotypes were grouped into 3 major clusters (A, B and C) with a mean dissimilarity 0.535 for 20 RADP markers. In the case of the 15 ISSR markers, a genetic distance between 0.19 (H-G13 vs. H-G12) to 0.78 (H-G5 vs. B-G6) was also observed, with four clades (A, B, C and D) with a mean dissimilarity of 0.485. According to STRUCTURE analysis, all genotypes were divided into two groups. Analysis of molecular variance (AMOVA) demonstrated a high-level genetic differentiation within a population 88% for RAPD and 87% for ISSR.
Keywords: *morphological traits, genetic relationship, genetic structure, random amplified polymorphic DNA, inter-simple sequence repeat*

Introduction

Almond (*Prunus dulcis* (Mill.)) D.A. Webb syn. *P. amygdalus* L. Batsch is a commercially important fruit plant, from the *Rosaceae* family (Zhu, 2014; Sakar et al., 2019). The place of wild almond is originated at the arid mountainous region of Central Asia and deserts of western China, Iran, Turkistan, Afghanistan, Kurdistan, and Southwest Asia with subsequent expansion into European and North African regions (Browicz and Zohary, 1996; Kester and Gradziel, 1996; Xu et al., 2004) and it is also grown commercially around the world. Global almond production for 2018/19 is an estimated 1.4 million metric tons (USDA, 2018). Botanists observed over 30 species, subspecies with ecotype (Grasselly, 1976; Ladizinsky, 1999). Genetically, Almond is diploid, the chromosome number is 2n = 2x = 16 with a genome size approximately 246 Mb (Sánchez-Pérez et al., 2019).

Almond is one of the vital plants that can grow under the rain-fed condition in Iraq, particularly in the Kurdistan region. Therefore, it is important to know the adaptation of this tree that able to tolerate the biotic and abiotic stresses. Almond is a large-sized tree, with long generation time and also has a low level of variability in morphology traits (Casas et al., 1999; Sorkheh et al., 2007, 2009; Zeinalabedini et al., 2008; Bouhadida et al., 2009). To provide information about genetic relationships it is important to study the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17391753

differences at the level of agronomic, morphological and biochemical traits (Khan et al., 2016). Genetic diversity is an important tool that breeders can use to detect and identify with differentiation all genotypes and also it is a useful tool to improve the chances of the selection of better segregates for various characters (Dwevedi and Lal, 2009). Using morphological traits to the identification of almond plants is restricted, because of their environmental variations. However, morphological traits, including seed length and kernel size normally can be used.

In Kurdistan, Iraq, information about almond genotypes has been poorly recognized. Therefore, the modern molecular genetic tool can be applied to identify and characterize the relationships among them. However, several similar studies have been performed regarding genetically recognized cultivars and wild species of almond.

Molecular markers have shown the vital role in crop breeding, particularly in genetic diversity research and gene bank. PCR-based DNA marker systems are generally used, including Random amplified polymorphic DNA (RAPD), inter-simple sequence repeat (ISSR), amplified fragment length polymorphism (AFLP) and more recently simple sequence repeats (SSRs) or microsatellites (Gupta et al., 2000).

Since no molecular evidence was obtainable concerning the almond genotypes grown in Sulaimani region, therefore, the consciousness and conception of the genetic diversity in Sulaimani almond accessions are important for the implementation of degree addressed to their usages and preservations. The present study was aimed to estimate the genetic diversity with relatedness among the most important almond genotypes and for the first time their population structure in Sulaimani was developed for almond genotypes by using RAPD and ISSR markers.

Materials and Methods

Locations and plant material

Five locations (*Fig. 1*, *Table 1*) were selected for this study with thirty-eight almond local genotype trees distributed, including Sharbazher (9), Mergapan (3), Qaradakh (5), Barznja (7), and Hawraman (14).

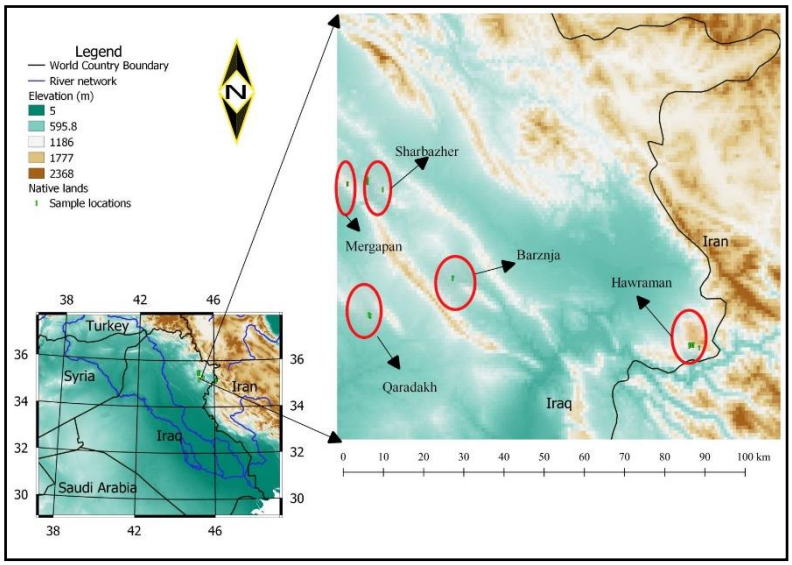

Figure 1. *Distribution of collection sites of study plant materials in Sulaimani governorate*

Q-G1 to Q-G5	Qaradagh	35°19′29″	45°19′69″	925.8
B-G1 to B-G7	Barznja	35°27′69″	45°42′21″	1154
H-G1 to H-G14	Hawraman	35°12′38″	46°07′80″	1402

Morphological study of seeds

Almond nuts were collected from each genotype (*Fig. 2*) Impurities such as damaged or broken nut, dust and dirt have been eliminated. For each nut, weight and size dimensions (the three axial dimensions) including length, width, and thickness of the nuts were measured by using a digital calliper with an accuracy of 0.01mm. The nuts were cracked, then using a hammer and kernel weighted to calculate shelling percentage.

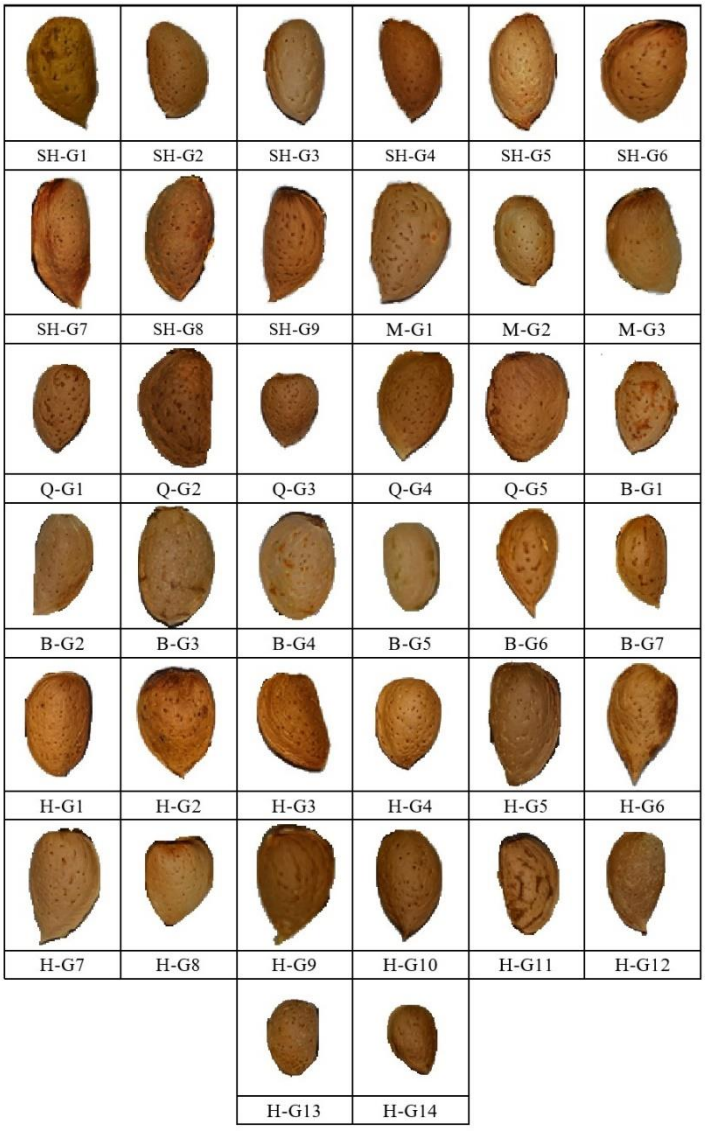

Figure 2. *Shows the different morphological shapes of all almond genotypes nut, (Scale 1:1.75)*

Genomic DNA extraction and purification

The CTAB DNA extraction protocol with some modifications was used to isolate genomic DNA, according to (Tahir and Hama Karim, 2011). Briefly, 1 gram of fresh leaves was ground and frozen in liquid nitrogen and then 2 ml of CTAB buffer was added and incubated at 60ºC for 60 min. (1 M Tris HCl (pH 8.0), 5 M NaCl, 0.5 M EDTA and 2 g of CTAB (cetyltrimethyl ammonium bromide)), the DNA sample was precipitated with 0.08 volumes of ammonium acetate and 0.54 volumes of ice isopropanol, and then the DNA pellet was washed with 1 ml of ice-cold 70% ethanol and then the dried pellet was resuspended in 50-100 µl of deionized water. DNA was treated with RNase to remove RNA contamination. The DNA concentration was analyzed by electrophoresis using a 1.5% agarose gel.

RAPD analysis

Twenty primers were utilized in this work, (*Table 2*). The reaction mixture (20 µl) was prepared for 1 volume sample (1x) which is 10 µl of master mix buffer with (0.7 µl) primer (20 pmol/ µl), 4 µl genomic DNA (100 ng/ µl) and then the total volume was completed up to 20 µl by distilled water. Amplification was carried out in a thermo-cycler (Master cycler) for 36 cycles, each consisting of an initial denaturation step at 94ºC for 10 minutes, denaturation at 94ºC for 1 minute, annealing temperature at at 36ºC for 1 minute with extension step at 72ºC for 2 minutes and then final synthesis step of 10 minutes at 72ºC, Amplification products were separated on 1.5% agarose gel in 1X TAE (Tris base, acetic acid and EDTA) buffer. Gels were run at a constant voltage of 100V for 60 minutes, then imaged using a UV trans-illuminator. The image was captured by a digital imaging system.

ISSR analysis

Fifteen primers were utilized in this study, (*Table 2*). The reaction mixture (20 µl) was prepared for one volume sample (1x) which is 10 µl of master mix buffer with 0.7 µl primer 20 pmol/ µl, 4 µl genomic DNA (100 ng/ µl) and then the total volume was completed up to 20 µl by distilled water. Amplification was carried out in a thermo-cycler (Master cycler) for 36 cycles, each consisting of an initial denaturation step at 94ºC for ten minutes, denaturation at 94ºC for 1 minute, annealing temperature at 50ºC for 1 minute with extension step at 72ºC for 2 minutes and then final synthesis step of 10 minutes at 72ºC, Amplification products were separated on 1.5% agarose gel in 1X TAE (Tris base, acetic acid and EDTA) buffer.

Design primers

Primers were designed regarding many papers including (Martins et al., 2003; Sharma et al., 2012; Pinar et al., 2015; Abodoma et al., 2017; Saleh et al., 2018).

Statistical analysis data and counting

ANOVA and comparison test among genotypes were performed by XLSTAT software. The scorable bands were coded manually as either present (1) or absent (0) (Tahir et al., 2019) and morphological data were converted to matrix data to create the PCA plot and dendrogram using Euclidean distance and Jaccard methods.

Results and Discussion

Morphological data analysis

Agro-morphological important traits in almond genotypes are nut phenotypic parameters including width, length, thickness, weight, shelling percentage for the economic and health sector. Therefore, identification of morphological traits can be discussed alongside with genetic diversity. To improve the gene pool, the physical traits are inappropriate because environmental factors have a direct influence on developmental stages of the plant with all traits consequently, they demonstrate the diversity among genotypes are just limited (Terzopoulos and Bebeli, 2008). (*Table 3*) shows the mean values of width, length, thickness, weight and shell to the kernel of nuts from thirty-eight almond genotypes, statistical differences were observed. Nut width of the almond genotypes ranged between 16.18 to 27.21 mm, length from 24.18 to 41.07 mm, thickness between 11.49 to 16.81 mm, nut weight from 2.13 to 7.52 g and shell to kernel percentage between 16.39 to 30.84%. It can be seen that our results nearly agree with Esfahlan

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17391753

et al., 2012. The values of some almond nut parameters in 40 almond genotypes statistically varied. Nut weight ranged between 3.23 to 8.34 g, nut length from 30.5 to 43.6 mm, nut width from 18.3 to 29.4 mm, and nut thickness 15.00 to 22.33 mm. Kodad et al. (2014) recorded that physical nut traits in 45 almonds with Moroccan genotypes the minimum and maximum nut width were 15.90-27.19 mm, nut length 19.25 to 41.24 mm, nut thickness 11.48-19.61 mm, nut weight 1.15-7.34 g and shelling percentage 19.91-63.79%. In addition, differences in agronomical nut data might be due to the insentience characteristics of genotypes (Kumar and Ahmed, 2015). Furthermore, geographical locations with cross-pollination by insects could be another evidence of almond diversity. (Kester and Gradziel, 1996; Woolley et al., 2000).

The principal component analyses (PCA) plot (*Fig. 3*) showed the distribution of all genotypes and morphological data on the plot. The plot demonstrated a negative relationship between shell to the kernel and nut weight. It displayed also, a positive linkage between nut width and nut thickness.

Allelic variation in almond accessions using RAPD and ISSR markers

RAPD and ISSR markers were used to analyze the genetic diversity of almond genotypes. The assessment of genetic diversity and relationships among almond specimens has been more important to improve the chances of better selection segregates for various characters (Pinar et al., 2015). The valuation of genetic diversity is significant not only for plant development but also for efficient management and conservation of germplasm resources. Information about genetic relationships is important to represent the differences at the DNA level and molecular characteristics about all genotypes. It is also significant for the breeding program which detects drought-resistant traits which is a vital trait to improve economically important crops (Khan et al., 2016). In our results of the primers tested, 20 (out of 21) RAPD and 15 (out of 17) ISSR primers were confirmed as amplified fragments for their reproducibility and high polymorphism (*Table 4*). The maximum, minimum and mean values of polymorphic bands were 5, 15 and 9.5 for RAPD and 4, 12 and 8 for ISSR, respectively. The PIC values were recorded for RAPD primes that ranged between 0.77 to 0.97 and for ISSR primers it was also verified between 0.35 to 0.96. The PIC values discovered are nearly similar to those reported such as The PIC values for 16 RAPD primers exhibited by Sharma et al. (2012) ranging from 0.26 to 0.87. Mean value of PIC was reported 0.77 using 80 primers of RAPD to 29 almond cultivars (Sorkheh et al., 2009). Shiran et al., (2007) demonstrated that the PIC values were confirmed as ranged 0.47 to 0.97 using 42 RAPD randomly primer to apply 39 almond varieties. In addition, for ISSR markers, range of PIC was got from (0.59 to 0.69) by using 21 primers that applied to 29 *prunus* species (Sarhan et al., 2015). In another research 9 ISSR primers were used in the peach plant, PIC ranged between 0.71 to 0.88 was documented (Tian et al., 2015). Furthermore, PIC values ranging from 0.13 to 0.47 and 0.12 to 0.47 were verified after using (37 RAPD and 38 ISSR) random primers for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17391753

45 peach cultivars respectively (Sharma and Sharma, 2018). Regarding the polymorphic bands, El Hawary et al. (2014) demonstrated 2.8 mean value of the polymeric band for 10 primers, and also mean of the polymorphic band was recorded as 8.36 (Gouta et al., 2008). Abodoma et al. (2017) also reported that the polymorphic band for using nine ISSR primer was 13.2 and mean value of polymeric band was 5.53 using 13 primers (Cabrita et al., 2014) recorded polymorphic band was 4.23 for 13 RAPD primer (Pinar et al., 2015) but 5 was got for 4 ISSR primers. Moreover, the average allele polymorphism was 18.6 per primer using ISSR primers applied to 29 *prunus* species (Sarhan et al., 2015).

Clustering and AMOVA analysis

Clustering analyses were performed for assessing the connection between Almond genotypes, based on the Jaccard similarity coefficients using the unweighted pair-group method (UPGMA). The dissimilarity coefficients were ranged between 0.32 (B-G3 vs. B-G4) (M-G2 vs. M-G1) to 0.75 (H-G5 vs. Q-G1), all 38 Almond genotypes were clustered into 3 groups (A, B and C) with a mean dissimilarity (0.54) for 20 RADP markers (*Fig. 4*), cluster A include H-G3, SH-G3, SH-G6, H-G4, H-G8, SH-G7, H-G11, H-G5, H-G9, H-G12, H-G7, H-G6, H-G2 and H-G10, only Q-G1 was observed in cluster B, the rest of the genotypes were found in cluster C. In addition, dissimilarity values were also observed between 0.19 (H-G13 vs. H-G12) to 0.78 (H-G5 vs. B-G6) by using 15 ISSR markers which clustered all genotypes into A, B, C and D with a mean dissimilarity of 0.49 (*Fig. 5*). Cluster A includes only H-G7, and group B is consent of all genotypes without cluster A, C, D) group C involves H-G1, SH-G6 and SH-G7, H-G3, H-G5, H-G4, H-G6 and H-G14 belong to cluster D. In addition, both RADP and ISSR markers, exhibited a dissimilarity between 0.32 (B-G3 vs. B-G4) to 0.72 (H-G1 vs. H-G9) and clustered all genotypes into 4 groups (A, B, C and D) with a mean dissimilarity of 0.52 (*Fig. 6*). Cluster A, include H-G7, group B involves H-G4, H-G6, H-G8, H-G5, H-G11, H-G10, H-G12, H-G13, H-G2 and H-G9, cluster C includes all genotypes that are not in cluster A, B, and D and cluster D includes H-G14, H-G3, SH-G3, SH-G6 and SH-G7. Many researchers registered regarding Almond genetic diversity and their relationships. Martins et al. (2003) studied the genetic diversity of Portuguese *Prunus dulcis* cultivars and their relationship using (RAPD) and (ISSR) markers, the UPGMA dendrogram also achieved a good degree of confidence between associations which was a cophenetic correlation higher than 0.80 for 124 amplified fragments. In addition, four main clusters included *P. dulcis* cultivars (cluster I); P5 (cluster II); *P. webbii* (cluster III); and *P. persica* (cluster IV), the outgroup. Pinar et al. (2015) demonstrated that dissimilarity coefficients were 0.90 and clusters and sub-clusters of the dendrogram had values of cophenetic correlation higher than 0.85 between genotypes by using the UPGMA method for the total number of amplified RAPD plus ISSR fragments with a dendrogram consisting of nine main clusters.

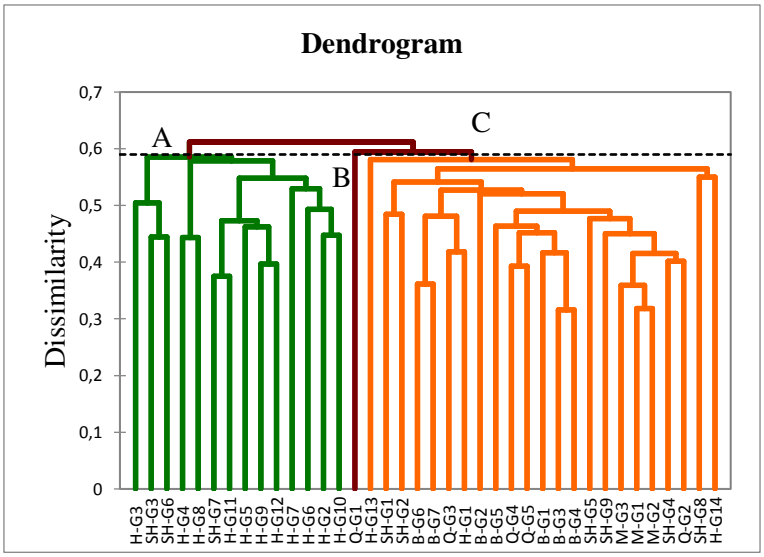

Figure 4. *Cluster tree created by UPGMA method based on 20 RAPD markers among 38 almond genotypes*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)

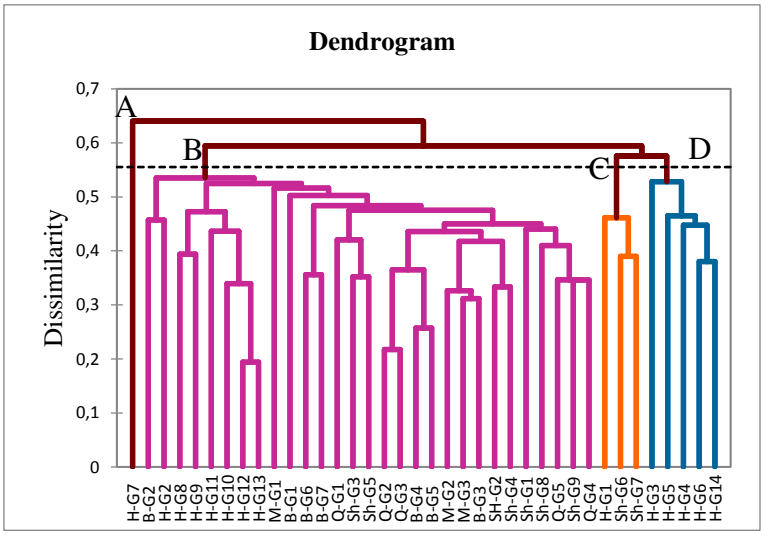

Figure 5. *Cluster tree created by UPGMA method based on 15 ISSR markers among 38 almond genotypes*

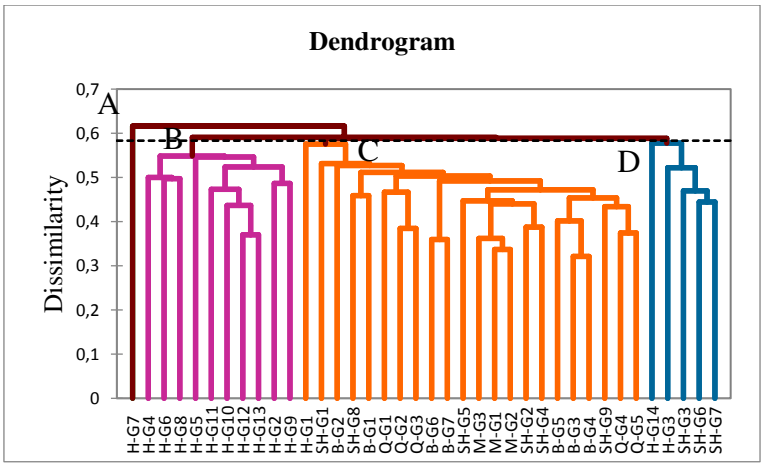

Figure 6. *Cluster tree created by UPGMA method based on 20 RAPD with 15 ISSR markers among 38 almond genotypes*

The genetic variety among the 86 almond cultivars and genotypes were assessed using 15 SSR marker and also UPGMA cluster analysis based on the similarity matrix coefficient was analyzed. Genetic similarities ranged from 0.03 (*P. tenella* and 'Ne Plus Ultra') to 1.00 (three accessions from Akdamar Island and Turkey) with an average of 0.29. Almond genotypes were clustered according to their pedigree and geographic origin. Based on the dendrogram of 86 almond cultivars genotypes, and wild species two groups of different size were formed, with *P. tenella* forming an outgroup and separated from the rest of the genotypes (Halász et al., 2019).

Analysis of molecular variance (AMOVA) of the 38 Almond genotypes in RAPD analysis demonstrated 88% of the total variation within the populations, and 12% was credited to differences between populations (*Table 5*). In addition, the ISSR marker revealed high variance in the intra-populations (87% of the total variation), and merely 13% could be qualified to differences between sub-populations. AMOVA analysis for 86

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17391753

genotypes using 15 SSR markers revealed that considerable genetic variation occurred within populations (71.30%), and genetic variation among populations was 28.70% which is a significant reaching value (Halász et al., 2019). This level of variation among populations is much higher than the value estimated for *P. sibirica* (Wang et al., 2014) or *P. mahaleb* (Jordano and Godoy, 2000), and that shown by Fernández i Martí et al. (2015) in almond.

Genetic structure for all genotypes using RAPD and ISSR markers

STRUCTURE method was used to collect evidence about population structure for almond genotypes depending on allele frequencies (Evanno et al., 2005) therefore, in this work, according to Delta K, genotypes were divided into two groups or sub-populations, group 1 (green line) and group 2 (red line). For RAPD and ISSR (*Fig. 7A and B*) clusters were also represented by colour, the red line in RAPD and the green line in ISSR consisted of Hawraman location, but the green line in RAPD and the red line in ISSR conceited other locations including Sharbazher, Mergapan, Qaradakh and Barznja. In addition, a combination class of genotypes may refer to more than one background. For example, samples SH-G3 and Q-G1 in RAPD markers (*Fig. 7A*), and only sample Sh-G1 in ISSR marker (*Fig. 7B*) could possibly have a complicated history linking intercrossing or practicably resulting from the gene flow between taxa, in addition, the high variability between genotypes may be the consequences of the changing climates found within the locations. The true number of clusters (K) in a sample of individuals was observed and determined for 20 RAPD and 15 ISSR markers, that the real highest K value was K= 2 for each marker (*Fig. 7C and D*).

Allele frequencies using STRUCTURE analysis was investigated to determine the genetic constitution of different groups. The Evanno criterion gave a strong signal for K = 9 indicating nine genetically distinct subgroups resided within the studied genotypes (Halász et al., 2019). Our results are assessed depending on genetic diversity and relationships between different accessions in different locations of Sulaimani governorate, that had some morphological similarities within genotypes and molecular studies also have verified it. It can be said that this hypothesis may be conducted the self-incompatible nature of the almond plants. Janick (1990) demonstrated that the high heterosis of the cultivars is mostly due to cross-pollination among them and also it is recorded high genetic variability. In addition, growing almonds in different regions have also been isolated during the time period that has progressed of characteristic ecotypes.

Conclusions

This work aimed to assess the genetic diversity using RAPD and ISSR mark with nut agronomical traits to 38 almond accessions grown in Sulaimani Iraq region. According to our research, Agronomical nuts (width, length, thickness, weight and shell to kernel data) were studied for each genotype that mean values of those parameters were significantly documented. Genetically, the number of polymorphic bands, major allele frequency, gene diversity and the polymorphism information content (PIC), were demonstrated. The polymorphic bands of mean value were 9.5 for RAPD and 8 for ISSR. The PIC values were recorded for RAPD primers ranging between (0.77 to 0.97) and for ISSR primers it was also verified between 0.35 to 0.96. Jaccard similarity coefficients were achieved between 0.32 (B-G3 vs. B-G4) (M-G2 vs. M-G1) to 0.75 (H-G5 vs. Q-G1) and clustered into 3 clusters (A, B and C) with a mean similarity of 0.54 for 20 RADP markers. For 15

DOI: http://dx.doi.org/10.15666/aeer/1801_17391753

ISSR markers, 0.19 (H-G13 vs. H-G12) to 0.78 (H-G5 vs. B-G6) were also observed, and clustered into 4 clusters (A, B, C and D) with a mean similarity of 0.49. In addition, based on the analysis of STRUCTURE software, RAPD and ISSR were analyzed and were divided into two groups, analysis of molecular variance stated a low variation among groups (12%) for RAPD and (13%) for ISSR. Therefore, the consequence of the genetic diversity in Sulaimani Almond accessions is important for breeding as well as to the implementation of degree addressed to their usages and preservations.

Our recommendations for future researches will be conducting quantitative traits loci analysis and genome-wide associated to determine QTL that associated with drought tolerance in almond genotypes, and also to assist future conservation and breeding programs to use different locations and accessions of almonds with using various types of markers including SNIPs, SRAPs, ALFPs, and SSRs.

Acknowledgements. We are grateful and thankful to Prof. Dr. Nawroz Abdula-razzak Tahir for his help with the software analysis and statistical analysis and also to Dr. Jamal Mahmood Faraj for his helpful comments and advice on an earlier draft of the manuscript.

THE EFFECT OF DEFICIT IRRIGATION APPLIED IN DIFFERENT PHENOLOGICAL PERIODS ON SAFFLOWER YIELD AND QUALITY

KARAŞ, E.

Osmangazi University, Department of Biosystem Engineering, Eskisehir, Turkey
(e-mail: ekaras@ogu.edu.tr)

(Received 15th Oct 2019; accepted 23rd Jan 2020)

Abstract. A field study was carried out to investigate the effect of deficit irrigation applied in the different phenological periods of safflowers (*Carthamus tinctorius* L.) at the Central Anatolian region in Turkey between 2007 and 2009. A randomized split block design in fourteen subjects with three replications was used. According to the results, the highest yield was obtained from the issue when there was no water stress during the growing period. It was found that there was a decrease in yield from the subjects when periodic water deficit was applied at various rates. At the end of the research, the most effective periods for yield were determined as flowering, vegetation, and yield formation. The average seasonal water consumption was between 234 and 591 mm; the highest and the lowest grain yield was 5.10 t ha^{-1} and 2.48 t ha^{-1}, respectively. Irrigation water usage efficiency (IWUE) ranged between 7.3 kg ha^{-1} mm^{-1} and 11 kg ha^{-1} mm^{-1}. The amount of irrigation water applied had no effect on oil ratios ranging from 28.89% to 30.66%. The effect of irrigation water applied was observed only on stearic and linoleic fatty acids. The coefficient of determination (r^2) of water-yield relationships during the experiment was obtained as 0.44, 0.71, and 0.68, respectively.
Keywords: *water use efficiency, evapotranspiration, water–yield relationship, fatty acids, oil content*

Introduction

The effects of global warming, which has increased markedly since 1980, are much more noticeable in arid and semi-arid climates (Pankova and Konyushkova, 2014; Cook et al., 2014). Due to the increasing temperatures, drought in agricultural areas makes the management of soil water in agricultural lands more and more important (Diogo, 2018; Shkolnik et al., 2019). Drought forecasts suggest that it will be more effective in the Mediterranean basin, including the Central Anatolia region (Hertig and Tramblay, 2017; Lionello et al., 2017). The main effects of drought on agricultural areas are the decrease in rainfall, the increase in recurring periods of aridity, and the lowering of groundwater due to excessive irrigation and low penetration (Gouveia et al., 2017; Caloiero et al., 2018).

Management of soil moisture in the root area is vital for plants, determination of critical and water-sensitive periods and possible drought scenarios (Pan et al., 2018; Grecksch, 2019). The main objective of water management is to maximize yield by determining the periods during which the plant is most susceptible to water shortages and the levels of sensitivity during these periods. Thanks to the development of water management strategies in plant breeding, the main objective of productive agricultural management on a watershed basis are to irrigate more land with existing water and improve the efficiency of water use (Bacelar et al., 2013; Choudhury and Singh, 2016). The development of water-saving deficit irrigation programs is also a way of ensuring food safety (Ward and Pulido-Velazquez, 2008; Shammout et al., 2018).

In Turkey, production of oilseeds (sunflower, cotton, soybean, rapeseed and safflower seeds) ranges from 2.3 to 2.7 million tonnes annually. Oilseed production distribution in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17551769

Turkey consists of sunflower (46%), cottonseed (41%), soybean (6%), canola (5%), and safflower 2% (TUIK, 2018). Although safflower is a widely recommended plant in arid conditions such as exists in Central Anatolia, some preliminary studies have shown that the plant will produce very positive results from irrigable conditions. Many studies have been carried out on plant water consumption, water use efficiency, yield, and quality under limited irrigation conditions of the safflower in Turkey (İstanbulluoğlu, 2009; İstanbulluoğlu et al., 2009; Öztürk et al., 2009). However, the research on growing safflower in arid and semi-arid conditions as in Central Anatolia has not been sufficient. This study aims to investigate the yield, some physical characteristics (grain weight, fat ratio) and changes in the fatty acid composition at various irrigation levels during the phenological periods of safflower plants in an arid and semi-arid climate.

Material And Method

Site Description

The experimental area is located at the Soil and Water Resources Research Institute in the Alpu plain, east of Eskişehir province in Central Anatolia, Turkey. The trial site coordinates are 39^{o} 46' north latitude and 30^{o} 36' east longitude, and the elevation is 780 m above sea level.

Climate

The climate characteristics of the research area are continental and fall under the influence of the Central Western Anatolia climate. In general, summers are hot and dry, and winters are cold and snowy. The average annual temperature is 10.7^{0}C, the first frost is on average October 18, the last frost is on average April 20, the lowest temperature is -26.7^{0}C, the average annual rainfall is 343.2 mm, the evaporation value is 975.7 mm and the annual average relative humidity is 62% (SWRI, 2011). The monthly average temperature, rainfall and relative humidity values of the years when the trial period was carried out are given in *Table 1*.

Table 1. *Some climatic values of the experimental area during the study*

Soil

Soil analysis tests, including physical (structure, volume weight) and chemical (pH, total salt, lime, phosphorus, potassium, organic matter) as well as infiltration tests were performed on the soils taken up to a depth of 120 cm at the research area (Tüzüner, 1990). The soil of the test area has a clay structure, consisting of slightly alkaline alluvial soils with pH values ranging between 7.50 and 8.03, and salt values varying between 0.102% and 0.187%. Although heavily structured, it is generally classified as too calcic. The soil of the test sites is defined as having high phosphorus, sufficient potassium, and low organic matter.

Irrigation water quality

The pH value of the irrigation water samples taken from the deep well in the research area was 6.8, the EC value was 0.747, the SAR value was 1.10, and no boron problem was detected (Boyacı and Karas, 2011).

Safflower variety

The safflower plant variety, Dincer, which was used in the experiment, was registered in 1977 by the Eskişehir Anatolian Agricultural Research Institute. Plant height is around 90–110 cm, the flower color is orange, the grain color is white and the plant has a thorny structure. The plant usually lasts from 127–130 days in the growing season (Boyacı and Karas, 2011).

Experimental design and field work

The experiment was conducted with a randomized split block design with 14 subjects and 3 replications (see *Table 2*). Irrigation subjects were arranged considering three different phenological periods (vegetative [V], flowering [F], yield formation [Y]) during the growing period. The plot areas were mouldboard ploughed in the fall and cultivated twice in the spring.

Table 2. *Trial subjects*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17551769

In the research, no water stress occurred in the subjects of irrigation (VFY) during the growing period of the plant. On the other hand, there was a certain amount of water stress in all other subjects and at least one period. For example, in VFY_0, no water stress occurred during vegetative and flowering periods and irrigation water was applied to meet plant water consumption needs during these periods; however, no irrigation was applied during the yield formation period. The index value in any period indicates the rate of application of irrigation water in that period. For example, the application of $V_{60}FY$, which is given as the subject of S_8 in *Table 2*, shows that 60% of plant water consumption is given in the vegetative period and full irrigation is performed during flowering and yield formation periods.

The plots were arranged in October (4.5 m x 6.0 m = 27 m^2), planted at the beginning of April and harvested (3.9 m x 5.0 m = 19.5 m^2) at the beginning of September. In the experiment, safflower was planted in 30 cm plant-row spacing and 10 cm plant-on-plant row. Fertilization was carried out according to soil analysis results. Base fertilization was applied to the soil by mixing before planting. All the phosphorus fertilizer and half of the nitrogen fertilizer were given up to planting depth of 4–6 cm with planting. During the second fertilization period, the remaining nitrogen was applied under the soil. The fertilizer requirement of the plant was realized according to the research results proposed by Yıldırım (2005); all parcels were based on 16 kg N, 8 kg P_2O_5 as a pure substance. 20-20-0 compound fertilizer with planting, Ammonium nitrate (33%) fertilizer was used as the top fertilizer.

Irrigation treatments, water use, and soil moisture measurements

In the experiment, the V, F and Y phenological periods were selected for the determination of irrigation periods in the experiment. Also taken into consideration were the principles specified by Doorenbos and Kassam (1979). Irrigation applications were carried out considering the effective root depth of 90 cm. Irrigation water was given to test plots utilizing a furrow method with plastic pipes and measured with a water meter. Soil moisture measurements were taken weekly from 0–30, 30–60 and 60–90 cm depths and determined by the gravimetric method.

Water budget equality was used to calculate plant water consumption.

$$ET_a = I + P - R - DP + CR \pm \Delta SF \pm \Delta SW \qquad \text{(Eq.1)}$$

where ETa: Actual evapotranspiration (mm), I: irrigation water (mm), P: precipitation (mm), R: surface runoff (mm), DP: deep percolation (mm), CR: capillary rise, ΔSF: subsurface flow (mm), ΔSW: change in soil water content (mm).

In the experiment, rainfall and irrigation water are directly measured values. Since the amount of water given at the effective root depth is as much as the field capacity, it is assumed that there is no deep percolation.

The agricultural operations and observations including irrigation made during the trial years are given in *Table 3*.

Seed Oil Content

The seeds were dried in the oven for 4 hours at 40°C and then ground using a blender. 4 grams of dried safflower seeds were extracted with petroleum ether for 6 hours in a Soxhlet system according to the AOCS method (AOCS, 1993). The n-hexane and oil mixture obtained after extraction was filtered and separated under vacuum using a rotary

evaporator (Heidolph® brand Laborota 4000 Efficient) at 45°C. The crude oil ratio was calculated by weighing the obtained safflower oil weight.

Fatty Acid Composition

The fatty acid composition of the safflower oils was analyzed by gas chromatography according to the AOCS standard method. The oil samples were diluted with hexane and converted into methyl esters by esterification. Fatty acid methyl esters were analyzed by Agilent 7890A model gas chromatography using a Supelco 2380 capillary column (60 m x 0.25 mm x 0.20 μm) and flame ionization detector (FID). Helium was used as carrier gas at a flow rate of 20 cm s^{-1}. Injection, furnace and detector temperatures are 250, 185 and 260°C, respectively. 1 μL of methyl ester sample was injected into the device with a split ratio of 1/100. Fatty acid methyl esters were determined by comparing retention times with reference standards. The amounts of fatty acid methyl esters were determined by using internal standard (Methyl nonadecanoate). The contents of palmitic (16:0), stearic (18:0), oleic (18:1), and linoleic (18:2) acids were determined using a computing integrator. The effects of the independent variables on oil content and palmitic, stearic, oleic, and linoleic acid concentrations of the oil were analyzed on a percentage basis.

Statistical Analysis

Statistical analysis of the data obtained from the research was carried out following the procedure proposed by Yurtsever (1984). All data were subjected to ANOVA based on general linear models for factorial arrangement of treatments in a completely randomised design using the Statview statistical package (SAS Institute, 1998). Multiple comparisons with Duncan were used to determine the effects of treatment.

Water Use Efficiency

Water Use Efficiency (WUE) is defined as the amount of carbon assimilated as biomass or grain (Yield, Y kg ha^{-1}) produced per unit (ET, mm) of water used by the crop (kg $ha^{-1}mm^{-1}$).

$$WUE = \frac{Y}{ET} \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17551769

Irrigation Water Use Efficiency (IWUE): It takes into account the amount of irrigation water (IW, mm) applied during the trial period (kg $ha^{-1}mm^{-1}$).

$$IWUE = \frac{Y}{IW} \quad \text{(Eq.3)}$$

Water use–yield relationship

The data obtained from the study were used linear regression to obtain the relationship between seasonal ET and yield. Seasonal yield response factor (ky) for each year was determined using the Stewart model (Stewart et al., 1977).

$$(1 - \frac{Ya}{Ym}) = ky(1 - \frac{ETa}{ETm}) \quad \text{(Eq.4)}$$

where, Ya, actual yield (kg ha^{-1}); Ym, maximum yield (kg ha^{-1}); ETa, actual evapotranspiration (mm), ETm, maximum evapotranspiration (mm); ky, yield response factor

The ETa and ETm values in the Stewart equation are the actual ET and maximum ET values during the study. The ETa / ETm value in the equation is considered to be 1.00 for the absence of plant water stress; It is calculated by comparing the ETa value measured for other subjects where water stress occurs to the ETa value measured for the subject without water stress. The meaning of the Ky value can be interpreted as follows considering the results obtained:

Ky >1: crop response is very sensitive to water deficit with proportional larger yield reductions when water use is reduced because of stress.

Ky<1: crop is more tolerant to water deficit, and recovers partially from stress, exhibiting less than proportional reductions in yield with reduced water use.

Ky =1: yield reduction is directly proportional to reduced water use.

Results and Discussion

The effect of water stress on grain yield

The statistical results obtained during the study are given in *Table 4*, *Table 5* and *Figure 1*. Seed yield ranged between 2.48 and 5.10 t ha. The highest yield was obtained from full irrigation (S_1) application and the lowest yield was obtained from the non-irrigation (S_{14}) subject. Seed yield showed significant fluctuations between years according to water applications. In the second and third years of the experiment, higher yields were recorded in the parcels where full water was applied, whereas no significant differences were observed between the years in S_{10} application. In other applications, different reactions have occurred. This has led to significant interactions of the year x application. The combined analysis of the results have shown that seed yield was higher in the second year of the experiment compared to the other experimental years. While the highest seed yield was obtained from full irrigation application, the lowest yield was obtained from the rainfed conditions in the experiment. In general, decreasing irrigation water causes a reduction in seed yield. In the experiment, the flowering period was the most sensitive to yield loss, followed by the vegetation and yield-formation periods, respectively. The graph of the yield in the experiment carried out is given in *Figure 1-A*.

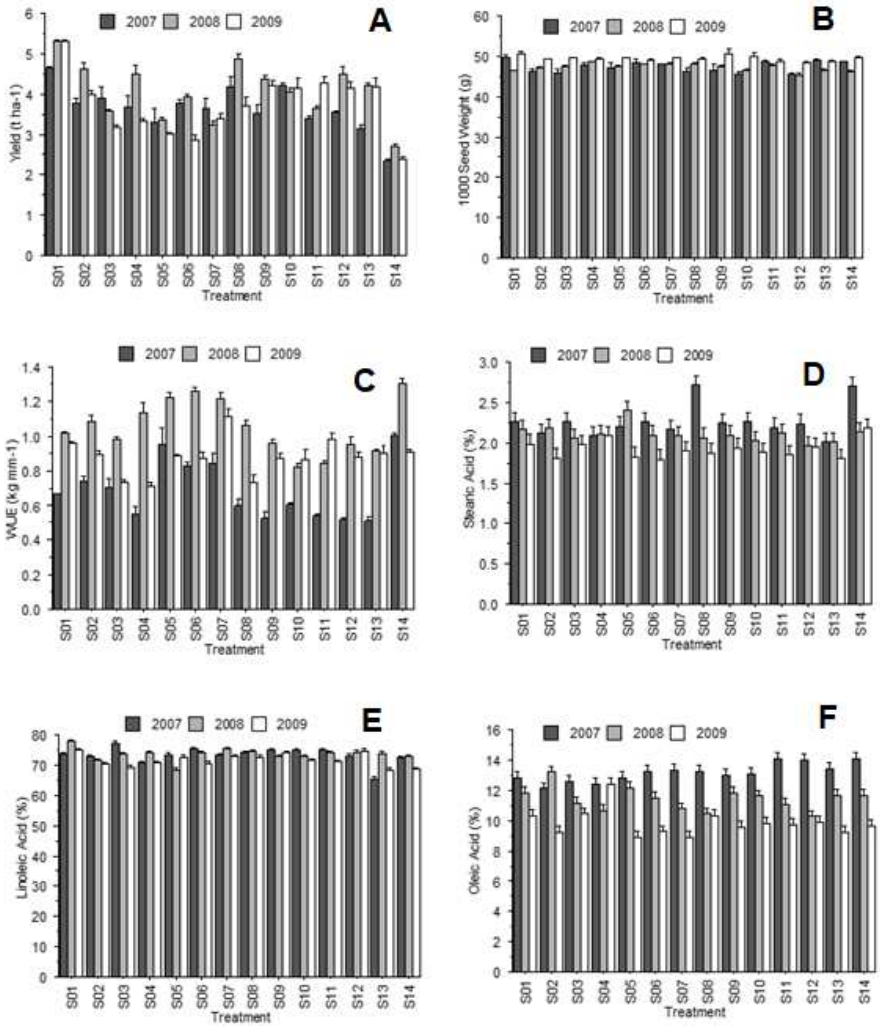

Figure 1. *Duncan grouped data in the experiment. A, yield (t ha^{-1}); B, 1000 Seed weight (g); C, WUE, kg mm^{-1}; D, stearic acid (%); E, Linoleic acid (%); F, Oleic acid (%)*

While Leonard and French (1968) obtained the highest yield as 3.68 t ha^{-1} with irrigation until the end of flowering, the lowest yield was obtained as 0.8 t ha^{-1} from irrigated subject applied until the beginning of flowering. Albel (1976) stated that the flowering period reached the maximum value of plant water consumption and that termination of irrigation during this period caused significant losses in yield. Hang and Evans (1985) indicated that water stress causes shortening in plant height, early flowering, early ripening and decrease in seed yield. Dashora and Sharma (2006) received the highest seed yield from the subject that was irrigated twice during flowering and yield formation periods. Nabipour et al. (2007) obtained the highest yield from the subject of full irrigation, whereas the lowest yield was obtained from the subject without irrigation during the flowering period. Istanbulluoglu et al. (2009) said that the effect of pre-flowering water deficit on winter safflower cultivation had more effect on the yield. Ghamarnia et al. (2010) mentioned that seed yield depends on the amount of water available in the soil. Sharrifmoghaddasi and Omidi (2010) point out that the effect on yield components of stopping irrigation after the flowering period is weak. Jabbari et al. (2010) reported that water limitation before flowering causes drastic effects. Omidi et al.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17551769

(2012) stated that drought stress before flowering importantly influenced seed yield per plant and the number of buds per plant. The reduction rate of grain yield of safflower changed from about 10% to 38%, considering the decrease of soil moisture level. Santos et al. (2018) specified that deficit irrigation in phenological stages remarkably impacted plant height, diameter, length, fresh weight, dry weight and number of stems. They pointed out the benefit of irrigation during the vegetation period but stated that irrigation during the flowering period was more effective.

Seed Weight

The highest 1000 seed weight is achieved in full irrigation, while there is a significant reduction in limited irrigation issues. The 1000 seed weights obtained in the third year of the experiment are higher than in the first two years. While the S_5, S_8, S_9, S_{11}, S_{13} and S_{14} subjects are in the same group statistically, the data of the S_4, S_6 and S_7 subjects are listed after the statistics of full irrigation. The effect of full watering during the vegetative period led to a higher seed weight of 1000 compared to the flowering and yield formation periods. The graph of the 1000 seed weight in the experiment carried out is given in *Figure 1-B*.

Irrigation Water Use Efficiency (IWUE)

The highest IWUE value was obtained from the S_{14} subjects where no irrigation was applied and from the S_7 subjects where irrigation was performed only during the yield formation period. Full irrigation did not give the highest IWUE value. The lowest IWUE values were observed in S_3, S_4, S_8, S_9, S_{10}, S_{11}, S_{12} and $S_{13,}$ in which 40% and 60% of deficit water were applied in the vegetative, flowering and yield formation periods. Subject S_1 and subject S_2 were statistically in the same group. In the annual assessment, all trial years were in different groups, while in 2008 group A, which received the least rainfall during the irrigation period, in Group B in 2009 and in 2007, in which the highest rainfall occurred in the vegetative period were in the (c) group. The graph of the IWUE in the experiment is given in *Figure 1-C*.

Low irrigation water applications generally resulted in higher IWUE values. Our results are in agreement with Lovelli et al. (2007), Istanbulluoglu (2009) and Singh et al. (2016). Conversely, Kar et al. (2007) indicated an increase in the water use of the additional irrigation number. As the irrigation number increased, the IWUE value increased. In a two-year study, the IWUE value was 1.23 kg ha^{-1} mm^{-1} with one irrigation and 2.11 kg ha^{-1} mm^{-1} with a 71% increase with two irrigations. The highest IWUE was achieved with the mean value being 2.96 kg ha^{-1} mm^{-1} with three supplemental irrigations. Abd El-Lattief (2013) obtained the highest IWUE value for irrigation when there was a 50% reduction in soil moisture levels with 20 plants per square meter.

Oil Rate and Fatty Acid Composition

The irrigation subjects applied did not have any effect on the oil ratio of the safflower. The results of this study are also confirmed by Albel (1976), Hang and Evans (1985), Hamrouni et al. (2007) and Omidi et al. (2012). Conversely, while Amini et al. (2013) determined an 8.8% reduction of the mean oil content due to water-deficit stress, Hasanvandi et al. (2014), observed an increase in oil content under irrigation conditions.

When the results of the fatty acid composition were taken into account, no effect of restricted irrigation practices on fatty acids other than stearic and linoleic acid could be

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17551769

determined. In the stearic acid composition, where four different groups were formed, the subject S_{14}, where irrigation water was never applied, formed group (a). The graphs of the stearic, oleic and linoleic acid composition are given in *Figures 1-D, 1-E and 1-F*, respectively. Similar findings were found by Cosge et al. (2007). Hamrouni et al. (2007) indicated that excessive water stress led to a decrease in linoleic acid ratios, while moderate stress increased all the fatty acids proportionately. Ashrafi and Razmjo (2010) found that stearic, oleic and linoleic fatty acids in the safflower plant decreased by 5 to 14% depending on the degree of drought stress.

Irrigation water requirements and evapotranspiration

Table 5 summarizes the average evapotranspiration, irrigation water requirement, the number of irrigation treatments, conserved proportional irrigation water, WUE, IWUE and the yield values of applied irrigation water issues.

The amount of irrigation water applied to the experimental subjects and plant water consumption values differed due to variable climatic conditions and precipitation. The lowest ET value was naturally occurring at 234 mm from the subject S_{14} where no water was given, and the highest ET value was 591 mm from the subject S_1 where full irrigation was performed. Although the ET values of S_2 and S_3 subjects, which did not irrigate only during the flowering and yield formation periods, showed significant differences during the year, the values were very close to each other on a three-year average. In spite of this proximity in terms of average value of water consumed, the average yield values obtained for 3 years led to the yields per hectare being statistically different in terms of S_2 and S_3 yields of 4.14 and 3.56 tons, respectively. In this case, it can be said that the flowering period is more sensitive to water constraints than the yield formation period. In the vegetative period, the average ET value for the S_4, where irrigation was not performed, was 510 mm and the average yield was 3.84 tons ha^{-1}. When these three periods are compared with each other, flowering, vegetative and yield formation can be listed in terms of sensitivity to water stress. In this case, when limited irrigation needs to be implemented due to lack of water in the irrigation network, the restriction should be applied in other periods, excluding the flowering period.

For the subjects S_5, S_6, and S_7 only one irrigation was carried out during the growing period. In terms of ET value, the highest plant water consumption was in the flowering period (S_6) with an average of 364 mm, followed by yield formation (S_7) with 335 mm and vegetative (S_5) with 322 mm. Although the ET values of the S_6 and S_7 periods showed a 42 mm consumption difference on average, they were in the same group in terms of average yield with 3.56 and 3.52 t ha^{-1} yield, respectively. In this case, it can be said that there will not be any difference in the preference of one of the flowering or yield formation periods in irrigation networks where there is only one irrigation opportunity during the year.

The subjects S_8, S_{10}, and S_{12}, where 60% water is applied for a single period compared to full irrigation, represent subjects where irrigation is applied at 60% during the vegetation, flowering, and yield formation periods. This means that two of these three periods are fully irrigated and 60% of water is applied for the remaining period. The mean ET values of S_8 and S_{10} were 553 and 554 mm, respectively, and the yield values were 4.25 and 4.13 t ha^{-1}, respectively. While the S_8 and S_{10} issues are in the same group in terms of yield, their irrigation water needs are 383 and 365 mm, respectively. The ET value for S_{12} was 544 mm, the yield was 4.07 t ha^{-1} and the irrigation water requirement was 363 mm.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17551769

The subjects S_9, S_{11}, and S_{13} represent subjects where 40% of total irrigation is provided during water application periods. These issues indicate that 40% of the full irrigation is given in the plant root zone and the other two periods are fully irrigated. The measured ET values for these subjects are 536 mm, 499 mm and 513 mm, respectively. The yield values obtained for these subjects, where irrigation water was applied three times, were 4.04, 3.78 and 3.85 tons per hectare, respectively, and each of them was statistically different. The water savings for the subjects were 15.7%, 22%, and 22.7%, respectively, whereas all three subjects were in the same group in terms of water application efficiency. The results of the yield–response factor are given in *Figure 2*.

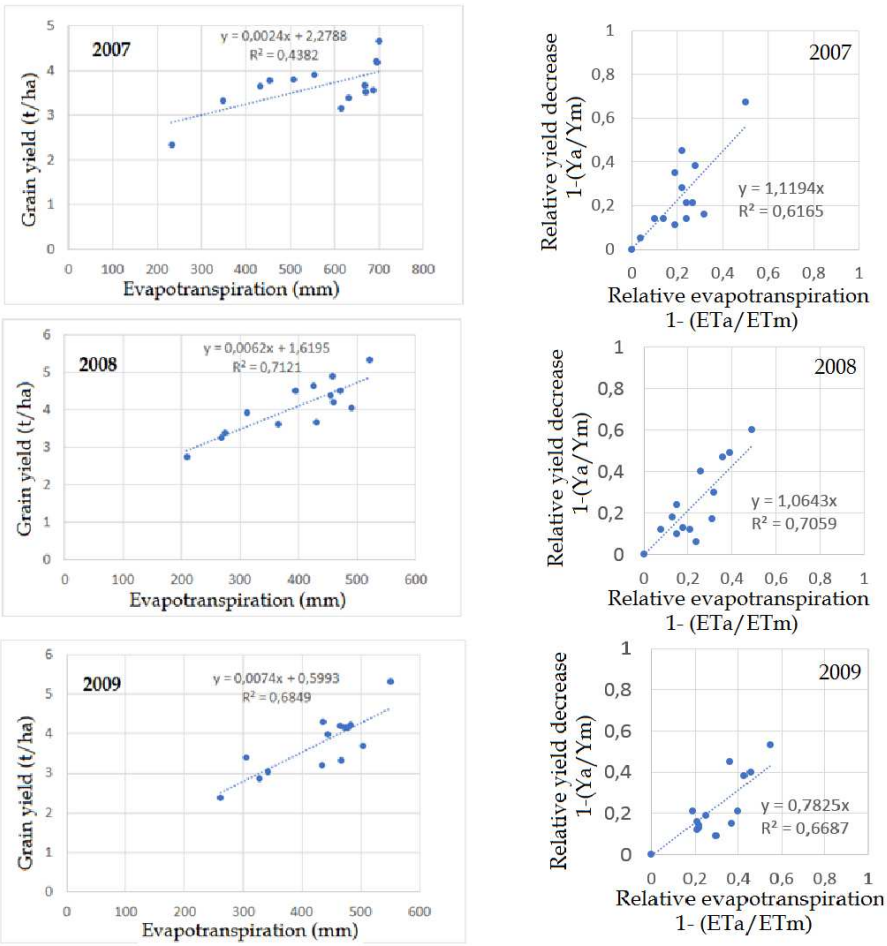

Figure 2. *Relationship between grain yield and evapotranspiration (left side), Relationship between relative evapotranspiration deficit 1 – (ET_a/ET_m) and relative yield decrease 1 – (Y_a/Y_m) (confidence level $p<0.01$) (right side)*

Water–yield relationships and yield response factor (k_y)

Irrigation water and plant water consumption and yields of the subjects were evaluated mutually and water–yield relationships were obtained during the experiment. Since yields obtained from plant water consumption values vary from year to year, water–yield relationship graphs are given separately for the years in which the experiment is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17551769

conducted. Since the maximum amount of irrigation water applied does not exceed the field capacity, the water yield relation is indicated by a linear equation.

The k_y values for the experimental years of 2007, 2008 and 2009 were 0.77, 0.84 and 1.15, respectively (mean = 0.92). The obtained k_y values for the whole growth period in this study were very close to the value of 0.80 proposed by Doorenbos and Kassam (1979), 0.93 by Lovelli et al. (2007) and 0.97 by Istanbulluoglu et al. (2009). The yield response factor (k_y) for each specific growth period proved to be an important criterion to decide which stage was the most sensitive to water. According to Lovelli et al. (2007), the k_y value, which is under 1 for safflower, indicates that the decrease in production is very low. It means that there is not much change in yield and that the plant is more resistant to water stress. Pourghasemin and Zahedi (2009) indicated that the effects of the decrease in soil moisture levels on plant growth vary according to the percentage of flowering. The decrease in soil moisture, plant height, leaf area index, plant dry matter, the number of trays per plant, bud seed weight and seed number per harvest index were not reduced at 50% of flowering. On the other hand, the decrease in soil moisture in the period when flowering is 100% leads to a decrease in these characteristics.

Phenological periods were evaluated separately by taking into consideration the values obtained during the three years of the study. The mean values obtained for the vegetation, flowering, and yield formation periods were 1.03, 1.18 and 1.00, respectively. In this case, the flowering period takes the first place in terms of its effect on yield, followed by the vegetative and yield formation periods. According to Istanbulluoglu et al. (2009), the safflower plant is most susceptible to water stress during the vegetative period, whereas Omidi et al. (2012) and Santos et al. (2018) stated that it was most susceptible during the flowering period.

Conclusions

The obtained results showed that for maximum yield in safflower cultivation, irrigation should be done without problems during all developmental stages of the plant. The flowering period is the most sensitive period for safflower productivity. Therefore, there is no compensation for the water deficit during the flowering period. The yield formation period was determined to be the second most sensitive period for soil moisture in terms of irrigation. Irrigation during this period increases the weight of 1000 grains, with especially the hectoliter weight being higher. When the k_y values obtained are evaluated together with the yield, the effect of water stress that may occur during the yield formation is seen. In this study, the effects of the safflower plant on the fat content and the fatty acid composition were investigated. The results showed that water deficit had no effect on the fat ratio, but it was found that water deficit did affect the stearic and linoleic acid ratios in the fatty acid compositions.

(Received 16th Oct 2019; accepted 8th Jan 2020)

Abstract. Genetic diversity in eggplant cultivars has drastically decreased due to developed varieties having similar desirable characteristics. In recent years, the breeders have taken much effort to enrich eggplant (*Solanum melongena* L.) genome by utilizing local populations and wild relatives similarly to the case of other plant species. In addition, wild relatives make it possible to benefit from their resistance genes which provide tolerance to biotic and abiotic stress factors. In this study, preservation and maintenance of genetic diversity by utilizing wild eggplant species to alleviate the restrictions in eggplant breeding programs caused by the limited genetic background through creating interspecific crosses was established as the main goal. In total, nine species chosen among the wild relatives of eggplant were crossed with two inbred lines developed from *Solanum melongena* L. Hybrid seed was available only in five crosses. Just, 38 lines developed in F4 stage from *Solanum insanum*. These lines were examined morphologically by using 27 descriptors. The data was analyzed by NTSYSpc: Numerical Taxonomy and Multivariate Analysis System (Version 2.0) program for understanding their phylogenetic relationship. A high variance changing in between 27% and 97% was observed among them. This result showed that they have good potentials to be used in breeding programs.
Keywords: *ancestor, genetic diversity, phylogenetic relationship, relative*

Introduction

Eggplant is one of the most valuable vegetables highly consumed in populated countries like India, China, Indonesia, Japan, the Philippines, in Asian countries, also in European and African countries (Frary et al., 2007; Looney, 2016). It has rich contents of minerals, antioxidants, fiber and vitamins (Kalloo, 1993; Scorsatto et al., 2017), which makes it suitable for human nutrition. Its production quantity is increasing year by year in the world. A significant part of commercialized eggplant F1 hybrid varieties have black color fruits and they are quite similar to each other (Muñoz Falcón et al., 2009). The breeder's genetic resource capacities and variants have become decreased because the gene pools used in breeding programs have been focused to develop F1 varieties that are indistinguishable from one another. Furthermore, the wide-spreading use of these commercial varieties pose a risk to the extinct of genetic diversity in a long term period (Cericola et al., 2013). Another problem faced by the breeders is that these commercial varieties are susceptible to biotic and abiotic stress factors (Rotino et al., 2014; Kacjan Maršić et al., 2014). In recent years, several studies have been launched to overcome of these problems. Eggplant's wild relatives have given opportunity to provide the enrichment of genetic diversity, improve resistance to biotic and abiotic stress factors and develop nutritional quality (Rotino et al., 2014; Syfert et al., 2016).

The studies on genetic relationship of eggplant wild relatives in genomic levels demonstrated their potential breeding values. The genetic diversity were determined among the eggplants including the usage of SSR marker systems. The close genetic relationship

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17711781

were revealed among *S. anguvi* and *S. aethiopicum*. Moreover *S. melongena* and *S. aethiopicum* showed high similarity. *S. macrocarpon* showed less genetic similarity. *S. linnaeanum* showed a close genetic relationship with *S. aethiopicum* compared with other species (Tümbilen et al., 2011). Constructed genetic map to found out phylogenetic relationship by using AFLPs markers has been revealed that Asian plants indicated one species *S. insanum* (*S. incanum*+*S. undatum*) as their ancestors. Another valuable wild relative of eggplant is *S. incanum* which is being used in eggplant breeding programmes for developing ILs against drought resistance. Also *S. linnaeanum* can be good resource for breeding programs regarding bacterial wilt resistance (Knapp et al., 2013). According to transcriptome analysis, the *S. aethiopicum* accession has higly intraspecific polymorphisms compared with *S. incanum*. But these African eggplants have limited potential for breeding programs in contrast to previous studies (Gramazio et al., 2016). An investigation result on gene divergence between wild and domesticated eggplants clearly showed that *S. aethiopicum* and *S. integrifolium* from section Oliganthes were placed in the same clade, but *S. sisymbriifolium* in the Sisymbriifolium clade was in the most distant clade from the cultivated eggplant on the generated phylogenetic tree (Wei et al., 2019).

Although eggplant has a large number and valuable of wild relatives, most of them has not been fully evaluated in breeding programs due to sexual barriers encountered during the interspecific crosses (Sihachakr et al., 1994). For example, it was declared that *S. melongena* were crossed with 19 well known relatives and fertile hybrids have been obtained only from four wild relatives' (*S. incanum, S. Iinneanum, S. macrocarpon*, and *S. aethiopicum)* crosses (Daunay and Lester, 1989). *S. aethiopicum* L. and *S. macrocarpon* L. have been the most remarkable species for the breeders (Daunay et al., 2019). Also, an inbred line successfully produced through interspecific hybridization from *S. linneanum* to ensure resistance against Verticillium wilt has been reported (Liu et al., 2015). BC and F2 progenies, having high phenolic content that are the health-beneficial compounds, obtained from hybridization of *S. melongena* and *S. incanum* have been evidence for genetic progress (Prohens et al., 2013). Despite all these successes obtained in interspecific hybridization of wild species and cultivar form of eggplant so far, the use of outputs is limited in the breeding program in practice. There is still no available commercial eggplant cultivar has been improved by using its wild relatives excepting rootstocks (Plazas et al., 2016). So there is still a need for further studies achieving gene pool having high genetic variability that can be useful for intense and public breeding programs from these precious resources.

The aim of this work is to develop more distant inbred lines in eggplant by taking advantage of its ancestors and contribute to increase genetic diversity which is the most important factor in increasing the success of breeding programs.

Materials and methods

Totally nine wild relatives and two inbred lines of *Solanum melongena* were used in the study. All the plant materials belonging to the wild relatives of eggplant were provided from INRA, in the Unit of Genetics and Breeding of Fruits and Vegetable, Avignon, France, by a senior researcher, Daunay, M. C. The inbred lines P45 and P5/2, having high General Combining Ability, were developed in a breeding program carried out Bati Akdeniz Agricultural Research Institute (BATEM) Antalya, Turkey. The detailed information about plant materials code, species name and origin used in the study were given in *Table 1*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17711781

Table 1. *The plant materials code, species name and origin used in the study*

Code	Species name	Origin of materials
MM132	*S. macrocarpon* L.	INRA, France
MM195	*S. linnaeanum* Hepper & Jaeger	INRA, France
MM232	*S. aethiopicum* L. Group Gilo	INRA, France
MM497	*S. violaceum* Ort.	INRA, France
MM511	*S. virginianum* L.	INRA, France
MM684	*S. incanum* L. group C	INRA, France
MM1602	*S. viarum* Dunal	INRA, France
MM1689	*S. anguivi* Lam.	INRA, France
MM510	*S. insanum* (*S. melongena* L. group E)	INRA, France
P45	*S. melongena* L. (inbred line)	BATEM, Turkey
P5/2	*S. melongena* L. (inbred line)	BATEM, Turkey

The plants of study were grown under glasshouse conditions. Two inbred lines (P45 and P5/2) belonging to *S. melongena* used as females were crossed with nine wild relatives of eggplant. The fertile F1 hybrids obtained from interspecific cross were selfed to produce F2 plants. The most fertile F2 plants were selected to construct lines and F3 to F4 progenies were raised from initial P45 x *S. insanum* and P5/2 x *S. insanum* crosses. Totally 38 lines in F4 stage were generated. These lines morphology-based phylogenies were examined with 27 descriptors selected from UPOV (Union of Plant Variety), IPGRI (International Plant Genetic Research Institution) and experiences of breeder (*Table 2*).

Table 2. *The traits, descriptors and score range used in observation for inbred lines generated from interspecific hybridization of S. melongena (P45) and S. insanum*

Traits	Description and Score range
Plant habitat	1=Open, 3=Bushy
Plant height	1=Long, 3=Intermediate, 5=Short
Stem thickness	1=Thick, 3=Intermediate, 5=Thin
Stem hairiness	1=Dense, 3=Intermediate, 5=Tenuous
Stem color	1=Grayish-green, 3=Green, 5=Green-purple 7=Purple
Shoot tip color	1=Grayish-green, 3=Green, 5=Green-purple 7=Purple
Length of internodes	1=Long, 3=Intermediate, 5=Short
Leaf color	1=Green, 3= Light green, 5= Dark green
Leaf size	1=Large, 3=Intermediate, 5=Small
Leaf hairiness	1=Dense, 3=Intermediate, 5=Tenuous

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17711781

Descriptions and score range were modified from UPOV and IPGRI eggplant descriptors. The characteristics were scored according to and compared with recognized cultivar *S. melongena* cv. Long Purple. All observations determined by measurement or counting were made on 10 plants or parts taken from each of 10 plants. Numerical data regarding fruit characteristics for each line were collected from ten harvested fruits.

The relationship among inbred lines was investigated by the technique of UPGMA, the clustering procedure was carried out using NTSYS-PC version 2.2 (Rohlf, 1998). Through the utilization of clustering technique UPGMA via SHAN module, the dendrograms were created. The cophenetic correlation coefficient was determined with the Mantel technique so as to assess the clustering effectiveness.

Results and discussion

The F1 hybrids from some interspecific crosses between the inbred lines and wild species were produced to create novel diversity that is peculiar to wild species. Only five interspecific hybrids were attained from crosses between P45 which is a parental line and *S. macrocarpon*, *S. linnaeanum*, *S. aethiopicum*, *S. incanum* and *S. incanum* among the nine species were tested in the study. Also, P5/2 produced just four hybrids from *S. macrocarpon*, *S. linnaeanum*, *S. incanum* and *S. incanum* crosses. However, interspecific F1 hybrid of *S. aethiopicum* was unfertile. The interspecific hybridization between inbred lines and *S. violaceum, S. virginianum* and *S. anguvi* were unsuccessful (*Table 3*). Some hybrids and their parents obtained from *S. melongena* (P45) x *S. incanum*, *S. melongena* (P45) x *S. macrocarpon*, *S. melongena* (P45) x *S. insanum*, *S. melongena* (P5/2) x *S. insanum* crossing are shown in *Fig. 1*.

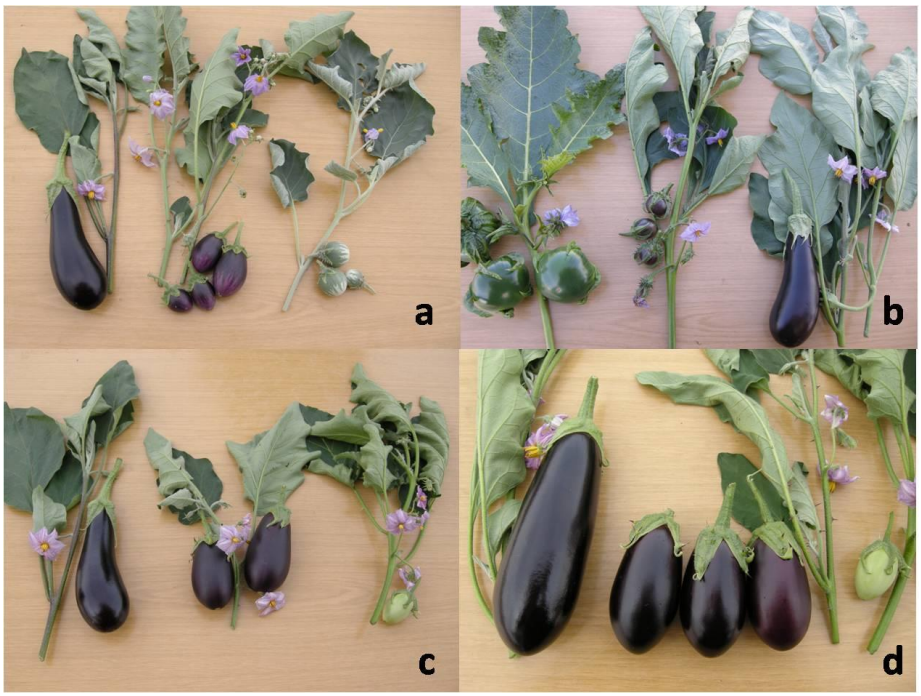

Figure 1. *Some hybrids and their parents obtained from crosses of S. melongena (P45) x S. incanum (a), S. melongena (P45) x S. macrocarpon (b), S. melongena (P45) x S. insanum (c), S. melongena (P5/2) x S. insanum (d)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17711781

The production of F2 generation plants were realized by hand pollination of F1 plants obtained from only three crosses performed among P45 and three wild relatives (*S. macrocarpon*, *S. incanum* and *S. insanum*) and P5/2 x *S. insanum*. Only, the progenies derived from inbred lines (P45 and P5/2) and *S. insanum* crosses were appropriated to sustain of F4 generations having desirable morphologic characters. 38 inbred lines in F4 stage were produced from YAB3-YAB15: P45 x *S. insanum*, YAB7-YAB16: P5/2 x *S. insanum* crosses. The other progenies generated from *S. macrocarpon* and *S. incanum* showed inconvenient characteristic specials sourced from recombination. And they were not sustainable for breeding studies. These findings were consistent with some results presented in previous studies, but not with the others. Schaff et al. (1982) reported that the fertile F1 and F2 plants have been produced from *S. melongena* x *S. macrocarpon* crosses where as the F1 hybrids could be obtained after embryo rescue from *S. melongena* x *S. aethiopicum* and *S. melongena* x *S. insanum*. *S. melongena* x *S. gilo* produced only sterile F1 hybrids. Also, the producing fertile hybrid from *S. macrocarpon* was notified by Kashyap (2002). In another study, Bletsos et al. (2004) obtained success from one cross among three crosses of *S. melongena* and *S. macrocarpon*. They stated that the female genotype plays a major effect on the success of interspecific cross. Similarly, we detected maternal effect in our study. For example, although P45 produced F1 hybrid in hybridization with *S. aethiopicum* but P5/2 did not show good performance in hybridization. This means that crossability of P45 with wild relatives can be sourced from its ancestor genes in the background. Additionally, F1 hybrids produced from crosses P5/2 and two wild relatives of eggplant (*S. macrocarpon*, *S. incanum*) had ungerminated seeds. In other study, Gowda et al. (1990) claimed contrarily that the interspecific cross of *S. macrocarpon* produce sterile hybrids due to the ovule abortion. It has been reported by Schaff et al. (1982) that the subsequent progenies were limited due to the recombination effect observed in the formation of F2 produced from *S. macrocarpon* hybrids. Taher et al. (2017) also mentioned translocation formation during meiosis in plants. Davidar et al. (2015) found out that the interspecific cross between *S. insanum* and eggplant cultivars by hand pollination had low fruit set. However, Prohens et al. (2013) informed that the highly valuable BC1P2 plants have been developed from *S. incanum* for phenolic compound improvement of functional quality. In another study, a new wild genepool consructed from interspecific cross of *S. melongena* and *S. elaeagnifolium*. This genepool carries to BC1 generation had intermediate attribute according to their parents and it is quite valuable for eggplant breeding, as it was reported by García-Fortea et al. (2019). Furthermore, Kouassi et al. (2016) have made interspecific cross between six eggplant varieties and 10 accessions of wild relatives. They obtained 44 interspecific hybrids *S. insanum, S. anguivi, S. dasyphyllum, S. incanum, S. lichtensteinii,* and *S. tomentosum.* The first backcross generations from crosses with hybrids between *S. melongena* and *S. insanum* had been achieved. Identically, the most efficient wild relative of eggplant was *S. insanum* in our study.

Using morphologic descriptors, the phylogenetic relationships among 38 inbred lines were revealed. While 24 of the 27 criteria used revealed the morphological differences among the inbred lines, 3 criteria regarding stem, shoot tip and leaf color did not affect the separation of the lines. The eigenvalue was 92% for 5 determinants. Mantel t-test values were approximately t =6.5842, p =1.0000 for the 2-way technique of Mantel Test (Mantel, 1967). Matrix correlation (r) was 0.87 (as normalized Mantel Z-Statistic) and this value was in acceptable levels. The r value verified a significant relationship

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17711781

between genetic distance matrices. The graph created from comparison of similarity matrices contains points indicating high correlation (*Fig. 2*).

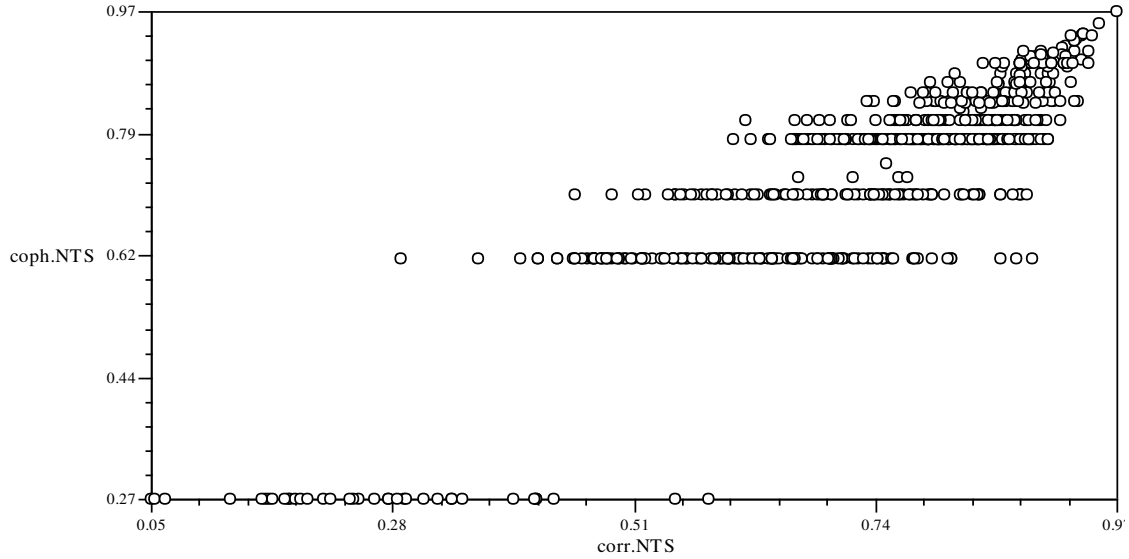

Figure 2. *The correlation between the genetic distance matrices constructed from morphological data of F4 inbred lines improved from interspecific cross between S. melongena and S. insanum using Mantel tests*

The dendrogram was formed with matrices of distance by following the unweighted pair group technique with arithmetic means (UPGMA) for phylogenetic examination (*Fig. 3*). The rates of similarity in accordance with inbred lines' coefficient similarity varied between 0.27 and 0.97. Following the UPGMA method, the lines in F4 stage generated from interspecific crosses were divided into 2 primary groups. One inbred line formed the first group (A). This line was considerably distinct compared to all other inbred line genotypes. 37 inbred lines as a majority formed the second group (B) and they were once again divided into 2 different subgroups. The first subgroup (C) consisted of four inbred lines that were developed from P45 x *S. insanum*. The greatest similarity was discovered in the 2nd subgroup (D). The inbred lines of YAB 16/9-3 and YAB 16/9-4 which belonged to the 2nd subgroup demonstrated high genetic similarity with 97% similarity rate. Although, YAB3/1-4 and YAB3/1-6 were developed from same the crosses, they had the furthest genetic distance (27% similarity rate). It was observed in the dendrogram that the lines developed from both sources were dispersed scatter inside each other. The lines which were developed from both sources did not show a significant distribution amongst themselves. The appearance regarding fruit characteristics of some lines in F4 stage are given in *Figure 4*.

Similarity rates in other studies related to intercrosses of eggplant wild relatives are as follows. Kaushik et al. (2018) evaluated 45 hybrids that were generated from inbred *S. melongena* and *S. insanum* intercrosses by using 14 morphological and agronomic descriptors. A broad range of genetic diversity among these genotypes was also founded by them. *S. melongena* consisting eighty-eight accessions, and four wild relatives (*S. insanum, S. incanum, S. integrifolium* and *S. sysimbriifolium*) have been examined to determine genetic similarity by using molecular markers. The lowest and highest similarity rate was found to be as 0.47 and 0.67, respectively (Behera et al., 2006).

DOI: http://dx.doi.org/10.15666/aeer/1801_17711781

Likewise, Karihaloo et al. detected in both molecular (1995a) and enzyme electrophoretic (1995b) studies that the similarity rate of *S. melongena* and *S. insanum* is more than 91%. In contrast, the similarity rate changed in between 0.27 and 0.97 in our findings and the genetic diversity had considerably high values.

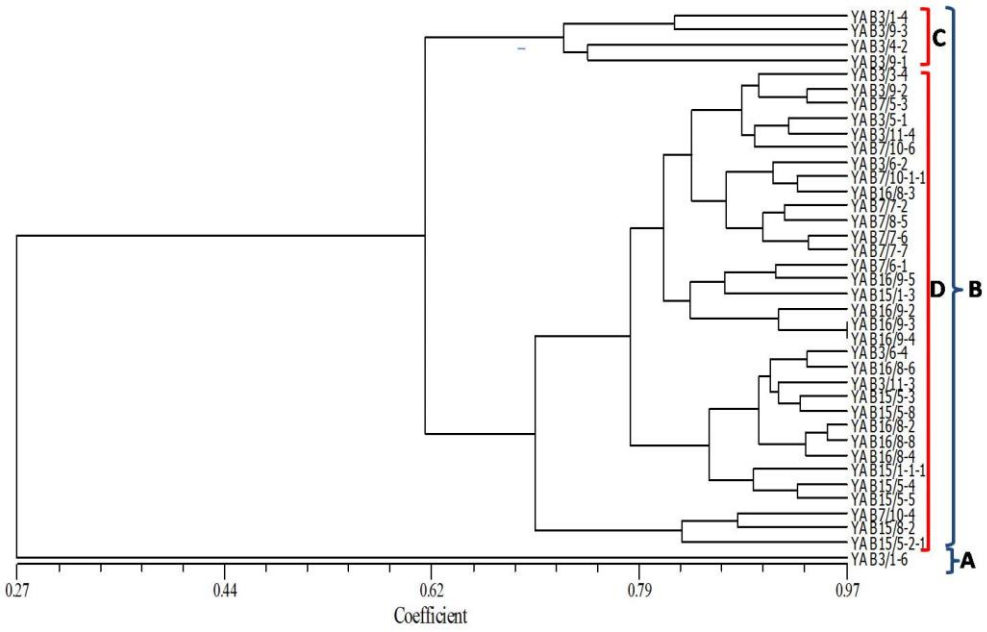

Figure 3. *Dendrogram generated based morphological data of 38 inbred lines (YAB3-YAB15: P45 x S. insanum, YAB7-YAB16: P5/2 x S. insanum) using the Underweighted Pair-Group Method with Arithmetic Mean cluster analysis of DICE (1945) genetic similarity coefficients*

DOI: http://dx.doi.org/10.15666/aeer/1801_17711781

It was specified by Kaushik (2019) that *S. insanum* which was used as a tester for observing specific combining ability (SCA) and general combining ability (GCA) components effects and heterosis rates was a better tester for important morphological features. Although *Solanum insanu*m L., natural plant of Asia and Africa, carried great potential for breeding studies, it has not paid enough attention by the breeders. Because of having great potential to cross with eggplant cultivar forms, more effort is needed to use it in breeding programs (Ranil et al., 2017).

Conclusion

This study yielded a first report related on genetic diversity of inbred lines developed in interspecific hybridization. Solanum insanum, ancestor of Solanum melongena, was identified as a good source for emerging survival next generations of inbred lines. It was defined that these lines carried F4 stage had a wide diversity in point of morphologic characters, carried biotic/abiotic stress resistance and being a good source for improving new eggplant variety that shows multiple resistance against some important stress factors. Since the success of these interspecific hybridization programs are highly dependent upon the parents used, a serious effort should be required on new interspecific crosses by using different female parents.

In conclusion, eggplant successful hybridized with *S. insanum*. Integrossion of ancestor genes to the cultivar form provided increase of genetic diversity. The developed lines from the *S. insanum* can contribute to develop commecial variety because they have the desired features like purple-colored fruit, without prickles plants etc. Our results may be relevant for the breeders and contibute to the enhancement of eggplant gene pool.

Abstract. This study compared the soil water characteristics of croplands (wheat) and orchards (apple orchard) after the reclamation of hollow villages in the Weibei rainfed highland in Shaanxi Province, China. Soil water content in the 0–150 cm soil profile was monitored during apple tree growth from March to September in 2018. The results showed that the water content of different soil layers varied through time and space in both croplands and orchards. Soil water content was significantly higher in orchards than croplands, whereas soil water stress exhibited an inverse trend. A significant drought occurred in the 0–120 cm soil profile of croplands from mid-April to mid-July, especially before the rainy season (mid-May to mid-July). Water stress was most likely to occur at the 20–60 cm soil depth. There were 78 days of soil water stress in the 20–40 cm soil layer, and soil water content was below the permanent wilting coefficient for 42 days in the 40–60 cm soil layer. Therefore, orchards are more sustainable than croplands for agricultural production after the rehabilitation of hollow villages in the Weibei area, and the development of a tree-fruit industry here is reasonable.
Keywords: *soil water, wheat field, apple orchard, spatiotemporal dynamics, water stress*

Introduction

Hollow villages have long been a problem in China, which are the result of rural residents leaving their villages in search of employment in large cities (Cheng et al., 2001; Xu, 2004; Li and Li, 2008). In response to this phenomenon, the Chinese government implemented a series of land reclamation policies (Wang, 2019; Guo et al., 2005; Fan et al., 2011; Qian et al., 2011; Chen et al., 2014).

Previous research has investigated the spatial characteristics of hollow villages (Wang et al., 2005), their evolutionary features (Xue and Wu, 2001), causes of formation (Zhong, 2008), and potential effects (Lei, 2002; Feng and Chen, 2003). It was affirmed that the reclamation of hollow villages increased agricultural land use and improved the living environment of local residents (Zhu et al., 2010). However, not knowing how to use the land after reclamation has plagued people. Soil water status is one of the most important factors for determining the suitability of different land uses (Vachaud et al., 1985; Grayson and Western, 1998; Kim and Barros, 2002; Jacobs et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17831797

2004; Vereecken et al., 2007; Famiglietti et al., 2008; Guber et al., 2008; Brocca et al., 2010; Wang et al., 2012).

The Weibei rainfed highland has experienced a transformation of agricultural production from crops to fruits. In this study, we determined the spatial and temporal variability of soil water by monitoring the soil water profile in croplands and orchards after the reclamation of hollow villages. Our results could be useful for the selection of appropriate land uses in the Weibei rainfed highland after the reclamation of hollow villages.

Materials and methods

Study area

The study area was located in Yuandi Town, Xunyi County, Shaanxi Province, China (E108°08′ –108°52′, N34°57′–35°33′). The hollow village had been under reclamation for 20 years in the northern boundary of Guanzhong Plain (*Fig. 1*). The terrain is relatively complex being mountainous in the northeast with lowlands in the southwest. The area is a typical loess plateau gully in terms of landform type, and it is cut into four north-south loess ridges by gullies. The ridges were wide and flat. The soil type is mainly black loess. The top-loose and bottom-compacted soil structure shows the features of "Mengjin (gold-covered)" soil profile configuration, with a high capability for water and fertility conservation (Dörner et al., 2015). The deep and loose geological conditions can meet the growth requirements of crops and fruit trees.

Figure 1. *Sampling area chart*

The Yuandi Town hollow village land reclamation project area included abandoned and vacant homesteads throughout the territory. The project mainly included leveling land, irrigation installation, field road construction, cropland shelterbelts, and other projects. One focus was the land leveling project, in which the old walls around the hollow villages were leveled, plowed, and reclaimed as agricultural land with a slope that could ensure the uniformity for irrigation. A balanced fertilization method was used to establish the tillage layer of cropland or orchard in the reclaimed land, in order to meet the growth requirements of crops or fruit trees. The topsoil of the reclaimed land

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17831797

contained: organic matter, 9.7–11.7 $g \cdot kg^{-1}$; total nitrogen, 0.4–1.0 $g \cdot kg^{-1}$; total phosphorous, 1.5–1.6 $g \cdot kg^{-1}$; and total potassium, 21.2–24.2 $g \cdot kg^{-1}$.

Sample collection

To monitor soil water, three fields of winter wheat were selected after the reclamation of hollow villages in Yuandi Town. The winter wheat cultivar tested was *Triticum aestivum* L., whose growth period lasts from October to June of the following year. In addition, three young apple orchards (<10 years old) were selected in the same vicinity of the wheat fields. The apple variety tested was *Malus domestica* Borkh. 'Red Fuji', whose growth period lasts 184 days from mid-March to mid-September. Wheat fertilization was performed by a single application of all fertilizers as basal dressing during soil preparation, whereas apple tree fertilization was applied by ditching. There were no other plants or weeds covering the ground of croplands or orchards.

Soil samples were collected with a 6 cm-diameter soil drill once a month from March (leaf budding) through September (apple harvest) in 2018. For each treatment, three replicate plots (500 m × 400 m per plot) were sampled. In each plot, five points were randomly selected in a plum-blossom pattern (*Fig. 2*), and each sampling unit was smaller than 20 ha. The replicate samples from three plots were mixed and five replications per treatment were obtained. Three soil samples from the same soil layer were mixed to form a composite sample of the eight soil layers along the 0–150 cm profile (0–10 cm, 10–20 cm, 20–40 cm, 40–60 cm, 60–80 cm, 80–100 cm, 100–120 cm, and 120–150 cm).

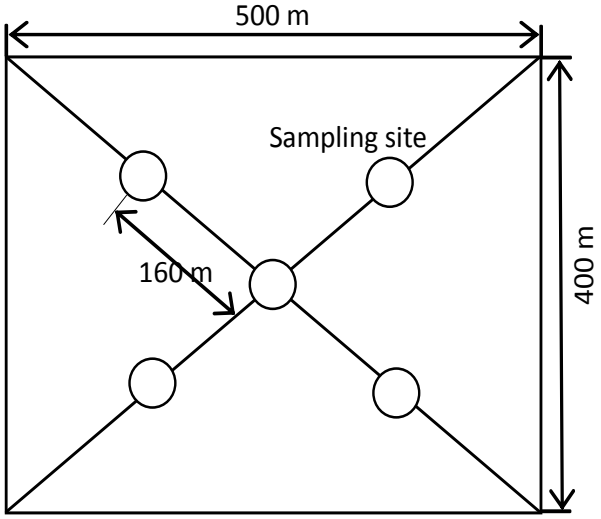

Figure 2. *Distribution of soil sampling points in each plot*

Test methods

The soil samples were transported to the laboratory within 2 h of collection and immediately weighed using an electronic balance (0.0001 g) upon arrival. Soil water content of each soil layer was determined by oven-drying at 105 °C for 24 h (Gardner, 1965). Then, the 60% field capacity in each soil layer was calculated (*Table 1*), which was equivalent to the soil water stress point, or the capillary fracture water content (Chen et al., 2008).

Data are means ± standard deviation (n = 5)

Daily rainfall was measured in Xunyi for 2018 using a SDM6A stainless ombrometer (Fenghai, Tianjin, China). Monthly values were calculated from the daily values for January to November (*Fig. 3*). The year 2018 was a normal water year, in which the rainfall from July to September accounted for 60.4% of total annual rainfall. The total rainfall was 569.1 mm over the growth period of apple from growth initiation in March to fruit harvest in September 2018 (Xunyi County Chronicle Compilation Committee, 2018).

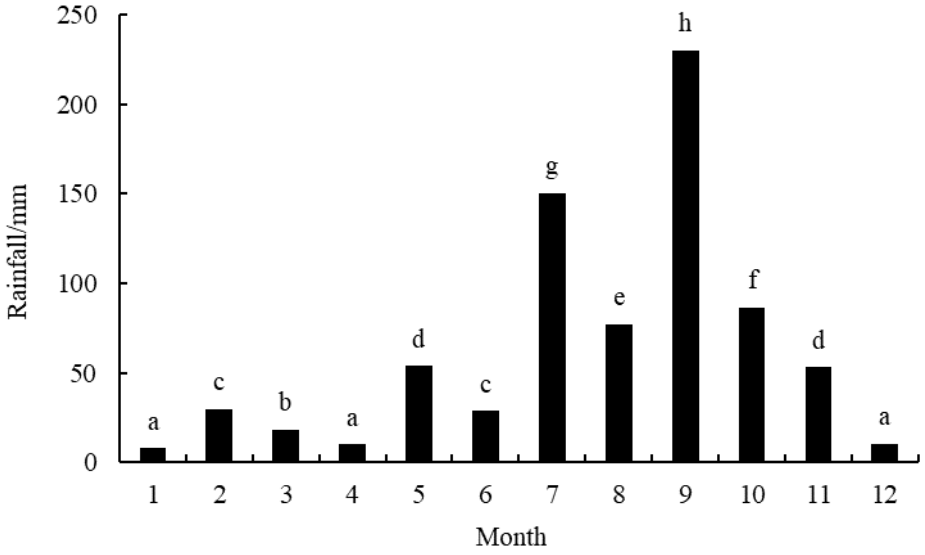

Figure 3. *Monthly precipitation in Xunyi County, Shaanxi Province, China for 2018 (n = 3, based on daily rainfall measured using a stainless ombrometer from January to November)*

Data analysis

To evaluate soil water changes during crop growth, soil water content and its changes were divided into four states using the field capacity, 60% field capacity, and permanent wilting coefficient as thresholds (*Table 2*). Then the percentage of days of each water state in apple growth period (184 days) was calculated for croplands and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17831797

orchards to quantitatively analyze the soil water status under different land use types. Mathematical modeling was carried out using Excel 2016 to simulate the process of changes of soil water content in each soil layer during apple tree growth.

Table 2. *Water content and evaluation indexes*

Soil water range	Evaluation of water status
Greater than field capacity	Water excess state (waterlogging)
Between the field capacity and 60% of field capacity	Easy to use state of water
Between 60% of field capacity and permanent wilting coefficient	Water stress state
Less than permanent wilting coefficient	Invalid state of water (drought to death)

When the soil water content exceeded field capacity, the oxygen supply was limited and drainage was needed. The most preferable state of water supply was when the soil water content was between field capacity and capillary fracture water content (equivalent to 60% of field capacity). Water stress became greater as it got closer to the permanent wilting coefficient, which was considered the state of drought and death. If the duration of water stress was short, then some drought-tolerant crops may recover, but if water stress occurs too long than even rehydrated plants will not recover.

Data are means ± standard deviation (n = 5). Statistical analysis was performed by t-test with SPSS Statistics 18.0 (SPSS Inc., Chicago, USA). A P value of less than 0.05 was considered to indicate statistical significance.

Results and discussion

Analysis of temporal and spatial changes in soil water content

Figure 4 illustrates the process of changes of soil water content through time and space for croplands and orchards during apple tree growth. After a long winter, in the spring stage, the soil water content of croplands in the 0–10 cm soil layer was 1.92% lower than that of the orchards (*Fig. 4a*). This result indicates that although the apple trees shed their leaves in winter, the dense trunks changed the wind speed and temperature near the ground, which could reduce the loss of soil water. During the whole growth period of apple trees, the water content of the 0–10 cm soil layer in orchards was always higher than that of croplands, and mostly in the most comfortable state of water. In croplands, the soil water content was in water stress or transient drought for 4 months, and the decline of soil water content was most obvious from March to April when soil water content fell below the permanent wilting coefficient. However, the drought was less serious in orchards. The maximal relative difference in soil water content between croplands and orchards occurred at the end of April when the sustained drought was most severe, and the soil water content of orchards was 56.04% higher than that of croplands. The minimal relative difference was found in August during the rainy season, with the soil water content of orchards being 10.03% higher than that of croplands. The difference in soil water content was generally large in the drought period, while it became smaller difference during the compensatory period of soil water.

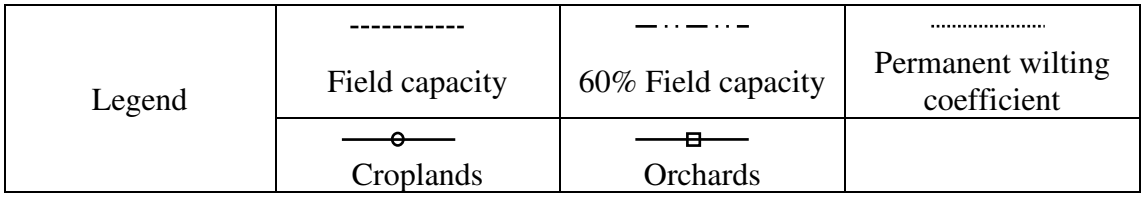

Figure 4. *Changes in soil water content with time in 0 to 150 cm profile (a) 0–10 cm soil layer, (b) 10–20 cm soil layer, (c) 20–40 cm soil layer, (d) 40–60 cm soil layer, (e) 60–80 cm soil layer, (f) 80–100 cm soil layer, (g) 100–120 cm soil layer, (h) 120–150 cm soil layer*

In the 10–20 cm soil layer (*Fig. 4b*), the water content of the croplands was also consistently lower than that of orchards. The soil water content of orchards varied between field capacity and capillary water content, which was in a suitable state of water condition. However, the water content of 10–20 cm soil layer in croplands continued to decline from the beginning of spring and did not gradually recover until mid-June before the rainy season. The maximal relative difference in soil water content between croplands and orchards occurred in mid-June, when the soil water content of orchards was 61.40% higher than that of croplands. The minimal relative difference appeared in August, with the soil water content of orchards being 0.35% higher than that of croplands. The difference in soil water content diminished in the rainy season compared with the drought period. In the 20–40 cm soil layer (*Fig. 4c*), the temporal changes in soil water content of croplands and orchards were synchronous with the change in the upper soil layer (0–20 cm). However, the effect of weak rainfall on soil water content was negligible and did not have a significant trend like the 0–20 cm soil layer. In the 20–40 cm soil layer, the maximal relative difference in soil water content between croplands and orchards occurred in May, 7.15%, whereas the minimal difference appeared in August, 0.59%.

Compared with the upper and lower soil layers, the 40–60 cm soil layer showed the highest degree of desiccation during apple tree growth (*Fig. 4d*). The maximal relative difference in soil water content between croplands and orchards occurred in June, and a 51.68% increase was found in the soil water content of orchards relative to croplands. The minimal relative difference appeared in August, with the soil water content of orchards being 3.55% higher than that of croplands. The characteristics of water consumption and compensatory period of water change in the 60–80 cm soil layer were also obvious (*Fig. 4e*). The greatest difference of water content occurred in June (5.69%), and the minimal difference occurred in August (0.86%). The soil water content of croplands was lower than that of orchards, but the relative difference in soil water content between different land use types was reduced in this soil layer. The largest relative increase in soil water content of orchards relative to croplands was 40.64%.

The soil calcium layer and the loess parent layer occurred at deeper soil depths. During the growth period of apple trees, the deep soil water content of croplands and orchards changed in the most comfortable state between field capacity and capillary water content, and there was no problem of drought stress. The compensation period of deep soil water also lagged about 1 month behind soil layers above 40 cm (*Fig. 4f, g, h*). At the end of the rainy season, the soil water compensation amount had been significantly higher than the field capacity, which will inevitably move further into the deeper soil layer. The greatest difference in soil water content in the 60–80 cm soil layer between croplands and orchards occurred in June (7.01%), and the minimal difference

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17831797

occurred in August (0.36%). The maximal relative increase in soil water content of orchards relative to croplands reached 44.83% in the 80–100 cm soil layer, 40.52% in the 100–120 cm soil layer, and 31.46% in the 120–150 cm soil layer.

Through the layer-by-layer analysis of the variation of soil water content over time in croplands and orchards after many years of reclamation in Weibei area, we found that the effect of vegetation on the water content of the soil profile can be reflected across the whole 0–150 cm gradient, but the difference decreased with increased soil depth. The cropland soil had a relatively heavy and long-term drought in the middle and deep soil layers, but this drought was temporary with the arrival of the rainy season. However, the soil water content of the orchard was always higher than that of croplands during the growth period, there was almost no obvious water stress, and no internal dry soil layer was found within the spatial scale of the study.

Mathematical simulation of soil water change process

In any case, soil water is a process of fluctuation. The effects of water stress or severe water deficiency on plant growth processes depend not only on the severity of stress and water scarcity, but more importantly on the duration of stress and scarcity. The greater the degree of stress and deficiencies, the greater the harm to plants, the longer the continuous stagnation, the more likely the plant to die in drought even if rehydrated. Thus, this paper took the soil water constant as the threshold and the duration of the soil water content (d) as the index to quantitatively analyze the soil water status of croplands and orchards after the reclamation of hollow villages.

To improve the reliability of the quantitative analysis results, it was first necessary to carry out mathematical simulations of the process of changing the soil water content of each soil layer during the growth period of apple trees (*Fig. 4*). The model was mainly to change the line graph of the soil water content change process in various soil layers of *Figure 4* into curves to more accurately calculate the soil water change. The statistical results were shown in *Table 3*.

Table 3. *The mathematical simulation of soil water change in different cover conditions in Weibei*

Quantitative analysis of soil water status in cropland

As can be seen from *Table 4,* the soil water excess period was 7 days, the water susceptibility period was 98 days, the water stress period was 73 days, and the water

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17831797

ineffective period was 6 days in 0–10 cm soil layer during the growth period of apple trees, which accounted for 3.80%, 53.26%, 39.67%, and 3.27% of the apple trees growth period, respectively. Soil water accumulation in the excess period, water susceptibility period, water stress period, and water ineffective period accounted for 20.10%, 46.20%, 32.61%, and 1.09% in the 10–20 cm soil layer. Compared to the 0–10 cm soil layer in the rainy season, the soil water of the 10–20 cm soil layer was retained and the number of days in water excess increased significantly, which may be directly related to the tightening of the subsurface soil of croplands after the land reclamation, the increase of soil bulk density, the use of chemical fertilizers, and the shallow rotary tillage over many years (Zhu, 2014; Wang et al., 2017). Compared to the 0–20 cm soil layer, the spring soil drought increased significantly in the 20–40 cm soil layer and there was also a long period of soil layer water retention and excess water similar to the 10–20 cm soil layer in the rainy season, which reflected the compaction of cropland soil.

Compared to the 0–40 cm soil layer, there was no excess water in the 40–60 cm soil layer. The soil drought in spring was more serious, and the water ineffective period had a longer duration, which indicated that crops were threatened by drought. There was no water ineffective period in the 60–80 cm soil layer during apple tree growth, where the drought had been relatively eased compared to the 20–60 cm soil layer.

In the 80–100 cm soil layer, there were 34 days of excess soil water, 121 days of water susceptibility, and 29 days of water stress during apple tree growth. In the 100–120 cm soil layer, there were 25 days of excess soil water, 152 days of water susceptibility, and 7 days of water stress, which accounted for 13.59%, 82.61%, and 3.81% of the apple tree growth period, respectively. There was no water ineffective period in the 80–120 cm soil layer. There were 8 days with excess soil water and 176 days of water susceptibility, which accounted for 4.35% and 95.65% of the apple tree growth period.

During the apple tree growth period, the cropland soil drought mainly occurred from the spring to the early summer. The drought was more serious in the 20–60 cm soil layer, especially in the 40–60 cm soil layer, and the soil water stress gradually decreased below 60 cm. The water retention period in the 10–40 cm soil layer was longer than that of the 0–10 cm surface layer, which indicated that compaction was a problem and water conduction was blocked. In the rainy season, there was a phenomenon of excessive water retention in the soil section to varying degrees, so the "internal dry soil layer" can be reclaimed during the rainy season.

Quantitative analysis of soil water status in orchard

As can be seen from *Table 5,* the soil water content was always accessible in the 0–10 cm soil surface from mid-March to mid-July. However, the days of effective soil water were reduced to 12 days from mid-July to mid-September. Due to the rainy season, the soil water in the 0–10 cm soil layer was in a surplus for up to 50 days, accounting for 27.17% of the total days of apple tree growth. There was no water stress period. Excessive water at the surface provided a prerequisite for replenishing water in deep soil. From mid-March to mid-July, the soil water content in the 10–20 cm soil layer had been in effective water state. From mid-July to mid-September, the days of effective water decreased in lieu of excess water, which occurred for 35 days in total and accounted for 19.02% of the total days of apple tree growth. The soil water susceptibility in the 20–40 cm soil layer accounted for 83.43% of the apple tree growth

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17831797

period. From mid-July to mid-September, water surplus occurred for 36 days and accounted for 19.57% of the total days of apple tree growth.

The water content in the 40–60 cm soil layer was water-susceptible from mid-March to mid-July. Other than the water-susceptibility period, excess water occurred in 8 days from mid-July to mid-September, accounting for 4.35% of the apple tree growth period. The water content in the 60–80 cm soil layer had been in a state of water efficiency during apple tree growth period.

The 80–100 cm soil layer was effective water state from mid-March to mid-July. Excess water occurred in 39 days from mid-July to mid-September, accounting for 21.2% of the apple tree growth period. The soil water content in the 100–120 cm soil layer was mostly in a water-susceptible state during apple tree growth. Excess water occurred in 37 days, accounting for 20.11% of the apple tree growth period. In addition to the water-susceptible state, there was also a water surplus period of 17 days in the 120–150 cm soil layer, which accounted for 9.24% of the total days during apple tree growth.

The soil water status of orchards during the growth period of apple trees was not affected by water stress and there was deep movement of soil water during the rainy season after the reclamation of hollow villages in Weibei area.

Analysis of soil water stress in croplands and orchards

We also found that cropland soil water stress after hollow village reclamation was significantly stronger than that of orchards in Weibei rainfed highland. Adjusting the existing agricultural structure by converting large areas of cropland into orchards alleviated the sharp distinction between natural precipitation and soil water mitigation (Glaser et al., 2013). Further statistical analysis of *Tables 4* and *5* showed that orchard soil water content did not reach the level of water stress and water ineffectiveness in the 0–150 cm soil profile. However, cropland experienced soil water stress throughout the entire 120 cm soil profile. Some studies previously found that the total water requirement for growing apples in Weibei area was about 500 mm (Wang and Zhang, 2000). However, the average daily water requirement for wheat has been estimated to be about 5 mm (Wang et al., 2018).

The percentage of days of effective soil water in apple tree growth period tended to decrease in the top soil layers then increase with soil depth, which accorded with the polynomial variation law of $y = 1.54x2 - 7.18x + 55.96$ (where y is the percentage of water equivalent days, %, x is the soil depth, cm, $R^2 = 0.9587$). The length of cropland water stress in the 20–40 cm soil layer was longer than the water susceptibility time, in which the existence of such long-term water stress made it extremely difficult to recover without precipitation or irrigation. The number of days of excess water in croplands was significantly less than that in orchards between mid-July to mid-September, which indicated that water stress in croplands was stronger than orchards and that recovery was more difficult. Trees canopies can suppress evaporation from the soil more so than croplands, which can greatly alleviate the problem of soil water stress caused by improper crop selection after reclamation. However, after the apple harvest, soil water consumption in orchards fall after fruit production and leaf drop. Thus, the excess water from the autumn rainy season may cause short-term waterlogging, which suggests that attention should be given to improving soil water permeability when planting apple trees (Nolz et al., 2014).

Conclusions

(1) After the reclamation of hollow villages, the soil water content of orchards was significantly higher than that of croplands due to the difference in the amount and timing of water demanded by these land use types.

(2) There was no soil drought stress in orchards during the growth period. More specifically, the soil water content throughout the 0–150 cm soil profile was stable between field capacity and capillary water content (stress point). On the contrary, the soil drought in croplands was severe in degree, length, and depth from spring to early summer. Soil water stress lasted for 78 days in the 20–40 cm soil layer. The soil water content was below the permanent wilting coefficient for 42 days in the 40–60 cm soil layer.

(3) There was a significant drought in the entire 0–120 cm soil profile from mid-April to mid-July, especially before the rainy season between mid-May and mid-July, and water stress was most likely to occur in the 20–60 cm soil layer.

Therefore, future study should focus on the development of soil water conservation technologies in the Weibei rainfed highland after the reclamation of hollow villages. In particular, the results obtained in this study indicate that vegetation coverage has a pronounced effect on soil water conditions in the reclaimed land. Therefore, it is necessary to strengthen the research regarding the selection and effect of "cover crops" based on water-saving technologies such as straw mulching and plastic mulching that have been applied extensively. An effective approach to inhibit water consumption via evaporation from land surface is to select suitable cover crops based on local climate conditions and minimize the exposure time of bare croplands as much as possible.

(Received 19th Oct 2019; accepted 8th Jan 2020)

Abstract. Searching for new plants that could phytoextract soil macro-nutrients is one of the main research interests nowadays. In the present study, nine native plant species were collected to determine their potential to uptake six macro-nutrients from the soil of a sewage sludge dump site (SS) in comparison with a reference site (RS). The results showed that the studied native plants can accumulate the macro-nutrients in their tissues regardless of their size or vegetative stages. The concentrations of all macro-nutrients (except K) in the tissues of the most studied plant species were positively correlated with those in the soil. The stoichiometric ratios vary among species and depend on many limiting factors. The values of bioaccumulation and translocation factors were > 1.0, indicating the high tendency of the plants to accumulate the macro-nutrients. *Portulaca oleracea* growing in the SS accumulated larger quantities of macro-nutrients compared to two perennials growing at the same place. *Phragmites australis*, *Rumex dentatus, Portulaca oleracea, Bassia indica, Amaranthus viridis* and *Pluchea dioscoridis* from the SS; and *Portulaca oleracea, Rumex dentatus, Pluchea dioscoridis* and *Solanum nigrum* from the control site showed the highest element accumulation indices, which could be recommended for the phytoextraction of macro-nutrients. We recommend using the studied species in mitigation of the eutrophic status of agricultural soil amended with sewage sludge.
Keywords: *bioindicator, biosolids, Nile delta, nutrient elements, phytoextraction, wastewater treatment plants, wild plants*

Introduction

Sewage sludge is defined as an organic byproduct of the treatment of municipal and/or industrial wastewater. It contains high amounts of macro-nutrients and heavy metals (Eid and Shaltout, 2016). It is used as fertilizers in many agricultural lands and it has significant positive influences on soil fertility and plant macro-nutrients (Aráujo et al., 2007). On the other hand, the presence of toxic levels of heavy metals in the sludge

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17991817

due to the contribution of industrial effluents may have adverse effects on agriculture and food chain (Singh and Agrawal, 2007; Eid et al., 2018a). Moreover, availability of nitrogen and phosphorus from sludge-amended soils and their transfer in runoff may lead to eutrophication of soil and downstream surface water (Quilbé et al., 2005). The worldwide production of sewage sludge is increasing with the populations, as well as their use as soil amendments on agricultural lands (Moreno-Caselles et al., 1997; Eid et al., 2018a). Numerous studies on the use of sewage sludge as soil amendments have been conducted on agricultural crops, wood- and wetlands (e.g., Fuentes et al., 2007; Yu et al., 2014; Eid et al., 2017a, b, 2018b, 2019, 2020a, b, c). Few studies were conducted on wild native plants (e.g., Ho and Wong, 1994; Korboulewskya et al., 2002; Farahat and Linderholm, 2013; Eid and Shaltout, 2016).

Native plants are key species in the ecosystems and play important roles in degrading and removing macro-nutrients, heavy metals, and other pollutants from the environment (Eid and Shaltout, 2016). This green technology is called "Phytoremediation" (Peng et al., 2008). It includes many methods, one of them is phytostabilization, where plants are used to immobilize metals and store them in their below-ground tissues and/or soil. In addition, plants may play an important role in element removal (phytoextraction) through many ways, such as absorption and cation exchange (Chandra et al., 2017).

Many studies were conducted to investigate the influences of sewage sludge on the growth, yield and solute contents in crops and forest trees (e.g. Henry et al., 1994; Antolín et al., 2010; Singh and Agrawal, 2010). Some other studies tried to identify the health risks that could be associated with using sewage sludge and/or sewage wastewater in agriculture (e.g., Singh and Agrawal, 2007; Galal, 2016; Farahat et al., 2017; Eid et al., 2018a). Most of these studies were interested in evaluating the role of plants in phytoremediation of heavy metals, but not macro-nutrients. The soil pollution by macro-nutrients is unusual, but especially problematic when involves eutrophication. These levels of high concentrations of macro-nutrients in the soil will adversely affect the biodiversity of native species and it may introduce only the species that grow well on eutrophic soil (El-Sheikh et al., 2012; Shaltout et al., 2019). In addition, over-use of sewage sludge in agricultural practices may lead to over concentrations of macro-nutrients that lead to eutrophication of soil and downstream surface water (Quilbé et al., 2005). The application of sewage sludge in high quantities to the agricultural lands without prior knowledge to its chemical structure may lead to presence of high non-desirable concentrations of macro-nutrients (Quilbé et al., 2005). Presence of native species that able to uptake extra concentrations of macro-nutrients and reduce the macro-nutrient loads in soil will represent a good service to the ecosystem.

Wild plants play an important role in macro-nutrient cycling through uptake, sequestering and release of macro-nutrient elements (Eid et al., 2012a). Utilization of these wild plants as phytoremediators in eutrophic habitats requires emphasis on the effect of macro-nutrient loadings on these plants, but this effect has received little attention and is still not well understood (Eid et al., 2010; Zhao et al., 2013). According to the authors' knowledge, so far no studies have been carried out in Egypt on the grown plant of native species at a sewage sludge dump site in comparison with the reference site in the context of their usefulness for macro-nutrients phytoremediation. Therefore, the wider objective of this study was to assess the removal efficiency of macro-nutrients by nine native plant species grown at a sewage sludge dump site (SS) in Egypt. The specific objectives of the present study were to: (1) to assess the ability of nine Tropical and Mediterranean native plant species grown on SS to accumulate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17991817

macro-nutrients in their tissues compared to a reference site (RS); and (2) to examine the roles of these nine species as potential bioindicators of macro-nutrients. The results of the present study could be useful when designing a phytoremediation system.

Materials and methods

Study area

The study area is the dump site of Kafr El-Sheikh Wastewater Treatment Plant in the northern Nile Delta, Egypt (Lat. 31° 05′ 05.42″ N, Long. 30° 57′ 43.24″ E), and the adjacent agricultural farms are the reference site (RS) (Lat. 31° 04′ 53.46″ N, Long. 30° 57′ 31.60″ E). The RS is located about 1 km away from the dump site and its soil type is clay. The climatic conditions are warm summers (20 to 30 °C) and mild winters (≥10 °C) (EMA, 1980).

Field sampling process

The sampling process was carried out at six locations, three of which represent each of the SS and RS (*Fig. 1*). Nine native plant species dominating the study area were chosen at each site (*Amaranthus viridis* L.: *Amaranthaceae*, slender amaranth, annual herb, often 60-80 cm tall; *Bassia indica* (Wight) A. J. Scott: *Amaranthaceae*, kochia, annual richly branched herb, often 2 m tall; *Conyza bonariensis* (L.) Cronquist: *Asteraceae*, flax-leaf fleabane, annual herb, often 75 cm tall; *Portulaca oleracea* L.: *Portulacaceae*, common purslane, glabrous fleshy herb, may reach 40 cm in height; *Rumex dentatus* L.: *Polygonaceae*, toothed dock, annual or biennial herb, erect stem up to 70-80 cm in height; *Solanum nigrum* L.: *Solanaceae*, black nightshade, herb or short-lived perennial shrub, often 30-120 cm tall; *Lycopersicon esculentum* Mill.: *Solanaceae*, tomato, perennial in native habitat, but cultivated as annual, grows up to 1-3 m in height. *Phragmites australis* (Cav.) Trin. ex Steud.: *Poaceae*, common reed, perennial robust reed, erect stem up to 5 m in height; and *Pluchea dioscoridis* (L.) DC.: *Asteraceae*, camphorweeds, richly branched hairy shrub, often 2-3 m high). For each plant species, three mature and healthy replicates were collected from each sampling location during May 2014. Plants were identified following Boulos (1999, 2002, 2005). In the laboratory, samples were carefully washed with tap water over a 4 mm mesh sieve to minimize material loss, separated into leaves, stems and roots, oven dried at 85 °C to a constant weight, and then ground using a metal-free plastic mill. Roots were collected by excavated carefully around the root system of each plant. At each sampling location, a composite soil sample was collected as a profile from three holes, each about 20 cm deep. The soil samples were air dried and passed through a 2 mm sieve to separate gravel and debris.

