(Received 1st Apr 2019; accepted 31st Oct 2019)

Abstract. Drought stress hinders root and shoot growth, leaf area, biomass accumulation, plant fresh and dry weight signifying the severe losses of plant growth and development. During drought stress, different genes are activated that increase the drought tolerance efficiency of plants. In this study, *DREB1A* gene was transformed in wheat cv. Lasani-08 to improve drought tolerance efficiency after optimizing in planta *Agrobacterium* mediated transformation protocol. The results reveal that 3.0 mg/l 2, 4-D and 6 h soaking period were found to be the best combination for in planta transformation. The inoculation of seeds with *Agrobacterium* suspension before germination of apical meristem was proved to be the best time for obtaining more transformation efficiency (6.38%) as compared to seeds inoculation after germination of apical meristem. Molecular analyses of transgenic plants through PCR, Southern blotting and RT-PCR confirmed the presence, number of copies and expression profile of transgene in T_1 generation. The drought tolerance efficiency was assessed in T_2 transgenic plants on the basis of agronomical and biochemical analyses. These detailed analyses reveal that *DREB1A* gene has fostering effect on the expression of a large number of genes by means of enhanced germination frequency, germination rate index, shoot, root and coleoptiles lengths, relative water contents, proline contents and total chlorophyll contents of transgenic plants relative to control plants. In summary, our results propose that *DREB1A* is involved in improving drought stress tolerance of transgenic wheat by sustaining growth and yield of plants.
Keywords: *drought stress, DREB1A, in planta transformation, proline contents, relative water contents, transgenic wheat, total chlorophyll contents*

Introduction

Wheat (*Triticum aestivum* L.) is an important cereal crop and it plays a significant role in food security of the world. It is a major crop of Pakistan (Ishaq and Memon, 2016; Mehmood et al., 2016; Abbas et al., 2017). The contribution of wheat to GDP is 3.4% and its share in agriculture value addition is 13.8% (Adeel et al., 2017). Pakistan has to produce extra food grains to meet the dietary needs of the increasing population which is currently over 191.71 million (Pakistan Economic Survey, 2014-15). Overall

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_19992024

dietary needs of the population have reached to twenty million tons wheat (Anjum et al., 2016). However, its productivity is affected by many environmental stresses due to sudden climatic changes and scarcity of water (Alghabari et al., 2015). Due to limitation of water resources, wheat cultivation area has been exposed to water shortage. Due to climatic changes and continuous droughts in summer, the yield losses have been more intensified. Severe yield losses can occur by drought stress because it can happen at any stage of development in wheat especially in arid and semi-arid areas (Farooq et al., 2011). Drought stress obstructs root growth, shoot growth, leaf area, biomass accumulation, plant fresh and dry weight signifying the severe losses of plant development (Xue et al., 2003; Jan et al., 2017). The degree of drought sensitivity is dependent on developmental phase of wheat plants because some developmental stage can cope with the drought, while others are highly sensitive to drought. For example, if wheat is vulnerable to drought stress before anthesis stage, then reduction in plant height, number of ears and leaf area will occur (Hassan et al., 1987). While the number of kernels per ear and weight of kernels of wheat is reduced if the drought stress occurs at lateral stages of development (Sieling et al., 1994). Soil moisture stress at heading stage caused reduction in shoot growth, while no drought effect was evident on root growth (Saidi et al., 2008). Similarly, 37% yield reduction was recorded by shortage of water at booting to maturity stage, while this loss was increased to 44%, when drought stress befell at heading to maturity stage (Prasad et al., 2011).

Plants have adopted many mechanisms to tolerate the effects of drought such as metabolic accumulation of organic solutes including proline, glycine betaine, sugars etc. (Zhu, 2001) wax accumulation (Chen et al., 2003) production of antioxidant enzymes (Mowla et al., 2002), abscisic acid accumulation (Marcotte et al., 1989) and through transcription factors (Jain et al., 2001). During drought stress, different genes are activated and increase the drought tolerance of plants. These include *BADH*, *WXP1* and *DREB1A* (Zhang et al., 2005; Pellegrineschi et al., 2004). Researchers are trying to cope with drought problem using *Agrobacterium* mediated genetic transformation (Cheng et al., 1997; He et al., 2010). In this phenomenon, T-DNA region of the Ti-plasmid is excised, transformed into the host plant tissue and integrated into the genome of the plant (Ali et al., 2016). *Agrobacterium* mediated genetic transformation depends upon different factors affecting the rate of transformation (Amoah et al., 2001; Yenchon and Te-chato, 2012; Wu et al., 2003).

Genetic engineering approach is fast and precise means (Cushman and Bohnert, 2000) of genetic improvement of crops transferring only desirable genes into crop of interest (Jones, 2005). *DREB1A* gene enhanced the drought tolerance ability of transgenic plants triggering the expression of twelve (*CBF3/DREB1A*) target genes in non-stress condition, while 27 extra genes were stimulated in water stress conditions without involving growth retardation (Oh et al., 2005). Target genes of *CBF3/DREB1A* includes RNA binding proteins, transcription factors, KIN (cold inducible) proteins, Phospholipase C, Sugars transport proteins, Osmoprotectant biosynthesis proteins, Carbohydrate metabolism related proteins, Late embryogenesis abundant (LEA) proteins and the Proteinase inhibitors (Seki et al., 2001).

Gene transformation of wheat is still comparatively difficult as compared to other cereals due to relatively longer genome and being tissue culture recalcitrant crop. So, there is strong need to improve and select the proper methodology of genetic transformation. In planta *Agrobacterium* mediated transformation is a cheap and fast method to develop transgenic plants. It was previously used for the development of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_19992024

transgenic maize (Brunecky et al., 2011), tomato (Shah et al., 2015; Ali et al., 2018), rice (Andrieu et al., 2012), tobacco (Brunecky et al., 2011) and wheat (Borisjuk et al., 2019; Khan et al., 2019).

Keeping in view the above facts, the present study was planned to optimize the in planta transformation protocol for transformation of *DREB1A* gene through *Agrobacterium* strain EHA101 in wheat cultivar Lasani-08. During this study, concentration of 2, 4-D and soaking time of seeds were optimized. Comparison was made between two procedures of seeds inoculation i.e. inoculation before germination of seeds and inoculation after germination of seeds. The T_2 transgenic plants were scrutinized on the basis of agronomical and biochemical characteristics.

Materials and methods

Experimental sites and source of explants

During our previous research study (Khalid et al., 2013), we confirmed that among six wheat cultivars namely Lasani-08, Inqalab 91, Tatara, Chakwal 97, GA-02 and Khyber obtained from Crop Science Institute (CSI), NARC Islamabad, one cultivar Lasani-08 was found to be the best for regeneration. Therefore, in this study we used cv. Lasani-08 and optimized factors affecting in planta transformation and then screening of transgenic plants was done on the basis of agronomical as well as biochemical characteristics. Optimization of in planta transformation protocol as well as transgenic wheat plants carried out in NIGAB, NARC, Islamabad, Pakistan, while screening of drought tolerance of transgenic line was done at Plant Physiology Lab, PMAS, Arid Agriculture University, Rawalpindi, Pakistan.

Agrobacterium-mediated in planta transformation

The experimental procedure of in planta transformation has been shown in *Figure 1*. *Agrobacterium* strain EHA101 carrying binary plasmid PCAMBIA containing *DREB1A* gene under 35 S promoter with *hpt* (plant selectable marker gene) and kanamycin resistance gene (bacterial selectable marker gene) was used in this study (*Fig. 2a*). Seeds of wheat cv. Lasani-08 were washed with tap water to remove dust and surface sterilization was done with 70% ethanol for 30 s, 60% Clorox for 15 min and then washed with autoclaved distilled water 3-5 times to remove the Clorox from the surface of seeds. Sterilized seeds were placed on filter paper and soaked in distilled water supplemented with different concentration of 2, 4-D (2.0, 3.0 and 4.0 mg/l) for 3, 6 and 9 h to get the suitable combination of soaking time and 2, 4-D for maximum transformation efficiency. On the other hands, in case of inoculation after germination, seeds were soaked in distilled water devoid of 2, 4-D until emergence of coleoptiles. Subsequently, seeds were peeled off with the help of forceps at the top of embryo to expose the embryonic apical meristem. O.D of overnight bacterial culture was maintained at $O.D_{600\ nm} = 0.8 - 1.0$ by photonanometer for co-infection. Embryo tip was cut with sharp blade, injured with acupuncture pin No.35 and a drop of *Agrobacterium* suspension was inserted. Then these seeds along with embryonic apical meristem were dipped in inoculation medium (*Agrobacterium* suspension containing 3.0 mg/l 2, 4-D and 300 μM acetosyringone) for 40 min. The culture was placed for 48 h in dark at 28 °C in growth chamber for co-cultivation. The *Agrobacterium* attached with seeds during co-cultivation were eliminated by washing with autoclaved distilled water then

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_19992024

with MS liquid supplemented with 500 mg/l cefotaxime sodium. Sterilized seedlings were transferred in chiller at 5 °C for further development. Pre-selection media (MS liquid supplemented with 3.0 mg/l BAP, 500 mg/l cefotaxime sodium) was used for first 3-5 d. Then culture was transferred to selection media (MS liquid, 250 mg/l cefotaxime and 50 mg/l hygromycin). These seedlings were vernalized for further 2-3 weeks and hygromycin selected seedlings were transferred to glass house under controlled conditions for further growth and development.

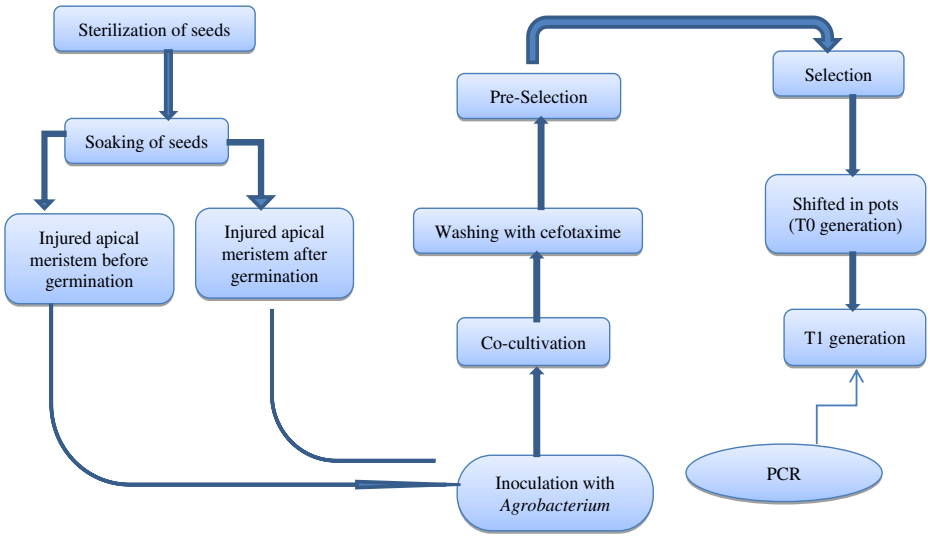

Figure 1. *Flow diagram showing the development of wheat transgenic plants via in planta method of Agrobacterium-mediated transformation*

Confirmation of transgenic plants

The 3-weeks old hygromycin resistant seedlings (T_0 generation) were shifted to glass house till maturity. The transgenic seeds of T_0 generation were further sown to get T_1 generation. When plants of T_1 generation reached up to 2-3 leaf stage, genomics DNA was isolated from fresh leaves by CTAB method (Murray and Thompson, 1980) and then PCR was performed using *DREB1A* gene specific primers; F 5'-TGAACTCATTTTCTGCTTT-3' and R 5'-TAATAACTCCATAACGATA-3'. The product of PCR was run on 1% gel electrophoresis for 30 min at 100 V current and visualized by gel documentation system (Alpha imager HP) under UV light. The 5 µl of each PCR product was loaded in gel with the help of 2.0 µl bromophenol blue for each sample as loading dye. 1 kb ladder was used to compare size of required band (649 bp).

Southern blotting

The copy number of inserted gene in transgenic plants was determined through southern blotting. For probe preparation, plasmid DNA was isolated and amplified by PCR using *DREB1A* primers. About 50 µl of PCR product of plasmid DNA was run on 1.5% gel electrophoresis applying 50 V voltage, 100 A current and 50 W power for 30 min. The required band was visualized under UV light in gel documentation system and cut the gel around the band and transferred the band along with gel in Eppendorf tube. Binding buffer of 600 µl was mixed, incubated for 10 min at 56 °C with continuous shaking at the rate of 500 rpm in incubator. After melting, gel was shifted

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_19992024

into column and centrifugation was done at 14000 rpm for 1 min. Filtrate was discarded and pellet was washed with 700 µl washing buffer having ethanol through centrifugation at 14000 rpm for 1 min and then filtrate was discarded. The 50 µl elusion buffer was added at mid of membrane and incubated for 1 min in centrifuge machine and then started centrifugation at the rate of 14000 rpm for 1 min. The pure DNA was eluted and stored at -80 °C. DNA (10 µg) of three transgenic plants (K1, K2, K3) of T_1 generation obtained from in planta transformation was digested with HindIII endonuclease. Then samples were run on 0.8% agarose gel. Subsequently, it was blotted on a nylon membrane. Non-Radioactively labeled (Fermentas Biotin DecaLabel DNA labeling kit) 649 bp PCR amplified fragment plasmid DNA was used as a probe.

RNA isolation and cDNA synthesis

Leaf sample (80 mg) was homogenized with the help of 1 ml Tri reagent, and then this homogenized mixture was placed at room temperature for 5 min in Eppendorf tubes. 2 µl of chloroform was added in this homogenized mixture and vigorously shaking was done for 15 s. The homogenate was placed at room temperature for 2-15 min and then centrifugation was done at 12000 rpm for 15 min. After centrifugation, a colorless aqueous phase (having RNA) was appeared on the top of Eppendorf tube. This colorless aqueous phase was taken into new Eppendorf tube and 500 µl isopropanol was added into each sample and stored for 5-10 min at room temperature. Again, centrifugation was done for 8 min at 12000 rpm. Supernatant was poured out and 70% ethanol (1 ml for each sample) was used for washing RNA pellet, vertexed following centrifuge at 7500 rpm for 5 min. Ethanol discarded and pellet remained in Eppendorf which was air-dried for 3-5 min. RNAase free water was used to dissolve RNA pellet. This dissolved form of RNA incubated for 10-15 min at 55-60 °C temperature and then stored at -80 °C for further used. For cDNA synthesis, PCR profile was set as 65 °C for 5 min, 42 °C for 80 min and 72 °C for 10 min. 20 µl reaction volumes were used for each sample. Conventional PCR was carried out in two steps. In step one, PCR tubes were placed in PCR machine for 5 min at 65 °C. Each PCR tube contained RNA (4 µl), oligodT (1 µl) and water (9.5 µl). After 5 min, they were chilled in ice for 2-3 min. In step 2, for each sample, a master mixture containing RT buffer (4 µl), dNTPs (1 µl) and RT (0.5 µl) was prepared before starting first step PCR. This master mixture (5.5 µl) was added into chilled PCR tubes getting total volume of 20 µl in each PCR tube. Then, these PCR tubes were immediately placed in PCR machine at 42 °C for 80 min and 72 °C for 10 min (PCR profile was already set). After completion of cDNA synthesis, samples were stored at -20 °C for further use in RT-PCR.

RT-PCR analysis

In order to check the expression of desired gene, RT-PCR analysis was performed. For it, a reaction volume (20 µl) was used in each PCR tube. This reaction volume was made by mixing cDNA (2 µl) with master mixture (18 µl). For master mixture, 10.5 µl water, forward (1 µl) and reverse (1 µl) primers, 2.4 µl $MgCl_2$, 0.4 µl dNTPs, 0.3 µl Taq Polymerase and 2 µl Taq DNA buffer were mixed. PCR profile was set as: initial denaturation temperature 94 °C for 5 min for 1 cycle; for 35 cycles temperature profile was set as denaturation at 94 °C for 1 min, annealing at 50 °C for 1 min and extension at 72 °C for 1 min. At the end of one cycle, final extension temperature was set at 72 °C for 10 min.

DOI: http://dx.doi.org/10.15666/aeer/1802_19992024

Evaluation of drought tolerance of transgenic plants on the basis of agronomical characteristics

The transgenic plants were scrutinized for their drought tolerance at three stages. At first stage, Polyethylene Glycol (PEG) solution was applied on petri plates to induce artificial drought stress (-2, -4, -6 and -8 bars osmotic stress) in laboratory. The stock solution of PEG 8000 (25% w/v) was prepared using autoclaved distilled water. Then dilution of different concentration was prepared starting from 6.0%, 8.0% up to 24.0%. The osmotic potential was measured using osmometer (Osmomate 030) at Central Laboratory PMAS, Arid Agriculture University, Rawalpindi, Pakistan. The reading was taken in osmomol/kg which were converted into MPa using formula = CRT, here C = Osmolality in moles per kg, R = .0083 and T = 25 °C + 273. MPa value was converted into bars by multiplying -10. A graph (standard curve) was plotted between PEG percentage and bar values. Four levels of PEG (-2, -4, -6 and -8 bar) osmotic stress were used to induce drought at germination stage of transgenic and non-transgenic (control) plants by sowing seeds on moist filter papers with different levels of PEG solution at 25 °C. The healthy seeds were sterilized with 60% Clorox for 15 min followed by four to five times washing with autoclaved distilled water. Subsequently, they were placed in petri plates having two filter papers wet with 5 ml of different PEG-solution. Petri plates were kept in growth chamber at 25 °C and data about germination of seeds was recorded daily for 8 days. At second stage, drought stress was induced withholding water to transgenic and control plants in pots under glass house conditions. At third stage, transgenic plants were screened out on the basis of drought tolerance efficiency relevant to crop yield.

Data about germination percentage were recorded after the interval of 24 h up to 8 days. The calculation was made using this formula:

$$\text{Germination (\%)} = \frac{\text{Number of seeds germinated}}{\text{Total number of seeds used}} \times 100 \quad \text{(Eq.1)}$$

Germination rate index was determined using the formula described by Camargo and Vaughan (1973):

$$\text{Germination rate index} = \frac{\text{Number of seeds germinated}}{\text{day}} \quad \text{(Eq.2)}$$

The length of shoot, root and coleoptiles were measured in cm with the help of scale at the 8th day of experiment.

Evaluation of drought tolerance of transgenic plants on the basis of biochemical characteristics

The drought was induced at vegetative stage of T_2 transgenic and control plants withholding water for 8 days. Relative water contents (RWC) of transgenic and control plants were determined following method proposed by Barrs and Weatherley (1962). Fresh leaves were excised from plants, sealed within aluminum file and plastic bag and quickly transferred to lab. Fresh weight was taken immediately after arrival in Laboratory. Then, turgid weight was taken after soaking leaves into distilled water for 6 h at room temperature. Dry weight was taken after drying the samples at 70 °C in an oven. Finally, the calculation of RWC was made with the help of following formula:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_19992024

$$\text{RWC}\,(\%) = \frac{\text{Fresh weight} - \text{Dry weight}}{\text{Turgid weight} - \text{Dry weight}} \times 100 \quad \text{(Eq.3)}$$

Proline contents (mg/g fresh weight) were determined following the method devised by Bates et al. (1973). Fresh leaf sample (0.25 g) was ground and homogenized with 5 ml of 3% sulfosalicylic acid. Extract was poured into test tubes and allowed to set down the debris. Then, 2 ml of supernatant was taken into another test tube mixed with 2 ml ninhydrin reagent (ninhydrin = 1.25 g, glacial acetic acid = 30 ml and 6 M phosphoric acid; 20 ml) and 2 ml glacial acetic acid. Samples were boiled in water bath at 100 °C for 1 h and then reaction was immediately stopped in ice. After cooling, 4 ml toluene was added into each sample and shaken vigorously for few seconds, and upper layer of toluene appeared after few seconds. Supernatant was collected into another set of test tubes. Absorbance of supernatant was taken by spectrophotometer using the wavelength of 520 nm. Toluene was used as a blank.

$$\text{Proline contents}\left(\frac{\text{mg}}{\text{g}}\text{FW}\right) = \frac{(\text{Absorbance of sample}) \times (\text{k value}) \times (\text{Dilution factor})}{\text{Weight of sample}} \times 100 \quad \text{(Eq.4)}$$

Here FW denotes fresh weight.

Total chlorophyll contents (mg/g fresh weight) were measured in Plant Physiology Lab, PMAS, Arid Agriculture University, Rawalpindi, Pakistan according to the method of Arnon (1949). Fresh leaves (5 g) were immersed in 10 ml of 80% ethanol; tubes were capped and digested the samples at 80 °C for 10 min in water bath. Green extract immediately was cooled down in incubator (as a dark room) to give protection from light because it degrades the chlorophyll. Optical density was measured after 3 h for chlorophyll "b" and chlorophyll "a" at 663 nm and 645 nm, respectively using spectrophotometer. Ethanol (80%) was used as a blank.

$$\text{Total chlorophyll contents}\left(\frac{\text{mg}}{\text{g}}\text{FW}\right) = \frac{(20.2 \times \text{OD at 645 nm}) + (8.02 \times \text{OD at 663 nm})}{\text{Weight of sample}} \times \text{V} \quad \text{(Eq.5)}$$

$$\text{Chlorophyll a contents}\left(\frac{\text{mg}}{\text{g}}\text{FW}\right) = \frac{(12.7 \times \text{OD at 663 nm}) - (2.69 \times \text{OD at 645 nm})}{1000 \times \text{Fresh shoot weight (g)}} \times \text{V} \quad \text{(Eq.6)}$$

$$\text{Chlorophyll b contents}\left(\frac{\text{mg}}{\text{g}}\text{FW}\right) = \frac{(22.7 \times \text{OD at 663 nm}) - (4.69 \times \text{OD at 645 nm})}{1000 \times \text{Fresh shoot weight (g)}} \times \text{V} \quad \text{(Eq.7)}$$

Here: V = Volume of extract (ml); OD = Optical density; FW = Fresh weight.

Drought tolerance efficiency (%)

Comparison between transgenic and control plants was done on the basis of drought tolerance efficiency. The transgenic and control plants of T_2 generation were divided into two groups. Each group contained both transgenic and control plants. Drought stress was applied to one group withholding water, while 2nd group plants were kept as a control with continuous irrigation. Drought tolerance efficiency (DTE) was calculated keeping the yield of both groups by following the equation of Fischer and Wood (1981):

$$\text{Drought tolerance efficiency}\,(\%) = \frac{\text{Yield under stress condition}}{\text{Yield under non-stress condition}} \times 100 \quad \text{(Eq.8)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_19992024

After calculating drought tolerance efficiency, both values were compared and difference was calculated that how much drought tolerance ability of transgenic plants increased through transformation of *DREB1A* gene.

Improvement in wheat for drought tolerance = (DTE% of transgenic plants) – (DTE% of control plants).

Improvement in transgenic plants regarding average spike length, grains per spike, 100-grain weight was measured in both conditions i.e. normal and stress conditions and compared with control plants.

Statistical analysis

Data were recorded in percentage and statistical analysis was carried out applying ANOVA with two factorial CRD using statistics 8.1. Three replications were used for each treatment. The significance of treatment means was further analyzed using LSD test.

Results

Optimization of soaking time and 2, 4 D for in planta transformation

The effects of two treatments (3 and 9 h soaking time) were non-significantly different from one another, while 6 h soaking time was significantly different from these two treatments showing maximum hygromycin resistant plants (18.31% on average basis) on selection media (*Table 1*). Similarly, no significant differences were found between 2.0 and 4.0 mg/l of 2, 4-D, while 3.0 mg/l 2, 4-D showed significant difference from the other two treatments giving 21.8% hygromycin resistant plants. Subsequently, soaking time 6 h and 3.0 mg/l 2, 4-D yielded 25.12% plants survived on the selection media. Conclusively, seeds were soaked in distilled water containing 3.0 mg/l 2, 4-D for 6 h to get maximum transformation efficiency of our desired gene (*Table 1*).

Table 1. *Effect of various soaking times and 2, 4-D concentrations on transformation efficiency (%)*

Soaking time (h)	Hygromycin resistant plants (%)			
	2 mg/l (2, 4-D)	3 mg/l (2, 4-D)	4 mg/l (2, 4-D)	Mean
3	10.53 e	20.42 b	9.23 e	13.39 b
6	15.97 c	25.12 a	14.85 cd	18.31 a
9	14.85 cd	19.87 b	11.20 de	15.31 b
Mean	13.78 b	21.80 a	11.76 b	

Each value is the mean of three replications. Mean values following by the different letters show significant differences ($p \leq 0.05$). For 2, 4-D, LSD value was 2.22 at $p \leq 0.05$. For soaking time, LSD value was 2.22 at $p \leq 0.05$, while for interaction of 2, 4-D and soaking time, LSD was 3.86 at $p \leq 0.05$

Optimization of apical meristem incubation method for in planta transformation

Table 2 shows that three hundred seeds were surface sterilized for each experiment i.e. inoculation before and after germination of apical meristem. Out of which 250 and 263 seeds were co-cultivated, respectively. After co-cultivation, these seeds were washed with MS liquid media having 500 mg/l cefotaxime then transferred to regeneration media. The regeneration frequency was 48 and 40.68% when seeds were inoculated before and after

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_19992024

germination, respectively (*Table 2*). In case of inoculation after germination, apical meristem was blindly injured through cut end of coleoptiles, so it might be damaged cells of mother germ lines due to which regeneration frequency was low, while in case of before germination embryo was visible and was easily targeted for injury. These results suggested that injury of apical meristem before germination of apical meristem was better than that of after germination. Injury should be made very carefully so that germ line mother cells remained safe from damaging. Hygromycin (50 mg/l) was used in selection media and 25 and 0% hygromycin resistant plants were obtained from seeds which were inoculated before and after germination, respectively (*Table 2*).

Table 2. *Assessment of inoculation method for incubating apical meristem before and after seed germination*

In planta transformation steps	Inoculation of apical meristem before seed germination	Inoculation of apical meristem after seed germination
Number of treated seeds	300	300
Number of co-cultivated seeds	250	263
Number of regenerated seeds	120	107
Regeneration percentage	48%	40.68%
Number of hygromycin resistant plants	30	Nil
Hygromycin resistant percentage	25%	Nil
Number of seeds sown in T_1 generation	50	Nil
Number of germinated seeds	47	Nil
PCR positive plants	3	Nil
Transformation efficiency	6.38%	0%

Transformation efficiency was measured by the number of PCR positive plants divided by the total number of explants cultured on selection medium, expressed in percentage

Molecular analysis of wheat transgenes

Seeds of hygromycin resistant plants (T_0 generation) were pooled, out of which only 50 seeds were sown due to limited space and T_1 generation was obtained. 47 seeds were germinated and when seedlings were at 2 to 3 leaf stage, they were confirmation by PCR using *DREB1A* specific primers. The results indicated that 3 plants were PCR positive showing transformation efficiency of 6.38% (*Table 2; Fig. 2b*). These plants were also found positive by PCR using *hpt* specific primers (*Fig. 2c*). In order to assess the inheritance pattern of transgene, segregation analysis was performed by normal PCR using *DREB1A* specific primers. The segregation ratio of three transgenic plants has been shown in *Figure 3*. The data indicated that segregation ratio was 5:5, 4:5 and 2:7 in K1, K2 and K3 transgenic plants, respectively that exhibited non-Mendalian inheritance pattern (*Table 3*). Trizole reagent was used for isolation of RNA from the leaves of transformed plants. cDNA synthesized from RNA was used for amplification of *DREB1A* gene through PCR using gene specific primers. The results show the differential expression pattern of transgenic plants i.e. some transgenic plants gave good expression, while few produced weak expression (*Fig. 4*). Southern blotting was done to detect the number of copies of desired gene in three transgenic plants (K1, K2 and K3) that indicated 1-2 copies of gene (*Fig. 5*).

Germination of T_2 transgenic plants improved in response to drought stress

The seeds of the transgenic plants were tested for germination frequency and germination rate index. The transgenic and control seeds were placed on filter paper soaked with different concentrations of PEG solution (-2, -4, -6 and -8 bar osmotic stress) to induce artificial drought stress under controlled condition. *Figure 6* indicated that the transgenic and control plants had significant difference ($P = 0.0000$) at 5% alpha level. Similarly, a significant difference among different treatments of PEG stress as well as among the interaction of transgenic plants, control plants and PEG stress for germination frequency and germination rate index. But there was non-significant difference ($P = 0.2607$) in terms of the interaction of plants and PEG stress at 5% alpha

DOI: http://dx.doi.org/10.15666/aeer/1802_19992024

level. The results showed that the highest germination frequency (94.97%) was recorded in transgenic plants as compared to control plants (80.83%) at -2 bar osmotic stress (*Fig. 6*). Similarly, more germination rate index (5.5) was found in transgenic plants than that of control plants that yielded 2.8 germination rate index (*Fig. 7*).

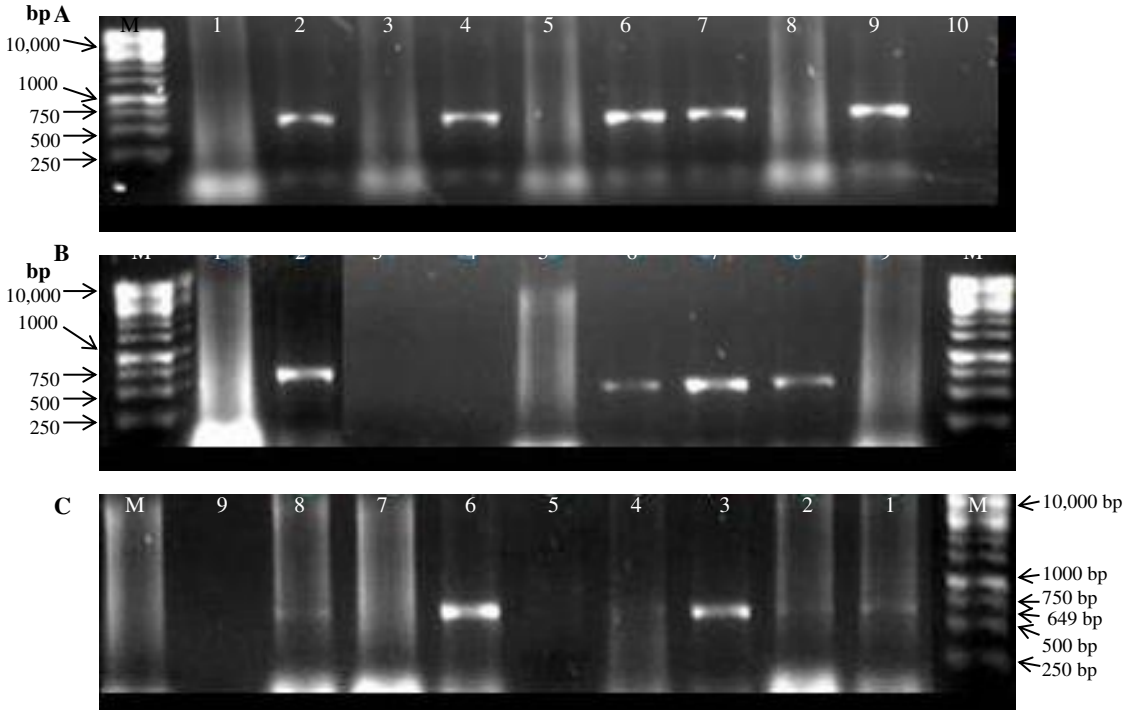

Figure 3. *Segregation analysis of three transgenic plants of wheat (K1, K2 and K3). Seeds obtained from T_1 transgenic plants were sown in pots for T_2 generation. Segregation pattern of DREB1A gene was noticed through PCR using DREB1A specific primers. The segregation ratio was 5: 5, 4: 5 and 2: 7 for three transgenic plants K1, K2 and K3, respectively. The total 28 plants of T_2 generation were tested through PCR for the presence of DREB1A gene using DREB1A specific primers. Results shows that out of these tested plants, 11 plants were PCR positive having DREB1A gene in their genomes. It indicates that transformation was successful in these plants and gene was stably inherited into T_2 generation*

Length of shoots, roots and coleoptiles of T_2 transgenic plants improved in response to drought stress

Seedling stage is an appropriate stage for testing drought stress tolerance using PEG-8000 in laboratory condition. During this study, it was confirmed that the increased concentration of PEG prevented the growth, and survival of seedling and PEG concentration was found to be inversely proportional to the shoot length. After 8 days, it was noticed that the lethal effect was more prominent in control plants as compared to transgenic plants. The data in *Figures 8–10* indicate that shoots, roots and coleoptiles length of transgenic plants were significantly different to control plants (non-transgenic plants). The results showed that the shoots, roots and coleoptiles length of transgenic plants were 13.11, 5.77 and 5.6 cm, respectively at -2 bar osmotic stress as compared to their non-transgenic counterparts that showed 12.46, 3.27 and 3.3 cm shoots, roots and coleoptiles length. While at -8 bar osmotic stress, the transgenic plants gave 7.49, 5.4 and 2.93 cm shoot, root and coleoptile lengths which were comparable to their non-transgenic counterparts that produced 3.47, 1.84 and 1.64 cm shoot, root and coleoptiles lengths. Our results showed that shoots, roots and coleoptiles length reduced with the increase in the stress level. But this reduction was more prominent in control plants.

Increased relative water contents of T_2 transgenic plants under drought stress

Water is a limiting factor for plant growth and development. It maintains the turgor pressure in plant cells and involves in all physiological function of plants. So, the plants which maintain the high relative water contents in their cells have good performance under drought stress as compared to the plants having low water contents (Ali et al., 2015). In this regard relative water content was measured in transgenic and control plants at germination stage inducting the drought stress through PEG, while at vegetative stage drought stress was induced withholding water for 8 d. The significant difference ($P = 0.0000$) were recorded between transgenic and control plants and interaction of transgenic and control plants with PEG stress (*Fig. 11*). The highest relative water contents (92.28%) were recorded in transgenic plants as compared to control plants (76.63%) at -2 bar osmotic stress. When PEG stress increased then RWC decreased significantly in control as well as in transgenic plants. But in transgenic plants RWC was not reduced significantly as osmotic stress increased from -2 to -4 bar osmotic stress. *Figure 12* shows the significant difference ($P < 0.05$) between treatments, cultivars (Transgenic and control plants) but non-significant difference ($P = 0.210$) in terms of interaction among treatments and cultivars (Transgenic and control plants). During this experiment, drought stress was induced withholding water for 8 d. The highest relative

DOI: http://dx.doi.org/10.15666/aeer/1802_19992024

water contents (67.46%) was found transgenic plants which were comparable to those of control plants that yielded 40% relative water contents (*Fig. 12*).

Proline contents of T_2 transgenic plants improved in response to drought stress

Osmotic adjustment is the mechanism of drought tolerance in which plant cells accumulate different osmoprotectants such as polyols, proline, proteins and polyols etc. These osmoprotectants protects the cells membranes from stress conditions (Filippou et al., 2014). These compounds accumulated in higher quantities under stressed condition and acted as osmoprotectants (Strange and Yancey, 1994), among these, proline (amino acid) enhances the stability of proteins and membranes under water stress conditions (Anjum et al., 2017). Moreover; its concentration increased with the increase in drought levels (Mujtaba et al., 2007). *Figure 13* shows the significant difference ($P < 0.05$) between transgenic plants and control plants in terms of proline contents and a significant difference between treatments as well as between the interaction of cultivars (transgenic and control plants) and treatments (drought stress by withholding water). The data showed that proline contents increased significantly in transgenic and control plants after drought stress. This increase in proline contents from1.03 µmol/g to 7.06 µmol/g that was more prominent and significant in transgenic plants as compared

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_19992024

to control plants (0.86 µmol/g to 3.50 µmol/g) under normal and drought conditions, respectively. The reason of this higher accumulation of proline contents in transgenic plants might be due to function of *DREB1A* gene that triggers the other genes related to mechanism of production of proline under drought stress. The higher proline contents in transgenic plants indicated that these are more drought tolerance than control plants.

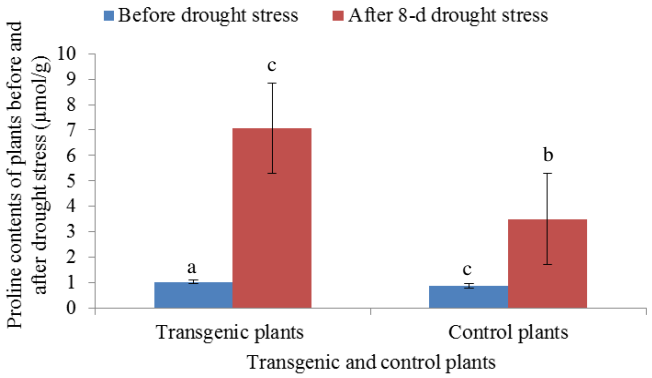

Figure 13. *Effect of 8-d drought stress on proline contents (µmol/g FW) of transgenic and control plants of wheat. The drought stress was induced by withholding water for continuous 8-d and then drought tolerance was assessed in transgenic plants on the basis of proline contents (µmol/g FW). The error bars indicate standard error. Means not sharing a letter in common differ significantly at 5% probability level*

Increased chlorophyll contents of T_2 transgenic lines after drought stress

Chlorophyll is the most effective parameter for the selection of drought tolerant wheat genotype under drought stress conditions (Rad et al., 2012). The data in *Figures 14–16* showed that the chlorophyll contents decreased non- significantly in transgenic plants (before and after drought stress), while they were decreasing significantly in control plants. The significant difference of chlorophyll contents was recorded between transgenic and control plants after drought stress. These results indicated that transgenic plants have capability to sustain their chlorophyll contents in drought stress and behave as drought tolerant wheat plants as compared to control plants. This capability of transgenic plants was developed due to the function of *DREB1A* gene in their genome.

Improved agronomic characteristics of T_2 transgenic plants in term of drought tolerance efficiency

The *Table 4* showed the significant differences ($P < 0.05$) between treatments as well as between transgenic lines and control plants for the parameters (spike length, grains per spike and 100-grains weight). The *Table 4* shows the comparison of transgenic plants with no-transgenic plants (control plants). It was observed that in normal conditions, spike length (10.7 cm), grain per spike (57) of transgenic plants was significantly higher than non-transgenic plants i.e. 10.2 cm (spike length) and 53 (grains per spike), respectively. Similarly, weight of 100 grains (4.72 g) of transgenic lines was a little bit higher than non-transgenic plants (4.63 g). But in case of drought conditions the reduction in spike length, 100 grains weight and grains per spike were much lower in transgenic plants as compared to non-transgenic plants (*Table 4*).

Table 4. *Improved agronomic characteristics and drought tolerance efficiency of transgenic plants*

Characteristics	Transgenic plants		Control plants	
	Normal condition	Drought stress	Normal condition	Drought stress
Spike length (cm)	10.7 a**	9.6 c	10.2 b	8.5 d
Number of seeds per spike	57 a	46 c	53 b	31 d
100-grain weight (g)	4.72 a	4.25 b	4.63 a	2.15 c
Drought tolerance efficiency (DTE)	90%*		46.43%	
Improvement in DTE	DTE of transgenic plants – DTE of control plants = (90) - (46.43) = 43.57%			

Each value is the mean of three replications. For comparison of spike length, LSD value was 0.36 at $p \leq 0.05$. For comparison of number of seeds per spike, LSD value was 4.32 at $p \leq 0.05$, while for comparison of 1000-grain weight; LSD value was 0.1001 at $p \leq 0.05$. *Calculation based on 100-grain weight in normal and stress condition. **Means not sharing a letter in common differ significantly at 5% probability level

Drought tolerance efficiency (DTE) is a criterion to compare drought tolerance cultivars. It was proposed by Fisher and Wood (1981). It is a good index for determination of drought tolerant wheat cultivars. So, this index was used for transgenic plants and control plants. The data in *Table 4* showed that the drought tolerance efficiency of transgenic plants (90%) was much higher than control plants (46.43%). So, the total improvement in DTE of transgenic plants was 43.57%. This increase in drought tolerance efficiency was due to the presence of *DREB1A* gene in transgenic plants. This transcription factor might trigger other genes to produce such proteins which protect the plants from drought stress and also maintain the water balance in cells of leaves. So, as a result chlorophyll contents stable in leaves and maximum food were synthesized which was stored in the form of grains. It was also used as criteria for drought and heat resistance in spring wheat (Bahar and Yildrim, 2010) they reported the range of 65-98% (DTE %) in drought tolerance wheat cultivars.

Discussion

Wheat ensures the food security of the world, but it is severely affected by scarcity of water due to limited water resources. Drought can occur at any developmental stage of wheat that drastically limits its yield. Plants have to adopt some tolerance mechanisms to endure the severity of water shortage. Genetic improvement of wheat can cope with drought problem using *Agrobacterium*-mediated method. Dehydration-responsive element-binding 1A (*DREB1A*) gene enhances the drought tolerance ability of transgenic plants activating the expression of drought related target genes (Oh et al., 2005). In planta method of genetic transformation is a technique of gene transformation which has low cost, does not require sterilized environment and it avoids laborious hardworking tissue culture steps.

During this study, inoculation before seed germination was found to be optimum for maximum transformation efficiency of in planta transformation because inoculation media fortified with 3.0 mg/l 2, 4-D decreased the cell division and delayed the process of differentiation. As a result, *Agrobacterium* got maximum time to transfer its T-DNA

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_19992024

to apical meristem cells. While in case of inoculation after germination, seeds were soaked in distilled water only without 2, 4-D, so no transformation was obtained. The cell division and differentiation processes in meristematic cells increased rapidly with the increase of soaking time due to which the probability of infection to cells by *Agrobacterium* was decreased. These processes needed to be slow down for infection of target cells by *Agrobacterium* (Razzaq, 2005). The piercing of meristematic cells with needle facilitates *Agrobacterium* to reach and infect the germ line mother cells. In case of inoculation after germination, no hygromycin resistant plants were visualized indicating that there would be two possibilities; first was damaging cells of mother germ lines and second was that *Agrobacterium* could not reach and infect the germ line mother cells due to large number of layers of cells formed on outer surface of germ line mother cells. On the contrary, 25% hygromycin resistant plants were obtained in case of inoculation before germination indicating that at this time, germ line mother cells could easily be targeted and *Agrobacterium* could easily reach and infected the target cells. The similar studies were reported by Razzaq et al. (2005) who conducted in planta transformation of wheat and sixty-three kanamycin resistant plants were reported. Out of these sixty-three plants, only three plants were PCR positive and one plant produced seeds. Bratic (2007) transformed the buckwheat via in planta transformation and compared the efficiency of two different procedures, i.e. vacuum infiltration and infiltration by syringe. It was concluded that vacuum infiltration was more efficient than that of infiltration by syringe. Rao et al. (2008) reported in planta transformation of pigeon pea in which primary transformants were chimeric in nature. Due to this reason, T_0 plants were not tested for the confirmation of gene through PCR. PCR was performed in T_1 generation and 13.71% transformation efficiency was reported. Cheng et al. (2003) analyzed the transgenic wheat by southern blotting and reported that 67% transgenic wheat plants obtained a single copy of transgene. Yao et al. (2006) developed transgenic wheat and reported that in transgenic line, one to four hybridizing bands were displayed, but most of the lines showed single copy of inserted genes. In present study inheritance pattern of transgene was shown as non-Mendelian ratio. Similarly, Yin et al. (2004) reported 10-50% transgenic plants showing non-Mendelian inheritance; either they were produced by gene gun or *Agrobacterium* mediated transformation. They concluded that this non-Mendelian segregation ratio might be due to the nature of the gene and recipient genome.

The results of our study suggested that *DREB1A* gene improved the germination frequency and germination rate index of transgenic seeds as compared to the seeds of control plants. Early and best germination rate of any crop is a pre-requisite to establish new seedlings. The problem of low germination of seeds exists in most of the wheat cultivars especially when moisture level in soil is very low. Water stress limits the germination frequency, germination rate index as well as emergence of seedling due to loss of seed vigor. During this study, it was also noticed that all transgenic seeds obtained from in planta *Agrobacterium tumefaciens* mediated transformation showed non-uniform germination under different PEG stresses. It was due to segregation of *DREB1A*. Our findings are supported by the results of Pellegrineschi et al. (2004); Kasuga et al. (1999) who conducted research studies in wheat and Arabidopsis, respectively and found non-uniform germination. Germination rate index and germination frequency were higher in seeds of transgenic plants as compared to control plants. These were considered good parameters for screening drought tolerant wheat cultivars. Our results also revealed that with increasing PEG stress levels, germination

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_19992024

frequency and germination rate index were decreased. Our findings are harmonious with the earlier research study by Qayyum et al. (2011) who reported that germination time and germination frequency became low with increasing level of osmotic stress from 0 to -8 bars induced by PEG.

High relative water contents are a resistance mechanism to tackle drought stress (Ritchie et al., 1990). So, relative water content is a tool to discriminate drought sensitive and drought resistant wheat cultivars (Fahliani and Assad, 2005). Amirjani and Madhiyeh (2013) and Bayoumi et al. (2008) induced drought stress under field conditions withholding water and noticed that drought tolerance wheat cultivar had higher relative water contents as compared to drought susceptible wheat cultivar. Our findings were similar with the findings of Raziuddin et al. (2010) who reported that drought tolerance wheat cultivars attained maximum relative water contents as compared to other cultivars during stress induced by PEG 6000. Similarly, Rab et al. (2012) assessed the drought tolerance and drought sensitive wheat cultivars hydroponically by inducing drought through 20% PEG and found higher relative water contents (RWC) at cellular levels in drought tolerance wheat cultivar as compared to drought sensitive one. Drought tolerant wheat cultivars maintained higher RWC in their leaves as compared to drought sensitive cultivars (Keyvan, 2010). Ritchie et al. (1990) reported that RWC were stable in early days of water stress in both drought tolerant and drought sensitive genotypes but it decreased significantly after 8 days of water stress in drought sensitive genotypes. From these results it was concluded that transgenic plants exhibited high relative water contents due to overexpression of *DREB1A* gene.

Our findings are consistent with the findings of Qayyum et al. (2011) who reported the progressive increase of proline contents with the increase of osmotic stress from 0 to -08 bar. Similarly, Raziuddin et al. (2010) reported that when PEG-6000 was used to induce drought stress, proline contents increased up to 10 fold in response to 40% PEG. Bayoumi et al. (2008) reported that drought tolerant wheat cultivar had higher proline contents as compared to drought susceptible cultivars. A similar nature of study was conducted by Moaveni (2011) who recorded more accumulation of proline contents in transgenic wheat plants under drought stress as compared to control plants. Valifard et al. (2012) classified two wheat varieties i.e. Zagros (drought tolerant) and Pishtaz (drought susceptible) and reported that proline increased significantly in tolerant one. These results indicate that proline is a part of defense mechanisms which confers water deficit tolerance to wheat cultivars. The increase of proline contents under drought stress has been reported in previous research studies such as Pigeonpea (Kumar et al., 2011), Brassica (Khan et al., 2010) and bean (Stoyanov, 2005) suggesting that it is a common osmolyte which accumulated in drought conditions. Moussa and Abdel-Aziz (2008) reported that the drought tolerant maize genotype "Giza-2" had accumulated more proline contents than that of drought sensitive maize genotype "Trihybrid-321". Proline improves the drought tolerance at cellular level by stabilizing cytosolic pH, protecting protein and enzyme structure, providing organic nitrogen for growth and survival of plants and also acts as a source of energy (Hare et al., 1999; Errabii et al., 2006; Ashraf and Foolad, 2007; Bayoumi et al., 2008).

Present study reports an enhanced accumulation of chlorophyll contents in transgenic wheat plants as compared to their control counterparts under drought stress. Our results of transgenic plants do not agree with the results of Amirjani and Madhiyeh (2013). This research group reported a significant reduction of total chlorophyll contents in transgenic plants under drought stress. In our study, improvement of chlorophyll

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_19992024

contents in transgenic plants might be due to overexpression of *DREB1A* gene triggering drought tolerant genes that produce certain proteins due to which stability of chlorophyll contents was recorded in them as compared to control plants. Consistent with our findings, Moaveni (2011) assessed drought tolerance efficiency of wheat by measuring chlorophyll contents and reported that chlorophyll contents were significantly improved in transgenic plants as compared to control plants. The chlorophyll contents were significantly higher in transgenic plants as compared to control plants. The philosophy of increased chlorophyll contents in transgenic plants might be possible that DREB1A transcription factors switch on others genes producing chemicals that lower the stress level, protect the plant cells and maintain the water balance in cells. While in control plants, chlorophyll contents were limited due to water stress and they could not maintain their structures. The chlorophyll contents are considered as a good parameter to differentiate drought tolerance and drought sensitive germplasms (Rong-Hua et al., 2006). Drought stress decreased the level of water in mesophyll cells of leaves and as a result chlorophyll pigment degraded and damaged the photosynthetic machinery (Bogale et al., 2011).

Drought susceptible index (DSI) and drought resistance index (DRI) have been used to determine the drought tolerance ability of plants (Fisher and Maurer, 1978; Bidinger et al., 1982). These indices were used to differentiate drought tolerance and drought susceptible cultivars (Dong and Liu, 2005). Drought resistance index has a positive or negative value. If this value is more than 1.3 then that the cultivar lies under the category of drought resistant and if this value is less than -1.3 then cultivar lies under the category of drought sensitive (Akcura et al., 2011). Song-ping et al. (2007) calculated the drought resistance index using the formula DRI = Grain Yield under stress / Grain Yield under normal condition. When it was correlated with other parameters then it was found that this index was correlated with coleoptiles length of the recombinant inbreed line (RILs) of rice under moisture stress. Parameshwaarppa (2007) conducted a similar type of study and concluded that the genotypes which had least DSI value gave more yield, the highest drought tolerance efficiency and the highest drought tolerance index as compared to the other cultivars. They were also in argument that these cultivars maintained the highest harvest index under drought stress conditions.

Conclusion

It was concluded that injury and inoculation of apical meristem was found to be better before seed germination as compared to after seed germination. The transformation efficiency (6.38%) was recorded based on PCR positive plants before germination. Under drought stress, germination percentage and germination rate index was higher in transgenic plants as compared to control plants. Proline contents were significantly increased which was a good indicator of drought tolerance. The stability of transgenic plants was higher as compared to control plant owing to more relative water contents, chlorophyll contents as well as length of shoots, roots and coleoptiles. The total improvement of transgenic plants in terms of drought tolerance efficiency (43.57%) was higher in transgenic plants as compared to control plants.

(Received 28th May 2019; accepted 28th Nov 2019)

Abstract. This phytosociological study was carried out in the steppe of Fatik Mountains in Sanliurfa, between the years 2002-2005. At the end of this study, it was underlined that the dominant vegetation type was steppe in the region and different steppe associations were determined. These were also; *Festuco callieri–Teucrietum poliae* ass. nova, *Astragalo strictifolii–Salvietum sclarea* ass. nova, *Phlomido bruguieri–Thymbretum spicatae* ass. nova, *Asphodelo aestivum–Teucrietum poliae* ass. nova, *Cynodo dactyloni–Bromoetum danthoniae* ass. nova, and *Prosopo farctae–Avenetum erianthae* ass. nova. During the floristic surveys, 153 taxa belonging to 26 families and 107 genera were identified. *Poaceae* with 31 taxa (20.3%), *Asteraceae* with 24 taxa (15.7%), *Fabaceae* with 22 (14.4%), and *Apiaceae* with 13 taxa (8.5%) were the richest families.
Keywords: *steppe vegetation, grazing, ecosystems, characteristic species, association*

Introduction

Turkey is located at the intersection of two important gene centers namely the Mediterranean and Near East and has the ninth highest biodiversity among terrestrial countries. Natural species of most cereals cultivated for human consumption grow on steppe ecosystems (Ture and Bocuk, 2007).

Fatik Mountain, located at the southwestern part of Şanlıurfa, was selected as the research area since it has a peculiar steppe vegetation and has been paid less attention so far as "Adıgüzel and Aytac, 2001" mentioned earlier. The studied area is in the C7 square according to grid system adopted by Davis (1988). Phytogeographically located in the Irano–Turanian Floristic Region, extending between the longitudes of 37.2 North and 37.3 and between the latitudes of 38.6 and 38.7 East (Anonymous, 1995).

The central, eastern and southeastern parts of Turkey belong phytogeographically to the Irano–Turanian region (Zohary, 1973). The Irano–Turanian region is separated into two parts the West and the East Irano–Turanian subregions. There are three provinces in Turkey belonging to the West Irano–Turanian subregion namely; Central Anatolian, Irano–Anatolian and the Mesopotamian provinces. According to this classification, Southeast Anatolia is located in the Mesopotamian province of the West Irano–Turanian subregion (Zohary, 1973).

According to Flora of Davis (Davis 1965-1985; Davis et al.; 1988; Güner et al., 2000) some researchers among them Kotschy, Sintenis, Davis, and Zohary have visited and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20252041

gathered plant specimens from Şanlıurfa by Baytop (2003). Some floristic and taxonomic studies were carried out in and around Southeast Anatolia (Kaynak and Ketenoğlu, 1980; Malyer, 1981-1983; Kaynak, 1987-1989a, b; Yıldırımlı, 1992-1994; Yıldız and Aktoklu, 1996; Ertekin and Saya, 1997; Ertekin, 2002; Adıgüzel and Aytac, 2001; Aslan and Turkmen, 2001-2003; Turkmen et al., 2002; Akan et al., 2005; Aydoğdu and Akan, 2005). But there has been no vegetational research data except for a study carried out by Zohary (1973). In addition, Southeast Anatolia is one of the most little known or unknown regions of Turkey (Davis, 1965-1985; Çırpıcı, 1987; Donner, 1990).

In the region, the natural areas are used as pastures like in all arid countries. Artificial pasture culture has not been demanded yet. It has been stated that it contains wheat, beans in pastures in arid regions and includes drought-resistant different vegetation types and other herbaceous plants such as Savanne, Praerie, Steppe, Maguis, Phyrgana. (Gençkan, 1983). This understanding and using of pastures are applied in Şanlıurfa on large scale, like in the most of regions of Turkey. In this region the open places which are out of using, belong to state, like slopes, stony, rocky places, stream beds, hills etc. (Çullu et al., 2002). Şanlıurfa is one of little researched region in Turkey (Aslan, 2015). It has 724.529 ha of area. 263.507 ha of this area is used as natural pastures. In the region, the pastures have the poorest plant cover (10-15%) in Turkey. 0.82 ha of area is divided for each cow. In the past years there have been significant changes in the diversity of plants in this area due to random overgrazing and in some years fires (steppe fires) due to the abundance of animals. But, when the pastures of the region are taken into consideration it is necessary to divide 4 ha area for each cow. This shows that the pastures are used five times excessively. Excessive and irregular using have caused succession and degradation. The primary vegetation has transformed to secondary vegetation and converting towards semi-desert ecosytem (Atamov et al., 2004).

The characteristic vegetation type is steppe in this region (Atamov et al., 2004). The threat factors are excessive grazing and transforming of natural pastures to agricultural areas. Because of increased industrial activities, urbanization, tourism activities, creating new agricultural areas, mining activities, using agricultural methods and overgrazing, the natural structures of steppe ecosystems have been getting destroyed (Ture and Bocuk, 2007). 74 taxa are under threat and of these 10 taxa on Karacadağ, 13 taxa in Ceylanpınar are endemic (Özhatay et al., 2003; Aslan, 2018). In Şanlıurfa, the steppe vegetation is dominant because of ecological, geographical and antropogenic factors. Usually, animals eat legumes, grasses and similar crops, which are fresh and delicious for a period of one year. However, the perennial shrub, smelly and prickly plants are not preferred.

Under effects of topographic and edafic factors, different steppe vegetation types are found in the region. In this steppe, wheats are dominant and different plants can be found, which have life forms like geophytes, camephytes, cryptophytes, hemicryptohytes and terophytes. In some districts, some remains of forest and rare old trees are found. In addition, the efemeres which grow rapidly and complete their life cycles in short time after spring and autumn rains are present in the vegetation.

The constant plants are perennial herbs, shrubs and trees that are seen rarely (Atamov et al., 2007). But, the efemeres are found and affect quality of fodder plants and yields positively.

In the region, watery agriculture has been made for years. Agricultural method applied to irrigation in semi-arid and arid regions depending on the characteristics of the plant sown or to obtain higher yields. Since these areas are not natural areas, weed yield

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20252041

is considerably reduced due to the excess number of animals. Holophytic areas have risen 394%. The agriculture of wheat and cotton have been stopped in some places because of salinity and these areas have been used as pastures for the last 15 years (Çullu et al., 2002).

Materials and methods

The city Şanlıurfa in Southeast of Anatolia is between 37° 49' 12" – 40° 10' 00" East meridian and 36° 41' 28" – 37° 55' 50" North parallel. In Şanlıurfa the uneven areas are at percentage of 60.4%, mountains 22%, plains 16.3% and plateaus 1.3%. Harran plain, covering the study area, is one of the most important agricultural areas of Turkey and located between 36°47' and 39°15' east longitude and 36°40' and 37°41' north latitude within the borders of the province of Şanlıurfa in Southeastern Anatolian region. The most important plains are named Harran, Suruç, Viranşehir, stayed on south part of Şanlıurfa. Ceylanpınar plain are stayed on southwest. In addition, Halfeti, Hilvan and Bozova plains have large areas. The average altitude is 375 m. The lowest plain is Harran plain. Viranşehir plain is at east, Suruç plain is at west of Harran plain. It is 141 535 ha (Anonymous, 1995) (*Figs. 1, 2* and *3*).

Floristic and phytosociologic research studies were carried out between the years 2000-2005 at Karacadağ, Tektek, Fatik, Kaşmer, Nemrut, Kalecik mountains and Direkli Hills where are used as natural pastures. Regular geobotanical trips were organized. Plant specimens were collected and preserved according to the herbarium techniques. These were identified with the help of "Flora of Turkey and the East Aegean Islands" (Davis, 1965-1985, 1988; Güner et al., 2000) and other relevant publications (Akman et al., 2001) as well as the flora of Syria, Iraq and Iran. In addition, the plants of Birecik Dam lake area and halophytic plants in Akçakale were gathered and classified (Ertekin and Saya, 1997; Ertekin, 2002; Adıgüzel and Aytac, 2001; Aslan, 2002; Aslan and Türkmen, 2001-2003; Kaya, 2002; Atamov et al., 2004; Akan et al., 2005; Aydın, 2003; Aydoğdu and Akan, 2005; Ayalp, 2005; Atamov et al., 2005).

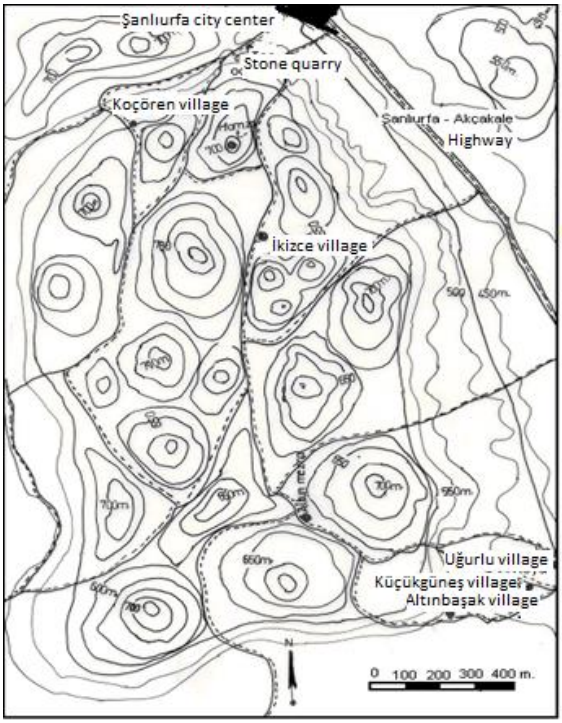

Figure 2. *The map of Fatik Mountains*

Figure 3. *A photo of the research area*

Braun-Blanquet's (1964) method was used for the naming of phytosociological plant groups. Plants were sampled twice a month during certain vegetation periods and plant samples were taken to identify the plants and examine the necessary materials.) These plants have been protected in the Herbarium of Harran University. The climatic data were taken from the Sanliurfa Meteorology Station and has been evaluated according to these data. Approximately 500 g. soil samples were taken from 5 cm under the soil in the research areas in spring, summer and autumn. The soil samples were dried naturally and analysis of them were made by the Ministry of Agriculture and the Rural Affairs General Directorate of Rural Services Sanliurfa Research Institute.

Results and discussion

As it is seen in *Figure 4* and *Table 1,* the climate in Şanlıurfa is arid from June to October in a long period. In this period, most annual plants die. Only perennial herbs, shrubs and trees are alive. Semiarid Mediterranean climate occurs in research area. According to Emberger the precipitation–temperature coefficient (Q) is 42.94 (Akman, 1990). Annual mean temperature is 18.7 °C. The maximum mean temperature (M) is 46.8 °C, in July. The minimum mean temperature (m) is -6.8 °C, in February. Annual rainfall is about 457.8 mm (Anonymous, 2001) and the seasonal precipitation regime is winter, spring, autumn and summer. This is the first variant of the East Mediterranean precipitation regime. The ombrothermic diagram shows dry and rainy periods (*Fig. 4*).

In the different plant associations in the steppe vegetation, the avarage productivity changes between 1.0-7.0 kg m^{-2}. Excessive aridity and temperature have caused decreasing productivity and quality of fodder plants in pastures. From the end of autumn to the middle of spring, the efemeres grow and these plants increase the quality and productivity of fodders by 2-3 times. At the end, yield of natural pastures, number of fodder plant species and their populations have been reduced day to day because of excessive and unconscious grazing, migration, negative habitat conditions like aridity and temperature. The plants which have prickle, etheric oils, latex, poison, bitter and fluff have spread out. Excessive grazing has caused the transforming of the primary steppe to secondary and then semi-desert to desert vegetation.

In most of the places in this area, the covering degree of the flora is 40-50%. And this is the characteristic property of half-desert and desert type associations. The flora

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20252041

has generally made up of a single layer and the average height of the grass covering is 10-20 cm.

On the contrary, the number of plants which are not eaten by animals have been increased. Thus, the primary steppe vegetation has been transformed to secondary and it is seen that the succession has been transformed to semi-desert conditions.

Immigration is widespread in this region and emigrants migrate from East Anatolia to use pastures for grazing. Thousands of sheep destroy the all immature and senile groups of plants. The yield of pastures has been decreased. This situation has caused transforming from steppe to desertation.

In the flora of Şanlıurfa, 71 families, 798 taxa belonging to 342 genera have been determined (Atamov et al., 2004). 135 of these plants were monocotyledonaes, 663 were dicotyledonaes.

The number of plants belonging to *Poaceae* family were more than others in spite of having less species (56) than *Fabaceae* (101). The dominant taxa which spread out in naturel pastures were as follows: *Bromus japonicus* Thunb. subsp. *japonicus, B. squarrosus* L., *B. sterilis* L., *B. tectorum* L., *Avena sterilis* L. subsp. *sterilis*, *Aegilops triuncialis* L. subsp. *triuncialis, A. neglecta* Req. ex Bertol, *Festuca callieri* (Hackel ex St. – Yves) F. Markgraf subsp. *callieri*, *Hordeum murinum* L. *subsp. glaucum* (Steudel) Tzvelev.

Some plants belonging to *Fabaceae,* have fodder quality. Most of them are used as fodders. These were as follows; *Astragalus onobrychis* L., *A. aleppicus* Boiss., *A. immarginatus* Labm., *A. dactylocarpus* Boiss., *Medicago rigidula* (L.) var. *rigidula, Onobrychis caput-galli* (L.) Lam. *O. crista-galli* (L.) Lam. *O. galegifolia* Boiss. *O. kotschyana* Fenzl. *Trifolium scabrum* L., *T. speciosum* Willd., *T. dasyurum C.* Presl, *T. angustifolium L.* var *intermedium, T. boisseri* Guss. ex Boiss., *T. meironense* Zoh., *T. campestre* Schreb., *Trigonella monspeliaca* L., *T. mesopotamica* Hub. Mor., *Vicia mollis* Boiss., *Coronilla orientalis* Miller var. *orientalis, C. scorpioides* (L.) Koch, *Hedysarum varium* Willd.

In the research area, 153 taxa belonging to 26 families and 107 genera were identified. *Poaceae* with 31 taxa (20.3%), *Asteraceae* with 24 taxa (15.7%), *Fabaceae* with 22 (14.4%), and *Apiaceae* with 13 taxa (8.5%) were the richest families.

Braun-Blanquet's (1964) method was used for the naming of phytosociological plant groups.

32 sample parcels were evaluated and 6 new associations and their upper categories are as follows:

Astragalo–Bromotea Quezel 1973
Astragalo–Bromotalia Quezel 1973
Agropyro–Stachyon Quezel 1973
1. *Festuco callieri–Teucrietum poliae* ass. ova

Festuco callieri–Teucrietum poliae ass. nova

There were no trees and shrubs in its structure. Only grass layer was present and covering was 40-80%. The length was between 10 and 35 cm (*Table 2*).

Festuco callieri–Teucrietum poliae association was spreading out where the calcereous main rock, gravelled and small pit areas. According to chemical and physical properties of soils where the association was spreading out homogenous, pH was between 7.0 and 7.71, the rate of lime ($CaCO_3$) was 3.8%, phosphorus (P_2O_5) was 5.2-5.3 kg dec^{-1}; potassium (K_2O) was 118.8-308.8 kg dec^{-1} and organic component was 2.17-2.48% (*Table 3*).

Phlomido bruguieri–Thymbretum spicatae ass. nova

Phlomis bruguieri and *Thymbra spicata* subsp. *Spicata* were the characteristic species of this association. It was spread out on the south part of the Fatik mountain, between Ikizce village and Altun mezra village. The gradient was 15-30% and the altitude was between 610 and 850 m (*Table 6*).

The association contained only one layer like the others, grass layer. The average length was 12-25 cm and rate of covering was 50-60% (*Table 6*).

Classis: *Astragalo–Bromotea* Quezel 1973

Ordo: *Onobrychido armenae–Thymetalia leucostomi* Akman, Ketenoğlu Quezel 1984

Alliance: *Phlomido armeniaceae–Astragalion microcephali* Akman, Ketenoğlu Quezel 1986

It was spreading out at red-brown soils. According to chemical and physical properties of soils, pH was: 7.70, the rate of lime ($CaCO_3$) was 3.8%, phosphorus (P_2O_5) was 5.3 kg dec^{-1}; potassium (K_2O) was 118.8 kg dec^{-1} and organic component was found as 2.48% (*Table 3*). The yield of pasture was 1.0-1.5 ha^{-1} 29 taxa were determined from this association (*Table 6*).

Astragalo strictifolii–Salvietum sclarea ass. nova

Astragalus strictifolius var. *strictifolius* and *Salvia sclarea* were the characteristic taxa of this association. It was determined between Fatik and Ikizce villages at northeast direction. The altitude was 600-750 m and the gradient was between 20 and 35%. The association composed of only grass layer except *Astragalus strictifolius* var. *strictifolius*. The average length was between 20 and 25 cm and the covering was between 50 and 65%. The number of taxon was between 10 and 18 (*Table 8*).

Classis: *Astragalo–Bromote* Quezel 1973

Ordo: *Astragalo–Bromotalia* Quezel 1973

Alliance: *Agropyro–Stachyon* Quezel 1973

This association was spreading out at the red-brown soils on the arid stone. According to chemical and physical properties of soils, pH was: 7.42, the rate of lime ($CaCO_3$) was 6.8%, phosphorus (P_2O_5) was 4.5 kg dec^{-1}; potassium (K_2O) was 108.0 kg dec^{-1} and organic component was measured as 2.35% (*Table 3*). The yield of dry grass was between 300 and 400 g m^{-2} 35 taxa were determined (*Table 8*).

Conclusion

In the region, due to excessive and uncontrolled grazing, steppe vegetation has turned into secondary vegetation rather than semi-desert and desert-type vegetation. Therefore, these areas should be controlled and over-grazing should be prevented. In natural pastures, the value of the forage plant and the most suitable pasture capacity should be determined. The productivity of pastures is related to the composition of plant species and habitat factors (Braun-Blanquet, 1964). Morphological structures and ecological habitat forms are one of the most important subjects that should be studied in pasture research projects.

First, the quality and quantity of a pasture should be examined. In the region, plant sociological characteristics of the dominant steppe vegetation change during the seasons. The efemers change the productivity and quality of the pastures. In pastures, forage crops have been reduced due to overgrazing, others spread if inedible to animals. These areas have been abandoned for agriculture and have become barren due to overgrazing. In the future research of these areas, controlled pasture stocking should be carried out together with controlled irrigation for the formation of productive pastures, and even pasture forage crops suitable for barren areas should be selected and trials should be conducted in the area. National and regional pasture management plans should continue to be implemented effectively, sustainable productivity must be ensured and these areas should be put back into service of Turkish livestock.

Abstract. Genetic diversity is the base of biological polymorphism and also the basic part of biological diversity. Significant role is played by genetic diversity and paternity of germplasm in cotton breeding. Genetic diversity in representative sets of advanced cotton genotypes was studied at molecular level employing polymorphic simple sequence repeats. Of seventy-two advanced cotton genotypes, thirty microsatellites primer pairs were studied, 29 showed to be polymorphic. DNA markers amplified fragments of 100 to 300 bp in size. The polymorphism information contents ranged between 0.76 and 0.99. Cluster analysis clearly grouped the 72 genotypes into seven groups A, B, C, D, E, F, G based on Nei's coefficient similarity matrix. Group B was found to be the most genetically distinct group when compared to other groups. However, group B had most of the candidates of under observed genotypes. This study exposed two major clusters of cotton cultivars and recognized the cotton genotypes which were genetically different. These results can be used as reference and baseline information to other researchers/breeders. The resolution to the genetic associations of these cotton accessions could be improved by increasing the number of more mapped markers.
Keywords: *cotton, genetic diversity, SSR markers, Pakistan, Gossypium, genome wide characterization*

Introduction

Man has been refining the domestication of crop plants by giving selection emphasis to the traits that suit to his agro-ecological and socioeconomic needs. Like many other crops, selection preference has been made for the improvement of the different traits in cotton. The process is being continued for centuries that has resulted in cultivars far different from the wild types in particular habitat and potential. During the last 30 years, Excessive breeding emphasis has led to some sort of genetic uniformity among the currently cultivated high yielding varieties and advanced lines (Van Becelaere et al., 2005). There is no precise knowledge of extent of exploitable variability beyond simple inherited traits during breeding of improved crop traits. Also it is not clear yet that what extent the different breeding strategies have been facilitating to broaden or narrow the genetic diversity in the breeding nurseries of cotton. Cotton belongs to Gossypieae tribe of the Malvaceae family. The main area for its cultivation is tropical as well as subtropical regions. Cotton genus Gossypium consists of almost 50 species that is contributing in making it the largest species in the Gossypieae tribe (Ashokkumar et al., 2011).

Cotton crop has great importance in agriculture, industry and trade in continents like Africa, Asia and South America. The cotton genus Gossypium has always been attracting the scientists' attention (Puspito et al., 2015). As far as the commercial

DOI: http://dx.doi.org/10.15666/aeer/1802_20432056

species of cotton are concerned, the *G. hirsutum* accounts for greater than 90% of world production, *G. barbadense* accounts for 3-4%, *G. arboreum* and *G. herbaceum* together accounts for 2%. By using selective breeding and hybridization of the above mentioned species many varieties of cotton have been developed. Humans use cotton as a source of natural fiber. However, cotton is also known as an oilseed crop and it is also the protein source for animals feed. Most of the cotton fiber is found in white color but it may also be found in brown, green and some mixing of these colors naturally (Chapagain et al., 2006). Above and beyond cotton fiber, edible oil is also extracted from cotton seeds. Cotton raw material is also used in poultry and livestock feed (Moiana et al., 2012). Cotton is being produced in many countries of the world, but China, US, India and Pakistan are producing two third of the global production (Ehsan et al., 2013).

In developed as well as developing countries, cotton is the cash crop (Puspito et al., 2015). The credit of being the oldest seed known so far goes to cotton seed. As far as Pakistan is concerned, the cotton is known as cash crop and its fiber is known as "White Gold" (Ahmad, 2018). The cropped area of cotton in Pakistan is about 2961 thousand hectares. In Pakistan, increase in cotton bales' production has been observed to the last years i.e. 14.98 million bales against 12.8 million bales (Economic Survey, 2014-15). In Indus Valley it has been cultivated since 3500 BC. In Balochistan it is cultivated near Bolan Pass (Li et al., 2008). Old-style variety identification technology using the old test and method involves rising plants to maturity and evaluating various phenotypic features which differentiate individual plants. It is difficult to collect morphological data because of environmental influence on morphological characters and also the time factor; other limitation includes explicit differentiation of genotypes (Rana et al., 2007).

Cultivated species of cotton are showing low level of genetic diversity as indicated by previous research. Due to lack of genetic diversity, cotton cultivars with stress resistance, improved yield and quality potential are in great danger (Li et al., 2008). It has been observed that genetic diversity is decreasing in breeding programs. This decrease in genetic diversity is leading to decline in yield improvement through crop breeding, since diversity is essential for selection (Rana et al., 2007). Orthodox breeding techniques are insufficient to explain the multifaceted traits. The choice of markers used for the estimation of diversity is of great alternative now a days as it gives alternatives to variety selection in the initial phase of breeding approach. The marker assisted selection is used to identify the superior parents in a cross. The advantage of this technique is to reduce the time and costs required for development of novel accessions (Bukhari, 2014). Genomics have come into being by doing advances in DNA marker technology. DNA repeats that comprise two to five nucleotide core units are known as simple sequence repeats (SSR) that are short and uncertain repetitive DNA sequences (Dongre et al, 2005). SSR markers have the advantage of being a PCR based marker, co-dominant, multi allelic, genetic marker system (Ullah et al., 2012). DNA markers (SSRs) have been used widely for the genetic diversity analysis as well as identification researches. Just because of high polymorphism rates, SSR markers are highly informative. This marker system is cheap to analyze when compared with other marker system. SSR regions are dispersed all over the genomes (Varshney et al., 2005). By using molecular markers, genetic diversity of cotton can excellently be estimated and this type of study offers beneficial information on the selection of parents in the expansion of cotton varieties and crossbreeds as well (Wu et al., 2006; Ullah et al., 2012). Fewer studies have been reported so far in Pakistani cotton germplasm. So this study was designed by keeping in view the importance of DNA markers to study

diversity among local cotton advanced lines, the genetic variability and estimation of relatedness and to illustrate genotypes with diverse fingerprints of selected advance cotton genotypes using SSR markers.

Materials and methods

The present research was conducted in National Institute for Genomics and Advanced Biotechnology (NIGAB), National Agricultural Research Center (NARC), Islamabad to estimate the genetic diversity among 72 Pakistani advanced cotton lines using thirty simple sequence repeats (SSR) markers. The seeds of 72 advanced cotton genotypes were acquired from National Coordinated Varietal Trial (NCVT), Pakistan Central Cotton Committee (PCCC) at NIGAB, NARC (*Table 1*). The 72 advanced cotton lines were categorized into two populations 1 and 2 based on unweighted pair group method with arithmetic mean (UPGMA). Thirty SSR primer pairs were selected for genotyping (*Table 2*). The Cotton Marker Database (CMD; http:// www.cottongen.org) was explored to select primers. All the markers were selected by reviewing the literature. Only those markers were selected which were polymorphic in others cotton genome.

Experiment 1: Morphological characterization of cotton

Cotton seeds of each genotype were sown in the field using Randomized Complete Block Design (RCBD) with four replications under natural environmental conditions. Recommended cultural practices were adopted to grow the crop. Experimental layout was designed in four replications i.e. four rows for each line and in each row 20 plants were maintained. Plant to plant and row to row distances were maintained as 30 cm and 75 cm, respectively. Following traits were evaluated on 180 days after sowing. The data on plant height were recorded on five randomly selected plants using meter rod. Each plant was measured from soil to top of the main stem at crop maturity. Internodal distance was measured from one node to the other node on the same stem. Data on number of bolls per plant were recorded on five randomly selected plants by counting the number of bolls on each selected plant. Data on number of branches per plant were collected on five randomly selected plants by counting the number of branches of each selected plant. Data on boll weight were recorded on five randomly selected plants using weighing balance. Data on plant type were recorded whether they were conical or bushy type. Data on yield per plant were also recorded. The data recorded on each trait were subjected to analysis of variance (ANOVA) by using Minitab 16 software. Tukey's Test was applied to access the significance among the mean differences.

Experiment 2: Molecular characterization of cotton on the basis of SSR markers

Cotton seeds of each genotype were sown in the field of NIGAB at NARC, Islamabad using RCBD with three replications under natural environmental conditions. Recommended cultural practices were adopted to grow the crop. Young leaf tissue was collected from all the genotypes for DNA extraction. DNA extraction was carried out as per the procedure described by (Doyle et al., 1987). DNA was checked by measuring absorbance on nano-spectrophotometer. Purity was investigated by the absorbance ratios; 230/260 while concentration at 1 optical density. Polymerase chain reaction (PCR) amplification was performed in an automatic Applied Bio Systems Thermal Cycler (Veriti 96 well) at 94ºC for 5 min, afterward 35 cycles each containing of three phases: one phase of denaturation at 94ºC for 40 sec, one phase of annealing at specified temperature for each primer pair (*Table 2*) for 40 sec and an extension phase for 1 min at 72ºC followed by final extension of 10 min at 72ºC. On 1.5% agarose gel stained with ethidium bromide, amplified products was electrophoresed at 80 V for 45 min and then visualized by means of gel documentation system (Alpha Innotech).

DNA amplifications with each SSR primer were repeated three times to guarantee reproducibility. In three separate amplifications for each primer, bands were considered reproducible and scorable only after careful observation and comparison. Scoring was made on visualizing the bands. Each DNA fragment was transformed into binary character matrices i.e. 1 for presence, 0 for absence. The band size was determined using the software available with gel documentation system. The Minitab 16 was used to build dendrogram for cluster analysis. Sub population statistics, AMOVA, number of allele per locus and expected/observed heterozygosity was calculated using R language citation (locus_table, mlg, nei.dist and plot_poppr_msn) via poppr-package.

Results

Experiment 1: Morphological characterization of cotton

Grand mean of each trait have been shown in *Table 3*. Highly significant results were observed at P<0.05 among 72 NCVT lines of cotton germplasm for five traits i.e. plant height (cm), internodal distance (cm), number of bolls, total number of branches and boll weight (*Table 4*). The NCVT 1624 was the tallest (138.43 cm), while genotype NCVT 1668 produced the shortest (44.09 cm) plants. Highly significant differences were also observed within 72 NCVT lines of cotton germplasm. The NCVT 1630 showed minimum internodal distance (1.4 cm), while genotype NCVT 1624 produced the maximum internodal distance (4.76 cm). Highly significant differences were also observed within 72 NCVT lines of cotton germplasm for this trait as depicted in *Table 4*. The NCVT 1624 showed maximum number of bolls (59) per plant, while genotype NCVT 1651 produced the minimum (2) number of bolls per plant. Non-significant differences were observed among seventy-two NCVT lines of cotton germplasm regarding their number of branches per plant (*Table 4*). However, NVCT 1634 showed maximum number of branches per plant (26), while genotype NCVT 1609 produced the minimum (4) number of branches per plant.

Experiment 2: Molecular characterization of cotton

A total of 30 primers consisting of di, tri, tetra and penta nucleotide repeat motifs were used for initial screening with 6 genotypes, namely NCVT 1601, NCVT 1602, NCVT 1603, NCVT 1604, NCVT 1605 and NCVT 1606 were used for PCR amplification using all the 30 primers. Out of these, one primer gave no amplification, while rest of twenty-nine primers gave clear band patterns, and subsequently used to analyze the entire set of 72 genotypes. Thirty simple sequence repeats (SSRs) belonging to BNL, CIR and JESPER series were used to analyze genetic diversity among 72 cotton varieties. Out of these, six markers i.e. BNL 1551, BNL 3089, BNL 1672, BNL

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20432056

2634, BNL 3031 and BNL1414 contained (AG)n repeat motif, CIR 246, CIR 133, CIR 148 and CIR 122 primer contained (TG)n repeat motif, JESPER 0065, JESPER 0152 and JESPER 0092 primers contained (GAA)n repeat motif, CIR 376 and JESPER 0251 primer contained (CA)n repeat motif, BNL 1053 and CIR 364 primers contained (AC)n motif, BNL 4108 and JESPER 0220 primers contained (GA)n repeat motif and BNL 3649 primer contained (TC)n repeat motif,. Apart from these, JESPER 0153 primer contained (CTA)18, JESPER 0135 primer contained (CT)11, JESPER 0114 primer contained (GT)12, JESPER 0101 primer contained (TA)3(GT)15, CIR 393 primer contained (TG)7(T)9, CIR 320 primer contained (T)9(N)2(TG)8, CIR 253 primer contained (TC)15(N)8(AC)5(N) 7(CA)8, CIR 203 primer contained (TG)11(N)1(TG)5, BNL 3255 primer contained (GC)6AT(AC)14 repeat motifs (*Table 2*).

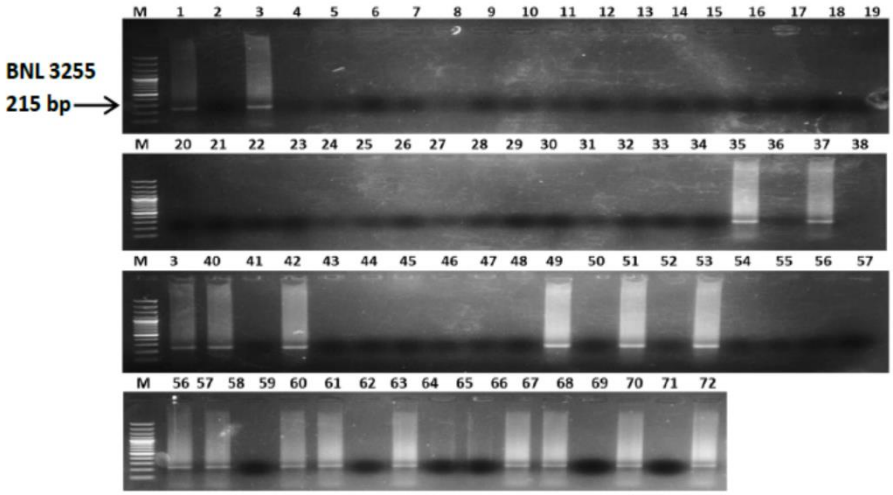

Figure 1. *BNL 3255 representative gel picture, 1-72 genotypes, 100bp ladder DNA, band size of 215 bp*

Out of thirty markers, twenty-nine markers were reproducible. These twenty-nine DNA markers amplified fragments of 100 to 300 bp in size through SSR profiling. On the basis of amplification percentage, markers were categorized into three groups. Sixteen markers i.e. BNL 1551, BNL 1414, BNL 3031, BNL 3255 (*Figure 1*), BNL 3649, BNL 4108, CIR 133, CIR 148, CIR 203, CIR 253, CIR320, JESPER 0092, JESPER 0101, JESPER 0135, JESPER 0152, JESPER 0220 gave low amplification (0-35%). Nine markers that are BNL 1053, BNL 1672, BNL 2634, BNL3089, CIR 246, CIR276, JESPER 0065, JESPER 0114, JESPER 0300 gave average amplification (36-60%). Four markers i.e. CIR 393, JESPER 0251, JESPER 0153, CIR 364 gave high amplification rate that was above 60% while one marker CIR 122 gave no result in any of the accession. The 72 advanced cotton lines were categorized into two populations 1 and 2 based on UPGMA. The population 1 contains 30 genotypes and population 2 was comprised of 42 genotypes.

The Nei's coefficient of similarity was used to construct the cluster diagram (*Figure 2*). All the genotypes were categorized into seven groups A, B, C, D, E, F, G based on Nei's coefficient. Group B was found to be the most genetically distinct/ dissimilar group when compared to other groups. However, group B have most of the candidates of under observed genotypes. Conversely group D, E and F, G have

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20432056

similarity index of 1.3. The *Figure 3* shows significant population differentiation at all levels given that the observed data does not fall within the distribution expected from the permutation. The expected and observed heterozygosity is listed in *Table 2* along with the number of alleles per locus for each primer along with their polymorphism information content. The greatest number of allele observed was 4 and minimum number of allele per locus is 1 as depicted by population genetics. *Table 5* shows the variation within samples, between samples and population. Here, F value is -35.49, and p-value is very high in case of variation within samples. In other words, the variation within samples means and among different groups variation is much larger than the variation of allele presence within each group, at p-value is less than 0.01.

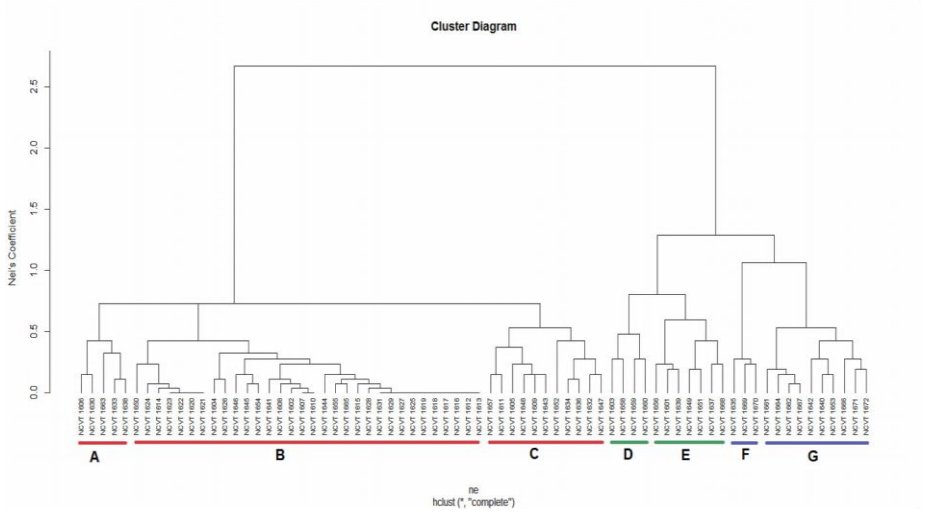

Figure 2. *Cluster dendrogram based on Nei's coefficient for two populations (Pop 1 indicates population 1 and Pop 2 indicates population 2)*

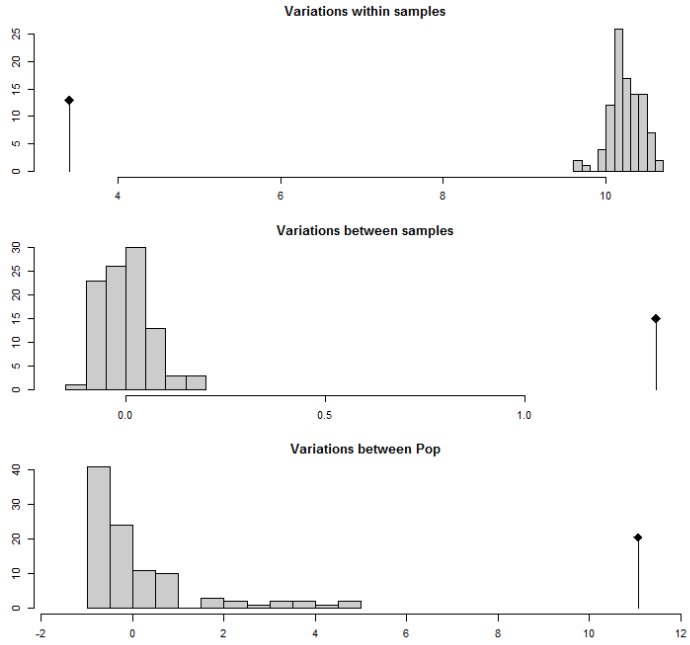

Figure 3. *AMOVA to check variations within samples, between samples and population*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20432056

Table 5. *AMOVA test to check variation within samples, between samples and population*

	Test	Obs	Std. Obs	Alter	P-value
1	Variations within samples	3.411277	-35.494080	Less	0.01
2	Variations between samples	1.328667	21.379898	Greater	0.01
3	Variations between Pop	11.063446	8.363728	Greater	0.01

Population Genetics parameters i.e. MLG multilocus genotypes showed that the genotypic richness is indeed higher in population 2 than that of population 1 when considering equal sample sizes with the standard error of 1.76 in both poulation. Diversity measures incorporate both genotypic richness and abundance. There are three measures of genotypic diversity employed by poppr used for statistical analysis, the Shannon-Wiener index (H), Stoddart and Taylor's index (G), and Simpson's index (lambda). Graphical representation of two population with respect to H, G, Lambda and E.5 constants are depicted in *Figure 4*. In our study, comparing the diversity of pop1 to pop 2 shows that H is greater for pop 1 (3.40 vs. 2.80), but G is also greater (30.0 vs. 9.0). Thus, our expectation that diversity is lower for population 1 than that of population 2 is accepted in the case of H, which is likely due to the sensitivity of the Shannon-Wiener index to genotypic richness in the even sample sizes, and rejected in the case of G *Figure 4*.

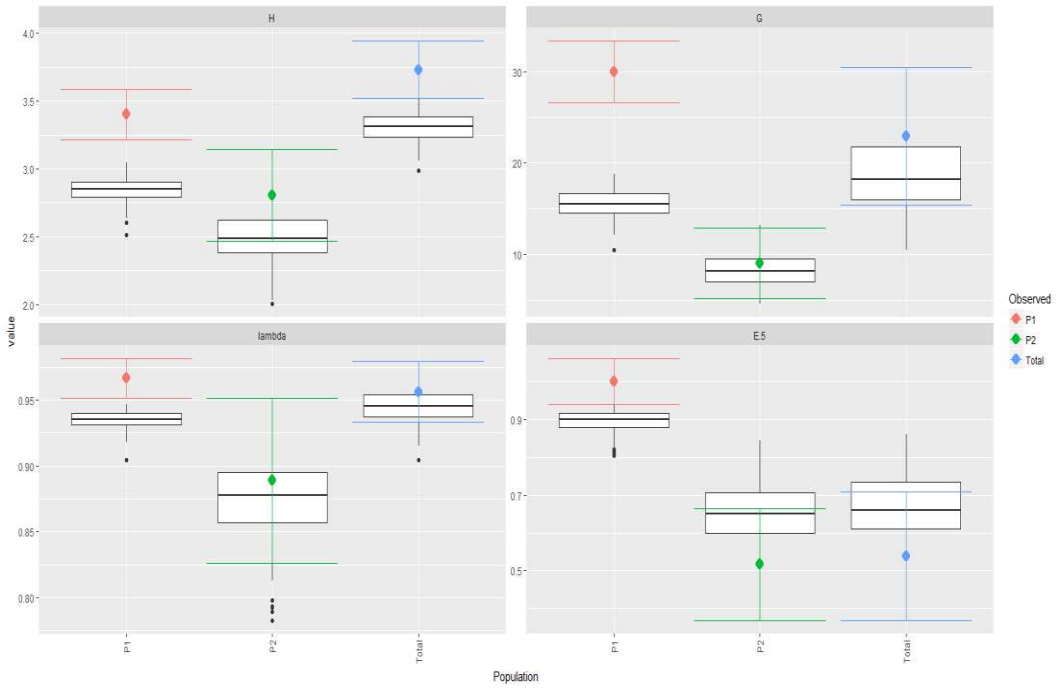

Figure 4. *Graphical representation of two populations with respect to H, G, Lambda and E.5 constants*

Evenness is a measure of the distribution of genotype abundances, wherein a population with equally abundant genotypes yields a value equal to 1 and a population dominated by a single genotype is closer to zero. In our study, the pop 1 has E.5 = 1.00 and the population 2 has E.5 = 0.516 (*Figure 4*). This indicates that the MLGs observed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20432056

in the population 1 are closer to equal abundance than those of population 2 (*Figure 4*). Indeed, when we look at a distribution of the MLGs for each population type it shows there are many more unique locus in population 1 as compared to the population 2 *Figure 5*.

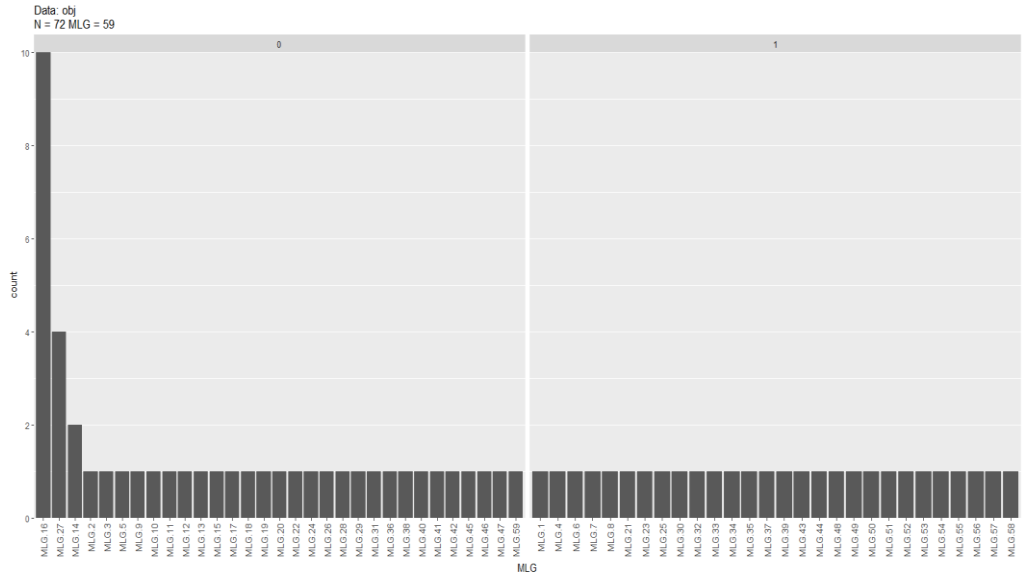

Figure 5. *Bootstrap analysis for MLG calculation against two populations*

Discussion

For characterization of any germplasm first step is to examine the material morphologically (Bidinger et al., 2009; Shen et al., 2017). All plant breeders still understand the value of enhancing plant genetic level by breeding available genetic variability. The results from different crops suggested that genetic diversity is very significant in breeding (Smartt, 1990; Reddy et al., 2005; Rasul et al., 2007). In this research the dendrogram clearly indicates two main clusters. The two groups A and B with the least value of 0% similarity were observed. The band sizes that obtained through SSR primer pairs were matched with the sizes of bands described in literature (Nguyen et al., 2004; Han et al., 2006). The scoring was based on bivariate as 1 is for presence and 0 is for absence. With respect to primer, the frequencies of scored bands or alleles were calculated (Upadhyaya et al., 2001).

Similar loci identified for every marker were assessed by scoring pattern. Twenty-nine (96.6%) out of the 30 SSR markers were evaluated and the results showed monomorphic fragments through the 72 varieties. Thus, the results are representing homogeneity of the cotton genome (Lacape et al., 2006). In sampled genome, SSR markers exhibited significant amount of variation on the basis of monomorphic bands as one genotype is giving the band, while the same band is absent in the other genotype (Fu, 2006). As far as polymorphism is concerned, no polymorphism was noticed among the experimental genotypes. This was expected from previous diversity analyses (Iqbal et al., 1997; Lacape et al., 2006). Irregularities among cultivar clustering on the basis of morphological and marker based dendrogram is just because of the markers that were not trait specific used for this study (Zhang et al., 2005). However, the SSR markers are depicting the genetic diversity to great extent. Inconsistencies between genotypes

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20432056

clustering and known parentage should not be surprising for these cotton genotypes with such a narrow genetic base (Iqbal et al., 1997; Zhang et al., 2005).

The limited sample size of the genome of cotton exposed by only 29 SSR markers may subsidize to this type of variations (Fu, 2006). There is still need of using more mapped markers across the experimental genotypes that will progress the resolution to the genetic associations of these cotton varieties. On the other hand, the genetic relatedness estimated by this study still exhibit a beneficial direction for cotton breeding. This data is more helpful than that of other techniques used for parental selection and old-style pedigree analysis (Bowman et al., 1996). The values of similarity among cotton germplasm can change if more cotton varieties along with the experimental genotypes or varieties are evaluated or more markers applied. Also, the findings specify the distinctiveness, but not necessarily the relatedness of varieties (Fu, 2006). Regardless of some restrictions, the relative measure of genetic distinctiveness stated here offers useful information for selecting specific germplasm with diverse genetic background for a cotton-breeding program (Fu et al., 2007).

It has been observed that the current study is applicable in many ways. Like, considering polymorphism, the diversity among these cotton cultivars was less suggesting that the range of diversity for preservation of germplasm and breeding in future should be broadened. For selecting diverse plants for cotton breeding, the findings on genetic distinctiveness are beneficial. As this study exposed two major clusters of cotton cultivars and recognized the cotton cultivars which were genetically different. The classification of cotton varieties by the use of SSR primer pairs provides significant information to considerate the genetic diversity of top Pakistani cotton germplasm and to expand the cotton breeding program. It also gives a useful guide for selecting particular germplasm with diverse genetic background.

Conclusion

Relatively low genetic diversity has been revealed by this SSR analysis among experimental Pakistani cotton cultivars. Unique cotton cultivar was identified using the morphological analysis eagle 2 i.e. NCVT 1624. Molecular characterization depicted the homogeneity of the under study cotton genome as monomorphic bands were observed, while polymorphism was detected across the experimental genome via 29 markers. To conserve the elite cotton germplasm and developing future cotton breeding programs in Pakistan, these findings are useful. On the other hand, the genetic associations that have been estimated exhibit a beneficial direction for cotton breeding. It is recommended that more mapped markers across the genome should be used in future research that would improve the resolution to the genetic relationships as well as associations of the experimental cotton accessions. Regular assessment of National Cotton Varietal Trial should be carried out in order to update the diversity level of national cotton germplasm for cotton breeders.

Abstract. In context of Bonn Challenge commitment, Pakistan has implemented Billion Tree Afforestation Project (BTAP), the initiative of forest restoration and afforestation. The current research was a pilot one which evaluated the success of plantation and assessed growth performance and survival rate. A total of 115 sample plots (0.07 ha size) were laid out in 17 randomly selected sites extended over 1982 ha. Further, Sentinel-2 images were used to derive vegetation indices and regressed indices values with volume and survival percentage. Results showed that all plantation sites showed good performance in terms of survival rate (above 80%). Highest growth performance was exhibited by *Eucalyptus camaldulensis* which mean height was1.297 (m) and the lowest was of Deodar 0.35 (m). Among Sentinel-2 indices, Transformed Normalized Vegetation Index (TNDVI) has the highest value of R^2 of 0.425 whereas in case of survival percentage, Normalized Difference Vegetation Index (NDVI) has the highest value of R^2 of 0.859. Stepwise regression model showed that relationship between NDVI and volume was strongly significant compared to other indices. NDVI differencing of Landsat-8 2013 image and Sentinel-2 2018 image showed that in NDVI range were increased from 0.68 to 0.85, thus showed mosaic restoration and afforestation activities of BTAP.
Keywords: *Sentinel-2, vegetation indices, forest restoration, Landsat-8, Eucalyptus camaldulensis*

Introduction

Forests are among those ecosystems on earth that not only provide services to mankind but its biological, ecological and environmental services are manifold (Trumbore et al., 2015; Mori, 2017). Forests are of immense socioeconomic importance as a source of timber, pulpwood for paper making, fuel, and many non-wood products. Globally, forested region has been diminished for last 25 years from almost 31.6 to 30.6% from 1990 to 2015 respectively (FAO, 2015). Globally, about one to two billion hectares land degradation was identified by Global Partnership on Forest Landscape Restoration (Pistorius et al., 2017). Restoration of deforested areas and degraded areas can play significant role in environmental change mitigation (Guerra-De la Cruz and Galicia, 2017), conservation of biodiversity (Zwiener et al., 2017; Alves-Pinto et al., 2017) and yielding products and services that support local people's livelihoods (Ulian

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20572072

et al., 2017). Reducing Emission from deforestation and Forest Degradation (REDD+) is a globally accepted climate change mitigation initiative that primarily focused on emission reduction and ensuring forest conservation, sustainable forest management and enhancement of carbon stocks (Kelly, 2018; Hein et al., 2018; Bos et al., 2017). REDD+ can only be possible when afforestation, reforestation and plantation activities are supported and encouraged at local and regional scales (Kuemmerle et al., 2017).

The Bonn Challenge launched in 2011, is a global initiative of large-scale afforestation, reforestation and plantation programs to increase global forest stocks (De Jong et al., 2017). The Bonn Challenge not only further strengthens the present objectives of Global Partnership on Forest Landscape Restoration (GPFLR) but also provide opportunities for REDD+ and Convention on Biological Diversity (CBD) Aichi targets (Pistorius et al., 2017; Pistorius and Freiberg, 2014). Under the Bonn Challenge, different countries including Argentina, Colombia, Costa Rica, Ecuador, Ethiopia, Ghana, India, Madagascar, Mexico, Mozambique, Niger, Peru, Rwanda, Uganda, US Forest Service and Pakistan (Khyber Pukhtunkhwa) have committed large scale afforestation, plantations and restoration of forests (IUCN, 2018). The Bonn Challenge is committed to reforest and reclaim the degraded forests of about 150 million ha by 2020 and will approach to hit the target of 350 million ha till 2030 under New York Declaration on Forest Climate Summit (Pistorius and Freiberg, 2014; Climate Summit, 2014). The 150 million ha target will bring many benefits including about 84$ billion per year to national economies and the restored forests will have capacity of 1 $GtCO_2e$ per year sequestration (FAO, 2016). Among Bonn Challenge members, the US Forest Service has committed 15 million ha by 2020, the highest compared to other members. US Forest Service has restored about 12.3 million ha of degraded forests or land (IUCN, 2018). Recently, nine countries (Tunisia, Turkey, Iran, Morocco, Lebanon, Algeria, Portugal, Spain and France) have endorsed Agadir Commitment to strengthen Forest and Landscape Restoration (FLR) mechanism so as arrive at Bonn Challenge Commitment (FAO FLRM, 2017). The Bonn Challenge also ensure implementation of many globally agreed commitments by climate change bodies such as United Nations Framework on Climate Change (UNFCCC), Convention on Biological Biodiversity (CBD), United Nation Convention to Combat Desertification (UNCCD) and United Nations conservation programs (Asner et al., 2017).

In the context of Bonn Challenge, the Khyber Pukhtunkhwa (KPK) province of Pakistan, situated in northern part of the country, has started massive tree plantation and restoration programs of degraded forests in June 2015. KPK government has committed 0.35 million ha of forests restoration and afforestation by 2020. The potential benefits will include 120 million USD and 0.04 $GtCO_2$ sequestrations by 2020 (Laestadius et al., 2015). Pakistan is a forest deficit country with total land area of 88.43 million ha; with total forest area of 4.60 million forest and forest plantations which are equivalent to 5.23% of the total land area (Bukhari and Bajwa, 2012). About 40% of country forests are located in Khyber Pakhtunkhwa (KPK) province of Pakistan. The KPK province has diverse geo-ecological formation including many forest and vegetation types, ranging from at 250 m above mean sea level in the south to 7708 m high in the North. Around 20.25 of the area is forested with trees of fluctuating thickness and, and nine major vegetation type. Adding Alpine pastures to it makes almost one-third (28.98%) of the province under forest ecosystem. Almost same proportion of land (30.08%) is under agriculture (including orchards). Another 10.67% of the area is under rangelands (Go KP, 2016). Previously various forestry-based conservation and development projects

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20572072

have been completed in the past in Khyber Pukhtunkhwa, with the collaboration of provincial forest department, national government institution and international organizations. Some of the more famous projects include Malakand Social Forestry Project, Siran Forest Development Project and Kalam Integrated Development Project (Ahmed and Mahmood, 1998).

BTAP has been driven by present KP Government's dream of Green Growth which binds in the necessities to develop approaches towards sustainable forestry in Khyber Pukhtunkhwa. The project aimed to generate green jobs, gender equality and empowerment, also preserving Pakistan's forest resource while parallel addressing to the worldwide issue of environmental change (Go KP, 2015). The provincial forest department has initiated this project with primary targets to plan, support, design methodologies and launch sustainable forestry in KP through local communities' participation and to promote forestry-based employments. The project has been implemented in two phases; Phase-I in 2014-15 while Phase-II implementation was done in 2015-2017. The main targets of the project were establishment of departmental and private nurseries, closure within forests (fencing an area within forest for restoration purpose), plantation on communal and private lands, reclamation or rehabilitation of bad sites, reclamation of saline and waterlogged areas, roadside, canal side and railway side plantations and generating employment opportunities at local level (WWF, 2017). The project activities were monitored by third party, the World Wide Fund for Nature Pakistan (WWF-Pakistan). WWF-Pakistan has published phase wise monitoring reports and found that the project activities were successful (WWF, 2017, 2016).

Previously different researches reported growth and survival of different species as an indicator of plantation success (Leslie et al., 2018; Varghese et al., 2017; Yamada et al., 2016; Rawat et al., 2017; Edo et al., 2017). Pistorius et al. (2017) studied various opportunities, comparative cost and benefits of Forest Landscape Restoration (FLR) in Ethiopia under the Bonn Challenge and reported that FLR comprises mainly of five major components namely participatory forest management, degraded land restoration, afforestation on regional scale, woodland improvement and forest-based value chain investments. Rubilar et al. (2018) reported that productivity and sustainability in intensively managed plantations can be maintained through controlled genetic, environmental and silvicultural interactions. Binkley et al. (2017) examined growth and survival of *Eucalyptus camaldulensis* at different plantation sites along gradient at 36 locations. Sabastian et al. (2018) reported plantations success depends upon soil and slope as growth parameters such as diameter growth respond differently to these factors. Poersch et al. (2017) analyzed the growth of different *Eucalyptus camaldulensis* species and its relation with variables to identify differences in growth pattern, the study found the height growth was strongly affected by minimum temperature. Da Silva et al. (2010) estimated the carbon sequestration potential of road side planted *Eucalyptus camaldulensis* and considered the specie good for road side afforestation.

In large unreachable areas use of remote sensing is a cost-effective method of collecting data and provides an alternative source of data for extrapolating and estimating forest variables (Franklin et al., 2003). The data obtained can be quickly updated and compared with existing data, and the method can be easily incorporated with geographical information systems. These techniques have been effectively combined in many studies and factually noteworthy relationships between the spectral values (computed via Landsat satellite sensors) and field-estimated variables have been accounted for diameter at breast height, age and total height (Donoghue et al., 2004),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20572072

volume (Poulain et al., 2010) and biomass (Ali et al., 2018). Secondly, Sentinel-2 is a state of the art sensor launched on 23 June 2015 by the European Space Agency (ESA). Contrasted with Landsat-8, Sentinel-2 imagery at high spatial resolution (10 m), this is expected to provide more accurate results (Rembold et al., 2015; Ali et al., 2018) and offering the capacity to detect small changes in vegetation. Sentinel-2 mission is a land observing star grouping of two indistinguishable satellites (Sentinel-2A and Sentinel-2B) that convey high resolution optical imagery. The framework gives a worldwide inclusion of the Earth's territory surface and is described by its high temporal frequency of ten days, which makes it suitable for temporal vegetation assessment. Keeping the unprecedented success of BTAP it is essential to evaluate the different interventions of the project; in this context the current study was designed. The main objectives of the study was to assess the overall survival rate, growth rate and to evaluate and compare growth performance of different tree species raised under the BTAP in district Dir lower Khyber Pukhtunkhwa, Pakistan. Further, the aim of the present study was to look at the connection between an arrangement of field-estimated factors and spectral data obtained by the Landsat-8 OLI (Operational Land Imager) sensor and Senetinel-2 image.

Materials and methods

Study area

In North Western part of Khyber Pakhtunkhwa province, District Dir lower is located and is spread over an area of 1583 km^2 (*Fig. 1*). The state lies most on the Panjkora River, which start in the mountainous area of Hindu Kush and join the Swat River close Chakdara. Apart from small areas in the south-west, Dir is a rocky, mountainous zone with peaks getting higher to 55,000 m (16,000 ft) in the north-east and 3,000 m (9,800 ft) along the watersheds, with Swat toward the east and Afghanistan and chitral toward the west and north. The topography of the district Dir Lower is dominated my mountains and hills which are part of the ranges/branches of southern Hindukush with the highest peaks in the northern part of Dir. The significant valleys of District Dir Lower include: Maidan, Jandool, Timargara, Samarbagh and Asband. District dir lower has the population of 1,435,917 according to the 2017 census report. The considered population of Dir Lower was 1.0937.091 in 2015 with same growth among the 1981 and 1998 census, i.e. 3.42% per annum (Population Census Organization, 2017).

Forest inventory

Stratified random sampling technique was adopted for the selection of sample plots within plantation sites. Sites were selected randomly from the list plantation provided by project management unit of Billion Tree Afforestation Project Office, Peshawar, Khyber Pukhtunkhwa. The total number of sampling plots was 115 in 17 different plantation sites keeping in view time and available resources. The detail of the sites, number and distribution of sample plots has been explained in *Table 1*. Sampling intensity is the sampled area divided by total area of plantation site and multiplied by 100. Sampling intensity has changed from site to site because of different area, species composition, accessibility and time limitation. The number of plots was calculated by dividing total area divide by plot size and multiplying it with sampling intensity. Field data collection was conduct from 25th September 2017 to 13th October 2017. Altogether, 115 circular plots every one of surface area 1000 m^2 was set up. The plots were geo

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20572072

referenced in respect to a reference in respect to a reference frame work (WGS 84 Datum/UTM zone 43N). Sub meter GNSS receiver GPS was used in collecting plot data. Data was collected from 115 circular sample plots having 15 m radius while considering slope correction with the help of measuring tape and reference points. The number of sample plots varies with the area of plantation sites as per sampling. For the collection of data measuring tape is used along with Sunnto Clinometer. The total number of plants as per 10 feet by 10 feet spacing was 1076 plants in 0.07 ha plot size. Due to time shortage, we measure height and girth of 20% ± 5 plants randomly in each sample plot and note it in the prescribed inventory forms. Then next plot location was assigned keeping in view 200 m plot to plot distance and particular angular measurement. Measurements were conducted with great care as accuracy of assessment of growth performance depends upon these variables. As the plantation was raised in three phases as per BTAP activities, but my study only conclude the data of one phase which phase II measurement of species growth was assessed by measuring two attributes; girth and height and age of the plantation. Height and girth are considered best indicators of growth performance comparatively. The height of trees was found according to the formula in *Equation 1* (WWF, 2016):

$$H = (\tan\theta \times d) + a \quad \text{(Eq.1)}$$

where:
H = Total height of tree in meter
θ = angle of tree to the top of the tree from observers' eyes
d = distance between the tree base and the observer in meter
a = Observer eye height in meter

Moreover, for survival rate pit density was counted as per departmental procedure and then it was up scaled to per hectare. The Pit density is the number of pits per unit area as explained in *Equation 2* (WWF, 2016). It is an important indicator for assessing the success of a plantation program. Pit density was calculated for ten sampled sites with 10 feet × 10 feet spacing which results in 1075 plants per hectares.

$$N = \frac{D \div 3.28^2}{A} \quad \text{(Eq.2)}$$

where:
N is the number of pits per hectare
D is the distance between two plants in feet
A is the area in square meters

Survival rate of plantation is the most important indicator for assessing the success or failure of plantation. The pit density and empty pits data was used to determine the survival rate of the plantation. Survival rate depends how much out of the total sowed seed or planted plants survived and will likely to become healthy plants in future (*Eq. 3;* WWF, 2016). The less number of empty pits the greater survival percentage for the particular site. Plot wise survival rates was up scaled to site wise survival rate by using pit density data and plantation areas.

$$S_p = \frac{N_s}{N_t} \times 100 \quad \text{(Eq.3)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20572072

where
S_p is the survival percentage
N_e is the number of empty pits per hectare
N_t is the number of total pits per hectare

All the enumerated plants were arranged by species name, number of trees per plot and site to know the species composition of all sampled plantation sites. Further, besides sampling planted in the pits, natural regeneration also plays out in the plantation areas. Natural regeneration was also observed during sampling in each site. Regeneration enumeration was divided into two categories, one having less than 9 inches height (not established) and other having more than 9 inches height (established). The site wise natural regeneration was also calculated as per collected data from sampled sites.

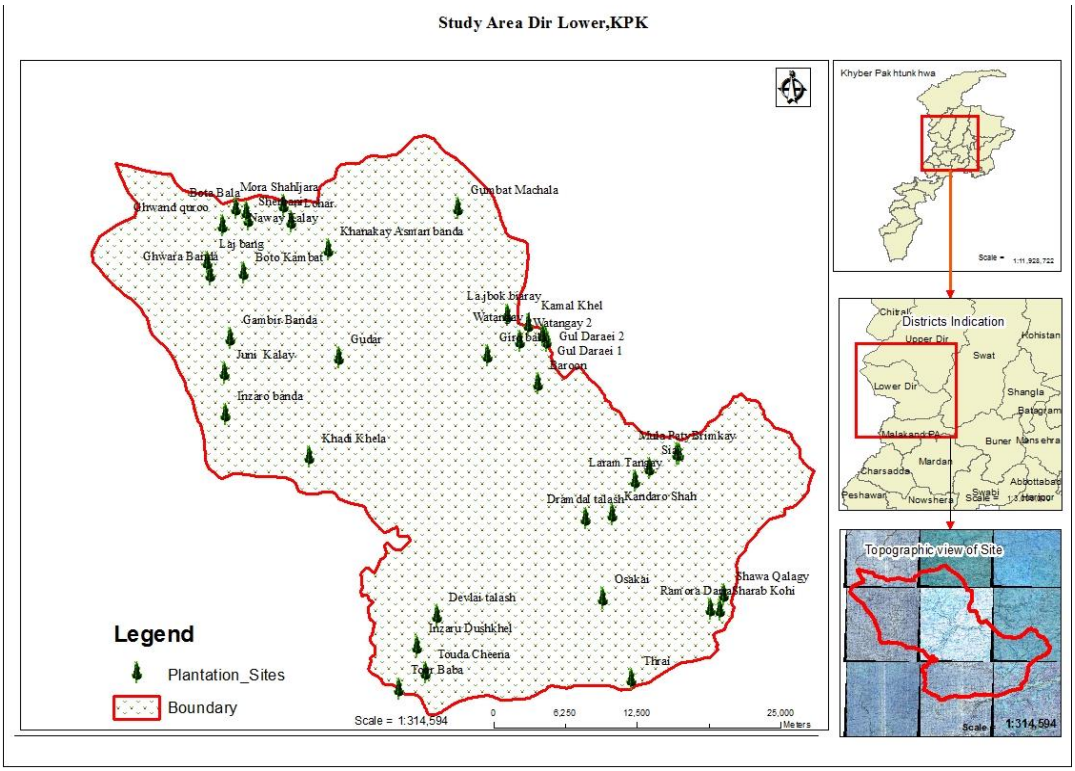

Figure 1. *Map of study area*

Remote sensing

The Landsat-8 Operational Land Imager (OLI) sensor image of in the study was acquired from the USGS Earth Explorer (http://earthexplorer.usgs.gov/). The image was acquired at the same time as the field sampling was carried out at the start of afforestation programs (January, 2014). The image was acquired as level L1T (i.e., they were geometrically rectified with ground control points). Landsat-8 image was carefully preprocessed by radiometric correction, topographic and dark object subtraction methods in ENVI 5.3. The Digital levels (DL) of each band were changed over to surface reflectance by perusing the model parameters and the geometrical attributes incorporated into the image metadata. Band 1 to 7 (B1, B2, B3, B4, B5, B6 and B7) of Landsat-8 OLI were used in the present study. The Sentinel-2 image was acquired from Copernicus Open

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20572072

Access Hub (https://scihub.copernicus.eu/). The Sentinel product was named as S2_MSI_Level-1C with processing Level-1C. Product bands ranged from 443 to 2190 nm with Band 2, 3, 4 and 8 in 10 m, Band 5, 6, 7, 8A, 11 and 12 in 20 m and Band 1, 9 and 10 in 60 m. Sentinel-2 image was corrected for atmospheric effects by applying the Sen2Cor version 2.2.1 software (Main-Knorn et al., 2015). The atmospheric correction transforms the Top-of Atmosphere level 1C product to Bottom-of Atmosphere atmospheric and terrain corrected product (level 2A) and its usability are described by Vuolo et al. (2016). A number of vegetation indexes and other derived parameters (Normalized difference vegetation index, *NDVI*; Modified soil adjusted vegetation index, M*SAVI*; Perpendicular Vegetation Index (PVI), Difference Vegetation Index (DVI), Transformed Normalized Difference Vegetation Index *(TNDVI)* were computed from the atmospherically and topographically corrected image bands and then included in the volume estimation models for evaluation as possible regress or variables.

Statistical analysis

Scatter plots were generated to analyze the relationship between volume (m^3) and individual indices (NDVI, MSAVI, PVI, DVI, TNDVI). Correlation and regression analysis (simple and stepwise models) were performed between volume (m^3) and spectral indices. Different models were established (linear, polynomial, power, logarithmic and exponential). Coefficient of determination (R^2) was calculated for each model with the level of significance ($P \leq 0.05$). As a result, model fulfilling the condition of highest value of R^2, was selected for effective biomass estimation and generation of biomass map as well.

Results

Pit density

Pit density of all these plantation sites have been summarized in *Table 1*. The total area of sampled sites was 1980 ha and total numbers of pits were 2107789 with 1065 (Average) number of pits per hectare. The highest pit density was found at Lram Tngaeishah village with 1086 pits per hectare while Inzrudushkhl kmalkhel the lowest number of pits with 1022 pits per hectare. As per third party monitoring of BTAP, WWF reported that total plantation on areas in the study area was 1998.6 ha and total number of plants was 2150493 with10 by 10 feet average plant to plants spacing (WWF, 2017). *Table 1* also showed plot wise Information about survival rate of all sampled sites. Almost all of the sampled plantation sites showed better survival percentage i.e. above 70%. As per plot level measurements, the highest survival percentage was observed at Shrbkohy Ramoradra with 91% whereas the lowest survival percentage was at Gambirghwara Banda area with 72%. The comparatively high rate of survival is probably due to choice of species i.e. most of the plantations consist of Chir and *Eucalyptus* which shows very high survival rate in especially Eucalyptus shows high resistance for survival in harsh conditions and secondly due to intensive care provided by the department. Regarding site wise survival rates, the Shrbkohy Ramoradra showed the highest success rate with 91% survival percentage while Gambirghwara Banda showed the lowest success rate among the sampled sites with 72% survival. The BTAP monitoring (WWF, 2017) also reported that in northern circle of project area, the highest survival rate was found of Upper Dir 93.8% in compared to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20572072

other forest divisions while the rest were 90, 84.75, 82.97, 82.5, 81.5, 78, and 67 of Dirkohistan, Lower Dir, Swat, Buner, Kalam, Malakand and Alupri respectively. Yamada et al. (2016) conducted a study about the growth and survival of different tree species planted to renovate biodiversity at river side's and within Palm Plantations. Survival rates of 351 seedlings were above 90% during 3 years after planting. Rawat et al. (2017) evaluated multipurpose trees raised in three villages (Jaminikhal, Manjgaon, Hadiya) in India for biodiversity conservation and degraded lands restoration. After four years of plantation, survival rates were 96.6%, 90.3% and 71.1% for Jaminikhal, Manjgaon, Hadiya respectively. Poersch et al. (2017) reported survival rate of 96.43% for *Eucalyptus camaldulenis* in 12 months.

Growth rate of different species

The growth performance of different species is given in *Table 2*. Highest growth performance was exhibited *Eucalyptus camaldulensis*. *Eucalyptus camaldulensis* attained an average height of 1.29 m. This high growth was due to very good conditions of the sites where *Eucalyptus camaldulensis* has been planted. On the other hand, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20572072

remaining species have the average height growth of, 1.12, 0.96, 0.85, 0.79, 0.76, 0.58, 0.54, 0.45, 0.44, 0.44, 0.36 and 0.35 m of Robinia, Willow, Ailanthus, Shisham, Bakain, Chir*, Persian Pine,* Ippleipple, Walnut, Kail, Phulaei and deodar respectively. Data on growth performance of different tee species at different sites were also recorded to determine variation in growth at different sites. Leslie et al. (2018) studied growth functions for *Eucalyptus camaldulensis*, where *Eucalyptus camaldulensis* trees have attained height (m) of 0.5, 1.4, 1.5 and 2 m in 5, 14 and 29 respectively and overall mean height of 10.6 m in 5.5 years. Varghese et al. (2017) studied growth and wood properties of *Eucalyptus camaldulensis* raised from local seed sources and clones, the study reported that plants grow from local sources grow faster than clones. Poersch et al. (2017) evaluated monthly diameter and height growth of *Eucalyptus camaldulensis* during 12 months, diameter increment was recorded form 3.35 cm to 10.27 cm and height increment was recorded from 2.15 to 6.56 cm.

Table 2. *Detail of species utilized in plantation sites along with their age, DBH, height and volume (n = 115)*

Species	Age (month)	Dia (cm) mean	Height (m) mean	Volume (m^3) mean
Pinus roxburghii	17	4.15	0.59	0.0326
Eucalyptus camaldulensis	17	5.29	1.30	0.0540

Melia azedarach	17	3.2	0.76	0.0006

Relationship between volume (m^3) and Sentinel-2 spectral indices

Different vegetation indices were assessed for their correlation with volume (m^3). Results obtained for different regression models for each index are shown in *Figure 2*. Among these indices TNDVI and NDVI has the highest value of R^2 of 0.425, followed by MSAVI with $R^2$0.41. Similarly, applying various regression models (linear, polynomial, power, logarithmic and exponential) the values of R2 change as per data behavior and model assumptions. Vafaei et al. (2018) reported that integration of Sentinel-2A with ALOS-2 PALSAR-2 can enhance vegetation estimation with greater accuracy. Among these two estimations of Sentinel-2A was more accurate. Adan (2017) reported that indices computed from Sentinel-2A have better potential to estimate biomass in contrast to vegetation indices of other sensors.

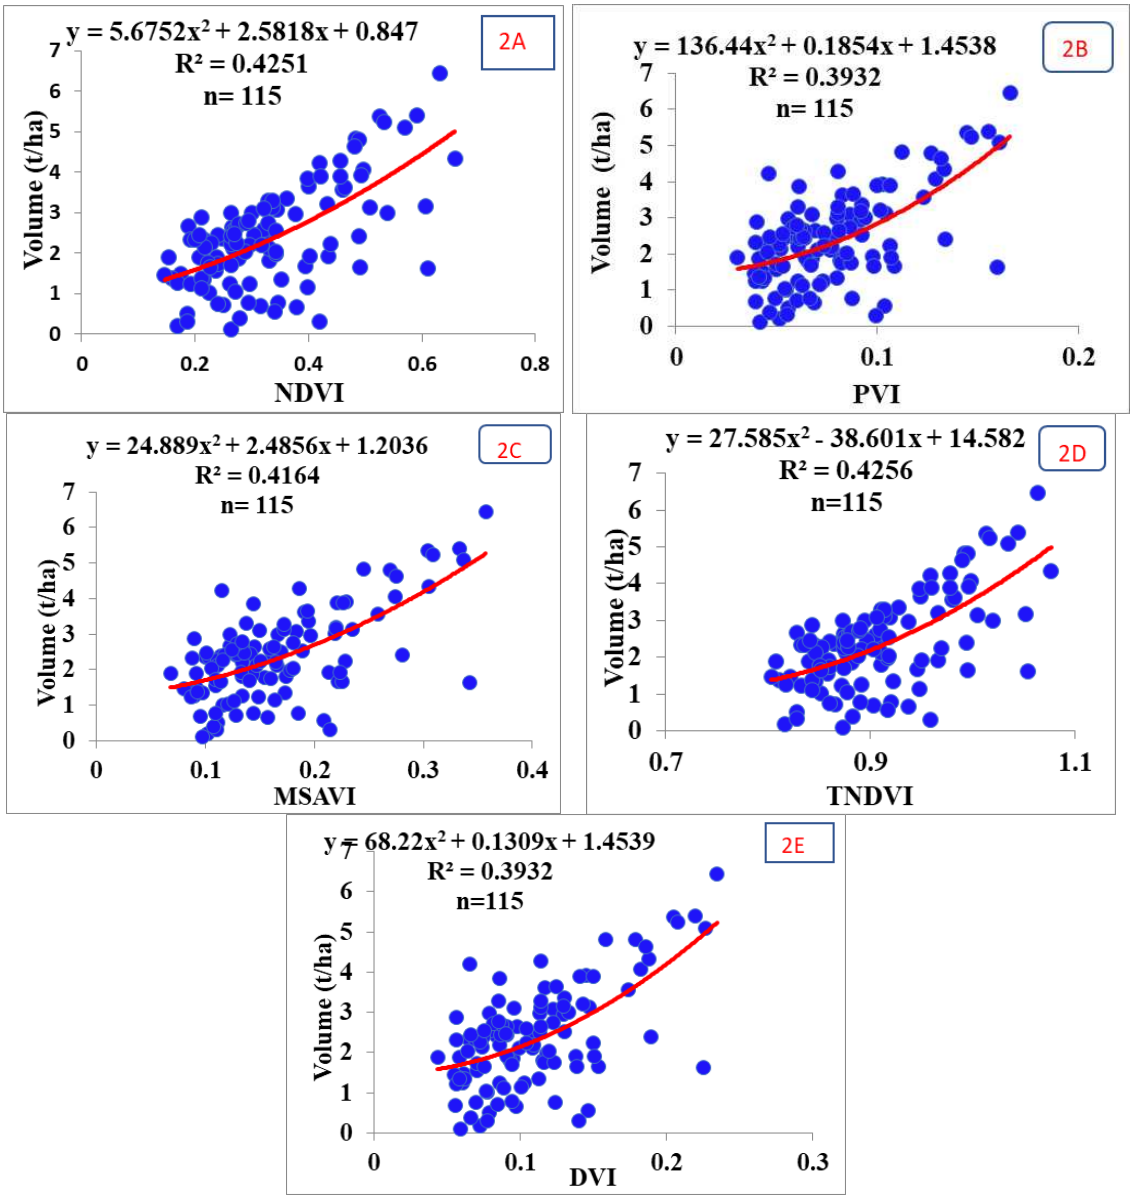

Figure 2. *Scatterplots of spectral indices and volume (t/ha); where NDVI, PVI, MSAVI, TNDVI, DVI were shown by Figure 2a, b, c, d and e respectively*

Relationship between survival percentage and Sentinel-2 spectral indices

Different vegetation indices were assessed for their correlation with survival percentage. Results obtained for different regression models for each index are shown in *Figure 3*. Among these indices NDVI has the highest value of R^2 of 0.859, followed by SAVI and DVI with 0.65 and 0.566 respectively. Similarly, applying various regression models (linear, polynomial, power, logarithmic and exponential) the values of R2 change as per data behavior and model assumptions.

Stepwise regression model

The stepwise Regression Model showed that NDVI was the best predictor for volume mapping at BTAP plantation sites. NDVI map was relatively the best to map

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20572072

biomass among other indices. *Table 3* depicted that the relationship of NDVI and volume was strongly significant while the rest of the indices (TNDVI, MSAVI, DVI, PVI) was not significant under stepwise criteria (Probability-of-F-to-enter < = .050 and Probability-of-F-to-remove > = .100). The correlation matrix showed that NDVI has the highest correlation followed by TANDVI and MASVI with R^2 values of 0.648, 0.645 and 0.637 respectively.

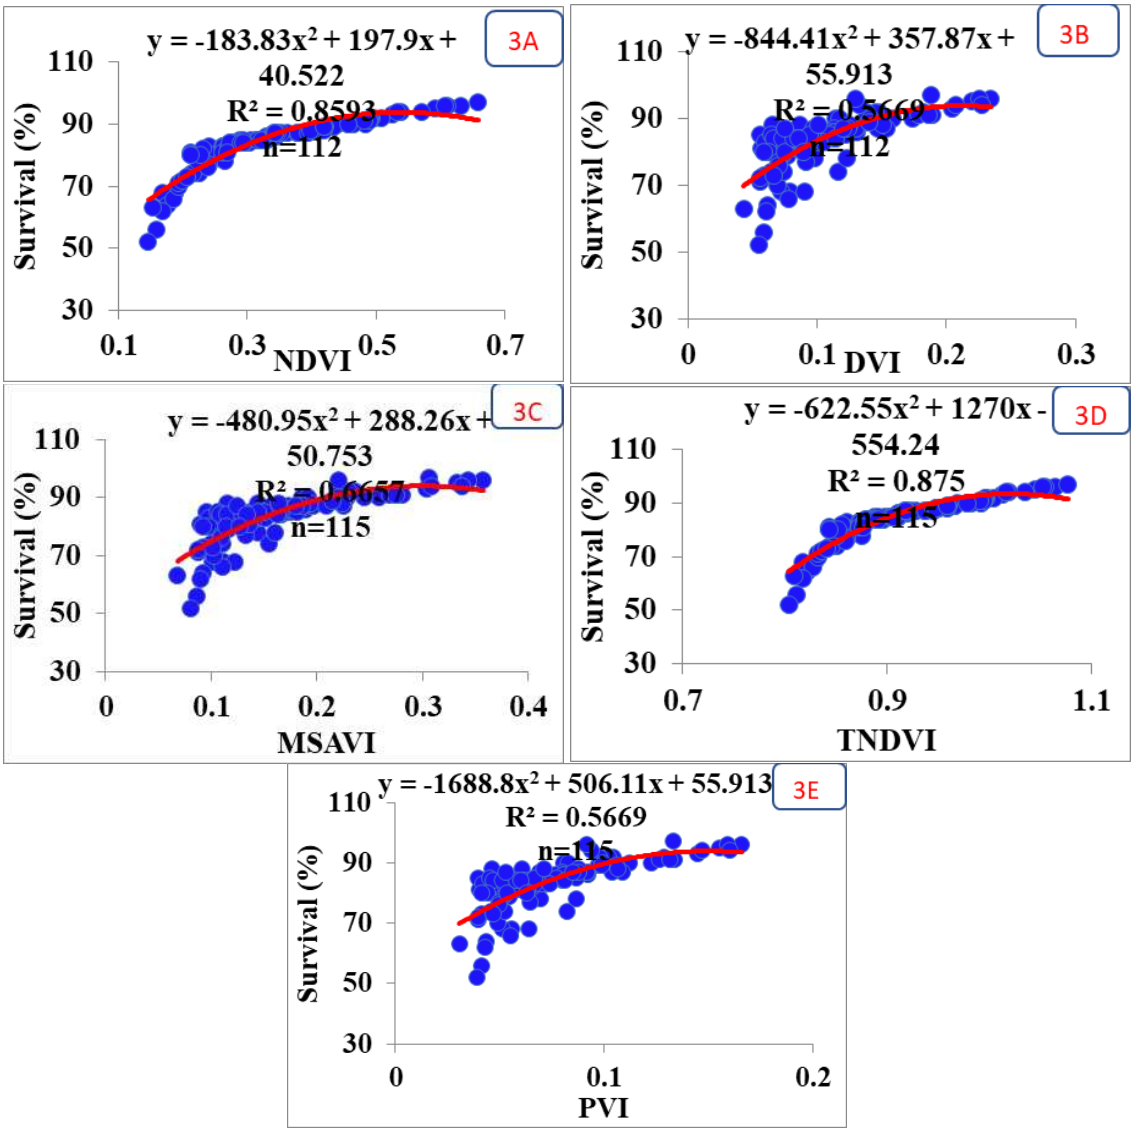

Figure 3. *Scatterplots of spectral indices and survival rate (t/ha); Where NDVI, PVI, MSAVI, TNDVI, DVI were shown by Figures 2a, b, 3c, d and e, respectively*

Whereas the overall R^2 of model was 0.420 with standard error of 0.949. Volume map of the plantation sites was produced using raster calculator in ArcGIS 10. Further, NDVI differencing showed that in NDVI range was from -0.65 to 0.68 in 2013 and the upper limit (value) was increased to 0.85 in 2018. Thus showed mosaic restoration and afforestation activities of BTAP. The lower sub-images of *Figure 4* compared same plantation sites before and after the project activities which showed substantial increase

DOI: http://dx.doi.org/10.15666/aeer/1802_20572072

in the vegetation cover from 2013 to 2018. Thus it can be concluded that BTAP activities were efficiently managed and supervised by the department. WWF (2016, 2017) and World Economic Forum (2017) reported that project activities were successful and meet its Bonn Challenge commitment by the end of 2017.

Conclusion

The present research evaluated the BTAP success by survival rate and growth performance of major multipurpose species raised in 15 randomly selected sites of Dir lower Forest division. The overall survival rate and growth performance of plantations was found satisfactory. However, the share of *Eucalyptus camaldulensis* is more than other species which needs to be balanced in the future plantations. Pit density is found bit lesser than the required 10 feet by10 feet spacing and in few sites it was 10 x 11 space i.e.1065 pits per hectare observed. Highest growth performance was exhibited *Eucalyptus camaldulensis*. *Eucalyptus camaldulensis* attained an average height of 1.29 m. This high growth was due to very good conditions of the sites where *Eucalyptus camaldulensis* has been planted. On the other hand, the remaining species have the average height growth of,1.12, 0.96, 0.85, 0.79, 0.76, 0.58, 0.54, 0.45, 0.44, 0.44, 0.36 and 0.35 m of Robinia, Willow, Ailanthus, Shisham, Bakain, Chir*, Persian Pine,* Ippleipple, Walnut, Kail, Phulaei and deodar respectively. Data on growth performance of different tee species at different sites were also recorded to determine variation in growth at different sites. Correlation between mean height (m) and mean diameter (cm) for all species was good and showed the overall data behavior shows good growth at present stage. If proper monitoring and management is continued for coming years, then these plantation will become fully established and contribute to successful implementation of Forest Landscape Restoration (FLR) under the Bonn Challenge commitment. To achieve future implementation and monitoring, based on the data collected during the field survey, personal observations of the researcher and interaction with staff of Forest Department and members of local community, some recommendation were suggested. There is a need to repeat such studies in the future to assess and monitor the survival rate and growth performance of plantations raised under BTAP. Due to shortage of time this study could not cover all the sites where plantations were raised. It is therefore advisable to conduct assessment of plantations in the sites not covered under the present study. It is also recommended to investigate the impacts of BTAP Plantations on ecological systems such as biodiversity, hydrological patterns and carbon sequestration after 5-10 years to ascertain the impacts on the ecosystem.

We also exhibit that using the free of charge Landsat-8 and Sentinel-2 data and open source software is a possible alternative achieving assure results for BTAP plantation spatial and temporal monitoring. The study suggested that Sentinel-2A product has considerable potential to estimate biomass and map forest areas. The Sentinel-2A item

DOI: http://dx.doi.org/10.15666/aeer/1802_20572072

has nearly substantial spatial inclusion and high goals to perform proficiently for estimation of biomass than other open source sensors information items.

(Received 5th Mar 2019; accepted 25th Nov 2019)

Abstract. Noise is one of the health and environmental problems of our age, and it is an undesirable phenomenon that annoys people. Increasing and uncontrolled noise creates physical, physiological and psychological problems, chasing people away from urban life and leading them back to nature. Since the urban parks, which are one of the places to relax, are intensely preferred by people, the noise here should be controlled. In this study, to determine the noise level of the Hudavendigar Urban Park located in the district of Nilufer, Bursa, Turkey, where the transportation routes are intense, measurements were performed, and the results were statistically interpreted. Measurements were carried out at 6 locations selected across the park, in summer, and winter, morning, lunch and evening hours, on weekdays and weekends. In this study, the noise sources indoor and outdoor of the park were determined, and the regions which exceed the limit values given in the Regulation on the Assessment and Management of Environmental Noise were confirmed. As a result of the study, the differences in noise measurements were significant in the summer and winter periods of the Hudavendigar Urban Park according to the statistical analysis.
Keywords: *noise measurements, noise pollution, recreation area, statistical analysis, urban park, Turkey*

Introduction

The effects of noise on the environment and people have increased by technology, industry and transportation. The noise defined as an unpleasant, unwelcome, uncomfortable acoustic phenomenon has become an environmental problem that needs to be controlled (Şerefhanoğlu, 1991; Aydın and Ateş, 1997).

Today, the effects of noise on the environment and human beings can not be estimated. Temporary or permanent hearing loss occurs in people exposed to prolonged and intense noise. Lower levels of noise make it difficult for people to have mutual communication, cause stress, and insomnia, and hamper human peace and prevent them from working efficiently (Balcı, 1994). With a noisy life, the factors that wear people up and down are increasing. There is a society in which noise resistance and tolerance are increasingly reduced.

Despite the diversity of the effects of noise on human, the limit values related to noise levels and disturbances are given in *Table 1* (Donoghue, 2004; Aslan and Yıldız, 2017).

The effect of noise on human beings is not only addressed by the high levels of noise, but also by its frequency (Rosenberg, 1991). The level of effect varies according to the duration, severity, frequency of the noise, whether it is continuous or intermittent. Also, the health and age of people exposed to noise cause differences in the degree of influence (Aydın and Ateş, 1997).

Although the term environmental noise generally used for sources outside the structures, noise sources commonly found in the interior environment of the buildings

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20732085

and various places. In-building noise sources are particular noises that affect fewer people and can often be prevented with good external insulation (Kurra, 2009; Belek, 2017). Because the external noise sources affect a broader human population, the measures should be at the national level to minimize the noise generated by these sources.

Table 1. *Noise levels and disturbances (Donoghue, 2004)*

Degree	Noise Level dB(A)	Disturbances
1	30-65	Confusion, discomfort, anger, anger, sleep disorder and concentration disorder
2	65-90	Physiological reactions increased blood pressure, acceleration of heartbeat and respiration, decreased pressure in brain fluid, sudden reflexes
3	90-120	Increased physiological reactions, headaches
4	120	Permanent damage to the inner ear, disturbance of balance
5	140	Serious brain destruction

For this purpose, the Regulation on the Assessment and Management of Environmental Noise (RAMEN) No: 27601, dated 04.06.2010 (Anonymous, 2010), has begun to address noise control at the national level. Also, noise action plans, auxiliary guidelines, and informative publications are prepared by different institutions (Anonymous, 2004, 2011, 2012).

Noise measurements are essential in noise control. Generally, these measurements are performed to check if the environmental noise is within the required limit values or to avoid a negative effect on human (Belek, 2017). The studies on noise pollution have been widely used to determine noise levels from highway traffic (Karadayı, 2001; Aktürk et al., 2003a; Çetin, 2010; Ilgar, 2012; Delikanlı et al., 2014; Sharma et al., 2014; Kalıpçı, 2017), rail systems (Aktürk et al., 2003b; Neitzel et al., 2009; Kablan, 2012; Oruç, 2017) and machinery in some industrial plants (Şahin, 2003; Sakarya, 2016), or to address the effects of noise on human health (Singh and Davar, 2004; Özbıçakçı et al., 2012; Tür, 2016).

There are very few studies on noise pollution in urban parks in the literature (Zannin et al., 2006; Szeremeta and Zannin, 2009; Bayramoğlu et al., 2014; Özer, 2014, 2015, 2017). However, urban parks located within the areas where people can relax in nature by moving away from urban life, are significant for the peace of human life. To control and prevent noise occurring in these areas, the number of studies related to noise pollution should increase.

In this study, noise measurements were carried out at 6 points determined in the Hudavendigar Urban Park in the Nilufer district of Bursa province in the summer and winter periods, and the measurement results were evaluated statistically. The noise sources inside and outside the park were determined, and the regions exceeding and approaching the limit values were specified in the RAMEN.

Materials and Method

Hudavendigar Urban Park created on both sides of the Nilufer Stream of Bursa city in Turkey, is the largest urban park in the city, which has an area of approximately 510 thousand m^2. The measurements were carried out to determine the noise level in the park, which is in the center of the city and in an area with high access roads.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20732085

In the study, firstly the methods of noise pollution studies were investigated (Bayramoğlu et al., 2014; Özer, 2014, 2015), and sensitive points in terms of noise were determined by looking at the map of the park. When determining the points, parking entrance and exit points, parking lot, proximity to motor traffic, tennis courts and football fields were taken into consideration. These points are shown on the map (*Figure 1*) by giving measurement numbers, the coordinates of the measurement points are given in *Table 2*.

Figure 1. *Display of measurement points on the map (Anonymous, 2018a)*

Table 2. *The coordinates of measurement points (Anonymous, 2018b)*

Measurement points	Measurement coordinates	
	x	y
1	670544.22	4452165.38
2	670212.43	4452358.63
3	670012.58	4452166.61
4	670026.68	4451687.42
5	670499.32	4451918.18
6	670403.56	4452005.65

The noise measurements were made at determined points on Monday and Thursday on weekdays and Saturday or Sunday, at the weekend, in the morning, lunch and evening times, in October, November, December in 2016 and July, August, September

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20732085

in 2017. The measurements were carried out in three minute periods on sunny days when the weather was rainless and windless. The measurement hours are 08:00-09:00 a.m., 12:00-1:00 p.m. and 5:00-6:00 p.m. according to the overtime start-end hours, and people may prefer to go to the park.

The noise measurements were taken from a height of 1.2 meters to a location at a 45-degree angle, close to the traffic roads that limit the parking areas and from the middle of the parking area (Göksu and Karabulut, 2014). It was taken to measure at least 1.5 m away from the noise reflective surfaces, such as trees, walls, and buildings in order not to cause the noise to be reflected and cause the actual noise to taken incorrectly. All subsequent measurements were taken from the same points and positions, the first measurement conditions (same point, same height, same direction, same time, etc.) were not changed (Morgül and Dal, 2012). Average air temperature, humidity and wind speed at the time of measurement are recorded.

The sound meter (EXTECH 407738, Massachusetts, USA) was used to determine the noise level in this study. The measurements are in the maximum equivalent noise level (Leqmax) and are in the A-weighted volume (dBA) unit. In this context, the 90 values from the single point of the park, a total of 540 values from 6 points were determined and Leq, which is the equivalent noise level, is translated according to *formula 1*.

$$Leq = 10\ Log 1/10 \sum_{i=1}^{n} 10^{Li/10} \quad \text{(Eq.1)}$$

where,

- Leq : Equivalent noise level (dBA).
- n : Number of noise measurements.
- Li : Noise level in measurement.

Thus, for a total of 27 hours in the park, 30 days measurements were made. These values were subjected to oneway variance analysis in a general linear model by using JMP 7 (SAS Inst. Inc., NC, USA) software, and their importance status was examined. Means were compared with LSD test by using MStatC software. The reasons for the values were evaluated and discussed according to the RAMEN.

Results and Discussions

This study was carried out on the determination of noise pollution in the Hudavendigar Urban Park located in Nilufer district of Bursa, Turkey. The noise measurements of the park were carried out in successive winter and summer periods. A comparison of minimum, maximum and average values for the summer and winter periods was performed at 6 points determined in the park and the number of measurements exceeding 65 dBA which is the limit in RAMEN were given in *Table 3*. The variance analysis results were given in *Table 4*. The differences between seasons, measurement points and measurement time were significant statistically during the study period ($P<0.01$). But the variation within measurement days was not significant ($P>0.05$). Noise levels in the park evaluated according to the noise-sensitive areas in the RAMEN Appendix VII, and 245 of the total 540 measurements were found to exceed the limit value of 65 dBA during the day. The regional, seasonal and temporal changes of noise measurements in Hudavendigar Urban Park and the possible sources of noise levels are discussed in detail in the following sections.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20732085

The average noise level of the Hudavendigar Urban Park was determined as 64.63 dBA. The average noise levels in other studies are 66.62 dBA in Yüzüncüyıl Park in Erzurum (Özer, 2017), 67.69 dBA in Aziziye Park (Özer, 2014), 60.07 dBA in Yakutiye Park (Özer, 2015), 63.74 dBA in Meydan Park in Trabzon and 64.67 dBA in Fatih Park (Bayramoğlu et al., 2014). These results show that the average noise levels in urban parks are close to each other.

Regional Variations of Noise Measurements

The 1st point is the most used area of Hudavendigar Urban Park's entrance-exit gates. At the same time, it looks at Dikkaldırım Street, where there is heavy traffic. The measured values were higher than the park average for winter and summer measurements because the park is an entrance-exit zone, and due to high number of people-related mobility and the proximity to the street. The measured values at this point of the park have generally increased as a result of vehicles. Traffic lights around the measuring points increased the car stop-start, while the noise of the horns increased in parallel with the traffic during the pedestrian crossing and the work hours. The road traffic noise in Bursa had become a significant problem in a study conducted by Karadayı (2001). This result supports the conclusion that the traffic noise around Hudavendigar Urban Park also increases the noise level in the park. As a result of the 1st point measurements, the maximum value was 90.8 dBA, and 88 out of 90 measurements exceeded 65 dBA.

The selected point 2 is on the walking path of Hudavendigar Urban Park, located in the vicinity of the bridge where Nilufer River is lowered from a certain height and is close to the intersection of Dikkaldırım Street, where the traffic of motor vehicles is much. While noise levels increased overall at all points during the summer period, there were decreases in the noise levels at the 2nd point, and the measurement results which exceeded the RAMEN limit value of 65 dBA. Because the water level of the river is low

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20732085

in this area and the intersection works during the winter months increased the noise in this period. The maximum noise level of the 2nd point was 84.3 dBA, and 41 of 90 measurements exceeded 65 dBA, which is the limit value of RAMEN.

The 3rd point located in the western part of the Hudavendigar Urban Park, where the football fields and the children's playground are densely populated. With the increase in the use of football fields and children's playground at this point in the summer, especially at noon and evening times, the noise levels increased more than 10 dBA on average according to winter. As a result of the measurements at point 3, the maximum value was 87.8 dBA, and 28 out of the 90 measurements exceeded 65 dBA, which is the limit value of RAMEN.

Nilufer River flows around the 4th point of the park, and there are picnic areas, benches, tennis courts and one watchtower. Because the tennis games took place in the closed area in winter, there were no sound levels to create unrest. However, in the summer period, the level of noise increased when the tennis was played on open courts. Especially in the winter period, the value above 65 dBA which is the RAMEN limit value is not read, in summer period the value above 65 dBA is recited 14 times. While the maximum noise level was 87.8 dBA, it was that 14 out of the 90 measurements in total exceeded 65 dBA.

There are children's amusement parks, basketball courts and kiosks around the 5th point, which is overlooking the entrance and exit doors of the park and Bent Street. The measured values are very close to or exceeded the limit value because this point is a park entrance and exit zone, and due to the high number of people-related mobility, closeness to the street and the presence of children's amusement parks, basketball fields and kiosks. The maximum noise level was 85.0 dBA, and 74 of the total 90 measurements made at this point were found to exceed 65 dBA, which is the limit value of RAMEN.

There is a large tea garden, restaurant and lake around the 6th point selected in the center of the park. Due to the preference of closed areas during winter, the results are generally below the limit values. However, with the warm weather, the preference of the tea garden and the open spaces of the restaurant, the opening of loud music in the tea gardens and the choice of kayak trips on the lake increased, the noise levels increased towards the evening hours. As a result of the measurements at point 6, the maximum value was 77.8 dBA, and 16 out of 90 measurements exceed the limit value of 65 dBA in the RAMEN.

When the results of the noise measurement values at 6 points in the park were examined, the differences between these values was statistically significant (*Table 5*). According to these results, the highest noise level was at the 1st point during the study. The 1st point of the noise measurements in Hudavendigar Urban Park is the most used area of the entrance-exit gates and at the same time looking at the Dikkaldırım Street where the traffic is heavy, explains why the highest noise values were obtained at this point.

Table 5. *Variation of noise levels among measurement points*

Seasonal Variations of Noise Measurements

There were differences in noise measurements of Hudavendigar Urban Park, in the summer and winter periods. The noise sources inside and outside the park for summer and winter periods caused the differences. The maximum noise levels for the summer and winter measurements of 6 points determined in Hudavendigar Urban Park are shown in *Figure 2*.

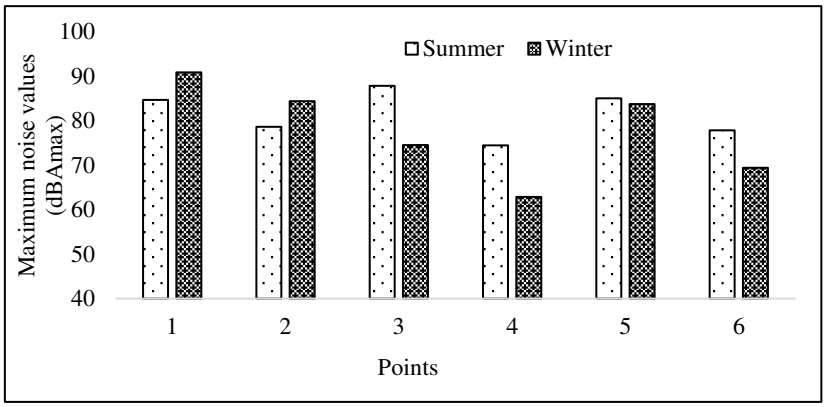

Figure 2. *Maximum noise levels according to the points in summer and winter measurements*

In the winter measurements of the Hudavendigar Urban Park, traffic-related noise has come to the fore. Since sports and recreation activities are carried out in closed areas, noise caused by these activities has remained passive according to non-park noise sources. 110 out of 270 measurements carried out during the winter period exceeded 65 dBA which is the limit value of RAMEN.

With the increase in the use of sports and recreation activities in summer, the noise levels caused by these activities increased significantly compared to winter. Traffic-induced noise levels are close to winter measurements. 135 out of 270 measurements carried out during the summer period were over 65 dBA, the limit of RAMEN. According to the statistical evaluation of winter and summer measurements, the difference between the measurement values of the two seasons was significant (*Table 6*).

Table 6. *Variation of noise levels among seasons*

Season	Min (dBA)	Average** (dBA)	Median (dBA)	Max (dBA)	Standard deviation	Standard error	$LSD_{0.05}$ Value
Winter	46.70	63.24[b]	62.90	90.80	8.43	0.51	4.22
Summer	49.00	65.98[a]	66.60	87.80	9.12	0.56	

[**]P<0.0001 level is significant, [a-b] Means in a column with different superscripts significantly differ.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20732085

In a study on the determination of noise pollution caused by traffic and recreational use in Çorlu city, noise levels were higher in winter than in other periods. It is thought that the population density in the region and accordingly the number of vehicles are not to decrease by winter holidays etc. (Ünver, 2008). In the Hudavendigar Urban Park, while the noise levels were higher in the regions close to the transportation roads during the winter months, it was observed that there were lower levels in park areas in winter when compared to the summer season. In a study conducted in Düzce city, the noise values of the park areas in summer were higher than in winter (Yerli and Demir, 2015). The results show that the parking areas are used more intensively in summer than in winter, and similar results also considered for Hudavendigar Urban Park.

Temporal Changes of Noise Measurements

In summer and winter measurements, there are more traffic and vehicle-related noise increases in the morning times during the week, and there is an increase in noise levels due to the active use of sports and recreation areas in the lunch and evening times during the weekend.

Noise levels according to morning, noon and evening hours

The maximum noise levels of 6 points determined in Hudavendigar Urban Park in the morning, noon, and evening times during the winter and summer periods are shown in *Figure 3*.

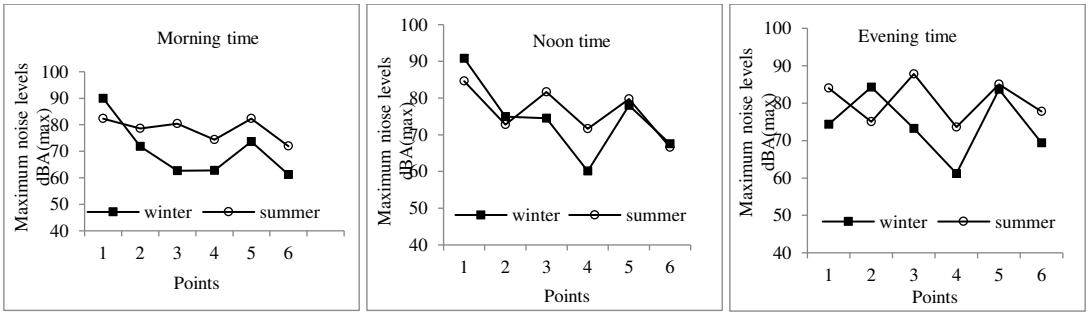

Figure 3. *Maximum noise levels of winter and summer periods according to morning, noon and evening hours*

In the morning measurements, the maximum value was at the 1st point with 90 dBA. Since the morning measurement time interval is the time for people going to work by their vehicles, significant traffic density has been observed mainly on the streets near the 1st and 5th points and high noise levels have been read at these points.

The maximum value was 90.8 dBA and 84.6 dBA at the 1st point in the winter and summer periods, respectively. There were substantial differences in noise levels between the 3rd and 4th points at noontime because children's playgrounds at these points and activities such as football and tennis are preferable at noon during the summer.

The maximum value of the park points in the evening hours was 87.8 dBA at the 3rd point in the summer period. In the summer period, noise levels increased due to the active use of sports and recreation areas. The differences between the measurement

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20732085

times of noise values were significant according to statistical analysis (P <0.0001) (*Table 7*).

The highest noise value was measured as 68.75 dBA in the evening at the Yüzüncü Yıl Park in Erzurum (Özer, 2017), in another study conducted in Aziziye Park (Özer, 2014), the highest noise value in the evening time was read as 69 dBA, the highest noise value in Yakutiye Park (Özer, 2015) was determined as 64.29 dBA in the evening. In Hudavendigar Urban Park, the highest noise value was 77.4 dBA in the evening time. In a study conducted in the Düzce city of Turkey, the parking areas were used more intensively and until late hours in the summer than in winter. The noise levels in day and evening in summer are higher than in winter months (Yerli and Demir, 2015). A similar situation exists for Hudavendigar Urban Park.

Table 7. *Variation of noise levels among measured times*

Hours	Min (dBA)	Average** (dBA)	Median (dBA)	Max (dBA)	Standard deviation	Standard error	$LSD_{0.05}$ Value
Morning	46.70	62.41[b]	60.55	90.00	9.22	0.69	
Noon	49.00	64.81[a]	65.00	90.80	8.94	0.67	2.00
Evening	50.20	66.61[a]	66.90	87.80	7.99	0.59	

**P<0.0001 level is significant, [a-b] Means in a column with different superscripts significantly differ.

Noise levels of weekday and weekend

The change in the levels of weekday and weekend noise measurements of 6 points in the Hudavendigar Urban Park in the winter and summer periods are shown in *Figure 4*.