Chemical analysis

Soil samples were analyzed for organic matter (OM) content using loss-on-ignition method at 550 °C for 2 h (Wilke, 2005). Soil-water extracts at 1:5 were prepared for the determination of pH and electric conductivity (EC). Macro-nutrients (except N) in soil and plant samples were extracted from 0.5 to 1 g using a mixed-acid digestion method. EC and pH were measured using conductivity and pH meters, respectively. Calcium, Mg, Na and K were determined by atomic absorption, while total P was determined by spectrophotometer using the ammonium-molybdate method. Total N was determined in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17991817

plant and soil samples using a CHN Elemental Analyzer (Yanako CHN Corder MT-5, Japan). All these procedures are outlined in Allen (1989) and APHA (1998).

Figure 1. *Location map of study area showing the sampling sites. SS: sewage sludge dump site, RS: reference site*

Calculations

The bioaccumulation factor (BF) was calculated to determine the efficiency of the plant for accumulating a macro-nutrient from the soil (Xiao et al., 2011):

$$BF = \frac{\text{Concentration of a macronutrient in belowground tissues (mg/kg)}}{\text{Concentration of the same macronutrient in soil at the same site (mg/kg)}} \quad \text{(Eq.1)}$$

The translocation factor (TF) was calculated to depict the ability of plants to translocate a macro-nutrient from below- to above-ground tissues (Gupta et al., 2008):

$$TF = \frac{\text{Concentration of a macronutrient in aboveground tissues (mg/kg)}}{\text{Concentration of a macronutrient in belowground tissues (mg/kg)}} \quad \text{(Eq.2)}$$

The element accumulation index (EAI) was used to assess the overall performance of macro-nutrient accumulation in plants (Liu et al., 2007):

$$EAI = (1/N)\sum_{j=1}^{N} Ij;\ Ij = \frac{x}{\delta x} \quad \text{(Eq.3)}$$

where N is the total number of the analyzed macro-nutrients and I_j is the sub-index for a macro-nutrient j, obtained by dividing the mean concentration of a macro-nutrient (x) by its standard deviation (δx).

Statistical analysis

Before performing an analysis of variance (ANOVA), the data were tested for their normality of distribution (Shapiro-Wilk's W test) and homogeneity of variance (Levene's

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17991817

test), and when necessary, the data were log-transformed. Macro-nutrients data for nine plant species were subjected to a three-way ANOVA (the assumptions have been met) to identify the interactions in the independent variables (species, tissues, and sites). The significance of variation in the relative concentrations of the different macro-nutrients (considering whole plant), one species at a time at the two different sites (SS/RS) was assessed using a paired *t*-test, while one-way ANOVA was used to analyze the variation among species within the same site. The significant differences between means, among the nine plant species were identified using the Tukey HSD test at $P < 0.05$. The significance of variation in soil quality parameters between the SS and RS was assessed using a paired *t*-test. EAI data for nine plant species were subjected to a two-way analysis of variance (ANOVA-2) to test the differences between species and sites. Correlations between the concentrations of macro-nutrients in plant tissues and soil samples (the SS and RS) were evaluated using the Pearson's *r* coefficient. Statistical analyses were carried out using Statistica 7.1 (Statsoft, 2007). Stochiometric ratios were calculated for some of the analyzed macro-nutrients. To identify statistically significant differences in the stochiometric ratios among different sites, the paired *t*-test was performed.

Results

The soil of the SS was rich in OM, N, P, Ca and it was also slightly acidic, while EC, Mg, Na and K concentrations of the RS were significantly higher than those of the SS (*Table 1*). Macro-nutrient concentrations in the soil of the SS had the following sequence: Ca > N > Mg > Na > K > P; while in soil of the RS the sequence was: Ca > Na > Mg > K > N > P.

Table 1. *Mean ± standard error (n = 3) of soil physico-chemical characteristics for sewage sludge dump site and reference site, where the present study was carried out*

Characteristics	Sewage sludge dump site	Reference site	*t*-value	*p*
EC (mS cm^{-1})	0.04 ± 0.01	3.46 ± 0.08	38.9	0.001
pH	6.40 ± 0.08	7.76 ± 0.03	14.8	0.000
OM (%)	51.50 ± 0.23	6.74 ± 0.07	148.6	0.000
N (mg g^{-1})	30.27 ± 0.52	2.00 ± 0.23	37.9	0.001
P (mg g^{-1})	2.36 ± 0.09	0.89 ± 0.02	14.9	0.000
Ca (mg g^{-1})	53.36 ± 0.57	40.90 ± 1.39	10.1	0.000
Mg (mg g^{-1})	6.34 ± 0.18	8.29 ± 0.29	6.3	0.000
Na (mg g^{-1})	6.22 ± 0.26	8.50 ± 0.20	15.5	0.000
K (mg g^{-1})	4.69 ± 0.07	6.03 ± 0.13	14.7	0.000

t-values represent the paired t-test, EC: electric conductivity, OM: organic matter content

Regarding the studied plant species, concentrations of N, P and Na were significantly affected by site; those of N, Ca, Mg and Na were significantly affected by plant species, while those of N, Ca, Mg and K were significantly affected by plant tissue (*Table 2*). N, P and K concentrations were significantly higher in the plant species of the SS as compared to the RS (*Table 3; Appendix 1*). In addition, concentrations of N, P, Ca, Mg and Na were higher in the leaf; but K was higher in the stem. The highest N, P and K concentrations (48.2, 3.2 and 80.2 mg g^{-1}, respectively) was observed in *P. oleracea*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17991817

grown at the SS, while the lowest (17.7, 0.3 and 17.7 mg g^{-1}, respectively) was observed in *P. dioscoridis*, *A. viridis*, *C. bonariensis* and *P. australis* grown at the RS (*Table 3*). The highest Ca and Mg concentrations (45.1 and 15.2 mg g^{-1}) were observed in *L. esculentum* and *P. oleracea* has grown at the RS, while the lowest (8.9 and 1.4 mg g^{-1}) were observed in *P. australis* has grown at the same site. The highest Na concentration (53.0 mg g^{-1}) was recorded in *B. indica* has grown at the SS, while the lowest (2.8 mg g^{-1}) was detected in *S. nigrum* has grown at the RS.

Table 2. *Results of three-way ANOVA (F-values) of macro-nutrients concentrations of nine native plant species in north Nile Delta, Egypt*

Site: Sewage sludge dump site/Reference site, Species: nine native plant species, Tissue: fruit/leaf/stem/root. *: $p < 0.05$, **: $p < 0.01$, ***: $p < 0.001$, ns: not significant (i.e., $p > 0.05$), df: degree of freedom

All the investigated species were characterized by a bioaccumulation factor (BF) > 1.0 for some macro-nutrients (*Fig. 2*). *A. viridus* showed the higher BF value for K (14.4), *P. oleracea* showed higher BF values for N (1.3), P (1.6) and Mg (1.5), *R. dentatus* showed the higher BF value for Na (3.3). At the RS, *B. indica* showed the higher BF value for Na (2.8), *P. oleracea* showed higher BF values for N (12.3) and Mg (0.9), *L. esculentum* showed higher BF values for P (3.6) and Ca (1.1), and *P. dioscoridis* showed the higher BF value for K (6.9).

In the present study, the translocation factor (TF) varied among the studied sites, plant species and among the macro-nutrients (*Fig. 3*). Regarding the SS, *A. viridus* had the highest TF for Mg (3.8), *B. indica* for Na (5.2), *P. oleracea* for K (1.6), *S. nigrum* for N (2.2), *L. esculentum* for P (2.0) and *P. dioscoridis* for Ca (2.3). At the RS, *B. indica* had the highest TF for P (98.0), *C. bonariensis* for Mg (3.12), *P. oleracea* for Ca (1.9) and Na (3.4), and *R. dentatus* for N (4.1) and K (2.0).

Element accumulation index (EAI) were significantly higher in all plant species at the SS as compared to the RS (except *C. bonariensis* and *P. dioscoridis; Fig. 4*). The species with the highest EAI at the SS were *P. oleracea* (41.6), followed by *P. australis* (30.6), *R. dentatus* (27.7), *P. dioscoridis* (27.4), *A. viridis* (26.9) and *B. indica* (26.7). In contrast, *C. bonariensis* showed the lowest EAI value (19.2). In addition, *P. oleracea* (31.0), followed by *P. dioscoridis* (29.5), *R. dentatus* (24.7) and *S. nigrum* (24.5) that had the highest EAI in the RS, while *P. australis* (16.3) had the lowest. Positive linear correlations were detected between N, P, Ca, Mg and Na concentrations in all tissues of *A. viridus* and the soil of both sites (*Appendix 2*); N, P, Ca and Na for *B. indica*; N and P for *C. bonariensis*; N, P, Ca and Na for *P. oleracea*; Ca for *R. dentatus*; N, P, Mg and Na for *S. nigrum*; N and Na for *L. esculentum*; N, P, Ca and Na for *P. australis*; N for *P. dioscoridis*.

t-values represent the paired t-test. Means in the same columns (for each site) followed by different letters are significantly different at $p < 0.05$ according to Tukey HSD test. *: $p < 0.05$, **: $p < 0.01$, ***: $p < 0.001$, ns: not significant (i.e., $p > 0.05$)

Regarding the stoichiometric ratios, both SS and RS were only significantly different in K/Na and P/K ratios at $p < 0.01$ (*Table 4*). For individual plant species, it was noticed that the following stochiometric ratios were significantly different among sites: P/K in *B. indica*, N/P and K/Na in *A. viridus,* N/P in *C. bonarensis*, K/Na in *P. australis*. On the contrary, *S. nigrum*, *P. dioscoridis* and *L. esculemtum* showed no significant differences in the estimated stoichiometric ratios among sites.

Discussion

The collected soil from the SS was characterized by a higher N concentration than the RS, which could be ascribed to the high organic matter in its contents. The present study showed that the tissues of the studied plant species were characterized by high macro-nutrient concentrations at the SS more than at the soil of agricultural farms (control). This could be ascribed to the low pH value of the SS and its high concentrations of these elements. The results of some previous investigations indicated that the land application of sewage sludge increased soil N and P content (Bai et al., 2012), and plant uptake of N and P (Andres et al., 2010).

The uptake of macro-nutrients by plants varies among species and depends on the macro-nutrient demands of each species to apply their physiological and biochemical requirements. Plants differ both in their capacity to acquire macro-nutrients from the soil and in the amount of macro-nutrients they need per unit growth, the macro-nutrient concentrations in their tissue, and the time and extent to which they withdraw macro-nutrients during leaf senescence before leaf abscission (Kabata-Pendias, 2011). Lambers et al. (2008) reported that plants differ in the concentration of macro-nutrients in their

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17991817

tissue, depending on environment, allocation to woody and herbaceous tissues, developmental stage, and species. Moreover, N, P, and K are the macro-nutrients that most frequently limit plant growth. However, N tends to limit plant productivity on young soils, whereas P becomes increasingly limiting as soils age. The presence of high concentrations of N, P, Ca and K in the sampled plants from the SS compared to control site because these elements are essential for the plant growth. However, the presence of a specific mineral in plant tissues does not imply that the plant needs this mineral for growth. For example, high Na concentrations are not required for growth (Lambers et al., 2008).

The presence of high macro-nutrients concentrations in leaves compared to the other tissues because leaves are the main sink for minerals in plants. Macro-nutrients associated with metabolism (e.g., N, P, and K) have their highest concentrations when a leaf or other tissue is first produced, then concentrations decline by dilution during cell wall formation and then by resorption of macro-nutrients during senescence, while the roots have intermediate concentrations. Species differ in the macro-nutrient requirement for growth but the physiological mechanisms for this are not always known (Woodward et al., 1984). The variations in macro-nutrient concentrations in various parts of plants have been ascribed to compartmentalization and translocation through the vascular

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17991817

system (Kim et al., 2003). As stem plays the role of a transferring tissue, minimum concentrations of macro-nutrients were found in stem (Planquart et al., 1999).

The evaluation of the bioaccumulation factor (BF) represents a simple method to characterize quantitatively the transfer of available macro-nutrients from the soil to the plant (Branzini et al., 2012; Farahat et al., 2017), while its ability to translocate them from the roots to the shoots is measured using the translocation factor (TF). Both BF and TF can be used to estimate a plant's potential for phytoremediation purposes (Galal and Shehata, 2015). According to Zu et al. (2005), BF > 1.0 were found in macro-nutrient- and heavy metal-accumulating plants, whereas they were typically < 1.0 in macro-nutrient- and heavy metal-excluding plants. TF > 1.0 indicate that the plant is effective in the translocation of macro-nutrients from root to shoot tissue (Ma et al., 2001). In the present study, all studied species were characterized by BF values > 1.0 for some of the macro-nutrients, showing that they can accumulate macro-nutrients and are therefore more suitable for phytoextraction purposes. In the present study, the accumulation of macro-nutrients was done regardless of their stem size or life form of the species. For instance, *P. oleracea* as short (20-40 cm) annual herbaceous plant tend to accumulate high concentrations of N, P and K more than other perennial tall species e.g., *P. dioscoridis* and *P. australis*. The same observations were reported by Farahat and Linderholm (2013) for medicinal native plants that irrigated by sewage wastewater. Although the BF values for some macro-nutrients were > 1.0, which means that our study species could accumulate these macro-nutrients, but none of them are hyper-accumulator (Kabata-Pendias, 2011).

The presence of TF values > 1.0 for N, P, Ca, Mg, and K mean that plants allocate the macro-nutrients in their vegetative parts because it is essential for growth. This behavior is opposite in many cases to the TF values for heavy metals that estimated in many aquatic and terrestrial plants (e.g., Galal and Farahat, 2015; Galal and Shehata, 2015; Eid et al., 2018a). This could be attributed to the fact that macro-nutrients are more essential for plant growth than heavy metals (Lambers et al., 2008). As a rule, when a plant has TF value > 1.0 for a certain mineral, this indicates the its suitability for the phytoextraction of this mineral, while TF value < 1.0 indicates its suitability for the phytostabilization of this mineral. For instance, *A. viridus* and *B. indica* are good phytoextractor for N, P, Ca, Mg and Na

Plant species accumulate different elements simultaneously, so the element accumulation index (EAI) was used to assess the overall performance of macro-nutrient accumulation in the studied plant species. Thus, in the present study, the highest EAI values of *P. oleracea*, *P. australis*, *R. dentatus*, *P. dioscoridis*, *A. viridis* and *B. indica* from the SS; and *P. oleracea*, *P. dioscoridis*, *R. dentatus* and *S. nigrum* from the cultivated field soil, indicates that these species are better able to accumulate macro-nutrients, and are therefore more suitable for phytoextraction purposes.

The stoichiometric ratios vary among species and depends on many limiting factors. For instance, N:P ratios are, on average, higher in graminoids than in forbs and higher in stress-tolerant species than in ruderals. This ratio declines with increasing growth rates (Lambers et al., 2008). The whole-plant biomass N:P ratios may vary up to 50-fold, due to differences in macro-nutrient uptake, biomass turnover, root allocation, and reproductive output (Aerts and Chapin, 2000). In the present study, there were few ratios that are significantly different among sites and species. In our opinion the availability of water and macro-nutrients in the studied sites interacts differently according to the species. This agrees with the findings of Lü et al. (2012) and Farahat

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_17991817

and Linderholm (2015). They reported that in rich N habitats, water availability can modulate the plant nutritional and stoichiometric responses to increased N and other macro-nutrients.

The present study proved that the concentrations of all macro-nutrients (except K) in the tissues of the most studied plant species were positively correlated with those in the soil. Such correlations indicate that these species reflect the cumulative effects of environmental pollution from the soil, and thereby suggesting their potential use in the biomonitoring of most macro-nutrients examined. This indication is supported by several studies according to which the total quantity of some macro-nutrients in a soil is correlated with the quantity of macro-nutrients absorbed by plants (Bonanno, 2011, 2013; Bonanno and Lo Giudice, 2010; Eid et al., 2012a, b; Eid and Shaltout, 2014). Moreover, plants with macro-nutrient concentrations strongly correlated with those in the soil have been considered potential indicators of macro-nutrient availability (Alyemeni and Almohisen, 2014).

Conclusion and recommendations

In this study, it was found that some plant species were more effective in absorbing certain macro-nutrients compared to other species that grown in the same soil. *L. esculentum* can bioaccumulate many of the macro-nutrients from sewage sludge without excessive quantities of macro-nutrients being translocated into the edible portions of the plant (fruits). In the present study, establishing a pattern of translocation of macro-nutrients from root to shoot of a plant can be very useful in biological monitoring of macro-nutrient contamination as well as a selection of macro-nutrient accumulator species. The highest EAI values of *P. oleracea*, *P. australis*, *R. dentatus*, *P. dioscoridis*, *A. viridis* and *B. indica* growing in the SS; and of *P. oleracea*, *P. dioscoridis*, *R. dentatus* and *S. nigrum* growing in the cultivated field soil, indicate that they are better able to accumulate macro-nutrients and are therefore more suitable for phytoextraction purposes.

Due to the noticeable high concentrations of macro-nutrients in the different tissues of the studied species, we recommend it in mitigation of the eutrophic status of SS when applied to the agricultural lands. This will be achieved through leaving these weeds grow prior to cultivation of the agricultural crops. This needs further investigation to determine the best density for each native species that helps efficiently in reducing the macro-nutrients load of sewage sludge on the cultivated plants.

Abstract. This study has been done in the pine forests, located in Çamlık within Çatalca Forest Management's (İstanbul-Turkey) Silivri Forestry Department, in 2018. The purpose of the study was to investigate biological efficacy of GALLOPRO PINOWIT® commercial pheromone product against *Monochamus galloprovincialis* (Olivier), *Ips sexdentatus* (Boerner), *Orthotomicus erosus* (Wollaston) and *Hylurgus ligniperda* (Fabricius) insect pests on the field. In the study, Scandinavian three funnel traps were used and SMC-ORTIR, TRIPHERON-IPSSEX and TRIPHERON-ORTERO pheromone preparations were used as comparison products. For the evaluation of collected insects count data, two-way ANOVA analysis has been used, variance between preparations-insect counts have been investigated using t test and activity of each preparation has been designated as %. According to the results obtained, it can be concluded that Gallopro Pinowit® preparation can be effectively used against pest insects *Ips sexdentatus*, *Orthotomicus erosus*, *Tomicus sp.* and *Monochamus galloprovincialis* which cause serious damage to coniferous trees.
Keywords: *pheromone, Scolytidae, pine forests, Çamlık, Silivri, biotechnical, Scandinavian type three-funnel trap*

Introduction

Insect pests are undoubtedly an important factor threatening sustainability of forests and forestry products. According to FAO's 2010 data, almost 35 million ha of forest area is being devastated by forest pests every year (Yalçın et al., 2016).

Bark beetles (*Scolytidae*) have an important place among forest pests. Many researchers, local and foreign (Defne, 1954; Can, 1964; Ekici, 1971; Sekendiz,1974; Hakyemez et al., 2013; Serez,1986, 1987; Öymen,1989; Pfeffer,1995; Selmi,1998; Oğurlu, 2000; Faccoli, 2004; Kanat and Laz, 2005; Sarıkaya, 2008; Wong et al., 2017) carried out studies on bark beetles and provided information regarding status of bark beetles in Turkey's forests. During some years, those insects can even cause great economic loss by reproducing in mass under appropriate conditions.

Pheromones are a biotechnical method which is used effectively against bark beetles damaging and causing great losses in forests. Pheromone is a sort of odor, released by both male and female insects to find their mates. Each species has a pheromone to communicate with each other (Galko et al., 2016; Straw et al., 2013). The case of monogamous insects, females, and in polygamous insects, both sexes release these pheromones. The pheromone which is used to communicate among the same species is called "Allomone" while pheromone released by different species is called "Kairomone" (Serez, 1987).

In other terms, pheromones are released by an individual insect and have an effect on behavior of the same species (Coulson and Witter, 1984).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18191827

Pheromones are species-specific. This property brought forward the idea of collecting insects in mass and then exterminate them. They can be synthetically produced and can be used to capture insect pests with special traps (Baker, 2008).

Pheromones do not have any negative impact on beneficial life forms, such as parasites and predators, honey bees, vertebrates and humans. For that reason, its area of usage is expanding every year. Primary reason of emergence of pheromone traps is their ability neutralize pests without disturbing the natural equilibrium with ease (Küçükosmanoğlu and Arslangündoğdu, 2002).

Use of pheromones play an important role in controlling bark beetle population in recent years. Consequently, it is imperative to investigate efficacies of pheromones manufactured by various companies and that consumers then use those successful products in controlling insects.

In forests (Turkey), pheromone traps started to be used in 1982 and their usage increased exponentially since then. Considerable results have been obtained against bark beetles with this method (Serez, 1987).

Applications of this method are constantly increasing in the recent years. It has been stated that in the 40,000 pheromone traps set up by Ministry of Forestry of Turkey, an average of 100 million pest insects are captured every year. Those captured insects are both exterminated and used as feed for the predator insects grown specifically for biological combat (Yalçın et al., 2016).

Hundreds of pheromones have been discovered that are used to monitor the presence and abundance of insects and to protect plants and animals against insects. Pheromones are increasingly efficient at low population densities, they do not adversely affect natural enemies, and they can, therefore, bring about a long term reduction in insect populations that cannot be accomplished with conventional insecticides (Witzgall et al., 2010).

Insecticides do not achieve a long-term pest population decrease. In contrast, an observation shared by many working with pheromone-based control is that continuous long-term use does decrease population levels of target species (Ioriatti et al., 2008; Weddle et al., 2009).

This stud has been done to determine efficacy of Gallopro Pinowit® pheromone which contains Ipsdienol (1.6%), Ipsenol (1.9%), Alphapinene (47.7%) and Ethanol (48.8%) and used against *Monochamus galloprovincialis*, *Ips sexdantatus, Orthotomicus erosus* and *Hylurgus ligniperda*, in the pests' target pine forest area between 04.05.2018 and 28.08.2018.

Gallopro Pinowit is a newly produced pheromone. Therefore it has been the subject of our study.

Materials and methods

In order to determine the field for trials and evaluating presence of target pest population, appraisal tours have been done in the pine forest which is under Istanbul (Turkey) Regional Forestry Directorate's supervision, with the help and support of Department of Combatting Forests Pests. Previous years' reports have been considered and pine stands in Çamlık, Çatalca Forestry Department – Silivri Forest Department have been selected as the trial area (*Fig. 1*).

There are 20-25 years old *Pinus maritima* (Maritime Pine), *P. nigra* (Black pine) and *P. pinea* (Stone pine) trees (*Fig. 2*). The elevation of the study area ranges from 117 to 176 m above sea level (a.s.l.). In this study, 24 funnel type traps (*Fig. 1*), L shaped

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18191827

wooden stakes to fix on the ground and pheromone preparations (GALLOPRO-PINOWIT, SMC-ORTIR, TRIPHERON-IPSSEX, TRIPHERON-ORTERO) have been used (*Table 1*). Funnel type trap is preferred for most often used in Turkey (*Fig. 3*).

The location coordinates of the traps has been included in *Table 1* data.

SMC ORTIR® (Liquid)

Content:	Ipsidenol (25 mg), 2-methly-3 buten-2-ol (1500 mg), Cis-Verbenol (80 mg)
Registration:	5525/18.05.2006
Production:	Jan-2018
Lot No:	115-50-1
Manufacturer:	ChemTica Internacional S.A., P.O. Box 40301, Santo Domingo, Costa Rica

Tripheron IPSSEX® (Granule)

Content:	Ipsdienol (105 mg)
Registration:	1/14.12.2001
Production:	Feb-2018
Lot No:	540-621-1
Manufacturer:	Trifolio-M GmbH, Dr Hans Wilhelmi-Weg 1, 35633 Lahnau, Germany

Tripheron ORTERO® (Granule)

Content:	Ipsdienol (30 mg), Metil-butenol (1500 mg), Cis-Verbenol (100 mg)
Registration:	3/14.12.2001
Production:	Feb-2018
Lot No:	540-624-1
Manufacturer:	Trifolio-M GmbH, Dr Hans Wilhelmi-Weg 1, 35633 Lahnau, Germany

Figure 3. *Funnel type trap*

One week after the traps were placed, captured insects were gathered from each trap, placed inside jars and brought to the lab and counted on petri dishes. For the evaluation of collected insects count data, two-way ANOVA analysis has been used, variance

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18191827

between preparations-insect counts have been investigated using t test and activity of each preparation has been designated as %. Trial area's dense population of target insects (*I. sexdentatus*, *O. erosus*, *T. destruens*, *T. minor*, *T. piniperda*, *M. galloprovincialis*) and collected insect amounts were noted. Total number of *Tomicus* species has been included to the table data.

The months in the study were not considered as a factor. Because the working time does not include all months.

During trials, except Gallopro Pinowit, all other preparations have been renewed on 29.06.2018. According to instruction guidelines, Gallopro Pinowit keeps its activity for 18-20 weeks, therefore during trials we have also tested its durability in field.

Results and discussion

Identified species on pheromone traps in the trial area were mostly; *Ips sexdentatus*, *Orthotomicus erosus*, *Tomicus destruens*, *Tomicus minor*, *Tomicus piniperda* and *Monochamus galloprovincialis*. Apart from those, many Coleoptera species (pest or predators) were found in the pheromone traps.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18191827

Gallopro Pinowit® had the most captures. Additionally, during rainy days while other pheromone preparations had their performances decreased, however, Gallopro Pinowit® preparation continued to work without being affected.

Counts during field application of pheromone preparations, statistical processes and evaluations after that has been shown in detail in *Tables 2, 3* and *4*.

No phyto-toxicological effects have been detected on trees of the site during field trials.

When preparations were compared, Gallopro Pinowit's attractivity was found to be: *I. sexdentatus* 20.27%, *O. erosus* 2.52%, *Tomicus sp.* 88% and *M. galloprovincialis* 80%. SMC ORTIR's attractivity for the same species, respectively 21.43%, 56.34%, 3.77% and 10.31%; Tripheron IPSSEX's attractivity, respectively 39.87%, 4.74%, 4.55% and 7.85%; Tripheron ORTERO's attractivity, respectively 18.43%, 36.40%, 3.68% and 1.84%. The results indicate, unlike other dispensers which have been renewed (29.06.2018), Gallopro Pinowit's performance still exhibited sufficient insect attractivity throughout trial period (which can also be seen from the ratios) as indicated on the usage instructions.

This assessment also conforms with the results of variance analysis and from dispensers' attractivity and count of insect species aspect, there is an important difference of $p = 0.001$ between. With regards to attracting pest insects, preparations had no difference of $p = 0.05$ meaning all dispensers have attracted more or less respectively.

Conclusions

As a result, field trial and counts clearly show that pheromone preparation, commercially known as, Gallopro Pinowit® can be effectively used against *Ips sexdentatus*, *Orthotomicus erosus*, *Tomicus sp*. and *Monochamus galloprovincialis*, important pests of coniferous trees.

Pheromones are indeed elegant and safe tools for insect control. The fascination of being able to control insect populations through species-specific manipulation of sexual communication, without adversely affecting other, beneficial organisms, has been a driving force for research on insect pheromones during four decades.

The importance of pheromone-based methods is accentuated in view of increasing problems associated with the use of conventional insecticides. However, for a more widespread use of pheromones, application techniques must become more reliable and more economic. The key to further development is closer communication and

DOI: http://dx.doi.org/10.15666/aeer/1801_18191827

collaboration between academic research institutions, plant protection industry and extension services (Witzgall, 2001).

Use of pheromones for controlling pest population has significant advantages over chemical treatments to humans, to environment and to other life forms by not harming those. For that reason, beside taking preventive measures, greater success will be achieved when field-tested and proven biologically efficient pheromone preparations are used in controlling bark beetle population.

Acknowledgements. We would like to kindly thank to Ömer ÜLKÜ and Cengiz ÜLKÜ (Verim İnşaat ve Turizm Ltd. Company) who requested biological efficacy study of Gallopro Pinowit® and provided their help in both logistics and preparing this research paper, to Mr. Ahmet Yasin ÇELEN (Pest Control Department Manager - Istanbul District Directorate of Forestry) and finally to Mrs. Gaye ERCAN (Head of Silivri Forestry Department) for providing their valuable contributions in the field studies.

(Received 26th Oct 2019; accepted 30th Jan 2020)

Abstract. The aim of this study is to develop the land quality index (LQI) based on expert opinion and multi-criteria decision support approaches for agricultural lands. The study was conducted on 8 soil series and 20 land units belonging to the lands of Ankara-Güvenç Basin, Turkey which covers about 17.5 km^2, representing the ecological conditions of a semi-arid climate. In this research, 9 main indicators were chosen including depth, slope, stoniness, bulk density (BD), texture, electrical conductivity (EC), pH, organic matter (OM) and $CaCO_3$. Analytical Hierarchical Process (AHP) method was used a pairwise comparison of indicators. As a result of the LQI assessment, while 17.14% of the lands were classified as "High" and 37.41% Moderate, the agricultural quality class of 41.55% of the studies land was determined as "Low" and "Very Low" and mapped in GIS. In this study, it was determined that the final index value of the land was affected by depth (24.2%), slope (21.1%) and bulk density (16.6%) indicators with high weight coefficients. In addition, the values of the LQI were compared with Normalized Difference Vegetation Index (NDVI) values for testing and it has been determined that land quality assessment for agricultural usage has been performed with high accuracy for NDVI (r^2 = 0.74%). Finally, the results of the study showed that the LQI was achieved for micro basin scale under semi-arid climate conditions.
Keywords: *analytic hierarchy process, GIS, land indicators, NDVI, semi-arid climate*

Introduction

Sustainable agricultural production is most important target of agricultural policies of developed or developing countries (Kumar and Jhariya, 2015). In the line with this target, these policies aim to balance the soil with the requests of the product to be grown and to ensure the long-term efficiency by optimizing the resource utilization (Joshua et al., 2013). To achieve these aim and objectives, the determination of land quality in the planning of sustainable agricultural practices has been one of the important ecological approaches in the World (Xue et al., 2019). Land quality is defined as the capacity of the functions resulting from the nature of the soil within a certain ecosystem and depending on its use under a certain management (Karlen et al., 2013). The determination of this capacity requires a multi-decision approach that requires the standardization and weighting of the effects of many factors that affect each other, such as physical, chemical, morphological, topographic and climatic soil characteristics, which are interrelated and differentiated (Mokarram and Mirsoleimani, 2018). Many methods have been developed for land quality assessment, from qualitative or semiquantitative visual approaches (Shepherd, 2009) to quantitative methods based on laboratory analysis and calculating land quality index using mathematic and statistical methods (Karlen et al., 1998; Imaz et al., 2010; Askari and Holden, 2014). The indexing methods are most commonly used (Rahmanipour et al., 2014), usually integrating several indicators associated with soil functions appropriate to the intended use into a quantitative factor that can be used for multi-criteria decision making (Karlen et al., 1998). Thus, AHP (Saaty, 1980), which is the Multiple Criteria Decision Analysis, is preferred in the evaluation of multiple -

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18291845

heterogeneous factors (Ceballos and Lopez, 2003; Malczewski, 2006; Dengiz and Sarıoğlu, 2013; Akıncı et al., 2013; Askari and Holden, 2014; Xue et al., 2019; Özkan et al., 2019). AHP is a decision-supported method that divides complex multiple-factor problems into a hierarchical structure (Yang et al., 2008). At the same time, integration of analytical models with geographic information system (GIS) is reliably used by researchers in the production and interpretation of LQI maps (Malczewski, 2006; Yalew et al., 2016). The LQI is commonly developed using a four-step process: indicator selection, indicator standardization and scoring to sub criteria, weighting of indicators according to importance level, and calculation of scores into a model (Andrews et al., 2004; Askari and Holden, 2014; Xue et al., 2019). But there is no comprehensive LQI that can be used as a universal method across regions and scales (Zhang et al., 2004), and many LQI have been developed for specific purposes and index are usually valid under particular environmental conditions (Imaz et al., 2010; Askari and Holden, 2014). Thus, it can be unexpected that there is index that can determine the land and soil characteristics for all geographies, type of usage and plant species for land quality (Bydekerke et al., 1998; Store and Kangas, 2001). At the same time, it is not practically possible to develop a model that can represent all ecological variables and sociocultural habits, but in theory it is not economic in terms of time, labor and cost (Doran and Parkin, 1996). Therefore, similar studies should be conducted to determine the quality of agricultural lands under different management systems in Turkey (Dengiz et al., 2014). In this study, it was aimed to develop an agricultural land quality index which is genuine to the semi-arid terrestrial climate ecology of Central Anatolia and applicable in the similar geographies by using the expert opinion and AHP approaches. In addition to that, the land of the region was mapped in GIS environment by scoring quality of the basin lands. At the same time, the success of the developed index was tested by comparing the plant density values derived from Sentinel 2A satellite image. Finally, the quality map was produced in GIS environment to decision makers and agricultural policy producers to be a base for land management planning.

Materials and Methods

Field description and study

Güvenç Basin is located between 40° 08′ 39″ - 40° 06′ 13″ North latitudes, 32° 44′ 39″ - 32° 47′ 59″ East longitudes in the Ankara province of Central Anatolian, Turkey (*Fig. 1*). The total area of the basin is 17.5 km^2 and its altitude above sea level between 1040 m and 1440 m. The distribution of land use types for the basin consist 45% of wheat, 35% of pasture, 11.2% of heath and garden, 8.2% of no tillage and rocky, 0.6% of pond (Turan and Dengiz, 2015).

In the study, phase separations (depth, texture, slope, stoniness) and spatial distributions of the soil series mentioned in the detailed survey report and map of the basin were used (Dengiz and Baskan, 2005). Thus, land quality assessments were made at the level of mapping unit. The soils of study area were classified into 8 different series, Typic Xerofluvent, Mollic Xerofluvent and Aquic Xerofluvent in 20 mapping units (land units) and Lithic Xerorhent in subgroups according to soil taxonomy (*Table 1*) (Soil Survey Staff, 1999). In order to determine soil properties affecting land quality, eight disturbed and undisturbed soil samples which are representing the predefined soil series were taken from topsoil between 0-30 cm depth in year of 2018 according to Soil Science Division Staff (2017). Basin soils reflect the typical soil characteristics in different slope

groups formed from alluvial deposits of physiographic units and high calcareous, low-moderate organic matter content, high pH, stoniness and different depth classes developed under semi-arid climate conditions of Central Anatolia region. This situation indicates the presence of land in the basin which will represent different quality classes.

Climate characteristics

Based on the climate values of the region for many years; it represents semi-arid climate characteristics of hot and dry summers and cold and rainy winters. The average annual rainfall and average temperature in the region for the last 20 years is 478.1 mm and 11.4°C, respectively. The hottest month is July with 24.0°C and the coldest month is January with an average of -3°C (Anonymous, 2017). According to soil climate regime of Newhall simulation model (Van Wambeke et al., 2000), the study area has Mesic soil temperature regime and Xeric (Dry Xeric in subgroup) moisture regime. Particularly, potential evapotranspiration is higher than precipitation between April and October. Soil needs irrigation particularly between May and July.

Indicator selection, sub-group scoring and weighting

Nine parameters affecting crop development in agricultural land quality index; depth, slope, stoniness, BD, texture, EC, pH, OM and $CaCO_3$ were selected as the evaluation parameters using many literature (Huddleston et al., 1987; McVay et al., 1989; Soil Survey Staff, 1999; Arshad and Martin, 2002; Hazelton and Murphy, 2007; De La Rosa and Van Diepen, 2009; Iojă et al., 2014; Mustafa et al., 2017; Aldababseh et al., 2018). In this study, land indicators were produced as digital layers in GIS environment from the study report and map of the regional soils. The values of other indicators were obtained from the results of laboratory analysis. The laboratory analyses conducted in the research are presented in *Table 2* and the descriptive statistics of the results are given in *Table 3*.

Table 2. *Physicochemical analysis and methods performed in the study*

Indicators	Units	Procedure	References

The selection of indicators to determine the quality of the land is very important (Zhan et al., 2016). There are many characteristics that affect the quality of lands under different agricultural uses in varying amounts and it is not possible to use all of them (Karlen et al., 2013). In this regard, Doran and Parkin (1996), have suggested the use of as few parameters as possible in modeling approaches. Thus, it is known that there is a high correlation between some physical, chemical and biological properties, it is not practically possible to use all of them as indicators at the same time and it is stated that it is contrary to the basic principles of land evaluation measurement paradigm (Andrews et al., 2004). In another aspect, when numerous soil analysis is performed for model production, the application of the developed index becomes cumbersome (Askari and Holden, 2014). For this reason, the indicators used in the study were chosen according to an expert opinion and literature knowledge by taking into consideration the quality representation from one or more soil properties and their effectiveness is presented in *Table 4*, and sub-factor scoring of parameters is presented in *Table 5*. In addition, in the selection of land indicators, the phases specified in the detailed soil map and which are defined as limiting factor to plant growth were used.

In the study, score values between 1 and 4 were assigned for the parameters of each indicator. The criterion classes are given as 4 in case agricultural farming is allowed and take value of 1 if agricultural farming is not allowed. These two values were evaluated according to the limiting factor and degree. Analytical Hierarchical Process (AHP), which is a multi-criteria decision-making algorithm, was used in pairwise comparison of the indicators of the study (Saaty, 2008).

Calculation to land quality index values of mapping units

In order to determine the land quality scores of the study area, a parametric approach healed Linear Combination Technique (LCT) was applied to 20 different mapping units prepared by ArcGIS 9.3 (ESRI, 2010), a geographic information system program. LCT is a practical and reliable mathematical equation used in several similar studies in the evaluation of sub-factor scores and weight ratios of the parameters together (Eastman and Jiang, 1996; Dengiz and Sarıoğlu, 2013; Romano et al., 2015). The model for the LCT approach is presented in the following *Equation 1*.

$$LQI = \sum_{i=1}^{n} (Wi \,.\, Xi) \qquad \text{(Eq.1)}$$

Here LQI, Land quality index; Wi, i weight value of parameters; Xi, sub-criteria score belonging to i parameters; n, the total number of parameters discussed. Land quality index class ranges calculated according to Jenks (1967), were determined using the basis of ArcGIS 9.3 software (*Table 6*). The index values calculated for all mapping units were categorized according to the ranges of natural diffraction from the histogram graph (Zhang et al., 2015). In this way, an index was developed according to the degree of effect of the region-specific parameters on the final score value.

Table 6. *Agricultural land quality classes*

Land Quality	Classes	Index Values
High	I	> 2.850
Moderate	II	2.554-2.849
Low	III	2.061-2.553
Very Low	IV	< 2.061

Land quality classes were categorized as a “High: I’ where there are no limiting factors for agricultural plant cultivation and development, “Moderate: II” where there are some slightly restrictive factors, “Low: III’ where there are factors affecting cultivation at a severe level and “Very Low: IV’ under conditions unfavorable for plant cultivation.

Determination of biomass density

Today remote sensing imaging is considered one of the main sources of information about the land vegetation (Campbell and Wynne, 2011; Singh et al., 2018). Vegetation index represent the most common remote sensing technique used for this purpose (Al-Doski et al., 2013; An, 2018), while NDVI is the most commonly used vegetation index (Tucker, 1979; DeFries et al., 1995; Garrigues et al., 2007; Tyagi and Bhosle, 2010; Olimb et al., 2018). For this purpose, Song et al. (2016), have stated that prediction coefficient with R^2 of 0.87 was found between NDVI values obtained from Landsat 8 OLI satellite images for winter wheat at different growth periods and the yield values in a farm-based study. NDVI is sensitive to active photosynthetic compounds and is, therefore, a popular method used to measure the biomass of vegetation or “greenness” in a defined area (Mezera et al., 2017). Thus, the fit between biomass of winter wheat from the field and the NDVI values obtained for the same locations were well and significantly ($P < 0.05$) correlated in the two regions, with coefficients of determination of 0.82 and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18291845

0.92 (Li et al., 2019). In this study, a multitemporal Sentinel–2A images in the year 2018, May were used to calculate NDVI values which were utilized for validation LQI classes with biomass density. NDVI values were calculated according to the *Equations 2*.

$$NDVI = (NIR - RED) / (NIR + RED) \quad \text{(Eq.2)}$$

where,
NDVI= Normalized Difference Vegetation Index
NIR = Near infrared band
RED = Visible red band.

Sentinel–2A has (1) a temporal resolution lower than a week, (2) a spatial resolution of up to 10 m, and (3) narrow bands in the red and red-edge region, which makes it a highly reliable sensor for agricultural monitoring (Pasqualotto et al., 2019). The image was downloaded free of charge from the ESA server (https://scihub.copernicus.eu/) that provides Level–2A images that are geometrically and atmospherically corrected with top-of-canopy (TOC) reflectance as cloud-free (Pandžić et al., 2016). In addition, it was used Erdas Imagine 9 (ERDAS, 2009) to perform NDVI analysis, and ArcGis 9.3 (ESRI, 2010) software was used to store data and generate thematic maps.

Spatial statistical analysis and map production in GIS

The Spatial Analysis tool of the software ArcGIS version 9.3 (ESRI, 2010) was used to spatially compare the LQI classes and NDVI values of the land units. The LQI and mean NDVI values of the land units were extracted using the Zonal Statistics tool and imported into MS Excel. Thereafter, all the data were statistically compared and regression equations, graphs, and accuracy coefficients (r^2) were produced.

Results and Discussions

In the study, the weight values of 20 mapping units based on pairwise comparisons for selected indicators for the determination of agricultural land quality were presented in *Table 7*.

Consistency Ratio; CR = 0.09 (<0.10) was determined by pairwise comparisons and the method was found to be valid (Saaty, 2008). In the pairwise comparison of obtained indicators evaluated by AHP; (1) land conditions for plant cultivation, (2) the importance of indicators and parameters relative to each other, (3) the elimination of the restrictive effects of the parameters and (4) by considering the degree of change of the parameters in the regional soils, weight scores were determined. Thus, in the studies carried out at the regional scale, the weight value of the region-specific characteristics (such as pH and $CaCO_3$) is lower compared to other parameters, but high level scoring of non-economic (e.g. slope degree, effective soil depth) and continuous risk (stoniness) properties in the land improvement or modification is recommended (Patrono, 1998; Dengiz and Sarıoğlu, 2013; Ahmed et al., 2016). However, it is known that their presence in the environment is not necessary for crop production, but if it is found to influence soil quality (e.g. organic matter), it should also have a moderate weight ratio (Riley et al., 2008). Due to all these evaluations, as a result of the pairwise comparisons by taking into account the ecology of the region, the effect levels of the indicators considered in the agricultural land quality measurement of the basin soils were evaluated in 3 groups as high, moderate and low. The results of AHP applications indicated that depth (24.2%), slope (21.1%) and texture

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18291845

(16.6%) indicators had a high-level weight coefficient. Although plants can grow in soils at different depths under favorable climatic conditions, usually optimum root development occurs in soils with high soil depth (Sarkar et al., 2014). It is can be explained by taking high weight coefficients of soil depth in the evaluation of land quality. In addition, the depth of the soil is very variable in the basin, which increases its impact on the assessment. Similarly, Slope degree is known to influence land quality for agricultural purpose and the assessment of land quality is important in determining soil-management practices (Paz-Kagan et al., 2016), and in recent studies, soil scientists have stated that the determination of land quality is particularly important to identify low-quality soils caused by high slopes (Vinhal-Freitas et al., 2017; Nabiollahi et al., 2018). Soil texture is another important factor used in the assessment of land quality (Aderonke and Gbadegesin, 2013), influencing the behavior of plant growth with infiltration rate, structure type and soil-water movement (Ahmed et al., 2016; Ennaji et al., 2018). In the light of past research, the effect levels of these indicators have high coefficients in the evaluation of the land quality in terms of plant cultivation.

On the other hand, stoniness (10.6%), bulk density (8.3%), EC and organic matter (5%) had moderate level of weight values. This is also a finding of the fact that the rehabilitated land conditions and the physical properties that can be improved by organic matter increasing applications can positively change the land quality index class. Thus, it has been stated that the mechanization is facilitated by the removal of the stoniness problem and increased values of crop emergence and yield in the agricultural lands were indicated (Miller and Guthrie, 1984; Sauer et al., 2010). Similarly, the positive effects of organic matter on water retention, soil compaction, aeration and biological activity reduce the restrictive effect of bulk density and improve land quality (Kurzatkowski, 2004; Guo et al., 2015). In addition, salinity problems were not determined according to EC values. However, intensive fertilizer and irrigation practices based on agricultural activities in the study area, the evaluation of salinity potential as potential risk is required (Miransari and Smith, 2007). This was reflected in the indicator's weight values and the effect of reducing the quality classes was modeled in case of a dramatic increase in EC values. With the application of AHP, pH (4.7%) and $CaCO_3$ (2.9%) indicators established a function with low weight scores. Both factors indicate changes in the calcareous- high calcareous and slightly alkaline classes in the value ranges specific to the terrestrial climatic conditions of Central Anatolia. Although these indicators have high impacts on product-based land assessment studies (Andrews et al., 2004), due to the characteristic features in the determination of land quality at the regional scale, it has functioned at low impact levels. Thus, pH directly or indirectly affects many physical, chemical and biological events occurring in the soil (Baridón and Casas, 2014), it is known that phosphorus and trace elements decrease their movement ability in the soil at high pH values and plant uptake of toxic elements increases in acid reaction soils (Leonard et al., 1976). Similarly, it is stated that $CaCO_3$ content is a factor that should be prevented especially in the applications such as phosphorus fertilization (Erdal et al., 2000). Therefore, it is required to functionalize pH and $CaCO_3$ indicators in LQI for being taken into consideration in managerial planning. The LQI map generated for the Güvenç basin is presented in *Fig. 2* and the LQI classes and their spatial distributions of each mapping unit are presented in *Table 8*.

As a result of the study, the lands indicating distribution in all conformity classes were determined in Güvenç basin. According to the generated LQI map, 302.13 ha area (17.14%) was classified as Quality High in the study area. Although these areas have 0-1% stoniness and heavy structure together or separate effects, they are the most suitable agricultural areas within the basin. The 659.52 ha (37.41%) of the total study area was defined as 'Moderate'. These areas have soil depths of 50-100 cm and have lands found in different slope groups (1-6). However, heavy structure factor (Heavy Clay), high bulk density for clay structure, low organic matter content and stoniness problem varying between 2-15% reduce the LQI value. As a result of LQI assessment, 732.57 ha (41.55%) land was classified as low-very low due to soil depth of 0-50 cm and very steep slope (> 12%) in the study area. It was determined in the ground control that these areas were mostly used for pasture. Although this situation increased the organic matter content of soils, it did not have a class increasing effect on the final index value. In this study, it was determined that the effect of pH, EC, $CaCO_3$ and organic matter indicators on quality final index values of the regional land did not create significant differences and this situation was caused by the fact that the indicators had similar values both in the fields and in themselves. The most important soil problems seen in the basin are soil depth, slope and stoniness. However, although some lands have a flat slope, high organic material content and soil depth of 25-50 cm, 5-15% stoniness problem, heavy texture and high bulk density required these areas to be classified as Low Quality. Similarly, areas with 0-2% stoniness, high organic matter and 5-15% $CaCO_3$ content but soil depth of 0-25 cm and slope of 6-12% were also included in the very low-quality class. However, it is foreseen that if the necessary conservation measures are taken (ground leveling planning, deep tillage and cracking, addition of organic matter, stone collection), the low-quality regional lands can be classified as moderate or high quality.

Validation of the LQI

The final index values of the quality classes determined as a result of the LQI evaluation were compared with NDVI ratios derived from Sentinel-2A satellite image in 2018-May using linear regression analysis. The evaluation of the data, $r^2 = 0.74\%$ relationship was determined (*Fig. 3*).

The validation values obtained showed that the use of AHP-LCT in sub-factor weighting of selected criteria for LQI gave reliable results. At the same time, it was concluded that NDVI values can be used to test the index developed in cases where biomass data of vegetation are limited in local based studies. Similarly, a significant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18291845

correlation was observed between the NDVI values of plants for the month of May and biomass (r^2 = 0.69), using the SPOT 2 satellite images (Usul, 2010). Further, a strong correlation was reported between NDVI and biomass density (Salazar et al., 2007; Olimb et al., 2018; Li et al., 2019), and NDVI provided a more accurate estimation of biomass than the other vegetation index for the purpose of assessing land cover and soil quality by remote sensing technique (de Paul Obade and Lal, 2013; Lambert et al., 2018).

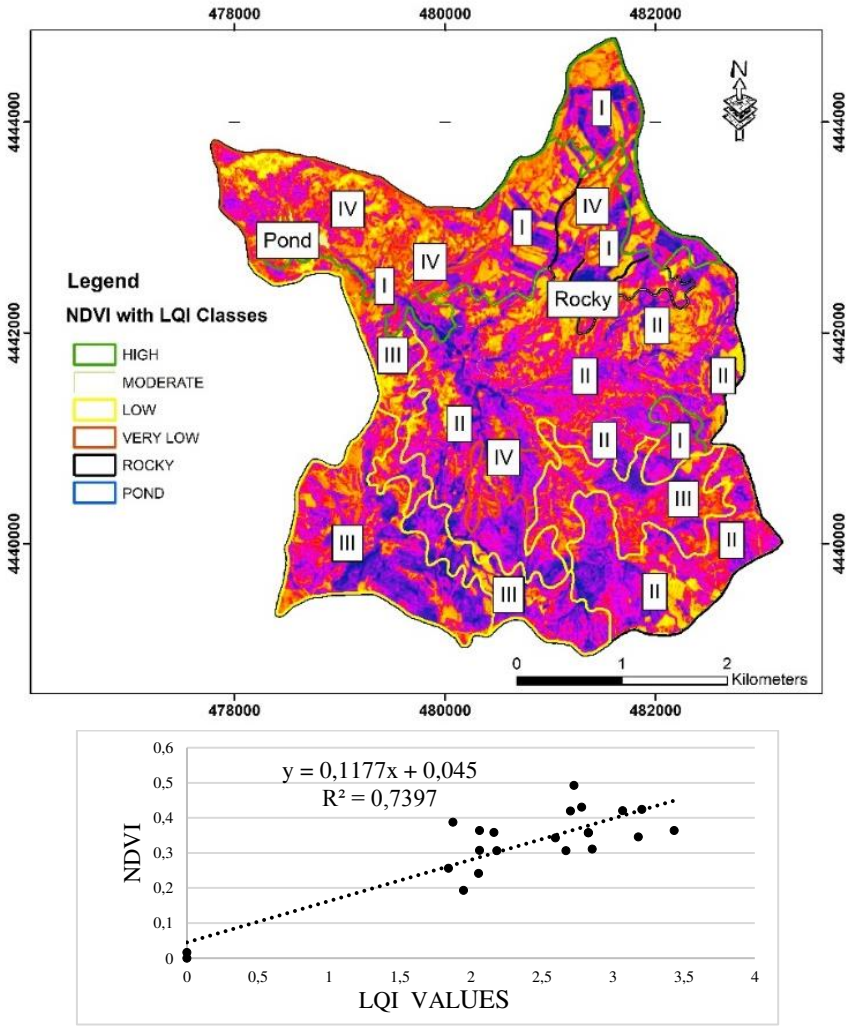

Figure 3. *Distribution of LQI classes on NDVI map from Sentienel 2A and regression graph*

Conclusion

In order to determine the quality index of agricultural land, which is compatible for semi-arid climate and integrated with GIS a practical LQI has been developed and found successful in Central Anatolia region due to showing a high relationship with canopy reflectance values. The most remarkable finding of the study is that the parameters selected for the LQI is the necessity to represent the study area, their topography, and the change in soil properties. In this way, region-specific evaluations can be made, and more reliable results are obtained. Thus, nine parameters used in the determination of land quality classes for Güvenç Basin reflect both the regional pedology and the effect of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18291845

climate characteristics. Another important point here is the weighting of the effect level of the selected parameters on each other and on the land quality. The AHP method used for pairwise comparison and weighting of parameters in the study presented a reliable index approach in the determination of land quality for agricultural purposes. While the relationship between each factor and AHP method is revealed, it is consistent to make common decision weights where the literature knowledge and expert opinion overlap (Expert System). Thus, the study showed similarity with the previous research findings that AHP has high capacity for integration of heterogeneous data. The obtained all findings showed that the development and use of region-specific index in the determination of the quality of agricultural land will enable the production of more accurate and reliable policies. In this way, climate, physiography and soil characteristics of different geographies can be evaluated within itself. Otherwise, evaluating our own lands with parametric approaches which are used in many studies but developed in different region ecologies causes wrong inferences. For instance, public institutions in Turkey for producing agricultural policy uses the Storie Index for land evaluation and classification. However, this approach scores the characteristics of the terrain indicated in the scoring of parameters to the same extent for different geographies. This reduced sensitivity in the assessment of land of different geography, such ecology particularly Turkey. At the same time, the indicator ratios specified in many parametric models are multiplied by each other and the effect level of each indicator is considered equal in terms of agriculture. In this case, even if a very important parameter such as effective soil depth in terms of agricultural land quality gets low score, high value of other parameters decreases the level effect of depth and improves the class of agricultural land quality. The most important advantage of regional-based index approaches is that, in addition to sub-categorizing the selected indicators at a regional scale, they weight the relevant indicators according to the regional characteristics. Thus, all factors can be evaluated according to the importance level of the specific region. However, since the different indicators (e.g. macro-micronutrients, heavy metals, biological factors) can be easily adapted to the index, it can be suggested that they can be reconstructed in areas indicating different soil properties. With all these evaluations and contributions, it will be ensured that the index fully represents the ecology of the region in which it is developed. The capabilities of satellite images of the basin were also utilized in the study. Our results have demonstrated the potential use of NDVI derived from high-resolution, multitemporal Sentinel–2A images for the comparison of biomass density with land quality scores in the basin. Similar studies have suggested that if there is limited data on vegetation, a different option of validation may be used. Moreover, the usability of vegetation indices for monitoring and estimation of land quality was evaluated with a different perspective and a window was opened for future research. In this way, changes in land quality determined by using parameters which were representing agricultural areas can be monitored by using vegetation indices in the following years compared with the past findings, and the cause of radical changes in biomass reflections could be determined by field studies. As a matter of fact, sustainable agricultural techniques suggest applications based on sustainability of land quality and productivity for agriculture areas in today and future. Consequently, land quality map for study area generated using AHP, GIS and LCT, can enhance the planning alternatives within an area with meaningful strategy in terms of location. Therefore, the present model will provide logical guidance for new land allocation of agricultural usage for decision makers.

EFFECTS OF EMITTER SPACING AND IRRIGATION RATE ON THE YIELD, QUALITY AND ENERGY REQUIREMENTS OF DRIP-IRRIGATED TOMATOES (*SOLANUM LYCOPERSICUM* L.)

KARAŞ, E.

Department of Biosystem Engineering, Osmangazi University, Eskisehir, Turkey
(e-mail: ekaras@ogu.edu.tr)

(Received 29th Oct 2019; accepted 30th Jan 2020)

Abstract. An experiment with a randomised split plot design was performed to assess the yield, irrigation water use efficiency, energy requirements and quality of tomatoes (*Lycopersicon esculentum* cv. BT236 F_1) grown with drip irrigation on the Alpu Plain in north-western Central Anatolia, Turkey. During a trial period involving three replications from 2009 to 2011, a Class A pan was used to measure the daily evaporation values of treatments in split plots with different emitter spacing (25 cm and 50 cm) and irrigation rates (20%, 30%, 40% and 50% of the evaporation rate of the Class A pan). Among the results, annual evaporation during the trial period ranged from 550.9 mm to 721.4 mm, and whereas higher irrigation rates afforded higher yields, lower ones afforded higher irrigation water use efficiency (IWUE). The average weight, vitamin C content, total soluble solid (TSS) content and pH values for tomatoes, all used in the proposed irrigation ratio, were 149 g, 99.18 mg kg^{-1}, 6.21% and 4.17, respectively. The energy requirement of irrigation water for diesel and electric consumption changed from 42 to 105 L and 140.6 and 351.4 kWh/ha, on average, respectively.
Keywords: *drip irrigation, irrigation water use efficiency, energy consumption, tomato quality*

Introduction

Tomato cultivation in Turkey plays an important economic role and it constitutes almost 40% of the total vegetable production (Aksoy and Kaymak, 2016; Guvenc, 2019). Global tomato production is currently 130 million tons. China, the European Union, India, the USA, and Turkey are known to be the top five largest tomato producers. These five producers account for 70% of global production (Eurofresh, 2016). Tomato breeding in Turkey is displaying a rising trend, which enables the country to keep its position as one of the biggest tomato producing countries in the world.

There are three cases of irrigation, which can be classified as: inadequate, excessive and optimum. First, inadequate irrigation leads to the formation of stress conditions by limiting the uptake of plant nutrients and water consumption, resulting in some quality problems and reduced yield (Lisar et al., 2012). Second, excessive irrigation causes leaching of the plant nutrients together with water and thus reduces water and nitrogen utilization efficiency (Xu et al., 2013; Huang et al., 2018; Thapa and Scott, 2019). Application of excess water to the soil not only affects seed germination and aeration of the root zone but also leads to many environmental problems such as waterlogging and salinization, contamination of groundwater's by minerals (Malash et al., 2008; Greene et al., 2016; Biswas and Kalra, 2018), nitrogen loss through leaching (Oenema et al., 2015; Shrivastava and Kumar, 2015; Musyoka et al., 2019; Rotiroti et al., 2019) and increasing irrigation costs (Kuşçu et al., 2013). Third, optimum irrigation ensures maximum water and nitrogen usage with optimal plant growth by avoiding excess water and loss of plant nutrients. Excessive usage of water not only causes a reduction in the amount of irrigated area but also more energy

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18471862

supply to carry the water into the area which is going to be irrigated. Therefore, proper management of water usage is of considerable significance for sustainable agriculture and energy conservation.

In the world's arid and semi-arid regions, water use efficiency (WUE) in general and IWUE in particular are persistent concerns as water becomes an increasingly limited resource. During the past half-century, water management has intensified in an effort to increase WUE (Medrano et al., 2015; Hatfield and Dold, 2019), which has been shown to relate closely to the method applied. Of available methods, drip irrigation, in use for nearly 50 years, has been accepted as the most efficient method of maintaining soil moisture in the root zone. Drip irrigation not only controls the amount of water used but also affords plants the efficient uptake of nutrients and pesticides (Shock, 2006). The Class A evaporation pan is one of the universally used and easy-to-control tools for water management. The results of various studies have shown that the low level of error in estimates makes Class A pan a favorable tool for the establishing of water consumption and irrigation scheduling for many plants (Ayas, 2015; Senyigit and Arslan, 2018). Numerous surveys have been conducted to assign the pan (k_p) and crop coefficients (k_c) of tomato in the drip irrigation method (Smajstrla and Locascio, 1990; Locascio and Smajstrla, 1996; Kırnak and Kaya, 2004; Harmanto et al., 2005; Ertek, 2011). In coarse-textured soils, the water requirements of tomatoes varied from 0.5 to 1.0 times the pan evaporation (Locascio and Smajstrla, 1989; Locascio et al., 1989), and in finer-textured soils, the results were highly similar: 0.75 times the pan evaporation for spring crops (Locascio et al., 1989) and 0.5 times the pan evaporation for fall ones (Olson and Rhoads, 1992).

Because sustainable agriculture involving the responsible use of water resources is necessary to meet the nutritional demands of expanding populations and to ensure the continuity of economic development, the study presented here was performed to assess the yield, IWUE, quality and energy requirements of drip-irrigated tomatoes using data gathered with a Class A evaporation pan.

Materials and methods

Experimental site and analysis

This research was conducted between the years 2009 and 2011 in Eskişehir-Alpu, Turkey, located at 39° 46' N, 30° 31' E, with a mean elevation of 780 m. The province is placed in a territory of a semi-arid climate with a mean temperature of 10.7 °C, the relative humidity of 62.1%, annual precipitation, and evaporation are 343.5 and 976 mm, respectively. Some of the climatical values throughout the research duration were given in *Table 1*.

Soils in the study area are almost homogenous and classified as Aridisol considering United States Department of Agriculture (USDA) Soil Taxonomy (Soil Survey Staff, 2014). Three soil samples from each plot were taken using an auger from three depths (0-30, 30-60, and 60-90 cm). General characteristics of the soil before the experiment were given in *Table 2*.

Soil particle size analysis was determined by using hydrometer method (Gee and Or, 2002), $CaCO_3$ content of the soil by Scheibler calcimeter (Loeppert and Suarez, 1996), soil organic matter by Smith-Weldon method (Nelson and Sommers, 1996), soil phosphorus content by sodium bicarbonate method (Kuo, 1996), pH value by using glass electrode pH meter (Thomas, 1996) and soil electrical conductivity (EC) value

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18471862

using standard EC electrode (Rhoades, 1996), respectively. Field capacity (FC) and wilting point (WP) moisture contents were obtained in -0.033 MPa and -1.5 MPa pressures, respectively, using a membrane extractor (Cassel and Nielsen, 1986). Available water (AW) was measured from the difference between the moisture contents of FC and WP. Bulk densities were determined by using the core method (Grossman and Reinsch, 2002). The infiltration rate was determined by a double ring infiltrometer. The AW content of the soil was 53.8 mm for 30 cm depth. The characteristics of irrigation water were determined by the methods proposed by the AWWA (American Water Works Association; Greenberg et al., 1992; *Table 3*).

During the research, trial plots were installed in different parts of the land having the same soil characteristics.

Irrigation scheduling

Irrigation scheduling was prepared based on the water holding capacity (WHC) for top 0-30 cm depth. The net irrigation depth (d_{net}), which is accepted as 40% of field capacity, was about 25.0 mm for the experimental area. Amounts of waters to be applied were calculated by the multiplication of d_{net} with evaporation rates. Irrigation water was applied when the evaporated water from the Class A pan reached to the calculated d_{net} value of the soil. There was not a constant irrigation interval during the research period. The coefficient of Class A pan (k_p) was assumed as 1.00 for evaporation calculations. Wetting areas were determined by using the method suggested by Keller and Bliesner (1990). The maximum and minimum wetting areas were found as 30.7% and 18.5%, respectively.

The irrigation water (I, m^3) amount was calculated using the following equation:

$$I = A \times E_p \times k_p \times E_r \quad \text{(Eq.1)}$$

where A is the plot area (m^2); E_p is the accumulated evaporation for irrigation interval (10^{-3} mm); k_p, pan coefficient (1.00); E_r is the evaporation rate (%).

Daily evaporation data were obtained from the weather station placed in the study area. Before the experiment, all plots were irrigated until they reach field capacity for the depth of 0-30 cm. Subsequent irrigations were carried out when the cumulative evaporation amount measured daily from the class A pan reached 25 mm.

In this study, the moisture changes in the soil were checked by three tensiometers measuring soil moisture to 0-90 cm depth (0-30, 30-60 and 60-90 cm). Soil moisture measurements were followed in only one replicate of the experimental subjects. Since the maximum amount of irrigation water applied in each irrigation was 25 mm, no pressure changes were observed in the tensiometers at depths below 30 cm. Thus, no deep percolation was detected under the depth of 30 cm in the measurements made during the trial.

Experimental design

The experiment was organized as a split-plot randomized block design with three replications in 24 plots, each measuring 31.2 m^2 (6.0 m length × 5.2 m width), with a separate strip of 2 m between them (*Figs. 1* and *2*).

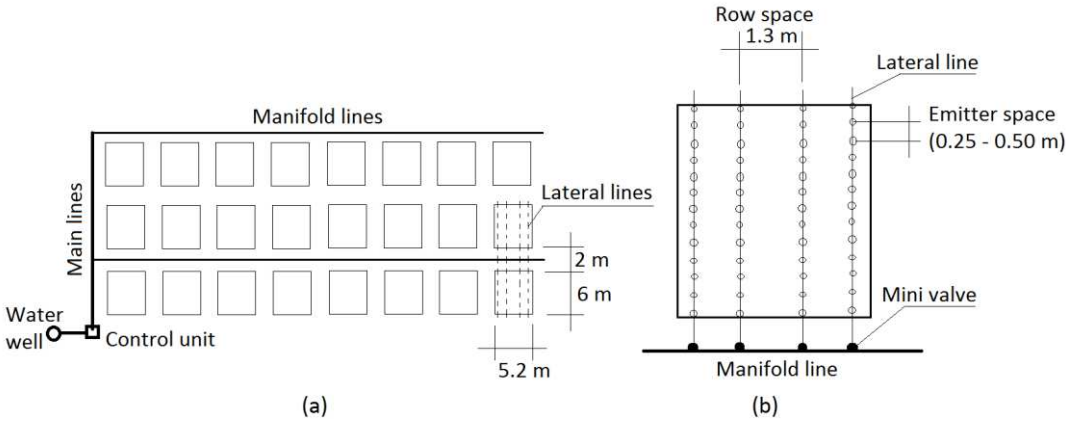

Figure 1. *General view of the irrigation system in the research area (a), and lateral lines, row and emitter spaces (b)*

DOI: http://dx.doi.org/10.15666/aeer/1801_18471862

Figure 2. *General view of the parcels and plants in the trial area*

The irrigation water, pumped from a deep well (15 m in depth), was conveyed to experimental plots with main and sub-main poly-etylen (PE) lines of 75 mm diameter. The control unit of the irrigation system had a hydro-cyclone filter, a sand filter, a screen filter, a mesh filter, pressure gauges, and a fertilizer tank with a dosage pump. Lateral lines with a diameter of 16 mm were laid down perpendicular along each tomato row at 1.3 m spacing. The flow rate of the drippers in the lateral lines was 4 L/h at a working pressure of 1 atmosphere. The evaporation rates of Class A pan (A: 20%, B: 30%, C: 40%, and D: 50%) and the emitter spaces (a: 25 cm, and b: 50 cm) were selected as main and subplot in the experiment, respectively. Two weeks old tomato seedlings were transplanted into the plots in the middle of May. The chemical fertilizing applications were carried out as suggested by Hartz (2006). There were four lateral lines in each plot. Row spaces between lateral lines were 1.3 m. There were 12 plants in each line and a total of 48 plants in each plot. IWUE values were calculated according to the method proposed by Howell (2001). The energy requirement for irrigation water is calculated considering diesel and electric systems. Statistical analyses were achieved with SPSS 17.0 (SPSS Inc, 2008). Data were tested by ANOVA with the factors years, evaporation rates, drip space, and yield and the possible interaction between both factors. Duncan's multiple comparison test was used to determine mean differences.

Tomato quality analysis

Samples for quality analysis were made in the first week of September to determine the fruit weight, pH, TSS and vitamin C values in tomato fruit in all trial years.

Fruit Weight: The average weights of tomato fruits randomly taken around 5 kg from the middle rows of the experimental plots were determined.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18471862

pH: Tomato juice was prepared by pouring the fruits into the blender for 10 min. Then, buffer solutions were prepared by pH meter, 10 mL of tomato juice was added into a 50 mL beaker. The pH of the obtained sample was measured using a pH meter (pH-Vision, model 6071, Taiwan).

Total soluble solids (TSS): The TSS was determined as a percentage (%) value at 20° using a digital refractometer (Atago Co. Ld., Japan) in three replicates of 1 kg sample.

Vitamin C content: It was determined in tomato puree using the method determined by Riemschneider et al. (1976).

Energy requirements

In the Alpu plain where the experiment is conducted, irrigation water is commonly taken from deep (>6 m) wells using electric submersible pumps and from shallow wells (≤6 m) using diesel-consuming motor pumps. The aquifer formation in the Alpu plain is ground alluvial. Its thickness varies between 5-95 m. The depths of the drilling wells drilled in the plain are between 11-250 m and their yield is 10-50 L s^{-1}.

The average well flow rates of 50 m^3 h^{-1} are considered as two different sources, diesel and electric. In order to calculate the energy need, the energy consumption of the 17 hp diesel fuel consuming engine pump, which is widely used in the Alpu plain, is taken into consideration. The diesel fuel consuming pump is used to supply water from wells that are no deeper than 6 m and the hourly flow rate of 2/3 gas is 50 m^3. The energy requirement of the electric submersible pump with an hourly capacity of 50 m^3 from deep wells up to 50 m in the study area is taken into consideration.

Results and discussion

Yield and irrigation water use efficiency

The use of Class A pan is a common practice in the field trials for the calculation of plant water consumption and irrigation water amounts. Although the coefficient of Class A pan (k_p) was assumed as 1.00 for evaporation calculations in this study, many studies used different coefficients such as 0, 0.25, 0.50, 0.75, and 1.00 (Locascio and Samjstrla, 1996), 0.75 (Harmanto et al., 2005), and 0.80 (Kırnak and Kaya, 2004). These studies have shown that the highest yields were obtained by assuming a pan coefficient of 0.75 and 1.00.

The effects of deficit irrigation on yield, seasonal water application (IW), and IWUE are given in *Table 4* and *Figures 3* and 4.

Table 4. *Effects of deficit irrigation on yield, seasonal water application and IWUE*

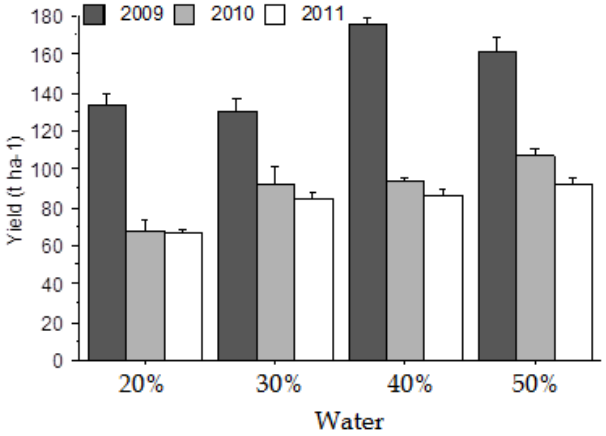

Figure 3. *Effects of deficit irrigation (% of ER) on the yield of tomato (t/ha)*

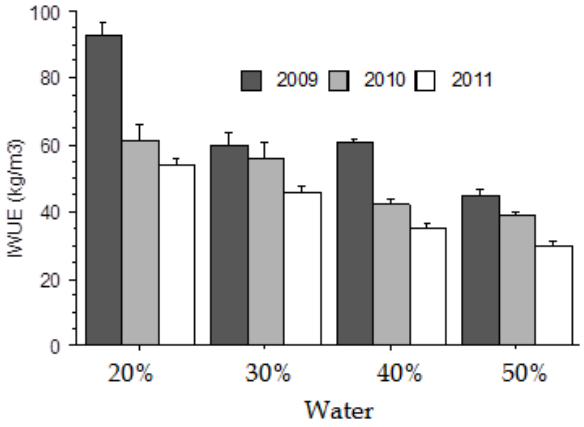

Figure 4. *Effects of deficit irrigation (% of ER) on IWUE (kg/m^3)*

There were significant differences between the years studied. The yields obtained in the first year of the study (2009) were higher than that of the following two years (2010 and 2011). The reason for reduced yield in these years could be related to the negative effects of climatic conditions in the growing season (earlier frost occurring date) and disease (Early blight, Septoria leaf spot, Fusarium wilt, Verticillium wilt) development. In 2009, while the highest yield was obtained from the subject where 40% of evaporation was applied (40% of ER) as 175.6 t ha^{-1}, the yield of the highest seasonal water application (50% of ER) was found as 161.6 t ha^{-1}. The lowest yields were obtained from 20% and 30% of ER as 133.3 and 129.9 t ha^{-1}, respectively (*Fig. 3*). While the amount of seasonal water application is twice between the subjects 20% and 40% of ER, the amount of increase in yield is found just as 31.7%, in 2009. Except for 2009, the highest and the lowest yields were obtained from the subjects where the highest and the lowest irrigation waters were applied, respectively. The minimum and maximum yields per hectare were found as 67.6 and 107.0 tons for 20% and 50% of ER for 2010, respectively. The amount of seasonal water application was 1100 and 2760 m^3 for these subjects. Although the amount of irrigation water applied in 2011 was relatively higher than that of 2010, the yields obtained were almost similar for the same subjects. The highest yield per hectare was obtained from 50% of ER as 91.7 tons, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18471862

the lowest from 20% of ER as 66.4 tons. In general, the increase in the amount of water applied to the increased yield obtained. However, there was no clear trend between the amount of water applied and the extent of the response. While the amount of applied water between 50% of ER and 20% of ER was 2.5 folds, the amount of increase in yield was found as 21.2%, 58.3%, and 38.1% for years 2009, 2010, and 2011, respectively.

The values of IWUE calculated for various deficit irrigation practices in all experimental years are summarized in *Table 4* and *Figure 4*. The IWUE gradually decreased from 50% of ER to 20% of ER, providing that tomato uses the water more efficiently under stress conditions. As expected, the highest and the lowest IWUE values were obtained from 20% and 50% of ER, respectively. Irrigation time and frequency play an important role in tomato production and productivity, hence in IWUE. Chen et al. (2013), have found that full irrigation at the seedling stage did not affect tomato yield and fruit quality. On the other hand, tomato yield decreased significantly depending on the degree of water stress applied during flowering and fruit development periods. Marouelli et al. (2004), have stated that the highest WUE in tomato occurs between flowering and fruit formation stages. Therefore, it is necessary to plan irrigation considering the water content of the soil at different growth stages of the plant. Continuous monitoring of soil moisture content is of vital importance. Results of this study have shown that even under deficit irrigation conditions high yields can be achieved by continuous monitoring of soil moisture.

All crops take water from wherever it is most readily available within the root zone. Most of the studies conducted on tomato are focused on the effective root depth of 50-60 cm. However, it is well known that on average 40% of water uptake is assumed to be taken from the upper quarter of the rooting depth, and 30% from the second quarter. Therefore, 25-30 cm rooting depth is responsible for 70% of water uptake. This study demonstrated that, even under deficit irrigation conditions, 30 cm rooting depth can be considered as an effective rooting depth for tomato and performing irrigation when 40% of the available water holding capacity calculated for 30 cm soil depth is evaporated from the Class A pan can give fairly good results. Emitter spacing did not affect yield and IWUE.

Fruit quality

The results of the application subjects on fruit weight, pH, TSS, and vitamin C are given in *Figure 5*.

Fruit Weight: The effect of irrigation water on fruit weight was significant both in terms of annual and amount of irrigation water. The average fruit weights of 2009 and 2011 were in the same group with 159.25 and 156.25 grams respectively, while the results obtained in 2010 constituted another group with 138.58 grams. Differences between irrigation practices led to different fruit weights each year. The highest fruit weight was obtained from the highest irrigation application in three years. In 2009, evaporation ratio of 50% gave the highest fruit weight with statistical group a followed by 30%, 40% (ab) and 20% with group b. Similarly, evaporation ratio of 50% was the best application for fruit weight while the lowest value was observed in evaporation rate of 20% in 2010. In 2011, 50% was the first statistical group while the others followed with the same group.

The effect of deficit irrigation on tomato fruit quality has been investigated in many studies (Colla et al., 1999; Machade and Oliviera, 2005; Patane and Cosentino, 2010; Patane et al., 2011; Garnett et al., 2013; Cantore et al., 2016; Hashem et al., 2018). The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18471862

effect of limited irrigation on fruit quality is generally inversely related to fruit yield. The results show the effect of irrigation water applied, but their impact on quality is unstable. Fruit weight is a factor that is largely affected by the amount of irrigation water or applied water stress. Some studies indicate that fruit weight increases with irrigation water, whereas stress conditions decrease. In our study, fruit weights were affected by water stress in the other two years (2010 and 2011) except in the first year (2009). In general, the highest amount of irrigation water applied gave higher fruit weight values. According to the three-year average results of the study, it is understood that all the subjects except 50% ER, where the highest irrigation water is applied, give the same average fruit weight values statistically. Mitchell et al. (1991) reported the decrease in tomato fruit weights due to deficit water and salinity as 37% and 42%, respectively. Similar results are pointed out by Yurtseven et al. (2005), It was observed that raising salinity levels in irrigation water resulted in a dramatic decrease in fruit weight. Birhanu and Tilahun (2010) and Patane et al. (2011) observed that deficit irrigation reduces fruit weight due to water stress. In the study conducted by Helyes et al. (2012), fruit weights obtained by the cut off irrigation in the early period with full irrigation in tomato did not differ statistically. However, the average fruit weights obtained by cultivation under rainfed conditions were lower than full irrigation.

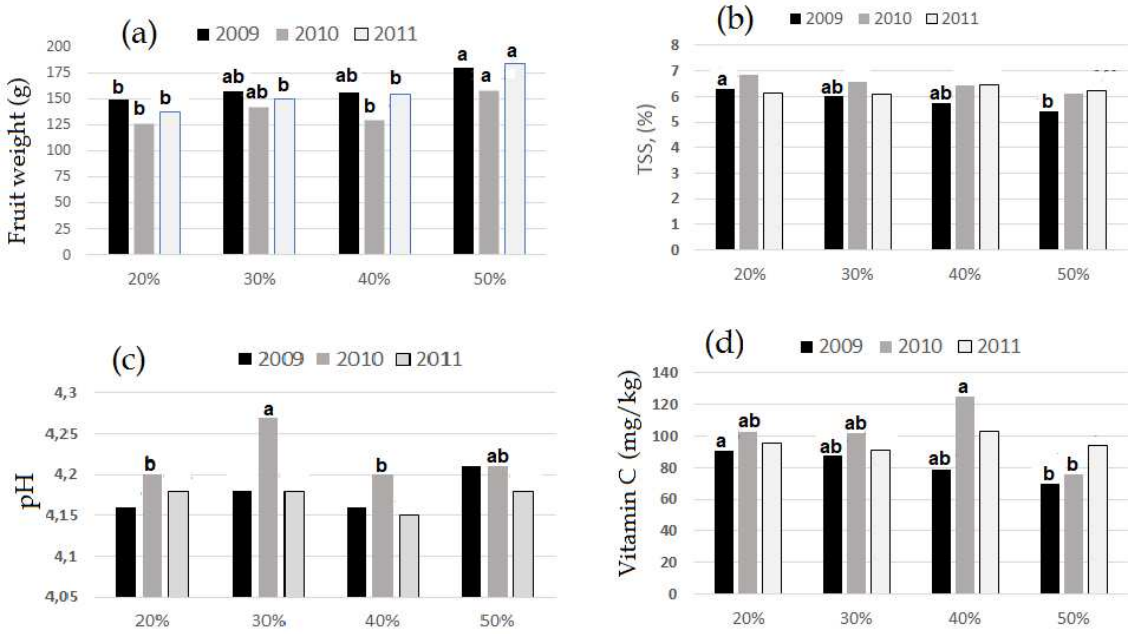

Figure 5. *The effects of applied irrigation water on fruit weight (a), TSS (b), pH (c), and Vitamin C (d)*

TSS: The TSS contents differed both in terms of year and amount of irrigation water. In general, the average values for 2010 and 2011 are in the same group and 2009 is in another group. In terms of average values of the issues, the highest TSS content was obtained as 6.43% on the lowest application rate (20% of ER). The results obtained in 2009 in terms of irrigation practices gave the same result as the general average. The data for this year gave the highest value of 6.31% for 20% of ER and 5.42% for 50% of ER. The impact of irrigation practices for 2010 and 2011 was statistically insignificant. The values obtained in terms of TSS followed a decreasing trend for the first two years

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18471862

due to the decrease in the amount of irrigation water: TSS = 6.6 - 0.291 ER (r^2 = 0.996) equation (TSS as Brix, and ER: Applied water as Evaporation Rate, %) for 2009 and TSS = 7.085 - 0.243 ER (r^2 = 0.983) for 2010. No meaningful equality has occurred for 2011.

In Mohammed et al.'s (2018) study, considering the vegetative, flowering and fruit maturity stages during tomato cultivation, the lowest TSS values occurred in the control plants, which were not exposed to any water stress, whereas the highest occurred when deficit water was applied during fruit maturity. Other researchers, by contrast, have demonstrated the inverse relationship between deficit irrigation and TSS (Zegbe-Dominguez et al., 2003; Garcia and Barrett, 2006; Helyes et al., 2012; Kuşçu et al., 2014). Contrary to those results, Dumas et al. (2003) observed that the effect of deficit water on TSS content was negligible, and Yurtseven et al. (2005) found that TSS content in tomatoes increased by 100% when exposed to irrigation water with a salinity of 10 dS m^{-1} compared to controls. Expanding upon those results, Birhanu and Tilahun (2010), who observed that moderate drought stress caused significant increases in the TSS content of tomatoes, proposed that the increased TSS content of tomatoes grown in soil with a water deficit directly related to their decreased water content. Added to that, Banjaw et al. (2018) found that TSS content in tomatoes increased with stress and varied among cultivars, while their water content decreased. Last, Mitchell et al. (1991) noted that terminating irrigation 50 days before harvest prompted significant increases in the quality of tomatoes in terms of TSS content.

pH: While the difference in the amount of irrigation water applied for pH values was observed only in 2010, there was no difference between 2009 and 2011 data. When the general average results of the years are compared, 2010 constitutes group a, while 2009 and 2011 constitute 4.18 and 4.17, respectively. No effect of the mean values of irrigation water on pH was determined.

The pH of tomatoes is determined primarily by the acid content of the fruit. The acidity of the fruit is also important as a contributor to the flavor of the tomato products (Anton et al., 2010). The acidity values of vegetables and fruits vary according to species, varieties, growing period and maturity. According to the US Food and Drug Administration Food Safety and Applied Nutrition Center (CFSAN), the acidity value of fresh tomatoes ranges from 4.3-4.9, while the pH range for canned tomatoes and tomato paste is 3.5-4.7. The range for tomato juice is 4.1-4.6. The acidity of fresh tomatoes may be closely related to their maturity. As the tomato fruit ripens, its acidity decreases and the pH approaches 4.9 ends of the previously described range. Canned tomatoes are typically more acidic than fresh tomatoes due to the effect of canning, and Canned tomatoes have a pH of about 3.5 (Mohammed et al., 1999; CFSAN, 2019). According to Hernández-Suarez et al. (2008), tomato fruit with a pH below 4.5 is classified as acidic. pH is important due to acidity influences the thermal processing conditions required for producing safe products (Garcia and Barrett, 2006). Based on this information, it can be said that the pH value of tomato fruit juice obtained in our research is all acidic. Many research findings show that the amount of irrigation water applied is not effective on the pH of tomato fruit juice. These results are consistent with those reported by Nuruddin et al. (2003) and Amor and Amor (2007). In contrast, Wahb-Allah and Al-Oman (2012) mention the positive effect of deficit water on pH. Increased salinity levels in irrigation water caused by the production of smaller sized fruits, but this leads to a decrease in the pH of the fruit juice (Yurtseven et al., 2005).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18471862

Vitamin C: The rates of irrigation water applied were statistically different in both year and rate. Although the year 2010 data is the year in which the highest value is obtained, it is in the same group in 2011 as the general average. On the other hand, 81.80 in 2009 constituted the other group. According to 2009 data, the highest vitamin C value was obtained from the issue of 20% of ER with the lowest water application, the 40% of ER subject was in the (ab) group, and the 30% and 50% of ER subjects were in the (ab) group. The results in 2010 differed from the previous year; this time 40% ER constitutes group (a) an alone, 50% of ER group (ab) and 20% and 30% both group (b). The 2011 data showed no difference in terms of vitamin C values measured according to the applied irrigation water data. According to the 3-year average data, the differences in irrigation water issues on vitamin C were observed statistically. According to the results of the research, there is an inverse relationship between the amount of vitamin C and evaporation rates, depending on the water stress applied in general. As the amount of irrigation water applied in 2009 and 2010 increased, vitamin C values decreased. According to Dumas et al. (2003), vitamin C content in tomato depends on the growing season, favorable plant nutrients and environment. Studies are indicating that the change in the scope of vitamin C is an element of increasing plant water consumption and variety features (Mahajan and Singh, 2006; Mitchell et al. 1991). Lovelli et al. (2017) found that no significant effects were observed on the vitamin C content.

Energy requirements

Energy requirements for diesel fuel and electric powered pumps of the irrigation subjects are shown in *Figure 6*.

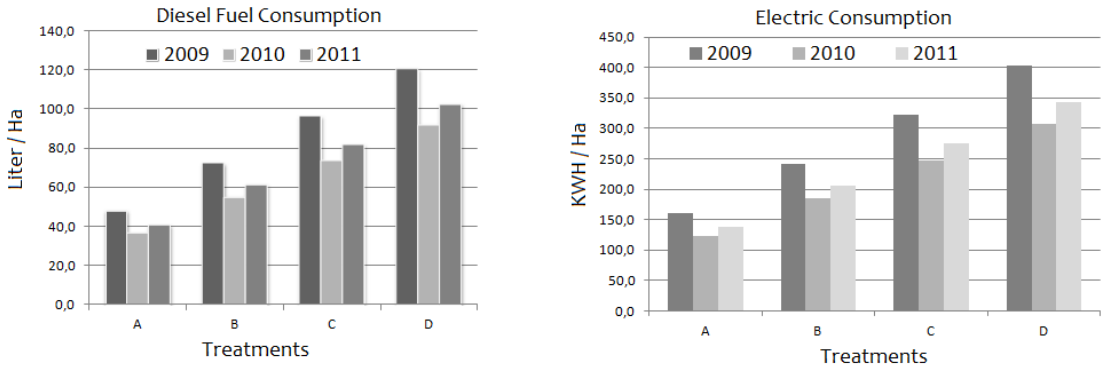

Figure 6. *Energy requirements for diesel fuel and electric powered pumps of the treatments*

While diesel fuel consumption for the irrigation subject is changing from 42 to 105 L, electric consumption ranged between 140.6 and 351.4 kWh/ha, averagely.

In the study, considering the distance between the lateral lines, the equality that can be used in the calculation of the amount of irrigation water that can be applied in heavy textured soils is found as follows:

$$Q = 8663.3\ X^{-0,996}\ (r^2 = 0.99) \qquad \text{(Eq.2)}$$

where Q: irrigation water per hectare as m^3; X: lateral line spacing (X, cm).

DOI: http://dx.doi.org/10.15666/aeer/1801_18471862

Conclusion

Banjaw (2017) states that deficit irrigation is an optimization strategy implemented in a way that there is no decrease in yield during certain growth periods of the plant. Restricted irrigation provides storage of water in areas with water shortage and the use of water saved during long dry periods to ensure sustainable yield. Reducing irrigation water is an opportunity to save water by reducing production costs, as well as minimizing leachable nutrients such as nitrogen by deep infiltration.

The research that used the pan coefficient in tomato irrigation time planning has been carried out under various soil, climatic conditions. Application variations such as pan coefficient, lateral and emitter spacing, irrigation interval can give different results in a similar climate, even in the same climatic and soil conditions. Therefore, it is not possible to make generalizations and to say of the existence of a single truth. The results obtained with this can be evaluated by comparing the data within them.

The amount of evaporating water from the class A pan represents a saturated condition in which there is no water shortage in the soil. Although the plant's developmental status (i.e. root and leaf growth) varies, their response to water stress is also different. In many studies conducted using class A pan, a constant Kpc was used during the growing period. However, the results obtained from many studies showed that plants' reactions to periodic water constraints were not the same. Considering this situation, the use of different coefficients for each period can be one of the solutions that can be used for irrigation planning by using Class A pan for optimum water and nutrient management and saving water in the root zone. It may be possible to develop regional equities or use of coefficients, taking into account the climate and soil conditions.

An equation was developed to be used for different lateral spacing for heavy textured soils, taking into account the proposed evaporation rates obtained. In that process, lateral intervals and the amounts of irrigation water required for each lateral interval were analyzed together. When different lateral spacings are used, the volume of irrigation water per hectare can determine.

The root system of many plants in the vegetable group is shallow depth. Optimal irrigation programs can be developed on soils with different soil structures without causing deep penetration and therefore no leaching and stress on plants. For this reason, future research programs should be focused on improving IWUE and nutrient utilization efficiencies, especially by preventing water and nutrient losses. In this way, significant savings in irrigation energy can be achieved.

EFFICACY OF IPM, MASS TRAPPING AND CHEMICAL CONTROL IN THE SUPPRESSING OF MEDITERRANEAN FRUIT FLY, [*CERATITIS CAPITATA* (WIEDEMANN) (DIPTERA: TEPHRITIDAE)] IN CITRUS

ELEKCİOĞLU, N. Z.

Cukurova University, Vocational School of Karaisalı, Department of Plant and Animal Production, 01170 Adana, Turkey
(e-mail: nelekcioglu@cu.edu.tr; phone: +90-322-551-2057; fax: +90-322-551-2255)

(Received 22nd Jul 2019; accepted 25th Nov 2019)

Abstract. The management of the Mediterranean fruit fly, *Ceratitis capitata* (Wiedemann) (Diptera: Tephritidae) in Turkey is mainly through chemical control. In this study, the effectiveness of the integrated pest management (IPM), mass trapping and chemical control were compared in an orange orchard in Tarsus (Mersin) during 2015 and 2016. The IPM program was based on the use of the synthetic food attractant lure Biolure, paired with sanitation of infected fruits and chemical control if necessary. In mass trapping plots the female targeted attractant lure Biolure and the male targeted sex attractant lure Trimedlure were used. Chemical control was based on bait treatments with Spinosad. The efficiency of the applications was evaluated according to the rate of infected fruits during harvest. The highest number of flies was detected in the Control plot as 404 flies/trap/week in 2015 and in Chemical Control plot as 429 flies/trap/week in 2016. No statistical difference was found between the applications regarding the number of male flies weekly captured and number of infected fruits. However, it was determined that the ratio of infected fruits in the IPM plot was lower than that of other plots (1.57% in 2015 and 0.89% in 2016) at harvest, followed by Biolure, Trimedlure and Spinosad, respectively. It was concluded that IPM, which included the application of several methods, was the most effective control practice for *C. capitata.*
Keywords: *Ceratitis capitata, food attractant, IPM, lure, sanitation, spinosad*

Introduction

The Mediterranean fruit fly, *Ceratitis capitata* (Wiedemann, 1824) (Diptera: Tephritidae) is a significant quarantine pest. It is spread out over a wide area around the world due to its high tolerance to climatic changes compared to many other fruit fly species. Worldwide, *C. capitata* has over 579 fruits and vegetables as hosts (Liquido et al., 2017). It causes economic damage to many fruit species in Turkey, first and foremost to citrus fruits. The pest completes its generation on these hosts before the citrus fruits mature, therefore, pest population is higher on citrus. Yield loss can reach 100% if the necessary pest control measures are not taken (Thomas et al., 2001; Umeh et al., 2004). The economic consequences of its presence include not only direct losses in yield and increased control costs, but also indirect damage, which is usually higher, such as loss of export markets, severe restriction of exports of most commercial fruits as a result of quarantine laws, and the cost of maintaining facilities for fruit treatment and eradication (Radonjić, 2013). There are various control methods used for this pest, including chemical control (bait application, foliar application), biotechnological control (mass trapping) and the release of sterile insects, which is applied in some countries (Martinez-Ferrer et al., 2010; Anonymous, 2018; Gëzhilli et al., 2018). Bait application is recommended in Turkey as it allows the maintenance of natural balance, protects human and environmental health and enables the reduction of the number of insecticides used in chemical control. Due to the limits of chemical control, alternative solutions that do not

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_185199

leave pesticide residues have been sought after and trials based on mass trapping have been conducted. In Turkey, the use of biotechnological control techniques has been continuous since the 1970s. The effect of different attractants or trap and attractant combinations on the pest has been studied (Zümreoğlu, 1990; Epsky et al., 1999; Başpınar et al., 2011). Various studies, in which male and female attractants were used, have been performed in *C. capitata* mass trapping (Heath et al., 2004; Navarro-Llopis et al., 2008; Satar and Tireng, 2016). Trimedlure has been reported as the most effective and the most used male-specific attractant for detection and suppressing *C. capitata* (Hill, 1987; Tan et al., 2014). Heath et al. (1997) developed a synthetic food lure system that attracts both females and males (Biolure, 3-component fruit fly attractant). This attractant has been commonly used in many studies in order to monitor and suppress the pest population (Epsky et al., 1999; Cohen and Yuval, 2000; Papadopoulos et al., 2001; Broughton and De Lima, 2002; McQuate et al., 2005; Navarro Llopis et al., 2008; Martinez-Ferrer et al., 2012). Although it has increased over the years, only a limited number of producers apply the mass trapping method for *C. capitata* control in Turkey. While some producers think this control method is not sufficient for suppressing the pest, others think the method is difficult to apply. For this reason, they prefer chemical control, which is easier and cheaper but requires repetition at certain intervals. However, problems such as labour and loss of time have also been reported in the application of this method, particularly in large orchards. The damage rate varies between 8-15% in mass trapping applications performed on citrus orchards (Satar and Tireng, 2016; Demirel and Akyol, 2017; Yayla and Satar, 2017). It has also been reported that successful results were obtained with the application of mass trapping in an integrated pest management program and that 0.5% damage rate was achieved as a result of cultural control and other methods together until harvest (Martinez-Ferrer et al., 2012). The objective of this study was to compare the effectiveness of male-targeted and female-targeted *C. capitata* attractants, IPM and also chemical control against *C. capitata*.

Materials and methods

Groves and trapping scheme

The trial was conducted on a citrus orchard located in the eastern Mediterranean region of Turkey (Tarsus/Mersin). The orchard (36°55'04.90" N, 34°56'06.12" E) was a 7,5 ha area, drip irrigated and 15 m above sea level. It was planted with orange trees (*Citrus sinensis* var. Washington navel) that were 20 years old. Up until the experiment began, Spinosad was applied as bait (1 L/10 L-with 10 day intervals) in the orchard against *C. capitata*. The orchard was surrounded by a mandarin orchard on the north, a factory on the east and an area of field crops on the west and south. It was divided into six plots, with each plot being 1 ha for different treatments. All plots were besides each other at one edge of the orchard whereas only the control plot was at the other edge. Two rows were kept between the plots as barriers. To evaluate the efficacy of the applications, a randomized block design with four replicates was used. The following treatments were compared: 1) Chemical control with Success 0.24 CB bait application (CC), 2) Mass trapping with male attractant Trimedlure (MMT), 3) Mass trapping with female attractant Biolure, (3 component female-biased attractant - ammonium acetate, trimethylamine and putrescine) (FMT), 4) Integrated pest management program (Mass trapping with female attractant Biolure + sanitation by eliminating the punctured dropped fruits weekly + bait application if necessary) (IPM), and 5) Untreated control (C) (*Table 1*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_185199

The insecticide treatments on the chemical control plot were performed according to the bait application method (Anonymous, 2015). Spinosad (1 L/10 L) was applied as insecticide at 10-day intervals and 150 ml pesticide-water mixture was used per tree. The remaining trees in the orchard were also treated with Spinosad. In the first mass trapping plot (MMT), experiments were performed using Eostrap® invaginada traps (Sanidad Agricola Econex, Santomera, Murcia, Spain) baited with %95 Trimedlure (formulated in a polymeric plug-type dispenser) (Sanidad Agricola Econex, Santomera, Murcia, Spain) and 2.2- dichlorovinyl dimethyl phosphate (DDVP) tablet (Sanidad Agricola Econex, Santomera, Murcia, Spain) as insecticide. A trap density of 20 traps/ha was applied for capturing adult males in both years. In the second mass trapping plot (FMT), Tephri-traps baited with synthetic female-targeted food attractant lure marketed as BioLure®UnipakTM (AgriSense-BCS Ltd., Pontypridd, South Wales, UK) and the insecticide dichlorvos (DDVP strips) (AgriSense-BCS Ltd., Pontypridd, South Wales, UK) were used (*Fig. 1*). A trap density of 50 traps/ha was applied for capturing adult females and males in both years. The adults captured in the traps were counted and recorded separately as females and males. In IPM plot the program was designed identically to the FMT plot. All the infected fallen fruits from all trees on this plot were collected once a week and destroyed. In addition, Spinosad was treated as bait when it was necessary.

Table 1. *Treatment regimes during the study period*

No	Trials		Treatments
1	Chemical control	CC	Spinosad bait application - 1L/10L
2	Mass trapping	MMT	Trimedlure male attractant - 20 traps/ha
3	Mass trapping	FMT	Biolure female attractant - 50 traps/ha
4	Integrated pest management	IPM	Mass trapping with Biolure + sanitation by eliminating the punctured dropped fruits + bait application if necessary
5	Untreated control	C	-

Figure 1. *Trapping devices used in the field trials: a, b: Tephti trap with Biolure, c, d: Eostrap with Trimedlure*

Treatments and population monitoring

Ceratitis capitata population was monitored by counting the males captured in 10 Jackson traps with Trimedlure as the attractant, hung on each tree in the middle row of all the plots. The traps were checked once a week. In the plots with Biolure use, the number of females was determined by counting the females captured in 10 traps which were marked at the beginning of the study. In all plots, mass traps and monitoring traps were hung in 29 August 2015 and 30 August 2016. They were hung at a height of 1.5-2.0 m from the ground in a shaded part of the canopy facing the south-east and were homogeneously distributed throughout the plots. The pheromone dispensers in the Eostrap traps were changed once every 90 days, while the pheromone dispensers in the Biolure traps were changed once every 120 days. Furthermore, the pheromone dispensers in the monitoring traps were changed once every 6 weeks.

Fruit damage assessment

Ten trees were chosen randomly from the middle row of all plots. The fallen fruits from these trees were collected every week, recorded as healthy or infected and removed from the orchard. The main assessment was performed during harvest; 100 fruits were controlled randomly from all sides of these trees and recorded as healthy or infected. The damage ratios (%) were calculated from the results of both counts.

Statistical analysis

The effect of applications on the male captures and fruit damage was analysed using a one-way Anova, where the applications were used as independent variables and "number of males captured" and "total number of infected fruits" were used as dependent variables. Means were separated by Tukey's honestly significant difference (HSD) test at $P<0.05$. All analysis were performed using the Microsoft statistics program SPSS 25.0. Damage ratio (%) was determined from the number of infected fruits recorded weekly and during harvest. The impacts of the IPM, mass trapping and bait treatments on the pest population were measured according to the Abbot formula [Effectiveness % = (Infected fruit % in Control - Infected fruit % in Trials/ Infected fruit % in Control) x 100] by the infected fruit reduction between the plots (Abbott, 1925). Results were expressed as percentage of damaged fruits.

Meteorological data were obtained from 'Tarsus Soil and Water Sources Research Center' located 2 km away from the tested orchard.

Results

Ceratitis capitata flight activity

The number of *C. capitata* males captured in Jackson traps on the CC plot were low in number throughout September for all applications in 2015 and 2016. In 2015, pest population started to increase as of October and reached the highest number on the second half of the month (22.10.2015). Pest population was determined as 369 flies/trap/week averagely for this period, remained within similar levels from the end of October to the mid of November and showed a decreasing trend in the following counts until harvest. The average number of males was determined as 124.64 adults/trap for this plot throughout the season. The first Spinosad treatment in this plot was carried out on 28 September 2015. Treatments continued at 10-day intervals, and a total of 8 treatments

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_185199

were performed until the harvest on 17 December 2015. In 2016, pest population peaked at the end of October (31.10.2016) with averagely 429 flies/trap/week. Throughout the season, the average number of males for this plot was 122.79 adults/trap (*Table 2*). The first insecticide was treated on 03 October 2016, and a total of 7 treatments were performed until harvest on 22 December 2016. In the MMT and FMT plots, the highest number of adults in 2015 were recorded at the end of October as averagely 325 and 256 flies/trap/week, respectively. Pest population showed a decreasing trend until harvest (*Fig. 2*). The average number of males on these plots throughout the season was determined as 120.14 and 104.14 adults/trap, respectively (*Table 2*). On the IPM plot, pest population started to increase after the second half of October, and the highest number of adults was counted as 383 flies/trap/week on average on 29 October 2015. In order to increase the efficiency of mass trapping, Spinosad bait was applied just after this date. The pest population immediately decreased after the application. The average number of males on this plot throughout the season was determined as 109.29 adults/trap. The number of males captured in the traps was highest in the Control plot. The highest number of adults was again determined at the end of October (29.10.2015) as averagely 404 flies/trap/week. The number of males on this plot throughout the season was averagely 141.71 adults/trap (*Table 2*).

*Means followed by the same letter within a column are not significantly different by Tukey's multiple comparison test where P<0.05

Considering all applications, pest population was determined to be high particularly from the second week of October until the mid of November. Although the highest number of adults was counted in the Control plot, no statistical difference was determined among the applications (F=0.273; df=4, 65; P = 0.894). In 2016, the highest number of adults was captured on 31 October 2016, with averagely 429, 383, 397, 286 flies/trap/week for the CC, MMT, FMT, IPM plots, respectively. In the Control plot, the highest number of adults was determined one week before the other plots on 24 October 2016 with an average of 356 flies/trap/week. Throughout the season, the average number of males were determined as 122.79, 110.14, 114.79, 111.87, and 137.57 adults/trap in the CC, MMT, FMT, IPM, and Control plots, respectively (*Table 2*).

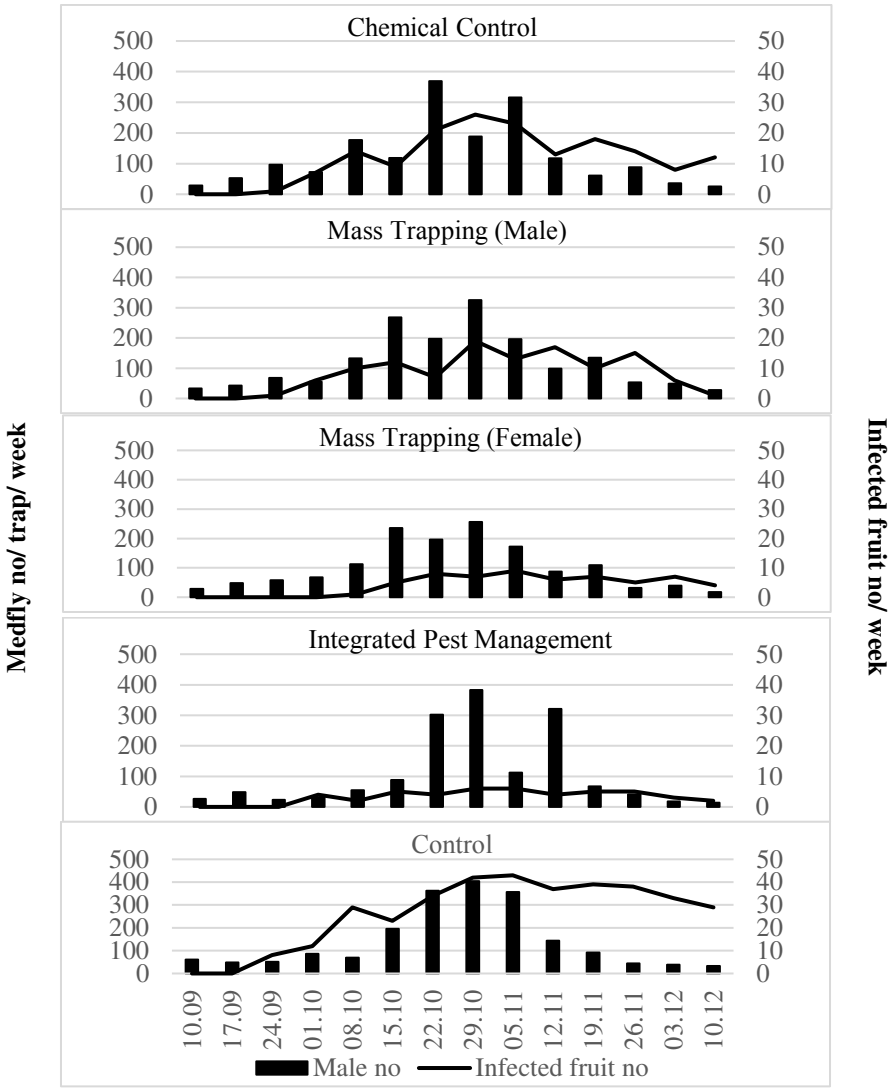

Figure 2. *The number of males captured in the Jackson traps and the infected fruits in the plots comparing different methods against Ceratitis capitata in Tarsus (Mersin) in 2015*

In 2016, until harvest, the adults continued to be captured in the traps on all the plots (*Fig. 3*). No insecticides were treated on the IPM plot this year. The highest number of males was determined in the Control plot, however, no statistical difference was determined among the applications this year (F=0.138; df=4, 65; P=0.968).

On the FMT plot, the number of females was higher than the males. In 2015, 4.312 and 4.925 females were captured from the FMT and IPM plots, respectively. Accordingly, the rate of males on the FMT plot was determined as 25,27%, while the rate of females was determined as 74,73%. In addition, the ♂:♀ ratio was 23,70% : 76,30% on the IPM plot. In 2016, the total number of females on the FMT plot was 5.039, and number of males was 1.607. The rate of females was determined as 75,82%, while the rate of males was 24,18%. A total of 6.857 adults were collected from the traps on the IPM plot in the second year of the study, and the ♂:♀ ratio was determined as 22,83% : 77,17%. It has been observed that the number of females captured in traps is three times higher than males.

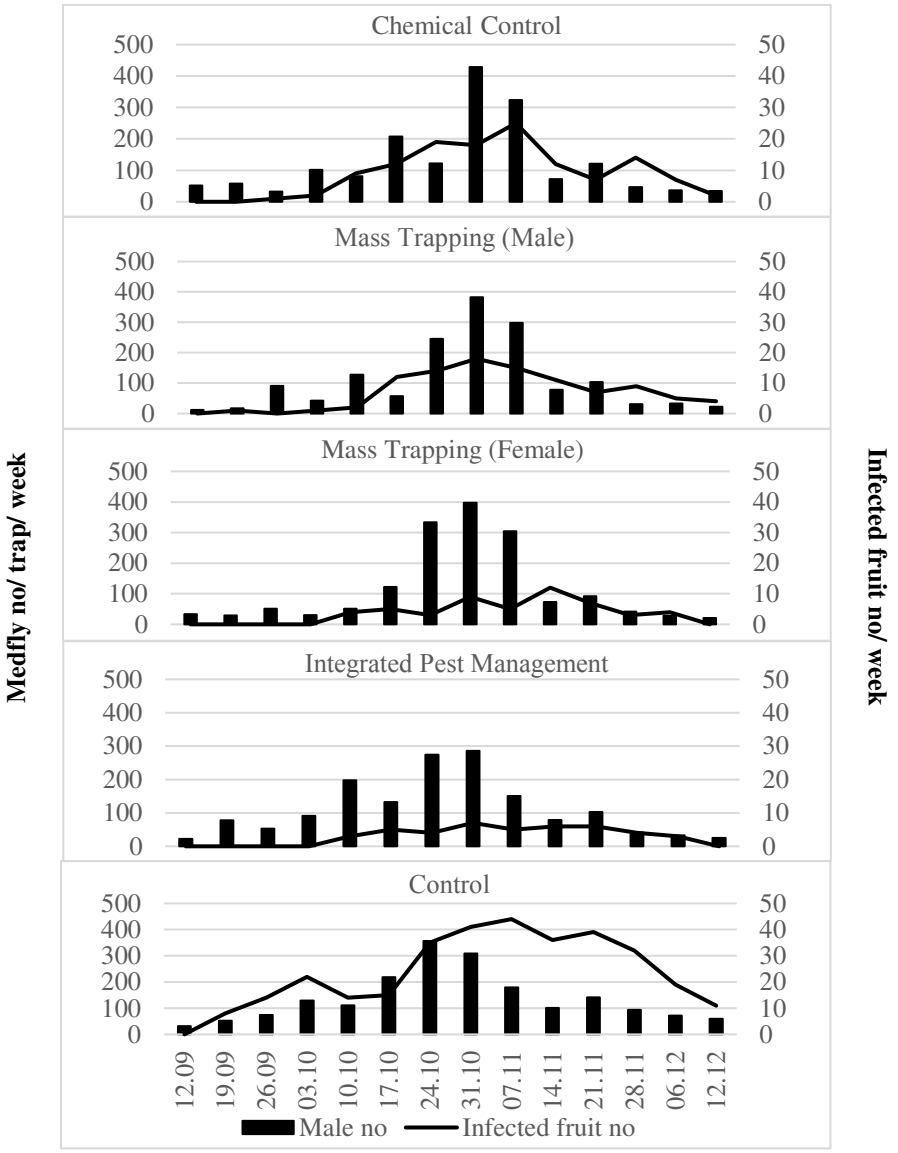

Figure 3. *The number of males captured in the Jackson traps and the infected fruits in the plots comparing different methods against Ceratitis capitata in Tarsus (Mersin) in 2016*

Fruit damage assessment

The average number of punctured fruits due to *C. capitata* infection in different applications is given in *Table 2*. In 2015, the first infected fruits were observed in the CC, MMT and Control plots on 24 September 2015, in the IPM plot on 01 October 2015 and on 08 October 2015 on the FMT plots (*Fig. 2*). Throughout the season, the highest number of infected fruits was observed in the Control plot (an average of 26.21 fruits). The maximum number of infected fruits (an average 43 fruits) on this plot was observed on 05 November 2015. This date corresponds to the week after the date when the highest number of adults were captured in the traps. The lowest number of infected fruits was observed on the IPM plot (an average of 3.29 fruits). Among the infected fruits throughout the season, it was observed that the difference between applications was statistically significant. CC, MMT, FMT and IPM plots were in the same group while the Control plot

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_185199

was in different group (F=16,919; df=4, 65; P<0.001). Similar results were also obtained in 2016 (*Fig. 3*). The number of infected fruits observed in the CC, MMT, FMT, IPM and Control plots throughout the season were 9.14, 7.07, 3.71, 3.07 and 23.57, respectively. Following the *C. capitata* infection, the difference between the weekly number of the dropped fruits was determined as statistically significant among the applications. CC, MMT, FMT and IPM plots were in the same group, while Control was in another group (F=15.388; df=4, 65; P<0.001).

Since all the applications were performed on the same orchard, impacts of the climatic factors affected all plots. No rainfall that required the applications to be repeated was experienced throughout the study. Therefore, it was considered that there were no conditions among applications that were caused by climatic factors (*Fig. 4*). The average temperature in august was 27.1 and 29.9°C in 2015 and 2016, respectively. The temperature followed a decreasing trend until harvest, but until November it was over 21°C both years. The relative humidity was over 50% and no heavy rainfall that limited the pest population occured during the study both years.

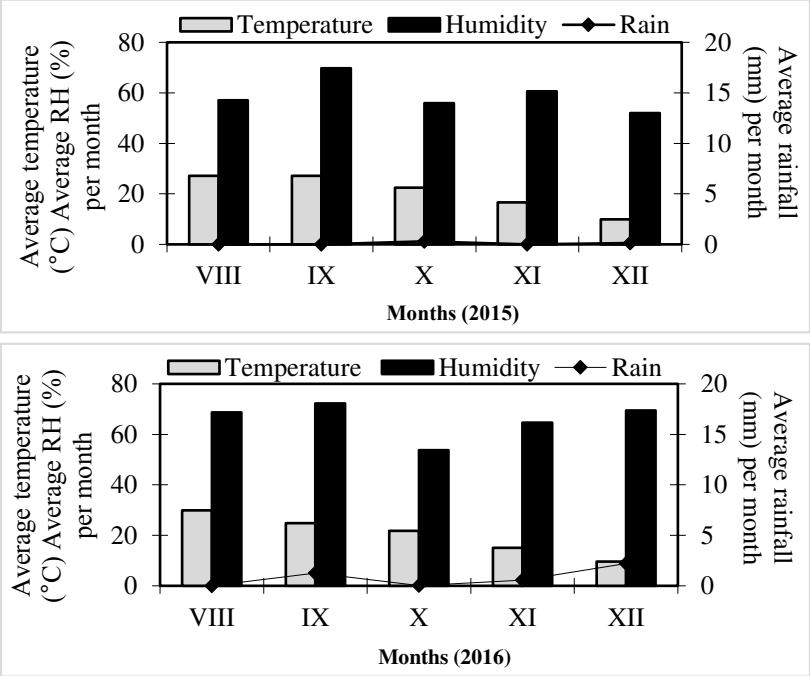

Figure 4. *Climatic datas in Tarsus (Mersin) in 2015 and 2016*

At the harvest, the efficiency of the CC, MMT, FMT and IPM applications against *C. capitata* in 2015 was 88.62%, 91.46%, 94.21% and 95.33%, respectively. The difference between the applications were statistically significant (F=10.892; df=3, 36; P<0.001). The CC, MMT, FMT and IPM applications showed average efficiency of 87.43%, 90.65%, 94.29% and 97.17%, respectively in 2016.

A statistical difference was determined between the applications (F=17.188; df=3, 6; P<0.001) and between the years (F=20.456; df=3, 6; P<0.001 in 2015, F=12.148; df=3, 6; P<0.001 in 2019). It was determined that the ratio of infected fruits in the IPM plot was lower than that of other plots (1.57% in 2015 and 0.89% in 2016) at harvest, followed by Biolure, Trimedlure and Spinosad, respectively (*Table 3*).