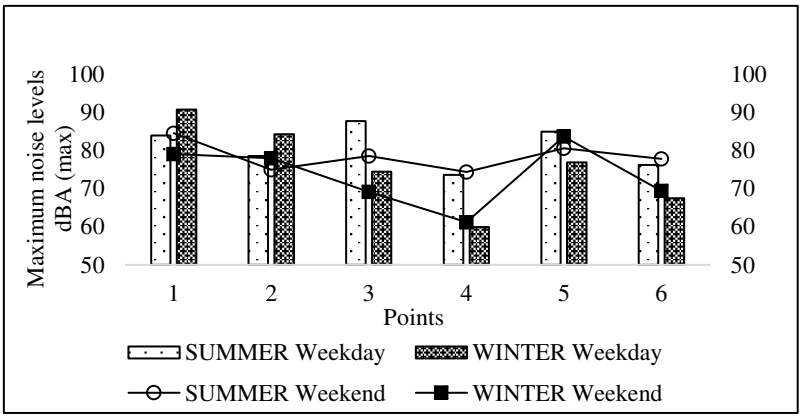

Figure 4. *Maximum noise values during weekdays and weekends in winter and summer periods*

As seen in *Figure 4*, there is a general increase in noise levels according to the winter period measurements in the weekday values of the summer period. There are increases in the summer period noise levels due to more summer activities in the park. Due to the intersection work carried out in the north of the park during the weekdays in the winter period, both the equipment used and the traffic generated caused an increase in noise levels at points 1 and 2.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20732085

There is an increase in summer measurements at weekends. It is thought to be because in-park activities are carried out in open areas and people prefer to use the park in hot weather.

Conclusions

In this study, measurements were made to determine the noise level in the Hudavendigar Urban Park, located in the Nilufer district of Bursa, which is an important recreation area for the urban population. These measurements were carried out for a total of 30 days during the summer and winter periods, including morning, lunch and evening hours. Observations and statistical data interpreted the measurement results. It was determined that the sensitive points exceed the limit values specified in the RAMEN and approach the limit values, and the points with noise differences have been associated with the purposes of the park. The findings of the measurements are summarized below:

- The traffic noise was prominent in the winter period measurements of the Hudavendigar Urban Park. Since sports and recreation activities are carried out in closed areas, noise caused by these activities is passive according to non-park noise sources. The 110 of 270 measurements exceeded 65 dBA, which is the limit value of RAMEN. In winter measurements, the highest value was 90.8 $dBA_{(max)}$ at the 1st point in November.
- With the increase in the use of sport and recreation activities in the park in summer, the noise levels caused by these activities have increased significantly compared to winter measurements. Traffic-induced noise levels are close to winter measurements, and 135 out of 270 measurements exceeded 65 dBA. In summer measurements, the highest value was 84.6 $dBA_{(max)}$ at the 1st point in noontime in July.
- In summer and winter measurements, traffic and vehicle noise increased throughout the park in the morning, and noise levels increased due to active use of sports and recreation areas especially at noon and evening hours during the summer. In the morning and noon measurements, the highest values were read in the summer and winter periods at the 1st point, while the highest winter values in the evening measurements were at the 5th point and the highest summer value at the 1st point. The highest values of the morning hours are 82.3 dBA (max) in summer and 90 dBA (max) in winter, the highest values of noon are 84.6 dBA (max) in summer and 90.8 dBA (max) in winter, the highest values of the evening hours were 85 dBA (max) in summer and 84.3 dBA (max) in winter.
- The noise levels during the weekdays in the summer period showed a general increase compared to the winter period. This increase is due to the more use of activities in the park in summer. In winter measurements, the high values in points 1 and 2 are affected by the intersection study in the north of the park and the traffic. The highest noise measurement value on weekdays was read at 90.8 $dBA_{(max)}$ at noon in November at the 1st point in winter.
- On the other hand, there is an increase in the summer measurements. Because in-park activities are carried out in open areas, and people prefer the park more in hot weather. The highest value of the weekend was read as 84.6 $dBA_{(max)}$ at noon in July at the 1st point in summer.

As a result of this study, which was carried out to determine noise pollution in urban parks in Bursa, the differences in noise measurements in summer and winter periods in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20732085

Hudavendigar Urban Park were observed. It was interpreted as a result of the measurements that the vehicle traffic around the park increased the noise level in the winter period, and the intensive use of the activities in the park increased the noise level, especially in the summer. It was concluded that it would be beneficial to take various measures by focusing on the noise-enhancing factors in the park to prevent people coming to the urban park to relax from these levels and not to exceed the RAMEN limit value.

Abstract. Global warming induced by greenhouse gases (GHGs) is already a reality and will continue to increase resulting in a severe climate change. The aim of the paper is twofold. First, to investigate the GHGs emissions between the year of 2004 and 2016 in four major urban cities, representing the residential band of Kuwait. Results showed a clear steady yearly increase in GHGs emissions, with more emissions in summer compared to winter, possibly due to the high consumption rate of fossil fuel for cooling purposes and traffic activities. Results also revealed a diurnal variation in GHGs emissions, plausibly attributed to the combined effects of busy traffic hours as well as respiration by the living organisms and/or from soils. A second objective in this paper is, to develop a reliable connectionist models such as neural networks for predicting GHGs emissions. Radial basis function (RBF) network due to its known approximation capabilities, localization of its transfer functions and its efficient training algorithms, showed a superior performance in predicting GHGs emissions. Parity and time series plots of the predicted concentrations against the observed concentrations demonstrated the appropriateness of connectionist modelling as a fast and precise tool for monitoring and forecasting the GHGs emissions.
Keywords: *GHGs trend, CO_2 and CH_4 emissions, artificial neural network, radial basis function, model performance*

Introduction

The threat of global warming induced by human-driven emissions of carbon dioxide (CO_2), methane (CH_4), and other greenhouse gases, as well as land-use changes, has become a reality acknowledged by billions of people. Although it is established that 57% of man-made CO_2 emissions can be removed by the biosphere and oceans (Walsh et al., 2017), the level of atmospheric CO_2 has increased progressively through the years as a result of human activities, including deforestation, combustion of fossil fuels, and power generation (Balch et al., 2016; Sterman et al., 2018). Methane atmospheric concentrations have increased by almost 150% since pre-industrial times, which corresponds to a radiative force of $0.48 Wm^{-2}$ (Jędrysek et al., 2015). Based on current trends, extreme events such as temperature extremes, heat waves, and heavy rains are likely to increase in both frequency and intensity. This will eventually induce a rise in Earth's temperature, including its seas.

DOI: http://dx.doi.org/10.15666/aeer/1802_20872107

Continuous monitoring of global warming-induced emissions has become an urgent step in mitigating and managing such emissions. Several attempts have been made to monitor the changes of atmospheric CO_2 and CH_4 in different regions around the world. As for 2016 (WDCGG, 2018), CO_2 records were reported as follows: Italy (427.6 ppm), Poland (427.7 ppm), Korea (416.3 ppm), Hungary (410 ppm), and Hong Kong (408 ppm). In India (region of Ahmedabad), CO_2 concentrations varied between 382 and 609 ppm with the annual average of 413 ± 13 ppm during the period of November 2013 to May 2015 (Chandra et al., 2016). In Pakistan, a significant increase in CO_2 concentration was noted from January 2010 (390 ppm) to December 2015 (400 ppm), leading to an increase of 1.75 ppm/year (Mahmood et al., 2016). Similar observations were also reported in South Korea (Shim et al., 2018). CH_4 trend was also investigated in different cities over the world and results revealed a steady increase with a range of 1.95 to 2.10 ppm as of the year of 2016 (WDCGG, 2018). Tracking the trend of GHGs at least during the past three decades, it reveals an increase in the level of greenhouse gases (GHGs) worldwide.

Thus, it is imperative to develop novel and better techniques to estimate concentrations of global warming-induced gases like CO_2 and CH_4. Several approaches have been suggested to model and forecast atmospheric gases. These include for example the atmospheric dispersion model (Loh et al., 2008), statistical regression models that determine the underlying relationship between a set of input data (predictors) and targets (predictands) (Mason and Baddour, 2008), and artificial neural network- based models (ANN) to predict future pollutant concentrations (Ozcan et al., 2006; Kunt et al., 2016; Zhang and Ding, 2017). Notably, ANN has shown promising results and gained more attention in recent years due to its superiority in modelling nonlinear correlations between input and output variables (Amoura et al., 2011; Nezhad et al., 2011; Zhang et al., 2016; Parvizi et al., 2018). ANN has numerous advantages over traditional phenomenological or semi–empirical models. One is its rapid information processing and ability to develop the mapping of input and output variables (Guclu and Dursun, 2010). Other features include the ANN's higher accuracy in predictions over other types of models (Noor et al., 2018) and its ability to handle huge and complex systems within many interrelated parameters (Tahboub et al., 2016).

Due the powerful, accurate, and fast prediction algorithm, ANN models have been used to forecast different pollutant concentrations (Wu et al., 2011) on numerous time scales with acceptable results. Hassan and Dong (2018) predicted the tropospheric ozone (O_3) concentrations using ANN as a function of meteorological conditions and several air quality parameters. Sahin et al. (2004) used the multi-layer perception neural network (MLP-NN) model to predict the daily level of carbon monoxide (CO) in Turkey (Istanbul) using meteorological parameters as predicators. Pawul and Sliwka (2016) applied ANN to predict the concentrations of benzene, CO, and nitrogen oxides (NOx). Elminir and Abdel-Galil (2006) modeled particulate matter (PM_{10}), CO, and nitrogen dioxide (NO_2) based on different climatological variables in Egypt. Rahimi (2017) applied MLP-NN to predict NO_2 in Tabriz, Iran. Several other researchers have used NN techniques to forecast pollutant concentrations (Kurt and Oktay, 2010; Elangasinghe et al., 2014; Russo et al., 2015; Zhao et al., 2018) and the consensus is that an NN can be a useful tool for predicting atmospheric pollutants.

The aim of the present study is twofold. Firstly, to provide a descriptive picture of the current and the trend of GHG's emission in four representative urban areas in Kuwait. Secondly and most importantly, to develop practical, robust, and effective neural networks that forecast the concentration of GHG, specifically, CO_2 and CH_4 emissions in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20872107

Kuwait. In order to accomplish this, the hourly, daily, seasonal, and yearly records of CO_2 and CH_4 emissions along with their meteorological conditions for the 13-year period were statistically investigated in four major urban cities, representing the residential band of Kuwait. Throughout the investigation, several combinations of artificial neural network (ANN) structures and types, including linear (L), multilayer perception (MLP), and radial basis function (RBF) networks, were tested and optimal models were selected. The neural networks were trained until the network training error achieved the specified acceptable error. The developed NN models in this study yielded feasible, reliable, and efficient prediction of CO_2 and CH_4 concentrations.

Methodology

Study areas

Kuwait is situated in western Asia, between latitudes 28°30'and 30°5' North and longitudes 46°33' and 48°30' East, with a total area of 17,818 km^2. It is bounded by Saudi Arabia in the south and southwest and with Iraq in north and northwest. The total population of Kuwait as of 2018 is about 4.56 million; of whom 1.38 million Kuwaitis and 3.18 million are expatriates. Kuwait's economy is heavily reliant on oil exports through its three refineries, namely Mina Al-Ahmadi (MAA), Mina Abdullah (MAB) and Mina Shuaiba (SHU). These three refineries with a total capacity of 936,000 bpd produce of a variety of refining products to fulfil the international client's needs. Fossil fuels combustion of and fugitive emissions release from oil and gas operations are most prevailing sources of GHG emissions in Kuwait. In this study, to gain overall picture about the trend of GHG in Kuwait, four representative urban areas spatially distributed along the residential band in Kuwait, were selected. These urban areas are Ali Sabah Al-Salem (far-south), Al-Riqqa (South-middle), Mansouriya (Middle), and Al-Jarha (far north), see *Figure 1*. Ali Sabah Al-Salem area is the last inhabited city in the south of Kuwait toward the borders with Saudi Arabia. It is next to highest capacity oil refineries (Mina Al-Ahamdi and Mina Abdullah) in the country. It is also adjacent to several small to large petrochemical industries. This city is surrounded from east by express highway (No.30) and by express highway (No.40) in west, which afterward merges together in one road (No.40) leading to Saudi Arabia borders. The residential area of Al-Riqqa is surrounded by numbers of residential areas in south, north, and west. In east, it is overlooking express highway (No.30) that extends from downtown of Kuwait to borders with Saudi Arabia. In south, it is also proximate to oil refineries (Mina Al-Ahamdi and Mina Abdullah). Al-Riqqa is adjacent to various small to middle scale commercial and industrial areas (e.g. car mechanics). Mansouriya residential area is located in the middle of Kuwait City with a total population of 8992. Mansouriya is typical residential area surrounded with a network of roads in north, south, and east. In west, it is facing express highways No. 40 which cross most of residential areas and connect the city center with south border of Kuwait. The city is few kilometers from numerous commercial buildings and famous traditional shopping centers. In North-West of Mansouriya, there are quite numbers of small-medium industrial business. Al-Jarha city is located in north-west of Kuwait City and it is one of the largest cities in Kuwait with total inhabitants of about 484,502 residents. It is surrounded by numerous emission sources such as Al-Jarha wastewater treatment, desalination and power plans, and different scales of industrial and commercial shops. Numbers of express highway pass through the city include 6^{th} ring

DOI: http://dx.doi.org/10.15666/aeer/1802_20872107

road, highway 80 that connects the city to Abdali on the Iraqi border and highway No.70 that links the city to Kuwait border with Saudi Arabia.

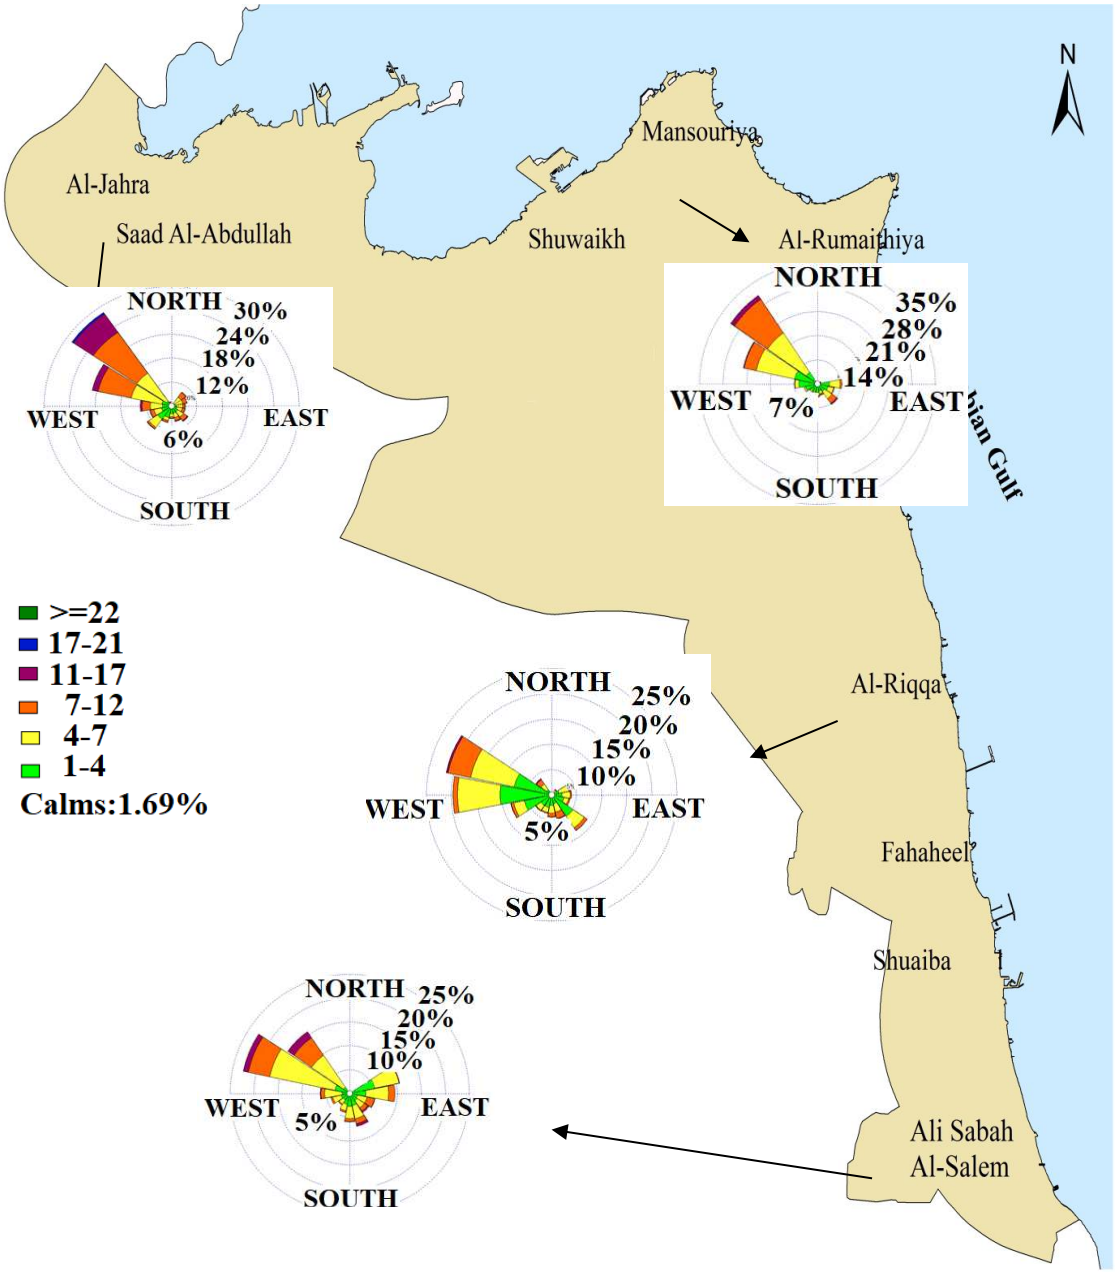

Figure 1. *Selected monitoring sites for quantifying and modeling of Greenhouse gases (GHGs) emissions*

Meteorological conditions

Kuwait is characterized by a desert-type environment and hot climate. Kuwait is experienced sharply by two distinct seasons; summer which last from May to October and winter which extends from November to April. Kuwait is typically arid with very hot summers, with average temperatures vary from 42 to 46°C. In winter, the weather is usually mild to relatively cold with temperatures from time to time even falling below

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20872107

4°C. Dust storms and high concentration of particulate matter (PM) are prevailing characteristic of summer in Kuwait. Humidity is a unique feature of Kuwait climate, starts mid-August and last over September. Over at least the past two decades, relative humidity (RH) ranged from 47.5 and 49.5%, with mean yearly maxima varying from 84 to 95%. From one year to other, RH level could exceed 95%, which is ascribed to high seawater temperatures coincident with tropospheric temperature inversions.

Figure 1 shows wind rose plots for residential areas of Ali Sabah Al-Salem, Al-Riqqa, Mansouriya, and Al-Jarha, for the year of 2016. It is apparent that the prevailing wind directions were strongly northwest winds (~25-33% of time) and mild south to southeasterly winds (~23-28% of time). The average wind speeds (*Table 1*) varied from 2.5± 0.4 m/s to 3.8± 0.5 m/s in summer and between 1.6 ± 0.23 m/s and 2.9 ± 0.22 m/s in winter. In terms of seasonal variation, there is no marked variation in the wind direction throughout the year (*Table 1*).

Data collection and analysis

The dataset for CO_2 and CH_4 were provided by Air Pollution Monitoring Division of the Kuwait Environment Public Authority (KUEPA). The monitoring stations were placed at Ali Sabah Al-Salem (28.957°N 48.154°E), Al-Riqqa (29.146°N 48.107°E), Mansouriya (29.358°N 47.993 °E), and Al-Jarha (29.3366°N 47.6755°E) and they are equipped with a state-of-art sampling devices and analyzers approved by US-EPA with accuracy of 98-99%. The CO_2 and CH_4 emission were measured using a CO_2/ CH_4/H_2O analyzer (Picarro G1301, US) whereas meteorological conditions such as relative humidity, wind speed, wind direction, and temperature were concurrently monitored using mobile monitoring station (Thermo Scientific, USA). Air probe was approximately between 10-15 m above sea level in all urban cities investigated. Measurements were taken at hourly intervals, which resulted in 8760 per year for each CO_2 and CH_4, with a total of 113,880 data points for each CO_2 and CH_4 for the entire period of 13 years (2004-2016). To study the diurnal cycle, the average concentration at each hour (0-23 hrs) was calculated in each urban area for the entire study period. As for seasonal variations, data were split into two prevailing seasons in Kuwait, summer and winter.

Statistical analysis

Descriptive statistical analyses were performed to demonstrate the overall picture of the CO_2 and CH_4 emissions and their corresponding meteorological conditions. Pearson's correlation (R) analysis and one-way analysis of variance (ANOVA) are used to determine whether there are any statistically significant differences between the means of data set with p value < 0.05. All statistical analyses, neural network modellings and model qualification were made using statistical software package (STATISTICA, StatSoft, USA) and R, version R 3.5.1.

Artificial neural network modeling (connectionist modelling)

Significant number of literature have shown different applications of neural networks for solving different types of problems, most of which can be broadly classified into classification, function approximation or prediction problems. The proficiency of neural networks is attributed to its ability to detect patterns and relationships in the data provided to them during the calibration or training phase. Generally, neural networks are classified according to (a) the network topology e.g. feed forward and recurrent architectures, (b) the network transfer function e.g. sigmoid, radial basis (c) the network learning algorithms e.g. supervised or unsupervised learnings (Karray and De Silva, 2004). The neural network architecture is depicted in *Fig. 2*. Parallel and distributed processing units called neurons or nodes are arranged within three layers, namely, input, hidden and output layers. Each neuron in the input layers is connected to the adjacent layer in the hidden layer through connection weights. Similarly, each neuron in the hidden layer is connected to the adjacent hidden layer or to the output layer through connection weights. In fact, these weights are the model parameters to be estimated using the input/output training sets. The output of each neuron is weighted, summed and passed to nonlinear transformation e.g. sigmoid function. For a chosen network's topology and transfer function, the neural network modelling is reduced to the problem of estimating the connection weights among the neurons such that a certain measure of the mismatch between the observed and predicted values is minimized. More specifically, the cumulative error E_c to be minimized may be given as:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20872107

$$E_c = \frac{1}{2}\sum_{k=1}^{n}\sum_{i=1}^{q}\left(t_i(k) - o_i(k)\right)^2 \quad \text{(Eq.1)}$$

where n is the total number of training points, q is the total number of neurons at the output layer, t_i is the target value and $o_i(k)$ is the network's output from the k^{th} neutron for the i^{th} training point. Accordingly, the optimization problem of the neural network can be formulated as:

$$\min_{\mathbf{w}} E_c = \min_{\mathbf{w}} \frac{1}{2}\sum_{k=1}^{n}\sum_{i=1}^{q}\left(t_i(k) - o_i(k)\right)^2 \quad \text{(Eq.2)}$$

where the vector w contains the network weights between all the neurons of the network. In the present study, two feed forward architectures, namely multilayer perceptron network (MLP) and the radial basis function network (RBFN) have been considered to predict CO_2 and CH_4 concentrations in 4 urban cities in the state of Kuwait (*Fig. 2*).

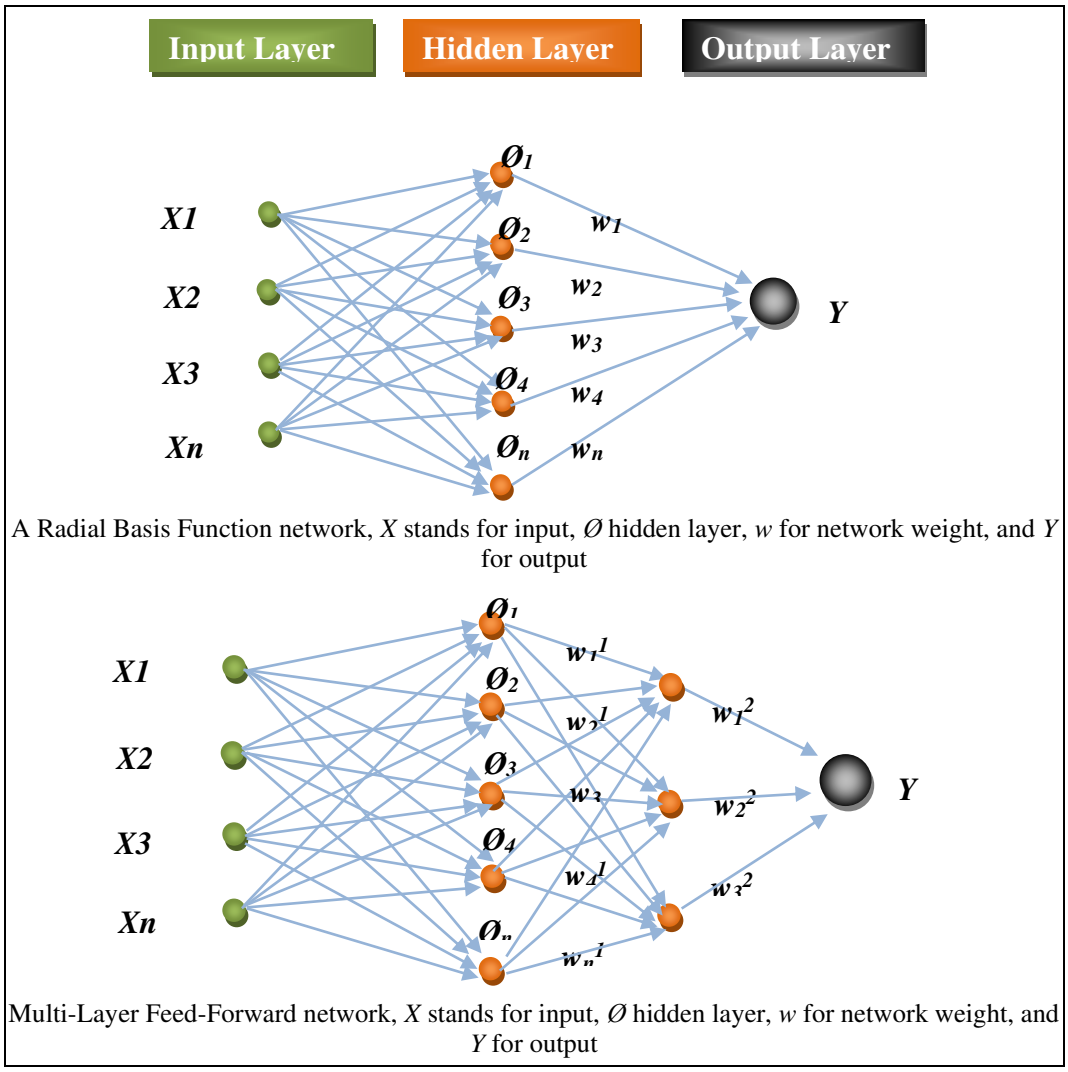

Figure 2. *Architecture of developed artificial neural network (ANN) models*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20872107

Both, MLP and RBFN are examples of feed forward network with different prediction capabilities (Karray and De Silva, 2004). MLP uses global transfer function such as sigmoid function

$$\text{sigmoid}(x) = \frac{1}{1+\exp(-x)} \quad \text{(Eq.3)}$$

whereas RBFN uses local basis functions such as Gaussian kernel

$$g_i(\mathbf{x}) = \exp\left(\frac{\|\mathbf{x}-\mathbf{v}_i\|^2}{2\sigma_i^2}\right) \quad \text{(Eq.4)}$$

where x is the input vector and v is the center of the radial basis function g_i and σ_i is the width/scaling parameter. While MLP uses back propagation algorithm (supervised learning) to estimate the network weights, RBFN use a two-stage training strategy. In the first stage, the parameters of the radial basis function (v and σ_i) are estimated using unsupervised learning e.g. *k*-means method, while in the second stage the network weights are estimated using gradient methods. A remarkable feature of the RBFN is that the weight between the input and the hidden layers are all equal to one and only the weights between the hidden and the output layer are to be estimated. In the current work, a total of 8,640 hourly concentration readings of CO_2 and CH_4 and their corresponding climatological variables, namely; ambient air temperature, relative humidity, wind speed, and wind direction, were used as input to build the ANN model. About 60% of the total data was used to train the network, 20% was used as a validation set, and the remaining 20% was used as test data. In testing step, the networks have one output, either CO_2 or CH_4 concentration. Training and testing data are normalized before presenting them to the networks. Normalization is an important pre-processing step, in particular, when the input and output variables of the network are of different order of magnitude as can be seen from *Table 1*. Although some rules of thumbs exist for selecting the number of hidden layers and the number of neurons, in practice, the appropriate number is determined through trial and error until certain error criterion is satisfied. There are several advantages of neural networks against other empirical modelling techniques. More importantly is the filtering capacity of neural networks. The reason of the latter is that no single node solely responsible of correlating a certain input to a specific output, but all the nodes contribute differently to the correlation structure extracted from in the input-output pattern presented to the network during the training phase (Baughman and Liu, 1995). On the contrary, for other regression techniques, if one of the variables is missing or very noisy, the model will likely give inaccurate result because each variable is associated with a unique parameter or weight. On the other hand, neural networks suffer from several limitations. The main disadvantage of neural networks is the necessity of large amount of training data. The latter is insignificant if large amount of historical data is available. Another disadvantage of neural networks is that the estimated weights are suboptimal solution, that is, no global solution can be guaranteed. One way to tackle the sub-optimality problem is to reinitiate the weights of the network several times during the training phase until stable weights are obtained.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20872107

Statistical performance indices

To evaluate the performance of all artificial neural network (ANN) models, commonly used statistical performance indices suggested by the US EPA, such as mean absolute error (MAE), root mean square error (RMSE), and fractional bias (FB) were used (Riswadkar and Kumar, 1994; Patel and Kumar, 1998; Kumar et al., 2006). The MAE is used to measure the closeness of predicted and observed values. In general, the smaller the MAE values, the smaller the difference between the predicted results and the actual data and the better the prediction performance of the network model.

$$\mathrm{MAE} = \frac{1}{\mathrm{n}} \sum_{\mathrm{i}=1}^{\mathrm{n}} \left| \mathrm{P_i} - \mathrm{O_i} \right| \qquad \text{(Eq.5)}$$

With respect to an acceptable model, RMSE values should be small and the RMSE should approach zero in an ideal model. RMSE is commonly used as a measure of the overall model performance:

$$RMSE = \sqrt{\frac{1}{n} \sum_{i=1}^{n} (P_i - O_i)^2} \qquad \text{(Eq.6)}$$

Fractional bias, a non-dimensional factor, is a measure of the difference between the average observed and the average predicted values and is written in symbolic form as:

$$FB = \frac{(\bar{O} - \bar{P})}{0.5(\bar{O} + \bar{P})} \qquad \text{(Eq.7)}$$

The FB parameter varies between -0.5 and +0.5 and a perfect model has an FB value of zero. FB>0 indicates an underestimate in predicted concentrations while FB<0 indicates an overestimate. In equation 5-7, n is the number of data points, P is the predicted data point, and O is the observed data point.

Results and discussion

Trend of GHG emissions in the ambient atmosphere

To gain better insight into the development of GHG emissions in the ambient atmosphere in Kuwait, the yearly mean concentrations for the period of 13 years (2004-2016) were statistically assessed in four representative urban cities (Ali Sabah Al-Salem, Al-Riqqa, Mansouriya, and Al-Jarha), as shown in *Figure 1*. CO_2 yearly mean concentrations in this study were plotted with those measured at the Mauna Loa Observatory in Hawaii for sake of comparison with the world CO_2 trend (*Figure 3a*). Over the period 2004 to 2016, there were considerable increases in the GHG emissions in the urban cities in Kuwait. CO_2 level varies between 342±18 ppm (Ali Sabah Al-Salem) and 350±13 ppm (Al-Jarha) in 2004. The CO_2 concentrations (*Figure 3a*) have shown an upward trend since 2004, with an 11% to 25% increase in 2016 in all urban cities. Prior to 2015, the CO_2 emissions quantified through monitoring networks in urban cities in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20872107

Kuwait were below those observed at Mauna Loa site (*Figure 3a*). In 2016, the CO_2 emission ranged from 394 ± 10 ppm to 425 ± 14, exceeded CO_2 emissions reported at the Mauna Loa site (404.21 ppm). In terms of CO_2 variation over the years, one-way analysis of variance (ANOVA) showed significant differences (p<0.05) among the urban cities.

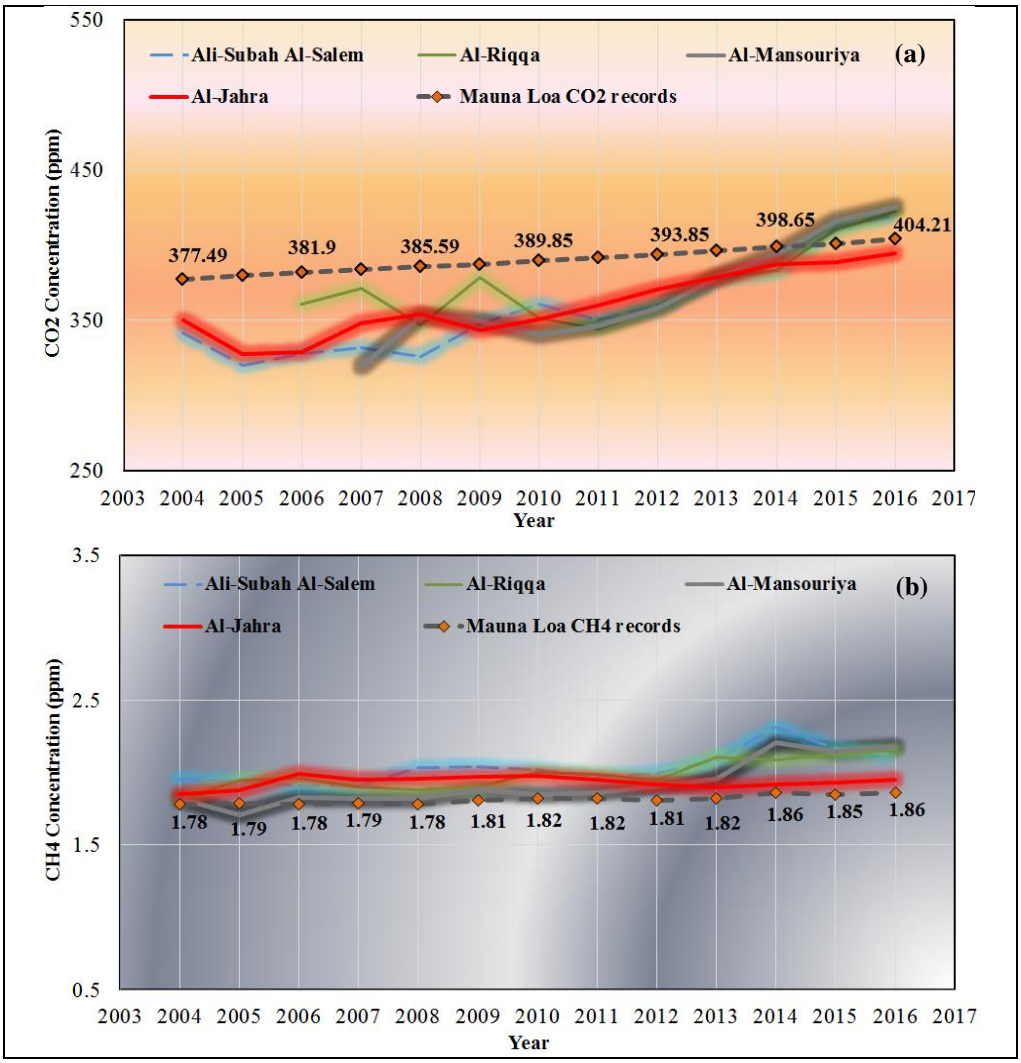

Figure 3. *Yearly trend of (a) CO_2 and (b) CH_4 concentrations in urban areas in Kuwait*

In comparison with other countries in the world, CO_2 levels in this study for the year of 2016 were compared with CO_2 reported in the same year by The World Data Centre for Greenhouse Gases (WDCGG, 2018). The average yearly CO_2 emission in Kuwait was 415.6 ppm, which is lower than those obtained in Poland (427.7 ppm), and Italy (427.6 ppm) and similar to those found in Korea (416.3 ppm), Hungary (410 ppm), Hong Kong (408 ppm), and USA (408 ppm), and higher than those reported in UK (404.6 ppm), Canada (404.5 ppm), Australia (400.8 ppm), and New Zealand (400.6 ppm).

The burning of fossil fuels (oil, gas and coal) for various activities such as transportation, electricity and heat supply, and water treatment is the main source of CO_2 emission in the atmosphere. The magnitude of CO_2 emissions is linked to the carbon content of the fuel as for instance oil and coal has approximately 25% and 40% more

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20872107

carbon content than natural gas, respectively. The extent of CO_2 in the atmosphere is the result of balance of the fluxes between the oceans, the biosphere and the atmosphere. CO_2 circulates from and to the atmosphere via direct absorption/release phenomenon, respiration of plants and the decomposition of organic-matter in soil, and absorption of CO_2 through photosynthesis. To limit the level of atmospheric CO_2 emission, burning of fossil fuels pattern and energy mix should be highly considered.

CH_4 is the second crucial GHG with global warming potential (GWP) of 28 times greater than CO_2 over a 100-year time horizon (IPCC, 2013). It was reported that CH_4 is responsible for about 17% of rise in the total radiative forcing as results of long-lived GHG in the atmosphere during the period of 1750-2016 (WMO, 2017). CH_4 trend, in same urban areas and years span to those of CO_2, was also investigated in Kuwait and results are presented in *Figure 3b*. CH_4 concentrations varied between 1.82±0.09 to 1.94±0.1 ppm in all tested urban areas in Kuwait in 2004. Since 2004, CH_4 concentrations have increased by 100-360 ppb by the end of 2016, with varying rates in the tested urban areas, corresponding to an average range of increase of 8-27 ppb yr^{-1}. It is imperative to note that most CH_4 concentrations observed in all four urban areas exceeded Mauna Loa levels during 2004-2016 (*Figure 3b*). However, the average yearly CH_4 concentration in this study (2.10±0.10 ppm) in the year of 2016 was consistent with CH_4 records reported in other countries in 2016 (WDCGG, 2018) such as Italy (2.00 ppm), Hungary (1.97 ppm), Viet Nam (1.95 ppm), USA (1.97 ppm), and Canada (1.97 ppm). Methane is released to the atmosphere by anthropogenic sources including production and consumption of fossil fuel, biomass burning, and landfills and by natural processes such as wetlands and termites. Conversely, CH_4 level decreases in the atmosphere due to its reaction with hydroxyl radical (OH), persist for about 10 years. Despite the fact that CH_4 is a potent GHG, its influence is comparatively short-lived.

Seasonal and diurnal variation

GHG concentrations were compared in summer and winter, as these are the prevailing season in Kuwait, to learn more about seasonal variability. For the sake of brevity, the comparison in GHG concentrations was limited to 2016. Descriptive statistics of CO_2 and CH_4 concentrations, as well as climate conditions such as temperature, RH, wind speed, and wind direction, during summer and winter for four urban cities are listed in *Table 1*. In summer, the highest mean value of CO_2 emission was 430 ± 12 ppm and found in Al-Riqqa and the lowest value (398 ± 3.5 ppm(was observed in Al-Jahra. In winter, the highest mean value of CO_2 emission was 418 ± 24.6 ppm and observed in Al-Riqqa while the lowest mean value (390 ± 7.2ppm) was found in Al-Jahra. Maximum concentrations of CO_2 (summer = 440 ppm; winter = 467 ppm) were measured in Al-Riqqa while minimum concentrations (summer = 387 ppm; winter = 380 ppm) were found in Al-Jahra. One-way analysis of variance (ANOVA) demonstrated a significant difference ($p<0.05$) between summer and winter in all urban areas in this study. A seasonal variation of CO_2 is obvious in all the urban cities in this study with an overall higher level of CO_2 in summer than winter. This finding is consistent with reported CO_2 in major urban areas (Ghauri et al., 2007; Bergeron and Strachan, 2011). The high CO_2 level in summer is presumably due to the consumption rate of fossil fuel for cooling purposes (e.g., air conditioning) and traffic activities. The temperature in summer reaches 50°C in Kuwait and the air conditioning is in use all day in houses, government buildings, and businesses in the private sector. Increased CO_2 concentration is not restricted to local sources; it can also come from long-range transport from distant source areas.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20872107

The level of CH_4 in summer and winter was also investigated (*Table 1*). Similar observations to those of CO_2 were reported. The mean concentrations of CH_4 were between 1.92 ± 0.08 ppm and 2.25 ± 0.20 ppm in summer and from 1.87 ± 0.2 ppm and 2.11 ± 0.2 ppm in winter. The highest mean concentration of CH_4 was observed in Al-Riqqa during the summer and winter while the lowest values were found in Al-Jahra. Maximum CH_4 records in summer (2.70 ppm) and in winter (2.50 ppm) were also found in Al-Riqqa. Seasonal differences in all urban cities were statistically significant (ANOVA, $P<0.05$). CH_4 levels in this study exhibited higher levels in summer than in winter in all monitored urban areas (*Table 1*). Such observations were consistent with those reported in different parts of the worlds (Sikar and Scala, 2004; Ito et al., 2005; Ghauri et al., 2007; Satar et al., 2016).

Diurnal variation

Diurnal cycles of GHG emission in the four urban areas for the entire year of 2016 are plotted in *Figure 4a,b* to understand their short-term variability. CO_2 diurnal pattern (*Figure 4a*) in all tested urban localities were almost similar, but vary with magnitudes according to ANOVA analysis ($p<0.05$).

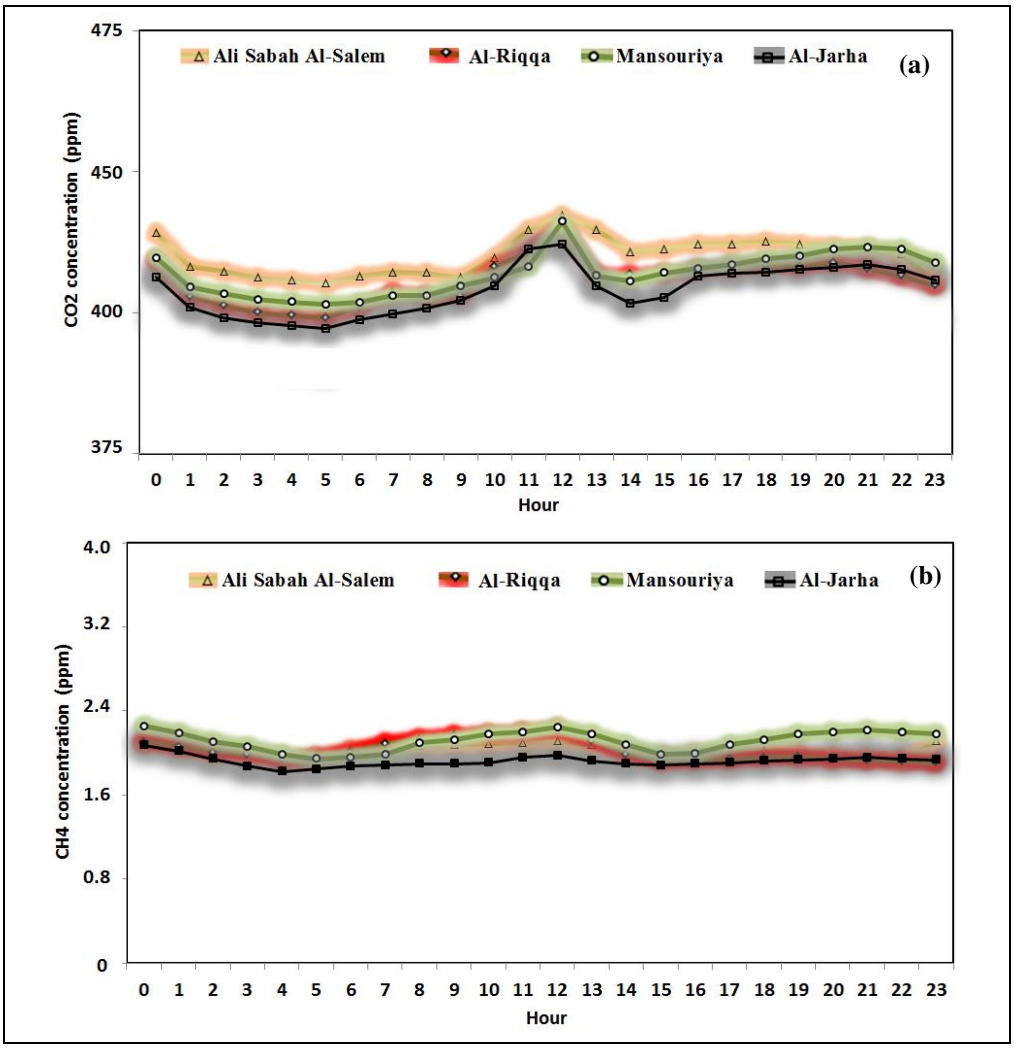

Figure 4. *Diurnal variations of (a) CO_2 and (b) CH_4 concentrations in urban areas in Kuwait*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20872107

As shown in *Figure 4a*, the increased CO_2 records were observed during three intermittent intervals of day along the entire year; one at near midnight (around 12 am); another at noon time (around 12 pm), and the last between 4 pm and 9 pm. In the latter two periods, high CO_2 levels could be ascribed to busy traffic hours in this study, which is consistent with other urban areas with strong anthropogenic activities, such as vehicular emissions as a result of burning fossil fuels (Aikawa et al., 1995; Takahashi et al., 2002; Gratani and Varone, 2005). While increased level of CO_2 at near midnight (around 12 am) could be possibly attributed to the combined effects of respiration by the living organism and/or from soils, the minimum levels occurred at the night/morning transition between 3 am and 5 am is likely due to decreases anthropogenic CO_2 emissions. Another decrease in CO_2 was observed in the afternoon, which can be attributed to photosynthetic activities (Spittlehouse and Ripley, 1977; Baez et al., 1988; Nasrallah et al., 2003) and the expansion of the mixing height (Aikawa et al., 1995). The CH_4 diurnal cycle was also investigated and the results are shown in *Figure 4b*. The CH_4 diurnal pattern was similar to those observed with CO_2, which implies that both CO_2 and CH_4 have common emission sources. Diurnal results in this study are consistent with other similar studies (Smith et al., 2002; Aikawa et al., 2006; Satar et al., 2016).

Modeling of GHG using artificial neural network (ANN) models

The forecasting of GHG (mainly CO_2 and CH_4) trends has received significant attention in recent years. The International Energy Agency (IEA) reported that 71% of energy-related GHG emissions were attributable to urban areas and it is assumed to grow by 5% by 2030 (IEA, 2008). As mention in methodology section, the number of hidden layers as well as the number of neurons within the hidden layers is usually determined by trial and error. A number of trials were carried out to determine the optimal number of hidden layers, number of neurons in the hidden layers, learning rate, and the learning algorithm. Among several ANN architectures evaluated, five cases are selected and listed in *Table 2*. For the MLP, sigmoidal functions were used whereas Gaussian functions were used for RBF based networks. In searching for the best network weights, conjugate gradient descent was used for MLP. On the other hand, and since two-stage training phase is used for RBF networks, *k*-mean centering and the pseudo-inverse (singular value decomposition) algorithm were used to determine the radial basis functions' parameters and the output layers' weights, respectively. In addition, two positive constants have to be set during the networks learning phase, namely the learning rate and the momentum coefficient. The latter become important especially for networks with large number of inputs-outputs and complex architecture. The rule of the learning rate is to regulate the rate at which the weights are adjusted while the momentum coefficient is a surplus that is added to the adjusted weights to speed up the training. The latter are important to avoid trapping in local minima and an unstable learning (Baughman and Liu, 1995). After several trials, the learning rate and the momentum was set to 0.5 and 0.7, respectively. The observed and predicted values of CO_2 and CH_4 concentrations for the best five models are presented in *Figures 5 and 6*, respectively. Among these five optimal models for each urban area, the best model was selected based on a low value of error mean, absolute error mean, and standard deviation ratio and high correlation coefficients (r). These performance indices differently demonstrate the association between observed and predicted concentration values of CO_2 and CH_4 as predicted by the ANN model as shown in *Table 2*. The higher correlation coefficient showed that the predicted CO_2 and CH_4 concentration values using the ANN model are in good agreement with the observed CO_2

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20872107

and CH_4 concentrations as shown in *Table 2*. The correlation coefficients (r) of the parity plots of the selected optimal models for CO_2 were 0.76, 0.81, 0.72, and 0.73 for areas Ali Sabah Al-Salem, Al-Riqqa, Mansouriya, and Al-Jarha, respectively. For CH_4, the correlation coefficients were 0.77, 0.66, 0.72, and 0.96 for areas Ali Sabah Al-Salem, Al-Riqqa, Mansouriya, and Al-Jarha, respectively. It is worth highlighting that all the optimal models for CO_2 and CH_4 were radial basis function (RBF) network models for all urban cities investigated. The RBF network has shown great promise in this sort of problem due to several of its features, including its very good functional approximation capabilities (Park and Sandberg, 1991), which arise naturally as regularized solutions of ill-posed problems (Poggio and Girosi, 1990) and are utilized well in the theory of interpolation (Powell, 1987). In addition to these features, the intrinsic structure of the RBF network allows learning in stages, which leads to a reduction in training time. This has indeed resulted in the widespread use of RBF networks in numerous practical problems.

To further check the accuracy of the developed model, a time series plot of the predicted versus the observed for CO_2 and CH_4 is shown in *Figures 7 and 8*. The performance statistics, MAE, RMSE, and FB, of the selected optimal ANN for the four urban areas for CO_2 and CH_4 are given in *Table 3*. The MAE ranged between 5.4 and 15.8 ppm and RMSE varied from 6.9 to 15.5 ppm for CO_2 in all tested urban areas. It is imperative to note that the slightly higher numbers of RMSE in the modeling of CO_2 are due to squaring the errors that tends to heavily weight statistical outliers and therefore a large RMSE may result even though errors may be small and fairly satisfactory elsewhere. Another important point to note is that the annual mean concentration of CO_2 varied between 394 and 425 ppm in the four tested urban areas and, therefore, performance statistics values, differences between the observed and the predicted, listed above represent 1.5% to 4.4% of the total concentrations, which can be deemed acceptable. Concerning CH_4, the MAE values were between 0.11 and 0.21 ppm and RMSE ranged from 0.1 to 0.31 ppm for all tested urban areas. FB was also calculated to test whether predicted values were underestimated (FB>0) or overestimated (FB<0). The FB values for CO_2 and CH_4 approach zero (-0.001 to -0.008 for CO_2 versus -0.001 to -0.04 for CH_4). Overall, the statistical performance indicators reveal that ANN models can estimate CO_2 and CH_4 concentrations in urban areas for the given data set with decent accuracy. To the best knowledge of the authors, there is no nonlinear predictive models that were used in Kuwait to monitor the concentrations levels of CH_4 and CO_2 in the atmosphere. These forecasting models would be beneficial for concerned authorities for planning and proposing environmental legislations to monitor and limit the levels of GHG in Kuwait.

Conclusions

In the present work, GHG emission for 13-year period was investigated in hourly, daily, seasonal, and yearly basis to gain overall picture about the trend of GHG emissions in Kuwait. Records confirmed year-year rising pattern in GHG emissions, higher levels in summer than in winter, due to enormous burning of fossil fuel for cooling purposes and traffic activities. Elevated levels of GHG emissions were observed both at noon and between 4 pm and 9 pm probably ascribed to busy traffic hours while during midnight are likely due to the combined effects of respiration by the living organism and/or from soils. Subsequently and most importantly, the capabilities of multiple linear regression and two types of neural networks, MLP and RBFN for forecasting GHG emissions have been investigated. Among the developed models and based on different statistical

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_20872107

performance indices, RBF models outperformed the multiple linear regression and MLP in all urban cities investigated. The RBF exhibited high performance in predicting GHG due to several reasons including its precise functional approximation capabilities and its intrinsic structure that permits learning in stages, which leads to a decrease in training time. This indeed explains the popularity use of RBF networks in numerous practical problems. This study and similar studies would be used as a control tool by government and decision makers for formulation of climate change policies in urban cities compatible with international standpoints.

(Received 24th Jul 2019; accepted 8th Jan 2020)

Abstract. The aim of this research was to identify the species composition and quantitative and qualitative structure of ground beetles inhabiting conventional potato cultivations. The study was conducted over the 2008 and 2011-2013 period in eleven localities in the Subcarpathian region (*Podkarpacie*). Beetles were captured using Barber pitfall traps. A total of 7406 beetles were caught, which were classified in 29 genera and 54 species. Small zoophages proved to be the most numerously represented trophic group, whereas the species that were caught as greatest numbers at the study sites were as follows: *Harpalus rufipes*, *Pterostichus melanarius*, and *Poecilus cupreus*. The obtained results demonstrate that anthropogenic factors affect both the trophic structure of ground beetle populations and their habitat preferences. At the same time, species with wide ecological tolerance and lower susceptibility to anthropogenic pressure were promoted. It was also shown that the maintenance and appropriate management of diverse biocoenoses in agricultural space contribute to increased diversity of Carabidae found in agrarian areas.
Keywords: *carabids, cropping, species diversity, SE Poland*

Introduction

Beetles of the ground beetle family (Carabidae) are an important group of animals found in agrocenoses. Among them, omnivorous or partially herbivorous species can be distinguished (Clark et al., 1993; Kromp, 1999), but in the majority of cases representatives of Carabidae belong to non-specialized zoophages, thus being a factor regulating the numbers of some herbivorous species (Thiele, 1977). These active predators feed on both invertebrates (Mollusca) and phytophagous representatives of different taxa of the class Insecta (Coleoptera: in particular, Chrysomelidae, Lepidoptera, and Hemiptera, including Aphididae and Thysanoptera) (Wiltshire and Hughes, 2000; Sunderland, 2002; Schmidt et al., 2003).

The lack of food specialization of zoophagous carabids is manifested both in the wide species spectrum for potential victims and in the possibility of hunting different pests at different developmental stages (pre-imagoes and imagoes). At the same time, it should be noted that herbivorous carabids (obviously excluding phytophagous species that cause economic damage) can reduce weed density from 60 to 80% during one growing season (Ward et al., 2011). Therefore, we can consider Carabidae to be particularly valuable organisms in the aspect of controlling pests of cultivated plants.

For growing potato (*Solanum tuberosum* L.), the most dangerous pest is the Colorado potato beetle (*Leptinotarsa decemlineata* Say). Under field conditions, natural enemies can contribute to weakening a Colorado potato beetle population by 23–78% by destroying eggs, young larvae, and adult beetles (Karg, 1976; Sosnowska et al., 2009). The most important Carabidae species that are mentioned as predators significantly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21092128

reducing Colorado potato beetle numbers include *Pterostichus melanarius* (Ill.), *Poecilus cupreus* (L.), and *Harpalus rufipes* (De Geer) (Koval, 1999; Oberholzer and Frank, 2003). Observations on the carabid fauna of potato cultivations have been conducted, among others, in Latvia (Bukejs, 2009), Russia (Cinītis, 1962; Koval and Guseva, 2008), Russia, Moldova, and Ukraine (Koval, 2012), Finland (Kinnunen and Tiainen, 1999), Austria (Kromp, 1990; Traugott, 1998; Juen et al., 2003), and Romania (Varvara, 2010). In the United States, such observations have been conducted, among others, by Zhang et al. (1998), Werling and Gratton (2008), and Rondon et al. (2013).

In Poland such research has been carried out predominantly in the northern and western parts of the country, in the following Voivodeships: Zachodniopomorskie (Fedorko, 1983), Warmińsko-Mazurskie (Kosewska et al., 2008), Wielkopolskie (Nijak, 2005; Kosewska and Nijak, 2012; Nijak et al., 2014), Dolnośląskie (Jasiński et al., 2015), and Świętokrzyskie (Huruk, 2006). The studies regarding the ground beetle fauna inhabiting potato cultivation s in south-eastern Poland that have been published thus far are only fragmentary (Szewkienicz and Olbrycht, 2012; Konieczna et al., 2015). Therefore, this publication presents more detailed results of a study on the species composition, quantitative structure, and ecological characteristics of ground beetles inhabiting conventional potato cultivation s in this region for the first time.

Material and Methods

Study sites

Observations on the species composition and numbers of ground beetles (Col., Carabidae) were conducted in eleven localities of south-eastern Poland during the 2008 and 2011-2013 growing seasons (*Fig. 1*). The study area comprised conventional potato (*Solanum tuberosum* L.) cultivations and the research covered thirteen sites. Samples collected in 2008 related to the sites in: Cierpisz, Olimpów, and Przeworsk. In Słonne, the selected site was investigated in 2011. Samples collected from potato cultivations in two growing seasons (2012-2013) related to the sites in Pakoszówka and Wiśniowa. In 2013 the sites in the following localities were studied: Drohojów, Kosina, Olszynka, Równia, and Wacławice.

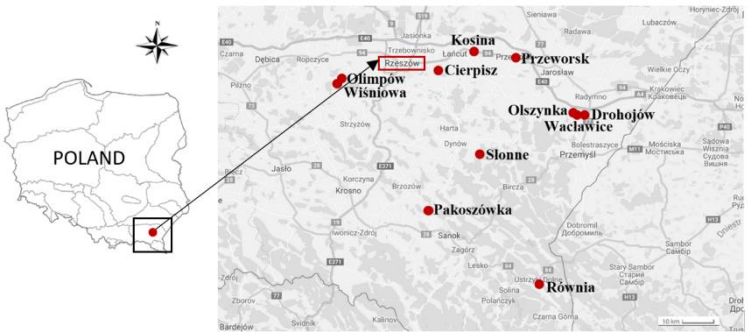

Figure 1. *Location of study sites (the authors' own figure based on www.lepidoptera.eu/utm)*

In a large majority of cases, potato cultivations where observations were conducted were surrounded by diverse habitats. Apart from intensively agriculturally used areas, such as cultivation fields, areas with lower agronomic pressure (meadows and pastures)

DOI: http://dx.doi.org/10.15666/aeer/1802_21092128

and wooded areas (field trees and shrubs, forests) can be distinguished among them. The description of biocenoses adjacent to the potato cultivation s and areas of the study sites (in ares) are shown in *Table 1*, whereas the geographical characteristics, soil quality classes as well as a list of potato cultivars and cultivation protection products used in their cultivation are presented in *Table 2*.

Catching of ground beetles

At each site, two Barber pitfall traps were set up at a distance of 2 m from each other. The pitfall traps were made of plastic containers placed flush with the ground level and filled with preserving fluid (25% ethylene glycol solution) to 1/3 of their volume. At individual sites, the traps were emptied every 2 weeks throughout the entire growing season of potato (starting from the last 10 days of April and ending in the first 10 days of September).

Nomenclature and Statistical Analyses

Identification of ground beetles was made using a study by Hurka (1996). The systematics of Carabidae followed a publication by Stachowiak (2008). The dominance structure (D) was described adopting the following classes: eudominants D5 (> 10% of individuals of an assemblage), dominants D4 (5.1–10%), subdominants D3 (2.1–5%), recedents D2 (1.1–2%), and subrecedents D1 (< 1%) (Trojan, 1980). The diversity indices used to analyze beetle assemblages were as follows: Margalef's species richness diversity index (d) (Trojan, 1998), Simpson's dominance index (λ), Shannon's species diversity index (H'_{ln}), and also Pielou's evenness index (J') (Magurran, 2004). The ecological and zoogeographical characteristics of carabids were described based on a study by Huruk and Barševskis (2014).

To determine similarities between the assemblages of beetles captured at individual sites, cluster analysis applying the Ward agglomeration method was used, in which the Euclidean distance was accepted as a measure of similarity. The obtained results were statistically analyzed using Statistica v.12 and Excel 2016 software.

Results

During the study conducted, a total of 7406 beetles were caught, representing 29 genera and classified in 54 species. The number of individuals and species caught as well as the indicators describing biodiversity at individual sites are collected in *Table 3*, whereas the dominance structure (D) of ground beetles at individual sites is shown in *Table 4*. The total numbers (N) and overall dominance (D) as well as the ecological and zoogeographical characteristics of species caught are presented in *Table 5*.

In terms of total numbers, *H. rufipes*, *P. cupreus*, and *P. melanarius* were species found in greatest numbers. At individual sites, these species also occurred in large numbers, but only *H. rufipes* was recorded at all study sites. The highest number of species was found at site 12 (21 taxa). At the same time, it was the site where the highest number of individuals was recorded (1272 exx.). The lowest number of species (11) was found at site 9, while as regards the number of individuals – at site 3 (59 exx.).

Overall, four dominance classes were distinguished, with the highest percentage of the least numerous class, i.e. subrecedents (D1) (46 species, more than 85% of the entire assemblage).

The recedent class (D2) was represented by 2 species that accounted for 3.7% of the total number. Three species (5.6%) were classified both in the eudominant (D5) and subdominant (D3) classes. The dominant class (D4), however, was not recorded. A slightly different dominance structure was observed at individual sites. Among all study areas, all dominance classes were only found at five of them (sites 1, 4, 9, 10, and 13), but still with a distinct proportion of subrecedents. The degree of dominance reached the highest value at site 1 (λ=0.58) (*Fig. 2a-b*, *Tables 4* and *5*).

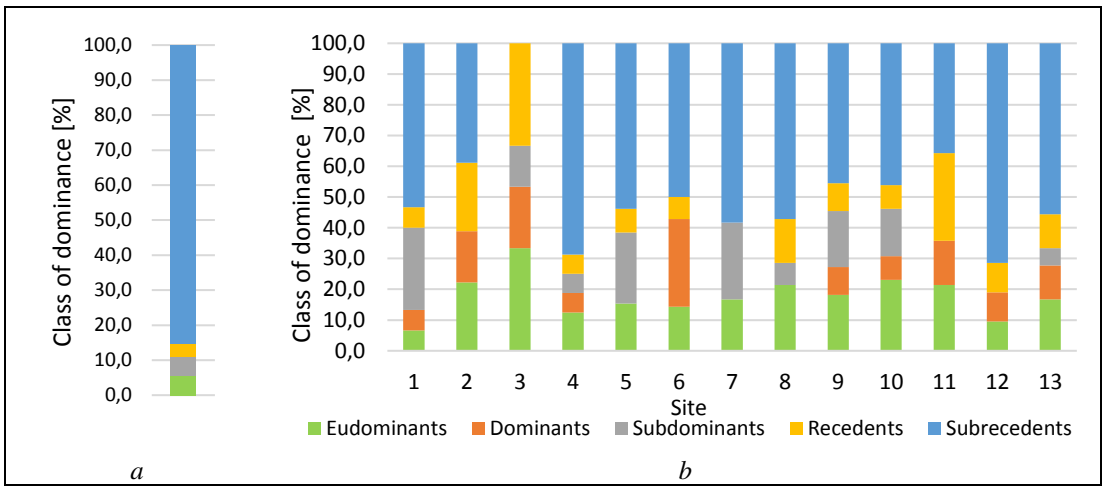

Figure 2a-b. *Overall percentage of particular dominance classes of Carabidae (a) and at individual sites (b)*

Forest, open area, open area and forest, riparian and synanthropic species were found to be present in the Carabidae assemblage. Open area species constituted the dominant group and they accounted for 46.3% of the entire assemblage, whereas their percentage at individual sites ranged 31.3-73.3%. The group of forest species was second ranking and their percentage was 22.2% of the total number. At individual sites, however, it was the third ranking category with an average percentage of 19%. A comparable proportion was determined for open area and forest species. Overall, they made up 20.4%, whereas the average for the study areas was 23.5%. Riparian species constituted 9.3% of the entire assemblage, while synanthropic species were least numerous. In this category, only *Broscus cephalotes* (L.) with a percentage of 1.9%. The above-mentioned five habitat categories were only found at one site (no. 12). At the other sites, the number of distinguished categories was 3 (sites 1, 2, and 13) or 4 (sites 3, 4, 5, 6, 7, 8, 9, 10, and 11) (*Fig. 3a-b*, *Table 5*).

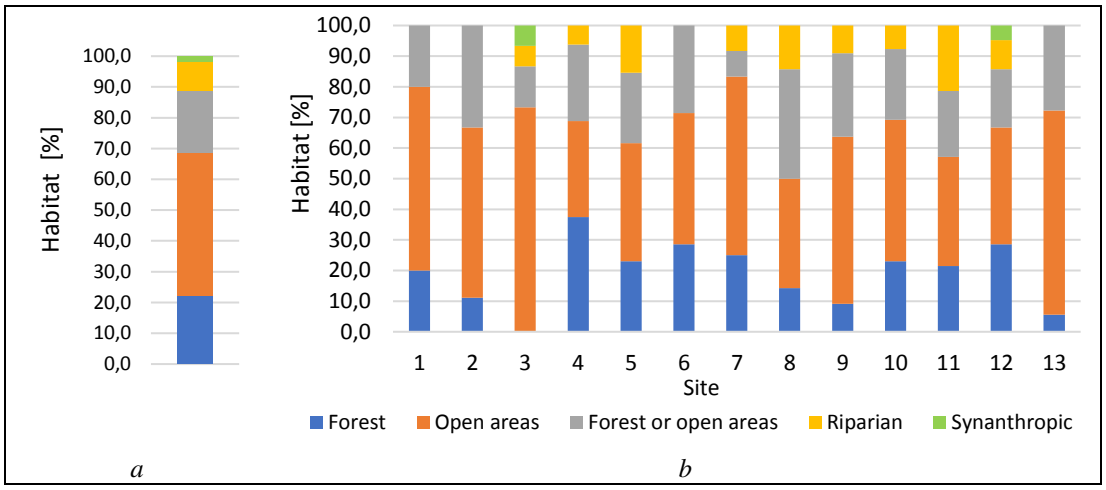

Figure 3a-b. *Overall percentage of habitat categories of Carabidae (a) and at individual sites (b)*

The analysis of the trophic structure showed three components to be present. Small zoophages were represented in largest numbers both in total terms and at individual sites. Overall, their percentage was 63%, whereas for the study sites the average percentage of this trophic group was 55.9%. Small zoophages were the second ranking class in terms of numbers only at two sites (4 and 9). Large zoophages, in turn, were found at 12 sites, with visible fluctuations in their numbers, similarly to the previous group. Their total percentage was 24.1%. At site 1, no species belonging to this trophic group were found. Hemizoophages were least numerous, accounting for 13% of all species. In quantitative terms, they occurred in greatest numbers at site 9 (*Fig. 4a-b*, *Table 5*).

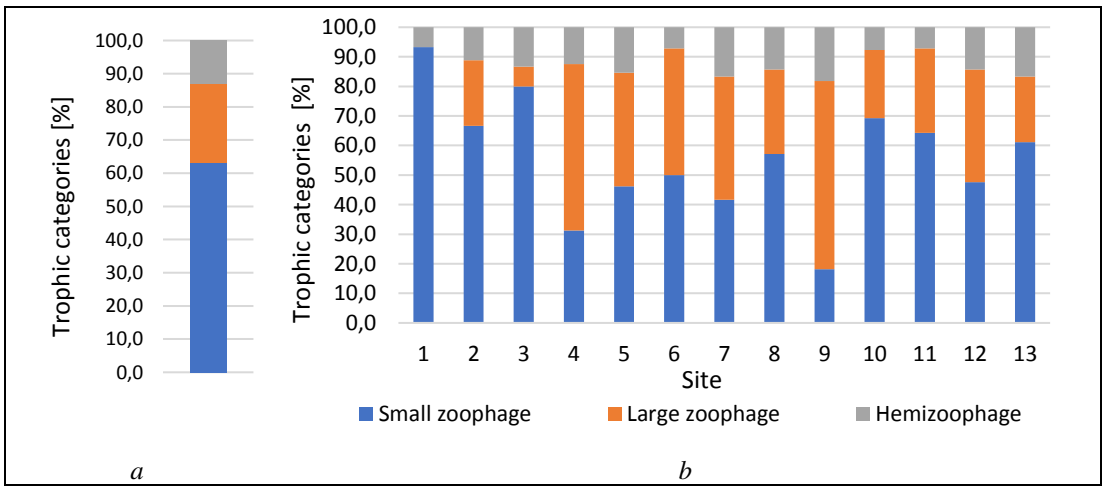

Figure 4a-b. *Overall percentage of particular trophic categories of Carabidae (a) and at individual sites (b)*

As far as moisture preferences are concerned, three types were distinguished. Species found in large numbers in habitats of diverse nature in terms of moisture, i.e. mesohygrophiles, constituted the largest group. Their percentage in the entire assemblage was 57.4%. At individual sites, this percentage ranged between 57.1% (site 11) and 90.9%

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21092128

(site 9) (on average 72.2%). Fewer hygrophilous species, that is, associated with strongly moist and wet environments, were found. They accounted for 37% of all carabids identified. At individual sites, in turn, the average percentage of this group was 24.6%. They occurred in greatest numbers at site 11 where their percentage was 42.9%. The only site where hygrophilous species were not observed to be present was site 9. Xerophiles, i.e. dry-loving species preferring environments with low humidity and strong insolation, were the last and at the same time least numerous group. Overall, they accounted for 5.6% of all species found, but at individual sites their percentage contribution was lower, averaging 3.1%. Xerophilous species were recorded at six sites (3, 5, 8, 9, 12, and 13); among them, site 9 was found to have the highest percentage (9.1%) (*Fig. 5a-b*, *Table 5*).

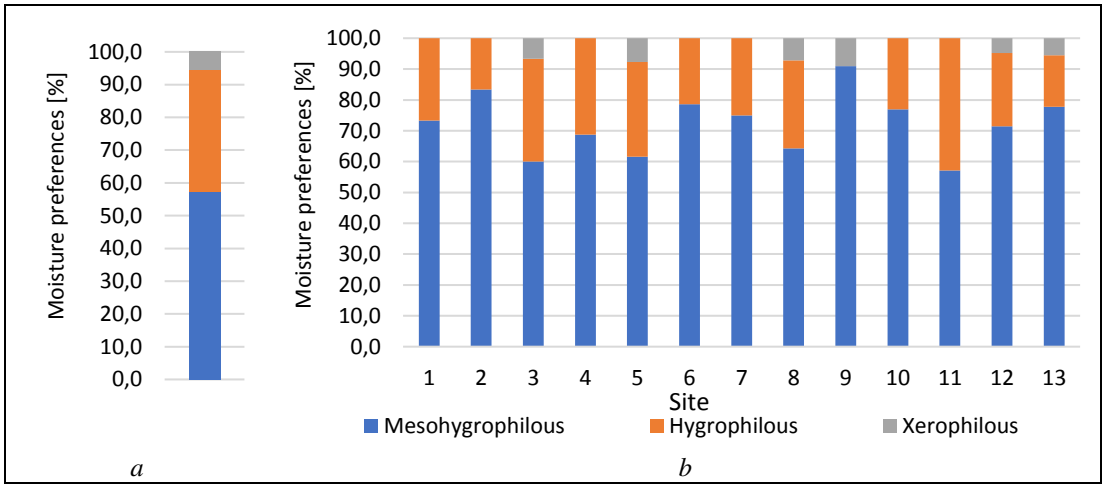

Figure 5a-b. *Overall percentage of particular moisture preferences of Carabidae (a) and at individual sites (b)*

In the assemblage of Carabidae caught, two breeding types were distinguished: species overwintering in the form of imago, i.e. spring breeders, and species being autumn breeders, that is, overwintering at the pre-imaginal stage. Spring breeding was found in 63% of ground beetles identified, while for individual sites the percentage of this category ranged from 46.2% to 72.2%, with an average value of 60.8%. The proportion of autumn breeders was lower, with their overall percentage standing at 37%. The lowest percentage of autumn breeding species was recorded at two sites: 2 and 13 (27.8% at either of them). Site 10, on the other hand, was observed to have the highest percentage of this ecological category, which was 53.8% of individuals collected at this site (*Fig. 6a-b*, *Table 5*).

The carabid fauna comprised seven zoogeographical elements. Overall, Palearctic species were most numerous, accounting for 55.6% of species found. Euro-Siberian species had a lower percentage: 20.4%. The other elements were represented by a much lower number of species: European (7.4%), Holarctic and Mediterranean (5.6%), montane European Forest Province (3.7%), and Euro-Arctic (1.9%). Palearctic and Euro-Siberian species were found at all sites. *Cychrus caraboides* L., as the only representative of the Euro-Arctic element, was only found at site 4 (1.9% of all species) (*Fig. 7c*). At the same time, this site and site 12 were shown to exhibit the greatest variation in ground beetles in terms of range (6 elements). Sites 3 and 7 were least chorologically varied as only 3 elements of this ecological category were recorded there (*Fig. 8a-b*, *Table 5*).

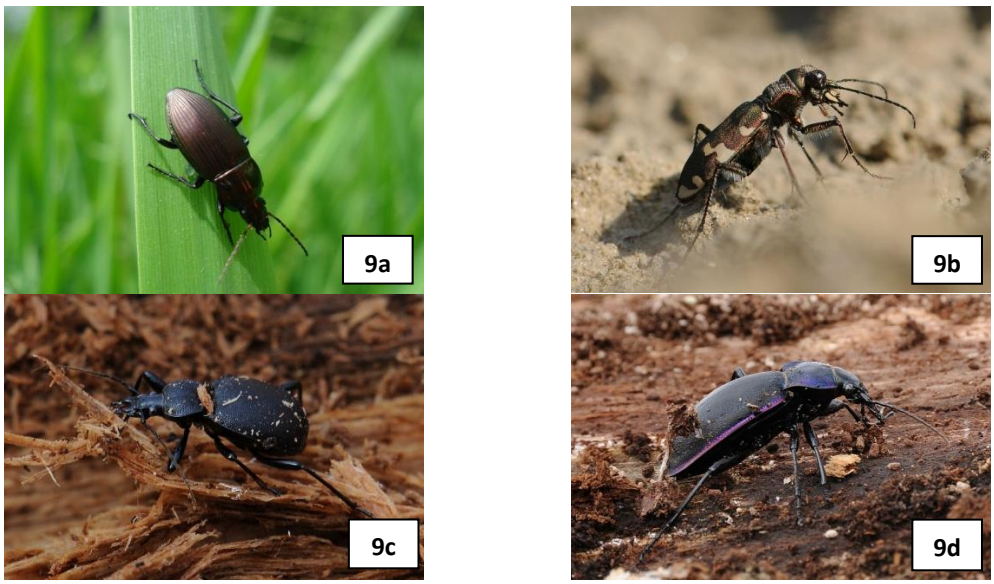

Figure 7a-d. *Representatives of different ecological groups of zoophagous Carabidae caught in potato cultivations at selected sites in Subcarpathian Voivodeship: (a) Poecilus cupreus (L.) – representative of the eudominant class (D5), open and wooded area species; (b) Cicindela hybrida L. – xerophile, open area species; (c) Cychrus caraboides L.– representative of the Euro-Arctic element, forest species; (d) Carabus violaceus (L.)– representative of the subrecedent class, forest species (photo by T. Olbrycht)*

In overall terms, the assemblage's diversity indices were as follows, respectively: Shannon's species diversity H'_{ln} = 1.94, while Pielou's evenness J' = 0.49. The values of the above-mentioned indices at individual sites differed from the total value. The species diversity index (d) reached the highest value at site 3 (d = 7.91), whereas the lowest one at site 7 (d = 4.02). The other biodiversity indices also had the minimum and maximum values, respectively, at the same sites: H'_{ln}= 2.37 (the highest value at site 3), H'_{ln} = 0.94

DOI: http://dx.doi.org/10.15666/aeer/1802_21092128

(the lowest value at site 7), J' = 0.88 (the highest value at site 3), J' = 0.38 (the lowest value at sites 1 and 7). The Simpson dominance index (λ) was 0.24.

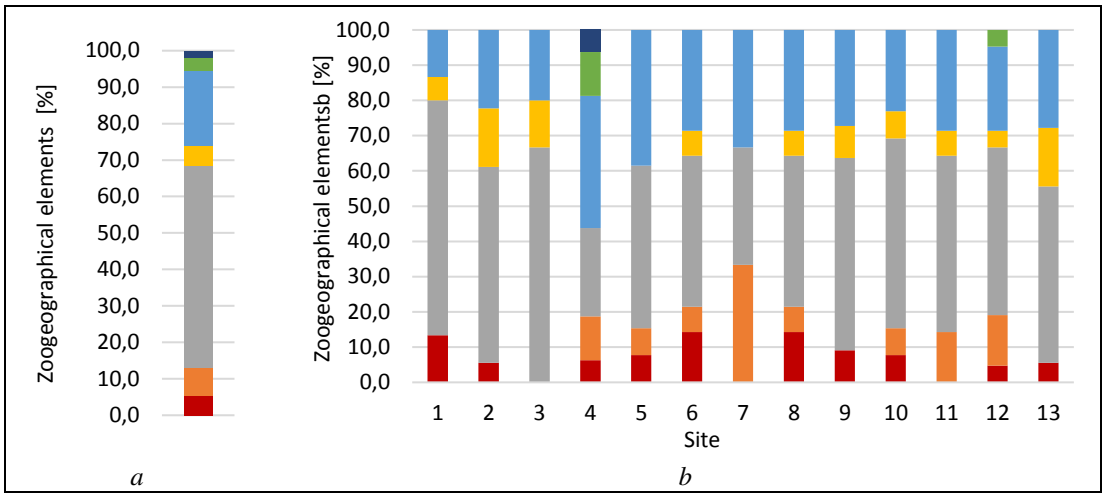

Figure 8a-b. *Overall percentage of zoogeographical elements of Carabidae (a) and at individual sites (b)*

The analysis of similarities between the Carabidae assemblages caught at individual sites revealed that sites 6 and 13 as well as sites 4 and 7 were most similar to each other in terms of beetles inhabiting them. Site 12 occupied a separate position in the dendrogram (*Fig. 9*).

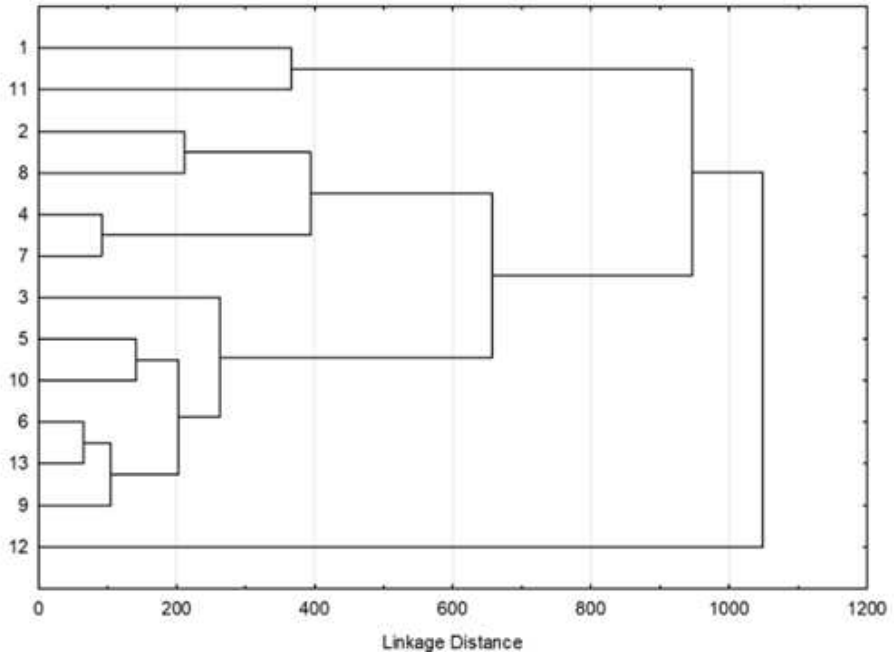

Figure 9. *Dendrogram of faunistic similarity of Carabidae inhabiting potato cultivations at selected sites in Subcarpathian Voivodeship. Cluster analysis by the Ward method, the Euclidean distance as a measure of similarity*

Discussion

According to the research by Basedow et al. (1976) and Thiele (1977), in one-year studies 20-35 species are found in the qualitative structure of ground beetles of cultivation fields in Central Europe. 54 Carabidae species were recorded in the cross-sectional study of potato cultivations in the Subcarpathian region, while the average number of species per site was 15. The highest number of species was shown at site 12 (21 species identified). The number of beetles caught is dependent not only on environmental factors (temperature, humidity, climate) and the adopted research methodology (number of traps, study period), but in the case of agricultural ecosystems also on the type of cultivations, application of cultivation protection products, soil type, and adjacent biocenoses (Thiele, 1977; Aleksandrowicz, 2002; Bale et al., 2002; Huruk, 2002, 2006; Irmler, 2003; Kosewska and Nijak, 2012; Nijak et al., 2013).

The number of Carabidae species captured in potato cultivations varies. Compared to other publications, Koval (2012) showed a very large number of ground beetle taxa - 171 species. However, it is worth noting that this study, designed to determine the adaptation of Carabidae as zoophages feeding on *Leptinotarsa decemlineata*, was conducted within the area of nine regions in three countries (Russia, Ukraine, and Moldova) and covered a nearly 30-year study period. Another review publication reports a much lower number of species than in the study by Koval (2012), but almost twice higher than in the case of one- or two-year observations. In Latvia Bukejs et al. (2009) revealed 59 ground beetle species. This review included studies from the period 1960-2009. On the other hand, studies conducted over a shorter period of time present different results. A four-year study on the species composition of ground beetles of potato cultivations differing in soil type which was conducted in Russia showed a total of 58 taxa, out of which the number of species identified ranged from 26 to 34 depending on the site. In turn, a two-year study carried out in Latvia revealed a total of 44 Carabidae species (34 species in the first year of the study, 38 – in the second one) (Bukejs, 2009). As far as the number of species is concerned, similar results were obtained by Juen et al. (2003) in Austria. These authors recorded 46 imaginal species and 25 species at the larval stage. In Austria research was also conducted by Kromp (1990) and Traugott (1998) and the study results were also similar in their case. Kromp (1990) demonstrated a total of 48 species, whereas Traugott (1998) - 49. A smaller number of species was reported by Nijak et al. (2013) who described 39 taxa, Nijak et al. (2014) - 34 species, Kinnunen and Tiainen (1999) - 35 species, whereas Kosewska and Nijak (2012) - 32 species. A one-year study was also done by Jasiński et al. (2015) who found 11 (the first site) and 7 (the second site) species under organic farming system.

The most frequently occurring species (D5-eudominants) in the Subcarpathian region were *H. rufipes*, *P. cupreus*, and *P. melanarius,* which are components of epigeic Carabidae fauna commonly found in cultivation fields (Thiele, 1977). *H. rufipes* was a species that occurred most frequently at individual sites. At most of the sites, this species constituted the eudominant class (D5) and was classified as dominant (D4) only at two sites (1 and 11). It also proved to be the most numerous in other authors' studies (Juen et al., 2003; Kosewska et al., 2008; Kosewska and Nijak, 2012; Nijak et al., 2014).

Poecilus cupreus was the second most numerous Carabidae species in this study investigating the Subcarpathian region. This species occurred at 11 sites (it was not found at sites 4 and 7). Nevertheless, the numbers of this beetle in an agricultural ecosystem vary. In the study by Bukejs (2009), it was the most numerous species (whereas *H. rufipes* was a subrecedent). In the research of Kosewska and Nijak (2012), it achieved the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21092128

subdominant status in integrated farming, whereas in organic farming - the subrecedent status. Under organic potato cultivation, in turn, Jasiński et al. (2015) showed this species to be an eudominant (D5) at site I, while at site II it was not found. In the study by Kosewska et al. (2008), *P. cupreus* was a dominant, whereas in the study by Traugott (1998), in turn, it proved to be an eudominant.

Similarly to *P. cupreus*, *P. melanarius* was a species that occurred in very large numbers both in the Subcarpathian region and in Austria (Traugott, 1998; Juen et al., 2003). It proved to be dominant (D4) or subdominant (D3) at locations in western Poland (Kosewska and Nijak, 2012), whereas in Latvia a subrecedent (D1) (Bukejs, 2009). In the present study, this species occurred at 12 sites where it constituted the eudominant (D5) or dominant (D4) class. Its numbers were lower only at one site (no. 5) where it was classified as a subdominant (D3). But it was not found at site 1.

A characteristic feature of the distribution of dominance of carabids inhabiting cultivation fields is the presence of a small number of dominant species with a very large proportion of individuals and a larger number of common species but represented by low numbers of individuals (Baranová et al., 2013). We see a very clear confirmation of this finding in the structure of Carabidae occurring at site no. 12. The analysis of the dendrogram (*Fig. 9*) revealed that this site stood out most in relation to the other study sites. In quantitative terms, the following eudominant species prevailed: *H. rufipes* and *P. melanarius*, which accounted for 77.9% of the assemblage (991 individuals). But in qualitative terms, this class accounted for 9.5%, similarly to dominants and subdominants (either of these classes was represented by two species). The recedent class was not found, whereas subrecedents were the most numerous class (71.4% of the assemblage, 15 species).

As reported by Czechowski (1981), agronomic practices used in cultivation fields promote the occurrence of open area species. The obtained study results confirm this dependence since nearly a half of species recorded are grouped in this ecological class (49% of individuals). Open area and forest species (ecotone ones) as well as forest species constituted the second ranking class, in terms of numbers, accounting for 23.5% and 19%, respectively. The presence of these species in the agrarian structure results from the presence of dendroflora in agricultural landscape and the migration capacity of ground beetles that seek both shelter and food in biocoenoses adjacent to cultivations (Krzysztofiak, 2001). Riparian species were less numerous (7.6%), while synanthropic species, which were represented only by one species – *B. cephalotes* (1.9% of the total number), were least numerous.

Trophism is another important factor used to analyze the carabidofauna structure. Both in qualitative and quantitative terms, zoophages were predominant in the entire carabid assemblage (47 species, 87% of the total number). The proportion of hemizoophages was small (7 species, 13% of the total number). However, the proportion of zoophagous species was not even as small zoophages were predominant (34 species, 63% of the total number). At site 1, no large zoophages were found at all, whereas small zoophages accounted for 93.3% of the assemblage. In turn, a high predominance of large zoophages was observed at two sites (4 - 56.3%, and 9 – 63.6%). The dominance of large zoophages is a very beneficial phenomenon, evidencing good condition of an environment (Szyszko, 1997). The dominance, both quantitative and qualitative, of predatory species is important from the ecological point of view because it may provide environmental resistance since zoophagous carabids reduce significantly the number of phytophagous species that threaten agricultural cultivation plantations (Koval, 1999; Aleksandrowicz, 2004).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21092128

Nonetheless, the prevailing tendency towards a higher number of small zoophages is a typical phenomenon, characteristic of habitats that are subjected to adverse impacts of external factors; an increase in this tendency causes the numbers of hemizoophages to grow (Pałosz, 1995; Leśniak, 1997). Worth noting is also the fact that out of the total number of 13 species of large zoophages, 8 of them were beetles of the genus *Carabus*. It is a satisfactory result because in the research of other authors this number is usually lower. Juen et al. (2003) showed 3 species, both Bukejs (2009) and Jasiński et al. (2015) found 2 species, whereas Kinnunen and Tiainen (1999) only 1. Kosewska and Nijak (2012), in turn, did not demonstrate any species belonging to this genus. Varvara (2010) recorded a higher number of species of the genus *Carabus* occurring in potato cultivations. 11 species were described but this study covered a larger area (5 regions) and a longer study period (18 years).

It is also worth noting the fact that 3 species belonging to the genus *Carabus* caught in these studies are protected in Poland (*C. ulrichii* Germar, *C. convexus* F., and *C. coriaceus* Ill.). It was surprising to record two riparian species: *Pterostichus ovoideus* (Sturm) and *Carabus linnei* (Panz.). Both species were found in investigations of agrocenoses but not in potato cultivations (Konieczna et al., 2015). In a study by Szewkienicz and Olbrycht (2012), however, *P. ovoideus* was found in organic potato cultivation in the Subcarpathian region.

The analysis of moisture preferences showed mesohygrophilous species to have a dominant proportion (57.4%), with a much lower percentage of hygrophilous species, strictly associated with wet biocenoses (37%). According to Thiele (1977), the predominance of mesohygrophilous species is typical for European agroecosystems. Only 3 species, *Cicindela hybrida* L., *Harpalus griseus* (Panz.), and *H. affinis* (Schrank), represented dry-loving (xerophilous) species (5.56%).

The beetles caught were also characterized in terms of their breeding preferences. In the studied material, spring breeding species were predominant (63% of the assemblage - 34 species), whereas autumn breeding was represented by 20 species (37% of the assemblage). Similar results were obtained by Borowski et al. (1996) who indicated this breeding preference as characteristic of Carabidae occurring at sites where cultivation protection products are used. The variation in phenology is confirmed by the difference in the catch rate of individual species since the largest numbers and fluctuations were observed in spring and summer months.

Palearctic (55.6% of the total number) and Euro-Siberian (20.4% of the total number) species predominated in the studied material. As reported by Czechowski (1981) and Huruk (2006), these are zoogeographical elements characteristic of cultivation fields. Wide range spectra are characteristic of species occurring in environments subjected to greater pressure of external factors. Natural or semi-natural habitats, on the other hand, favor the occurrence of species with narrower zoogeographical ranges (Leśniak, 1997; Huruk et al., 2014). *C. caraboides* was such a species, the only representative of the Euro-Arctic element which was only found at one site (no. 4).

Species diversity is an important indicator describing a Carabidae assemblage (Nijak et al., 2013). The total value of H'_{ln}=1.94 and the values obtained at individual sites (H'_{ln} ranging 0.94-2.37) are comparable with results obtained by other authors: H'_{ln} =2.108 (Kosewska et al., 2008), H'_{ln} =1.98 and H'_{ln} =2.38 (Kosewska and Nijak, 2012), H'_{ln} =2.17 and H'_{ln} =1.58 (Jasiński et al., 2015). A higher value of this index characterizes assemblages with a quite good internal structure (species distribution), though not very numerous. The highest value of this indicator was observed at site 3, which was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21092128

characterized by the lowest number of individuals (59) and a medium number of species (15). The Pielou evenness index (J') represents the equal distribution of individuals among all species. The total value of this index in the carabid assemblage was J'=0.49, which could have been due to a large (dominant) proportion of rare species. In turn, at site 3 where the subrecedent class was not observed, the value of this index was highest among all sites studied (J'=0.88). Another indicator used to analyze the Carabidae assemblage was the degree of species dominance (λ). This parameter assigns a lower weight to the occurrence of rare species, paying greater attention to common species, and takes on higher values in communities dominated by one or several species. The highest value of this index was recorded at site 1 (λ=0.58) where only one eudominant (*P. cupreus*) was found; its contribution to the assemblage was 633 individuals (75.7% of the assemblage). The lower the value of this index, the more equal distribution of individuals among species. The lowest values of λ were observed at two sites: 3 (λ=0.12) and 2 (λ=0.15). Not all dominance classes were found at these sites but the proportions of individual species recorded there were relatively equal. Huruk (2006) obtained similar results, which was related to the dominant contribution of one species. The sites that were characterized by the highest value of the dominance index, that is, they were dominated by one or two species, exhibited the lowest values of the diversity indices: site 1 (λ=0.58; H'_{ln} =1.03) and site 2 (λ=0.55; H'_{ln}=0.94) (*Fig. 10*).

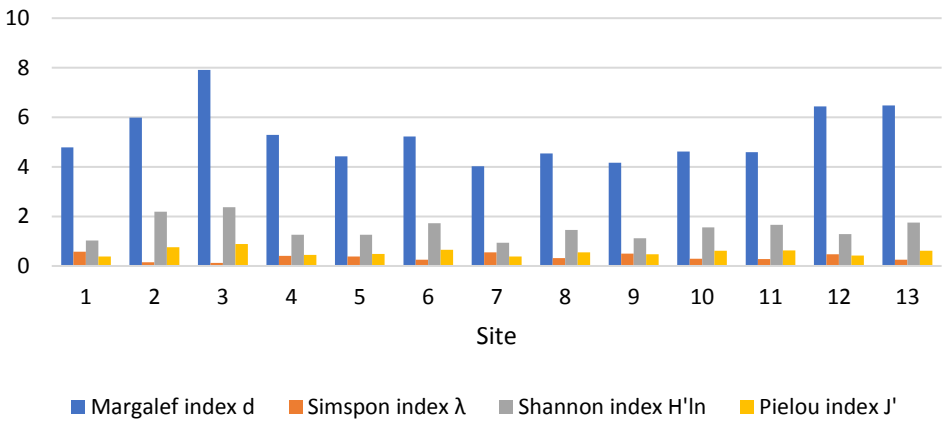

Figure 10. *Indices of α-diversity: species diversity of Margalef (d), Shannon (H'_{ln}), Simpson concentrate of dominance (λ) and Pielou's Evennes (J')*

Application of cultivation protection products can be another factor determining the qualitative and quantitative structure of ground beetles. In the studied material, samples were only taken from sites subjected to various agronomic practices. Due to the fact that no comparative observations were conducted based on control samples (i.e. without application of insecticides, for instance), one cannot determine the direct effect of anthropogenic factors on the occurrence of beetles.

As evidenced by research, changes in agricultural practices beneficially affecting the diversity of Carabidae include, among others, reduced use of pesticides and organic farming (Andresen and Eltun, 2002; Koss et al., 2005), but also changes in cultivation practices (Andersen, 2003) and reduced herbicide application (Thorbek and Bilde, 2004). The effect of insecticides (deltamethrin) was investigated by Kaczmarek (1992) and Aleksandrowicz (2002) who showed chemical treatments to adversely influence

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21092128

assemblages of ground beetles. Intensively cultivated potato plantations create adverse habitat conditions for most carabids (Werling and Gratton, 2008).

Nonetheless, not always does the impact of agronomic practices on the Carabidae structure cause a decrease in biodiversity. The studies by Kosewska et al. (2013) and Nijak et al. (2013) revealed that chemical protection in integrated potato cultivation does not affect adversely the preservation of the diversity of ground beetles. On the other hand, Kosewska et al. (2014) demonstrated that integrated cultivation protection can contribute to increased diversity of Carabidae. Insecticide application was not shown to have an adverse effect, but herbicide and fungicide application proved to have a significant impact on the structure of ground beetles.

Habitat factors, such as adjacent biocenoses, are an important element affecting the occurrence of Carabidae in cultivation fields. As demonstrated by Weibull et al. (2003), the vicinity of diverse biocoenoses has a major importance for the preservation of biodiversity of ground beetles in conventional cultivations. In most cases, the investigated cultivation sites in the Subcarpathian region were characterized by substantially diverse natural landscape in the form of bordering or adjacent field trees and shrubs, meadows, and forests. Among the study areas, only sites 8 and 9 bordered exclusively with agriculturally used areas. Potato cultivations located in the surroundings of low diversity habitats were characterized by the occurrence of a smaller number of both beetle species and individuals. Site 9 where the lowest number of species and a relatively low number of individuals were recorded was surrounded by cultivations of another potato cultivar and oilseed rape cultivations. In turn, the number of species and individuals was observed to increase at site 8 that also bordered with agricultural cultivations. This could have been associated with the type of the adjacent cultivation. The fields bordering with this site were sown with maize, rye, and wheat. Unlike potato cultivations, monocotyledonous cultivations are characterized by a high and dense canopy. Agronomic practices essentially involve soil preparation before seeding and harvest itself; these factors create more favorable living conditions for Carabidae than in the case of root cultivations, which is confirmed by the research conducted by Kinnunen and Tiainen (1999), Kosewska et al. (2008), Gailis and Turka (2014), and Jasiński et al. (2015). Potential microclimatic conditions prevailing not only in cultivation fields, but also in biocoenoses adjacent to them, influence the distribution of species of different moisture preferences. Dry-loving species were found in 6 cultivations studied and among them the highest percentage was shown at site 9. The presence of xerophiles can be explained, among others, by the similarity to bordering habitats (also potato cultivations), their low diversity (oilseed rape cultivations), and also more intense sun exposure. No moisture-loving species were observed there. In turn, among all study areas the highest proportion of moisture-loving species was observed at site 9 whose surroundings were most strongly diversified compared to the other sites, in particular in terms of moisture (shrubs, pastures, a meadow, a stream, ponds).

Moreover, the sites where the present study was carried out were characterized by agricultural production conducted in small-area farms which differ from large-area plantations (the largest potato cultivationping area – 70 ares). The mosaic agricultural landscape specific for the Subcarpathian region promotes the preservation of biodiversity. Comparative studies of the Carabidae species composition and numbers of individuals occurring in cultivation fields and adjacent areas indicate that edge habitats are of essential importance in agroecosystems. Such habitats are generally characterized by a smaller number of recorded individuals and a higher number of identified species

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21092128

(Thienemann's rule). Conscious shaping of agricultural landscape by preserving marginal habitats, field margins, and tree stands promotes the maintenance of biodiversity in an agro-ecosystem (Twardowski and Pastuszko, 2008; Szafranek and Woszczyk, 2012; Konieczna et al., 2015).

Conclusions

The following most frequently occurring species: *H. rufipes*, *P. melanarius*, and *P. cupresus*, can be considered to be typical for agriculturally used areas, including potato cultivations. These are species with wide ecological tolerance and lower susceptibility to anthropogenic pressure.

On the basis of the results obtained, it cannot be said that the intensity of chemical treatments related to potato protection affects the number and biodiversity of ground beetles.

On the other hand, the structure of neighboring arable fields and the presence of forest and midfield afforestations plays an important role. In this mean the maintenance and appropriate management of diverse biocoenoses in agricultural space contribute to increase diversity Carabidae in agrarian areas.

To better understand the impact of the agricultural environment on the structure of Carabidae, it would be necessary to analyze both the impact of individual environmental factors as well as the impact of the use of individual fertilizing and crop protection products. This type of research should be carried out under controlled conditions (controlled and examined samples) and outside production farms (experimental plots).

Abstract. Baby spinach (*Spinacia oleracea* L.) is grown for its nutritional benefits, edible leaves and medicinal purpose. The use of crop amendments such as inoculation with plant growth-promoting bacteria (PGPB) together with fertilizers for crop cultivation is more sustainable as it reduces the excessive use of fertilizers and increases crop yield. The aim of this study was to evaluate the physiological and phytochemical response of baby spinach cultivars to different levels of Nitrogen, Phosphorus, Potassium and Sulphur (NPKS) nutrition, amended with *Bacillus subtilis* strain BD233 inoculation. A factorial field experiment with treatments arranged in a randomized complete block design (RCBD) was carried out. The results showed that NPKS fertilization significantly affected the total biomass of baby spinach but not *B. subtilis* (BD233) inoculation and cultivar or their interaction. The level of chlorophyll varied between cultivars ranging from 19.96 ± 1.62^{b} mg/m^2 and 24.79 ± 1.98^{a} mg/m^2, however, no significant differences occurred in stomatal conductance among the three cultivars. However, significant difference was observed on compounds among cultivars with NPKS fertilizer application in most identified compounds such as patuletin-3-glucosyl-(1-6)[apiosyl(1-2)]-glucoside, spinacetin-3-glucosyl-(1-6)[apiosyl(1-2)]-glucoside, (S)-Malate and N-Acetyl-D-tryptophan. Therefore, the study recommends that fertilizer at 22N:22P:30K:5S kg/ha and 33N:33P:45K:7S kg/ha amended with *B. subtilis* inoculation be considered when cultivating baby spinach.

Keywords: *chlorophyll content, green leafy vegetables, multivariate analysis, Plant Growth Promoting Bacteria (PGPB), stomatal conductance*

Introduction

Baby spinach (*Spinacia oleracea* L.) is grown for its nutritional benefits, edible leaves and medicinal purpose (Schrader and Mayberry, 2003; Kerr, 2014; Mudau et al., 2015). It is extensively cultivated in Europe due to favorable conditions and high demand (Kerr, 2014). In South Africa, baby spinach is available to consumers as a fresh, salad mix and as a frozen and canned product (Zikalala et al., 2016). Its growing popularity led to baby spinach being grown worldwide. However, essential nutrients and phytochemical concentrations of baby spinach are affected by climatic conditions, agronomic practices and postharvest factors such as stage of harvesting (Kalt, 2005; Bergquist, 2006), cultivars (Masufi et al., 2019), storage temperature and time (Bergquist, 2006).

The production of plants requires an accurate supply of nutrients whilst a slight variation in nutrient balance may have a negative effect on crop growth and nutrition status (Sedibe and Allemann, 2012). The availability of nitrogen, phosphorus and potassium in soils during production are essential to improve growth and vegetable quality (King et al., 2008). However, sustainable and proper use of synthetic chemical fertilizer is essential. Using improved production practices and technologies enhances crop growth (Shine and Guruprasad, 2012) and these techniques mitigate the effect of poor growing conditions including nutrient imbalance (Sedibe, 2012). The use of crop amendments together with fertilizers is more sustainable as it reduces excessive use of fertilizer (Diacono and Montemurro, 2010). These amendments respond differently from that of fertilizers, in as much as it only influences plant vigour (Yakhin et al., 2016).

The use of plant growth promoting bacteria (PGPB) in crop amendments is gaining popularity (Diacono and Montemurro, 2010). Inoculation with *Bacillus* strains showed increase in vegetative growth of crops (Pupathy and Radziah, 2015; Çakmakçi et al., 2007), however, their effect on chemical composition has not been well documented. *Bacillus* strains are among the most commonly used phosphate solubilizers and have been reported to increase phosphorus uptake (García-López and Delgado, 2016) there by improving plant growth and is less toxic to human and widely exists in soils (Wu et al., 2016). The aim of this study was to evaluate the effect of combined Nitrogen, Phosphorus, Potassium and Sulphur (NPKS) fertilization at different levels on physiological and phytochemical composition of baby spinach cultivars amended with *Bacillus subtilis* BD233.

Materials and Methods

Experimental site

The study was conducted at Agricultural Research Council - Vegetable and Ornamental Plant Institute (ARC-VOPI) in Roodeplaat farm, situated in the sourish mix of bushveld, 25 km north of central Pretoria, KwaMhlanga (R573) road; GPS coordinates: 25,56S;28,35E (Gauteng province, South Africa). The area is a relatively cool subtropical climate with summer rainfall and cold, dry winter.

Bacterial strain and preparation

Bacillus subtilis strain BD233 was obtained from the Agricultural Research Council-Plant Protection Research Institute (ARC-PPRI) in Pretoria, South Africa. *Bacillus subtilis* strain BD233 were cultured using a LB agar plates after incubation under dark conditions at 28°C for 24 h. The bacterial cells were harvested from LB agar plates into liquid LB media to yield 8.547x109 colony forming units (cfu) mL^{-1} determined by serial dilution with plate counts (Zhang et al., 2008). Baby spinach cv. Anna, Edna and Ohio seeds were surface decontaminated by washing in 0.35% (v/v) sodium hypochlorite and stirred for 5 min. The used sodium hypochlorite solution was discarded, and decontaminated seeds were washed three times with distilled water. Seeds were then left to dry under the laminar flow prior to planting in seedling trays filled with compost growth medium on 9 January 2016. Germination took place 7 days after planting and seedlings were transplanted after 3 weeks when the plants had 4 leaves each.

Experimental design and layout

The experiment was a 5x2 factorial arranged in a randomized complete block design (RCBD) with three replicates. Five NPKS fertilizer ratios consisted of 0 (0:0:0:0 kg/ha), 25% (11:11:15:2 kg/ha), 50% (22:22:30:5 kg/ha), 75% (33:33:45:7 kg/ha) and 100% (45:45:60:10 kg/ha) of the recommended fertilizer application for baby spinach (Nemadodzi et al., 2017) and *Bacillus subtilis* strain BD233 amendments (zero *B. subtilis* (B-) and *B. subtilis* (B+) application) to three cultivars of baby spinach (Anna, Edna and Ohio) were evaluated.

Experimental plot size (2.2x2.2 m^2) used consisted of in-row and interrow spacing of 20 cm and 10 cm, respectively. Fertilizers were applied a week after transplanting followed by inoculation with 100 ml of *Bacillus subtilis* strain BD233 LB per plant a week after fertilizer application. Lime ammonium nitrate (28% N kg/ha) was applied as the N fertiliser source, phosphorus was supplied in the form of superphosphate (83% P kg/ha), potassium was supplied in the form of potassium chloride (50% K kg/ha) and sulphur was applied in the form of gypsum (17% S kg/ha). Irrigation was based on the soil moisture conditions for a period of 2.5 h per irrigation using sprinkler irrigation and weeds were removed manually by hands.

Physiological parameters

Plants were harvested at 35 days after planting and washed with running water. Chlorophyll content, upper-leaf stomatal and lower-leaf stomatal conductance and total biomass (fresh mass and dry mass) were measured on three baby spinach cultivars namely, Anna, Edna and Ohio. Chlorophyll content was measured using Spad 502 Chlorophyll Meter (Minolta Camera Co. Ltd., Japan) a non-destructive method on healthy mature leaves with homogeneous green colour. Stomatal conductance was measured between 11:00 to 13:00 using SC-1 Leaf Porometer instrument (Decagon Devices USA). Leaf porometer determine stomatal conductance using the actual vapour flux from the leaf through the stomata. At harvesting, freshly harvested material of baby spinach was oven dried at 45ºC for 24 h (Bashan et al., 2017). Both fress mass and dry mass were weight to determine the total biomass.

Ultra High Performance Liquid Chromatography–Mass Spectrometer (UHPLC-MS) solvent extraction and preparation

Mature leaves of baby spinach were harvested, and oven dried at 45ºC for 24 h before grounded into a fine powder using a pestle and mortar and stored in airtight tubes in an 80°C refrigerator. Thereafter, about 50 mg of ground leaves were weighed subsequent extraction using 15 ml methanol-water. The mixture was sonicated for 20 min at room temperature and centrifuged at 1300 rpm for 15 min. The mixture was filtered through 0.45 µm syringe filters and the supernatant (1 ml) was transferred into 2 ml amber glass vials for UHPLC-MS analysis (Mncwangi et al., 2014).

UHPLC-MS analysis

The method described by Mncwangi et al. (2014) was adopted with minor changes. The UHPLC analysis was performed on a Waters Acquity Ultra-High-Performance Liquid Chromatography system with PDA detector (Waters, Milford, MA, USA). UHPLC separation was achieved on a UHPLC Ultra C18 column (100 mm × 2.1 mm, i.d., 5-µm particle size, Restek) maintained at 35°C. The mobile phase consisted of 0.1%

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21292140

formic acid in water (solvent A) and LC-MS grade methanol (solvent B) at a flow rate of 0.3 ml/min. The gradient elution was applied as follows: 85% A: 15% B to 65% A: 35% B in 4 min, thereafter, changed to 50%: 50% in two min, to 20% A: 80% B in 1 min, maintaining for 1 min and back to an initial ratio in 0.5 min. The analysis time was 9 min. Samples were introduced into the mobile phase with an injection volume of 1.0 µl (full-loop injection) for samples and 2.0 µl for reference standards. The UHPLC system was interfaced with a Xevo G2QTof MS (Waters, USA). The following mass spectrometry operating conditions were applied: source – ESI negative mode; capillary voltage – 3 kW; cone voltage 30 V; calibration – sodium formate; lock spray – leucine enkaphalin and scan mass range – at 200–1500m/z.

Statistical analysis

Analysis of variance (ANOVA) data of agronomic parameters was conducted using Statistica version 10.0 and all-pairwise comparison tests were performed to detect differences among means at a significance level of $p \leq 0.05$. Significant means were separated using the Duncan Multiple Range Test. UHPLC-MS data was processed by XCMS version 3.5.1 (2016) and analysis of variance across metabolites treatment means was performed using SAS statistical package version 20. The chemometric analysis was performed using the MetaboAnalyst 3.0. (2017). Partial Least Squares - Discriminant Analysis (PLS-DA) was performed to identify compounds responsible for differentiation among cultivars and treatments. Compounds were identified using the Compass data analysis 4.3 and annotated by MetFrag version 2.1. (2010).

Results and Discussion

Physiological parameters

This study evaluated the effect of different levels of NPKS fertilization, on some physiological parameters (chlorophyll content, stomatal conductance and total biomass) of three baby spinach cultivars amended with *B. subtilis*. The results showed significant varietal differences in baby spinach's response to the treatments. Among the three cultivars, cv, Edna had the highest chlorophyll content (24±1.84 mg/m^2) and stomatal conductance (27.24±1.84 and 10.03±0.96 m^2/smol^{-1} upper and lower, respectively) compared to cv. Ohio with the lowest values (*Table 1*). The differences in baby spinach could be attributed to the genotypic predisposition of the cultivars tested in this study. The findings of the present study are consistent with the findings of Makus (2013) who reported differences in chlorophyll content of spinach cultivars, Samish and Lazio, grown under the same soil type treated with sulphur. Singh et al. (2014) also reported differences in chlorophyll content among cultivars, Siberian kale and Japanese kale.

There was a significant difference observed in the upper and lower stomatal conductance among the three cultivars, with cultivar Edna having the highest upper stomatal conductance and lower stomatal conductance (*Table 1*). The findings of the current study concured with the findings of Khan et al. (2009), who reported a high significant decrease in stomatal conductance of mustard cv. SS2 than Pusa Jai Kisan with increasing NaCl concentration. The results also indicated that cultivar type had no effect on the total biomass of baby spinach, ranging from 0.31g to 0.40 g. The results correlated with the findings by Masufi et al. (2019) who reported no significant difference on baby spinach cultivar ohio, guitar F1, Lazio F1, monstrous, viroflay and dash.

In this study, different levels of NPKS fertilization significantly affected the measured physiological parameters. Baby spinach treated with a higher dose of fertilizer had higher chlorophyll content compared to control and in general, there was a steady increase in chlorophyll content with increase in NPKS fertilization level (*Table 1*). Similar trend was observed by Pramanik and Bera (2013), who reported gradual increase in total chlorophyll content of hybrid rice with increasing nitrogen levels from zero to 200 kg ha^{-1}. These results confirm that nitrogen is important in the formation of chlorophyll molecules (Gairola et al., 2009). However, in contrast, the increase in NPKS fertilization caused decreases in the stomatal conductance. The stomatal conductance of the control plant (0.10 ± 0.01 $m^2/smol^{-1}$ (upper) and 17.74 ± 1.07 $m^2/smol^{-1}$ (lower)) was the highest compared to the other treatments (*Table 1*). In agreement with results of the study, Nemadodzi et al. (2017), reported similar findings in chlorophyll content and stomatal conductance with the application of NPK fertilization at a ratio of 45:45:60 on baby spinach. The NPKS fertilization level significanly ($p<0.001$) affected the total biomass of baby spinach. In general, plant dry biomas increased with increases in the level of fertilization. However, the current study for plants fertilized with the highest NPKS level 45:45:60:10 kg/ha had the highest total biomass (0.60 g) compared to control. The results are in agreement with the findings of Nemadodzi et al. (2017) who reported that N and P fertilization significantly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21292140

affected both the leaf fresh and dry weights in their study. The results contradicted by the findings of Boroujerdnia and Ansari (2007) who reported an increase in dry weight of romaine lettuce with an increase in N levels from 60 kg/ha to 180 kg/ha. Furthermore, Singh et al. (2004) conducted a study on the effect of NPK fertilizers on the growth of basil where it was found that fertilizer application at 75:40:40 kg/ha significantly increased the dry weight over the control of basil. In okra, no significant difference was reported in dry weight with increasing NPK fertilizers from 10 to 13 grams (Gloria et al. 2017).

From the results obtained in this study, it was evident that *Bacillus subtilis* (BD233) amendments influenced the chlorophyll content of baby spinach. *Bacillus subtilis* (BD233) had a significant ($p \leq 0.05$) effect on the chlorophyll content of baby spinach, however, there was no significant differences in stomatal conductance (*Table 1*). These results concurred with findings of Turan et al. (2014) who assessed the effect of *B. subtilis* on cabbage seedling growth and observed an increase in chlorophyll content compared to the control. Elsewhere, Ekinci et al. (2014) also found similar findings on cauliflower transplants grown under greenhouse conditions. Anjum et al. (2007) reported that an increase in leaf chlorophyll content stimulate plant growth. The stomatal conductance was not affected by the application of *Bacillus subtilis* BD 233, these findings accorded well with those of Porcel et al. (2014) who reported no effect on stomatal conductance when inoculation with *Bacillus* strain on tomato plants. The results also showed that *Bacillus subtilis* (BD233) exhibited no effect on the total biomass of baby spinach cultivars, the results concurred with the findings of Canbolat et al. (2006) who observed none statistical difference between bacterial inoculation and P fertilizer in terms of dry weight of barley seedling.

The interaction of cultivar and *B. subtilis* (BD233) was significant for the chlorophyll content and stomatal conductance of baby spinach. In addition, cv. Edna amended with *Bacillus subtilis* (BD233) had higher chlorophyll content (28.43±2.66 mg/m^2) and stomatal conductance (9.04±1.75 and 10.42±1.55 m^2/smol^{-1} for upper and lower, respectively) compared to the other cultivars with or without amendment with the bacteria (*Table 1*).

Phytochemical response

There has been a lack of a considerable research report on metabolites response of baby spinach to *Bacillus subtilis* BD 233 and different levels of NPKS using an untargeted approach. Thus, MS/MS was carried out to identify compounds and their differences with respect to the response of three selected baby spinach cultivars to the different treatments employed in this study. The results of this study demonstrated a wide range of compounds which included the patuletin-3-glucosyl-(1-6)[apiosyl(1-2)]-glucoside (m/z 787, Rt. 5.39), spinacetin-3-glucosyl-(1-6)[apiosyl(1-2)]-glucoside (m/z 801, Rt. 5.94), spinacetin-3-(2¢¢-feroylglucosyl)(1-6)[apiosyl(1-2)]-glucoside (m/z 977, Rt. 6.40), and (S)-Malate (m/z 133, Rt. 0.86). Baby spinach metabolites showed significant differences in response to cultivar and NPKS fertilization. Cultivar Ohio exhibited high concentration in most compound which were slightly significant when compared to cv. Anna and Edna (*Table 2a,b*). However, there were no significant differences in cultivar on compound suvorexant (m/z 449, Rt 6.20), 4-(beta-D-Glucopyranosyloxy)-2-hydroxy-6-pentadecylbenzoic acid (m/z 525, Rt 6.84) and (S)-malate (m/z 133, Rt 0.86). Among the compounds identified, *B. subtilis* inoculation and the interaction of NPKS fertilization with *B. subtilis* only had a slight significant difference ($p \leq 0.05$) on compound 2-(1-hydroxyethyl thiamine diphosphate (2-)) (m/z 465, Rt 5.20) (*Table 2a,b*). Similar compounds were previously reported by Bergquist et al. (2005), who observed a relatively stable total flavonoid content during normal retail storage conditions.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21292140

N-Acetyl-D-tryptophan (m/z 245, Rt. 5.55) was reported by Okazaki et al. (2009) on spinach leaves when treated by altering the ratio of NH_4^+/NO_3^- in the culture solution. However, 5-[(2-{[2-Acetamido-2-deoxy-3-O-(beta-D-galactopyranosyl)-alpha-D-galactopyranosyl] oxy} ethyl) carbamoyl]-2-[6-(dimethylamino)-3-(dimethyliminio)-3H-xanthen-9-yl] benzoate (m/z 837, Rt. 7.02), 5-(Pentafluoro-lambda~6~-sulfanyl)-2H-benzimidazole-2-thione (m/z 272, Rt. 0.61), (2S,3R)-2,3-Dihydroxy-5-oxohexanedioate (m/z 191, Rt. 1.06), 2-(1-hydroxyethyl)thiamine diphosphate(2-) (m/z 465, Rt. 5.20), suvorexant (m/z 449, Rt. 6.20), 4-(beta-D-Glucopyranosyloxy)-2-hydroxy-6-pentadecylbenzoic acid (m/z 525, Rt. 6.84), 1-(5''-Phosphoribosyl)-5-amino-4-imidazolecarboxamide (m/z 337, Rt. 5.84), Diacetylacteoside (m/z 707, Rt. 6.98),5,7-Dihydroxy-2-(4-hydroxy-3,5-dimethoxyphenyl)-4-oxo-4H-chromen-3-yl-beta-D-erythro-hexopyranosiduronic acid (m/z 521, Rt. 7.09), 2-(3,4-Dihydroxyphenyl)-5,7-dihydroxy-6-methoxy-4-oxo-4H-chromen-3-yl 6-O-acetyl-beta-D-erythro-hexopyranoside (m/z 535, Rt. 7.34), Narirutin (m/z 579, Rt. 5.60), 4-[3-(Benzyloxy)-1-(beta-D-glucopyranosyloxy)propoxy]butanoic acid (m/z 429, Rt. 7.40), 4-[(Nitrooxy)methyl]benzyl N-{(5Z)-7-[(1R,2R,3R,5S)-3,5-dihydroxy-2-{(1E,3R)-3-hydroxy-4-[3-(trifluoromethyl)phenoxy]-1-buten-1-yl}cyclopentyl]-5-heptenoyl}glycinate (m/z 679, Rt. 6.71), were not identified in previous studies on baby spinach.

PLS-DA score plot was used to assess the significance of class discrimination (*Fig. 1A,B*). The supervised comparison of baby spinach treated with different levels of fertilizers and *Bacillus subtilis* BD233 revealed distinct grouping among the control, 33N:33P:45K:7S kg/ha and 45N:45P:60K:10S kg/ha. The first component of the data was effective in separating the control from samples treated with fertilizers. Most of the fertilizer treated samples are on the left side of the plot and samples treated with fertilizers and *B. subtilis* on the right side of the plot (*Fig. 1A,B*).

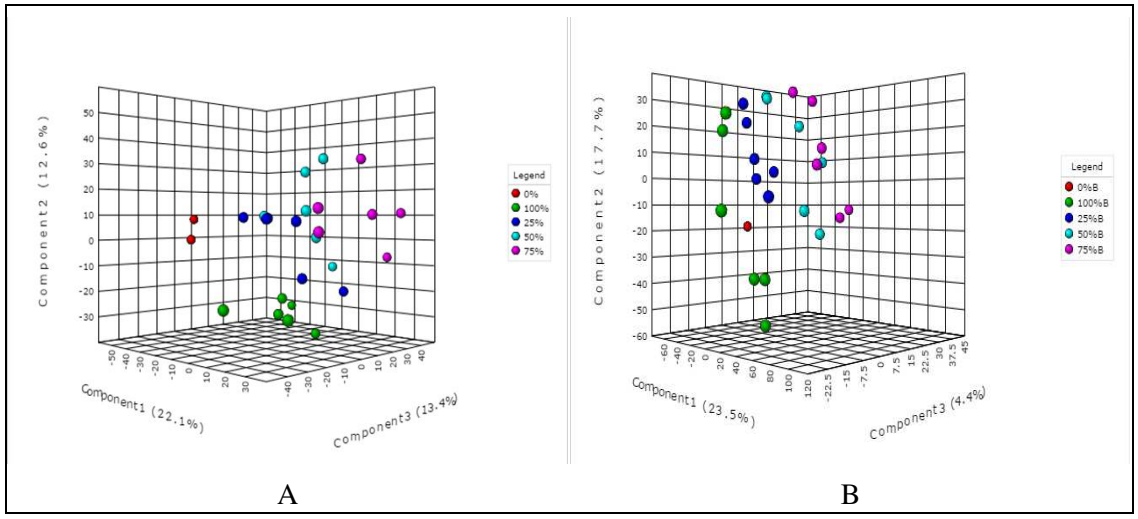

Figure 1. *Partial Least Squares - Discriminant Analysis (PLS-DA) 3D scores plot from LC-MS for baby spinach treated with different rates of fertilizers and Bacillus subtilis BD233. 0%=0N:0P:0K:0S kg/ha, 25% =11N:11P:15K:2S kg/ha, 50% =22N:22P:30K:5S kg/ha, 75% =33N:33P:45K:7S kg/ha, 100% =45N:45P:60K:10S kg/ha and B= Bacillus subtilis BD233*

Conclusion

The current study showed evidence of differences in the chlorophyll content of the baby spinach cv. Anna, Edna and Ohio with the same treatments, however, no differences observed in stomatal conductance and total biomass among the three cultivars. Inoculation with *B. subtilis* also yielded the same results where no significant differences were observed in chlorophyll content, stomatal conductance and total biomass. Fertilizer application at 33N:33P:45K:7S kg/ha and 45N:45P:60K:10S kg/ha influenced the physiological parameters when compared to the control of the study. The results confirmed that plants treated with 11N:11P:15K:2S kg/ha and 22N:22P:30K:5S kg/ha baby spinach cv. Ohio is rich in flavonoids such as patuletin-3-glucosyl-(1-6)[apiosyl(1-2)]-glucoside (m/z 787, Rt. 5.39), spinacetin-3-glucosyl-(1-6)[apiosyl(1-2)]-glucoside (m/z 801, Rt. 5.94) and spinacetin-3-(2¢¢-feroylglucosyl)(1-6)[apiosyl(1-2)]-glucoside (m/z 977, Rt. 6.40), which have the potential protective response against cancer and heart diseases and also their antioxidative properties. Meanwhile, baby spinach cv. Anna, Edna and Ohio were found to be highly concentrated with amino acids such as (S)-Malate (m/z 133, Rt. 0.86) when no treatment applied, 2-(1-hydroxyethyl)thiamine diphosphate(2-) (m/z 465, Rt. 5.20) in all fertilizer application levels except the control, N-Acetyl-D-tryptophan (m/z 245, Rt. 5.55) when treated with 11N:11P:15K:2S kg/ha and Diethyl ({4-(6-oxo-7,11-diazatricyclo[7.3.1.0~2,7~]trideca-2,4-dien-11-yl)-3-[(3,4,5 trimethoxybenzoyl) amino] benzoyl} amino) malonate (m/z 675, Rt. 7.40) when no treatment applied, which are essential for tissue growth and repair, as well to assist in muscle building. There was a significant difference in the compounds among cultivars and NPKS fertilization. The study recommends that fertilizer at 22N:22P:30K:5S kg/ha and 33N:33P:45K:7S kg/ha amended with *B. subtilis* inoculation be considered when cultivating baby spinach. However, the metabolite profiling of baby spinach needs further investigation to determine the influence of *B. subtilis* application and levels of NPKS on flavor characterization.

Acknowledgements. The authors would like to thank SAKATA for providing seeds for the experiment and NRF (Grant No: 100503) for providing funds for this study.

Conflict of interests. The authors declared that there is no conflict of interests regarding the publication of this paper.

(Received 9th Sep 2019; accepted 25th Nov 2019)

Abstract. A robust adaptive model to predict and to control the greenhouse microclimatic condition is pivotal for better crop production and growth. The current research assesses the use of multiple linear regression (MLR), autoregressive integrated moving average (ARIMA), and multi-layered perceptron (MLR) for predicting indoor microclimate greenhouse, located in South Korea. The data were collected from the local weather station and regional weather station data named M1 (local weather station data combined with the regional weather station data), M2 (regional weather station data), and M3 (local weather station data), which were used as the input variables for the prediction. Four dependent variables were predicted (two temperature variables and two humidity variables) by each of the models using M1, M2, and M3 data sets. Performances of the models were evaluated with the coefficient of determination (R^2), the root mean square error (RMSE), the mean square error (MSE), and the mean absolute error (MAE). The simulation results showed that the prediction by the MLP model was highly correlated to the measured data with less RMSE, MSE, and MAE. Besides, seasonal based analysis results reinforce that the MLP performs a better simulation in different environmental conditions. Moreover, the M1 data were propitious for better performance than other data sets, which specifically improves the accuracy of the simulation results for humidity predictions. The present study developed a simple and powerful MLP model to predict the microclimate of the greenhouse, which may integrate into greenhouse controller devices through cloud technology in the future.
Keywords: *ARIMA, greenhouse, indoor microclimate, MLP, MLR, model comparison*

Introduction

Currently, one of the major challenges in worldwide agricultural productivity is climate change. Reducing food hunger is becoming an immense challenge due to the abnormal increase in the world population. Adopting precision farming methodologies such as greenhouse farming technology protect from the vulnerability of agriculture production (Kurt et al., 2017). From the last few decades, precision farming methodologies have boosted agriculture production due to the emergence in advanced technologies such as sensors, actuators and microprocessors, IoT based greenhouse systems, and big data analytics. In recent years, production in greenhouses has become more popular than ever before. The global smart greenhouse market is estimated to grow from 680.3 million in 2016 to 1.31 billion USD by 2022 (Leonetti, 2018). The key factors driving the smart greenhouse market include; improving the indoor farming space, vegetation on farmer preferences, high demand for quality, favorable government regulations, etc. The indoor microclimatic parameters such as temperature and humidity is an essential aspect of controlling the crop interaction with the environment. Enhancing microclimatic conditions in a greenhouse leads to improve crop quality and quantity of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21412161

production since these crop properties directly influenced by the microclimate parameters (Santosh et al., 2017). Therefore, considering control of temperature and humidity is essential when a farmer plans to start planting in greenhouse facilities.

A robust, adaptive, and accurate model is essential to predict the indoor temperature and humidity of the greenhouse to develop an ideal control strategy for a greenhouse microclimate (Luan et al., 2011). Various static and dynamic models have been developed to predict and control microclimatic conditions in earlier studies (Lu and Viljanen, 2009; He and Ma, 2010; He et al., 2014; Shi et al., 2018). Most often, substantial studies carried out regression models, time series models, computer intelligence approaches, and hybrid approaches to predict the short term as well as long-term time series based variables (Cheng and Ni-Bin, 2011). A comprehensive performance assessment of the different prediction models helps to develop an ideal control strategy for greenhouse microclimate (Uchida and Pieters, 2004). The current study is hypothesised to make a comparative study between the performance of the physical models and the computational models. Likewise, the foremost objective of this study is to evaluate the performance of the physical model (multiple linear regression (MLR)), the time series forecast model (autoregressive integrated moving average (ARIMA)) and the computational model (multi-layered perceptron (MLR) with back propagation-BB training algorithm) with limited input variables. Numerous studies considered the outdoor environmental parameters along with indoor parameters such as soil temperature, plant phenotypes, and ventilation as accessible input variables for predicting the indoor microclimate of a greenhouse (Lu and Viljanen, 2009; He and Ma, 2010). However, the present study performs the prediction of greenhouse microclimate using a minimum number of input variables. For the data collection, most of the researches established a specific local weather station rather than the regional weather station to model the indoor climate of a greenhouse (Behrang et al., 2010; Singh and Tiwari, 2017), besides various studies consider the regional weather stations data for their greenhouse indoor climate modeling (Liu et al., 2018; Shi et al., 2018). The other objective of the current study is to predict microclimate using local weather station (near to the greenhouse) environmental parameters as well as the regional weather station data from the zonal weather station.

Literature review

Regression models are more often developed and applied for prediction in fields such as greenhouse microclimate, energy consumption, heat transfer, meteorological forecast, business forecast, and others (Feinberg and Genethliou, 2005). Generally, MLR model performances include the incorporation of deterministic influences, stochastic influences, and exogenous influences. Researchers considered standard errors as the dominant central point for evaluating regression models. Taki et al. (2016) utilized an MLR model to predict the temperature, humidity, soil temperature, and soil moisture level of a greenhouse in Iran. That study proves that the regression model is capable of making accurate predictions with minimal root mean square error (RMSE) and a higher coefficient of determination (R^2). Likewise, several studies that employed MLR techniques for their predictions (Davis, 2003; Zhao and Xue, 2010).

Most climatic-based variables follow a series type of wave correlated to time so that the time series forecast models could contribute to series based predictions. Moving average, exponential smoothing, and autoregressive integrated moving average (ARIMA) are frequently used techniques in prediction, which performed by past observations; ARIMA is more prevalent among time-series predictions (Khashei and Bijari, 2011).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21412161

Hasni et al. (2010) designed an ARIMA model to predict the temperature flow of a greenhouse. In that study, various time series models were utilized and stimulated to predict the greenhouse temperature from 11 days of data. That literature concluded that the ARIMA models could efficiently produce a better forecast for long seasonal time series with high frequency. However, these models could not provide an exact forecast, which could be considered as a supplemental tool for environmental planning and decision-making for a seasonal based prediction.

In recent years, the development of advanced software technologies creates a platform to govern and analyze big data using a computational approach, which includes; artificial neural networks (ANN), convolutional neural networks (CNN), etc. ANN model is a robust computational method for classifying flow data, which may perform well for solving non-linear problems using their inner-parallel architecture (Atia and El-madany, 2017). Capabilities such as self-adaptive strategy, data-driven, extract the relationship between the inputs and outputs of a process, etc. makes ANN-based modeling as valuable and attractive for non-linear data predictions (Neshat et al., 2011). ANN models used with several algorithms including; multilayer perceptron (MLP), Support Vector Machine (SVM), backpropagation (BP), etc. which are included with or without various transfer functions. The performance of the models differs according to the description of the problem, target data, and processing time. MLP algorithm is popular among ANN models to solve various aspects of microclimatic prediction problems (Dombayci and Gölcü, 2009; Taki et al., 2015; Leopold et al., 2016). Since the MLR models have the capability to self-learn during the training, most of the studies are successful and statistically significant in terms of various error checking methods such as RMSE, Mean absolute error (MAE), and mean squared error (MSE).

Though there were performance tests between regression and ANN models in several researchers, most of the comparative studies have been carried out between the physical models and ANN models or else time series models and ANN (Taki et al., 2015, 2016; Hande et al., 2016; Nury et al., 2017). For instance, Taki et al. (2016) study made a comparison between the dynamic model and MLP model to predict the air temperature and roof temperature of a greenhouse and his literature concluded that the performance of MLP (ANN) model was better than the other models based on the small RMSE and mean absolute percentage error (MAPE). Mehdi et al. (2013) carried out a study about the accuracy of the prediction model between ANN, adaptive neuro-fuzzy inference system (ANFIS), and regression model and concluded that the MLR models are better in terms of simple and straightforward statistical methods then ANN. The efficiency of any model improved by the addition of more relevant input variables along with normalization. The current study used limited input details with non-preprocessed data.

Materials and Methods

Experimental site, materials and data collection

The study was conducted in a greenhouse facility, which maintained by the smart farm research center of Gyeongsang National University, South Korea, with GPS coordinates N35°09′09″, E128°05′44.99″ (Google earth). A flat arch-shaped, 2-layer polyethylene covering with 0.1 mm and 0.075 mm thickness patched, UV-Resistant greenhouse was used for this research. The dimensions of the greenhouse are shown in *Figure 1* with more details. The greenhouse was entirely operated by a UBN Farmlink™ v 3.0 (South Korea) farm management technology that collects and stores the data from the sensor node. A

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21412161

wireless sensor node, which shown in *Figure 2* was utilized to record the temperature and humidity data. In this research, two sets of temperature, humidity sensors were placed in the front and backside of the greenhouse which is displayed in *Figure 1*. The control system of the experimental site has three major parts that are the network controller, actuator, and wireless sensor nodes. All the electronic devices and data loggers were calibrated to minimize the device errors before the starting time of the experiment.

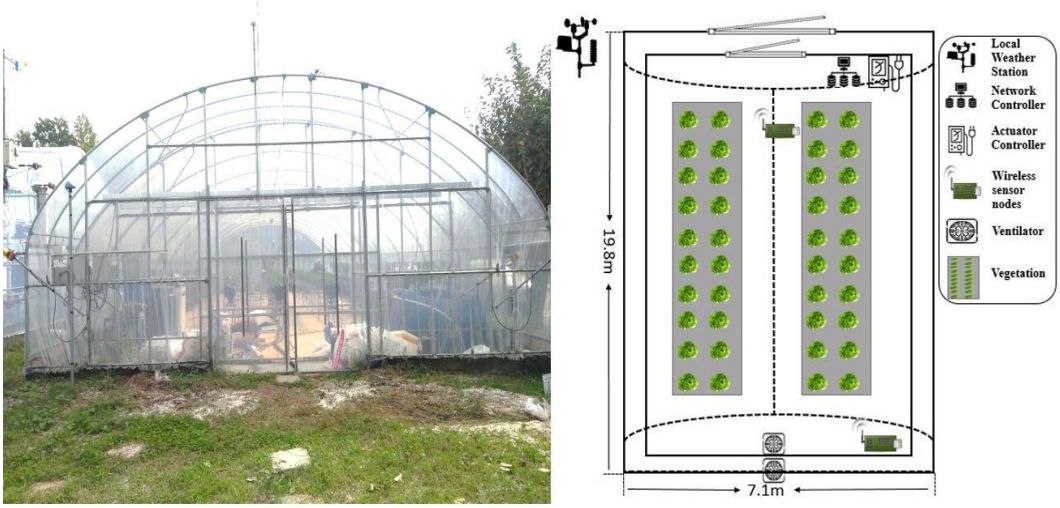

Figure 1. *Image of the experimental greenhouse and layout of the experimental setup*

Figure 2. *Images of local weather station, network controller with the data logger, wireless sensor nodes used in the experimental site*

A weather station which is contiguous to the greenhouse (Campbell Scientific, United States) comprising a data logger (LoggerNet 4.0) displayed in *Figure 2*, managed the acquisition of local weather data. The data collected from the local weather station was considered as 1st outdoor parameter. The regional weather data for the above-mentioned coordinates were collected from the Korea meteorological administration office, Seoul, South Korea. That data considered as 2nd outdoor parameter. The present study used both regional weather station data as well as local weather station data for prediction. This

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21412161

outdoor parameter 1 and 2 were considered as independent parameters, while indoor temperature and humidity were used as dependent variables for the entire prediction model. Temperature, humidity, temperature - humidity index, and solar radiation intensity data are considered input data sets for this experiment. The data loggers record data every 10 min interval in the period between April 2018 to January 2019; 70% of the data were used for training, and 30% used for validation. South Korea has four distinct seasons, which are spring (March-May), summer (June-August), autumn (September-November) and winter (December-February). During the summer period and autumn period the strawberry plants were grown on the experimental greenhouse. Since there is no particular climatic season for rainy or monsoon in the current region, the rainy days were considered based on the regional metrological report. Also, there are no simultaneous rainy days during this both period, so that 5 different days of every season from the validation data sets were considered as the rainy period data sets to find the performance of the model during that particular period. In June (2018), 5 days was selected as a rainy (for summer season) data (from 11^{th}–15^{th}). During that period the average air temperature was 21.8°C (19°C-27°C) and the average rainfall of the month was 70.42 mm. For the rainy days model validation in the winter season was considered from November (1^{st}–5^{th}). During that period the average rainfall of the month was 32.9 mm, and the average temperature was 10.9°C (8.3°C-12°C). All neural network models used for this study were designed by using MATLAB (R2018b (Version 9.5), Mathworks, USA) software. Likewise, all other statistical analysis works were done with IBM SPSS Statistics (version 26, IBM, USA) and OriginPro (version 9.0, Originlab, USA) software packages.

Prediction models

Multiple linear regression (MLR) model

Regression models develop the relationship between the dependent and independent or response variables involved in the process. Factors such as designing simplicity, comparatively accuracy, and a less amount of input data make the regression model as accessible tools for prediction. The functions of MLR can express by the following (*Equation 1*),

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \cdots + \beta n X n + \varepsilon \quad \text{(Eq.1)}$$

where Y is the response variable (temperature or humidity), β_0, β_1, β_2… β_n - are regression coefficients estimated based on a record of observations, ε refers to the residual (Braun et al., 2014).

Time series model (ARIMA)

The autoregressive integrated moving average model (ARIMA) is the most preferred model in recent times used to forecast metrological parameters, especially in the short-term forecasting area (Murat et al., 2018). The combination of autoregressive (AR) model (p), moving average (MA) model (q) called ARIMA (p, d, q), which is a generalized random walk model. First, the time series is d-differenced to render it stationary. If d =0, the observations are modeled directly, and if d = 1, the differences between consecutive observations are modeled (Patel et al., 2014).

AR (p) is the relationship between the observation and number of lagged information, which can be expressed by *Equation 2*,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21412161

$$X_t = C + \sum_{i=1}^{p} \emptyset_i x_{t-1} + \varepsilon_t \quad \text{(Eq.2)}$$

where X_t is the autoregressive operator of order p, C is the constant, ϕ_i refers to the parameter of the model, x_t is the value that observed at t, and ε_t stands for random error. The MA (q) model calculates the dependency between an observation and a residual error from a moving average model applied to lag observations. The moving average mathematically expressed by *Equation 3*,

$$X_t = \varepsilon_t + \sum_{i=1}^{q} \theta_i \varepsilon_{t-i} \quad \text{(Eq.3)}$$

where X_t is the autoregressive operator of order q, θ_i is the parameter of the model, ε_t is the error term. The combination of the autoregressive and moving average model that expressed in terms of (*Equation 4*),

$$Y_t = c + \sum_{i=1}^{p} \phi_i y_{t-i} + \sum_{j=1}^{q} \theta_j \varepsilon_{t-j} \quad \text{(Eq.4)}$$

where Y_t is the predicted value, c is the constant, ϕ_i is the coefficient determined by AR, and θ_i is the determined coefficient of the MA model. The ARIMA model was used as a prediction model to predict the indoor temperature and humidity for the greenhouse.

Multilayered perceptron algorithm

Multilayered perceptron is one of the commonly used feed-forward layered networks due to its low complexity and its ability to solve the nonlinear criteria. In general, the neural network model is included with various learning adaption techniques. Apart from the input, hidden, and output layer elements, the weights, and bias are the vital elements involved in the process of output layer calculation (Taki et al., 2016). The weights are calculated using the following *Equation 5*,

$$Y_j = \sum_{i-1}^{n} w_{ij} I_i + \beta_j \quad \text{(Eq.5)}$$

where Y_j is the weight values, I_i is the input variables, w_{ij} is the weight between input parameters, and neuron j and β_j is the bias. The structure of the network explained in *Figure 3*.

Next, an activation function is used to generate the output of neurons that is decided according to weight values. Different types of activation functions including log, hyperbolic, exponential, and sigmoid can be used in MLP. The most popular activation function to solve the nonlinear function is sigmoid (Taki et al., 2016), so that the current study used sigmoid as the transfer function of the MLP. The sigmoid transfer function is expressed by *Equation 6*,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21412161

$$f(\theta) = \frac{1}{1 + e^{-\theta}} \quad \text{(Eq.6)}$$

Once each neuron and the transfer functions are calculated, the final output layer which is expressed by the following *Equation 7*,

$$y_k = \sum_{i=1}^{n} w_{kj} f_i + \beta_k \quad \text{(Eq.7)}$$

The next essential framework for performing any ANN model is training the network. The feed-forward back-propagation network undergoes supervised training, with a finite number of pattern pairs consisting of an input pattern and a desired or target output pattern (Taki et al., 2016). Since the back-propagation technique minimizes the cost error function, it is commonly used for training algorithms for MLP. For this study, MLP with the feed forward-back propagation model network was designed in the MATLAB software with various transfer functions and adaption techniques. The single hidden layer including a sufficient number of neurons is capable of predicting non-linear variables with the desired output. Based on past studies, the single-layered MLR with random combinational neuron models were used in these studies.

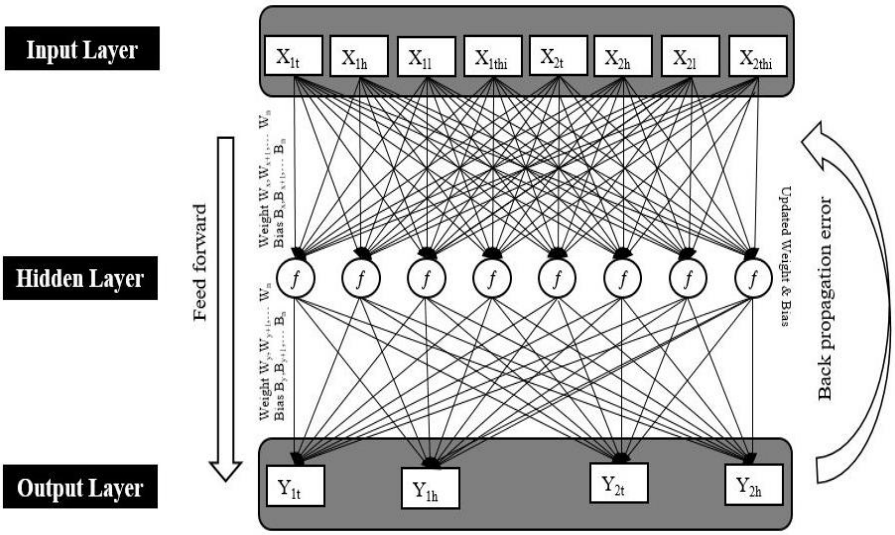

Figure 3. *Structure of the MLP with the function of feedforward and backpropagation method*

Input and output parameter modeling

The data were collected from the local weather station and regional weather station data named M1 (local weather station data combined with the regional weather station data), M2 (regional weather station data), and M3 (local weather station data), which were used as the input variables for the prediction. Four dependent variables were predicted (two temperature variables and two humidity variables) by each of the models using M1, M2, and M3 data sets. The comprehensive explanation of the models, as shown in *Table 1*. These same mixed models used for all of the modeling techniques that are used for the evaluation in this examination.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21412161

Table 1. *Input and output variables of M1, M2, and M3*

Model	Input variables	Output variables
M1	Regional weather station temperature (X_{1t}), Regional weather station humidity (X_{1h}), Regional weather station solar intensity (X_{1l}), Regional weather station temperature-humidity index (X_{1thi}), Local weather station temperature (X_{2t}), Local weather station humidity (X_{2h}), Local weather station solar intensity (X_{2l}), Local weather station temperature-humidity index (X_{2thi})	Indoor temperature (front) (Y_{1t}), Indoor humidity (front) (Y_{1h}), Indoor temperature (back) (Y_{2t}), Indoor humidity (back) (Y_{2h})
M2	(X_{1t},X_{1h},X_{1l},X_{1thi})	(Y_{1t},Y_{1h}) &(Y_{2t},Y_{2h})
M3	(X_{2t},X_{2h},X_{2l},X_{2thi})	(Y_{1t},Y_{1h}) &(Y_{2t},Y_{2h})

Model evaluation criteria

Various statistical indicators were used to evaluate the prediction model. The coefficient of determination can well measure the degree of proximity between the actual data and the predicted values. For a comprehensive evaluation, the results of the models were analyzed by the coefficient of determination (R^2), the root mean square error (RMSE), the mean square error (MSE) and the mean absolute error (MAE) (Lu and Viljanen, 2009). R^2, MAE, RMSE, and MSE can be expressed by the following equations (*Equations 8-11*),

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(y_i - p_i)^2}{\sum_{i=1}^{n}(y_i - \frac{1}{n}\sum_{i=1}^{n} y_i)^2} \quad \text{(Eq.8)}$$

$$RMSE = \sqrt{\frac{\sum_{i=1}^{n}(y_i - p_i)^2}{n}} \quad \text{(Eq.9)}$$

$$MSE = \frac{\sum_{i=1}^{n}(y_i - p_i)^2}{n} \quad \text{(Eq.10)}$$

$$MAE = \frac{\sum_{i=1}^{n}|y_i - p_i|}{n} \quad \text{(Eq.11)}$$

Results and discussion

MLR model results

The indoor temperature and humidity data were predicted using MLR. As mentioned earlier, stepwise and feed-forward methods were used during the time of testing. Even though the feed-forward method performs very similar to the stepwise approach, the stepwise approach outperforms in predicting the temperature as well as the humidity variables. The overall better performance of the MLR was with M1 in terms of R^2 value, and the evaluation results showed in *Table 2*. MLR prediction has the coefficient of determination 0.955 in M1, while M3 has 0.952. The least value, which was from M2

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21412161

with 0.708 with is 74% lesser than the higher prediction value. Importantly, MAE was similar in M1 (stepwise) and M3 (both stepwise and feed-forward), which resemble the maximum capacity of both the model. The prediction accuracy of M1 for Y_{2t} lower than the M1 (R^2=0.953) when compared to M3, but MSE and RMSE were lower in M3, which cannot be ignorable. All three models were predicted the Y_{2t} lesser than the Y_{1t}. Both M1 and M3 performs well for predicting the temperature variables in MLR modeling with less error with statistical substantiation.

Table 2. *Performance of the MLR analysis*

Predicted variable	Model	R^2	MAE	MSE	RMSE
Y_{1t}	**M1**	0.955	1.23	2.21	1.48
	M2	0.708	2.36	9.29	3.04
	M3	0.952	1.24	2.21	1.48
Y_{2t}	**M1**	0.953	1.21	2.16	1.47
	M2	0.682	2.41	9.80	3.13
	M3	0.950	1.18	2.04	1.42
Y_{1h}	**M1**	0.832	6.12	57.66	7.59
	M2	0.544	8.74	159.56	12.63
	M3	0.823	8.44	122.85	11.08
Y_{2h}	**M1**	0.824	6.85	72.66	8.52
	M2	0.524	9.73	201.48	14.1
	M3	0.812	10.0	167.36	12.93

In the case of humidity prediction, the results were clearly announcing the M1 predictions are better than the other two in terms of all model evaluation criteria. The overall performance ranking of the models for humidity prediction results was the same as the temperature prediction ranking of the models, accordingly M1, M3, and M2 (least). The difference between the highest and lowest performance was 71% in Y_{1h} prediction modeling in terms of R^2. Overall, the maximum R^2 of Y_{1h} was 0.832, which was obtained in M1 with MAE =6.12 and RMSE =7.59. In Y_{2h} prediction, MAE and RMSE were high in both M3 and M2, unlike temperature prediction, especially in M2. More detailed prediction curve, as shown in *Figure 4*. However, the following key points were observed during MLR model evaluation,

- Even though the M1 and M3 performance was similar, M1 successfully helps to make predictions better than the M3.
- Unlike the prediction of temperature variables, the prediction of the humidity variables is less in terms of correlation and evaluation. The detailed results of the MLR models are shown in *Table 2*.

ARIMA model results

The mixed autoregressive and moving average (ARIMA) model prediction performance results shown in *Table 3*. The better performance of predicting Y_{1t} with M1 has R^2=0.959, MAE=0.9, and RMSE=1.16, followed by M3 (R^2=0.95). Even though both M1 and M3 have a similar coefficient of determination but MAE and RMSE were high in M3. Y_{2t} resembled the pattern of Y_{1t} prediction, MAE and RMSE were higher in M1 than the M3. Anywhere of the model, M2 does not over 70% in terms of R^2 value for both temperature and humidity variable predictions also MSE, and RMSE was very high from the other two models. Since this experiment uses the moving average model, the model

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21412161

fits according to the different percentile of the full data set. From the observations, temperature variables fit was the same in all percentile, whereas humidity fit was low at the initial time, and gradually it increases and after 50 percentile. For instance, Y_{1h}'s R^2 was 0.818 in 5 percentile, and it gradually increases up to 70 percentile and its reach to the maximum best fit by the model 0.838. Not only R^2, MAE, and RMSE also been adjusted after percentile of data changes. For M1 obtained Y_{2h} prediction bet fit with 0.821 followed by M3 with 0.796. However, this model was performed well against temperature prediction; nevertheless, humidity predictions have low efficient performance.

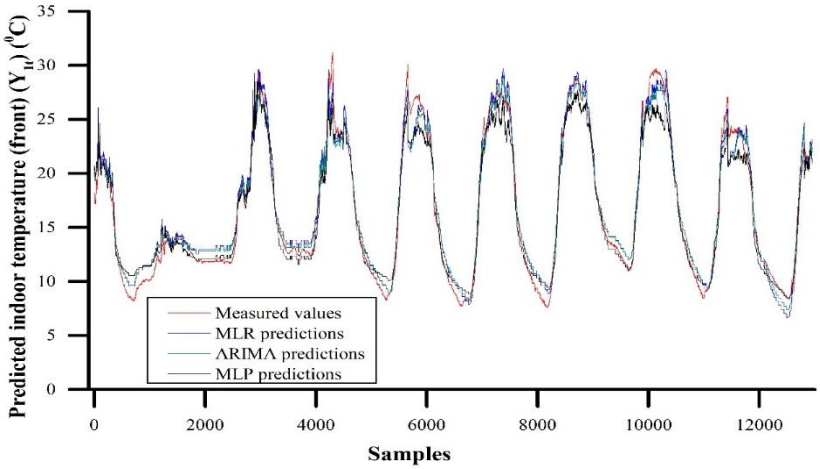

Figure 4. *Comparison of actual data and predicted indoor temperature (front) (Y_{1t}) by MLR, ARIMA and MLP models*

Table 3. *Performance of the time series model analysis*

Prediction variable	Model	R^2	MAE	MSE	RMSE
Y_{1t}	**M1**	0.959	0.90	1.35	1.16
	M2	0.665	2.68	11.20	3.34
	M3	0.958	0.92	1.41	1.19
Y_{2t}	**M1**	0.953	0.92	1.45	1.20
	M2	0.641	2.69	11.20	3.34
	M3	0.952	0.94	1.50	1.22

MLP model results

A multilayered perceptron feed-forward network with a back-propagation training algorithm was developed to predict the desired variables. The back propagation-training algorithm based on the Levenberg-Marquardt (LM) was used to simulate the prediction with more optimization. The transfer function used for this MLP was sigmoid since the desirable variables follow the sigmoid pattern. Still, there is a lack of detailed information

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21412161

regards fixing the hidden neurons, and this examination used random increasing neurons that start from minimum elements. All the random neuron combination results were referred to as *Table 4*. The training algorithm randomly generated bias and weight during this examination. For Y_{1t} prediction, M3 (5 neurons) has the highest performance that is with R^2=0.9793; MAE=0.85; RMSE =1.21 followed by the M3 (15 neurons). In M3 prediction, most of the validation gives better results than the M1 model in terms of R^2. All combinations of M3 have more than 0.96 R^2 values, whereas M1 result from 0.91 to 0.97. The highest evaluation criteria results obtained by M1 was with 20 neurons. Results of Y_{2t} resemble the same pattern as Y_{1t}; M3 model performs a higher than the M1. The top prediction of Y_{2t} variable in terms of R^2 = 0.974 obtained in M3 (30 neurons) with MAE=1.04; nevertheless, M1 prediction has the lowest MAE and RMSE values (MAE=0.95; RMSE=1.3; R^2=0.966) which could not negligible while consider for modeling. The least performance from the M2 models, which are extremely lower when compared to the other two models. Therefore overall performance shows that the M3 has a high R^2, and M1 has a lower number of error values.

Table 4. *Performance of the MLP model analysis with various neuron combinations*

For Y_{1h} predictions, M1 (5 neurons) has the highest R^2 (0.9093) among all other combinations with lower error values MAE=4.72 and RMSE=6.30 followed by 35 neurons set (R^2=0.8592; MAE =6.40; RMSE =8.96) in M1. The top prediction of M3 obtained from 40-neuron combination, but the error values higher than the second and third highest predicted combinations. Prediction results for the Y_{2h} have the highest in M1 (40 neurons) in terms of R^2 was 0.8154, whereas 5 neuron prediction has the lowest MAE=7.66 also it has the least RMSE value. Other than the 5, 10 and 40 neuron combinations, all M1 combinations were performed poor in terms of correlation and determination. The overall results of this model explain that neurons not linearly related to the performance. Maximum iteration was observed during both testing, and cross-validation period was 1000, whereas 400 iteration was the minimum. During the time of making the neuron combination randomly, other neurons combinations also have been tested, for instance, in between to the 5-10 combinations indiscriminately 6 or 7 also used to avoid the lesser accuracy. However, the random test results were not accurate than the highest prediction so that the random combination results not shown in *Table 4*.

Compression between MLR, ARIMA and MLP models

Previous studies prove that traditional statistical models are potential tools for predicting the environmental parameters in a more precise manner (Mehdi et al., 2013); also, several studies developed a high accurate computational model for the prediction (Taki et al., 2015; Shi et al., 2018). According to this results the highest accuracy of predicted values Y_{1t} for MLR, ARIMA and MLP accordingly 0.955; 1.23; 2.21; 1.48 (R^2; MAE; MSE; RMSE), 0.959; 0.90; 1.35; 1.16 and 0.9793; 0.85; 1.47; 1.21. For the Y_{1t} prediction, the MLP model has a higher R^2 and MSE, whereas ARIMA performed well in terms of RMSE and the MAE. MLR has two methods that are stepwise and feed-forward, and MLP has varied the combination of neurons. So according to the variable Y_{1t} MLP model prediction with 5-neuron combination doing the best performance in this examination. Y_{2t} best predictions in MLR, ARIMA and MLP model as follows 0.954; 1.20; 2.14; 1.46 (R^2; MAE; MSE; RMSE), 0.952; 0.94; 1.50; 1.22 and 0.974; 1.04; 1.92; 1.32. Even though R^2 is higher in the MLP model, ARIMA has the lower MAE, MSE and RMSE values that could not be ignored. Unlike temperature prediction, all three models have some limitations while simulating the humidity variables. M1 and M3 performed well during the temperature prediction in any prediction model, whereas for the humidity predictions, M1 help to improve the accuracy of each model. Most of the time, the highest number neurons combination fails to predict the humidity during MLP simulations and their error values were high when the neurons increased. The performance of MLP was 0.9093; 4.72; 39.73; 6.30 (R^2; MAE; MSE; RMSE), other than this model, no other model has no closer output to this model. 0.832; 6.12; 57.66; 7.59 was the performance of M1 in MLR and 0.838; 5.9; 54.96; 7.41 was obtained by the ARIMA. In between the 1000-2000 samples, all the models predicted beyond the limit and at these values impacted most in prediction. All these model performance graphs were displayed in *Figures 4-7*.

In Y_{2h} predictions MLR model performs better than the other models with the 0.824; 6.85; 72.66; 8.52 (R^2; MAE; MSE; RMSE) followed by the MLP 0.8154; 7.87; 121.02; 11.00. The predicted value graph shown in *Figure 7*, particularly at some point in time, the humidity value reached the maximum level, in that cases other than the MLR does not predict the changes. While observing the curves, MLP follows the same pattern but predicted more than the actual peak times. The overall performance of the MLP model

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21412161

was better than the other models except for Y_{2h} predictions in terms of R^2 and error values. The validation results with the post-regression model fit in the sense of R^2 shown in *Figure 8*, though Y_{2t} has some distinguished data scattering, Y_{1t} and Y_{2t} measured data were not much distributed, and it lies on the same level. The effects of non-normalized real-time data visible in evidence of Y_{1h} and Y_{2h} regression from *Figure 8*. From the analysis, error validation, and R^2, the MLP performs higher than the other models used in this literature.