Discussion

Ceratitis capitata flight activity

Several mass trapping systems have been developed to control *C. capitata* worldwide. Depending on the strength of the attractant, this tactic targets females or males. In Turkey, there is very little mass trapping for the pest. Başpınar et al. (2011), Satar and Tireng (2016) and Demirel and Akyol (2017) reported that the mass trapping is being used successfully against *C. capitata*.

Results obtained from this study showed that considering all applications, pest population was determined to be high particularly from the second week of October until the mid of November in 2015 and 2016. The highest number of males was determined in the Control plot, however, no difference was determined among the applications both years. The fact that the number of males captured in the traps from different plots was not statistically different in both years has suggested that the pest showed homogeneous distribution among applications in the orchard. In 2015 and 2016, although the fruits had not reached infection maturity, the adults captured in the traps showed that the flies had flown to the study orchard from neighbouring orchards which had hosts of the pest. However, while pest population was low at the beginning of September, when the study started, the population increased when the fruits changed colour and the number of males captured in the traps was high in October and November. There are many studies in Turkey and in the world on the population dynamics of *C. capitata*. Katsoyannos et al. (1998) in their study performed in Chios (Greece) determined the highest number of adults captured in traps were in October and November. In addition, Martinez-Ferrer et al. (2010) determined similar results with mandarins in Spain and Boulahia-Kheder et al. (2012) with mandarins and oranges in Tunisia. Demirel and Akyol (2017) reported that pest population increased in October and November, in the mass trapping study performed with Eostrap invaginada traps in a satsuma mandarin orchard in Hatay (Turkey). Elekcioğlu (2013) stated that *C. capitata* population peaked in June, between 2008-2010 in a Washington navel orchard in Adana, which had similar climatic conditions to the orchard in the present study. The reason for this population increase during this period, when the fruits haven't yet reached infection maturity, is that there were other hosts for the pest around the study

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_185199

orchard and the fact that the pest reproduced. The pest population increased on these fruit trees and moved to citrus in the late summer or autumn. A high number of adults were captured from the mid of September until the mid of November in the study years and six to nine treatments were done per year on the citrus according to the weather conditions. The present study showed parallel results with the literature. It is considered that the high pest population and the fact that they reproduced in the citrus fruits during this period is due to the decrease in or non-existence of host plants, apart from the citrus species.

It has been observed that the number of females captured in traps is three times higher than males in the present study and in different studies from the literature that had different pest population, citrus type, traps, climatic conditions, etc. It is considered that capturing females is crucial for *C. capitata* control since the number of eggs laid decreases automatically. While males were captured primarily in the traps on MMT plot, females were also captured, even though the number of females was lower than males. Leza et al. (2008) determined that the rate of females varied between 70.10% : 78.70%, in which they used Biolure as a food lure and different insecticides. In their study performed on mandarins by using Tephri traps with attractants containing ammonium acetate, putrescine and trimethylamine as food, which is identical to the attractants used in the present study. Mediouni-Ben Jemâa et al. (2010) determined that the rate of females varied between 68.79% - 73.70% and 72.26% - 72.30% in a Washington navel orange orchard. Satar and Tireng (2016) determined the ♂:♀ rate as 27.00% : 73.00% and 31.00% : 69.00% in their mass trapping study, where they used ammonium acetate+chlorohydrate trimethylamine+diamineopentane as food for the pest control in an Okitsu wase mandarin orchard.

Fruit damage assessment

In all applications, the infected fruits were first observed at the end of September and the first half of October. After then, the number of infected fruits increased with the increasing pest population. The lowest number of infected fruits was observed in the IPM plot in both years. It is considered that the females were primarily attracted to the smell of the food and therefore directed to the traps with the yellow plates and did not infect the fruit in this plot. The bait application for suppressing the population in this plot during the high pest population contributed to reducing the population. The IPM plot was followed by FMT, MMT and CC plots, respectively.

The results show similarities with the study of Leza et al. (2008), who obtained the most successful result for *C. capitata* control when they used Biolure as attractant (50 Probodelt trap/ha) and one bait application of fenthion or Spinosad or lambda-cyhalothrin if required. The pest damage rate varies in the mass trapping studies in the literature on different citrus species. Boulahia-Kheder et al. (2010) reported more than 30% damage with only mass trapping in a Navel orange orchard in Tunisia. However, they determined a 5% damage rate on Navel orange at harvest with 4 foliar Spinosad treatments, sanitation and female mass trapping with Moskisan + Biolure as attractant (Boulahia-Kheder et al., 2015). In Spain, Martinez-Ferrer et al. (2012) detected <2% infected fruit rate with early maturing mandarin varieties (Loretina and Marisol) by using 50 Maxitrap (Probodelt®) traps/ha baited with Ferag CC D TM (SEDQ) + chemical treatments with Malathion or Spinosad. Nevertheless, it was determined that population decreased in midseason for Clemenules, and even in the case that the number of traps was reduced by half, the population still decreased, and less than 0.5% of infected fruit rate was detected. Demirel and Akyol (2017) determined 10.91% and 8.56% rate of infected fruits in 2011-2012, respectively, in a Satsuma mandarin orchard

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_185199

in Hatay (Turkey) by using Eostrap traps (48 traps/0.7 ha and 23 traps/0.7 ha) baited with 95% Trimedlure. In their study, they also used Eostrap traps, as this study, and obtained similar results despite having a higher number of traps per hectare. Yayla and Satar (2017) determined this rate as 8.57% in 2015 and 15.03% in 2016, in which they used Lastfly Ceratitis (4 traps/ha) traps for an Okitsu wase mandarin variety in Adana (Turkey). Various mass trapping systems have been developed worldwide for the control of fruit flies. These systems target capturing males or females according to the effect of the attractant. Better results have been reported from many mass trapping studies that used female-targeted attractants (Leza et al., 2008; Navarro-Llopis et al., 2008; Médiouni-Ben Jemaa et al., 2010; Trabelsi and Boulahia-Kheder, 2011; Boulahia-Kheder et al., 2015; Vargas et al., 2018). Biolure, which contains 3 synthetic components and targets mostly females, has been determined as one of the most suitable attractant for *C. capitata* (Epsky et al., 1999). In various Mediterranean countries, significant decreases have been reported in damage for citrus fruits or different hosts in IPM programs using this attractant (Navarro-Llopis et al., 2008; Martinez-Ferrer et al., 2012). The type of attractant is highly important for capturing a high number of females. The use of trimethylamine, the most efficient attractant, with ammonium acetate and with or without putrescine gives outstanding results against the pest (Heath et al., 2004). Food attractants containing more ammonium acetate and trimethylamine are most successful for capturing insects (Navarro-Llopis et al., 2008; Başpınar et al., 2011). Katsoyannos et al. (1999 a,b) determined that traps using 3-component synthetic lures are more specific for *C. capitata* than other female-targeted traps, and attract less non-target insects than 2-component lures and hydrolysed proteins. Broughton and De Lima (2002) reported a significant decrease in pest population and the number of infected fruits in their study in Western Australia using Biolure as an attractant compared to bait application using Spinosad. Furthermore, a higher number of females was captured by using Biolure, independent of trap type, climate, host plant or pest population. Miranda et al. (2001) stated that synthetic food lures (putrescine, ammonium acetate, and trimethylamine) were highly efficient on both high and low populations in their mass trapping study that targeted capturing *C. capitata* females in Spain. Mass trapping has been reported as an increasing controlling method in Turkey and worldwide against *C. capitata* in larger sized orchards (Broumas et al., 2002; McQuate et al., 2005; Demirel and Akyol, 2017; Yayla and Satar, 2017). Cohen and Yuval (2000) expressed that more successful results were obtained with increasing orchard size, and that this was due to the fact that trap systems and attractants are improved over time. In this study, as stated by researcher, regular implementation of control methods (chemical or biotechnological) in neighboring orchards, and regular collection and destruction of fallen fruits throughout the orchard contribute in reducing the pest population in the application orchard beyond any doubt. Organic farming orchards achieved the most success in *C. capitata* control due to the consumption of the fallen fruits by chickens and ducks, resulting in the destruction of pest larvae and pupae, in addition to mass trapping (80 traps/ha) (Leza et al., 2008). A more holistic and successful pest control is achieved in cases where several or all control methods consisting of biological, biotechnological, chemical and cultural practices are applied (Rachid and Ahmed, 2018). It can be suggested that the reason for the decreased pest population in some plots, as observed in this study, may be due to the decrease in the pest population posed with two years of trap application. However, it is thought that this should not be considered as a result that is always valid. Despite the regular pest control in an orchard, if there is no efficient control in neighbouring orchards, adults from these orchards will always pose a threat for the application orchard. The fact that the neighbouring

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_185199

orchards belong to the same producer, and that the producer applied control methods in these orchards contributed to the decrease in the population. The efficiency of pest control with mass trapping in wide areas has been observed better in this study.

Climate characteristics, besides food source, could influence the diversification of *C. capitata* activity, development and distribution (Cohen et al., 2008). *C. capitata* prefers hot and dry areas over wet and cold areas (Israely et al., 2005). Mersin Province which is in the Mediterranean region of Turkey has a Mediterranean climate: hot dry summer, wet mild winter. The optimum temperature for the development of this pest is between 21-26.7°C. The effect of rainfall on the medfly population has been related to a decrease in adult captures on rainy days and an increase a few days later, because flies are generally inactive during periods of moderate to heavy rainfall (Papadopoulos et al., 1996; Cohen et al., 2008). In the present study no heavy rainfall that limited the pest population occured during the study both years. Moustafa et al. (2014) mentioned that *C. capitata* population is significantly affected by some weather factors especially temperature degrees. Relative humidity plays a minor role in the build-up of the pest population (Ghanim and Moustafa, 2009; Ghanim, 2017). The average temperature in august was 27.1 and 29.9°C in 2015 and 2016, respectively. The temperature followed a decreasing trend until harvest, but until November it was over 21°C both years. The relative humidity was between 52% and 72%. Kasap and Aslan (2016) specify that the pest is active at daily average humidity of 40-80%. No heavy rainfall that limited the pest population occured during the study both years. According to Ghanim and Moustafa (2009) and Ghanim (2012, 2017), the activity of *C. capitata* is mainly correlated with the presence of fruit ripening of its host plants. It is unavoidable that global warming also will affect *C. capitata* population as other insects. *C. capitata* is likely to spread to other regions in Turkey in the near future (Kaya et al., 2017).

Conclusion

According to the results, the highest number of flies was detected in the Control plot (404 flies/trap/week) in 2015 and in Chemical Control plot (429 flies/trap/week) in 2016. Between the trials no statistical difference was found regarding the number of male flies weekly captured and number of infected fruits. The ratio of infected fruits in the IPM plot was lower than other plots (1.57% in 2015 and 0.89% in 2016) at harvest, followed by Biolure, Trimedlure and Spinosad, respectively. It was concluded that, the use of food lures to attract females, which are mainly responsible for the population growth of, was more ideal for mass trapping in the control of *C. capitata*, instead of traps using sex pheromones to attract males. IPM was the most effective control method for *C. capitata.* It is evident that the sanitation by eliminating the punctured fruits together with the bait application decreased the infected fruit number moreover the tolerance of the pest is 'zero' during export. Since citrus is an important export product for Turkey, a combination of several techniques as part of an integrated pest management approach can provide an inclusive, permanent and effective strategy, with a limited negative effect on the environment. It is unavoidable that global warming will affect *C. capitata* population. Therefore, the pest control may be necessary in winter months in the near future. Integrated control of *C. capitata*, if properly carried out, thought to be successful in minimizing the pest population. In order for the IPM programme for the pest to be successful, an organization must be established, cooperation between growers, extension agents and researchers encouraged and a national policy drawn up that supports the IPM programme for citrus.

Abstract. The article aimed to assess the net ecosystem metabolism (NEM), and photosynthesis performance of *Pocillopora acuta* coral on the reef flat and reef slope of the southeast fringing reef of Phuket, Thailand, from June 2017 to January 2018, using 30 x 45-cm benthic oxygen flux chambers and a Junior Pulse Amplitude Modulated fluorometer. The results showed the NEM at both sites was significantly higher in the dry season. The effective quantum yield of *P. acuta* on the reef slope was significantly higher than that of the reef flat in both seasons. The maximum quantum yield showed seasonal variation, which was significantly higher on the reef slope during the dry season than that in the wet season. This study demonstrated temporal and spatial variations in ecosystem metabolism and photosynthetic activity due to different physical characteristics, such as light intensity, which is the main driver of coral reef ecosystem and different biological characteristics, such as the percentage of live coral, the number of microalgae and the symbiont density. The results provide a better understanding of how *P. acuta* responds to changes in depth and season and why corals on reef slopes might be more susceptible to bleaching than corals on reef flats.
Keywords: *coral metabolisms, oxygen evolution, benthic chamber, photosynthetic capacity, zooxanthellae*

Introduction

Coral reefs are among the most productive and biologically diverse ecosystems in the world (Slavov et al., 2016), with a gross primary productivity of 1-15 g C m^{-2} day^{-1} (*ca.* 0.4-5.5 kg C m^{-2} $year^{-1}$) (Douglas, 2010). Coral reefs cover 600,000 km^2 of the earth's surface or 0.1-0.5% of the ocean surface (Crossland et al., 1991; Moberg and Folke, 1999). Coral reef ecosystems are constructed by reef-building scleractinian corals (Buddemeier et al., 2004), coralline algae and other calcifying organisms (Smith et al., 2006), providing an important habitat for many marine organisms, such as microalgae, macroalgae, molluscs, crustaceans, and vertebrates, including fish and marine mammals (Harrison and Booth, 2007). Coral reefs support a huge number of people with goods and services in the form of food production, coastal protection and tourism, and provide ecosystem services with a value of 36,794 \$ ha^{-1} yr^{-1} to 2,129,122 \$ ha^{-1} yr^{-1} (Costanza et al., 2014). Scleractinian corals are major contributors to the productivity of coral reef ecosystems (Lesser, 2011). However, many coral reefs are suffering serious decline due

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18631881

to global climate change and human activities, such as overfishing, agricultural run-off, deforestration that increases soil erosion and runoff then increases sediment load into coral reef, tourism, and industrialization (Moberg and Folke, 1999; Hughes, 2008).

Since the last century, an increase in global temperatures caused by the rising CO_2 concentration in the atmosphere has led to a 0.6˚C increase in seawater temperature (Solomon et al., 2007). Elevated sea temperatures can result in a rise in sea level due to the changing of density and volume of water and the melting of the polar ice caps. Moreover, increases in temperature also increase precipitation and evaporation, which leads to more frequent and intense storms (Emanuel, 2005). Further, reductions in pH and CO_3^{2-} ions, which are essential for calcification ($CaCO_3$ deposition), affect a range of marine organisms including scleractinian corals. Many studies have shown that ocean warming causes coral bleaching, the expulsion of symbiotic dinoflagellates (zooxanthellae) from coral tissue, and influences the health and survivorship of scleractinian corals (Jokiel et al., 2008; Randall and Szmant, 2009). Other environmental stresses include forms of marine pollution, such as nutrient enrichment and sedimentation, have also been found to reduce growth, increase mortality, and cause bleaching in coral worldwide (Alva-Basurto and Arias-González, 2014).

The aquatic light environment plays a major role in the productivity, physiology and ecology of corals (Mass et al., 2010). Light intensity decreases and light quantity (spectrum) changes with increasing depth. Zooxanthellae are capable of photoacclimation to different light regimes (Mass et al., 2010). Photoacclimation includes changes in chlorophyll pigment concentrations, chloroplast volume, the number and length of thylakoids, and the light utilization efficiency of photosynthesis and respiration (Mass et al., 2010). Exposure to high irradiance also leads to photoinhibition, a down-regulation of the photosynthetic process (Li et al., 2018) and coral bleaching (Lesser, 2011). These processes could result in changes to the productivity of corals.

There are many types of coral response to seasonal and spatial variation which include changes in pigment, photosynthesis and metabolism. Fitt et al. (2000) and Warner et al. (2002) found a similar pattern of response with season in biomass, zooxanthellae density and photosynthetic rate, which are lowest during summer and highest during winter, whereas metabolism shows the opposite trend (Kayanne et al., 2005; Falter et al., 2012). Coral at different depths has also demonstrated spatial variation with the highest variation of maximum quantum yield (F_v/F_m) found in coral at 1-2 m depth, but coral at 3-4 and 14 m had higher values (Warner et al., 2002).

Mass coral bleaching has been a major issue in Thailand for decades and some threatened areas have not yet recovered (Yeemin et al., 2013). Many studies have shown that coral bleaching, the loss of endosymbiotic dinoflagellates associated with coral, is caused by thermal and light stress leading to photoinhibition, which damages chloroplasts and photosynthetic apparatus, resulting in oxidative stress (the production and accumulation of reduced oxygen species) (Lesser, 2011; Downs et al., 2013). Coral bleaching is different from seasonal variation in zooxanthellae density, and the number of functional photosystem II (PSII) reaction centers (Lesser, 2011). It has been suggested that the frequency and intensity of bleaching increases with anthropogenic climate change. The susceptibility of corals to bleaching varies greatly among coral genera and reef areas (Pratchett et al., 2013). It has been found that symbiont density is a function of environmental conditions (e.g., nutrient pollution, irradiance), whilst the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18631881

susceptibility to bleaching increases in corals with higher symbiont densities (Cunning and Baker, 2013).

A reduction in coral growth, increased mortality, and coral bleaching can lead to the degradation and loss of biological diversity of the reefs, which can affect the structure and functions of coral reef ecosystems. Therefore, it is important to identify which reef areas and coral species are most resilient to the effects of global climate change and other disturbances in order to support coral reef management (Cunning and Baker, 2013). Mass coral bleaching has been a major issue in Phuket but the ecophysiology of corals and zooxanthellae from this area has not often been investigated (Yeemin et al., 2013). The measurement of photosynthesis and ecosystem metabolism of coral is essential to understanding these threatened species. Understanding the ecophysiology of corals and zooxanthellae under different environmental conditions is important for predicting the potential for, severity, and consequences of coral bleaching.

The aim of this study was to investigate seasonal variation (wet and dry) in ecosystem metabolism and photosynthesis of corals at two depths. This study will provide a better understanding of how coral species respond to changes in depth and season and which corals are more susceptible to bleaching.

Materials and methods

Study site

Phuket Island is located in the southern part of Thailand, on the Andaman Sea coast. The island is partly fringed by reefs with a total area of about 6 square kilometers of reef. The study site is located on the southeastern tip of Phuket Island (*Fig. 1*) (Panwa Cape: 7°48'06.9"N, 98°24'24.4"E). The reef is characterized by extensive reef flats that extend up to 200 m from shore (Brown et al., 2002) with a depth that increases at the reef edge (5 m).

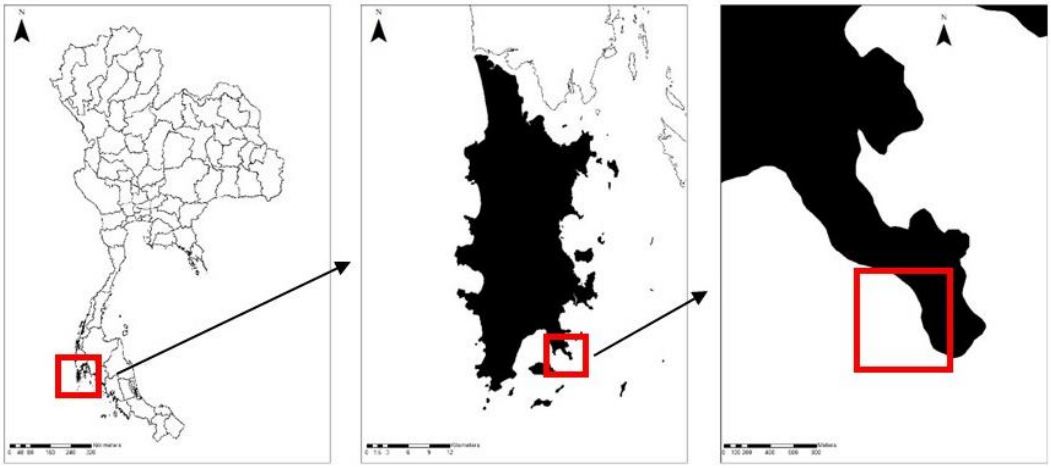

Figure 1. *Panwa Cape, Phuket Province, Thailand*

In this study, three photographic transects (Jokiel et al., 2015) were placed next to each other parallel to the shoreline in two areas (reef flat and reef slope) to determine the coral percentage cover and the number and types of substrate (e.g. coral, coral

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18631881

rubble, sand, rocks, algae) at Panwa Cape, Phuket Province (*Fig. 1*) (Panwa Cape: 7°48'06.9"N, 98°24'24.4"E) in June 2017 using Coral Point Count with Excel extensions (CPCe) (Kohler and Gill, 2006). A digital camera with a wide-angle lens was used to obtain the images by positioning the camera above a 0.25 m^2 quadrat every 50 cm along the 30 m transect line without overlap. A total of 60 images per transect line were obtained covering a total of 45 m^2 per area (Jokiel et al., 2015).

The primary productivity and photosynthetic activity of *P. acuta* from two depths at the same sampling site (7°48'06.9"N, 98°24'24.4"E) were investigated from June 2017 to January 2018 using benthic oxygen flux chambers (three replicates/depth/month). The benthic oxygen flux chambers were modified from Olivé et al. (2016) and their design is described below and illustrated in *Fig. 2*. They were deployed for 3 h for incubation (Camp et al., 2015).

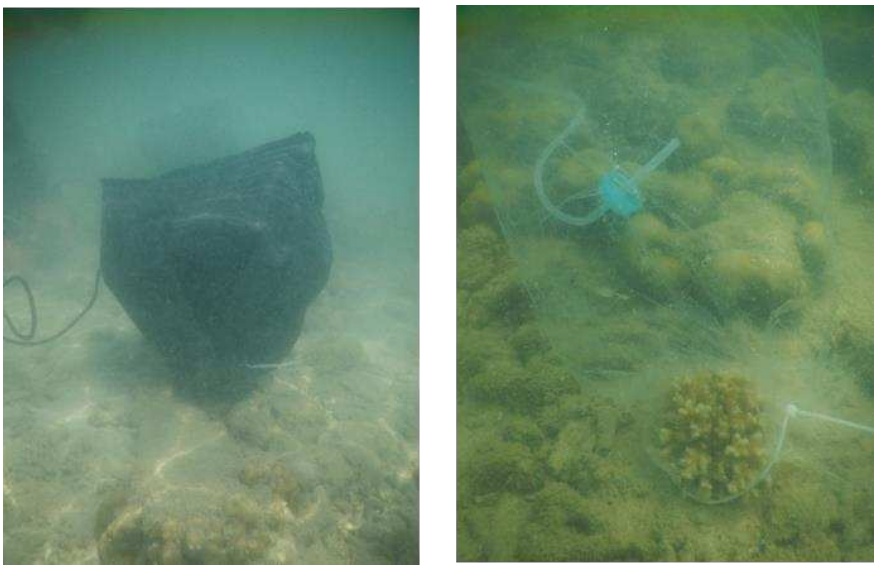

Figure 2. *Dark* (*left*) *and light* (*right*) *benthic oxygen flux chamber (n=3)*

Coral samples were collected at the same sampling site for photosynthetic measurements (four replicates/depth/time). Photosynthetic activity was investigated as chlorophyll fluorescence using a Junior Pulse Amplitude Modulated fluorometer (Junior-PAM: Walz GmbH, Effeltrich, Germany) *in situ* after which the coral samples were frozen and transported to the laboratory for analysis of their zooxanthellae density and pigment contents to support the photosynthesis data.

Physical and chemical parameters (e.g. light intensity, temperature, pH, dissolved oxygen, salinity) from two depths from each time of sampling were determined using a YSI Pro Plus multiparameter meter (YSI Inc. / Xylem Inc, USA) and a Hobo data logger (OneTemp Pty Ltd, Australia).

Productivity

The productivity of *P. acuta* was investigated by determining the dissolved oxygen evolution in benthic chambers over time under light (transparent chamber) and dark (non-transparent chamber) conditions to determine the ecosystem respiration (Re), gross ecosystem metabolism (GEM) and net ecosystem metabolism (NEM). The benthic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18631881

oxygen flux chambers consisted of 30 x 45-cm polypropylene cylinders accommodating a 6 liter-volume of water (*Fig. 2*), which was sufficient to measure the ecosystem metabolism without hypoxia during light or anoxia during darkness within a 3 h incubation period (Camp et al., 2015). The chambers were flexible due to the nature of the plastic bags from which they were constructed and allowed the propagation of external turbulence to the interior of the chambers (Barrón and Duarte, 2009). The benthic chambers were placed above the coral colony *in situ* and secured with a valve for water collection using a syringe to measure the dissolved oxygen concentration hourly. The GEM, NEM and Re were calculated using the standard equations (*Eq.1* and *Eq.2*) following Olivé et al. (2016).

$$NEM = GEM - Re \quad \text{(Eq.1)}$$

$$NEM \text{ or } Re = [(O_2)_{final} - (O_2)_{initial}]/[(T)_{final} - (T)_{initial}] \quad \text{(Eq.2)}$$

Photosynthetic efficiency

The photosynthetic activity of the coral-zooxanthellae was determined through the measurement of chlorophyll (Chl) *a* fluorescence, zooxanthellae density and the photosynthetic pigment concentration. Photosynthetic performance was determined by performing rapid light curves (RLCs) using a junior-PAM fluorometer (Walz, Germany). RLCs with nine increasing actinic light intensities were applied with 0.8 s saturating pulses (>4500 µmol photons m^{-2} s^{-1}) between each actinic light intensity, every 10 s. The effective quantum yield of PSII ($\Delta F/F_{m'}$; Schreiber, 2004), F_v/F_m, maximum relative electron transport rate ($rETR_{max}$), minimum saturating irradiance (I_k) and initial slope (α) of the RLCs were calculated using curve fitting protocols following Ralph and Gademann (2005).

Symbiont density and pigment contents

The coral samples (nubbins) were airbrushed into 10 mL of 0.2-µm-filtered seawater to remove the tissue from the skeleton. The slurry was centrifuged at 4,000 rpm for 4 min to separate the symbiont cells from the animal tissue (Hill and Ralph, 2007). The supernatant containing animal tissue was discarded, and the symbiont pellet was resuspended in 10 mL of 0.2-µm-filtered seawater, then homogenized for 10 s at 15,000 rpm and centrifuged again. The pellet was resuspended in 1 mL filtered seawater for cell counts and chlorophyll analyses. For zooxanthellae density analysis, four replicate cell counts were performed using a haemocytometer under a light microscope. The cell density was determined per cm^2 following coral surface area calculations using the paraffin wax technique (Hill and Ralph, 2007). For the photosynthetic pigment concentration (chlorophyll (Chl) *a* and c_2) analysis, the algal pellets were resuspended in 90% acetone and stored in darkness overnight at 4˚C. After centrifugation, the chlorophyll *a* and c_2 (µg cm^{-2}) were then determined using the standard spectrophotometric method of Ritchie (2006) (*Eqs.3 and 4*), with absorbance measured at 630, 664 and 750 nm (Winters et al., 2009).

$$\text{Chlorophyll } a = (-0.4574 \times A_{630\ nm}) + (11.4754 \times A_{664\ nm}) \quad \text{(Eq.3)}$$

$$\text{Chlorophyll } c_2 = (23.3900 \times A_{630\ nm}) + (-3.5322 \times A_{664\ nm}) \quad \text{(Eq.4)}$$

Water quality

Physical and chemical parameters such as temperature, salinity, dissolved oxygen and pH were measured with a YSI Pro Plus multiparameter meter (YSI Inc. / Xylem Inc, USA) in both sites (reef flat and slope) and inside the benthic oxygen flux chambers at the initial time.

Statistical analyses

Two-way ANOVA was used to test for significant differences among depths over time in chlorophyll fluorescence parameters, percentage cover, productivity (GEM, NEM, Re), zooxanthellae density and pigment contents. Tukey's Honestly Significant Difference post-hoc test was used to identify the statistically distinct groups. All tests were performed with a significance level of 95%. If the data did not meet the assumptions of normality (Kolmogorov-Smirnov test) and equal variance (Levene's test), the data was transformed using the square root or $\log_{10}$. If the transformed data did not meet the assumptions, non-parametric tests were used.

Results

Coral diversity

The results showed a total of 9 families and 17 genera on the reef flat and 12 families and 25 genera on the reef slope (*Appendix Table 1*). On the reef flat, the mean percentage cover of live corals, dead corals, sand and sponges were 43.93%, 51.64%, 4.36% and 0.06%, respectively (*Fig. 3*) and the dominant genus were *Porites* sp. (31.38%), followed by *Favites* sp. (4.80%) and *Goniastrea* sp. (3.35%) (*Fig. 4a*). On the reef slope, the mean percentage cover of live corals, dead corals, sand and sponges were 21.65%, 62.53%, 15.44% and 0.38%, respectively (*Fig. 3*) and the dominant genus were *Porites* sp. (5.05%), followed by *Acropora* sp. (2.84%) and *Goniastrea* sp. (2.49%) (*Fig. 4b*). Shannon's diversity indexes of reef flat and reef slope were 1.13 and 2.67, respectively.

The coral status of the reef flat and slope were categorized as fair (25-49.9%) and poor (0-24.9%), respectively following the standard criteria for assessing the health of coral reefs (Madduppa and Zamani, 2011).

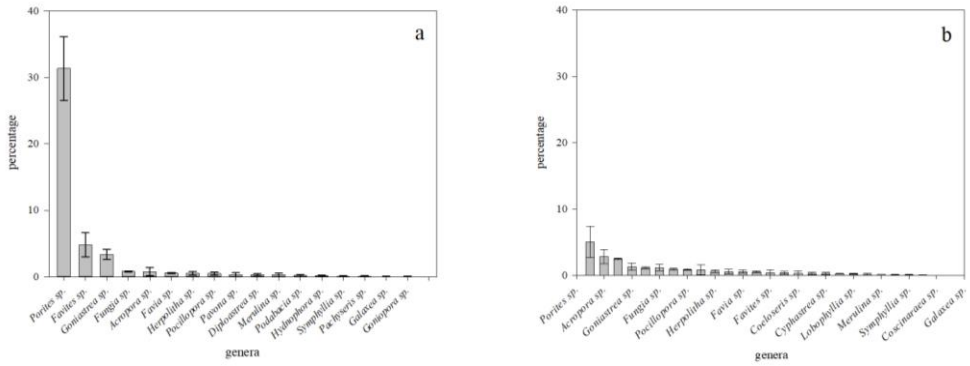

Figure 4. *Percentage cover of coral genus from reef flat* (*a*) *and reef slope* (*b*)*. Data represents Mean±SE (n=3)*

Primary productivity

The GEM on the reef slope ranged from 281.44 (±63.95) to 994.47 (±167.33) mmol O_2 m^{-2} d^{-1} and 313.93 (±45.38) to 860.62 (±268.66) mmol O_2 m^{-2} d^{-1} for the reef flat (*Fig. 5b*). The results, however were not significantly different between sites or seasons (p>0.05). The NEM on the reef slope ranged from 184.07 (±71.02) to 867.41 (±206.84) mmol O_2 m^{-2} d^{-1} and 130.32 (±18.79) to 646.69 (±239.39) mmol O_2 m^{-2} d^{-1} for reef flat. On the reef slope, the NEM was significantly higher in the dry season (p=0.01) (*Appendix Table 2*). The Re on the reef slope ranged from -60.81 (±4.73) to -97.37 (±24.50) mmol O_2 m^{-2} d^{-1} and -112.76 (±17.09) to (-204.52 (±70.85) mmol O_2 m^{-2} d^{-1} for the reef flat. The results, however were not significantly different between either sites or seasons (p>0.05).

Photosynthetic performance

The $\Delta F/F_{m'}$ on the reef slope ranged from 0.640 (±0.010) to 0.661 (±0.010) and 0.614 (±0.017) to 0.661 (±0.010) for reef flat (*Fig. 6a*). The $\Delta F/F_{m'}$ of coral on the reef slope was significantly higher than that on the flat in both seasons (p=0.002) (*Appendix Table 2*).

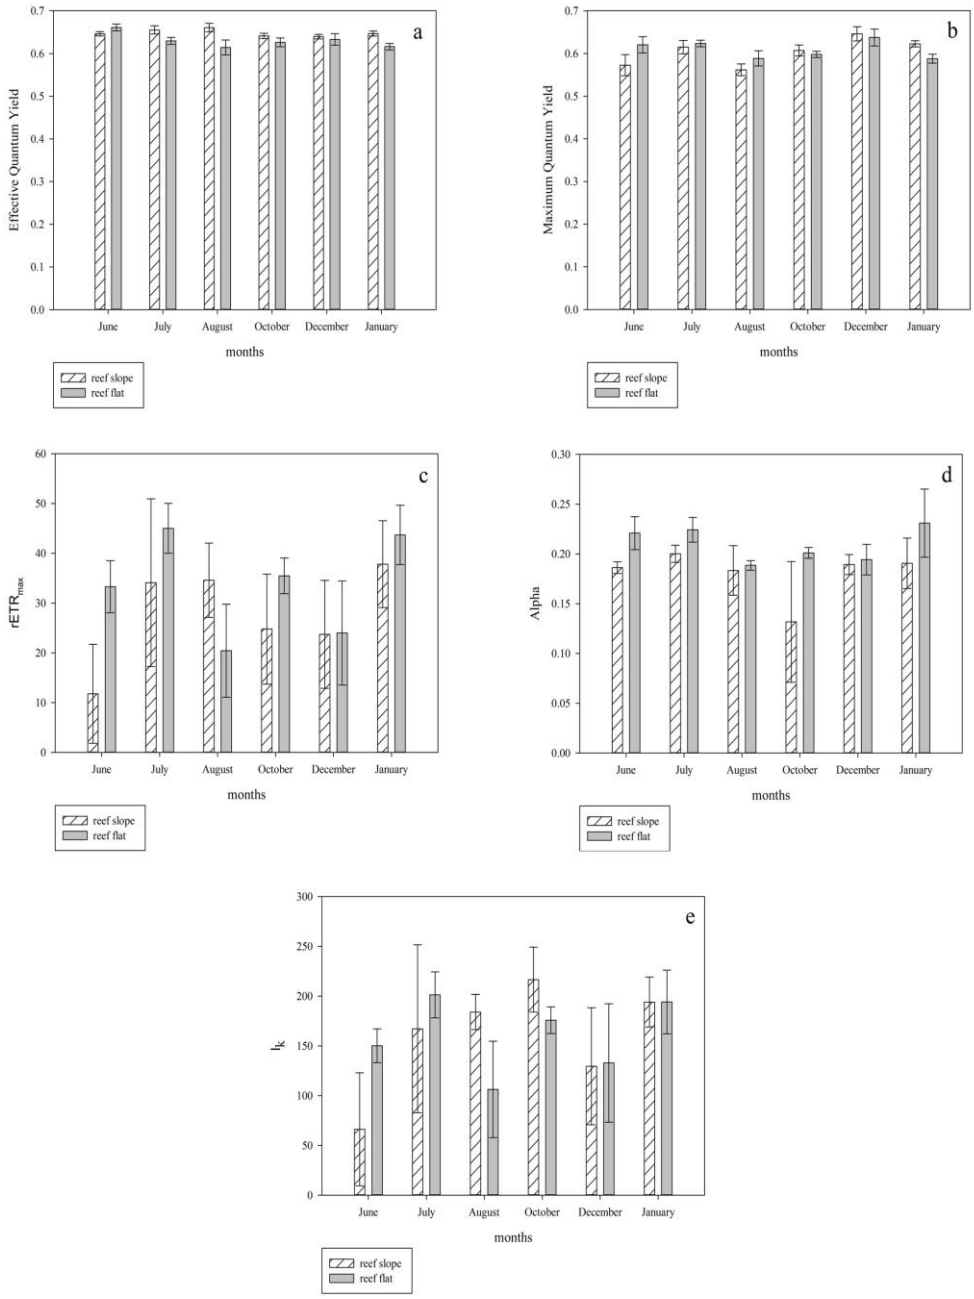

Figure 6. *Photosynthetic performance (effective quantum yield of PSII ($\Delta F/F_{m'}$) (a), Maximum quantum yield of PSII (F_v/F_m) (b)), maximum relative electron transport rate ($rETR_{max}$) (c), initial slope (α) (d)) and minimum saturating irradiance (I_k) (e) of P. acuta from reef flat and reef slope. Data represents Mean±SE (n=4)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18631881

While the F_v/F_m showed its maximum of the range at December (0.646 (±0.017) and 0.637 (±0.020)), minimum of the range at August (0.562 (±0.014) and 0.588 (±0.018)) for the reef slope and flat, respectively (*Fig. 6b*). The F_v/F_m of the corals on the reef flat was significantly lower than that for the reef slope in the dry season as well as being higher in the wet season (p=0.034) (*Appendix Table 2*).

The average $rETR_{max}$ (*Fig. 6c*) of the corals on the reef slope in both the wet and dry seasons tended to be higher than those on the reef flat but there was no significant difference between either sites or seasons (p>0.05). However, the Initial slope (α) of the corals on the reef flat was significantly higher than that on the slope (p=0.037) (*Appendix Table 2*).

The I_k ranged from 66.19 to 216.68 µmol photons m^{-2} s^{-1} for corals on the reef slope and 106.33 to 201.32 µmol photons m^{-2} s^{-1} for those on the reef flat (*Fig. 6e*). However, the results produced no significant differences between either sites or seasons (p>0.05).

Symbiont density

The cell density of corals on the reef slope and flat was in the range of 4.55 x 10^6 (±0.97 x 10^6) to 11.84 x 10^6 (±3.88 x 10^6) cells cm^{-2} and 2.96 x 10^6 (±0.83 x 10^6) to 6.84 x 10^6 (±0.69 x 10^6) cells cm^{-2}, respectively (*Fig. 7*). However, there were no significant differences between either sites or seasons (p>0.05).

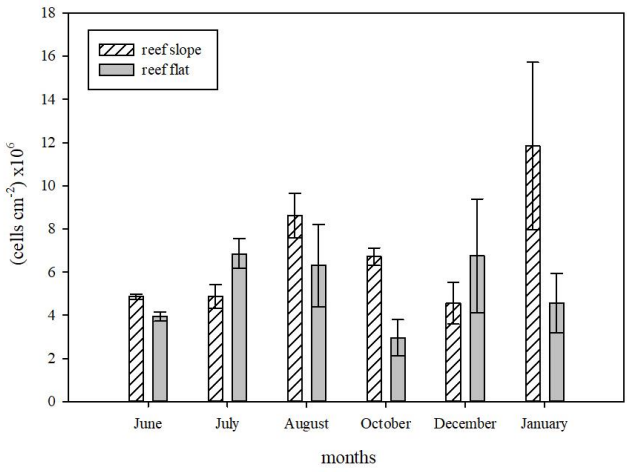

Figure 7. *Symbiont density of P. acuta from reef flat and reef slope. Data represents Mean±SE (n=4)*

Chlorophyll a and c_2

The chlorophyll *a* of *P. acuta* corals on the reef slope ranged from 0.016 (±0.005) to 0.071 (±0.013) µg mm^{-2} and on the reef flat ranged from 0.023 (±0.005) to 0.047 (±0.017) µg mm^{-2} (*Fig. 8a*). While the Chlorophyll c_2 of corals on the reef slope ranged from 0.006 (±0.002) to 0.014 (±0.002) µg mm^{-2} and on the reef flat ranged from 0.005 (±0.001) to 0.039 (±0.031) µg mm^{-2} (*Fig. 8b*). However, there were no significant differences between either sites or seasons (p>0.05).

Discussion

Coral diversity

This is the first study of the coral photosynthesis and reef ecosystem metabolism of the southeast fringing reef of Phuket Island. The results showed more percentage cover of live coral but but less coral genera on the reef flat than the reef slope, which might be due to different levels of irradiance at different depths as suggested by Hughes et al. (2015), who found that light is the main factor affecting coral growth and zonation. In the present study the light intensity on the reef flat was noted to be double that on the reef slope. Higher Shannon's diversity indexes on the reef slope (2.67) suggested that there was more coral diversity there than on the reef flat. This is due to differences in physical parameters such as the sediment accumulation rate, light availability and depth, which are limiting factors for different coral species (Kahng et al., 2019) with different levels of resilience (Putnam et al., 2017). Slow growing massive corals, such as *Porites* sp. and *Goniastrea* sp. can survive in conditions of air exposure (Meixia et al., 2008) and demonstrate more tolerance to a changing environment (van Woesik et al., 2011). In contrast, fast growing, branching species, such as *Acropora* sp. and *Pocillopora* sp. (Al-Sofyani and Floos, 2013), prefer a limited range of temperatures (Williams et al., 2017), but have a greater ability to adapt to higher sediment accumulation rates because of their ability to self-clean (Duckworth et al., 2017). Consistent with Brown et al. (1999), the results of the present study show that massive coral species dominate the reefs because they are physiologically adapted to intertidal living. Moreover, Meixia et al. (2008) showed similar results, finding that *Porites lutea* was the dominant species with zonal characteristics with more coral species occurring on the reef slope than the reef flat.

Ecosystem metabolisms

Ecosystem metabolism is a biomass indicator which reflects energy storage in coral and the health of corals in each area, as well as how corals act as a carbon sink. The factors which affect ecosystem metabolism in the ocean are the light intensity, the time of day or year, the weather (Sathyendranath and Platt, 2001), adaptation of phytoplankton, the temperature and the available nutrients. The main factor is light intensity (Hughes et al., 2015) and that is usually correlated with depth.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18631881

The NEM showed seasonal variation with higher metabolism in the dry season (*Appendix Table 2*). When the light intensity data (measured with a HOBO data logger) was compared, it was found that the reef flat had twice the light intensity of the reef slope which led to a higher rate of metabolism. The lower light intensity on the reef slope is caused by greater water depth reducing the light intensity (Kahng et al., 2019). Irradiance is important for photosynthesis of symbiotic algae living with corals and coral reefs metabolisms (Iluz and Dubinsky, 2015) and affect dissolved oxygen which is an indicator of coral reef metabolism (Camp et al., 2015). Moreover, the sediment accumulation rate on the reef slope (11.76 g m^{-2} d^{-1}) was three times higher than that on the reef flat (3.70 g m^{-2} d^{-1}). A high sediment accumulation rate can reduce the light intensity which is the main factor in zooxanthellae's photosynthesis and ecosystem metabolism (Iluz and Dubinsky, 2015). Differences in sediment accumulation rates depend on seasonal variation and weather (Browne et al., 2019). Furthermore, biological characteristics such as the percentage of live coral cover, macroalgae and cyanobacteria also affect the NEM. This study revealed that the reef flat had a greater percentage of live coral cover, macroalgae and cyanobacteria than the reef slope which led to a higher NEM.

The results of the present study were also broadly similar in respect of oxygen evolution (130.79-867.41 mmol O_2 m^{-2} d^{-1}) to those of Camp et al. (2015) who found that the ecosystem metabolic activity (P, R and G) of three coral species, *Mussismilia harttii*, *Siderastrea* cf. *stellata* and *Porites astreoides* were in the range of 43.2-158.4 mmol O_2 m^{-2} d^{-1}. Moreover, all the ratios of GEM to Re were higher than 1 indicating that this ecosystem is autotrophic and that *P. acuta* is an important species in high productivity coral reef ecosystems.

Photosynthesis efficiency

Seasonal or spatial variation in photosynthesis and the photosynthetic capacity of corals have been observed in previous studies (Levy et al., 2004; Kuffner, 2005; Ulstrup et al., 2011; Sawall et al., 2014). These variations occur due to changes in environmental factors such as light intensity (Iluz and Dubinsky, 2015), temperature (Levy et al., 2004; Caroselli et al., 2015), salinity (Sandoval-Gil et al., 2012), sediment accumulation rate (Rogers, 1990), water velocity (Lesser et al., 1994) and other chemical factors (Redfield, 1958).

Browne et al. (2015) estimated the coral health of four common inshore reef corals in response to seasonal and anthropogenic changes in water quality, and found that temperature has the greatest influence on branching coral (*P. damicornis*). Moreover, higher sedimentation rate and nutrient availability in the rainy season might affect coral health and physiology (Brown et al., 1999).

The $\Delta F/F_{m'}$ of *P. acuta* in this study showed spatial variation in both seasons suggesting that coral on the reef slope has higher photosynthesis efficiency than that of the reef flat since there is higher light intensity on the reef flat (*ca.* 600 µmol photons m^{-2} s^{-1}) and this value exceeded the I_k (*Fig. 6e*) at the same site leading to photoinhibition in the reef-flat coral. While the light intensity on the reef slope (*ca.* 300 µmol photons m^{-2} s^{-1}) was lower it was closer to the I_k than the light intensity on the reef flat, which means that although photoinhibition still occurs, it is of less effect. Therefore, the photosynthesis of symbionts on the reef slope is more efficient. Further, when comparing between seasons, the results showed higher photosynthesis efficiency for the coral on the reef slope in the wet season since the $\Delta F/F_{m'}$ and I_k values were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18631881

closer in the same season at each site. Moreover, diel variation of photosynthesis, which is down-regulated by intense light in the afternoon (Hill and Ralph, 2005) also reduced the $\Delta F/F_{m'}$ in this study.

On the other hand, no significant difference of $\Delta F/F_{m'}$ was noted on coral on the reef flat in different seasons since the shallow water condition meant that only highly tolerant corals can survive. This finding is consistent with that relating to F_v/F_m, which showed the same pattern. F_v/F_m representing the photosynthetic capacity of zooxanthellae and indicating coral stresses. When compared between seasons, the coral on the reef flat showed no significant differences in respect of F_v/F_m. On the other hand, the coral on the reef slope showed high variation between seasons with the F_v/F_m lower than that on the reef flat in the wet season but higher in the dry season. This might be due to the higher accumulation of sediment in the wet season. Sediment reduces the light available to coral and increases coral stress which is reflected in the F_v/F_m (Zhao and Yu, 2014). A Similar trend were was found for the symbiont density and pigment content but these indices are not as sensitive as the F_v/F_m.

The initial slope (α) showed some spatial variation with the reef-flat coral α being greater in both seasons. The results showed that the reef-flat coral had a greater ability to harvest light and a higher photosynthetic ability, and these adaptations led to the reef-flat corals higher photosynthesis efficiency. On the other hand, comparisons of symbiont density and pigment content did not show any significant differences between sites although the α values were different, indicating that the reef-slope corals were exposed to an unsuitable environment which did not allow them to adapt and led to photosynthetic stress.

The I_k is one of the main factors which can reveal the adaptation of coral (Zhao and Yu, 2014). The present study found no significant difference in I_k due to the high sediment accumulation rate on the reef slope (76.11 g m^{-2} d^{-1}) (*Appendix Table 3*) which was three times as great as that on the reef flat (70.3 g m^{-2} d^{-1}) (*Appendix Table 4*) and led to the corals being stressed. Sediment was one of many factors which reduced the photosynthesis efficiently of the reef-slope corals, while the lower sediment accumulation on the reef flat was more suitable and allowed the corals to adapt. The reef-flat corals with better α adaptation were able to reduce their pigments and zooxanthellae cells whereas the reef-slope corals did not do so and this resulted in the finding of no significant differences between either sites or seasons in the I_k and $rETR_{max}$ indices.

The effect of sediment on zooxanthellae photosynthesis was demonstrated in Philipp and Fabricius (2003) who showed that the $\Delta F/F_{m'}$ and F_v/F_m respond to sediment (79-234 mg cm^{-2}) and exposure time (0–36 hr) by being reduced. In addition, the photosynthesis and adaptation of zooxanthellae are affected by depth. Mass et al. (2007) revealed that the adaptation of *Stylophora pistillata* through a depth range of 5-65 m produced a lower Re, P_{max}, I_c and I_k as the depth increased. On the other hand, the α increased with depth.

There is a limitation in using the Junior PAM (Walz GmbH, Effeltrich, Germany) since it is not a submersible device. Therefore, photosynthetic measurements that are not derived *in situ* might be in error, and this would affect the $\Delta F/F_{m'}$ representing the sensitivity to light intensity flux. Including dark adapted measurements before fitting the RLCs which might lead to the opening of all the reaction centers which would affect the I_k and $rETR_{max}$ values, which in this study showed no significant differences between either sites or seasons.

Symbionts density and chlorophyll concentration

The photosynthesis data, zooxanthellae cell density and chlorophyll concentration in the coral tissues were measured and the results produced no significant differences between either sites or seasons. This might be due to photo-acclimation of the zooxanthellae on the reef flat by reducing the numbers of cells and pigment (Cooper and Ulstrup, 2009) while the zooxanthellae on the reef slope did not, which might be due to the predominance of the *Symbiodinium* genotype (Hennige et al., 2009).

Cooper and Ulstrup (2009), who estimated the spatial variation in the photophysiology of the zooxanthellae of *P. damicornis*, found that photoacclimation occurred in both shallow and deep corals but via different mechanisms. Thus, to deal with changes in irradiance, changes in symbionts such as the size and the location of their zooxanthellae, the zooxanthellae density and the chlorophyll contents might have occurred (Zhao and Yu, 2014). In addition, Frade et al. (2007) found a correlation between the *Symbiobinium* genotype (clade) in the coral genus *Madracis* and the water depth, with clade B7 being a generalist while clades B13 and B15 were restricted to shallow and deepwater reef environments, respectively. There have also been found to be differences in terms of the photoacclimation response for each genotype (Hennige et al., 2009). Meanwhile, Philipp and Fabricius (2003) found that the cell density and pigment concentration of zooxanthellae per coral surface area decreased with increased amounts of sediment but the decrease was not as fast as those noted in the $\Delta F/F_{m'}$ and F_v/F_m.

The optimal zooxanthellae densities found in the present study were lower than those found by Wooldridge (2016; 1-3 (x 10^6) cells cm^{-2}) and this might be due to the study site being a marine attraction. Human activities, urban run off or wastewater could lead to high nutrient concentrations in the water, which can lead to an increase in cell density, pigment and maximum gross photosynthesis (Marubini and Davies, 1996). However, the $rETR_{max}$, I_k, symbiont density and pigment showed no significant differences between sites or between seasons and this might be due to the better adaptation of reef-flat coral demonstrated by the reduced number of cells and pigment (Cooper and Ulstrup, 2009). Nevertheless, the environment on the reef slope was not suitable to adaptation by corals.

The lack of any correlation between ecosystem metabolism and zooxanthellae photosynthesis might be due to the assessment of ecosystem metabolism representing all living things in the chamber that including coral, algae and plankton, whereas photosynthesis was assessed based only on zooxanthellae.

Chambers

The design of the benthic chambers by which oxygen flux was measured described above in *Materials and Methods* entailed the limitation that its chamber shape was more suited to be deployed to collect data from branching or sub-massive coral or from coral where the colony size was smaller than the chamber. On the other hand, the design of the chamber was cost effective. Camp et al. (2015) used a flexible chamber to measure the ecosystem metabolic activity (P, R and G) of three coral species, *Mussismilia harttii*, *Siderastrea* cf. *stellata* and *Porites astreoides*. The results of that study produced values which were broadly similar to those produced by the present study. Further, Olivé et al. (2016) estimated the ecosystem metabolism using chambers in a seagrass meadow and the results were also broadly in-line with those from the present study.

Conclusion

An assessment of GEM, NEM and Re was conducted in a tropical coral reef at the Southeast tip of Phuket Island, Thailand between June 2017 and January 2018. The findings of this study suggest that coral diversity is a result of a combination of light intensity, sediment accumulation, depth, other physical and chemical factors and ecosystem metabolism is mainly driven by the number of organisms, the light availability and depth.

Due to limitations of this chamber design, benthic oxygen flux chamber can estimate only in ecosystem scale and be deployed only on branching corals. The design of the chamber should be improved for measuring on various kinds of colony shape (e.g. plate, massive and branching). Real-time data collection on dissolved oxygen, irradiance and temperature inside the chamber could be developed.

This study provides a better understanding of how corals from different habitats respond to changes in season and are more susceptible to bleaching. The data from this study can be used for marine and coastal management and conservation.

CO-APPLICATION OF HUMIC ACID AND *BACILLUS* STRAINS ENHANCES SEED AND OIL YIELDS BY MEDIATING NUTRIENT ACQUISITION OF SAFFLOWER (*CARTHAMUS TINCTORIUS* L.) PLANTS IN A SEMI-ARID REGION

EKIN, Z.

Faculty of Agriculture, Department of Field Crops, Van Yuzuncu Yil University, Van, Turkey (e-mail: zehraekin@yyu.edu.tr; phone: +90-432-225-1056; fax: +90-432-225-1104)

(Received 16th Nov 2019; accepted 30th Jan 2020)

Abstract. Faced with the deterioration of natural resources, current trends in agriculture are focused on seeking eco-friendly methods to improve plant growth promotion and crop productivity. Plant growth promoting rhizobacteria (PGPR) and humic substances can improve crop production in sustainable farming due to their various features. This study examined how humic acid (HA) and inoculation with PGPR (*Bacillus megatorium* and *Bacillus subtilis*) affect the agronomic performance of safflower (*Carthamus tinctorius* L.*)* in a semi-arid environment. In the field experiments, PGPR inoculated and non-inoculated safflower seeds were cultivated in soil treated with humic acid (0, 200, 300, and 400 kg ha^{-1}), alone or in combination. It was observed that PGPR and HA improved growth, yield parameters and seed mineral contents. Their plant growth responded positively to inoculation with *Bacillus* sp. strains owing to the N-fixing and P-solubilizing capabilities, whereas greatly positive response in the seed yield and quality was found when applied in combination with humic acids. The combined application of 300 and 400 kg ha^{-1} HA with *Bacillus subtilis* inoculation enhanced seed and oil yields by an average of 162% and 221% relative to the control plants. This study confirms that integrated management strategies can ensure higher crop productivity of safflower in sustainable and semi-arid environments.
Keywords: *energy crop, humic substances, plant growth promoting rhizobacteria, seed yield, sustainable agriculture*

Introduction

Safflower *(Carthamus tinctorius* L.) is an annual oilseed and energy crop belonging to the *Asteraceae* family. The crop was once grown for colorful petals used in food coloring, fabric dyes, flavoring agent and medicinal use (Ekin, 2005). Nowadays, scientific interest in this species is mainly due to its high quality vegetable oil for nutritional and industrial applications. However, safflower has gained importance in recent years as a result of its vegetable oil for human consumption and biodiesel production in arid and semi-arid regions in the world. Safflower is also one of the most adapted oilseed crops to dryland cropping systems with good drought tolerance due to its deep taproot, but it's sensitive to dry soil condition in which kernel filling (flowering) are affected by water stress conditions (Dajue and Mündel, 2006).

To improve the plant productivity, it is of paramount importance to supply adequate water and nutrient acquisition in semi-arid regions typically characterized by variable and unpredictable rainfall, large diurnal ranges in temperature, frequent strong winds and poor moisture storing capacity of soils (Chavoushi et al., 2019). Moreover, this is crucial to producers in semi-arid regions of world and Turkey, including eastern Anatolia, south eastern Anatolia and central Anatolia. In particular, water resources need to be used efficiently because of the anticipated water scarcity in the face of global warming and the increasing competition between domestic, industrial, and agricultural water consumptions. Therefore, it is imperative to improve the drought tolerance of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18831900

crops as well as its salt tolerance, heavy metal stress tolerance and disease resistance, and to protect soil health and fertility under the changing circumstances. Currently, there are no economically viable technological means to facilitate crop production under various stress conditions. Towards a sustainable agricultural vision, the uses of plant growth promoting rhizobacteria and humic acid might also be a promising alternative eco-friendly approach, which helps in protecting the soil health, increasing the nutrient uptake capacity and water use efficiency and decreasing the effects of drought, salinity and heavy metal pollution etc.

Plant growth promoting rhizobacteria (PGPR) are bacteria colonizing rhizospheres of plant that, unlike fertilizers and pesticides, depend on various mechanisms like nitrogen fixation, solubilization of phosphate, production of different phytohormones like indole-3-acetic acid, gibberellic acid and cytokines for its success in promoting crop yield (Calvo et al., 2014). In this sense, plant growth promoting rhizobacteria can be used to enhance plant health and promote plant growth rate without environmental contamination. For decades, varieties of PGPR including the species *Pseudomonas, Bacillus, Enterobacter, Klebsiella, Azotobacter, Variovorax Azosprillum*, and *Serratia* have been well studied in various field crops as rhizosphere-colonizing microorganisms (Glick, 2012), such as wheat (Rosas et al., 2009; Hungria et al., 2010; Rana et al., 2012), sugar beet and barley (Cakmakci et al., 2001, 2006), sugarcane (Silva et al., 2017), sunflower (Shadid et al., 2012), rice (Lucas et al., 2009), bean (Hoyos-Carvajal et al., 2009), canola (El-Howeity and Asfour, 2012), maize (Thonar et al., 2017) and soybean (Cassán et al., 2009). However, only limited data are reported in the beneficial effects of PGPR on safflower growth promotion. The literature on PGPR regarding safflower included mostly *Pseudomonas*, *Azosprillum* and *Azotobacter* spp. inoculation which were used to improve nitrogen uptake (Mirzakhani et al., 2009; Soleymanifard and Sidat, 2011; Sharifi et al., 2017; Nosheen et al., 2018), root morphology (Nosheen et al., 2011) and protein quantity and quality of safflower seeds (Nosheen et al., 2016). The various studies also reported that inoculation of specific PGPR species like N_2-fixing *Bacillus subtilis* and phosphorus solubilizing *Bacillus megatorium* instead of synthetic chemicals may serve as an effective alternative and environmental friendly practice since they improve plant nutrition by increasing N and P uptake by plants (Cakmakci et al., 2001; Esitken et al., 2003). But, up till now no data are available with respect to the use of this genus in safflower plants.

Similarly, humic acid (HA) are naturally-available substance in the soil that are end products of microbial decomposition and chemical degradation of dead biota. Humic substances can promote plant growth through improvement in root architecture and morphology, enhancement of nutrient availability, uptake and translocation, promotion of plant physiology and development due to their hormone-like activities and promotion of soil biological activity (Puglisi et al., 2013; Canellas and Olivares, 2014; Ahmad et al., 2016). In the various experiments, direct effects of humic acid on plant growth were well described in cultivation of various crops, such as potato (Suh et al., 2014), tomato (Olivares et al., 2015), maize (Canellas et al., 2013), Hungarian vetch (Esringu et al., 2016) and blueberry (Schoebitz et al., 2016). However, basic mechanisms and benefits of the combined application of humic substances and plant growth promoting rhizobacteria have been recently demonstrated for several plant species grown under field conditions and have been attributed to an increase in the adaptation of seedlings to stress conditions, which result to cause an increase in the macro- and micro nutrient uptakes and root growth (Nardi et al., 2009; Dobbss et al., 2010; Busato et al., 2012;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18831900

Puglisi et al., 2013; Canellas and Olivares, 2014). Olivares et al. (2015) observed that co-application of humates isolated from vermicompost with diazotrophic endophytic *Herbaspirillum seropedicae* inoculation can increase significantly nitrate uptake, nitrate reductase activity, fruit biomass, leading to to increased tomato yield. The researchs previously reported that humic substances have potential as enhancer of plant growth promoting bacteria inoculation benefits (Canellas et al., 2013; Esringu et al., 2016; Schoebitz et al., 2016; Silva et al., 2017).

Keeping in view the characteristics of plant growth promoting rhizobacteria and humic acid as a helping way for crop plants to be grown in arid and semi-arid areas we hypothesized that they can enhance the agronomic performance of safflower through the activation of natural processes like nutrient release and uptake by various mechanisms described above. Extensive root system created by improved root growth and architecture by plant growth promoting rhizobacteria and humic acid can also enhance the seed quality by increasing the uptake of nutrients by exploring more and more soil volume. Stimulation of biological activity by humic acid can further enhance nutrient cycling through the action of microorganisms. In this regard, to evaluate the potential of plant growth promoting rhizobacteria and humic acid for agronomic performance of safflower we planned 2 years field experiment in a semi-arid environment. In this experiments we used *Bacillus megatorium* M3 (P-solubilizing), *Bacillus subtilis* OSU-142 (N_2-fixing) and humic acid (obtained from leonardite).

Materials and Methods

Study Site

Field experiments were carried out under rainfed conditions at a research farm located in Ahlat district (38° 46'N and 42°30'E with an altitude of 1722 m) in Eastern Anatolia region, Turkey during 2010 and 2011 (*Fig. 1*). The climate at this location is classified as continental with a total long-term average (1958-2017) precipitation of 562.6 mm mainly in winter. Annual mean air temperature is 9.3°C, with an average temperature of -2.5°C in January and 21.9°C in July. Annual mean relative humidity is 63.8%. The study site climate variables were collected from weather station and averaged for each month (*Table 1*). In 2010 and 2011, total precipitation during the crop season (from April to August) was 291.0 mm, and 269.4 mm, respectively, and the long-term average for the same period was 136.2 mm (*Table 1*). The mean air temperature was 16.5°C, 16.0°C in 2010, 2011, respectively, and long-term average was 16.1°C.

Table 1. *Climate data: Monthly means of climate variables for the crop seasons of 2010, 2011 and long-term average (LTA: 1958-2017) in Ahlat, Turkey*

Figure 1. *Map of study site*

Prior to the experiments, soil samples were collected in the experiment site and analyzed for their physical and chemical properties using the methods described in Soil and Plant Analysis Laboratory Manual by Ryan et al. (2012). Soil samples were collected in the top 30 cm (<2 mm fraction) of soil at different locations of the experiment site. The experiment site soil was silt-clay-loam with a pH of 7.41, total nitrogen content of 0.15 g kg^{-1}, organic matter content of 1.60%, $CaCO_3$ content of 6.8%, electrical conductivity of 1.16 dS m^{-1}, available phosphorus content of 7.95 mg kg^{-1}, available potassium content of 196 mg kg^{-1}, available manganese content of 3.30 mg kg^{-1}, zinc content of 1.44 mg kg^{-1}, iron content of 5.85 mg kg^{-1} and copper content of 0.59 mg kg^{-1}.

Plant Material and Experimental Design

Safflower (*Carthamus tinctorius* L.) var. Dincer, Turkey of origin, which exhibits early maturity, spineless, open-pollinated, yellow-orange flower color, white seed color,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18831900

28-32% oil content and high-linoleic oil type, was used as plant material. The field trials were set up a factorial design including the two following factors: four HA doses (0= without the addition of HA, 20= 200 kg ha^{-1} HA, 30= 300 kg ha^{-1} HA and 40= 400 kg ha^{-1} HA) and three PGPR applications (B0= no bacterial inoculation, B1: *Bacillus subtilis* OSU-142 and B2: *Bacillus megatorium* M3) with three replications.

Humic Acid Characteristics, PGPR Culture Condition and Seed Inoculation

Agro-Lig, a commercial product, was produced through crude humic acids derived from leonardite and provided by Altintar Chemicals Company (Turkey). Agro-Lig contains total humic acid 85%, total organic matter 75%, pH 3.5-5.5, max moisture 22%, silicon 0.5%, iron 0.5%, magnesium 0.5%, calcium 3.0%, sodium 0.3%, manganese 0.02%, copper 0.0003%, potassium 0.07%, titanium 0.02%, barium 0.03%, boron 0.01%, cobalt 0.0002% dry matter basis. Three HA doses (200, 300 and 400 kg ha^{-1}) were prepared by Agro-Lig in granule form.

The two plant growth promoting rhizobacteria strains (*Bacillus subtilis* strain OSU-142 and *Bacillus megatorium* strain M3) tested were kindly procured at Atatürk University, Department of Plant Protection, Turkey. Currently, these strains are protected in culture collection unit in the Department of Genetic and Bioengineering, Faculty of Engineering at Yeditepe University, İstanbul, Turkey. The choice of these two bacteria is based on their published ability to act as potential biostimulants and biofertilizers. The gram-positive *Bacillus megatorium* M3 has demonstrated abilities to increase the solubilization of inorganic phosphates and to promote plant growth in various plant species (Cakmakci et al., 2001; Orhan et al., 2006). The gram-positive *Bacillus subtilis* OSU-142 is an efficient root colonizer and has been shown to N_2-fixing under field conditions (Cakmakci et al., 2001, 2006). Moreover, it has widely shown the potential to improve plant growth and nitrogen acquisition when inoculated to various plant species (Cakmakci et al., 2001, 2006; Esitken et al., 2003; Orhan et al., 2006; Elkoca et al., 2010; Acikgoz et al., 2016; Ekin, 2019). These strains are indigenous, and are kept in nutrient broth (NB) with 15% glycerol at −80°C for long-term storage, and grown on nutrient agar (NA) for routine use. Single colonies were transferred to 500 ml flasks that contained NB and incubated aerobically on a rotating shaker (150 rpm) overnight at 28°C (Cakmakci et al., 2001, 2006). The bacterial suspension was then diluted in sterilized water to final concentration at cell densities of 10^9 colony forming units (CFU) ml^{-1}. Seeds were surface sterilized prior to bacterial inoculation with 95% ethanol then sterilized with 10% chlorox for 3 min and washed successively 3–4 times with distilled water. Seeds were inoculated with the liquid cultures of rhizobacteria (*Bacillus megatorium* M3 and *Bacillus subtilis* OSU-142*)* mixed with 10% sugar solution for 30 min, and were stored overnight to dry under room temperature.

Crop Husbandry and Data Recording

The tillage system was fall plow and spring cultivate. Different doses of humic acid (granule form) were applied to the soil in humic acid treated plots, according to the layout. Humic acid was applied once during planting and then mixed well with the soil. PGPR inoculated and non-inoculated seeds were sown in early April in each year. In the present study, plots were 1.5 m wide and 5 m long and consisted of five rows spaced 0.3 m apart. Plot stands were over sown and hand-thinned approximately at the first four-true leaf stage to 10 cm apart within a row. Throughout the growth season, the production system was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18831900

managed based on management practices recommended for the region, which included weed control by hand as required. The safflower plants were manually harvested at the stage of physiological maturity, when most of the leaves turn a brown color and very little green remains on the bracts of the latest flowering heads in late August in each year. Data collecting on the plant height (cm), stem diameter (mm), number of branches per plant, number of capitula per plant, number of seeds per capitulum and capitilum diameter (cm) were recorded for ten randomly selected safflower plants in the central three rows of each plot. The seed yield was expressed in t ha^{-1}. The seed oil and total nitrogen contents were determined by Soxhlet extraction and Kjeldahl methods. Then, total N content was also used for the calculation of the seed protein concentration by multiplication with a conversion factor of 6.25 (Ryan et al., 2012). For mineral content analysis (P, K, Ca, Mg, Fe, Zn, Cu, Mn), safflower seed was ground in a Wiley Mill to pass through an 840-µm screen and wet-digested in HNO_3:$HClO_4$ (6:2 v/v) with the Advanced Microwave Digestion System, Ethos Easy, then analyzed with the Inductively Coupled Plasma Optical Emission Spectrometry (iCAP 6000 SERIES, ICP Spectrometer).

Data Analysis

The data were tested for homogeneity and normality of residuals using the Kolmogorov–Smirnov and Bartlett tests, respectively. Afterwards, a combined analysis of variance (ANOVA) was used to compare the effects of humic acid doses and bacterial treatments by field experiment interactions for 2 years using PROC GLM of SAS 9. Mean comparisons were conducted using Fisher's least significant difference ($LSD_{0.05}$) test.

Results

Morphological and Yield Parameters

The results regarding morphological and yield parameters of safflower in relation to humic acid dose and plant growth promoting rhizobacteria inoculation are presented in *Table 2*. Highly significant increases were observed in safflower growth and yield parameters after inoculation with PGPR (*Bacillus* strains), and further improved after combined application with humic acid doses. When compared to plant growth promoting rhizobacteria treatments both with and without humic acids, it was observed that inoculation with *Bacillus subtilis* OSU-142 (B_1) was more effective when compared to *Bacillus megatorium* M3 (B_2). Furthermore, a significant interaction between the tested factors was observed in the case of stem diameter, number of branches and capitula per plant, number of seeds per capitilum, capitilum diameter and 1000 seed weight, whereas plant height was highly influenced by humic acid dose and plant growth promoting rhizobacteria inoculation with no significant HA x PGPR interaction (*Table 2, Fig. 2*). The tallest plant height values were recorded in both *Bacillus subtilis* OSU-142 inoculation and 400 kg ha^{-1} HA dose, while the highest numbers of capitula per plant and seeds per capitulum, largest capitilum diameter and 1000 seed weight values were recorded in co-application of *Bacillus subtilis* OSU-142 with 300 and 400 kg ha^{-1} HA doses (HA_{30}+B_1 and HA_{40}+B_1). Likewise, the application of 400 kg ha^{-1} HA dose significantly increased numbers of branch per plant and seeds per capitulum at both B_1 and B_2 inoculation by 81.3% and 90.6% in branch numbers and 85.5% and 83.6% in seed numbers increases when compared to the untreated control plants, respectively (*Table 2, Fig. 2*).

[1]20, 30 and 40 treatments refer to safflower plants growing under field condition with 200, 300 and 400 kg ha^{-1} of HA; B_0 treatment without any application of the bacteria, B_1 treatment with *Bacillus subtilis* OSU-142 inoculation; B_1+20, B_1+30, and B_1+40 with *Bacillus subtilis* OSU-142 and 200, 300 and 400 kg ha^{-1} of HA, respectively; B_2 treatment with *Bacillus megatorium* M3 inoculation; B_2+20, B_2+30, and B_2+40 with *Bacillus megatorium* M3 and 200, 300 and 400 kg ha^{-1} of HA, respectively. Means followed by different letters are different by LSD test. *: $P < 0.05$, **: $P<0.01$, ns: not significant; CV: coefficient of variations

Seed Yield and Quality Parameters

Seed, oil and protein yields and certain quality parameters of safflower were significantly affected by plant growth promoting rhizobacteria and humic acid treatments based on the two-year average data (*Table 3*). For most of the measured quality parameters, no significant interaction between plant growth promoting rhizobacteria and humic acid application was recorded, except for the seed yield and fertile and sterile seed ratio (*Table 3, Fig. 3*).

DOI: http://dx.doi.org/10.15666/aeer/1801_18831900

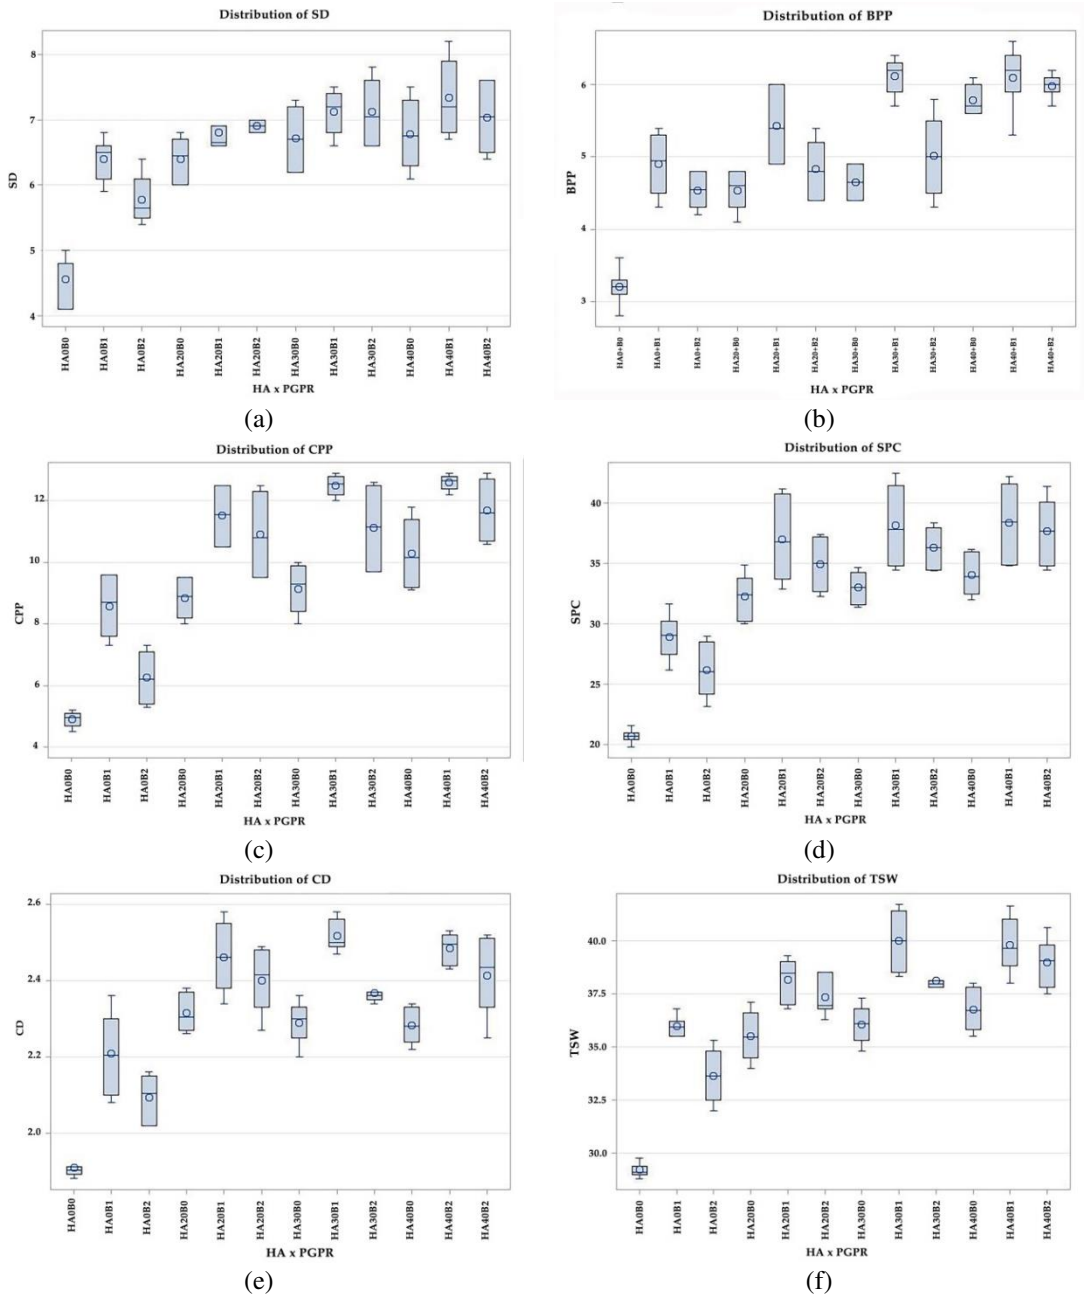

Figure 2. *Stem diameter (mm) (**a**), number of branch per plant (**b**), number of capitula per plant (**c**), number of seeds per capitilum (**d**), capitilum diameter (cm) (**e**) and thousand seed weight (g) (**f**) of safflower affected by bacterial inoculation and humic acid. B_0: without bacteria; B_1: B. subtilis OSU-142; B_1+20, B_1+30, and B_1+40: B. subtilis OSU-142 with 200, 300 and 400 kg ha^{-1} of HA, respectively; B_2: B. megatorium M3; B_2+20, B_2+30 and B_2+40: B. megatorium M3 with 200, 300 and 400 kg ha^{-1} of HA, respectively*

Fertile and sterile seed percentages, the most important quality characteristics for safflower, were significantly affected by both plant growth promoting rhizobacteria and humic acid treatments; however, its co-application significantly reduced sterile seed percentage, whereas an opposite trend was observed for the fertile seed percentage (*Table 3*). The highest fertile seed and lowest sterile seed percentages were recorded in co-application of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

both PGPR strains with 300 kg ha^{-1} humic acid dose (HA_{30}+B_1 and HA_{30}+B_2), whose values were higher by 9.0 and 8.6% and lower by 85.1% and 79.9%, respectively, compared to the untreated control. In the present study, a significant interaction between the tested factors was also observed for the seed yield (*Table 3*). Inoculation with *Bacillus subtilis* OSU-142 triggered ameliorative effects in terms of seed yield at both 300 and 400 kg ha^{-1} humic acid doses and led to an increase in seed yield by 163.6% and 161.4%, respectively, when compared to the control (*Table 3, Fig. 3*). Furthermore, its effect was much more pronounced than that of inoculation with *Bacillus megatorium* M3. Among the humic acid doses, the highest seed yields were also recorded with the application of 300 and 400 kg ha^{-1} humic acid doses which was statistically similar (*Table 3*).

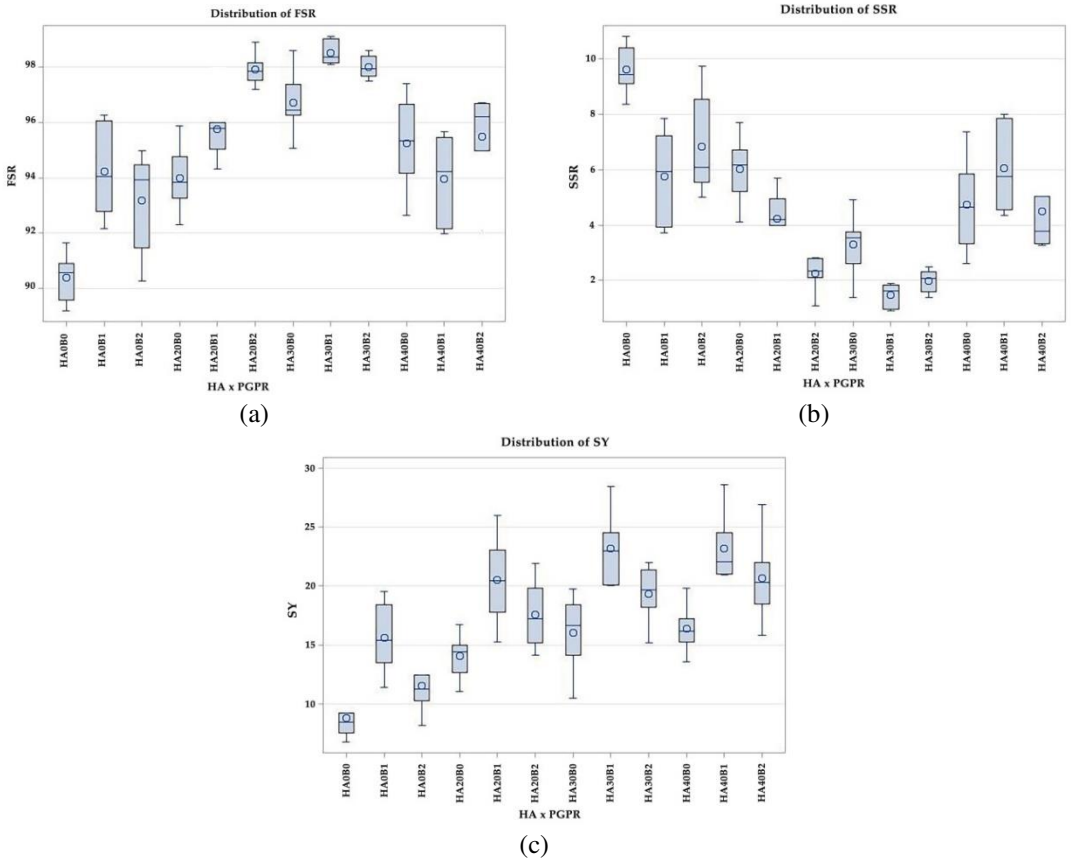

Figure 3. *Fertile seed ratio (%) (**a**), Sterile seed ratio (%) (**b**) and seed yield (t ha^{-1}) (**c**) of safflower affected by bacterial inoculation and humic acid. B_0: without bacteria; B_1: B. subtilis OSU-142; B_1+20, B_1+30, and B_1+40: B. subtilis OSU-142 with 200, 300 and 400 kg ha^{-1} of HA, respectively; B_2: B. megatorium M3; B_2+20, B_2+30 and B_2+40: B. megatorium M3 with 200, 300 and 400 kg ha^{-1} of HA, respectively*

Neither humic acid doses nor plant growth promoting rhizobacteria inoculation had a significant influence on protein content in seeds, whereas seed oil concentration, oil and protein yields were highly influenced by humic acid dose and PGPR application with no significant HA x PGPR interaction (*Table 3, Fig. 2*). The oil concentration in seeds was positively affected by increasing the humic acid doses with no significant effect for inoculation with B_1 and B_2 (30.5% and 30.4%, respectively), and the highest value by 31.3% was recorded with 400 kg ha^{-1} humic acid application (*Table 3*). However, significant increases in oil and protein yields were obtained with separate 300 and 400 kg ha^{-1} humic acid dose and *Bacillus subtilis* OSU-142 applications (*Table 3*).

Mineral Composition of Seeds

The two years long field trials demonstrated that safflower seed mineral composition was significantly affected by both plant growth promoting rhizobacteria and humic acid treatments, however, these integrated administrations significantly increased the mineral concentrations in seeds (except for Cu) when compared to single treatments (*Table 4)*. The Cu concentration in seeds was only negatively affected by both increasing humic acid doses and inoculation with PGPR strains.

[1]20, 30 and 40 treatments refer to safflower plants growing under field condition with 200, 300 and 400 kg ha^{-1} of HA; B_0 treatment without any application of the bacteria, B_1 treatment with *Bacillus subtilis* OSU-142 inoculation; B_1+20, B_1+30, and B_1+40 with *Bacillus subtilis* OSU-142 and 200, 300 and 400 kg ha^{-1} of HA, respectively; B_2 treatment with *Bacillus megatorium* M3 inoculation; B_2+20, B_2+30, and B_2+40 with *Bacillus megatorium* M3 and 200, 300 and 400 kg ha^{-1} of HA, respectively. Means followed by different letters are different by LSD test. *: $P < 0.05$, **: $P<0.01$, ns: not significant; CV: coefficient of variations

The study results indicated that increasing the humic acid dose from 200 kg ha^{-1} to 400 kg ha^{-1} was accompanied by a linear increase in important mineral contents such as the P, K, Ca and Fe (*Table 4*). Furthermore, plant growth promoting rhizobacteria inoculation significantly improved in these contents after combined application with humic acid dose. The highest P concentration was obtained with *Bacillus megatorium* M3 bacterial treatment in 400 kg ha^{-1} humic acid dose by 95.6% increase when compared to control, while the highest K, Ca, Mg, Fe and Mn concentrations were recorded with the 400 kg ha^{-1} humic acid dose with *Bacillus subtilis* OSU-142 bacterial inoculation (56.1%, 62.9%, 81.1%, 63.8% and 44.0% increases in K, Ca, Mg, Fe and Mn when compared to control, respectively). For Zn concentration, a significant interaction between the HA and PGPR factors was observed, where the inoculation with plant growth promoting rhizobacteria strains in all of humic acid doses significantly increased Zn accumulation in seed about 68.3% - 76.4 %, compared to untreated safflower plants (*Table 4, Fig. 4*).

B_0: without bacteria; B_1: B. subtilis OSU-142; B_1+20, B_1+30, and B_1+40: B. subtilis OSU-142 with 200, 300 and 400 kg ha^{-1} of HA, respectively; B_2: B. megatorium M3; B_2+20, B_2+30 and B_2+40: B. megatorium M3 with 200, 300 and 400 kg ha^{-1} of HA, respectively*

Discussion

In the present study, the plant growth-promoting rhizobacteria (*Bacillus megatorium* and *Bacillus subtilis*) and humic acids isolated from leonardite, individually or in combinations, was applied on safflower plants grown in the field trials under semi-arid conditions. Both plant growth promoting rhizobacteria inoculation and humic acid doses

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18831900

significantly increased the growth parameters, seed yield and mineral concentrations in seeds (except for Cu) in comparison with control plants (grown in without PGPR and HA application), and further improved when applied in combination with humic acids. Inoculation of N_2-fixing *Bacillus subtilis* strain OSU-142 effectively improved plant growth when compared to P-solubilizing *Bacillus megatorium* strain M3 and control, and increased plant height by 21.8%, stem diameter by 11.8%, numbers of branch and capitula per plant by 22.1 and 34.5%, respectively, number of seeds per capitilum by 17.1, seed and oil yields by 47.1 and 61.5%, when compared to the untreated control plants. Inoculation of *Bacillus megatorium* M3 produced the highest P concentration in seed, while the highest K, Ca, Mg, Fe and Mn concentrations were recorded with *Bacillus subtilis* OSU-142 bacterial inoculation (56.1%, 62.9%, 81.1%, 63.8% and 44.0% increases in K, Ca, Mg, Fe and Mn when compared to control, respectively). The inoculation with PGPR strains in all of humic acid doses significantly increased Zn accumulation in seed about 68.3% - 76.4 %, compared to untreated safflower plants. Nitrogen and water requirements are the major limiting factors in safflower plant growth and productivity (Dajue and Mündel, 2006). Cakmakci et al. (2001) reported that inoculation of N_2-fixing *Bacillus subtilis* OSU-142 may satisfy nitrogen requirements of sugar beet and barley under field conditions in highland areas, and this bacteria inoculant significantly improved seed yields. Another field studies indicated that *Bacillus megatorium* might have phosphorus dissolving ability since it gave similar increases in growth and yield consistently to alone P application (Cakmakci et al., 2006; Orhan et al., 2006; Elkoca et al., 2010). Furthermore, the various studies with *Bacillus subtilis* and *Bacillus megatorium* reported remarkable growth and yield increases in potato (Ekin, 2019), common bean (Elkoca et al., 2010), sour cherry (Karakurt et al., 2011), raspberry (Orhan et al., 2006), apricot (Esitken et al., 2003) and some turfgrass species (Acikgoz et al., 2016). However, no data were reported on growth promotion with inoculation of this *Bacillus* genus in safflower plants. The literature on plant growth promoting rhizobacteria regarding safflower included mostly *Pseudomonas*, *Azosprillum* and *Azotobacter* spp. inoculation which were used to improve nitrogen uptake (Mirzakhani et al., 2009; Soleymanifard and Sidat, 2011; Sharifi et al., 2017; Nosheen et al., 2018), root morphology (Nosheen et al., 2011) and protein quantity and quality of safflower seeds (Nosheen et al., 2016). These researchers mainly observed marked changes in primary safflower metabolism in response to plant growth-promoting bacterial species; there were also strong effects of PGPR applied in improving root morphology and plant growth, and increasing endogenous hormonal levels (indole-3-acetic acid and gibberellic acid) in safflower leaves.

In the present study, humic acid treatment increased growth parameters and yields above values in controls (*Tables 2 and 3*). The increasing the humic acid dose from 200 kg ha^{-1} to 400 kg ha^{-1} generally was accompanied by a linear increase in growth parameters (except capitilum diameter and sterile seed percentage). Humic acid doses affected not significantly capitilum diameter only, while 200 kg ha^{-1} humic acid dose significantly decreased the sterile seed percentage compared to the control (*Tables 2 and 3*). However, the highest seed yields recorded with the application of 300 and 400 kg ha^{-1} humic acid doses which was statistically similar (*Table 3*). In different studies, safflower crops showed consistent increases with humic acid treatments at the different locations (Basalma, 2014; Mehraban and Miri, 2017). Enhanced plant growth and seed yield were also suggested to explain the beneficial effects of humic acid. Hajghani et al. (2016) similarly promoted the safflower growth and development as well as seed and oil

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18831900

yields by humic substance application. Previous reports had shown that the beneficial effect of humic substances on plant growth may be related to increased fertilizer and water use efficiency, reducing soil compaction, enhancing total root area (especially lateral root emergence and root hairs) and plant biomass (Canellas and Olivares, 2014) and increasing soil microflora (Puglisi et al., 2013). In various field experiments, direct effects of humic acids on plant growth were well described in cultivation of various crops, such as potato (Suh et al., 2014), tomato (Olivares et al., 2015), maize (Canellas et al., 2013) and Hungarian vetch (Esringu et al., 2016). However, Canellas and Olivares (2014) recently reviewed the effects on plant metabolism of humic substance alone and in combination with plant growth promoting rhizobacteria, and theirs agronomical relevance.

Humic acid and plant growth promoting rhizobacteria application significantly affected plant growth development and production of safflower seed; however, their co-application further increased these agronomical parameters. Inoculation with *Bacillus subtilis* OSU-142 triggered ameliorative effects in terms of seed and oil yields at both 300 and 400 kg ha^{-1} humic acid doses; these effects enhanced seed and oil production by average 162% and 221%, respectively, relative the control plants in semi-arid conditions (*Table 3, Fig. 3*). Previous reports had shown that integrated effects of plant growth promoting rhizobacteria and humic acid further increased plant growth, seed yield and quality in safflower (Mirzakhani et al., 2009; Sharifi et al., 2017), probably because of synergisms between improved nutritional status and plant stimulation factors; the net effects increased branch numbers, capitilum and stem diameters, 1000 seed weight, seed oil percentage, seed and oil yields and mineral compositions of seeds (*Figs. 2, 3 and 4*). Furthermore, humic substances are the most complex and biologically active organic matter compounds in the soil and stimulates both plants and microbial activities including plant growth promoting rhizobacteria through a number of mechanisms (e.g. through humic extracts of leonardite, compost or other organic fertilizer) (Nardi et al., 2009; Puglisi et al., 2013; Canellas and Olivares, 2014). PGPR enhancement of soil is largely attributable to biological N_2 fixation, phosphorus solubilization and increases in the availability of nutrients in the rhizosphere. Availability of nutrients increases in response to root surface area enhancement, which is one of several architectural and biochemical changes in the root system induced by humic substance (Nardi et al., 2009; Canellas and Olivares, 2014). Inoculation of humic acids with plant growth promoting rhizobacteria may be used for both plant growth stimulation (Dobbss et al., 2010; Busato et al., 2012; Schoebitz et al., 2016; Silva et al., 2017; Shah and Wu, 2019) and plant disease protection (Cakmakci et al., 2001). The studies with co-application of humates and different PGPR strains previously reported remarkable growth and yield increases in safflower (Sharifi et al., 2017; Nosheen et al., 2018).

Conclusions

Recently, interest in safflower production has been renewed as a result of drought tolerance and the suitability of its oil for nutritional, industrial or biofuel purposes. This study shows that safflower variety Dincer adapted well to semi-arid conditions of Turkey and is a viable alternative to other oilseed crops. In the study, alone application of safflower seeds with both humic acid and plant growth-promoting rhizobacteria (*Bacillus megatorium* and *Bacillus subtilis*) produced highly increases in terms of seed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_18831900

and oil yields of safflower in semi-arid area. However combined application of plant growth promoting rhizobacteria and humic acid significantly improved growth and yield more than alone application of each partner under rainfed field condition. This increase was also supported by the enhancement of nutrient contents in the safflower seeds. Finally, the Bacillus inoculants should be assessed for their potential to increase crop yields and food production under real field environment and this integrated approach could be become an effective method for safflower production under semi-arid conditions in sustainable agriculture systems.

Abstract. Mass-balanced models were constructed for pre and post fishing ban period to compare the possible impacts of the introduction of the fishing closure management practice on the reservoir resources through estimating the trophic status and energy flow. The decreased biomass of high value fishes (Carps, Sheatfishes, Tilapia, *Anabas testudineus* and Knife fishes) despite the implementation of fishing closure pinpoints the excessive fishing pressure on these target species. However, the increased biomass of minnows and clupeids may pose a serious threat to reservoir stability and sustainability altering the trophic structure. Mixed trophic impact indicates that functional groups at the lower trophic level had positive effect on most of the groups. The ratio of primary production/respiration was 13.154 and 1.969 during pre-ban and post-ban season respectively. The relative overhead increased (22.48%) while ascendancy was found to be lower (-0.43%) during the post-ban period. The reservoir was more vulnerable to disruptions before the implementation of fishing ban. Some ecosystem attributes such as TPP/TB, TB/TST, TPP/TR, TPP – TR reveal that the Kaptai reservoir gained higher resilience, stability, maturity and complexity in food web after discontinuing the unlimited fishing access but it still requires attention to overcome the stresses associated with human activities.
Keywords: *Kaptai reservoir, ascendancy, food web, sustainable management, overfishing*

Introduction

The determination of ecosystem structure, flow of energy through trophic interaction and its functional integrity has been widely recognized to ensure a sustainable habitat for living resources (Christensen and Pauly, 1995). Information about ecosystem structure and functions measuring the transferred biomass within ecological groups and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19011924

trophic efficiency could help investigate the possible impacts of changes on different groups and ecosystem as well (Christian et al., 1996). The ecological attributes of an ecosystem delineated from fish population, components of the community, environmental status and flow of energy indicate the quality of an ecosystem. The Ecopath model incorporated different approaches of theoretical ecology (Odum, 1969; Ulanowicz, 1986) to analyze the energy flows between ecosystem components and to define the ecosystem maturity, resilience and stability. It predicts the health of an ecosystem, trophic functioning and its capacity to uphold the biological production. Furthermore, ecosystem properties help to investigate how fish population response to natural and human-made perturbations and thus support effective fisheries management. Moreau et al. (2001) stated that, the output of Ecopath model contributes in the management decision process where multi-species inhabit together.

The Kaptai reservoir is considered as one of the largest supports for freshwater capture fisheries in Bangladesh. It shows both lacustrine and riverine characteristics due to its construction damming a river and multiple other uses by surrounding community. However, due to the rapid economic development and natural perturbations since last few decades the reservoir has experienced ecological changes and severe stresses. Multi-disciplinary uses of reservoir, hydroelectric power generation, overfishing, and oil discharge from mechanized fishing and navigation boats have posed a serious threat to the reservoir fishery and ecology by degrading the water quality. In general, the multiple uses of reservoirs along with excessive fishing pressure, changes in diet make these systems as "unstable ecosystem". The impact is evident by the remarkable decline in the productivity of high-value fishes in this reservoir (Khatun et al., 2019). This was due to high accessibility to this reservoir resource.

Therefore, the detailed study is warranted to get information of the developmental status of this ecosystem facilitating the thoughtful understanding on the structural and functional principles of the whole system, which will be helpful to know the impact of human perturbations. Unfortunately, no attempt has been carried out yet to know the structure, function, existing trophic interactions and energy flow among different functional groups of the Kaptai reservoir unifying the available information. A mass-balance ecosystem model summarizes the changes in the species and helps to compare the direct and indirect effects of one species on others and the overall functioning of the system as well. The ecosystem-based software Ecopath with Ecosim (EwE) allows the analysis of mass-balance trophic models of aquatic ecosystem (Christensen et al., 2005). Furthermore, it helps to compare between the models of two different periods of same ecosystem.

Since the 1980's, fishing has been banned for different period in the Kaptai reservoir depending on season, weather, production target etc. However, fishing closure from May 1st to July 31st has become a routine management practice from the year 2003 onwards in this reservoir. Considering this, we constructed two models of the Kaptai reservoir ecosystem for two different periods with different management approaches, the pre ban fishing, 2001 and post ban fishing, 2016. The study was conducted to assess the possible effect of fishing closure on whole ecosystem, to quantify the energy flows and biomass of different ecological groups, to compare the ecosystem structure, trophic interactions and trophic efficiencies of pre and post fishing closure. In doing so, this contribution will help to know the significance of seasonal fishing banning management on the ecological production, health and stability of the tropical reservoir system. Further remedial management measures also could be suggested identifying the existing bottlenecks and executing the wise use of this reservoir resource.

Materials and methods

Study site

The Kaptai reservoir (22°22' N and 23°18' N latitude, and 92°00' E and 92°26'E longitude), the largest synthetic freshwater reservoir of South-East Asia and first man-made reservoir of Bangladesh was constructed primarily for the purpose of hydro-electric power generation on the River Karnafuli in 1961 (*Fig. 1*). It encompasses an area of 688 km^2 with the average depth of 9 m and average annual temperature of 27 °C. It receives nutrient-enriched waters from rivers, which helps to increase biological productivity and sustain high value fisheries. About 73 species of fishes belonging to 47 genera and 25 families, 2 species of freshwater prawn and 1 species of dolphin have been described in this reservoir (Ahmed, 1999). Among these, 31 species contribute commercially. Artisanal fishing approaches are typically used here to exploit fishery. Unfortunately, indiscriminate use of multispecies gears without concerning about the proper mesh size and mechanization of fishing vessels are putting the signs of excessive fishing effort on the aquatic resources. Surprisingly, since 1999, clupeids have been dominating the reservoir as it breeds profusely in reservoir. In the early post-impoundment period carps used to be the predominant reservoir species contributing 81.4% of the total catch (Ahmed et al., 2006) but it steadily decreased to only 0.96% in 2016 (DoF, 2016). On the other hand, clupeids are increasing at a rate of 8.7% annually (Ahmed et al., 2006) while it contributed 59% of the total catch in 2016 (DoF, 2016).

Modelling approach

The preliminary Ecopath software was based on the approaches developed by Polovina (1984) to analyze flows of energy between ecological groups of an aquatic ecosystem. Later on, subsequent modifications took place (Christensen and Pauly, 1993; Pauly et al., 2000; Christensen et al., 2002) following Ulanowicz (1986). Moreover, Odum's theory of ecosystem development was also incorporated in Ecopath model. In this study, mass-balanced Ecopath models were constructed using 14 ecological components for pre fishing ban (2001) and post fishing ban (2016) periods integrating the available information on food intake, population dynamics, catch and biomass of same or similar system. We used a user-friendly Ecopath with Ecosim suite version 6.5 (Christensen et al., 2008) in our study to construct Ecopath models to compare the changes between the continuous fishing and self-imposed fishing ban. The assumption of EwE is based on the two following equations e.g. 1) production = Catch + Predation + Net migration + Biomass + Accumulation + Other mortality; and 2) Consumption = Production + Respiration + Unassimilated Food. This is expressed by the following equation (*Eq. 1*) proposed by Christensen et al. (2005):

$$Bi * \left(\frac{P}{B}\right) i * EEi = Yi + \sum(Bj) * \left(\frac{Q}{B}\right) j * DCij + EXi \qquad \text{(Eq.1)}$$

Here, *Bi defines* the biomass of prey group *i*; *P/Bi* is the production/biomass ratio of group *i*; *EEi* represents the ecotrophic efficiency; *Yi* is its yield (fishery catch); *Bj* defines the biomass of predator group *j*; *Q/Bj* is the food consumption per unit biomass of *j*; *DCji* is the fraction of *i* in the diet of *j* and *EXi* is the export of (*i*).

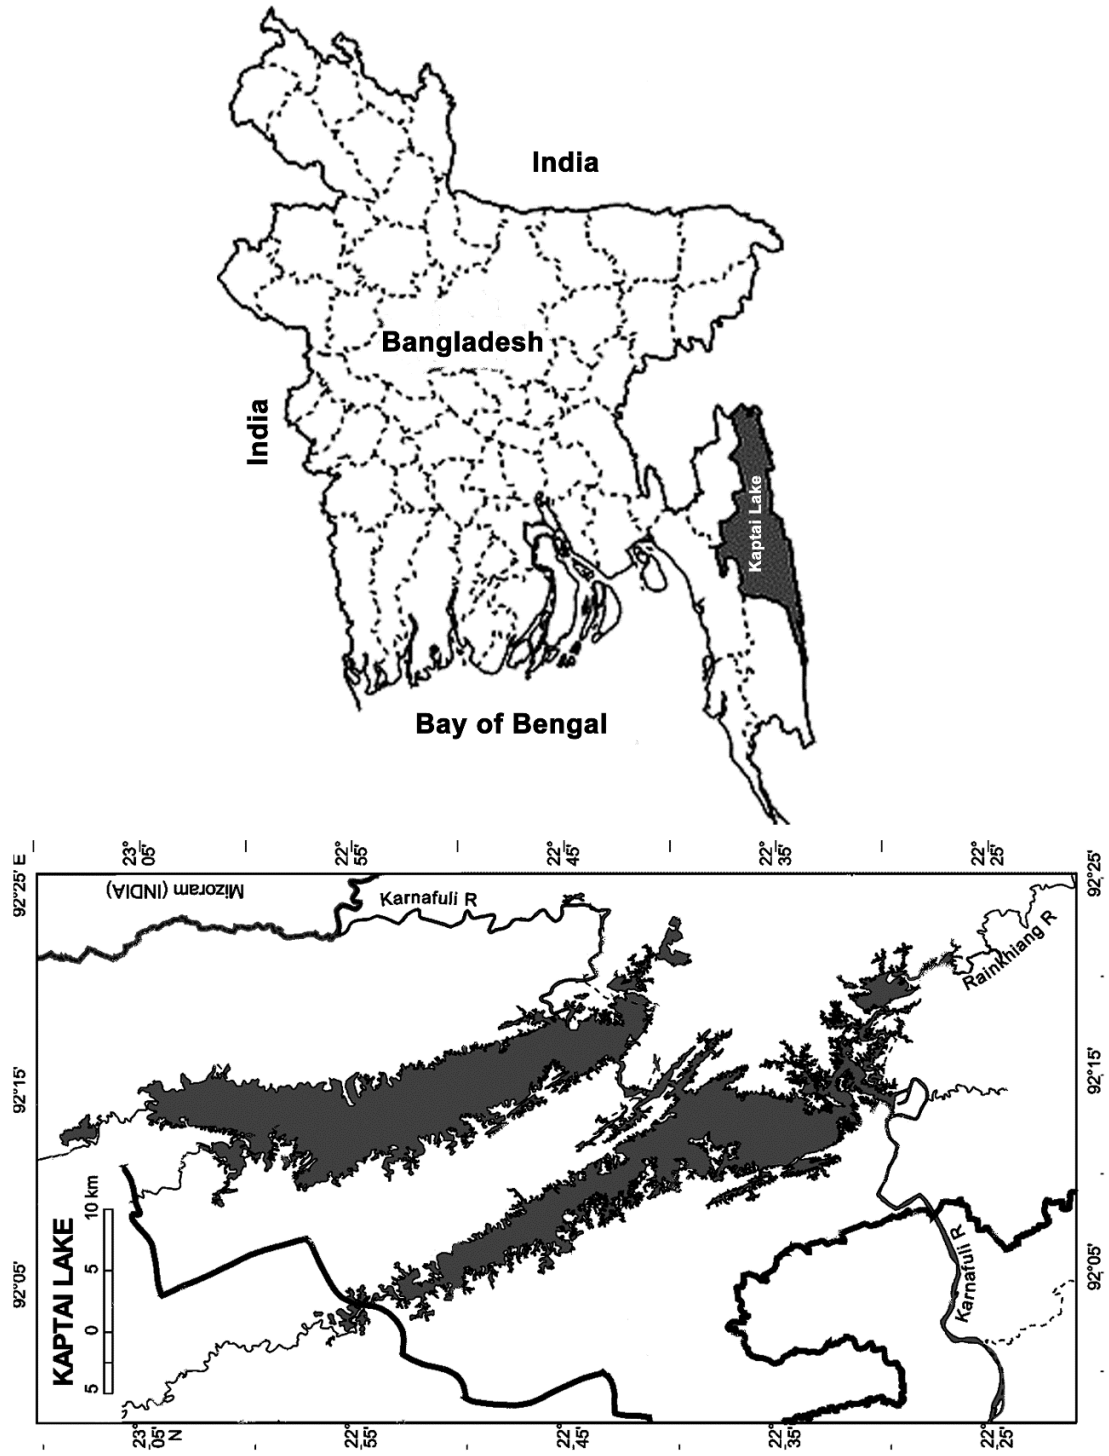

Figure 1. *Geographical location of Kaptai reservoir*

Model parameterization

The model input parameters include biomass *B* (t/km^2), production/biomass *P/B* (yr^{-1}), consumption/biomass *Q/B* (yr^{-1}), Ecotrophic efficiency (*EE)* and diet composition (must be entered as input). Inputting any three of the former parameters will estimate the fourth one. *EE* is the proportion of the production that is consumed or predated. EE

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19011924

should be between 0 and 1. Since there is no empirical relationship to calculate EE, Ecopath model calculates it as output (Christensen et al., 2000). However, in absence of any other parameter EE could be set as 0.95 for highly exploited groups (Christensen and Pauly, 1992). The biomass of both phases was determined from the annual landing information provided by Bangladesh Fisheries Development Corporation (BFDC). We used $B = Y/F$ (here Y = annual average yield of a group, F = fishing mortality) equation proposed by Gulland (1971) to calculate the biomass. In absence of landing data of any group, we used *EE* as 0.95 (for minnows and prawns in 2001). The total fish biomass was found to be 5.256 t/km^2 and 6.245 t/km^2 during pre-ban and post-ban period respectively. *EE* was also set as 0.95 to balance the model where the diet adjustment was ineffective. Notably, *EE* cannot be greater than 1 in a balanced model. The biomass of unexploited groups such as insects and larvae, zooplankton and phytoplankton for both phases was either estimated by the model or obtained from other models. The input and output values of both models are presented in *Table 1*.

The ratio of production over biomass (*P/B*) is considered as equivalent to total mortality *Z* (Pauly et al., 2000). Total mortality *Z* (=Fishing mortality *F* + natural mortality *M*) was estimated following Beverton and Holt (1993) while natural mortality *M* was calculated using Pauly's empirical equation (Pauly, 1984). Consumption (*Q*) is the food intake by a group over a specific period. Consumption/biomass (*Q/B*) was calculated using the empirical equation developed by Palomares and Pauly (1998) along with the help of Fishbase database for every species of each group and the average value was taken as group *Q/B* value. P/B and *Q/B* for some functional groups were obtained from other studied models (*Table 1*).

The diet matrix (*Table A2* in the *Appendix*) of different groups was collected either from the available literatures (Khumar and Siddiqui, 1989; Mamun et al., 2004; Islam et al., 2006; Weliange and Amarasinghe, 2007; Azadi and Mamun, 2009; Sarkar and Deepak, 2009; Mondal and Kaviraj, 2010; Srivastava et al., 2012; Roy et al., 2013; Gupta, 2015; Sakhare and Jetithor, 2016) or from Fishbase (www.fishbase.org; Froese and Pauly, 2019). The model was balanced in a way so that for each group *EE* does not exceed 1, *P/Q* remains between 0.1 and 0.3 and *P/R* ratio (production/respiration) ranges from 0 to 1. The estimated pedigree values were observed 0.56 and 0.533 for the year 2001 and 2016 respectively, which agrees with the statement of Christensen et al. (2002).

Ecological groups

Ecological groups were classified depending on population parameters, food and feeding habits, preference of habitat, physiology, taxonomy, body size and distribution. About 14 functional groups for each year including nine fish groups and one group of prawn were selected as per their abundance and economic importance. The selection of other groups were based on their preference in fish diet. Despite of the role as grazing ground for carps we excluded macrophytes for their minor presence in diet matrix (Panikkar et al., 2015). We used information from available literatures (see *Table A1*) and FishBase (www.fishbase.org; Froese and Pauly, 2019) to bridge the gaps.

Carps

Carps are the most popular reservoir fishes. The most dominant carps include *Labeo rohita, Catla catla, Cirrhinus cirrhosis, Labeo calbasu, Labeo bata, Labeo gonius* and *Cyprinus carpio*. Stocking of carps is a routine management practice in Kaptai

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19011924

reservoir, which is done to decrease the reduction of fish due to excessive fishing pressure. Despite of this stocking a clear declining trend has been noticed in carp production. These fishes feed on zooplankton, phytoplankton, detritus etc.

**P/Q* defines production/consumption, *OI* represents omnivory index

Catfishes

Mystus spp. formed this group. *M. aor* and *M. seenghala* are the dominant catfishes in this reservoir. Other catfish includes *M. cavasius, M. vittatus* and *M. tengara*. Catfishes are mainly caught by gill net, seine net and sometimes by hook and line. They

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19011924

are voracious eater and carnivorous by nature. Their food consists of carps, minnows, clupeids, insects and larvae, etc. Cannibalism is also a common feature among catfishes.

Sheatfishes

Wallago attu and *Ompok pabda* are grouped as sheatfishes. A decreasing trend during the study periods suggests excess fishing pressure on these fishes. Minnows, Prawns and Detritus were found as their main food item.

Tilapia

Both species of Tilapia, *Oreochromis mossambicus* and *O. niloticus* are dominant in this reservoir and play an important role in the total reservoir production. They are well known as voracious feeder and feed on mainly on phytoplankton and zooplankton. Tilapia can survive in much stress conditions.

Anabas testudineus

Anabas testudineus, locally known as koi is a popular freshwater perch in Bangladesh. The decrease production of this fish even after banning fishing reveals excessive fishing pressure on it. They feed on zooplankton, minnows, clupeids, insects and larvae, etc.

Knife fishes

The production record states that the productivity of *Notopterus notopterus* and *N. chitala* has decreased two times recently than the unlimited fishing access period. Knife fishes feed on small fishes, prawns, insects and larvae and so on.

Snakehaed

Channa marulius, *C. striatus* and *C. punctatus* constitute this group. These air-breathing fishes are mainly piscivorous and feed on small fishes especially minnows, clupeids and prawns. The production of these voracious feeders declined despite of the fishing ban implementation.

Minnows

Puntius sarana and *Amblypharyngodon mola* are the most abundant minnows of Kaptai reservoir. The closure of fishing management helped this fishery to increase tremendously. These fishes are caught on any small mesh size nets, hooks and dragnets. They feed on phytoplankton, zooplankton and minor portion of detritus.

Clupeids

Corica soborna and *Gudusia chapra*, commonly known as “weed fishes” contribute the major portion in the reservoir fishery as the breed profusely there. According to the production history, their production increased at higher rate after the introduction of the fishing closure. Interestingly, they compete for their diet with carps providing a forage base for catfish development. Zooplankton, phytoplankton, detritus and aquatic insects mainly form their diet.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19011924

Prawns

The freshwater prawn *Macrobrachium lamarrei* is commonly available type of prawns in Kaptai reservoir. Since there is no information available for this species, we adopted the input data from Reyes (1993). Detritus forms their main diet besides insects and larvae, zooplankton and phytoplankton.

Insect/larvae

Aquatic insects and larvae play important role in the diet of carps, minnows and clupeids. This functional group consist of midges, mayflies, caddisflies, caddisworms, oligochaetes, insect larvae, bivalves and gastropods. We adopted the input value of this ecological group from Villanueva et al. (2006).

Zooplankton

The main constituting form of zooplankton refers to Copepods (*Diaptomus*, *Cyclops* and nauplii), cladocerans (*Daphnia*, *Cheriodaphnia*, *Moina*), and rotifers (*Keratella*, *Filinia*, *Brachionus*, *Asplanhna*). These are the main food item of major and minor carps, Tilapia and *A. testudineus*. Limited data encouraged us to adopt data from other models (Lauzanne, 1983; Moreau and Villanueva, 2002; Traore et al., 2008).

Phytoplankton

Chlorophyceae, Myxophyceae, Bacillariophyceae and Dinophyceae create the phytoplankton group. Among them Chlorophyceae (*Spirogyra*, *Volvox*, *Coelastrum* and so on), Myxophyceae notably *Microcystis*, Bacillariophyceae (*Navicula*, *Gyrosigm*a, *Fragilaria* etc.) and Dinophyceae such as *Ceratium* and *Peridinium* are dominant here. Information of phytoplankton for pre-ban and post-ban phase were obtained from Traore et al. (2008) and Panikkar et al. (2015) respectively. Balancing the models was also the reason of this choice.

Detritus

We used the biomass of detritus as 0.35 t/km^2 for the year of 2001 (Panikkar et al., 2015) and 1 t/km^2 for the year of 2016 (Traore et al., 2008) from similar systems. The biomass of detritus adopted for both period was estimated using Pauly's equation of empirical relationship (Pauly et al., 1993).

Model analysis

Mixed trophic impact (MTI) routine developed by Ulanowicz and Puccia (1990) has been integrated in EwE to assess the relative impact biomass change of one group on another in an ecosystem trophically. Another routine incorporated with EwE that turns the complex food web into simpler one is defined as "Lindeman spine" (Lindeman, 1942). It aggregates the complex fractional trophic levels into discrete one and calculates the transferred energy flow and efficiency from one trophic level to the next. Ecopath can identify probable extinction prey group due to excessive predation by a large number of predator groups (Pauly et al., 2000). The impact of closure management practice on the basic pattern changes of reservoir system were determined comparing the trophic structure and transfer efficiency during both periods. This

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19011924

comparison will help the managers to get some ideas of the reservoir at ecosystem level and may drag their concern for further management steps.

A number of ecosystem attributes have been included in EwE following Odum (1971) to assess the ecosystem maturity. The comparison of net primary production/biomass, biomass/total system throughput, net primary production/total respiration and net primary production - total respiration - these four ecosystem indices were done to know the basic difference about the resilience of the reservoir in both phases. Another three attributes such as ascendancy, overhead and developmental capacity developed by Ulanowicz (1986) were compared to know the overall ecosystem health and stability in both periods.

Results

Some of the parameters of resulted mass-balanced Ecopath models explain the quantitative trends of pre and post ban-fishing implementation for Kaptai reservoir. Our study focus was to compare some parameters for same reservoir for pre-fishing closure period (2001) and post-fishing closure period (2016).

Trophic relationship

The basic inputs of the balanced models and the estimates are shown in *Table 1*. Close observation shows that the biomass of high value fishes such as Carps, Sheatfishes, Tilapia, *Anabas testudineus* and Knife fishes decreased between 2001 and 2016 despite of fishing closure. This might be due to the excessive fishing pressure on these target species, poor implementation of fishing acts, hazardous environment etc. The biomass of the top predator Snakehead and Catfishes along with some other low value fishes from trophic level II for instances minnows, clupeids and prawns increased after stopping the unlimited fishing access throughout the year. Study states that, in spite of fishing ban enforcement, *EE* values of all commercially important fish groups were higher in 2016 compared to 2001 (*Table 1*). Important role of these groups in food web and huge predation pressure might be the reasons behind this. Lower *EE* values of primary producer and detritus in 2001 compared to post fishing-ban explains them as underexploited during this period. *EE* of phytoplankton in 2001 ($EE = 0.148$) indicates that most of the primary production died due to less predation pressure by plankton eater zooplankton. *EE* value for detritus was higher in post fishing-ban phase ($EE = 0.243$) compared to pre fishing-ban phase ($EE = 0.036$) indicating that the lower accumulation of biomass than consumption. It reveals the better utilization of detritus by some groups (snakehead, clupeids, and minnows) with greater biomass in post fishing closure period.