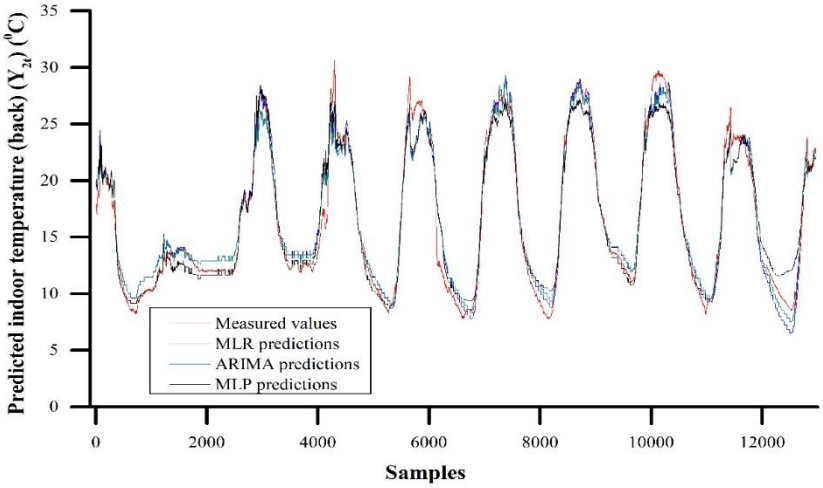

Figure 5. *Comparison of actual data and predicted indoor temperature (back) (Y_{2t}) by MLR, ARIMA and MLP models*

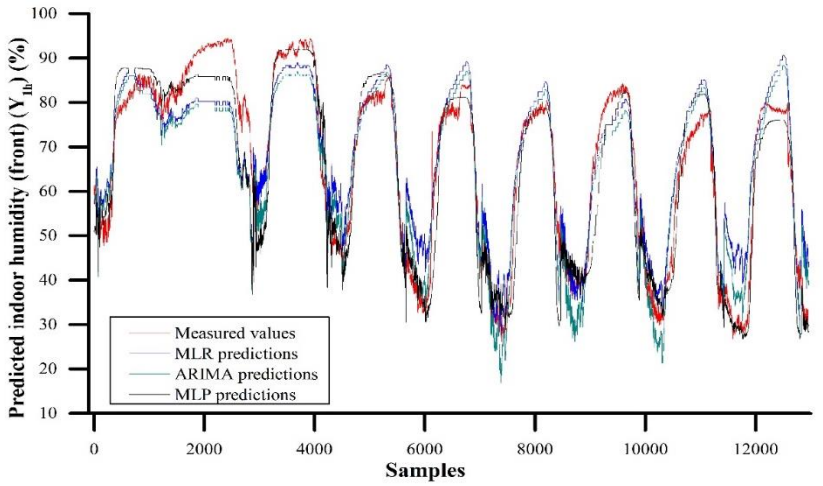

Figure 6. *Comparison of actual data and predicted indoor humidity (front) (Y_{1h}) by MLR, ARIMA and MLP models*

Seasonal based appraisal

According to the model evaluation results, the authentic resulted models were subjected to the seasonal based intensive test. The predicted data sets were separated according to the four seasons, and the results were appraised with the same evaluation criteria which are used for the whole year data sets. From the seasonal based analysis

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21412161

results during the spring period, for Y_{1t} prediction the MLP model outperformed (R^2; MAE; MSE; RMSE: 0.9589; 0.971; 1.765; 1.328) followed by the ARIMA (0.948; 1.111; 2.378; 1.542). In Y_{2t} predictions, the ARIMA performed better R^2 (0.8858) than the MLR (0.8768) model, based on the other criteria (MAE; MSE; RMSE) the MLR model have the lower mean error values (1.067; 2.23; 1.494) than the ARIMA model (1.34; 2.981; 1.726). In terms of R^2 values the ARIMA model followed by the MLP model (0.8814). For the Y_{1h} variable MLP performed better prediction (R^2=0.8447) which was followed by the ARIMA (R^2=0.7989). MLP has the highest R^2 (0.7843) for Y_{2h} among all models. Likewise, for all four seasons the most of MLP prediction has a good correlation with the measured temperature variables (autumn season R^2 for MLP (Y_{1t}=0.9589), summer season R^2 (Y_{1t}=0.8143; Y_{2t}=0.829), winter season R^2 (Y_{1t}=0.8432; Y_{2t}=0.8372)). Even though, in spring season Y_{2t} prediction performed well in ARIMA (R^2=0.8858; MAE=1.348; RMSE=1.726) followed by MLP (R^2=0.8814; MAE=1.215; RMSE=1.653) in terms of MAE and RMS values the MLR has the lower errors (R^2=0.8768; MAE=1.067; RMSE=1.494). Apart from spring season Y_{2t} prediction MLP outperformed in temperature prediction followed by ARIMA.

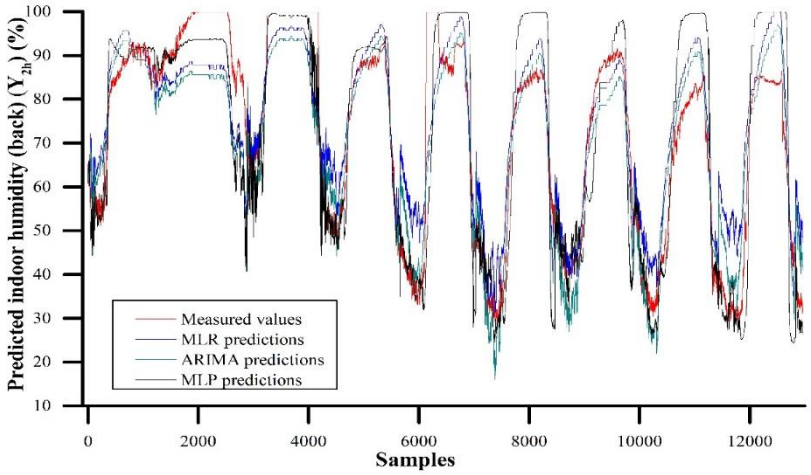

Figure 7. *Comparison of actual data and predicted indoor humidity (back) (Y_{2h}) by MLR, ARIMA, and MLP models*

Unlike temperature predicted data, the humidity predicted variables relationship with measured values was uncertain in MLR and ARIMA. The pattern of humidity prediction results resembles the prediction model results. In all the four seasons, MLP achieved better results (spring season results for MLP (Y_{1h}: R^2=0.8447; MAE=4.568; RMSE=6.378; Y_{2h}: R^2=0.7843; MAE=5.136; RMSE=7.539), summer season results (Y_{1h}: R^2=0.845; MAE=5.150; RMSE=7.187; Y_{2h}: R^2=0.7026; MAE=7.052; RMSE=9.588), autumn season results (Y_{1h}: R^2=0.9040; MAE=4.827; RMSE=6.446; Y_{2h}: R^2=0.8764; MAE=6.935; RMSE=9.045) winter season results (Y_{1h}: R^2=0.631; MAE=4.202; RMSE=4.930; Y_{2h}: R^2=0.471; MAE=5.976; RMSE=7.868)). Even though, the MEA and RMSE values were less when compared with total prediction model results, the R^2 values are less in seasonal based analysis. Especially in the winter season humidity prediction performed less among the all seasons. Moreover the prediction accuracy was higher than the overall all prediction during the autumn season. The coefficient of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21412161

determination values displayed in the *Figure 9* to understand the model prediction accuracy in a comparative manner.

The cumulative validation results of all the three models for the rainy days in winter and summer displayed in *Figure 10*. Among these rainy days' validation, the winter season prediction was better in MLP for temperature and humidity data (Y_{1t}: R^2=0.8773; MAE=0.351; RMSE=0.488; Y_{2t}: R^2=0.7475; MAE=0.940; RMSE=1.000; Y_{1h}: R^2=0.9062; MAE=1.475; RMSE=2.919; Y_{2h}: R^2=0.7413; MAE=6.852; RMSE 6.976) followed by the ARIMA model performed better than MLR. When compared to the entire winter season results the rainy days' prediction has better R^2 values especially for the humidity variables. The humidity predictions were more reliable in MLR models when compared to other models. Even though the ARIMA model has a higher R^2 (Y_{1t}=0.8071; Y_{2t}=0.763) then the MLR (Y_{1t}=0.7927; Y_{2t}=0.7603) model in Y_{1t} and Y_{2t} predictions, the MAE and RMSE were less in MLR (Y_{1t} ; MAE=0.812; RMSE=1.143: Y_{2t} ; MAE=1.320; RMSE=1.863) than ARIMA (Y_{1t} ; MAE=0.868; RMSE=1.251: Y_{2t} ; MAE=1.526; RMSE=2.085). Apart from that, the overall MLP predictions were surpassed than other models.

Discussion

Prediction model

The present study predicted the temperature and humidity of a greenhouse with different approaches. The MLR models are simple and easy to handle; likewise the MLR predicts the temperature variables similar to the other models. Apart from the temperature variables, the MLP (computational model) performs better than the other models. It seems that the scenario of extrapolating beyond the range of the data, regression models face limitations to perform well; it decreases the model reliability. Though several studies developed a prediction model for greenhouse temperature prediction (Lu and Viljanen, 2009), the indoor humidity prediction with neural network models are lacking in literature due to its more complicated mechanism involved that depends on thermal behaviors or temperature prediction. Leopold et al. (2016) developed a neural network model to predict the indoor temperature and humidity with the Indoor temperature (R^2=0.970) and indoor humidity (R^2=0.694). The current study MLP model performed better than the literature mentioned above, in both temperature 1 (R^2=0.9793), temperature 2 (R^2=0.974), humidity 1 (R^2=0.9093) and humidity 2 (R^2=0.8154) prediction. However, the previous study used more input parameters with a large number of parameters; our model performed well with less number of input variables. Previous studies used different input factors to train their model for the highest accuracy, since the variables may affect by the indoor micro-climatic condition such as wind speed, solar radiation, soil moisture, rainfall, etc. (Lu and Viljanen, 2009; Choab et al., 2019). For instance, Taki et al. (2015) predicted the greenhouse indoor room temperature from 9 input parameters, and that study has the R^2 of 0.9941, which is higher than the current study (R^2=0.9793). However, the complexity of the prediction model increased if there are several input parameters while comparing it to our model is simpler than his model. Besides, his study conducted only on indoor

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21412161

temperature, not on indoor humidity. Preparation of data sets, preprocessing and normalizing the input data techniques are involved in mapping the data linearly over a specific range that increases the accuracy of the model. Particularly in models that used with neurons, the activation function can be performed within the limited range of values so that normalized data which ranges from [0, 1] can able to produce meaningful results during the neural network performance (Jayalakshmi and Santhakumaran, 2011; Taki et al., 2015). For instance, Shi et al. (2018) study designed a model for prediction of indoor temperature and relative humidity based on the cloud database by using a back-propagation neural network model. Unlike current literature, that model used improved techniques to train the network. However, that model accuracy was higher than our study (indoor temperature R^2=0.974 and indoor humidity R^2=0.917), the authors have mentioned that the preprocessing of the data during the training time increases the complexity of the model and the simulation time though the accuracy is improved. Our current model has no such kind of limitations including the training and stimulation time since the input variables were limited. This research has done with the aim that not only concluded with robustness and capability of various prediction model; also the extension of this research is to implement the high accuracy model in real-time control devices for the greenhouse control strategy. The current research prompted to analyze without modifying the data that was collected from cloud and sensors so that the entire study utilizes the actual data as the input to train the model also the model validation also conducted in the real-time datasheet. The strawberry plants were grown in the greenhouse during the time of the experiment, and it may affect the humidity very much. Rather than the temperature, humidity can easily be affected by many ways like change in rain amount and ventilation rate of the greenhouse, which are unfortunately not included as input parameters in this research, such limitation predicted both two indoor humidity parameters as a challenging factor (Lu and Viljanen, 2009). The deviation between the affected data and predicted data for especially in humidity prediction is inevitable, which needs attention while these models implement in real-time. When compared to the MLR and ARIMA, MLP learns the distribution of the data in a short period. The seasonal based analysis affirms that the MLP has surpassed performance than other models. Even though the country located in the temperate zone in geographical aspects, the wider temperature difference between summer and winter (much precipitation also occurs during both seasons) made the predictions as an intricate methodology. So that a quickly adaptable algorithm can able to fulfill the short time predictions as the desired manner. Most importantly, while talking about real-time implementation, predicting time is also a decisive factor. This current study MLP model performs quickly than the other models since the input parameters are well formulated.

Input variable model

By comparing M1, M2, and M3 models after post prediction analysis, most of the time M1 (local weather station data combined with the regional weather station data) helps to get more accuracy. During the time of temperature prediction (Y_{1t} and Y_{2t}), M3 performs better among the models used for this research. For instance, during the Y_{1t} prediction, best performance of M3 0.64% higher than the M1's best performance by R^2 comparison and 0.83% higher during Y_{2t} predictions. For Y_{1h} prediction, the M1's highest performance 6.05% higher than the M3's best performance and 1.48% higher during Y_{2h} prediction in terms of R^2 values. While comparing the MAE and RMSE value, during the time of Y_{1h}, M1 has 31% of lesser MAE and 34% of less RMSE values than the M3 model

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21412161

also in Y_{2h} prediction M1 has 31% of lesser MAE and 30% less RMSE than M3. Since the eccentricity between the predicted values and measured values, especially in cases of humidity predictions, these deviations unable to ignored or negligible. The individual performance of the regional weather station data is not up to the mark in this indoor microclimatic prediction, and it performs well if combined with local weather station data. The foremost point of every forecast is to obtain the maximum accuracy prediction so that the addition of regional weather station data has driven the model to higher performance than the normal one, though it was without undergoing any modified with optimized statistical methods such as normalization and sampling.

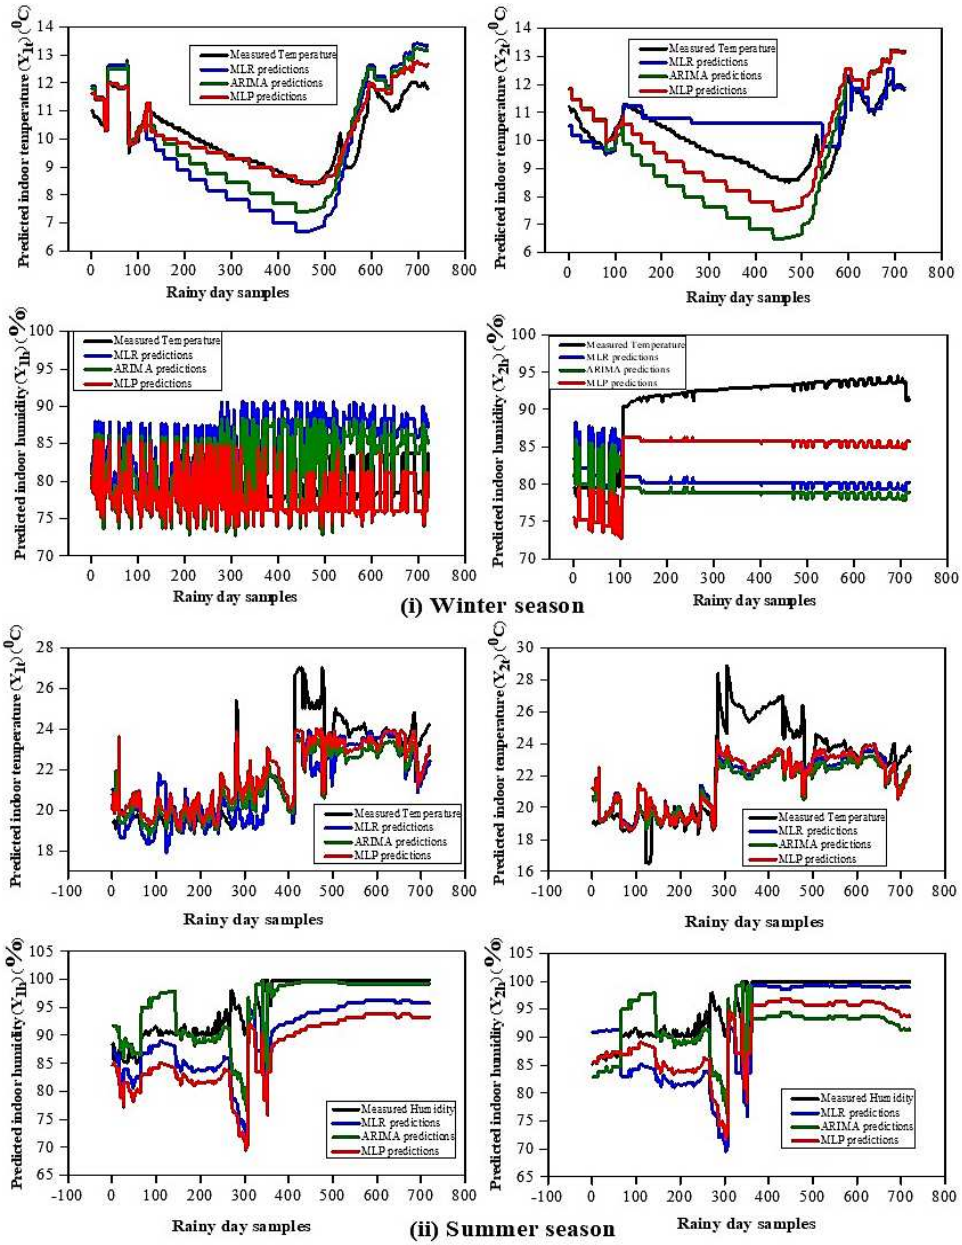

Figure 10. *Comparison of measured data and predicted Indoor temperature (front) (Y_{1t}), Indoor temperature (back) (Y_{2t}), Indoor humidity (front) (Y_{1h}), Indoor humidity (back) (Y_{2h}) by MLR, ARIMA, and MLP models for (i) Rainy days sample in winter season, (ii) Rainy days sample in summer season*

Conclusion

By mimicking the plant behavior according to the environmental growing conditions, the growers can produce better plants and save energy as well. With the use of the temperature controllers, humidification, and de-humidification control capabilities resulting in production of stronger and healthier plants. The current research presents a comparison between physical, time series model, and computational models to select the best method to predict the two indoor temperature parameters and two indoor humidity parameters for a greenhouse from external weather parameters. Also, predicting the indoor parameters with local weather station data and regional weather station data. According to the results, this study concluded with the following salient points,

[1] The results of performance evaluations showed that the regression model and the ARIMA model has incompetent results in particular for humidity predictions and should improve mathematic-experimental equations related to this parameter. For real-time implementation of this model, a fine-tuning and optimization required to strengthen the efficiency of the model.

[2] Either in the physical model or computational model, the addition of regional weather data as input for the prediction model that can increase the accuracy prediction value. Whereas the data addition produces desired output when using the other local weather parameters input data set nevertheless it is less performable when used as an individual input data set.

[3] The MLP (with BB training) model performed surpass then other models for the non-linear variables of greenhouse microclimate. According to the R^2, MAE, RMSE, and MSE evaluations proofing that the superiority in prediction with the MLP model. For the real-time implementation, time consumption for learning and prediction as well needs to consider as one of the primary parameters, which could be possible by the MLP model.

[4] The present study developed a less complicated and fast learning MLP model, which is compatible with the online method, such as cloud-based modeling. In the future, the current model can be integrated into the computer through cloud technology in greenhouse controller devices to achieve better efficiency.

[5] By following this same methodology can develop models to predict soil temperature, soil moisture level, fuel consumption for heating and humidification, and CO_2 emission in the greenhouses. It is possible to use the same try to collect some suitable data related to the above-mentioned parameters and investigate these features. Modeling soil temperature, soil moisture level, fuel consumption for heating and humidification, and CO_2 emission would create more opportunities to utilize the advanced technologies for agriculture and modeling for better crop yield as well as a healthier environment for plants.

Abstract. Accurate estimation of soil water dynamics, soil evaporation and crop transpiration are of great importance to make the best use of water in agriculture. In this study, the EU-Rotate_N model, which had been widely used for water and nitrogen dynamics for vegetables crops, was improved and evaluated for its capacity of simulating soil water movement under the condition of relatively high groundwater table. Rigorous validation of the newly modified model against data from two experiments on lettuce and tomato revealed that the simulated values of soil water content at various depths during crop growth were much better than those computed with the original model, compared with the measured values. The calculated statistical indices of the Nash–Sutcliffe model efficiency coefficient and the model agreement index were 0.556 and 0.808, respectively, for the Lettuce experiment, while the corresponding figures were 0.750 and 0.938 for the Tomato experiment. This indicates that the improvement of EU-Rotate_N model was a success, and the modified model could be used in crop production for water and nitrogen management more widely. Finally, the further improvement of the model to enhance its accuracy of predicting soil water dynamics was discussed.
Keywords: *soil water dynamics, EU-Rotate_N model, agricultural water management, SPAC system, agro-hydrological modelling*

Introduction

Soil moisture is a key variable for understanding hydrological process in the vadose zone. Agricultural and irrigation management practices largely depend on a timely and accurate characterization of temporal and spatial soil moisture dynamics in the root zone because of the impact of soil moisture on the production and health status of crops and salinization (Vereecken et al., 2008; Greenwood et al., 2010; Dogan et al., 2019). Additionally, soil moisture also plays a major role in the organization of natural ecosystems and biodiversity.

Mathematical models are powerful tools to estimate water and nutrients requirement of crops, which is essential information required to devise best farming practices in agriculture. The simulations of agricultural systems for water and nutrient cycles have increased drastically over the last two decades, in line with the development of more powerful hardware and software, and use-friendly interfaces, see reviews by Cannavo et al. (2008) and Kumar et al. (2013). Accurate modeling of water movement is crucially important for agro-hydrological models. Numerous studies on simulating water movement in the soil-crop system have been proposed for various crops grown under

DOI: http://dx.doi.org/10.15666/aeer/1802_21632177

diverse conditions (Ahuja et al., 1993; Brisson et al., 1998; Shaffer and Brodahl, 1998; Šimunek et al., 1999; Rahn et al., 2010; Zhang et al., 2010; Sun et al., 2012; Kumar et al., 2013; Sun et al., 2013; Wang et al., 2013; Mohammad et al., 2014; Karandish and Šimůnek, 2018; Landl et al., 2019). Amongst these models, there were two approaches in simulating water dynamics in the soil. On the one hand, the mechanistic models described the movement of water in the soil by the Darcy's law, and the basic flow equation was solved numerically, as shown in RZQM (Ahuja et al., 1993) and Hydrus-2D (Šimunek et al., 1999) models. On the other hand, empirical approaches were used for soil water movement in agro-hydrological models such as STICS (Brisson et al., 1998), NLEAP (Shaffer and Brodahl, 1998), N_ABLE (Greenwood, 2001) and EU-Rotate_N (Rahn et al., 2010) models. In the empirical approaches the soil was divided into several layers, each with a specific water storage capacity according to the soil texture or its physical properties. Water entering a particular soil layer was stored until the moisture level reached field capacity, with water above this limit draining to the lower adjacent layer, at a rate varying among models. Soil water content at field capacity played a determinant role in the transport of water in the empirical approaches.

Since the algorithms used in the empirical approaches are fairly simple and parameters are relatively limited and easily available, empirical approaches are still widely used in agro-hydrological models for predicting soil water movement (Greenwood, 2001; Zhang et al., 2007, 2009; Pedersen et al., 2010). The EU-Rotate_N model (Rahn et al., 2010), which was developed recently with a similar approach for soil water movement, has shown encouraging results in simulating various crops on different sites under diverse climate conditions (Doltra and Muñoz, 2010; Guo et al., 2010; Rahn et al., 2010; Sun et al., 2013; Soto et al., 2014). Guo et al. (2010) concluded that the EU-Rotate_N model, which was initially designed for the use in European outdoor field conditions, could be applied in typical greenhouse in China without major modifications. Sun et al. (2013) calibrated and validated the EU-Rotate_N model for greenhouse tomato, and found the simulated values of soil water content were in good agreement with measured data. Similar results were also reported in the study by Soto et al. (2014). However, the experiments in the above studies on different crops were conducted under the condition of low groundwater table as the EU-Rotate_N model was originally designed for, and no reports were available on the accuracy of the simulated soil water content for crops grown under the relatively high groundwater table.

The main purposes of this study were twofold: (1) to modify the algorithm for soil water movement in the EU-Rotate_N model to enable it for crops grown under different groundwater conditions, and (2) to evaluate the modified model against data from two field experiments on lettuce and tomato conducted under relatively high groundwater condition.

Materials and methods

Improvements of the EU-Rotate_N model

EU-Rotate_N model was originally designed for simulating water and nitrogen dynamics in the soil-crop system for crop rotations (Rahn et al., 2010). The modules for crop growth and nitrogen requirement were identical with those in N_ABLE (Greenwood, 2001), which was well validated over a wide range of crops. The modules for soil water movement were newly developed. A cascade approach for soil water flow was employed. The algorithm for such an approach was simple, but did not work well

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21632177

universally. For the situations of relatively high groundwater table, modification of the algorithm is essentially required.

In the original EU-Rotate_N model, the soil was divided into 5 cm layers, and a capacity-based algorithm was used to calculate downwards water movement between soil layers (Rahn et al., 2010). In this approach, at any layer, the excessive water above field capacity (θ_{FC}) drained to the layer below, provided that the soil in that layer was not saturated. The amount of water that drains on a given day, Dr_i (mm), was limited by a drainage coefficient, C_{dr}, which accounted for the effect of the soil hydraulic conductivity (Doltra and Muñoz, 2010), i.e.:

$$Dr_i = \begin{cases} C_{dr}(\theta_i - \theta_{FCi})T_i & \theta_i > \theta_{FCi} \\ 0 & otherwise \end{cases} \quad \text{(Eq.1)}$$

where θ_i (cm^3 cm^{-3}) represents soil water content of the layer i, θ_{FCi} (cm^3 cm^{-3}) is the water content at field capacity, and T_i (mm) is the thickness of the soil layer. The drainage coefficient C_{dr} is calculated using the following equation:

$$C_{dri} = (\theta_{si} - \theta_{FCi}) / \theta_{si} \quad \text{(Eq.2)}$$

in which θ_{si} (cm^3 cm^{-3}) is the soil water content at saturation in the layer i.

It has been demonstrated that the above algorithm performed well in predicting soil water content under the condition of deep groundwater table (Wang et al., 2013; Doltra and Muñoz, 2010; Guo et al., 2010; Soto et al., 2014). However, when the groundwater table is relatively high, drainage may not occur in some part of the computational domain. Also, in the event of soil water content in a layer is smaller than that in the layer below for a given soil, no drainage would happen either. Therefore, in order for the model to deal with such situations, alterations of the algorithm for soil water movement of the model are required. In this study, we proposed the following algorithm for computing soil water drainage. The total amount of water drainage between soil layers, for a given soil layer i, was assumed to be the sum of the excessive water above saturation, Dr_{i1}, and the drained water induced by soil water content between field capacity and saturation, Dr_{i2}, i.e.

$$Dr_i = Dr_{i1} + Dr_{i2} \quad \text{(Eq.3)}$$

where Dr_{i1} (mm) is the excessive water above saturation, Dr_{i2} is the drainage amount caused by soil water above field capacity.

$$Dr_{i1} = \begin{cases} (Dr_{i-1}/T_i + \theta_i - \theta_{si})T_i & Dr_{i-1}/T_i + \theta_i - \theta_{si} > 0 \\ 0 & otherwise \end{cases} \quad \text{(Eq.4)}$$

where Dr_{i-1} (mm) is the drainage amount from the soil layer above *i-1*.

The equation for calculating Dr_{i2} (mm) is given below:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21632177

$$Dr_{i2} = \begin{cases} C_{dr}(\theta_{si} - \theta_{FCi})T_i & Dr_{i1} > 0 \\ C_{dr}(Dr_{i-1}/T_i + \theta_i - \theta_{FC})T_i & Dr_{i-1}/T_i + \theta_i > \theta_{FC_i} \text{ and } \theta_i + Dr_{i-1}/T_i > \theta_{i+1} \\ 0 & otherwise \end{cases} \quad \text{(Eq.5)}$$

where θ_{i+1} is the soil water content in the layer below $i + 1$.

Experiments

The experiments on lettuce (Lactuca sativa L.) and tomato (S. lycopersicum) were carried out on the farm of Haitong Times Agricultural Co Ltd, Cixi, Ningbo, Zhejiang province, in eastern China (121.50°E, 30.11°N). The location is 7 km away from the seaside. The soil in the farm is silty loam, with fairly uniform distribution in the profile. The soil physical properties are shown in *Table 1*.

Table 1. *Soil physical properties in the experimental site*

Soil layer (cm)	Texture (-)	Sand (%)	Silt (%)	Clay (%)	Bulk density (g cm^{-3})
0-20	*Silty loam*	48.5	46.8	4.7	1.19
> 20	*Silty loam*	49.1	46.5	4.4	1.45

A fully randomized method was used in the experimental design. The field was divided into 7 experimental plots. The plots for the Tomato experiment were 6 m × 30 m, and the size for the Lettuce experiment was 6 m x 10 m. Lettuce was sowed on 3 June 2014 and harvested on 31 July 2014, while tomato was transplanted on 23 April 2014 and harvested on 15 August 2014. Lettuce was broadcast sowed, having an averaged plant population of 70 plants m^{-2}. Tomato plants were spaced at 30 cm within the row and 60 cm between rows. No irrigation was applied during the experiments, except for a small amount of irrigation in the seedling stage to help plants to develop. Fertiliser management was in accordance with local farming practice which was used for growing the same crops in the farm over the years. Pests control was carried out by conventional pesticides, when it was required. Weeds were managed manually.

Soil volumetric water content was measured with the SM100 sensors (Spectrum Technologies, Inc., Aurora, IL, USA). The SM100 sensors were positioned at the 10, 30, 50 cm depths in both the Lettuce and the Tomato experiments (unfortunately the sensors at the 30 cm depth did not function properly in the Tomato experiment). Since the measurements of soil water content in the soil profile were used for testing the model, it was not necessary to collect data from the depths too close to each other. The selection of soil depths with 20 cm intervals for sensors in this study was according to common practice for similar crop experiments. Sensors were installed in the soil horizontally. Prior to the installations, the SM100 sensors were calibrated using soil pillars with difference water content in the lab according to the product's manual. The volumetric water content data were recorded every 30 min on a Watchdog 1400 data logger (Spectrum Technologies, Inc., Aurora, IL, USA).

Daily air temperature and relative humidity were provided by a local weather station. Solar radiation was automatically measured and recorded every 30 min with a pyranometer (Mod. TBQ-2, JinZhou Sunshine Meteorological Science Co., Liaoning, China). Since the model uses a daily time step, the frequency of every 30 min for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21632177

collecting solar radiation was considered sufficient enough. Rainfall was measured and recorded by Watchdog Data-Logging Rain Gauge (Spectrum Technologies, Inc.). Both solar radiation and rainfall were collected at the weather station installed on the experimental site. The observation of groundwater table was carried out in a well which was dig in the experimental field. The measured values of daily mean air temperature, relative humidity, rainfall and solar radiation are shown in *Figure 1*.

Preparation of model run

Model parameterization

The parameters required to run the modified EU-Rotate_N model were the same as those for the original model listed in Rahn et al. (2010). Basically, the data from soil, crop and weather were required in the simulations. In this study, the model was used for modeling water dynamics in the soil-crop system, and therefore the data given below were only for this purpose.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21632177

The required soil data were fairly simple and limited, including characteristic soil water content at saturation, field capacity and the permanent wilting point. Such a dataset was obtained by applying the Saxton and Rawles' (2006) approach to the measured soil physical properties. Saxton and Rawles' (2006) proposed a set of pedotransfer functions for estimating characteristic soil water content and soil moisture-tension relationships for various types of soils. The derived equations were based on soil texture and soil particle distribution (Saxton et al., 1986), and have been used extensively in previous studies for determining characteristic soil water content and soil hydraulic functions (Fry et al., 2014; Nyeko, 2015).

Crop data used in the EU-Rotate_N model were the dates of crop planting/sowing and harvest, and the durations of the various crop growth stages and their associated dual coefficients for potential soil evaporation and crop transpiration. The durations of the initial, development, middle and late stages for the crop were calculated according to the proportionalities over the entire growth period given in the FAO56 (Allen et al., 1998) for a given crop. Also, the corresponding values of crop coefficient were taken from the FAO56. Thus, on any day during growth the values of potential evaporation and transpiration could be calculated, given the reference evapotranspiration ETo was known. The detailed procedure for calculating ETo was given elsewhere (Allen et al., 1998).

Weather data were mainly used for estimating daily ETo. The weather variables, including daily air temperature, relative humidity, solar radiation, wind speed and rainfall, were all measured in the way described above, and were used directly in the simulations.

Computational domain and boundary conditions

The calculated soil depth in the EU-Rotate_N model was fixed to 200 cm (Rahn et al., 2010, 2007). The soil column was evenly divided into 40 layers with a thickness of 5 cm each layer. The model operated on a daily basis. The upper boundary condition in both experiments was set as atmospheric, i.e. the top soil layer subject to rainfall and evaporation. The lower boundary was specified as the soil below the 70 cm depth in saturation based on the observations. The time of the first measurements and the measured values of soil water content along the profile were used as the starting point and the initial conditions of the simulations.

Model evaluation

To evaluate the ability of the modified model to predict the values of temporal and spatial soil water content, statistical analyses were carried out using the indices of the Nash–Sutcliffe model efficiency coefficient (*NSE*) (Nash and Sutcliffe, 1970), the root of the mean squared errors (*RMSE*) and the model agreement index (*d*) (Willmott, 1981). These indices were used extensively in assessing hydrological models in previous studies.

$$NSE = 1 - \frac{\sum_{i=1}^{n} (Y - Y')^2}{\sum_{i=1}^{n} (Y - \overline{Y'})^2} \quad \text{(Eq.6)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21632177

$$d = 1 - \frac{\sum_{i=1}^{n}(Y - Y')^2}{\sum_{i=1}^{n}(|Y - \overline{Y'}| + |Y' - \overline{Y'}|)^2} \quad \text{(Eq.7)}$$

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(Y - Y')^2} \quad \text{(Eq.8)}$$

where n is the total number of samples, Y and Y' are the simulated and measured values, respectively, and $\overline{Y'}$ is the average of the measured values. For a perfect match between simulation and measurement, both *NSE* and *d* are equal to 1, and *RMSE* is 0.

Results and discussion

For the evaluation of the modified model, both the original and modified models were first run against the same measured data collected from the experiments on lettuce and tomato. The simulated results were then compared to make an objective assessment of the performance of the modified model.

Overall evaluation of the modified model

The overall comparison of temporal and spatial soil water content between simulation and measurement for both Lettuce and Tomato experiments is shown in *Figure 2*, and the quantitative statistical results are listed in *Table 2*. In both experiments, the simulated values are highly correlated with the measured values (*Fig. 2*). The gradient of the best fitted lines is approximately 1 and the intercept is close to 0. The regressions of the simulated values against the measured values give a high R^2 value greater than 0.61. The calculated values of *NSF* and *d* are greater than 0.56 and 0.81, respectively, while the *RMSE* value is smaller than 0.027 cm^3 cm^{-3}. The calculation of *NSF*, *d* and *RMSE* values were also carried out for the simulated results from the original model. The calculated *RMSE* were 0.038 and 0.036 cm^3 cm^{-3} for lettuce and tomato, respectively, greater than those from the modified model (*Table 2*). The values of *NSF* were -1.838 for lettuce and 0.562 for tomato, much worse than those from the modified model. This was especially true for the Lettuce experiment where *NSF* value even went to negative, indicating that the original model was unable to make reasonable predictions. All these indices suggest that the original model performed poorly and the modified EU-Rotate_N model was capable of re-producing measurements of soil water content fairly well. This proves that the improvement of the model was essential and successful.

Detailed comparisons of soil water content between the measured and simulated values with the modified EU-Rotate_N model at various depths in both experiments during crop growth were carried out (*Figs. 3* and *4*). Also shown in the graphs were the simulated results of soil water content from the original EU-Rotate_N model. It is evident that the simulated results from the modified model were far better than those from the original model, compared with the measured values. Not only did the modified model produce the same variation patterns in soil water content, but also the values were in good agreement with the measurements throughout the growing periods. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21632177

original model, on the other hand, failed to produce the results comparable with the measurements. The discrepancies between the measurement and simulation with the original model increased with time, especially at the deeper depths. The principal reasons for the discrepancies were due to the inability of the original model to handle the lower boundary condition of soil at saturation and the inappropriate algorithm for downwards water flow between soil layers. Clearly, *Figs. 3* and *4* demonstrated that the modification of the model was essential to simulate the crops in the present experiments. The work carried out in this study was a significant improvement of the original model to extend its use for modeling water dynamics in the soil-crop system under more diverse conditions.

Table 2. *Statistical indices of the simulated results of soil water content*

Experiment	*RMSE* (cm^3 cm^{-3})	*NSE* (-)	*d* (-)
Lettuce	0.024	0.556	0.808
Tomato	0.027	0.750	0.938

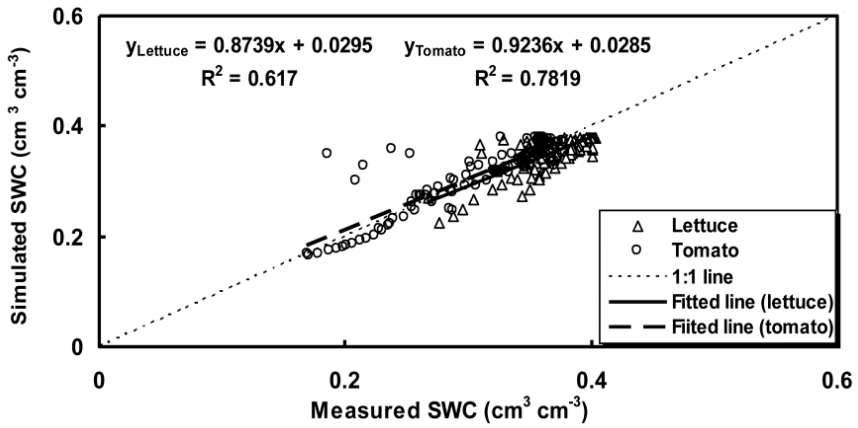

Figure 2. *Overall comparison of soil water content (SWC) between simulation and measurement.*

In the Lettuce experiment soil water content remained high and fairly constant at the 30 cm and 50 cm depth, except for the beginning and towards the end of the experiment (*Fig. 3*). This could be attributed to the fact that during the most period of the experiment the amount of rainwater exceeded the crop evapotranspirational demand. Over the experiment the cumulative rainfall reached as high as 367.6 mm. At the 50 cm depth, the soil was near its saturation throughout the experiment caused by combined effects of excessive rainfall, high groundwater table and the short rooting depth of the crop. Marked changes in soil water content at the 10 cm depth were observed and simulated in the Tomato experiment (*Fig. 4*). Soil water content decreased steadily at the beginning of the experiment due to the dry spell during the period. Big increase in soil water content occurred during the heavy rain period between 16th June to 30th June when an increase of 0.18 cm^3 cm^{-3} was recorded and 0.19 cm^3 cm^{-3} was simulated. High and fairly constant soil water content during 1st July to 10th July was observed for the reason explained in the Lettuce experiment. At the later stages of the experiment there

DOI: http://dx.doi.org/10.15666/aeer/1802_21632177

were 3 dry-wet cycles which coincided with the rain pattern (*Fig. 1*). The changes in simulated soil water content at the 50 cm depth were small, in good agreement with the measurements (*Fig. 4*).

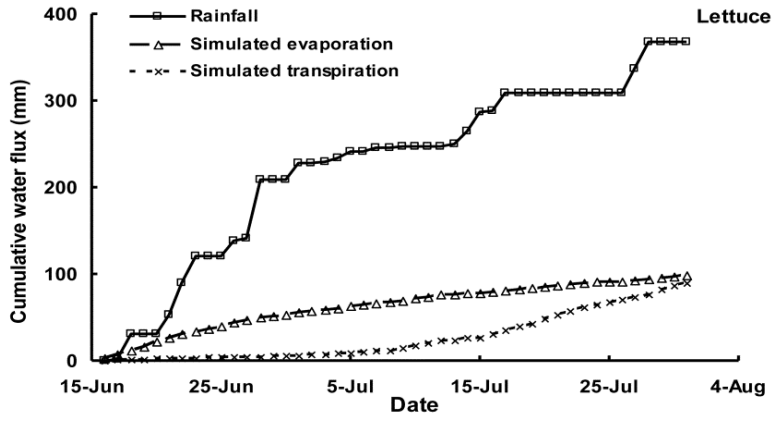
The simulated soil evaporation and crop transpiration

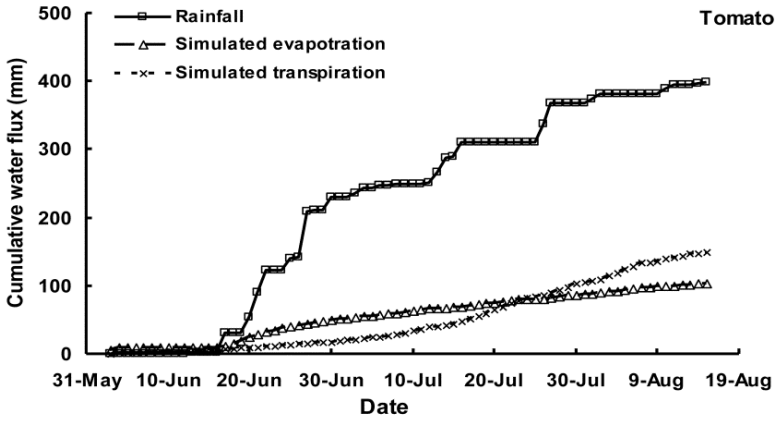
Figure 5 shows the cumulative simulated soil evaporation and crop transpiration during growth, together with the cumulative rainfall. In both experiments, the simulated seasonal evapotranspiration approximately equaled the potential value, suggesting that the crop demand for water for the maximum growth was basically met. This was primarily down to the fact that the experiments were carried out in the fairly wet season. The cumulative seasonal potential evapotranspiration were 188.8 mm and 251.8 mm for the Lettuce and Tomato experiments, respectively, far less than the cumulative rainfall of 367.6 mm and 398.5 mm in the same periods. This indicates that the crop evapotranspiration was mainly met by the rainfall, not so much by the initially stored soil water. High soil evaporation occurred at the early crop development stage (*Fig. 5*). At this stage the ground cover was less intense and thus the evaporation demand was larger. Contrary to soil evaporation, the big crop transpiration happened when the crop

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21632177

was at its mid-season and later development stage. It should be pointed out that due to the combined effects of lack of rainfall (*Fig. 1b*) and the dry soil on the surface (*Fig. 4a*), soil evaporation was neglectable before 16th June in the Tomato experiment even when the crop was small (*Fig. 5b*).



(a)



(b)

Figure 5. *Cumulative rainfall, simulated evaporation and transpiration in the Lettuce experiment (a) and in the Tomato experiment (b)*

Crop water uptake from the rooting depth

It is interesting to quantify the proportions of crop transpiration made by roots in various part of the rooting depth. There have been reports that each quarter of the rooting depth from the surface accounted for about 40%, 30%, 20% and 10% of the total water uptake (Molz and Remson, 1970; Kumar et al., 2013). In both experiments in this study the potential crop transpiration was all basically met (*Fig. 5*), indicating that roots in the various parts of the root zone absorbed the assigned amount of potential transpiration. Since the assignment of potential transpiration was according to the root distribution in the soil profile, the proportion of water uptake in each rooting depth was equal to that of the root distribution. In the EU-Rotate_N model, root distribution was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21632177

normalized in the soil in the manner of $\int_0^1 e^{-\alpha z} dz$ with α being the shape parameter controlling root distribution, z being 0 at the surface and 1 at the bottom of the root zone (Rahn et al., 2010). α was parameterized to be 2 for both lettuce and tomato in the model. This worked out that each quarter of rooting depth from the upmost contributed about 46%, 28%, 17% and 10% of the total water uptake, respectively, in agreement with the experimental evidence by Molz and Remson (1970) and Kumar et al. (2013). The EU-Rotate_N model is a generic model for water and nitrogen management in crop production, and has up-to-data been parameterized for a wide range of crops (Rahn et al., 2010). For all the crops in the model the shape parameter α varies from 1.5 to 3. *Table 3* shows the proportions of roots in each quarter of the normalized rooting depth calculated from different shape parameter values. Broadly they are in reasonable ranges.

Table 3. *Proportion of roots in each quarter of the normalised rooting depth*

α[a]	(0~1/4) RD[b]	(1/4~1/2) RD	(1/2~3/4) RD	(3/4~1) RD
1.5	0.40	0.28	0.19	0.13
2	0.46	0.28	0.17	0.10
3	0.56	0.26	0.12	0.06

Drainage coefficient

A capacity-based algorithm with a single drainage coefficient was used in each soil layer in the simulations of soil water movement in the EU-Rotate_N model. The biggest advantage of such an algorithm is its simplicity, and the values of characteristic soil water content are relatively easier to obtain, compared with the soil hydraulic parameters describing soil water retention and conductivity curves. In this study the drainage coefficient was calculated with *Equation 2,* and the results appeared to be encouraging, as shown in other previous studies (Doltra and Muñoz, 2010; Soto et al., 2014). However, *Equation 2* might not be universally held due to the complexity of the soil, and the EU-Rotate_N model treated the drainage coefficient as an optional model input (Rahn et al., 2010). If possible, the model users should calibrate this parameter to get better results.

The numerical simulations of soil water movement using the Richards' equation are more accurate, and normally involved in complicated numerical schemes such as the finite element method (FEM) and finite difference method (FDM). Recently there was a simplified numerical scheme, named Integrated Richards Equation (IRE) method, proposed and tested in the soil-crop system for water cycle (Yang et al., 2009). This scheme, based on the work by Boone and Wetzel (1996) and Lee and Abriola (1999), applied a simple and explicit FDM approach on each soil layer with a small time step. It has been demonstrated that with a time step of 0.001 d the IRE method could produce the simulated results as accurately as those from FEM. Since the IRE method employed an algorithm similar with that from the capacity-based method, the procedures for modeling water dynamics in the soil-crop system with the basic flow equation were greatly simplified. Such an approach could be utilized in the EU-Rotate_N model in the future so that the model could be more flexible in using different approaches for the simulations of soil water movement.

Conclusions

A simple and effective algorithm has been proposed and tested in this study to simulate soil water movement for the EU-Rotate_N model. The simulated values of soil water content at various depths agreed fairly well with the measurements gathered from two experiments on crops with different rooting depth. Compared with the original model, the modified model with the new algorithm for soil water dynamics has greatly enhanced the accuracy of predicted soil water content. This suggests that the modification of the model was successful, and the model could be used more widely for water management in crop production.

Abstract. One hundred and twenty-six surface diatom samples were analysed to investigate the characteristics of their assemblages and the seawater migration pathway from the inshore waters of the western Bohai Bay. For this task we used correspondence analysis (CA) and discussed the seawater pathway according to the distribution of freshwater diatoms and their abundance. Result shows that a total of 49 species and 32 genera are identified, of which *Cosinodiscus excentricus*, *Cosinodiscus radiatus*, *Actinocyclus normanii* and *Cyclotella stylorums* are the dominant species. The study area is divided into four diatom combination zones. The freshwater diatoms are regularly distributed in the study area and range from 0.48%-13.13%. In the waters south of the Duliujian River estuary, the proportion of freshwater diatoms decreases from south to north, indicating that the water currents tend to move in the same direction. In the southeastern sea area of the Lingang Economic Zone, due to land reclamation and hydrodynamic condition changes, freshwater diatoms are deposited. In the bay north of the Haihe River estuary, coastal currents are characterized by a clockwise circulation.
Keywords: *surface diatom, CA analysis, pathway of currents, sedimentary environment*

Introduction

Bohai Bay is located on the west bank of the Bohai Sea and is a typical semi-closed bay slope; thus, the water exchange capacity is inadequate. After many coastal rivers merge into the inshore waters of the western Bohai Bay, terrigenous sediments have trouble moving to the middle of the Bohai Sea or to the open sea. The coastal land reclamation project along the Bohai Bay has affected the hydrodynamic conditions and ecological environment of the coastal waters (Tu et al., 2017). Four hundred and thirty-two species of plankton have been identified in the Bohai Sea, of which diatoms are the dominant species (Li and Tao, 2000). Diatoms are sensitive to environmental changes and are affected by temperature, salinity, eutrophication, and fluid dynamics (Hendey and Part, 1964; Leroy et al., 2018). Many scholars have studied the ecological and geographical distribution of diatom species and their relationship with the sedimentary environment, but the characteristics of surface diatoms and the formation of diatom combinations vary between regions (Karpuz and Schrader, 1990; Cunningham and Leventer, 1998; Artemova, 2018).

Worldwide, research on surface diatoms in seas has been extensive. Cárdenasa et al. (2019) studied the way diatoms, bulk sediment composition and geochemical proxies

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21792196

respond to oceanic domains and polar to subpolar frontal systems in surface sediments across the Drake Passage. Results show the relevance concerning the composition of surface sediments and ocean productivity, terrigenous input, the intensity of ocean currents, and ice proximity. Weckström and Juggins (2006) explored the relationship between surface sediment diatom assemblages and 15 environmental variables for providing potential means for quality assessments of coastal waters in the Gulf of Finland. In the Canary region, Modern diatom and C_{org} distribution patterns were investigated to quantitatively determine the influence of coastal upwelling and Saharan dust on the flux of sedimentary components (Nave et al., 2001). Hay et al. (2003) used the distribution patterns of diatom microflora in the Effingham Inlet off the west coast of Vancouver Island to determine the impact of coastal oceans on the interior of the Effingham Inlet Fjord. Perez et al. (2018) researched environmental gradients associated with the freshwater input and oceanic water intrusion of the Río de la Plata estuary (RdlP), and assessed diatom species distribution in surface sediment samples related to such environmental gradients. Researchers also investigated the distribution and combination of diatom in the surface sediments of the South China Sea and revealed the sedimentary environment and hydrodynamic changes in the sea; diatom combination are of great significance for tracking water currents and water masses (Ran and Jiang, 2005; Wu et al., 2013). Chen et al. (2019) determined the variation of the distribution of diatoms in surface sediments on the inner shelf of the East China Sea affected by season and typhoon. As for the East China Sea and the Yellow Sea, diatom combinations, as well as their impact on the environment have also been studied (Chen et al., 2000; Wang et al., 2001, 2009). However, at present, most diatom research concerning the Bohai Bay involves sea areas of >10 m isobaths (Shang et al., 2006; Liu et al., 2015). As for the inshore waters of the western Bohai Bay, Shang et al. (2012) studied surface sedimentary diatoms in the intertidal zone and adjacent sea areas, revealing that salinity and depth are essential factors controlling the distribution of diatoms.

Due to the low proportion of freshwater diatoms in Bohai Bay, the study of surface diatoms in that area has mainly concentrated on saltwater and brackish water diatoms, while few studies have been performed on freshwater diatoms (Chen et al., 2014; Xu et al., 2017; Pan et al., 2019). On the western coast of the Bohai Bay, many rivers are developing, thus freshwater diatoms inhabiting freshwater systems are often carried into the sea by those rivers, moving under the influence of tide and currents. The Bohai Bay is Semi-closed, and thus, the freshwater diatoms entering the sea impacts on the diatom species in the sea.

In recent years, large-scale coastal land reclamation projects along the Bohai Bay have changed the original coastline and affected the distribution of diatoms in the sea. Therefore, 126 surface samples were collected from the inshore waters of the western Bohai Bay for diatom identification and analysis. We analysed the characteristics of diatom combinations using correspondence analysis (CA) in the study sea area. Besides, we discussed the seawater pathway in the inshore waters of the western Bohai Bay according to the distribution of freshwater diatoms and their abundance.

Study area

The study area is located in the inshore waters of the western Bohai Bay, China (*Fig. 1*). The water depth ranges from 1 to 10 m in the isobath. Seabed topography tiltes from east to west and the slope is relatively low and flat. There are four types of sediments in the area, including sand, silty sand, sandy silt, and clay silt. The distribution of silt is the most extensive. The particle size has a distribution trend that gradually tapers from north to south and from inshore to offshore (Institute of Marine

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21792196

Geology, Institute of Oceanology, Chinese Academy of Sciences, 1985; Tian et al., 2010; Ding et al., 2019). As a semi-closed inland sea, water temperature, salinity, and other factors are mainly affected by season and freshwater injections (Institute of Marine Geology, Institute of Oceanology, Chinese Academy of Sciences, 1985). The hydrodynamics in the sea are mainly affected by tides, currents, and waves. The current is affected by the warm Yellow Sea current, and the coastal current (Zhao et al., 1995). The study area is adjacent to the lowland plains, and the elevation is generally below 3 m. There are many rivers on the plains that terminate in the sea. From north to south, such rivers include the Jian River, the Jiyun River, the Chaobaixin River, the Yongdingxin River, the Haihe River, the Duliujian River, the Ziyaxin River, and the Shibei River. Most of those rivers are seasonal or sewage rivers, carrying sediment into the sea, and thus, providing a source of sediment. In recent years, land reclamation on the west coast of the Bohai Bay has destroyed the original natural coastline (Wang et al., 2010), which has complicated the current and tide in the region.

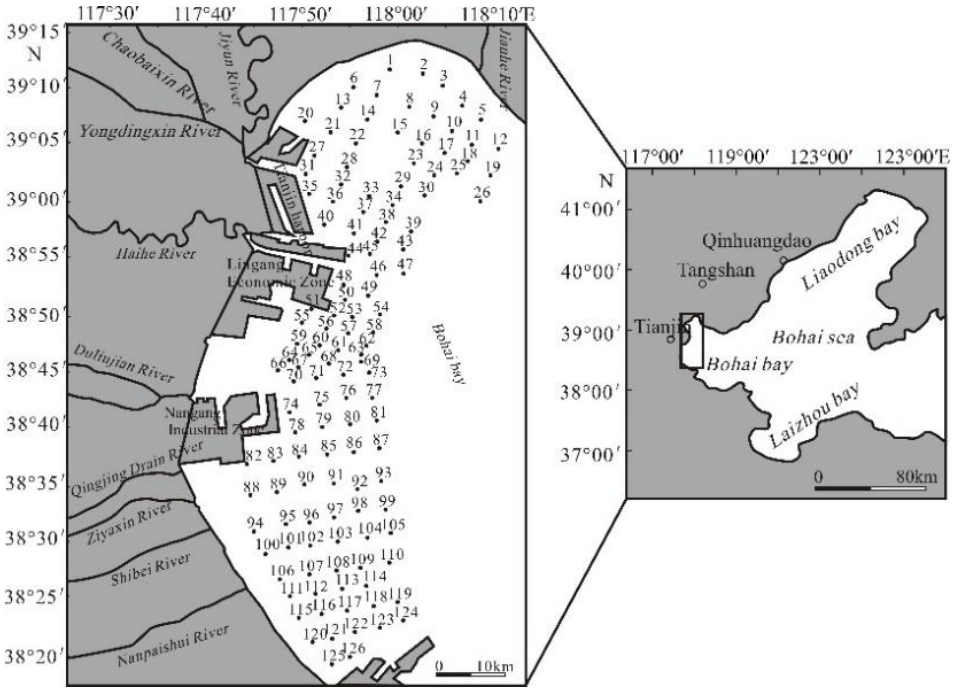

Figure 1. *Sampling sites in the inshore waters of the western Bohai Bay*

Materials and methods

One hundred and twenty-six surface diatom samples were obtained by the Tianjin Center of the China Geological Survey in August 2017 from the inshore waters of the western Bohai Bay (38°21'N- 39°10"N, 117°39'" E-118°11 'E) (*Fig. 1*). Samples were taken with grab or box corer. The top sediments were prepared for diatom analysis according to Renberg (1990) and Smol et al. (2001). Preparation was proceeded as follows: 1 g dry sample was weighed into a 250 mL flask and treated with 10% HCl overnight to remove carbonates. Then, samples were treated with 30% H_2O_2 for 24 h to remove organic material. Next, flasks were incubated with 250 mL distilled water for 24 h to disperse the clay material. The supernatant was then decanted after at least 24 h. The above steps were repeated 3-4 times. Subsequently, samples were adjusted to a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21792196

volume of 50 mL, and 0.5 mL of the solution was dripped onto a coverslip on a hot plate. After drying, the coverslip was placed on a glass slide coated with a neutral balsam to prepare diatom flakes. Approximately 3–4 flakes were generated per sample. Counting was performed with a Nikon 53-1 Nikon optical microscope at 400x magnification and photographed with a Nikon imaging system. For surface sediments, at least 500 diatom valves were enumerated. The absolute abundance of diatoms per station was calculated.

CA was used to analyse the characteristics of diatom assemblages using canoco4.5 software. Due to the low abundance of some diatom species, species appeared in at least two sediment samples and had a proportion of more than 1% in at least one sample were selected for analysis (Bennion, 1994; Hall and Smol, 2010).

Results

Diatom identification

One hundred and twenty-six surface sediment samples were analysed from the study area. A total of 49 species and varieties of diatoms from 32 genera are identified (*Fig. 2*). Saltwater diatoms mainly include *Cosinodiscus excentricus* and *Cosinodiscus radiates*, but also include *Actinocyclus normanii*, *Dictyocha fibula*, *Cyclotella striata*, *Cyclotella stylorum*, *Thalassiosira nizschioides*, *Paralla sulcata*, *Trachyneis aspera*, *Actinoptychus senarius*, *Surirella fluminensis*, *Triceratium favus*, *Eucampia Zoodiacus*, *Nitzschia kerguelensis* and *Navicula clementis*. Brackish water diatoms are mainly *Diploneis bombus* and *Nitzschia granulata*, but also include *Auliscus caelatus*, *Diploneis suborbicularis*, *Diploneis smithii*, *Nitzschia compressa*, *Rhaphoneis surirella*, *Rhaphoneis amphicero*, *Trybliоptychus cocconeiformi*, *Rhopalodia gibberula*, *Grammatophora macilenta*, *Opephora martyi*, *Navicula marina*, *Actinoptychus annulatus*, *Rhizosolenia imbricate*, *Nitzschia lorenziana* and *Dimeregramma minor*. Freshwater diatoms are found in low abundance in 93 stations, including *Achnanthes hauckiana*, *Synedra tabulata*, *Epithemia adanata*, *Pleurosigma normanii*, *Pinnularia nobils*, *Hantzschia amphioxys*, *Navicula radiosa*, *Nitzschia gracilis*, *Gomphonema tumidum*, *Melosira granulata*, *Nizschia amplectems*, *Synedra ulna*, *Nitzschia palea*, *Rhopalodia gibba*, *Ellerbeckia arenaria*, *Eunotia valida* and *Gyrosigma acuminatum*.

The dominant diatom species that can reflect the characteristics of the community, and control the community structure were determined according to the formula of Shen and Shi (2002), shown as *Formula (1)*:

$$Y=n_1*f_1/N \quad \text{(Eq.1)}$$

where n_i is the number of individuals of all species, f_i is the frequency of a given species in each sample, and N is the total number of individuals counted for each sample. A Y value > 0.02 indicates a dominant species.

According to the calculations, four dominant species are found, and all of which are saltwater species, including *Cosinodiscus excentricus*, *Cosinodiscus radiatus*, *Actinocyclus normanii* and *Cyclotella stylorums*. Among those species, *Cyclotella stylorums* is a dominant species from the Duliujian River estuary to the Nanpaishui River estuary, whereas its abundance in other sea areas is low.

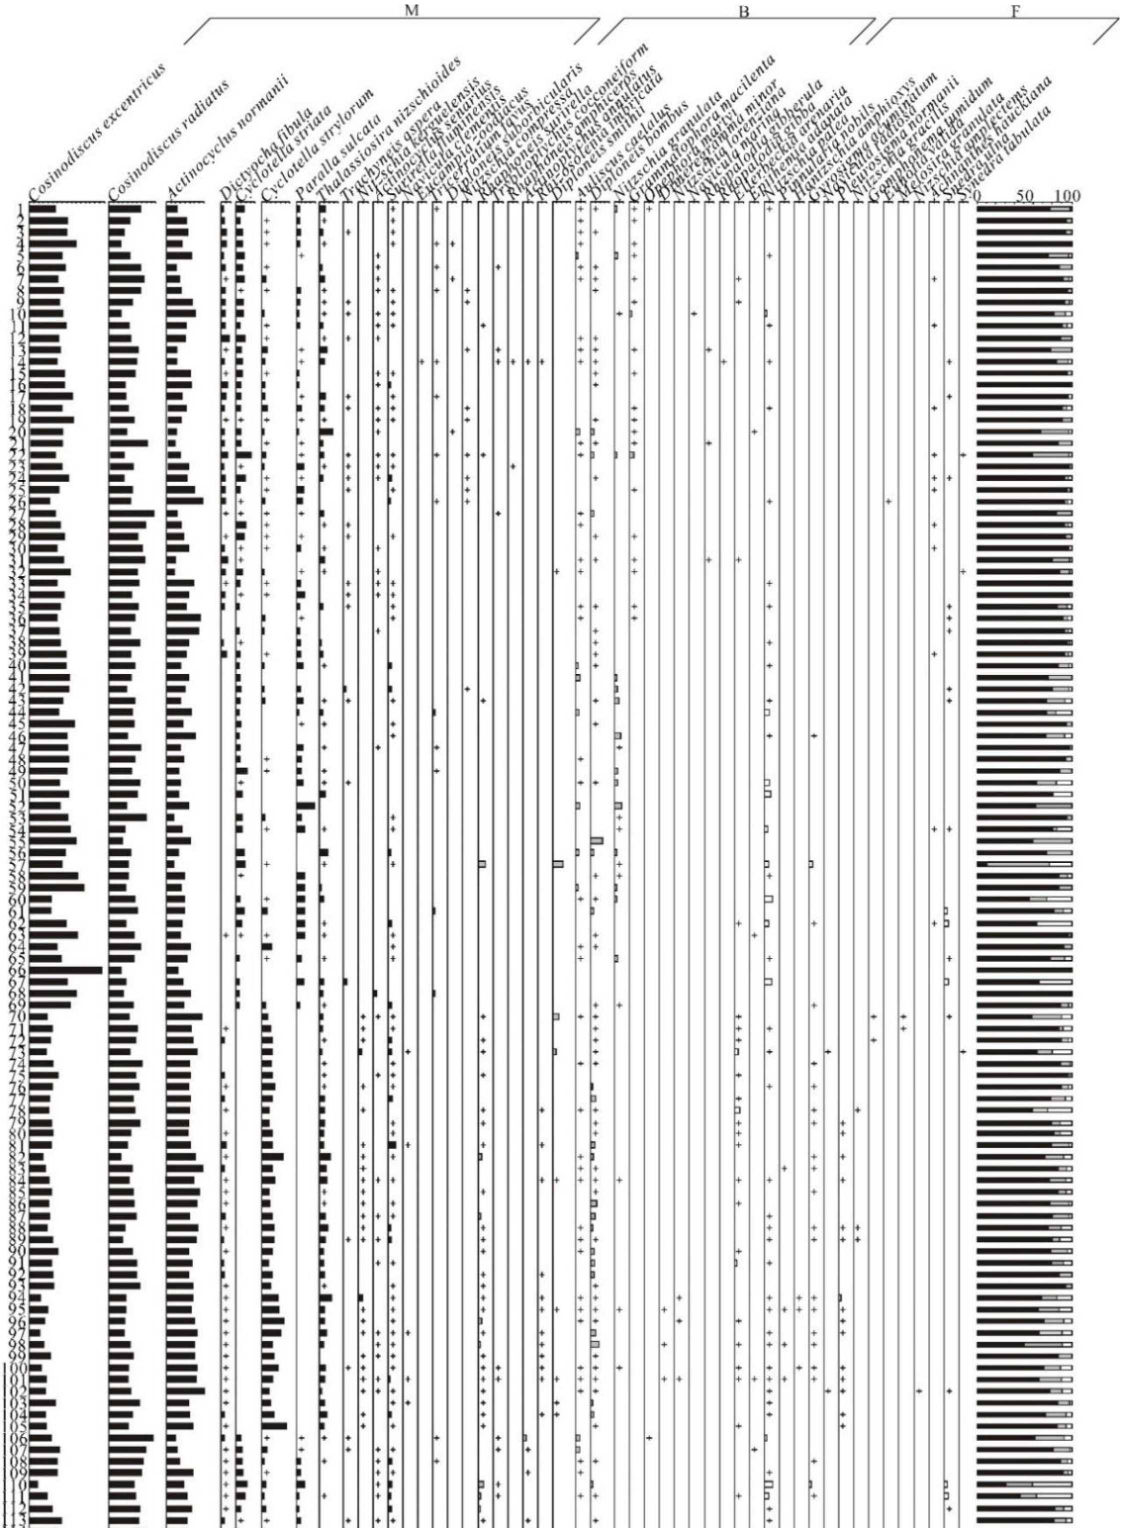

Figure 2. *Species of diatoms in the study area*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21792196

The distribution of diatoms

The distribution profiles were plotted using ARCGIS (ARCGIS version 10.2) according to the diatoms abundance, percentage of saltwater, brackish, and freshwater species at each station (*Fig. 3*).

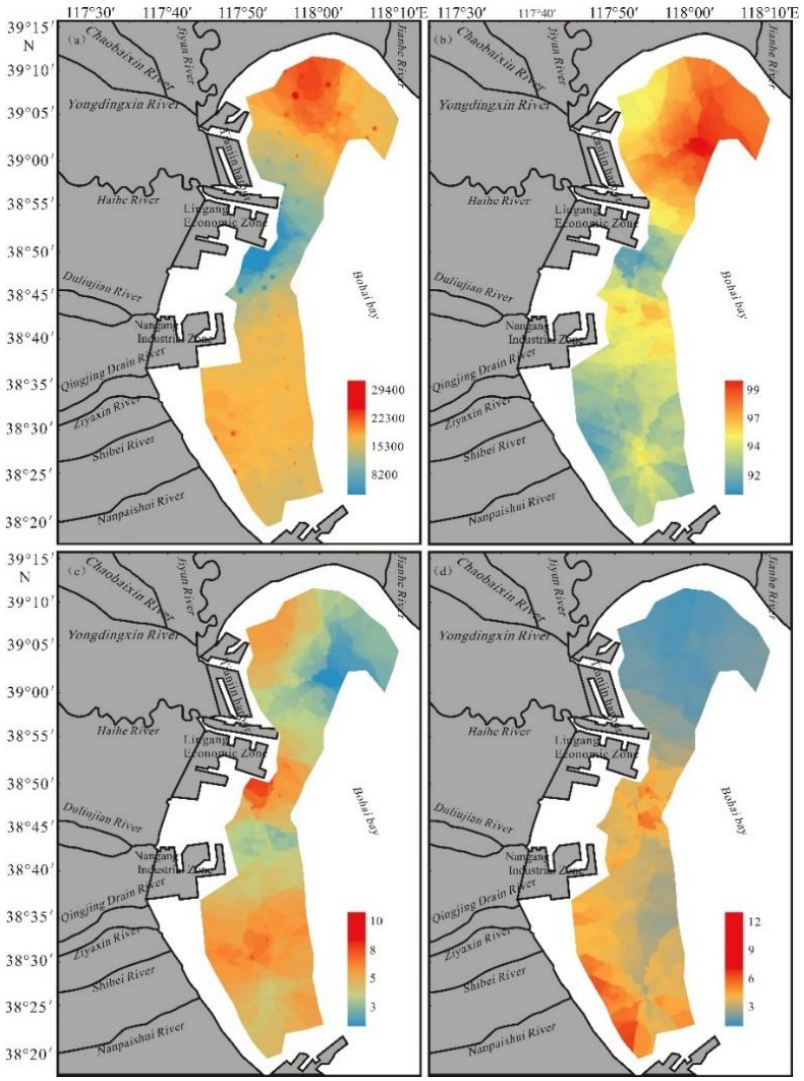

Figure 3. *The distribution of saltwater, brackish water, freshwater species and Diatom abundance in the study area (a- Diatom abundance; b- content of saltwater diatoms; c- content of brackish water diatoms; d- content of freshwater diatoms)*

The abundance of diatoms in the study area ranges from 800 to 30,600 /g, with an average of 12,979 /g. The diatoms in the bay north of the Haihe River estuary are the most abundant. Among the sample sites, the abundance of diatoms at stations 1–3, 6–8, 13–16, 18–19 and 21–22 on the northwest shore reach 15,800–30,600 /g, which is higher than the average of the study area. Diatoms are second most abundant in the sea south of the Duliujian River estuary at 7,000–21,000/g. Diatom abundance in the sea

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21792196

between the Haihe River Estuary and the Duliujian River estuary is the lowest, with a range of 800-20,300/g.

Saltwater diatoms are distributed throughout the study area and have the highest proportion, with a proportion of 72.73% to 100.00%. Saltwater diatoms have the highest proportion in the bay north of the Haihe River estuary, and the proportion from shore to sea direction increases. The proportion of saltwater diatoms in the sea south of the Haihe River estuary is lower than that in the bay north of the Haihe River estuary. Among the sea south of the Haihe River estuary, the stations in the waters adjacent to the Nangang Industrial Zone (stations 64, 71–72, 74–77, 79–81 and 83–87) have a high proportion of saltwater diatoms, ranging from 92.86% to 98.84%. The proportion of saltwater diatoms in other stations is varied and ranges from 72.73% to 100.00%.

The proportion of brackish water diatoms is 0.00%-19.70% in the study sea area. In the bay north of the Haihe River estuary, the proportion of brackish water diatoms tends to decrease from the shore to the sea. The proportion of brackish water diatoms in the western coastal waters of the bay (at stations 1, 6, 13, 14, 20, 21, 22, 27, 31, 32, and 35) is relatively high compared to the inner bay, with a proportion of 3.05%–12.37%. The brackish water diatom proportion at the stations in the inner bay (stations 7–9, 11, 15–18, 23–26, 28, 30, 33–34, and 36-39) is low, ranging from 0% to 1.98%. In the sea south of the Haihe River estuary, the proportion of brackish water diatoms is relatively high in the southeastern sea area of the Lingang Economic Zone (stations 49, 50, 52, 55–57, 59–60, 65 and 70) and the sea south of the Nangang Industrial Zone, compared to the waters adjacent to the Nangang Industrial Zone, ranging from 3.77% to 19.7%. The proportion of brackish water diatoms in the waters adjacent to the Nangang Industrial Zone (stations 66, 67, 68, 71, 75 and 80) is relatively small, ranging from 0% to 1.89%.

The proportion of freshwater diatoms is 0.00%-13.13% in the study sea area. Freshwater diatoms are mainly distributed in the sea south of the Haihe River estuary, with a ratio of 0% to 13.13%, and the proportion decreases from the shore to the sea. The proportion of freshwater diatoms in the sea south of the Shibei River estuary (stations 94-95, 97–98, 100–102, 106, 110–112, 115–117, 119, 122 and 125-126) is the highest, reaching 2.22%–13.13%. Additionally, within that region, the proportion of freshwater diatoms shows a trend of initial decreases and subsequent increases from the shore to the sea. The freshwater diatom proportion in the sea area north of the Shibei River estuary decreased. The proportion of freshwater diatoms in the bay north of the Haihe River estuary is lowest, ranging from 0% to 2.14%. No freshwater diatoms are found at stations 15, 16, 23, 29 and 34 in the inner bay.

Discussion

Characteristics of diatom assemblages

CA was used to analyse the characteristics of diatom assemblages. In the scatter plot of the main taxa in the CA (*Fig. 4*), the locational distribution of diatom species reflects the composition of the major diatom species. The closer the location of the distribution of species in the figure, the closer the relationship between diatom species. The *Fig. 4* shows that the main diatom species are divided into four groups. Group I is the dominant species of diatoms, including *Cosinodiscus excentricus*, *Cosinodiscus radiatus*, *Actinocyclus normanii*, *Actinocyclus senarius* and *Surirella fluminensis.* The freshwater species, *Synedra ulna* and *Nitzschia palea* are also distributed throughout the study area. Group II is mainly brackish water diatoms, including *Grammatophora macilenta*, *Diploneis suborbicularis*, *Nitzschia compressa*, *Trybliоptychus*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21792196

cocconeiformi, *Rhopalodia gibberula*, *Actinoptychus annulatus* and *Auliscus caelatus*, as well as the saltwater diatoms, *Dictyocha fibula*, *Triceratium favus* and *Epithemia adanata*. Group III includes *Cyclotella striata*, *Trachyneis aspera* and *Paralla sulcata*, as well as the brackish water species, *Nitzschia granulata*, and the freshwater species, *Achnanthes hauckiana*. Group IV is mainly saltwater diatoms, including *Cyclotella stylorum*, *Thalassiosira nizschioides*, *Synedra tabulata*, *Ellerbeckia arenaria*, *Gyrosigma acuminatum*, *Nitzschia kerguelensis*, *Navicula clementis*, *Pleurosigma normanii*, *Navicula radiosa* and *Surirella fluminensis*, as well as the brackish water species, *Diploneis smithii*, *Rhaphoneis surirella*, *Diploneis Bombus* and *Rhizosolenia imbricata*.

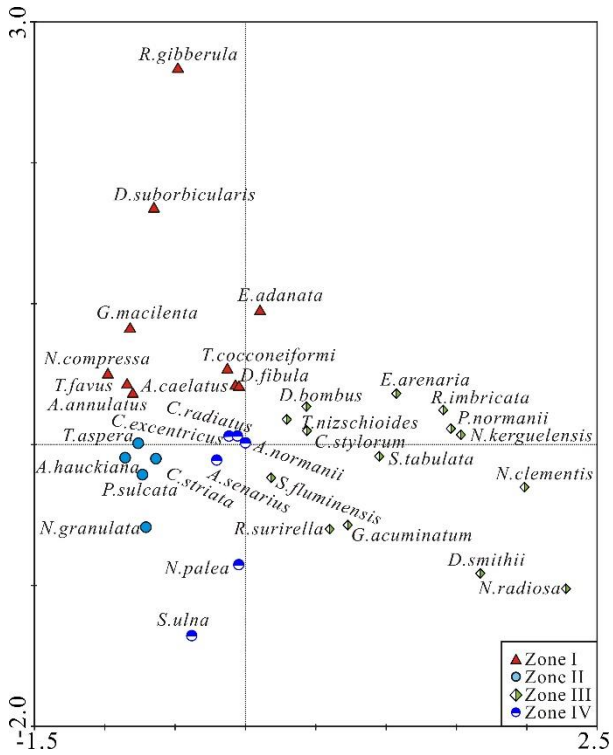

Figure 4. *Scatter diagram of CA main taxa*

Corresponding to the CA scatter diagram of diatom station (*Fig. 5a*), stations containing similar diatom species are distributed in adjacent locations. Therefore, the study area is divided into four diatom combination zone, according to the diatom combination division *(Fig. 5b*). Zone I includes stations 1–32, 34–35 and 38–39. Zone II includes stations 33, 36–37, 40–63 and 65–69. Zone III includes stations 64 and 70-105. Zone IV includes stations 106-126.

Zone I is distributed in the bay north of the Haihe River estuary. The abundance of diatoms in Zone I is 6500-30600 /g, and the average abundance is 15417 /g. *Cosinodiscus excentricus-Cosinodiscus radiates-Actinocyclus normanii* is the dominant diatom combination, with a proportion of 79.67%. The proportion of saltwater diatoms is 86.60%–99.48%, and the average proportion is 96.44%.Among the main saltwater species, *Cyclotella striata*, *Cyclotella stylorum*, *Triceratium favus* and *Paralla sulcate* are inner Bay indicator species (Kazuo and Kiyoshi, 1990; Chiba and Sawai, 2014),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21792196

with a proportion of 9.47%. *Dictyocha fibula* is seawater muddy intertidal indicator species (Kazuo and Kiyoshi, 1990; Chiba and Sawai, 2014), *Thalassiosira nizschioides* and *Actinocyclus senarius* are pelagic indicator species in the ocean (Kazuo and Kiyoshi, 1990; Chiba and Sawai, 2014), with a proportion of 2.94%. The proportion of brackish water diatoms is 0%-12.30%, with an average proportion of 2.92%. Among the main brackish water species, *Rhaphoneis surirella*, *Auliscus caelalus* and *Opephora martyi* are seawater sandy intertidal indicators species (Kazuo and Kiyoshi, 1990; Chiba and Sawai, 2014), with a proportion of 0.78%, *Diploneis bombus* is seawater muddy intertidal indicator species, with a proportion of 0.72%. *Trybliоptychus cocconeiformi* is indicator species of the seaweed field (Kazuo and Kiyoshi, 1990; Chiba and Sawai, 2014), with a proportion of 0.11%. Freshwater diatoms are found in the sea along the Yongdingxin River estuary and the Jian River estuary, ranging from 0.50% to 2.14%. The main diatom species are *Achnanthes hauckiana*, *Synedra ulna* and *Nitzschia palea*. Among those species, *Achnanthes hauckiana* often appeares in the estuary, coastal waters, and land lakes (Hartley, 1996). *Synedra ulna* lives in eutrophic environments with a salinity of less than 2% (Chiba and Sawai, 2014). *Nitzschia palea* can survive in highly polluted and highly corrosive waters (Kosugi, 1988). *Synedra tabulate, Ellerbeckia arenaria, Rhopalodia gibba, Eunotia valida and Epithemia adanata* are also found at individual stations. Among those species, *Eunotia valida* lives in oligotrophic environments (Fontana et al., 2014).