Trophic structure

The trophic structure of the Kaptai reservoir has three trophic levels (*Fig. 2*). In both seasons' catfishes, sheatfishes, snakehead and knife fishes are found to be the top predators of the system (*Table 1*). The trophic levels could be either fractional (Christensen and Pauly, 1992) or integers (Lindeman, 1942). The resulted energy flows are shown in *Figure 3* while the transfer efficiencies at each trophic level generated from the trophic aggregation routine are presented in *Table 2*. It shows that majorities of the biomasses and flows are concentrated in two lower trophic levels (I and II). Trophic

DOI: http://dx.doi.org/10.15666/aeer/1801_19011924

level II mainly involved the flow from zooplankton (primary herbivore). TLIII involved the flows from clupeids, tilapia, *Anabas testudineus* and prawns while catfishes, sheatfishes, snakehead and knife fishes dominate the flow from trophic level IV. The mean transfer efficiency for 2001 and 2016 were 6.718% and 9.752% respectively (*Table 2*). The trophic aggregation routine shows the presence of six trophic levels in both seasons.

Table 2. *Transferred efficiency at different trophic levels for pre fishing ban (2001) and post fishing ban period (2016) for Kaptai reservoir*

Phase/TL	II	III	IV	V	VI	Mean transfer efficiency (%)	Total flow proportion from detritus
Pre fishing ban	3.743	11.17	7.255	6.232	7.458	6.718	46%
Post fishing ban	5.378	12.55	13.74	13.83	16.18	9.752	32%

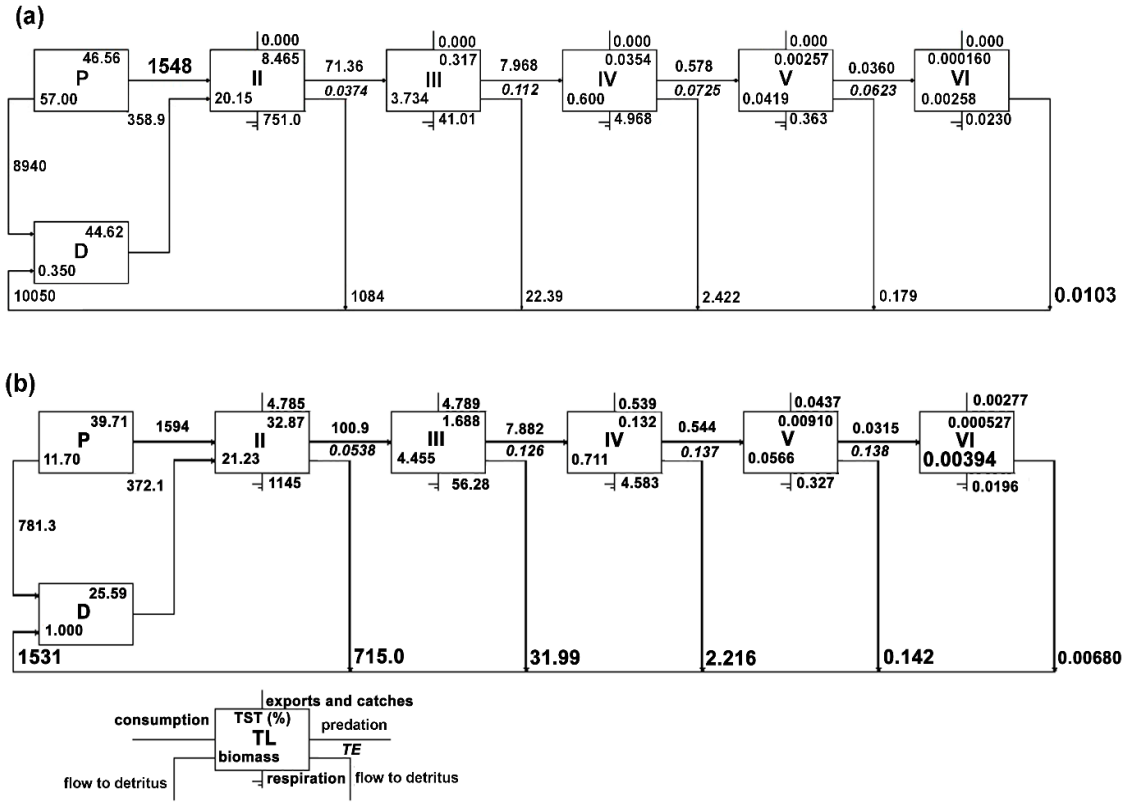

Figure 3. *Trophic aggregation routine presenting transferred flows of Kaptai reservoir during (a) pre-ban phase, 2001 and (b) post-ban phase, 2016*

Mixed trophic impact

The MTI routine on the Kaptai reservoir in two periods are illustrated in *Fig. 4a* and *b*. It assesses the relative impact (direct or indirect) of increase of one group on others in the system. Prey and predator have positive and negative impact on each other respectively. Almost all groups had negative impacts on themselves suggesting competition for same resources. The insignificant decline exhibited by some groups was due to presence of competition within groups for food and habitat. Tilapia and *Anabas testudineus* had almost no effect on other groups. Minor increase in predator depicts the reduction of prey biomass. Functional groups at the lower trophic level such as phytoplankton and detritus shows positive effect on most of the groups. Phytoplankton shows positive impact on its primary consumers such as zooplankton, minnows, clupeids, tilapia and carps.

In contrast, zooplankton showed most negative effect on phytoplankton. The increase in phytoplankton biomass had positive effect on some groups at higher TL but minor negative impact on prawns in both periods. Snakehead had greater negative effect on maximum groups in pre fishing-ban phase than post fishing-ban period. Interestingly, it shows positive impact on catfishes in both seasons. An increased biomass of catfishes shows the decreasing of several groups biomass in both terms while the impact was greater in pre-ban time. Both catfish and snakehead had positive effect on prawns in pre fishing closure course but no effect after fishing ban period. However, the subsequent increase in catfishes led to the decline in the abundance of carps.

Summary statistics

Ecopath computed some important indices of ecosystem maturity and stability supporting Odum's theory (Odum, 1969) and are shown in *Table 3*. A decrease of total system throughput, TST (-73.144%) from pre fishing closure stage to post closure period is evident. An increase of total biomass/total system throughput (50%) and a decrease of *TST* (-87.9%), *PP/B* (-51.61%) and PP/R (-11.185%) were observed indicating the post ban period more stable and mature. About 84.76% detritus

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19011924

accumulation decreased from 10049.52 t/km^2/year during pre-fishing closure to 6073.396 t/km^2/year in post-ban period. The fish biomass of Kaptai reservoir was greater in post-ban phase (6.245 t/km^2) than pre-ban phase (5.256 t/km^2) which could be due to the presence of greater amount of small fishes in recent years.

Table 3. *Summary attributes computed for pre-fishing ban (2001) and post-fishing ban period (2016) in Kaptai reservoir*

Indices	Value pre-ban	Value post-ban	Unit	% difference Post ban - pre ban / pre ban*%
Sum of all consumption	2078.591	2167.709	t/km^2/year	
Sum of all exports	9690.649	1168.645	t/km^2/year	
Sum of all respiratory flows	797.351	1206.455	t/km^2/year	
Sum of all flows into detritus	10049.52	1530.586	t/km^2/year	-84.76
Total system throughput	22616.109	6073.396	t/km^2/year	-73.144
Sum of all production	10981.11	2875.284	t/km^2/year	
Calculated total net primary production	10488	2375.1	t/km^2/year	
Primary production required for catch		699.0	t/km^2/year	
Total primary production/total respiration	13.154	1.969		-11.185
Net system production	9690.649	1168.645	t/km^2/year	
Total primary production/total biomass	128.647	62.250		-51.61
Total biomass/total throughput	0.004	0.006	/year	50%
Net primary production-total respiration	9690.649	1168.645		-87.94
Total biomass (excluding detritus)	81.526	38.154	t/km^2	
Connectance index	0.423	0.417		
System omnivory index	0.196	0.198		
Ecopath pedigree index	0.56	0.533		
Measure of fit, t*	2.242	2.091		
Throughput cycled (including detritus)	310.5	348.1	t/km^2/year	
Ascendency	52.61	30.13	%	-0.43
Overhead	47.39	69.87	%	0.47
Predatory cycling index (% of throughput without detritus)	3.65	3.061		
Finn's cycling index	1.373	5.732	% of total throughput	
Finn's mean path length	2.156	2.557	-	

Different flows such as total consumption, total exports, total flows into detritus and the total system throughput as well were bigger in 2001 than 2016 (*Table 3*). Greater values of ecosystem indices suggest that the food web of pre fishing ban season was better than the post- fishing ban period (*Table 3*). Ascendancy was found to be lower (-0.43%) in post-ban season while overhead was lower in pre-ban (47.39%) phase than post ban (69.87%). Connectance index (CI) reflects the proportion of total probable connections in an ecosystem. On the other hand, system omnivory index (SOI) refers the diversification in diet of different groups. SOI is alternative to CI. The model for 2001 had 0.423 and 0.196 connectance index and SOI respectively while it was 0.417 and 0.198 respectively for the model of 2016. Both models had similar values for CI and SOI.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19011924

Finn's cycling index (with detritus) increased at a considerable rate after stopping the unlimited fishing access. Higher Finn's cycling index (5.732) and mean path length (2.557) in post-ban time reveals the much more importance of detritus in the system.

The species with low biomass but structuring role in the ecosystem food web are defined as keystone species. They strongly influence the dynamics of the whole ecosystem and the abundance of other species maintaining their own low biomass (Libralato et al., 2006). The keystoneness of different functional groups of Kaptai reservoir before and after banning fishing is shown in *Figure 5a* and *b*.

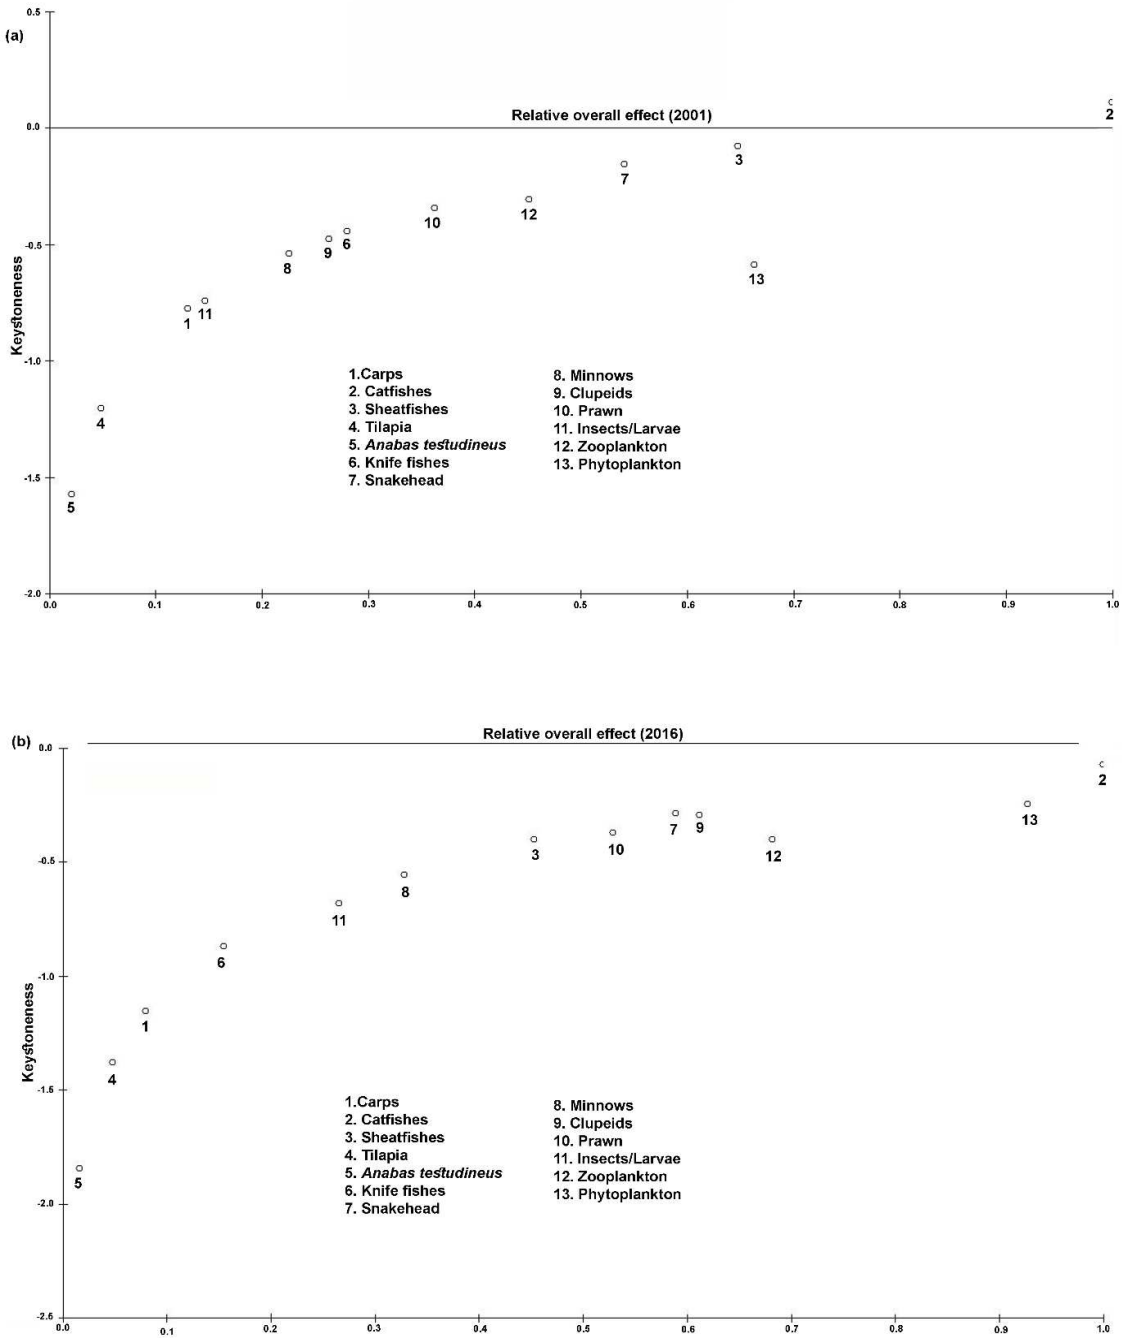

Figure 5. *Keystoneness index for different ecological groups of Kaptai reservoir during a) pre-ban (2001) and b) post-ban period (2016). Higher keystone index and higher relative overall effect denote the keystone species of this ecosystem*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19011924

The species are considered as keystone when the proposed keystoneness index value gets close to or greater than value "zero". Catfish, sheat fishes and snakehead were identified as keystone species in pre-ban period. In post-ban fishing time catfish stood as keystone species along with phytoplankton. In both terms, catfish had relatively higher effect and therefore it had an important role in the maintenance of the ecosystem structure.

Discussion

Sustainability of exploited resources and their effective management require ecosystem-based approach. We used Ecopath with Ecosim to balance the biomass and annual yield of the main interacting groups of pre stopping unlimited access for fishing (2001) and post fishing closure period (2016). Current work will visualize the existing reservoir ecosystem' complexity to the respective management bodies, which may help them to modify the present fishery regimes. The higher ecotrophic efficiency of some groups such as catfish, tilapia, sheatfishes, and *Anabas testudineus* in post-ban fishing period can be attributed either by increasing fishing predation or by predation pressure by other groups (Gamito and Erzini, 2005). The less abundant groups with higher EE (tilapia, sheatfishes, and *Anabas testudineus*) during post-fishing closure season indicates that they utilized the available biomass more efficiently. The flow to detritus of these groups were also lower compared to pre fishing ban period because of the higher competition of the consumers. This supports the finding for Lake Nakuru (Moreau et al., 2001). The increasing biomass with increasing EE (i.e. clupeids) might be due to the raise in predator biomass (e.g. catfish) in post-ban time. Low EE of phytoplankton (pre ban phase) granting the presence of Tilapia which mainly feed on phytoplankton might be due to grand biomass of phytoplankton or may have any other alternative food source (Fetahi and Mengistou, 2007). The exclusion of bacteria as a functional group might attributed to the lower EE of phytoplankton in 2001 (Fetahi and Mengistou, 2007). The decrease of some groups due to uncontrolled fishing effort and relatively higher predation rate may cause the ultimate increase of some other groups. For example, the biomass of minnows and clupeids increased as they had weaker completion for food with Carps or lower predation risk on them. This may lead alterations in trophic structure and could be a potential threat for reservoir stability and sustainability of the reservoir resources.

Theoretical ecology says, transfer efficiency decrease approaching toward the higher trophic levels (Odum, 1971) and this decreasing trend was observed in both phases in the Kaptai system. Comparatively low transfer efficiency was found in pre-ban phase (6.718%). It could be due to the lower utilization of primary producer during this phase. However, Moreau et al. (2001), Tomaczak et al. (2005), and Panikkar and Khan (2008) also documented a low value of transfer efficiency in their studies due to the same reason. The mean transfer efficiency this system after banning period (9.752%) was within the average range (8-15%) (Christensen and Pauly, 1993; Wolff, 1994). The post-ban transfer efficiency was higher than the observation of same phase from Wyra reservoir (7%) and lower than other studies (Bradford-Grieve et al., 1994; Mohamed et al., 2005). In addition, TE of TLV was lower than TLVI, which suggests that a smaller scale of production consumed within this trophic level. Furthermore, the greater TE at every TL after post-ban period indicates better energy flows within the system network. It suggests that, during post fishing ban period most of the groups were utilized at

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19011924

higher level by either fishing predation or predation by other groups. In addition, detritus was found to be about 46% of total system throughput in pre ban phase and 32% in post-ban stage indicating its important role in the ecosystem. It implies the reservoir system as phytoplankton based while importance of detritus as food was also evident. The contribution of detritus in Kaptai reservoir supports the range of other tropical system (Christensen and Pauly, 1993).

Mixed trophic impact is known as an ordinary form of sensitivity analysis (Majkowski, 1982). It helps to predict the direct and indirect impact of one group on others in near future. Group competition for same resources was obvious in both phases as all groups had negative impact on themselves except detritus (Christensen et al., 2000). Detritus, as it is not a living group, had no effect on itself in Kaptai system like other studies (Christensen and Pauly, 1993; Moreau et al., 2001; Fetahi, 2005; Fetahi and Mengistou, 2007; Panikkar and Khan, 2008). The positive effect of detritus on most groups would have beneficial role for detrivorous fish groups, especially for prawns. This observation is supported by Gamito and Erzini (2005) and Panikkar and Khan (2008). Phytoplankton had positive impact on most groups but interestingly it had negative impact on itself, which might be due to the competition for nutrients (Moreau et al., 1997). No impact of Tilapia and *Anabas testudineus* might be attributed due to the presence of their very low biomass in the system or may be their main food item was not entered to the diet matrix due to limited information (Neira et al., 2004). Bangladesh Fisheries Development Corporation (BFDC) liberates 30 mt of carp fingerlings every year in the Kaptai reservoir. Nevertheless, a noticeable decline of carps due to the increase in catfish biomass was observed during this study. Catfishes exert predation pressure on stocked carps (see *Table A2*). Future works are suggested to investigate why the carp production does not increase in spite of huge fingerling liberation. Does the predation pressure by the catfishes solely influence their tremendous reduction or is there any other hidden reasons related to environmental changes?

Ecosystem undergoes through many developmental phases and acquires maturity by the orderly succession of community development (Odum, 1969). Ecopath computes some important ecosystem indices related to ecosystem maturity and stability (Christensen, 1995). The present comparative mass-balance models of before and after fishing closure shows the health development of the tropical Kaptai reservoir due to this management practice. TST in pre-ban phase was greater than post-ban phase as younger ecosystem has higher TST. The decrease of the flows throughout the system during post-ban period along with ascendancy supports the finding of Ulanowicz (1986), and Ulanowicz and Norden (1990). The ratio of total biomass on total system throughput (TB/TST) should increase over time and maturity. In mature system, it stores energy in system' components and conserve it (Ulanowicz, 1986). Again, total primary production/total biomass (TPP/TB) tends to be lower from developmental phase toward mature state due to high biomass or low production rate (Christensen, 1995). The ratio of total primary production/total respiration, TPP/TR tends to be "1" for mature system. Higher TPP/TR (13.154) in pre-ban phase compared to post-ban (1.969) interprets the later phase as more mature. It is obvious that the reservoir had enough strength to fight against human perturbations such as overfishing, pollution, water diversion etc. for acquiring this sort of maturity. TPP/TR values of both phases for Kaptai reservoir was higher than Wyra reservoir (Panikkar and Khan, 2008), Bakreswar reservoir (Banarjee et al., 2016). On the other hand, Ravishankar sagar reservoir (10.36) has greater TPP/TR than post-ban phase but lower compared to pre-ban phase of Kaptai reservoir

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19011924

(Panikkar et al., 2015). Christensen (1995) did study to rank the ecosystem maturity indicators and concluded that disturbances reduce maturity. The present paper also examines some of the vital ecosystem attributes such as TPP/TB, TB/TST, TPP/TR, TPP – TR and reveals that the Kaptai reservoir got more resilience after stopping the unlimited fishing access throughout the year than pre-ban phase. Therefore, the post-ban phase shows more maturity and stability as well compared to pre-ban phase.

Ascendancy and overhead are related to ecosystem stability, maturity, eutrophication and human perturbations (Aoki 1995; Christensen 1995; Ulanowicz, 1997; Neilsen and Ulanowicz, 2000). Overhead represents the presence of strength in an ecosystem to overcome any disturbances. The impact of the introduction of fishing closure is evident as the relative overhead increased (22.48%) during the post-ban period. It also signifies more resilient trophic network in post-ban than pre-ban period supporting the findings of Althauser (2003). Nevertheless, about 10% changes in relative overhead was observed in marine upwelling system during pre and post stressed period (Heymans et al., 2004). The ascendancy and overhead values are comparable with the findings of Panikkar and Khan (2008) and Panikkar et al. (2015).

Connectance index (CI) and system omnivory index (SOI) denote the existing complexity in the food web structure and the diversity in diet matrix. These also describe the level of maturity of an ecosystem. CI and SOI values tend to be higher in mature ecosystem. The values of CI and SOI were found as (0.423, 0.196) in pre-ban phase and (0.417, 0.198) in post-ban phase respectively. The similar CI indicates the similar diet in both terms. CI and SOI of the Kaptai reservoir for both periods were comparatively greater than the Bakreswar reservoir (Banerjee et al., 2016), Ravishankar sagar reservoir (Panikkar et al., 2015) while it was similar to lake Ayame (Traore et al., 2008). Moreover, higher CI indicates the importance of detritus as alternative diet in the system, diversity in diet of some groups and some sort of maturity as well.

Finn's cycling index (FCI) has correlation with system maturity, stability and resilience. A higher FCI value represents more mature and stable ecosystem (Odum, 1969). Greater FCI in post-ban (5.732) phase than pre-ban (1.373) supports more maturity and resilience during post-ban phase. FCI values for the kaptai reservoir was lower than Bakreswar reservoir (Banarjee et al., 2016) while greater than Ravishankar sagar reservoir (Panikkar et al., 2015). Ecopath computed predatory cycling index (PCI) excluding detritus cycles. PCI was a bit higher in pre-ban period (3.65) than post-ban (3.06). FCI and PCI values also support the statement of being more mature, complex and detritus dependent ecosystem. Higher Finn's mean path length (FMPL) in post fishing closure period (2.557) compared to pre fishing closure era (2.156) also suggest post-ban period with more maturity and complexity. However, high FCI value indicates an ecosystem as mature one but a very high value describes the ecosystem at vulnerable condition (Christensen and Pauly, 1993). In that sense, the Kaptai reservoir seems to be a bit sensitive to disruptions.

A similar study was done to assess the impact of fishing ban management practice for a tropical Wyra reservoir, India (Panikkar and Khan, 2008). They found (-82.7%) decrease of total flows during post-ban period while it decreased (-73.144%) in Kaptai reservoir. Lower ascendency (-0.14%) and higher overhead (0.05%) after the introduction of fishing closure supports our finding for Kaptai reservoir. TPP/TR for both reservoirs decreased after the implementation of management approach but it was closer to 1 for Wyra reservoir (1.053) compared to Kaptai reservoir (1.969) indicating Wyra more mature. In brief, the comparative mass-balanced models for pre-ban (2001)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19011924

and post-ban period (2016) support the improvement of "health" for Kaptai reservoir due to management interventions during this period. The similar observed improvement for Wyra reservoir encourages implementing this environmental management measure for the stability of the reservoir and its resources.

Moreover, overfishing, both in marine and freshwater sector is a matter of concern nowadays to meet the increasing food security throughout the world. It does not only influence the aquatic resources but also the ecosystem. These are the driving forces to do detailed study of the aquatic ecosystems to ensure efficient management for the sustainability of the aquatic resources and greater the stability of the reservoir ecosystem. Uncontrolled fishing pressure impact the trophic structure of an ecosystem significantly. It also accelerates the rapid reproduction and reduce the size of fishes (Travers et al., 2010). Thus, the decrease of top predators from higher trophic levels and the increase of smaller size fishes was termed as "fishing down the food web". Overfishing accelerate the fish species to suffer from the reduction of genetic diversity within and among population for long time before extinction (Musick et al., 2000). Selective fishing intensifies the alteration of genetic diversity, heritable difference in yield and life history traits of any particular fish species (Reviewed by Kenchington, 2003). Calculating the effects of overfishing on the molecular genetic level and in understanding life history traits will be helpful to get prior idea about stock status and level of extinction of any particular species. Further studies are suggested to know the possible effects of overfishing on ecosystem and molecular level.

Conclusion

Ecosystem modelling are now widely used for stock assessment and for the development of fisheries management policies for tropical fisheries. This study explains how fishing closure management helped the reservoir to get more maturity, stability, resilience and more complexity in food web than previous period. Moreover, TPP/TR near to unity predicts the reservoir as a healthy ecosystem but still it seeks attention to overcome the stress due to exercising overfishing. Our study also reveals that the Kaptai reservoir was more vulnerable to disruptions before the introduction of fishing ban management practice. In spite of its remarkable contribution to the capture fisheries of Bangladesh due to natural and human perturbations especially for the high catching activities, the reservoir resources have collapsed. Although, the fishing closure management step along with other practices led this system to achieve more maturity than before but still the reservoir fishery has been experiencing excessive fishing effort. Therefore, we can conclude that further necessary ecosystem-based management actions will help to be a sustainable aquatic resource in Bangladesh fighting against any natural or anthropogenic perturbations. Notably, the most abundant but low economic fish in the reservoir such as *Corica soborn*, *Gudusia chapra* could be used as processed food or as fishmeal. This paper provides a framework of better understanding of the trophodynamics of the Kaptai reservoir and the effects of taking environmental-based fisheries management. However, the scarcity of relevant data and uncertainties in input parameters especially for lower trophic level could be some feasible limitations of this study. Despite of these uncertainties we regard that the constructed models provide reasonable presentation of the Kaptai ecosystem structure and dynamics. Therefore, future works for instances collecting data with intensive care for further study related to ecosystem dynamics, study of effects of climate changes and pollutants on reservoir

DOI: http://dx.doi.org/10.15666/aeer/1801_19011924

resources, detailed study of the present modelling using Ecosim are recommended to explore new fishery policies for the reservoir sustainability.

Abstract. The removal of a Basic Blue 41 (BB41) and Basic Red 09 (BR09) from an aqueous solution by biochar derived from *Arachis hypogaea* shell (Groundnut shell) was studied. The sorption of cationic dyes (BB41 and BR09) was studied by varying biochar dosage (1–10 g/L), solution pH (3–10), temperature (30 to 50 °C), contact time (0–360 min) and initial dye concentration (25–200 mg/L). At optimum biochar dosages of 2 g/L (BB41) and 1 g/L (BR09), solution pH (8), initial concentration of dye (50 mg/L), and equilibrium time (240 min), groundnut shell derived biochar recorded BB41 and BR09 uptakes of 22.322 and 40.655 mg/g. The kinetic research confirmed that the biosorption rate was quick for groundnut shell-based biochar, and the results were effectively modeled using the Pseudo's first-order and second-order kinetic models. The sorption isotherm studies exhibited that the Sips model provided better results with high correlation coefficients.

Introduction

Dyes have been used as coloring agents in the textile industries for many years (Wu and Ng, 2008). Different types of dyes are used for diverse applications in the textile manufacturing process; among these, cationic dyes are used the most (Zolliger, 2003).

During the manufacturing of textiles, an enormous quantity of waste sludge and chemically contaminated water are generated. This chemically contaminated wastewater taints the water quality and soil fertility of the affected land cover. Compared to wastewaters released from other industrial applications, those from textile manufacturing are incredibly complex (Gokulan et al., 2019a).

The appearance of colors in the chemically contaminated sewage could be highly visible and harmful even at lower concentrations (Nigam et al., 2000). These polluted wastewaters not only damage the aesthetic nature of the aquatic ecosystem but also affect the photosynthetic activity of aquatic environments by reducing the level of light penetration through it (Kang et al., 2019). These polluted waters contain toxic and carcinogenic substances that must be treated before being discharged into the aquatic systems (Siddique et al., 2017). However, treatment technologies are often not sufficient to remedy these volumes of wastewater (Gokulan et al., 2019b). Since the removal of wastewater is considered as an environmental challenge and mandate of government legislations made in force of these industries to focus on effective treatment of wastewater techniques.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19251939

In order to arrest these environmental challenges, various treatment techniques have been used for the removal of dye from wastewater in textile processing units, as insisted by the legislative mandate of government. The most commonly used treatment techniques are Fenton process, photo-Fenton processes (Rosembergue et al., 2019), photoelectro-Fenton (Paz et al., 2020), photo-ferrioxalate (Sankar et al., 2015), reverse osmosis (Sahinkaya et al., 2019), electrochemical oxidation (Nidheesh, 2018), adsorption (Mu et al., 2019), chemical coagulation/flocculation (Beluci et al., 2019).

There are certain disadvantages and limitations of existing dye removal methods in real-time applications. For example, the operating cost of the process is expensive, and they would generate particular wastes that should be treated and disposed of in order to avoid collateral pollution of the environment (Hua et al., 2019). Biological-adsorption can be defined as the uptake of pollutants by inactive biomass through physiochemical treatments (Bhagavathi et al., 2019). Hence adsorption process is viable in dye removal for industrial applications due to its simplicity and sustainability of a broad variety of sorbents that can be used in water treatment (Gupta et al., 2009; Mironyuk et al., 2019).

For this purpose, adsorption by agricultural waste by-products have great potential for removal of different pollutants (Mohebali al., 2019) has proved to be an efficient remediation technique for removing various contaminants such as Dyes (Charola et al., 2018; Wakkel et al., 2019), COD (Mohammad-pajooh et al., 2018) Phenol (da Gama et al., 2018) and heavy metals (Mohammad-pajooh et al., 2018; Liu et al., 2019). In addition to that, agro wastes, by-products are low-cost, available in abundance around the world, renewable resources, eco-friendly, and easy to regenerate (Zhou et al., 2015).

Arachis hypogaea or Groundnut shells are the residual waste produced after the eradication of groundnut seed from its pod. This is a vast agricultural waste with a minor rate of degradation (Zheng et al., 2013). However, groundnut shells have diverse applications such as bioethanol production biodiesel production, carbon nano-sheet formation, and enzyme production. These shells are used as feedstock for biochar preparation, too (Duc et al., 2019). Biochar is a new and popular alternative for the treatment of dye-bearing effluents to selectively isolate dye molecules (Gokulan et al., 2019c). Since the biochar derived from the Groundnut Shell contains various bioactive and different functional compounds, it can be assessed as a feasible bio-sorbent for the adsorptive removal of cationic dyes.

Moreover, the use of groundnut shell derived biochar as a biosorbent in the adsorptive removal of cationic dyes (Basic Blue 41 and Basic red 09) has not been reported, so far. Therefore, in this study, the Groundnut shell derived biochar (GnSB) was examined for the adsorptive removal of Basic Blue 41 (BB41) and Basic Red 09 (BR09) as a model cationic dye and characterized in detail. The influencing parameters of adsorption, including biochar dose, solution pH, initial dye concentration, and temperature, were correlated with the sorption capacity of the biochar. The adsorptive performance of biochar for the removal of BB41 and BR09 was evaluated and modeled.

Materials and methods

Biomass and chemicals

Groundnut shell leftover after the removal of seeds from its pod in the oil mills was used. These shells were obtained from various agro oil processing units in and around Karumathampatti village of Coimbatore city in Tamil Nadu, India. The collected

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19251939

groundnut shells were used as a feedstock for biochar preparation. These feedstocks were initially washed up with water to remove soil with dust and then exposed to natural sundry for 48 h. Further, the feedstocks were dried up to at 70 °C for 24 h and then pulverized to less than 100 mm for biochar production (Luo et al., 2015). BB41 and BR09 cationic dyes of analytical grade and all other analytical grade chemical agents were obtained from Sigma Aldrich, India. The dye solution was prepared by the dissolution of the required amount of BB41 and BR09 in deionized water. The solution pH of the dye was adjusted to the desired value using 0.1 M HCl or 0.1 M NaOH (Jegan et al., 2016). The chemical structure and characteristics of all the cationic dyes were illustrated in *Figure 1* and *Table 1*.

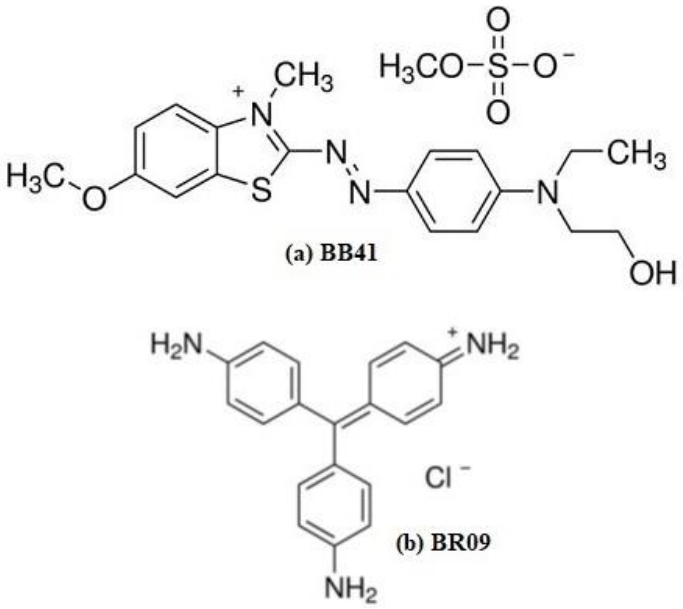

Figure 1. *The structure of cationic dyes Basic Blue 41 (a) and Basic Red 09 (b)*

Table 1. *The characteristics of cationic dyes*

Dyes	Empirical formula	Colour index	Molecular weight (g/mol)	λ max (nm)
Basic Blue 41	$C_{20}H_{26}N_4O_6S_2$	11105	482.57	618
Basic Red 09	$C_{19}H_{17}N_3$ HCl	42500	323.82	546

Pyrolysis of biomass

The biomass of 100 g was kept in a crucible covered with small holes of alumina foil and then flamed at a preferred temperature in a muffle furnace (Mahdi et al., 2017) and maintained it for 120 min in the existing operating conditions under O_2 limited environment (Luo et al., 2015). The heating rate was maintained at 5 °C/min in the pyrolysis, and the resultant biochar was further allowed to cool to room temperature overnight. This experiment was performed at different temperatures (300, 350, 400, 450, and 500 °C) with three trails at each condition to find out the optimum condition. The resultant biochar was moved to a desiccator and further used for various sorption studies.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19251939

Characterization of biochar

The Scanning Electron Microscope was used to determine the surface morphological conditions of the biochar using ZEISS- GeminiSEM. Before analysis, all dried biochar samples were coated with a thin layer of gold for electrical conduction. A Fourier Transform Infrared (FTIR) spectrophotometer (Thermo Scientific Ltd., USA & Nicolet 6700) has been used to study the availability of different surface functional groups on the sample. Before these analyses, these dried samples were assorted with KBr to form pellets (Zama et al., 2017).

Adsorption studies

By optimizing the operating parameters with a target to achieve the maximum sorption uptake, batch trial experiments were performed. The biochar dose was added to a 250 mL of Erlenmeyer flask consist of 100 mL of dye concentration, and it was mixed well using an incubated shaker at 200 rpm for 6 h. Then centrifuged for 10 min at 4000 rpm. Finally, the dye concentration was measured from the UV-Spectrophotometer using the supernatant. These adsorption trials were performed for different process conditions.

Isotherm and kinetic studies

In order to determine the maximum dye sorption capacity of the biosorbent, isotherm experiments were carried out by varying the concentrations from 25 to 200 mg/L. The experiment trials were performed at the desired pH, temperature, and adsorbent dosage. The amount of dye sorbed was determined by the differences observed between the amount of dye added to the biomass and the amount present in the supernatant using *Equation 1:*

Biochar uptake: $$Q = \frac{V(C_0 - C_e)}{W} \quad \text{(Eq.1)}$$

The removal efficiency (%) was calculated by using *Equation 2:*

$$\text{Removal efficiency (\%)} = \frac{C_0 - C_e}{C_n} \times 100 \quad \text{(Eq.2)}$$

where Q is the uptake of dye by sorbent mg/g, V is the dye solution volume (L), C_0 is the initial concentration of dye used (mg/L), C_e is the final (equilibrium) concentration of dye remained in the solution (mg/L), and W is the mass of biochar (g).

Four different equilibrium isotherm models were used to fit the experimental data of BB41 and BR09, biosorption onto Groundnut Shell Biochar as given in *Equations 3, 4, 5* and *6* (Ayawei et al., 2017).

Freundlich model:

$$Q = K_F C_e^{\frac{1}{nF}} \quad \text{(Eq.3)}$$

Langmuir model:

$$Q = \frac{Q_{max} b_L C_e}{1 + b_l C_e} \quad \text{(Eq.4)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19251939

Sips model:

$$Q = \frac{K_s C_e^{\beta_s}}{1 + a_s C_e^{\beta_s}} \quad \text{(Eq.5)}$$

Toth model:

$$Q = \frac{Q_{max} b_T C_e}{[1+(b_T C_e)^{\frac{1}{n_T}}]^{n_T}} \quad \text{(Eq.6)}$$

where Q_{max} is the maximum uptake of dye by the sorbent (mg/g), n_F is the Freundlich exponent, K_F is the coefficient of the Freundlich model (mg/g) (L/mg) $^{1/n_F}$, b_L is the equilibrium coefficient of Langmuir model (L/mg), a_s is the coefficient of Sips model (L/mg), β_s is the exponent of Sips model, K_s is the isotherm coefficient of Sips model (L/g). b_T is the constant of Toth model (L/mg), and n_T is Toth model exponent.

The kinetic models have been utilized to describe the sorption kinetics as provided in the following equations (*Eqs. 7* and *8*):

Pseudo-first-order kinetic model:

$$Q_t = Q_e\ (1 - exp(-k_1 t)) \quad \text{(Eq.7)}$$

Pseudo-second-order kinetic model:

$$Q_t = \frac{Q_e^2 k_2 t}{1 + Q_e k_2 t} \quad \text{(Eq.8)}$$

where Q_t is the dye uptake capacity at any time t (mg/g), Q_e is the equilibrium dye uptake capacity (mg/g), k_1 (1/min) and k_2 (g/mg.min) are the rate constants of the pseudo-first and pseudo-second-order models, respectively.

Results and discussion

Effect of pyrolysis on biomass

The yield of biochar was strongly influenced by the pyrolytic atmosphere. The biochar yield was defined as a weight percentage of the biochar recovered after pyrolysis (Ronsse et al. 2013). *Figure 2* illustrates the pyrolytic temperature influences on biochar yields for the feedstocks. It was evident that the surge in pyrolytic temperature results in decreases the yield of biochar. This was due to more decomposition of residues at higher temperatures. After a cautious assessment of the results presented in *Figure 2*, the maximum biochar yield was obtained at 350 °C was used for further studies.

Characterization of groundnutshell derived biochar

The surface morphological functionalities of the cationic dye bounded biochar derived from the groundnut shell were assessed by the scanning electron microscope, as shown in *Figure 3*. From this figure, it is evident that the groundnut shell surface was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19251939

observed to be smooth before pyrolysis, and it is found to be pore and rough after pyrolysis. The surface sites of the biochar after pyrolysis was enlarged and attained more binding action between the cationic dyes onto the biochar. The change in action on the surface of biochar revealed that ion exchange had happened between the adsorbent and adsorbate (Gokulan et al. 2019d) which in turns on adsorption, this adsorption of cationic dyes on the surface of biochar decreases its porosity, as reported (Ahmadi et al., 2012).

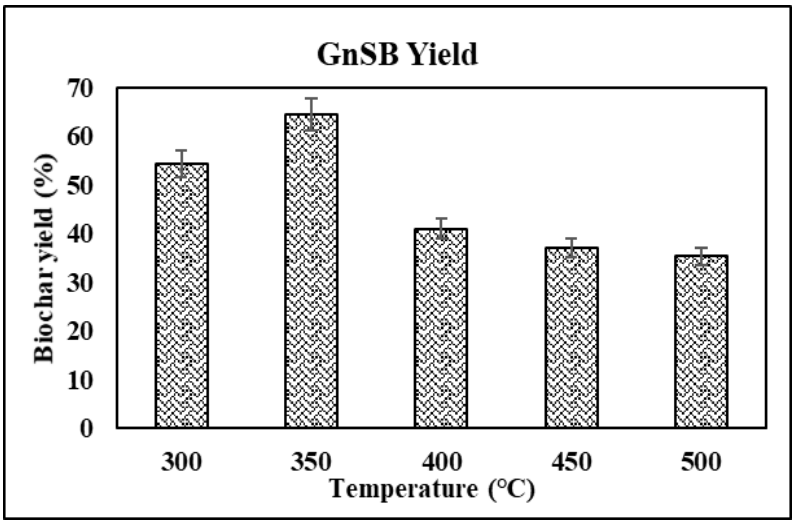

Figure 2. *Effect of pyrolysis temperature on the biochar yield*

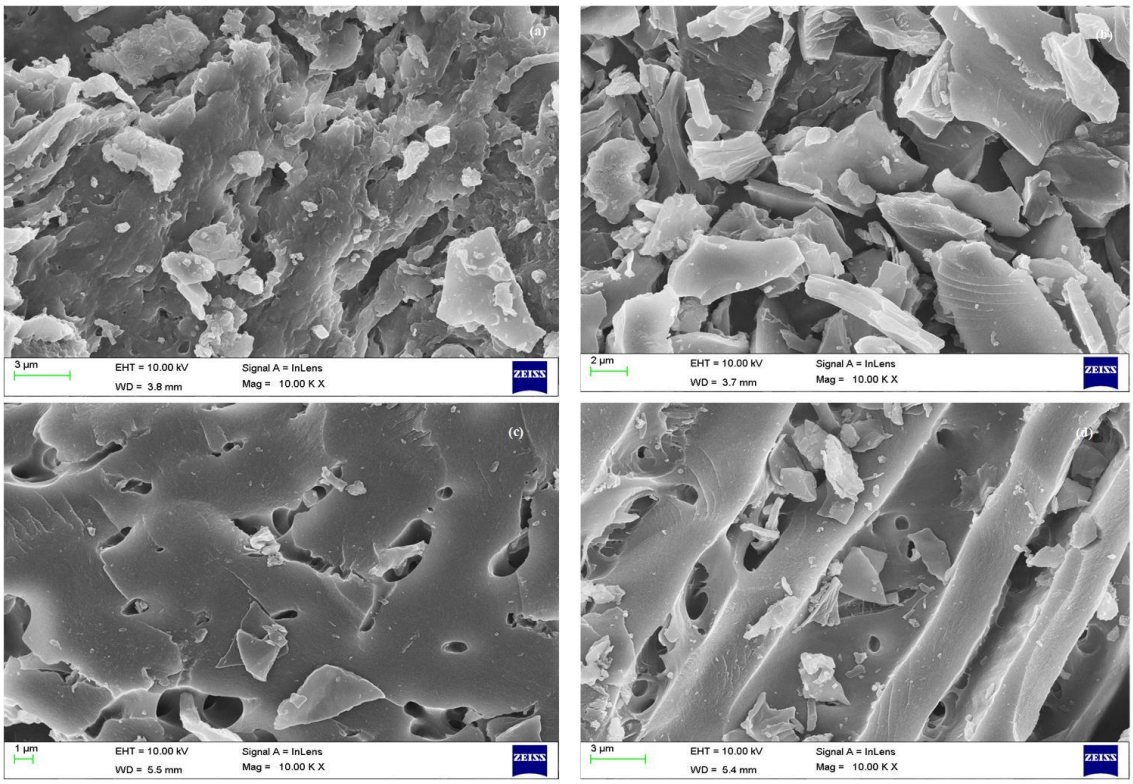

Figure 3. *SEM images of Groundnut Shell (GnS) (a), GnS derived Biochar (GnSB) (b), BB41 bounded GnSB (c) and BR09 bounded GnSB (d)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19251939

In the Energy Dispersive Spectroscopy (EDS) analysis, strong peaks of C, N, O and S are obtained as depicted in *Figure 4*. The results demonstrated that carbon (67.00% to 69.53) and nitrogen (6.13% to 7.31%) content increases and whereas oxygen (26.78% to 23.01%) and sulphur (0.09% to 0.014%) content decreases after pyrolysis. This decrease is due to the decarboxylation and dehydration with subsequent loss of hydroxyl and aliphatic groups.

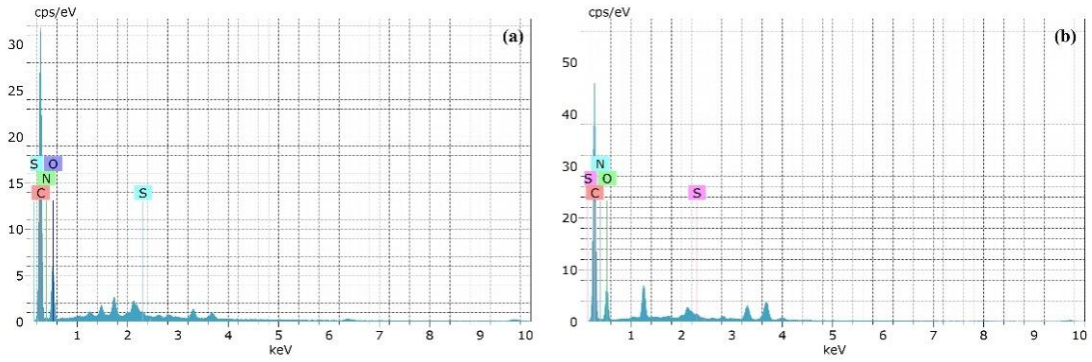

Figure 4. *EDS spectrum of groundnut shell (a) and groundnut shell derived biochar (b)*

The FT-IR spectrum of groundnut shell derived biochar, and cationic dyes bounded biochar are presented in *Figure 5*. The spectrum shows a number of peaks, which indicates the complex nature of the biochars.

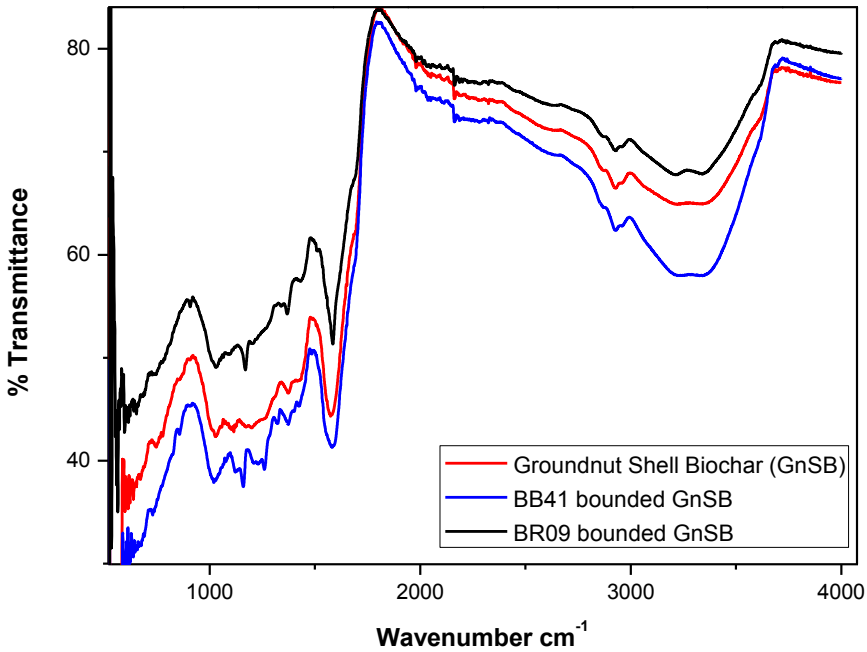

Figure 5. *FT-IR spectra of groundnut shell biochar and basic dyes bounded biochar*

The FT-IR spectrum of biochar barbed out the presence of strong bands at 613 cm^{-1} (C–H (alkynes) band), 744 cm^{-1} (C–H bend), 1114 cm^{-1}(C-O stretch (primary alcohols), 1574 cm^{-1} (C = C stretch, N-H bend) 2928 cm^{-1} (C-H stretch (Alkanes and Alkyls)) and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19251939

3339 cm^{-1} (O–H, N-H, stretch). After batch experiments, the biochar spectrum is insignificantly affected by a particular temperature. However, when the BB41 is adsorbed on the biochar surface, several adsorption peak bands are observed at 616, 732, 1160, 1583, 2926, and 3341 cm^{-1}. The peak at 732 cm^{-1} can be indorsed to aromatic compounds (Nasuha et al., 2010). When the BR09 is adsorbed, the peaks are observed at 595, 747, 1170, 1588, 2924, and 3349 cm^{-1}. From the FT-IR spectrum, it is clear that the biochar bounded with cationic dyes revealed the shifts in a functional group, and it is due to the transformation of various ions existent in the active sites of the surface of the adsorbent by dyes sorption. These changes indicate that functional groups on the biochar may be the potential adsorption sites for biosorption of cationic dyes.

Effect of biochar dosage

The influence of biochar dosage is shown in *Figure 6*. Biochar dose was varied from 1 to 10 g/L. From the study, it was evident that the percentage removal increases with an increase in biochar dose and a decrease in dye uptake capacity. For Instance, the removal efficiency of BB41 and BR09 increases from 83.82 to 95.71% and 92.59 to 97.84%, when the dosage increased from 1 to 10 g/L. The experimental rise in efficiency with the surge in biochar dosage could be due to the presence of diversified functional groups and surface sites of the biochar (Slimani et al., 2014). Furthermore, the dye uptake decreases on increasing the biochar dosage. For example, the sorption ability of BB41 and BR09 by groundnut shell derived biochar declined from 41.913 to 4.786 mg/g and 46.299 to 4.892 mg/g, when the biochar dosage increased from 1 to 10 g/L. At low and high sorbent dosages, the dye sorption uptake is greatly affected. Similar results were reported (Vijayaraghavan et al., 2015; Jegan et al., 2016). Comparing the % of removal and dye sorption uptake values, a dose of 2 g/L and 1 g/L, was selected as an optimal dose for BB41 and BR09 for further experiments.

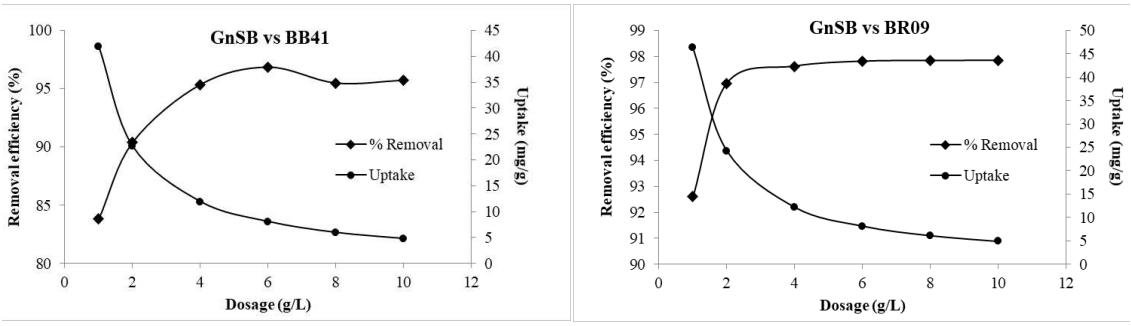

Figure 6. *Effect of biochar dose on the BB41 & BR09 removal efficiency and sorption uptake capacity*

Effect of pH

The pH is the vital parameter which regulates not only the sorption capacity but also the sorption efficiency. With due consideration, the experimental trials were conducted at an optimized biochar dose and desired initial dye concentration of 50 mg/L, the temperature of 35 °C by varying the pH (3-10). *Figure 7* illustrates the influence of pH on dye sorption capacity and the percentage of removal. While varying the pH from 3 to 8, the sorption uptake capacity of groundnut shell derived

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19251939

biochar onto BB41 and BR09 are increased from 20.01 to 22.60 mg/g and 39.17 to 46.30. Similarly, the percentage of removal also increases from 80.06 to 90.39% and 78.34 to 92.59%, for BB41 and BR09. The initial pH value may influence to increase or decrease the uptake. The increase in the value of pH may decrease the concentration of active H^+ ions, which simultaneously raises the negatively charged sites (Premkumar and Vijayaraghavan, 2015). Due to this negatively charged surface area, the sorption of cationic dye molecules gets increased through electrostatic forces of attraction (Santhi et al., 2016). Comparing the extent of removal and dye sorption capacity values of GnSB favored BR09 followed by BB41. However, the pH value of 8 was taken as optimal for peak performance.

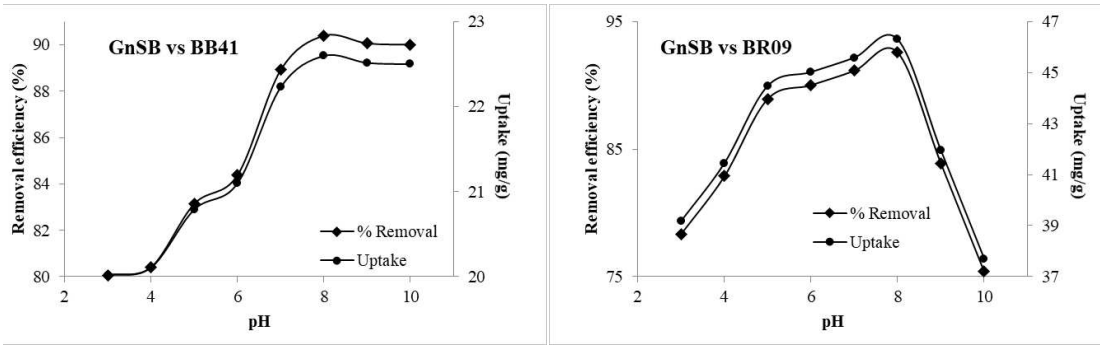

Figure 7. *Effect of solution pH on the BB41 & BR09 removal efficiency and sorption uptake capacity*

Effect of temperature

Figure 8 shows the effect of temperature on the removal efficiency of cationic dyes onto GnSB at different temperatures within the range of 30 to 50 °C at optimized biochar dose and pH with a fixed dye concentration of 50 mg/L were examined. The percentage of BB41 and BR09 removal by GnSB are varying from 90.40 to 80.96% and 92.60 to 77.96%. The surge in temperature accelerates the degree of diffusion of solute and thus strongly influences the uptake capacity of adsorbent towards solutes (Kankilic et al., 2016). While increasing the adsorption temperature of BB41 and BR09 adsorption indicates the fall in uptake capacity. Similar results were reported (Zeng et al., 2006). With this investigation, an ideal temperature of 35 °C has opted for the BB41 and BR09 sorption process.

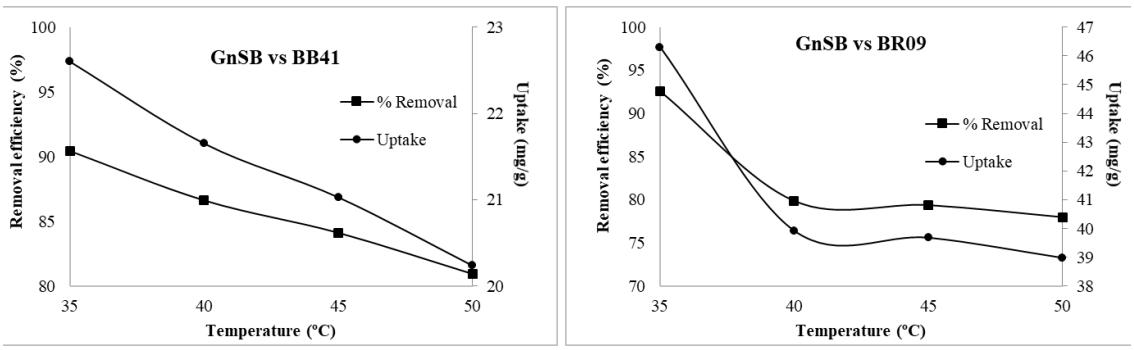

Figure 8. *Effect of adsorption temperature on the BB41 & BR09 removal efficiency and sorption uptake capacity*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19251939

Influence of initial dye concentration

The influence of initial dye concentration on the sorption of cationic dyes onto GnSB was experimentally carried out by varying the initial concentration from 25 to 200 mg/L for the optimized biochar dose and pH with ideal temperatures as shown in *Figure 9.* From the experiment data, it was evident that % removal of cationic dyes decreased with a surge in dye concentration. At higher concentrations, the available dye molecules in the solution do not interact with adsorbent binding sites due to the limited number of active sites that become saturated at a certain concentration (Saha et al., 2010). However, the dye sorption capacity at equilibrium condition was increased with a surge in dye concentration. This was due to the initial concentration of the cationic dye, which provides a significant driving force to overcome any mass transfer resistance of the dye between the aqueous and the solid phases (Pirbazari et al., 2014). With due consideration on all these above facts, 50 mg/L was selected as optimal for BB41 and BR09 concentration for GnSB.

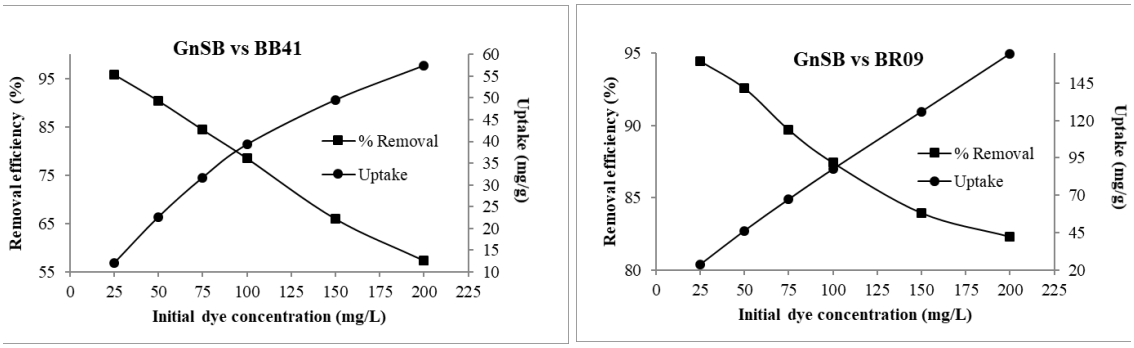

Figure 9. *Effect of initial dye concentration on the BB41 & BR09 removal efficiency and sorption uptake capacity*

Sorption isotherms

The analysis and design of the sorption process require the relevant adsorption equilibrium conditions, which is the most important set of information in understanding an adsorption process. Adsorption equilibrium provides fundamental physiochemical data for evaluating the applicability of the sorption process as a unit operation. By varying the initial concentration of cationic dyes of 25, 50, 75, 100, 150 200 mg/L at optimized pH value and temperature, the adsorption isotherm was determined. From the experiment data, it was seen that sorption potential improved with the increase in initial dye concentration.

To facilitate the adsorption capacities, the equilibrium adsorption models of Freundlich (1906), Langmuir (1916), Sips (1948), and Toth (1971) models were employed. Freundlich and Langmuir are the two-parameter isotherm models, and Sips and Toth are the three-parameter isotherm models used (*Table 2*). In two-parameter isotherms, the Freundlich model was found to be the best-fit isotherm data when compared to other with low correlation coefficient (<0.992) and high % error values, and it can be summarized that K_F and n_F of GnSB were in the following order: BR09 > BB41. The Sips isotherm model has shown a better prophecy of experiments with minimal error and a high correlation coefficient (>0.994) when compared to Toth

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19251939

isotherm model. BR09 followed by BB41 are provided the maximum constant values for sips model when compared to others.

Sorption kinetics

The sorption kinetics of cationic dyes onto GnSB was carried out by varying the dye concentration from 25 to 200 mg/L at optimized operating parameters until the equilibrium condition attained. The experimental kinetic data indicated that the rate of dye sorption capacity was rapid during the initial hours of the contact, followed by slow attainments in equilibrium. This rapid sorption in the early hours is due to the accessibility of the free functional groups on the biochar surface and, thus, a high concentration gradient that inhibits the system (Zhu et al., 2018). In the same manner on varying initial concentrations of BB41 from 25 to 200 mg/L, equilibrium BB41 uptake capacity of groundnut shell derived biochar increased from 11.40 to 81.27 mg/g. By comparing the different cationic dyes, GnSB exhibited the highest uptake of 164 mg/g for BR09 at 200 mg/L, followed by BB41 (81.27 mg/g).

Conclusion

The following conclusions are derived from the present study:

a. The biochar derived from groundnut shell biomass at 350 °C through slow pyrolysis was obtained to be the most operative biosorbent.
b. The biosorption capacity of GnSB was sturdily dependent upon the biochar dosage. Experiment trials show that maximum dye sorption capacity was attained at 2 and 1 g/L of biochar dosage for BB41 and BR09 sorption.
c. The solution pH sturdily influences the sorption capacity of GnSB with a pH value of 8 as an optimal condition for the efficient removal of cationic dyes.
d. The SEM and FT-IR analyses exhibited the presence of various functional groups on the surfaces of GnSB.
e. The sorption equilibrium was attained within 240 min, and the biosorption rate was fast. Application of BB41 and BR09 kinetics data disclosed that pseudo's first-order kinetics is better in prediction than the second-order model.
f. According to the Langmuir model, the maximum biosorption capacity of BB41 and BR09 was identified as 59.888 and 256.219 mg/g for GnSB, respectively.
g. From these results, it can be concluded that biochar derived from Ground Shells could be used as a practical bio-based sorbent for the removal of BB41 and BR09 molecules in wastewater.
h. In the future the study may extend in the use of treated or modified biochar for wastewater treatment.

(Received 19th Nov 2019; accepted 10th Feb 2020)

Abstract. *Sargassum fusiforme* (hijiki) is a popular edible seaweed in some Asian countries. However, it has been shown to have high concentrations of arsenic, mainly the more toxic inorganic arsenic. In this study, we determined the concentration, species, distribution, and absorption kinetics of arsenic (As), and the influence of different exogenous substances on its absorption. Arsenic content in the mature stage of *hijiki* reached up to 84.37 mg/kg dry weight. Inorganic arsenic (iAs) accounted for 68% of the total arsenic, while Arsenate (As (Ⅴ)) accounted for more than 50% of total inorganic arsenic. The contents of arsenic in different *hijiki* organs decreased in the following order rhizoid > stem > leaf > airbag. Subcellular distribution of arsenic in untreated *hijiki* decreased in the order: cell walls > cell organelles > cytoplasm. In *hijiki,* arsenate had a higher absorption rate than arsenite (As (III)), with V_{max} and k_m about 2 times and 3 times those of As (III), respectively. The absorption of As (V) was inhibited by phosphorus, but was not affected by glycerol. The opposite was true in the case of As (III) adsorption. Sodium vanadate significantly increased the efflux of As (V), but had no effect on As (III). Carbonylcyanide-p-chlorophenyl hydrazone (CCCP) and glycerol inhibited the arsenite efflux, but had no influence on arsenate.

Keywords: *arsenic speciation, arsenic distribution, arsenic absorption, influx, efflux*

Introduction

Arsenic is a semi-metal or metalloid which is widely distributed in the environment and it is present in both terrestrial and aquatic systems (Wang et al., 2019). It is a known human carcinogen (Rosen, 2002; García Salgado et al., 2008; Carey et al., 2012). The Agency for Toxic Substances and Disease Registry (ATSDR) ranked arsenic at the top of the substance priority list (ATSDR, 2018). The toxicity of arsenic is especially associated with liver, bladder, lung, and skin cancer (Rose et al., 2007). This element occurs in various chemical forms with different toxicological characteristics in the environment and organisms (Kohlmeyer et al., 2003; Panuccio et al., 2012). Arsenic speciation in the environment is complex and includes both inorganic and organic forms. Inorganic arsenic comprises of arsenate and arsenite. Organic arsenicals include monomethylarsonic acid (MMA), dimethylarsinic acid (DMA), trimethylarsine (TMA), tetramethylarsonium ion (TMA), arsenobetaine (AsBet), arsenocholine (AsCho), and arsenosugars (Kohlmeyer et al., 2003; Quaghebeur et al., 2005). Moreover, inter-conversions between species regulated by both biotic and abiotic processes have been reported (Carey et al., 2012).

Generally speaking, inorganic arsenicals are more toxic than their organic counterparts (Nogueira et al., 2018), and arsenite is much more toxic, soluble, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19411952

mobile than arsenate (Quaghebeur et al., 2005; Raab et al., 2007; Yang et al., 2016). Organic arsenicals such as DMA and MMA usually have lower toxicities. Therefore, determination of arsenic speciation is essential for understanding and evaluating the safety of edible organisms which accumulate arsenic.

Marine algae are usually thought of as "health food" and consumed directly as such. This is because of the nutritional and therapeutic benefits that they provide. *Sargassum fusiforme* (*hijiki*), a brown edible algae (*Phaeophyta, Sargassum*), is traditionally consumed by the Japanese as one of seaweed foodstuffs due to its richness in essential minerals, and dietary fibre content. The total fiber in *hijiki* was much higher compared with other seaweeds, such as *Laminaria japonica*, *Porphyra tenera*, which showed more benefits to human health especially to intestines. (Zheng et al., 2013) However, marine algae have a greater ability to accumulate arsenic and usually have higher arsenic contents than terrestrial organisms (Hanaoka et al., 2006). In terrestrial organisms, the arsenic content rarely exceeds 1 μg/g (dry weight), while it ranges from 1 to 100 μg/g in marine organisms (Ichikawa et al., 2006).

The concentration of arsenic varies in different organisms, as well as its species. In rice, the predominant inorganic arsenic is arsenite, whereas in marine algae, inorganic arsenic is present mostly as arsenate (Kohlmeyer et al., 2003). It has been reported that the arsenic species in marine organisms are usually organic arsenicals such as arsenobetaine and arsenosugars which are forms considered less toxic than the inorganic forms of arsenic (Ichikawa et al., 2010). However, there are exceptions. In *hijiki,* the concentration of iAs is up to 135 mg/kg of dry weight, while the content of inorganic arsenic may range from 50 to 80% of its total arsenic content (Almela et al., 2005; Yokoi et al., 2012). Thus, the high contents of inorganic arsenic in hijiki have raised serious toxicological concerns among consumers in the past decades (Wondimu et al., 2007). Indeed, the Food Inspection Agency of Canada (2001), the UK Food Standards Agency (2004), and similar institutions in other countries, have warned consumers not to eat hijiki (Wondimu et al., 2007; Yokoi et al., 2012).

In this study, we determined the concentration, species, distribution, and absorption kinetics of arsenic, and the influence of different exogenous substances on its absorption.

Materials and Methods

Sample preparation

The research was carried out in the year of 2016. The samples used in this research were cultivated, in Dongtou breeding base of Zhejiang Mariculture Research Institute (Dongtou County, Zhejiang Province, China), under natural conditions. In order to track the changes of arsenic content in hijiki, we took samples at monthly interval from January to May, that was cover the growth period of hijiki from seedling to maturity. There were two varieties of hijiki were sampled. Fresh weight of the native species (250 g of whole plant) was sampled monthly, whereas 250 g of each Korean sample (whole plant) was collected from January to March. Three separate samples were collected each time. The samples were washed in seawater, kept in plastic bags, and immediately transported to the laboratory. All samples were then washed with tap water, followed by washing three times in ultra-pure water. Thereafter, each sample was freeze-dried to a constant mass and ground to homogenous powder before use. For the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19411952

study of arsenic distribution, different organs (stem, leaf, air sac and rhizoid) were separated before freeze-drying, and then ground to homogenous powder.

Determination of total arsenic in hijiki (S. fusiforme) and different hijiki organs

Milled sample of *hijiki* (0.2 g) was added to 6 ml concentrated nitric acid. The mixture was left for 12 h, and then digested in a MARS 5 microwave oven. Each sample was digested in triplicate. The following conditions were used in the microwave digestion which was modified by Han et al. (2009): the temperature was increased to 120°C in 5 min, held for 5 min, then increased to 160°C in 5 min, kept constant for 20 min, and finally increased to 180°C for 20 min. After dilution and filtering, the digest was brought to a final volume of 25 ml with ultra-pure water. Then, total arsenic was measured using hydride generation-flame atomic absorption spectrometry (HVG-FAAS).

Determination of inorganic arsenic

The inorganic arsenic was extracted in accordance with the procedure of National Standards of China (National Food Safety standard, 2003).

Hijiki powder (1.00 g) was weighed into a 25 ml test tube, and 20 ml of 50% (v/v) hydrochloric acid was added. The mixture was kept in a water bath at 60°C for 18 h, during which time it was shaken several times in order to complete the extraction. On cooling to room temperature, the solution was filtered, and 1 ml potassium iodide (10% m/v) - thiocarbamide (5% m/v) was added to 4 ml of the filtrate. The volume of the solution was made up to 10 ml with ultra-pure water. Inorganic arsenic was determined using HVG-FAAS.

Determination of arsenic speciation

Arsenic speciation was determined using the method referred to in the manufacturer's manual of the SA-10 Atomic Fluorescence Speciation Analyzer. Each *hijiki* sample was weighed (0.5 g) and put in a test tube, 4 ml of 10% (v/v) HCl was added. Then, the sample was spun at 100 rpm in a water bath at 70°C for 1 h, and 4 ml of ultra-pure water was added. The mixture was warmed in a water bath at 70°C for 1 h, and centrifuged at 3000 rpm for 15 min. The supernatant (2 ml) was mixed with 2 ml 20% (v/v) hydrogen peroxide and put into a water bath at 70°C for 20 min. Thereafter, the mixture was filtered through a 0.45 μm filter membrane before injection into a chromatographic column. The speciation was analysed using SA-10 Atomic Fluorescence Speciation Analyzer (SA-10 AFSA). Triplicate analyses were performed for each sample.

Subcellular distribution of arsenic in hijiki

Fresh sample (0.5 g) and samples treated with 5 μmol/L and 50 μmol/L A sodium arsenate (As) for 24 h were used for subcellular distribution experiments. The samples were homogenized with precooled homogenate, and all homogenization and separation processes were carried out on ice. The total volume of homogenate and tissue was controlled at about 20 ml. The homogenate was transferred into a 50-ml centrifuge tube, and ultrasonic cell breaker was used for ultrasonic crushing. Thereafter, it was centrifuged in a high-speed freezing centrifuge for 30 sec at 300 g, and the precipitate (cell wall component) was collected. The supernatant was centrifuged in a high-speed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19411952

freezing centrifuge for 45 min at 20000 g. The bottom debris contained the cytosolic organelles, while the supernatant was the cytosolic portion containing macromolecular organic matter and inorganic ions in the cytoplasm and vacuole. Each of the portions from centrifugation was subjected to microwave digestion, and the content of arsenic was determined as described earlier.

Kinetics of arsenic uptake by hijiki

Fresh *hijiki* samples were cleaned with ultra-pure water and dried with absorbent paper. About 15-g samples of *hijiki* were weighed and put in 0.5 L artificial seawater with different concentrations of arsenate or arsenite (0, 10, 20, 40, 60 and 80 μmol/L), each of which was repeated 3 times. After 30 min of treatment, all samples were soaked in phosphate buffer solution (1 mmol/L K_2HPO_4, 5 mmol/L MES, 0.5 mmol/L $CaCl_2$, pH 6.0) for 10 min to wash off the As on the surface (Xu et al., 2007). Then, samples were washed with ultra-pure water, and the surface water was removed with absorbent paper, followed by drying. Finally, the arsenic content was determined as described earlier.

Arsenic influx and efflux in hijiki

This experiment was used to determine if arsenate and arsenite are taken up via the P and aquaporin transporters, respectively. The effect of P ($K_2HPO_4 \cdot 3H_2O$) and glycerol on arsenic influx were investigated. Shoots of the plant (about 15 g) were subjected to three treatments: control (50 μmol/L sodium arsenate As (Ⅴ) or sodium arsenite As (Ⅲ) solution +100 μmol/L P ($K_2HPO_4 \cdot 3H_2O$) or + 20 mmol/L glycerol. After treating for 1 h, the samples were immersed in 1 mmol/L K_2HPO_4 solution containing 5 mmol/L MES and 0.5 mmol/L $CaCl_2$, pH 6.0, in ice bath for 10 min to wash off the surface As (Xue et al., 2012). Then, the samples were washed and dried to constant weight, and ground into powder. The arsenic content was determined after microwave digestion.

The metabolic inhibitor carbonyl cyanide m-chlorophenylhydrazone (CCCP), P-type ATPase inhibitor sodium vanadate, and glycerol were used to investigate whether the efflux of As by *hijiki* followed the same transport pathway as its influx. The samples of *hijiki* treated with 50 μmol/L arsenate As (V) or arsenite As (III) for 24 h were soaked in 1 mmol/L K_2HPO_4 solution containing 5 mmol/L MES and 0.5 mmol/L $CaCl_2$, pH 6.0, in ice bath for 10 min (Xue et al., 2012). Then the samples were cleaned and divided into 4 groups, and exposed to fresh artificial seawater with different treatments: control (artificial seawater), 1 μmol/L CCCP, 200 μmol/L sodium vanadate, or 10 mmol/L glycerol. After 2 hours of treatment, 25 ml water samples were taken from each group, and the arsenic content was determined after filtration with 0.45 μmol/L microporous membrane.

Triplicate analyses were performed for each sample. The final results were expressed in mean±SD.

Results

Total and inorganic arsenic contents

The total and inorganic arsenic contents at different growth stages of the two *hijiki* varieties (Chinese and Korean) are shown in *Table 1*. The total arsenic concentration varied from 35.05 to 84.37 mg/kg (dry weight) at different growth stages from January

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19411952

to May. With growth of the seaweed, the total arsenic concentration increased. The variation in the levels of inorganic arsenic was in accord with that of total arsenic concentration, varying from 24.21 to 58.00 mg/kg dry weight. Thus, the arsenic concentration in the two hijiki varieties increased with growth.

Table 1. *Arsenic contents at different stages of growth of two Sargassum fusiforme varieties*

Stage of growth	Native variety			Korean variety

t-As: total arsenic. i-As: inorganic arsenic. percentage of i- As: percentage of inorganic arsenic. ND: not determined. Data are expressed in mg/kg dry weight, and are mean of triplicate assays. The final results were expressed in mean±SD

The percentage of inorganic arsenic varied from 68.74 to 86.31% in the native variety. In general, in native *hijiki*, the percentage of inorganic arsenic decreased with growth. This trend was close to those reported previously i.e. 69 to 72% (Rose et al., 2007).

Arsenic contents in different hijiki organs

The arsenic contents of different *hijiki* organs showed a lot of variation. The arsenic levels in the rhizoid, leaf, air sac and stem were 31.92, 27.23, 20.66 and 14.66 mg/kg dry weight, respectively. These results are shown in *Figure 1*.

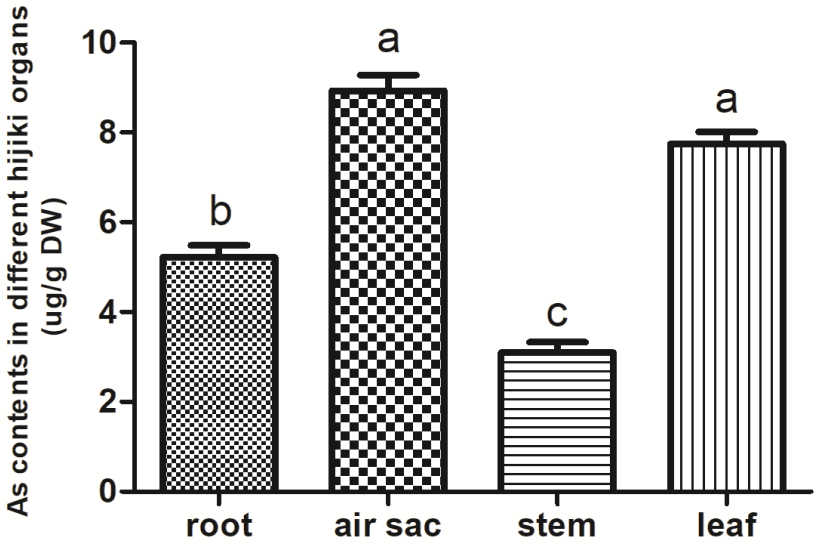

Figure 1. *Arsenic contents in different organs of Sargassum fusiforme*

DOI: http://dx.doi.org/10.15666/aeer/1801_19411952

Subcellular distribution of arsenic in hijiki

The subcellular distribution of arsenic in *hijiki* is shown in *Figure 2*. The results showed that the subcellular distribution and compartmentalization of arsenic in *hijiki* differed greatly. In the untreated *hijiki*, the content of arsenic decreased in the order: cell wall > organelle > cell fluid, accounting for 48, 33 and 19% of total arsenic, respectively. However, the arsenic content in each component of *hijiki* increased after 5 and 50 μmol/L arsenic treatment. After 5 μmol/L sodium arsenate treatment, the order of arsenic content was: cell wall > cell fluid > organelle, accounting for 53, 24 and 23% of the total, respectively. After 50 μmol/L As treatment, the content of arsenic in each part was in the order of cell wall > cell fluid > organelle, accounting for 51, 11 and 38% of the total, respectively. The content of arsenic varied in the order of cell wall > cell fluid > organelle after treatment with 5 μmol/L As and 50 μmol/L As, with highest proportion of arsenic in cell wall. Moreover, the increment in arsenic level in cell wall was the largest after 5 μmol/L As treatment, but the increment of arsenic in cell fluid was the largest after 50 μmol/L As treatment. Thus, the increase in arsenic was mainly concentrated in the cell wall of *hijiki* under low concentration of arsenic, while the increase in arsenic was mainly concentrated in the cell fluid after treatment with high concentration of arsenic.

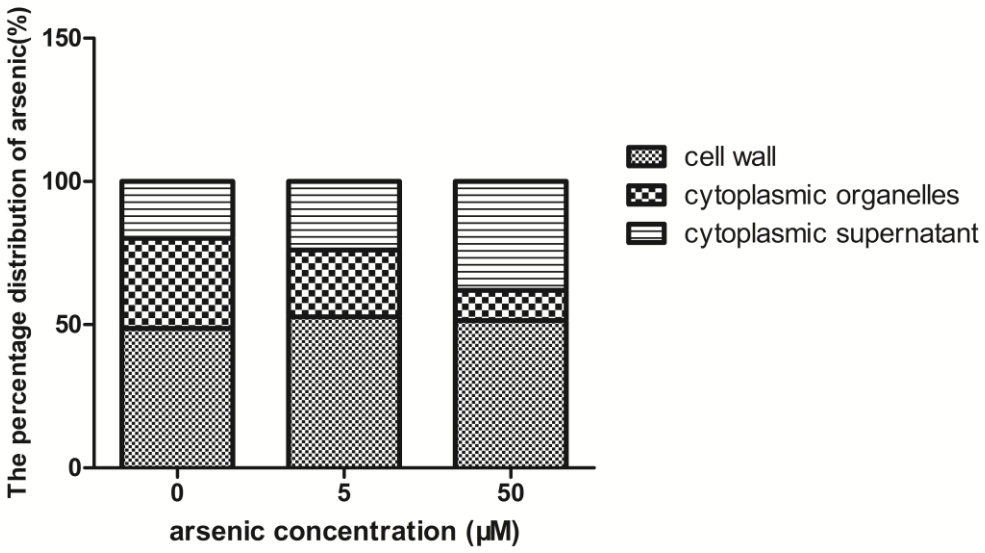

Figure 2. *Subcellular distribution of arsenic in Sargassum fusiforme*

Results of arsenic speciation analysis

The species of arsenic were determined with SA-10 Atomic Fluorescence Speciation Analyzer. The contents of arsenic species in each growth stage of the two *hijiki* are shown in *Table 2*. In this study, the extraction efficiency ranged from 75 to 90%. Irrespective of the growth stage, inorganic arsenic (especially arsenate) was always the main form of arsenic present, accounting for about 77 to 88% of the total arsenic.

The contents of four arsenic species decreased in the order: AsV > AsIII > DMA > MMA. The organic arsenic content was negligible: the DMA and MMA contents were 1 - 4% and 1 - 3% of the total arsenic, respectively.

Native: native *hijiki* variety. Korean: Korean *hijiki* variety. t-As: total arsenic. As (Ⅴ): arsenate. As (Ⅲ): arsenite. DMA: dimethylarsinic acid. MMA: monomethylarsonic acid. Results expressed in mg/kg dry weight and as mean of triplicate assays

Kinetics of arsenic uptake

The results showed that with increase in As concentration, arsenic absorption increased gradually, and the trivalent arsenic tended to be stable when the arsenic concentration reached 20 μmol/L. The absorption of the pentavalent arsenic tended to be stable after the arsenic concentration reached 60 μmol/L (*Figure 3*). The kinetics of arsenic and arsenate were in accord with the Michaelis–Menten equation, with R^2 values of 0.9744 and 0.9624 for arsenic and arsenate, respectively. The V_{max} for arsenate uptake (1202 ng/g DW min) was about twice that of arsenic uptake (619 ng/DW min). The K_m value of arsenate (12.91 μmol/L) was about three times that of arsenic (4.591 μmol/L).

DOI: http://dx.doi.org/10.15666/aeer/1801_19411952

Arsenic influx and efflux in hijiki

After treatment with 50 μmol/L As for 1 h, the contents of arsenic and arsenate in *hijiki* were 61.8 and 39.9 μg/g dry weight, respectively. The absorption of arsenic was significantly higher than that of arsenate, about 1.5 times higher. The absorption of arsenate was obviously inhibited by phosphorus, while arsenic was not inhibited by phosphorus. Although glycerol inhibited the absorption of arsenic, it had little effect on the absorption of arsenate (*Figure 4*). In the control group, the amount of arsenic in *hijiki* was slightly higher than that of arsenate. After CCCP, sodium vanadate and glycerol were added to the solution. Sodium vanadate significantly increased the efflux of arsenate, but it had no effect on the efflux of arsenic. Treatment with CCCP and glycerol inhibited the efflux of arsenic, but there was no significant difference between them, and they had little effect on the efflux of arsenate (*Figure 5*).

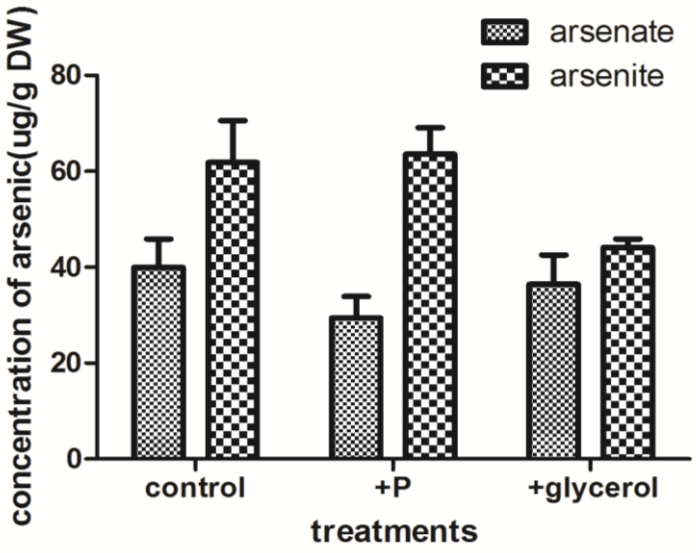

Figure 4. *Influence of P (100 μmol/L) and glycerol (20 mmol/L) on the uptake of arsenate and arsenite*

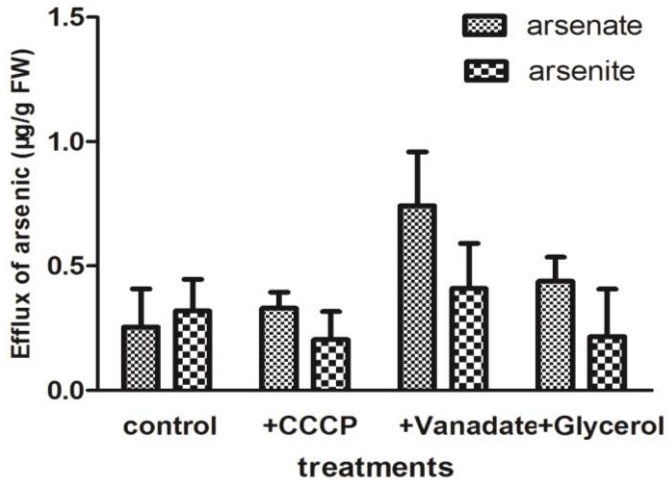

Figure 5. *Effects of CCCP (1μmol/L), sodium vanadate (200 μmol/L), and glycerol (10 mmol/L) on the efflux of arsenate and arsenite*

Discussion

Several studies have reported total and inorganic arsenic contents in seaweeds. A study on a wide variety of seaweeds found that the concentrations of total arsenic varied from 2.2 to 149 mg/kg dry weight, and that the total arsenic content was related to the type of seaweed, decreasing in the order: brown seaweed > red seaweed > green seaweed (Almela et al., 2002). The arsenic contents of *hijiki* were especially high (68.3 to 149 mg/kg dry weight), as had been reported in the literature, which indicated that it could attain 179 mg/kg dry weight (Almela et al., 2002, 2006; Rose et al., 2007; Hamano-Nagaoka et al., 2008; Yokoi et al., 2012). Thus, the contents detected in the present study were high, but were still low, when compared to values reported in other studies. In the organs, the levels decreased in the order: rhizoid > leaf > air sac > stem. Since rhizoid is an inedible part of *hijiki*, this result suggests that *hijiki* with more stem and leaves than air sac should be selected.

In this research, the total arsenic content of the native *hijiki* was always higher than that of the Korean *hijiki.* These results differ from those of Ichikawa (2006), in which the ranges of total arsenic concentrations in *hijiki* gathered from the shores in Japan, South Korea, and China were 41.7- 46.7, 65.6 - 79.8, and 36.0 - 48.6 mg As/kg, respectively. Besides, arsenic concentrations in *hijiki* grown in gulfs were higher in than those in *hijiki* grown in coastline of open sea. This may have been influenced by lower pollutant concentrations and increased circulatory flow in the coastline of open sea. However, the arsenic concentrations in *hijiki* increased with growth. In this study, we also detected the arsenic content in the seawater from where the *hijiki* planted. The results showed that the content of arsenic in seawater is very low (1-7 ug/L). So we think that the arsenic contents in *hijiki* were not consistent with that in the seawater. The high content of arsenic in *hijiki* is not caused by the amount of arsenic in seawater. This may indicate that the accumulation of high arsenic content in *hijiki* was not caused by the arsenic content of seawater but by the high ability of arsenic absorption of hijiki.

Marine organisms have been examined extensively for arsenic species in recent decades. Marine animals contain mainly arsenobetaine, and nearly no MMA, DMA, TMA, AsCho, or TMAs (Kohlmeyer et al., 2003). Arsenosugars and arsenobetaine have been found in bivalves (Lai et al., 2001). In fish, there is hardly any inorganic arsenic or arsenosugars but trimethylarsoniopropionate has been detected in fish muscle (Francesconi et al., 2000). Many scholars have reported that the main arsenic species in *hijiki* is arsenate, and the level can reach approximately 65% of the total arsenic (Kohlmeyer et al., 2003; Raab et al., 2005; Hanaoka et al., 2006; Ichikawa et al., 2006; Hamano-Nagaoka et al., 2008). Park et al. (2019) also found that arsenate was the predominant arsenic species in *hijiki,* accounting for approximately 60% of the total arsenic content. These are similar to the results of this study, although the proportion of arsenate was greater (77 to 88%): the proportion of arsenite was between 10 to 20%. The concentration of organic arsenic was low, the DMA content being just 1 to 4% of the total arsenic present, and the MMA content was much smaller. These data are in agreement with the findings of Ichikawa et al. (2006).

In this study, after treatment with 50 μmol/L arsenic and arsenate for 1 h, the content of arsenate in *hijiki* was higher than that of arsenic. Compared with arsenic, arsenate had higher V*max* and smaller K_m value in *hijiki*, and the absorption of arsenate was higher than that of arsenic. Compared with other aquatic plants such as *Azolla caroliniana, Azolla filiculoides* and *Ceratophyllum demersum*, *hijiki* has higher degree of absorption and lower K_m value for arsenate (Xue et al., 2012). This also shows that *hijiki* has a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19411952

transport system with high affinity for arsenate. In the study of Xue et al. (2012), the V_{max} values of arsenic and arsenate in *C. demersum* were 214 and 128 nmol/L/g DW min, respectively, which were lower than that in *hijiki.* The K_m values of arsenic and arsenate in *C. demersum* were 18 and 120 μmol/L, respectively, which were about 1.5 and 25 times, respectively higher than that of *hijiki.* Compared with *C. demersum, hijiki* had higher affinity for arsenic and arsenate.

Phosphorus and arsenic are homologous elements. The chemical properties of phosphate and arsenate are similar. Therefore, in higher plants, arsenate enters plants by sharing the same uptake and transport protein with phosphate (Asher and Reay, 1979). The absorption process is mainly completed by the coordinated transport of arsenate or phosphate ($H_2PO_4^-/H_2AsO_4^-$) and protons. The results of this study also showed that the absorption of arsenic in *hijiki* was inhibited by P in the environment, indicating that As and P share the same absorption channel in *hijiki*. Some plants can adjust the expression of phosphate transporters to reduce the absorption of arsenate, thereby adapting to the high concentration of arsenic pollution in soil (Meharg and Hartley Whitaker, 2002).

Unlike arsenate, the absorption of arsenic is not affected by phosphate. Arsenic has been shown to be able to enter the cell through water channel proteins in many plants (Meharg and Jardine, 2003; Zhao et al., 2009). Xue et al. (2012) found that the absorption of arsenate by *C. demersum* was significantly inhibited by P ($K_2HPO_4 \cdot 3H_2O$) in solution, but was not inhibited by glycerol and Sb ($C_4H_4KO_7Sb \cdot 1/2H_2O$) in solution, while the absorption of arsenic was the opposite. This also shows that the uptake of arsenate in *C. demersum* shares the same transport protein with phosphate, and arsenic can enter the cells of *C. demersum* through water channels. In this study, it was found that the absorption and efflux of arsenic in *hijiki* were inhibited by glycerol, which is consistent with the previous results for *Saccharomyces cerevisiae* and rice (Wysocki et al., 2001; Meharg and Jardine, 2003). It can also be concluded that, like other plants, arsenate is mainly transported in and out of cells by active transport, while arsenic is mainly transported in and out of cells by passive transport.

Conclusion

Overall, the results support the view that *hijiki* has a high concentration of inorganic arsenic. The dominant arsenic species in *hijiki* was found to be arsenate. To guarantee public food safety, besides warning people not to eat *hijiki,* future research into the selection of a *hijiki* variety which accumulates less arsenic, such as the Korean *hijiki* studied here, is recommended. Moreover, it is important to select a variety which has more leaves and stem instead of varieties with more air sacs. Harvesting *hijiki* a little earlier may also be a way of ensuring decreased accumulation of arsenic.

Research on the absorption and metabolism of arsenic can help in understanding of the mechanism of arsenic uptake and transport. This study lays the foundation for As control technology in *hijiki,* and is important for the safety of edible *hijiki,* and the development of *hijiki* industry. But what does the mechanism of arsenic absorption in *hijiki*? How to reduce the arsenic absorption of *hijiki*? These are all issues that need further study in the future.

Abstract. Tropical and subtropical regions have seen an alarming increase in vector-borne diseases especially tick-borne diseases. Ehrlichiosis is one of the most important vector-borne disease from a zoonotic perspective and it can be even more lethal in dogs and humans a compromised immune system. This study was conducted to determine the prevalence and molecular characterization of *E. canis* in Van province of Turkey. A total of 387 blood samples were collected from dogs in Van veterinary clinics in 2019. Extracted DNAs were run through Nested PCR using the appropriate primers. A total of 79 samples out of 387 were *E. canis* positive at 389 bp revealed by Nested PCR. Sanger method was used for DNA sequencing of two selected positive samples. Phylogenetic analysis revealed that relevant amplicon was 100% compatible with 16S RNA gene isolated from *E. canis* in many geographical regions.
Keywords: *ehrlichiosis, molecular characterization, Nested PCR, phylogenetic analyses, prevalence, tick*

Introduction

Tick-borne diseases in cats and dogs have seen an upward trend in recent years posing public health risks especially for those having close contact with their pets (Claerebout et al., 2013; Maia et al., 2014). Tick-borne bacterial and protozoal infections affect the dogs in many parts of the world depending on the distribution of vectors (Aktas et al., 2015). Ehrlichiosis is a zoonotic disease mentioned at the top of list and its pathogenicity becomes more lethal in immunocompromised dogs and humans (Perez et al., 2006). Ehrlichia sp. are obligate intracellular parasites infecting the blood cells. The etiologic agent of canine monocytic ehrlichiosis (CME) is *E. canis* should be resides in canine monocytes and macrophages. Depending on the immune status of the host, CME may be asymptomatic or symptomatic causing severe anemia, leukopenia, thrombocytopenia, fever, and even death especially in dogs with poor immunity (Kakoma et al., 1994; Mathew et al., 1996; Oliveira et al., 2019). Vector-borne diseases especially those involving ticks as vectors are highly prevalent in tropical and subtropical regions (Springer et al., 2019). To date, DNAs of *E. chaffeensis*, *E. ewingi*, and *E. muris* have been isolated from canine blood from South Central United States, Europe and Costa Rica

DOI: http://dx.doi.org/10.15666/aeer/1801_19531960

(Skotorczak, 2003; Little et al., 2010; Springer et al., 2019). In our previous study, *E. canis* was identified in the ticks collected from stray dogs in Van region of Turkey (Ayan et al., 2019). However, the prevalence and molecular characterization of *E. canis* in stray dogs were not carried out in Van province. Therefore, the present study was conducted to determine the prevalence and molecular characterization of *E. canis* in stray dogs in the Van province, Turkey so that proper strategies may be devised to control the infection.

Materials and Methods

Collection of samples

Blood samples were collected in EDTA vacutainers from 387 stray dogs presented at three veterinary clinics (Kent Veterinary Clinic (121 samples), Cetin Veterinary clinics (129 samples), and Tamara Pet Veterinary clinic (137 samples)) in central Van in 2019 as shown in *Figure 1*. Blood samples were transported to the laboratory in cold chain at -20ºC for further analysis.

Figure 1. *Map of Turkey showing the localities of the investigation area for collection Ehrlichia canis from dogs. In 2019, 387 specimens were collected from 3 veterinary clinics in Van centre in Van province of Turkey*

DNA extraction

Extraction of DNA from each blood sample was carried out using Invitrogen PureLink™ Genomic DNA Mini Kit (USA, K182002) according to the procedure outlined in the kit protocol. Extracted DNAs were stored at -20ºC until PCR amplification.

PCR amplification

The 16S rRNA gene region of *E. canis* was amplified using nested PCR. The first amplification primers: ECC (5′ AGAACGAACGCTGGCGGCAAGC-3′) and ECB (5′ CGTATTACCGCGGCTGCTGGCA-3′). The second amplification primers: ECAN5 (5- CAATTATTTATAGCCTCTGGCTATAGGA-3′) and HE3 (5′-TATAGGTACCGTCATTATCTTCCCTAT-3′) (Murphy et al., 1998; Alves et al., 2014;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19531960

Makino et al., 2016). For this purpose, each reaction contained 12.5 pmol forward primer, 12.5 pmol reverse primer, 0.625 U of HOT FIREPol DNA polymerase (Solis BioDyne, Tartu, Estonia), 1X PCR Buffer (Solis BioDyne, Tartu, Estonia), 1 mM $MgCl_2$ (Solis BioDyne, Tartu, Estonia), 120 µM dNTP (Solis BioDyne, Tartu, Estonia), extracted DNA samples (50-200 ng) and DNase/RNase Free Distilled Water (Gibco Thermo Fisher Scientific, Waltham, MA USA) were mixed to make a final volume of 25 µL. PCR was performed in Eppendorf Mastercycler® pro automatic thermal cycler. In the first stage of Nested PCR: 95°C for 15 min and 37 cycles of 95°C for 1 min and 30 seconds, annealing at 55°C for 1 min and 30 seconds and 72°C for 1 min and 30 seconds, followed by a final extension 72°C for 10 min. In the second stage of Nested PCR: 95°C for 15 min and 40 cycles of 95°C for 1 min, annealing at 65°C for 1 min and 72°C for 1 min, followed by a final extension 72°C for 10 min. The amplified products were separated on a 1.5% agarose gel and visualized by Safe-T stain (BioShop, Canada) staining under imaging system (Syngene Bio Imaging System).

DNA sequencing and phylogenetic analysis

Two positive samples, confirmed by PCR, were selected at random and DNA (forward and revers) sequence was determined according to the Sanger sequencing method. Forward and reverse sequences of each sample were compared using the Bioedit Sequence Allignment Editor Program (Hall, 1999). Finally, the resulting DNA sequences were compared with the similar sequences in NCBI database using BLAST. The evolutionary history was inferred by using the Maximum Likelihood method based on the Kimura 2-parameter model (Kimura, 1980). The tree with the highest log likelihood (-951,11) is shown. The percentage of trees in which the associated taxa clustered together is shown next to the branches. Initial tree(s) for the heuristic search were obtained automatically by applying Neighbor-Join and BioNJ algorithms to a matrix of pairwise distances estimated using the Maximum Composite Likelihood (MCL) approach, and then selecting the topology with superior log likelihood value. A discrete Gamma distribution was used to model evolutionary rate differences among sites (5 categories (+G, parameter = 0,1908)). The tree is drawn to scale, with branch lengths measured in the number of substitutions per site. The analysis involved 15 nucleotide sequences. All positions containing gaps and missing data were eliminated. There were a total of 362 positions in the final dataset.

Evolutionary analyses were conducted in MEGA X (Kumar et al., 2018).

Ethical considerations

All the procedures involved in the study were approved by the local ethics committee of Van Yuzuncu Yil University, Van, Turkey vide letter no. VAN YUHADYEK/2019/10 dated 31 October 2019.

Results

In the first stage of nested PCR, *Ehrlichia* spp. specific bands of 458 bp were obtained. Nested PCR revealed that *E. canis* specific 389 bp bands were obtained in 79 of 387 samples Agarose gel images for amplicons of each samples in the PCR shows in *Figure 2*.

The results showed that a 20.41% positivity of *E. canis* detected in Van province. Two of the 79 samples were randomly selected for sequence analysis. The DNA sequences

DOI: http://dx.doi.org/10.15666/aeer/1801_19531960

obtained from Sanger sequencing were 100% compatible with the *E. canis* specific 16S rRNA gene in NCBI database. The sequences of two positive samples obtained from Bioedit Sequence Allignment Editor program were 359 bp and 367 bp, respectively. The tree with the highest log likelihood (-943.20) is shown. The percentage of trees in which the associated taxa clustered together is shown next to the branches. Initial tree(s) for the heuristic search were obtained automatically by applying Neighbor-Join and BioNJ algorithms to a matrix of pairwise distances estimated using the Maximum Composite Likelihood (MCL) approach, and then selecting the topology with superior log likelihood value. The tree is drawn to scale, with branch lengths measured in the number of substitutions per site. The analysis involved 16 nucleotide sequences. All positions containing gaps and missing data were eliminated. There were a total of 357 positions in the final dataset. Phylogenetic analysis of *E. canis* in dogs from Van province of Tukey showed that there were no genetic differences between the two samples based on the relevant amplicons as shown in *Figure 3*.

Discussion

Tick-borne diseases, a cosmopolitan problem resulting in subclinical or severe infections in their hosts, are increasingly affecting the public and animal health around the globe (Hofmann-Lehmann et al., 2016). Zoonotic importance of canine tick-borne pathogens has increased in the recent years as dogs play a major role as reservoir host, Ehrlichiosis being one of those diseases (Ozubek et al., 2018). In the present study, the prevalence of *E. canis* in dogs in Van province was investigated on a molecular basis. At the end of the study, *E. canis* DNA was detected in 79 (20.41%) of 387 blood samples collected. This is the first report that describes the molecular detection of Ehrlichiosis in dog populations in Van, Turkey. Previous studies have reported the prevalence of *E. canis* in dogs in different parts of Turkey and the world alike, including some reports investigated the prevalence based on molecular studies. According to the molecular studies conducted in Turkey, the prevalence of *E. canis* 23 out of 219 blood samples in Diyarbakır was (10.5%) (Ozubek et al., 2018), *E. canis* was not detected in 133 samples from Konya (Guo et al., 2017), 58 out of 400 blood samples in Kayseri was (14.5%) (Duzlu et al., 2014), 37 out of 757 samples collected from different provinces (Elazığ, Diyarbakır, Erzurum, Ankara, Nevşehir, Adapazarı, İzmit, Mersin, Giresun, İzmir) was 4.9% (Aktas et al., 2015), 47 out of 400 blood samples in Thrace was 11.75% (Cetinkaya et al., 2016), 3 out of 12 dogs with clinical symptoms in Ankara (Unver et al., 2005). Similarly, Hofmann-Lehmann et al. (2016) reported that 14 out of 249 blood samples collected from Sicily (Italy) and Portugal were *Anaplasma platys* and *E. canis* positive whereas the DNA of *E. canis* was not detected in samples from Swirzerland, Spain, and Terasa and Bologna regions of Italy. In addition, Cardoso et al. (2016) reported *E. canis* in 5.8% of 103 blood samples in Luanda region of Angola and Alho et al. (2017) found *E. canis* in 3.1% of 64 blood samples in Qatar. In contrast, *E. canis* DNA was not found in 97 blood samples collected from Iraq (Otranto et al., 2019). In this study, Ehrlichia infection in Van, Turkey was found to be 20.41% prevalent that is high. There may be different reasons underlying the high prevalence of related infections in the region. Inadequate external parasite spraying in dogs and the presence of *R. sanguineus* in the region can be considered as the main reasons for the high prevalence of Ehrlichiosis. The importance of this disease is increasing all over the world including Turkey. It is noteworthy that global warming, environmental and ecological changes, and the existence of appropriate habitats increase the impact of ticks that results in frequent emergence and re-emergence of tick-borne diseases of zoonotic importance (Inci et al., 2016).

Vector hemoparasites can be diagnosed by examining the clinical signs and blood staining methods, however, diagnostic may arise attributed to the similarities in symptoms and microscopic structures of the etiologic agents. Consequently, test based on serological and molecular techniques should be preferred in order to diagnose the hemoparasites. Nonetheless, it becomes difficult to extricate between current and previous exposure to pathogens that might result in false negative results in case of acute ehrlichiosis. Therefore, diagnosis based on molecular tests is the best option (Neer et al., 1998; Little et al., 2010; Aktas et al., 2015; Springer et al., 2019). The most common method used to diagnose ehrlichiosis is one-step PCR analysis to amplify the 16S rRNA gene region, however, its sensitivity is low. Therefore, diagnosis through Nested PCR increases the sensitivity and is more relaiable (Bulla et al., 2004; Macieira et al., 2005; Nakaghi et al., 2008; Santos et al., 2009). However, non-specific amplification among the strains of Ehrlichia species due to highly conserved 16S rRNA gene and higher risk of DNA cross-contamination are inevitable in this method (Labruna et al., 2007).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19531960

Consequently, the sequencing and phylogenetic analyses are important so as to prove the accuracy of the results in addition to identify the molecular similarity among the species (Sumner et al., 2000).

E. canis, a proteobacter that causes ehrlichiosis, possess a 16S rRNA gene consisting of 1380 bp in size. In our study, we identified and amplified a gene of 390 bp in size that is repeatedly employed in the molecular diagnosis of *E. canis*. The DNA sequence analysis of the region revealed the identification of a subtype of *E. canis* that is distributed in different geographical regions. The DNA sequence analysis of our *E. canis* DNA samples showed 100% similarities with those of NCBI database isolated from *E. canis* in different geographies such as Elazığ/Turkey (Accession number: KY594915), Panama (Accession number: MF789353), Egypt (Accession number: MG564257), Romania (Accession number: MG241317), India (Accession number: MF706367), Mexico (Accession number: MG029071), and Brazil (Accession number: MF153962). All genomic analysis is possible using new generation sequencing technologies along with the identification of new or unknown subtypes of proteobacter *E. canis*.

Conclusion

In conclusion, this molecular study confirmed the presence and prevalence of *E. canis* in dogs in Van province of Turkey. This shows that Ehrlichiosis in dogs in this region may pose threats to public health especially in immunocompromised people. We believe that the density of dog population and lack of effective control of ticks especially in stray dogs are the possible predisposing factors for this high prevalence of ehrlichiosis in dogs in Van, Turkey. In order to determine the zoonotic potential of ehrlichiosis, it is necessary to compare the genetic factors and genetic proximity of ehrlichiosis in humans with that of dogs. As the tick-borne diseases are increasing around the globe, we believe that the control of ticks in domestic animal and effective treatment of animals infested with ticks will be key to preventing tick-borne diseases. Since the Van province shares its border with Iran, ticks and tick-borne diseases in this region have potential to create an international problem. In addition, changing climatic conditions and human migration have created variability especially in vectors of vector-borne diseases. Therefore, further studies in this area should not only focus *R. sanguineus*, but also other tick species by molecular methods. In addition, scientists in the countries sharing the border in the region should carry out joint and collaborative studies especially in terms of vector diseases and the molecular proximity of the agents should be demonstrated.

Abstract. In this study, we selected karst areas of rocky desertification in southern China as a subject analyze the nutrient transport patterns of the plant–litter–soil continuum and the effect of soil environmental factors on plant stoichiometry in two areas: potential-mild and moderate-severe rocky desertification. The results show that (1) the carbon (C), nitrogen (N), and phosphorus (P) contents of plant leaves in karst areas are higher than those of litter or soil; (2) the plant leaves have a high C storage capacity, P sufficiency, and N deficiency; and (3) the Monte Carlo test of eight soil environmental factors showed that the influences of soil environmental factors on plant stoichiometry vary with the level of rocky desertification. In the area of potential-mild rocky desertification, soil pH, TP, C:P, and SOC were the main driving factors. In the area of moderate-severe rocky desertification, soil TP, TP, C:N, and SWC were the primary driving factors. The comprehensive analysis can provide a theoretical basis for nutrient transport and soil environmental factor regulation in areas with different levels of rocky desertification. It is necessary to target the primary factors for fertilization management and nutrient transport protection in future rock desertification control.
Keywords: *ecosystem, rocky desertification degree, nutrient cycling, environmental factor*

Introduction

The karst region in southern China, centered in Guizhou, is one of the three continuous karst distribution centers in the world and one of China's four ecologically fragile areas, making it the nation's key ecological development hinterland and poverty alleviation core area (LeGrand, 1973; Sheng et al., 2015; Wang et al., 2016a; Wang et al., 2016b). The karst rocky desertification ecosystem has low environmental capacity and poor anti-interference ability and is thus vulnerable to disruptions in ecological security and regional economic and social development (Xiong et al., 2016). Since the 1990s, a large number of vegetation restoration projects have been carried out in the region to promote the comprehensive management of rocky desertification, but the artificial vegetation ecosystem constructed is monotonous in structure and poor in stability, making it ill equipped to mitigate the ecological problems caused by the ecological environment with its shallow and noncontinuous soil layer and poor water conservation capacity (Zeng et al., 2015). Under intensive interference by human activities, natural secondary forests dominated by viny and thorny shrubs and scrub-grassland were formed (Zhong et al., 2018). Therefore, vegetation restoration and reconstruction are a necessary measure for the control of karst rock desertification.

Ecological stoichiometry is a discipline that studies the balance between important elements, such as carbon (C), nitrogen (N), and phosphorus (P), in ecosystem interactions (Zhao et al., 2019). Plant stoichiometric characteristics can characterize the plant's ability

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19611979

to maintain internal stoichiometric stability while reflecting its adaptability to environmental changes (Sterner and Elser, 2002; Elser et al., 2010). In this way, they can provide the basis for the equilibriums of energy and chemical elements of the ecosystem as well as the structure and function of the ecosystem and soil nutritional diagnosis (Elser et al., 2000; Zhao et al., 2016). In the past, the characterization of stoichiometric characteristics has been focused on individual components of the ecosystem (e.g., soil, vegetation, or litter) or plant organs (plant leaves or fine roots, etc.) (Pena-Claros, 2003; Wu et al., 2010; Wang et al., 2011). Some other studies only examined the differences in stoichiometric characteristics and their intraspecies variation in different succession stages and during seasonal changes. These studies demonstrated that the stoichiometric characteristics of C, N, and P of plant leaves vary with vegetation type, functional group, and species (Sterner and Elser, 2002; Agren, 2004; Reich, 2003), but they rarely addressed the comprehensive situation of the community composed of trees, shrubs, and grasses and thus failed to integrate ecosystem components or comprehensively characterize the stoichiometric characteristics by taking into account environmental factors (Hu et al., 2014; Cao et al., 2015).

Soil is an important factor of terrestrial ecosystems (Gusewell, 2004). To examine the variation characteristics of nutrient elements, it is necessary to thoroughly investigate the conversions between the nutrient return from litter decomposition, soil nutrient supply, and plant nutrient demand in different environments (Xiang et al., 2015). Soil environmental factors not only provide plant nutrients but also catalyze and regulate the process of litter decomposition, thereby sensitively reflecting the direction and intensity of the driving mechanism of nutrients in different karst areas of rocky desertification. Currently, the nutrient element transfer and its regulation mechanism in karst areas with different levels of rocky desertification have rarely been addressed, and there has been no study on the soil environmental factors that drive the plant stoichiometry (including leaf stoichiometry and litter stoichiometry), making it difficult to systematically reveal the coupling mechanism between plants and the environment. Therefore, it is necessary to conduct an in-depth stoichiometric study that takes plants and soil as a whole (Du et al., 2016, 2017).

In this study, our aims were to: (1) examined vegetation, litter, and soil as a whole system and investigated the stoichiometric characteristics of karst areas. (2) Describe the elemental circulation and balance mechanism of the soil–litter–vegetation continuum in environments with different levels of rocky desertification. (3) Revealed the synergistic driving effect of soil environmental factors on the stoichiometric characteristics of plant leaves and litter. Our findings are conducive to strengthening the management and protection of the ecological environment in areas of rocky desertification and provide a theoretical basis for the management of vegetation restoration and reconstruction in karst areas of rocky desertification.

Materials and methods

Overview of the study area

The Salaxi Rocky Desertification Comprehensive Management Demonstration Area of Bijie and the Guanling-Zhenfenghuajiang Rocky Desertification Comprehensive Management Demonstration Area (*Fig. 1*) are the two most representative areas of rocky desertification in Guizhou Province of southwest China, with diverse rocky desertification levels and typical rocky desertification status. These were selected as the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19611979

study area. Both demonstration areas have been used as special study cases for the comprehensive control of rocky desertification of Guizhou Province from 1995 to 2019.