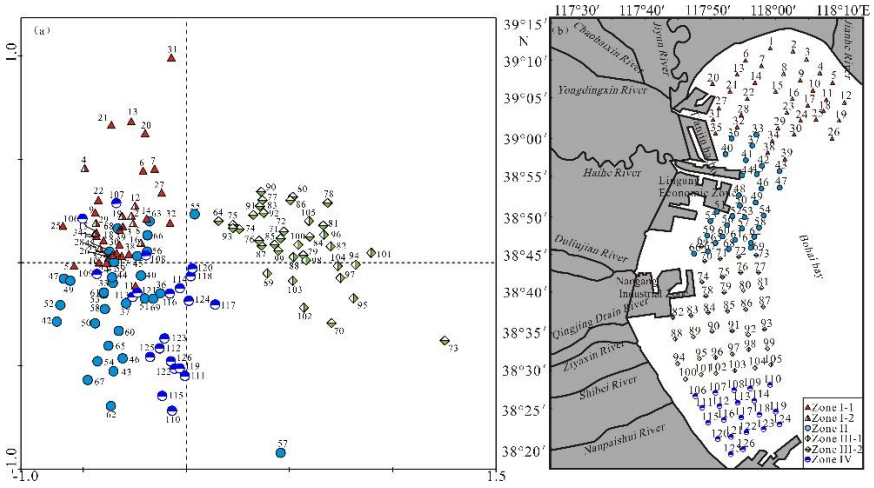

Figure 5. *CA scatter diagram of diatom station and diatom combination zone in the study area (a: CA scatter diagram of diatom station; b: diatom combination zone)*

The freshwater diatom proportion in the sea along the Yongdingxin River estuary is 0.56%-1.53%, with a decreasing trend from south to north. The freshwater diatom proportion in the sea along the Jian River Estuary is 0.50%–2.14%, with a decreasing trend from north to south. A total of 36 diatom species are found in zone I, with the most diversity and abundance in the four diatom combination zones. Because the tidal energy in the northwestern part of the bay is weak, and the barrier effect of the Luan River delta in eastern weakens the energy of the current (Pei et al., 2009). Thus, zone I is abundant in diatoms due to the suitable environment for their survival. According to the proportion of freshwater diatoms, zone I is divided into two sub-zones (I-1 zone and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21792196

I-2 zone). The I-1 zone includes the sea along the Yongdingxin River estuary (stations 1, 6–7, 13–14, 20–22, 27–28, 31–32, 35 and 38–39) and the sea along the Jian River estuary (stations 5, 9–11, 17–18, 24–26 and 30). The proportion of saltwater diatoms in zone I-1 is relatively low, but the proportion of brackish water species is high. In the sea along the Yongdingxin River estuary, the proportion of brackish water diatoms is 0.68%-12.37%, and the average proportion is 4.60%, which is much higher than the average value of zone I. Freshwater diatoms are found in the zone I-1. Due to the influence of the two rivers entering the sea, the maritime nature of area I-1 is weak, and is influenced by the action of the river. Xu et al. (2008) found that there is a low-salt sea area near the intersection of the Yonghexin River and the Jiyun River. The lowest salinity value is 27.21‰ (Xu et al., 2008), which is consistent with the trend in diatom species in zone I-1.

Zone I-2 is distributed in the inner bay (stations 2–4, 8, 12, 15–16, 19, 23, 29 and 34). The proportion of saltwater diatoms in zone I-2 is the highest in the overall study area, and no freshwater diatoms are found. Therefore, zone I-1 is an intertidal zone that is relatively strongly influenced by rivers, while zone I-2 is an inner bay that is not affected by rivers.

Zone II is mainly distributed in the sea between the Haihe River estuary and the Jian River estuary. The abundance of diatoms is the smallest, ranging from 800 to 21,000 /g, with an average abundance of 7,359 /g. *Cosinodiscus excentricus-Cosinodiscus radiates-Actinocyclus normanii* is the dominant diatom combination, with a proportion of 81.74%. The proportion of saltwater diatoms is 72.73%-100.00%, and the average proportion is 93.69%, which is lower than that in Zone I. The main saltwater diatoms include the inner bay indicator species (*Cyclotella striata*, *Cyclotella stylorum*, *Triceratium favus* and *Paralla sulcata*), with a proportion of 9.11%, and the pelagic indicator species (*Thalassiosira nizschioides*), with a proportion of 1.41%. The proportion of brackish water diatoms is 0%–19.7%, and the average proportion is 3.90%, which is higher than that in zone I. The main brackish water diatoms include the seawater muddy intertidal indicator species (*Diploneis bombus*, *Nitzschia granulata* and *Diploneis smithii*), with a proportion of 0.97%, and seawater sandy intertidal indicator species (*Rhaphoneis surirella*, *Auliscus caelalus*), with a proportion of 0.76%. The proportion of freshwater diatoms ranges from 0% to 11.50%, which are distributed throughout stations 33, 36–37, 40, 42–44, 46, 50-51, 54, 57–58, 60–63, 65, 67 and 69. The main freshwater diatoms are *Synedra ulna*, *Achnanthes hauckiana*, *Melosira granulate* and *Gomphonema tumidum*. A small amount of *Epithemia adanata* and *Ellerbeckia arenaria* is also discovered. The proportion of freshwater diatoms in stations 50–51, 54, 57, 60, 62, and 67 reachs 7.68%, which is higher than the average value in zone II.

Since 1967, the Duliujian River has contained a moisture barrier in the downstream estuary, causing serious silting of the river under the water barrier, and resulting in very low annual runoff, which has weakened the river's energy transfer to the sea. Thus, the impact of the Duliujian River on the proportion of freshwater diatoms in zone II is negligible. The sediments in zone II are mainly affected by the Haihe River (Tian et al., 2010; Han et al., 2011). Freshwater diatoms entering the sea are deposited by waves and tides, which are the main reasons for the high proportion of freshwater diatoms. Zone II is the least abundant zone among the three diatom combination zones, with a total of 24 species of diatoms found in zone II. Under the influence of the Haihe River, the salinity of the sea area is lower than that of the surrounding sea area. At the same time, the wave and tidal action of the sea area is dominated by hydrodynamic forces, and the sediments entering the sea are formed fine sand deposits during repeated waves and tides (Pei et al., 2010). Under complex hydrodynamic conditions, diatoms are not easy to preserve

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21792196

due to their friction with coarse particles, which is also the reason for the lowest abundance of diatoms in zone II. Therefore, zone II is an intertidal zone that is affected by rivers and tides.

Zone III is distributed in the sea between the Duliujian River estuary and the Nanpaishui River estuary. The abundance of diatoms is 10400-21000 /g, and the average abundance is 15005 /g. *Cosinodiscus excentricus-Cosinodiscus radiates-Actinocyclus normanii-Cyclotella stylorum* is a dominant diatom combination, with a proportion of 84.82%. The proportion of saltwater diatoms is 72.73%-100%, and the average proportion is 93.69%. The main saltwater diatoms include seawater muddy intertidal indicator species (*Dictyocha fibula*), which have a proportion of 4.67%, and pelagic indicator species (*Thalassiosira nizschioides* and *Actinocyclus senarius*), which have a proportion of 4.39%. The proportion of brackish water diatoms is 0.58%–12.35%, and the average proportion is 4.46%. The main saltwater diatoms include seawater muddy intertidal indicator species (*Diploneis bombus*, *Nitzschia granulata*, *Diploneis smithii* and *Nitzschia lorenziana*), with a proportion of 2.67%, seawater sandy intertidal indicator species (*Rhaphoneis surirella*, *Auliscus caelalus* and *Dimeregramma minor*), with a proportion of 1.48%, and the indicator species of the seaweed field (*Trybliоptychus cocconeiformi*), with a proportion of 0.03%. The proportion of freshwater diatoms ranges from 0.58% to 7.69% and is distributed in stations 70–91, 94–98 and 100–105. Freshwater diatoms in zone III are the most diverse of the four combination zones, reaching 14 species. Additionally, the species of freshwater diatoms change, compared to the zone I and zone II. The main freshwater diatoms are *Nitzschia palea*, *Ellerbeckia arenaria*, *Gyrosigma acuminatum* and *Pleurosigma normanii*. Among those species, *Ellerbeckia arenaria* lives in eutrophic conditions (Fontana et al., 2014) and *Gyrosigma acuminatum* often lives in marsh environments (Chiba and Sawai, 2014; Chen, 2016). *Pinnularia nobils* lives in lakes with salinities of less than 2‰ (Zhang et al., 2012). *Hantzschia amphioxys* are freshwater species that live in alkaline environments (Kazuo and Kiyoshi, 1990; Kashima, 1992), and *Gomphonema tumidum* lives in swamp wetlands (Kazuo and Kiyoshi, 1990; Chiba and Sawai, 2014). *Melosira granulate* lives in eutrophic lakes (Jin, 1982; Kazuo and Kiyoshi, 1990; Kashima, 1992), while *Nizschia amplectems* lives in alkaline marsh wetlands (Kazuo and Kiyoshi, 1990; Kashima, 1992). Few *Synedra tabulate*, *Epithemia adanata* and *Synedra ulna* are found at individual stations.

According to the analysis of diatom combinations, zone III is divided into two sub-regions (regions III-1 and III-2). Zone III-1 includes stations 82, 88–89, 94–98 and 100–105, and locates along the Qingjing drain estuary, the Ziyaxin River estuary and the Shibei River estuary. The proportion of saltwater diatoms in Zone III-1 are the lowest in the study area, ranging from 84.57% to 95.52%. The proportion of brackish water diatoms and freshwater species is relatively high compared to zone III-2, with a proportion of 2.05%–12.35% and 0.75%–4.82%, respectively. Due to the influence of many rivers entering the sea, zone III-1 is strongly influenced by rivers, causing intense mixing of saltwater and freshwater. Thus, there is a low salinity sea area (Xu et al., 2008). Zone III-2 includes stations 64, 70–81, 83–87, 90–93 and 99, and is weakly affected by the river. The proportion of diatoms in saltwater in zone III-2 is higher than that in zone III-1, ranging from 86.89% to 98.84%. The proportion of brackish water diatoms and freshwater diatoms decreases compared to zone III-1, with proportions of 0.58%–9.84% and 0%–7.69%, respectively. Therefore, zone III-1 is an intertidal zone that is strongly affected by rivers. Zone III-2 is a subtidal zone that is weakly affected by rivers.

Zone IV is located in the sea south of the Nanpaishui River estuary and the zone includes stations 106–126. The abundance of diatoms is 7000-20600 /g, and the average

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21792196

abundance is 13795 /g. *Cosinodiscus excentricus-Cosinodiscus radiates-Actinocyclus normanii* is a dominant diatom combination, with a proportion of 74.81%. The proportion of saltwater diatoms is 78.79%–97.14%, and the average proportion is 91.91%. The main saltwater diatoms include the inner bay indicator species (*Cyclotella striata*, *Cyclotella stylorum* and *Paralla sulcata*), with a proportion of 10.51%, pelagic indicator species in the ocean (*Thalassiosira nizschioides* and *Actinocyclus senarius*), with a proportion of 2.97%, and seawater muddy intertidal indicator species (*Dictyocha fibula*), with a proportion of 1.09%. The proportion of brackish water diatoms is 1.48%–9.48%, and the average proportion is 4.37%, which is similar to that in zone III. The main brackish water diatoms include seawater sandy intertidal indicator species (*Rhaphoneis surirella* and *Auliscus caelalus*), with a proportion of 3.03%, and seawater muddy intertidal indicator species (*Diploneis bombus*), with a proportion of 0.79%. The freshwater diatoms in the zone IV accounte for the largest proportion, ranging from 0.65% to 13.17%, and are distributed in stations 106–117, 119–123, 125 and 126. Freshwater diatoms mainly include *Synedra ulna*, *Nitzschia palea* and *Gyrosigma acuminatum*. Few *Ellerbeckia arenaria*, *Pleurosigma normanii* and *Epithemia adanata* are found at some of the stations. After freshwater diatoms enter the sea under the action of the river, a portion of freshwater diatoms are transported offshore by the inertia of the river, and another portion of freshwater diatoms migrate northward under the influence of coastal currents. We find that the proportion of saltwater diatoms in zone IV have a trend of increasing first and then decreasing from the coastal sea to the offshore. However, freshwater diatoms show the opposite trend. In the offshore (stations 108, 109, 110, 119 and 122-123), the proportion of freshwater diatoms increases, ranging from 1.14% to 13.13%, which are more than the coastal sea (stations 107, 118 and 120-121), ranging from 0%-1.55%. However, the species of freshwater diatoms in the offshore sea are similar to the species of freshwater diatoms in the nearshore sea. In addition to normal tidal hydrodynamics, the sea area is also affected by wind and waves on the shore (Pei et al., 2009), which is the reason for the changing trend of freshwater and saltwater diatoms. Therefore, zone IV is an intertidal-subtidal zone strongly affected by rivers.

The main diatom species and sedimentary environments in the study area are summarized in *Table 1*.

The function of freshwater diatoms in the seawater flow pathway

The distribution of freshwater diatoms is consistent with the diatom combination zones. The proportion of freshwater diatoms is the highest in zone IV, and the southern part of zone III (94–98, 100–117, 119–123, 125 and 126), ranging from 0.65% to 13.13%. Under the influence of the river that flows into the sea, freshwater diatoms, such as *Synedra ulna*, *Nitzschia palea*, *Ellerbeckia arenaria*, *Gyrosigma acuminatum*, *Pleurosigma normanii*, *Pinnularia nobils*, *Hantzschia amphioxys* and *Nizschia amplectems* enter the sea. After freshwater diatoms enter the sea, some diatoms are transported offshore by the inertia of the river, and form a sedimentary trend perpendicular to the coastline, while another portion of the freshwater diatom move northward under the action of the current.

Table 1. *Dominant diatom assemblages, proportion of freshwater diatoms and deposition environment in study area*

Zone station	Salt, brackish and freshwater species /%	Main diatoms assemblages /%	Freshwater diatoms /%	Deposition environment
I-1	95.62 3.46 1.10	*Cosinodiscus excentricus* (33.15),*Cosinodiscus radiates* (27.30),*Actinocyclus normanii* (18.09),*Cyclotella striata* (5.19),*Dictyocha fibula* (3.14)	*Nitzschia palea* (0.40), *Achnanthes hauckiana* (0.30), *Synedra ulna* (0.12)	intertidal zone relatively strongly influenced by rivers
I-2	98.31 1.69 0	*Cosinodiscus excentricus* (38.49),*Cosinodiscus radiate* (22.89),*Actinocyclus normanii* (20.85),*Cyclotella striata* (4.44),*Dictyocha fibula* (3.47)	not found	inner bay not affected by rivers
II	93.69 3.90 3.86	*Cosinodiscus excentricus* (39.89),*Cosinodiscus radiates* (23.27),*Actinocyclus normanii* (18.58),*Cyclotella striata* (3.47),*Nitzschia granulata* (1.57)	*Nitzschia palea* (2.49), *Synedra ulna* (0.86), *Achnanthes hauckiana* (0.14)	intertidal zone affected by rivers and tides
III-1	91.36 5.58 3.06	*Actinocyclus normanii* (28.56),*Cosinodiscus radiates* (19.63),*Cosinodiscus excentricus* (19.08),*Cyclotella stylorum* (13.94),*Thalassiosira nizschioides* (5.32)	*Pleurosigma normanii* (0.93), *Gyrosigma acuminatum* (0.72), *Nitzschia palea* (0.60)	intertidal zone very strongly affected by rivers
III-2	94.22 3.78 2.49	*Actinocyclus normanii* (27.58),*Cosinodiscus radiates* (26.95),*Cosinodiscus excentricus* (22.90),*Cyclotella stylorum* (9.83),*Thalassiosira nizschioides* (3.04)	*Ellerbeckia arenaria* (1.26), *Gyrosigma acuminatum* (0.31), *Nitzschia palea* (0.28)	subtidal zone weakly affected by rivers
IV	91.91 4.37 4.12	*Actinocyclus normanii* (27.54),*Cosinodiscus radiates* (26.12),*Cosinodiscus excentricus* (21.15),*Cyclotella striata* (5.24),*Cyclotella stylorum* (2.82)	*Nitzschia palea* (2.51), *Synedra ulna* (1.05), *Gyrosigma acuminatum* (0.44)	intertidal-subtidal zone strongly affected by rivers

The proportion of freshwater diatoms in the central and northern stations of zone III (74-91) decrease, ranging from 0.58% to 7.69%. Compared with the southern sea, the proportion of *Nitzschia palea*, *Ellerbeckia arenaria*, *Gyrosigma acuminatum*, and *Pleurosigma normanii* are decreased, while *Synedra ulna* is not observed in the sea. The proportion of freshwater diatoms in zone II (stations 40, 42–44, 46, 50–51, 54, 57–58, 60–63, 65, 67 and 69–73) increases, ranging from 0.48% to 11.5%. The species of freshwater diatoms in zone II have changed, compared to zone III and zone IV; *Pleurosigma normanii* is not observed in the sea, while *Melosira granulate, Gomphonema tumidum*, and *Synedra ulna*, albeit in low proportions. The proportion of the freshwater diatoms, *Nitzschia palea*, *Ellerbeckia arenaria*, and *Gyrosigma acuminatum* increases, especially in stations 50–51, 54, 57, 60, 62, and 67, reachs 7.68%, which is higher than the regional average in Zone II.

Since 1967, the Duliujian River has contained a moisture barrier in the downstream estuary, causing serious silting of the river under the gate, and resulting in very small annual runoffs, and a weakening the river's water flow to the sea. Thus, the impact of the Duliujian River on the proportion of freshwater diatoms in zone II is negligible. The increase in freshwater diatom proportion in zone II is mainly affected by the land reclamation project along the Haihe River estuary. Due to the construction of the Lingang Economic Zone, the hydrodynamic conditions in the sea near the Haihe River

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21792196

estuary have been changed. At high tide, the flow rate in the southeastern side of the Lingang Economic Zone increased due to local flow, while during ebb tides, the flow rate in the southeastern side of the Lingang Economic Zone is reduced significantly. Therefore, sediments from the Haihe River are deposited, causing changes in the substrate (Nie and Tao, 2008). Also, due to the impact of the reclamation project on coastal currents, the deposition of freshwater diatoms increased in zone II. The freshwater diatoms in zone I are distributed in the sea along the Yongdingxin River Estuary and the Jian River Estuary. The main diatom species are *Achnanthes hauckiana*, *Synedra ulna*, *Nitzschia palea* and *Ellerbeckia arenaria*. Freshwater diatoms in the sea along the Yongdingxin River estuary (stations 1, 7, 14, 20, 22, 27–28, 31–32, 35 and 38–39) ranges from 0.56% to 1.53%, and shows a downward trend from south to north. The freshwater diatom proportion in the sea along the Jian River Estuary (stations 5, 9–11, 17–18, 24–26 and 30) is 0.50%–2.14%. The diatom species are similar to those in the waters along the Yongdingxin River estuary, and shows a decreasing trend in proportion from north to south.

In summary, the changes in the proportion of freshwater diatoms indicated the flow of seawater in the study area (*Figure 6*). In the summer, the current flows from south to north in the sea south of the Diujian River estuary. Due to the influence of the Haihe River flowing into the sea and the influence of the land reclamation project on the tide and currents from the Duliujian River estuary to the Haihe River estuary, the hydrodynamic conditions of the sea have changed. In the bay north of the Haihe River estuary, the current flows from south to north along the west coast, then the coastal current flows along the north coast, and then flows to the southeast, a clockwise water current is formed.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21792196

Conclusions

According to the diatom combinations of surface sediments in the inshore waters of the western Bohai Bay and the distribution of freshwater diatoms, the following results and conclusions are obtained:

(1) A total of 49 species and varieties of diatoms from 32 genera are identified in the study area. Four dominant species are found, and all of which are saltwater species, including *Cosinodiscus excentricus*, *Cosinodiscus radiatus*, *Actinocyclus normanii* and *Cyclotella stylorums*. Diatom abundance in the bay north of the Haihe River estuary is the highest, while diatom abundance in the sea south of the Duliujian River estuary is the second. Diatom abundance in the sea between the Haihe River Estuary and the Duliujian River estuary is the lowest and is affected by the flow of the Haihe River, as well as tides.

(2) All 126 stations are dominated by saltwater diatoms. Saltwater diatoms have the highest proportion in the bay north of the Haihe River estuary. The proportion of saltwater diatoms in the sea south of the Haihe River estuary is lower than that in the bay north of the Haihe River estuary. The brackish water diatoms are mainly distributed in the Yongdingxin River estuary, the sea southeast of the Lingang Economic Zone and the sea south of the Nangang Industrial Zone. In the bay north of the Haihe River estuary, the proportion of brackish water diatoms tend to decrease from the shore to the sea. Freshwater diatoms are found at 93 stations with a proportion of 0.48%, and are regularly distributed in the study area.

(3) According to the diatom combination analyses, the study area is divided into four sedimentary areas. Zone I is distributed in the bay north of the Haihe River estuary and is divided into an intertidal zone (I-1 zone), which is strongly influenced by rivers, and the Inner Bay zone (I-2 zone), which is not affected by rivers. Zone II is distributed in the sea between the Haihe River estuary and Duliujian River estuary. It is an intertidal zone affected by the Haihe River, tides, and tidal currents. Zone III is distributed in the sea between the Duliujian River estuary and the Nanpaishui River estuary. It is divided into the intertidal zone (III-1), which is strongly influenced by rivers, and the subtidal zone (III-2), which is weakly affected by rivers. Zone IV is distributed in the sea south of the Nanpaishui River estuary. It is an intertidal-tidal zone that is strongly influenced by rivers.

(4) Trends in the distribution and abundance of freshwater diatoms in the inshore waters of the western Bohai Bay indicates that the land reclamation project on the west coast of the Bohai Bay affects the tide and water current, which changes the sediment transport direction. In the summer, the currents move from south to north in the sea south of the Haihe River estuary. The construction of the Lingang Economic Zone has changed the hydrodynamic conditions of the local waters, causing the rivers to enter the sea form sedimentary areas in the southeastern waters of the Lingang Economic Zone. In the bay north of the Haihe River estuary, a clockwise water current is formed.

（5）In this paper, we discussed the diatoms assemblage and the seawater flow pathway in summer. In future research we will investigate about whether the diatom assemblage changes with the season and freshwater could reflect the seawater flow pathway in winter.

Abstract. The fact that open water contributes to lowering air temperature is well known in urban landscape planning. Water bodies have been used as tools to reduce the urban heat island effect (UHI). However, the extent to which a water body propagates the cooling effect from the lakeshore is still largely unknown. This study aimed to (1) provide evidence for cooling air temperature on the surrounding urban lakeshore; (2) verify the effect of different land covers surrounding the lakeshore on lowering air temperature; and (3) determine the cooling effects at different distances from the different lakeside areas. Based on urban weather station data and on measured data from Daming lake, Jinan, China, the analytic results reveal significant cooling adjacent to the lakeshore with an average cooling of nearly 1℃ from July to August. Following the air temperature drop, the cooling effect becomes increasingly weaker, reaching the lowest value of 0.3℃ in October. Vegetated area causes more of a cooling effect than permeable or impermeable surface. However, the cooling difference between permeable surface and impermeable surface was less significant. At all measuring sites, the cooling level at a horizontal distance of 40 m from the lakeshore was less than 0.6℃.
Keywords: *urbanization, temperature monitoring, water bodies, cooling effect, vegetated landscapes*

Introduction

Over the past twenty years, urbanization and industrialization have been accelerating in developing countries. Although urbanization and industrialization improves the living-standards of urban inhabitants, these changes bring a series of environmental problems, such as the urban heat island effect, air pollution, and industrial waste (Rizwan et al., 2008; Sun and Chen, 2012; Singh et al., 2017; Li et al., 2018). The urban heat island (UHI) is an increasingly serious problem in many countries. The so-called UHI is simply defined as a metropolitan area that has a warmer near-surface air temperature than its surrounding rural areas (Unwin, 1980; Chang et al., 2007; Su et al., 2012). Aside from the UHI effect on temperature, the UHI has other negative impacts on weather and climate, air pollution, health and welfare, and energy consumption (Rosenfeld et al., 1995).

Water bodies, such as lakes, rivers, ponds, and streams, have the potential to lower surface temperature through continuous evaporation, particularly on sunny days when more water can be absorbed by the air. Each gram of evaporating water absorbs 2500 J and reduces the surface temperature very effectively (Grinzato et al., 2002). In urban landscape planning and design, water bodies are prominent features. They play the dominant role in urban development as well (Ding and Cao, 2004; Cai et al., 2018; Dai

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21972211

et al., 2019). Additionally, urban water bodies are one of the important units of urban ecological systems at the scale of the entire city (Ding and Cao, 2004; Li et al., 2008; Gober et al., 2009; Xu et al., 2010). There have been numerous studies aimed at confirming the effects of water bodies on the UHI in the past few decades, and the data sources to measure urban heat island effect mainly include remotely sensed thermal infrared (TIR) data, in situ data and moving observation data. In recent years, TIR data have been widely employed to retrieve land surface temperature (LST) (Weng, 2009; Guillevic et al., 2014; Li et al., 2014). Sun and Chen (2012) explored the intensity and efficiency of cooling effects of urban water bodies in Beijing city, the LST data were extracted from ASTER images of August 8, 2007, the result showed the mean cooling intensity and efficiency was 0.54 °C/hm and 1.76 °C/hm/ha, respectively. Gupta et al. (2019) found that average temperature drop of 7.51°C and 3.12°C is observed during summer and winter, respectively for three years near the Sukhna Lake in Chandigarh city. However, most of the studies on the impacts of rivers on the UHI are confined to the scale of urban river segment. Moreover, the data were collected by conducting an on-site measurement. Murakawa et al. (1991) reported that the drop in the air temperature above the Ota River, Hiroshima, Japan, reached 5℃ on sunny days in the warmer seasons and that the cooling effect propagated a few hundred meters horizontally and more than eighty meters vertically. Another study based along the River Don, Sheffield, UK, demonstrated that the average cooling effect over the river reached nearly 1℃ when the ambient temperature exceeded 20℃ (Hathway and Sharples, 2012). The above studies are based on microclimatic conditions of an urban river. In addition, limited published studies exist on the cooling effect of water bodies at the urban scale. In the desert city of Phoenix, United States, Gober et al. (2009) found that an increasingly irrigated landscaping lowered night-time temperatures in the urban core. Two other studies revealed that the UHI effect was influenced by the surface area of urban water bodies and their geometry (Sun and Chen, 2012; Oláh, 2012). Additionally, in the city of Dongguan, China, research showed that a negative linear relationship exists between water surface area and decreasing ambient temperature at the spatial scale of 500 m x 500 m cells (Li et al., 2008). However, an analysis of a network of hobby-meteorological observations in the Netherlands showed that an open water surface area brought a significant increase of the 95 percentile of the UHI (Steeneveld et al., 2014).

Because most studies focusing on the relationship between the UHI and water bodies are limited to a river or a few rivers (Gober et al., 2009; Hathway and Sharples, 2012; Du et al., 2016), the literature on the role of a lake or pond in mitigating the UHI is limited. In comparison to a river, the different effect of a lake on mitigating the UHI is evident in many ways. For example, a river usually flows at a certain speed, while a lake is generally still. Compared with the heat absorbed by a river flowing downstream, the processes of heat absorption and emission from a lake's surface occur at nearly the same site. In addition, a lake usually occupies a larger area than a river in a specific block area of a city. As evaporation causes heat absorption from the ambient environment, it leads to a drop of the lake's surface temperature. Therefore, a lake may have a greater potential to moderate the UHI effect than a river in a city. In the planning and design of an urban lake, the designer should therefore not only pay attention to landscape forms and landscape aesthetics but also put more focus on their design's effect on the urban thermal environment, especially the landscape surface effect. Different landscape surfaces have different abilities to reduce the UHI effect. Vegetation and trees can provide shading and cooling through evapotranspiration, as the solar radiation intensity in tree shade is nearly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21972211

10% of the radiation in the open air (Givoni et al., 2003). Conversely, an artificial surface, such as concrete and asphalt, absorbs more heat during the day and release it into the ambient environment, resulting in an increase in the ambient temperature. Therefore, the planner and designer should put some emphasis on the rationality of the land cover.

Although the work discussed above has shown the effectiveness of urban water bodies in mitigating the UHI, the research does not give direct evidence of lowering the ambient temperature in a complex surrounding environment. Furthermore, the efforts of previous researchers are concentrated on how water bodies affect the variation of the surrounding air temperature through evaporation. They do not consider the effect of land cover on the lakeshore and the propagation of cooling from the lake into the ambient environment. Thus, a study evaluating the microclimate effect of a lake on moderating the UHI is necessary. This study will focus specifically on the urban lake because a natural lake or an artificial lake can provide many ecological benefits; it can store fresh water and clean water, recharge groundwater, protect biological diversity, control flooding, and regulate climate (Han, 2006). Thus, the functions of climate regulation that arise from an urban lake should be considered by the urban planner and designer. Meanwhile, it is important to provide the evidence of the potential that urban lakes have to lower air temperature and the extent to which different adjacent land covers affect and propagate cooling. The objectives of this study include (1) providing the evidence for cooling air temperature on the surrounding lakeshore; (2) verifying the effect of different land covers of the surrounding lakeshore on lowering air temperature; and (3) determining the cooling effects at different distances from the different banks of the lake.

Methods

Study area

The study area is situated in Daming lake Park, Jinan, China. Daming lake is a natural lake and the largest lake in Jinan city. The park covers 104 ha, including the water surface area (58 ha) and the land area (46 ha). This lake is shallow, ranging in depth from 1 m to 3.5 m (Wang et al., 2010). The water of four springs converges in the lake through three main water inlets that are situated at the southeast, south, and west bank of the lake. The lake water flows into the Xiaoqing River from the northern water gate and a water outlet. The lakeshore is fringed with shrubs, trees and grass on the ring shape of the lake, and the paved road and the bridges are the main connections between pavilions, the ancestral hall, and other buildings (*Fig. 1a,b*). The temperature difference, which resulted from the UHI of Jinan city, reached approximately 0.56℃ during the day and nearly 2℃ at night in July 2007, whereas the difference rose to nearly 1℃ during the daytime and up to 2.74℃ at night-time in October 2007 (Ran et al., 2010).

Description of measurement sites

Three automatic urban weather stations (UWS1, UWS2 and UWS3) were selected to evaluate the cooling effect of the waterfront of Daming lake. All of the UWS surrounding the study area were situated on the second ring road in the city. The maximum distance from a UWS to the centre of Daming lake was 2.5 km, and the minimum distance was 1.4 km (*Fig. 2*). The GPS coordinates of three UWS are shown in *Table 1*. The sites of the UWS were in built-up areas. Two of them were located in the open square, where the UWS instrument (ZQZ-A, Suzhou, China) was installed adjacent to several trees at a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21972211

height of 1.5 m above the grass lawn. The weather data provided by the instruments included air temperature, relative humidity, atmospheric pressure, wind speed, wind direction, and precipitation. The other UWS was sited on the green roof of a 5-storey building. Its instrument (ZQZ-A, Suzhou, China) was installed at the same height above the green roof to monitor air temperature and precipitation. Weather data were recorded hourly when the instrument worked properly. Additionally, all of the instruments were calibrated every year. Because the altitudes of the three sites were from 36.8 m to 39.0 m, and the altitude of the Daming lake water surface is 23.9 m, the height difference between the three UWS sites and Daming lake was too slight to take into account a lapse rate.

To assess the cooling effect of the lake, three sites (*Fig. 1*) on Daming lake located at the west, south and east bank of the lake were chosen. The conditions of the three measurement sites were similar to those at the UWS in all respects. The GPS coordinates of measure sites are shown in *Table 1*. A type of measurement sites was adjacent to several trees that had some grass and shrub cover. Images of the sites are shown in *Fig. 3-A2*, land surface of B type is permeable, and C type is impermeable. Their images are also shown in *Fig. 3-B2* and *Fig. 3-C1*, respectively.

To estimate the propagation of the cooling effect from the lakeshore to the ambient environment, nine research sites composed of three types of land covers were selected. These land covers (*Fig. 3*) included (1) vegetation, mainly covered by green grass and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21972211

shrubs; (2) permeable paving, paved by holey concrete brick; and (3) impermeable paving, constructed by impermeable concrete brick. Site A1 was located on the western lakeshore, where concrete brick was paved at a distance of 1-2 m from the lake bank. Green grass and shrubs were planted adjacent to the brick far from the lakeshore; the planted area was approximately 20 m×30 m. Sites A2 and A3 were similar in all respects, with green grass, shrubs and trees planted at a distance of approximately 30 m from the lakeshore. A concrete road approximately 3 m wide passes through the green area at a distance of approximately 15 m from the lakeshore. Sites B1 and B2 were smaller scale areas of approximately 15 m×20 m, with willows and other trees at heights of approximately 4 m around them. For site B3, its scale is smaller than that of the two sites B1 and B2, occupying an area of approximately 4 m×15 m with trees and shrubs surrounding it. Sites C1, C2 and C3 were adjacent to the lakeshore. Site C1 was located at the southern gate of Daming lake; it was an open square with a decorated archway and several trees. Site C2 was located at an open place with an area of approximately 30 m×20 m. Site C3 was located at the north bank of the lake, was fringed with several trees, and contained impermeable concrete brick extending to approximately 30 m from the waterfront.

Figure 3. *Images of every site type: a) vegetational site, b) permeable site, and c) impermeable site*

Survey methods

Measurements of air temperature, water temperature and relative humidity were conducted from July to October in 2012, survey times of air temperature and water temperature at the lakeshore focused on 9:00-21:00, and the time of measurement at different lakeshore forms was from 10:00 to 22:00. Measurements of air temperature and water temperature were taken with mercury thermometers (Wuqiang Thermometer Company, Hengshui, China). This thermometer has an accuracy of ±0.1℃ between 0℃ and 50℃ and a resolution of 0.1℃. All of the instruments were calibrated before the surveying period. Measurement campaigns were carried out in the periods of 21-26th July, 15-17th August, 13-16th September and 13-18th October. In the course of temperature measurement, mercury thermometers were shielded with a simple instrument shelter. Air temperature at the lakeshore was recorded 4 times per day (9:00, 13:00, 17:00, and 21:00), and surveying campaigns at different lakeshore forms were performed 4 times per day (10:00, 14:00, 18:00 and 22:00) at 10 m intervals from the lake edge to 40 m away. Water temperature was measured hourly from 9:00 to 21:00. When the surveyor stood at the bank, the mercury thermometer was placed 0.1 m vertically below the water surface. During September and October in Jinan, the prevailing winds were mostly from the northwest to west directions. Wind speed usually ranged from 0 to 3 m/s, so special days

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21972211

in autumn were chosen when wind speed slowed below 1.0 m/s. For evaluating the role of the lake water body and lakeshore form in mitigating the UHI, the surveyor spent more than two minutes to accurately measure temperature at every site. The measurement location was 1.5 m above the ground.

The paired-samples *T*-test was applied for a significance level $\alpha = 0.05$. Thus, if a *p-value* was computed to be less than 0.05, then the temperature difference would be considered statistically significant. The statistical significance (*p*), *t*-statistic (*t*), and degrees of freedom (*df*) are found in the latter data analysis. The effect size (*r*) based on Pearson's correlation is used to measure the strength of the relationship between measuring the lakeshore air temperature and the UWS's.

Results

Role of the urban lake in mitigating the UHI

Part of the purpose of this paper is to assess the cooling effect of the lake, and therefore, we chose the study period between 21st July and 18th October. To estimate the temperature difference between the urban weather stations and the lakeshore, the measuring sites were selected for their vegetation cover. As such, the measuring conditions of urban weather stations (UWS1, UWS2 and UWS3) were similar to that of the lakeshore. The sites of the lakeshore are referred to as A1, A2 and A3, and the temperature differences between the urban weather stations and the lakeshore based on the measurement periods are calculated using:

$$\Delta T_i = T_i - T_{UWS} \quad \text{(Eq.1)}$$

where T_{UWS} is the mean temperature from the three urban weather stations, the index *i* is the reference for the individual lakeshore (A1, A2 or A3), and T_i is the arithmetical mean value of the monitoring data at the same measuring time for every monitoring period. A negative value of ΔT_i indicates cooling adjacent to the lake in comparison to the urban weather stations. *Fig. 4a-d* shows the value of ΔT_i for different time periods at different sites adjacent to the lake. All of the monitored air temperatures are lower than the air temperature at the urban weather stations.

The air temperature varied from 22.7℃ to 30.9℃ during the measuring period in July and varied from 23.1℃ to 31.7℃ in August, compared with a variation from 17.8℃ to 27.6℃ in September and from 14.1℃ to 20.1℃ in October. The temperature difference at different measuring times for one day in July and August is illustrated in *Fig. 4a-b*. During most hours of the day, it was lightly cloudy and the wind velocity varied from 0.3 ms^{-1} to 0.7 ms^{-1}. Analysing the temperature differences at different times, the mean of temperature difference was 1.0℃ and 1.2℃, respectively. The cooling effect was more significant in August than July. At the same time, the highest temperature difference at 9:00 was approximately equal between July (-1.9 to -1.1℃) and August (-1.8 to -1.1℃), and the lowest temperature at 21:00 in July was -0.7 to -0.3℃, compared with August (-0.6 to -0.4℃). Furthermore, temperature differences were also influenced by the measuring location in two periods: in July, the lowest temperature difference was recorded at site A2, where the mean of the temperature difference was 0.7℃, and the highest temperature difference was recorded at site A1, where the mean of the temperature difference reached 1.2℃. The paired-samples T-test result shows the value

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21972211

of t, df, p and r, t (119) =3.50, p<0.05, and r=0.81. Similarly, in August, the level of cooling is lowest at site A2, where the mean of the temperature difference is 0.8℃, while site A1 presents the highest level of cooling, where the mean of the temperature difference is 1.2℃ (t (119) =3.49, p<0.05, r=0.74).

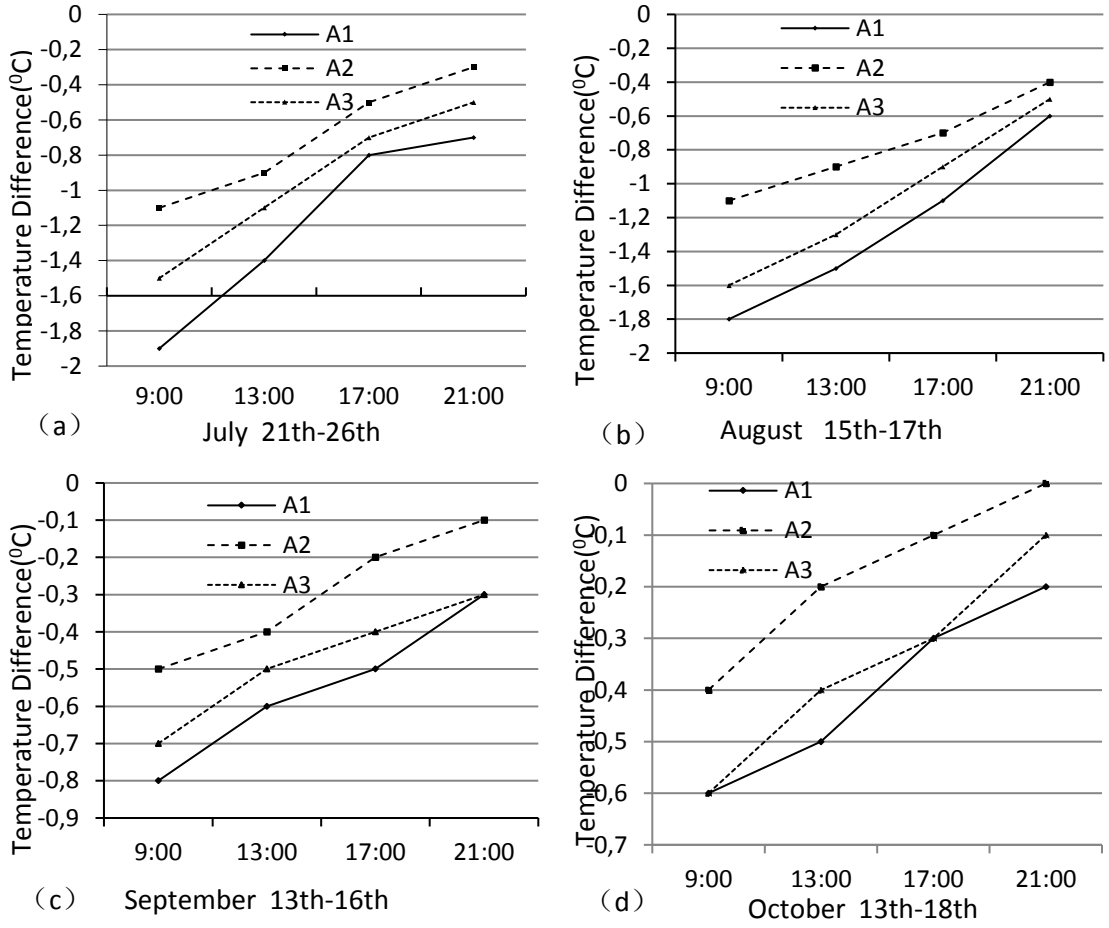

Figure 4. *Temperature differences for different sites at different periods, ΔT is the mean of the temperature differences in each measuring period*

Fig. 4c-d shows the temperature difference at different measuring times for one day in September and October. Calm conditions (0.4-1.0 ms^{-1}) were encountered in the two monitoring sessions, and light cloudiness was observed for the two periods. Likewise, the variation of the temperature difference is similar to that discussed above, so similar conclusions can be derived from the two periods. However, the mean of the temperature difference is 0.4℃ and 0.3℃, respectively, in September and October, so the cooling effect is less significant in these two periods than in the former two. The highest temperature difference arises at 9:00 (-0.8 to -0.5℃ and 0.6 to 0.4℃ in September and October, respectively) and the lowest at 21:00 (-0.3 to -0.1℃ and 0.2-0℃). In September, the lowest temperature difference also arises at site A2, where the mean of the temperature difference is just 0.3℃, and the highest temperature difference is at site A1, where the mean of the temperature difference reached 0.6℃ (t (119) =2.07, p<0.05, r=0.89). In October, the lowest temperature difference is recorded at site A2, where the mean of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21972211

temperature difference is 0.2℃, and the highest temperature difference is calculated at A1, where the mean of the temperature difference is up to 0.4℃ (t (119) =1.12, p>0.05, r=0.90).

The average temperature difference is calculated from the measured data from the three lakeside measurement points (A1, A2 and A3) at 4 different times per day during the study period. The temperature difference between the lakeside sites and the urban weather stations for different observation times is illustrated in *Fig. 5*.

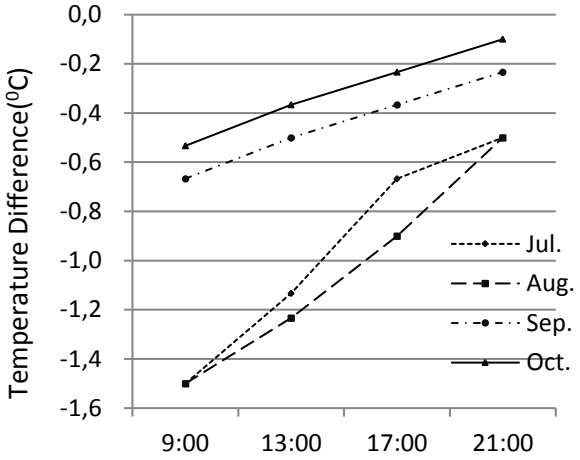

Figure 5. *Temperature differences at different time periods; ΔT is the mean of the temperature differences at the measuring times in each month*

The cooling effect is more significant in July and August than in September and October. The highest levels of cooling are shown in August, and the level of cooling in July is close to that in August, wherein the mean temperature difference is just 0.2℃ lower in August than July. Likewise, the cooling effect is no more significant in September than in October. The mean temperature difference is just 0.1℃ lower in September than in October.

The paired-samples *T-test* is applied to determine if temperature differences are significant among the four month. In terms of the statistics, the p value between July and August is 0.922, which is greater than the α level (α =0.05), so we fail to reject H_0. That is, there is insufficient evidence to claim that the temperature difference may be different from each other in the two month. Similarly, the statistical results show that the temperature differences are insignificant in September and October. However, the statistical result suggests that the temperature difference between August and September is significant, where the p value is less than 0.05. The full statistical results are shown in *Table 2*.

Table 2. *The paired-samples T-test for paired comparisons from July to October*

Pair	M	Std. D	t	df	P
Jul. – Aug.	0.04	3.90	0.10	119	0.92
Aug. –Sep.	-0.55	3.10	-1.93	119	0.05
Sep. – Oct.	-0.14	2.14	-0.70	119	0.48

M is for the temperature difference between the two months. Also shown is the standard deviation (Std. D), the t statistic (t), the degrees of freedom (df), and the two-tailed significance (P)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21972211

Effect of different lakeshore forms on the UHI

The cooling from the lake varies with the different forms of the lake bank, as illustrated in *Fig. 6*, with greater cooling found at the vegetated site and with less cooling at the impermeable site. Furthermore, a higher ambient air temperature contributes to greater cooling from July to October. The air temperature is higher in August than in the other measuring months, and the cooling effect is the most significant. Three type of urban forms (A is a vegetated site, B is a permeable site and C is an impermeable site) are adjacent to the lakeshore. At the A sites in August, the mean temperature difference reached 1.6℃ at 10:00. At the same time, the average temperature difference was just 0.8℃ and 0.6℃, respectively, at the B sites and C sites. Moreover, the level of cooling fell from 10:00 to 22:00. Similarly, a difference in the cooling effect derived from the different lakeshore forms was found in the other measuring months, but the difference of cooling was insignificant between B and C. By October, the difference of 0.03℃ between B and C is negligible.

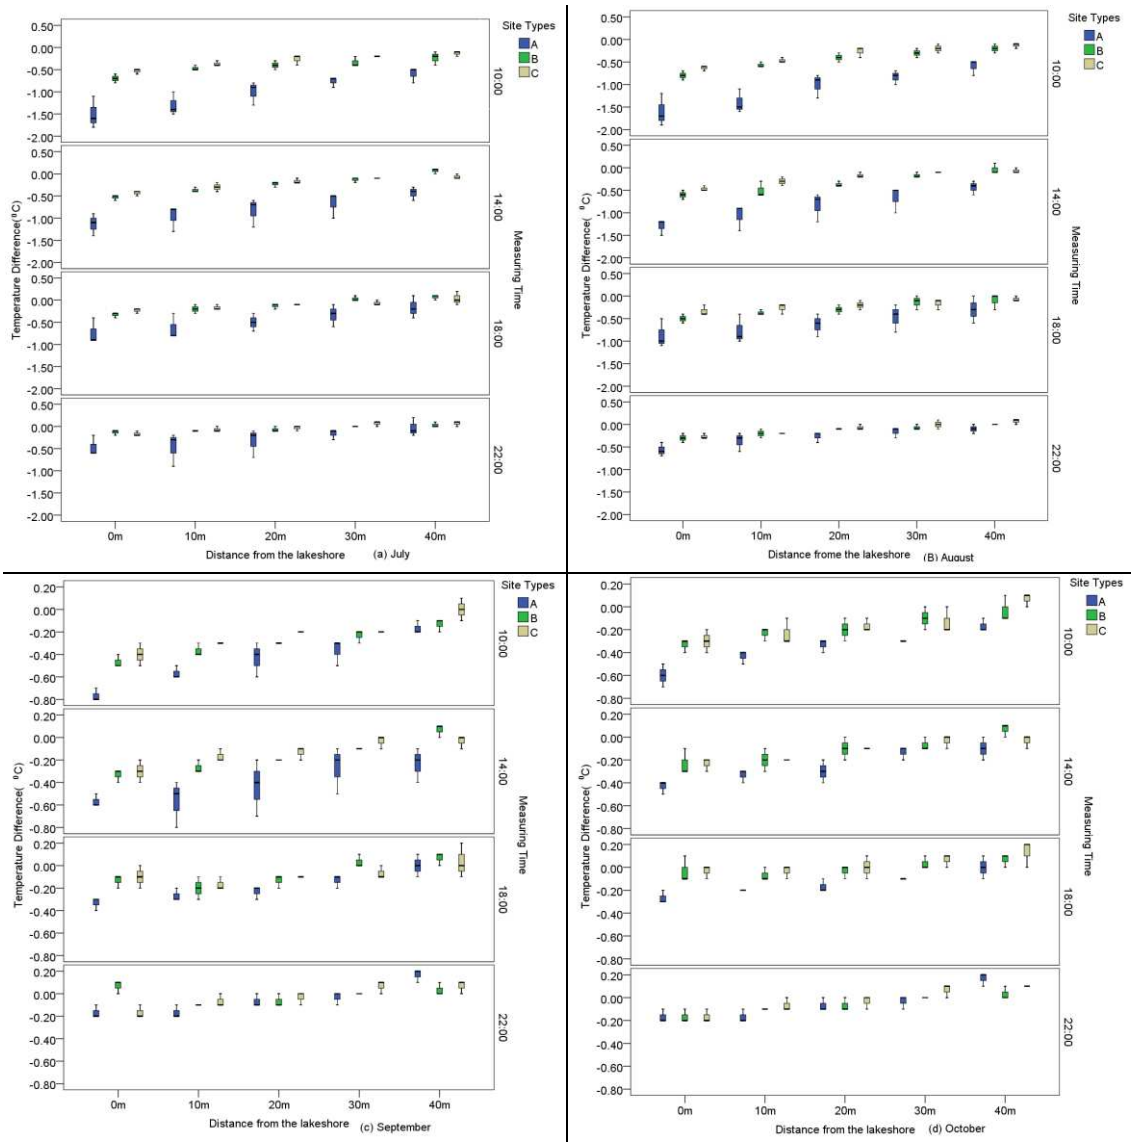

Figure 6. *Temperature differences at different distances from July to October, A represents the vegetated site, B represents the permeable site, and C represents the impermeable site*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21972211

Effect of distance from the water body on the UHI

The distance from the lake bank has significant effects on cooling. *Fig. 6* presents the variation in cooling across the different distances. Longer distances from the lakeshore are responsible for less cooling from July to October. At all measuring sites, the level of cooling 40 m from the lakeshore is less than 0.6℃, and there is little variation depending on the form of the lake bank in warmer months. For example, the temperature difference of A, B and C is just 0.6℃, 0.2℃ and 0.1℃, respectively, at 10:00 in August. However, the variation caused by lakeshore land cover can be ignored at 22:00 in October because each of the temperature differences of the three land covers is close to 0℃. Overall, the results indicate that vegetated sites next to the lake bank increase the cooling level. That is, the cooling effect is more significant at A sites than at B and C sites. *Fig. 6a-d* shows the average ΔT for each measuring time when combining the four periods, with values shown separately for the sites from 0 m to 40 m adjacent to the lakeshore. Very high levels of cooling are shown at the sites adjacent to the lakeshore, which reduce moving away from the lakeshore. The same trend of a cooling drop is observed from the morning to the night.

Discussion

Effect of the water body on cooling

Site A1 was located on the western lakeshore. Because concrete brick was paved at a distance of 1-2 m from the lake bank and the measuring location was 1.5 m above the water body adjacent to the lakeshore, there was no vegetation on the ground below the measuring location. Both site A2 and site A3 were also adjacent to the water body, and the measuring conditions of the two sites were similar to each other. The two measuring location were also 1.5 m above the water surface, but each of the grounds below the two measuring locations was filled with vegetation. The results above show that the cooling effect at A1 is more significant than that at the other two sites. However, the fact that vegetated land cover relieves urban heat is well known, so the result above also shows that the vegetated lakeshore form (A type) plays a greater role in lowering air temperature compared with the permeable sites and the impermeable sites. Why is the cooling effect at A1 the most significant? At the same time, the level of cooling is more significant at site A3 than at site A2. The difference in the cooling effect among the three measuring sites may relate to water temperature. Analysing the data on water temperature, the water temperatures at site A1 and site A3 are lower than that at site A2, especially in the early morning. In fact, cool spring water flows into the inlets of the lake, and A2 is further away from the water inlet compared with A1 and A3. *Fig. 7* shows the variation of the average water temperature at A1, A2 and A3 in August. Water temperature increases from 9:00 to 16:00, and it then declines in the latter measuring time intervals. The difference between the air temperature at the UWS and the water temperature rises from 9:00 to 13:00, and it then falls continually. The variation of the difference is out of sync with the cooling level, which suggests that other factors are also responsible for the cooling level.

Effect of climatic condition on cooling

Under the conditions of the same temperature interval, the level of cooling in July and August is more significant than that in September and October. Furthermore, there is a distinct cooling difference at different measuring times of the same month. *Fig. 8* shows

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_21972211

the variation of temperature differences in similar temperature conditions. The air temperature varied from 14.1 to 31.7℃ in the whole research period. With the maximum temperature difference of nearly 18℃, the interval of 2℃ is chosen in the statistical analysis. In the interval of 14-16℃, the mean of the air temperature at both 9:00 and 21:00 in October belongs to this interval, but the cooling effect at the two measuring times differs from 0.5 to 0.1℃. Furthermore, the difference in the cooling effect from 9:00 in July and 9:00 in August to 21:00 in July and 13:00 in September is more significant, from 1.5 to 0.5℃. However, the contribution to cooling at 21:00 in September and 17:00 in October is approximately equivalent in the interval of 16-18℃. Similar results are found at 13:00 in July and August in the interval of 30-32℃. These analyses suggest that other factors aside from the air temperature, such as solar light intensity, wind speed and water temperature, may have great influences on cooling. Research over the past two decades has shown significant correlations between temperature difference and these factors (Hathway and Sharples, 2012; Zhao et al., 2014; Li et al., 2014).

DOI: http://dx.doi.org/10.15666/aeer/1802_21972211

Advantages and limitations of the study

Numerous research have examined cooling effect of water bodies on the urban heat islands. this study employed the data from meteorological stations and field observation to evaluate the role of water bodies to mitigate urban heat islands during the two seasons. Hathway and Sharples (2012) found the cool island effect becomes more obvious during a spring/summer period as the temperature rose, and this conclusion was consistent with this paper and Xu et al. (2010), but we found that landscape type near lakeshore had different impact on cooling effect. Compared with data from meteorological stations and field observation, remote sensing images can provide more information on land use as well as retrieve land surface temperatures in larger areas. Many literature have showed the water bodies and adjacent landscape forms have important effect on land surface temperatures (Weng, 2009; Sun and Chen, 2012; Li et al., 2013; Kong et al., 2014; Cai et al., 2018). Although remote sensing images can retrieve land surface temperatures on a large scale, remote sensing images obtained are at a fixed time at a certain interval. In future studies, we will use field observation and remote sensing data to combine to analyse the cooling effect of water bodies.

Conclusions

In this study in Jinan, the statistical results show, first, that the urban lake plays a considerable role on cooling the air temperature around the lake bank. Second, the lakeshore type and distance from the lake bank have a significant effect on the level of cooling.

The analytic results reveal significant cooling adjacent to the lakeshore, with an average cooling of nearly 1℃ from July to August. Following the drop in air temperature, the effect of cooling increasingly weakened, and the level of cooling of 0.3℃ in October was less significant than that in July and August. The average temperature difference of the entire period tended to reach the maximum in the mornings, with cooling at the lake bank varying from 1.9℃ to 0.4℃ depending on the different lakeshore types and different months. Furthermore, the level of cooling declined from 9:00 to 21:00 each day. The results also show that highly vegetated lakeshores play a more significant role on cooling air temperatures than those lakeshores consisting of permeable or impermeable materials. Therefore, in the planning and design of an urban lake, the designers should not only focus on landscape forms and landscape aesthetics but also pay more attention to their effect on the urban thermal environment, especially the landscape surface effect. However, the results of this research were based on measurement data from only one urban lake for two seasons, and the research was conducted for only one metropolitan area. Future studies across metropolitan areas under different climatic conditions that combine measurement data with thermal infrared imaging would be desirable to confirm and refine these findings.

Abstract. The effects of exogenous hormones were optimized with different morphological characteristics of cuttings (cuttings from the different crown position, cuttings length and cuttings soaking time) for rooting in successive experiments to enhance the efficiency of vegetative propagation of *Magnolia biondii* Pamp. For this purpose, a series of experiments were conducted in a greenhouse. Application of exogenous hormones at different concentrations significantly affected the rooting of *Magnolia biondii* Pamp cuttings, we found that Indole-3-butyric acid (IBA) at 750 mg/L resulted in the highest rooting rate (78.89%). 750 mg/L IBA was further applied in all other experiments. Stem cuttings collected from the lower position of the plant crown showed higher rooting rate (79.67%) than upper and middle position. Hence, IBA 750 mg/L and cuttings collected from the lower position of the crown were further evaluated under different soaking times (60, 120, 240, 360 min) and found that 120 min soaking time significantly affected the rooting and achieved the highest rooting rate of 80.67%. In the last step of optimization of key factors that affect the propagation of *Magnolia biondii* Pamp, we checked the effect of cutting length by applying all the previously determined factors (IBA 750 mg/L, lower crown position, 120 min). We found longer cuttings (21-25 cm) gave the highest rooting rate (83.11%) rather than short cuttings. Hence, we found that optimal method includes IBA 750 mg/L, the lower part of the crown, 120 min of soaking time, and longer cuttings for vegetative propagation of *Magnolia biondii* Pamp to produce high-quality planting stock material.
Keywords: *Magnolia biondii Pamp, vegetative propagation, exogenous hormones, crown position, soaking time, cuttings length*

Introduction

Magnolia biondii Pamp belonging to family Magnoliaceae, is a deciduous and popular ornamental species distributed in northern China (Coombes, 2014). This species was discovered and introduced to the western hemisphere more than 70 years ago (Coombes, 2014). Its flowering time is from late winter to early spring before leaf growth and blooms single at the top of the branches, each flower has three sepals and six petals which shaped like spoons showing purplish-red color on the base and whitish on the rest of the part. Leaves of *Magnolia biondii* Pamp are unifoliate alternate, the leaf

DOI: http://dx.doi.org/10.15666/aeer/1802_22132229

blade is oblong-lanceolate or ovate-lanceolate glabrous on both sides. It grows up to 12 m and shows the best performance in sandy and loamy soil on above 600 m elevation.

Great differences in the rooting ability of cuttings exist among species and cultivars (Kester et al., 1990). Stem cuttings of some cultivars root so readily that the simplest facilities and care give high rooting percentages (Kester et al., 1990). On the other hand, cuttings of many cultivars or species have yet to be rooted (Kester et al., 1990). Cuttings of some difficult cultivars can be rooted only if specific influencing factors are taken into consideration and if the cultivars are maintained at the optimum condition (Kester et al., 1990). All the species neither propagate easily nor do they respond similarly to a single method of propagation (Kester et al., 1990). There is a lack of suitable propagation method for *Magnolia biondii* Pamp species on large scale through stem cuttings, but there are some published reports available in *Magnolia biondii* Pamp species (Zhang et al., 2003; Wang et al., 2017). However, these studies did not demonstrate a proper protocol for its propagation. So, we here optimized a complete propagation scheme for *Magnolia biondii* Pamp species.

On the other hand, the propagation method with stem cuttings is recommended for quicker establishment faster production (Kester et al., 1990). Adventitious rooting is a critical step in vegetative propagation because cutting do not form roots or they form poor quality root system (Villacorta-Martín et al., 2015). The formation of adventitious roots in mini-cuttings includes the formation of meristematic cells niches (i.e., initial cells and/or target cells), which are dependent on external and internal factors (Dettmer et al., 2009; Papp and Plath, 2011). Reproduction through cuttings is reproduction made by use of a piece taken from the stem, root, or leaf of a plant, cuttings are put in suitable environmental conditions and are forced to form roots (Sevik and Turhan, 2015). Adventitious roots are distinct from lateral roots in that they are formed from any tissue that is not a root, such as leaves and stems, naturally or in response to altered growth environments (Bellini et al., 2014; Geiss et al., 2009). Adventitious rooting is an essential step in the vegetative propagation of economically important horticultural and woody species (Geiss et al., 2009); therefore, it is very important to enhance their growth by using different plant growth regulators.

All classes of exogenous hormones auxin, cytokinin, gibberellin, ethylene, and abscisic acid, and ancillary compounds such as growth retardants/inhibitors, polyamines, and phenolics influence root initiation either directly or indirectly (Davis and Haissig, 1990). Exogenous hormones are commonly used in plant propagation methods to enhance the root development, number, and quality of roots. Generally, a high or low concentration of exogenous hormones supplemented in the propagation method could promote or inhibit cell growth. In several species, rooting competence has been associated with the presence of inductive factors such as exogenous hormones. Auxin and gibberellin particularly IBA, NAA, IAA, and GGR_6 have been reported to induce rooting in many of the plant species with varied success. The response of different exogenous hormones to percent success varied from species to species, changing physiological and environmental conditions. Most of the researchers have reported IBA and NAA as better growth regulators than others for inducing rooting in cuttings due to their stable nature. During the propagation through cuttings, there are some other factors that affect the rooting like environmental conditions, age of stock, rooting media, and concentration of exogenous hormones (Kester et al., 1990). Among

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22132229

all these factors, the concentration of exogenous hormones contributes significantly towards successful propagation.

Rooting ability of different plant species through stem cuttings can also be affected by the several factors such as the crown position of the parent plant, length of the cuttings and soaking time of the cuttings into the exogenous hormones (Kester et al., 1990; Leakey, 1983; Azamal and Mohinder, 2000; Elhaak et al., 2015). However, cuttings characteristics and these factors on the induction of rooting varies from species to species (Harrison-Murray and Knight, 1997). So, it imperative to include the characteristics of the cutting for the effective clonal propagation of plants (Luz et al., 2007; Lekha and Lalji, 2010).

Propagation through cuttings needs more concentration and scientific knowledge. Propagator need to keep thorough records of procedures and the seasonal condition of plant materials and conduct small tests to achieve optimum success for their particular propagation system (Dirr, 1989). Treatment of the cuttings with exogenous hormones, the size of the cuttings, humidity and bottom heat is desirable for rapid rooting. Cuttings must be taken from nutritionally healthy stock plants (Davies Jr, 1988). The propagation material for hardwood cuttings should be collected from healthy, fairly vigorous stock plants growing in full sunlight (Kester et al., 1990). All these factors and substances cannot be used without scientific knowledge, experiments and proper research. For this purpose and to give a proper scheme and scientific method to propagate *Magnolia biondii* Pamp, different experiments in the greenhouse and in the laboratory have been done. Despite being so special ornamental and medicinal features, this species got no attention for its propagation and research. *Magnolia Biondii* Pamp has not yet any published reports that demonstrate the potential for successful propagation.

The objectives of our study were to evaluate the effects of exogenous hormone type; soaking time on the rooting success; effect of the position of the stock plant crown and length of cuttings; and establish a proper cutting propagation scheme for *Magnolia biondii* Pamp to produce more elite clone plants.

Materials and methods

Plant material and experiment site

The plant material of *Magnolia biondii* Pamp cuttings were obtained from the seven-years-old mother plants located at the Silviculture test station of Beijing Forestry University at Jiufeng, Beijing in late June. The experiment was conducted in the greenhouse (temperature: 20-30 °C, relative humidity: about 80%) located near the test station in 2018-2019. The geographical coordinates of the test station are 40.3054" N and 116.05045" E (*Fig. 1*). This area has temperate humid monsoon climate zone with hot, variable rainy summers and dry cold winters. The average annual temperature is 12.5 °C with an accumulating temperature of 42 °C, and the number of annual sunshine hours is 2662 h.

Experiment-1: effect of exogenous hormones on the rooting

A complete randomized block design was set using six different concentrations (250, 500, 750, 1000, 1250, and 1500 mg/L) of four different plant growth regulators (GGR_6, NAA, IBA, IAA) along with water-treated control group (0 mg/L) with each plant growth

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22132229

regulator. A total of 28 treatments were performed in each replication and the experiment was replicated three times. The layout of the experiment was as follows (*Fig. 2*).

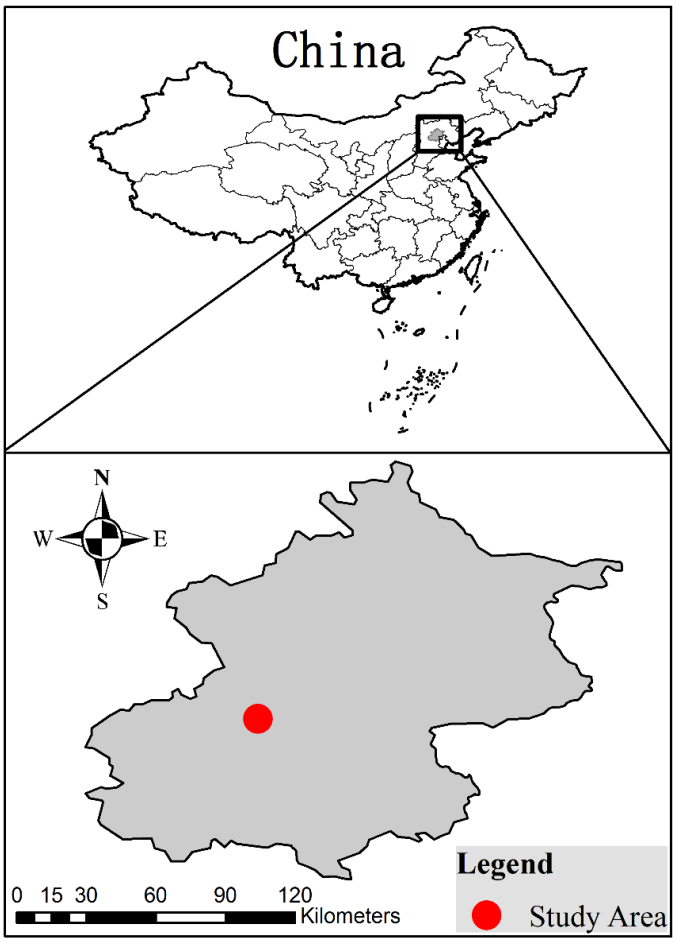

Figure 1. *Red point in the map shows the study area; Silviculture Test Station of Beijing Forestry University, Jiufeng Beijing, China*

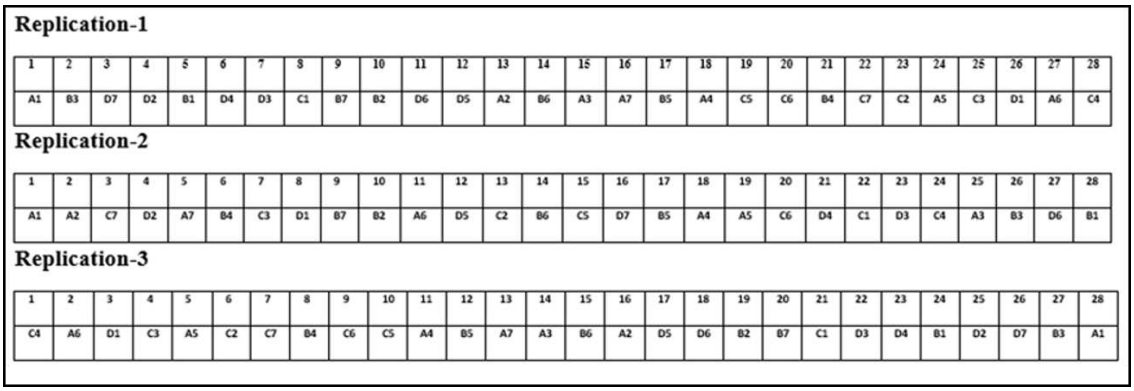

Figure 2. *Here A represents GGR_6, B represents NAA, C represents IBA, and D represents IAA. 1-7 represents different concentrations of plant growth regulator in which 1 represents 0 mg/L (control), 2 represents 250 mg/L, 3 represents 500 mg/L, 4 represents 750 mg/L, 5 represents 1000 mg/L, 6 represents 1250 mg/L and 7 represents 1500 mg/L*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22132229

Culture of *Magnolia biondii* Pamp stems cuttings were established in the greenhouse. The environment of the greenhouse was uniform and did not cause errors in the results of each block. The soil beds consisted of the river sand. The length and width of the soil bed were 6 × 1.5 m and depth was 15 cm. Before shifting the treated cuttings into the beds, the rooting media was fully disinfected by 0.2% potassium permanganate solution (fungicide). The soil was pulverized and misted well. Softwood branches were brought from the mother trees in the morning and converted into the desired stem cuttings. The prepared cuttings were washed under running tap water several times and then shifted into the carbendazim solution for 15 min to disinfect before sticking in the soil. Exogenous hormones concentrations were prepared and cuttings were kept into the concentrations for 30 min and then cuttings were implanted into the soil according to the proposed experimental design. Cuttings were irrigated through a misting shower system.

Experiment-2: Effect of stem cuttings collected from the different positions of the tree crown

This experiment was conducted to check the effect of the crown position of the stock plant on the rooting. For this experiment shoots for the preparation of cuttings were collected from three different crown positions (upper, middle, lower). These cuttings were treated with IBA 750 mg/L (selected from experiment-1). Thirty cuttings per treatment were used and the experiment was repeated three times.

Experiment-3: Effect of soaking time of the cuttings into the exogenous hormone

In this experiment, we evaluated the effect of soaking time of cuttings into the IBA 750 mg/L with the lower crown position that was selected in the first and second experiments respectively. Prepared cuttings were soaked for four different time periods i.e., 60 min, 120 min, 240 min and 360 min. Thirty cuttings per treatment were prepared and the experiment was replicated three times.

Experiment-4: Effect of cuttings size on the rooting

In this experiment, four classes of stem cuttings length were prepared to select the best cutting length for the propagation of *Magnolia biondii* Pamp. Four different classes of cuttings i.e., 5-10 cm, 11-15 cm, 16–20 cm and 21-25 cm were prepared from the lower crown position and soaked into IBA 750 mg/L for 120 min. Thirty cuttings per treatment were used and the experiment was repeated three times.

Analytical measurements

After the completion of experiments, cuttings were carefully uprooted and rinsed with the water. First of all, the number of roots of each cutting was measured by counting. The rooting rate was measured by *Equation 1:*

$$Rooting\ rate = \frac{Number\ of\ rooted\ cuttings}{Total\ number\ of\ cuttings} \times 100 \qquad \text{(Eq.1)}$$

For the measurement of total root length, root diameter, and root volume, roots were scanned and these scanned images were further analyzed with WinRHIZO Pro 2013a software to measure aforesaid root parameters.

DOI: http://dx.doi.org/10.15666/aeer/1802_22132229

Statistical analysis

Experiments were performed by following Complete Randomized Block Design (CRBD). Data were analysed using Analysis of Variance (ANOVA) method and least significant difference test ($LSD_{0.05}$) by using IBM SPSS Statistics v20. Graphs were prepared using Origin Pro 2018 software.

Results

Effect of exogenous hormones on the rooting

The macro propagation methods play an important role in the improvement of many plant species and have been discovered for the propagation of many valuable species, particularly the ornamental, aesthetical, rare and endangered species (Jamir et al., 2016). Propagation system through stem cuttings can be a significant step in vegetative propagation. This is the first research-based report which established a scientific method for the proliferation of roots from the stem cuttings of *Magnolia biondii* Pamp using different exogenous hormones.

The rooting rate was determined in term of rooting percentage. In this study, it was found that among different exogenous hormones, IBA with its different concentrations has a more obvious trend. With the increase in the concentration of IBA rooting rate increased and reached to its peak value and then decreased continuously with the increase in concentration. It showed the highest rooting rate at the concentration of 750 mg/L about 78% in comparison with other exogenous hormones i.e., GGR_6, NAA, IAA and control. Statistically significant differences ($F(6, 14) = 11.5$, $p = 0.0001$)) were found for IBA. While, GGR_6, NAA, and IAA also revealed the highest rooting rate at 750 mg/L (34%), 1000 mg/L (63%), and 1250 mg/L (43%) respectively. Moreover, there were also found statistically significant differences for all these exogenous hormones among different concentrations. Compared to all other exogenous hormones and their concentrations, GGR_6 performed very low rooting rate. IAA performed better than GGR_6, but with comparison to NAA and IBA, IAA has a very low rooting rate. So, IBA 750 mg/L comparatively performed best than other exogenous hormones (*Table 1*).

Table 1. *Effect of exogenous hormones on the rooting rate*

Conc. (mg/L)	GGR_6	NAA	IBA	IAA
0	24.44 ± 2.60^{ab}	25.56 ± 0.88^{d}	32.22 ± 1.45^{e}	17.78 ± 0.33^{b}
250	30.00 ± 1.15^{ab}	47.78 ± 0.88^{bc}	50.00 ± 1.53^{cd}	30.00 ± 1.53^{ab}
500	24.44 ± 0.88^{ab}	44.44 ± 1.20^{c}	56.67 ± 2.08^{bc}	35.56 ± 4.18^{ab}
750	34.44 ± 0.88^{a}	61.11 ± 1.20^{a}	78.89 ± 1.45^{a}	36.67 ± 3.51^{ab}
1000	18.89 ± 0.33^{bc}	63.33 ± 0.58^{a}	67.78 ± 1.33^{ab}	42.22 ± 1.67^{a}
1250	8.89 ± 0.88^{c}	56.67 ± 0.58^{ab}	50.00 ± 1.00^{cd}	43.33 ± 0.58^{a}
1500	7.78 ± 0.33^{c}	43.33 ± 1.15^{c}	38.89 ± 0.67^{de}	27.78 ± 0.67^{ab}

Values followed by the same letters show non-significant differences while different letters show significant differences ($LSD_{0.05}$) for each hormone at different concentrations. Data are mean ± SE

Different plant growth regulators resulted in significant differences in the mean number of roots per cutting. The number of roots was significantly ($P < 0.05$) effected

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22132229

by exogenous hormones. IBA 750 mg/L had the highest number of roots (20 pcs) which significantly differed with its other concentrations, control, and other exogenous hormones. Cuttings treated with the different concentrations of NAA had also significant ($F (6, 14) = 17.9$, $p = 0.0000$) ($P < 0.05$)) results. NAA 750 mg/L and NAA 1000 mg/L showed non-significant results i.e. 12 pcs and 11 pcs respectively but, they were significantly higher than its control (2 pcs). IAA did not show good results compared to IBA and NAA. IAA 1000 mg/L had the highest number of roots (5 pcs) compared to its other concentrations. Generally, GGR_6 had a very low mean number of roots. The highest mean number of roots within the GGR_6 concentrations were found at 750 mg/L (3 pcs) which did not have a much difference compared to its control (*Fig. 3a*).

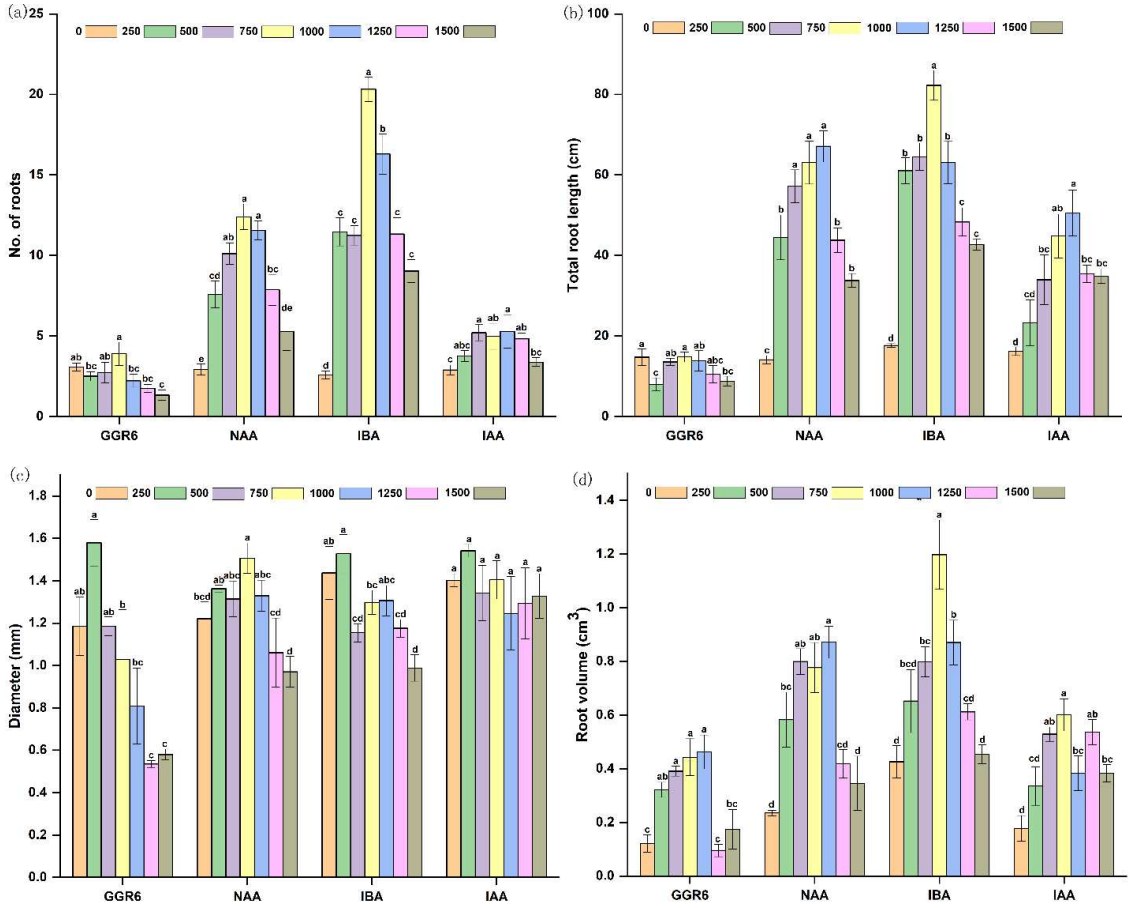

Figure 3. *Effect of different plant growth regulators on (a) the average number of roots per cutting; (b) mean total root length per cutting; (c) mean root diameter per cutting; (d) mean root volume per cutting at different exogenous hormones and their different concentrations. Alphabets on the top of each bar showing the $LSD_{0.05}$ difference. The same letters show the non-significant differences, while the different letters show the significant differences between different concentrations for each exogenous hormone*

One-way analysis of variance ANOVA indicated that mean total root length was significantly influenced by exogenous hormone application. Maximum mean total root length was found in IBA 750 mg/L (82 cm) which was significantly ($F (6, 14) = 38$, $p = 0.0000$) higher than control. Total root length in IBA increased continuously and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22132229

reached its peak at 750 mg/L and then decreased. NAA had also an obvious trend, as it increased continuously and reached its peak at 1000 mg/L with 67 cm mean total root length and then decreased. IAA significantly showed higher mean total root length at 1000 mg/L (50 cm) compared to control (16 cm). Among all four plant growth regulator types, GGR_6 showed very low root length. Results showed that GGR_6 had similar mean total root length to its control at 750 mg/L (*Fig. 3b*).