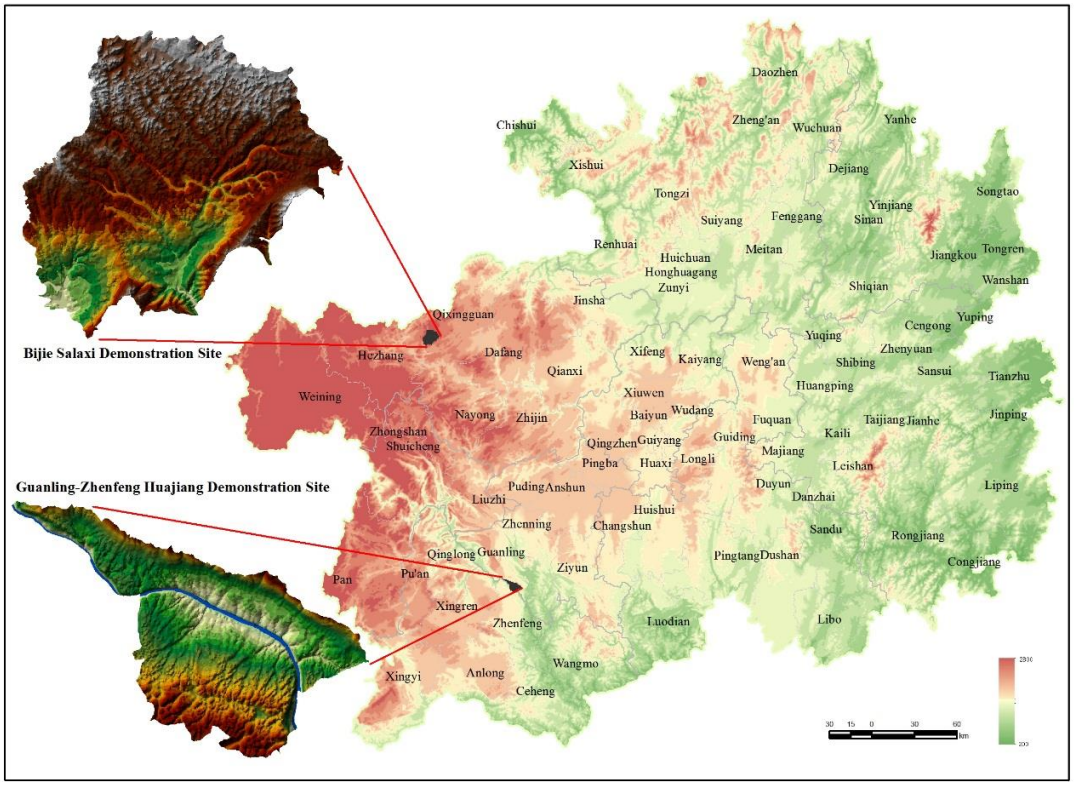

Figure 1. *The location of the two demonstration areas in Guizhou Province*

The Salaxi Rocky Desertification Comprehensive Management Demonstration Area of Bijie (*Fig. 2*), located in the northwest of Guizhou Province (105°01′10″-105°08′39″ E, 27°11′08″-27°17′30″ N) and the southwest of Bijie city, is within the tributary area of the Liuchong River Basin. It has a north subtropical humid monsoon climate (annual average temperature: 12 °C; annual average precipitation: 984.40 mm) and an altitude of 1,495-2,200 m (relative height difference: 705 m). The total size of the demonstration area is 86.27 km^2, of which the karst area accounts for 73.94%. The areas of potential, mild, moderate, and severe rock desertification account for 30.91%, 22.26%, 8.57%, and 3.09% of the karst area, respectively. The soil is dominated by zonal yellow soil, with a small proportion of yellow-brown soil and weathered calcareous soil. The native vegetation was mostly destroyed and is now dominated by secondary forests, in which *Pinus armandii*, *Pinus yunnanensis*, *Betula luminifera*, *Populus alba*, and *Quercus variabilis* dominate the arborous layer; *Pyracantha fortuneana*, *Rosa roxburghii*, *Cotoneaster franchetii*, *Hypericum chinense* L., *Rhododendron simsii*, and *Corylus heterophylla* var. *sutchuenensis* dominate the shrub layer; and *Trifolium repens*, *Lolium perenne*, *Dactylis glomerata* L., *Bromus catharticus*, and *Imperata cylindrica* dominate the grassland.

The Guanling-Zhenfenghuajiang Desertification Comprehensive Management Demonstration Zone of Bijie (*Fig. 3*) is in the southwestern part of Guizhou Province (105°36′30″-105°46′30″ E, 25°39′13″-25°41′00″ N) and the river banks of the Huajiang Valley of the Beipan River, which is to the south of Guanling County and the north of Zhenfeng County. It has a north subtropical monsoon climate (annual average

DOI: http://dx.doi.org/10.15666/aeer/1801_19611979

temperature: 18.4 °C; annual average precipitation: 1,100 mm) and an altitude of 450-1,450 m (relative height difference: 1,000 m). The total area of the demonstration area is 51.62 km^2, of which the karst area accounts for 87.92%, and the areas of potential, mild, moderate, and severe rock desertification account for 24.54%, 40.48%, 17.93%, and 17.06% of the total karst area, respectively. The soil is dominated by yellow soil and yellow calcareous soil. The natural vegetation in the area includes *Cupressus funebris*, *Eucalyptus* spp., *Tectona grandis*, *Koelreuteria paniculata*, and *Cladrastis platycarpa* (Maxim.) Makino in the arborous layer; *Broussonetia papyrifera*, *Viburnum foetidum* var. *ceanothoides*, *Alchornea trewioides*, and *Rhus chinensis* Mill. in the shrub layer; and *Pennisetum hydridum*, *Lonicera japonica*, *Miscanthus sinensis*, *Arthraxon hispidus*, and *Imperata cylindrica* in the grassland.

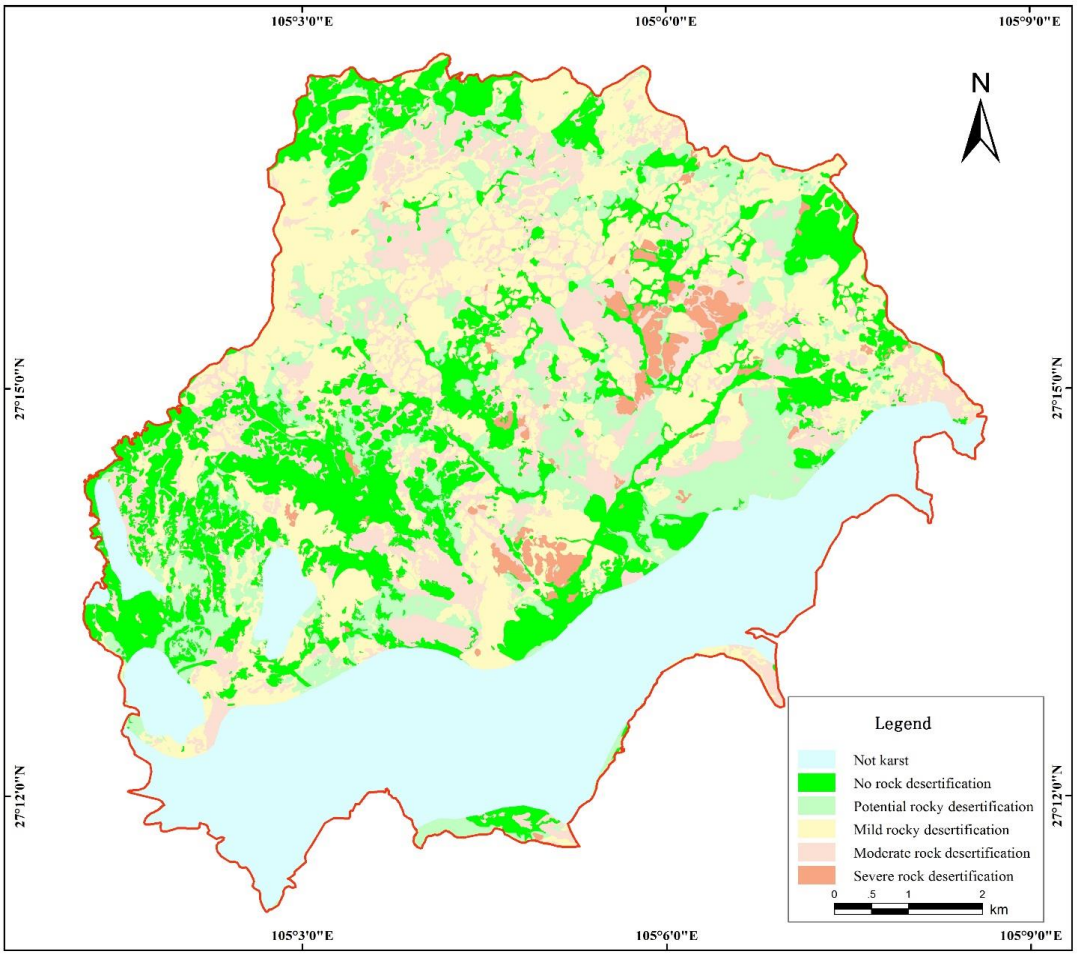

Figure 2. *The Salaxi Rocky Desertification Comprehensive Management Demonstration Zone of Bijie*

Sample collection

In the study area, the communities of trees, shrubs, and herbs with neat forests, uniform forest distribution, and similar average forest age were selected as subjects. In each demonstration area, 40 experimental plots were designed (80 in total in the two demonstration areas), including 27, 27, and 26 plots for trees, shrubs, and herbs,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19611979

respectively, in which typical quadrats of 20 m × 20 m were designed. The samples were collected in late August 2018, when plants were in the fast growth season. When collecting plant leaves, five to six healthy individual plants of the dominant species with similar vigor were randomly chosen from each quadrant, and healthy and mature leaves were collected from each of these plants facing four directions, i.e., east, west, south, and north, which were then mixed well and placed in a brown paper bag to be transferred to the laboratory. In each quadrant, approximately 350 g of each of dry, undecomposed, and semi-decomposed litter was collected from multiple spots. At each sampling site, soil samples were collected from the 0-20 cm soil depth (due to the shallow topsoil depth, in places with a topsoil depth shallower than 20 cm, the samples were collected from the actual soil depth) in 3-4 root zones in an S-shaped sampling line and mixed, from which 1 kg was taken using the quartering method and brought back to the laboratory. Plant leaves and litter were baked in an oven at 65 °C to constant weight and then pulverized to powder 0.1 mm in size. The soil samples were air-dried, removed of impurities such as animal and plant residues and gravels, and then ground using an agate mortar and sieved through a 100-mm sieve. The sieved soil sample was placed in a plastic bag for analysis of soil chemical properties.

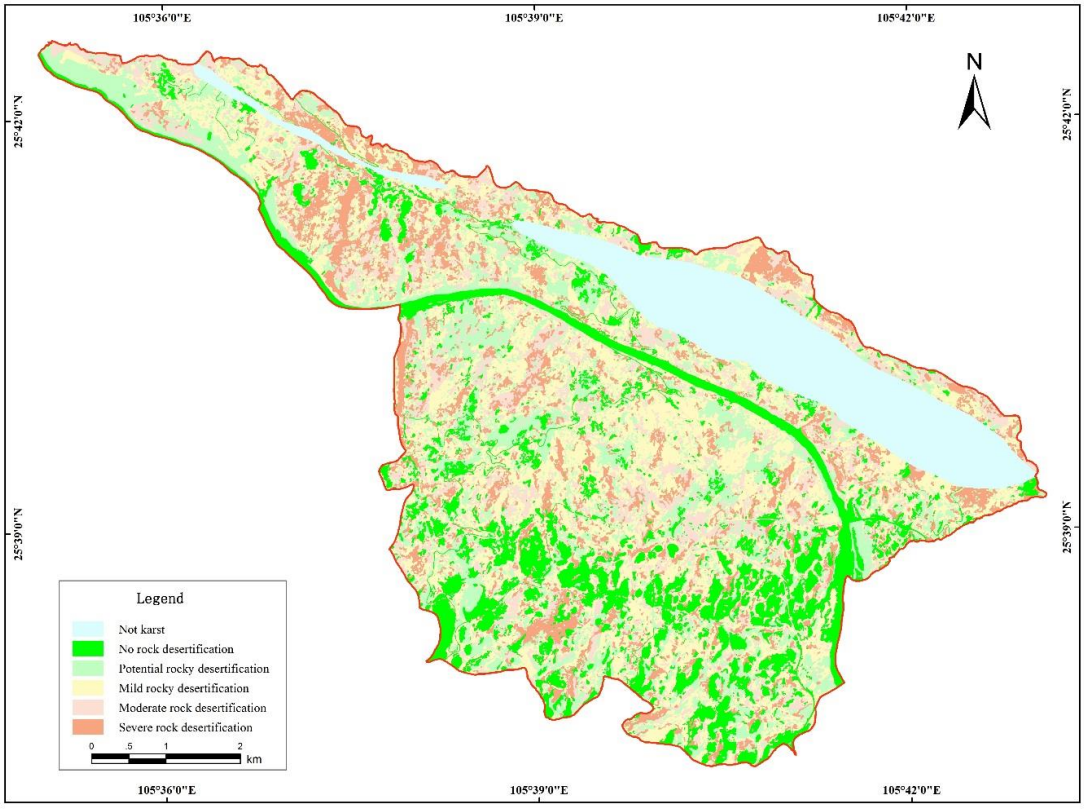

Figure 3. *The Guanling-Zhenfenghuajiang Desertification Comprehensive Management Demonstration Zone*

Sample analysis

The organic carbon (OC) contents of the leaf, litter, and soil were determined by oxidation with potassium dichromate under external heating, the total nitrogen (TN)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19611979

contents using the semi-micro Kjeldahl method after heating in perchloric acid-sulphate acid, and the total phosphorus (TP) contents using Mo-Sb colorimetry–UV spectrophotometry after heating in perchloric acid and sulfuric acid. Soil pH was determined using a potentiometer in the soil solution (water: soil ratio 2.5:1). Soil water content (SWC) was determined using the cutting ring method.

Data processing and statistical analysis

The nutrient content data of plant leaf, litter, and root-zone soil were performed with one-way analysis of variance and regression analysis. The result of a data distribution test showed that the contents of C, N, and P of plant leaf, litter, and soil samples mostly assumed nonnormal distributions but were normally distributed after logarithmic transformation, so their log-transformed values were described with geometric means. The significance test of multiple comparisons was performed using the least significant difference method, and $P < 0.05$ indicated that the difference was significant. The C:N:P comparison results were plotted using 3D Scatter software. The above-described statistical analyses of the data were performed within Origin 8.6 for Windows.

The soil C, N, and P contents of different sampling sites and their respective stoichiometric variation strengths were categorized into three levels (*Eq. 1*): low [coefficient of variation (CV) < 10%], moderate (10% < CV < 100%), and high (CV > 100%) (Zheng et al., 2004). According to the method of Xiong et al. (2011) (*Table 1*), the 80 experimental plots were categorized into two types: potential-mild rocky desertification and moderate-severe rocky desertification.

$$CV = \frac{SD}{MN} \times 100\% \quad \text{(Eq.1)}$$

SD is the standard deviation; MN is the mean.

Table 1. *Classification standard of karst rock desertification*

Rocky desertification level	Rock exposure rate	Vegetation + soil coverage	Reference indicator
No rock desertification	< 20	> 80	Nonterraced dry hillside land with a slope of ≤ 15°, dikes, construction land, etc., with good ecological environment, densely populated trees and shrubs, with no or insignificant soil erosion; suitable for agricultural, forestry, or animal husbandry production
Potential rocky desertification	20–30	80–70	Nonterraced dry hillside land and grassland, etc. with a slope of > 15°, with sparsely populated arbor, shrubby and herbaceous vegetation, and good soil-forming conditions but obvious soil erosion; showing a tendency of rock exposure
Mild rocky desertification	31–50	69–50	Rocks begin to be exposed, with obvious soil erosion, low vegetative patch structure, and dominance of sparse shrubs or artificial dry-land vegetation
Moderate rock desertification	51–70	49–30	Rocky desertification is intensifying, with severe soil erosion, shallow topsoil, dominance of rocky hillside land, and sparse shrub-grass zone
Severe rock desertification	> 70	< 30	Rocky desertification is severe, with essentially no soil erosion due to the absence of topsoil, and dominant with lands difficult to use that is about to lose agricultural value

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19611979

The relationship between plant leaf and litter stoichiometry and soil environmental factors was analyzed using Canoco 4.5 for Windows. First, we performed detrended correspondence analysis on the indicators and found that when the maximum value of the gradient length was less than 3, the linear ranking method was suitable, so we adopted the redundancy analysis of the linear model as the ranking model to examine the relationship between the stoichiometry and the environmental factors. The importance of soil environmental factors was ranked through the Monte Carlo test, and the effect of individual environmental factors on plant stoichiometry was determined using the *t*-value biplot of Canoco 4.5. When interpreting the biplot, if the arrowed connection line of a certain plant stoichiometric indicator was completely within a circle, then it indicated that this indicator was significantly correlated with the soil environmental factor (in the red circle: significant positive correlation; in the blue circle: significant negative correlation; the percentage and length of the arrow that fall within the circle represent the strength of the correlation) (Leps and Smilauer, 2003).

Results and analysis

Stoichiometric characteristics of nutrients of Karst rocky desertification ecosystems

The contents of C, N, and P in plant leaves in karst rocky desertification ecosystems were higher than those in litter or soil, while the ratios of C:N, C:P, and N:P of litter were higher than those of plant leaves or soil. The CVs of stoichiometric values of different nutrients differed, and the variations were mostly moderate. Overall, the CV of stoichiometric values of soil was the highest, followed by that of litter and that of plant leaves. The CV of stoichiometric values of soil was significantly different from those of soil or litter ($P < 0.05$) (*Table 2*).

Table 2. *Stoichiometric characteristics of nutrients in karst areas of rocky desertification*

The stoichiometric characteristics of plant leaf, litter, and soil under different levels of rocky desertification

The stoichiometric characteristics differed significantly between the areas with different levels of rocky desertification (*Fig. 4*). The C:N:P ratios of plant leaves, litter, and soil in the area of potential-mild rocky desertification were 361:7:1, 498:12:1, and 69:3:1, respectively, and those in the area of moderate-severe rocky desertification were 224:7:1, 301:6:1, and 29:3:1, respectively. Compared with the area with a higher level of rocky desertification, the area with a lower level of rocky desertification had higher ratios of C:N and C:P in the soil and plant leaves and higher ratios of C:P and N:P in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19611979

litter. The N:P ratio of plant leaves and litter were 7.25 and 12.58 in the area of potential-mild rocky desertification, respectively, and 6.91 and 6.64 in the area of moderate-severe rocky desertification. The results indicate that the C content and the N:P ratios of plant leaves and litter in the area of potential-mild rocky desertification are higher than in the area of moderate-severe rocky desertification.

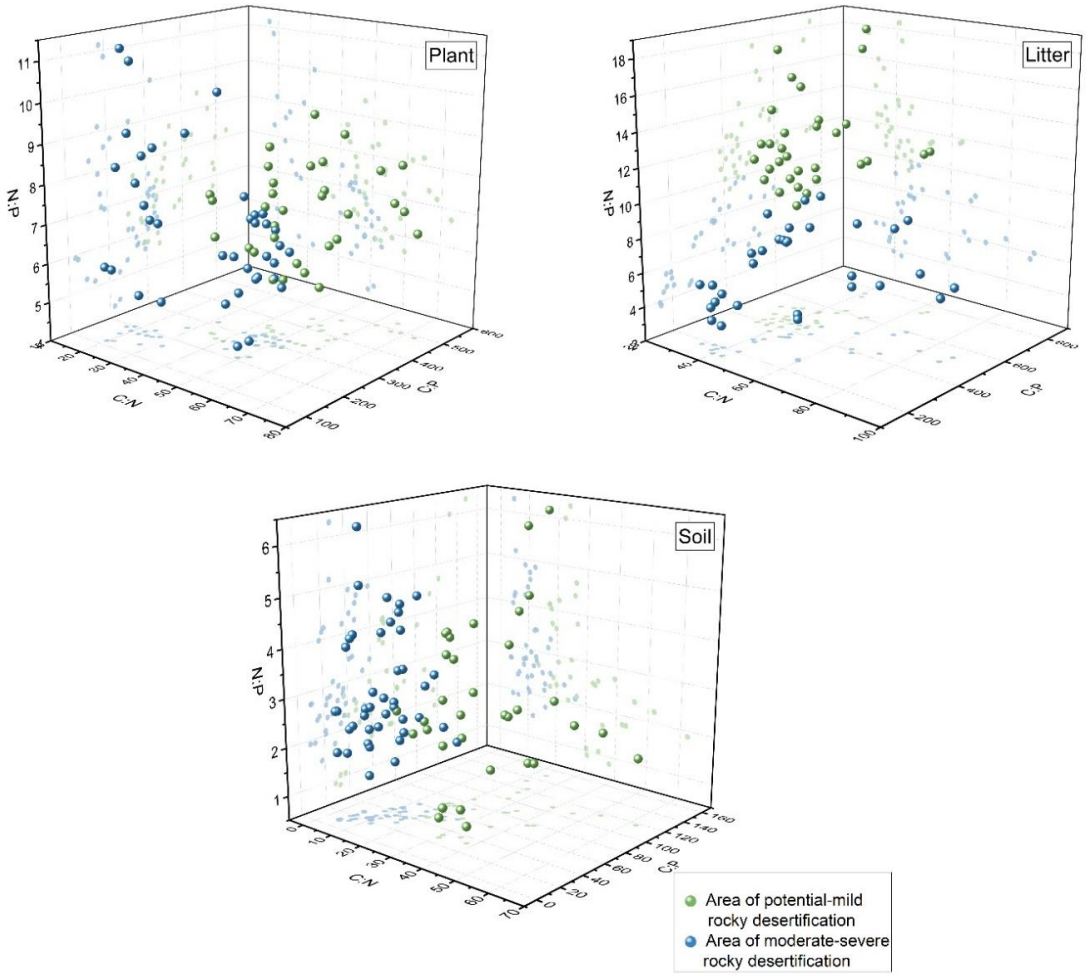

Figure 4. *Stoichiometric characteristics of areas with different levels of rocky desertification*

Relationship between stoichiometric characteristics of plant leaves, litter, and soil environmental factors in areas of rocky desertification

Stoichiometric characteristics of the areas of rocky desertification and RDA ordination of their respective interpretation powers

The stoichiometric characteristics and the RDA ordination of their respective interpretation powers (*Table 3*) showed that the cumulative interpretation power of the area of potential-mild rocky desertification and that of the area of moderate-severe rocky desertification on the first and second RDA ordination axes were 72.6% and 68.4%, respectively. The correlation between the stoichiometry of the first and second axes and the soil environmental factors of the area of potential-mild rocky desertification were 0.953 and 0.969, respectively, and the correlation between the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19611979

stoichiometry of the first and second axes and the soil environmental factors of the area of moderate-severe rocky desertification were 0.916 and 0.853, respectively. Therefore, the two ordination axes were essentially vertical, indicating that the ordination results were credible. The cumulative interpretation power on the relationship between the stoichiometry and the soil environmental factors was 80% and 90.9% for the area of potential-mild rocky desertification and the area of moderate-severe rocky desertification, respectively, accounting for 81.5% and 91.8% of the total interpretation power. These data indicate that the first and second axes can well reflect the relationship between the stoichiometry and soil environmental factors.

Table 3. *The stoichiometric characteristics and their RDA ordination analysis on the interpretation power*

	Ordination axis	**Axis I**	**Axis II**	**Axis III**	**Axis IV**
Potential-mild rock desertification	Interpretation power of stoichiometric characteristics, %	43.4	29.2	9.5	6
	Correlation between stoichiometric characteristics and the soil environmental factors	0.953	0.969	0.872	0.95
	Cumulative interpretation power of stoichiometric characteristics, %	43.4	72.6	82.1	88.1
	The cumulative interpretation power of stoichiometry-soil environmental factor relationship, %	48.3	80.0	91.4	98.1

	Total eigenvalue		1.00		

The 2-D RDA ordination results show that the lengths of arrowed connection lines of the soil environmental factors pH, TP, C:P, and SOC were the longest in *Figure 5a* and that those of C:P, TP, C:N, and SWC were the longest in *Figure 5b,* indicating that these soil environmental factors had good interpretation power for the differences in the changes in plant leaves and litter, which are consistent with the importance ordination results shown in *Table 4*. *Figure 5a* also shows that the directions of the arrows between C:P and DC:P, between pH or SOC and DC, and between TP or SWC and DP were consistent; that the angles between the lines were small; and that the factors had a positive correlation, indicating that C:P, pH, SOC, TP, and SWC had a positive effect on some plant ecological stoichiometric characteristics and were important factors affecting plant ecological stoichiometric properties in the area of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19611979

potential-mild rocky desertification. *Figure 5b* shows that the directions of the arrows between C:P and ZC:P, between TP and ZP, between C:P and ZC:P, between SOC or N:P and DN:P, and between SWC and ZN were consistent; that the angles between the lines were small; and that the factors had a positive correlation. The results indicate that C:P, TP, C:N, SWC, C:P, and N:P had a positive effect on some plant ecological stoichiometric characteristics and were important factors affecting plant ecological stoichiometric properties in the area of moderate-severe rocky desertification.

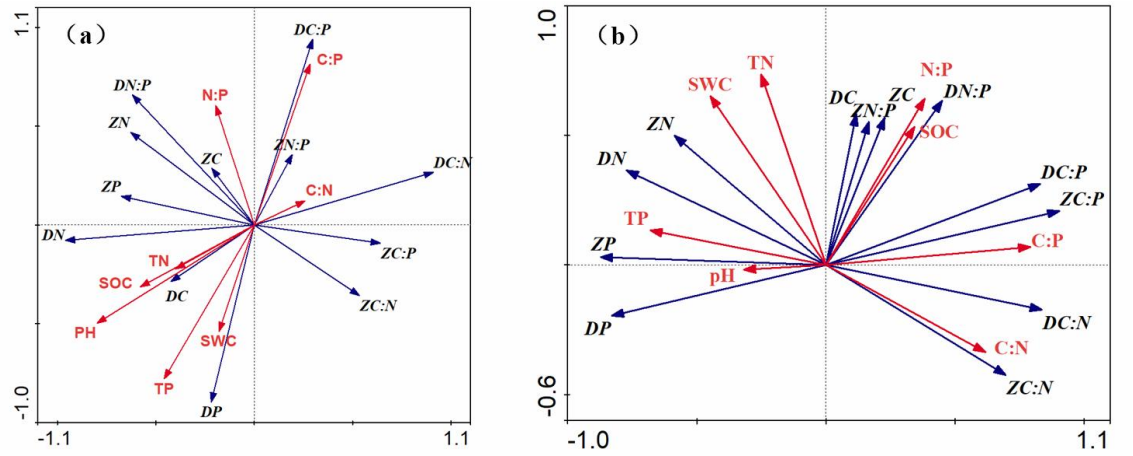

Figure 5. *Redundancy analysis on plant stoichiometric characteristics and soil environmental factors. Note: pH, SOC, TN, TP, C:N, C:P, and N:P are the soil pH, soil organic carbon content, soil total nitrogen content, soil total phosphorus content, and their respective stoichiometric ratios, respectively; ZC, ZN, ZP, ZC:N, ZC:P, and ZN:P are the organic carbon content, total nitrogen content, and total phosphorus content in plant leaves and their respective stoichiometric ratios, respectively; DC, DN, DP, DC:N, DC:P, and DN:P are the organic carbon content in the litter, total nitrogen content in plant litter, total phosphorus content in plant litter, and their respective stoichiometric ratios, respectively. Part (a) shows the RDA results of plant stoichiometric characteristics and soil environmental factors in the area of potential-mild rocky desertification. Part (b) shows the RDA results of plant stoichiometric characteristics and soil environmental factors in the area of moderate-severe rocky desertification*

Ranking the importance of soil environmental factors to plant stoichiometric characteristics

We performed the Monte Carlo test to rank the eight soil environmental factors (*Table 4*) and found that the effects of soil environmental factors on plant stoichiometric characteristics differed between areas with different levels of rocky desertification. The order of importance of the soil environmental factors in the area of potential-mild rocky desertification was pH > TP > C:P > SOC > N:P > TN > SWC > C:N. The effects of pH, TP, C:P, and SOC on plant stoichiometric characteristics were significant ($P < 0.05$). Compared with other soil environmental factors, pH could better represent the difference in plant stoichiometric characteristics. The order of importance of the soil environmental factors in the area of moderate-severe rocky desertification was C:P > TP > C:N > SWC > N:P > TN > SOC > pH. The effects of C:P, TP, C:N, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19611979

SWC were significant ($P < 0.05$), and compared with the other soil environmental factors, C:P better represented the difference in plant stoichiometric characteristics.

Table 4. *Monte Carlo test ranking of eight soil environmental factors*

	Soil factor	Order of importance	Interpretation power (%)	Importance (F)	Significance (P)
Area of potential-mild rocky desertification	pH	1	35.6	6.625	0.002
	TP	2	27.8	4.625	0.006
	C:P	3	23.4	3.666	0.012
	SOC	4	19	2.809	0.036
	N:P	5	13.5	1.874	0.128

Effects of individual soil environmental factors on plant stoichiometry

We generated impact diagrams of individual soil environmental factors using the t-value biplots of the first four factors affecting plant stoichiometry in the area of potential-mild rocky desertification (*Fig. 6*). The Canoco biplot for pH (*Fig. 6a*) shows that the DP arrow falls within the red circle and that the DC:P arrow falls within the blue circle, indicating that pH had a significantly positive correlation with DP but a significantly negative correlation with DC:P. *Figure 6b* shows that soil TP had a significantly positive correlation with DN:P and DN and a positive correlation with plant C, N, and P. *Figure 6c* and *d* show that the plant stoichiometric indicators do not fall within the circle but mostly pass through the red circle or the blue circle, indicating that the plant stoichiometric characteristics were correlated *(*$P < 0.05$) with the soil environmental factors C:P and SOC, but not highly correlated *(*$P < 0.01$).

The t-value biplot of the area of moderate-severe rocky desertification is shown in *Figure 7*. *Figure 7a* shows that the DC:N and ZC:N arrows pass through the red circle and that the ZC:N arrow has more of its length within the red circle, indicating that C:P had a positive correlation with DC:N and ZC:N (with a stronger correlation for ZC:N). *Figure 7b* and *c* show that DC, ZC, ZN:P, DN:P, DC:P, and ZC:P pass through the blue circle and the red circle, respectively, indicating that these environmental factors were correlated negatively with TP but positively with C:N. *Figure 7d* shows the analysis result of SWC, indicating that SWC had a significantly positive correlation with ZP and DP, which fall into the red circle, but a significantly negative correlation with DN:P, DC:P, ZC:P, and DC:N, which fall into the blue circle.

Discussion

Ecological stoichiometric characteristics of karst areas of rocky desertification

In this study, we examined the stoichiometric characteristics of plant leaves, litter, and soil of karst areas and found that the C, N, and P contents of plant leaves in karst areas of rocky desertification were higher than those of litter or soil. This was because the C, N, and P contents of plant leaves, an important nutrient storage organ, are much higher than in other plant organs (Minden and Kleyer, 2014). After fresh leaves fall, the organic components such as crude fat, tannins, and soluble sugars are decomposed, leading to significantly reduced C content in the litter (Yang et al., 2007). Litter had lower contents of N and P than leaves. This is because before leaves fall, the nutrients in the leaves are transferred to other components, absorbed, and utilized. The reduction in N may happen because the leaves utilizes nitrogen in photosynthesis, and high N use efficiency reduces the P content in litter (Zhao et al., 2016). Plants absorb N and P from the soil and further transfer some nutrients to plants through the nutrient reabsorption process, resulting in larger changes to the N and P contents in litter than in plant leaves, and thus the C:N and C:P contents are found in the order litter > plant > soil (Zeng et al., 2015). Soil nutrient content is an important indicator for evaluating organic matter composition and soil quality, and the soil nutrient variability in the same ecosystem is largely affected by environmental factors (Li et al., 2018). Soil nutrients in karst areas showed moderate variation but had significant fluctuations, which are caused by the changes in environmental factors derived from complicated landforms, high spatial heterogeneity, and the interference of human activities, which are consistent with the conclusions of Zhu et al. (2013) and Li et al. (2014).

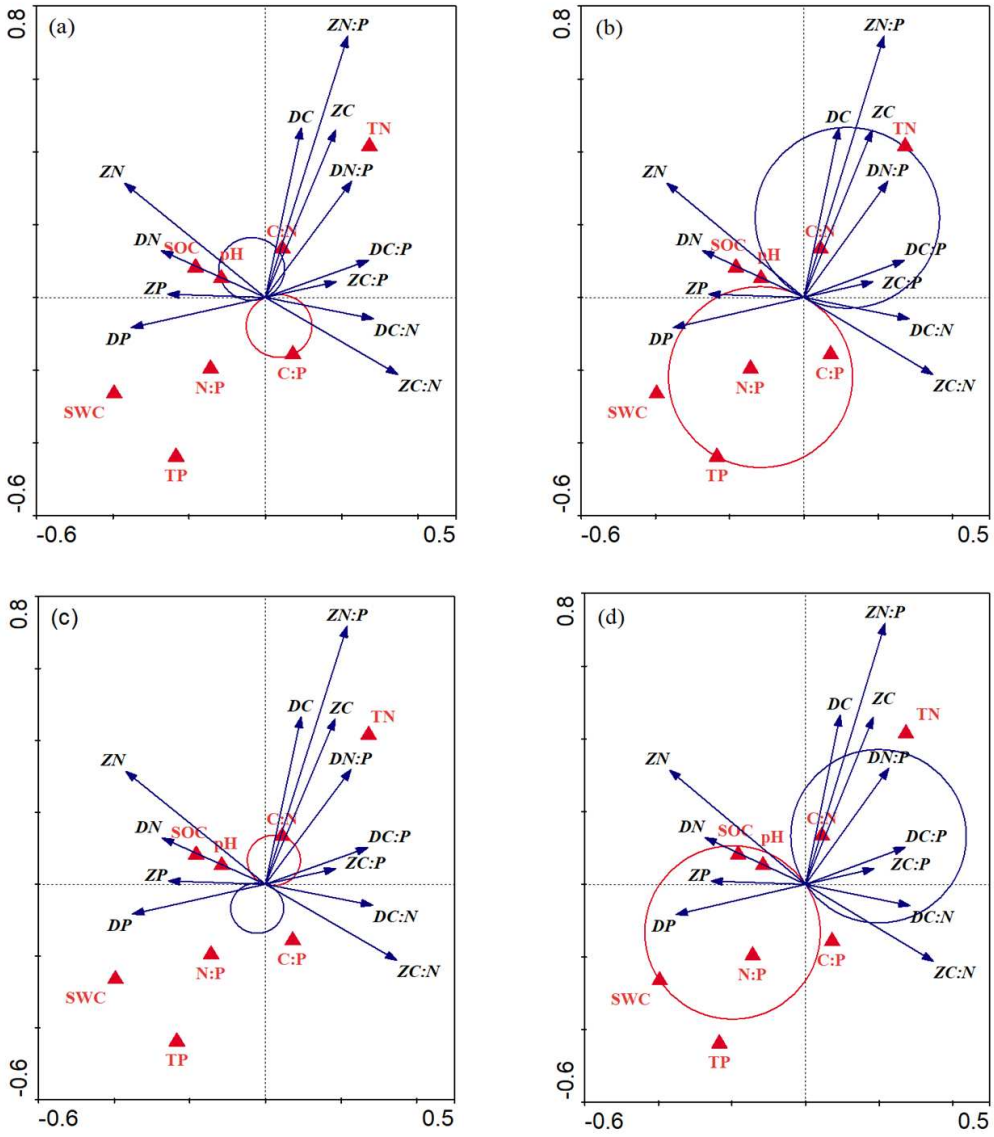

Figure 7. *Effect of individual soil environmental factors on plant stoichiometry in the area of moderate-severe rocky desertification. (a) C:P; (b) TP; (c) C:N; (d) SWC*

In this study, the soil P content of the areas of rocky desertification was 0.9 $mg \cdot g^{-1}$, which is lower than that of other ecosystems (Koerselma and Meuleman, 1996; Jiao et al., 2013). This was likely caused by the strong leaching effect derived from high precipitation in karst areas in southwestern China. However, compared with the average content of soil P in China (0.56 g/kg) (Tian et al., 2010), the P content of the karst areas is still higher, indicating that despite strong leaching effects in the rocky desertification environment, the P content of the karstification product from bare rocks can readily accumulate in the soil, showing a significant aggregation effect, which is consistent with the findings of Sheng et al. (2013). We also found that the average C content in plant leaves was 482.96 $mg \cdot g^{-1}$, which is higher than that (464.00 $mg \cdot g^{-1}$) of 492 terrestrial plant species around the world reported by Elser et al. (2000) and that (438.00 $mg \cdot g^{-1}$) of China's grassland ecosystem (He et al., 2006), indicating

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19611979

that the karst area has strong C storage capacity and thus high accumulation of organic matter. The average N content in plant leaves was 12.39 $mg \cdot g^{-1}$, which is significantly lower than that (20.09 $mg \cdot g^{-1}$) at the global scale (Reich and Oleksyn, 2004) and that of 753 species reported by Han et al. (2005), indicating N deficiency in the karst area, likely because the high precipitation in the region (over 980 mm annually) is prone to cause the leaching of available nitrogen, which has a high mobility.

Ecological stoichiometric characteristics of areas with different levels of rocky desertification

Due to differences in geographical conditions, the N and P contents and the stoichiometric characteristics of C:N:P of plant leaves in different habitats and different tree species vary profoundly (Reich and Oleksyn, 2004; Han et al., 2005). In this study, we found that the C content in plant leaves in the area of potential-mild rocky desertification was higher than that in the area of moderate-severe rocky desertification. Because the soil is a primary environmental factor in karst areas, its stoichiometric characteristics affect the plant community characteristics of areas with different levels of rocky desertification (Zhao et al., 2019). In the area of moderate-severe rocky desertification, the rock exposure rate was high, the vegetation coverage was low, and the biomass was low, leading to the reduced stock of soil organic carbon and the accelerated decomposition of organic matter and thus a lower C content than in the area with a lower level of rocky desertification. This finding is consistent with the findings of Yang (2000) and Long et al. (2002). They found that soil C:N is inversely proportional to the decomposition rate of organic matter and that the soil with a lower C:N ratio is faster at mineralization (Zhu et al., 2013). In this study, we found that the soil C:N ratio was 28.72 in the area of potential-mild rocky desertification and was 10.85 in the area of moderate-severe rocky desertification. The soil C:N ratio in the area of moderate-severe rocky desertification was lower than the global average (14.3) (Zhao et al. 2015), indicating higher rates of decomposition and mineralization of soil organic matter. The C:N and C:P ratios in plant leaves and soil in the area of potential-mild rocky desertification were higher than those in the area of moderate-severe rocky desertification because in the area of moderate-severe rocky desertification, topsoil was shallow and had high temperature and humidity, weak nutrient retention ability, and fast nutrient turnover, leading to low nutrient use efficiency and nutrient resorption rate in plants (Cui et al., 2015). The critical values for plant N:P are 14 and 16. When $N:P < 14$, the ecosystem is N-limited, and when $N:P > 16$, it is P-limited (Koerselman and Meuleman, 1996; Tessier and Raynal, 2003). In this study, we found that the N:P ratios of the area of potential-mild rocky desertification and the area of moderate-severe rocky desertification were 6.91 and 7.25, respectively, indicating that both areas were N-limited. In the shrub and grass vegetation of the karst areas, we found that N was deficient while P was sufficient, mainly because in these areas, the rock exposure rate was high, the vegetation coverage was low, nutrients were concentrated in the arborous layer, and the symbiotic nitrogen fixation system and the slightly weathered soil were scarce (Hedin, 2004). Thus, supplementation with N fertilizer during the control process can increase the N content of the vegetation. Our results indicate that the limiting factors inhibit vegetation recovery and development and that limiting factors should be effectively regulated in forest management strategies.

Driving mechanisms of the effect of soil environmental factors on plant stoichiometry

The chemical elements of vegetation are mainly derived from the soil, and their contents are closely related to their soil contents. C, N, and P are the basic constituent elements of plants that are converted in the plant–litter–soil continuum, manifesting the nutrient cycling and use efficiency (Zeng et al., 2015). Soil pH, TP, C:P, SOC, C:N, and SWC are the main driving factors affecting plant stoichiometry. The soil environmental factors TP and C:P significantly affected the stoichiometric characteristics of the vegetation in both areas of rocky desertification, indicating that the P level in plants is closely coupled with that in soil. Soil P level is positively correlated to C, N, and P levels in plant leaves, indicating that the soil P can facilitate the absorption of C, N, and P by plant leaves. The reason that P is an important factor is that the P in soil is directly produced by rock weathering and thus is a sedimentary element. In karst areas, soil and rock are in direct contact, which is prone to cause soil erosion and slides. Therefore, the fluctuation in the content of P exerts a greater influence on the ratios of elements than other fluctuations. In the future plant nutrient recycling and utilization processes, soil P should be optimized and adjusted to achieve nutrient balance.

The soil environmental factor TP was positively correlated with DN:P and DN (*Fig. 6b*) but negatively correlated with DC, ZC, ZN:P, DN:P, DC:P, and ZC:P (*Fig. 7b*), indicating that in environments with different levels of rocky desertification, the driving effect of soil environmental factors on plant nutrient absorption varies, which is consistent with the findings of Chen et al. (2018). The soil environmental factors TP (*Fig. 7b*) and SWC (*Fig. 7d*) in the moderate-severe rocky desertification demonstration area showed similar correlations in the analysis of the effects of individual environmental factors, indicating that the driving mechanisms of the two are identical. This is mainly because the high rainfall in the karst area accelerates TP leaching, which, coupled with ground runoff, leads to the simultaneous losses of soil TP and SWC and thus a certain correlation between TP and SWC. SWC showed a significantly positive correlation with ZP and DP and a significantly negative correlation with DN:P, DC:P, ZC:P, and DC:N (*Fig. 7d*), indicating that the increase in SWC significantly increases P contents in plant leaves and litter while decreasing the contents of C:N, C:P, and N:P of litter, indicating that SWC can effectively increase the nutrient transfer rate of plant leaves, resulting in reduced C:N, C:P, and N:P ratios in litter.

The changes to soil nutrient supply in the environment of karst rocky desertification can affect various plant physiological and biochemical reactions to some extent. After long evolutionary adaptation, plants form relatively stable elemental stoichiometries, which also reflects plants' adaptation strategy to extreme environments. The RDA on the area of potential-mild rocky desertification showed that soil pH played the most critical role in plant stoichiometry. Past studies have shown that soil pH directly affects the decomposition, mineralization, redox reaction, and enzyme reaction rates of soil organic matter, and species richness is positively correlated with pH value (Dick et al., 2000; Xu et al., 2006; Tian et al., 2019). The species richness and the pH-driving impact of the area of potential-mild rocky desertification was higher than those of the area of moderate-severe rocky desertification. Among the soil environmental factors in area of moderate-severe rocky desertification, soil C:P showed a more profound effect and a positive correlation with DC:N and ZC:N (*Fig. 7a*), indicating that the increase in soil C:P can promote the C:N in plant leaves, while the C:N in litter is fully in line with the characteristics of C:N in plant leaves, consistent with the conclusions on the stoichiometric characteristics of wetland plants and litter by Wang et al. (2011).

Conclusions

Nutrient cycling and transfer occur in the plant–litter–soil continuum in karst areas of rocky desertification, which is manifested in the C, N, and P contents in plant leaves being higher than those in litter or soil.

The leaves of plants in karst areas showed N deficiency, P sufficiency, and a strong C storage capacity. Supplementation with N fertilizer during the control process can increase the vegetation biomass yield.

The decomposition and mineralization rates of soil organic matter in the area of moderate-severe rocky desertification is higher than in the area of potential-mild rocky desertification. The order of importance of soil environmental factors in the area of potential-mild rocky desertification is pH > TP > C:P > SOC. The soil pH has the strongest driving effect on plant stoichiometry. The order of importance of soil environmental factors in the area of moderate-severe rocky desertification is C:P > TP > C:N > SWC. The soil C:P has the strongest driving effect on plant stoichiometry.

It is necessary to target the primary factors for fertilization management and nutrient transport protection in future rock desertification control. In the diagnosis of plant nutrient restriction, in addition to considering the role of soil environmental nutrient factors, it is also necessary to increase the mechanism of plant photosynthesis and respiration on the maintenance of plant nutrients, as well as the decomposition and interference of underforest microenvironment, soil animals and microbial activities on litter. In the future, we should increase the systematic research of multi-disciplinary, multi-angle and multi-thinking. At the same time, the environment and livelihood problems caused by stony desertification need to be paid more attention all over the world.

Abstract. The aim of the study was to develop a new model for the prediction of wildlife-vehicle collisions (WVC) in urban areas, more specifically in the city of Lublin (Poland) and its surroundings. Prediction new model probability of WVC will be a valuable tool for city planners and will increase road safety for drivers and animals. The number of WVC was compared with data on traffic intensity in the same period, land use forms and seasons of the year. The data were analyzed statistically and the values of the parameters were presented as the mean value and standard error or standard deviation. Almost half (42.7%) of the analyzed collisions took place on roads characterized by traffic that does not exceed 100 vehicles/day. The highest number of collisions with animals was reported in summer and spring, i.e. 91 and 78 events, respectively. There was also a highly significant positive correlation between the increase in the number of accidents with animals and the traffic intensity of 501-600 and 1101-1200 vehicles/day on the roads. The distances from river valleys, residential buildings, and industrial development turned out to be significant predictor variables for WVC.
Keywords: *wildlife-vehicle collisions, models probability of collisions, urban area, traffic intensity, wild animals*

Introduction

In the last decade, there has been a steady increase in the number of protected animal species (e.g. beaver by 76%) and medium wild game (e.g. hare by 40% or pheasant by 13%) in Poland, which is a positive phenomenon concerning the protection of biodiversity and genetic resources of populations of these species (GUS, 2010-2018). As shown by GUS data (2010-2018), the number of large game has increased (elk by 170%, red deer by 50%, roe deer by 12%, and fallow deer by 2.5%), which may have adverse consequences for both animals and humans. Animal overpopulation may lead to the reduction of the food base, which forces animals to migrate in search of better living areas and contributes to an increase in road events involving animals (Huijser et al., 2008; Tajchman et al., 2017A).

Wildlife-vehicle collisions (WVC) are one of the most widespread and persistent conflicts between humans and wildlife worldwide, especially since the increasing numbers of humans and animals inhabiting smaller areas (Huijser et al., 2009; Conover, 2010). In Poland and many other countries, it is very difficult to provide accurate data

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19811997

on road events with animals and their number is often underestimated because many collisions are not reported (Huijser et al., 2008; Snow et al., 2015).

In the Lublin region based on documentation data from the years 2011-2013 1073 deer-vehicle collisions occurred (Tajchman et al., 2017a), while in the city of Lublin in the period of 2009-2012 the number of incidents with wild animals was recorded to be 930 (Tajchman et al., 2017b). WVC are associated with financial consequences. In Poland, the cost of one collision with an animal was estimated at ca. 2 144 USD; the cost of an accident resulting in human body injury is 7 621 USD, and an accident with human casualties reaches 2 692 405 USD. The mean cost of the accidents in 2001-2010 was 45 657 961 USD. In Utah, the USA, the total cost of wildlife-vehicle collisions for the period of 1992-2001 was estimated at 470 million dollars (Tyburski and Czerniak, 2013). On average of São Paulo reported 2 611 animal-vehicle crashes per year. The total annual cost to society was estimated at 25 144 794 USD. The average cost for an animal-vehicle crash, regardless of whether human injuries and fatalities occurred, was 9 629 USD. The Brazilian legal system overwhelmingly (91.7% of the cases) holds the road administrator liable for animal-vehicle collisions, both with wild and domestic species. On average, road administrators spent 1 005 051 USD per year compensating victims (Abra et al., 2019). Huijser et al. (2008) have shown that collisions with large animals, e.g. deer or elk, result in the highest number of injuries and fatalities in humans. It is estimated that property damages associated with collisions with ungulates reach 300 million USD per year in Canada and over 6 milliard USD per year in the USA (the average cost per event: 6 717 USD). It has also been demonstrated that 90% of road collisions with cervids result in fatalities, and trauma is reported in 56-65% of humans (Conover et al., 1995; Transport Canada, 2003; Huijser et al., 2009).

Attention should also be paid to other species of animals that fall victim to vehicle wheels as well. Such investigations are rarely conducted, as collisions with e.g. a fox or a mink do not usually cause large material loss, or the damage is invisible at first glance.

The presence of animals has been shown to be strongly correlated with the type and function of the habitat, proximity to resources (such as food or shelter), and the reason for the presence of the animal at the roadside (e.g. foraging or attempt to cross the road). The frequency of collisions is also correlated with the features of the road itself (width, curvature, and surface type), climatic conditions, road traffic intensity, and driver's condition (Ramp et al., 2006).

Currently, increasing numbers of animals move to cities or migrate through urban areas (Kalinowska, 2008). Despite the threats to biodiversity posed by living in the city, there are also many undeniable advantages (Wheater, 1999). An important factor ensuring favorable conditions of living in cities is the absence of hunting events or other forms elimination of species, especially large birds and mammals. In cities, which are inhabited by large numbers of people, there is always food available for animals, due to the presence of garbage containers, waste bins, or kitchen leftovers. More importantly, the food is available throughout the year. The city also provides regular access to water in park water reservoirs or decorative fountains. An advantage for many animal species living in urban areas is the milder winters (the average temperature in the city is higher by at least 1 °C) (Wheater, 1999; Reichholf, 2009). All these factors promote animal migration to cities. The greater number of wild animals living in urban habitats is associated with an increased risk of animal-vehicle collisions, although the permissible speed of vehicles in built-up areas is 50 km/h (Road Traffic Department in Poland).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19811997

Knowledge of the determinants of animal migration and identification of specific areas with a high risk of this type of accidents can improve drivers' safety on newly built road sections. Methods for mitigation of such conflicts (wildlife-human) are a current priority for both city authorities and handlers of wildlife (Found and Boyce, 2011).

Gunson et al. (2011) suggested a need for future research to be focused on modelling specific to each animal species and modelling the measurement of predictive power in specific areas so that the models can be used in similar landscapes. There are sparse investigations of wildlife-vehicle collisions in medium-sized cities. Therefore, the present study will fill the gap in data on such accidents in such agglomerations as Lublin. Road ecologists have analyzed the available georeferenced localizations of WVC to identify their distribution patterns along roads (Puglisi et al., 1974; Krisp and Durot, 2007; Ramp et al., 2005, 2006; Mountrakis and Gunson, 2009). These analyses have revealed that WVC along roads do not occur randomly but are spatially concentrated for specific vertebrate species, including ungulates (Puglisi et al., 1974; Hubbard et al., 2000; Joyce and Mahoney, 2001) and other species (Clevenger et al., 2003; Ramp et al., 2006). Therefore, an attempt was made to detect such areas in the city of Lublin and its surroundings.

Material and methods

Study area

Lublin is a city in the eastern part of Poland (22°34'E 51°14'N) with an area of approx. 147 km^2. Its area comprises 195.75 ha of parks and gardens, 1674.29 ha of forests (occupying 11.35% of the land), 5633 ha of agricultural land (38.2%), including 4745 ha of arable land, 153 ha of orchards, and 452 ha of meadows and pastures, rivers (45.1 km long), and public roads (317.4 km/100 km^2). The city has 339 850 inhabitants and the population density is 2305 people/km^2 (Study of conditions..., 2019). The mean annual air temperature in the city is 7.3 °C. The lowest average monthly temperature is noted in February (-4.0 °C) and the highest value is recorded in July (18.2 °C). Negative temperatures are recorded from December to March, whereas hot days with air temperatures above 25 °C occur from April to September. The mean annual precipitation sum in the city is approx. 560 mm, with the highest values in July (77.0 mm) and the lowest in January (29.6 mm) (https://www.lublin.eu/mieszkancy/srodowisko/srodowisko-przyrodnicze-lublina/klimat/, Kłysik et al., 2008).

Collision data

The aim of the study was to carry out an analysis of wildlife-vehicle collisions in the area of Lublin city, Poland, between the beginning of December 2017 and the end of November 2018. Mutual correlations of the number of WVC with the traffic volume, land use, and seasons of the year were examined. Based on registered road events with wild animals, new models were developed to determine the risk of occurrence of collisions with wild animals in the city of Lublin. The animals were divided into large species (over 30 kg): fallow deer (*Dama dama*), wildboar (*Sus scrofa*), red deer (*Cervus elaphus*) (*Fig. 1*), and roe deer (*Capreolus capreolus*); medium animals: European badger (*Meles meles*), European beaver (*Castor fiber*), domestic ferret (*Mustela putoriusfuro*), raccoon dog (*Nyctereutes procyonoides*), stone marten (*Martes foina*)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19811997

(*Fig. 2*), red fox (*Vulpes vulpes*), European otter (*Lutra lutra*), brown hare (*Lepus europaeus*) and small: European hedgehog (*Erinaceus europaeus*), red squirrel (*Sciurus vulgaris*), etc., and other animal species.

Figure 1. *WVC with large animal (Cervus elaphus)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19811997

The data on wildlife-vehicle collisions in the city of Lublin they were collected from roads where there were no technical barriers. The information were reported to municipal services that arrive directly at the scene of the incident (to help injured animals and/or remove dead animals from the road). The collision sites were converted to GPS (Global Positioning System) coordinates with the use of a Hi-Target Qstar6 receiver with the accuracy of determination of a single point of 2.5 m. Next, using Arc GIS Pro 2.0 software, they were transferred as vectors onto digital maps of Lublin at an accuracy level corresponding to scale 1: 50000.

New landscape-based models and statistical analysis

The number of WVC was compared with data on traffic intensity (vehicle/day) in the same period, land use forms (residential buildings, industrial development, urban greenery, river valleys, agricultural areas, and forests), and seasons of the year. The data were analyzed statistically and the values of the parameters were presented as the mean value and standard error or standard deviation.

It was assumed in the study that the registered WVC sites might be located at a considerable distance from the actual place of the event, as large animals (e.g. red deer) are able to cover even another 800 m after the accident (Found and Boyce, 2011; Finder et al., 1999). Therefore, buffers with a radius of 800 m were established in the sites of collision with large animals. To create a result map showing the impact of land use on the probability of wildlife-vehicle collisions, Lublin was divided into six forms of land use mentioned above, which were considered important from the point of view of landscape ecology by Ng et al. (2008).

The impact of land use on the probability of wildlife-vehicle collisions was assessed by mounting the layers of collision maps onto a map showing the selected forms of land use. Then, in each site of collision, the distance (in a straight line) from the nearest land use forms was determined. Knowing the lengths of the sections connecting the collision sites with the forms of land use and using logistic regression, the following new models of the probability of collisions with animals were proposed (*Eq. 1*):

$$\ln\left(\frac{p_A}{1-p_A}\right) = \alpha_0 + \sum \alpha_i x_i \qquad \text{(Eq.1)}$$

where: ln - natural logarithm function, p_A - probability of collision, x_i - predictor variables, α_0, α_i - regression coefficients.

To develop new models for prediction of the risk of wildlife-vehicle collisions in the area of the city of Lublin and its surroundings, a random sample of points was determined for the location of roads (i.e. a land use form). The spatial data were processed in the ArcGIS for Desktop 10 environment. Next, to generate a grid of 300 objects, the Create Random Points tool, which is part of the data management tool set in the ArcToolbox application, was used. While generating the grid of objects, the minimum distance between two closest randomly designated points was assumed as ≥ 50 m. Subsequently, the data were verified manually. Based on estimation of the regression coefficients and with the use of logistic regression, models were generated for prediction of the risk of collision with medium and small (*Eq. 4*) (P_{AS}) and large animals (*Eq. 3*) (P_{AB}), as well as all animals regardless of their size (*Eq. 2*) (P_A). With the use of the ArcGIS tools, the model compliance with the actual data was 74.9%,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19811997

77.8%, and 73.5%, respectively. The predictor variables and the transforming function are presented in *Table 1*.

Table 1. *Marks of predictor variables and transforming function*

Prediction variable	Transformation	Designation
Distance from river valleys	$\log_{10}(x + 1)$	LR
Distance from forests	$\log_{10}(x + 1)$	LF
Distance from public greenery	$\log_{10}(x + 1)$	LG
Distance from agricultural land	-	A
Distance to housing	$\log_{10}(x + 1)$	LH
Distance from industrial buildings	$\log_{10}(x + 1)$	LI

LR- distance from river valleys, LF- distance from forests, LG- distance from public greenery, A- distance from agricultural land, LH- distance to housing, LI- distance from industrial buildings

Model of risk of collision with all animal species:

$$p_A = \frac{1}{1+\exp(0.3474 \cdot LR + 1.0709 \cdot LH - 1.1671 \cdot LI)} \quad \text{(Eq.2)}$$

Model of risk of collision with large animals:

$$p_{AB} = \frac{1}{1+\exp(0.4688 \cdot LR + 1.2746 \cdot LH - 1.2928 \cdot LI + 0.00027 \cdot LF)} \quad \text{(Eq.3)}$$

Model of risk of collision with medium and small animals:

$$p_{AS} = \frac{1}{1+\exp(0.3797 \cdot LR + 1.1130 \cdot LH - 0.9798 \cdot LI)} \quad \text{(Eq.4)}$$

where: LR- distance from river valleys, LH- distance to housing, LI- distance from industrial buildings, LF- distance from forests.

The statistical analyses of the probability of collision with medium and small animals were carried out at a significance level of $P = 0.05$ in the Statistical Analysis System (SAS, 2012). Distances from river valleys (LR), forests (LF), urban greenery (LG), agricultural land (LA), residential buildings (LH), and industrial development (LI) were regarded as dependent variables. With the exception of the distance from forests, the variables were transformed by the decimal logarithm to reduce the skewness of the distribution of the distances to the analyzed areas (Zar, 2010). Additionally, mutual correlations (CORR procedure) between the variables were analyzed to eliminate the highly correlated ones (Zar, 2010). The variables were then used as predictor variables in the logistic regression model with the maximum likelihood method (LOGISTIC procedure) for the resulting binary variable, specifying whether a collision had occurred at a given point (1 - collision, 0 - no collision at a random point) (SAS, 2012). To develop the final model, we used a full model with all potential predictor variables and different modes of choice of only relevant variables:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19811997

stepwise, forward, and backward elimination. The best model was selected using the Akaike information criterion, AIC (Akaike, 1974). To simplify the model, the interactions between the variables were disregarded. New models of the risk of wildlife-vehicle collisions were developed taking into account the division into large, medium, small, and all animal species.

Due to the large variability of the data in relation to the low number of collisions, a method used commonly in the case of concentration of events (hot spot analysis) had to be employed. It allows graphic representation of areas with high intensity of a given phenomenon (hot spot).

Results

The analyzed data showed that there were 291 collisions with animals in the city of Lublin and its surroundings during the study period, with almost half (42.7%) taking place on roads where the traffic intensity did not exceed 100 vehicles/day, and the collisions with medium and small animals accounted for 57.9%.

Areas especially susceptible to WVC (hot spots) in Lublin were identified where minimum two 800-meter buffers extending from the event sites overlapped (*Fig. 3*). The analyses demonstrated 105 hotspots in the area of Lublin, with more than half (58.1%) of the sites where only two buffers overlapped. Three buffers overlapped in 28.6% of the hot spots. In turn, 8.6% of the hot spots were located in sites with 4 overlapping buffers. Only 2.9% of and 1.9% the hot spots comprised 5 and 6 overlapping buffers, respectively (*Fig. 3*). The hot spots of collisions with large animals were located mainly in the areas of urban greenery (40.0%), agricultural land (20.0%), and forests (15.4%). In turn, the other collision hot spots were located near residential buildings (18.5%), industrial development (4.6%), and river valleys (1.5%). The vast majority (83.8%) of the hot spots of collisions with large animals were located on the outskirts of the city, along the main communication routes leading to the city center (*Fig. 3*).

The results of the analysis of the correlation between the traffic volume (vehicles/day) and the number of road collisions with wild animals revealed significant relationships between these factors (*Table 2*). There was no significant correlation between the increase in the number of wildlife-vehicle collisions and the increase in traffic intensity in any of the analyzed cases of events with large animals. An exception was the road sections with traffic intensity of 501-600 and 1101-1200 vehicles/day, where a highly significant positive correlation of the increase in the number of WVC with the increase in traffic intensity was demonstrated ($R = 0.4779$ and $R = 0.3589$, respectively). Similarly, in the case of collisions with medium and small animals, no significant positive correlations were found between the number of events and the increase in traffic intensity. However, there was a significant negative correlation ($R = -0.2774$) between the number of WVC and the increase in traffic volume on road sections exhibiting traffic intensity of 1101-1200 vehicles/day. This indicates that higher traffic intensity is correlated with a lower number of WVC (*Table 2*).

The analysis of the traffic intensity (vehicles/day) and the number of road collisions (regardless of the animal species) revealed a very strong negative correlation ($R = -0.3384$) between the number of WVC and the increase in traffic intensity on road sections with traffic intensity of 301-400 vehicles/day (*Table 2*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19811997

This indicates a significant decline in the number of collisions with animals at a higher traffic volume. In turn, there was a significant positive correlation between the number of WVC and the increase in traffic in the case of roads with 501-600 vehicles/day ($R = 0.2675$). Compared to the former correlation, this relationship is weaker but justified by the considerably lower impact of traffic on the number of wildlife-vehicle collisions.

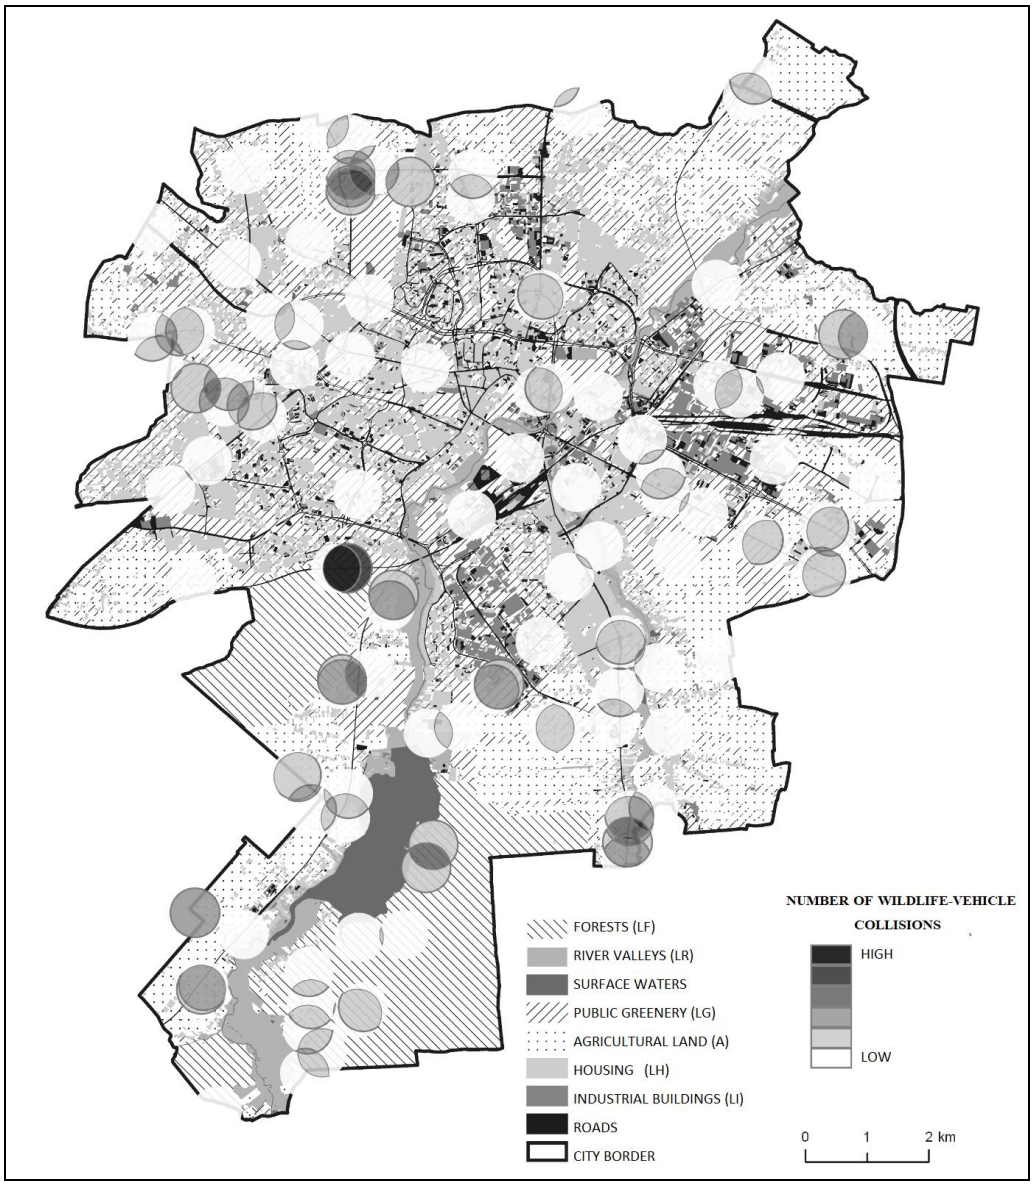

Figure 3. *Location and number of collisions (hot spot) with large animals in the city of Lublin*

No statistically significant correlation between the number of collisions and the season of the year was noted during the investigation period in the analysed area (Lublin). The highest number of WVC was recorded in summer and spring, i.e. 91 and 78 events with animals, respectively, which accounted for more than half (58.07%) of all recorded collisions (*Table 3*). The highest number of single collisions (79) and double collisions (two accidents in one place) was found for 12 city points in summer.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19811997

Also in spring, the vast majority of events were single collisions (68), double collisions took place in 8 city areas, and triple collisions were found in 2 city points; they constituted 87.18%, 10.26%, and 2.56%, respectively, of all collisions recorded at this time of the year (*Table 3*). In autumn, the vast majority of collisions (88.41%) were single collisions (68). Double collisions in autumn were recorded in 7 points of the city (10.14%). In the same season, 5 collisions were reported from 1 site in the city, which constituted 1.45% of all events recorded at this time of the year. The smallest number of wildlife-vehicle collisions, i.e. 53, which accounted for 18.21% of all collisions recorded in the investigation period, occurred in winter. As in the other seasons, the vast majority of collisions (96.23%) in this period were single events, while double events occurred only in two city locations (*Table 3*).

No significant correlations were found between the WVC and the forms of land use in any of the analyzed cases. The highest correlation was determined for forests and arable land ($R = 0.31$) and there was a negative correlation between arable land and industrial development ($R = -0.36$). In the case of large, medium, small, and all animals, models comprising only significant predictor variables were the best according to the AIC criterion. All methods for selection of the variables (stepwise, forward, backward) yielded the same models.

Regardless of the animal species, the distances from river valleys, residential buildings, and industrial development turned out to be significant predictor variables (*Table 4*). In the case of the first two variables, the risk of WVC increased with their decreasing value, while the risk of collision in the industrial development increased with the increasing distance from such areas.

Table 2. *Relationship between wildlife-vehicle collisions (WVC) and intensity of traffic road (for $P > 0.05$)*

DOI: http://dx.doi.org/10.15666/aeer/1801_19811997

In the analysis of collisions with large animals only, the variables indicated for all animals (distances from river valleys, residential buildings, and industrial development) and additionally the distance from forests (*Table 4*), for which it was found that the closer the distance to the forest the greater the risk of collision with large animals, turned out to be significant predictor variables. For the other predictor variables, the trend in the impact was similar to that in the case of all animals. While assessing the risk of collision with medium and small animals, the variables indicated for all animals, i.e. the distances from river valleys, residential buildings, and industrial development turned out to be significant predictor variables (*Table 4*). They had a similar effect to that noted in the analysis of all animals. The estimation of the probability of WVC shows the highest risk of such events in areas located on the outskirts of Lublin (Southern, South-eastern and north-western parts) (*Figs. 4–5*). A high risk of accidents with wild animals has also been identified for residential areas adjacent to the Bystrzyca and Czerniejówka river valleys in the central part of Lublin. The smallest risk of WVC was indicated near the industrial areas in the north and south of Lublin.

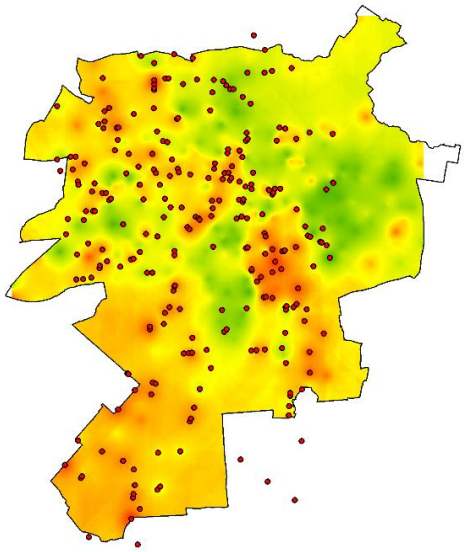

Figure 4. *The probability of an accident with wild animals, regardless of the species, in Lublin (red color - high probability, green - low probability)*

The analysis of the probability of collisions with animals indicates the greatest risk of collisions with large animals in an area located to the south-east from the center of Lublin (area adjacent to the Czerniejówka River valley) (*Fig. 5A*). It is a part of the city with compact single-family residential buildings with house gardens. A high risk of collisions with large animals has been noted in the southern part of Lublin, i.e. in the area of a large water reservoir (Zemborzycki Lake) surrounded by a forest complex, and in the central part - in a large city park (Ludowy Park) situated in the Bystrzyca River valley. As demonstrated by the analyses, areas located near the industrial development located in the northern, central, and southern parts of Lublin exhibit the lowest risk of collisions with large animals.

A B

Figure 5. *Maps of probability of collisions with animals in Lublin: A - with large animals, B - with medium and small animals (red color - high probability, green - low probability)*

The highest probability of collisions with medium and small animals was shown for the south-eastern part of Lublin (*Fig. 5B*). This is probably related to the presence of residential buildings and the Czermiejówka River valley. Other areas with a high probability of collisions with medium and small animals are located in the central and north-western part of the city. The central part of the city comprises residential buildings located in the immediate vicinity of dry loess gorges serving as a city park. In turn, the area located in the north-western part of the city is the Czechówka River valley near a two-lane express road (*Fig. 5B*). As in the case of large animals, a high risk of collisions with medium and small animals was estimated for the southern part of Lublin around the water reservoir (Zemborzycki Lake) and for areas to the north and south of the lake located near the wetlands of the Bystrzyca River valley, which flows out of this water body. Areas with the lowest risk of collision with medium and small animals, as in the case of large animals, are located in industrial development areas in the northern, central, and southern parts of Lublin.

Discussion

The present investigations have demonstrated that the number of WVC decreases with the increase of traffic intensity. This is consisted with the results reported by Forman and Alexander (1998), who showed a road avoidance effect. Busy roads sometimes deter animals sufficiently to prevent them from crossing (Clevenger et al., 2003); thus, animal mortality declines. The exceptions were road sections with traffic intensity of 501-600 and 1101-1200 vehicles/day, where there was a highly significant positive correlation between the increase in the number of WVC and the increase in traffic volume. This may be associated with the substantially higher speed of driving on these roads, and traffic intensity and speed are the main factors WVC, as shown in many studies (Forman and Alexander, 1998; Hubbard et al., 2000; Jones, 2000; Trombulak and Frissell, 2000; Dique et al., 2003; Seiler, 2003).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19811997

In the analyzed data from in the city of Lublin and its surroundings during the study period, there were no high correlations between WVC and land use forms. The sites of concentration of collisions with large animals (hot spots) were located mostly in the areas of urban greenery, agricultural land, and forest. This was confirmed in studies conducted by other authors (Hubbard et al., 2000; Nielsen et al., 2003; Farrell and Tappe, 2007; Ng et al., 2008), who found that wooded and open areas were the most attractive foraging sites for deer. The vast majority of sites of concentration of hot spots were located on the outskirts of the city along major communication routes leading to the city center. As demonstrated by Premo and Rogers (2001), there was an increase in collisions with deer in suburban areas.

The present study also showed the highest positive correlation between forests and arable land and a negative correlation between arable land and industrial development. These results are in agreement with those reported by Stewart et al. (2007) as well as Farrell and Tappe (2007), who have shown that cervids choose clearings with adjacent wooded areas and completely forested areas. The presence of open land near forested areas together with higher vehicle speeds and higher traffic volumes has been correlated with higher frequencies of deer-vehicle collisions (Bashore et al., 1985; Nielsen et al., 2003; Ng et al., 2008; McShea et al., 2008).

The analysis carried out in the city of Lublin and its surroundings shows the highest number of WVC in summer and spring. This is probably associated with the duration of the day and the seasonal activity of the animals. For many species of animals, spring is a time of reproduction, establishment of home ranges, fights for females, search for breeding places, and migration over distances larger than usual. Spring and summer are seasons when roebucks show increased activity establishing and protecting their territory (Ignatavicius and Valskys, 2018). In medium animals, e.g. fox and marten, this is a period of development of offspring and increased activity of females questing for food for their young ones (Goszczyński, 1995; Goszczyński et al., 1994; Herr, 2008). Interestingly, many studies indicate that autumn is another period (besides spring) with the highest number of accidents (39%). This season is a time of migrations to wintering grounds and mating in some species (especially deer). In this period, males are particularly vulnerable to the risk of road collision, as they expand their territories in search and fight for females (Tajchman et al., 2017A). Researchers agree that, despite the increased frequency of road collisions with ungulates in Europe and the United States in recent years, the events are not associated with the threat of extinction of species involved. It is prevented by the high reproduction rate of these species and/or the high ability to re-colonise habitats where the population has gone extinct (Found and Boyce, 2011; Hubbard et al., 2000).

The investigations studies carried out in the city of Lublin and its surroundings demonstrate that most of WVC cases involve medium and small animals (57.9%), with the greatest number of the events recorded in spring and summer. This phenomenon is disturbing, as the group of small animals often comprises species with small population sizes. Surveys carried out in Poland and Sweden (Seiler, 2004; Seiler et al., 2004) have shown that the brown hare is characterized by the highest rate of fatalities on the roads. It has been estimated that 35% of the 200,000 population of hares in Sweden dye in wildlife-vehicle collisions. The survival of populations of this species is also threatened in the Netherlands and Denmark, and mortality associated with collisions with motor vehicles may turn out to be an increasingly important factor limiting the population size of this species, which is endangered also in Poland. In the case of rare and endangered

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19811997

species, each individual dying under car wheels is a big loss. Quick recognition of the problem and mitigation actions can improve the status of the population. Intensive work is carried out to reduce otter mortality on the roads in Denmark and the death rate of the badger, i.e. a species threatened with extinction and decimated in wildlife-vehicle collisions, in the Netherlands (Lankester et al., 1991). Special attention should therefore be paid to this group of animals. In the present study, the risk of collisions with medium and small animals increased with the proximity to open water bodies or wetlands adjacent to roads (Gunson et al., 2011). This is in agreement with the results reported by Kanda et al. (2006), who noted collisions with small and medium vertebrates at low altitudes, which most likely provide favorable habitats for these animal species. The opposite was found for areas with higher road and building density (Bashore et al., 1985; Nielsen et al., 2003; Ng et al., 2008; McShea et al., 2008), which was also confirmed by the analyses carried out in Lublin. Interestingly, the present study has shown an increase in the number of WVC farther away from industrial development. This may be related to the fact that such facilities are most often located on the outskirts of the city, i.e. in open areas where animals dwell eagerly and humans are present only during working hours.

In the research carried out by Found and Boyce (2011) in the city of Edmonton, modelling was performed only for road collisions with cervids. It was demonstrated that the density of vegetation was by 52% higher in the established hot spots than in cold spots; additionally, the percentage of habitats available for animals was by 21% higher. This was also confirmed in the investigations conducted in Lublin showing that a closer distance to the forest was associated with a greater the risk of collisions with large animals. It should be remembered that increasing density of high vegetation causes poorer visibility and thus raises the risk of WVC due to the shorter time between noticing the animal and driver's reaction, which also increases the risk of WVC (Found and Boyce, 2011). Malo et al. (2004) emphasized that vegetation should be mown regularly within 40-80 m roadside buffers, which could lower the attractiveness of roadsides to herbivores. However, other studies have demonstrated that enlargement of the road width and visibility in roadside corridors increases the rate of WVC, as drivers move at higher speeds in such conditions. Another effective solution is the use of barriers or protective fences (Gunson et al., 2011).

Conclusion

Reliable and effective methods for WVC prediction and mitigation have become a priority for various city planners and wildlife handlers (Farrell and Tappe, 2007). Hence, similar studies should be carried out in all European cities with focus on the causes of the increased rates of wildlife-vehicle collisions. The existing WVC probability models should be used for graphic design - city maps with accident locations - hot spots. In addition, WVC probability models with individual groups of animals with similar biology and behavior should be constructed. This should be preceded by a thorough analysis of the number of WVC with large, medium and small animals. In aim of quick recognition of the problem and introduce mitigation actions which can improve the status of the animal population.

The distances from river valleys, residential buildings, and industrial development turned out to be significant predictor variables for WVCs. In the analysis of collisions with large animals, the variables were found that the closer the distance to the forest the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_19811997

greater the risk of collision increases. While assessing the risk of collision with small animals, the variables: the distances from river valleys, residential buildings, and industrial development turned out to be significant predictor variables. The highest number of WVC was recorded in summer and spring, which accounted for more than half (58.07%) of all recorded collisions. When planning the expansion of cities, pay special attention to the listed places, which depend on WVC, with particular regard to animal species or their groups using available minimizing solutions.

Moreover, migrating animals tend to take the easiest paths (Boone et al., 1996; Schippers et al., 1996; Larkin et al., 2004); hence, the risk of WVC increases when roads are situated at the ground level (Clevenger et al., 2003; Malo et al., 2004; Ramp et al., 2005). Such areas are found in most parts of Lublin. Roads run along embankments and are additionally fenced with acoustic screens preventing free migration of wild animals only in the northern part of Lublin. These are pilot studies, therefore in the future, it is worth investigating the number of WVC in correlation with the terrain level and the location of roads. In addition, human factors/behavior and weather conditions should also be taken into account.

Abstract. Rooting performance of Salakhani, a local variety of Iraq and Zivzik (*Punica granatum* L.), a local pomegranate of Siirt, were compared in our study. For this purpose, the effect of different doses of indole butyric acid (IBA) (0.00, 1000, 2000, 4000, 6000 mg / L) on rooting was examined. Cuttings were kept in the rooting environment for five months and rooting rates, root number, root lengths, survival rates, shoot lengths, shoot and leaf number were determined. Salakhani were found to be the best cultivar only in terms of the root length, sprout length, shoot number and leaf number. Zivzik were found to be the best variety with regard to the other properties. IBA application of 4000 ppm was found to be the best all the shoot number, leaf number and root length. The hormone dose of 6000 ppm was found to be the most beneficial for survival and rooting rates. Application of 1000 ppm was found to be the best dose among the doses of hormone only on account of root number.
Keywords: *plant growth regulators, Punica granatum L., cutting production, vegetative growth, hormone effect*

Introduction

Pomegranate is one of the first five important fruits together with fig, date, olive and grape which are old known cultivated plants. The domestication of pomegranate started 3000-4000 BC in the North of Iran and Turkey (Usanmaz et al., 2014). It is a perennial plant grown in tropical and subtropical regions (Schubert et al., 1999). Iran and the Himalayas of Northern India are the central origin of pomegranate. This fruit grows well in semi-arid temperate and subtropical climate and it is naturally grown in any climate with cool winter and hot summer. Pomegranate is deciduous in the subtropics and is evergreen in the tropical regions.

It is a species found in temperate forests that requires high temperatures in summer in order to reach full maturity and achieve commercial production (Melgarejo and Martinez, 1989). For most species of pomegranate, the suitable temperature degrees are between 21°C and 27°C during day-time and 15°C of night-time temperatures (Hartmann et al., 1997). It is naturally grown and is well adapted to the regional climate in Afghanistan, China, Morocco, Palestine, India, Iraq, Iran, Israel, Italy, Cyprus, Egypt, Syria, Saudi Arabia, Thailand, Tunisia, Turkey. Iran, Spain, Tunisia and Turkey are the countries exporting pomegranates (Özgüven and Yılmaz, 2000). India is first in terms of pomegranate production and production area. When it comes productivity, Spain (18.5 t/ha) comes first, traced by USA (18.3 t/ha). On the other hand, Iran (60.000 t/year) is first in point of exports, chased by India (37.176 t/year) (Chandra et al., 2006, 2008; Chandra and Meshram, 2010; Silva et al., 2013).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_201217

Pomegranate cultivation is done in different soil types, such as sand, gravel, clay and heavy clay soils. Optimal development of pomegranate is observed in deep, permeable, alkali and sandy loam soils. In Turkey, pomegranate cultivation can be done in all regions, except for very cold regions. Furthermore, pomegranate can withstand the lowest temperature range from -10°C up to -15°C, while the temperature lower than -20ºC causes the death of the plant. Period of vegetative growth ranges between 180-215 days. In addition, the flowering period ranges between 50-75 days, and the fruit growth and development period ranges between 120-160 days (Onur, 1983).

Its fruit is rich in vitamins, iron, folic acid, potassium and polyphenol antioxidants, which are used to treat different diseases and pomegranate extract is used as an alternative method for the treatment of especially different types of cancer, such as breast cancer and prostate cancer, skin cancer, colon cancer, and lungcancer. Pomegranate extract includes seed oil and pomegranate juice, pomegranate peel, and different parts of the plant roots, bark and flowers (Kavaklı et al., 2011). Several parts of pomegranate have the biological properties of extracts, which have been used in therapeutics, such as in the prevention of infection, inflammation, cancer, and in other applications (Miguel et al., 2010). Fruit juice is an excellent source of sugars, vitamins (B and C) and minerals, potassium, iron, antioxidants, polyphenols, and some parts of the pomegranate tree, such as leaves, immature fruits, fruit peel, flower buds are used inmedicinal applications and also for the tanning of leather. Wild pomegranate has a very tart flavor and is of a little value, it is used only as a souring factor. The double-flowered pomegranate used for decorative purposes (non-fruitful) is grown in parks and ornamental gardens for its beautiful red flowers and for the beauty of its appearance (Raj and Kanwar, 2010). Recent studies suggest that pomegranate juice contains anticancer, antimicrobial, and antiviral components (Reddy et al., 2007; Kotwal, 2007; Schwartz et al., 2009).

The propagation of pomegranate is performed either sexually by seeds or by using the vegetative method (asexual) with cuttings and less frequently it is performed using layers, suckers or graftings (Hartmann et al., 1997; Melgarejo et al., 2008; Polat and Çalışkan, 2009). The propagation from cutting (cloning) is an easy, quick and economical method which produces a plant of the same characteristics as the mother plant and which is uniform in sprouting, comes into bearing and fruiting earlier than the seedling and does not need any new techniques in grafting, budding and layering. The success of this process depends on some factors such as the condition of the mother plant, the age of the plant, planting time, temperature, and rooting media (Frey et al., 2006). Cutting is the simple and successful method of pomegranate propagation with 15-20 cm in length and of the pencil size or bigger in diameter and the use of semi-hardwood or hardwood rooting hormone is possible in this method (Melgarejo et al., 2008; Saroj et al., 2008; Polat and Çalışkan, 2009). The cuttings collected at the end of February have a higher rooting potential than those collected at the beginning of October (Polat and Çalışkan, 2009). Grafting is one of the propagation methods which is used for varieties to be propagated of which there are barely specimens from which cutting can be obtained; this process should be conducted at specific times, in May or in July, although it can also be done at the end of the summer (with dormant buds) (Melgarejo and Martinez, 1992). Tissue culture (micropropagation), which is another method of vegetative reproduction of fruit crops, helps in overcoming problems of sexual propagation, producing new plants of the same characteristics with their parents, quick, and mass production of planting materials (El-Agamy et al., 2009).

DOI: http://dx.doi.org/10.15666/aeer/1801_201217

Aim of this study is to compare effects of the application of IBA growth hormone on sprouting and rooting situations of two local pomegranate varieties, Salakhani, in Halabja province in North of Iraq and Zivzik, in South East of Turkey. There is no experiment about either Salakhani or Zivzik varieties on rooting with cuttings until now. Therefore this study is unique and important to guide subsequent studies.

Literature Research

Melgarejo et al. (2008) reported that the application of exogenous auxins to pomegranate cuttings resulted in the increase of rooting percentages up to three folds. Owais (2010) stated that the application of rooting hormones can increase the rooting percentage of pomegranate cuttings at the rate of 49-73%. Rooting is significantly increased by the addition of synthetic auxins (Hartman and Kester, 1983). Polat and Çalışkan (2009) revealed that some factors, such as the physiological conditions of the parent plant, cutting types, the dates of their taking and medium type, affect the rooting of pomegranate cuttings. They suggested that the cuttings collected at the end of February had a higher rooting potential than those taken at the beginning of October.

In other investigation accomplished under mist chamber by Singh (2014) it was shown that different concentrations of IBA had a significant effect on some growth characteristics of hardwood cuttings in *Punica granatum* L. It was noted that the maximum rooted percentage, root length, sprouted length and leaf number percutting were obtained at the 5000 ppm dose of IBA, while the minimum value was reached in the control group. Alikhani et al. (2011) conducted an experiment to determine the effects of the kind of medium and the kind of pomegranate cuttings on the rooting ability and growth of cuttings under greenhouse conditions. In this experiment, two different medium cultures (sand/peat and sand) and three kinds of pomegranate cuttings (one bud, three buds, more than three buds) were used. At the end of the study, it was revealed that the effect of cutting type on leaf number was significant ($\rho<0.05$). However, it was found out that the effects of medium and interaction between cutting type and medium type on leaf number were not so significant, additionally, the type of the cutting had an influence on leaf number. It was noted that the cutting type had a significant effect on shoot number. On the contrary, the effect of medium and interaction between cutting type and medium type on shoot number was not significant. In terms of raised bud numbers, the effect of medium and cutting type was not significant. However, the effect of cutting type on raised bud number and the effect of interaction between medium type and cutting type on raised bud number were significant. Eventually, the effect of medium and cutting types and the effect of interaction between them on root length were significant.

Abu-Zahra et al. (2013) examined in their study the application of exogenous auxins to ornamental plants such Rosemary, Hedera, Syngonium and Gardenia (all of them are difficult to root without using a rooting hormone) in six different concentrations of NAA (0, 1000, 2000, 3000, 4000 and 5000 ppm NAA). Result of their study showed that the highest rooting percentages as the number of roots, the best length, in comparison to the control treatment, were obtained with 3000 ppm NAA in Rosemary and Hedera cuttings, while the best results were obtained with 4000 and 1000 ppm NAA in Gardenia and Syngonium cuttings, respectively. Adekola and Akpan (2012) realized an experiment to assess the effect of the application of two growth hormones, NAA and IBA, on sprouting and rooting behaviours of Nigerian (*Jatropha*). The growth regulator was applied by adopting the slow dip method (for 24 h). In addition, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_201217

untreated replication was accepted as a control group. The results showed that there were no significant treatment differences in the survival percentage and sprouting behaviour of *J. curcas*. A slight selective response to the application of growth hormones was observed in terms of rooting behaviour, as IBA treated cuttings rooted better than the NAA-treated cuttings. However, the untreated cuttings gave the best performance for all the parameters assessed on the sprouting and rooting ability of *J. curcas*. Hence, the untreated cuttings can be used for the mass production of *Jatropha* since they are good propagating materials.

Sharma et al. (2009) executed an experiment to improve the rooting and reduce the mortality of rooted cuttings under field conditions. The results clearly indicated that the treatment of IBA 500 ppm with Borax 1% produced the greatest root number and root length in semi-hardwood and hardwood cuttings of pomegranate. Consequently, the semi-hardwood and hardwood cuttings of pomegranate cultivars. Ganesh treated with IBA 500 ppm + Boron 1%, IBA 300 ppm + Borax 2% and IBA 5000 ppm gave 100% survival of the rooted cuttings under field conditions. Babaie et al. (2014) investigated the effect of different IBA concentrations (control, 2000, 4000 and 6000 ppm) and the time of taking acutting (late June and early September) on the rooting growth and survival of *F. Binnendijkii* 'Amstel Queen' cuttings. Detected that at 6000 ppm and 4000 ppm of IBA and the time of cutting in early September, the highest percentage of rooting ranging from 100% to 96.66%, respectively, the longest root length (16.61 cm) and the greatest number of roots were recorded (15.69 and 14.27, respectively). Whereas the greatest length of new shoots was obtained in the IBA concentration of 2000 ppm and 4000 ppm in late June, the maximum number of new leaves was obtained in the IBA concentration of 2000 ppm and 4000 ppm, with the cutting taken in late June.

Ansari (2013) noticed in his testing that different media and pomegranate cutting separation dates had highly significant effects on rooting characteristics. If suitable media are used, a better cutting separation takes place at the end of they are in terms of a higher rooting percent and increasing root number (Singh, 2009; Janner, 2012; Young, 2012). Furthermore, among different media, vermiculite and its mix with sand were the best for a higher rooting percent and root number. A research actualized on five pomegranate varieties by Owais (2010) was determined all of them had root ability higher than 80% at 9000 ppm IBA treatment, and although the ability of generating roots was enhanced by IBA treatment, it seemed to be that much variability was related to the variety. Hardwood cuttings of pomegranate varieties seem to have a clearly higher root ability than those of semi-hardwood cuttings at different IBA levels for different pomegranate varieties.

Singh et al. (2011) carried out a search to study the effect of planting time and IBA (Indole Butyric Acid) on rooting and vegetative growth of pomegranate cuttings (Ganesh) with different concentrations of IBA 50, 100 and 200 ppm (s.d) for 24 h and IBA 1000, 1500, and 2000 ppm (q.d) for 15 s, on December 15 and January 15, respectively. The results showed that there were significant differences between the time of plantation, IBA treatment concentrations and their interaction with regard to sprouting and last survival percentage of cuttings and statistically significant differences were observed between the dates of plantation and IBA concentrations applied with regard to the number of roots, length of the longest root and root weight characteristics, as well as significant variations between the time of plantation and growth regulator concentrations were observed with regard to the plant height.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_201217

In another study succeeded in July, December and January by Kahlon (2007) it was shown that season and shoot part had a significant effect on the sprouting percentage and growth of pomegranate. Also, in that experiment was noted that the greatest sprouting was observed in January and the least one in July plantings and a much higher one was observed in January plantings. Furthermore, the sprouting percentage was the highest in the middle part when compared to the basal and sub-apical types of cuttings. Melgarejo et al. (2000) worked on the effect of 2000, 4000, 8000 and 12.000 ppm indole butyric acid (IBA) concentrations and wounding at the cutting base in pomegranate. Results showed that IBA markedly increased the percentage of rooting (although not at all concentrations), with a high concentration of 12.000 ppm producing the best results in the clones studied. Moreover, wounding carried out at the base of the cutting further increased the percentage of rooting in most of the clones studied.

Mehraj et al. (2013) achieved a trial to study the influence of IBA on the sprouting and rooting potential of (*Bougainville spectabilis*) stem cutting during the period from May to August, with different concentrations of Indole Butyric Acid (control, IBA in dust form, 500 ppm, 1000 ppm, 2000 ppm). The cuttings were soaked in IBA solution for (24 h) and the IBA dust was attached to the cutting just before the establishment in soil. They found out that IBA at 1000 ppm resulted in most sprouting, rooting and a higher survival percentage of rooted cuttings along with a higher number of roots, sprout buds, maximum root length and diameter. Singh et al. (2015) conducted one another experiment under valley condition to study the effect of different growing conditions (two different conditions, namely, shade house and mist chamber) and various concentrations (control, 1000, 1500, and 2000 ppm) of IBA on the rooting and shooting of hardwood cutting of phalas (*Grewia asetica* L.) in the month of September. Result of the study showed the greatest success of hardwood cuttings in the mist chamber growing condition, while IBA 2000 ppm gave the highest success rate of cuttings in all aspects, such as rooting percentage, the length of shoot, the length of root, thickening of root and leaf sprouting in the shoot.

Singh et al. (2014), performed a search in the mist house to study the effect of different concentrations (control, 1000, 2000, 3000, 4000, 5000 ppm) of IBA on inducing rooting in stem cutting (softwood cutting) of *Duranta erecta* var. golden. Softwood cuttings of *Duranta erecta* var. golden were obtained from 2 to 4-year-old plants and 15 cm long cuttings with the apical part. They found out that IBA at 4000 ppm resulted in the maximum percentage of rooted cuttings, followed by 5000 ppm concentration of IBA and the minimum percentage of rooted cuttings was observed under control. Fouda and Schmidt (1995) informed the effect of different concentrations (500, 1000, and 2000 ppm) of IBA on root development in *Rosa canica and Rosa rougosa* leafy cuttings. They found out that IBA increased rooting percentage in *Rosa canica*, the maximum rooting percentage was achieved with the cuttings collected at the beginning of June and treated with 1000 ppm IBA.

Ghosh et al. (1988) declared the effect of NAA and IBA on adventitious root formation in the stem cutting of pomegranate (*Punica granatum* L.) under intermittent mist. They found that IBA was more effective than NAA in inducing rooting of hardwood, semi-hardwood and softwood cutting. IBA at 5000 ppm resulted in the maximum rooting success (83.33%), but at higher concentration (10.000 ppm), a greater number of roots and increased root length were recorded. The greatest rooting success was obtained with hardwood cutting. Hedge and Sulikeri (1989) studied the effect of indole butyric acid (IBA) on the rooting in the air layers of pomegranate. In the trials

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_201217

with cv. Jyothi, mature shoots were treated with IBA at 250-1500 ppm and air layered between June and August. Rooting increased with IBA concentration from 84.38% at 250 ppm to 93.75% at 1500 ppm and 68.75% in the control.

Hansen (1986) carried out a research under the controlled greenhouse condition for 13 weeks to study the effects of cutting position and stem length in *Schefflera arboricola* and to develop propagation technique to obtain a fast and uniform root formation. Eight cuttings from the sub-apical to basal regions were excised from each stock plant. The stem length above the node was the same for all cuttings, whereas the stem length below the node was cut to different lengths, ranging from 0.5 to 3.0 cm. He found that cuttings from sub-apical positions rooted more slowly, produced fewer roots and had a lower rooting percentage than cuttings from the more basal regions, furthermore, the number of roots and rooting percentage increased with the length of the stem below the node.

Materials and Methods

Plant Material

This study was carried out in 2015-2016, at 25ºC room conditions in the Physiology Laboratory of the Department of Horticulture, Faculty of Agriculture, Siirt University in Turkey. In this experiment, a private orchard of pomegranate Salakhani and Zivzik were selected, and the plant age ranged between 20-25 years for Salakhani and 20-25 years for Zivzik and trees were selected on the basis of their uniformity in appearance, growth habits and vigour. Salakhani variety is a local pomegranate genotype grown naturally, specifically in Halabja province, Northern of Iraq, and Zivzik variety is considered to be one of the local varieties available in Siirt province in the Southeast of Turkey. Cuttings of Salakhani variety were collected from their natural area in Halabja and cuttings of Zivzik variety were collected from Zivzik Village in Şirvan district of Siirt at the beginning of the Spring.

Preparation of Experiment

Our experiment was conducted to study effect of different concentrations of (IBA) Indole Butyric Acid on rooting percentage, survival percentage, branches number, sprout length, root number, root length and leaves number of pomegranate cuttings of Salakhani cultivars and Zivzik cultivars, during the period from May to August. Five treatments (control, 1000 ppm, 2000 ppm, 4000 ppm and 6000 ppm) were applied in the experiment with three replications. 25 cm in lenght cuttings were obtained from 1 m in lenght cuttings. 10 cuttings were used per treatment in a pot with three replications. Therefore, there were 30 cuttings in each treatment and 300 cuttings in total were used in the experiment for both cultivars (Salakhani and Zivzik variety). The data on the root and shoot characteristics were collected five months after planting. Perlite and peatmoss were used as rooting media. A mix of peatmoss and perlite at a ratio 1-1 was used for both varieties.

Hormone solutions were prepared by dissolving 0.1, 0.2, 0.4 and 0.6 g, respectively, of IBA pure powder and diluting with 50% alcohol (ethanol), and adding 50% pure water to make 100 ml of each concentration. Pure water and alcohol were used as control treatment. Preparation process of cuttings was conducted in the laboratory of the Department of Horticulture, Agriculture Faculty, Siirt University. Vigorous shoots from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_201217

the previous year of grown and healthy pomegranate trees were used for obtaining the cuttings, and the cuttings of a standard size were washed with tap water. Subsequently, a sharp knife was used in the preparation of cuttings for the experiment to avoid the injury of the cutting. The cuttings of uniform lengths, approximately 15 cm in length, were taken in the month of February when the plants are dormant with wounding by making two opposite longitudinal incisions at the base of each cutting. At least three nodes were included in each cutting. The bottom of the cuttings was treated with hormone of Indole Butyric Acid (IBA) at different concentrations. Basal 1-1.5 cm portion of the cutting was dipped in the growth regulator solution of IBA for 10 seconds (q.d) and immediately inserted in the media at a slight angle to the vertical, to a depth of 10-11 cm (as shown in *Figure 1*).

Figure 1. *Preparing of the cuttings*

Experimental Procedures and Statistical Calculations

Parameters obtained from our experiment were measured in the laboratory of the Department of Horticulture, Siirt University. These traits included the rooting percentage, number of roots per cutting, survival cutting rate, number of shoots per cutting, root length (mm), sprout length (mm) and the number of leaves per cutting, which were recorded at the termination of the experiment (*Figure 2*) after five months, at harvesting early in August. The roots were examined by lifting cuttings carefully from the rooting media and washing them with tap water. The measurement process was conducted by a tape-measure. The data were collected from all of the cuttings and then the mean value was calculated. Experimental design used which was factorial design in randomised plots. The treatment in each experiment had three replicates and each pot (container) consisted of 10 cuttings. The results of the experiment were statistically analysed and the means were compared using Duncan's Multiple Range Test at the level of 0.05. All analyses were performed by JMP Version 5.0.1 statistical software and letterings were shown in graphs (*Figures 3 and 4*) and *Table 1*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_201217

Results and Discussions

The following findings were obtained in our rooting study. When the data on rooting percentage were examined, there was found 1% statistical significance in terms of varieties and hormone doses. While 5% significance level in terms of IBA type hormone interactions.

Figure 2. *A view of the experiment*

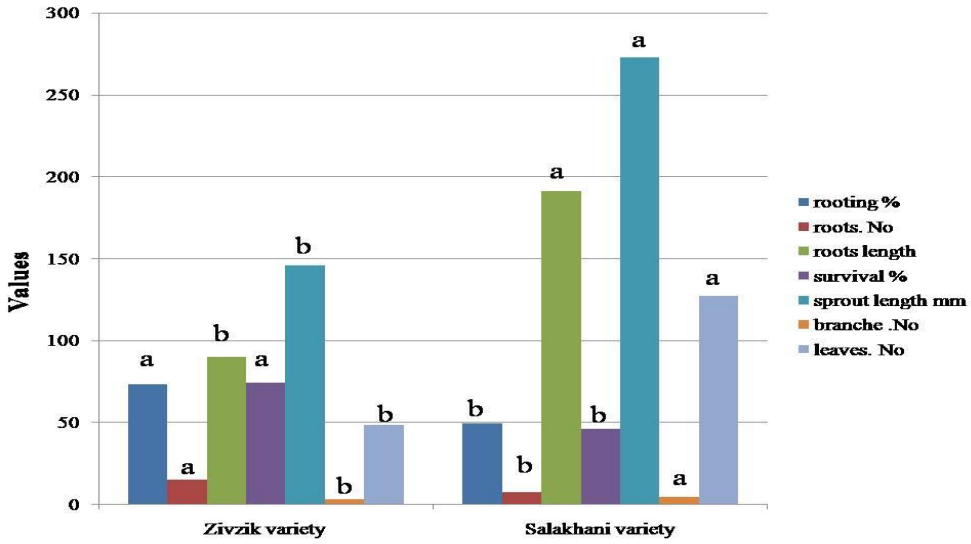

Figure 3. *Effect of different IBA treatments on rooting forms of Zivzik and Salakhani varieties. *Letterings were obtained from statistical data: P <0.001; 0.05% level of probability using LSD*

Rooting Findings

Rooting Percentage (%)

Highest percentage of rooting (73%) was observed in Zivzik variety, Siirt native. While, Salakhani variety was the second and last one with the rooting percentage of 49%, respectively (*Figure 3*). Among the hormone doses used, the highest percentage (72%) of the hormone dose was a demonstrated at 6000 ppm, while, the control group was the second one with 67% rooting percentage (*Figure 4*). The hormone dose group

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_201217

with the lowest percentage of rooting (43%) was the 4000 ppm dose group. The highest (93%) rooting percentage in the variant IBA hormone interactions was found to be related to the 6000 ppm dose applied to Zivzik variety, while the lowest value (23%) was obtained in the case of Salakhani variety with the 4000 ppm dose of IBA (*Table 1*). Hormone use is more effective in clones, especially in rooting fractions (Melgarejo et al., 2000). However, that the untreated stem cuttings had the best performance in terms of rooting of (*Punica granatum* L.) Salakhani variety could be due to the fact that growth hormones may not be the essential major factor influencing root induction in that variety. The rooting of cuttings may be influenced more by other factors such as the physiological age of cuttings and the status of rooting media in terms of aeration and drainage properties as stated by Narin and Watna (1983). In this experiment, the highest hormone concentration was the most positive effective dose in terms of the rooting percentage. This result is in conformity with the findings of Melgarejo et al. (2000) and Singh et al. (2015) who reported that the highest percentage of rooting was observed due to the increased hormone concentration. Similar results were also reported by Mehraj et al. (2013), Fouda and Schmidt (1995). Owais (2010) indicated that IBA had a significant effect on the rooting. Abu-Zahra et al. (2013) found different results, so it is thought that the hormones used are derived from different types.

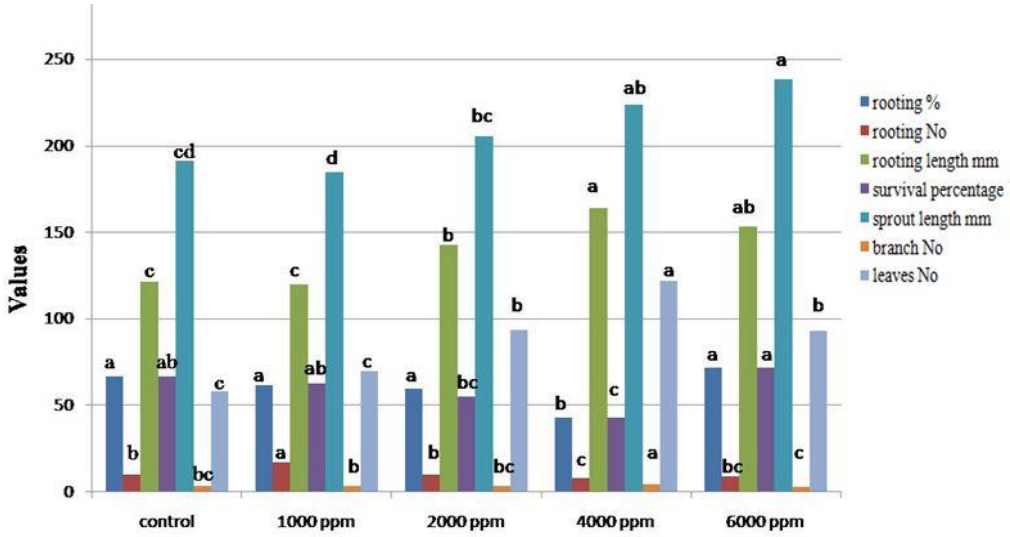

Figure 4. *Effect of IBA concentrations on survival performance and growth of the cuttings.*
**Letterings were obtained from statistical data: P <0.001; 0.05% level of probability using LSD*

Number of Root

When the measurements of rooted number were examined for Zivzik and Salakhani pomegranate, it was observed that Zivzik variety increased the number of roots up to two folds compared to Salakhani variety, whereas, the values obtained for both cultivars in the root number percentage were as follows: 14.7 for Zivzik variety and 7.03 for Salakhani variety (*Figure 3*). Considering the root characteristics such as the number of roots per cutting for both varieties (Salakhani and Zivzik cultivars), it was determined that Zivzik cultivars produced the maximum root number and that the IBA treatment at 1000 ppm produced the highest root number (17.06) and the lowest number of roots (7.93) was determined with IBA at 4000 ppm (*Figure 4*). When the table is examined

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_201217

according to the IBA type hormone interactions in terms of the number of rooted seedlings, it is seen that the number of seedlings rooted at the highest level (27.08) is in Zivzik variety at 1000 ppm. In contrast, the lowest number (5.44) of seedlings rooted is in Salakhani variety, with 4000 ppm of IBA (q.d) treatment (*Table 1*). From the present study, it is revealed that soaking the cutting in IBA solution increases the number of rootson cuttings due to the rooting ability of IBA. Hartmann et al. (1997) stated that the concentration of auxins substantially higher than that normally found in plant tissues may play an inhibitory role for the growth and root formation. Ramdayal et al. (2001) and Gupta et al. (2002) also found the maximum number of rootsat 1000 ppm IBA. The findings related to the number of rooted seedlings were found to be parallel with the findings of Ghosh et al. (1988) who applied doses of 5000-10.000 ppm, Hegde and Sulikeri (1989) who applied 250-1500 ppm IBA and Mehraj et al. (2013) who used doses of 500-1000 and 2000 ppm. The difference in regard to the findings of Abu-Zahra et al. (2013) could be attributed to the difference of hormones used.

Table 1. *Effect of the interaction among IBA doses and vegetative growth of the cuttings*

Cultivars	hormone doses	rooting rate (%)	roots number	roots length (mm)	survival rate (%)	shoot length (mm)	shoot number	leaves number

Length of Root (mm)

While the highest root length (191.05 mm) was determined in the seedlings belongs to Salakhani variety, Zivzik seedlings were the lowest one with the length of 89.92 mm (*Figure 3*). When the effects of hormone doses on root length were examined, it was found out that the longest roots (164 mm) were obtained at dose of 4000 ppm, whereas the lowest one (120.32 mm) was obtained at dose of 1000 ppm (*Figure 4*). At the same time, the control group without hormone treatment had longer lengths (121.53 mm) than the 1000 ppm dose group (*Figure 4*). Based on the analysis of variance of the effect of IBA type hormone interactions on root lengths, the highest root length values (230.76 mm) compared to other subjects were obtained in Salakhani variety with 6000 ppm IBA hormone (q.d) treatment, while the lowest root length values were obtained in Zivzik variety with 6000 ppm hormone dose (*Table 1*). Statistical significance at the 1% significance level was found in all subjects. The findings of Abu-Zahra et al. (2013)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_201217

were different, which was due to the differences in the hormones used. The findings of Hartman and Kester (1983) who indicated that rooted seedlings increased significantly; Owais (2010) and Sharma et al. (2009) who found that the longest roots were derived from hormone-containing plants; Singh et al. (2011) and Ghosh et al. (1988) who identified the statistical differences between practices are similar to the findings in this study.

Survival Cutting Rates

The highest value (74%) in terms of the survival rate was obtained from Zivzik variety. Whereas, the survival rate value measured in Salakhani variety used in the experiment was determined to be 46% as shown in *Figure 3*. Parallel results between the rooting rates and survival cutting rates were determined. When the effects of the hormones used in different doses on survival rates were examined, it was found that 6000 ppm of hormone application provided the highest survival rates with 72%, the control group (T0) was the second with 67% survival rates value while 4000 ppm hormone dose application was the last (*Figure 4*). When the values of the IBA type hormone interaction were examined in terms of the survival rates, it was determined that the highest value (93%) belonged to Zivzik variety with IBA at 6000 ppm. The interaction of Salakhani variety control group was better than other interactions. It is observed that Salakhani variety and 4000 ppm hormone dose interaction was in the last place with the value of 0.23% survival rates (*Table 1*).

Length of Sprout (mm)

The highest value of sprout length (272.58 mm) was found in Salakhani variety and the lowest value (145.59 mm) was found to belong to Zivzik variety (*Figure 3*). When the effects of hormone doses on sprout length were examined in Zivzik and Salakhani varieties, it was found that among the hormone doses applied 6000 ppm dose gave the highest (238.85 mm) sprout length and IBA at 1000 ppm hormone dose gave the lowest (185.09 mm) sprout length (*Figure 4*). Among the IBA type hormone interaction, the highest sprout length (300.23 mm) was determined in Salakhani variety with IBA at 6000 ppm and the lowest sprout length value (110.47 mm) was determined in Zivzik variety without hormone treatment (control group) as shown in *Table 1*.

Number of Shoot

It was determined that the average number of shoot in Salakhani variety (4.27) was higher than in Zivzik variety with 2.95 (*Figure 3*). According to the effects of hormone doses on shoots number, it was found out that the value belonging to 4000 ppm hormone dose application (4.31) was higher than the values of other hormone doses. The lowest shoots number (3.18) was found in 6000 ppm application (*Figure 4*). The shoots number of Salakhani variety observed in the hormone and variety interactions is superior to Zivzik variety. When the interactions were examined, the highest average value of shoots number (5.44) was obtained in Salakhani variety with the 4000 ppm IBA hormone dose and the lowest value of shoot number (2.58) was obtained in Zivzik variety with 2000 ppm (*Table 1*). Especially, the number of shoots and survival rates increased with the use of hormones in parallel with the findings of Janick (1972) and Hartmann and Kester (1983) who determined that the use of natural hormones increases the survival percentage as well as all vegetative developments in seedlings.

DOI: http://dx.doi.org/10.15666/aeer/1801_201217

Number of Leaves

When the varieties and hormone doses were examined in terms of the number of leaves, it was determined that the highest leaf number average value (127.05) was obtained from Salakhani variety and the lowest leaf number average value (48.05) was obtained from Zivzik variety (*Figure 3*). It was noted that the hormone dose of 4000 ppm had the highest mean leaf number value (122.09) and the control value was the lowest value of the mean leaf number (58.48) (*Figure 4*). It has been determined that the leaf number is influenced by the variety and hormone interaction but not statistically significant. However, the highest leaf number average value (177.44 mm) was obtained from the interaction of Salakhani variety with IBA at 4000 ppm (q.d) treatment and the lowest value (23.03 mm) was obtained from Zivzik variety without hormone treatment (control treatment) (*Table 1*). Babaie et al. (2014) who performed similar studies and used IBA as a hormone reported that the largest number of leaves was available at doses of 2000 and 4000 ppm. Mehraj et al. (2013) found that the maximum vegetative growth was achieved with 1000 ppm of IBA.

Furthermore, more adventitious roots were observed on the pomegranate seedlings belonging to Zivzik variety. Meanwhile, strong and thick roots were observed on the pomegranate seedling of Salakhani variety which was more when compared to Zivzik cultivars. Moreover, the period required for the first sprouting of Salakhani variety ranged between 10-11 days. Whereas, the period required for the first sprouting of Zivzik variety reached 12-13 days. The above-mentioned period was considered to be the period between the days of planting the cutting to the day of sprouting the first bud on the cutting.

Conclusion

Upon examining sprouting and rooting behaviour in stem cuttings, highly contrasting responses to IBA addition were indicated among various concentrations of IBA, each variety had superiority to the other one in different aspects. Zivzik variety had a higher value of rooting number, rooting percentage and survival percentage than Salakhani variety. Salakhani variety had a higher value of root length, sprout length, shoots number and the number of leaves than Zivzik variety pomegranate. The highest dose of hormone (6000 ppm) was found to be the most effective on rooting percentage, survival percentage and sprout length, while 4000 ppm was found to be the most effective on root length, shoots number and the number of leaves. The 1000 ppm dose was determined to significantly increase the root number compared to other doses. Regarding to the interaction effect of IBA doses, it was shown that the best performance in terms of rooting percentage, survival percentage, root length and sprout length was observed at the 6000 ppm dose of IBA, whereas 4000 ppm was found to be the most effective on shoots number and leaves number. The 1000 ppm dose was determined to significantly increase root number compared to other doses. Hence, it can be concluded from the present experiment that the higher concentrations of IBA (6000 ppm) and (4000 ppm) positively affect the sprouting and rooting ability in the stem cuttings of pomegranate cv. Zivzik and Salakhani. In contrast, the optimum IBA concentration for the number of roots per cutting was found to be 1000 ppm (Shoots and roots of the cuttings rooted in different hormone doses are given in *Figure 5* and *Figure 6*). Based on the findings of current investigation, the results have proved that Zivzik variety gives better results than Salakhani variety in terms of rooting percentage, survival percentage

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_201217

and roots number in Turkey environmental conditions. From the results obtained in the present experiment and discussion, from the economic point of view, it can be concluded soaking the cut stem on 1000 ppm IBA solution for 10 second (q.d) before the establishment of the stem cuttings show maximum result in terms of root number was obtained at the 1000 ppm dose of IBA and we recommend using 1000 ppm of IBA, which will provide a significant increase in root number compared to other doses. In conclusion, pomegranate cuttings with different doses of IBA were successfully rooted in our study. As it is known, pomegranate is produced without vaccination. Therefore, it is important that pomegranate seedlings can be reproduced quickly and rapidly with cuttings. Because of this reason, further studies also can be done using different hormones and their doses to obtain the best sprouting and rooting results for cuttings of both Salakhani and Zivzik variety.