Root diameter was observed almost the same in all treatments. Among all exogenous hormone types, GGR_6 at 250 mg/L showed highest mean root diameter (1.57 mm) and indicated the significant results ($(F (6, 14) = 7.98, p = 0.0007)$). GGR_6 at 500 mg/L showed significantly same mean root diameter (1.18 mm) to its control and then continuously decreased and reached to 0.53 mm at 1250 mg/L concentration. NAA 750 mg/L showed the highest mean root diameter (1.5 mm) among its all concentrations and control. IBA 250 mg/L significantly showed 1.5 mm mean root diameter. IBA 1500 mg/L significantly showed the lowest root diameter (0.98 mm). According to ANOVA, IAA showed non-significant results. IAA 250 mg/L showed a 1.54 mm root diameter which was non-significant to all its concentrations and control (*Fig. 3c*).

The application of plant growth regulators triggered and enhanced the root volume. Among all PGRs and their concentrations, IBA showed significant trend because IBA at 750 mg/L significantly ($(F (6, 14) = 10.8, p = 0.0001)$) showed highest mean root volume (1.19 cm^3) compared to all other exogenous hormone concentrations and its control group. Mean root volume trend was not obvious in NAA application because increasing and decreasing trend was found. NAA at 1000 mg/L showed maximum root volume (0.87 cm^3). IAA showed highest root volume at 750 mg/L (0.6 cm^3) which was not higher than IBA and NAA applications. IAA 1000 mg/L and 1500 mg/L showed non-significant results. GGR_6 showed low root volume compared to all other exogenous hormone applications. GGR_6 at 1000 mg/L showed the highest mean root volume (0.46 cm^3) which was non-significant to 750 and 500 mg/L concentrations. Lowest mean root volume was found in 1250 mg/L (0.09 cm^3) which was non-significant to its control application (*Fig. 3d*).

Principal component analysis

For the screening and evaluation of exogenous hormones and to provide a comprehensive analysis, the principal component analysis was performed on the first experiment. The variance and variance cumulative rate of each component is shown in *Table 2*. SPSS extracted two components along with their eigenvalues. The cumulative contribution of the two principal components is 94.387%.

Table 2. *Variance cumulative contribution rate of each composition*

Components	Initial Eigenvalue			Extracted sum square		
	Total	Variance (%)	Accumulation (%)	Total	Variance (%)	Accumulation (%)
1	3.880	77.609	77.609	3.880	77.609	77.609
2	0.839	16.778	94.387	0.839	16.778	94.387
3	0.126	2.529	96.916			
4	0.086	1.730	98.645			
5	0.068	1.355	100.000			

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22132229

Two principal component expressions and the formulas of the comprehensive scoring are sorted out as follows:

$$C1 = 0.0965\,X1 + 0.0958\,X2 + 0.0954\,X3 + 0.0471\,X4 + 0.948\,X5 \quad \text{(Eq.2)}$$

$$C2 = -0.032\,X1 - 1.20\,X2 - 0.2X3 + 0.881\,X4 - 0.083\,X5 \quad \text{(Eq.3)}$$

$$C = \frac{\lambda_1 C_1 + \lambda_2 C_2}{\lambda_1 + \lambda_2} \quad \text{(Eq.4)}$$

Among the formulas given above, C_1 indicates the main component 1 score while C_2 indicates the main component 2 score. C indicates the comprehensive score and X_1 to X_5 indicates rooting rate, total root length, number of roots, root diameter and root volume respectively. λ_1 and λ_2 indicate the variance of main component 1 and main component 2 respectively and it is known from *Table 5* that $\lambda_1 = 77.609$ and $\lambda_2 = 16.778$.

The five rooting parameters values are substituted into *Equations 2, 3* and *4*. The score and ranking of each treatment are listed in *Table 3*. According to the comprehensive ranking among four exogenous hormone treatments, the application of IBA to propagate *Magnolia biondii* Pamp has a better overall effect, especially at the concentration of 750 mg/L.

Stem cuttings collected from the different positions of the tree crown

Analysis of variance indicated that cuttings collected from different position of the tree crown significantly affected all rooting parameters. All the rooting parameters either continuously increased or continuously decreased according to the position of the tree crown. The highest rooting rate was achieved with the cuttings collected from the lower part of the tree crown. *Table 4* depicted that rooting rate varied from 19.0% (upper position) to 79.67% (lower position), whereas the number of roots ranged from 1.73 to 22 roots from the upper part to the lower part of the tree crown respectively. Total root length also significantly increased from upper position to middle and then highest total root length (113.67 cm) was found in the lower position of the tree crown. Root diameter showed significantly different results from all other rooting parameters. Maximum mean root diameter (1.41 mm) was achieved in the upper position of the tree crown while lowest mean root diameter (1.03 mm) was found in the lower position of the tree crown, and significant results were achieved ($F (2, 6) = 11.1$, $p = 0.0096$). Root volume showed an obvious trend, increased from upper position to the lower position of the crown. It showed the mean root volume of 0.28 cm^3 at the upper position and 1.08 cm^3 at the lower position of the crown.

Table 4. *The effects of the cuttings taken from different positions of the trees on the rooting*

Tree crown	RR (%)	NR (pcs)	TRL (cm)	RD (mm)	RV (cm^3)
Upper	19.00 ± 1.52^{c}	1.73 ± 0.27^{c}	17.40 ± 1.28^{c}	1.41 ± 0.05^{a}	0.28 ± 0.03^{b}
Middle	63.33 ± 0.66^{b}	11.12 ± 1.17^{b}	74.87 ± 2.94^{b}	1.11 ± 0.07^{b}	0.90 ± 0.13^{a}
Lower	79.67 ± 2.33^{a}	22.04 ± 1.65^{a}	113.67 ± 4.93^{a}	1.03 ± 0.04^{b}	1.08 ± 0.02^{a}

Values followed by the same letters show non-significant differences while different letters show significant differences ($LSD_{0.05}$) for each rooting parameter at different crown position. RR indicates the rooting rate, NR number of roots, TRL total root length, RD root diameter, and RV indicates root volume. Data are mean ± SE

Effect of cuttings immersion time into the exogenous hormone

The rooting rate varied significantly between different immersion time periods of cuttings into the exogenous hormone ($P < 0.05$, ANOVA) (*Table 5*). Maximum rooting rate (80.67%) was achieved in the cuttings treated with IBA 750 mg/L for 120 min, while the minimum rooting rate was found 62.67% for 360 min. Cuttings treated for 60 min also yielded 77.33% rooting which is non-significant to 120 min treatment. The maximum number of roots were found in the cuttings treated for 120 min (27.21 roots), while the minimum number of roots were found in the cuttings treated for 360 min (15.47 roots). Total root length, root diameter, and root volume had no significant differences for different immersion time.

The effect of different cuttings length on the rooting

In this study, four-length classes of the cuttings were used to check their effect on the rooting. Our results revealed that the length of the cuttings significantly affected the rooting rate, number of roots, total root length and root volume, while no significant effect was found in root diameter (*Table 6*). Direct relation was found between the length of the cuttings and rooting rate. Maximum rooting rate (83.11%) was found in the cuttings having 21-25 cm length while the minimum rooting rate was found in 5-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22132229

10 cm long cuttings (49.33%). Cuttings of class length 21-25 cm produced the highest number of roots (29.67), while the lowest number of roots were found in 5-10 cm length class cuttings (8.83). The highest total root length and root volume were also found in the longer cuttings (21-25 cm). In case of root diameter, non-significant results were found ($F(3, 8) = 1.30$, $p = 0.34$)). Maximum root diameter (1.26 mm) was found in the cuttings having the length of 11-15 cm while minimum root diameter (1.06 mm) was found in 16-20 cm long cuttings.

Table 5. *The effect of different time of immersion of the cuttings into the exogenous hormone on the rooting*

Time (min)	RR (%)	NR (pcs)	TRL (cm)	RD (mm)	RV (cm3)
60	77.33 ± 2.90^{a}	24.52 ± 0.86^{a}	116.85 ± 1.16^{a}	1.24 ± 0.09^{a}	1.15 ± 0.10^{a}
120	80.67 ± 2.33^{a}	27.21 ± 0.99^{a}	111.58 ± 4.61^{a}	1.19 ± 0.09^{a}	1.21 ± 0.23^{a}

Discussion

Adventitious rooting responses differently to different plant growth regulators. The previous findings also showed that exogenous hormones applications have apparent effects on rooting rate (Zhang et al., 2017; Sevik and Guney, 2013). The process of adventitious rooting is influenced by the number of internal and external factors (Kester et al., 1990; Kumar et al., 2009). Among the internal factors, the most important role is explained by the phytohormones, especially the auxins. These phytohormones cause the cells to change their elasticity, and as result cells absorb more water and energy that leads to more cell division. Therefore, it is generally accepted that auxins have a key role in the process of root initiation (Štefančič et al., 2005).

Among the different exogenous hormones such as GGR_6, NAA, IBA, and IAA are known to accelerate the rooting parameters in vegetative propagation through cuttings (Gehlot et al., 2014; Ibrahim et al., 2015). Therefore, in our study, we found the distinct differences in rooting rate, number of roots, total root length, root diameter and root volume due to different exogenous hormones application in the rooting of *Magnolia*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22132229

biondii Pamp cuttings. It was also found that cuttings treated with IBA treatment induce early and better root initiation. Therefore, the maximum rooting rate and number of roots were found at 750 mg/L concentration of IBA. The exogenous application of IBA has been reported to enhance cell division and to speed up the translocation and movement of carbohydrates and nutrients to the base of stem cuttings and enhances root growth (Kester et al., 1990; Aminah et al., 1995; OuYang et al., 2015b). These findings are also supported by the previous findings of Kester et al., 1990 that also found similar results in many herbaceous perennial crops. Similarly, in other plant species such as *Lippia javanica* L. (Soundy et al., 2008) and *V. paradoxa* and *C.F. Gaerth* (Akakpo et al., 2014), highest rooting was attained when stem cuttings were treated with IBA. In the case of total root length, we also found that cuttings of *Magnolia biondii* Pamp treated with IBA 750 mg/L showed improved root length and it might be because of early cells differentiation and elongation. Moreover, exogenous application of hormones initiates the synthesis of structural enzyme protein in the formation of the adventitious root leading to increase the root length through the acidification process (Kaushik, 2017). Similar conclusions were found by Sharma (2014) in Marigold, Swamy et al. (2002) in *Grewia optiva* and *Robinia pseudoacacia*, Grewal et al. (2005) *Dendranthema grandiflora* cv. Snowball and Singh et al. (2013) in Night Jasmine. Root diameter and volume are also an important factor for the development of a newly developed seedling to keep its root system stronger to reach its climax stage during the early development. Therefore, application of exogenous hormones helps the plants to develop stronger and thicker roots during the early developmental stage.

In the literature, auxins were found better to develop more thick roots and as a result, the root diameter is increased (Bhatt and Tomar, 2011). We also found the prominent effects of auxins (NAA, IBA, IAA) and gibberellin (GGR_6), but compared to auxins, the gibberellin (GGR_6) had a relatively better effect in the root diameter (Liu et al., 2005). Because the gibberellins are the third most commonly used plant hormones with a share of 17%. The most commonly used commercial gibberellin is GGR_6. It is mostly used for increasing the height of a plant or flower yield (Kumlay and Eryigit, 2011), but in our study GGR_6 significantly affected the root diameter compared to auxin group of hormones and to the control, that is consistent with the results provided by Liu et al. (2013) that GGR_6 treated cuttings had higher root diameter values than other exogenous hormones. While, in the case of root volume, IBA had a significant effect on the cuttings. The root volume is also one of the essential parameters used for the evaluation of root morphology. Root volume reflects the quality of root growth, larger the volume of the root, more the developed root system will be (Jie, 2012). Exogenous hormones application plays a vital role in the rooting of the different plant species. Many studies have shown that exogenous application of hormones results in the increased initiation of lateral roots (Chhun et al., 2003). The effect of hormones on rooting and plant development have been discussed in several studies, for example, Kesari et al. (2009) studied the effect of IBA, NAA and IAA on the rooting of *Pongamia pinnata* and found the maximum rooting rate in IBA treated cuttings. Similarly, Tchinda et al. (2013) conducted a series of experiments by using NAA and IBA for the propagation of *Ricinodendron heudelotti Baill* species. Sevik and Güney (2013) also studied the rooting potential of Melissa officinalis L. species through stem cuttings using IAA, NAA, IBA, and GA_3. Thus, these studies showed that, in general, the exogenous hormones have an effect on rooting and their results are in conformity with the results of our study. We found that through the whole experiment, cuttings treated with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22132229

exogenous hormones respond significantly towards the percent rooting. The differential response of the stem cuttings on various exogenous hormones has been ascribed to the chemical nature of the hormones and the mode of concentrations (Das, 2006). Our results were not impressive in all other hormone types other than IBA. Kester et al., 1990, mentioned that IBA could be used for general use because it is non-toxic to plants over varied concentrations than other auxins. To some extent, NAA also performed well compared to GGR_6 and IAA. This reveals that application of GGR_6 and IAA exhibits poor root ability and are unable to respond well in *Magnolia biondii* Pamp. Poor development of roots inhibits the success of vegetative propagation via stem cuttings (De Klerk, 2002). It was also found that, with the increase in exogenous hormone application, rooting also increased and then after reaching its peak value, it decreased with increase in concentration. Kester et al., 1990 mentioned that the higher concentration of exogenous hormones deters the initiation and elongation of roots and stimulates plant cell to produce ethylene.

After the successful screening of best hormone and its best concentration (IBA-750) for the rooting then it was combined with other factors for the optimization of successful propagation treatments the best results of rooting in *Magnolia biondii* Pamp cuttings. In this regard, first of all, we investigated how the time of soaking improved the rooting. We found that increasing the time of soaking (120 min) of cuttings into IBA 750 mg/L significantly increased the rooting and affected the rooting morphological characteristics of *Magnolia biondii* Pamp. Different time of soaking of the cuttings into the IBA significantly affected the rooting and it had various impacts on the morphological characteristics of *Magnolia biondii* Pamp cuttings which are in agreement with the finding of Panwar et al. (1999) and OuYang et al. (2015a), who studied the effect of exogenous hormones, length of the stem cuttings, and soaking time of the cuttings on the rooting of Norway spruce. Application of IBA 750 mg/L for 120 min significantly increased rooting rate, number of roots and root volume, while 60 min application enhanced total root length and root diameter. Maximum time application i.e. 360 min did not have good results which are in agreement to the previous results, who mentioned for Rosa species that, cuttings immersed for 360 min in IBA concentrations inhibited the rooting. Different environmental factors can influence and there can be variability in the results when cuttings are immersed for a long time period (Kester et al., 1990).

Cuttings of *Magnolia biondii* Pamp treated with IBA-750, and the best time of soaking was further evaluated to get the best results of rooting. We selected the three positions of the crown i.e., upper, middle and lower. Because the differences existed between the position of the crown on the donor plant for rooting percentage and other parameters (Fishel et al., 2003). We found that maximum rooting percentage was observed in the cuttings taken from the lower part of the crown. Similar results were found during the rooting process of *jack pine* when the cuttings were collected from the lower position of the crown, they significantly rooted more than the middle and upper position of the crown (Browne et al., 1996). Browne et al. (1996) studied that plant crown position play an important role in the rooting process, lower crown to the middle position of the crown typically show higher rooting frequency than the upper position of the crown. It has been extensively studied that cutting size can often be attributed to the origin of cuttings within and between shoots, and to its position within the stock plant (Leakey, 2004). In most of the tree species, rooting ability of cuttings has been reported to increase from the basal part of the tree crown that attributed to the accumulation of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22132229

carbohydrates (Kester et al., 1990). The effect of crown position on rooting may be caused by the variation in the physiological status of cuttings on stock plants (Kester et al., 1990).

Furthermore, we investigated how the length of the cuttings can be more effective in the propagation of *Magnolia biondii* Pamp species. So, for this purpose, we explored the IBA-750 with the best time of soaking and crown position to evaluate the effect of cuttings length on the rooting. In our study, significant rooting results were obtained for longer cuttings (21-25 cm). Longer cuttings rooted at a higher percentage than shorter cuttings and similar results were found in Ayous (Triplochiton scleroxylon) (Leakey, 1983; Leakey and Mohammed, 1985). The effectiveness of rooting by longer cuttings can be explained by different factors. The first factor is that the level of endogenous Auxins and other rooting-inducing factors may be lower in shorter cuttings, which leads to the reduced rooting percentage or the absence of rotting in shorter cuttings (Palanisamy and Kumar, 1997). The second factor is that longer cuttings store more carbohydrates (Tchoundjeu and Leakey, 1996), the carbohydrates of sugars (soluble carbohydrates) and storage carbohydrates (starches or insoluble carbohydrates) are important to rooting as building blocks of complex macromolecules, structural elements, and energy sources (Sturve, 1981; Haissig, 1984, 1986). So, these cuttings use the stored carbohydrates in root regeneration (Kester et al., 1990).

Conclusion

A protocol for vegetative propagation of *Magnolia biondii* Pamp was optimized with subsequent development of plants using stem cuttings as source material. The stem cuttings pretreated with exogenous hormone IBA 750 mg/L, time of soaking for 120 min, the position of the parent plant crown (lower position) and longer cuttings of 21-25 cm significantly affected on the rooting in the greenhouse conditions. This optimized protocol can ease to propagate *Magnolia biondii* Pamp and can be used to develop healthier and more profuse root system for the propagation and more clone plants. Further studies can be carried out in-depth by using morpho-anatomical studies and antioxidant activities to provide a more effective and feasible method of propagation for *Magnolia biondii* Pamp species.

(Received 7th Oct 2019; accepted 4th Dec 2019)

Abstract. In Pakistan the lack of development for local allometric equations has led to the use of simple generic volume equations which may generate errors in forest carbon estimates. This research was designed to quantify tree carbon stock and check the robustness of the existing models against local allometric models.The study was conducted in Hayat-ul-Mir subtropical scrub forest in Pakistan comprising of a bi-climax community of *Acacia modesta* Linn. and *Olea ferruginea* Royle.Tree measurements were taken in 47 plots of 0.04 ha and biomass carbon estimates were made using local allometric, existing generic pantropical model and i-Tree Eco tool.No significant difference in biomass carbon (ton/ha) was found between local (8.53) and pantropical models (8.68) for *A. modesta* and between the three models for *O. ferruginea* (10.92, 11.91 and 11.87 for local allometric, pantropical model and i-Tree Eco, respectively). All models fitted data well ($p< 0.001$), whereas the pantropical model incorporating three biophysical variables better predicted biomass and was found more robust for both species based on AIC, BIC, RMSE and R^2 adj. values. In the absence of local models, the pantropical model can provide better biomass estimates for deciduous and evergreen subtropical species to report carbon stock.
Keywords: *Allometry, volume, i-Tree Eco, pantropical, REDD+*

Introduction

Biomass carbon stock assessment is highly sensitive to the choice of adopted method due to differences in the biophysical factors incorporated into the model (van Breugel et al., 2011). Forest biomass carbon is partitioned mainly into aboveground (including stem, branches, and leaves) and belowground parts (including both fine and coarseroots) accounting for approximately 50% of the total biomass of the tree (Basuki et al., 2009; Yuen et al., 2016). For biomass estimation, various techniques are common ranging from site specific or locally developed to generic allometric/regression models and remote sensing techniques (Basuki et al., 2009; van Breugel et al., 2011). The most accurate and direct method of biomass quantification employs the use of destructive or semidestructive sampling in which fresh and oven dry weight of all components or parts of a tree is analytically determined by harvesting subsample of plants from sample plots. The results obtained give a precise estimate of the biomass carbon in a small sample area, and this technique is being used to develop site or species specific (local) regression models for the landscape based biomass estimations (Basuki et al., 2009; Yuen et al., 2016). The destructive harvest is often limited due to variable topography, environmental and financial constraints (Goussanou et al., 2016; Djomo and Chimi, 2017). To overcome this limitation researchers have devised non-destructive volume and allometric equations to estimate individual tree biomass, for which biomass carbon as a fraction is calculated (Philip, 1994; Yuen et al., 2016; Stas et al., 2017).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22312245

Allometry finds a mathematical explanation of how structural variables are related to biomass. This mathematical explanation or model is obtained by regressing total individual biomass of tree or its components against biophysical variables i.e. diameter at breast height (DBH), tree height and wood density (Chave et al., 2014; Yuen et al., 2016). Although generic allometric equations are considered applicable to wide range of species in diverse landscapes, but between the regions trees present different allometric relationships for biophysical variables depending on the environmental conditions such as climate and soil type. This requires the generic allometric models to be calibrated with local (site or species specific) allometries which gives a more precise estimate of tree carbon stock (Vieilledent et al., 2012). By this pre-calibration, the utility of generic models to wide range of environmental conditions and species increases when local biomass models are not available. Vieilledent et al. (2012) after a destructive sampling of 481 trees in Madagascar, developed local allometric equations and compared them with generic pantropical relations developed by Brown (1997) and Chave et al. (2005). The comparison showed that in the absence of local equations, the generic model proposed by Chave et al. (2005) based on height (Ht), DBH and wood density (WD) of tree species produced more accurate biomass estimates than other generic models considering only DBH or combination of DBH and WD.

The accuracy of the forest carbon estimates thus lies in the robustness of the allometric model adopted and also depends on the relationship between biophysical variables incorporated as predictors in the model (Gulzar et al., 2014). For instance, tree volume equations developed by foresters may relyon a geometric relationship of Ht, DBH and tree form factor and applies biomass expansion factoror species specific WD to estimate tree biomass (Philip, 1994; Nizami, 2012). While the generic or pantropical models are developed considering the climate of the region along with biophysical factors and also apply regression coefficients in determining tree biomass (Chave et al., 2014). Biomass estimations made through any of these methods can later be extrapolated to the whole forest or landscape scale level (Nizami, 2014).

A number of tools have also been developed to estimate tree biomass and carbon storage in urban and natural forest such as Carbon OnLine Estimator (COLE), U.S. Forest Carbon Calculation Tool (CCT), Center for Urban Forestry Research (CUFR) Tree Carbon Calculator (CTCC) and i-Treetools (Aguaron and McPherson, 2012; Nowak et al., 2013; Russo et al., 2014). i-Tree Eco, developed by the USDA Forest Service and Cooperators, is derived from the UFORE (Urban FORest Effects) and has widely been used to estimate the magnitude and monetary value of many of the ecosystem services provided by urban forests, including carbon storage and sequestration using the plot based or complete inventory data of forest. The use of meteorological data by i-Tree Eco as a baseline gives a better estimate of ecosystem services (Nowak et al., 2008). i-Tree Eco computes dry weight biomass, carbon storage and sequestration by applying species/genus/family specific allometric equations or average of hardwood/conifer equations using either DBH, a combination of DBH and Ht or Ht of the tree and crown characteristics (Nowak et al., 2013).

In order to implement REDD+ targets (Reducing Emissions from Deforestation and Forest Degradation) to reduce global greehouse gas emissions (Terakunpisut et al., 2007), it is mandatory for Pakistan to report its forest carbon stock and GHG emissions from other sectors in accordance with UNFCCC protocols. For this purpose, only a few allometric models have been developed in Pakistan for the estimation of biomass of individual tree components (stem, branches, twigs, leaves and root) or stem volume estimation (Nizami,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22312245

2014; Shaheen et al., 2016). Whereas, most of the studies have reported biomass estimates using volume relationships (Nizami et al., 2009; Nizami, 2012; Ahmad et al., 2014; Shaheen et al., 2016) which are now less recommended due to its limitations of incorporating fixed tree form factor and limited utility for closed canopy forests (Chave et al., 2005). No literature was found to the best of our knowledge using i-Tree Eco tool or on validation of generic allometric models to estimate tree carbon stock in Pakistan.

This study was conducted on the Hayat-ul-Mir (HM) Scrub forest, Soan Valley Pakistan to estimate tree biomass carbon stock. The forest is documented in detail by Parker (1915) and Champion et al. (1965) as cited by Khan et al. (2013). The vegetation type of scrub forest comprises of dry subtropical broad leaved deciduous and evergreen species covering a totalarea of 1.3 million hectares. The forest extends in the foothills and lowerslope of Himalayas, in the salt range, Kala-Chitta, and Sulaiman range. At suitable elevations, the forest is also seen throughout the country merging upward with sub-tropical pine and temperate forest and downward with tropical thorn forest. The dominant community of the scrub forest comprise of *Acacia modesta* (Linn.) Wall., *Olea ferruginea* Royle, *Tecoma undulata,* and *Pistacia integerima* however shrub cover is contributed by *Dodonea viscosa, Justica adhatoda, Zizyphus spp.* And *Nannorrhops ritchieana.* The local population benefits from the forest to fulfill its needs for fodder, fuelwood, timber and herbal medicines (Khan and Ahmad, 2015).

A number of studies have been conducted in Pakistan estimating tree biomass of different forest ecosystems. Nizami et al. (2009) has reported biomass carbon stock of sub-tropical pine forest in Lehterar and Ghoragali forest subdivisions in Murree hills using simple volume relationship. In another study by Nizami (2012), volume based biomass carbon estimates have been reported for sub-tropical pine forest, Kherimurat scrub and Sohawa forests comprising of vegetation stock of *Pinus roxburghii*, *Acacia modesta* and *Olea ferruginea*. Shaheen et al. (2016) have reported volume based and species specific allometric relationships for forest carbon stocka ssessment in subtropical Himalayan forest in Kashmir comprising a mixed vegetation of *Acacia spp*., *O. cuspidata*, *P. roxburghii, Punica gratum, Ficus spp., Broussonetia papyrifera, Melia azedarach, Mallotus philippensis* and *Delbergia sisso*. Other studies have reported biomass estimates of *Delbergia sisso* and *Picea smithiana* by destructive harvest in Daphar irrigated plantation in Punjab province and Kumrat valley in Khyber Pakhtun Khawa Province in Pakistan, respectively (Ahmad et al., 2014; Gulzar et al., 2014). In all of these studies, tree biomass was estimated from generic volume equations which are now less recommended for carbon accounting (Chave et al., 2005).

Current study was designed to 1) estimate tree biomass and carbon storage of *Acacia modesta* and *Olea ferruginea* in HM scrub forest and 2) to compare locally developed allometric equations to the existing models to evaluate their robustness and applicability for subtropical forest in Pakistan. It was hypothesized that increase in the number of biophysical factors in biomass model gives a better estimate of forest carbon stock.

Materials and Methods

Site description

The study was conducted in HM Scrub Reserve forest (32.54^{o} N and 72.31^{o} E) covering an area of 1646 ha in Soan Valley, district Khushab of Punjab province, Pakistan. Most of the hills in the valley have an average height between 400 to 1000 m and the highest point in the range i.e. Sakesar lies at a height of 1527 m. The forest

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22312245

classified as arid receives annual precipitation of 600 mm which falls mostly during the monsoon (July to September), with an average annual temperature of 24°C (minimum temperature 1°C in January and an average maximum temperature of 36°C in June) making the area hot and dry with frequent droughts during summer and frost in winter (Ahmed, 2013; Khan et al., 2013). The forest has a dominant vegetation stock of two climax (mosaic) species i.e. *A. modesta* (deciduous) and *O. ferruginea* (evergreen), however a rich understory of other species such as *Justicia adhatoda, Buxus sp.*, *Dodonaea viscosa* and other shrubs are present at different elevations in the forest (Ahmed, 2013). The invasion of exotic *Prosopis juliflora* species was also seen at some locations in the HM forest (*Fig. A1*).

Field data collection

For the non-destructive estimation of tree biomass carbon, 47 plots of 20 m × 20 m (0.04 ha) were taken in the forest (*Fig. 1*, *Table A1*) during November 2017 to December 2018. To estimate the tree above ground biomass (AGB), tree dendrometric variables such as Diameter at Breast Height (DBH) and the total height (Ht) of the tree was measured following UNFCCC protocols. For multi stem trees (which forked below 1.3 m height), the individual diameter of each stem was recorded, summed the DBH squares and their square root was taken (*Eq.1*) producing a single value of DBH for a tree. Tree basal area was computed using equation below (*Eq.2*) (Nizami, 2012).

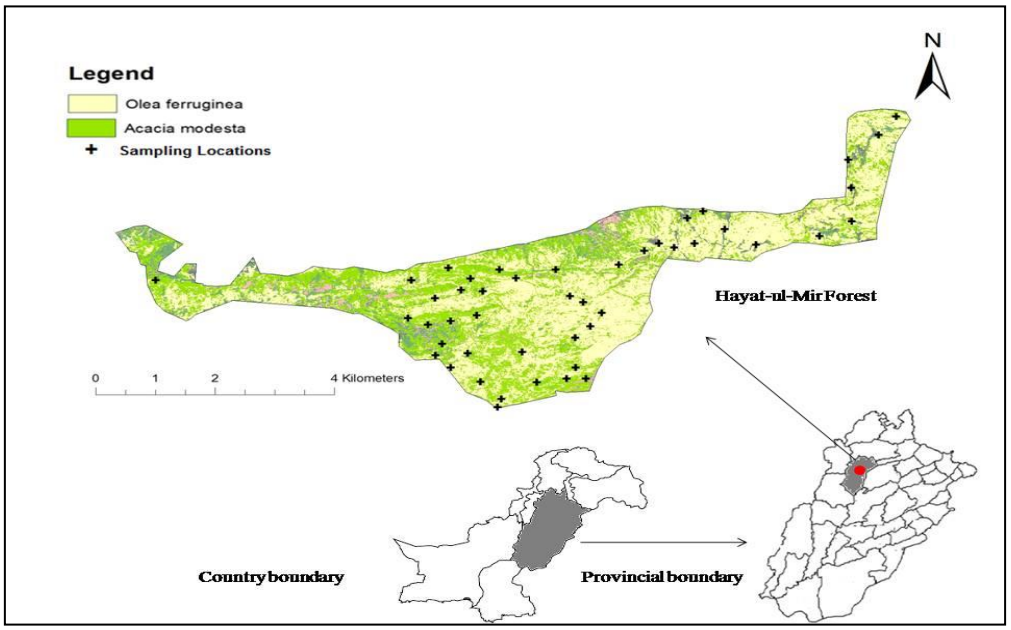

Figure 1.*Spatial distribution of sampling plots taken in the HM forest*

$$DBH = sqrt[DBH_1^2 + DBH_2^2 + \ldots DBH_n^2] \quad \text{(Eq.1)}$$

$$\text{Basal Area} = \pi/4 \times DBH^2 \quad \text{(Eq.2)}$$

The estimation of AGB of *A. modesta* and *O. ferruginea* in HM Reserve Forest was carried out using locally developed volume allometric equations which were considered

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22312245

as a benchmark to check the robustness of other two existing biomass estimation methods (non-destructive) for subtropical forest in cases when local equations are not available. This study is first of its kind to refine and caliberate existing generic biomass models against locally developed models for accurate carbon accounting under REDD+ in Pakistan and for other forests in subtropical region.

AGB estimation using locally developed volume equations

Local harvest based volume allometric equations (Pakistan Forest Institute, 1993) were used to estimate total volume of *A. modesta* (*Eq.3*) and *O. ferruginea* (*Eq.4*);

$$ln\text{TV} = -9.35092 + 0.36032\ ln\text{H} + 2.22653 ln\text{D} \quad \text{(Eq.3)}$$

$$ln\text{TV} = -9.3826 + 0.56528 ln\text{H} + 2.09297 ln\text{D} \quad \text{(Eq.4)}$$

Where TV is the total tree volume, *ln* is the natural logarithm, H is height and D is Diameter at Breast Height. These equations were used to compute individual tree volume of bi-climax community at HM forest which was later multiplied with species specific wood density (Philip, 1994; Nizami, 2012) adopted from World Agroforestry Database (Pearson and Brown 1932) to compute aboveground biomass (AGB).

AGB estimation using generic pantropical biomass allometric equation

The generic pantropical biomass allometric equation (Model 4 from Chave et al., 2014) was used to regress AGB of *A. modesta* and *O. ferruginea* against the product of height (m), DBH (cm) and species specific wood density (gcm^{-3}). This model (based on harvest data from 58 sites across tropics with variable vegetation and climatic conditions) is a revised and improved version of Chave et al. (2005) and was selected as it performs well across forest types in pantropical bioclimatic conditions (*Eq.5*). The model is reported with slightly high variance and mean percent bias when compared with local models but no detectable effect of environmental factors or region on AGB considering height, DBH and wood density as covariates.The previous version (Chave et al., 2005) of this model has been evaluated by Kebede and Soromessa (2018) for *O. europea* L. sub sp. *cuspidata* (synonym *O. ferruginea*) in Ethiopia where allometric equations were developed through semi-destructive harvest and were compared with species specific and generic allometric models. This model has also been previously documented for *O. europea* by Tesfaye et al. (2016) and Muhati et al. (2018).

$$AGB_{est}\ (kg) = 0.0673 \times (\rho D^2 H)^{0.976} \quad \text{(Eq.5)}$$

From the AGB_{est} obtained through local (*Eqs.3 and 4*) and generic allometric equations (*Eq.5*), belowground biomass (BGB) was calculated as 26% of the AGB (Nowak et al., 2008). The AGB and BGB were summed across individuals of both species and total tree biomass (TB) was converted into total tree biomass carbon (TBC) by multiplying with IPCC default factor of 0.50 as carbon accounts for 50% of the total biomass.

Calculation of carbon storage through i-Tree Eco tool

i-Tree Eco (v6.0) tool was used to estimate tree biomass and carbon stored in bi-climax community (*A. modesta* & *O. ferruginea*) of HM forest. For this purpose, hourly annual

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22312245

metrological data and field measurements of DBH, crown height, total tree height and crown light exposure (CLE) data was input into the tool to quantify total tree dry weight and carbon storage using species specific allometric equation. Crown light exposure was estimated considering number of sides of the crown exposed to sunlight following Bechtold (2003). The total tree (above and belowground) carbon in *A. modesta* and *O. ferruginea* was calculated using equation form 1 in the tool database (*Eq.6*).

$$\text{Carbon Storage} = \exp((A + B * \log(\text{Variable}) + (\text{Mean Squared Error}/2)/2 \quad \text{(Eq.6)}$$

where A and B are coefficients and Variable is DBH (*A. modesta*) or DBH & Height (*O. ferruginea*). The total tree dry weight biomass (including 26% of the belowground biomass) was converted to carbon stock by multiplying with a factor of 0.5 (Nowak et al., 2013). This tool was selected for being a novel approach which has not yet been used for tree species in Pakistan and also it additionally quantifies other ecosystem services along with biomass estimates.

The plot based (0.04 ha) biomass estimates were up-scaled to hectare level using an appropriate area based conversion factor and both existing methods were evaluated against locally developed equations to choose the best fit model for carbon stock assessment of the subtropical forests in Pakistan.

Data analysis

For data analysis, SPSS v.19 (Statistical Package for Social Sciences) was used. Independent sample *t*-test was performed to evaluate statistical relationship between biophysical factors (dendrometric factors) of the surveyed population of both species. Mean and standard errors of biomass and carbon estimates were computed to compare for the variation in estimates made by each method. Multiple comparisons were made using Repeated Measures ANOVA and Bonferroni statistics was used to find the significant differences in carbon storage estimates made by each method used in this study. Multiple linear and logistic regression analyses were also run to choose the best fit model based on their relative performance considering TB as dependent and biophysical factors (DBH, Ht, & WD) as independent variables (*Eq.7*).

$$Y = a + b_1X_1 + b_2X_2 + ...b_nX_n \quad \text{(Eq.7)}$$

In the equation above Y refers to the dependent variable, a is the Y-intercept, b_1 through b_n corresponds to regression coefficients and X represents independent variable(s). Goodness of fit statistics was considered for a model which had high value of R^2-adj., lowest AIC (Aikaike Information criteria), BIC (Beysian Information Criteria), RMSE (Root Mean Square Error) and p *value* ≤ 0.05. AIC and BIC were estimated by equations below (*Eq.8 and Eq.9*) where k = number of estimated parameters in the model and L = maximized likelihood function of the estimated model.

$$AIC = 2k - 2\ln(L) \quad \text{(Eq.8)}$$

$$BIC = \ln(n)k - 2\ln(L) \quad \text{(Eq.9)}$$

Results

Structural summary of the forest

In the HM forest, a total population of 399 trees (135 trees of *A. modesta* and 264 trees of *O. ferruginea*) was recorded in 47 survey plots (0.04 ha). Forest dendrometric characteristics have been presented in *Table 1*. *O. ferruginea* had higher tree density per hectare (150 trees/ha) than *A. modesta* (82 trees/ha). There was a significant difference in tree height ($t = 3.76$, $df = 397$, $p < 0.001$), DBH ($t = 3.11$, $df = 397$, $p < 0.01$) and basal area ($t = 3.14$, $df = 397$, $p < 0.05$) of both species but not in case of tree volume ($t = -0.251$, $df = 83$, $p = 0.802$) with highest mean DBH (20.69 ± 0.8 cm) and height (5.94 ± 0.1 m) recorded for *A. modesta* and basal area (4.46 ± 0.6 m^2/ha) and tree volume (17.10 ± 2.4 m^3/ha) recorded for *O. ferruginea* in the survey plots.

Table 1. *Dendrometric characteristics of the Hayat-ul-Mir Forest*

Species	Trees/ha	Height (m)	DBH (cm)	Basal area (m^2/ha)	Tree volume (m^3/ha)
		M ± SE	***M ± SE***	***M ± SE***	***M ± SE***
A. modesta	82	5.94 ± 0.1***	20.69 ± 0.8**	3.44 ± 0.4	16.22 ± 2.6
O. ferruginea	150	5.15 ± 0.1	17.78 ± 0.4	4.46 ± 0.6*	17.10 ± 2.4

***p < 0.001, **p < 0.01, *p < 0.05

Tree biomass and carbon storage

Both methods of biomass estimation used in this study produced comparable estimates for both species when evaluated against locally developed equations. On plot scale the TB and TBC of sampled population presented in *Table 2* shows that the generic allometric equation of Chave et al. (2014) produced slightly higher (70.88 ton and 35.44 ton) while i-Tree Ecotool produced lower (58.77 ton and 29.38 ton) TB and TBC estimates compared to the species specific local equations for bi-climax community (67.12 ton and 33.56 ton).

Table 2. *Total tree biomass and carbon storage in survey plots*

Species	**Tree biomass** (ton)			**Tree biomass carbon** (ton)		
	Local Eq.	**Chave et al. (2014)**	**i-TreeEco**	**Local Eq.**	**Chave et al. (2014)**	**i-Tree Eco**
A. modesta	28.66	28.96	16.97	14.33	14.48	8.48
O. ferruginea	38.45	41.92	41.80	19.22	20.96	20.90
Total	67.12	70.88	58.77	33.56	35.44	29.38

Figure 2 illustrates the mean of TB and TBC of both species of scrub forest estimated using the selected methods. It can be seen from figure below that i-Tree Eco produced lower TB and TBC estimates (10.34 ton/ha and 5.17 ton/ha) than generic pantropical allometric equation (17.36 ton/ha and 8.68 ton/ha) and local (17.06 ton/ha and 8.53 ton/ha) allometric equations when evaluated for *A. modesta*. However, in case of *O. ferruginea* both existing methods produced comparable but slightly higher estimates than local equation.

Repeated measures ANOVA with Greenhouse-Geisser correction showed that mean TB and TBC significantly differed between the methods for *A. modesta* ($F(1.536, 205.78) =$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22312245

31.22, p = 0.000) but not for *O. ferruginea* (F(1.429, 375.78) = 2.162, p = 0.132). For *A. modesta*, Post hoc test using Bonferroni correction revealed that the TB and TBC estimates of generic pantropical allometric equation of Chave et al. (2014) were not significantly different from the estimates of local equation (p = 1.000) but differed significantly in case of i-Tree Eco (p = 0.000) as shown in *Figure 2*.

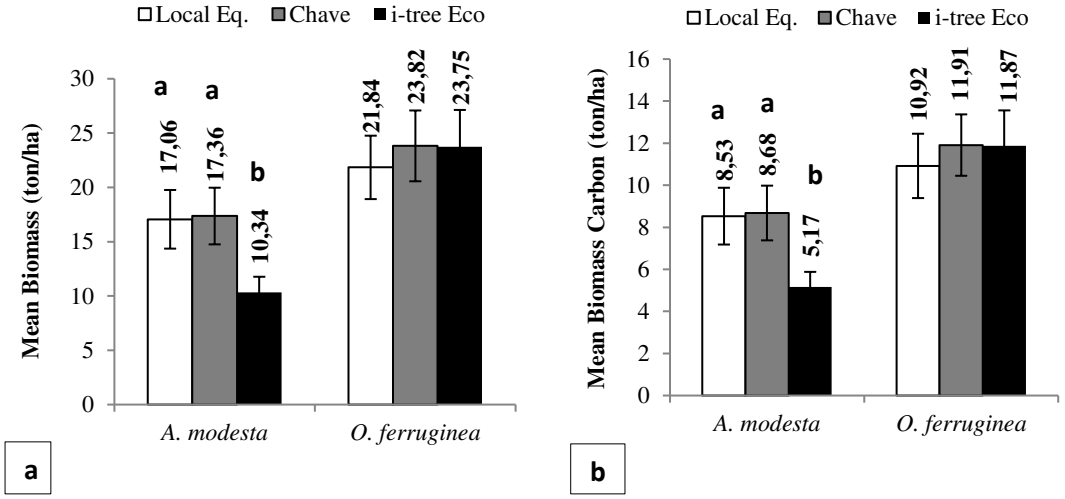

Figure 2.*Mean of (a) total biomass (TB) and (b) total biomass carbon (TBC) calculated using three different methods (bars with similar letters are not significantly different at p ≥ 0.05)*

Model assessment

The results of multiple linear regression analysis (*Table 3*) showed that the covariate DBH was statistically significant (p < 0.001) in all models for both species but height was not statistically significant in the local equations and i-Tree Eco (for *O. ferruginea* only). In case of both species, all of the models were good fit at p <0.001 but highest R^2-adj. (0.802), lowest AIC, BIC and RMSE were reported by generic pantropical allometric model of Chave et al. (2014) for *A. modesta*. However, for *O. ferruginea* the highest R^2-adj. (0.809) and lowest RMSE (0.093) were reported by local equation and lowest AIC and BIC by Chave et al. (2014).

Table 3.*Goodness of fit statistics of regression models for the prediction of TB across both species in the HM forest*

Discussion

This study provides a comparison of methods that can be used to predict the biomass carbon stock of subtropical forests in Pakistan. In this study both existing models compared against the locally developed equations showed goodness of fit statistics at $p < 0.001$. The individual significance of biophysical variables (DBH & Ht) in predicting TB was also assessed through regression analysis. In case of both species, the generic allometric model of Chave et al. (2014) was found better predicting TB considering both DBH and Ht. There was an insignificant relationship of height with TB showing that i-Tree Eco was predicting TB using DBH only suggesting utility of this tool to predict TB if height data is not available for these two species. i-Tree Eco provides a range of dataset of species specific allometric equations for many other species across diverse climatic range. The locally developed allometric equation for *A. modesta* and *O. ferruginea* also showed similar relation with DBH ($p < 0.001$) and tree height ($p = 0.793$ and $p = 0.104$, respectively) suggesting the relative importance of inclusion of individual biophysical variables in the local model.

Goodness of fit statistics of the models used in this study was evaluated on the basis of multiple criteria. Any model which had high value of R^2 adj., lowest AIC, BIC and RMSE was considered best model in predicting TB of bi-climax community of the HM forest. In case of this study, when compared to the locally developed allometric equations, the lowest AIC and BIC was found for the generic pantropical allometric model of Chave et al. (2014) for both species. This model also reported high value of R^2 adj. When evaluated for *A. modesta* but only slightly less than local equation for *O. ferruginea*. This generic model has originally been developed by taking harvest dataset of multiple species across the tropical region (Chave et al., 2014) and its evaluation in this study confirms its robustness and reliability for the forest carbon stock assessment in the subtropical region of Pakistan as well. Results of this study are consistent to the findings of Kebede and Soromessa (2018), reporting goodness of fit statistics of four species specific allometric equations for *O. europea* sub sp. *cuspidata* (synonym of *O. ferruginea*) at $p < 0.001$ and found a strong correlation of AGB with DBH and height but insignificant relation with wood density. Similarly these results are also consistent to the findings of Vieiledent et al. (2012) who reported generic models of Chave et al. (2005) as more reliable and producing less bias for TBC estimates of tropical forests when compared with other generic models.

Among the biomass and carbon estimates, the post hoc test showed no significant difference between the estimates made with local equation and generic allometric equation of Chave et al. (2014) when compared for *A. modesta*, but i-Tree Eco significantly underestimated the TB and TBC. Reasons for this underestimation might be because i-Tree Eco considered DBH only for *A. modesta* in its equation form 1 and also it computes the weight of wood only in TBC estimates for the deciduous tree species (Nowak et al., 2008). i-Tree Eco relying on DBH only did not perform well with low R^2 adj. and high RMSE and AIC compared to the local and pantropical models. Similar results have been reported by Ruiz-Peinado et al. (2012), Huy et al. (2016) and Djomo and Chimi (2017) stating that inclusion of two (DBH & Ht) or three covariates (DBH, Ht & WD) in allometric models better predict biomass than models with DBH only as covariate. From this analysis it can be inferred that in the absence of local allometric equations or restriction in doing destructive harvest to accurately measure the TBC, the pantropical model of Chave et al. (2014) can be used as an alternative to better

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22312245

predict the TBC relying on the field measurements of DBH, height and wood density in subtropical forest.

In case of *O. ferruginea*, the post hoc test showed no significant difference in the means of TBC estimated with local equation and other two existing models. The analysis suggests that both existing models accurately estimated TBC for subtropical scrub forest compared to the local model and can be considered as equal candidate models in predicting TBC if the local equations are not available. In such case it could be advantageous to select the pantropical equation of Chave et al. (2014) than i-Tree Eco considering their relative values of AIC, BIC and R^2 adj.

Most of the biomass estimates in Pakistan are made using generic volume equation of Philip (1994) which draws simple geometric relationship between the basal area (*Eq. 2*), height (H) and form factor (F) multiplied with species specific wood density (ρ) of tree ($AGB = \rho \times [BA \times F \times H$). This model was developed by foresters and is now seldom used in carbon accounting as it assumes fixed form factor and also cannot predict biomass if height data is not available in close canopy forests (Chave et al., 2005). A comparison of biomass estimates of this study has been made with other studies conducted on sub-tropical forests in Pakistan (*Table 4*). The TB estimates of *A. modesta* made using local allometric equation in this study are comparable to the findings of Nizami (2010, 2012) made through Philip (1994) in Kherimurat and Sohawa scrub forests in Pakistan. The species specific allometric equation used by Shaheen et al. (2016) underestimated the TB of *A. modesta* (12.7 t/ha) in the mixed forest at two sites in the Muzaffarabad District, Pakistan compared to the findings of this study. In case of *O. ferruginea* the TB was overestimated (approx. Four times) with volume equation (Philip, 1994) in Shaheen et al. (2016) than current study. The difference in the estimates might be due to the incorporation of differentset of biophysical variables in species specific, generic allometric and simple volume equations in both studies. Other reasons for the difference in the estimates might be related to the tree density, topographic and climatic differences as the subtropical forest in Muzaffarabad district is at a higher elevation, has low temperature and receives higher rainfall than the HM forest as summarized in *Table 4*. Located at the foothills of lesser Himalaya the subtropical forest in Muzaffarabad district is also under anthropogenic threats (not a protected forest) and the local population rely heavily on forest for its needs related to timber, food, fodder and fuelwood resulting in under reporting of actual tree biomass and carbon (Shaheen et al., 2016).

i-TreeEco has widely been used for the estimation of carbon storage and sequestration in urban forests across the United States and European countries. To the best of our knowledge none of the study citing i-Tree Eco for reporting carbon storage of tree species from Pakistan was found in the literature. The tool calculates carbon storage and sequestration using allometric equations based on natural forest-grown North American tree species and socan fairly be used for both natural and urban forests (Nowak et al., 2013; Russo et al., 2014). Results of this study (for *A. modesta*) are consistent to the findings of Russo et al. (2014) who compared the allometric equation against i-Tree Eco and CUFR Tree Carbon Calculator (CTCC) and reported the highest carbon storage value with the allometric equation (179.14 ton), followed by CTCC (140.15 ton) and lowest by i-Tree Eco (134.89 ton) in Bolzano's urban forest, Italy. Results of present study for *O. ferruginea* are contrary to the Aguaron and McPherson (2012) who compared four sets of allometric equations i.e. i-Tree Eco, i-Tree Street, CTCC and Urban General Equations and calculated CO_2 storage of Sacramento's urban forest.

The study reported highest estimates by i-Tree Streets (6.41 Mt) and CTCC (6.4 Mt) followed by urban general equations (5.1 Mt) and lowest estimates by i-Tree Eco (4.9 Mt). In both above mentioned studies i-Tree Eco produced the lowest estimates than other methods because in both studies AGB estimates were reduced by applying a correction factor of 0.80 before computing total tree dry weight. i-Tree Eco is designed on the basis of forest grown trees so this correction factor is applied to the open grown trees as they produce less aboveground biomass than forest grown trees (Aguaron and McPherson, 2012; Nowak et al., 2013; Russo et al., 2014). The latest version of i-Tree Eco however considers crown light exposure (CLE) in place of landuse and applies this correction factor to trees with 4 or 5 CLE. This might be one reason for differences in the estimates of HM carbon stock and other studies.

All of the methods used in this study have produced comparable results with relatively minor mean differences which might have arisen from the variation in the input of tree biophysical factors and/or values of coefficients used in allometric equations evaluated in this study. Findings of Huy et al. (2016) also reported dissimilar values of coefficients of allometric equations as one reason for the variation in AGB estimates of broadleaf evergreen forests in Vietnam.

Conclusion

Reporting and implementation of REDD+ targets in Pakistan requires accurate assessment of forest biomass carbon through reliable methods. This study conducted in the HM forest reported high tree density and biomass of *O. ferruginea* but at lower DBH and height than *A. modesta*. The study provides first evidence of applicability of existing generic biomass allometric models in the subtropical forest in Pakistan. All of the models used in this study fitted data well but among them the models considering both height and DBH as covariates better predicted total biomass than other (DBH only) based on R^2 adj., RMSE, AIC and BIC values. For *O. ferruginea* both existing models accurately predicted TB when compared to the local equation while in case of *A. modesta* significant underestimation of TB was reported by i-Tree Eco (DBH only model for this species). Considering the multiple criteria (AIC, BIC, R^2 adj. and RMSE) to evaluate the good fit statistics of the existing models against the local equations, the generic pantropical model of Chave et al. (2014) was found better predicting TB suggesting its wide applicability and robustness for both deciduous and evergreen species while i-Tree Eco for evergreen species only in subtropical forests in the absence of local allometric equations. The analysis done in this study is helpful in selecting an appropriate biomass model for subtropical region to report carbon stock changes under REDD+. The study suggests that local and generic subtropical models considering the additional effect of other factors like crown area, site characteristics and forest type must be developed and caliberated for more precise accounting of national carbon stock.

(Received 10th Oct 2019; accepted 30th Jan 2020)

Abstract. Following the designation of R-30 as a source of resistance to the three rusts; it was successfully introduced in a breeding program with Tamuz 2 using the pedigree method in 1997. The progenies of three successive generations (F3-F5) were screened for resistance to the three rusts under artificial inoculation conditions at the adult plant stage in Twaitha. Out of 135 hybrid lines, 12 promising lines were selected. The selected lines were introduced in a comprehensive evaluation test for yield potential and response to rusts and bunt diseases in different locations. As a result, the promising line "63" was selected due to its high grain yield in the presence and absence of rusts and bunt diseases. Yield potential of the genotype is 10-19% higher than that of the local commercial cultivars Araz and Tamuz 2. Maaroof was registered and released as a new cultivar with high yield potential and multi resistance to rusts and bunt diseases by the National Committee of Registration and Release of Agricultural Cultivars/Iraqi ministry of agriculture. There was a great emphasis on multiplication and delivery of the seeds to farmers. Yield potential of Maaroof on farm-scale was 3750 and 4750 kg/ha under rain-fed and irrigated conditions respectively.
Keywords: *Triticum aestivum, host resistance, wheat rusts, new genotypes, Iraq*

Introduction

Wheat (*Triticum aestivum* L.) is one of the most essential and strategic cereal crops for the majority of the world's population. It is the most critical staple food for about two billion people (36% of the world population). Worldwide, wheat provides nearly 55% of the carbohydrates and 20% of the food calories consumed globally (FAOSTAT, 2018). Wheat production area's in Iraq is divided into rain-fed and irrigated zones. Rain-fed areas are mainly in the north including Kurdistan region. An estimated 3.0 million tons of wheat were harvested in 2018, with a 14% reduction from 2017 production and 20% from the past five-year average, largely due to unfavorable environmental conditions. Nearly the same amount of wheat had been purchased by mid-August 2018 (FAO, 2018). In 2015, USDA projected that Iraq would continue to experience a long-term shortfall in wheat production and that it would need to import 3.8 million tons in 2015-16, followed by larger quantities each year after. By 2024-25, it projected that Iraq would require 4.9 million tons of wheat imports annually (USDA, 2015).

Biotic and abiotic stress particularly drought and salinity, are the leading causes of losses in wheat production. Many diseases can attack wheat, mainly caused by fungi, bacteria, and viruses. Yellow, brown and black stem rust diseases incited by the fungi *Puccinia striiformis* f. sp *tritici*, *P. triticina* and *P. graminis* f sp. *tritici* respectively are the most critical grain yield-limiting factor of wheat in Iraq followed by common bunt

DOI: http://dx.doi.org/10.15666/aeer/1802_22472258

disease; *Tilletia tritici* and *T. laevis* (Al-Maaroof et al., 2001, 2005, 2012). Yield losses due to the three rusts on wheat cultivars vary from 10 to 70% depending on the levels of resistance, stage of the crop at disease onset, pathogen races and, the environmental conditions (Al-Maaroof et al., 2001; Al-Maaroof and Nori, 2018).

Breeding for disease resistance is the most sustainable strategy to reduce yield losses, and also it is an environmentally safe approach to control the diseases (Line and Chen, 1995; Singh and Trethowan, 2007). Great importance is given to improve disease resistance in wheat using different breeding programs in Iraq (Ibrahim et al., 1993a,b). Several resistant and high yielding wheat cultivars were released in the nineteens (NCFRRAV, 2014). Successive release of the resistant cultivars participated in reducing grain yield losses caused by rust (Al-Maaroof et al., 2001, 2005, 2012). With the introduction of the resistant varieties new virulence's and races of rust pathogens also develop due to mutation or genetic recombination's that have contributed in switching resistance of these varieties (Al-Maaroof et al., 2003, 2005, 2010, 2012). Therefore, breeding for resistance to rust diseases and developing new resistant cultivars having higher yield potential became the main target in all wheat breeding programs and considered as the most economical and effective way to eliminate the use of fungicides and reducing crop losses caused by the disease (Singh et al., 2004).

The present study represents a long term breeding program for developing a new multi-resistant bread wheat cultivar "Maaroof" with different levels of resistance to brown, yellow, stem rust and common but diseases.

Material and Methods

Following designation of R-30 as a source of multiple resistance to the three rusts among hundreds of genotypes that was previously tested to rust diseases for five consecutive season under artificial inoculation conditions with the prevalent dominant races of the pathogens in different environmental conditions in Iraq (Al-Maaroof et al., 2002); it has successfully introduced in a breeding program with the promising local cultivar Tamuz 2 using the pedigree method in 1997. The progenies of three successive generations (F3-F5) were screened to the three rusts under artificial inoculation conditions at the adult plant stage in Twaitha research experimental station. The test variants were planted in a single 2-meter long, 30 cm apart. The highly susceptible cultivars Morocco and SaberBeg were used as spreaders. One hundred thirty-five hybrid lines were evaluated based on their desired agricultural characteristics, drought tolerance and resistance to rust and common bunt diseases in observation and preliminary comparative experiments with the parents under both irrigated and rain-fed conditions (Pessarakli, 2011). The best 12 selected genotypes were introduced in small scale yield trial conducted at Latifia and Bakrajo experimental stations in 6 rows plot of 4.0 m length spaced at 30 cm along with the local checks in RCBD with three replicates. Comprehensive evaluation test for grain yield potential, grain quality and response to the three rusts and bunt diseases were promoted in multi locations and agro-system in Large scale yield trial tests using RCBD with three replications in 16 rowed plots of 6.0 m length spaced at 30 cm. The recommended agricultural practices were adopted to raise a satisfactory crop as per ministry of agriculture (MOA) standards.

Artificial inoculations with a mixture of field collection of the three rust prevalent virulence's were carried out during March in each location using aqueous uredospore suspension to which two drops of Tween-20 were added to break the surface tension.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22472258

Seeds of each genotype were artificially inoculated with a bulk population of *T. tritici*, *T. laevis* and *T. intermedia* teliospores collected from different locations in the previous season at a rate of 0.5 g/100 g seeds. Inoculated seeds were mechanically mixed for 15 minutes by shaker at 80 rpm/minute (Gotes, 1996). Each genotype was planted by hand at a depth of 5 cm in two 1.5 m rows (5 g seed/line) spaced 30 cm between lines and 60 cm between treatments at Twaitha, Baghdad (Irrigated) and Talefar, Nineveh (Rain-fed).

Disease scoring for the three rusts was recorded as infection type on each genotype (Stakman et al., 1962; Lewllen et al., 1967) and disease severity as percent infection on the plants according to the modified Cobb's Scale (Peterson et al., 1948). Coefficient of Infection (CI) was calculated by multiplying the response value with the intensity of infection in percent (Roelfs et al., 1992). Infection percent of each genotype to common bunt disease was calculated at dough stage by counting the number of healthy and infected spike per each meter according to Dodov and Todorova (1974) modified method.

During the coordinated evaluation, data on agronomic traits including plant height, flag leaf area, stem width, spike length and awn length were recorded from ten random plants in each experimental unit; yield component traits including number of spike per square meter, spike weight, thousand grain weight, number of grain per each spike, grain weight per each spike were calculated from 50 randomly selected spikes from each plot at dough stage; grain yield was calculated by random harvesting of plant spikes in one meter square from the center of each plot at dough stage when the grain moisture was 14% (Bell and Fischer, 1994); disease resistance, quality attributes, and agronomical manipulations were also recorded (AACC, 2000; Salman and Mahdi, 2005). All the data were statistically analyzed at p=0.05 significant levels using the method of analyses of variance (ANOVA). Least significant differences at 5% level were used to compare the mean of traits.

The high yielding resistant promising genotypes were sent for registration and release by the ministry of agriculture. Great emphasis was done on multiplication of high-grade seed of the new cultivar "Maaroof" then delivering them to the farmers.

Results and Discussion

Results of screening (R-30/Tamuz2) hybrid variants to the three kind of rusts and common bunt diseases under artificial inoculation conditions at the adult plant stage and some other agronomic traits are represented in *Table 1*. In general, out of 135 tested variants; 18 resistant and 43 moderately resistant were identified to brown, yellow and stem rust diseases either alone or in combinations, while 38 genotypes out yielded their parents and 31 variants characterized with earliness on their parents. Eleven variants continued in their resistance to brown rust through the study period, while 8 and 5 variants explored resistant reaction to yellow and stem rust diseases, respectively. Moderately resistance reaction was diagnosed in 26, 19 and, 5 variants to brown, yellow and stem rust diseases, respectively. Common bunt disease resistance was identified in 5 resistant and 18 moderately resistant variants, respectively. Thirty-three and 65 variants were resistant and moderately resistant to lodging, while six variants only showed drought tolerance. Selection of the variants for further studies were carried out based on their resistance to the target disease alone or in combination accompanied with yield and yield components with other agronomic traits, where number of selected resistant and moderately resistant variants reached to 9, 12, 8, 14, 17 and 5 in brown rust, yellow rust,

DOI: http://dx.doi.org/10.15666/aeer/1802_22472258

stem rust, common bunt, lodging, and drought tolerance tests. Among the selected variants, the best 12 genotypes were introduced in small yield trails.

Table 1. *Host reaction of (R-30/Tamuz 2) hybrid variants to Yellow, brown stem rusts and common bunt diseases and some other related agricultural traits during 2001 to 2003 at Twaitha and Telafar experimental stations, Iraq*

Target Traits	Host Reaction*				Earliness	Out Yielded	No. of selected variants

LODGING	33	65	27	8	31	38	17
DROUGT TOLERANCE	6	18	63	48	31	38	5

*: R, resistant; MR, moderately resistant; MS, moderately susceptible; S, susceptible

The results of *Table 2* show that the average grain yield and yield components of the selected (R-30/Tamuz 2) hybrid variants compared to the local cultivar during three successive seasons 2004-2006 at Latifia; indicating that there is a clear superiority of 1-14% in the mean of grains yield of the selected genotypes on Tamuz 2. The advantage was attributed mainly to improving grain filling rate by 37% in the best variant and 10% increase in plant tillering trait (number of ears per square meter).

Table 2. *Grain yield and yield component performance of the selected (R-30/Tamoz 2) hybrid variants comparing with the local cultivar in micro trials at Latifia and Jaderiah experimental station, Baghdad, Iraq during 2004-06*

Variance analysis of the data indicates the presence of significant differences among the genotypes in the mean of grain yield. Variant 84 out yielded all other genotypes with 566.8 g/m^2 and significantly surpassed most of the other variants including the local cultivar followed by variant no.63 that produce 563.0 g/m^2, while the lowest grain yields were created by the local check and variant no.113 with 497.4 and 481.6 g/m^2, respectively. The high yield potential in genotype 84 is mainly attributed to the high number of spike per meter square (338.8), while in genotype 63 is due to the top grain weight and the number of spike per meter square (53.55 and 341.1).

Number of spike per unit area, number of grain per spike and grain weight are the principle grain yield component of wheat (Al-Eseel, 1998). Each character separately or in combination with each other can increase or decrease grain yield in wheat. Grain yield is a complex character that depends on a large number of environmental, morphological, and physiological factors (Alam et al., 2007). High significant differences in grain yield components among the genotypes indicate the role of hybridization as a breeding method to induce wide genetic variations in the second generation, which has assisted in selecting the promising genotypes in the segregated generations (Baktash, 2001).

Table 3 data represent grain yield and yield components of the selected (R-30/Tamuz 2) genotype compared to the common local cultivar during three successive seasons 2009-2011 under Bakrajo experimental station representing rain-fed cultivation system; Variance analysis of the data indicates the presence of significant differences among the tested genotypes in the mean of grain weight per each spike, the maximum value of grain weight was detected in genotype 84 (1.97 g) which was significantly surpassed all other genotypes followed by genotype 63 (1.93 g), while the lowest value of spike grains weight was recorded in genotype 10 (1.61 g). Significant differences were detected in the effect of the genotypes in thousand-grain weight; the highest value (42.32 g) was recorded in genotype 33, which was significantly surpassed all other genotypes except genotype 63. Results also showed significant differences among the genotypes in the number of grains per spike; the highest value of this trait (56.8) was detected in genotype 84, which was significantly surpassed all other genotypes followed by genotype 63, while the lowest grain number of spikes were produced by genotype 23 (*Table 3*).

Number of grains per spike is one of the crucial components of yield. That's why any change in this value will directly affect the grain yield of the cultivar (Rajaram et al., 1996). Many biotic and abiotic factors can reduce the grain number per spike; also, the higher seed rate can result from low grains in the spike (Al-Maaroof et al., 2001).

Genotype 63 significantly surpassed all the tested genotypes in the number of spikes per meter square by producing 587.3 spike per meter square followed by genotype 84, while the lowest spike number per unit area was produced by genotype 10 (434.5) (*Table 3*).

The number of spikes per unit area depends on the genotype and environment and strongly influenced by seed rate and plant density, high temperature enhances fast development of the plant and low tillers production (Loveras et al., 2004).

Significant differences also detected among the genotypes in the mean of grain yield. Genotype 63 out yielded over all other genotypes with 399.1 g/m^2 and significantly surpassed all other genotypes except genotype 84, while the lowest grain yields were produced by genotypes 83 with 326.6 g/m^2. The lesser grain yield production of the genotypes in 2010 compared with 2009 and 2011 is mainly due to the unfavorable environmental conditions and the severe epidemic of yellow rust in 2010 (Al-Maaroof et al., 2012).

The high yield potential of genotype 63 is mainly attributed to the higher number of spike per meter square (587.3), while in genotype 84 was due to the higher number of grains per spike and number of spike per meter square (54.3 and 447.1, respectively).

Based on the above data and information concerning the performance of the tested genotypes and their response to the main wheat diseases under different environmental conditions, Genotype 63 was candidate to the large scale yield trail and multi-location test with the dominant local wheat cultivars in each location and nominated for registration and release under the name of "Maaroof".

Macro wheat yield trial results at Bakrajo experimental station (*Table 4*) shows that grain yield of Maaroof ranged from 3878.5 to 4548.7 kg ha^{-1} as compared to cv. Aras and Tamuz 2 in 2012 and 2013 for which grain yields ranged from 3454.2 to 3975.6 and 3696.8 to 4346.3 kg ha^{-1}, respectively. The new cultivar Maaroof out yielded both local cultivars by 12.3-14.4% in Aras and 4.7-12.2% in Tamuz 2 in 2012 and 2013, respectively.

The mean high yield potential of Maaroof (4213.6 kg ha^{-1}) is mainly attributed to the high number of spike per meter square (601.2) which is significantly surpassed the mean of the same trait in Aras and Tamuz 2 by 5.3 and 14.5%, respectively. Tamuz 2 significantly surpassed Maaroof and Aras in the mean number of grain per spike by 7.5% and 14%, respectively, while Aras significantly surpassed Tamuz 2 in the mean number of spike per meter square by 8.7% (*Table 4*).

Multi-location comparison of the new cultivar "Maaroof" with the predominant check cultivar for grain yield in 7 locations with different agro-ecological zones representing the main wheat production area's across Iraq is given in *Table 5*. Results revealed that Maaroof gave 14.3% higher grain yield than the check cultivar Aras on the bases of 5 locations and 6.3% and on Tamuz 2 on the bases of four locations. Grain yield increase of Maaroof ranged from 1.5-42.6% on Aras and 1.5 to 6.3% on Tamuz 2 based on the locations. No significant differences were obtained in the grain of Maaroof and Adana in four locations except in Erbil where Adana out-yielded Maaroof by 6.3%.

Table 5. *Grain yield performance of Maaroof compared with the local wheat cultivars at multi-location yield trials during 2014-2015*

Location	Grain yield (kg ha^{-1})				LSD 0.05

Differences in genotype performance in different locations clearly state the interaction between the genotype and environment in each location as it is indicated in earlier studies (Annicchiarico, 2002).

Table 6 results represent a wide range of host reaction between the tested bread wheat cultivars with the natural populations of *P. striiformis, P. graminis* f.sp *tritici* and *P. triticina* pathogens started from high resistance reaction in Maaroof to high susceptibility in SaberBeg and Adana. Maaroof explored multiple resistance reaction to yellow and stem rust diseases and moderately resistance to brown rust diseases during the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22472258

severe Epidemics of the diseases through the study period. While all the local cultivars showed moderately susceptible to highly susceptible response to yellow and brown rust diseases, and only susceptible to highly susceptible response to stem rust disease. Furthermore, high significant differences between the tested cultivars in coefficient of infection value (C.I), the highest amount of C.I was recorded in Saber Beg and Maxipak to yellow rust (10.02 and 81.3, respectively), and brown rust disease (9.70 and 9.25) respectively, while to stem rust detected in SaberBeg and Adana (8.87 and 8.79, respectively). The new cultivar Maaroof showed the lowest C.I value to the three rust diseases. Maaroof significantly decreased the coefficient of infection value to yellow rust by 95-99%, Stem rust by 97-98% and brown rust by 90-95% as compared with the commercial wheat cultivars.

Table 6. *Mean coefficient of infection value (CI) and infection type (IT) of Maaroof to yellow, brown and black stem rust diseases as compared with the local wheat cultivars during the epidemic of each disease during 2010 to 2014*

Cultivar	Yellow Rust		Stem Rust		Brown Rust		Mean

LSD 0.05		1.23		0.85		0.91		0.99

1. IT: Infection Type, R= Resistant, MR= Moderately Resistant, MS= Moderately Susceptible, S= Susceptible, HS= Highly Susceptible (Stakman et al., 1962).
2. Coefficient of infection (CI): calculated by multiplying the Disease severity (DS)value with Infection Type (IT) (Roelfs et al., 1992).
3. Data transformed using Arcsine Transformation Formula for analysis purpose

The coefficient of infection value facilitates the statistical ranking or comparison between the genotypes with different responses to the disease. It is adding two separate factors in a single value results in nearly equal coefficient but from different disease score. The differences in the genetic background of resistance reflect the differences in the infection type toward the disease. The infection type in some cultivars may be changed by time due to the appearance of new virulences in the pathogen population. Some cultivar may stay resistant to many years, but after a period it will be susceptible. Al-Maaroof et al. (1995) mentioned Tamuz 2 was resistant at the time of release in 1992 while later on became susceptible. An unknown gene identified to confer resistance to Tamuz 2 (Al-Maaroof et al., 2005). The ability of the pathogen to change itself and its virulence and appearance of more aggressive pathogen might happen by the sexual reproduction, combination or crossing methods and other mechanisms. Hence, it is essential to study the pathogen population annually to recognize the new virulence's that may come from different countries mainly the disease is airborne, which make it very difficult to control, and it may overcome resistance of some cultivars after release

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22472258

according to boom and bust cycle (Roelfs et al., 1992). Possessing more resistant genes in one cultivar increased the time of resistance stability, and decrease the probability of developing new virulence's (Messmer et al., 2000; Marasas et al., 2001). Based on this fact, we started our breeding program to improve resistance level in Tamuz 2.

Recently, many new virulence's and races were detected in Iraq that can attack most of the local wheat cultivars, such as Yr27 in *P. striiformis* population and race TKKTF and TTTTF in *P. graminis* populations (Al-Maaroof et al., 2015; Al-Maaroof, 2017).

The new promising genotype "Maaroof" was a candidate for registration and release as a new wheat cultivar for irrigated and rain-fed area's in Iraq due to its higher grain yield potential over the local commercial cultivars in the presence and absence of rust diseases. Mean coefficient infection of the cultivar was 0, 1.2, and 4.3 to yellow, stem, and brown rust diseases, respectively. It was also moderately resistant to common bunt, leaf blotch diseases, and tolerant to drought (*Table 7*). Molecular marker analysis of Maaroof using twelve SSR markers indicated the presence of the known resistant genes *Lr24* and *Lr46* to leaf rust disease, *Yr29* to yellow rust disease and *Sr22*, *Sr36* and *Sr46* to stem rust disease. Presence of some other unknown resistant genes as well probably will participate in conferring the multiple resistance to this cultivar against the three rust diseases at the adult plant stage. Yield potential of the new cultivar "Maaroof" was 10-19% higher than Araz and Tamuz 2. Grain yield potential of Maaroof on farm-scale ranged from 3750 and 4750 kg/ha under rain-fed and irrigated conditions, respectively. Most of the agronomic traits, qualitative and quantitative characteristics of the new bread wheat cultivar "Maaroof" presented in *Table 7* which indicates that Maaroof has shown good suitability for industrial and product making as well. It possesses higher value for other quality traits like protein content (15%), hectoliter weight (79.1), Specific loaf volume (cm^3/g) (2.37) that fall in the category of good quality according to the grain quality standers (AACC, 2000). Physiochemical, rheological, and baking characteristics of Maaroof is also confirmed in earlier studies (Sabir and Al-Maaroof, 2018).

Table 7. *Some agronomic traits, qualitative and quantitative characteristics of the new bread wheat cultivar "Maaroof"*

Conclusions

The long term breeding program efforts led to the development of the new promising wheat cultivar Maaroof which was registered and released by the national committee of registration and release of agricultural cultivars/Iraqi ministry of agriculture according to order no. 40 dated 30th October, 2014 as a new cultivar with high yield potential under irrigated and rain-fed conditions coupled with multi-resistance to the three kinds of rusts and bunt diseases and has better quality traits.

The new variety may provide an excellent choice to the farmers in different agro-ecological zones of Iraq to increase wheat yield under low inputs and stress conditions. Furthermore, it can help in reducing the pollution risk of pesticide application in Iraq.

Acknowledgments. The first author is highly appreciable to the International Center for Agricultural Research in the Dry Areas (ICARDA) for providing seeds of the resistant sources to rust diseases, Ministry of Science and Technology (MOST) for funding the initial stage of the program, and College of Agricultural Sciences, Sulaimani University for their continuous support to the project of high grade seed production of the new promising wheat cultivar and delivering it to farmers.

(Received 17th Oct 2019; accepted 23rd Jan 2020)

Abstract. The purpose of this research was to determine the effect of slurry applied on its own and supplemented with mineral fertilizers or soil conditioners (UGmax and Humus Active) on the yield of *Lolium multiflorum* and on its total protein and crude ash contents. The research was conducted on the basis of a two-year (2016-2017) field experiment in which *Lolium multiflorum* forage grass of the Dukat variety was used. For the two growing seasons the highest average yield of the grass was obtained from plots with slurry application and mineral fertilizers. However, interaction of slurry with soil conditioners resulted in a lower yield compared to the plot where slurry was used on its own. The highest total protein content was obtained to *Lolium multiflorum* treated with slurry supplemented with mineral fertilizers. The highest crude ash content (an average across growing seasons and treatments) was recorded in the biomass of the third harvest, with the lowest amount recorded in the first.
Keywords: *fertilization, feed value, forage grasses*

Introduction

The primary nutrient that determines forage quality is protein. According to Brzóska and Śliwiński (2011) total protein is made up of true protein and non-protein nitrogen compounds. Kukułka and Kozłowski (2004) point out that the share of true protein in grass biomass is 80-95% of total protein, while non-protein nitrogen compounds constitute the other 5-20%. The content of this nutrient in forage is affected to the highest degree by the level of nitrogen fertiliser. However, the amount of nitrogen doses mainly increases the content of non-protein nitrogen in plants. For this reason, with intensive nitrogen application the share of true protein might be reduced by up to 50-60%.

According to Falkowski et al. (2000), total protein content in grass also depends on the species and even on the variety, habitat fertility with the level of nitrogen, the development stage of the plant, the weather, and the harvest.

In addition to total protein, crude ash content is equally important from the point deleted of plant nutritional value (Kitczak et al., 2011). Forage mineral content is dependent on the species composition, the stage of plant development during harvest, and on weather conditions. Chemical elements required by animals in large quantities are potassium, phosphorus, magnesium, and calcium. Equally important but absorbed in small quantities are microelement such as copper, zinc, or manganese (Falkowski et al., 2000).

DOI: http://dx.doi.org/10.15666/aeer/1802_22592268

The research was aimed at assessing the yield of *Lolium multiforum* biomass, as well as the content of total protein and crude ash as a result of slurry applied on its own and supplemented with soil conditioners or NPK mineral fertilisers.

Supplementing the slurry with biopreparations was supposed to show how it will affect the amount of biomass obtained as well as the content of protein and ash components in it. In addition, the experiment was to assess whether the addition of biological preparations to liquid manure is able to balance complementary mineral fertilization.

Materials and methods

The research was carried out on the basis of a two-year (2016-2017) field experiment established at the experimental facility of the University of Natural and Sciences and Humanities in Siedlce, with three replications and random layouts. The area of an experimental plot was 4.5 m^2 (1.5 x 3.0 m).

The main experimental factor tested in the research was slurry used separately and supplemented with NPK mineral fertilizers or soil conditioners with the commercial names of UGmax and Humus Active. The following research units were set up: (1) control (no treatment); (2) slurry; (3) slurry + UGmax; (4) slurry + Humus Active; (5) slurry + NPK.

The effect of slurry, soil conditioners, and mineral fertilisers was tested on the forage grass of the *Lolium multiflorum* species of the Dukat variety. It was sown in autumn 2015 at the sowing standard of 18 kg ha^{-1}. Slurry from dairy cows was used as natural fertiliser. It was applied each year in a total dose of 30 m^3 ha^{-1} divided into three equal parts used before each growth cycle.

Slurry had dry matter concentration of 10%, with a narrow ratio of C:N (8:1), while the concentration of selected macronutrients was as follows (g kg^{-1} DM): N-33.0, P_2O_5-16.0, K_2O-16, MgO-10.0 and Ca-21.0. Soil conditioners, according to the Institute of Soil Science and Plant Cultivation in Puławy, Poland, improve soil properties. Their composition is shown in *Table 1*.

Table 1. *Composition of soil conditioners*

Soil conditioner	Macronutrients (g kg^{-1})						Micronutrients (mg kg^{-1})				Microorganism and others
	N	P	K	Ca	Mg	Na	Mn	Fe	Zn	Cu	
UGmax	1.2	0.2	2.9	-	0.1	0.2	0.3	-	-	-	Lactic acid bacteria, photosynthetic bacteria, Azotobacter, Pseudomonas, yeast, actinomycetes
Humus Active	0.2	1.3	4.6	3.0	0.5	-	15	500	3	1	Permanent active humus with beneficial microorganisms

Soil conditioners were used annually before the first growth cycle at doses recommended by the manufacturer, i.e. UGmax (Ecodarpol company) at 0.6 L ha^{-1} and Humus Active (Bogdan company) at 50 L ha^{-1}. The addition of biologicals slurry was supposed to increase the use of manure nutrients by reducing losses, especially nitrogen. In addition, both biopreparations alleviate the symptoms of drought. Mineral nitrogen-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22592268

phosphate-potassium fertilisers (NPK) were used in the following doses: N – 100, P (P_2O_5) – 80, K (K_2O) – 120 kg ha^{-1}. Mineral nitrogen fertilizers were used in the form of ammonium nitrate (NH_4NO_3), phosphorus in the form of triple granular superphosphate ($Ca(H_2PO_4)_2$) and potassium in the form of potassium salt (KCl). Phosphorus was applied once a year before the first growth cycle, whereas nitrogen and potassium doses were divided into three equal parts: the first before the start of vegetation, the second and third before the second and third growth cycles.