Abstract. *Staphylococcus aureus* is a common cause of urinary tract infections associated with catheters. Biofilm is a community of microbial cells attached to a surface and is embedded in the extracellular polymeric substances. Catheters were collected from 157 patients; *S. aureus* was identified by molecular and conventional microbiological methods. *S. aureus* isolates showed a higher level of biofilm production, and all isolates showed biofilm production using Microtiter plate assay, while 89% of the isolates produced using Congo red agar method. All biofilm-producing isolates were positive for *icaC*, *icaD,* and *cna* genes, except isolate SA88, indicating the vital role of *ica* genes as markers of virulence in *S. aureus* infections. The difference in the inhibition of biofilm formation between the culture containing *Z. officinale* extract and the control was recorded. The high percentage of biofilm inhibition was 61.4 against SA04 at a concentration of 16%, whereas there is no effect on the formation of biofilm at concentrations 4, 2, 1, and 0.5% against each of SA36, SA48, and SA62. Quercetin lowers the formation of biofilm against SA36 of *S. aureus* at 32 µg/mL compared to a positive control (p= 0.0041), and the percentage of inhibition power reached to 92. At a concentration 32 µg/mL, the highest antibiofilm potential of ascorbic acid was 62 percent against SA86 strain, while at a concentration of 4 µg/mL, the minimum potency was recorded toward SA62 isolate.
Keywords: *bacterial isolates, catheters, biofilm-related genes, PCR*

Introduction

Staphylococcus aureus is responsible for causing a variety of human-acquired community and hospital-acquired infections worldwide. A significant number of *S. aureus* clinical isolates have evolved to be resistant to commonly used antibiotics (Jeong et al., 2019). The importance of nosocomial diseases caused by *S. aureus*, especially by methicillin resistant *S. aureus* (MRSA), is well known for its frequency, morbidity, mortality, and principally for its difficulty to treat (Shin et al., 2010; Saraiva et al., 2012). Resistance has also been reported against both newly introduced and last-resort drugs such as vancomycin, daptomycin, and linezolid used for the treatment of *S. aureus* infection. Therefore, new therapies against this series human pathogens need to be developed urgently (Nair et al., 2016). *S. aureus*, including antibiotic-resistant strains, are highly biofilm-producing bacteria and are dangerous causes of common infectious diseases in humans (Phuong et al., 2017; Wang et al., 2017). Due to genetic and metabolic adaptations of cells in films, the bacteria in biofilms are highly tolerant to antimicrobials. Biofilms consist of both the cells and the extracellular matrix produced by the cells (Shahmoradi et al., 2019), bacterial cell communities in a self-produced polymer matrix, and adhere to an inert or living surface (Onsare and Arora, 2015; Singh et al., 2015).

S. aureus is known to form biofilms, and it has been shown that reside in biofilms are highly resistant to antibiotics (Rodrigues et al., 2017), and also is a leading cause of skin

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_219236

structure infections and it is particularly associated with urinary tract catheters (Bayer et al., 2016; Trübe et al., 2019). *S. aureus* produces several virulence factors that enable it to colonize, adhere to surfaces and form biofilms, invade or escape the immune system, develop resistance to multiple antibiotics and cause host toxicity (Fey et al., 2003; Cheung et al., 2004). *S. aureus* is commonly observed, colonizing several parts of the body in healthy individuals (Kiedrowski and Horswill, 2011) and causing associated biofilm infections (Balamurugan et al., 2017). The ability of *S. aureus* to form an extracellular slime and constitutive a biofilm assists this organism to endure the host immune response, thus impairing clinical treatment since biofilm formation defends bacteria from antimicrobial agents (Foster, 2005). *Zingiber officinale* has been used for thousands of years as a culinary and medicinal herb. A recent study has shown that *Z. officinale* has antibacterial activity against *S. aureus,* and that is higher than the antibiotics on the market (Kim and Park, 2013). The rhizome is rich in secondary metabolites such as phenolic compounds (gingerol, paradol, and shogunal), volatile sesquiterpenes (zingiberene and bisabolene) and monoterpenoids (curcumin and citral). Among herbal extracts, the inhibitory effect of *Z. officinale* extract on microorganisms has been well documented (Ali et al., 2008). Previous studies have demonstrated that isolated compounds from *Z. officinale* possess potent antioxidant, antibacterial, antifungal, anticancer, and anti-inflammatory effects (Habib et al., 2008), as well as the impact of this extract on biofilm formation (Stoilova et al., 2007).

Quercetin, the most commonly studied flavonoid, has a wide range of biological activities, including antimicrobial activities (Hirai et al., 2010). Quercetin also influences quorum sensing, hence acts as an antibiofilm compound against *S. aureus*. It inhibits alginate production in a concentration-dependent manner, resulting in declination in the adherence during biofilm formation. It also reduces exopolysaccharide (EPS) production required for the initial attachment of bacteria. Some other reports also suggested that usinic acid show inhibitory effect on the *S. aureus* biofilm, and this has been hypothesized that this may be due to any interference in quorum sensing, but the exact mechanism of action is still indistinct (Roy et al., 2018). Based on quantification of the biofilm extracellular polymeric substances content and cell viability, quantitative proteome analyses and genome-scale metabolic modeling point to a vitamin C-dependent inhibition of the synthesis of polysaccharides that form the biofilm matrix. This proceeds *via* inhibition of the quorum sensing and other regulatory mechanisms, leading to repression of specific biosynthetic operons. Once the EPS content is reduced beyond a critical point, bacterial cells become exposed and more susceptible to killing by any external factors (Pandit et al., 2017).

Ascorbic acid has been shown to be an effective antioxidant, acting both directly through aqueous peroxyl radical's reaction and indirectly through the restoration of the antioxidant properties of fat-soluble vitamin E. Interestingly, ascorbic acid has been reported to increase the effectiveness of antibiotics *vs*. a wide range of bacteria through a synergistic effect, but this synergy's mechanism remains unclear (Helgadóttir et al., 2017).

The main objective of this study was using *S. aureus,* a model biofilm-forming microorganism, also investigated the effects of *Z. officinale* extract, quercetin, and ascorbic acid on biofilm formation using a static biofilm assay. The distinction in the inhibition of biofilm between the culture containing *Z. officinale* extract and the control.

Materials and method

Clinical isolate repository

In the period from July 2016 to March 2017, 157 samples taken from catheter patients received from the Rizgary Urinary Unit and Artificial Kidney Hospitals were investigated in Erbil City, Erbil, Iraq after cutting catheter (inside parts of the body) into 2 cm pieces and then incubating in brain heart infusion broth for 24–48 hrs. with shaking at 250 rpm, after that, the positive growth was cultured on Nutrient, Blood agar (BA), MacConkey and Mannitol Salt Agar (MSA) (Oxoid, UK).

Culture and identification

Primarily, isolates were cultured on MSA and BA (Oxoid, UK) and incubated at 37ºC for 24 hrs. The assumed colonies of *S. aureus* were identified by using conventional methods; include gram staining, biochemical tests which comprise: catalase, oxidase, urease, coagulase using tube coagulase test (TCT) (Karasu and Rathish, 2014), gelatin liquefaction, hemolysis, staphyloxanthin and protease, tellurite reduction, lipase and lecithinase production, dextrose reduction, carbohydrate fermentation and tellurite reduction, and DNase with methyl green, followed by VITEK II Compact System (bioMérieux, Inc., France). Finally, identity of the isolates was confirmed *via* polymerase chain reaction (PCR) (Alpha PCRmax, UK) based on identifying *16S* rRNA and *nuc* genes. The sequences of both genes and PCR setup can be found in *Table 1*.

Antimicrobial susceptibility screening

According to the references of the Clinical and Laboratory Standards Institute (CLSI) (CLSI, 2017), antimicrobial sensitivity testing was carried out against the following antimicrobials using disk diffusion method; Amikacin AK 30 µg, Azithromycin AZM

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_219236

15 µg, Ciprofloxacin CIP 5 µg, Clindamycin CD 2 µg, Erythromycin E 15 µg, Gentamicin G 10 µg, Levofloxacin LEV 5 µg, Netilmicin NET 30 µg, Nitrofurantoin NIT 300 µg, Norfloxacin NOR 10 µg, Oxacillin OX 1 µg, Penicillin P 10 U, Tetracycline TE 30 µg, Tobramycin TOB 10 µg, Trimethoprim+Sulfamethoxazole SXT 1.25+23.75 µg, and Vancomycin VA 30 µg (Bioanalyse, Turkey). A lawn of test *S. aureus* was prepared by evenly spreading 100 µL inoculums ($1.5*10^8$ CFU/ml) according to 0.5 McFarland (1907) standard solution with the sterilized swab on top of the entire surface of Mueller Hinton Agar plate (Oxoid, UK). The disks were resolutely applied onto the agar plates surface within 15 minutes of inoculation (Bimanand et al., 2018).

Assessment of biofilm synthesis by S. aureus

Congo red agar method

Phenotypical biofilm production in all *S. aureus* isolates was evaluated through culturing CRA plates and explained by (Szczuka et al., 2013; Khoramrooz et al., 2016). First of all, they prepared CRA plates by adding 0.8 g of Congo red (Merck, Germany) and 36 g of sucrose (Sigma, USA) to one liter of brain heart infusion agar (BHI) (Merck, Germany). The plates have been incubated for 24 hours at 37ºC. The morphology of colonies was then interpreted based on colony color as Bordeaux pink (red), almost black, black, and strong black. Strains with red colonies were classified as strains that are unable to produce biofilm, while nearly black color indicated a weak activity in biofilm production. Whereas, colonies that were very black and black were considered strong strains of biofilm producers.

Polystyrene microtiter plate assay

Biofilm production was quantitatively determined through an MTP method as defined by Yousefi et al. (2016). In short, bacterial isolates were grown with 0.5 percent glucose in trypticase soy broth (TSB) (Merck, Germany) and incubated at 37ºC overnight. Cultures with 0.5 percent glucose with 1:40 in fresh TSB were diluted (Sigma, USA). Two hundred µL of the diluted solution was added to Microtiter plate wells and incubated at 37ºC for 48 hrs. The negative control wells contained only 200 µL of TSB–0.5% glucose without bacterial suspension. Wells were gently washed with phosphate buffer saline (PBS) (pH 7.2) three times and fixed with methanol for 20 minutes, dried at room temperature, then stained with crystal violet 0.1 percent. The dye attached to the adhering cells was dissolved with 1 mL of 95% ethanol per well. Finally, optical density (OD) was obtained at 570 nm (A_{570}) for each well using ELISA reader (BioTek ELx800, USA). The average OD of negative control + 3 standard deviation (SD) of negative control was calculated for the optical density cut–off (ODc). Based on the absorbance of crystal violet stain linked to the adhered cells, biofilms formed by various strains have been analyzed and categorized (*Table 2*).

Table 2. *Classification of biofilm formation abilities by Microtiter plate method*

Cut-off value calculation	Mean of OD_{570} values results	Biofilm formation abilities
$OD > 4\times ODc$	$OD > 0.557$	Strong
$2\times ODc < OD \leq 4\times ODc$	$0.278 < OD \leq 0.557$	Moderate
$ODc < OD \leq 2\times ODc$	$0.139 < OD \leq 0.278$	Weak
$OD \leq 0.139$	$OD \leq 0.139$	None

Genomic DNA extraction

According to the manufacturer's instructions, genomic DNA was extracted from pure cultures through the Presto™ Mini gDNA Bacteria Kit (Geneaid, Taiwan); extract was eluted with an elution buffer of 100 µL. Before running PCR, extracts were stored at -20°C. The NanoDrop 1000 spectrophotometer (ThermoFisher Scientific, USA) was used to evaluate DNA concentration and purity in which one µL of the genome DNA was used to define DNA concentration and purity.

PCR screening of biofilm genetic determinants

In our research, detection in *S. aureus* isolates for biofilm-related genes was carried out using the PCR technique. The final volume of the PCR reaction was 25 µL using 12.5 µL of 2x HotStart Taq Master Mix, one µL of the DNA template, one µL of each primer (20 pmol) and 9.5 µL of ddH_2O. DNA amplification was done in a thermocycler PCR. Primers and amplification conditions for PCR programs are mentioned in *Table 1*. Amplified products were subjected to electrophoresis using 1.2% agarose (GeNet Bio, Korea) gel containing 1x GelRed DNA stain.

Ferric Reducing Antioxidant Power (FRAP) assay

To be able to measure the ferric reduction activity of our samples, the test was performed based on Benzie and Strain (1996). The FRAP solution was freshly prepared by combination of acetate buffer (0.3 Mol/L) (pH= 3.6), 2, 4, 6-tripyridyltriazine (TPTZ) (0.01 Mol/L in HCl (0.04 Mol/L) and $FeCl_3$ (0.02 Mol/L) (10:1:1) by volume, respectively. The test was performed by placing 100 µL of the tested chemicals in a test tube (Conc. 1 mg / mL) and 2 mL of the FRAP reagent, the samples were continuously shaken and leave in the dark place for 30 min. Then the absorbance at 593 nm was recorded. The standard ascorbic acid curve was prepared for comparison using various concentrations, as shown in *Fig. 1*. The FRAP value calculated by *Equation 1* for each compound. In this study, the test solution's yellow color reduces ferric complex with TPTZ (less color) to ferrous complex with TPTZ (violet color) changes to different shades of violet depending on each compound's reduced power. The higher reduction potential was determined by higher absorbance of the reaction mixture.

$$FRAP\ value\ of\ sample\ (\mu M) = Abs.(sample) \times \frac{FRAP\ value\ of\ standard\ (\mu M)}{Abs.of\ standard} \quad \text{(Eq.1)}$$

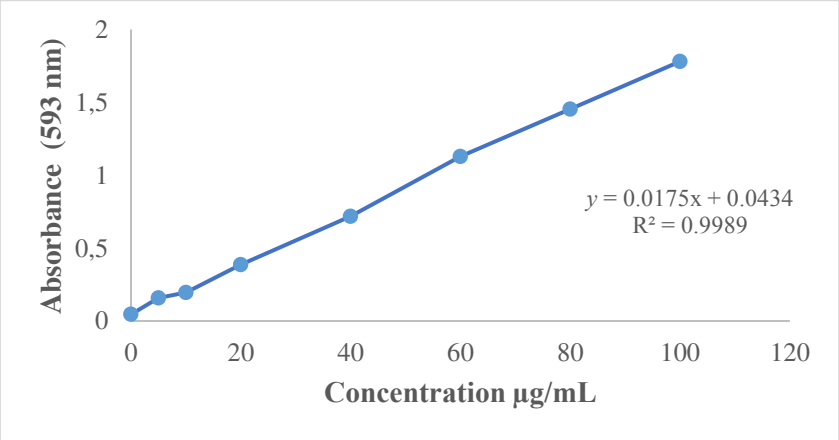

Figure 1. *The standard curve of ascorbic acid*

Biofilm formation inhibition test

Preparation of Z. officinale extract

Z. officinale extract was prepared under the protocol described by Kim and Park (2013). In short, 150 g of shredded rhizome of *Z. officinale* was mixed with 300 mL toluene. The debris was allowed to settle at room temperature for 24 hrs. A Whatman No. 1 filter paper (pore size = 11 µm) had been used for filtration of the supernatant. Then the mixture was stirred for 24 hrs. at room temperature using a magnetic stirrer. Then the mixture was left to form phases of water and toluene. Using a pipette, the water phase was collected and filtered through a 0.22 µm microfilter. The filtrate (100% *Z. officinale* extract) was used to test if *Z. officinale* extract inhibits the formation of biofilms.

Antimicrobial activity of quercetin

The antimicrobial activity of quercetin was performed by the microdilution method, already described previously, according to the CLSI. The range of concentration of quercetin used in this study was 2 to 256 µg/ml (Sérgio et al., 2018). The experiment was performed in triplicate.

Preparation and dilution of ascorbic acid

One milligram of ascorbic acid was dissolved in 1 ml of TSB medium to get a stock solution of 1000 µg/ml. Final concentrations of 2, 4, 8, 16, 32, 64, 128, and 256 µg/ml were obtained through serial dilutions to explore the antibiofilm activity against *S. aureus*. Ascorbic acid was mixed for two minutes with TSB medium and vortex. It was covered with aluminum foil to prevent light. At the time of their use, all solutions were prepared.

Static biofilm formation assay

To test the effect of plant extract on biofilm formation, a modified crystal violet assay was used. In sterile 96 well plates containing 50 µL of nutrient broth per well, two-fold serial dilutions of compounds were made. The concentration range of the compounds tested is 2 to 256 µg/mL in separate wells. Each well was supplemented with a 50 µL fresh bacterial suspension (0.5 McFarland) with growth control (*cells + broth*). The biofilm biomass was tested using the crystal violet staining assay after incubation at 37°C for 48 h (Kim and Park, 2013). The biofilm inhibition percentage was calculated using *Equation 2*.

$$Biofilm\ inhibition\% = \frac{OD\ growth\ control - OD\ sample}{OD\ growth\ control} \times 100 \qquad \text{(Eq.2)}$$

Data analysis

For statistical analysis, the Social Science Statistical Package (SPSS 24.0) software (SPSS Inc., USA) was used. The statistical significance was assessed through *Turkey's multiple comparisons*; the test was used to analyze the association between phenotypic biofilm formation methods and biofilm-related genes, and also the significant difference in biofilm inhibition percentage between active, positive–controlled biofilm producers and p-value < 0.05 was considered statistically significant.

Results

Isolation and characterization of S. aureus

Based on biochemical tests, isolates from one hundred catheter specimens (63.69%) were identified as *S. aureus* (*Table 3*). The strains were from samples belonging to 67 male patients (67%), and 33 female patients (33%). To support the identification of *S. aureus* isolates by a conventional method, VITEK II Compact System was performed, and all strains of *S. aureus* were reidentified by this system, some results contradicted the traditional tests and identified a different staphylococcal species than *S. aureus*. The present findings of the VITEK II system show that 83 isolates were identified as *S. aureus* among 100 isolates that were identified in the conventional method, and the remaining strains identified were *xylosus* (*n=6*), *sciuri* (*n=6*), *vitulinus* (*n=1*), *warneri* (*n=1*), *lentus* (*n=1*), *hemolytics* (*n=1*), and *gallinarum* (*n=1*). To further confirm the identity of the isolates, all *S. aureus* were examined for the presence of the *16S* rRNA and *nuc* genes to characterize and validate the *S. aureus*. All of the strains were confirmed as *S. aureus* by the occurrence of *16S* rRNA, and *nuc* genes (*Fig. 2*). About two-thirds of catheter-isolated bacteria were identified as *S. aureus*.

Susceptibility patterns of S. aureus against different antimicrobials

The results of the antimicrobial sensitivity test for all *S. aureus* isolates against 16 antimicrobials demonstrated various sensitivity patterns (*Table 4*). The highest resistant percentage recorded was against oxacillin (99%), followed by penicillin (97%). However, the lowest resistant 1% recorded was against each of gentamycin, nitrofurantoin, and trimethoprim-sulfamethoxazole.

Biofilm formation through microtiter plate test

The ability to form a biofilm was evaluated using the MTP described elsewhere (Yousefi et al., 2016). In this study, OD_{570} mean of microplate readings after crystal violet staining ranged from 0.216 to 0.827. The mean of negative control was 0.054. An ODc_{570} of biofilm formation was defined as 0.139. The strains were divided into four groups: non–biofilm producer (−), $OD_{570} \leq 0.139$; weak biofilm producer (+), $0.139 < OD_{570} \leq 0.278$; moderate biofilm producer (++), $0.278 < OD_{570} \leq 0.557$; strong biofilm producer (+++), $0.557 \leq OD_{570}$. Our data shows that 100% of *S. aureus* isolates were positive for biofilms, 21% of which were recorded as a strong producer of biofilms (*n=21*), 71% as a moderate producer of biofilms (*n=71*) and 8% as a weak producer of biofilms (*n=8*).

Biofilm formation determination by Congo red agar test

In vitro biofilm formation by the CRA method differs from MTP assay. Results show that 49% of the isolates (*n=49*) demonstrated strong biofilm formation (strong black), 15% were moderate biofilm producer, 25% weak biofilm producer, and 11% of the isolates were classified as non–biofilm producer. Statistically, there is not a significant difference (p= 0.8997) between the total percent formation in both MTP assay, and CRA methods for the detection of phenotypic biofilm formation among isolates of *S. aureus* was observed (*Table 5*). While there are highly significant differences among biofilm formation status when compared between both MTA assay and CRA method (*Fig. 3*).

Table 5. *Screening of S. aureus isolates from biofilm production by CRA and MPM assay*

Biofilm formation status	**Screening method**		***P*-value**

Detection of genes involved in biofilm formation

PCR assay was used to detect *icaA*, *icaB*, *icaC*, *icaD*, *cna*, *atl*, *fnbA,* and *fnbB* genes among the primary intention of this study are the genotypically characterization of biofilm responsible genes. Ninety-six percent of *S. aureus* isolates have been selected for this purpose. We evaluated the relationship between the formation of biofilm and the eight genes associated with biofilm. The distribution of these genes in *S. aureus* isolates is illustrated in *Table 6*. All of the eight genes were detected among isolates with different frequencies. As can be seen, the majority of *S. aureus* isolates (96% [*n=24*]) were found to be positive for *the icaC* and *cna* gene (*Fig. 4*). The prevalence rates of the *icaA*, *icaB*, *icaD*, *atl*, *fnbA,* and *fnbB* genes were unswervingly found to be 76%, 68%, 88%, 92%, 84%, and 80%, respectively. Nine of the isolates (36%) (*n=9*) that were biofilm producers were shown to possess all of the eight genes aimed to detect in the current study. A

DOI: http://dx.doi.org/10.15666/aeer/1801_219236

significant association was only observed between the presence of *icaB* gene (p= 0.028) and phenotypic biofilm formation in *S. aureus* isolates, while non-significant association was noticed for each of *icaA* (p = 0.2085), *icaC* (p=0.9894), *icaD* (p= 0.7238), *cna* (p= 0.9894), *atl* (p= 0.9004), *fnbA* (p= 0.5207) and *fnbB* (p= 0.3421) and phenotypic biofilm formation features.

FRAP reducing power

The antioxidant activity of the *Z. officinale*, quercetin, and ascorbic acid was measured by FRAP assay and has been presented in *Table 7*. It shows that electron-donating groups enhanced reducing power. Quercetin indicates that they are most effective electron donor and can reduce the oxidized intermediates highly reactive molecules like free radicals and reactive oxygen species of peroxidation processes and the FRAP value 10406.4 μM/g while the *Z. officinale* extract has low antioxidant activity (FRAP value = 5420.8 μM/g) when compared with both quercetin and ascorbic acid. Ascorbic acid usually used as a standard for preparing the standard curve and has high antioxidant activity (FRAP value = 8379.5 μM/g).

Effect of Z. officinale extract on biofilm formation

A static biofilm quantification assay was performed to evaluate the effect of *Z. officinale* extract on five strong biofilm isolates of *S. aureus*. *Table 8* shows the difference in biofilm inhibition between the culture containing *Z. officinale* extract and the control (i.e., no *Z. officinale* extract addition). The high biofilm inhibition percent

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_219236

were 61.4 at concentration 16% against SA04 while there is no any effect on biofilm formation at concentrations 4, 2, 1, and 0.5% against each of SA36, and SA62 isolates. Significantly, there were differences in biofilm reduction for *Z. officinale* extract at concentration 32, 16, and 8% (p= 0.0458, p= 0.0391, and p= 0.0247, respectively). In spite of decreasing of biofilm formation, there were no observed significant at concentrations 64, 4, 2, 1, and 0.5% (p= 0.1015, p= 0.1676, p= 0.8017, p= 0.8811, and p= 0.5925, respectively). The inhibition of *Z. officinale* extract to biofilm formation was not due to minor toluene contamination or something extracted from the glassware during the preparation of *Z. officinale* extract, which was confirmed by an experiment using mock extraction.

Antibiofilm activities of quercetin

Concerning the action of quercetin as antibiofilm, this molecule reduces biofilm formation against SA36 isolate of *S. aureus* at 32 µg/mL, and the inhibition potency percent reached to 92, and have a significant difference when compared to a positive control (p = 0.0041). Quercetin reduced biofilm formation at all concentrations against all five isolates except concentrations of 64 µg/mL against both SA36 and SA48 isolates. In particular, the lowest inhibited biofilm formation was 16%, and the highest was 92% (*Table 8*). Significant differences was recorded at concentrations 256, 8, 4, and 2 µg/mL when compared with positive control (p = 0.0221, p = 0.02, p = 0.0246, p = 0.0369) respectively.

Biofilm inhibitory activity of ascorbic acid

Once the antibiofilm efficacy of ascorbic acid has been determined, we analyze their potential action against *S. aureus* biofilm formation. MTP assessed this ability, and these results showed complete inhibition of biofilm formation by ascorbate when compared to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_219236

growth control (*Table 8*). The highest antibiofilm potency of ascorbic acid was 62% against SA86 isolate at concentration 32 µg/mL, while the minimum power was recorded at concentration four µg/ml a toward SA62 isolate. In spite of the low inhibition percent of biofilm formation, while there are a significant differences in the decreasing of biofilm formation at concentrations 256, 128, 32, and 16 µg/mL (p = 0.0003, p = 0.0062, p = 0.0079, and p = 0.0271) respectively when compared with OD of growth control.

Discussion

All 100 *S. aureus* isolates were branded as Gram-positive; further cultural characteristics and biochemical test results were stated in *Table 3*. Out of these isolates, 91 isolates were coagulase-positive *S. aureus*, and nine were recorded as coagulase-negative. Results obtained from the conventional biochemical tests and PCR method match with a statistical confidence of 91% (The remaining 9% non—reluctant possibly due to analysis conditions and sample preparation) between the methods. This probably will be due to the concealing of the clumping factor by the capsular polysaccharides or due to misidentification of particular clumping factor producing CoNS; by this means, lessening its efficiency, reliability, and sensitivity (Subramanian et al., 2017). An additional test used *S. aureus* identification is the DNase test. All isolates of *S. aureus* have been positive for DNase activity in the present study. Parallel results have been reported previously with a lack of clarification; thus, additional tests are required for confirmation purposes.

In our study, 78 *S. aureus* isolates showed the ability to hydrolyze gelatin, thus confirming the presence of the gelatinase enzyme. However, 81, 51, and 48 strains of *S. aureus* secrete protease, lipase enzymes, and nonwhite pigmented colonies, respectively. Among the 100 strains of *S. aureus* showed β–hemolytic, γ–hemolytic and α–hemolytic properties, 71 strains of *S. aureus* showed the ability of β–hemolysin and only two isolates expressed α–hemolysin, and 27 isolates demonstrated the γ–hemolytic activity. Likewise, hemolytic activity among 57 different clinical sources of *S. aureus* exhibited vigorous hemolytic activities and five clinical strains that had no ability of blood hydrolysis on blood agar (Tang et al., 2013). All isolates of *S. aureus* were undergone PCR assay using universally conserved *16S* rRNA and *nuc* genes, specifically designed primers were used for discrimination of *S. aureus* isolates (*Table 1*), and all of the strains were positive for both genes (*Fig. 3*). Antimicrobial susceptibility carried out for 16 antimicrobials through disc diffusion methods, and the results are presented in *Table 6*. The highly resistant percentage was seen against oxacillin (99%) followed by penicillin (97%), and the lowest resistant 1% recorded was against each of gentamycin, nitrofurantoin, and trimethoprim–sulfamethoxazole. Based on the antimicrobial susceptibility reports by Boada et al. (2018), among the 765 assessed *S. aureus* isolates, the maximum resistance rates were observed to a penicillin (87.1%), followed by azithromycin (11.6%), erythromycin (11.2%) and clindamycin (9.7%). Oxacillin and methicillin resistance mechanism is by gaining a gene that encodes a PBP2 homolog called PBP2a that is not susceptible to drug deed, and this is due to the serine residue that is not reachable by β–lactams at the active site of the TP of PBP2a (Foster, 2017).

Different results in both methods used for β–lactamase detection in all *S. aureus* isolates, the positive result in an iodometric method was 91%, while 73 isolates could produce β–lactamase through Cefinase disk. Most strains of *S. aureus* were resistant to penicillin; nearly 20% of *S. aureus* remained susceptible to penicillin (Parija, 2014).

DOI: http://dx.doi.org/10.15666/aeer/1801_219236

Clinical *S. aureus* isolates were examined for biofilm formation *via* phenotypic and molecular assays, and any possible association between biofilm formation and bacterial genetic lineage was investigated. *S. aureus* remains the most recurrently encountered bacterial pathogen and is responsible for a variety of mild to life-threatening infections (El-Huneidi et al., 2006). The ability of *S. aureus* to adhesion and form biofilm makes them more resistant against antibiotics. Bacterial virulence factors such as adhesion play a vital role in catheter-related infections. Staphylococcus' ability to settle in artificial material is linked to two main mechanisms; polysaccharide slime production and host matrix protein adsorption on the biomaterial surface. When the biofilm is produced, it would be easy to run away from immune systems and to cause chronic infections. While PIA is essential for the formation of biofilm by *S. aureus*, in this study, we found in these isolates more than one gene of *ica* operon, i.e. *icaADBC*, *cna*, *atl*, *fnbA* and *fnbB* genes are associated with the production of biofilm in these isolates.

Although many genes and conditions are responsible for biofilm production, our results demonstrated that *icaA*, *icaB*, *icaC*, *icaD*, *cna*, *atl*, *fnbA,* and *fnbB* genes have a critical role in the production of biofilms. In this work we found that 89 out of 100 strains were biofilm producers developing almost black (*n=25*), black (*n=15*) or strong black colonies (*n=49*) on CRA plate, while in MTP assay, all isolates produce biofilm with ranging from weak (*n=8*), moderate (*n=71*) and strong biofilm production (*n=21*). Comparatively, similar results have been achieved elsewhere, stating that 50% of clinical *S. aureus* isolates to form a biofilm (Kouidhi et al., 2010). Out of 100 bacterial isolates, the formation of biofilm was recorded in 60% of isolates by CRA method, while PCR detection of biofilm-related genes, *icaA*, and *icaD*, revealed that both genes were present in 78% of the isolates (Salehzadeh et al., 2016). Discrepancies have been reported between phenotypic and genotypic methods for the detection of *S. aureus* producing biofilms (Yazdani et al., 2006). Statistical analysis revealed there is no significant difference between the biofilm formation using the MTP assay and the CRA method ($p = 0.8997$). Numerous studies have confirmed that some *S. aureus* strains need *icaADBC* to form biofilms (Johnson et al., 2008). On the other hand, adhesion to host cells requires genes such as *fnbA*, *fnbB*, and *cna* that encode microbial surface constituents known as adhesive matrix molecules that are different from those involved in the adhesion on abiotic surfaces (Arciola et al., 2005).

In the present study, the prevalence of the *icaC*, *icaD,* and *cna* (96%) and *icaA*, *icaB*, *atl*, *fnbA,* and genes were found to be% 80%, 72%, 80% and 86%, respectively. This result may reflect the role of these genes in the pathogenicity of *S. aureus* isolates. However, *fnbB* was found in a lower percentage (60%). The prevalence of twelve genes involved in biofilm production explains that numerous factors may be useful in various stages of biofilm formation due to the ability of all the strains identified to form biofilm at different levels, but the gene incidence was different. Further research to clarify the expression of these genes in *S. aureus* strains should be considered (Nourbakhsh and Namvar, 2016), and they stated that the prevalence of the genes involved in biofilm production was: *icaA* (34.2%), *icaB* (29.7%), *icaC* (69.3%), *icaD* (54.8%), *fnbA* (38.1%), *fnbB* (46.6%), and *can* (18.3%). Similar to our study, several other researchers have shown that the formation of slime and biofilm in *S. aureus* is associated with the presence of *icaA* and *icaD* genes (Cramton et al., 1999; Arciola et al., 2001; Vasudevan et al., 2003). Production of intercellular adhesion molecules, e.g., by *icaABCD* and other genes, plays an essential role in staphylococcal biofilm. Biofilm production may be the fundamental reason for the increasing antibiotic resistance of *S. aureus* strains. A

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_219236

significant association was observed between the presence of genes such as *icaA*, *icaB*, *icaC*, *icaD*, *can*, *atl*, *fnbA* and *fnbB,* and biofilm formation. Although not all of the genes were found simultaneously in all the isolates of the biofilm producers, at least one of the related genes was detected in the entire isolates of the biofilm producers (except one strain). The ability to form biofilm in negative strains for one or more genes may be associated with some other genes associated with biofilm.

In the present study, the prevalence of the *icaC*, *icaD,* and *cna* (96%) and *icaA*, *icaB*, *atl*, *fnbA,* and genes were found to be% 80%, 72%, 80% and 86%, respectively. This result may reflect the role of these genes in the pathogenicity of *S. aureus* isolates. However, *fnbB* was found in a lower percentage (60%). The prevalence of twelve genes involved in production of biofilm explains that numerous factors may be useful in different steps of biofilm formation because all of the strains identified could form biofilm at various levels, but the incidence of genes was different. Further research should be considered to elucidate the expression of these genes in *S. aureus* strains. We investigated the effects of *Z. officinale* extract, quercetin, and ascorbic acid on biofilm formation using a static biofilm assay and using *S. aureus* as a model biofilm-forming microorganism, and found that quercetin inhibits the formation of biofilm when compared with *Z. officinale* extract and Ascorbic acid through the percentage of biofilm inhibition.

Conclusion

In the current study, a significant association between the presence of *icaA*, *icaB*, *icaC*, *icaD*, *can*, *atl*, *fnbA,* and *fnbB* genes and biofilm formation were observed. Although all of the genes were not found in all of the biofilm producer isolates, however, in the entire biofilm producer isolates (except one isolate) at least one of the related genes was detected. The ability of biofilm formation in isolates negative for one or more genes might be related to some other biofilm-associated genes. The most critical future suggestions are to use all active components which present in the *Z. officinale* against biofilm formation in different bacterial species and genera.

Acknowledgments. This work supported by Salahaddin University-Erbil, Erbil, Iraq, as the Ph.D. program (No. 15738 on December 12, 2015). The authors would like to thank and grateful to *Prof. Dr. Jawher F. Saeed* for his support and technical assistance and *Dr. Abdullah M.A. Qassab* for his scientific evaluating.

Abstract. A local oil spill is the main cause of hydrocarbon soil pollution. Biological treatment of oil polluted soil may be possible due to the presence of oil-utilizing microorganisms at the site. Several factors affecting soil oil degradation include hydrocarbons solubility, soil texture, ventilation, oil toxicity, availability of nutrients, etc. Many techniques are used in the bioremediation of oil polluted soil. In this study, the compost system was used to increase the oxygen transmission with the addition of nutrients (NPK), hay (bulking agent) and biosurfactants producing bacteria (*B. cereus* WR146) to enhance the hydrocarbons degradation in agricultural soil. After 3 months of biological treatment, crude oil content decreased to3.73-2.42% from the initial 4.20%. The percentage of crude oil degradation ranged from 20.1-44.5 depending on the treatment method used. Carbon dioxide development rates ranged from 30.6-55.0 μg g^{-1} day^{-1}, indicating a significant crude oil degradation due to aerobic microorganisms. There is no clear picture of whether nutrients and bulking agent increase the crude oil degradation rates in the current study. The results indicate that the bioremediation of soil polluted with crude oil is more efficient when using compost system, good ventilation, nutrients, and biosurfactants producing bacteria.
Keywords: *biodegradation, oil pollution, agricultural soil, biosurfactants, bacteria*

Introduction

Oils are the main source of energy in most industries and modern life. Leakages and accidental spills of oil and its products occur throughout production, export, refining, transport and storage. The quantity of leaking crude oil is estimated at 600,000 metric tons per year at the rate of 200,000 metric tons annually (Prathyusha et al., 2016). The introduction of hydrocarbons into the environment is one of the main causes of water and soil pollution. Hydrocarbons reach soils (including agricultural soils) from a variety of natural and anthropogenic sources. Technological hydrocarbons penetrate the soil after the soil surface is contaminated with crude oil and its products and hydrocarbon-containing materials. One of the most common anthropogenic sources is the leakage of underground storage tanks. Other major sources include spillage during refueling and lubrication. Sites where transportation and handling of crude oil are potential places for oil pollution. Shale oil retorting plants provide another source of hydrocarbon pollution (Boitsov et al., 2011; Pinedo et al., 2014; Ivshina et al., 2015). Although most of the hydrocarbons in the soil environment are of an anthropogenic nature, there are some natural sources of these substances. These may include the hydrocarbons resulting from the biogeochemical processes in the soil and those that migrate from the deep, oil-bearing ground layers. It also includes hydrocarbons released from the biodegradation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_237252

of organic matter. There is also accumulated evidences that some organisms, especially higher plants, are capable of synthesizing certain hydrocarbons that may also find their way into the soil. However, the natural sources are fairly simple and are unlikely to cause significant hydrocarbon pollution of the soil (Biache et al., 2014; Gennadiev et al., 2015). Soil contamination with petroleum hydrocarbons adversely affects human and animal health and plant production as most substances are toxic to living organisms. This contamination can also have long-term implications for soil quality and function and food quality (Agarry and Ogunleye, 2012; Tang et al., 2012; Ng et al., 2017). Most methods used to treat soil pollution include mechanical techniques, burial, vaporization, dispersal and washing. However, these methods are costly and can lead to the imperfect degradation of pollutants (Chee and Shih, 2019).

Bioremediation is defined as the employ of microorganisms to remove environmental contaminants for their various metabolic capacities, a satisfactory and acceptable technique for the removal and degradation of many pollutants, including oil and its products (Adams et al., 2015). Bioremediation technology is thought to be relatively inexpensive and effective (Nwankwegu et al., 2016). Biodegradation by natural microbiological communities is one of the main mechanisms by which oil contaminants can be removed from the environment and are cheaper than other treatment methods (Ron and Rosenberg, 2014).

The prosperity of the oil bioremediation depends on the provision and maintenance of favorable environmental conditions to improve oil degradation. Several researchers have reported several factors affecting the biodegradation rate of oil (Jahangeer and Kumar, 2013; Varjani and Upasani, 2017; Ali, 2019). An important need for bioremediation is the existence of microorganisms with suitable metabolic capacity. If microorganisms are found, optimum growth rates and microbial degradation of hydrocarbons can then be maintained by assuring sufficient nutrient and oxygen concentrations and a pH (6-9). The physiochemical properties of the oil and area of oil surface are also significant factors for the successful of bioremediation (Eze et al., 2014). The two techniques taken for the bioremediation of oil pollutants are the addition of microorganisms (eligible to degrade hydrocarbons) and surfactants [bioaugumentation], and the modification of the environment by adding fertilizers (N and P) or other cosubstrates limit the growth of microbes and aerating the contaminated site (composting and bulking) [biostimulation] (Ikuesan, 2017). The success of bioremediation attempts to clean up the crude oil spill from the Exxon Valdez tanker in Prince William Sound and the Alaska Gulf in 1989 generated considerable interest in the technology of microbial degradation and remediation (Atlas and Hazen, 2011).

Large numbers of hydrocarbons in crude oil are readily degraded, but others are more stable compounds, which include the hydrocarbons with a large number of methyl substitutes or intensive aromatic rings (Polycyclic Aromatic Hydrocarbon-PAHs) that have low solubility (Šolevic et al., 2011). so as to full degradation of such hydrocarbons must be available for microorganisms and their enzymes.

Surfactants were utilized to elevate the unsolvable organic matter bioavailability (ex. during desorption from solid materials). Surfactants (artificial and natural) were examined with different grades of hit (Biria et al., 2010; Rufino et al., 2014). Persistent organic pollutants can oxidize chemically, but this process seems to be expensive. The incorporation of chemical oxidation and biological remediation should be cost effective, where the primary chemical operation transforms contaminants into low toxic substances and compounds that can be biodegraded (Rufino et al., 2014).

The compost system with the presence or absence of bulking agents are used to promote oxygen input and improve aerobic biological degradation. In addition, the introduction of microbial nutrients and microorganisms with them can lead to significant degradation of petroleum hydrocarbons (Lukic, 2016; Sari et al., 2019) Most soil systems comprise oil-utilizing bacteria and fungi (Ikuesan, 2017; Ali, 2019), but their counts and metabolic characteristic could not be important. The bioaugmentation permits the addition of microbes with suitable metabolic capacity and an increase in the microbial community that can accelerate the process of bioremediation.

Most of the current studies have focused on assessing the factors that influence bioremediation or experimenting of appropriate products or procedures via the laboratory researches (Das and Chandran, 2011). Only a finite number of field experiences have been given persuasive proof of this technique. In this study, compost systems were examined with the addition of nutrients and microorganisms for the biological treatment of polluted agricultural soil by the leakage of crude oil in southern Iraq.

Materials and methods

Ten experimental fields were designed in contaminated agricultural soil with an accidental spill of crude oil in the Abu-Al-Khaseeb region (30°27'00" N, 47°59'27" E) of Basrah province in southern Iraq (*Fig. 1*), during the Spring of 2018. The oil spill covered about 500 m^2 of agricultural soil and reached a depth of 50 cm. The measurement of each designed field was 4 m length, 4 m width, and 50 m depth. The soil of fields was manually drilled using a hoe and shovel at a depth of 50 cm and turned to mixing crude oil with soil components. The fields were then processed in different increments as shown in *Table 1*. Some fields were fertilized by NPK (0.015 kg N 1 m^{-2}, 0.015 kg P_2O_2 1 m^{-2} and 0.015 kg K_2O 1 m^{-2}) to outdo the restriction of inorganic nutrients. Bermuda grass (*Cynodon dactylon* L.) hay (chopped to 4.5 cm size, p_b of 0.019 g cm^{-3}) was added to some fields at a 1:2 hay:soil volume ratio, as a absorbent agent for crude oil and a bulking agent to promote oxygen transport. The strain, *Bacillus cereus* WR146 (biosurfactant-producing bacteria), previously isolated from the same site, has been added to fields (25 ml kg^{-1} soil of bacterial suspension at 1×10^{-6} density were sprayed on the field surface) for the production of biosurfactant compounds. The strain was identified using standard biochemical and sugar fermentation test. The species level identification was done using 16S rRNA sequencing. *B. cereus* WR146 is a gram positive, motile, facultative and spore forming bacterium that can produce biosurfactant in 40 °C and salinities 25%. These capabilities make it a useful candidate to serve in microbial enhanced oil recovery processes. The purpose of installing of some plastic drainage pipes vertically in some fields was to enhance the transfer of oxygen by forming an air flow in the field based on variations in temperature between the inside of the field and the external atmosphere. *Table 2* shows the monthly range and annual average of some environmental factors affecting the soil of the study area, and hence bioremediation.

Three samples were collected from the soil under study prior to the design of the experimental fields to determine the soil properties, assess the level of crude oil pollution and estimate the content of bacteria. The first sample (I) was a soil with little oil pollution. The second (II) was a soil heavily polluted with crude oil. The third (III) was a soil unpolluted with oil located near the spill area. While two soil samples were taken from all experimental fields that were designed to determine the temporal difference in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_237252

populations of bacteria. One of the samples (IV) was from the surface of the field and the other (V) was 50 cm deep. The IV and V soil samples were taken for each field to take account of evaporation of hydrocarbon and to monitor the bioremediation process at both sites. Each soil sample consisted of five randomly collected samples (1 kg), each carefully mixed, and 100 g of each was taken and thoroughly mixed together. Some characteristics of the agricultural soil are given in *Table 3*.

For the five different samples, 1 g of soil was used to count heterotrophic bacteria (HB) and oil-utilizing bacteria (OUB) by the standard dilution plate method. The soil was suspended in 99 mL sterile water, shaken, 120 rpm for 30 min, this stock was used to prepare dilution series, 10^{-1}-10^{-10}. The HB were counted on nutrient agar medium. The OUB were counted on a solid mineral medium containing as sole sources of carbon and energy, 2 mL of sterile crude oil into a filter paper lining every Petri-dish cover, and tightly sealing the dish. The mineral medium (MM) was composed of 0.68 g L^{-1} KH_2PO_4, 1.79 g L^{-1} HPO_4, 0.35 g L^{-1} $MgSO_4$, 1 g L^{-1} NO_3NH_4, 0.4 mg L^{-1} $CaCl_2$, 0.4 mg L^{-1} $FeSO_4$, and 0.1 mL of solution containing 100 mg L^{-1} of H_3BO_4, $MnSO_4$, $ZnSO_4$, $CuSO_4$, and $CoCl_2$, and 20 g L^{-1} of agar. For each of the above soil dilutions, five replicate plates were inoculated with 0.25 mL each, and the plates were incubated at 30 °C for 48 h of HB and at 30 °C for 21 day of OUB. The bacterial colony numbers were counted, the mean values were obtained and taking the dilution factor into consideration, the total numbers of colony forming units (CFU) per gram dry soil were calculated.

Crude oil content in soil was determined by the method of Villalobos et al. (2008), a sample of 50 g was sieved through a 62 μm stainless steel sieve, which was dried for 12 h at 105 °C and mechanically homogenized. Exactly 10 g of soil was placed in a dried and weighed round flask. Anhydrous sodium sulphate (10 g) was then added to the flask and 35 mL of n-hexane were utilized for extraction process in a ultrasound bath. The extract was filtered over a column filled with 0.6 g of glass wool, 5 g of silica gel, and 1 g of celite respectively, and washed with 25 mL of n-hexane. The n-hexane was evaporated in a rotary evaporator and the residue of crude oil was then weighed. This execution was reiterated 3 time for each sample of soil to extract the most quantity of crude oil.

Soil microbial activity was estimated by measuring the concentration of carbon dioxide formed 10 days after incubation of samples of soil in glass-tight vessels in 20 °C. Water was append to the soils by 50-60% of water holding capacity. Concentration of carbon dioxide in the head space was analyzed by a Shimadzu (GC-14, Japan) gas chromatography provided with a Thermal Conductivity Detector (TCD) in 60 °C. The samples of gas were analyzed in 40 °C using of column (2 m) packed with Porapak Q with He as a carrier gas flowing at 40 mL min^{-1} rate. The gas analyses was achieved in triplicate. The values were expressed in μg CO_2 g^{-1} soil day^{-1}. The difference in carbon dioxide formation between unpolluted soil and crude oil polluted one was utilized to estimate the degradation of crude oil.

Effect of fertilizers on biodegradation was laboratory assessed, 0.66 mg g^{-1} of urea (nitrogen source), 0.31 mg g^{-1} of superphosphate (phosphorus source), and oleophilic fertilizer S200 (developed by IEP Europe, Madrid, Spain) in dosage as described by IEP Europe, were added to soil samples and tested. The S200 containing nitrogen (7.9%) and phosphorus (0.6%), consisted of a microemulsion of a saturated solution of urea as a nitrogen source in oleic acid as a carrier, an oleophilic phosphate ester as a phosphorus source and surfactant, and a viscosity reducer. The critical micelle dilution (CMD) of S200 was estimated and the critical micelle concentration (CMC) was measured by the surface tension method. The surface tension measurements were done by duNouy ring method using a KSV Sigma 701 model tensiometer and platinum ring at 20 °C (Lima et al., 2017). The CMC was then determined by plotting surface tension as a function of the S200 concentrations. A range of concentrations under CMC were used to evaluate the impact of S200 on biodegradation.

Biosurfactant role created by *B. cereus* WR146 in the elimination of crude oil sorbed on the soil surface has been investigated. The isolate was grown on 50 mL of MM supplemented with crude oil (1%, v/v) in a Erlenmeyer flask (250 ml) and was incubated at 37 °C for 4 days in an incubator shaker at 185 rpm. The bacterial cells were then harvested by centrifugation at 10,000 × *g* for 10 min. The resulting supernatant was examined for production of biosurfactant by oil spreading method and drop collapse test according to the method described by Barin et al. (2014) and Janaki et al. (2016) respectively. Surface tension measurement of biosurfactant positive sample was determined in a KSV Sigma 701 model tensiometer using the duNouy ring method at 23 °C (Lima et al., 2017). Emulsification ability of the sample was estimated by calculating E_{24} index (Hamzah et al., 2013). All the assays were performed in triplicate with distilled water as the control. The biosurfactant was purified by the centrifugation of culture broth at 12,000 × *g* for 20 min and extracted twice with chloroform and methanol (2:1, v/v). The solvents were evaporated by a rotary evaporator and the residue was purified in a silica gel (60-120 mesh) column. The sample was then eluted

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_237252

with chloroform and methanol (20:1 to 2:1 v/v). The fractions were collected and the solvents were removed by evaporation, the resulting residue was dialysed with distilled water and lyophilized. The crude biosurfactant was expressed in g L^{-1}. The isolated biosurfactant was then characterized by estimation of the protein concentration (by total protein test kit from Supplimed International, India) (Rufino et al., 2014), the total carbohydrate content (by the phenol-sulphuric acid method) (Lobna and Ahmed, 2013), the fatty acids content (by gas chromatography) (Rufino et al., 2014), and the peptide groups (by Lowry test) (Lowry et al., 1951).

Fifty gram of washed sand was mixed with crude oil (1 g) in flasks (250 mL) and 100 mL of water was added. Different concentrations of crude biosurfactant extract (0.001, 0.01, 0.1, 0.15, 1, 1.5, 3, 6, and 10 g L^{-1}) were prepared and then added to sand contaminated with crude oil in the flasks. The mixtures were shaken (75 rpm) for 2 days at room temperature. Controls treatment without biosurfactant extract were achieved.

Statistical analysis of the data was done by ANOVA, with differences by the least significant differences method being determined at 5% ($P < 0.05$). Statistical analysis was performed using SPSS 16.0 for Windows (IBM, Armonk, New York, USA).

Results

Table 4 shows the counts of HB and OUB in the I, II and III samples. The II sample generally contained the highest counts of HB and OUB. While the samples I and III contained a lower counts of HB and OUB respectively (*Table 5*). *Figure 2* exhibits the temporal variation in the counts of HB and OUB in IV and V soil samples of the fields 1 and 10. The results indicated that the counts of HB did not show clear tendencies in fields 1 and 10. Nutrient supplementation and aeration were not necessary to increase bacterial counts. While the counts of OUB increases in field 10, but after a period of time, their counts are similar to the counts of bacteria in field 1 (*Table 6*).

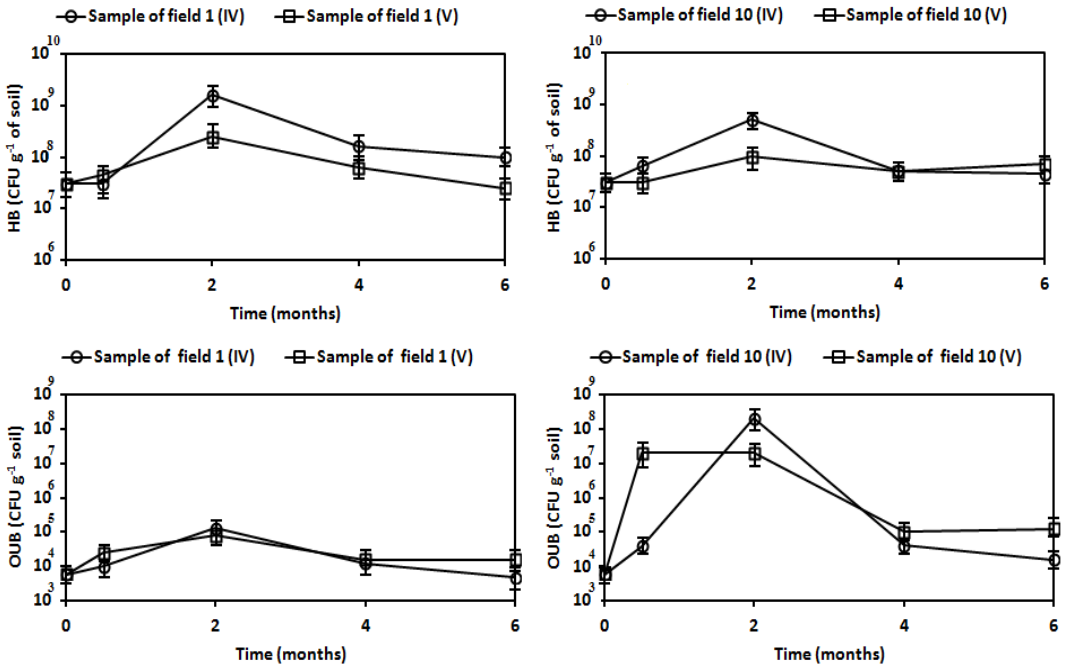

Figure 2. *Temporal variations in the counts of HB and OUB in experimental fields. Error bars represent standard deviation (95% confidence interval, C.I.)*

Crude oil content was measured in the soil samples obtained prior to the design of the experimental fields to gain an image of the average and highest grades of crude oil contamination in the study area. After the design of the fields, soil samples were collected from each field to acquire a zero-time determine of the crude oil concentration in the each field. There are apparent differences in the content of crude oil in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_237252

remediation fields because of their asymmetrical nature. Nevertheless, there is a obvious decline in crude oil content over time (*Fig. 3*). The results of the fields 1 and 10 indicated a reduce in crude oil content, with similarities in the rudimentary crude oil removal rates in both fields, which may be due to the elimination of volatile light compounds from the soil. After 3 months ago, crude oil was removed more in field 10 than field 1. No statistically significant differences were found in the elimination of crude oil from soil surface of fields 1 and 10 to illustrate the importance of bioaugmentation (*Table 7*). Low microbial effectiveness, estimated from the development of carbon dioxide in vitro was found in samples of surface soil. *Figure 4* and *Table 8* show variations in the development of carbon dioxide in V soil sample of all fields. Field 10 exhibited the highest degradation capability.

Table 9 exhibits the mean of alterations in crude oil content after three months of biological treatment in surface soil samples for all experimental fields. The proportion of crude oil content alterations in the soil has been transformed to daily rates of degradation of crude oil and carbon. The degradation was estimated depending on that content of carbon in crude oil ranges from 80-88% (Eschrich, 1980). The theoretical carbon dioxide rates based on carbon degradation were higher than those obtained from laboratory experiments (*Fig. 4*), which may be due to the loss of crude oil in the fields by evaporation. The laboratory average rates of carbon dioxide development in crude oil polluted and unpolluted soils fertilized with nitrogen and phosphorus were 30.6-55.0 μg g^{-1} day^{-1}. The laboratory temperature was 22 °C while the temperature of the fields ranged from 34-37 °C. The results of carbon dioxide development at soil samples, IV and V indicate that the lowest microbial effectiveness was in the unpolluted soil and active degradation was found in the polluted one.

Table 9. *Average changes in oil content over a three-month period of biological treatment in soil samples (IV) of experimental fields (2-10) and the rates of theoretical degradation*

	Time (months)			
	0	**1**	**2**	**3**

Production of carbon dioxide (μg g^{-1} day^{-1})	---	534.1	700.2	116.4

Adding S200 fertilizer to crude oil polluted soil with a less concentration than CMC improves the crude oil degradation process, while the addition of nitrogen and phosphorus only leads to higher degradation of crude oil. S200 fertilizer contains surfactant compound, an oleophile phosphate ester. The utilize of biosurfactant to liberation hydrocarbons sorbed on solid soil materials was less toxic than synthetic

surfactants. The current study demonstrated that the biosurfactants produced by *B. cereus* WR146 had a high capacity to desorption of crude oil from the sand up to 100% at a concentration of 6 and 10 g L^{-1} of the biosurfactants (*Fig. 5; Table 10*). The use of synthetic surfactants would logically improve the production of biosurfactant in oil-utilizing microbes, which are added or naturally found in the soil.

Discussion

Many large oil spill accidents in the marine environment have acquired considerable popularity in the media. While, smaller and more recurrent spills are often the most damaging to the ecosystem. Crude oil is not only directly toxic to organisms, but also has a suffocating impact (Buskey et al., 2016).

Bioremediation works, as documented in the literatures, may be confounding, especially when applied commercially. Where, there are predominatingly no endeavor to differentiate between the factors attributed to the success or fiasco of the process. Absolutely, each site has a unique case. All environmental factors such as weather, fertility of soil, pH, type of soil, etc. have an important impact on bioremediation. Climate is particularly important in Iraq, which can be considered a bit extremist continental in most of its regions. In the summer, when the effectiveness of bioremediation process is at its top, is long, sweltering, arid, and clear, resulting to water drop in experimental fields. While, the Winter is cool, dry, and mostly clear. The site under study is an area of the crude oil spill incident, which covered about 500 m^2 of agricultural land. The harmful impact of crude oil was on trees and other field crops,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_237252

which were killed due to crude oil concentrations through their root area. Agricultural soil was polluted with crude oil almost at a depth of 50 cm. The first solution to this trouble was to cover the crude oil polluted site with a surface layer of unpolluted soil.

In the present investigation, the compost system was used in bioremediation of crude oil in soil. This system has been works to improve rates of crude oil removal by biophysical methods. Where, a considerable removal of crude oil from polluted soil was observed after three months and reached 50% relying on the type of compost system. The carbon dioxide development rates in the laboratory (*Fig. 4*) were lower than the theoretical rates of carbon dioxide estimated (*Table 9*), suggesting that a large amount of crude oil was disposed by ventilation process. The rates of lab for carbon dioxide development indicate the need for 6 years or more for the degradation of crude oil. This is in the case that 2.81% of the crude oil components in the soil can be degraded. Customary, the presence of many volatile fractions in the crude oil will decrease the time of biological treatment, however, the bioremediation of crude oil in the soil will remain very long without any treatment.

The primary degradation is quickly for certain hydrocarbons in the manipulating system. Analysis by gas chromatography of soil contaminated with crude oil exhibited the effective disposal of low molecular weight hydrocarbons over time. While some compounds such as polycyclic aromatic hydrocarbons (PAHs) need longer degradation time when suitable oil-utilizing microorganisms are exist. The degradation of these compounds may also want desorption from solid surfaces. The utilize of surfactant compounds for desorb hydrocarbon contaminants and impact on their microbial degradation has been exceedingly investigated. Non-ionic surfactants can increase the degradation of many PAHs in the watery phase (Zhu and Aitken, 2010; Zhentian et al., 2015; Yu et al., 2014). While, Alden et al. (2016) reported that non-ionic surfactants at a higher concentration than the CMC prevented degradation of PAHs. It has been shown that the capability of eight artificial surfactants to solubilize PAHs is varied. The most hydrophobic surfactants were more likely to solubilize PAHs. Whilst conflicting outcomes were gained from studying the biodegradation potential of PAHs solubilized by artificial surfactants (Adrion et al., 2016). The most hydrophobic surfactants were less endured by bacteria (Zheng et al., 2015). Barrios et al. (2005) and Zhu and Aitken (2010) demonstrated that Brij 30 degraded with naphthalene, while the Triton X-100 was not degraded. However, the addendum of the surfactants did not impact the degradation rate of naphthalene or the final quantity degraded, in spite of ameliorated bioavailability.

The S-200 fertilizer has been utilized in the biological treatment of heavy fuel oil spilled from the oil tanker Prestige in November 2002 along the Atlantic coast of Galicia (Spain). Our experiments with soil (non-existent results) exhibited that the crude oil biodegradation rates with S200 fertilizer are low compared to the use of urea and phosphorus only. Fertilizer, S200 is a microemulsion made up of an artificial surfactant that is probable to be an inhibitor in the concentrations applied. The value of half maximal effective concentration (EC_{50}) of S200 fertilizer (Microtox bioassy) was 0.3 mg L^{-1}, which is more toxic than the EC_{50} value of biosurfactants produced by bacteria, *Bacillus cereus* WR146 (540 mg L^{-1}). Although the S200 fertilizer shows a inhibitory effect, it has the feature that the S200 in this oleophilic substrate does not wash readily from the soil.

Undoubtedly, the biosurfactants are lower toxic and more susceptible to microbial degradation than synthetic surfactants and are preferred in biological treatment. The production and employ of biosurfactants as raw extracts of microbial cultures or as purified materials is very costly. The biosurfactants can also be created from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_237252

monosaccharides or sugar alcohols and fatty acids through esterification of enzyme-catalysed in organic solvents (Satpute et al., 2010; Gumel et al., 2011). The growth of microorganisms that produce biosurfactants at the site would logically promote the desorption of hydrocarbon compounds. The present study exhibits that biosurfactants eliminate a large proportion of crude oil polluted to soil (non-existent results). The addition of biosurfactants-producing bacteria (*B. cereus* WR146) increases the removal of crude oil from the soil. This is reflected in soil samples taken from a depth of 50 cm from field 10, which displays the highest rates of carbon dioxide development (*Fig. 5*). It is necessary to evolve methods to increase the production of biosurfactants in the environment or introduce oil-utilizing microorganisms to the soil.

There are many factors that restrict the process of bioremediation in the term microbiology. The transfer of the organic contaminates mass from the soil particles to the liquid phase may be a restricting factor as previously explained, so synthetic and biosurfactants are used. Also, many enzymes embroiled in the bioremediation process require molecular oxygen. Therefore, the transfer of oxygen mass to the soil may be a critical factor in many cases. In the current bioremediation process, locally obtainable accessories have been utilized to attempt to help oxygen transfer.

An important aspect of bioremediation, which has acquired only a small amount of attentiveness, is that the microbiological restriction is likely to be due to the catabolite repression. When a assortment of carbon substrates are present, the bacterium will logically select the substrates that can be easily used. However, such substrates may be plentiful and the requisite bacteria are present, but the biodegradation of contaminants may not forward. There is some clue to suggest that *Bacillus* lack the catabolite repression of other bacteria. Actually, the presence of glucose may promote the microbial degradation of hydrocarbon pollutants (Xu et al., 2018). If this is the case, *Bacillus* will have a great characteristic over others, so the bacteria will be the ideal option in the bioaugmentation.

This study is destined to identify the effects of some commonly used methods to optimize treatment and stratify them more generally to other areas polluted with crude oil.

Conclusions

Based on the results of this research, it was concluded that a better outcome could be achieved for the biological treatment of crude oil polluted agricultural soil using the composting systems, good ventilation, nutrients and biosurfactants producing bacteria. The research also showed that a noticeable degradation of crude oil occurred after 3 months of bioremediation up to 50%. Further studies to determine the effectiveness of bioremediation in oils polluted soil are needed.

SEASONAL CHANGES OF SOME MICROBIOLOGICAL PROPERTIES OF SOILS IN A FIELD OF HAZELNUT *(CORYLUS AVELLANA* L.*)* GROWING

IRMAK YILMAZ, F.

Department of Soil Science and Plant Nutrition, Faculty of Agriculture, Ordu University, Ordu, Turkey
(e-mail: fundairmak@hotmail.com; phone: +90-452-234-5010; fax: +90-452-226-5269)

(Received 30th Jul 2019; accepted 25th Nov 2019)

Abstract. The aim of this study is to identify the effects of the compost obtained from hazelnut husks by using biological techniques, on soil quality at different sampling times. The composted hazelnut husk was used at 6 application doses and with 3 replications in order to increase the organic material content of the soils at doses of 0, 0.5%, 1%, 2%, 3% and 4%. The hazelnut husk compost was applied at the Akçatepe/Ordu/Turkey experiment area on the 23rd of November 2012 by using the mattock planting method. The soil samples were collected from the field at 4 different sampling seasons and consequently, various chemical and biological soil characteristics were detected. The results shows; certain doses and different sampling seasons have a significant effect on the beta-glucosidase, urease and acid phosphatase enzyme activities in soils; the most effective doses were 4% and 3%; the 1st and 4th seasons provided the best results. As for other biological characteristics the highest values were as follows: CO_2 production at 1% dose, microbial biomass-C value at 2% dose. The application of hazelnut husk compost, which has a rich organic matter content and is an organic material itself, to soils, promotes an increase in soil organic materials.
Keywords: *hazelnut husk, compost, soil enzymes, organic material, microbial biomass-C*

Introduction

The use of wastes, which have an important place in agricultural production, as an organic matter source for soils, has recently become a common practice. The utilization of wastes is also a solution for environmental pollution. Especially following the hazelnut (*Corylus avellana* L.) harvest season, its husk is either used as fuel, as cushions for animals or left aside as idle wastes. Especially in Turkey's Black Sea region, hazelnut is an important product. It is known that approximately 550.000 tons of shelled hazelnut is produced annually in this region. After the harvest, from 1 kg of fresh hazelnut, remains around 1/3 and from shelled hazelnut 1/5 (200 gr) of dry husk shell (Çalışkan et al., 1996; Bender Özenç, 2008; Amiri et al., 2017).

Turkey is the world's leading hazelnut producer, accounting for about 75% of world hazelnut supply. According to FAO data, Turkey is the first world hazelnut producer and exporter that covers approximately 70% and 82% of the world`s production and export respectively. It is followed by Italy with nearly 20% in production and 15% in export. That is why the Turkey is at the focus of the international academic studies about hazelnut, hazelnut husk compost etc. and references about these issues (FAO, 2019). Solely 10% of the hazelnut consumption is accounted in-shell, the rest of this ratio is shelled and evaluated for industrial objectives (Tous, 2001; Stévigny et al., 2007).

Especially in Giresun, Ordu, Trabzon and Samsun in the Black Sea Region and Sakarya in the Marmara Region, hazelnut cultivation is the main source of living. The Black Sea Region's ecological structure is suitable for hazelnut production. Thus

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_253262

hazelnut is an essential product in Turkey's economy. Most densely in the Black Sea Region, hazelnut is produced in 39 provinces of Turkey. Hazelnut production is mainly run as family-owned businesses. According to Republic of Turkey Ministry of Agriculture and Forestry, around 395 thousand families are economically focused on hazelnut production with a total area of 700 thousand hectares (GTB, 2013). The increase in world's population, accelerates the agricultural activities on soils. The excessive and unconscious use of fertilizers and chemicals common in traditional agricultural system, generates both environmental and soil issues. Most of soil issues arise from the wrong or misuse of it, which ends up with the soil impairment. The soil is a natural and living substance, which together with air and water contains millions of microorganisms and provides an environment for human beings, plants and animals to live. Even the smallest piece of land needs thousands of years to form; hence, our soils are invaluable within the ecosystem. Especially the benefits provided by the environment that soils render for plant production, show how crucial it is for human being's life. A healthy soil means a healthy plant production environment, which eventually connotes that plants grown on such lands will be healthier. In order to ensure healthier plants, to protect their quality features, fertility and sustainability, it is necessary to protect the soil idiosyncrasy. All these features are related to the quality of soils, the sustainability or developability of some characteristics, which appear in the soil quality (Aygün, 2015).

Microbial biomass carbon, CO_2 production (soil respiration) and dehydrogenase activity are commonly used parameters to identify the biological effects of organic and inorganic matters penetrated into the soils (Meli et al., 2002).

The application of hazelnut husk compost into the soils, provides an increase by means of organic matter, ensuring as a consequence many of its physical, chemical and biological features to improve. This application radically improved the microbial activities in the soil, by means of soil buffer capacity (thus chemical soil properties like pH, electrical conductivity, the amount of exchangeable cations, organic matter and total amount of nitrogen content; by means of physical properties: aggregate stability, bulk density, field capacity and wilting point; by means of biological properties: soil respiration and biomass-C content increased (Birol and Bender Özenç, 2011; Aygün, 2015; İslam, 2016).

The application of clinoptilolite, leonardite, organic commercial fertilizer (biofarm) and two different types of hazelnut husk (fresh and composted), which is a regional waste, as soil regulators in a certified organic hazelnut garden revealed positive postharvest developments by means of soil enzymes (dehydrogenase, urease, phosphatase and sulfatase) and the amount of microbial biomass (Özyazıcı et al., 2011).

Soil enzymes are basically produced by soil microorganisms, which are able to show the microbial activities observed in the soil environment and play a crucial role during the decomposition of organic matters and transformation of plant available nutrition elements (Xiu-Mei et al., 2008).

The aim of this study; is to examine the relationship between the effects of the application of the compost, at varying doses, obtained from hazelnut husk by using biotechnological techniques and the effects of sampling seasons on various biological and chemical properties of the soil.

Materials and methods

The experiment was carried out in the high tunnel greenhouse established in Ordu University experiment area. The study area is located in Ordu province, Altınordu district, Eastern Black Sea Region, Turkey in 2016. The province of Ordu is located between the northern latitudes of 37T 4534765, with eastern longitudes of 411638 (*Fig. 1*).

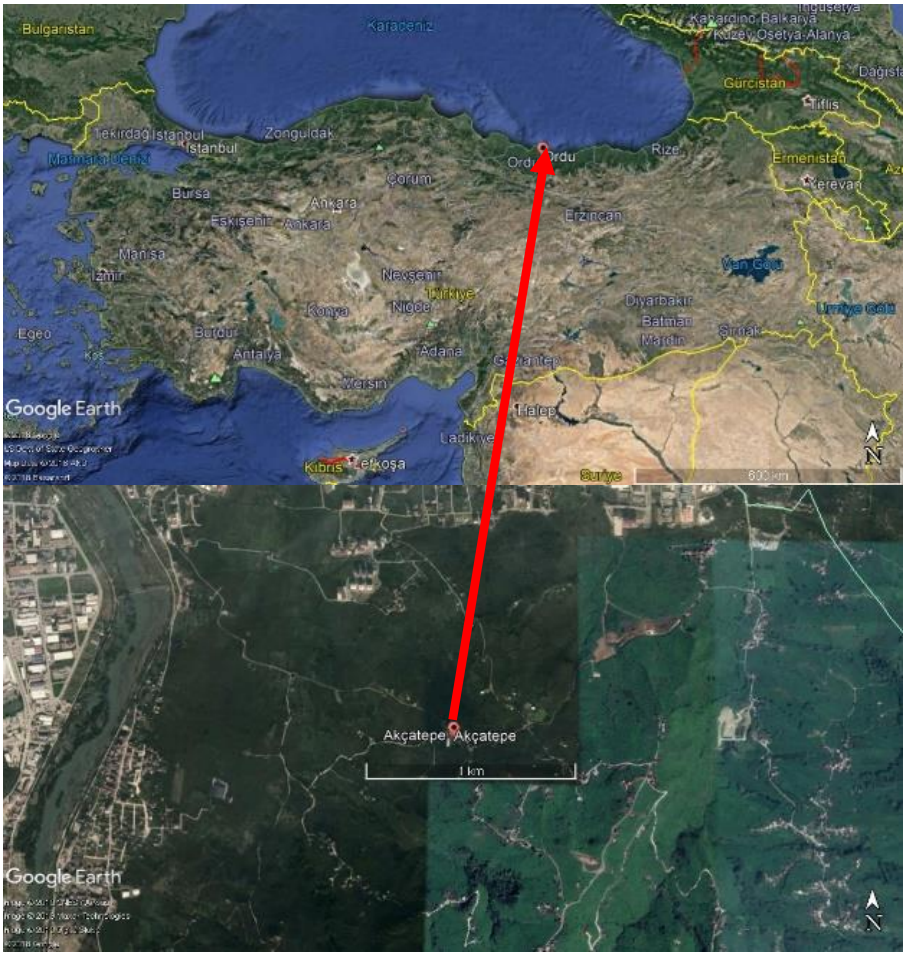

Figure 1. *Map shows the location of Akçatepe district experiment area in the Ordu Province, Turkey*

In this study, the compost of hazelnut husk, which was obtained by using microbial biotechnological methods, has been used as material. The field test (Akçatepe District) was conducted on the 23rd of November 2012; varying application doses of hazelnut husk compost were applied in order to increase the soils organic material content as of 0 (control), 0.5% (0.125 kg ha^{-1}), 1% (0.25 kg ha^{-1}), 2% (0.50 kg ha^{-1}), 3% (0.75 kg ha^{-1}) and 4% (1 kg ha^{-1}); the compost was applied uniformly to a 50-60 cm diameter circle around the hazelnut plots by mattocking and mixing with soil to a 10-15 cm depth. The sampling was realized in four sampling seasons: autumn (I, 25 November 2016), winter (II, 23 February 2017), spring (III; 24 May 2017) and summer (IV, 22 August 2017). The tests were carried out according to randomized blocks trial design with three replications (Aygün, 2015). Hazelnut husk (C/N ratio 55.71; pH 5.81; EC25 °C

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_253262

1.93 dS m^{-1}; 0.97% N) was collected from the hazelnut orchard, inoculated with carbon and the microorganisms used as energy sources were composted by windrow method and eventually used as a material in experiments using a windrow machine in the Research Facility of Soil Science and Plant Nutrition Department at Ondokuz Mayıs University, Samsun, Turkey. HHC properties are as follows: pH is 6.76, EC25 °C is 3.56 dS m^{-1}, organic matter (OM) content is 94.75%, total N content is 2.48% and C/N ratio is 22.16 (Kızılkaya et al., 2015a,b).

The loamy soil of the experiment land in Akçatepe shows a neutral ground reaction and a saline electrical conductivity (*Table 1*). The lime ($CaCO_3$), organic matter content, total nitrogen and available phosphorus contents in Akçatepe soil were adequate (Aygün, 2015).

Table 1. *The soils physico-chemical properties (Aygün, 2015)*

Analyses	Akçatepe Dist. (Ordu Province)
% sand	33.55
Texture % silt	27.86
% clay	38.59
Textural class	Loamy soil (CL)

Exchangeable K, cmol(+) kg^{-1}	0.444
Exchangeable Ca, cmol(+) kg^{-1}	39.90
Exchangeable Mg, cmol(+) kg^{-1}	1.26

Soil physico-chemical analyses

Soil samples, grated to 2 milimeters were kept waiting and prepared for the analyses in + 4 °C refrigerator immediately after, and biological analyses were initiated. To identify the properties of the sample soil, the texture was examined by hydrometer method as told by Bouyoucos (1962), soil reaction (pH) and saltiness (EC) by U.S. Salinity Laboratory Staff (1954), organic material by Nelson and Sommers (1982), total nitrogen by Bremner (1965), extractable potassium by Knudsen et al. (1982) as told by Müftüoğlu et al. (2012).

Soil biological analyses

For the biological analyses of the soil; CO_2 production was identified using the method told by Isermeyer (1952); microbial biomas-C by Anderson and Domsch (1978), β-Glucosidase Enzyme activity Eivazı and Tabatabai (1988), urease enzyme activity by Kandeler and Gerber (1988), acid phosphatase enzyme activity by Tabatabai and Bremner (1969) as told by Schinner et al. (1996).

Statistical analysis

At the end of the study, the variance analysis of the obtained data was performed using the JMP package program and the important results were evaluated according to the LSD test.

Results and discussion

The effects of the beta-glucosidase enzyme activity ($p < 0.01$), urease enzyme activity ($p < 0.01$) and acid phosphatase enzyme activity ($p < 0.01$) were relevant to application and season interactions effect revealed statistically significant results (*Table 2*). When the application doses of hazelnut husk compost and sampling seasons are taken into consideration, the highest β- glucosidase enzyme activity occurred at 0.1 kg ha^{-1} compost dose on the 4th season (summer), this value has been followed by the 2nd season (winter) application with a compost dose of 0.25 kg ha^{-1} and the lowest control was detected on the 1st season (autumn). As both the hazelnut husk compost application doses on the 4th season (summer) and sampling seasons multiplied, the beta- glucosidase enzyme activity of soils increased accordingly. It has been stated that the soil organic matter absorbs the beta-glucosidase enzyme and therefore induces the activity in the soil to continue (Wang et al., 2006). The β-Glucosidase enzyme activity is one of the essential soil enzymes, which is responsible for the C cycle (Nannipieri et al., 2002; Kayıkçıoğlu and Okur, 2011).

The urease enzyme activity's peak (73.55) occurred on the 1st season (winter) at a dose of 0.75 kg ha^{-1}, this was followed by the 0.125 kg ha^{-1} dose and these two doses were identified as the most effective ones. The lowest urease enzyme activity dose was 0.50 kg ha^{-1} and it was identified on the 4th season (summer). The applications of hazelnut husk increased the soils urease enzyme activity; however, during the summer season the increasing temperature accelerated the decomposition of organic materials, resulting in the 4th sampling season (summer) to reveal the lowest urease enzyme activity values.

As the strongest acid phosphatase enzyme activity occurs in the beta-glucosidase enzyme activity, a 1 kg ha^{-1} dose application of the hazelnut husk compost on the 4th sampling season (summer) revealed the highest values (32.15 µg *P*- N $g.d.s^{-1}$), whereas the lowest acid phosphatase enzyme activity value was identified during an application of a 1.25 kg ha^{-1} dose and on the 2nd (winter) sampling season (4.70 µg *P*- N $g.d.s^{-1}$). In

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_253262

previous studies, the effects of vegetable substances like wheat and corn stalk and as animal products, the effects of horse, hog and cow manure on soils were investigated, ultimately it was determined that all these applications boost the urease, phosphatase and interphase activities, revealing the lowest rate of increase in the interphase activity and the highest in urease and phosphatase activities (Guan, 1989; Aygün, 2015).

Among the application doses of the hazelnut husk compost, the highest soil respiration (0.60 mg CO_2/24 h/g) was detected at the 0.25 kg ha^{-1} application dose and the lowest (0.42 mg CO_2/24 h/g) at the compost's control application. The difference between these values was statistically highly significant ($p < 0.01$). Furthermore, through the application of this dose, the CO_2 production value revealed a 1.4 times increase comparing to the control application (*Table 3*).

Considering the sampling seasons, the highest CO_2 production value was identified on the 1st and 4th seasons (autumn and summer) (0.30 mg CO_2/24 h/g), whereas the lowest value was identified on the 3rd season (spring) (0.21 mg CO_2/24 h/g). The difference between these seasonal values was statistically highly significant ($p < 0.01$). The CO_2 production on the loamy soil of the experiment area, decreased gradually from the 1st sampling season (spring) to the 3rd (winter) and increased again on the 4th season (summer). The CO_2 formation in agricultural soils usually varies between 3.5 and 35 mg CO_2-C 100 $g.d.s^{-1}$ values (Alexander, 1961; Kayıkçıoğlu and Okur, 2013). It has been stated that the CO_2 amount in organic farms is higher than in conventional agriculture farms (Melero, 2006; Tuomisto et al., 2012).

Table 3. *The effects of application doses of the hazelnut husk compost on the sampling seasons, CO_2 production (mg CO_2/100 g^{-1} day^{-1}) based on doses, microbial biomass -C (MBC mg biyomas-C 100 $g.d.s^{-1}$) and other soil properties (organic matter OM:%, total N %, K: mg kg^{-1}, Mg and Ca: $cmol_{(+)}kg^{-1}$)*

When the application doses of hazelnut husk are taken into consideration, the microbial biomass -C (MBC) value was between 42.60 -74.85 mg biomass-C 100 $g.d.s^{-1}$ and the difference between the hazelnut husk doses were statistically insignificant ($p < 0.01$). The doses have increased the MBC values comparing to the control and the highest value was identified at a dose of 0.5 kg ha^{-1}.

When the sampling season is considered, the MBC value showed a regular increase from the 1st (autumn) season to the 4th (summer) season (except the 3rd- spring season); the highest value arose on the 4th season (summer) and the difference between seasons was statistically significant ($p < 0.01$).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_253262

In respect to hazelnut husk doses, organic matter (OM) content increased and this increment showed seasonal changes. The effects of doses were statistically insignificant, however the highest value has been observed at a dose of 0.125 kg ha^{-1}. When taking the sampling seasons into account, the highest organic material value was detected on the 2nd season (winter). The loamy soils own high surface areas and a high cation exchange capacity, thus showing protective features against the fragmentation of organic substances (Giller et al., 1997; Aygün, 2015). It was reported that organic waste applications radically improve the chemical features of loamy sand soils like the content of organic matter and exchangeable cations and enhance the soil quality (Candemir and Gülser, 2011). There are also other studies, which explain that hazelnut husk may be utilized as an organic material and nutritional source, which enhances the physical properties of the soils (Zeytin and Baran, 2003; Bender Özenç et al., 2019).

Garcia et al. (2004) investigated the effects of various plants on pH, EC, total organic carbon and carbon fractions, microbial biomass carbon, soil respiration, dehydrogenase, phosphatase, β-glycosidase and urease characteristics for 6 years. At the end of the researches they reported that; the aggregate stability, soil respiration, dehydrogenase, urease and phosphatase activities occur more strongly in plant growing soils; pH (7.5-8.0) and EC levels are lower compared to control; the total organic carbon and microbial biomass carbon available in the rhizosphere zone are higher compared to control application.

In consequence of statistical evaluations, the effects of hazelnut husk applications on total N were found insignificant, remaining within an interval of % 0.12-0.14 and showing the highest results at a dose of 0.25 kg ha^{-1}. However the sampling season was statistically significant ($p < 0.01$). When sampling seasons are considered, it was determined that the 2nd season (winter) revealed the highest total N content (0.50%), while the 1st season (autumn) demonstrated the lowest total N content (0.10%). Shenbagavalli and Mahimairaja (2012) on the other hand reported that as the incubation season extends, the mineral N values radically reduce. Besides, as an expected result, when the microorganisms decompose the organic materials in the soil in order to create a source of nitrogen, the nitrogen content of the soil decreases (Bender Özenç et al., 2019).

The effects of hazelnut husk compost doses on extractable K were significant ($p < 0.01$). The application of the hazelnut husk compost in different doses, increased the extractable K content of the soil. The highest K value was detected at a dose of 1 kg ha^{-1} (266 mg kg^{-1}) and increased 1.65 times compared to control.

In terms of the exchangeable Mg and Ca values, doses and sampling seasons were statistically significant ($p < 0.01$). According to doses, the exchangeable Mg value was between 7.70-5.09 $cmol_{(+)}kg^{-1}$ and the highest dose was 0.75 kg ha^{-1}, the exchangeable Ca value on the other hand was between 17.36-26.82 $cmol_{(+)}kg^{-1}$, showing the highest value at the control dose. The exchangeable Mg and Ca values were statistically significant in consideration of sampling seasons. The exchangeable Mg highest value (8.40 $cmol_{(+)}kg^{-1}$) was identified on the 1st sampling season (autumn), while it was the lowest (5.6 $cmol_{(+)}kg^{-1}$) during the 2nd (winter) and 4th (summer) sampling seasons. The exchangeable Ca value was between 18.22-26.47 $cmol_{(+)}kg^{-1}$ (2nd-winter and 1st-autumn season).

When the soil reaction is analyzed, the effects of the hazelnut husk compost on doses and sampling times revealed statistically significant results ($p < 0.01$). The highest pH value was identified at the control application (6.70), the lowest pH value on the other

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_253262

hand was determined at a compost application dose of 1 kg ha^{-1} (6.03). And when the sampling seasons are examined, the highest value was observed at the 1st (autumn) (6.52) and the lowest at the 4th (summer) season (6.08).

Conclusion

Within the scope of this study, where the effects of different application doses and sampling seasons of hazelnut husk compost, obtained through microbial biotechnological methods, on the soil various biological features were examined, the biological soil properties showed improvements and positive developments. While the beta-glucosidase and acid phosphatase enzyme activities were the highest at a dose of 1 kg ha^{-1}, the most effective sampling season was the 4th (summer) one. Urease enzyme activity on the other hand was more effective during the 1st (autumn) season and the 0.75 kg ha^{-1} dose was sufficient. For the production of CO_2 the 0.25 kg ha^{-1} dose, for MBC the 0.5 kg ha^{-1} dose, for total N and organic matter content the 0.125 kg ha^{-1} dose were sufficient. To blend the hazelnut husk compost, which is an organic material containing a large amount of organic matter, with the soil, provided the soil organic matter content to increase, which ultimately was an intended result. Increased doses of hazelnut husk compost to the soil, although there is an increase in the amount of organic matter due to dose increase. The optimum level of the compost to be applied must be decided, the initial organic matter content of the soil is recommended.

(Received 1st Aug 2019; accepted 14th Nov 2019)

Abstract. The field experiment was carried out in 2016-2019 at the Agricultural Experimental Station Zawady (52°03'N and 22°33'E) belonging to the University of Natural Sciences and Humanities in Siedlce, Poland. The experiment was established in a random layout (split - plot) with triplicates. The examined factors were I - three varieties of winter rape: Monolit, PX115, PT248. II - four types of foliar feeding: 1. control object, 2. biostimulator Aminoplant, 3. Foliar fertilizer Siarkomag + foliar fertilizer Bormax, 4. Foliar fertilizer Siarkomag + foliar fertilizer Bormax + biostimulator Aminoplant. The aim of the study was to determine the effect of foliar fertilizers containing amino acids, sulphur and boron on planting before harvest, plant height before harvest, root thickness, height to the first productive branching, deflection of three varieties of winter rape. The use of the Aminoplant biostimulator in combination with foliar fertilizers containing sulphur and boron significantly increased the planting density, the stem thickness at the root, the height to the first productive branching, compared to the control treatment. Foliar application of amino acids, boron, sulphur did not significantly increase the height of plants before harvesting and did not affect the deflection of the field.
Keywords: *plant density, plant height, stem thickness, height to the first productive branching, plant morphology before harvest, field deflection*

Introduction

Currently, one of the basic elements of agrotechnics of many crops is foliar feeding. This treatment entails the introduction of deficient nutrients to aboveground parts of plants (Szewczuk and Sugier, 2009). Singh et al. (2013) state that this is an alternative way to provide plants with missing macro and micronutrients consisting of sprinkling leaves with a dilute solution of mineral salts, chelates with the addition of a surface tension reducing agent. According to many authors (Fageria et al., 2009; Singh et al., 2013), foliar nutrition affects the correction of poor nutritional status of plants.

Kinaci and Gulmezoglu (2007) and Babaeian et al. (2011) believe that foliar spraying is very beneficial when the roots cannot provide the necessary nutrients to the plants, due to improper soil pH (pH), drying time, and heavy texture. Similarly, Kocoń (2009) emphasizes that it is much more beneficial to apply foliar spray instead of direct soil application.

According to Kaur et al. (2019), foliar feeding plays a significant role in areas with changing climatic conditions. Stress caused by drought reduces both uptake of nutrients

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_263273

through the roots and transport from roots to shorts, due to limited transpiration and weakened active transport (Yuncai and Schmidhalter, 2005). Well-nourished plants with essential nutrients are more resistant to abiotic stresses.

The reaction of plants to foliar nutrition varies greatly between plant species, growth stages, the concentration of the added nutrient solution and the relative water content in plant parts (Noreen et al., 2018).

The paper assumes a research hypothesis that biostimulators combined with foliar feeding can have a beneficial effect on the architectural elements of winter rape fields.

The aim of the study was to determine the effect of foliar fertilizers containing amino acids, sulphur, boron on planting before harvest, plant height before harvest, root thickness, height to the first productive branching, deflection of three varieties of winter rape (Monolit, PX115, PT248).

Materials and methods

Experimental and agronomic management

The field experiment was carried out in 2016-2019 at the Agricultural Experimental Station Zawady (52°03'N and 22°33'E) belonging to the University of Natural Sciences and Humanities in Siedlce, Poland. The experiment was established in a random layout (split - plot) in triplicate. The surface of each plot was 21 m^2. *Table 1* presents the agrotechnical factors included in the experiment.

Table 1. *Agrotechnical factors included in the experiment (RSD Zawady)*

Agrotechnical factors	
Three morphotypes	• Population morphotype (Monolit variety) • Restored morphotype with the traditional growth type (PT248) • Restored morphotype with semi-dwarf growth type (PX115 variety)
Four types of foliar feeding	• Control object – without using foliar feeding and amino acids • Biostimulator Aminoplant: I term – in autumn in the phase of 4-6 leaves (BBCH 14-16), II term – in spring after the beginning of vegetation (BBCH 28-30), III term – in the phase of development of flower buds (budding) – beginning of flowering (BBCH 50-61), at doses of 1.0 $dm^3 \cdot ha^{-1}$ • Foliar fertilizer Siarkomag + foliar fertilizer Bormax: I term – in autumn in the phase of 4-6 leaves (BBCH 14-16), II term – in spring after the beginning of vegetation (BBCH 28-30), III term – in the phase of development of flower buds (budding) – beginning of flowering (BBCH 50-61), at doses of 2.0 $dm^3 \cdot ha^{-1}$ + 0.5 $dm^3 \cdot ha^{-1}$ • Foliar fertilizer Siarkomag + foliar fertilizer Bormax + biostimulator Aminoplant: I term – in autumn in the phase of 4-6 leaves (BBCH 14-16), II term – in spring after the beginning of vegetation (BBCH 28-30), III term – in the phase of development of flower buds (budding) – beginning of flowering (BBCH 50-61), at doses of 2.0 $dm^3 \cdot ha^{-1}$ + 0.5 $dm^3 \cdot ha^{-1}$ + 1.0 $dm^3 \cdot ha^{-1}$

In the 2016-2017 growing season, the forecrop for winter rape was spring wheat, in the second and final year of research – winter triticale. The experiment was carried out on soil classified according to the World reference base for soil resources (2014) to the Haplic Luvisol group, sated, belonging to the very good rye soil complex, Iva valuation class. During the research years, the soil pH (pH in 1N KCl) was slightly acidic and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_263273

ranged from 5.68 to 5.75. The soil was characterised by a low total nitrogen content (average from 0.80 to 0.90 $g \cdot kg^{-1}$), phosphorous content (average from 0.33 to 0.55 $g \cdot kg^{-1}$), potassium content (average from 0.61 to 0.67 $g \cdot kg^{-1}$) and calcium content (average from 0.82 to 0.85 $g \cdot kg^{-1}$) and the average magnesium content (from 0.38 to 0.46 $g \cdot kg^{-1}$) and sulphur content (from 0.11 to 0.15 $g \cdot kg^{-1}$).

The soil was characterized by low abundance in available forms of phosphorus and average bioavailability in potassium and magnesium (*Table 2*).

Table 2. *Characteristics of soil conditions - Zawady Meteorological Station, Poland (2016-2019)*

Vegetation seasons	pH (1 $mol \cdot dm^{-3}$ KCl)	The content of available forms of elements ($mg \cdot kg^{-1}$)		
		P	K	Mg
2016-2017	5.70	81.0	200.0	63.0
2017-2018	5.68	75.0	199.0	60.0
2018-2019	5.75	79.0	202.0	59.0

After forecrop harvest, a set of post-harvest procedures was carried out using the ploughing aggregate + open cage roller, and then two weeks after the first procedure, pre-sow ploughing at the depth of 20.0 cm was carried out, using a ring roller at the same time. To prepare the soil for sowing and to mix fertilizers, a complex soil tillage unit was used. Before sowing, phosphorus-potassium fertilization was applied at the dose of 40 kg $P \cdot ha^{-1}$ and 110 kg $K \cdot ha^{-1}$ and the first dose of 40 kg $N \cdot ha^{-1}$. Fertilization was applied in the form of Lubofos at the dose of 600 kg. Fertilizing doses were supplemented with 55.9 $kg \cdot ha^{-1}$ of ammonium nitrate (19 kg $N \cdot ha^{-1}$), 29.6 $kg \cdot ha^{-1}$ triple superphosphate (13.6 kg $P \cdot ha^{-1}$) and 29 $kg \cdot ha^{-1}$ potassium salt (17.9 kg $K \cdot ha^{-1}$). The second dose of nitrogen in the amount of 100 $kg \cdot ha^{-1}$ was applied in spring, before vegetation started (BBCH 28-30) applying ammonium nitrate at the dose of 255.5 $kg \cdot ha^{-1}$ (86.9 kg $N \cdot ha^{-1}$) and ammonium sulphate at the dose of 62.5 $kg \cdot ha^{-1}$. The third dose of ammonium 60 $kg \cdot ha^{-1}$ was applied at the inflorescence emergence (BBCH 50). by applying ammonium nitrate at the dose of 176.5 $kg \cdot ha^{-1}$ (60 kg $N \cdot ha^{-1}$).

Winter rapeseed sowing was made at spacing between rows of 22.5 cm, assuming a case of 60 $pcs \cdot m^{-2}$. Sowing was made at the optimal time recommended for this region (in 2016 – on August 12, in 2017 – on August 14, and in 2018 – on August 13).

Chemical protection against weeds, diseases and pests was applied in accordance with the recommendations of good agricultural practice. Directly after sowing, herbicide Command 480 EC at the dose of 0.25 $dm^3 \cdot ha^{-1}$ was applied to carefully cultivated soil. Next, at the stage of BBCH 13-14, Fusilade Forte 150 EG at the dose of 2.0 $dm^3 \cdot ha^{-1}$ was applied. At the 4-8 leaves unfolded stage (BBCH 14-18) fungicide Horizon 250 EW was applied (0.75 $dm^3 \cdot ha^{-1}$). At the stem elongation stage (BBCH 30), flower bud emergence stage (BBCH 50-58), flowering (BBCH 60-69) – Proteus 110 OD insecticide was applied at the dose of 0.6 $dm^3 \cdot ha^{-1}$. At the beginning of flowering (BBCH 61) – Propulse 250 SE fungicide was applied at the dose of 1.0 $dm^3 \cdot ha^{-1}$. At the stage of first petals falling – Mondatak 450 EC was applied at the dose of 1.0 $dm^3 \cdot ha^{-1}$.

Rape was harvested in two stages in the first and second decade of July.

Immediately prior to harvest (BBCH 86-87) the case per 1 m^{-2} was marked and elements of field architecture were determined for a sample of 20 plants from each plot, such as:

- Plant height before harvest (cm)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_263273

- Stem thickness at the base (mm)
- Height of seating of the first productive branch (cm)
- Field deflection (%)

Weather conditions in vegetation period

During the years of conducting the experiment, varied weather conditions prevailed (*Table 3*). In the first *vegetation period*, the annual precipitation totalled 389.2 mm and was 8.9% lower compared to the multi-annual average (427.5 mm), while the average air temperature was similar and amounted to 7.9 °C. Based on the calculated Sielianinov hydrothermal coefficient, it was found that the years 2016-2017 and 2017-2018 were optimal. In the second year of research, the largest annual precipitation was recorded (414.5 mm), 13 mm lower than the average for 1996-2010, while the average air temperature was higher by 1 °C and amounted to 9.3 °C. The last year of research was the most dry and warm. The annual amount of rainfall was lower by 174.6 mm, while the temperature was higher than the long-term average by 1.6 °C.

Statistical analysis

The results of the study were statistically analysed with the use of the analysis of variance. The significance of variation sources was tested with the "F" Fischer-Snedecor test and the assessment of significance at the significance level of $p = 0.05$ between compared means - with Tukey's range test.

Results and discussion

Based on our own studies, it was found that the types of foliar nutrition significantly increased the number of plants determined before harvesting (*Table 4*). The largest plant density was recorded after the use of the Siarkomag foliar fertilizer with the Bormax foliar fertilizer and the Aminoplant biostimulator (object 4). After using the bioregulator with an amino acid, the plant density was only an average higher by one item compared to the control object. Jarecki et al. (2019) obtained a significant increase in the number of plants compared to the object without feeding after the application of the Insol5 foliar preparation in autumn, autumn and spring, autumn and twice in spring, while the value of this feature on the objects was the same. Different results were obtained by Czarnik et al. (2015) and Chwil (2016). Similarly, Jankowski et al. (2016a, b) under the influence of foliar application of boron did not find a significant effect of the factor on the value of this feature, as well as Szczepanek and Brach (2019) after the application of the Phostrade® BMo foliar preparation.

The genetic factor significantly influenced the planting before harvest (*Table 4*). The highest value of this feature was demonstrated in the PX115 semi-dwarf hybrid. The population variety Monolit had, on average, from 2 to 3 plants less per unit area compared to restored hybrids. Different results were obtained by Czarnik et al. (2015), who did not find significant differences between the Arot population variety and the Primus hybrid variety.

Preparations containing amino acids, sulphur and boron increased the height of plants before harvest on average from 2.3 to 5.5 cm, but the differences between the examined objects were statistically insignificant (*Table 4*). Similar results were obtained by Jarecki and Bobrecka-Jamro (2008) after the application of foliar fertilizers Basfoliar 36 Extra, Basfoliar 12-4-6 + S, Solubor DF, Adob Mn and mixtures of Basfoliar 36 Extra with Solubor DF, Basfoliar 12-4-6 + S with Solubor DF. Przybysz et al. (2008), Sikorska et al. (2018) after using the Asahi SL biostimulator obtained a significant increase in the plant height. Similarly, Rabiee et al. (2013), Riki et al. (2014) and Cheema et al. (2012) obtained a significant increase of this feature under the influence of foliar nutrition. Habbasha and Salam (2009) emphasized that the dual application of foliar fertilization in the rosette and budding phase has a more favourable effect on the plant height compared to the single dose used in autumn.

In own studies, the height of a hybrid with a traditional type of growth and a population variant was the same (*Table 4*). A similar tendency was noted by Sikorska et al. (2018), while Jarecki and Bobrecka-Jamro (2008) did not find significant differences in the amount of plants of the evaluated varieties (Lirajet, Marita, Lisek).

The application of foliar fertilization influenced the increase of stem thickness at the base from 0.42 to 10.4 mm. The highest value of this feature was noted on object 4 after the application of Siarkomag foliar fertilizer with Bormax and Aminoplant biostimulator (*Table 4*).

From the compared morphotypes, the largest stem thickness at the base was distinguished among the Monolit population variety, while the smallest among the restored hybrid with a traditional growth type (*Table 4*). Different results were obtained by Sikorska et al. (2018). The authors recorded the largest thickness of the stem at the base of restored hybrids (PT205 and PR44D06), and significantly smaller in the Monolit population variety.

The effect of foliar feeding on the thickness of the stem at the base depended on the genetic factor (*Table 4*). The studies have shown that on the control object the differences between the tested varieties were statistically insignificant. The use of the Aminoplant biostimulator (object 2) in restored hybrids PT248 and PX115 did not significantly affect the increase of the thickness of the stem at the base when

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_263273

compared to the object on which no foliar nutrition was applied. The largest significant increase was found in the population variety after the application of the Aminoplant biostimulator with sulphur fertilizers (object 3) and sulphur and boron (object 4), while the differences between variants 3 and 4 were statistically insignificant, and in the case of restored hybrids only after the application of the Aminoplant biostimulator in connection with foliar fertilizers containing sulphur and boron.

In own studies it was found that the height to the first productive branching on control objects and the biostimulator containing amino acids was the same. The highest value of this feature was noted after the use of preparations containing sulphur (object 3) and sulphur and boron (object 4) (*Table 5*). Sikorska et al. (2018) after using the biostimulator Asahi SL obtained an increase in the value of this feature by an average of 4.6 cm. While Jarecki and Bobrecka-Jamro (2008) did not find a significant influence of this factor.

The studied varieties were distinguished by varying height to the first productive branching. The highest first productive branching was noted in the population variety, significantly lower in the re-cultivated hybrid with the traditional type of growth (*Table 5*).

The types of foliar nutrition did not affect the field deflection of the studied varieties of winter rape. Among the studied varieties, the greatest deflection of the field was recorded in the population variety, while the differences between the restored hybrids were statistically insignificant (*Table 5*).

Weather conditions influenced a significant diversity of morphological characteristics marked before harvest (*Tables 6-7*). The sum of rainfall significantly higher than the average for many years in the period from March to April in the first year of research caused that the plants grew higher, had a greater thickness of the stem at the root, developed the first productive branching higher. The smallest values of these features were noted in the last *vegetation period*, in which the sum of precipitation in April was lower by 82.5% compared to the average for many years, and the average air temperature higher by 1.8 °C. The largest number of plants before harvest was noted in a warm and dry *vegetation period*, which was characterized by a higher average air temperature from November to April and a lower amount of rainfall in this period compared to the average for many years, while the smallest cast was demonstrated in 2017-2018, characterized by lower average air temperature in the period from February to March.

Values marked with the same letter do not differ significantly at $P \leq 0.05$. n.s. - non significant differences

Interactions of varieties and years of research have been found in relations to planting before harvesting, heights to the first productive branching, sowing of the field, which indicates the individual reactions of the studied varieties to climatic conditions prevailing in particular years of research (*Tables 6-7*). It was observed that all varieties were distinguished by the largest planting diversity in the driest and warmest year of research. The population variety had the same number of plants in the first and second growing season, while in the restored hybrids, the differences in the value of this feature in the last year of the research were statistically insignificant. The studied morphotypes were distinguished by the highest height to the first productive branching in the first year of study, the value of which was the same in the PT248 variety in the last two years of research, and in the semi-dwarf morphotype in 2016-2017 and 2017-2018.

Conclusions

1. The use of the Aminoplant biostimulator in combination with foliar fertilizers containing sulphur and boron significantly increased the planting density (on average by 4.7%), the stem thickness at the root (on average by 7.3%), the height to the first productive branching (on average by 6.9%), compared to the control object.
2. Foliar application of amino acids, boron, sulphur did not significantly increase the height of plants before harvesting and did not affect the deflection of the field.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_263273

3. The morphotype determined the morphological characteristics of the plants before harvesting. The largest plant density was found in the semi-dwarf hybrids, while the population variety was distinguished by the largest thickness of the stem at the base, the height to the first productive branching. The plant height was the same in the population morphotype and the restored hybrid with a traditional growth type.
4. The climatic conditions in the *vegetation period* the experiment significantly influenced the examined elements of the field architecture.
5. Foliar fertilization should be used as a permanent element of winter rapeseed cultivation technology, therefore further research is needed to evaluate the performance of these preparations on various soil types.

Acknowledgements. The research was carried out under the research project No. 363/S/13, financed from a science grant by the Ministry of Science and Higher Education.

(Received 5th Aug 2019; accepted 25th Nov 2019)

Abstract. A multi residue detection method for the quantification of six wide spectrum non-polar pesticides in the muscle of cattle, sheep, and goats was developed in this study. The method was based on a modified QuEChERS procedure adapted to gas chromatography coupled with mass spectrometry (GC–MS). About 150 meat samples were analyzed to detect and quantify pyrethroids (PYRs) including cypermethrin (CMT), deltamethrin (DMT), organochlorines (OCs) including hexachlorobenzene (HCB), α-hexachlorocyclohexane (α-HCH) and organophosphates (OPs), such as chlorpyrifos (CPS) and fenitrothion (FTN). Subsequently, the effects of boiling (100 °C, 30 min) and broiling (176 °C, 20 min) on the level of pesticides in the meat were tested. Acceptable responses of analytes were obtained at validation levels of 0.01 to 0.1 mg/kg. The linear coefficients (r^2) were ≥ 0.9997, and limits of detection (LOD) and limit of quantification (LOQ) values ranged from 0.004 to 0.014 and 0.012 to 0.043 mg/kg respectively. Satisfactory recovery (79.2 to 104.3%) was obtained for all spiked levels with acceptable relative standard deviation (RSD) (≤14.6%). The dominant compound found in cattle muscle was hexachlorobenzene (HCB), while deltamethrin (DMT) was the most dominant pesticide in sheep and goats samples. Boiling technique reduced meat pesticides significantly ($P < 0.05$), whereas the effects of broiling were questionable. The validation results confirmed that the proposed method can be utilized as a dependable screening apparatus and analytical procedure for quantitative determination of studied pesticides in animal tissues.

Introduction

The innovation of pesticides has played a vital role in the development of agriculture and veterinary science, and they have been irreplaceable until now. In veterinary

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_275288

medicine, pesticides are used for the treatment of external parasites, while in agriculture, they are used intensively for prevention and treatment of crops pre and post-harvests (Lainsbury, 2019). Their extensive use of pesticides has resulted in their widespread distribution and transfer to animals (MacBean, 2015). These contamination routes can lead to bioaccumulation of pesticides in food products of animal origin such as meat, fat, and milk, finally leading to pesticides being transferred to humans via the food chain (Castillo et al., 2012).

Pyrethroids (PYRs), organochlorines (OCs), and organophosphorus (OPs) pesticides are effective against variety of pests, have been widely used around the world (Castillo et al., 2012). Their extreme stability, low volatility, and probable indiscriminate use in the past have led to their high persistence in the environment and in organisms after exposure (Lainsbury, 2019). Among these groups of pesticides, non-polar pesticides are more hazardous than polar pesticides because they have a strong tendency to be stored in body tissues and only small amounts are excreted through kidneys (MacBean, 2015). Ingestion of tiny doses of pesticides daily or weekly may cause life-long illnesses, neurological problems, cancers, anemia, and cardiovascular illnesses in humans (MacBean, 2015).

Several methods have been used to quantify of pesticide residues in animal derived foods, but the key technique is: firstly, how several pesticides residues can be efficiently extracted from the complex matrixes; secondly, how cleaning up is performed to minimise matters co-extracts; thirdly, what analytical method should be proposed for accurate quantification.

QuEChERS (quick, easy, cheap, effective, rugged and safe) extraction technique is the most popular extraction method (Anastassiades et al., 2003). The method is based on acetonitrile extraction followed by a cleanup, using dispersive solid phase extraction (d-SPE) with a primary secondary amine (PSA), octadecylsilane (C18). At first, the method was simply used for determination of specified groups of pesticide in fruit and vegetables. Later, it was validated for a variety of pesticide groups in high fat content foods, such as meat and internal organs (Meligy et al., 2019), chicken eggs (Nardelli et al., 2018) and fish (Sahu and Nelapati, 2018).

Among chromatographic techniques, GC is the most frequently used technique (Vitha, 2016). The GC has been used for detection of multi-residues in liquid matrices (Schettgen et al., 2016), and complex tissue matrices (Letta and Attah, 2013). Variety of detectors have been used with GC, such as tandem MS (MS/MS) (Arioli et al., 2019), mass spectrometry (MS) (Meligy et al., 2019) electron capture detection (ECD) (Dimitrova et al., 2018). The most preferred by laboratories is GC, due to its high sensitivity suitability for halogen and non-halogen containing compounds (Grimalt and Dehouck, 2016). MS suffers more from sample matrix interferences than other detection methods (Meligy et al., 2019); this has made it difficult to optimize a method which reliably screens several groups of pesticides in a complex tissue.

Moreover, risk assessments of residues in meat are based on the level of residues in uncooked meat, even though a large proportion of consumed meat is either cooked or processed before consumption. In order to thoroughly assess the risks to consumers of pesticide residues, the effects of heat treatment on the residues should be considered (Kiranmayi et al., 2016; Yun-Sang et al., 2016). Studies have shown that heat treatment can cause considerable reduction of pesticide residues in food commodities (Witczak, 2009; Muthukumar et al., 2010). The presence of residues above the permissible levels is a major barrier in the approval of meats, as well as posing domestic public health

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_275288

issue. Therefore, to confirm the safety of meats, the levels of pesticides in meat should be determined professionally before and after heat treatments.

To date, no enough study performed to assess the effect of boiling at 100 °C for 30 min and broiling at 176 °C for 20 min on studied pesticides in meat tissues which are the most commonly used temperature (Goldwyn and Blonder, 2016).

The aim of this study was to optimize GC–MS and to adapt a modified QuEChERS method for detection and quantification of six pesticides belonging to three classes, by optimising experimental conditions in both sample preparation and chromatography using an acceptable validation procedure. With this technique the levels of the six pesticide residues in tissues and effects of boiling (100 °C, 30 min) and broiling (176 °C, 20 min) on the pesticides residual levels were measured.

Material and methods

Sample collection

Meat samples (n = 150) were randomly collected from adult cattle (n = 50), sheep (n = 50), and goat (n = 50) carcasses at the Sulaimaniyah slaughterhouse. Each sample was sliced into three equivalent portions of 50 g (150 × 3). The first portion (n = 150) was straightforwardly prepared for extraction and analysis. The second (n = 150) and third (n = 150) portions were boiled (100 °C, 30 min) and broiled (176 °C, 20 min) respectively. Blank meat samples were acquired from animals free from all pesticides obtained formally from the Brazilian Agricultural Research Cooperation Center. Samples collection and the study performed in Sulaimaniyah city/Kurdistan region of Iraq.

The blank samples were tested to confirm that they were free from the studied pesticides. Then aliquot of samples for selectivity study, the rest portion spiked and used for recovery, matrix matched standards calibration, and sensitivity studies.

Chemical and apparatus

All solvents were of pesticide-residue grade. Pesticides standards of cypermethrin (CMT)(94%), deltamethrin (DMT)(99%), hexachlorobenzene (HCB)(98%), α-hexachlorocyclohexane (α-HCH)(98%), chlorpyrifos (CPS)(96%) and fenitrothion (FTN)(95.5%) were obtained from Dr. Ehrenerstorfer ™ (Augsberg, Germany). Acetonitrile (ACN) (99.5%), acetic acid (99.9%) primary secondary amine (PSA) 40 μm particle size, octadecylsilane (C18, 50 μm), sodium chloride (NaCl), and anhydrous magnesium sulphate ($MgSO_4$) were obtained from Merck Ltd. Syringe filters (0.45 μm), and capillary columns, 30 m DB-5, with an internal diameter of 0.25 mm and thickness of 0.1 μm were purchased from Supelco Analytical Co., UK.

GC–MS system

The pesticides' concentrations were detected by gas chromatography, along with mass spectrometry. This was performed using a QP GC–MS gas chromatograph from Shimadzu (Kyoto, Japan), equipped with a mass-selective detector and capillary column of a 30 m DB-5, with 0.25 mm internal diameter and 0.1 μm film thicknesses. The injector, interface, and ion source temperatures were 250 °C, and splitless injection (1.0 min) was performed using helium as the carrier gas with a flow rate of 0.75 mL/min. The oven temperature was set to increase at a pace of 4 °C /min from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_275288

120 °C to 190 °C. Next, the temperature was increased from 32 °C/min to 270 °C, and held for 4 min. The mass spectrometer was operated with scan mode, put between *m/z* 45 and *m/z* 475 Daltons, which can detect analytes in a solvent to a limit of 1.0 mg/kg. The injection volume was 50 μL with a splitless injection mode.

Heat treatment

Samples were made into small patties of about 1.5 cm thickness. About 150 samples were placed separately into low-density water-impermeable polyethylene bags and cooked in boiling water (100 °C, 30 min) using a water bath (Memmert W200, Germany). Similarly, the other 150 samples were put in a glass bowl and broiled in a preheated air oven (Memmert 93/42 EEC, Germany), at 176 °C for 20 min, being turned over every 5 min. During the experiment, the water bath and oven temperature were monitored with a thermometer and oven thermometer gauge respectively.

Method of validation

Validation method for this study was carried out according to the internationally accepted SANTE/11813/2017 criteria, i.e., selectivity, recovery percentages, precision, linearity, and sensitivity. Method selectivity was tested by injection of 10 independent meat sample extracts into GC–MS. The absence of interfering peaks above a signal-to-noise ratio of 3 at the retention time window of interest was checked for each analyte. The target retention times of the analytes were identified by separately injecting analytical standards (10 mg/L) into the GC–MS apparatus. Multi-standard solutions were injected in to the GC–MS to check maximum retention time tolerance range (±0.2 min), and improve analytical validation. Recovery was determined by comparing the obtained concentrations with the same concentrations of the pesticides prepared in the dissolvent. The inter-day precisions (3 replicates in 3 successive days) were determined by analyzing all spiked levels through the injection of multi-standard solutions, containing six analytes, at concentrations of 0.010, 0.025, 0.050, and 0.100 mg/kg for control matrices. Since a different maximum residue limit (MRL) has been established for each analyte in meat, 0.01 – 0.1 mg/kg of standard solutions were spiked into blank matrices to obtain the highest method reliability during screening. The linearity test in meat was carried out by injecting six matrix-matched standards for calibration studies. Limits of detection (LOD) and quantitation (LOQ) were determined based on a signal-to-noise ratio, and concentrations showing peak intensity of signal-to-noise ratio of 3 and 10 were designated as LOD and LOQ, respectively.

Matrix-matched calibration (MMC)

According to SANTE/11813/2017 criteria, matrix constituents negatively influence the quantitation of target analyses in GC–MS analyses and may increase or decrease the analytical signals. Hence, matrix-matching (standards added to blank extracts) is performed mainly to minimize matrix effects. For the preparation of analytical MMC curves, individual stock solutions of HCB, α-HCH, FTN, CPS, CMT, and DMT were prepared in acetonitrile in Pyrex glass vials at a concentration of 100 mg/L and stored at -20 °C in dark amber bottles. Working standard solutions (WSS) was prepared at a concentration of 50 mg/L by diluting stock solution in acetonitrile. Matrix-matched calibration standards was prepared just before injection by diluting the working solutions and spiked into extracted blank samples to obtain concentrations of 0.010,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_275288

0.025, 0.050, 0.100, 0.200 and 0.500 mg/kg. The MMC curves for each compound were built, and coefficients (r^2) of calibration curves were used to assess linearity.

Preparation of meat samples

The extraction and cleanup procedures performed based on original QuEChERS method (Anastassiades et al., 2003) and (Lehotay et al., 2005) with few modifications. Meat samples were thawed at 4 °C overnight prior to use. Blank meat samples (2 g) were homogenised and fortified with 20 µL of each 10, 5, 2.5 and1 mg/L of multi-standards solution (including the six pesticides) to prepare samples of 0.1, 0.05, 0.025 and 0.01 mg/kg. These were mixed with the matrix for 2 min and left to interact for 30 min. The, blended meat samples were transferred to a 50 mL Falcon tube. Next, 4 mL of ACN (containing 1% acetic acid), 1.6 g of anhydrous $MgSO_4$, and 0.4 g of NaCl were added and the mixture was agitated in a vortex mixer for 1 min. The mixture was centrifuged at 3000 rpm for 3 min to separate the phases (liquid-liquid partition). The supernatant, corresponding to the organic solvent ACN, was transferred to a tube containing 70 mg of C18, 70 mg of the adsorbent PSA and 150 mg of $MgSO_4$. The tube was shaken by hand for half a minute, and centrifuged at 4000 rpm for 1 min. The supernatant was filtered by syringe filter (0.45 µm) to remove the excess of colouring materials. The filtered supernatant was subjected to evaporation under a stream of nitrogen (Hopkinton, LabX, USA) at 45 °C and stored at 4 °C. The solutions were transferred to an autosampler vial and injected into the GC–MS under optimum conditions.

Data processing and statistical analysis

Matrix-matched standards data were subjected to the computer programs of Excel (Analysis ToolPak, Regression) for sensitivity and F test. The obtained real samples data (concentration data for each pesticide and animal species, heat treatment data subjected to the Analysis of Variance (One-way ANOVA, Post Hoc = Duncan, using SPSS software (Version 18.0), multiple ranges used to significantly compare means ($p < 0.05$).

Results and discussion

Development of QuEChERS method

Traditionally, non-polar pesticides have been extracted by liquid-liquid extraction (LLE) and solid-phase extraction (SPE). These extraction procedures are not recommended as they are time-consuming, multi-step procedures and need large amounts of organic solvents (Kang et al., 2011). By contrast, the use of the QuEChERS technique has significantly reduced the demerits of traditional extraction procedures because of its small scale LLE and d-SPE (Lehotay et al., 2005). Hence, in the present study, the original QuEChERS method was considered, which was proposed by Anastassiades et al. (2003) and Lehotay et al. (2005). In the first step of the test, the method of (Anastassiades et al., 2003) was applied, in which 10 g of the meat sample and 10 mL of ACN, 4 g of $MgSO_4$, and 1 g of NaCl were used for liquid-liquid partitioning (LLP). For the second step (d- SPE), the method of Lehotay et al. (2005) was used, in which 50 mg of C18, 50 mg of PSA and 150 mg of $MgSO_4$ were added to the mixture. The method of Anastassiades et al. (2003) was used in the first step of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_275288

procedure because this method does not require buffers for the extraction of analytes. For the second step, the method of Lehotay et al. (2005) was used, because it provides better cleanup due to the use of a larger mass of PSA and the addition of C18. Unexpectedly, the obtained recovery values varied from 60 to 74%, with high RSD values (>20%). Hence, additional tests were carried out. In the second test, the QuEChERS method was modified. Meat samples (2 g), 4 mL of ACN, 1.6 g of $MgSO_4$, and 0.4 g of NaCl were used, as well as for the d-SPE, 70 mg of PSA, 70 mg of C18, and 150 mg of $MgSO_4$. The obtained recovery and RSD rates were satisfactory according to SANTE/11813/2017 (*Table 1*). Many parameters can influence the extraction efficiency, including the type of solvent, polarity, and cleanup sorbents including C18 and PSA (Okihashi et al., 2007). Hence, the second test, the ratio of ACN to sample weight was changed from1:1 to 1:2, and PSA and C18 were increased to 70 mg, and the quantity of $MgSO_4$ held constant with additional one filtration step.

The extraction of pesticide residues depends on the polarity of pesticides and type of matrix contained pesticides (Peng et al., 2016). In this test, ACN was selected for extraction of pesticides because of its effectiveness in the extraction of polar and non-polar pesticides from the diverse range of matrices. The cleanup step also improved by increasing PSA and C18 from 50 to to70 mg. The PSA could effectively eliminate polar matrix components, such as organic acids, certain polar pigments, and sugars. The C18 also thoroughly removed fatty acids, which are considered the main co-extract of the non-polar pesticides in meat, among other components (Paramasivam et al., 2011). $MgSO_4$ could also bind with organic acids, polar material and/or glucosides. The salt combination (NaCl, $MgSO_4$) produced heat and forced the majority of co-extracts into the acetonitrile layer. The filtration step finally could totally remove the coloring materials in the solution, prompted cleanup and prepared the solution for injection.

In this study, cleaning up step was mostly considered to optimise and adapt the QuEChERS technique; firstly, to obtain acceptable recovery and, RSD, and to maximize extraction efficiency, and peak resolution; secondly, insufficient cleaning up of samples from the co-extractives in the extract causes deterioration of the GC system and precludes reliable results (Peng et al., 2016). Optimization of the chromatographic conditions was carried out to obtain a good compromise between low chromatographic times and suitable peak resolutions. Under the optimized chromatographic conditions, a satisfying separation was achieved with symmetrical and narrow peaks in the retention times between 2.93 and 9.75 min (*Fig. 1A*).

The extraction efficiency of the proposed method was assessed by spiking meat samples with multi pesticides at four concentrations level (0.01, 0.025, 0.050 and 0.1 mg/kg). Good methodology efficiency was obtained in all concentrations regarding recovery percentages. To assess the possible existence of matrix effects, meat samples were extracted and spiked, and then they were compared with analytical standards at same concentrations. The calculations were performed using the peak areas and concluded that there were no significant differences between signal responses (ANOVA, $p > 0.05$).

Precision and recovery

Recovery percentages were evaluated by comparing the concentrations of spiked samples, with the nominal fortification level. The recovery of each analyte was verified by calculating their average and put in compliance with the recovery range reported in SANTE/11813/2017.

DOI: http://dx.doi.org/10.15666/aeer/1801_275288

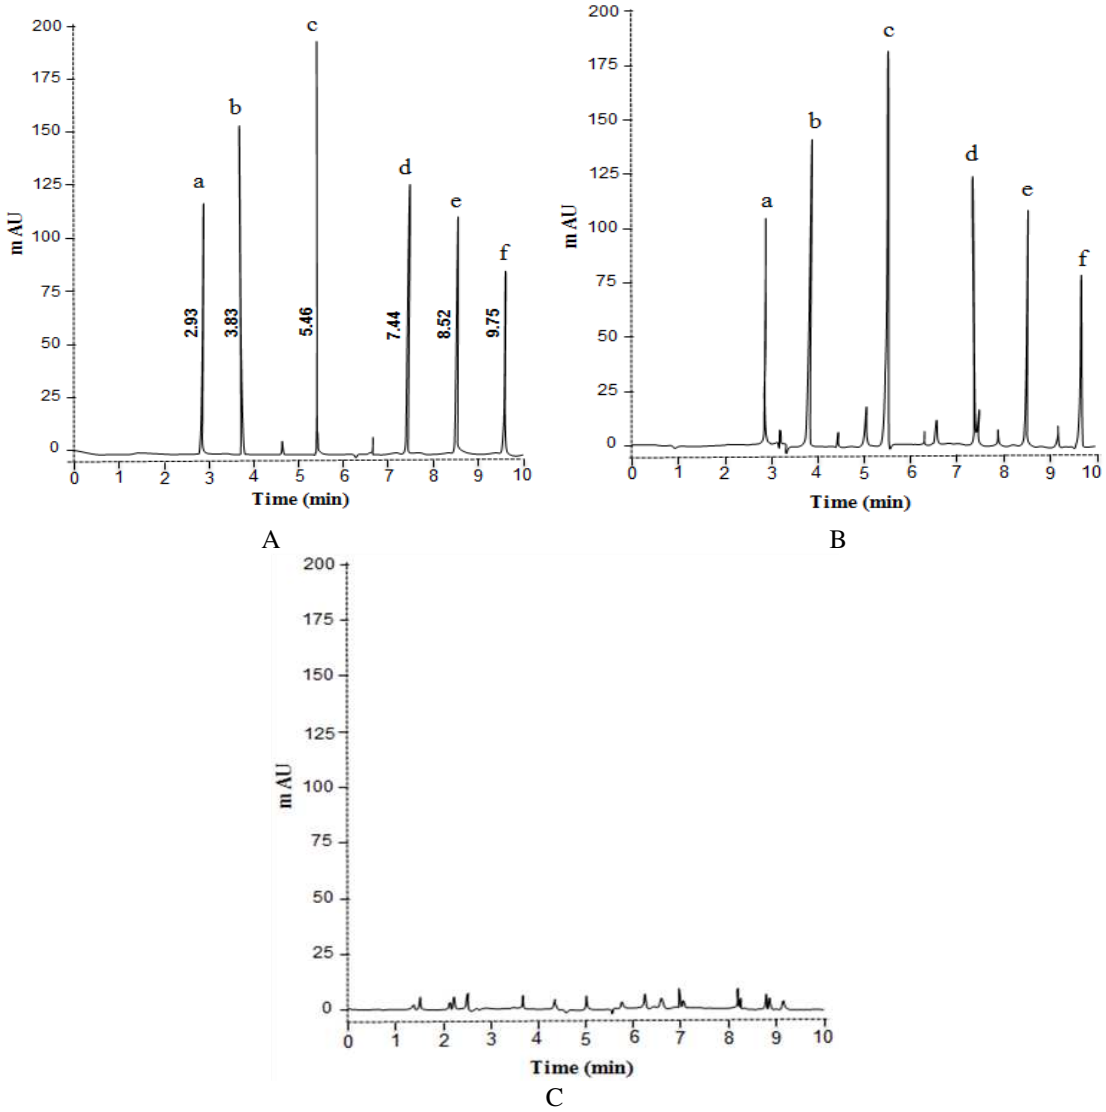

Figure 1. *GC chromatograms of QuEChERS method. A: A multi-standard solutions (10 mg/L). B: Spiked blank samples after extraction (0.1 mg/kg). C: Blank meat samples. a. Hexachlorobenzene; b. Hexachlorocyclohexane; c, Fenitrothion; d. Chlorpyrifos; e. Cypermethrin; f. Deltamethrin*

The recovery values and RSDs were obtained using meat samples spiked with four different concentrations (0.01, 0.025, 0.05 and 0.1 mg/kg). Acceptable recoveries (79.2 to 104.3%) were obtained for all spiked levels, demonstrating that the matrix of meat samples was not affected by the extraction of the analytes (*Table 1*). The precision of the method was determined in two stages: repeatability (intra-day) and intermediate precision (inter-day). The intermediate precision was expressed by the RSD of the results of nine analyses performed on three different days (n = 3), three analyses/day, by the same instrument. The obtained RSD in this work was 0.32-14.6% for different spiked concentrations, which meets the recommendation of the SANTE/11813/2017 guidelines (RSD ≤ 20%) (*Table 1*). These results demonstrate that the method possesses good accuracy and can be considered to be a useful tool for the screening of the six analytes in meat. Some of the tested compounds showed lower recovery than others.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_275288

This might be due to some kind of interaction which could not be corrected with matrix matching, or the samples might have been decomposed in the processes of extraction, cleanup, or evaporation (Okihashi et al., 2007). High RDS in some analytes might be due to a high level of co-extracts that interfered in the GC system. By contrast, some showed low RDS, which could be due to ion speculation (Okihashi et al., 2007). The main analytical problem in chromatographic analysis has been reported to be the complexity of the matrix together with interfering co-extractive substances. These factors may deteriorate the chromatographic column (Frenich et al., 2006). Therefore, the analysis of three groups of pesticides in meat samples is recommended that samples should be cleaned up thoroughly prior extraction process.

Table 1. *Recovery and relative standard deviations (RSD %) in different spiked concentrations (n = 3)*

Spiked matrix	**Recovery ± RDS (%)**					
Conc. (mg/kg)	CMT	DMT	HCB	α-HCH	CPS	FTN
0.01	79.2 ± 7.4	85.8 ± 1.7	85.8 ± 13.09	82.7 ± 3.8	88.3 ± 13.3	97.6 ± 6.3
0.025	82.7 ± 7	88.9 ± 1.8	86.1 ± 10.2	104.3 ± 4.6	91.4 ± 8.6	96.28 ± 3.1
0.05	86.8 ± 4.1	93.5 ± 1.3	88.6 ± 14.6	98.7 ± 5.1	92.1 ± 9	96.3 ± 4.8

Linearity and limits of detection and quantification

While, linearity can be tested using standard working solutions, in this study the spiked blank sample after extraction was used to correct matrix effects. The linearity was evaluated by constructing regression graphs at concentrations of 0.010, 0.025, 0.050, 0.100, 0.200 and 0.500 mg/kg. The acceptability of the regression model was also confirmed by using all the calibration datasets (six calibration points with three replicates at each calibration point). The regression was statistically analysed by the determination coefficients (r^2), and the homoscedasticity assumption was evaluated by plotting residue versus concentration. The coefficients (r^2) were ≥ 0.9997, and the residual plot showed that the errors were randomly distributed around the concentration axis. The *F*-test, performed according to the recommendation of the Analytical Methods Committee criteria reported by Johnson et al. (2010), and validated the linearity of a model for significance level of 0.05(Analysis ToolPak, Regression). According to Kaonga et al. (2015), the response of the detector to any analysed pesticide by GC was found to be dependent on the studied matrix properties Therefore; the achieved slope (r^2) values for the analytes were close to each other due to the similarity in the composition of the matrices.

Test sensitivity or matrix effects and fluctuation in baseline noise have a strong impact on LOD and LOQ values. For this reason, their validation under these conditions is mandatory. In this work, the LOD and LOQ values ranged from 0.004 to 0.014 and 0.012 to 0.043 mg/kg respectively (*Table 2*). The LOD and LOQ for all the studied compounds were lower than the maximum residue limits (MRLs) established by EU 396/2005 and EU No 149/2008. This suggests that the method can detect the studied pesticides at an adequately low level, which confirms its validity. The method described

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_275288

here provides higher sensitivity than methods used by other researchers for quantifying pesticides in meat such as, GC–MS (Meligy et al., 2019), GC–MS-MS (Meligy et al., 2019), and GC–ECD (Dimitrova et al., 2018). This aspect is the key-factor for evaluating analytical methods, because the lower the LOD values, the lower the probability of false negative results (Stefanelli et al., 2009).

Table 2. *Linearity range, regression equation, coefficients, limits of detection and limit of quantification*

Pesticides	Linearity range	Regression equation	r^2	LOD (mg/kg)	LOQ (mg/kg)
CMT	0.01-0.5	y = 1102 x + 2010.9	0.9998	0.014	0.043
DMT	0.01-0.5	y = 820.48x + 835.28	0.9999	0.009	0.027
HCB	0.01-0.5	y = 1120.2x + 1060.5	0.9999	0.006	0.019
α-HCH	0.01-0.5	y = 1442.3x + 846.02	0.9999	0.006	0.020
CPS	0.01-0.5	y = 1195.5x + 502.26	0.9997	0.014	0.043
FTN	0.01-0.5	y = 1900.6x + 679.8	0.9999	0.004	0.012

r^2: coefficient, LOD: limit of detection, LOQ: limit of quantification

Real samples analysis

In this work, the level of DMT in sheep samples was the highest (0.210 ± 0.010 mg/kg), followed by HCB in cattle samples (0.204 ± 0.008 mg/kg). The concentration of FTN presented the lowest residual in all the meat samples from cattle (0.040 ± 0.002 mg/kg), sheep (0.059 ± 0.003 mg/kg) and goats (0.019 ± 0.002 mg/kg) (*Table 3*).

The level of DMT and CMT detected in sheep and goat meat were high and exceeded than the acceptable limits of DMT (0.03 mg/kg) and CMT (0.05 mg/kg) set by EU R No.396/2005. These results agreed with other studies that also detected a high level of DMT from sheep and goats' meat near Sulaimaniyah (Abdulrahman, 2016) and with another study (Khashan, 2016) that found high DMT levels in cattle meat in Baghdad. High levels of HCB and α-HCH were also detected in cattle samples which exceed than the acceptable limits of HCB and α-HCH (0.02 mg/kg) set by EU R No.149/2008. The same result found in another research (Kiranmayi et al., 2016), which showed that the result is due to extreme use of these pesticides in agriculture.

The higher incidence of DMT, CMT, HCB and α-HCH might be due to the extensive use of these pesticides in livestock and agriculture due to their wide spectrum of biological activity and high stability in the environment (MacBean, 2015). These pesticides are mostly used in Kurdistan and northern Iraq because they are legally allowed to use DMT and CMT to control ticks, flies, fleas, lice, and mites in animal, and to treat seasonal crops with HCB and α-HCH for controlling fungal disease and mosquito and as an antifouling agent. The reason of finding high level of PYRs, OCs pesticide residues could be due to their rapid effects and low cost compared to OPs pesticides.

The OPs pesticides detected in meat samples in this study are CPS and FTN, which presented lower concentration residues than PYRs and OCPs in cattle, sheep and goat samples. The concentration of CPS residues found in cattle (0.124 mg/kg), sheep (0.110 mg/kg), and goat (0.071 mg/kg) samples were higher than acceptable limits (0.05 mg/kg) set by EU R No 396/2005. Moreover, the FTN residues in cattle (0.04 mg/kg) and goat (0.019) samples were less than the acceptable limit (0.05 mg/kg)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_275288

set by EU R No 396/2005 except sheep samples (0.059 mg/kg) which were almost about over the acceptable level. Low CPS levels also fund by Muhammad et al. (2010) and FTN have been found in buffalo and cattle grazing outdoor (Park et al., 2006). The low incidence of CPS and FTN could be due to low stability of the compounds in the environment and lower use by farmers due to their costs.

Statistically, there was a significant difference between animal species in terms of residual levels among all pesticides (ANOVA, $p < 0.05$) except α-HCH and CPS between cattle and sheep samples. In cattle samples, there was no significant difference between the CMT and DMT (ANOVA, $p > 0.05$), the rest pesticides residual levels were different statistically (ANOVA, $p < 0.05$). In sheep samples significant difference was noticed between all pesticides residual levels (ANOVA, $p < 0.05$) except CMT and CPS. While, in goat samples no difference was presented between DMT, HCB and α-HCH (ANOVA, $p > 0.05$), and no difference was also noticed between CMT and CPS.

Table 3. *Mean residual levels of the studied pesticides in meat tissues*

Pesticides	Fresh (cattle) samples (mg/kg ± RSE)	Fresh (sheep) samples (mg/kg ± RSE)	Fresh (goats) samples (mg/kg ± RSE)
CMT	$0.060^{Ab} \pm 0.004$	$0.102^{Cb} \pm 0.004$	$0.076^{Bb} \pm 0.003$
DMT	$0.057^{Ab} \pm 0.005$	$0.210^{Ce} \pm 0.010$	$0.100^{Bc} \pm 0.005$
HCB	$0.204^{Ce} \pm 0.008$	$0.131^{Bc} \pm 0.005$	$0.091^{Ac} \pm 0.004$
α-HCH	$0.152^{Bd} \pm 0.009$	$0.151^{Bd} \pm 0.006$	$0.090^{Ac} \pm 0.005$
CPS	$0.124^{Bc} \pm 0.007$	$0.110^{Bb} \pm 0.004$	$0.071^{Ab} \pm 0.005$
FTN	$0.040^{Ba} \pm 0.002$	$0.059^{Ca} \pm 0.003$	$0.019^{Aa} \pm 0.002$

Heat treatment

As shown in *Table 4,* boiling at 100 °C for 30 min reduced the concentrations of the pesticides significantly (ANOVA, $p < 0.05$) in cattle, sheep, and goat muscle tissues. On the other hand, the reduction in concentration of the studied pesticides after broiling at 176 °C for 20 min was questionable. The significant reduction of the six pesticides during boiling could be attributed to the volatility of these compounds and the elimination of these compounds due to fat rendering induced by exposure to high temperature for a long time, which does not happen in open heating treatments (Khan and Rahman, 2017).

In the boiling and broiling process, the most reduced pesticide group in cattle, sheep and goat samples was the PYRs including CMT and DMT (*Table 4*). Followed by OCs (HCB and α-HCH), and the least reduction of pesticides were OP pesticides including CPS and FTN (*Table 4*).

The dissipation percentages in both methods were higher for PYR and OC pesticides, when compared to OPs pesticides (*Table 4*). This might be due to the chemical and physical properties of these pesticides and variation in susceptibility to heat among the different chemical compounds in pesticides affected by boiling and broiling (Muthukumar et al., 2010). The reduction in level was almost similar between PYRs and OCs, whereas the reduction of OPs differed noticeably. However, there is no strong

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_275288

correlation between the physiochemical properties of PYRs and OCs. Since various parameters involving molecular weight, volatility (vapour pressure), hydrolysis rate, and water solubility affect the reduction rate, no conclusive statement can be made about the degree to each parameter to the loss of pesticides during boiling or broiling.

However, boiling at high temperatures is more advisable; it dissolves and washes away water-soluble vitamins and 60 to 70% of minerals (Yun-Sang et al., 2016). Although, effects of broiling process were less than boiling, it is still preferred to obtain the maximum nutritional values without sacrificing flavor by consumers. Hence, it is recommended that consumers might consume heat treated meat by boiling to avoid pesticide health issues, which could be better than tasty broiled meat contained higher pesticides residues.

Table 4. *Effects of cooking methods on the concentration of pesticides (mg/kg ± RSE)*

Pesticides	Species	Raw meat	Boiling at 100 °C for 30 min	Broiling at 176 °C for 20 min
CMT	Cattle	$0.060^{Bb} \pm 0.004$	$0.038^{Aa} \pm 0.003$	$0.051^{Bb} \pm 0.003$
	Sheep	$0.102^{Cb} \pm 0.004$	$0.059^{Ab} \pm 0.002$	$0.086^{Bb} \pm 0.003$
	Goat	$0.076^{Cb} \pm 0.003$	$0.048^{Ab} \pm 0.003$	$0.065^{Bb} \pm 0.002$
DMT	Cattle	$0.057^{Bb} \pm 0.005$	$0.036^{Aa} \pm 0.003$	$0.048^{Bb} \pm 0.004$
	Sheep	$0.210^{Ce} \pm 0.011$	$0.134^{Ac} \pm 0.007$	$0.172^{Be} \pm 0.009$
	Goat	$0.100^{Cc} \pm 0.005$	$0.065^{Ad} \pm 0.004$	$0.086^{Bc} \pm 0.005$
HCB	Cattle	$0.204^{Ce} \pm 0.008$	$0.139^{Ad} \pm 0.005$	$0.177^{Be} \pm 0.007$
	Sheep	$0.131^{Cc} \pm 0.005$	$0.088^{Ax} \pm 0.003$	$0.114^{Bc} \pm 0.004$
	Goat	$0.091^{Cc} \pm 0.004$	$0.057^{Ac} \pm 0.002$	$0.082^{Bc} \pm 0.003$

	Sheep	$0.059^{Ba} \pm 0.003$	$0.044^{Aa} \pm 0.002$	$0.054^{Ba} \pm 0.003$
	Goat	$0.019^{av} \pm 0.002$	$0.015^{av} \pm 0.002$	$0.017^{av} \pm 0.001$

[A, B, C]Different superscript letters denote significant differences within a row ($p \leq 0.05$)

[a, b, c, d, e]Different superscript letters denote significant differences within each species, between each pesticide ($p < 0.05$)

Conclusion

The goal of this study to develop a simple, accurate, and inexpensive method for the extraction and analysis of six pesticides from three different groups has been achieved. The method developed here can detect of pesticides residues in meat above the level of 0.01 mg/kg. The optimization of chromatographic conditions in this work involved the use of few organic solvents, suitable sample preparation, proper clean up and ensuring good extraction efficiency and response sensitivity. Hence, GC–MS adapted to solid phase extraction, and QuEChERS preparation were successfully employed for the quantification of pesticides residues in animal tissues. All six commonly used pesticides

DOI: http://dx.doi.org/10.15666/aeer/1801_275288

were found in cattle, sheep and goat samples, and only FTN in cattle and goat samples was lower than MRLs. The process of boiling at 100 °C for 30 min destroyed pesticides significantly, but it cannot reduce the concentration to safe level or below the MRLs, if the residuals begin at high level. Therefore, it is suggested that farmers should use pesticides in recommended amount and butchers should also avoid slaughtering animals directly after treatment with insecticides. Finally, consumers might consume boiled meat and meat products instead of broiled.

Further research could be applied on a wide range of PYRs, OCs and OPs pesticides to strongly find the effects of heat treatment on pesticides regarding their properties such as molecular weight, volatility (vapor pressure), hydrolysis rate and solubility behavior. The use of modified QuEChERS method in this study, for extraction of destroyed pesticides and byproducts after heating and detection by GC could be another part of the next research.

Acknowledgments. The authors would like to thank Food Hygiene laboratory at the College of Veterinary Medicine/University of Sulaimani, for the opportunity to use their specific equipment.

(Received 7th Aug 2019; accepted 28th Nov 2019)

Abstract. The aim of this study was to investigate changes of phenolic accumulation and antioxidant potential of goldenberry fruits collected from diploid plants, under colchicine treatments of different doses and exposure time, including colchicine induced synthetic tetraploid plants. Three colchicine application methods were utilized; i) immersion of seeds in colchicine solution at concentrations of 0.0, 0.6, 0.9% for 24 h and 36 h; ii) keeping germinated seeds (with 2-3 mm long roots) in a colchicine solution with concentrations of 0.6% and 0.9% for 24 h iii) incubation of seeds on semi solid nutrient medium containing 0.6% and 0.9% colchicine for 14 and 21 days. Total antioxidant activity of fruits varied according to the dose and exposure time of colchicine applications. The most important change was observed in the fruits of plants that turned tetraploid as a result of colchicine applications. Tetraploid fruits generally produced higher amounts of secondary compounds compared to diploid progenitors and their antioxidant capacity was also higher. However, the results show that polyploidization is important but cannot be generalized as a strategy to increase secondary metabolite production. It was determined that the relationship between total anthocyanin and total phenolic content with antioxidant capacity of fruits was significant and parallel. We suggest the use of the lowest colchicine concentration tested. 0.6% colchicine to enhance metabolite production cannot be generalized.
Keywords: *tetraploid, anthocyanin, phenolic, flavonoid, antioxidant*

Introduction

Goldenberry (*Physalis peruviana* L.) is a small fruit, belonging to the Solanaceae family. Recently it has gained much attention in our country and in the world, because of its nutritional, medicinal and industrial properties. Goldenberry is most important fruits that is recommended to be consumed as functional drinks and fruit due to high rates of water and oil soluble bioactive substances, vitamins and minerals (Ramadan Hassanien, 2011). Valdenegro et al. (2012) reported that goldenberry is a fruit rich in vitamin C, carotenoids and phenolic compounds. In phytochemical studies, flavonoids, saponins and phenols which are the main compounds in goldenberry fruit extracts, were also determined (Arun and Asha, 2006). It has been reported that goldenberry has a high antioxidant capacity and synergistic effects of different antioxidants. In addition, high levels of phenolic compounds in fruit have been reported (Ramadan and Mörsel, 2003; Ramadan Hassanien, 2011). Phenolic compounds are important in terms of human health as well as their contribution to color, taste and aroma of fruits (Valdenegro, et al., 2012). It is desirable some chemicals in plants to have protective, preventive and therapeutic effects from various diseases in humans.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_289302

Recently interest of researchers, in nutrient richness of fruits, vegetables and contain high levels of bioactive compounds that act as antioxidants, have been increasing. Plant breeders are trying to develop polyploid plants in order to increase the yield and certain useful fruit quality properties of the fruit. Polyploids have superior agronomic properties compared to diploids. An increase in the number of chromosomes could improve basic secondary metabolites and concentrations of preservatives (Gao et al., 1996; Głowacka et al., 2010; Hannweg et al., 2016; Nori et al., 2017). It has been reported that enzyme activity (Dhawan and Lavania, 1996; Lavania, 2005), secondary metabolites that are important for taste and flavor and biochemical profiles (Gao et al., 1996; Predieri, 2001; Urwin et al., 2007; Zhang et al., 2010; Carusoa et al., 2011; te Beest et al., 2012) in plants improved by polyploidy.

Numerous factors (abiotic and biotic) are directly effective on the biochemical pathways in plants and affect the metabolism of secondary metabolite products (Alkhsabah et al., 2018). Aina et al. (2019) stated that the levels of bioactive compounds and antioxidant activities of tomato fruits cultivated on different soil amendments showed strong relationship between the level of macronutrients in the soil and the level phenolics, flavonoids, beta-carotene and lycopene contents in tomato. Shafiq et al. (2019) reported that selenium content in garlic increased by sodium selenate application. A significant increase in total phenolic content, total flavonoid content and total antioxidant capacity was also observed in the garlic. It has been noted that gibberellic acid had a negative effect on the content of extract, flavonoids and ascorbic acid, while it had no effect on the anthocyanin level. The antioxidant activity determined by the DPPH assay depended on dose and the number of treatments was shown to decrease significantly with increasing application number. Gibberellic acid application had a significantly increased DPPH level compared to the control. The GA3 treatments were shown to have a significant influence on phenolic acid content (Kaplan et al., 2019).

In order to improve the quality of important medicinal compounds, the plants' natural secondary metabolite production potentials, aromatics can be artificially promoted and increased by experimental arrangements. These crops can hold a market value as functional food. The enhance nutrients in food crops is powerful strategy to overcome micronutrient deficiency.

The main purpose of this study were to determine the changes of total anthocyanin, phenolic, flavonoid contents, free radical scavenging capacity and total antioxidant activity of goldenberry fruits by colchicines ($C_{22}H_{25}NO_6$) application to the plants.

Materials and methods

This study was conducted in the University of Eskisehir Osmangazi (Eskisehir, TURKEY) laboratories and greenhous. *Physalis peruviana* cv. Golden Berry (average fruit diameter is 1-2 inch. Pulp is very flavorful and sweet) was used as plant material in this study**.** The treated seeds were sown into peat containing plastic seedling tray in the 1st week of March. 45 days old (at 4-5 true leaf stage) seedlings (*Fig. 1*) were transplanted to peat containing pots (15 L) at the end of May in plastic greenhouse.

All plants were irrigated with drip irrigation system (*Fig. 2*) and fertilized with 13 g of 15: 8: 25: 3.5 nitrogen: phosphorus: potassium: magnesium oxide per plant. During the growing season, the average temperature of greenhouse varied between 14-18 °C at night and 22-30 °C at daytime.

Figure 1. *Seedling at planting stage*

Figure 2. *Plants grown in pots and irrigated by drip irrigation system*

Colchicine at different doses and exposure times were applied to goldenberry seeds by different methods. Diploid plants that were not treated were evaluated as control. As a result of the applications, chromosomes of some plants were doubled (tetraploid; chromosomes were determined by flowcytometry, Comlekcioglu and Ozden, 2019). Fruits of plants in different application groups were used as material in this study.

Colchicine applications; i) keeping the seeds in colchicine solution (*Fig. 3A*) at 0.0 (T11), 0.6, 0.9% concentration for 24 h and 36 h (T1, T2, T3 and T4); ii) keeping germinated seeds (*Fig. 3B*) with 2-3 mm long roots in colchicine solution at 0.6% (T9) and 0.9% (T10) concentrations for 24 h; and iii) incubation of seeds on semi solid Murashige and Skoog (MS, 1962) medium (*Fig. 3C*) supplemented with colchicine at 0.6% and 0.9% concentrations for 14 and 21 days (T5, T6, T7 and T8).

Twenty seeds for each treatment, with three replications were used. Untreated diploid plants grown from untreated seeds were used as control. Ten plants (*Fig. 4*) with tree replication had been examined within a treatment for the evaluation of phenolic accumulation and antioxidant potential of fruits.

Fruits of plants in different application groups were harvested at full maturity (*Fig. 5*) and fruit weights were determined.

The doses and duration of colchicine applications and application methods are presented in *Table 1*.

T9	0.6	24 h	Germinated seed
T10	0.9	24 h	Germinated seed
T11	Control - Diploid control plants		
T12	Tetraploid plants - Colchicine induced		

Extraction of fruit samples

For extraction of the samples, the fruits were mashed in a cold blender. The 25 g homogenate was macerated in darkness for 24 h in 100 ml of ethanol containing 0.1% HCl. The extracts were then filtered through Whatman No.1 filter paper under vacuum and extraction was continued with the same solvent until the pulp was colorless. 50 ml of the extract was separated and used to determine the total amount of anthocyanin. The other 50 ml of the extraction was concentrated on a rotary evaporator by evaporating ethanol at 50 °C and used to determine total phenolic compounds and total flavonoids.

Determination of total anthocyanins (TA)

TA contents of the extracts were determined by pH-differential method (Giusti and Wrolstad, 2001). According to this method, fruit extracts were incubated in 0.025 M KCl buffer (pH 1.0) and 0.4 M CH_3COONa buffer (pH 4.5) for 15 min at room temperature. Absorbance was measured at 520 and 700 nm and the absorbance values were found by *Equation 1:*

$$A = (A\lambda 520 - A\ \lambda 700)\ pH\ 1.0 - (A\lambda 520 - A\ \lambda 700)\ pH\ 4.5 \qquad \text{(Eq.1)}$$

According to Wrolstad (1976), the total amount of anthocyanin was calculated as follows:

$$TA\ (mg\ kg^{-1}) = A \times MA \times DF \times 1000 / \varepsilon \times 1$$

A: absorbance, MA: Molecular weight of Malvidin-3-O-glucoside; 493.5 g mol l^{-1}, DF: Dilution factor, ε, molar absorption coefficient (28,000).

Determination of total phenolic compounds (TP)

TP contents of goldenberry fruit extracts were determined by modification of Slinkard and Singleton (1977) method. 2.37 ml H_2O and 0.15 ml Folin-Ciocalteu's reagent were added to fruit extract (0.03 ml) respectively. After about 8 min, Na_2CO_3

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_289302

(0.45 ml) was added and the contents were mixed thoroughly. After the mixtures were allowed to stand at room temperature for 30 min, the absorbance measured at 750 nm with spectrophotometer. The concentrations of the total phenolic compounds in the fruit extracts were expressed as mg of gallic acid equivalent (GAE) per kg of fresh weight (FW).

Determination of total flavonoids (TF)

Total flavonids contents of the samples were determined by aluminum chloride colorimetric method applied by Zhishen et al. (1999). 4 ml H_2O, 5 ml 0.3% $NaNO_2$ were added to 1 ml of fruit extract or standard catechin solution (20, 40, 60, 80, 100 mg l^{-1}). After 5 min, 0.3 ml of 10% $AlCl_3$ was added to the mixture. Then at 6 min, 2 ml of 1 M NaOH was added to the mixture and the total volume was completed to 10 ml with H_2O. The solution was mixed thoroughly. The absorbance measured at 510 nm with spectrophotometer. Total flavonide contents of the samples were given in µg catechin equivalent (CE) per g of FW.

Determination of total antioxidant activity (AA)

Antioxidant capacities of ethanolic extracts were determined by the 1,1-diphenyl-2-picrylhydrazyl (DPPH) free radical scavenging, Ferric Reducing Antioxidant Power (FRAP), and Phosphomolybdenum (Mo) methods.

The free radical scavenging capacity of the samples were measured by the 1,1-diphenyl-2-picrylhydrazyl (DPPH) method according to Blois (1958). 2.9 ml of DPPH (0.1 mM) was added to fruit extracts of various concentrations obtained by dilution with ethanol. After 15 min, the absorbance of the mixture was measured at 517 nm. The capacity of each application to reduce free radicals of the sample is determined in% by *Equation 2:*

$$\text{DPPH Inhibition (\%)} = [(Ac - As) / Ac \times 100] \quad \text{(Eq.2)}$$

Ac; control absorbance, As; absorbance of samples.

The determination of total antioxidant capacities of the samples was done by Phosphomolybdenum (MO) and Ferric Reducing Antioxidant Power (FRAP) methods. As described by Prieto et al. (1999) 0.3 ml (20 µg/ml) sample extract was mixed with 1 ml reagent solution (0.6 M sulfuric acid, 28 mM sodium phosphate, 4 mM ammonium molybdate) and incubated for 90 min at 95 °C. After the samples were quickly cooled in crushed ice to room temperature the absorbance at 695 nm was measured. The obtained values were expressed as µg ascorbic acid equivalent (AE) per ml extract by using the ascorbic acid standard curve prepared at different concentrations (20-250 mg ml^{-1}) of ascorbic acid used as positive control.

Ferric Reducing Antioxidant Power (FRAP) were determined according to Oyaizu (1986). 1 ml ethanolic fruit extracts (20 µg ml-1), 2.5 ml phosphate buffer solution (0.2 M pH: 6.6) and 2.5 ml 1% potassium ferricyanate ($[K_3Fe (CN)]_6$) solution were mixed. The mixture was incubated for 20 min at 50 °C and then cooled rapidly in crushed ice. Then, 2.5 ml of 10% trichloroacetic acid (TCA) was added to the mixtures and centrifuged at 2000 rpm for 15 min. The upper layer of the supernatant (2.5 ml) was diluted with distilled water and 0.5 ml of 0.1% $FeCl_3$ was added. Then the absorbance was read spectrophotometrically at 700 nm against water blank. Using the calibration curve of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_289302

Butylhydroxytolune (BHT) (20-250 mg/ml) at different concentrations used as positive control, the antioxidant activity of the samples was expressed as μg BHT per ml extract.

In the study, all analyzes were measured with three replications. The data presented here are the mean of three replications with ± SEM. The significance of the mean differences was determined by the least significant differences (LSD) test using the general linear model (GLM) at $P< 0.05$.

Results and discussion

The main objective of this study was to determine the effects of different doses and exposure times colchicine applications, resulted with or without chromosome doubling, on secondary metabolite profiles in goldenberry fruits.

The fruits of plants from different colchicine treatment groups were harvested at commercial maturity stage and 100 fruit weights were determined (*Fig. 6*).

In the study, 100 of the control group fruits were weighed as 356.58 g, followed by the fruits of T6 application group (367.65 g). The heaviest fruits were obtained from tetraploid plants in the T12 treatment group (411.25 g), while the fruit from all other colchicine treatment groups remained low in weight relative to the control (*Fig. 6*).

Total anthocyanin (TA), total phenolic compounds (TP) and total flavonoid content (TF) of the fruits of the plants treated with different colchicine showed significant differences.

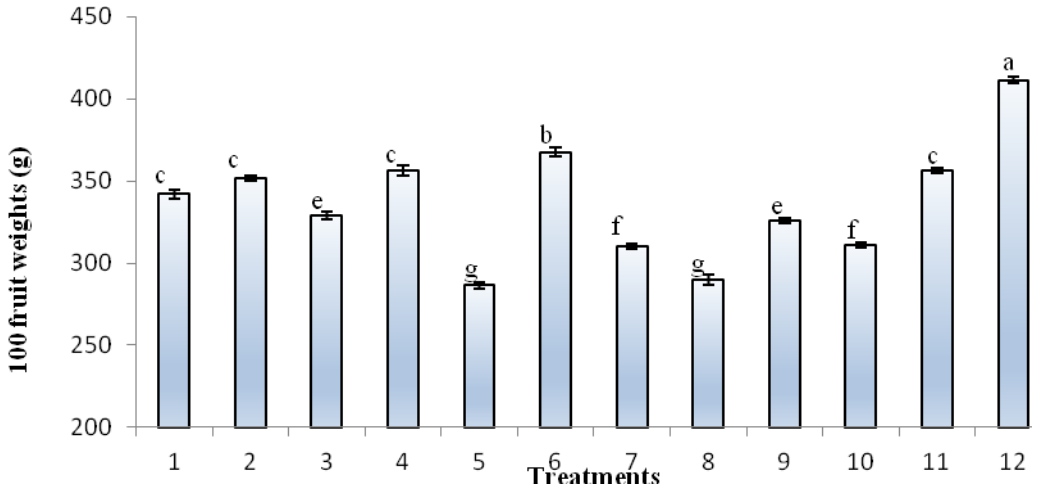

Figure 6. *Average weights of 100 fruit measured from different colchicine treatment groups. Different letters on the columns are expressed statistical difference at $P \leq 0.05$ determined by the LSD test*

TA content of ethanolic extracts of the goldenberry fruit is given in *Figure 7*. According to the analysis results, the highest (559.60 mg malvidin-3-glucoside kg^{-1} FW) was measured in tetraploid plant fruits, followed by the amount of anthocyanin (539.32 mg kg^{-1}) in T9 fruits. The anthocyanin contents of the tetraploid samples were found to be significantly higher than the control group. Except for the T9 application, the effect of all applications on the anthocyanin contents of the fruits was measured less than the control. TA value of tetraploid fruits increased by 9.1% compared to diploid.

DOI: http://dx.doi.org/10.15666/aeer/1801_289302

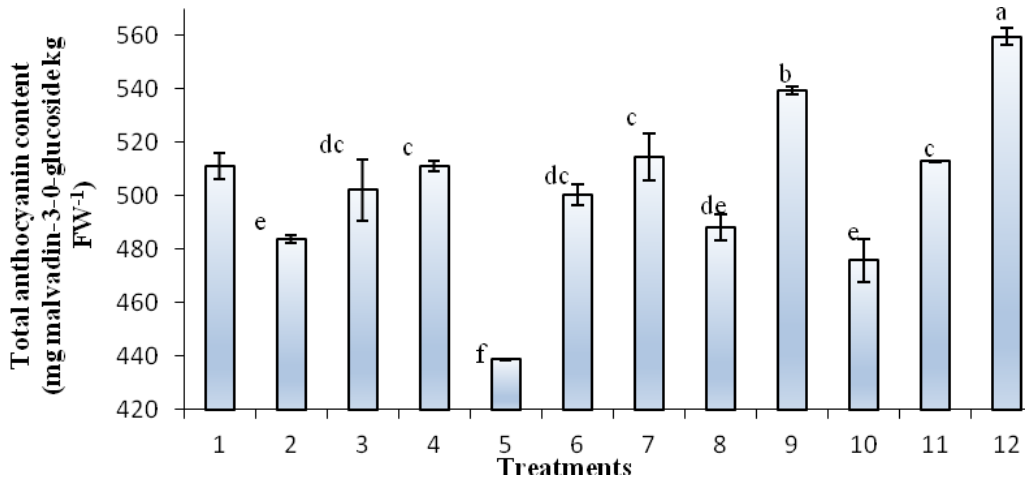

Figure 7. *Total anthocyanin content (mg malvidin-3-0-glucoside kg^{-1} FW) of goldenberry fruits from different colchicine treatment groups. Different letters on the columns are expressed statistical difference at P ≤ 0.05 determined by the LSD test*

TP contents of fruit extracts were expressed as mg GAE kg fresh weight using the gallic acid standard curve (*Fig. 8*). According to the results of the analysis carried out in the goldenberry fruits under the effect of different colchicine applications, the highest TP content was measured in the fruits of tetraploid plants (1128 mg GAE kg^{-1} FW). The tetraploid fruits were follow by T1 (1079.0 mg GAE kg^{-1} FW) T11 and T9 applications (*Fig. 8*).

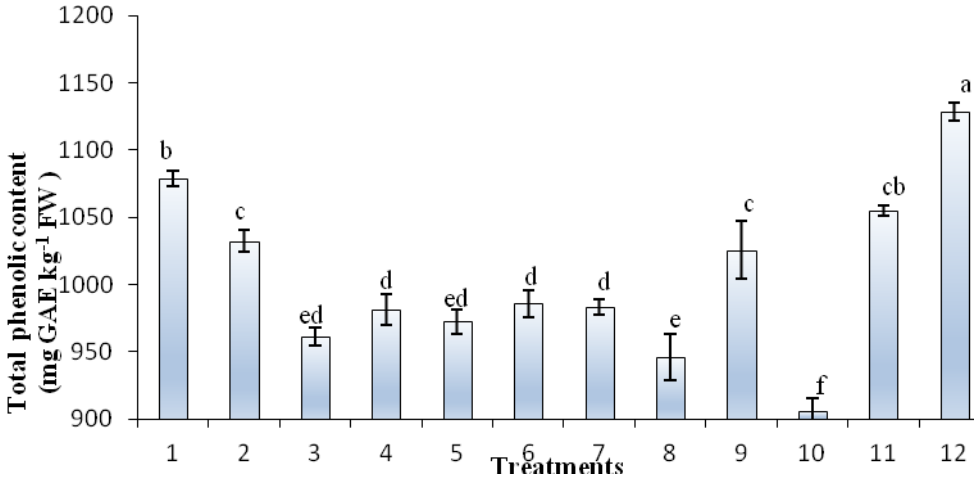

Figure 8. *Total phenolic content (mg GAE kg^{-1} FW) of goldenberry fruits from different colchicine treatment groups. Different letters on the columns are expressed statistical difference at P ≤ 0.05 determined by the LSD test*

In the study, tetraploid fruits phenolic compounds were also found to be richer than control group as in the anthocyanin content. Except for T1 and T12 applications, the effects of other colchicine applications on the TP content of the fruits were limited compared to the control group.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_289302

According to the analysis results, TF contents of fruits ranged from 579.38 µg CE g^{-1} FW (T10) to 1282.02 µg CE g^{-1} FW (T2). Unlike TA and TP, the increase in TF was found to be independent of chromosome doubling. The highest value was obtained from T2 application. This value was followed by flavonoid contents measured in T9 (961.84 µg CE g^{-1} FW) and T5 (906.57 µg CE g^{-1} FW) fruits. Fruits from T2 and T12 (tetraploid fruits) treatments had 88.7% and 21.95% respectively higher TF content than diploid progenitor control group. Tetraploid fruits showed an increasing tendency compared to diploids. Except for T3 and T10 treatments, the effects of colchicine applications on the TF contents of fruits were found to be significant compared to the control (*Fig. 9*).

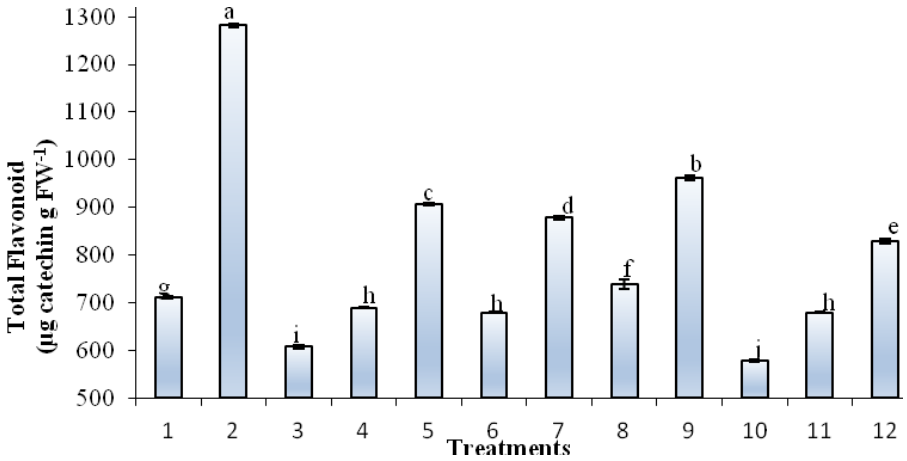

Figure 9. *Total flavonoid content (µg CE g^{-1} FW) of goldenberry fruits from different colchicine treatment groups. Different letters on the columns are expressed statistical difference at $P \leq 0.05$ determined by the LSD test*

The free radical scavenging capacity of fruit samples was determined by using a synthetic, stable free radical molecule of 1,1-diphenyl-2-picrylhydrazyl (DPPH) (Blois, 1958).

The ethanolic extracts of the fruits of the plants with different colchicine treatment groups were found to have different free radical scavenging capacity, and the highest inhibition capacity was determined in fruit of tetraploid plants.

When DPPH free radical scavenging capacity was compared between the application groups, the highest value (65.96%) compared to the control (50.82%) was measured in tetraploid fruits (*Fig. 10*).

The increase rate of free radical scavenging capacity in tetraploid fruits was 29.79% compared to diploid progenitors. These results show that antioxidant capacity (DPPH inhibition) in fruit was increased rather associated with chromosome doubling, as well as increasing TA and TP values. The effectiveness of other treatments was limited compared to the control and was found to be statistically insignificant. Results of total antioxidant activity of the samples determined by phosphomolybdenum method are given in *Figure 11*. The highest antioxidant capacity of fruit samples (130.03 µg AE ml^{-1} extract) was determined in tetraploid (T12) fruit samples.

As in the DPPH results, T12 was followed by T8 (116.57 µg GAE ml^{-1} extract) and T1 (114.926 µg GAE ml^{-1} extract). The effectiveness of other applications was considered to be limited or statistically insignificant compared to the control.

DOI: http://dx.doi.org/10.15666/aeer/1801_289302

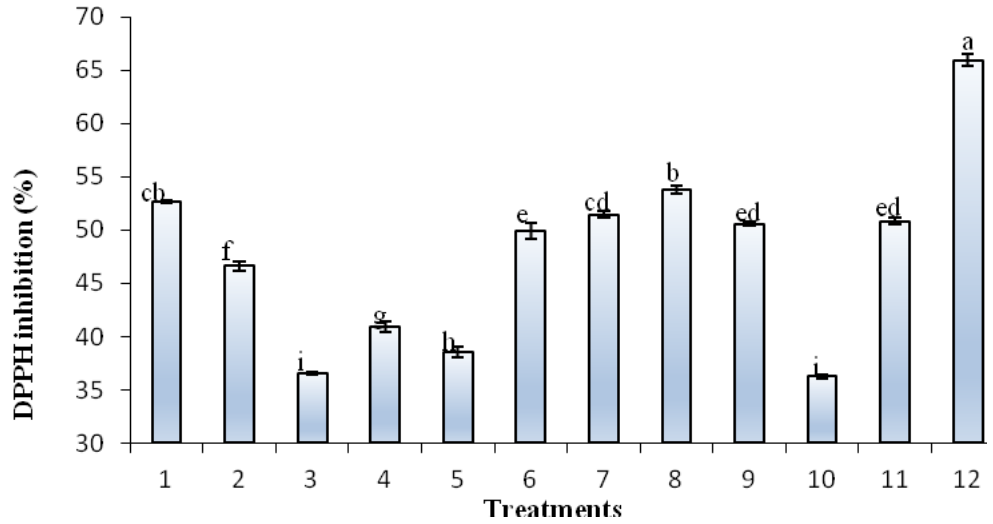

Figure 10. *DPPH free radical scavenging activity (%) of goldenberry fruit extracts from different colchicine treatment groups. Different letters on the columns are expressed statistical difference at P ≤ 0.05 determined by the LSD test*

The total antioxidant capacity of the fruits determined by the MO method was similar to the values determined by the DPPH method. Although different colchicine applications cause increasing or decreasing effects compared to control fruits, it was determined that the most important increase was obtained due to polyploidy (*Fig. 11*).

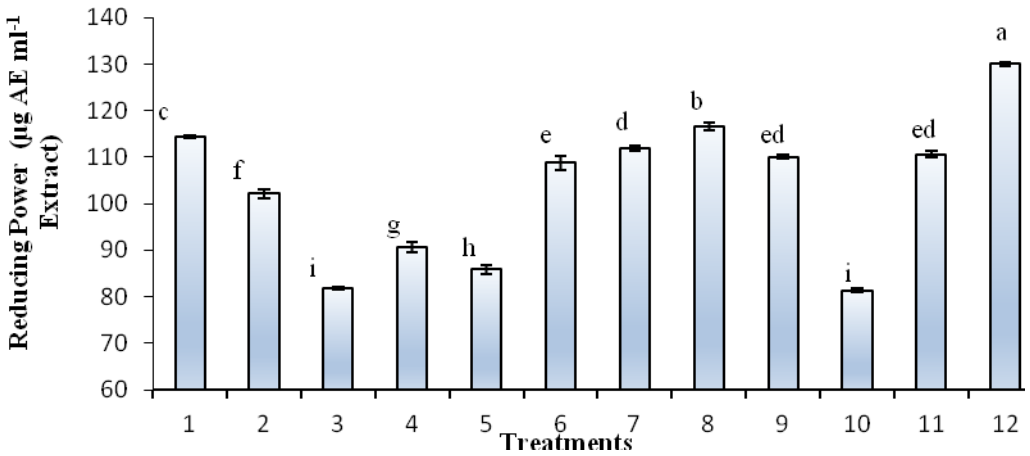

Figure 11. *Antioxidant activity (µg AE ml^{-1} extract) of goldenberry fruit extracts from different colchicine treatment groups determined by phosphomolybdenum method (reduction of Mo-VI to Mo-V). Different letters on the columns are expressed statistical difference at P ≤ 0.05 determined by the LSD test*

When the antioxidant capacity of ethanolic fruit extracts from different colchisin applications were evaluated, the highest value was determined as 218.85 (µg BHT ml^{-1} extract) in T2 application fruit samples. This was followed by T1 (107.35 µg BHT ml^{-1} extract), and fruit extracts from T9 treatment (83.21 µg BHT ml^{-1} extract) (*Fig. 12*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_289302

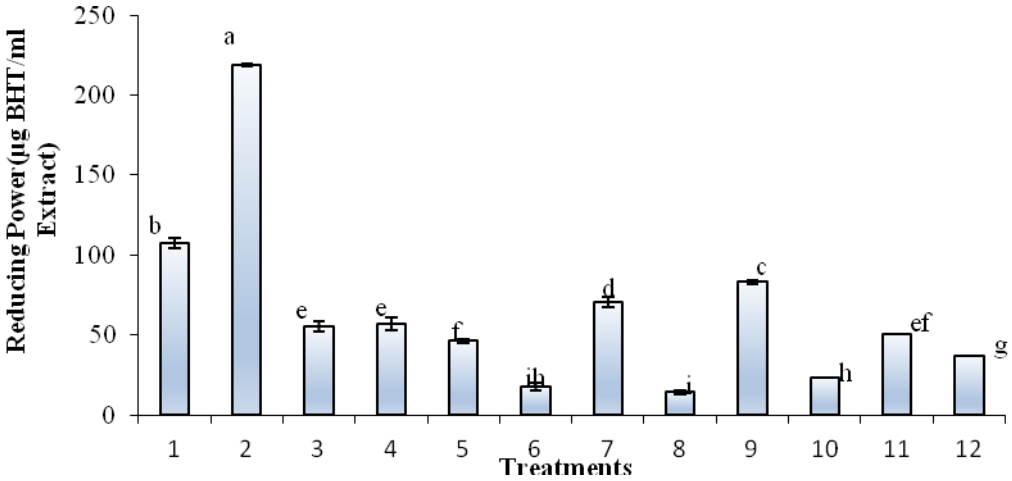

Figure 12. *Ferric Reducing Antioxidant Power (FRAP) (µg BHT ml^{-1} extract) of goldenberry ethanolic fruit extracts from different colchicine treatment groups. Different letters on the columns indicate the difference at $P \leq 0.05$ level determined by the LSD test*

According to the data obtained from the research, the secondary metabolite contents of diploid, colchicine treated and tetraploid plants showed significant differences. The amount of anthocyanin and phenolic compounds of tetraploid fruits was higher than diploid and colchicine treated fruits.

Different colchicine applications significantly affected the TA content of fruits ($P \leq 0.05$).

Among colchicine applications that could not induce chromosomes doubling, TA increases were determined in T9 compared to control. However, the greatest increase in TA content was determined by the increase in ploidy level. The highest TA (559.59 mg kg^{-1}) was reached in the tetraploid fruits (*Fig. 7*). TA value of tetraploid fruits increased by 9.1% compared to diploid. As a result of colchicine applications, the change in total phenolic content of fruits was found to be significant. Total phenolic contents ranged from 905.77 mg GAE kg^{-1} fresh weight to 1128.00 mg GAE kg^{-1} fresh weight (*Fig. 8*). As in TA content, the highest value was also determined in tetraploid fruits. It was determined that the effects of different colchicines applications on the total flavonoid content of the fruits were significant. Total flavonoids of the fruits ranged from 579.38 µg KE g-1 fresh weight (T10) to 1282.02 µg KE g-1 fresh weight (T2) (*Fig. 9*). Tetraploids showed an increasing tendency compared to diploid fruits. Colchicine application also caused an increase in TF compared to control, except T3 and T10 treatments. Among applications T2 fruits showed 88.7%, and T12 (tetraploid) fruits 21.95% higher TF contents than control (diploid progenitor) (*Fig. 8*).

The antioxidant capacities of the samples, expressed as DPPH scavenging (%) extract concentrations, were strongly influenced by colchicine applications. Increases and decreases were determined in different treatments compared to the control and tetraploid fruits (T12) had higher DPPH sweeping capacity than all other treatments (*Fig. 10*). The increasing rate in tetraploid fruits was 29.79% compared to diploid progenitor (*Fig. 10*). These results show that antioxidant capacity (DPPH inhibition) in fruit is increased in association with chromosome doubling, as in the increase in TA and TP values. In this study, total antioxidant capacity of the fruits determined by FRAP

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_289302

method decreased in contrast to increasing ploidy level. FRAP values were the highest in T2 (218.85 μg BHT ml^{-1} extract) and T1 (107.35 μg BHT ml^{-1} extract).

As a result of this research, total phenolic and flavonoid content of fruits of plants with different colchicine application and different ploidy level the samples swept the DPPH free radical and the Mo (VI) (*Fig. 11*) ions were reduced. The results presented in this study clearly indicate that the antioxidant activity was correlated with the phenolic content of fruits own.

In addition T3, T4, T7 and T9 treatments showed significantly higher antioxidant capacity than both diploid and tetraploid fruits with FRAP method (*Fig. 12*). Consistent with the results of this research, according to Özden and Özden (2014) research on 14 different fruit varieties, it is stated that antioxidant properties of fruits are related to total phenolic content of fruits.

Conclusions

Oxidation, a side effect of numerous physiological and biochemical processes in the human body, is an important and natural process. In many ways it is good, but it has the potential to be bad. In case of high oxidation, the body's aging and rusting rate increases. Damage caused by free radicals can be prevented by free radicals bounding to an antioxidant and swept from the body without damaging other cells. Therefore, high antioxidant content of foods slows down the aging process. The quantity of important medicinal compounds, aromatics, natural secondary metabolite production and antioxidant potentials of the plants can be artificially enhanced by experimental arrangements. Caruso et al. (2013) reported that tetraploid genotypes of *Solanum bulbocastanum* exhibited either a similar or a lower phenylpropanoids, tryptophan, tyrosine and chaconine content compared to the diploid parent.

Although fruits of tetraploid plants generally produce higher amounts of secondary compounds than diploid progenitors and have higher antioxidant capacities, our results show that polyploidization is important as a strategy to increase secondary metabolite production, but it cannot be generalized. It was determined that the relationship between total anthocyanin and total phenolic contents and antioxidant capacity of fruits was significant and parallel. Finally, colchicine can be used for polyploidization as strategy and we suggest the use of the lowest colchicine concentration tested, 0.6% colchicine to enhance metabolite production cannot be generalized.

(Received 28th Aug 2019; accepted 25th Nov 2019)

Abstract. This study was conducted to determine the residual effects of chicken manure on the yield and yield performance of eight onion varieties as second crops after lettuce under greenhouse condition. 14-16, Burgaz, Karbeyazı, Naz, NWG, Perwana, Seyhan, Şampiyon varieties and also four different doses of chicken manure at the rates of 0, 20, 40, 60 t ha^{-1} with the recommended dose of NPK were used. A non-fertilized parcel was used as control. The experiment was laid out in split plot design and replicated three times. Yield and yield components were investigated. According to the results residual effect of chicken manure and onion varieties as second crop significantly affected the yield and bulb production in the greenhouse condition. The application of chicken manure significantly improved yield, bulb weight, bulb height, number of shoot tip, number of dried leaf compared to control. Highest yields (72.99 t ha^{-1}) were obtained in the parcels where the chicken manure was applied at a rate of 20 t ha^{-1}. The onion cultivar Burgaz was more responsive to the chicken manure compared to other onion cultivars. The best yield was shown of Burgaz cultivar and the 20 t ha^{-1} chicken manure treatments by the interaction. As a result, this method is the most suitable for onion production.

Introduction

Onions are members of the *Allium* genus of flowering plants that also includes garlic, shallots, leeks and chives. Onion is rich in several phytonutrients that are recognized as important elements of the Mediterranean diet but it has received attention also for its biological properties and potential application in the treatment and prevention of a number of diseases (Lim, 2015; Marrelli et al., 2019). Onion (*Allium cepa* L.) is also a vegetable that is widely consumed due to its flavoring and health-promoting properties. Onions have many possible health benefits including reducing the risk of obesity, heart disease, and cancer. Onion bulb is a rich source of minerals like phosphorus, calcium, magnesium, iron, manganese and carbohydrates. It also contains protein, Vitamin C, Vitamin B6 and antioxidants and is rich in sulphur amino acids (Ware, 2017). Moreover, a variety of secondary metabolites have been identified in this species, such as flavonoids (particularly flavonols and anthocyanin), phytosterols and saponins (Griffiths et al., 2002; Marrelli et al., 2019).

According to the statistics, Turkey's bulb onion production is 1 930 695 tons over a 53 000-hectare area (Anonymous, 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_303314

Healthy life and environmental consciousness are important today. In this case it caused to increase on naturel feeding. With the development and perfection of market economy, agriculture and rural economy is coming to a new stage and the lives of people working in this sector, since there is now a demand for production of safe and high quality agricultural products (Liu et al., 2011). The reasonable use of organic manure can improve soil fertility and microbial content, decrease soil nitrogen accumulation and leaching loss, increase yield and quality, and improve human ecological environment (Yi et al., 2004; Gao et al., 2005; Liu et al., 2011).

Pollution with chemical fertilizers arose as an aim of health care, thus attempts were made for solving problems of chemical fertilization, and the organic farming technique represents a move towards an alternative system of agriculture (Abd-Allah et al., 2001; Yassen and Khalid, 2009). Organic material, such as sheep and chicken manure, improves soil physical properties (structure and aggregation) and soil chemical properties (decrease soil pH, increase cation exchange capacity and enhance most nutrients) that are important for plant growth (Snyman et al., 1998; Yassen and Khalid, 2009). Using of chemical matter was decreased and naturel productions get importance. But soil fertility is important in this case. Organic matter improves soil's physical, chemical, biological properties and is also effect the availability of nutrient. But high level organic material in soils especially in dry conditions may be caused unable effects and also it can create organo-mineral complex and it reduced the availability of some mineral (Sezen, 1995). Animal fertilizers are major source of organic matter for soil.

Organic fertilizer has been widely used as alternative fertilizers for organically grown fields (Jongtae, 2010). Organic manures can serve as alternative to mineral fertilizers as reported by Naeem et al. (2006) for improving soil structure (Dauda et al., 2008) and microbial biomass (Suresh et al., 2004).

Organic material, such as farmyard manure improves soil physico-chemical properties that are important for plant growth (Snyman et al., 1998). Decomposition of materials would provide additional nutrients to the growing medium which may lead to higher uptake of nutrient by the crop and subsequently high yield. Besides, organic manures have positive effect on root growth by improving the root rhizosphere conditions (structure, humidity, etc.) and also plant growth is encouraged by increasing the population of microorganisms (Shaheen et al., 2007; Kidanu, 2017).

Comparisons of conventional and organic farms matched by soil type indicated that organic practices improved soil fertility (Liebig and Doran, 1999). This included a 22% increase in organic matter, 20% more total N, lower bulk density and higher water holding capacity.

Organic farming provides several benefits to the growers. It reduces production cost and it is an environmentally friendly method of cultivation. Addition of organic fertilizers improves soil structure and enhances activities of useful soil organisms (Snyman et al., 1998; Ramesh et al., 2005). Agricultural commodities resulted from organic cultivation are good for human health. however, organic manures alone cannot provide sufficient quantities of required nutrients and are unable to give economic yield and hence, it is vital to find appropriate combinations of inorganic and organic manure to obtain financially viable yield of crops. Jayathilake et al. (2006) reported that integrated use of bio-fertilizer, organic manure and chemical fertilizers resulted in onion yield increase in comparison with the exclusive application of chemical fertilizers (Kidanu, 2017).

Organic manure increases the nutrient status of a soil which leads to increase in onion yield (Akoun, 2004; Kidanu, 2017).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_303314

Boyhan and Hill (2008) found that fertilizer requirements were higher with organic fertilizer sources compared with conventional fertilizers presumably because nutrients were less available in organic compounds due to slow mineralization rates.

Work has been done to predict the availability of plant nutrients from organic sources over time. Whitmore (2007), for example, found that 40% of the total N from composted chicken manure was available in the first year, with the remainder available in subsequent years at a rate of 6% to 12% per year.

A number of studies have been conducted evaluating the organic production of onions (Piazza et al., 2003; Sharma et al., 2004; Gonçalves and Sousa e Silva, 2004; Beek, 2005; Russo, 2005; Boyhan et al., 2006; Boyhan and Hill, 2008). These studies have evaluated fertility, insect control, weed control, transplant production, various cropping systems, and varieties (George et al., 2010; Ewais et al., 2010). Many researchers reported that soil application of chicken manure increased yield and yield criteria of onion (Shaheen et al., 2007; Dina et al., 2010; El-Shatanofy and Manar, 2011; Yoldas et al., 2011; Ali et al., 2018).

Onion shows significant response to organic and inorganic fertilizers (Nasreen and Hossain, 2000; Soleymani and Shahrajabian, 2012; Kidanu, 2017). Therefore, the usage of organic manures as alternative source of nitrogen would give better result in its growth and yield.

The objective of this study was to evaluate residual effect of organic manure and recommended NPK fertilizer on yield and bulb performance of onion (A*llium cepa* L.) as second crop under greenhouse condition.

Materials and Methods

The study was carried out in experimental area of the Ödemiş Vocational School, at the Ege University, in İzmir (38º16'N, 27º59'E), Turkey during the 2017 year. The experimental designs were split plot with three replications. Before sowing of lettuce, the chicken manure was applied to soil at the rates of 0 – 20 – 40 - 60 t ha^{-1} and also recommended dose of NPK (150:100:150 kg ha^{-1}). Mineral fertilizers have applied as NH_4NO_3 and K_2SO_4 formulated product. Five different treatments with control and three replications were conducted in 15 plots. In the control treatment neither organic nor mineral fertilization had been done. Lolla Rossa lettuce variety was sown and harvested at the end of vegetation. After harvesting the lettuce plant, onion varieties were sown in order to determine the residual effect of chicken manure and chemical fertilizer in greenhouse conditions. No nutrient addition was made for onion. In this study, during the growth period, weeds were removed by hand hoeing and irrigation was done on a regular basis. The spraying procedures and plant protection were regularly applied throughout the production.

Eight onion varieties called 14-16, Burgaz, Karbeyazı, Naz, NWG, Pewana, Seyhan, Şampiyon were used. They are long day / storage. Their fruits are a round, brown-shelled, widely known and kept Variety on the market due to its uniform nature. Due to their very strong root structure. Resistant to pink root rot and Fusarium. *Allium cepa* L. was planted in each plot with 30 cm between rows and 15 cm within the rows. Total plot length is 11.5 m and plot width is 6.2 m.

The composition of chicken manure that residual effect investigated was analyzed according to Kacar (1995) and is presented in *Table 1*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_303314

Soil samples (0-20 cm) were collected from the individual experimental plots (15 samples) at the beginning of onion vegetation. The soil sample was air dried, ground, and passed through 2 mm sieve for the determination of chemical parameters. pH (Jackson, 1967), total soluble salt (Anonymous, 1951), $CaCO_3$ (Kacar, 1995), organic matter content (Reuterberg and Kremkurs, 1951) were determined in the soil. Total N was also analyzed according to Bremner (1965), the available K^+, was determined after extracting with 1 N NH_4OAc by flame photometer (Atalay et al., 1986) and available P was measured by colorimeter (Olsen et al., 1954).

Table 1. *Some properties of chicken manure*

pH	8.55	**C/N**	12.1
Total Salt (ms/cm)	2.47	**P (%)**	0.70
Ash 550 ^{0}C (%)	79	**K (%)**	1.02
Organic Matter (%)	19.8	**Ca (%)**	1.37
Organic Carbon (%)	11.51	**Mg (ppm)**	3729
Total N (%)	0.95	**Na (ppm)**	1248

At the end of the vegetation, onions were harvested. Average bulb head weight, bulb height, bulb width and flesh thickness, number of storage leaf, number of shoot tip, and number of dried leaf were determined as growth and yield parameters.

Ten randomly selected plants were harvested from each plot (avoiding side effect) to record the data on data set for all characters. Bulb length and diameter refers to the height of the bulb and the average width at the widest point in the middle portion of the mature bulb measured using vernier caliper. Average bulb weight computed by weighing ten bulbs together and calculating the average. Total bulb yield was computed based on the weight of matured bulbs yield per plot and converted in to hectare base and expressed in tones. Marketable bulb yield was determined after discarding bulbs smaller than 3 cm in diameter, splitted, thick necked, rotten and discolored. Split bulbs percentage was determined by counting the number of split bulbs per plot and expressed in percentage in reference to total number of normal bulbs per plot.

The collected data on various parameters were statistically analyzed. Analysis of variance was computed and LSD was used to compare means. Trial statistical evaluation result of data was done using software package TARIST (Açikgöz et al., 1993).

Results and Discussion

Soil properties

Some chemical properties and macro-micro nutrient contents of greenhouse trial soil before onion sowing are presented in *Tables 2 and 3*. pH, organic matter, lime, P, K, Ca, Mg, Na, Fe, Zn, Mn, Cu values in the soil did not show any statistical difference between applications at the beginning of vegetation. On the contrary, total N content of the soil was significantly affected by the applications. The highest values (0.084%) were analyzed in the parcels which the chicken manure was applied as 40 t ha^{-1}.

Before onion sowing, greenhouse soil properties are neutral (6.6-7.3) except the parcels which the chicken manure was applied as 20 t ha^{-1}. However, in this application, soils showed slightly alkaline properties (7.4-7.8). Low humus (1.33-1.61%) and lime (0-2.5%) poor. When the productivity status of the soil is investigated, N is moderate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_303314

(0.05-0.1%); K (< 150 ppm), Ca (715-1430 ppm) poor; rich in P (3.26 ppm); Mg (> 114 ppm) is good; Fe (> 4.5 ppm), Zn (> 1 ppm), Mn (> 1 ppm) and Cu (> 0.2 ppm) is determined to be sufficient according to Güneş et al. (2000).

Onion yield and yield characteristics

Residue effect of chicken manure on yield and some quality criteria of onion as second crop after the lettuce production are given in *Table 4*.

Yield

In the greenhouse condition, the results showed significant differences in yield amongst treatments (p< 0.01) (*Table 4*). Highest yields (72.99 t ha^{-1}) were obtained in the parcels which the chicken manure was applied as 20 t ha^{-1}. This application increased yield by 8% compared to the control plots. But there is no statistically significant difference in yield between mineral fertilizer and 20 t ha^{-1} of chicken manure application. Similarly, Rumpel (1998), Sharma et al. (2003), Yoldas et al. (2011), Indira and Singh (2014) and Zewde et al. (2018) found that animal manure applications increased onion yield.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_303314

Many researchers also reported similar results that soil application of chicken manure increased yield and yield criteria of onion (Shaheen et al., 2007; Dina et al., 2010; El-Shatanofy and Manar, 2011; Yoldas et al., 2011; Ali et al., 2018).

Organic manures activate many species of living organisms which release phytohormones and may stimulate the plant growth and absorption of nutrients (Arisha et al., 2003). Organic manures improved the water holding capacity of soil and provide nutrients for a long duration due to less leaching of nutrients and increase efficiency (Carol et al., 1999). Mahala et al. (2018) reported that the increased yield and yield parameters with poultry manure might be because of rapid availability and utilization of nitrogen for various internal plant processes for carbohydrates production. Later on these carbohydrates may undergo hydrolysis and get converted into reproductive sugars which ultimately helped in increasing yield.

Table 4. *Residue effect of chicken manure on yield and some quality criteria of onion as second crop in the greenhouse condition*

Treatment	Yield	Bulb weight	Bulb width	Bulb height	Number of stored leaf	Number of shoot tip	Number of dried leaf
	(t ha^{-1})	(g no^{-1})	(cm)	(cm)	(no)	(no)	(no)

**: p<0.01; *: p<0.05; n.s.: not significant

Similar results were found by Jongtae (2010). In that research, no significant yield difference was found between chemical fertilization and organic fertilization with mulch.

Velmurugan and Swarnam (2017) explained similar to the results that rice grain yield was significantly affected by the residual effect of manures and inorganic fertilizer to okra.

Different our results, Abdelrezzag (2002) reported that chicken manure tended to reduce onion yield for all levels in comperation with fertilizer and control. The usage of organic manures as alternative source of nitrogen would give better result in its growth and yield (Nasreen and Hossain, 2000; Kidanu, 2017).

In the study, the highest yield was observed Burgaz variety (p< 0.01) (*Table 5*). Highest yield after Burgaz obtained with Şampiyon variety. The differences in yield among varieties can be caused by differences in genetic characteristics of varieties (Khan et al., 2011; Abou-El-Hassan et al., 2018).

Bulb weight

Treatments, variety and the interaction between onion cultivars and treatment affected bulb weight of onion significantly (p< 0.01). Highest values (219.006 g) were obtained in the parcels which the chicken manure was applied as 20 t ha^{-1} in the greenhouse (*Table 4*). This application increased weight of onion by 8% compared to the control plots. But there was no statistically significant difference in bulb weight between mineral fertilizer and 20 t ha^{-1} of chicken manure application. Similarly, Yohannes et al. (2013)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_303314

reported that farmyard manure and nitrogen fertilizer increased bulb weight. Organic fertilizers provide nutrients to the plants by decomposing and increase growth and yield. Manures improved the soil structure, fertile and availability of nutrient to the plant. Better nutrition of the plant; increase the cell division of plant tissues and the rate of photosynthesis. This is reflected in product growth and the bulb weight (Ewais et al., 2010).

Bulb weights of Burgaz variety (316.283 g) were higher than the others onion variety significantly (*Table 5*).

The interaction between onion cultivars and treatment for bulb weight was found statistically significant The highest bulb weights was obtained in Burgaz variety with 20 t ha^{-1} as 339.267 g in greenhouse condition.

Table 5. *Effect of variety on yield and same quality criteria of onion as second crop depending on residue effect of chicken manure in greenhouse condition*

Variety	Yield	Bulb weight	Bulb width	Bulb height	Number of storage leaf	Number of shoot tip	Number of dried leaf

**: p<0.01; *: p<0.05; n.s.: not significant

Bulb width

The residual effect of chicken manure and mineral NPK applications on onion bulb width was found significant (*Table 4*). Contrarily, Yohannes et al. (2013) and Mekonnen et al. (2017) reported that farmyard manure did not affect bulb width of onion in their work.

The highest bulb width (8.745 cm) was observed Burgaz variety (p< 0.01) followed by the bulb width (8.160 cm) in Şampiyon variety (*Table 5*). The interaction between onion cultivars and treatment for bulb width was statistically important. Maximum bulb width was obtained in Burgaz variety with 20 t ha^{-1} as 8.897 cm.

Bulb height

Onion bulb height was significantly (p< 0.01) affected by the residual effect of chicken manure and mineral NPK applications (*Table 4*). The highest value (7.513 cm) was determined in mineral NPK application and followed bulb height (6.49 cm) by the application of control. There is contrast with Yohannes et al. (2013) who reported that application of FYM at a rate of 45 ton ha^{-1} gave the highest mean bulb diameter (5.99 cm). Consistent with their results Metwally and Bary (1999) suggested that the poultry manure improve the bulb growth by enhancing the soil properties and overcome the leaching of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_303314

nutrients from the root zone. As different Mekonnen et al. (2017) reported that organic manure did not significantly influence bulb length.

In the study, bulb height of Şampiyon variety (8.820 cm) was reported higher than other varieties ($p< 0.01$) (*Table 5*). The interaction between onion cultivars and treatment for bulb height was also found significant. Maximum bulb height was obtained in Şampiyon variety with the mineral fertilizer NPK as 9.857 cm.

The differences in the responses to the applications of onion varieties may be genetic variation and also depending on the adoptability of variety in specific environment (Shah et al., 2012; Ali et al., 2018).

Number of storage leaf

According to statistical analyzes, number of storage leaf was affected from the treatments. But these characteristics have changed significantly in relation to the varieties (*Tables 4 and 5*). Highest value was obtained in Burgaz variety (3.101) followed by Şampiyon variety (2.778) (*Table 5*). There was statistically significant difference between Burgaz and Şampiyon variety. The interaction between onion cultivars and treatment had a significant effect on the number of storage leaf ($p< 0.01$). The number of storage leaf was highest in the application of 40 t ha^{-1} and Burgaz variety.

Number of shoot tip

The results presented in *Tables 4 and 5* showed that treatment and onion variety had significantly affected number of shoot tip of onion, where the interaction had also significantly affected. The highest number of shoot tip (1.730) was observed with the application of chicken manure at the rate of 20 t ha^{-1} (*Table 4*). While the lowest numbers of shoot tip (1.569) was observed in control application. Among the onion variety highest number of shoot tip was recorded in variety Burgaz (2.611).

Maximum number of shoot tip was obtained in Burgaz variety with the 40 t ha^{-1} of chicken manure application.

Number of dried leaf

Treatments, variety and the interaction between onion cultivars and treatment affected number of dried leaf of onion significantly ($p< 0.01$) (*Tables 4 and 5*). Highest value (7.395) was obtained in the parcels which the chicken manure was applied as 20 t ha^{-1} in the field. Number of dried leaf of Şampiyon variety (8.989) were higher than the others onion variety significantly (*Table 5*). The highest number of dried leaf was obtained in Karbeyazı variety with 20 t ha^{-1} as 10.220.

Conclusion

As a conclusion it was found that residual effect of chicken manures recommended NPK fertilizer and onion varieties as second crop significantly affected the yield and bulb production in the greenhouse condition. Residual of chicken manure increased yield, bulb weight, bulb height, number of dry shell, number of shoots of onion varieties. The highest results were obtained especially with 20 t ha^{-1} of chicken manure application in the greenhouse condition. The onion varieties Burgaz gave more response to the organic manure as compare with other onion varieties in yield, bulb weight, bulb height, bulb width, number of storage leaf. The lowest amount of animal manure improved many

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_303314

examined parameters significantly but increasing the rate of using the chicken manure had negative effects.

In today's world, where healthy life and environmental consciousness is gaining importance, it should be aimed to increase the conscious use of natural organic fertilizers.

Abstract. In order to effectively control the environmental behavior of cadmium in saline-alkaline soil, it is imperative to understand its adsorption capacity. In this study, the kinetics, adsorption isotherm and two environmental parameters (pH and addition of biochar) of the adsorption behavior of Cd (II) in three saline-alkaline soil samples from western Jilin province, China were investigated. This study was an optimal fit for the pseudo-second-order kinetics model, as well as Langmuir adsorption isotherm model. The adsorption effect was the strongest at a pH of 7, the addition of biochar could increase Cd (II) adsorption of the soil. The adsorption of Cd (II) by saline-alkaline soil was a spontaneous, disordered and heat-absorbing reaction. Compared with mildly and moderately saline-alkaline soil, the adsorption of Cd (II) by severely saline-alkaline soil was the highest, and the adsorption was the best when the pH was neutral. Moreover, the addition of biochar could increase the organic matter in the soil and improve the adsorption capacity of Cd (II).
Keywords: *heavy metal, saline-alkali soil, properties, pH, biochar*

Introduction

Saline-alkaline soil is a common soil type on Earth, accounting for about 7% of the total soil area of the world. It is widely distributed in arid and semi-arid regions of Asia, Australia, Africa and South America (Yang et al., 2018; Saifullah et al., 2018). China ranks third in the world in terms of saline-alkaline soil area, mainly distributed in the northeast, north China, northwest inland and coastal areas along the Yangtze River. In the western region of Jilin province, there are 3.2 million hm^2 of saline-alkali soil, which is one of the three most concentrated saline-alkali areas in the world (Shi et al., 2018), which has brought serious harm to the development of agriculture and animal husbandry in Songnen plain (Zhao et al., 2018; He et al., 2008).

With the rapid development of industrial and agricultural production, the sources of heavy metals in soil, including the use of pesticides, excessive application of chemical fertilizers, industrial wastewater, bio-fats and so on (Ashraf et al., 2019), especially phosphate fertilizer containing relatively high concentrations of cadmium, which is different deposits varies greatly, and the overall average concentration of cadmium in sediments is 21 mg/kg, ranging from 1 to 150 mg/kg (Roberts, 2014). Soil cadmium pollution is a serious problem in China and is the main cause of cadmium contaminated rice (Wu et al., 2018). According to 2014 National Soil Pollution Survey data, 16.1% of the soil pollution sites (including agriculture and industry) exceeded the allowable limit of the second-level soil environmental quality standards, among which heavy metal pollution sites accounted for 82.8%. Among them, cadmium exceeded the standard by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_315329

7.0% (He et al., 2019), and heavy metal pollution events such as “cadmium rice”, “blood lead” and “arsenic toxin” occurred frequently, which arouse people’s great attention to it (Zhai et al., 2019; Hwang et al., 2019; Jain and Chandramani, 2018). Cadmium is a non-essential element for plant and human growth and one of the most toxic heavy metal elements (Sun et al., 2018).

Into the soil of the Cd (II) in a dynamic balance of adsorption and desorption, because of the heterogeneity of soil surface, there are different adsorption sites, including the binding energy of the high level and the low level. When the lower initial concentration of exogenous Cd (II), Cd (II) was first adsorbed on the binding energy of high level, giving priority to with obligate adsorption, adsorption speed faster, with the increase of initial concentration of Cd (II), obligate adsorption points gradually reduced, Cd (II) from predominantly obligate adsorption to give priority to with non-obligate adsorption, adsorption speed slower (Naiya et al., 2009). In general, temperature, soil type, organic matter, and clay minerals content type and amount, iron, manganese oxide, and calcium carbonate content are different, all can lead to different adsorption quantity of Cd (II) in soil, which greatly influenced by the pH (Liao, 2006; Sprynskyy et al., 2011). The adsorption capacity of heavy metal increases with the increase of pH value. Wang (Wang, 2012) investigated 18 kinds of typical soil in China, the study found the temperature rising in different soil types on Cd (II) adsorption capacity increased, but instead of desorption quantity was reduced, soil showed that under the condition of high temperature on Cd (II) stronger adsorption ability, and difficult to desorption. A study conducted by Yuan et al. (2019) claimed that the addition of organic matter can effectively immobilize soil Cd (II) at an appropriate concentration in the environment by stimulating the reduction of primary oxidation components of soil by microorganisms. Li et al. (2007) studied Cd (II) in the black soil, yellow-brown soil, yellow soil, red soil of different graded composition of cadmium adsorption effect, four kinds of soil adsorption Cd (II) capacities were in the form of clay > silt > fine sand > coarse sand.

For adsorption of soil heavy metal and saline-alkaline soil restoration work have been reported more. In this study, we objected of the adsorption characteristics of Cd (II) in Jilin province three different saline-alkaline soil samples and the influence of adding biochar adsorption behavior for Cd (II), starting from the physical and chemical properties of saline-alkaline soil itself directly, to study the adsorption of Cd (II) in soil potential, in order to fully understand the degree of saline-alkaline of soil Cd (II) adsorption ability. Moreover, we studied the different pH values and the addition of biochar to saline-alkaline soil adsorption of Cd (II), to seek effective measures to control soil Cd (II) environment behavior, as well as to provide a theoretical basis for Cd (II) saline-alkaline soil restoration.

Materials and methods

Test samples

Sampling sites were located in Da ‘an Lesheng township west 10 km shop in Jilin province, China (45°33’4” N, 123°45’58” E). Because of terrain elevation difference and different slope direction, this place formed a natural depression “Disk depressions”, which subtle differences in the terrain height caused soil surface salinity distribution unevenly, formed a different saline-alkaline degree of soil in the micro-region (Wang et al., 2009; Martin et al., 2019). The sampling terrain was shown in *Figure 1*. In the “Disc

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_315329

depression" in the micro-region, sampling sites were taken the surface soil in 0-20 cm arranged according to different contour lines and removed off the sundries such as gravel, root plants and straw from the soil samples, then air-dried through a 100-mesh sieve, and stored in self-sealing bags for later use.

With the increase of terrain height in different micro-regions, pH value of soil, conductivity and total salt content gradually increased. Three test samples were determined in three separate contour lines, which were respectively: mildly saline-alkaline soil, moderately saline-alkaline soil, and severely saline-alkaline soil. The basic physical and chemical properties of the soil were given in *Table 1* and the water-soluble salt content in *Table 2*.

Test design

Different saline-alkaline soil of Cd (II) adsorption kinetics test

Took the sample (0.5000 ± 0.0005) g in a centrifuge tube, added 25 mL Cd (II) solution with concentration of 20 $mg \cdot L^{-1}$ in the background solution of 0.01 $mol \cdot L^{-1}$ $NaNO_3$(Analytical purity), oscillated the sample for 1, 5, 10, 20, 30, 60, 120, 240, 360, 480, 600, 1440 min, centrifuged for 10 min in a high-speed tabletop centrifuge of 10000 $r \cdot min^{-1}$ (TDL-40B from Agilent Company in America), and then filtered. The concentration of Cd (II) in the supernatant was determined by the atomic absorption spectrophotometer (TAS-990 from Pursee Company in Beijing, China).

Different saline-alkaline soil of Cd (II) adsorption isothermal test

The sample (0.5000 ± 0.0005) g was placed in a centrifuge tube, and 25 mL Cd (II) solution with a concentration gradient of 10, 20, 30, 50, 100, 150, 200 and 300 $mg \cdot L^{-1}$ solutions were added with 0.01 $mol \cdot L^{-1}$ $NaNO_3$ as the background solution. The adsorption isotherm was determined by oscillating for 24 h at a constant temperature of 25 °C (adsorption kinetics test confirmed that adsorption saturation had been reached for 24 h). Repeat isothermal adsorption experiments were performed at temperatures of 15 °C, 25 °C and 35 °C, to study the effect of different temperatures on adsorption.

Different pH and added biochar in saline-alkaline soil of Cd (II) absorption test

The pH of the background solution was adjusted to 3.0, 5.0, 7.0, 9.0 and 11.0 with 1 $mol \cdot L^{-1}$ HCl (Analytical purity) and NaOH (Analytical purity) solution. Added 0.00%, 0.5%, 1%, 3%, 5% and 10% biochar [The tested biochar is made from corn stalks that have passed through a 20 mesh sieve. Pyrolyzed in a muffle furnace (Jiangsu Zhengfei Electric Furnace Factory) at 500 °C for 3 h, after the end of pyrolysis, cooled to room temperature, passed through a 100 mesh sieve)]. Kept constant temperature and shocked for 24 h at 25 °C, and determined the concentration of Cd (II) in the supernatant.

Data processing and calculation

All experiments were repeated three times. The obtained data were calculated and plotted by Excel 2010 and Origin 8.5.

The adsorption capacity of the solution

Equation 1 was used to measure the adsorption capacity of the solution.

$$q_t = \frac{(C_0 - C_t)V}{m} \quad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_315329

where q_t is the adsorption amount of Cd (II) (mg·kg^{-1}); C_0 is the initial concentration of Cd (II) (mg·L^{-1}). C_t is used to measure the concentration of Cd (II) in the supernatant (mg·L^{-1}). V is the volume of Cd (II) solution (mL); m is the mass of soil or soil plus biochar (g).

Kinetic model

Pseudo-first-order kinetic model:

$$q_t = Q_{e,1}(1 - e^{-k_1 t}) \quad \text{(Eq.2)}$$

Pseudo-second-order kinetics model:

$$q_t = \frac{Q_{e,2}^2 k_2 t}{1 + Q_{e,2} k_2 t} \text{ (Nonlinear form)} \quad \text{(Eq.3)}$$

Elovich model:

$$q_t = a + b\ln t \quad \text{(Eq.4)}$$

where q_t is the adsorption amount of Cd (II) at time t (mg·g^{-1}); In *Equation 2,* $Q_{e,1}$ and k_1 represent the adsorption equilibrium quantity (mg·g^{-1}) and the adsorption rate constant (g·mg^{-1}·min^{-1}) of Cd (II) respectively. In *Equation 3,* $Q_{e,2}^2$ and k_2 represent the adsorption equilibrium quantity (mg·g^{-1}) and adsorption rate constant (g·mg^{-1}·min^{-1}) of Cd (II) respectively. In *Equation 4, a* is the adsorption constant related to the maximum adsorption capacity, and *b* is the adsorption rate coefficient, which is a measure of how fast the reaction rate decreases with the extension of time.

Isotherm model

Langmuir model:

$$q_e = \frac{K_L q_m C_t}{1 + K_L C_t} \text{ (Nonlinear form)} \quad \text{(Eq.5)}$$

Freundlich model:

$$q_e = K_F C_t^{1/n} \text{ (Nonlinear form)} \quad \text{(Eq.6)}$$

where q_e is the equilibrium adsorption amount of Cd (II) (mg·g^{-1}); q_m and K_L is Langmuir model parameters, representing the maximum adsorption capacity (mg·g^{-1}) and adsorption energy (L·mg^{-1}) of Cd (II), respectively. K_F and n are Freundlich model parameters, representing Cd (II) adsorption capacity (mg·g^{-1}· (mg·L^{-1})$^{-1/n}$) and adsorption strength, respectively.

The thermodynamic model parameter calculation

$$K_d = \frac{(C_0 - C_t)V}{C_t m} \quad \text{(Eq.7)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_315329

$$\ln K_d = \frac{\Delta S^\circ}{R} - \frac{\Delta H^\circ}{RT} \quad \text{(Eq.8)}$$

$$\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ \quad \text{(Eq.9)}$$

where ΔG° is the standard free energy change (kJ·mol^{-1}), ΔH° is the standard enthalpy change (kJ·mol^{-1}) and ΔS° is the standard entropy change (kJ·mol^{-1}), K_d is the thermodynamic equilibrium constant (mL·g^{-1}), R is the ideal gas constant R (8.314 J·mol·K^{-1}), T is the temperature (K), the value of ΔH° and ΔS° are the slope and intercept of lnK_d-T^{-1} diagram, respectively.

Correlation coefficient significance test

Find the correlation coefficient significance test table, and then determine the degree of freedom (n-2), where n represents the number of samples; find the value corresponding to a0.001, a0.005, a0.01 in the test table, and the fit will be obtained. The correlation coefficient r value is compared with a to determine the level of significance. For example, if $r > a$, it is extremely significant.

Results and discussion

Study on adsorption kinetics of Cd (II) in different saline-alkaline soils

The initial concentration of Cd (II) was 20 mg·L^{-1}, and the adsorption capacity of Cd (II) in mildly, moderately and severely saline-alkaline soil changed with time, as shown in *Figure 2*.

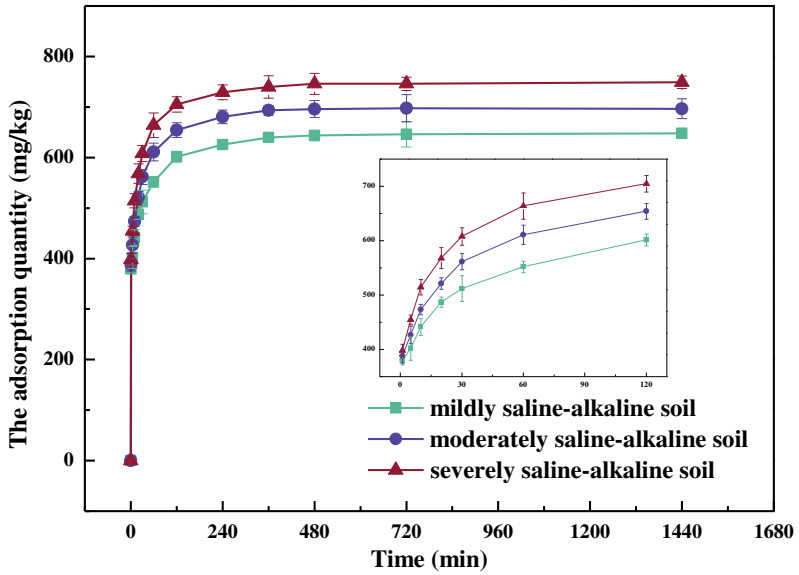

Figure 2. *Adsorption kinetics of Cd (II) in sample soil with three different saline-alkaline stresses*

The adsorption process of Cd (II) in the three tested soil samples can be divided into three stages: fast adsorption, slow adsorption, and equilibrium adsorption (*Figure 2*). Within 0~120 min was the rapid adsorption stage, the adsorption capacity of mildly,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_315329

moderately and severely saline-alkaline soil accounted for 92.840%, 93.941% and 94.126% of the total adsorption capacity, respectively. The adsorption rate of Cd (II) in the three tested samples was: severely saline-alkaline soil > moderately saline-alkaline soil > mildly saline-alkaline soil. At the initial stage of adsorption, there were many adsorption sites on the soil surface, and the adsorption rate was fast.

When the adsorption sites on the soil surface reached saturation, Cd (II) was adsorbed to the internal sites of the soil, and the adsorption rate slowed down up to a threshold (Tsang et al., 2007; Arias et al., 2005). These interactions including different interactions: first, surface complexation reactions which are basically inner-sphere surface complexes of the Cd (II) and the respective surface functional groups; second, electrostatic interactions where the Cd (II) form outer-sphere, complexes at a certain distance from the surface; third, hydrophobic expulsion of metal complexes containing highly nonpolar organic solutes, and fourth, surfactant adsorption of metal–polyelectrolyte complexes due to reduced surface tension (Bradl, 2004).

The pseudo-first-order kinetic model is a single adsorption process, while the pseudo-second-order kinetic model usually describes the chemical adsorption process, including electron sharing and transfer (covalent bond and ion exchange) between adsorbents and adsorbents (Ho, 2006). Elovich tends to describe a series of reaction mechanisms such as solute diffusion at the solid-liquid interface. The adsorption kinetics of Cd (II) in mildly, moderately and severely saline-alkaline soils were fitted by the pseudo-first-order kinetic model, pseudo-second-order kinetic model, and Elovich model. The fitting results were given in *Table 3*.

Table 3. *Adsorption kinetics fitting parameters of Cd (II) in soils with three different saline-alkaline stresses*

Soil type	Pseudo-first-order kinetic model			Pseudo-second-order kinetic model			Elovich model		
	$Q_{e.1}$	k_1	r	$Q_{e.2}$	K_2	r	a	b	r
Mildly saline-alkaline soil	548.225	103.094	0.828**	594.169	0.001	0.931**	360.163	44.615	0.993**
Moderately saline-alkaline soil	591.688	111.385	0.815**	649.824	0.001	0.938**	379.229	50.402	0.992**
Severely saline-alkaline soil	635.225	119.060	0.810**	702.594	0.001	0.948**	403.729	54.919	0.991**

**Highly significant correlation (n = 12, $r0.05$ = 0.576, $r0.01$ = 0.708)

It can be seen from *Table 3* that the fitting effect of pseudo-first-order dynamic model was the worst, and the correlation coefficient r value was the minimum of 0.810-0.828. The Elovich model had the largest correlation coefficient r value, which was 0.931, 0.938 and 0.948, respectively. However, according to the fitting model, the equilibrium adsorption capacity of mildly, moderately and severely saline-alkaline soil to Cd (II) was 360.163, 379.229 and 403.729 $mg \cdot kg^{-1}$, respectively, which were significantly different from the experimental values of 648.000, 696.500 and 749.000 $mg \cdot kg^{-1}$, respectively. The pseudo-second-order kinetic model could better describe the Cd (II) adsorption characteristics of the three sample soil, and the r values of the correlation coefficients are 0.931, 0.938 and 0.948, respectively. The fitted equilibrium adsorption capacities of 594.169, 649.824 and 702.594 $mg \cdot kg^{-1}$ were closed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_315329

to the experimental values. The pseudo-second-order kinetic model was usually used to describe the chemical adsorption process, and it was concluded that the adsorption of Cd (II) in the three kinds of soil was dominated by chemical adsorption (Rao et al., 2010).

Adsorption isotherms of Cd (II) in different saline-alkaline soils

The Cd (II) solutions of 0, 20, 30, 50, 100, 150, 200, and 300 mg·L^{-1} were added to the mildly, moderately, and severely saline-alkaline soil, and were oscillated for 24 h at a constant temperature of 25 °C to determine the adsorption capacity of Cd (II), as shown in *Figure 3*.

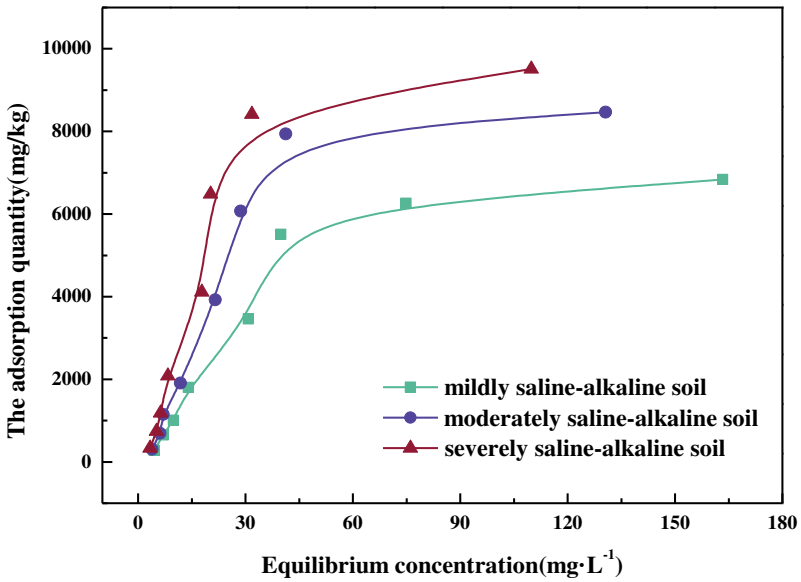

Figure 3. *Adsorption isotherms of Cd (II) in sample soil with three different saline-alkaline stresses*

It can be seen from *Figure 3*, with the increasing of Cd (II) concentration, three kinds of soil on Cd (II) adsorption quantity also promoted, *Table 1* showed that three of the pH value of the soil samples were 8.68, 9.42, 11.08, respectively, all belong to saline-alkaline soil. Due to Cd (II) hydroxide insoluble in water, after the Cd (II) into the soil and water mixture, Cd (II) with OH^- formed hydrated metal ions in the solution or hydroxide precipitation, the model was as follows:

$$Cd^{2+} + 2H_2O = Cd(OH)_2 \downarrow + 2H^+ \quad \text{(Eq.10)}$$

With the increasing concentration of Cd (II) ions, Eq.10 reaction continued to the right, and the hydroxide precipitation of Cd (II) continues to be generated (Wang et al., 2019), which showed that the adsorption capacity of soil to Cd (II) gradually increased. At the same concentration of Cd (II), the adsorption capacity of Cd (II) in the three tested soil was: severely saline-alkaline soil > moderately saline-alkaline soil > mildly saline-alkaline soil. When the concentration of Cd (II) in the equilibrium solution was 0-50 mg·L^{-1}, the slope of the adsorption isotherm was large, that meaning the adsorbed amount of Cd (II) in the three soils increased rapidly with the increasing of Cd (II) concentration.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_315329

When the equilibrium concentration of Cd (II) was greater than 50 $mg \cdot L^{-1}$, the slope of the adsorption isothermal curve gradually decreased, and the maximum adsorption capacity of the three kinds of soil reached 1798.803, 1909.739 and 2083.779 $mg \cdot kg^{-1}$, respectively. That was, the change range of the adsorption capacity of Cd (II) reduced until it finally reached adsorption saturation. Since obligate adsorption was dominant in the region with low adsorption capacity, most Cd (II) may be adsorbed at high energy sites, and the adsorption speed was fast. After reaching a certain saturation, obligate adsorption sites gradually decreased, and Cd (II) changed from obligate adsorption to non-obligate adsorption, with a slower adsorption speed (Hu et al., 2010).

The adsorption isotherms of mildly, moderately and severely saline-alkaline soil to Cd (II) was fitted by Langmuir and Freundlich models, and the fitting parameters were shown in *Table 4*.

Table 4. *Adsorption isotherm parameters of Cd (II) on three different soils with saline-alkaline stress*

Soil type	Langmuir parameter			Freundlich parameter		
	q_m	K_L	r	n	K_F	r
Mildly saline-alkaline soil	9573.048	0.021	0.963**	553.913	1.924	0.907**
Moderately saline-alkaline soil	12046.321	0.026	0.941**	787.720	1.940	0.907**
Severely saline-alkaline soil	13248.917	0.032	0.938**	958.990	1.947	0.867**

**Highly significant correlation (n = 8, $r0.05$ = 0.707, $r0.01$ = 0.834)

As can be seen from *Table 4*, Langmuir model was used to better fit the adsorption process of Cd (II) of the three soil samples, and the correlation coefficient r values were 0.963, 0.941 and 0.938 respectively. The K_L value in the Langmuir model represents the adsorption affinity constant (Xie et al., 2019), and the larger K_L was, the better the adsorption effect. In the adsorption process of Cd (II) in the three soils, K_L values were 0.021, 0.026 and 0.032, respectively, all of which were greater than zero, indicating that the adsorption reaction could be spontaneous at room temperature. The K_F value in the Freundlich model represents the adsorption capacity of Cd (II). The higher the K_F value is, the stronger the adsorption capacity is. The K_F values in the three kinds of saline-alkaline soil were 553.913, 787.702 and 958.990, respectively, which were consistent with the conclusion obtained in the Langmuir model that was: severely saline-alkaline soil > moderately saline-alkaline soil > mildly saline-alkaline soil. The n value in the Freundlich model can represent the adsorption strength, and the larger n value is, the stronger the adsorption strength will be (Ma et al., 2015). The n values of the three kinds of soils were 553.913, 787.720 and 958.990, respectively, indicating that the severely saline-alkaline soil had more and more complex energy adsorption sites.

Study on adsorption thermodynamics of Cd (II) in different saline-alkaline soil

Within the test temperature range (15, 25, 35 °C), thermodynamic fitting parameters of Cd (II) adsorption in mildly, moderately and severely saline-alkaline soil was shown in *Table 5*.

It can be seen from *Table 5* that, with the increasing of temperature, the adsorption capacity of three kinds of soil to Cd (II) gradually increased, and the adsorption capacity of severely saline-alkaline soil was the largest. The Langmuir model had the best fitting

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_315329

effect on Cd (II) adsorption in the three soil, and the correlation coefficient r was greater than 0.915. The higher the temperature was, the more favorable it was for Cd (II) adsorbed on the soil surface to diffuse into the particles, for the transformation of the outer complex to inner complex, and for the transformation of thermodynamically unstable combination to stable combination (Xie et al., 2019). According to the different temperature adsorption capacity, can calculate the 3 different saline-alkaline soil adsorption thermodynamic parameters of $\Delta H°$, $\Delta G°$ and $\Delta S°$, $\Delta G°$ on behalf of the reaction is a spontaneous or spontaneous reaction, $\Delta H°$ on behalf of the reaction is an endothermic or exothermic reaction, $\Delta S°$ representative is an orderly or disorderly reaction, the thermodynamic parameters as shown in *Table 6.*

Table 5. *Thermodynamic models for adsorption of Cd (II) at different temperatures*

Soil type	Temperature T (°C)	Langmuir parameter			Freundlich parameter		
		q_m	K_L	r	n	K_F	r
Mildly saline-alkaline soil	15	9427.858	0.018	0.960**	475.065	1.860	0.909**
	25	9573.048	0.021	0.963**	553.913	1.924	0.907**
	35	13820.899	0.018	0.915**	594.036	1.711	0.863**
Moderately saline-alkaline soil	15	10195.745	0.023	0.955**	647.129	1.963	0.894**
	25	12046.321	0.026	0.941**	787.720	1.940	0.870**
	35	14591.058	0.023	0.970**	743.431	1.752	1.323**
Severely saline-alkaline soil	15	10568.180	0.029	0.956**	802.741	2.054	0.887**
	25	13248.917	0.032	0.938**	958.990	1.947	0.867**
	35	14799.801	0.032	0.937**	978.863	1.846	0.874**

**Highly significant correlation (n = 8, r0.05 = 0.707, r0.01 = 0.834)

Table 6. *Thermodynamic parameters of Cd (II) in three sample soil*

Soil type	Temperature T (°C)	ΔG (kJ·mol^{-1})	ΔH (kJ·mol^{-1})	ΔS (J·mol^{-1}·K^{-1})
Mildly saline-alkaline soil	15	-21.773	9.554	0.109
	25	-23.404		
	35	-25.036		
Moderately saline-alkaline soil	15	-22.084	9.080	0.108
	25	-23.707		
	35	-25.330		
Severely saline-alkaline soil	15	-22.223	8.588	0.107
	25	-23.828		
	35	-25.433		

It can be seen from *Table 6*, experimental design temperature 15 °C, 25 °C and 35 °C range, three kinds of soil $\Delta G°$ values are less than zero, the adsorption process is spontaneous, and with the increasing of temperature, $\Delta G°$ gradually became smaller, the higher the temperature of three kinds of soil Cd (II) adsorption spontaneous stronger; Three kinds of soil reaction enthalpy changing $\Delta H°$ were positive, suggests that Cd (II) in three kinds of soil adsorption process was endothermic reaction; $\Delta S°$ greater than zero, which indicated that adsorption process was disorderly.

Effect of pH on Cd (II) adsorption in soil

pH is one of the most important factors affecting soil adsorption and desorption of Cd (II) (Li et al., 2013). In the pH range of the test (3.0~11.0), the adsorption of Cd (II) by mildly, moderately and severely saline-alkaline soil was shown in *Figure 4*.

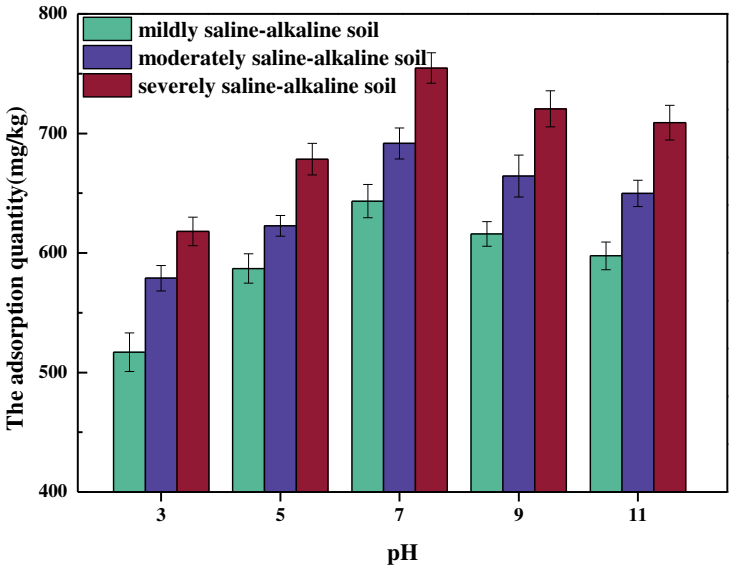

Figure 4. *Effect of different pH values on adsorption of Cd (II) in three sample soil*

It can be seen from *Figure 4* that, with the initial pH of the background adsorption solution increasing, the adsorption capacity of the three tested soil to Cd (II) first increased and then decreased. When the pH of the background solution was 7.0, the adsorption capacity of Cd (II) was the largest, and the adsorption capacity of mildly, moderately and severely saline-alkaline soil to Cd (II) was 643.344 $mg \cdot kg^{-1}$, 691.604 $mg \cdot kg^{-1}$ and 754.728 $mg \cdot kg^{-1}$, respectively. According to different adsorption mechanisms, pH may mainly affect Cd (II) adsorption by affecting the hydrolysis of Cd (II), the exchange between Cd (II) and H^+, the type of adsorption surface, the adsorption surface charge, and the distribution coefficient of Cd (II) in the competitive system. There was a close relationship between pH and Cd (II) adsorption (Adhikari et al., 2003). When pH was low (pH < 7), Cd (II) was subject to competitive adsorption of H^+, with a small amount of adsorption (Xie et al., 2019). With the increase of initial pH, OH^- increased, while the competitive adsorption of H^+ decreased and the adsorption of Cd (II) increased. At a high pH (pH > 7.0), there were a large number of surface functional groups such as sialons, inorganic hydroxyl groups and organic functional groups in the soil, which had negative charges with ·OH functional groups that broke the bond with the side and adsorbed with Cd (II) to form inner ring compounds, increasing the adsorption capacity of Cd (II) (Bradl, 2004).

Effect of adding biochar on Cd (II) adsorption

Biochar is a kind of porous, stable, carbonaceous and highly aromatic solid material obtained by pyrolysis of biomass under hypoxic or anaerobic conditions (Bashir et al., 2018), which has abundant functional groups. The effects of different biochar additions on Cd (II) adsorption capacity were shown in *Figure 5*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_315329

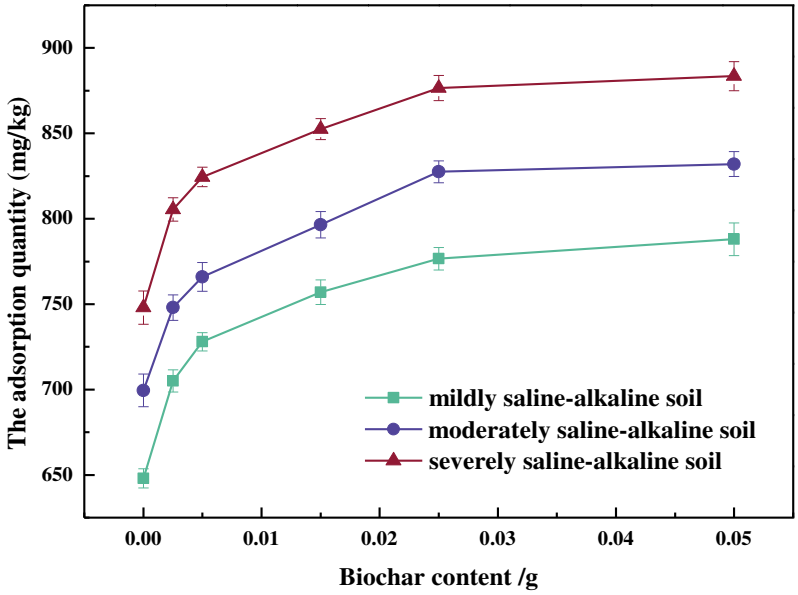

Figure 5. *Relationship between the addition of biochar and pH on adsorption of Cd (II) in three sample soil*

It can be seen from *Figure 5* that, with the increasing of biochar quantity, the adsorption capacity of mildly, moderately and severely saline-alkaline soil to Cd (II) gradually promoted. Due to the high content of organic matter in biochar, organic matter will react with Cd (II) to form stable complexes (Van Poucke et al., 2018). Surface complexation (inner- and outer-sphere) forms multiatom structures with unique metal-functional groups interactions, playing a predominant role in adsorption of heavy metals onto biochar. For example, heavy metals can be effectively bound by complexation with the carboxyl, phenolic and lactonic functional groups in biochar (Yang, 2019). The addition of biochar will increase the content of organic matter in the three kinds of soil, thus increasing the adsorption capacity of Cd (II). Among them, mildly saline-alkaline soil organic matter content was the lowest, so the increase of adsorption to Cd (II) was the largest, increasing by 21.605%. The three soil tends to be saturated when the biochar content reaches a certain level.

Conclusion

This study examined the kinetics, adsorption isotherm of three different saline-alkaline soil and two environmental parameters (pH and addition of biochar) on Cd (II). Our results indicated the following: (1) The adsorption process of Cd (II) in three different saline-alkaline soil showed a trend of first fast and then slow. The pseudo-second-order kinetic model had a better fitting effect on adsorption kinetics. (2) The adsorption capacity of Cd (II) was: severely saline-alkaline soil > moderately saline-alkaline soil > mildly saline-alkaline soil and the adsorption capacity gradually increased with the increase of Cd (II) concentration. The Langmuir model fitted the adsorption isotherm well. (3) The adsorption of Cd (II) by saline-alkaline soil was a spontaneous, disordered and heat-absorbing reaction under the test temperature 15 °C, 25 °C, and 35 °C.(4) Cd (II) adsorption effect of three soil was the best when pH was 7.0 between 3.0 and 11.0. (5) With the addition of biochar, the adsorption of Cd (II) in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_315329

sample soil was increased, and which in mildly saline-alkaline soil promoted most significantly.

Our research demonstrated the importance of temperature, pH and organic matter in controlling the environmental behavior of cadmium in saline-alkaline soil. For example, Cd content in the same area saline-alkaline soil in summer will be lower than the same year winter, especially severely saline-alkaline soil areas, considering adding the biochar to increase soil organic matter content, reducing the content of Cd in soil, or adopting dripping irrigation technology to decrease the soil pH around the crop root, reducing Cd in the soil solution and thus reducing crop uptake Cd. As a result, the investigation of saline-alkaline soil's characteristics will improve the saline-alkaline soil restoration technology which is a benefit to the environment and human health. Hence, there have two methods to recover saline-alkaline soil: one of it is to adjust pH in soil to neutral to remove heavy metal. In addition, its perspective to research environmental-friendly adsorbents like biochar with more active sites, lower energy cost and could recycle wastes as stalks.

Abstract. Anaerobic digestion (AD) of chicken manure (CM) is easily inhibited by excessive ammonia. To determine early warning indicators of this process, mesophilic AD of CM was conducted by organic loading rate (OLR) from 1.0 to 7.0 g volatile solids (VS)/(L·d). Process parameters were monitored every day. At the maximum stable OLR of 5.0 g VS/(L·d), the volumetric methane production rate reached the maximum value of 1.13 L/(L·d), and the yield of methane was 178 ml/g VS. Meanwhile, the total and free ammonia nitrogen increases to 3900 and 300 mg/L (the maximum value), respectively. Bicarbonate alkalinity (BA) and volatile fatty acid (VFA) values were 12200~17400 mg/L and 1000~2200 mg/L, respectively. This process was severely inhibited by high ammonia concentration when the OLR reached 6-7 g VS/(L·d). According to our study, the most useful early warning indicators are CH_4/CO_2, VFA/BA, and individual VFAs for AD of CM.

Keywords: *chicken manure, anaerobic digestion, organic loading rate, early warning indicators, ammonia inhibition*

Abbreviations: AD: anaerobic digestion; CM: chicken manure; OLR: organic loading rate; VFA: volatile fatty acid; BA: bicarbonate alkalinity; TAN: total ammonia nitrogen; FA: free ammonia; CSTR: continuous stirred tank reactor; TS: total solid; VS: volatile solid; HRT: hydraulic retention time; FID: flame ionization detector; PA: partial alkalinity; IA: intermediate alkalinity; TA: total alkalinity; VMPR: volumetric methane production rate; MY: methane yield; ORP: redox potential

Introduction

Anaerobic digestion (AD) is an effective approach to minimizing organic waste and recovering valuable energy (Cioabla et al., 2013). AD is a multi-stage biochemical process (MBP) in which complex organic materials undergo the reaction series of hydrolysis, acidogenesis, acetogenesis, and methanogenesis. Each metabolic stage is controlled by various types of microorganisms, which differ in their habitat requirements, nutritional needs, ability, and growth kinetics to tolerate environment stresses.

Chicken manure (CM) has higher nitrogen contents than other substrates, such as cow manure, pig manure, waste active sludge, and food waste (Qiao et al., 2011). This nitrogen is translated to amino acids, which can be used to synthetize substrate for cell utilization. However, excess nitrogen is further decomposed to ammonia, which exerts a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_331343

toxic inhibitory effect on microorganism metabolism, and causes failure of AD under high organic loading rates (OLR) (Angeladaki et al., 2003; Malollari et al., 2016). Several previous studies have reported AD inhibition at 1.5 to 4.0 g N/L of ammonia concentrations for different strains and culture conditions (Hashimoto, 1986; Hendriksen et al., 1991), and severe inhibition at higher ammonia concentrations. Ahring (1995) reported that AD of livestock was inhibited when ammonia nitrogen (AN) concentrations were 3000~4000 mg/L. Hashimoto (1986) and Zeeman (1985) reported that AD process was imbalanced at 2500 mg/L and 1700 mg/L of total ammonia nitrogen (TAN), respectively. Furthermore, methanogens are severely inhibited, and more than 80% of methane production is suppressed, at TAN values of 8000 mg/L (Krylova et al., 1997).

However, the non-ionized form of ammonia nitrogen: free ammonia (FA), also influences AD inhibition. Studies have shown that it is FA rather than TAN that inhibits methanogenesis. For example, AD inhibition in livestock waste and swine manure occurred at FA concentrations of 700~1100 mg/L (Kayhanian, 1994).

Hence, to maintain steady operation, most large-scale AD are usually operated at low OLR, resulting in a less efficient, low biogas production, and less economic process (Tampio et al., 2014). Ensuring stable AD under high OLR is an urgent problem that should be solved. Previous research has involved monitoring and controlling the process to improve stability and efficiency (Li et al., 2014), using a number of parameters including pH, alkalinity, volatile fatty acids (VFAs), AN, methane contents, biogas production, coupling indicators, and alkalinity ratios. However, the early warning indicators of AD inhibition differed in each study.

Review of literature

Fischer et al. (1984) found that propionic acid rises prior to the failure of digesters for treating swine waste. Nakakubo (2008) concluded that butyrate, valerate, and iso-butyrate could be used as the warning indicators in continuous stirred tank reactors (CSTR) for pig manure treatment, whereas acetate and propionate were not suitable. Li (2014) performed AD of food waste by a CSTR, and concluded that several coupled indicators, such as alkalinity ratios (IA/BA, BA/TA), VFA ratio, and alkalinity (VFA/BA) could be used for reflecting the metabolism of AD system to generate rapid and effective early warnings. Furthermore, Martín-González (2013) recommended an IA/PA ratio < 0.3 for maintaining stable operation in mesophilic AD process of sorted organic fractions from municipal solid waste.

However, there are few studies evaluating the instability of chicken manure anaerobic digestion. Therefore, early warning indicators applicable to indicate instability during the CM AD process were determined in this study. Instability mechanisms of high-nitrogen substrate AD were analyzed. Controlled measures were recommended to ensure stable mesophilic AD of CM.

Materials and methods

Substrate and inoculum

Five batches of CM were collected from a chicken farm (Chengdu, China), then, the CM was stored at 4 °C after removing visible bristles. CM characteristics, such as the

total solid (TS), volatile solid (VS), total carbonate (C %TS), total nitrogen (N %TS), and the ratio of C and N (C/N) were analyzed and listed in *Table 1*.

Table 1. *Composition of chicken manure*

Characteristics	Batch 1	Batch 2	Batch 3	Batch 4	Batch 5
TS (g/kg)	207.1	174.4	155.8	215.3	262.3
VS (g/kg)	119.0	122.0	119.0	125.0	146.0
Carbon (%TS)	29.6	29.8	30.1	30.5	29.0
Nitrogen (%TS)	3.1	3.2	3.2	3.3	2.3
C/N	9.5	9.4	9.4	9.3	12.9
Ammonia nitrogen (mg/L)	2800	3000	2820	2900	2750

The inoculum was the digested residue taken from an AD for pig waste treatment. The inoculum was acclimated for 25 d in the CSTR system under mesophilic conditions (35 °C) fed CM as a substrate until the methane contents were > 60%. The pH in the acclimated inoculum was 7.5.

AD

A bench-scale CSTR with a working volume of 55 L was operated at mesophilic conditions (35 ± 2 °C) as shown in *Figure 1*. The reactor was designed by laboratory, which was heated by the electric heating layer and mixed with a motor. An gas flow-meter and online biogas analyzer were used to measure the biogas produciton and contents of methane (CH_4) and carbon dioxide (CO_2), respectively. Other indicators, such as temperature, pH, and redox potential, were monitored using the online liquid monitoring system. The substrate tank was stirred 8 times per day at 40 rpm for 30 min to maintain the material in a constant state.

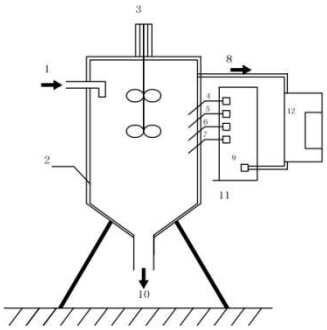

Figure 1. *Schematic diagram of the CM AD in CSTR. (1. Feed inlet, 2. Heating layer, 3. Rabbler, 4. pH probe, 5. Oxidation reduction probe, 6. Electrical conductivity probe, 7. Temperature probe, 8. Air outlet, 9. Gas flow indicator, 10. Discharge outlet, 11. Instrument cabinet, 12. Automatic monitoring instrument for methane analysis)*

The mesophilic AD of CM was carried out at OLRs of 1.0, 2.0, 3.0, 4.0, 5.0, 6.0, and 7.0 g VS/(L·d). After successful start-up, AD was operated in semi-continuous mode. The substrate was added once per day after sampling. By restricting the total feed to

Analytical methods of samples

TS and VS were measured by standard methods (Walter et al., 1998). C and N were monitored by a Vario EL element analyzer (Elementar Analysensysteme GmbH, Germany). Daily gas production and cumulative gas production were analyzed online by the gas flowmeter manufactured by Beijing Sevenstar Electronics Co., Ltd in China. Biogas compositia analyses were performed online by an automatic biogas analyzer made in Wuhan Cubic Optoelectronics Co., Ltd, China. Individual VFA were measured by a gas chromatographer (GC, Agilent-6890N) equipped with a flame ionization detector (FID) (Li et al., 2010). Partial alkalinity (PA), total alkalinity (TA), intermediate alkalinity (IA), and bicarbonate alkalinity (BA) were monitored by a ZDJ-4B Automatic Potentiometric Titrator (Shanghai Precision & Scientific Instrument Co., Ltd, China), in accordance with the methods of Anderson and Yang (1992). The alkalinity was titrated to a PA of pH 5.75, and an IA of pH 5.75 to 4.30 (Ripley et al., 1986). The pH end-point for TA was 4.00. BA was calculated from *Equation 1* (Jenkins et al., 1983).

$$BA = 1.25\,PA \quad \text{(Eq.1)}$$

where BA is bicarbonate alkalinity (mg/L) and PA is partial alkalinity (mg/L). TAN was determined by Nessler's reagent spectrophotometry according to Chinese Standard (GB 7479-87). The FA was calculated by *Equation 2* (Kayhanian, 1999).

$$FA = \frac{TAN \times K_a}{K_a + [H]} \quad \text{(Eq.2)}$$

where FA is represented by FA concentration (mg/L), TAN is represented by TAN concentration (mg/L), K_a is represented by temperature dependent dissociation constant (25 °C:0.564×10^{-9}, 35 °C:1.097×10^{-9}, 55 °C:3.77×10^{-9}), and [H] is represented by hydrogen ion concentration (10^{-pH}).

Results and discussion

Volumetric methane production rate (VMPR) and methane yield (MY)

Methane generation is an important parameter for the stability of AD. VMPR and MY were to describe the biogas production process. The HRT was 20 days and OLR was maintained at a steady-state in the latter 10 days. *Figure 2a* and *b* presents the VMPR and MY of seven OLRs 1.0–7.0 g VS/(L·d).

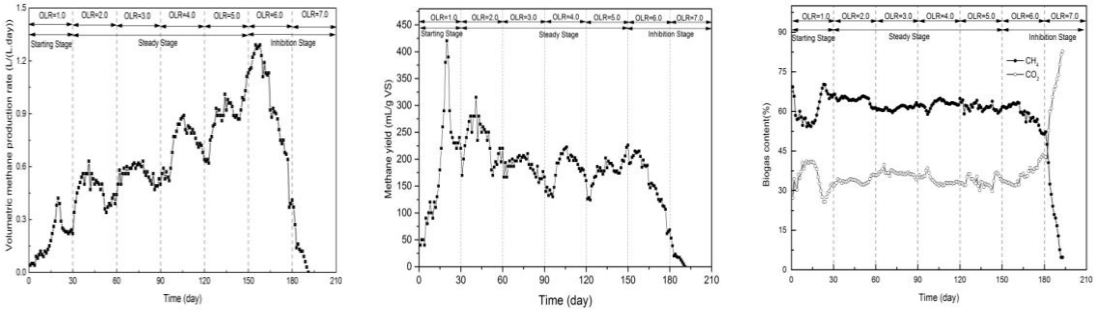

Figure 2. *Evaluation of (a) volumetric biogas production rate, (b) material yield, and (c) biogas content*

During the starting stage, VMPR was low (0.22–0.39 L/(L·d)). Subsequently, AD reached a steady stage, where VMPR increased continually with the increase in OLR. The VMPR was achieved at 0.44, 0.57, 0.81, and 1.13 L/(L·d) at OLR of 2.0, 3.0, 4.0, and 5.0 g VS/(L·d), respectively. As AD reached the inhibition stage (6.0–7.0 g VS/(L·d)), VMPR began to decline until methane production ceased on day 191.

MY reflects the biotransformation of substrate by AD microorganisms, which illustrates the metabolic process of microorganisms. In the starting stage, MY was in the range of 220–390 mL/g VS. With OLR increase, the MY of AD displayed a narrower range between 155 and 225 mL/g VS. During the inhibition stage, MY decreased sharply to zero.

Biogas contents

CH_4 is the terminal metabolite of anaerobic digestion, and it can directly reflect the metabolic activity of methanogens (Charles et al., 2011). As shown in *Figure 2c,* in the initial 20 days of the starting stage, CH_4 content was less than 60% and CO_2 content was approximately 40%. During the steady stage, the CH_4 and CO_2 contents were maintained at 60%–65% and 30%–35%, respectively. As OLR increases to 6.0–7.0 g VS/(L·d), the CH_4 contents decrease to < 60% on the 165th day. Then, CH_4 contents drop rapidly to < 50% on 180th day, while CO_2 contents increase.

VFAs

VFAs are the important intermediate metabolite of AD, which are mainly generated from hydrolysis and acidogenesis. All VFAs must first be degraded to acetate then degraded to methane. The conversion rate of different individual VFAs varies in the following order: acetate > n-butyrate > propionic acid (Ren et al., 2003). Propionic acid value was suggested as early warning indicators for the AD failure of pig manure

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_331343

treatment (Pullammanappallil et al., 2011). Hill (1988) showed that *iso*-acid value would be a better indicator, while Ahring (1991) recommended that the concentration of butyrate acid and its isoforms could be indicated early AD instability.

In this study, individual VFAs, including acetate, propionate, *n*-butyrate, *iso*-butyrate, *n*-Valerate, and *iso*-Valerate, were detected each day, as shown in *Figure 3*. It was clear that each individual VFA increased with OLR, especially during the inhibition stage. Individual VFAs fluctuated slightly as the OLR to 1.0 g VS/(L·d), owing to the microorganism community adapting to the new material. During the steady stage, VFA levels maintained a stable range. As the OLR lower than 4.0 g VS/(L·d), acetate and propionate concentration remained below 1000 and 100 mg/L, respectively. Values of *n*-butyrate, *iso*-butyrate, *n*-Valerate, and *iso*-Valerate were bellow 60, 50, 10, and 80 mg/L, respectively. With the OLR increase from 4.0 to 5.0 g VS/(L·d), the concentration of acetate and propionate reached more than 1500 and 250 mg/L, respectively.

As OLR higher than 5.0 g VS/(L·d), individual VFAs increased dramatically. Among these, acetate and propionate increased by more than 4 and 9 times during the inhibition stage to 14387 mg/L and 2818 mg/L, respectively. The other VFAs, such as *n*-butyrate, *iso*-butyrate, *n*-Valerate, and *iso*-Valerate, increased by approximately 40, 26, 32, and 19 times during the instability period, respectively. This could lead to the irreversible acidification of AD, adversely affecting the methanogenesis process and even terminating gas production. The detailed VFA changes are listed in *Table 3*.

Table 3. *Significant changes in indicator level during inhibition stage*

Indicators	Sudden change	Days of sudden change (d)	Threshold of inhibition	Warning time (d)
CH_4 (%)	56→54	175	< 55	16

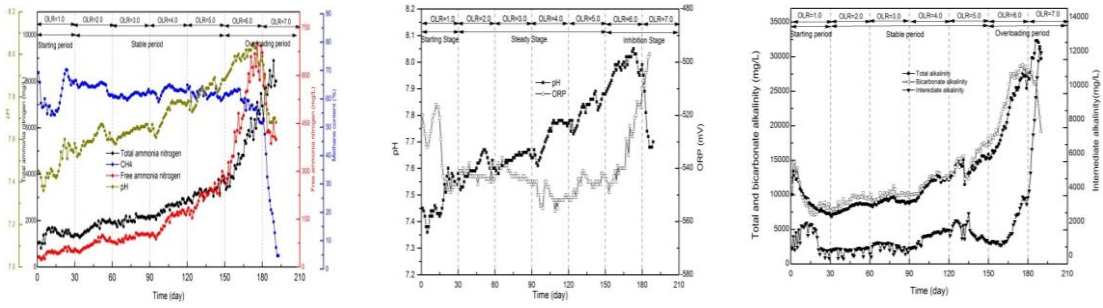
Total ammonia nitrogen (TAN) and free ammonia (FA)

Ammonia is produced from nitrogenous compounds, which contain protein, phospholipids, nucleic acids, and other nitrogenous lipids (Kayhanian, 1999). Theoretically, all organic nitrogen material in the feedstock can be converted to ammonia (NH_3 and NH_4^+). Relationship between the ionized and non-ionized forms of ammonia nitrogen is shown in *Equation 3*. NH_3 is suggested as the main factor of AD inhibition due to its freely membrane permeable (Kroeker et al., 1979).

$$NH_3 + H_2O \rightarrow NH_4^+ + OH \quad \text{(Eq.3)}$$

In this study, the ammonia nitrogen content of substrate was 4000 mg/L. TAN increased slowly from 1040 mg/L to 3700 mg/L at day 1 to day 150 (1.0–5.0 g VS/(L·d)) shown in *Figure 4a*. The methane content was over 60% during these stages. FA increased from 46 to 224 mg/L with pH increasing. The level of TAN and FA was low; approximately 3000 and 200 mg/L, respectively, and no inhibition occurred. This contrasts with the conclusion of Velsen (1979), that is TAN concentration above 3000 mg/L exerts an inhibiting effect on the reactor. With OLR increased to 6.0 g VS/(L·d), TAN and FA increased dramatically. On day 167, TAN concentration was higher than 5000 mg/L, FA exceeded 500 mg/L, and the methane content decreased slightly to < 60%, which was consistent with VFAs increase. Methane contents remained at 55%–60%, but volumetric methane generation rate decreased sharply, from 0.91 to 0.43 L/(L·d), during days 167–180. Therefore, the reactor was severely inhibited.



a b c

Figure 3. *Evaluation of (a) total ammonia nitrogen and free ammonia nitrogen, (b) pH and redox potential (ORP), and (c) alkalinity*

After 180 days, TAN increased continuously to above 8000 mg/L, pH decreased from 7.99 to 7.68, respectively, leading to a slight decrease in FA, with the average value being 456 mg/L. When the VFA levels were higher than 6600 mg/L, volumetric methane production rate decreased < 0.4 L/(L·d). When biogas production ceased, TAN, VFA, and FA levels reached 8009 mg/L, 20945 mg/L, and 400 mg/L, respectively. TAN increased steadily, with no sudden changes. FA concentration showed a positive correlation to pH value (correlation coefficient: 0.846). Therefore, TAN and FA values on their own were proved unsuitable for indicating AD instability. It is essential to combine them with other indicators to decide threshold of TAN and FA that inhibits the process of AD.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_331343

pH

pH is a crucial parameter related to growth and metabolism of microorganism. Accumulation of VFAs could cause pH to rapidly decrease in the low buffering capacity digester. However, in the high buffering capacity digester (Anderson et al., 1992), especially during fermentation of high ammonia nitrogen material, pH levels gradually increase until failure. In this study, as shown in *Figure 4b,* pH value increased from 7.48 to 7.98 during the first 173 days. Although the pH level declined after day 174, it remained in the normal range, with pH at an average of 7.74. The pH value was in the optimal range for fermentation during inhibition stage; however, biogas production and methane content were low. Synergistic action between NH_3, VFAs, and pH lead to a special state called the "inhibited steady state" (Li et al., 2008). Therefore, pH is not regarded as an early warning indicator in high ammonia nitrogen systems.

Redox potential (ORP)

The redox potential (ORP) reflects the redox situation in the microbial cell. It is related to the level of NADH/NAD^+, which affects the growth and metabolism of microorganisms (Graef et al., 1999). Some studies suggested a good correlation between the accumulation of VFAs and ORP (Switzenbaum et al., 1990). As shown in *Figure 4b,* ORP fluctuated from -530 mV to -510 mV in the first 17 days of the starting stage. Despite the increase of OLR, ORP remained lower than -530 mV until day 167. The sharp increase in ORP may be due to microorganisms oxidizing NADH to NAD^+ by producing propionic acid and hydrogen (*Eqs. 4-5*). Hydrogen was not detected in the gas phase during AD in this study. That is because hydrogen was consumed by homoacetogenic bacteria or hydrotrophic methanogens (*Eqs. 6-7*). However, the variation of ORP should be based on the NADH and NAD^+ concentration. In future, it is necessary to quantitatively determine concentrations of NAD^+ and other related enzymes.

$$C_6H_{12}O_6 + 2NADH + 2H^+ \rightarrow CH_3CH_2COOH + 2H_2O + 2NAD^+ \quad \text{(Eq.4)}$$

$$NADH + H^+ \rightarrow 2NAD^+ + H_2 \quad \text{(Eq.5)}$$

$$CO_2 + 2H_2 \rightarrow CH_3COOH \quad \text{(Eq.6)}$$

$$CO_2 + 4H_2 \rightarrow CH_4 + 2H_2O \quad \text{(Eq.7)}$$

Alkalinity

During AD, buffering capacities are typically evaluated using alkalinity levels, including TA, BA, PA, and IA. Before sudden change of pH, alkalinity is sensitive to accumulation of VFAs. In the anaerobic digester, TA was proved to be insensitive as the result of the combination of VFA and bicarbonate (Björnsson et al., 2001). BA has an empirical correlation with VFA accumulation (Hawkes et al., 1994); thus, BA is used to neutralize VFA instead of TA (Moosbrugger et al., 1993). However, as the ammonia adds alkalinity to the system in the high ammonia system, the relationship is not observed in response to ammonia overload.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_331343

As shown in *Figure 4c,* alkalinity level showed a constant increasing trend, while the TAN level in the digester increased continuously. During the steady stage, that is 2.0–5.0 g VS/(L·d)), the TA, BA, and IA were at the range of 9000–15000 mg/L, 10000–17000 mg/L, and 900–2500 mg/L, respectively. For an OLR of 6.0 g VS/(L·d), TA and BA increased obviously from 15000 to 27000 mg/L, 17000 to 28000 mg/L, respectively. IA levels exceeded 3000 mg/L on day 174. After 180 days, BA decreased from 28000 to 19000 mg/L until biogas production ceased, owing to the IA level increasing dramatically to 12576 mg/L, the maximum value. In high ammonia system, the main buffers in AD are bicarbonate (HCO_3^-) and NH_3, with a pKa of 6.3 and 9.3, respectively (Moosbrugger et al., 1993) The accumulation of VFA did not lead to a decline in pH or BA because the ammonia reacts with the accumulated VFA before BA due to the higher pKa. The accumulated VFAs consume BA, producing equivalent IA. Therefore, TA and BA are unsuitable warning indicators due to their insensitivity to the high ammonia system. IA does response to the overloading, so it is thought to be an effective indicator during AD of CM.

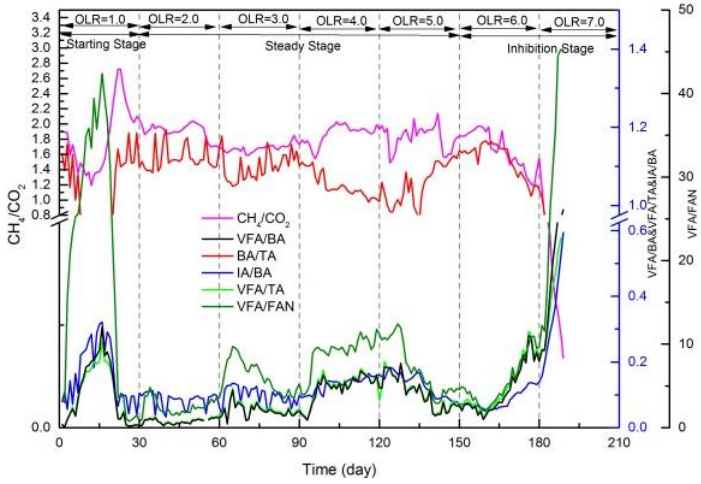


Figure 4. *Development of coupling indicators*

Screening for early warning indicators

Gas production rates are potential indicators in the metabolic status of the digester. Lowering gas production rate, compared with influent rate of organic matter, provides a warning of soluble acid product accumulation in the liquid phase. Unfortunately, that is the result of an imbalance rather than a warning of an imbalance. Changes in the biogas production rate depend on HRT, OLR, and feed composition. Moreover, gas production rate is low sensitive to overload compared to other process indicators. Therefore, it is not a significant early warning indicator. Warning time was defined as the day on which the biogas production ceased minus the day of sudden change in this study. Biogas production ceased on day 191.

Several studies defined alkalinity ratio as monitoring parameter to indicate AD instability. Actually, diverse stability limit values have been proposed in many studies dealing with various substrate and experimental conditions (Rincón et al., 2008). In the mesophilic lab-scale upflow anaerobic sludge blanket (UASB) which is reating potato-starch wastewater, the IP/PA ratio of 0.4 was suggested to ensure reactor stable, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_331343

IA/PA below 0.3 was proposed to maintain operation stable in the AD of municipal solid waste. In this study, combined parameters, including the ratio of CH_4/CO_2, VFA/TA, VFA/BA, VFA/FAN, IA/BA, and BA/TA were calculated, as shown in *Figure 4,* and evaluated as potential indicators of AD instability.

During the starting and stable stages, all ratios became relatively stable after 20 days. However, during the inhibition stage, the ratios increased or decreased by varying degrees. The VFA/BA and VFA/TA curves almost overlapped. Before 150 days, the ratios of VFA/TA and VFA/BA were below 0.2. After 174 days, the ratios increased sharply to 0.98 and 0.66, respectively, until gas production ceased. However, there were no crucial sudden changes in the ratios of IA/BA and BA/TA. Before 182 days, the range of IA/BA was 0.05–0.15 whereas BA/TA was 0.8–1.2 prior to 187 days. The sharp curve of the VFA/FA ratio was similar to that of VFA/TA and VFA/BA. Before 181 days, the ratio of VFA/FA was below 12. Early warning days and sudden changes in each indicator are listed in *Table 3*.

According to the early warning times of VFAs indicators, propionate is later than all other individual VFAs, which is including acetate, n-butyrate, i-butyrate, n-valerate, and i-valerate. In theory, individual VFAs are the most sensitive early warning indicators. Meanwhile, among the combined indicators, the early warning order was VFA/BA = VFA/TA > CH_4/CO_2 > IA/BA > VFA/FA > BA/TA. The VFA/TA, VFA/BA, and IA/BA indicators represent acid-base balance in the system., VFA/TA and VFA/BA were dominant indicators for comprehensively reflecting process status in the high ammonia nitrogen system. The warning time of CH_4 was the same as CO_2; however, the ratio of CH_4/CO_2 showed an earlier warning time than individual biogas contents. Therefore, individual VFAs, as well as the combined indicators, including CH_4/CO_2 and VFA/BA, can be selected as early warning indicators for AD of CM instability under mesophilic conditions. The thresholds of each indicator are shown in *Table 3*.

In our experiments, the biogas content was determined online by an automatic biogas analyzer. CH_4/CO_2 was more sensitive to AD instability owing to the superposition effect. Individual VFAs can be detected online by gas chromatography or near-infrared spectroscopy. It is more convenient for indicators to be monitored online to control AD instability. Therefore, the ratio of CH_4/CO_2 and individual VFAs can be monitored online in real time, enabling effective warnings of AD instability during CM engineering applications.

Inhibitory conduction process

High ammonia concentration of substrate and increasing OLR led to ammonia nitrogen accumulation in the system., The difference in intracellular pH caused transformation between NH_4^+ and NH_3 due to ammonia molecules diffusing into the cells of methanogens. Accumulated NH_4^+ may inhibit the methane-synthesizing enzyme, NH_3 could break the imbalance of protons and result in a potassium deficiency (Kayhanian, 1999). High concentrations of NH_3 mainly inhibit the metabolism of methanogens, particularly aceticlastic methanogens, as well as severely affecting the growth rates of hydrogen-utilizing methanogens (Björnsson et al., 2001). H_2 and CO_2 is used by homoacetogenic bacteria to produce acetate. These factors caused the increase of acetate concentration during the inhibition stage. Subsequently, the accumulation of propionate, n-butyrate, iso-butyrate, n-valerate, and iso-valerate was observed owing to the inhibition of syntrophic VFA-oxidizing bacteria. With ammonia nitrogen

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_331343

concentration increasing, the pH of the system increased continuously. The NH_3 reacted with CO_2 induced duringad to form bicarbonate. The buffering capacity increases during AD owing to the reaction. Therefore, BA and TA increased during the stable stage. Due to the accumulation of VFA, on day 180, BA was consumed, producing IA, and releasing the gas phase as CO_2. Therefore, BA decreased and IA increased. At the same time, CO_2 content increased and CH_4 content declined sharply. Finally, acetotrophic methanogens and hydrotrophic methanogens were completely inhibited, causing biogas production to cease.

Conclusions

For AD of CM with high ammonia nitrogen concentration, increasing the OLR led to ammonia accumulation, and high pH values led to the release of free ammonia. This effected the growth and metabolism of methanogens, causing VFA accumulation and termination of biogas production. For the early warning of AD instability, CH_4/CO_2, VFA/BA ratios, as well as individual VFAs, are regarded as effective indicators. To measure AD stable operation at a high OLR, it is critically to take suitable measures, including dilution, bioaugmentation, and other efficient methods. In this study, the high-ammonia nitrogen materials were selected for AD, and the instability early warning indicators were obtained, which provides a theoretical basis for the stable operation of high ammonia nitrogen materials under high loading rate. Furthermore, in the future study, it is necessary to research the microbial community structure in order to analyze the mechism of the instability deeply.

Abstract. Pricklyash has important economic, medicinal and ecological value. Pricklyash rust is one of the main diseases of the plant, it often causes discoloration, necrosis and abscission of Pricklyash leaves. When the disease is serious, it can cause entire leaves of pricklyash to fall off and infect repeatedly, which can lead to the weakening of pricklyash, even death, and seriously affects its yield and quality. The spore morphology of pricklyash rust with different symptoms was observed and ITS sequence was analyzed and compared, the results showed that 60 samples of pricklyash rust collected from wild pricklyash, Qujing pricklyash, red pricklyash and green pricklyash belong to Basidio-mycotina, Teliomycetes, Uredinales, Coleosporaceae, *Coleosporium*, *Coleosporium zanthoxyli*. By comparing and analyzing the results of previous studies on *Dendrobium* rust with of pricklyash rust, it was found that *Dendrobium* rust and pricklyash rust were clustered in two populations and the genetic similarity coefficient of ISSR was 0.67. The genetic diversity of *Dendrobium* rust was richer than of pricklyash rust.
Keywords: *pricklyash rust, coleosporium, population genetic structure, molecular marker*

Introduction

Pricklyash (*Zanthoxylum* spp.) belongs to deciduous small trees or shrubs of Rutaceae, *Zanthoxylum* spp. There are about 250 species of pricklyash in the world, widely distributed in tropical and subtropical regions of Asia, Africa, America and Oceania (Huang, 1997). China is the first country to produce pricklyash and also one of it main cultivating countries in Asia (Li, 2014). There are about 39 species and 14 varieties of pricklyash in China, ranging from Liaodong Peninsula in the Hainan Island in the south, Taiwan in the southeast, and Southeast Tibet in the west (Huang, 1997). Artificially cultivated varieties have green (green pricklyash) and red (red pricklyash) fruits after ripening (Li, 2014).

Pricklyash is not only an important seasoning, but also a key traditional Chinese medicine (Gu, 2015). Pricklyash has a strong aromatic odor, which can mask other smells, disperse cold in the warm, cool down body temperature and relieve pain, thus

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_345355

can be used to treat many diseases. With the continuous understanding and analysis of chemical constituents of pricklyash, it has been found that pricklyash contains a variety of chemical constituents which are beneficial to human health and disease treatment. Its rich α-linolenic acid, palmitic acid, linoleic acid and polyunsaturated fatty acid have anti-cancer, anti-inflammatory, anti-oxidation, bacteriostasis, insecticidal and antiseptic effects (Chen, 2016; Chang, 1997; Lee, 2012; Li, 2009; Liu, 2007; Mi, 2014; Paik, 2005). In addition, pricklyash has a strong root system which grows rapidly and has many advantages, such as water and soil conservation, good growth in arid and barren areas, and thus can be used to improve the ecological environment (Gu, 2015). With important economic, medicinal and ecological values, pricklyash has attracted the attention of governments at all levels and enterprises. By 2014, the planting area of pricklyash in China was 1.67×10^6 hm^2 while that in Yunnan Province was 3.03×10^5 hm^2, which accounts for more than 10% of the total planting area of pricklyash in China. Yunnan Province is one of the important production bases of pricklyash in China (Gu, 2015).

Pricklyash rust (*Coleosporum zanthoxyli*) is a common leaf disease in the cultivation area of pricklyash which is less harmful to fruits and infects both seedlings and grown plants of pricklyash (Cao, 1989, 1994; Zhang, 2006). Tt often causes discoloration, necrosis and abscission of pricklyash leaves. When the disease is serious, it can cause the whole leaves of pricklyash to fall off and infect repeatedly, which can lead to the weakening of pricklyash, even death, and seriously affects the yield and quality of pricklyash. In recent years, pricklyash rust has occurred in large areas in Shandong, Shaanxi and other major pricklyash production areas, causing great losses to pricklyash production (Cao, 1989, 1994; Chen, 2007).

Coleosporium zanthoxyli which causes pricklyash rust, belongs to Basidiomycetes, Uredinales, Melampsoraceae, *Coleosporium* fungus. The process of the study of Chinese prickly ash rust, *Coleosporium* fungus can be observed from rust spores of summer and winter spore on the pricklyash, the other rust spore type has not been observed, and its life cycle was unclear. At present, there are few studies on the morphology of *Coleosporium zanthoxyli* and the population genetic structure of *Coleosporium zanthoxyli* on different types of pricklyash. Therefore, on the basis of previous investigation, rust samples from red, green and wild pricklyash in Qujing, Yunnan Province were collected in 2018 and were observed carefully. The population genetic structure of *Coleosporium* on different *Coleosporium zanthoxyli* was analyzed by ISSR molecular markers, and was compared with those on Dendrobium rust. The comparative analysis was carried out in order to provide theoretical basis for the prevention and control of pricklyash rust and the related research fields of *Coleosporium*.

Materials and methods

Materials

Collection of pricklyash rust samples

In this study, rust samples from red, green, wild and local pricklyash were collected from Qujing (N26°53’49”, E103°34’42”), Yunnan Province. When collecting rust samples, the collected rust samples were packed independently with absorbent paper, recorded and then air-dried or stored in a refrigerator at – 80 °C for reserve. Details of the samples are shown in *Table 1*.

Primer ISSR

The molecular markers used in this study were fungal ribosomal rDNA-ITS primers (forward primers: TCCGTAGGTGAACCTGCGG; reverse primers: TCCTCCGCTTATTGATATGC) (Chen, 2007), and six ISSR primers designed and developed by our team. All the primers were synthesized by Shanghai Invitrogen Company. Detailed information is shown in *Table 2*.

Table 2. *The primers used in genetic analysis*

Primer name	**Primer sequence**	**Tm/**°C
ISSR1	AGAGAGAGAGAGAGTC	50
ISSR2	AGAGAGAGAGAGAGKG	48
ISSR3	ACACACACACACACTG	50
ISSR4	ACACACACACACACWC	52
ISSR5	ACACACACACACACYA	50
ISSR6	AGAGAGAGAGAGAGTC	50

Instruments used

The main instruments used in this experiment are: ultra clean workbench, autoclave, drying box, electronic balance, HH-4 digital constant temperature water bath pot, Microfuge18 centrifuge, Blue Shield 522 visible light gel electrophoresis transmission meter, ABI-9700 PCR, 78HW-1 constant temperature heating magnetic stirrer, GeneQuant Pro protein nucleic acid analyzer, Imagequant-300 gel imaging system, ABI-3730XL genetic analytical system, Lycra fluorescence microscope and stereomicroscope.

Methods

Morphology identification of Coleosporium

The symptoms of rust samples collected were carefully observed, and both sides of the susceptible parts of rust plants' leaves were recorded by camera. The morphology of pathogens in the susceptible parts was observed by stereomicroscope, the symptoms were recorded, the spores of rust were picked up for observation, and the infected tissues were cut into water slides to observe the structure of sporulation tissues. The spore morphology, color and size were recorded.

Extraction of Coleosporium DNA

The genomic DNA of plant rust was extracted by Chelex-100 method (Liu, 2015). The details are as follows: 150 uL Chelex-100 (concentration percentage is 20%, 1/3

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_345355

chelex should be absorbed) solution is absorbed by a pipette into a 1.5 mL centrifugal tube, 5 uL supernatant of Chelex-100 is absorbed by a 10 uL pipette to the lesion with rust spores, and the rust spores on the lesion are washed repeatedly so as to elute the spores off the lesion as far as possible, and the washed spores are sucked into a 1.5 mL centrifugal tube containing 150 uL Chelex-100 solution by a 10 uL pipette. The centrifugal tube was placed in boiling water for 2 min, oscillated on vortex oscillator for 20 s, centrifuged for 10 s, then water bath for 5 min, oscillated for 20 s and centrifuged for 30 s. The obtained supernatant is the extracted DNA, which is stored in the refrigerator at -20 °C for reserve.

Molecular identification of Coleosporium

The total volume of PCR reaction was 50 uL according to ITS sequence analysis of common primers of fungi ITS sequence, among which: 2×phanta max ×Buffer 25 uL (the final concentration of Mg^{2+} is 2 mM), dNTP Mix 0.2 mM, Phanta Max Super-Fidelity DNA Polymerase 1U, primers ITS1 and ITS4 0.5 mM, template DNA 25 ng/uL. A negative control group of ddH_2O was established for each reaction. Amplification was performed by ABI-PCR. The reaction procedures were as follows: pre-denaturation for 3 min at 95 °C, denaturation for 15 s at 95 °C, annealing for 15 s at 57 °C, extension for 30 s at 72 °C, running for 35 cycles; extension of 5 min at 72 °C, preservation at 4 °C; after the end of PCR, 5 uL PCR fidelity product was mixed with 2 uL loading-buffer which contains anthocyanin (1 mL Loading buffer + 10 uL Anthocyanin), conducted electrophoresis with 1.5% agarose gel for 45 min under 120 V, and then photographed with gel imaging system so as to analyze PCR product initially. The PCR product with identical fragment size was recycled with gel, and then cloned to test its sequences; sequence comparative analysis of the tested ITS sequences was conducted on NCBI website, and the ITS sequences of different plant Coleosporium were clustered by the neighbor-joining method using the software of molecular evolutionary genetics analysis (MAGE 5.1) (Saitou, 1987).

Population genetic structure analysis

The total volume of ISSR-PCR reaction for population genetic structure analysis of various plant rust was 30 uL, including: 10×Easy Buffer (containing Mg^{2+}) 3.0 uL, 2.5 mM dNTPs 2.4 uL, ISSR primer 1.2 uL, TaqE 0.3 uL, template DNA (25 ng/uL) 1 uL, ddH_2O 22.1uL. Coleosporium was used as positive control group and ddH_2O as negative control group each time. The reaction procedures were as follows: pre-denaturation for 2 min 30 s at 95 °C; denaturation for 30 s at 94 °C, annealing for 1 min at 50 °C (the specific annealing temperature of each primer was shown in *Table 2*), extension for 1 min at 72 °C, running for 35 cycles; extension for 10 min at 72 °C, preservation at 4 °C; after the end of PCR, 5 uL PCR product was mixed with 2 uL Loading-buffer which contains anthocyanin (10 uL/mL anthocyanin), conducted electrophoresis with 1.5% agarose gel for 45 min under 120 V, and then photographed with gel imaging system so as to analyze PCR product initially. Samples with PCR products were sent to Kunming Shuo Qing Biological Co., Ltd. for further analysis with ABI-3730XL genetic analysis system.

ISSR-PCR amplified fragments were analyzed by genetic analysis system. The size of ISSR-PCR amplified fragments ranged from 100 bp to 700 bp (internal standard ABI-LIZ1200). The fragments of PCR products obtained by genetic analysis system

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_345355

were transformed into 01 matrix. The PCR products were packed in a box with a width of 10 bp. The population structure was analyzed by unweighted pair group method of with arithmetical averages (UGPMA) cluster analysis NTSY spc 2.1 soft (Rohlf, 2000).

Results and analysis

Oberservation of pricklyash rust symptoms

By observing the rust samples collected from wild pricklyash, Qujing pricklyash, green pricklyash and red pricklyash, it was found that there are various types of symptoms of rust infection (*Fig. 1*). In the early stage of pricklyash rust, pricklyash leaves produced one or more spots of varying sizes. With the deepening of infection, yellow to orange naked summer spore piles appeared on the back of pricklyash leaves. The size of summer spore piles was 0.1-0.7 mm, and the size of winter spore piles was 0.2-1.0 mm at the corresponding parts of late summer spore piles. Some of the lesions of pricklyash rust are irregularly distributed, forming a lesion (wild pricklyash rust) by a single summer spore pile; some are centered on one point with others forming a circle (Qujing pricklyash rust and green pricklyash rust); others are centered on one point, surrounded by two circles, and at the later stage of infection, the outer circle turns red-brown (red pricklyash rust).

Figure 1. *Symptoms of different types of pricklyash rust*

The pathogenic morphology of pricklyash rust was observed under a microscope. It was found that the color of summer spores of pricklyash rust varied from light yellow to yellow. Most of the summer spores were oval, elliptical, rough and warty. The size of summer spores was 30-60 um × 18-25 um (*Fig. 2*). There are 3-4 cells in the winter spores, the top 3 cells are yellow and the base cell is colorless, and the spore size is 55-91 um × 18-29 um (*Fig. 3*). The winter spore often germinates from the top cells and grows germ tubes.

ITS sequence analysis of pricklyash rust

In this paper, the ITS sequences amplified by fungal ITS universal primers were compared and analyzed on NCBI website. It was found that the rust collected from red pricklyash, green pricklyash, Qujing pricklyash and wild pricklyash belongs to Basidiomycotina, Teliomycetes, Uredinales, Coleosporaceae, *Coleosporium*, *Coleosporium zanthoxyli* (*Table 3*). The genetic relationship of the rust samples collected from different types of pricklyash was analyzed by MAGE 5.1. The results showed that except for YHJ-2 having 96% coverage rate and 97.83% similarity rate with *Coleosporium zanthoxyli* of registration number MH465095.1 published on NCBI website, ITS sequences of other samples have 99% or above coverage rate and 99% and above similarity rate with *Coleosporium zanthoxyli* of registration number MH465095.1, especially the 7 samples of QJHJ-1, QJHJ-2, YHJ-3, HHJ-1, HHJ-3, LHJ-1, HHJ-2, which have 99% coverage rate and 100% similarity rate.

Table 3. *Comparison of ITS sequences of pricklyash rust fungus with different symptom types*

Sample name	Query cover%	E-value	Ident %	Homologous species	Accession	Host
QJHJ-1	99	0.0	100.00	Coleosporium zanthoxyli	MH465095.1	Qujing pricklyash
QJHJ-2	99	0.0	100.00	*Coleosporium zanthoxyli*	MH465095.1	Qujing pricklyash
QJ-HJ-3	99	0.0	99.87	*Coleosporium zanthoxyli*	MH465095.1	Qujing pricklyash
YHJ-1	100	0.0	99.85	*Coleosporium zanthoxyli*	MH465095.1	Wild pricklyash
YHJ-2	96	0.0	97.83	*Coleosporium zanthoxyli*	MH465095.1	Wild pricklyash
YHJ-3	99	0.0	100.00	*Coleosporium zanthoxyli*	MH465095.1	Wild pricklyash

HHJ-2	99	0.0	99.73	*Coleosporium zanthoxyli*	MH465095.1	Red pricklyash
HHJ-3	99	0.0	100.00	*Coleosporium zanthoxyli*	MH465095.1	Red pricklyash
LHJ-1	99	0.0	100.00	*Coleosporium zanthoxyli*	MH465095.1	Green pricklyash
LHJ-2	99	0.0	100.00	*Coleosporium zanthoxyli*	MH465095.1	Green pricklyash

In this paper, the genetic relationships between the obtained ITS sequences of pricklyash rust, the ITS sequences of Dendrobium Coleosporium in our previous studies and the ITS sequences of *Coleosporium zanthoxyli* of registration number MH465095.1

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_345355

published on NCBI website were analyzed by MEGA5.10 software. It was found that Dendrobium Coleosporium could be clustered into categories I, II and III, and all of *Coleosporium zanthoxyli* were clustered in category I except from TP-SH-3 and TP-SH-4, which were clustered in category III. The rust collected from other Dendrobium species were clustered in category II.

Genetic diversity analysis of different pricklyash rust

Popgene 1.32 software was used to analyze the genetic diversity of four different types of pricklyash rust. The results (*Table 4*) showed that the population level, Nei's gene diversity index (H), Shannon's information index and percentage of polymorphic loci of wild pricklyash rust were the largest, indicating that the genetic diversity of wild pricklyash rust was the richest, followed by Qujing pricklyash rust, while red pricklyash and green pricklyash have similar genetic diversity. Generally speaking, the genetic diversity of the four types of pricklyash rust is not much different. At the same species level, the percentage of polymorphic loci was 82.72%, the number of observed alleles (Na) was 1.8272, the number of effective alleles (Ne) was 1.2383, the genetic diversity index (H) and information index (I) were 0.1551 and 0.2560, respectively. The number of polymorphic loci was 268, and the percentage of polymorphic loci was 82.72%, indicating the rich genetic diversity of pricklyash rust population (*Fig. 4*).

Table 4. *Genetic diversity of rust fungi populations on different pricklyash*

Population code	Alleles (Na)	Effective allele (Ne)	Nei gene diversity index (H)	Shannon's (I) Shannon information index	Number of polymorphic loci	Percentage of polymorphic loci
HHJ	1.5556	1.1976	0.1277	0.2068	180	55.56
LHJ	1.537	1.2041	0.1292	0.2069	174	53.70
YHJ	1.6296	1.2465	0.1577	0.2519	204	62.96
QJHJ	1.5031	1.2368	0.1424	0.2199	163	50.31
Average	1.5563	1.2213	0.1393	0.2214	180	55.63
Total of species	1.8272	1.2383	0.1551	0.2560	268	82.72

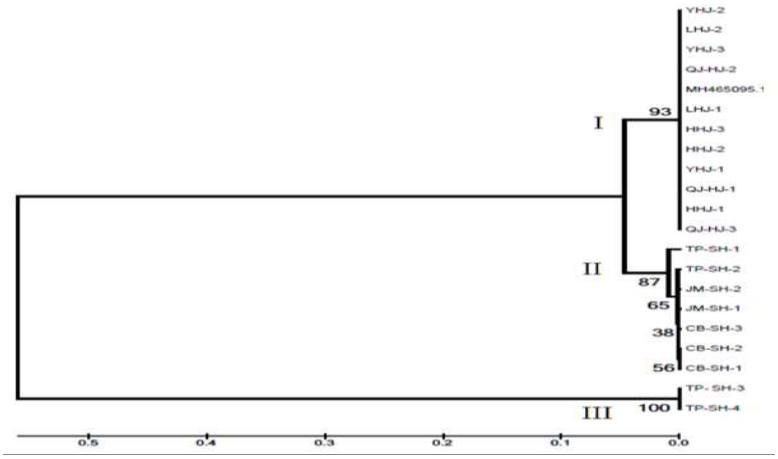

Figure 4. *ITS sequence comparison dendrogram of different pricklyash and Dendrobium rust. Note: MH465095.1 is: ITS sequence of Zanthoxylum bungeanum with login number MH465095.1 published by NCBI website; ITS sequences of TP-SH-1, TP-SH-2, TP-SH-3, TP-SH-4, JM-SH-1, JM-SH-2, CB-SH-2, CB-SH-3 are the experimental data of this group (Pu, 2019)*

NTsis software was used to analyze the population genetic structure of different types of pricklyash rust. The results (*Fig. 5*) showed that the similarity of four pricklyash rust populations was above 0.74, which was relatively high, and the genetic structure was more complex, and the classification was not very obvious. Especially for wild pricklyash rust and Qujing pricklyash rust, the clustering was dispersed.

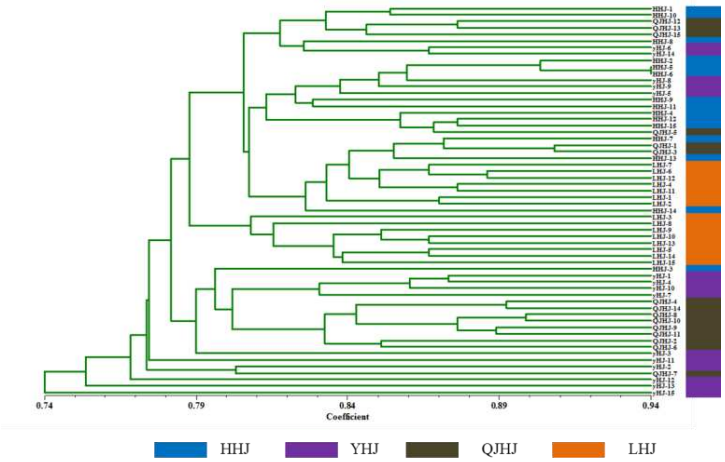

Figure 5. *Population genetic structure of rust on different pricklyash*

Population structural genetic analysis of Coleosporium

The ISSR molecular markers designed by the team were used to analyze the population genetic structure of rusts collected from different varieties of pricklyash and Dendrobium. NTsis software analysis results (*Fig. 6*) showed that rusts on pricklyash and on Dendrobium were clustered in two groups, namely, rusts on Dendrobium clustered in category I while rusts on pricklyash clustered in category II with a similarity coefficient of 0.67, which means that the population differentiation between the rusts on pricklyash and the rusts on Dendrobium was obvious.

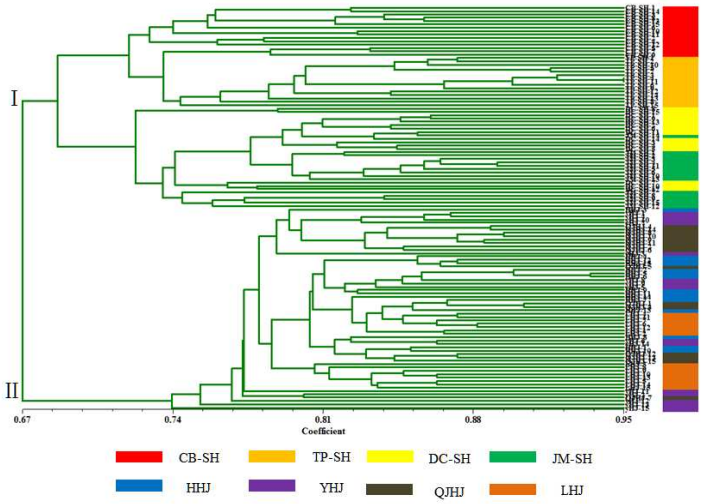

Figure 6. *Population genetic structure of Coleosporium on different pricklyash and Dendrobium. Note: CB-SH, TP-SH, DC-SH and JM-SH are the experimental data of our group (Pu, 2019)*

Discussion

Pricklyash (*Zanthoxylum* spp.) has many species. There are about 250 species of *Zanthoxylum* spp. plants in the world. There are about 50 species, 13 varieties and 2 variants of *Zanthoxylum* in China. Artificially cultivated varieties have green (green pricklyash) and red (red pricklyash) fruits after ripening. pricklyash rust is one of the common diseases on pricklyash, it often causes discoloration, necrosis and abscission of pricklyash leaves, which seriously affects the yield and quality of pricklyash.

The symptoms and spore morphology of 60 samples of rust collected from red pricklyash, green pricklyash, Qujing pricklyash and wild pricklyash were observed in this study. It was found that the symptoms of rust were varied and the size of summer spores of rust varied greatly. ITS sequence analysis showed that these pricklyash rusts with different symptoms and collected from different types of pricklyash were caused by *Coleosporium*. Scholars have reported that *Coleosporium zanthoxyli* is hosted by 9 species of *Zanthoxylum* plants, such as pricklyash and wild pricklyash, as well as *Dendrobium candidum*, *Dendrobium globosa*, etc. (Xi, 2018). Moreover, the ITS sequences of pricklyash and Dendrobium rusts were compared and analyzed to find that most of them had a high similarity of 0.96 (*Fig. 4*), but the population genetic structure of *Coleosporium* derived from pricklyash and Dendrobium was quite different. Therefore, for the highly host-specific *Coleosporium rust*, whether pricklyash rust and Dendrobium rust can be infected by each other requires further research and study.

After analysis, it was found that the population genetic structure of rust on pricklyash was rich. From the ISSR population genetic structure map, we can see that rust on wild pricklyash are distributed in all large populations, which indicates that some rust on wild pricklyash may have close genetic relationship with rust samples on Qujing pricklyash, red pricklyash and green pricklyash. It is speculated that rust on wild pricklyash may be transmitted to each other. *Figure 5* shows that the population differentiation of rust on Dendrobium and rust on pricklyash is obvious. The population genetic similarity coefficient of ISSR is 0.67. The rust on Dendrobium and rust on pricklyash are clustered in two populations respectively. Moreover, Dendrobium rust is closely related to the host varieties of *Dendrobium*, but pricklyash does not show this pattern. This may be mainly due to the fact that the collected samples of *Dendrobium* rust come from greenhouse cultivation, and the possibility of its transmission in the air is relatively small, while pricklyash rust is collected from the field, and its rust spores can be transmitted with the airflow. It can be seen from this paper that while preventing and treating pricklyash rust on different varieties of pricklyash, control of rust on wild pricklyash needs to be further strengthened.

Conclusions

(1) The spore morphology of pricklyash with different symptoms of pricklyash rust was observed, and ITS sequence was analyzed and compared to show that the symptoms of rust on wild pricklyash, Qujing pricklyash, red pricklyash and green pricklyash were various. The pathogens causing different symptoms of pricklyash rust belong to Basidio-mycotina, Teliomycetes, Uredinales, Coleosporaceae, *Coleosporium*, *Coleosporium zanthoxyli.*

(2) By comparing and analyzing the results with previous studies on Dendrobium rust, we found that rust on Dendrobium and rust on pricklyash were clustered in two populations, and the genetic similarity coefficient of ISSR was 0.67.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_345355

(3) The genetic structure of *Coleosporium* on wild pricklyash was rich. The *Coleosporium* on wild pricklyash can be clustered into *Coleosporium* on other varieties of pricklyash, which means that *Coleosporium* on wild pricklyash may be the source of infection of other types of pricklyash rust.

Abstract. Diurnal changes of K^+, Ca^{2+}, Na^+ and Mg^{2+} contents in *Nitraria tangutorum*, *Lycium ruthenicum*, *Peganum harmala* L and *Reaumuria soongorica* were measured to investigate the variation in singular characteristics in dominant plants from Minqin Desert. Sequence of ions contents excluding *Reaumuria soongorica* in an ascending order were $Na^+ > K^+ > Mg^{2+} > Ca^{2+}$, while in *Reaumuria soongorica* it was $Na^+ > Mg^{2+} > K^+ > Ca^{2+}$. Diurnal changes of Ca^{2+} contents in *Nitraria tangutorum* and *Reaumuria soongorica* were not obvious, while, that of Mg^{2+} and K^+ contents had similar U-curve trends in *Nitraria tangutorum*. Na^+ contents varied greatly, content of Mg^{2+} was negatively correlated with light intensity, and positively correlated with K^+ content. Diurnal changes of Ca^{2+} content in *Lycium ruthenicum* were bimodal, while Mg^{2+} content had a U-curve and was negatively correlated with Na^+ content. Diurnal changes of K^+ and Ca^{2+} content in *Peganum harmala* L were not significant, while those of Mg^{2+} content showing U-curve positively correlated with Na^+ content, which had similar trends in *Peganum harmala* L and *Lycium ruthenicum.* Diurnal changes of K^+ and Na^+ contents presented U-curves in *Reaumuria soongorica*, while Mg^{2+} content showed a inverted U-curve. There were no significant correlations between ions, total ions sequence was *Peganum harmala* L > *Lycium ruthenicum* > *Reaumuria soongorica* > *Nitraria tangutorum*.
Keywords: *desert plants, dominant species, illumination intensity, ions contents, correlation*

Introduction

Desertification was the land degradation process in arid area, semiarid area and semi humid region caused by multiple factors including natural factors and human factors. It often caused decreasing in terrestrial ecosystem stability, the reducing in biodiversity and ecological carrying capacity, the degradation in physical and chemical properties of soil, which resulted in ecological environment fragmentation and loss of land productivity (Chen, 2014). Desertification was one of the major ecological environmental problems around the world, while China was one of the countries seriously affected by desertification in the world, and the economic loss caused by desertification had become billions of Yuan (Qi, 2011). Gansu Province was one of the provinces threaten heavily by desertification, especially in Minqin Country. It has become one of the most drought-ridden and desertification hazards regions in China even the world, and it also one of the four birthplaces of sandstorms in Northern China (Yao, 2014; Zhou, 2005). Minqin Country of Gansu Province located in the northeastern of Hexi Corridor, the lower Shiyang River. It was a narrow oasis area between the Tengger Desert and Badan-Jilin Desert. It was an important green barrier to stop two big dessert joining which play an important role in ecological security (Dai,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_357368

2008). At the moment, the oasis in Minqin Country was facing the ecological and environmental crisis (Wei, 2015). So it had great significance in combating desertification of Minqin Country, protecting ecological environment in oasis, and constructing ecological safety barrier of China.

The growth and health status of vegetation determined the recession and expansion of oasis, and the growth of vegetation need nutrient elements. Potassium, calcium, sodium, magnesium was the essential nutrients elements for plants growth and development. Potassium could affect the procedure of plants growth, development and physiological metabolism. Investigating results from Chen et al. (2017) showed the lacking of potassium could restrain the growth of plant roots, and decreased the root-shoot ratio; blocked the synthesis of photosynthetic products at the same time, and declined biomass in the end. Calcium was effective in plant yield increasing and disease prevention, it also played an important role in maintaining the structure stability of cell membrane and cell wall, participating in regulating growth, development and intracellular homeostasis. Calcium was also widely involved in signal transduction in response to various abiotic and biological stresses as a second messenger in plants (Liu, 2014). Deficiency of sodium could cause chlorosis in plants, while high sodium content in soil could cause soil salinization which was a threat to plant growth. Wang et al. (2012) investigated the response from seed germination and seedling growth of *Lycium ruthenicum* to stress, and found that with the increasing concentration of sodium salt, the seed germination rate decreased, and inhibition of seedling growth appeared. Magnesium had important nutritional and physiological functions on plants. It was the central ion of chlorophyll, and activator for many kinds of enzymes which took part in energy metabolism (Wang, 2016). The plants lacking of magnesium could seriously affects the normal growth of plants by the suppression of chlorophyll synthesis and various enzymes activation (Li, 2017), so the investigation on the content and characteristics of these elements could help us for the further understanding of growth characteristics, drought resistance, and stress resistance mechanism of plants.

The investigations of physiological and ecological adaptability for desert plants at present mostly focused on the photosynthesis, transpiration, water use efficiency, and the relationship with the arid environment of desert plants (Zhou, 2005; Su, 2013), while there were only research in the fields of ionization and ion absorption equilibrium for different desert plants (Bai, 2010). Our investigation mainly analyzed the change characteristics of contents of four ions (K^+, Ca^{2+}, Na^+, Mg^{2+}) in desert dominant plants, and the correlation of ion contents with light intensity, which could help people to explore the characteristics of resistances and mineral substances absorption of plants under desert and arid conditions.

Materials and methods

General situation of research area

The research area located in Minqin county of Gansu Corridor in Gansu Province, China (101°49′-104°12′ E, 38°3′-39°27′ N), Tenggeli Desert was in its northeastern, Badanjilin Desert in the northwestern, and oasis zone was in the central.

It was one of the typical Desert oasis in China whose mean altitude was 1400 m, and it was constituted of three kinds of basic landform such as desert, plain, low mountains and hills. The weather in Minqin Country was cold in winter, hot in summer, small amount of rainfalls and droughts, abundant sunlight, strong evaporation, which was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_357368

typical temperate territoriality monsoon climate, annual average precipitation was 113.8 mm, average annual evaporation capacity was as high as 2604.3 mm, the annual average temperature was 7.8 °C, the annual average sunshine hours were 3073.5 h, and frostless season was 162 d. Vegetation in research was desert vegetation, which was mainly consisted of herb, shrub and subshrub, included *Reaumuria soongorica*, *Peganum harmala* L, *Lycium ruthenicum*, *Nitraria tangutorum*, *Artemisia desertorum*, and *Ephedra przewalskii* (Chang, 2008).

Experimental methods

We choose the representative community plots near the Qingtu Lake in Minqin County (102° 51 9 E, 38°34 3 N) in August2017, and set up three quadrats 10 m × 10 m, then statistic the kinds, density, height, coverage of plants in quadrats. We calculated the dominance of every plants (Wang, 2016), and selected four kinds of plants with greater superiority, *Nitraria tangutorum*, *Lycium ruthenicum*, *Peganum harmala* L and *Reaumuria soongorica*. Samples were picked up from overground part of plants every 2 h from 7:00 a.m. for 7 times. Plants samples were prepared by drying , grinding and sieving, the contents of ions such as K^+, Ca^{2+}, Na^+ and Mg^{2+} were measured by Atomic Absorption Method (LBA600,2015.China), determination of local luminous intensity was from Portable Photosynthesis Measurer LI-6400 (LI-COR,1995.USA). The software program SPSS 19.0 was used for statistical analysis of data, program Origin 9.0 for making graphs, respectively.

Statistical methods

Calculation method of coverage

Coverage was the percentage of summation of canopy projection area of all individuals with same kind in quadrats, because the canopy projection was oval, so the calculation formula was:

$$\text{Canopy Projection Area} = \text{Long Crown} \times \text{Short Crown} \times \pi / 4 \quad \text{(Eq.1)}$$

Calculation methods of density radio, coverage radio and height radio

$$\text{Density Radio} = \text{Relative Density} / \text{Maximal Relative Density in Quadrat} \quad \text{(Eq.2)}$$

$$\text{Coverage Radio} = \text{Relative Coverage} / \text{Maximal Relative Coverage in Quadrat} \quad \text{(Eq.3)}$$

$$\text{Height Radio} = \text{Relative Height} / \text{Maximal Relative Height in Quadrat} \quad \text{(Eq.4)}$$

Calculation method of dominance

$$\text{Dominance} = (\text{Density Radio} + \text{Coverage Radio} + \text{Height Radio}) / 3 \quad \text{(Eq.5)}$$

Results

Diurnal changes of four kinds of ion contents in Nitraria tangutorum

Diurnal changes of contents of K^+, Ca^{2+}, Na^+ and Mg^{2+} in *Nitraria tangutorum* were shown in *Figure 1*. Diurnal variation of K^+ content in *Nitraria tangutorum* presented U-shaped curve, K^+ content was 31.38 $g \cdot kg^{-1}$ at 7:00 a.m., then it declined over time and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_357368

reached minimum value of 15.83 g·kg-1 at 13:00 p.m., which rose again to 30.28 $g \cdot kg^{-1}$ at 19:00 pm. Diurnal change of Ca^{2+} content was not obvious with time passed, which mainly in range of 1.36 $g \cdot kg^{-1}$ – 2.55 $g \cdot kg^{-1}$. While there is large variation in content of Na^+ which was unchanged from 07:00 – 11:00 a.m.; after 11:00 a.m., Na^+ content decreased significantly and reached minimum value of 24.60 $g \cdot kg^{-1}$, then it recovering gradually after 13:00 a.m. and achieved 46.71 $g \cdot kg^{-1}$. Diurnal changes tendency of Mg^{2+} content was also U-type curve. Mg^{2+} content was 8.49 $g \cdot kg^{-1}$ at 7:00 a.m., decreased gradually and reached minimum value of 5.03 $g \cdot kg^{-1}$ at 15:00 p.m., then it recovering gradually to 8.95 $g \cdot kg^{-1}$ at 19:00 p.m. Content change of K^+ and Na^+ has the greatest change than other ions in *Nitraria tangutorum*. The range from maximum to minimum value of K^+ contents was 15.50 $g \cdot kg^{-1}$, which was 30.37 $g \cdot kg^{-1}$ of Na^+ content.

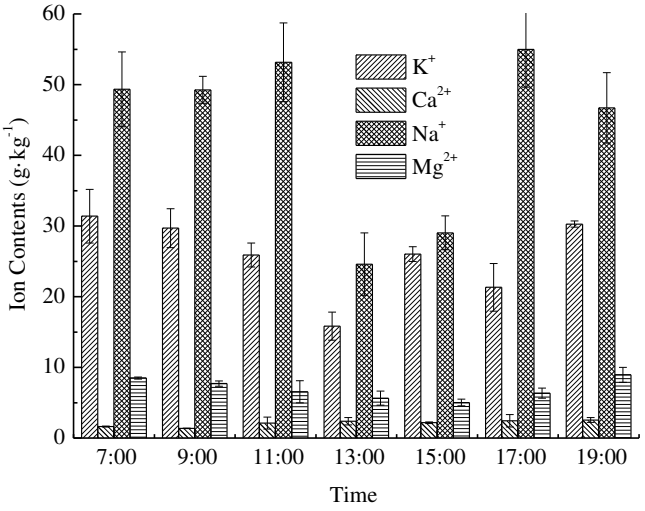

Figure 1. *Diurnal changes of four kinds of ion contents in Nitraria tangutorum*

Diurnal changes of four kinds of ion contents in Lycium ruthenicum

Diurnal changes for contents of K^+, Ca^{2+}, Na^+ and Mg^{2+} in *Lycium ruthenicum* were shown in *Figure 2*. Diurnal variation tendency of K^+ content in *Lycium ruthenicum* was W-curve. Content of K^+ in *Lycium ruthenicum* was 47.55 $g \cdot kg^{-1}$ at 7:00 a.m., then it decreased to minimum value of 19.73 $g \cdot kg^{-1}$ at 09:00 a.m., recovering to 44.62 $g \cdot kg^{-1}$ at 11:00 a.m., and decreased gradually to lower value of 31.51 $g \cdot kg^{-1}$ at 17:00 p.m. It increased to 35.86 $g \cdot kg^{-1}$ at 19:00 p.m. in the end. Diurnal change of K^+ content was always lower than Na^+ content in *Lycium ruthenicum* except at 07:00 a.m. Diurnal variation tendency of Ca^{2+} content appeared double-peak type, and reached peaks of 4.14 $g \cdot kg^{-1}$ / 3.65 $g \cdot kg^{-1}$ at 11:00 a.m. and 17:00 p.m., respectively. Content of Na^+ increased gradually from 07:00 a.m. to 13:00 p.m, and reached 57.91 $g \cdot kg^{-1}$ at 13:00 p.m., then it decreased and shown a lower value of 45.24 $g \cdot kg^{-1}$ at 15:00 p.m, and which increased to a maximum value of 66.10 $g \cdot kg^{-1}$ at 17:00 p.m. Diurnal change tendency of Mg^{2+} content was U-shape curve, which declined gradually during 07:00 a.m. to 15:00 p.m. and reached minimum value of 9.73 $g \cdot kg^{-1}$ at 15:00 p.m., then it recovering to 12.03 $g \cdot kg^{-1}$ at 19:00 p.m. Great change of ion contents in *Lycium ruthenicum* was the K^+ content (whose difference between the maximum and minimum value was 27.82 $g \cdot kg^{-1}$) and Na^+ content (whose difference between the maximum and minimum value was 40.72 $g \cdot kg^{-1}$).

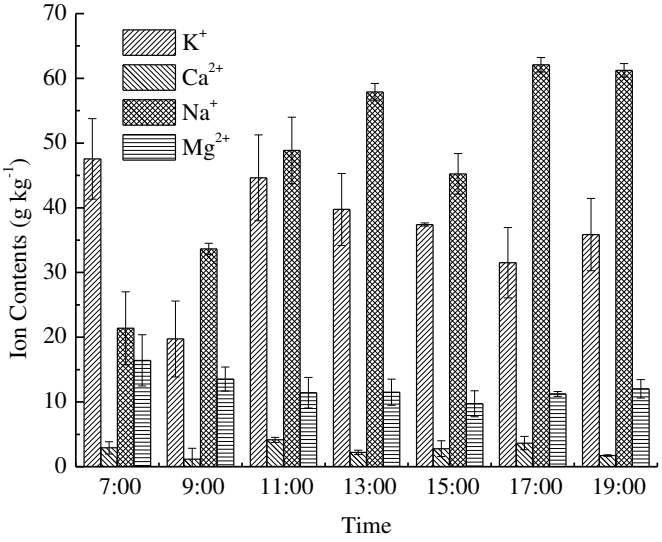

Figure 2. *Diurnal changes of four kinds of ion contents in Lycium ruthenicum*

Diurnal changes of four kinds of ion contents in Peganum harmala L

Diurnal variation in contents of K^+, Ca^{2+}, Na^+ and Mg^{2+} in *Peganum harmala* L were shown in *Figure 3*. Potassium content in *Peganum harmala* L decreased gradually within 07:00 a.m. – 11:00 a.m., and reveal a minimum value of 19.36 $g \cdot kg^{-1}$, then it increased and reached a maximum value of 26.22 $g \cdot kg^{-1}$ at 13:00, and becoming decreased to 23.20 $g \cdot kg^{-1}$ at 19:00 p.m. Diurnal change of calcium content was not obvious the value kept stable at 1.33 $g \cdot kg^{-1}$. Sodium content increased gradually with 07:00 a.m. – 13:00 p.m., and reached 92.51 $g \cdot kg^{-1}$ at 13:00 p.m., then it decreased to the minimum value at 48.18 $g \cdot kg^{-1}$ at 15:00 p.m., and increased to 96.77 $g \cdot kg^{-1}$ at 19:00 p.m. Diurnal change curve of magnesium content was double-peak curve, content of Mg^{2+} increasing gradually from 07:00 a.m. to 11:00 a.m. and reached peak value of 11.42 $g \cdot kg^{-1}$ at 11:00 a.m., then it decreasing gradually and reached a lower value of 8.35 $g \cdot kg^{-1}$ at 15:00 p.m. Content of Mg^{2+} increased to the maximum value of 13.44 $g \cdot kg^{-1}$ at 19:00 p.m. Greatest change of ion contents in *Peganum harmala* L was sodium content, whose difference of maximum and minimum value was 48.59 $g \cdot kg^{-1}$.

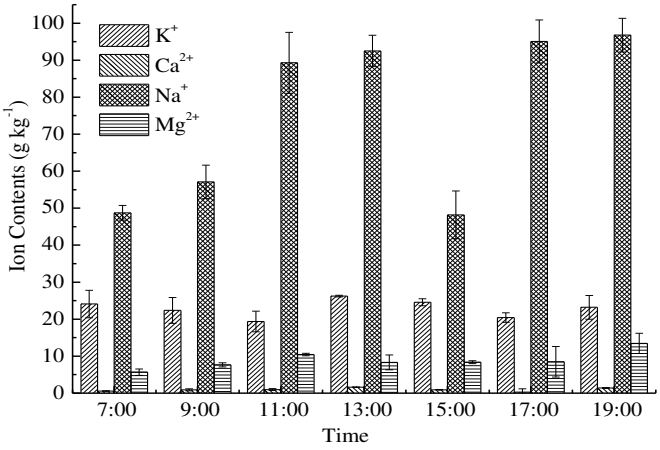

Figure 3. *Diurnal changes of four kinds of ion contents in Peganum harmala L*

Diurnal changes of four kinds of ions in Reaumuria soongorica

Diurnal variation in contents of K^+, Ca^{2+}, Na^+ and Mg^{2+} in *Reaumuria soongorica* were shown in *Figure 4*. Diurnal change tendency of potassium content in *Reaumuria soongorica* was a U-shape curve. Content of K^+ decreasing gradually during 07:00 a.m. – 13:00 p.m. and appeared a minimum value of 11.03 $g \cdot kg^{-1}$ at 13:00 p.m., then recovering to 14.79 $g \cdot kg^{-1}$ at 19:00 p.m. Calcium content changed little over time. It decreasing gradually during 07:00 a.m. – 13:00 p.m. and appeared a lower value of 2.74 $g \cdot kg^{-1}$ at 13:00 a.m.; then it increasing and reached 3.71 $g \cdot kg^{-1}$ at 15:00 p.m. Later it decreasing and reached a minimum value of 2.45 $g \cdot kg^{-1}$ at 17:00 p.m., afterwards it increasing and reached a maximum value of 3.86 $g \cdot kg^{-1}$ at 19:00 p.m. Sodium content increasing during 07:00 a.m. – 09:00 a.m. and reached a maximum value of 49.62 $g \cdot kg^{-1}$ at 09:00 a.m. Afterwards, the change tendency of sodium content was U-shaped curve, Na^+ content decreasing during 09:00 a.m. – 15:00 p.m. and the minimum value of 38.87 $g \cdot kg^{-1}$ appeared at 15:00 p.m., then sodium content increasing to 43.19 $g \cdot kg^{-1}$ at 19:00 p.m. Magnesium content increasing gradually during 07:00 a.m. – 11:00 a.m. and reached a maximum value of 25.26 $g \cdot kg^{-1}$ at 11:00 a.m., then it became decreasing, a minimum value of 17.38 $g \cdot kg^{-1}$ appeared at 17:00 p.m., afterwards it increasing to 23.42 $g \cdot kg^{-1}$ at 19:00 p.m. Contents of sodium and magnesium in *Reaumuria soongorica* changed a lot. The difference between maximum and minimum value of Na^+ content and Mg^{2+} were 10.75 $g \cdot kg^{-1}$ and 7.88 $g \cdot kg^{-1}$, respectively.

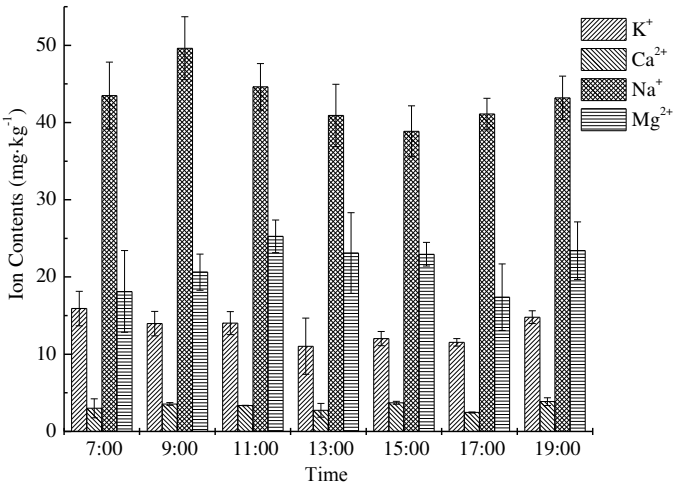

Figure 4. *Diurnal changes of four kinds of ions in Reaumuria soongorica*

The average content of four ions and their total amount in four plants

Average contents of the elements investigated and total ions of four plants were shown in *Figure 5*. Elements contents sequences of K^+, Ca^{2+}, Na^+ and Mg^{2+} in *Nitraria tangutorum*, *Lycium ruthenicum* and *Peganum harmala* L were all $Na^+ > K^+ > Mg^{2+} > Ca^{2+}$. The sequence of four element contents in *Reaumuria soongorica* was $Na^+ > Mg^{2+} > K^+ > Ca^{2+}$. For the four plants investigated, the average content of Ca^{2+} was the least, average content of Na^+ was the most. The ascending sequence of average Ca^{2+} content in plants was *Reaumuria soongorica* (3.24 $g \cdot kg^{-1}$) > *Lycium ruthenicum* (2.66 $g \cdot kg^{-1}$) > *Nitraria tangutorum* (2.09 $g \cdot kg^{-1}$) > *Peganum harmala* L (0.94 $g \cdot kg^{-1}$), which for Na^+ average content in plants was *Peganum harmala*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_357368

L (75.39 $g \cdot kg^{-1}$) > *Lycium ruthenicum* (47.77 $g \cdot kg^{-1}$) > *Nitraria tangutorum* (43.87 $g \cdot kg^{-1}$) > *Reaumuria soongorica* (43.11 $g \cdot kg^{-1}$). Sequence for total amount of ions in four plants was *Peganum harmala* L > *Lycium ruthenicum* > *Reaumuria soongorica* > *Nitraria tangutorum*. Total amount of four ions in *Peganum harmala* L was twice of it for *Lycium ruthenicum*, four time of it in *Reaumuria soongorica*, 8 times of it in *Nitraria tangutorum*.

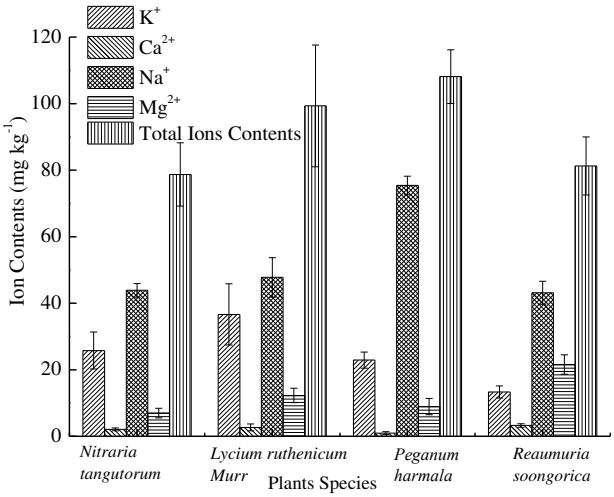

Figure 5. *Average content of four ions and their total amount in the four plants*

The correlation between ion content and light intensity in plants

Pearson correlation analysis between total amount of ions and light intensity in four plants was shown in *Figure 1*. Magnesium content in *Nitraria tangutorum* was significantly negatively correlated with light intensity at the 0.01 level (-0.896), while the Mg^{2+} contents in *Lycium ruthenicum* and *Reaumuria soongorica* had little correlations with light intensity, and Mg^{2+} content in *Peganum harmala* L had no correlations with light intensity. The correlations between the contents of K^+ and Na^+ with light intensity was not significant, while the contents of K^+ and Na^+ in *Lycium ruthenicum* and *Peganum harmala* L cannot be correlated with light intensity, content of K^+ in *Reaumuria soongorica* was negatively correlated with light intensity at the 0.05 level (-0.700). Content of Na^+ had no correlation with light intensity, while contents of Ca^{2+} in *Nitraria tangutorum*, *Lycium ruthenicum* and *Rsa* also cannot be correlated with light intensity, and Ca^{2+} content in *Peganum harmala* L had little correlation with light intensity. Contents of Mg^{2+} and K^+ in *Nitraria tangutorum* had significant positive correlation (0.731) at the 0.05 level, while in *Lycium ruthenicum* Mg^{2+} content was significantly negatively correlated (-0.738) with Na^+ content at the level of 0.05, in *Peganum harmala* L Mg^{2+} content was significantly positively correlated (0.670) with Na^+ content at the level of 0.05; and there had weak correlations between the ions content in *Reaumuria soongorica* (*Table 1*).

Discussion

The plants of *Nitraria tangutorum*, *Lycium ruthenicum*, *Peganum harmala* L and *Reaumuria soongorica* had the effect of desert soil improvement and ecological balance

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_357368

maintenance, they had good adaptability to grow in desert environment in Minqin Country. *Nitraria tangutorum* was a kind of plant in *Zygophyllaceae*, *Nitraria tangutorum*, whose appearance was xeric shrubs, xerophytie, or undershrub. It has the characteristics to resist drought, wind erosion, sand burial and saline alkali tolerance. *Nitraria tangutorum* was high branched structure, and tufted creep in sandy land, semi-flow or mobile dune. It could produce adventitious root or new branch easily if it was buried by sand (Zhou, 2005). *Lycium ruthenicum* belonged to plants of *Solanaceae* wolfberry with many branch and characteristics of wind, sand, drought, and high-temperature resistance, and its fruits were abundance of anthocyanin and trace elements (Chen, 2011; Gu, 2014) which had highly economic and medicinal value. So it was one of the minority plants in arid area which could not only fixate sand and resist drought, but also can generate economic benefits. *Peganum harmala* L was a kind of perennial plant belongs to *zygophyllaceae*, it was widely spread in arid and semi-arid area with developed root system with drought resistance and saline alkali tolerance (Liu, 2011). *Reaumuria soongorica* belongs to subshrub or shrub, it was the major constructive species in dessert and grassland in China, and widely spread in the arid hungriness regions of our country. It has strong ability of saline alkali tolerance and sand fixation (Liu, 2011).

Table 1. *Correlation between ion content and light intensity in plants*

Plants		Light intensity	K^+	Ca^{2+}	Na^+	Mg^{2+}
Nitraria tangutorum	Light intensity	1				
	K^+	-0.656	1			
	Ca^{2+}	0.133	-0.535	1

*Data were significant correlation under the P value degree of 0.05 level. **Data were significant correlation under the P value degree of 0.01 level

Potassium ion plays an important role in promoting plant growth, protein synthesis, carbohydrates formation and transportation. It also has close relationship with drought resistance of plants, and could also increase the adversity resistance, decrease the water potential of the leaves under the condition of drought to rise the relative water content

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_357368

(Wang, 2016). The photosynthesis, photorespiration, growth and development were all effected, by the content of K^+ (Gattward, 2012), the differences of K^+ sorption, conversion and transportation in various kinds of plants were controlled by genetic gene (Wang, 2009). The highest contents of potassium ion in the plants of our research field was *Lycium ruthenicum*, the decreasing sequence was *Nitraria tangutorum*, *Peganum harmala* L, the *Reaumuria soongorica* was in the end. The results may indicate that the *Lycium ruthenicum* has stronger adaptability under drought stress than other plants. There are great variation in K^+ absorption contents of 4 plants, which may be resulted from the differences in plant species and genetic gene. Zhao et al. (2005) investigated the diurnal photosynthesis changes in *Nitraria tangutorum*, the results showed that with the increase of light intensity and temperature, the net photosynthetic rate and stomatal conductance of *Nitraria tangutorum* decreased, and the stomatal closure induced midday-depression of photosynthesis; when temperature decreased, the stomatal conductance increased. The research of *Nitraria tangutorum and Sarcozygium xanthoxylon* from *Ulanbuh Desert* (Huang, 2016) compared their characteristics diurnal photosynthesis changes in autumn, the results also showed their midday-depression of photosynthesis was caused by stomatal factor. The diurnal changes tendency of K^+ contents in *Nitraria tangutorum* and *Reaumuria soongorica* were similar to the characteristic of diurnal photosynthesis changes, the K^+ contents was lowest at noon. Luminous intensity was correlated with K^+ content of *Reaumuria soongorica*, which did not have obvious correlation with K^+ content of *Reaumuria soongorica*. The results may be attributed to the reasons that the K^+ contents in *Nitraria tangutorum* and *Reaumuria soongorica* dominated their changes of stomatal conductance and photosynthetic rate, while the K^+ contents in *Lycium ruthenicum* and *Peganum harmala* L did not have obvious relationship with their stomatal conductance and photosynthetic rate. Perhaps there are other ions took part in the procedure, so we need further research.

Calcium was a component of plants structure, which increased the growth of cells and roots (Li, 2017). The content of Ca^{2+} will change will change with the kinds, organs and growth conditions of plants, the extra Ca^{2+} content will be used as the nutrition for the growth of new organs, satisfied the stability of cell membrane, maintained the structural function of cell walls, increased the stress-chilling and chilling-chilling of plants, also it could regulate the responses of stress, the growth and development of plants as well (Wang, 2016). Investigations from Larkindale (2002) showed that high temperature damage maybe resulted in oxidative damage of plant cell membrane, while the contents of Ca^{2+} in plants have significant effect on recovering the oxidative plant damage from high temperature. Calcium contents of *Nitraria tangutorum*, *Lycium ruthenicum* and *Reaumuria soongorica* differs little (about 1.0 $g \cdot kg^{-1}$) in this research, which had no correlation with luminous intensity. However, content of calcium in *Peganum harmala* L was least in four plants, which was weakly dependent with luminous intensity. The results may demonstrated that *Nitraria tangutorum*, *Lycium ruthenicum* and *Reaumuria soongorica* had stronger drought-resistance than *Peganum harmala* L under drought-stress.

Contents of Na^+ in plants related its salt-tolerance, the absorption, transportation and storage determined weather plants could live under salt-stress. Different plants had different way for salt-tolerance, some kinds of plants remained their internal and external environment stable by osmotic adjustment, some kinds could make active choice whether to absorb Na^+, or activated the functions of potassium-absorption and sodium-excretion to control ions-balance and increase salt-tolerance (Garthwaite, 2005).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_357368

Sodium contents of four plants investigated in this paper were relatively high. Content of sodium was highest in *Peganum harmala* L, which was lower in *Lycium ruthenicum*; sodium contents in *Nitraria tangutorum* and *Reaumuria soongorica* nearly equal. Total ionic content was highest in *Peganum harmala* L of four plants, which refer to that *Peganum harmala* L had strong absorptive capacity for ions in soil, it was easily existence in soil with high salinity, strong salt-tolerance. Sodium contents in four plants had acute diurnal changes, in 13:00-15:00 p.m., sodium contents in four plants were all decreased, which may refer to the reason that Luminous intensity was too strong in this period which could affect the permeability of plants, decrease transportation of Na^+, and then reduce the content of Na^+.

Magnesium ion could be the activator of many kinds of enzymes, it took part in synthesis of fat, protein, carbohydrate and nucleic acid, which also regulated content of Mg^{2+} in their stable metabolic library (Liao, 2003). Magnesium was the center atom of chlorophyll in photosynthesis, which played important role by directly involving in photosynthesis, promoting carbon assimilation, adjusting the distribution of Excitation energy of chloroplast and so on. There were antagonistic relationship between potassium and magnesium. Ohno and Grunes (1985) considered antagonistic action happened in transport process of Mg^{2+} from root to overground part of plants. Huang et al. (1992) also thought that there was negative correlations between the transportation of Mg^{2+} and concentration of K^+. The increase of Mg^{2+} content and decrease of K^+ content showed that the existence of K^+ restrained absorption of Mg^{2+} in plants. The increasing Mg^{2+} content and decreasing contents of Na^+ and K^+ demonstrated that the existence of Na^+ and K^+ restrained Mg^{2+} absorption in plants. The increase of Mg^{2+} content and increase of Ca^{2+} content showed perhaps there were antagonism between Mg^{2+} and Ca^{2+}, the existence of Ca^{2+} suppressed absorption of Mg^{2+}. There were research showed absorption contents of Mg^{2+} decreased with the increasing luminous intensity. For the four plants in this research, the Mg^{2+} contents were lower at noon, this may be resulted from the Mg^{2+} absorption suppression by the intense illumination at noon.

Conclusions

The ability for ion absorption of K^+, Ca^{2+}, Na^+, Mg^{2+} in different plants were various. The amount of Na^+ in four plants were highest while the amount of Ca^{2+} was lowest compared with amount of four ions. The increasing sequences of four ions in plants of *Nitraria tangutorum*, *Lycium ruthenicum* and *Peganum harmala* L was $Na^+ > K^+ > Mg^{2+} > Ca^{2+}$, while the order of ions contents in *Reaumuria soongorica* was different that the content sequence of ions was $Na^+ > Mg^{2+} > K^+ > Ca^{2+}$. Diurnal variations of Ca^{2+} contents in *Nitraria tangutorum*, *Reaumuria soongorica* and *Peganum harmala* L was slight, while the diurnal variation of Ca^{2+} content in *Lycium ruthenicum* was bimodal, and the two peak values were 4.14 $g \cdot kg^{-1}$ and 3.65 $g \cdot kg^{-1}$, respectively. The diurnal variations of Mg^{2+} contents presented U-shaped curves in *Nitraria tangutorum*, *Lycium ruthenicum* and *Peganum harmala* L, which followed by an inverted U-curve in *Reaumuria soongorica*. Diurnal variations of K^+ contents in *Nitraria tangutorum* and *Reaumuria soongorica* was U-curves, which was strong in *Lycium ruthenicum* and slight in *Peganum harmala* L. Diurnal variation of K^+ contents in *Nitraria tangutorum* was strong, while it in *Lycium ruthenicum* increased in the morning, and kept stable in the afternoon, and its tendency were also U-shaped curve in *Peganum harmala* L and *Reaumuria soongorica*. Mg^{2+} content was positively

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_357368

correlated with K^+ content in *Nitraria tangutorum*, while Mg^{2+} content was negatively correlated with Na^+ content in *Lycium ruthenicum*. Mg^{2+} content was positively correlated with Na^+ content in *Peganum harmala* L, but Mg^{2+} content and Na^+ content in *Reaumuria soongorica* didn't have significant correlations. Sequence of total ion contents in four plants was *Peganum harmala* L > *Lycium ruthenicum* > *Reaumuria soongorica* > *Nitraria tangutorum*. Mg^{2+} content was negatively correlated with illumination intensity in *Nitraria tangutorum* under the *P* value degree of 0.01 level and in *Reaumuria soongorica* under *P* value degree of 0.05 with correlation coefficient equal to -0.700.

(Received 29th Aug 2019; accepted 25th Nov 2019)

Abstract. This study was carried out to determine the Coccinellidae (Coleoptera) species and their preys in Adana Province of Turkey. The samples were collected from medicinal and aromatic plants in 2016-2018. Coccinellidae species were sampled by using sweep-net, handheld aspirator or by handpicking. Total of 1470 individuals were collected and 28 species belonging to 20 genera were identified. The common species according to their frequency were; *Coccinella septempunctata* (Linnaeus) (24.56%), *Hippodamia* (Adonia) *variegata* (Goeze) (15.92%), *Scymnus pallipediformis* Günther (11.29%), *Chilocorus bipustulatus* (L.) (5.65%), *Scymnus levaillanti* M. (5.51%). Coccinellid species were found widely distributed in both localities studied, whereas, Sarıçam locality represented higher diversity indices of Shannon-Weiner's (2.810) and Simpson's (0.076). Similarity index was observed as 0.727. A total of 42 pest species were observed. Twenty predator species were recorded to be primarily feeding on aphids. For almost all coccinellid species, population was highest in spring and in the early summer. Beetles were collected from 54 medicinal and aromatic plants with 18 species from the Lamiceae and 12 species from the Asteraceae families.
Keywords: *medicinal and aromatic plant, Coccinellidae, Coccinella septempunctata, aphid, Lamiaceae, diversity*

Introduction

In Turkey, 30% of the plant species in the natural flora are medicinal and aromatic plants (MAPs) (Faydaoğlu and Sürücüoğlu, 2011). These plants are becoming increasingly important in terms of being potentially integrated into alternative cropping systems, a raw material supply for the food industry, used as a complementary environment in alternative wards, and as organic pesticides in controlling pests at different habitats, which have become more widespread in recent years. The essential oils of MAPs are generally used in drugs, cosmetics, perfumes, aroma therapy and other industrial branches. In order to competently evaluate the sustainable production and market potential of medical and aromatic plants, they must be of the required quantity and quality (Bayram et al., 2010). The use of MAPs is increasing throughout Turkey and the world nowadays as control of pest insect species that restrict the production is gaining importance. Chemical control is the main control method against pest species in protecting agricultural products. Using pesticides against pests in MAPs, which are used mainly for therapy, is known to negatively affect human health. Consequently, control methods that do not disrupt natural balance, and cause resistance problem are appropriate for ecological and sustainable agriculture are needed. In line with these points, biological-based techniques are being proposed for the management of pest. Biological control is one of these methods. In this context, researches on the determination of the pest species and natural enemy fauna of medicinal and aromatic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_369388

plants in Turkey will be helpful. Coccinellidae family (ladybirds), which most of them are predators, is one of the natural enemies that feeds on aphids, scale insects, whiteflies, mites and small arthropods. Due to the predatory nature of most of the coccinellids, they have an important role in biological control-based pest management in agricultural production (Khan et al., 2007; Uygun and Karabüyük, 2013). 6000 Coccinellidae species from 360 genera have been reported worldwide (Tomaszewka and Szawaryn, 2016). In Turkey 104 species from 39 genus and 6 subfamilies have been recorded recorded (Uygun and Karabüyük, 2013). Many studies have been done on the determination of coccinellid species on various plant species in almost all regions of Turkey (Uygun, 1981; Ölmez, 2000; Tezcan et al., 2003; Aslan and Uygun, 2005; Özgen and Karsavuran, 2005a; Bolu et al., 2007; Efil et al., 2010; Portakaldalı and Satar, 2010; Özsisili, 2011; Gözüaçık et al., 2012; Şahin and Işık, 2014; Kaplan et al., 2019). However, the studies on the determination of coccinellid species on medicinal and aromatic plants in Turkey is very limited. Few studies have been conducted in the Aegian region of Turkey. Investigation of coccinellidae species at geographically different habitats and on different plants are important and crucial at revealling biological diversity and the potential of biological control and organic agriculture.

The objective of this study is to explore and identify ladybird species associated with medicinal and aromatic plants, and their prey species in Adana Province of Turkey. The results will be helpful in solving entomological problems on MAPs.

Materials and Methods

Study site

This study was conducted during 2016-2018 in Sarıçam and Karaisalı district of Adana. Coccinellid specimens were collected from CU Ali Nihat Gökyiğit Botanical Garden (Balcalı/Sarıçam) and CU Karaisalı Vocational School Campus (Karaisalı) from MAP plots (*Fig. 1*).

Both districts are located in southern Turkey (Balcalı: 37° 3’2.53’N;35°21’15.49’E - 23 meters above sea level, Karaisalı: 37° 15’12.96’N;35°4’7.28’E - 235 meter above sea level) and represent typical Mediterranean climate: hot dry summers and wet mild winters.

Sampling and laboratory processing of specimens

In Sarıçam 200 and in Karaisalı 30 MAPs were investigated. Collection of coccinellid beetles was carried out once per week during March-December and biweekly during the other months. All the plant parts from randomly chosen 10 plants were examined from each MAP plots. Collection of both beetles and pest species differed according to plant and pest species; by shaking and knocking branches into a standard sweeping net for 10 seconds, by a handheld aspirator or by handpicking. Coccinellid individuals on short plants were captured by using sweepnet and then they were sucked by an aspirator. All plants from each medicinal and aromatic plant (herbaceous, trees and shrubs etc.) plots were examined visually and the coccinellid individuals were picked by hand or handheld aspirator. Insects were then transferred to the killing bottles and brought to the laboratory for pinning and labeling. Coccinellid specimens were tagged with information about host plants, locality and date for identification (Uygun, 1981). Pest and plant species on which larvae and adult beetles

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_369388

were found feeding constantly on were considered to be potential host pest and plants. To increase our confidence in the determination of true pest associations, obvious damage levels on the vegetation and number of adult beetles feeding observed were also taken into consideration. High population density of feeding beetles was accepted as the main factor in related host plant determination. Beetles on plants without a pest were ignored and controlled the following weeks. The predator larvae were also collected with the preys to obtain adults in the laboratory. Specimens of aphids, mites and thrips were directly taken from the plants with fine brush and then placed separately in Eppendorf tubes containing 70% elthy alcohol (Hille Ris Lambers, 1950; Atakan and Uygur, 2005). Each plant sample infected by scale insects and whiteflies was cut and put into first a paper bag and then a plastic bag. Separately labelled samples were taken away to the laboratory. Scale insects and whiteflies on plants were put into Eppendorf tubes with 70% elthy alcohol for further examination (Kosztarab and Kozár, 1988) The identification of the specimens were performed by specialized experts. All of coccinellid specimens were deposited in the laboratory of Department of Plant and Animal Production, Karaisalı Vocational School, Cukurova University, Turkey.

Statistical analysis

Collected data were employed for stastistical analyses to calculate species diversity and similarity in different localities by applying Shannon-Wiener and Simpson's diversity indexes and Sorenson similarity index (Magurran, 1988; Southwood and Henderson, 2000).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_369388

Shannon-Wiener diversity index (H'):

$$H' = - \Sigma\, p_i \ln(p_i) \quad \text{(Eq.1)}$$

where, p_i: proportion of i^{th} species to others, ln: Natural logaritm.
The index values are among 0.0 and 5.0. In the majority of cases the calculated values range from 1.5 to 2.5. The values above 2.5 indicate that the habitat is stable and has high diversity, whereas all values below 1.5 indicate a degraded habitat or low diversity.

Simpson diversity index (S):

$$S = 1 - \Sigma\, n_i\,(n_i - 1) \,/\, N\,(N-1) \quad \text{(Eq.2)}$$

where, i: Number of species, n_i: Individual number in a species, N: Total number of individuals in all species in a community.

The value of S ranges from 0 to 1. With this index, 0 represents infinite diversity and 1 no diversity. That is, the bigger the value the lower the diversity.

Species similarity between two communities was calculated by Sorenson's index (SQ):

$$SQ = 2J \,/\, a+b \quad \text{(Eq.3)}$$

where, J = number of similar species in both communities, a = total number of species in community A, b = total number of species in community B.

The value of SQ ranges from 0 to 1. With this index, 0 represents no similarity and 1 complete similarity. That is, the bigger the value the higher the similarity.

Meteorological data were obtained from HOBO data logger placed in the botanical garden in Sarıçam and 'Ministry of Food, Agriculture and Livestock, Karaisalı District Directorate of Agriculture and Forestry' in Karaisalı located one km away from the tested orchard.

Results

Ladybirds were collected from totally 54 species of MAPs from Sarıçam and Karaisalı districts of Adana (Turkey); 50 of the MAP species were in Sarıçam and 20 of the MAP species were in Karaisalı (*Fig. 2*).

A total of 1470 coccinellid specimens representing 5 subfamilies, 20 genera and 28 species were collected in both provinces during 2016-2018 (*Table 1*). Species are listed in *Table 1* with habitat information, sampling year and abundance data. The number of individuals collected in 2018 (647 individuals belonging to 25 species) were higher than those collected in 2017 (579 individuals belonging to 25 species) and in 2016 (244 individuals belonging to 13 species).

The species were from the subfamilies Chilocorinae, Coccidulinae, Coccinellinae, Scymninae and Sticholotidinae. Subfamily Chilocorinae represented four species, Coccinellinae 10 species, Scymninae 12 species, and Coccidulinae and Sticholotidinae represented one species each. Scymninae was determined as the richest species subfamily in the area comprising 12 out of 28 species collected (*Fig. 3*). The most frequently collected coccinellid species of the study were; *Coccinella septempunctata* (Linnaeus) (24.56%), *Hippodamia* (Adonia) *variegata* (Goeze) (15.92%),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_369388

Scymnus pallipediformis Günther (11.29%), *Chilocorus bipustulatus* (L.) (5.65%), *Scymnus levaillanti* M. (5.51%). *Psyllobora vigintiduopunctata* (L.) had the least relative abundance (0.07%) with only one specimen found (*Table 2*).

Figure 2. *Adult and larval coccinellid individuals on Mentha piperita (a), Salvia officinalis (b), Coriandrum sativum (c), Matricaria chamomilla (d). Coccinella septempunctata L. adult and larvae (a,b, c), Scymnus larvae (d)*

The prey preferences of Coccinellidae family species determined in this study showed differences between the species. Twenty seven of these species are predators while one of them is phytophagous, *P. vigintiduopunctata.* Twenty species were determined to be aphidophagus. *Cheliomenes propinqua*, *Brumus (Exochomus) quadripustulatus, E. nigromaculatus, Nephus (Sidis) hiekei*, *N. nigricans*, *N. includens*, *Pharoscymnus pharoides* were recorded feeding on primarily the mealybugs. *C. bipustulatus, Brumus (Exochomus) quadripustulatus*, *Rhyzobius lophanthae*, *Rodolia cardinalis, Scymnus rubromaculatus, S. pallipediformis*, *S. (Pullus) subvillosus* were recorded feeding on the scale insects and coccids. One species (*S. gilvifrons*) was only feeding on mites while another species (*S. pallipediformis*) fed on aphids, scale insects and cicadellids. *Clitestetus arcuatus* were detemined to be primarily feeding on whiteflies and on aphids. *P. vigintiduopunctata* fed both on fungi and aphids. *C. septempuntata* primarily fed on aphids and also on thrips. It was determined that *P. pharoides* and *S. leveillantii* were also fed on red spiders. The primary host of the most encountered coccinellid species were aphids; *C. septempunctata* was determined to feed on 8 aphid species on 10 MAPs, *H. variegata* on 12 aphid species on 15 MAPs, and *S. pallipediformis* on 5 aphid species on 6 MAP species. Coccinellid species were determined to feed on totally 42 pest species; 19 aphid, 8 coccid and pseudococcid, 5 diaspidid, 4 aleyrodid, 3 spidermite, 2 cicadellid and 1 thysanopter species. The MAPs found on, prey, location, capture months and adult number of each coccinellid species are given in *Table 2*.

According to data obtained from sampled Coccinellid species and specimens number; species richness was 27 and 17 in Sarıçam and Karaisalı agroecosystems, respectively (*Table 3*). Specimens number was parallel to species number (953 in Sarıçam and 531 in Karaisalı). Among the districts, Sarıçam had higher biological

DOI: http://dx.doi.org/10.15666/aeer/1801_369388

diversity than Karaisalı with Shannon-Wiener diversity index value of 2,810 and Simpson diversity index value of 0.076.

Sorenson similarity index value was 0,727. According to index value Sarıçam and Karaisalı agroecosystems are similar in the ratio of 72.7% in terms of coccinellid species.

S: Sarıçam, K: Karaisalı, n: Total Abundance of Species

Climatic data of the study years of Sarıçam and Karaisalı were given in *Figure 4*. The family Coccinellidae was found to be fluctuating throughout the sampling period. Seasonal abundance peaked in spring (including April-May). In April the highest population (530 adults) was recorded. Thereafter gradually decreased and continued until the end of the year (*Fig. 5*). For almost all subfamilies, dominance and species richness values were maximum in spring and in the early summer (*Table 2*).

Ladybirds were collected from totally 54 species of MAPs belonging to 20 families from both provinces. Eighteen MAP species were from the Lamiaceae, 12 from Asteraceae, and 3 from Malvaceae families, and 1 or 2 species from the others (*Fig. 6*).

Discussion

Coccinellids are predators primarily of Hemipteran pests such as aphids, mealybuds and scale insects. The majority members of the family have received considerable research attention because of their potential to act as biocontrol agents (Kılınçer et al., 2010). Prey preferences of Coccinellidae species showed differences between the species in this study. Most of the species primarily preferred aphids. Nearly 68% (in Middle Europe) and 35% (worldwide) of the coccinellids are aphidophag, whereas 20% (in Middle Europe) and 36% (worldwide) are reported to be coccidophag. It is concluded that the distribution of the coccinellids are related to their preys distribution (Klausnitzer and Klausnitzer, 1972). Hodek and Honek (1996) reported that the species from Scymnini tribus feed on scale insects in ratio of 62% and 23% for aphids. Eighty-five percent species from Coccinellini tribus feed on aphids, psyllids and Chrysomelidae family. Uygun and Karabüyük (2013) states that Coccinellids, which has a large amount of predators, feed on spider mites, cicadellids, whiteflies, aphids, scale insects, mealybugs, coccids and larvae of Lepidoptera, Coleoptera and Hymenoptera.

The most abundant coccinellid species, *C. septempunctata* which constituted 24.56% of the specimens has been reported to have a wide variety of host species from the family Aphididae. It can be found in all type of habitats and agro-ecosystems on different crops worldwide feeding voraciously on aphids (Horion, 1961; Uygun, 1981; Aslan and Uygun, 2005; Zare et al., 2013), mealybugs and psyllids (Ullah et al., 2012), scale insects (Uygun, 1981; Zare et al., 2013) and thrips (Sanjta and Chauhan, 2018). In this study it was collected from various medicinal and aromatic plants infested with aphids and thrips (*Table 2*). *C. septempunctata* has been reported to on with pest species from the families Aphididae, Callaphididae, Chaitophoridae, Cicadellidiae, Coccidae, Diaspididae, Lachnidae, Pemphigidae, Psyllidae, Psyllidae, Tingidae (Hemiptera) in Turkey (Erler, 2002; Bolu et al., 2007).

Hippodamia (*Adonia*) *variegata* was the second dominant species (15.92%). Primarily, it prefers Aphididae species, although it has other host species such as psyllids and scale insects (Uygun, 1981; Ives et al., 1993; Ullah et al., 2012). *H. variegata* was found on more MAP species than *C. septempunctata*. Tezcan and Uygun (2003) determined this species as one of the most encountered species collected from *Origanum* spp. fields in Manisa province of Turkey. Göven and Özgür (1990) and Yumruktepe and Uygun (1994) reported that *H. variegata* feeds on aphids and thrips. Aslan and Uygun (2005) collected this species from *M. arvensis* infested with *Aphis affinis* del Guercio and *Ovatus mentharius* (van der Goot), and from *Achillea millefolium* infested with *Brachycaudus helichrysi* (Kalt.) in Kahramanmaraş. It has a wide variety of prey species from the families Aphididae, Aleyrodidae, Chaitophoridae, Coccidae, Diaspididae, Psyllidae (Hemiptera) (Özgen and Karsavuran, 2005a,b; Bolu et al., 2007).

Scymnus pallipediformis was the other dominant species in this study (11.29%). It mainly preys on aphids and to a lesser extent on scale insects and cicadellids (Aslan and Uygun, 2005; Bolu et al., 2007). In this study it was also found feeding on aphids, scale insects and cicadellids. Furthermore, it is reported to feed on species from Chaitophoridae, Coccidae and Psyllidae families in Turkey (Ölmez, 2000; Aslan and Uygun, 2005).

Chilocorus bipustulatus is a common predator of many scale insect, mealybug and waxscale species of Coccoidea family (Uygun, 1981). This armored-scale lady beetle

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_369388

was the most abundant and important predator species collected from diaspidids and coccids. It also feeds on whiteflies and aphids (Karaat and Göven, 1986; Telli and Yiğit, 2007). Bolu et al. (2007) reported that both adults and larvae of this ladybeetle feed on Coccoid species, especially on the nymphs and the eggs of *Planocoocus citri* Risso (Hemiptera: Pseudococcidae).

Stethorus gilvifrons is specialized to spider mites (Uygun, 1981; Uygun and Karabüyük, 2013) and is the most abundant species feeding on smites (*T. cinnabarinus, T. urticae* and *P. tarsenomuslatus*) in this study. It also feeds on aphids, scale insects, coccids and psyllids (Erler, 2002; Aslan and Uygun, 2005; Bolu et al., 2007). Aslan and Uygun (2005) collected this species from *M. arvensis* feeding on *A. affinis* Del Guercio in Kahramanmaraş.

Clitostethus arcuatus is primarly a whitefly predator (Uygun and Karabüyük, 2013) and in this study it is the only predator species primarily feeding on whiteflies. Most of them were collected in autumn months from mainly whitefly infested medicinal and aromatic plants (*Table 2*). Besides whiteflies, it also feeds on aphids and mites (Ulusoy and Ülgentürk, 2003; Kaya Başar and Yaşar, 2011).

Rodolia cardinalis is the main natural enemy of *Icerya purchasi,* used in the biological control of this pest in citrus worldwide successfully (Kılınçer et al., 2010; Anonymous, 2019). *I. purchasi* is a polyphag pest on ornamental plants in Turkey (Kaydan et al., 2013) and the presence of it on lavender, rosemary and thyme was reported for the first time in Turkey (Elekcioğlu, 2018). Because of the many uses of these plants, a reduction of its productivity would have a significant economic impact for Turkey. So the presence of this ladybeetle on these plants is thought to be very important.

Psyllobora vigintiduopunctata was the only phytophagous species feeding on fungi from Erysiphaceae family (Horion, 1961; Cruz et al., 1990; Yiğit and Soylu, 2002). It was also observed feeding on aphids as Düzgüneş et al. (1982) mentioned. In this study it was reported on *Hypericum perforatum* feeding on aphids and on *Rosa x damascena* and *H. perforatum* on fungi.

In Turkey, a limited number of survey studies have been reported on the pest species and natural enemy fauna on MAPs which well matches the results of this study. Zarkani and Turanlı (2019) collected *C. septempuctata*, *H. variegata*, *Adalia bipunctata* (L.), *Scymnus frontalis* (Fabricius), *Exochomus nigromaculatus* (Goeze), *Cryptolaemus montrouzieri* Mulsant from *Salvia officinalis* fields in İzmir province (Turkey). They observed *A. bipunctata*, *C. septempuctata* L., *E. nigromaculatus*, *H. variegata*, *C. montrouzieri* Mulsant and *S. frontalis* (Fabricius) feeding on *Aphis passeriniana* (Del Guercio) (Hemiptera: Aphididae) and *Eucarazzia elegans* (Ferrari). Tezcan et al. (2003) detected 9 coccinellid species from thyme fields (*Origanum* spp.) in Manisa Province (Salihli and Turgutlu districts) of Turkey: *S. frontalis*, *S. inderihensis* Mulsant, *S. quadriguttatus* Fürsch, *S. rubromaculatus* (Goeze), *Nephus nigricans* Weise, *E. nigromaculatus* (Goeze), *H. variegata*, *Coccinula quatuordecimpustulata* (Linnaeus) and *C. septempunctata*. *S. frontalis*, *S. rubromaculatus* and *H. variegata* were the most abundant species. *C. septempunctata* was the most encountered species among coccinellid species at thyme fields in Denizli and Manisa. Its population was higher during May-June (Şahin and Işık, 2014). Their results are in conformity with data collected in this study. In order to determine the predator and parasitoid insect species in the oil-bearing rose fields in Isparta province, Demirözer and Karaca (2014) determined 8 coccinellid species. The most abundant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_369388

species were: *A. bipunctata*, *A. fasciatopunctata revelierei* Mulstant, *C. bipustulatus* (Linnaeus), *C. septempunctata*, *E. quadripustulatus*, *H. variegata*, *Oenopia oncina* (Olivier) (Coleoptera: Coccinellidae). Metin (2017) detected *C. septempuctata* as a predator insect species in lavender fields (*Lavandula angustifolia* and *Lavandula x intermedia*) in Isparta Province.

Spring and early summer were found more favorable for the family Coccinellidae. The most important reason for this is that aphids are more intense in this period. In addition, mites were also seen in this period. Pest species belonging to Diaspididae, Coccidae, Pseudococcidae and Monophellidae families were also seen apart from spring and so their predators were collected in other months. In spring period the vegetative growth of the plants are intensive and most of them are at flowering period. It is known that plant chemistry is the main factor influencing the feeding behaviour and host selection of phytophagous insects. Secondary melabolites work as important feeding stimulants in the selection of host plants (Matsuda, 1988; Jolivet, 1992). Plants secrete essential oils or protective chemical oils when they are attacked by pests (Rhoades, 1985). The nectar and pollens of flowers and their chemical contents and chemicals secreted by vegetative parts and roots are attractive to pest species in turn of the natural enemies (Knudsen et al., 1993; Riudavets, 1995; Atakan and Pehlivan, 2018). However, some of the medicinal and aromatic plants are repellent, prohibitive and toxic to some insects pests because of the chemical ingredients they have (Bakkali et al., 2008; Zoubiri and Baaliouamer, 2014; Bayram and Tonğa, 2017). Scalera (2006) states that *Ocimum basilicum* L. (Lamiaceae) is an attaractive plant to natural enemies and mainly flowers are the attractive plant parts. According to the author, to attract many other species of beneficial insects to an area, plants with essential nectar and pollen that bloom at different periods throughout the year must be provided. Yarrow, tarragon, fennel and marigold are plants attractive to ladybirds. *Foenoculum vulgare* Mill. (Apiaceae) is a promising nectar or pollen source and can be considered as an attractive source for ladybirds (Kopta et al., 2012).

The number of coccinellid species were found to be more on the MAPs from the Lamiaceae and Asteraceae families. It is thought that it is either influenced by MAP species or the pest species feeding on them. Plant volatiles can act as chemical signals that influence the behavior and distribution of both herbivores and natural enemies (Rhoades, 1985; Dicke and Grostal, 2001; Thöming et al., 2014). There are complex trophic relationships between plants, herbivores and natural enemies. The compounds released as a result of the feeding herbivores in plants are chemical signals to find the hosts and prey of the natural enemies of the herbivores (Tunca et al., 2011). Some volatile compounds and secondary compounds are reported to be attractive or abductive for many parasitoid and predators (Song et al., 2011; Tang et al., 2013; Wan et al., 2015; Togni et al., 2016). Aromatic plants can affect arthropod community composition and reduce herbivore populations by attracting beneficial insects such as generalist predators. Aromatic plants, *Tagetes patula* L. (Asteraceae) and *Nepeta cataria* L. (Lamiaceae) increase the resistance of apple trees to *Aphis citricola* van der Goot (Hemiptera: Aphididae) both directly, by reducing the population of *A. citricola* through chemical repulsion, and indirectly, by increasing the *Harmonia axyridis* (Pallas) (Coleoptera: Coccinellidae) population through chemical attraction in the field and the laboratory (Song et al., 2017). Informations about the mechanisms governing host and prey search behavior in natural enemies is crucial for the success of the control program.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1801_369388

The complexity of the food chain between living organisms in any ecosystem increases the resistance of that ecosystem to external environmental pressures. In other words, the strong relationships between the living organisms in the ecosystem will prevent the excessive increase in the population density of the species, thus preventing the domination at the habitat. The results of the biodiversity parameters of the present study, shows that both of the study sites have high species diversity which means they have stable agroecosystems. Predator species belonging to the Coccinellidae family play an important role in the formation of agroecosystems having natural balance. The increase of the specimens number as of the years in both localities shows that there is a natural balance between the pest species and coccinellid species. Generally, coccinellids are density-dependent predators, i.e. their number rises as the prey number increases (Dixon, 2000). The predaceous role of coccinellids benefits from the maintenance of field diversity, which supports the population of prey such as aphids, thrips and mites (Iperti, 1999). Ladybirds migrate between various crop fields throughout the season depending upon the availability of prey and habitat disturbance (Maredia et al., 1992). Dixon (2000) reports that the number of species largely depends on the number of preys. For example, in spring (April) most of pests yield great populations, thus the amount of feeding for coccinellids increases too, in the present study.

The results of this study is thought to be helpful in the production of medicinal and plants, especially for the pest management. Distribution and existing periods of the predators would help farmers in choosing the control methods. The results would be used in biological control studies within integrated pest management programs against the pest species in larger fields. Since the use and production of medicinal and aromatic plants are increasing in Turkey, the Ministry of Agriculture and Livestock of Turkey should consider granting support to farmers in MAP production. It is thought that this study will contribute to the determination of insect biodiversity of medicinal and aromatic plant fields in Turkey.

Conclusion

The coccinellid beetles are considered economically very important in agro-ecosystem as they have been successfully employed in the biological control of many injurious insects. The present study aimed at explore and identify the coccinellid fauna of the medicinal and aromatic plants in Sarıçam and Karaisalı Districts of Adana (Turkey). A total of 28 species belonging to 20 genera were identified and 5 subfamilies. Diversity indexes were high in both localities studied. This study is a preliminary step in the description of the insect and natural enemy fauna (Coccinellidae) of medicinal and aromatic plants and can be used as a reference study for similar faunistic studies in the future. These findings will finally lead to the development of a conservation-based biological control strategy for indigenous plant protection programs. There are no registered pesticides against pests that can be used in medicinal and aromatic plant fields in Turkey. In order to prevent pest species from becoming a potential pest, care must be taken to protect the beneficial species and increase their effectiveness. Therefore, unnecessary spraying should be avoided and appropriate specific pesticides should be used if necessary.

Acknowledgments. The author is grateful to Dr. Nedim UYGUN (Cukurova University Agricultural Faculty, Department of Plant Protection) for determining coccinellid species, Dr. Ekrem ATAKAN,