The experiment was set up on the soil with granulometric composition of loamy sand, the order of anthropogenic soils, the type of culture earth soil, and the subtype of hortisole (Polish Soil Classification, 2011). Chemical analysis of the soil found that carbon concentration in organic compounds (C_{org}) was 14.50 g kg^{-1} DM, with total nitrogen of 1.36 g kg^{-1} DM. The ratio of C:N was 10.6:1, and the pH value was 6.7. The concentration of absorbable forms of phosphorus (170.00 mg kg^{-1} DM) and magnesium (84.00 mg kg^{-1} DM) was high, with moderate concentration of potassium (114.00 mg kg^{-1} DM).

Hydrothermal conditions were determined on the basis of meteorological data from the Hydrological and Meteorological Station in Siedlce. In order to measure temporal variability of weather conditions and their effects on plant growth and development Sielianinov's hydrothermal coefficient (*Table 2*) was determined (Bac et al., 1993). It was calculated using the monthly sum of atmospheric precipitation (P) and the monthly sum of average daily air temperatures (Σt), applying the formula: $K = P/0.1\ \Sigma t$ (Skowera and Puła, 2004).

Table 2. *The value of Sielianinov's hydrothermal coefficient (K) in the growing seasons*

Year	Month						
	April	**May**	**June**	**July**	**August**	**September**	**October**
2015	1.36	1.87	1.64	0.59	1.92	0.64	0.12
2016	1.22	2.63	0.87	1.08	0.18	1.46	1.94
2017	2.88	1.15	1.08	0.45	0.96	1.92	1.90

$K \leq 0.4$ extremely dry (ed), $0.4 < K \leq 0.7$ severely dry (sd), $0.7 < K \leq 1.0$ dry (d), $1.0 < K \leq 1.3$ moderately dry (md), $1.3 < K \leq 1.6$ optimal (o), $1.6 < K \leq 2.0$ moderately wet (mw), $2.0 < K \leq 2.5$ wet (w), $2.5 < K \leq 3.0$ severely wet (sw), $K > 3.0$ extremely wet (ew)

The optimal value of this coefficient was the range of $1.3 < K \leq 1.6$ (Skowera and Puła, 2004). In the first year (2016) the optimum thermal and humidity conditions occurred only in the month of September, with severely wet May, while June, July, and August, the most important months for plant growth and development of plants, were dry, moderately dry, and extremely dry. In the second year of the experiment the period from May to August ranged from moderately dry to severely dry, and the optimum conditions were not recorded during any month of the growing season.

During the two-year experiment in each growing season three harvests of grass were collected. Immediately after each harvest fresh matter was weighed, and a sample of 0.5 kg was collected to determine the yield of dry matter and to perform chemical analyses. The yield of dry matter was determined with the drying method. Total protein and crude ash content was measured with the near-infrared spectroscopy method (LSDS), using the LSDFlex N-500 with the ready-to-use INGOT calibration for dry forage. The

method is described in detail in the Polish standard of PN-EN ISO 12099:2010 and in the literature (Burns et al., 2010; Reddersen et al., 2012).

Analysis of variance for a three-factor experiment was used to process the results statistically. The significance of the effect of various treatments on the value of the tested traits was checked with the Fisher-Snedecor F test. The statistical program of Statistica 6.0-2001 was used for calculations.

Results

Dry matter yields (*Table 3*) of *Lolium multiflorum* showed a significant variation depending on the treatment applied and the harvest. In the first and second year the highest yield, 12,40 and 12.90 Mg ha^{-1}, respectively, was obtained from the plot where slurry was supplemented with NPK fertilisers. The lowest biomass yield was on the control plot (8.70 in the first and 9.50 Mg ha^{-1} in the second year.

In the first and second year the highest yield, 12,40 and 12.90 Mg ha^{-1}, respectively, was obtained from the plot where slurry was supplemented with NPK fertilisers. The lowest biomass yield was on the control plot (8.70 in the first and 9.50 Mg ha^{-1} in the second year. The addition of soil conditioners to slurry did not significantly increase the biomass of the grass compared with plots treated with slurry only. In the first year of the research the biomass yield on the plot treated with slurry and the Humus Active soil conditioner was lower than on the plot with slurry applied on its own. In the second year, plants responded with a lower yield to both of the soil conditioners added to slurry.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22592268

The amount of biomass in individual harvests, as an average for treatments, was the largest in the first one (4.04 and 4.30 Mg ha^{-1}), but the smallest in the third (3.26 and 3.22 Mg ha^{-1}). The biomass yield (average for years) was significantly higher only on the plot where slurry was supplemented with mineral NPK (12.65 Mg ha^{-1}) than in plants where slurry was applied on its own (11.90 Mg ha^{-1}).

The total protein content in grass dry matter (*Table 4*) was significantly differentiated across treatments and growing seasons. The largest average protein content was in plants treated with slurry supplemented with mineral NPK; in the first year it was 162.8 g kg^{-1} DM, in the second 163.4 g kg^{-1} DM. The smallest average protein content of *Lolium multiflorum* was recorded on control: 128.4 g kg^{-1} in the first and 129.4 g kg^{-1} in the second year of the experiment.

The addition of soil conditioners to slurry did not have a more favourable effect on protein content than the effect of slurry applied on its own. The mean protein content in plants treated with soil conditioners and slurry was lower than on plots treated with slurry only. Mean (across years and treatments) protein content decreased in consecutive harvests, and it was the largest in the first (155.4 g kg^{-1}) and the smallest in the third (145.9 g kg^{-1}).

Table 4. *Protein concentration in Lolium multiflorum dry matter (g kg^{-1})*

Growing season (B)	Harvest (C)	Treatments (A)					Means

Another ingredient in assessing feed quality is crude ash. Crude ash content in *Lolium multiflorum* dry matter (*Table 5*) significantly varied in both years. In the first year of research, the largest accumulation of crude ash (107.3 g kg^{-1}) was recorded in the biomass of the grass treated with slurry only. In the second year, on average, the most crude ash was on plots with slurry and mineral fertilizers (119.5 g kg^{-1}).

The smallest crude ash content in the first year of research was in plants treated with slurry and NPK (102.3 g kg^{-1}), and in the second on the control plot (102.7 g kg^{-1}).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22592268

Across harvests, in the first year the largest ash content was recorded in the biomass of the third one (113.3 g kg^{-1}) and in the second one (114.4 g kg^{-1}), with the lowest amount in the first harvest of the first year (97.3 g kg) and in third one in the second year (107.9 g kg). Crude ash content, the average of years and harvests, was the smallest on the control plot (103.6 g kg^{-1}) and the largest in plants treated with slurry and mineral fertilizers (110.9 g kg^{-1}).

Discussion

Due to the fact that *Lolium multiflorum* is a short-term grass it can be used for alternating grassland. Studies have shown that its yields ranges from 9.10 to 12.65 Mg ha^{-1}. According to Jankowski et al. (2008) *Lolium multiflorum* is a high-productivity species. This is also confirmed by the study of Borowiecki (2002a, b), according to who the *Lolium multiflorum* yield can range from 9 to 12 Mg ha^{-1}.

In the present studies the best results in the form of increased biomass of the grass (an average across years and harvests) were recorded on plots where slurry was supplemented with mineral fertilizers. Olszewska (2008) points out that the yield is the basic criterion for assessing treatment effectiveness. A yield increase as a response to natural fertilizer applied to grassland was also recorded by Barszczewski et al. (2011). The present studies showed that slurry supplemented with soil conditioners increased the amount of biomass of the grass, and it was 16-20% greater than on the control plot, while slurry supplement with NPK fertilizers increased the yield by 40%.

According to Kryszak et al. (2012) as well as Jankowska-Huflejt (2012) periodic shortage of water reduces the yield of meadow plants below their potential.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22592268

In the first year (2016) the optimum thermal and humidity conditions were only in the month of September, with severely wet May, while June, July and August, which are the most significant months for the growth and development of plants, were dry, moderately dry, and extremely dry. In the second year of the experiment (2017), the period from May to August ranged from dry to very dry, and the optimum conditions were not recorded during any month of the growing season.

The optimum total protein content is very important from the point of view of grass nutritional value. According to Grygierzec (2012) the lowest protein content in forage, necessary for the proper digestion process, should ranged from 150 to 170 g kg^{-1} DM. In contrast, according to Jankowska-Huflejt et al. (2011), *Lolium multiflorum* biomass should contain about 115 g kg^{-1} DM. In the present experiment protein content was within the limits of 128.9 to 163.1 g kg^{-1} DM, and it was undoubtedly the nitrogen introduced in the form of slurry and mineral fertilizer that increased it.

Kotlarz et al. (2010) as well as Kasperczyk (2004) confirm that the level of nitrogen fertilizer determines total protein content in forage. Many authors (Ciepiela, 2004; Jankowska et al., 2008; Szkutnik et al., 2012) point out that total protein content is not always increased in proportion to the applied nitrogen fertilizer. A lower total protein content in dry matter may be due to the high yield potential of the species and it can be caused by dilution of the content of this ingredient in the higher amount of biomass.

In the present experiment protein content in biomass depends on the harvest from which it originates. The dependence of the harvest impact on total protein content in grass was confirmed in the studies of Łyszczarz (2003) and Tonn et al. (2013). According to Juszczyk and Rękorajski (2007) the components of crude ash are chemical elements whose adequate quantity in forage is necessary for the normal growth and development of animal organisms, while excessive content (above 150 g kg^{-1} DM) may result from contamination of plant material with soil (Nazaruk et al., 2009).

Throughout the research crude ash content in *Lolium multiflorum* ranged from 89.5 g·kg^{-1} to 123.9 g kg^{-1} and did not exceed the above value, which shows the purity of the plant material analysed. Kotlarz et al. (2010) and Grzelak and Bocian (2009) point out that low content of crude ash of 40 g kg^{-1} DM in the forage may be related to low concentration of minerals in the soil and to species composition of the forage.

In the present experiment, the analysis of the content of this parameter clearly showed a significant effect of slurry application in comparison with the control plot. An increase in crude ash in meadow forage as a result of natural fertiliser application was also noted by Jankowska-Huflejt and Wróbel (2010); Barszczewski et al. (2010) as well as Wróbel et al. (2013).

In the present experiment in the first year crude ash content in *Lolium perenne* increased in subsequent harvests (from 97.3 to 113.3 g kg^{-1}). In the second year a reverse trend was recorded. Barszczewski et al. (2010) found that ash content in meadow plants varied depending on harvest time.

The obtained test results clearly show that the supplementary use of biopreparations did not affect the increase of the grass grown or the protein content in it compared to the facilities where the slurry itself was used. Only the addition to the slurry of mineral fertilization improved the value of these parameters in relation to the operation of the slurry itself.

DOI: http://dx.doi.org/10.15666/aeer/1802_22592268

Conclusions

1. The dry matter yield of *Lolium multiflorum* significant varied across treatments and harvests. In both years of the research the highest yield of the grass was on the plot treated with slurry and mineral fertilizers, and the interaction of slurry with soil conditioners resulted in a decrease in the yield compared to the slurry-only plot.
2. Total protein content in *Lolium multiflorum* forage was significantly dependent on the treatment and growing season. The largest total protein content was recorded in biomass from the plot where slurry was applied together with mineral fertilizers, but this was not significantly different from plants treated with slurry only.
3. The growing season had a significant impact on crude ash content in the grass. The greatest amount of ash (on average from growing seasons and treatments) was recorded in *Lolium multiflorum* of the third harvest, while the least crude ash in the first one.
4. The obtained research results showed a beneficial effect of the slurry interaction only with mineral fertilization, while the interaction with biopreparations did not bring the expected effects. The most likely cause could be adverse hydrothermal conditions in both growing seasons of the crop. Therefore, the assessment of the interaction of slurry with biopreparations requires further research.

GENETIC STRUCTURE OF HONEY BEE (*APIS MELLIFERA* LINNAEUS, 1758) SUBSPECIES BASED ON tRNA^{leu}-COX2 AND ND5 REGIONS OF mtDNA

TOZKAR, C. Ö.

Yüzüncü Yıl University, Faculty of Agriculture, Department of Agricultural Biotechnology
Van, Turkey
(e-mail: tozkar@gmail.com)

(Received 17th Oct 2019; accepted 5th Feb 2020)

Abstract. Diversity of ecological conditions in Anatolia enables many species to adapt to different environments. Thus Turkey is inhabited by various strains of *A.m. mellifera* Linnaeus, 1978*; A.m. mellifera carnica, A.m. mellifera anatoliaca, A.m. mellifera caucasica, A.m. mellifera syriaca,* and *A.m. mellifera meda*. Analysis of mtDNA variants is a widely used tool to determine the phylogenetic relationships at the species and subspecies levels. In this study sequencing results of tRNA^{leu}-COX2 and ND5 gene segments of mtDNA were presented in comparison with some previously published mitochondrial haplotypes. According to the UPGMA dendogram and estimates of evolutionary distances, divergence among the subspecies and ecotypes were not verified strongly. Reproductive isolation barriers could be uneffective and lead to the exchange of the genetic materials between the populations. Intensive care should be taken while managing the colonies of different subspecies in bee yards. Degradation of biodiversity of honey bee subspecies through hybridization was also reported at wider geographic areas rather than small breeding units in some studies. Broad ranges of isolated colonies of subspecies should be established with proper selection studies to reduce the hazards of migratory beekeeping activities. Succesful management practices are needed through better beekeeping technologies and beekeeper training programmes to prevent the homogenization of the genetic structure of different subspecies and to conserve honey bee diversity.
Keywords: *hybridization, gene introgression, phylogenetic analysis, artificial sympatry, biodiversity*

Introduction

The natural dispersion areas of *A. mellifera* L. include Central Asia, Europe, Near East and sub-Saharan Africa and the species has also been introduced to East and Southeast Asia, Australia and the Americas (Ruttner, 1988). At least 29 subspecies of *A. mellifera* have been acknowledged and seperated into four main lineages based on their morphometric, genetic, ecological, physiological, and behavioral features (Han et al., 2012).

A. m. capensis, *A. m. intermissa*, *A. m. litorea*, *A. m. monticola*, *A. m. sahariensis* and *A. m. scutellata* are African subspecies from north and south Sahara belonging to mtDNA group A (2) mainly *A. m. mellifera* and some *A. m. iberiensis* are the subspecies of western and northern European populations of group M (3) group C is composed of southeastern European and northern and eastern Mediterranean populations, containing *A. m. carnica*, *A. m. ligustica*, Turkish and Georgian *A. m. caucasica*, *A. m.* meda and Turkish *A. m. anatoliaca*; and (4) group O includes *A. m. syriaca*, and perhaps other subspecies from Turkey and the Middle East and the last group is Y from the east African country of Ethiopia. Divergence among some subspecies within each lineage was also recognized (Ruttner, 1988; Arias and Sheppard, 1996; Franck et al., 2000).

Although it was not possible to distinguish the classes C and O by sequencing and restriction analysis, they were classified as C (Arias and Sheppard, 1996). Group O verification was performed by examination of mitochondrial DNA and analysis of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22692284

microsatellites (Arias and Sheppard, 1996; Franck et al., 2000; Palmer et al., 2000). Anatolian ecological diversity helps adaptive species to evolve in various environments. Thus Turkey hosts five subspecies of *A. mellifera; A. mellifera carnica, A. mellifera anatoliaca, A. mellifera caucasica, A. mellifera syriaca,* and *A. mellifera meda* (Ruttner, 1988). No other country today has so many different breeds of honey bee. Most of the geographical regions of Turkey is comprised of *A. m. anatoliaca* except for the northeastern part where *A. m. caucasica* dominates and *A. m. meda* exists in the southeastern part of the country. Thrace region of European Turkey is inhabited by *A. m. carnica* (Palmer et al., 2000), while the southern part of the country near Hatay is occupied by *A. m. syriaca* (Kandemir et al., 2000).

It is understood that morphological characteristics are vulnerable to the effects of selection and environmental changes, therefore they are not accurate and adequate to reconstruct phylogenetic relationships. The variation of mtDNA can be used as an additional and more reliable genetic marker for both classification and phylogenetic analysis of honey bee subspecies (Avise et al., 1987; Franck et al., 2000).

Honey bee lineages can be discerned by sequence analyses of the mitochondrial DNA (mtDNA) region between the cytochrome oxidase subunits I and II genes (CoxI–CoxII intergenic region). Throughout population genetics studies, evolutionary lineages and groups of subspecies can be distinguished by differences throughout length and sequence within the mitochondrial genome of honey bees (Garnery et al., 1992; Franck et al., 2000; Palmer et al., 2000). Numerous mitochondrial regions, such as 16s rDNA (Marino et al., 2002b; Bouga et al., 2005; Kekeçoğlu et al., 2009), ND2 (Arias and Sheppard, 1996), ND5 (Bouga et al., 2005; Martimianakis et al., 2011), cytochrome C oxidase I (COI or Cox1) (Bouga et al., 2005; Martimianakis et al., 2011), and the tRNAleu-COII region (COI-COII intergenic region) (Garnery et al., 1992; Franck et al., 2000; Palmer et al., 2000; Susnik et al., 2004; Munoz et al., 2009; Özdil et al., 2009a,b) have been studied to determine honey bee subspecies' diversity and phylogenetic relationships. tRNA^{leu}-COX2 intergenic region is a noncoding region found between a leucine tRNA gene and the cytochrome oxidase II gene and variation in this region may help to distinguish some mitochondrial haplotypes (Canovas et al., 2008).

The objective of this research was to find out the genetic structure and phylogenetic relationships of five *A. mellifera* subspecies and ecotypes of Turkey through direct sequencing of tRNA^{leu}-COX2 and ND5 mitochondrial regions with the comparison of reference mtDNA haplotypes that were published in previous studies.

Materials and methods

Sampling and DNA isolation

Subspecies and ecotypes were taken from their native habitats representing different regions of Turkey and then the colonies were located in a common garden at Middle East Technical University campus in the centre of Ankara. Subspecies were categorized according to their origin and distinguishable morphological characteristics prior to DNA isolation. Workers were collected in 95% ethanol and air-dried prior to the extraction. Four samples from each of the subspecies were used for DNA extraction. The extraction of DNA from thorax tissue by Qiagen DNeasy® Blood & Tissue Kit (www.quiagen.com).

The quantity of eluted DNAs was checked by Nanodrop ND-1000 (Thermo Fisher Scientific, Inc. Wilmington, Delaware, USA). By loading 2 ul of each sample, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22692284

absorbance ratios of A260/280 and A260/230 were measured and DNA concentrations were quantified in ng/ul. To examine the phylogenetic relationships between the subspecies, E2-H2 primer pairs were used to amplify tRNA^{leu}-COX2 intergenic region and ND5 primer pairs were used to amplify ND-5 mitochondrial region. The sequence for forward primer, E2 was 5'-GGC AGA ATA AGT GCA TTG-3', and the reverse primer, H2 was 5'-CAA TAT CAT TGA TGA CC-3' whereas the sequence for ND5_F was 5'-TCG AAA TGA ATA GGA TAC AG-3' and ND5_R was 5'-GGT TGA GAT GGT TTA GGA TT -3'.

PCR was run in a total volume 30 µl of the following reaction mixture: 10 mM of each primer 3 µl of 10X reaction buffer with $MgCl_2$, 2mM of dNTP mix, 2 u of Tag polymerase, 20 ng DNA. For E2-H2 primer pair, the following reaction profile was used: initial denaturation at 94°C for 5 min, followed by 35 cycles of; 94°C for 45 sec, 48°C for 45 sec, 62°C for 2 min, and final elongation step of 20 min at 65°C. For ND5 primer pair, initial denaturation 94°C for 4 min, 35 cycles of 94°C for 1 min, annealing at 50°C (ND5) for 1 min, and extension at 72°C for 2 min, followed by a final extension step at 72°C for 15 min.

The amplified products obtained were next electrophoresed on 1.5% agarose gel to verify the size of the fragment length of 520 bp for tRNA^{leu}-COX2 intergenic region and 721 bp for ND5 mitochondrial region. PCR products were subsequently purified with QIAquick PCR purification kit (QIAgen) and directly sequenced with E2 and ND5-F sequencing primers commercially by Macrogen (Rockville, MD, USA).

Statistical details of the phylogenetic analysis

For the phylogenetic analysis, DNA sequences from this study and additional reference sequences from Genbank were trimmed and aligned using Clustal W (Thompson and Higgins, 1994). The resulting sequences were organized and compared with the published mitochondrial tRNA^{leu}-COX2 intergenic region and ND5 sequences available in Genbank. The sequences obtained in this study were deposited to Genbank with accession numbers MN701721 to MN701744 for ND5 region and MN701745 to MN701763 for tRNA^{leu}-COX2 region.

BLAST searches of the international sequence database (NCBI [National Center for Biotechnology Information] BLASTN search [http://www.ncbi.nlm.nih.gov/]) were used to include the sequences of the outgroup and the sequences of species most closely related subspecies to to the analysis. Phylogenetic and molecular evolutionary analyses were conducted using MEGA version 6 (Tamura et al., 2013).

UPGMA dendogram was built and estimates of evolutionary divergence between sequences were calculated using the same software. The analytical formulas and the bootstrap approach used to measure standart estimation errors. Comparisons were done nucleotide-by-nucleotide (Nei and Kumar, 2000).

Results

Relationships between the subspecies within tRNA^{leu}-COX2 intergenic region

Fragment length was 520 bp for tRNA^{leu}-COX2 intergenic region (*Fig. 1*). tRNA^{leu}-COX2 region within the samples of this study consisted of 2 variable sites, 2 parsimony informative sites and conserved region was 493 bp. According to the dendogram based on the statistical analysis of sequencing results of tRNA^{leu}-COX2

Samples of Carnica subspecies clustered with two *A. m. carnica* breeding lines (JQ778293) and JQ778292 with 69% bootstrap value. Because they have C→T transition at position 354. They also showed close proximity to *A. m. anatoliaca* (FJ357802) and *A. m. mellifera* haplotype C1h (KF274641) and *A. mellifera* haplotype C2i (JQ977703) with a distance of 0.001.

Samples of Syrian and Caucasian subspecies were grouped within the same branch with *A. m. anatoliaca* clone 6313 (AY618914) and *A. m. meda* (FJ357807) with a bootstrap value of 66% because they all have A→T transversion at site 158. They were also closely related to *A. m. caucasica* (FJ357808) with a branch length of 0.001. *A. m. caucasica* (FJ357808) included additional C→T transition at site 362.

A. m. anatoliaca clone 6043 (AY618913), *A. m. anatoliaca* (FJ357805) *A. m. anatoliaca* clone 6322 (AY618915), *A. mellifera* isolate C2s (JF723979), *A. mellifera* haplotype C31 (HQ287900) were clustered together apart from the samples of this study with the branch length of 0.002 (*Fig. 2*). *A. m. syriaca* (AY618917), *A. m. syriaca* (AY618916) and *A. mellifera* mitotype A4 (EF033650) and *A. mellifera* mitotype A1 (EF033649) formed separate branches distant from the remaining groups with 74% and 62% bootstrap values.

According to nucleotide number of differences model, pairwise differences between Yigilca and Mugla ecotypes were 0.00. These ecotypes differed from the other subspecies with a distance value of 1.00. Pairwise distance between Syrian and Caucasian subspecies were also 0.00 and a dissimilarity was observed between this group and Carnica subspecies with a magnitude of 2.00. *A. m. meda* (FJ357807) which was clustered with Syrian and Caucasian samples, was distant from Carnica subspecies with a pairwise distance of 2.00 and dissimilar to Mugla and Yigilca ecotypes with a pairwise distance of 1.00 (*Table 1*).

A. m. anatoliaca (FJ357805) Van and *A. m. anatoliaca* (FJ357802) Aydin-C shared the same distance of 1.00 to Mugla-Yigilca group and the distance of 2.00 to Carnica, Syriaca and Caucasian samples. *A. m. anatoliaca* (FJ357804) Aydin-Kusadasi showed pairwise difference of 1.00 with Carnica, Syrian and Caucasian samples while this haplotype indicated similarity with Mugla and Yigilca ecotypes (pairwise distance = 0.00). The distance between *A. m anatoliaca* (FJ357798) Bolu and Mugla-Yigilca group was 2.00 while this haplotype was more distant from Carnica, Syriaca and Caucasian samples with a magnitude of 3.00 (*Table 1*). The branching pattern had a bootstrap value of 81% for UPGMA method.

Relationships between the subspecies within ND5 region

The amplified PCR product of NADH dehydrogenase subunit 5 (ND5) gene was 721 bp (*Fig. 3*). The dendogram based on the phylogenetic analysis of sequencing data for NADH dehydrogenase subunit 5 (ND5) gene, the samples included to this study did not reveal any genetic divergence and they were grouped in the same branch with *Apis mellifera* ND5 gene haplotype 3 (GU060468), *Apis mellifera* ND5 gene haplotype 1 (JN410833) and haplotype 5 (JN410837) and did not show much difference from *Apis mellifera* ND5 gene haplotype 2 (JN410834), haplotype 3 (JN410835), haplotype 4 (JN410836), haplotype 1 (GU060466), haplotype 2 (GU060467), haplotype 3 (GU060468), haplotype 4 (GU060469), haplotype 6 (GU060471) and haplotype 7 (GU060472) with a bootstrap value of 66% (*Fig. 4*). They indicated a pairwise difference of 0.01 with haplotype 8 (GU060473).

Discussion

Relationships between the subspecies

In this study the genetic relationships of the subspecies was revealed by direct sequencing of mtDNA based on tRNA^{leu}-COX2 and ND5 genes. Fragment lengths can be determined with certainty but the identities of many of the mitochondrial haplotypes can't be specified by RFLP patterns alone. Genetic variation can be established with greater sensitivity of DNA sequencing.

For systematic and population biology, the mtDNA that is maternally inherited without recombination is a pivotal tool. DNA sequence data analysis can be performed in a simple phylogenetic context, making mitochondrial data advantageous over morphometric data. Sometimes there may be differences between morphometric and mitochondrial data sets, when previously isolated populations of honey bees come into contact through human transportation or range expansion and mtDNA haplotypes may be introgressed into new populations as a result of mating (Palmer, 2000). While mtDNA's uniparental inheritance appears to be a downside, it retains an notable source of data by preserving information on queen and queen lines that shed light on the history and phylogeography of *A. mellifera*. However, the mitochondrial genes are interrelated and the evolution of different regions of the mitochondrial genome at different rates leads to incompatible phylogenetic and phylogeographical patterns (Henriques et al., 2019).

Subspecies of C evolutionary lineage pinpoints a short sequence with a lack of length variability. Mitochondrial haplotypes can be discriminated via single nucleotide polymorphisms (Franck et al., 2000; Sušnik et al., 2004). Thus conservative mtDNA regions are more convenient than length polymorphisms to identify molecular variation within C lineage subspecies. The analysis of tRNA^{leu}-COX2 intergenic region indicated identical genetic information for Mugla and Yigilca sharing similarity with *A. mellifera* haplotype C2d (JQ977701) which was also frequent in *A. m. macedonica* Greek populations and observed in *A. m. carnica* Crotian subpopulations which meaned that these two ecotypes also carried mixed genetic information of different subspecies aside from *A. m. anatoliaca*. Mugla and Yigilca honey bees are ecotypes of *A. m. anatoliaca* thus they mostly shared similarity with *A. m. anatoliaca* haplotypes such as *A. m. anatoliaca* clone 5973 (AY618912), *A. m. anatoliaca* (FJ357804) from Aydin-Kusadasi. These ecotypes were also closer to *A. m. anatoliaca* haplotype C1e (FJ357802) from the center of Aydin which were studied by Özdil et al. (2009b). tRNAleu-COX2 region of Mugla and Yigilca ecotypes also carried *A. mellifera* haplotype C12 (FJ037777). In the study of Solorzano et al. (2009), *A. mellifera* haplotype C12 was the most prevalent mitotype acknowledged as basal ancestral mitotype and it corresponded for 47% of the *Apis mellifera* 'C' lineage samples and was found in 13 of the 22 sampled locations including Aegean (Mugla, Izmir), Black Sea (Yigilca, Giresun), Marmara (Kirklareli, Canakkale, Bursa), Mediterrenean (Hatay) regions.

Microsatellite analysis of honey bees from Turkey (Bodur et al., 2007) indicated that Kirklareli region had the lowest levels of gene flow but mtDNA results of Solorzano et al. (2009) did not support the genetic distinctiveness of this region because all sampled colonies consisted of mitotype C12. It was also concluded by Palmer et al. (2000) and Kandemir et al. (2006) that Thrace populations were not divergent from Anatolian

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22692284

populations. In the current study, Carnica samples branched out separately away from C12 mitotype with a pairwise distance of 1.00. According to Solorzano et al. (2009), the incompatibility between mitochondrial and nuclear markers may reflect the maternal inheritance of mitochondrial DNA, and nuclear markers might be representing the polyandrous matings of queens with genetically distinct drones that makes the population in this region diverse. Samples of Carnica subspecies clustered with two *A. m. carnica* breeding lines JQ778293 and JQ778292 from Eastern Serbia. They also showed close proximity to *A. m. anatoliaca* from Aydin and *A. m. mellifera* haplotype C1h of German honey bee and *A. mellifera* haplotype C2i from Eastern Serbia which could result from human and biological influences that mix populations and compromise their purity.

Samples of Syrian and Caucasian subspecies were grouped within the same branch with *A. m. anatoliaca* clone 6313. This clone (TrDra-2 haplotype) was found to be widely distributed in Eastern Anatolia and also observed in Black Sea (7.09%), Mediterrenean (5.48%), Marmara (7.50%), Central Anatolia (3.92%) and Aegean (3.03%) regions (Kandemir et al., 2006). Syrian and Caucasian subspecies also shared the same branch with *A. m. meda* (FJ357807) and were closer to *A. m. caucasica* (FJ357808). The former was C2g haplotype from Iran and the latter was C2h from Ankara- Kazan (Özdil et al., 2009b). C2h haplotype from Ankara-Kazan were found to be similar to published sequences of *A. m. caucasica* (Garnery et al., 1992). Honey bee populations spreading along the northern coast from Kırklareli to Artvin were stated to be *A. m. anatoliaca* or an ecotype of it (Kandemir et al., 2000; Kekeçoğlu, 2007; Kekeçoğlu and Soysal, 2010; Çakmak et al., 2014). According to the results of Kambur and Kekeçoğlu (2018), *A. m. caucasica* was not found in each province of northeast of Turkey because of beekeeping activities. This resemblance of Caucasian subspecies to other subspecies could be attributed to the widespread use of Caucasian bees by many beekeepers in different provinces. The existence of close relationship between these subspecies (Syriaca and Caucasica) and a variety of haplotypes is coherent with the hypothesis that Anatolian zone is close to the origin of the speciation *of Apis mellifera* (Ruttner, 1988).

A. m. anatoliaca clone 6043 (AY618913), *A. m. anatoliaca* C2a haplotype from Van (Özdil et al., 2009b), *A. m. anatoliaca* clone 6322 (AY618915*)*, *A. mellifera* isolate C2s haplotype from Spain (JF723979) were clustered together apart from the samples of this study. The frequency of haplotype *A. m. anatoliaca* clone 6043 (TrDra-1) ascended from east to west in Turkey, the highest frequency was discovered in Thrace and with the lowest in northeastern Anatolia where *A. m. caucasica* prevailed. *A. m. anatoliaca* clone 6322- TrDra-3 haplotype which accounted for C2b (Franck et al., 2000) was identified in eastern Anatolia, Ardahan and Van (Kandemir et al., 2006).

A. m anatoliaca haplotype C1a from Bolu (Özdil et al., 2009b) and *A. mellifera* haplotype C2v from Romania were clustered together and genetically distinct from Mugla-Yigilca ecotypes as well as Caucasica, Carnica and Syrian subpecies by demonstrating more distance.

In the study of Kandemir et al. (2006), TrDra-4 haplotype (AY618916) which was detected in one province (Kastamonu) on the Black Sea coast and corresponds to C2a. *A. m. carnica* haplotype of Franck et al. (2000) was submitted as *A. m. syriaca* clone 6783 to the Genebank. In the same study, TrDra-5 haplotype (AY618917) was also submitted as *A. m. syriaca* clone 6800 to the Genbank. These clones as well as *A. mellifera* mitotypes A1 and A4 were far from Syrian and other samples of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22692284

subspecies included in this study with a particular branching pattern. *A. mellifera* mitotypes A1 and A4 from Brazil and Uruguay also clustered apart from the other haplotypes included in the mtDNA analysis.

Conspicuous differences were not detected between honey bee subspecies and ecotypes in tRNA^{leu}-COX2 region in this study. Henriques et al. (2019) concluded in their study that care should be taken with regard to the results of analysis of tRNA^{leu}-COX2 region and this may not be a suitable marker for detecting relationships between honey bee colonies. The large numbers of indels and duplications of large fragments and homoplasy in this region reduce the accuracy of this region in relation to the capturing of maternal history.

Relative to other mitochondrial regions, the ND5 region was studied less at population level. According to the analysis of mitochondrial NADH dehydrogenase subunit 5 (ND5) gene, the samples of this study belonged to the same clade with *Apis mellifera* ND5 gene haplotype 3 (GU060468), *Apis mellifera* ND5 gene haplotype 1 (JN410833) and haplotype 5 (JN410837). In the study about phylogenetic relationships among *A. mellifera* subspecies depended on sequencing of mtDNA segments, ND5 haplotype 3 (GU060468) was monitored in *A. m. carnica* (Martimianakis et al., 2011). ND5 haplotype 1 (JN410833) was Anatolian haplotype captured in the samples from Konya-Sızma and haplotype 5 (JN410837) was found in honey bees from the South-East part of Turkey where mostly inhabited by *A. m. meda* (Özdil and İlhan, 2012).

NADH dehydrogenase subunit 5 (ND5) gene segments of our samples also did not point out any discrepancy from *Apis mellifera* ND5 gene haplotype 2 (JN410834-from Antalya and Konya), haplotype 3 (JN410835-widely distributed Anatolian haplotype among samples of Balıkesir, Bolu-Yığılca, and Konya), haplotype 4 (JN410836-Caucasian haplotype from Ardahan and Ankara) within the study of Özdil and İlhan (2012). In that study, the races couldn't be seperated from each other according to the NJ dendogram based on ND5 sequences, because they belonged to East European (C) lineage.

Our samples also did not differ from ND5 haplotypes of some other races such as haplotype 1 (GU060466) of *A. m. anatoliaca* (Bartin), *A. m. meda* (Osmaniye), *A. m. carnica*; haplotype 2 of *A. m. ligustica* (GU060467); haplotype 4 of *A. m. cecropia* (GU060469); haplotype 6 (GU060471) and haplotype 7 (GU060472) of *A. m. adami* (Martimianakis et al., 2011). Overall, a common branching pattern of the honey bee subspecies and ecotypes of this study with *A. m. anatoliaca*, *A. m. meda*, *A. m. carnica, A. m. ligustica* ND5 haplotypes of the other studies presented a coherent result by revealing the close relations at the species and subspecies level. It is known that the pattern typical of *A. m. carnica/A. m. ligustica* is considered to prevail across Turkey (97.9%) (Kandemir et al., 2006). It is not surprising to observe similarity to *A. m. ligustica* haplotype because its adaptability to various climatic conditions makes it a favored species to export globally. Consequently, the introduction of this species has usually been the main cause of genetic changes in local species (De la Rùa et al., 1998; Garnery et al., 1998a,b). Appearance of *A. m. meda* and *A. m. ligustica* in the same cluster was also congruent with the finding about the similarity between *A. m. meda* (Iranian) and *A. m. ligustica* (Italian) based on several characters of morphology and behavior (Ruttner et al., 1988). Settar (1983) showed that honey bee subspecies in Aegean region were transitional populations between *A. m. caucasica* and *A. m. ligustica*. In another study showing the haplotypes obtained in honey bee populations of Thrace region, some of the samples with variation were found to have *A. m. caucasica*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22692284

origin and hybridization between Caucasian/Anatolian and Carniolan/Macedonian haplotypes was detected. The reasons for this situation is thought to be the intense introduction of Caucasian queen bees and migratory beekeeping activities (Ünal and Özdil, 2018). Also some studies proved that there were mixed populations of *A. m. syriaca* and *A. m. meda* in both southeast and the eastern parts of Turkey (Palmer et al., 2000; Kandemir et al., 2000).

According to the study of Kambur and Kekeçoğlu (2018), the groups representing the Aegean and Marmara regions coincided and intertwined with the provinces representing the Eastern Anatolia. Those results indicated that bee biodiversity was significantly affected by commercial queen use activities.

Turkey is at the crossroads between Europe, Asia and the Middle East with a wide variety of climates and habitats. There are many subspecies and ecotypes of honey bees within these ranges such as *A. m. anatoliaca, A. m. caucasica, A. m. meda,* and *A. m. syriaca* as described by Ruttner (1988). Honey bees have been able to adapt to a variety of ecological environments including three phytogeographic regions; Euro-Syberian; Mediterranean; and Irano-Turanian where several honey bee ecotypes appeared with many morphological, biochemical, physiological, and behavioural adaptations. Widespread migratory beekeeping activities and the demand of exporting and establishing Caucasian bees (*A. m. caucasica*) in new locations contribute to transplantation and mixing of populations impacting the integrity of the ecotypes and the geographical variations among them.

Conclusion

Molecular data on mitochondrial DNA (mtDNA) tRNA^{leu}-COX2 and ND5 sequences inferred that all the subspecies and ecotypes in this study were not so diverse genetically. There is a possibility that reproductive isolation couldn't be achieved and gene introgression could have occured between them because of the close proximity of the colonies in the bee yard or in the past, the genetic structure of the colonies could have already mixed and exchanged in their native habitats from where they were originated and sampled. Phylogenetic analysis of this study would be more effective and strong if sample size was increased by including more colonies of the subspecies. Degradation of honey bee biodiversity in some locations of Turkey were reported previously by many studies. Overlapping of samples representing subspecies from different regions could mean that honey bee biodiversity could not maintain its current status and the use of commercial queen bee has significantly affected the biodiversity of honey bee in Turkey. Each of the subsepecies has its own unique behavioral and morphometric characteristics that make them well suited to their local environments, but hybridization and modification of the existing genetic pool among local bees can appear through fragmentation of land resources via urbanization, uncontrolled reproduction, the introduction of queen bees from other mtDNA lines and the preferences of the beekeepers to use different breeds for high yield (Güler, 2010). Thus local honey bee subspecies and ecotypes may lose their novel characteristics. Due to their social nature of the honey bees at the individual and colonial reproduction level, the distribution of mitochondrial markers are affected and diversified by commercial breeding and migratory beekeeping activities. Identification and protection of natural honey bee gene resources is vital for the development of beekeeping. Conventional methods are not not suitable to define the hybrids and not sufficient to prevent gene

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22692284

flow among subspecies. Thus identification of hybrids must be enhanced to improve conservation management. Also next-generation sequencing of bee transcriptomes and genomes will extend the number of genes and data and provide new approaches to resolve phylogenetic relationships. Pure breeding populations are also a major instrument for an improved conservation management. Detailed beekeeping information of different regions needs to be collected systematically before making future conservation programmes. The mechanisms of hybridization and mating distances may assist protection of honey bee subspecies. Apicultural researches about identifying and improving local genetic lines must be encouraged and granted. Beekeeping policies must be regulated to minimize human induced artificial sympatry of honey bee populations. Conservation of honey bee biodiversity is a very necessary step to preserve the biological equilibrium in ecological environment, to meet the agricultural demands of humans and to benefit from production potentials in breeding and hybridization studies in the future.

Acknowledgements. The laboratory work was financially supported by the USDA-ARS Bee Research Laboratory. I especially would like to thank Dr. Jay D. Evans for his support about the research.

(Received 18th Oct 2019; accepted 30th Jan 2020)

Abstract. This study was conducted to investigate in vitro regeneration potential of *Centaurea amaena*, a critically endangered and an endemic plant in Turkey. For this purpose, cotyledon, leaf and cotyledon node explants were cultured in Murashige and Skoog (MS) media supplemented with different concentrations of 6-benzylaminopurine (BAP; 1-4 mg L^{-1}), thidiazuron (TDZ; 0.3-1.2 mg L^{-1}) or *meta*-Topolin (*m*T; 0.5-4 mg L^{-1}) with or without 0.5 mg L^{-1} α-naphthalene acetic acid (NAA). In axillary shoot regeneration experiments from cotyledon node explants, the greatest number of shoots per explant (9.975) was obtained from 4 mg L^{-1} *m*T-containing MS media, which yielded a shoot regeneration frequency of 70.83%. In indirect organogenesis experiments, the greatest number of shoots per explant in cotyledons (4.152 shoots/explant with the shoot regeneration frequency of 55.00%) was obtained from 1 mg L^{-1} *m*T-containing media and the greatest number of shoots per explant in leaves (4.132 shoots/explant with the shoot regeneration frequency of 50.00%) was obtained from 4 mg L^{-1} *m*T-containing media. Only callus induction was observed in TDZ-containing media or combinations of TDZ concentrations with NAA. About 50.00% root formation was achieved from half-strength MS medium containing 2.0 mg L^{-1} indole-3-butyric acid.
Keywords: *axillary shoot regeneration, BAP, mT, organogenesis, TDZ*

Introduction

Centaurea amaena Boiss. & Balansa belonging to the *Phalolepis* section of the Compositae family is classified as CR B2ab (i,iii) based on IUCN criteria (Atasagun et al., 2013; Atasagun and Aksoy, 2018). The species occurs over the stony slopes of Yılanlı Mountain, located between 38° 38' - 38° 41' N longitudes and 35° 30' - 35° 35' S latitudes to the west of Kayseri, Turkey and naturally grows in arid environments at altitudes of between 1.170-2.300 m (Atasagun and Aksoy, 2018). The species exists in two localities in Kayseri with distribution area of about 0.55 km^2. Number of individuals was identified by Atasagun and Aksoy (2018) as 5672. Atasagun and Aksoy (2018) indicated that the species had a quite isolated distribution between Erciyes and Yılanlı mountains of Kayseri; it was an endemic species under the threat of extinction mostly because of anthropogenic effects, animal grazing, stone quarry activities, Erciyes Mountain master plan, negative impacts of seasonal conditions based on altitude of spread zones, use of plant seeds by *Oxycarenus sp.* of Heteroptera suborder as nutrient and all these issues reduced formation of new individuals and negatively influenced the growth and development of the population.

C. amaena is rich in phenolics and flavonoids, thus has a strong antioxidant activity. Plants can be used as raw and processed food preservers and natural additives in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22852293

pharmaceuticals, alternative medicine and natural treatment (Albayrak et al., 2017). *C. amaena* is under the threat of extinction and thus urgent measures should be taken to prevent extinction and for propagation of the species. Conservation is the effective storage of the diversity in the gene pool until its actual or potential use, and the introduction of this genetic diversity into the use of humanity. There are two primary conservation systems including in situ and ex situ conservation (Şehirali et al., 2015). In situ conservation means preservation of natural resources in their own habitats. However, ex situ conservation has become the most common practice for the conservation of plant genetic sources (Şehirali et al., 2015). Within the scope of ex situ conservation, in vitro tissue culture techniques are used. In recent years, several endangered and endemic species have been propagated and preserved from quite small quantity of plant material through these techniques without any significant impacts on wild populations (Erdağ and Emek, 2005a, b).

In previous studies, successful in vitro regeneration of *Centaurea* species were achieved from leaf, hypocotyl, cotyledon, node, soot tips, inflorescence stem parts-like explants with the aid of different cytokinin and auxin sources (Mallon et al., 2010; Aydoğan and Erdağ, 2015; Atalay and Erişen, 2017; Türkoğlu et al., 2018). In the different studies related to *Centaurea* species, the most commonly used cytokinins were BAP, kinetin, zeatin, TDZ and N6-(2-isopentyl) adenine (2-iP). Generally, BAP has been reported as the most efficient source of cytokinins for in vitro propagation of *Centaurea* species (Cuenca and Amo-Marco, 2000; Curkovic-Perica, 2003; Mallon et al., 2010; Atalay and Erişen, 2017). While the lowest response was obtained from zeatin, 2-iP and kinetin-containing media in *C. ultreiae* and from TDZ and kinetin-containing media in *C. lycaonica*, the use of kinetin was successful in *C. paui* (Cuenca et al., 1999) and *C. tchihatcheffii* (Ozel et al., 2006). In recent years, meta-topolin has been used to promote in vitro shoot regeneration as an alternative cytokinin source (Dimitrova et al., 2016). The use of *m*T as a cytokinin source in *Centaurea* species have not been reported before and there are no studies about in vitro regeneration of *Centaurea amaena*. Therefore, this study was conducted to produce an efficient in vitro regeneration method for *Centaurea amaena* and the effectiveness of BAP, TDZ and *m*T as a source of cytokinins was examined.

Materials and methods

Plant material and achene sterilization

Centaurea amaena Boiss & Balansa was used as the plant material of the present study. Mature seeds of the species were collected in limited numbers from the natural habitat, Yılanlı Mountain (Kayseri-Turkey), and seeds were preserved at +4 °C for later uses in further analyses. All experimental procedures were conducted at Tissue Culture Laboratory of Field Crops Department at Erciyes University Agricultural Faculty. Sterile distilled water and 50% diluted H_2SO_4 were used for surface sterilization of the seeds. Seeds were initially kept in this solution for a minute, rinsed through sterile distilled water, kept again in 50% diluted commercial bleach (ACE) in a magnetic stirrer for 10 min and finally rinsed through sterile distilled water three times and were germinated in sterile petri dishes with MSO media containing MS mineral salt and vitamins, 3% sucrose and 0.7% agar. About 15-20 seeds were placed into each magenta vessel (Sigma-Aldrich, 77 × 77 × 97).

DOI: http://dx.doi.org/10.15666/aeer/1802_22852293

Indirect organogenesis

The cotyledon obtained from 2-weeks-old seedlings and leaves from about 1-month-old seedlings were used as explants for indirect organogenesis. Explants were cultured in MSO media containing different concentrations of TDZ (0.3-1.2 mg/l), BAP (1-4 mg L^{-1}) or *m*T (0.5-4 mg L^{-1}) alone or in combination with NAA (0.5 mg L^{-1}). About 7-8 weeks after the initiation of culture processes, callus induction ratio (%), shoot regeneration frequency (%) and number of shoots per explant were determined (*Fig. 1A*).

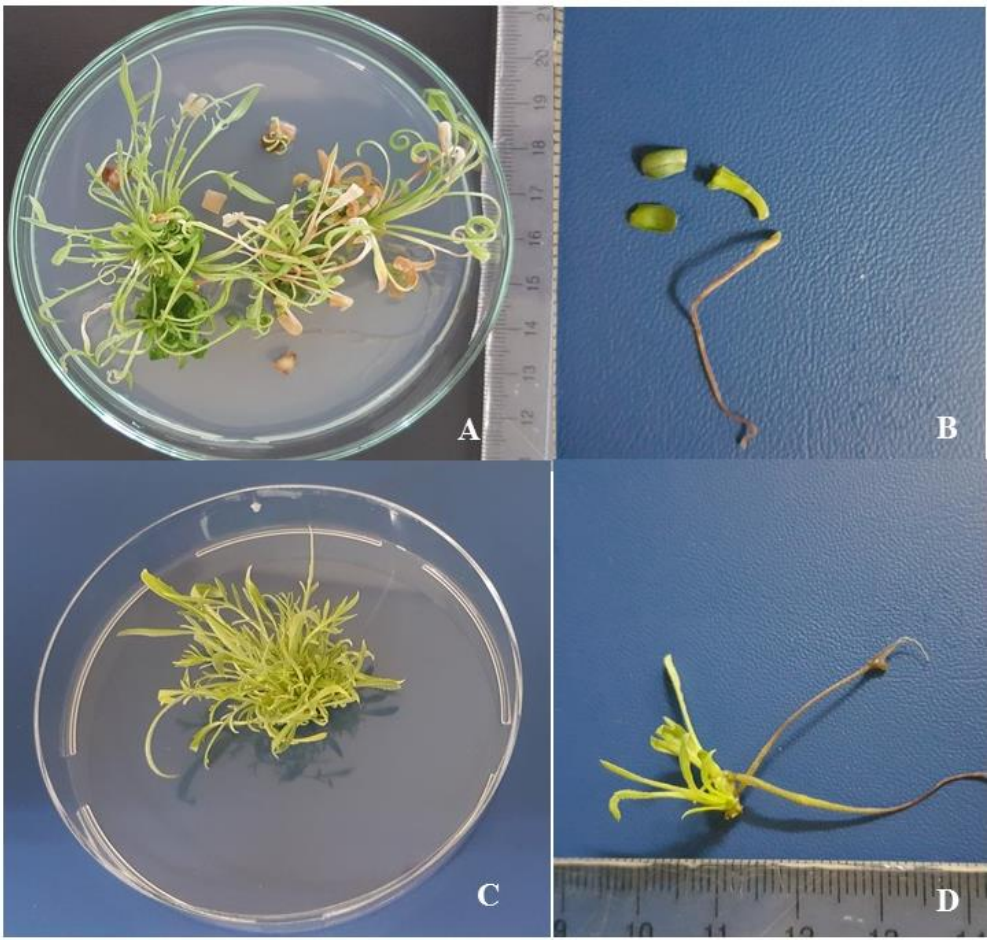

Figure 1. *In vitro propagation and rooting of Centaurea amaena. A - Indirect organogenesis from cotyledon explant on MSO medium supplemented with 4 mg L^{-1} mT, B - Isolation of cotyledon node explant, C - Axillary shoot regeneration form cotyledon node explant on MSO medium supplemented with 4 mg L^{-1} mT, D - Root formation of Centaurea amaena*

Axillary shoot regeneration

Cotyledon node explants were isolated from the plantlets about 15-20 days after initiation of germination processes and were cultured in Magenta Vessels with MSO media containing different concentrations of TDZ (0.3-1.2 mg L^{-1}), BAP (1-4 mg L^{-1}) or *m*T (0.5-4 mg L^{-1}) with or without 0.5 mg L^{-1} NAA (*Fig. 1B-C*). About 7-8 weeks after the initiation of culture processes, shoot regeneration frequency and number of shoots per explant parameters were determined.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22852293

Rooting

Regenerated shoots were rooted in half-strength MS media containing 0.5, 1 or 2 mg L^{-1} IBA, 3% sucrose, solidified with 0.7% agar (*Fig. 1D*).

Experimental conditions

Entire sterile processes were conducted in a sterile cabin with a hepa-filter and horizontal air flow. Before the initiation of the sterile processes, the cabin was whipped with 96% ethyl alcohol, the cabin was then left open for 20 min and sterilized under UV light. All tools, equipment, distilled water and growth media used in this study were sterilized in an autoclave under standard conditions (1.2 atm pressure, 121 °C temperature, 20 min). Growth medium pH values were arranged as between 5.5-5.8 before agar supplementation. All cultures were grown under 16:8 light:dark photoperiod, 22 ± 2 °C temperature and 3000 lux light intensity.

Data analysis

Experiments were conducted at completely randomized design with 4 replications. Each replication had 6 (for cotyledon node) or 10 (leaf and cotyledon) explants. Before variance analysis, percentiles were subjected to "arcsine" transformation. Variance analysis was performed with SPSS software. Means were compared with the aid of Duncan's multiple range test.

Results and discussion

Indirect organogenesis

For plant regeneration through organogenesis in *C. amaena,* cotyledon and leaves taken from the plantlets obtained from sterile seeds were cultured in 20 different media containing different concentrations of BAP, TDZ or *m*T alone or in combination with NAA. About 7-8 weeks after the initiation of culture processes, callus induction ratio, shoot regeneration frequency and number of shoots per explant were determined. Callus induction ratios varied between 50 - 100%. While type of explant did not have any significant effects on callus induction ratios, PGR (plant growth regulator) concentrations and combinations had significant effects on callus induction ratios ($P < 0.01$). While the greatest callus induction ratios were obtained from BAP, BAP-NAA, *m*T-NAA, TDZ and TDZ-NAA-containing treatments, the lowest callus induction ratios were obtained from only *m*T-containing treatments (*Fig. 2*). Similarly, Atalay and Erişen (2017) also indicated that callus induction ratios in *Centaurea lycaonica* varied with the PGRs and reported high ratios for BAP-NAA and TDZ-NAA combinations. Researchers also identified differences in callus morphology of *C. lycaonica* based on PGR type and combinations.

PGRs and PGR × explant interactions had significant effects on shoot regeneration ratios and number of shoots per explant. Shoot regeneration frequencies varied between 0.00-57.50% in cotyledon explants and between 0.00-62.50% in leaf explant (*Table 1*). In both types of explants, callus induction was observed but shoot regeneration was not observed in TDZ-containing media. Similarly, Atalay and Erişen (2017) in *Centaurea lycaonica* and Aydoğan and Erdağ (2015) in *Centaurea zeybekii*, reported callus induction but no shoot regeneration in TDZ-containing media. In addition, Kazeroonian

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22852293

et al. (2018) indicated that type of cytokinin affected shoot regeneration and TDZ promoted callus induction rather than shoot regeneration in *Chrysanthemum morifolium* petiole explant. Dewir et al. (2018) reported that TDZ may result in various anomalies including inhibition of shoot proliferation, shoot elongation, etc., and indicated low TDZ concentrations, pulse treatment or short-duration TDZ treatments as efficient strategies to eliminate such anomalies. However, TDZ was also indicated as a strong synthetic cytokinin-like substance for shoot regeneration in several plant species (Erişen et al., 2011; Yorgancılar and Erişen, 2011; Uzun et al., 2014).

Table 1. *Effects of PGRs on adventitious shoot regeneration from cotyledon and leaf explants of Centaurea amaena*

PGRs	Shoot regeneration frequency (%)		Number of shoots per explant	
	Cotyledon	Leaf	Cotyledon	Leaf

0.6 mg L^{-1} TDZ + 0.5 mg L^{-1} NAA	0 e	0 e	0 h	0 ı
1.2 mg L^{-1} TDZ + 0.5 mg L^{-1} NAA	0 e	0 e	0 h	0 ı

*Values within a column followed by different letters are significantly different at 0.05 significance level using Duncan's multiple range test

The greatest numbers of shoots per explant were obtained from 1 mg L^{-1} *m*T, 4 mg L^{-1} *m*T, 1-2 or 4 mg L^{-1} *m*T + 0.5 mg L^{-1} NAA treatments in cotyledon explants and from 4 mg L^{-1} *m*T, 2 mg L^{-1} BAP and 1 mg L^{-1} BAP + 0.5 mg L^{-1} NAA treatments in leaf explants (*Table 1*). Optimum PGR type and concentration varied with explant type. Similarly, Erişen et al. (2011) reported differences in shoot regeneration of explants based on PGR concentrations and combinations in *Astragalus cariensis*. Success of a culture is influenced by type and concentration of applied cytokinin since cytokinin uptake, transport and metabolism varied with the plant species and cytokinin interacted with endogenous cytokinin of the explants (Magyar-Tabori et al., 2010).

Axillary shoot regeneration

PGRs had significant effects on shoot regeneration frequency and number of shoots per explant ($P < 0.01$). Shoot regeneration frequency of cotyledon node explants varied between 12.50-87.50% and the greatest shoot regeneration frequency was obtained from BAP, BAP-NAA, *m*T and *m*T-NAA treatments (*Table* 2). The greatest number of shoots per explant (9.975 shoots) was obtained from 4 mg L^{-1} *m*T treatment and followed by 2 mg L^{-1} *m*T and 0.5-1 mg L^{-1} *m*T. Only *m*T-containing media had greater number of shoots per explant than BAP and TDZ-containing media. When the BAP-containing media were assessed in themselves, it was observed that the greatest number of shoots per explant (3.582 shoots) was obtained from 2 mg L^{-1} BAP treatment. BAP was also indicated as an appropriate cytokinin for axillary shoot regeneration in shoot apices of *Centaurea ultreia* (Mallon et al., 2010) and node explants of *Centaurea lycaonica* (Atalay and Erişen, 2017). Similarly, in present study, BAP-containing media were found to be more efficient than TDZ, however just *m*T-containing media were identified as the most efficient for axillary shoot regeneration from cotyledon node. There were not any studies in literature about the use of *m*T as a source of cytokinin in *Centaurea* species, but it was reported in studies on cassava, pelargonium and sweet basil that *m*T improved in vitro shoot proliferation and shoot quality (Wojtania, 2010; Köszeghi et al., 2014; Chauhan and Taylor, 2018). Fajinmi et al. (2014) demonstrated *m*T as a quite active and an alternative cytokinin to BAP and other cytokinins for shoot regeneration in shoot tip explant of *Coleonema album*. Such an efficiency of *m*T is mostly attributed to chemical structure allowing production of O-glucoside metabolites from hydroxyl group of side chain of *m*T and rapid translocation of it in plant tissues (Fajinmi et al., 2014). In only *m*T-containing media, number of shoots per explant increased with increasing *m*T doses. Dimitrova et al. (2016) also reported increasing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22852293

regenerations with increasing *m*T doses in *Pyrus communis*. As compared to only *m*T-containing media, number of shoots per explant decreased in *m*T-NAA combinations. But contrary to present findings, *m*T-NAA combinations increased the number of shoots per explant in *Coleonema album* and *Huernia hystrix* (Fajinmi et al., 2014; Amoo and Van Staden, 2013). Such differences were mainly attributed to synergic, antagonistic and additional interactions between auxins and cytokinin based on plant species and type of tissue (Coenen and Lomax, 1997).

Table 2. *Effects of PGRs on axillary shoot regeneration form cotyledon node explant of Centaurea amaena*

Rooting

Regenerated shoots were rooted in ½ MS media containing 0.5, 1 or 2 mg L^{-1} IBA. About 5-6 weeks after the initiation of culture processes, percentage of root-forming shoots were respectively identified as 33.33, 38.89 and 50.00%. IBA was also identified as an available auxin for promotion of rooting of regenerated shoots in *Centaurea rupestris* and *Centaurea arifolia* species (Curkovic-Perica, 2003; Yüzbaşıoğlu et al., 2012).

Conclusions

The primary target of the present study was to investigate regeneration potential of *Centaurea amaena*. In present experiments, 4 shoots per explant were obtained from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22852293

cotyledons and leaves and 10 shoots per explant were obtained from the cotyledon nodes of *C. amaena*. It was concluded based on present findings that *m*T and BAP were efficient cytokinins for in vitro regeneration of *C. amaena*. Regenerated shoots were rooted in half-strength MS medium supplemented with IBA. A simple and efficient propagation procedure was developed in this study for the critically endangered species *C. amaena*. This procedure could be useful for the in situ and ex situ conservation of this valuable genetic source. However, the genetic stability of regenerated plants must be verified using molecular markers in further studies.

Abstract. The establishment of urban forests are the way to reduce the impact of urban development on biodiversity. This study aimed to analyze the distribution and diversity of butterflies in various urban forests in North Minahasa Regency, North Sulawesi, Indonesia. Butterfly sampling was conducted in four urban forests. The sampling employed the sweeping technique following a the transect line. The results obtained included as many as 5 families of butterfly, consisting of 56 species and 985 individuals. Using the distribution pattern of butterfly species based on the Morisita index, 52 species were found classified as aggregate. The highest species diversity was found in the Kuwil City Forest. Diversity of butterfly species was negatively correlated with air temperature, light intensity, and wind speed. According to the similarity index of the butterfly species community, it was found that the Kaki Dian City Forest, Kenangan City Forest, and Kuwil City Forest shared a high similarity, while the Talise City Forest did not share many similarities with the other urban forests. The diversity of butterflies in urban forests was influenced by the surrounding area, the complexity of the composition of vegetation structures, water availability, and abiotic environmental factors.
Keyword: *aggregate, environmental, Morisita, sweeping technique, vegetation structures*

Introduction

Developing facilities and infrastructure in urban environments can support the activities of local dwellers and will improve the economy of the urban area, but urban development and human activity can also cause environmental quality to decline. This is because the urban area is filled with built-up area, while many green open spaces have been converted into areas of offices, settlements, trade, industry, ports, airports, and other urban infrastructure (Kusmana, 2015). Land-use change in urban areas raises various environmental problems and can affect and threaten the existence of biotic communities within it (Azahra et al., 2016). Land-use change can also have an impact on biodiversity (Bergerot et al., 2011; Lee et al., 2015).

Plants and animals that live in urban ecosystems often experience local extinction due to loss of habitat, habitat degradation, and fragmentation (McKinney, 2002; Clarket et al., 2007). Some studies reported that species composition and species abundance, such as bird abundance (Motegi and Yanai, 2005; Rubèn and Ian, 2009), ant abundance

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22952314

(Lee and Kwon, 2013), and butterfly abundance (Bergerot et al., 2011; Lee and Kwon, 2012), are lower in urban areas than in rural areas.

The establishment of urban forests is one of the efforts to reduce the impact of urban land-use change on biodiversity. According to Law No. 63 of 2002, urban forests serve to improve and maintain the microclimate and aesthetic value, absorb water, create a balance and harmony of the physical environment of the city, and support the preservation of biodiversity. Urban forests also have potential as a means of conserving biodiversity, including the butterfly community (Azahra et al., 2016).

Butterflies that live in urban ecosystems have a very important role in maintaining biodiversity. Adult butterflies help pollinate flowering plants so that the natural propagation process of plants can occur (Borror et al., 1992; Speight et al., 1999; Plona, 2002; Perveen and Haroon, 2015). Butterflies can also be used as bioindicators of environmental change because they are easily surveyed, quickly react to changes in the environment, and have high mobility and preferences for certain habitats (Lee et al., 2014; Dennies et al., 2017). Butterflies are also easily recognizable both taxonomically and ecologically (Kim et al., 2012).

Most butterfly species are cosmopolitan so that they can be found in various types of habitats, from forest to urban areas, and in various environmental conditions (Braby, 2004; Koh and Sodhi, 2004). The biggest threat to the survival of butterflies is humans. The beauty of colorful butterfly wings attracts people's attention and interest to collect them. Land conversion, tree felling, housing development, pollution, and the use of insecticides and herbicides contribute to the extinction of butterflies. Butterflies lose their host plant and lack food due to these environmental changes (Handayani et al., 2015; Thangjam et al., 2018).

Urban forest as one of the butterfly habitats in urban areas has a high conservation value, but on the other hand, the environmental disturbance that occurs indicates the causes of various changes in the environmental conditions of the urban forest that have an impact on the communities in it, including the butterfly community. Thus, habitat protection is very important to support the survival of butterflies. The existence of urban forests in North Minahasa Regency can be an effort to preserve biodiversity, one of which is butterflies.

The existence and availability of data regarding the distribution and diversity of butterflies in urban forests in North Minahasa have a crucial meaning in the initial steps of conservation of butterfly species in urban areas. Research on butterflies in urban forests in North Minahasa Regency has never been conducted before, so there are no detailed and published data on the distribution and diversity of butterflies. Considering the important role of butterflies in an ecosystem, research on the distribution and diversity of butterflies in various urban forests in North Minahasa Regency needs to be conducted. This study aims to analyze the distribution and diversity of butterflies (Lepidoptera: Rhopalocera) in various urban forests in North Minahasa Regency, North Sulawesi Province.

Materials and methods

Study area and types of urban forests

This research was conducted from May 2019 to August 2019. Sampling locations were four urban forests, namely, Kuwil City Forest, Talise City Forest, Kenangan City Forest, and Kaki Dian City Forest, in North Minahasa Regency, North Sulawesi

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22952314

Province, Indonesia (*Fig. 1*). The locations of this research were four urban forests in North Minahasa Regency. The selection of locations was based on city forests that have been commissioned through North Minahasa District Regulation Number 2 of 2012 concerning urban forests.

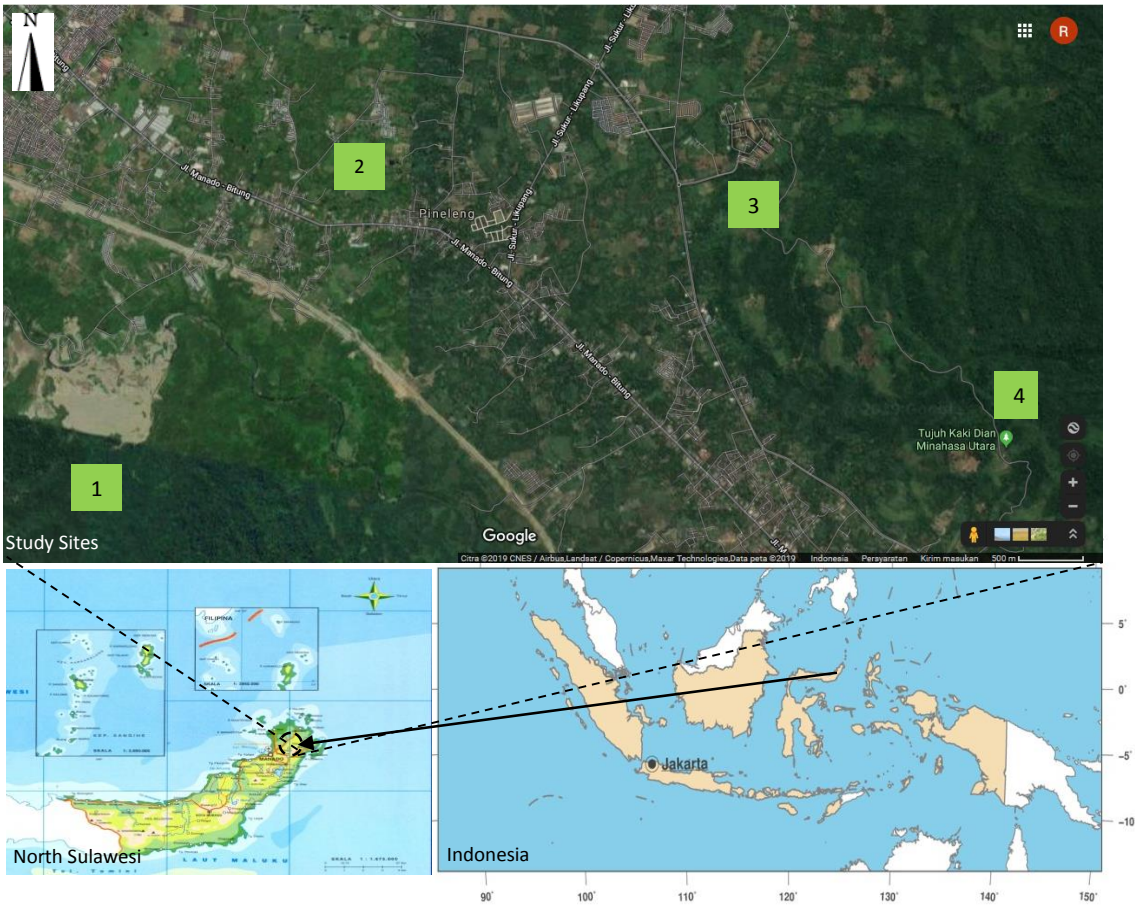

Figure 1. *Map of the study area in North Minahasa Regency (1. Kuwil City Forest, 2. Talise City Forest, 3. Kenangan City Forest, 4. Kaki Dian City Forest)*

Descriptions of the four urban forests are as follows:

1. Kaki Dian City Forest, which is located in Airmadidi Urban Village in the Mount Klabat forest area and covers an area of ± 37 Ha. The forest types that surround this urban forest are secondary forests and primary forests in protected forest areas. Vegetation cover is dominated by tall trees with medium diameter. The plant species found were dominated by species from the family Moraceae (genus Ficus) and Anacardiaceae, followed by species from the family Euphorbiaceae (*Fig. 2a, b*). The coordinates of the sampling points in the Kaki Dian City Forest were transect 1 N: 01°26'12.49" E: 124°59'32.46", transect 2 N: 01°26'12.72 E: 124°59; 34.58; transect 3 N: 01°26'18.25" E: 124°59'32.66, and transect 4 N: 01°26'00.69" E: 124°59'40.35". The air temperature in this urban forest ranged from 28.0 to 31.6 °C, humidity ranged from 61 to 67.0%, light intensity ranged from 599.0 to 725.0 lux, wind speed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22952314

ranged from 0 m/s to 0.8 m/s, with altitudes between 553 masl and 654 masl (*Table 1*).

2. Kenangan City Forest, which is located in the area of the North Minahasa Regency Government office, covering an area of ± 15 ha. The area around Kenangan City forest is office center and plantation land. Vegetation that covers this urban forest consists of a collection of trees that were intentionally planted and native trees at that location (*Fig. 2c, d*). The coordinates of sampling in the Kenangan City Forest were transect 1 N: 01°27'23.17" E: 124°58'27.04", transect 2 N: 01°27'23.17" E: 124°58'27.04", transect 3 N: 01°27'23.20", E: 124°58'27.04", and transect 4 N: 01°27'23.20", E: 124°58'27.04". The air temperature in this urban forest ranged from 31.3 to 32.6 °C, humidity ranged from 58.0 to 61.5%, light intensity ranged from 789.0 to 955 lux, while wind speed ranged from 1.0 to 1.9 m/s with altitudes between 295 to 372 m asl (*Table 1*).
3. Kuwil City Forest, which is located in Kuwil Village, Kalawat District, covering an area of ± 43 Ha. The area around this urban forest is plantation land and settlements (*Fig. 2e, f*). The sampling coordinates of the Kuwil City Forest were transect 1 N: 01°26'17.80" E: 124°55'61.67", transect 2 N: 01°26'14.77" E: 124°55'28.94", transect 3 N: 01°26'12.76" E: 124°55'32.10, and transect 4 N: 01°26'12.49" E: 124°55'53.16". The air temperature in this urban forest ranged from 28.5 to 29.6 °C, humidity ranged between 74.0 and 75.0%, intensity light ranged from 548.0 to 722.0 lux, wind speed ranged from 0 to 0.1 m/s with altitude between 95 and 119 m asl (*Table 1*).
4. Talise City Forest, which is located in Kolongan Village, Kalawat District, covering an area of ± 6 Ha. The area around this urban forest is fish ponds, plantations, and settlements (*Fig. 2g, h*). The sampling coordinates of the Talise City Forest were transect 1 N: 01°27'36.43" E: 124°56'27.70", transect 2 N: 01°27'34.01" E: 124°56'29.09", transect 3 N: 01°27'30.96" E: 124°56'22.42", and transect 4 N: 01°27'29.04" E: 124°56'24.21". The temperature of the city forest ranged from 32.2 to 33.0 °C, humidity ranged from 46.5 to 50.0%, the light intensity ranged from 850 to 962.5 lux, with altitudes between 147 and 166 m asl (*Table 1*).

Figure 2. *Some photos of sampling site: Kaki Dian City Forest (a, b), Kenangan City Forest (c, d), Kuwil City Forest (e f), Talise City Forest (g, h)*

DOI: http://dx.doi.org/10.15666/aeer/1802_22952314

Sampling and identification of butterfly samples

Sampling employed the purposive random sampling method. In each type of urban forest, four transect lines were made with a length of 300 m each. Sampling was conducted along the transect line using butterfly net (sweep net). Butterfly sampling was conducted for 4 days every month for 4 months. Sampling was performed every month for four months. Sampling was done monthly for 4 months. Butterfly sampling for 4 months was quite representative and can provide information about the diversity of butterflies in urban forests of North Minahasa Regency. This is because those four months were during dry season when the weather conditions were sunny. Those conditions were very suitable for butterflies to live. During this period, most of nectar-rich plants began to flower, thus providing butterflies food sources and supporting the life and breeding of butterflies"

Table 1. *The environmental factor in four urban forests in North Minahasa Regency*

Urban forest	Transect	Environmental factors				
		Temperature (°C)	Humidity (%)	Light (Lux)	Wind (m/s)	Altitude (M asl)
Kaki Dian	1	28.00	61.00	599.00	0.80	591.00

Samples were taken at 08.00-14.00 Central Indonesia Time (GMT + 8). The collection of butterfly samples was conducted during the day, because butterflies are active only during the day. Only one specimen per species was collected. If the same species was accidentally caught, the butterfly would be released.

The process of identifying specimens used identification books. The identification books used were Butterflies of the South East Asian Island, Part I Papilionidae, Part II Pieridae-Danaidae, Part III Satyridae-Lybytheidae, Part IV Nympalidae (I), Part V

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22952314

Nympalidae (II) (Tsukada and Nishiyama, 1981, 1982a, b; 1985, 1991), Insects of the Mount Halimun National Park in the Western Part of Java (Amir et al., 2003), Practical Guide of Butterflies in the Bogor Botanical Garden (Peggie and Amir, 2006), Agricultural Entomology (Jumar, 2000).

In taking samples, environmental factors were also measured. Environmental factors included air temperature and humidity, which were measured using a Thermohygrometer (Deko 637 Thermo-hygrometer), wind speed, which was measured using Anemometer, and light intensity, which was measured using a Lux meter (Lutron LM8010 Type K). Meanwhile, the altitude and coordinates were determined using the Global Positioning System (Garmin GPSMAP 78s).

Data analysis

Analysis of observational data included the distribution of butterfly species, species diversity, correlation between species diversity and environmental factors, and similarity index of butterfly species between urban forests. The distribution of butterfly species was calculated using the Morisita index according to Krebs (1999):

$$\text{Morisita Index (Id)} = n\left(\frac{\sum X^2 - N}{N\,(N-1)}\right) \quad \text{(Eq.1)}$$

Annotation: Id: Morisita disperse index; n: number of plots; x: number of individuals per plot; $\sum X^2$ = sum of squares of all species for each plot; N: total number of individuals with the following conditions: Id = 1 distribution pattern is classified as random (random), Id > 1 distribution pattern is classified as aggregate, and Id < 1 distribution pattern is classified as uniform.

Species diversity was calculated using the species richness index, species diversity index, and species evenness index. Species richness was calculated using the Margalef richness index (R1) with the formula:

$$\text{RI} = \frac{S-1}{LogN} \quad \text{(Eq.2)}$$

Annotation: RI: Richness Index, S: Number of species (n1, n2, n3, ...), N: total individuals in sampling. According to Magurgan (1988), the criteria used to interpret richness were: RI < 3.5: low species richness, RI = 3.5-5: moderate species richness, RI > 5: high species richness.

The species diversity index was calculated using the Shannon-Wiener index (Ludwig and Reynold, 1988):

$$H' = -\sum_{i=1}^{s}(P_i \ln P_i) \quad \text{(Eq.3)}$$

Annotation: Pi = ni/N; H'ː Shannon-Wiener diversity index, ni: number of individuals per species; N: number of individuals of all species. The criteria used to interpret the species diversity index, according to Magurran (1988), were: H' < 1.5: low diversity, H' = 1.5-3.5: moderate diversity, H' > 3.5: high diversity.

Meanwhile, species evenness employed Shannon evenness index (E) (Magurran, 2004):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22952314

$$E = \frac{H'}{\ln S} \quad \text{(Eq.4)}$$

Annotation: E: evenness index, H': Shannon-Wiener diversity index, S: number of species (n1, n2, n3, ...). Magguran (1988) stated that the criteria used to interpret evenness were: E' < 0.3: low evenness, E' 0.3 - 0.6 : moderate evenness, E' > 0.6: high evenness.

Furthermore, species dominance (D) was calculated by Simpson index to determine the level of dominance of certain species of butterflies in a community (Magurran, 1988). The formula used to calculate dominance was:

$$D = \Sigma (ni/N)^2 \quad \text{(Eq.5)}$$

Annotation D: dominance index, ni: number of individuals of k-I species, N: total number of individuals. Indicators of the dominance index are if D = 0.00-0.50, it means the dominance is low. If 0.50 < D < 0.75, it indicates moderate dominance. Whereas, 0.75 < D < 1.0 shows high dominance.

To determine the relationship between species diversity (species richness index, species diversity index, species evenness index, and species dominance index) and environmental factors (air temperature, air humidity, light intensity, wind speed and altitude), Spearman rank correlation was performed. Correlation test used the Statistica program version 6 (Stat Soft, 2001).

To find out the similarity of butterfly communities between urban forests, Sørensen similarity index was used and the data used were the presence and absence of butterfly species (Magurran, 1988). The index was calculated using Biodiv 97, which is a macro software on Excel (Shahabuddin et al., 2005). Dissimilarity value (1-Sørensen index) was used to make two-dimensional ordination of all samples using multidimensional scaling (MDS) and dendrogram (Schulze and Fiedler, 1998). The similarity of butterfly communities between urban forests was calculated based on the Sørensen similarity index. The data used were data on species and species abundance of each habitat type (Cheng, 2004).

Sørensen dissimilarity matrix was then used to create MDS (Multidimensional Scaling) and dendrogram of butterfly species similarity. Multidimensional Scaling (MDS) was used to describe similarities or distances of some observed objects. The result of MDS analysis was a two-dimensional mapping of the objects of observation. MDS arranged the location of the observation objects so that it had the right placement on a two-dimensional map based on the similarity or dissimilarity matrix that has been inputted. After the two-dimensional map was obtained, the distance of the objects of observation could be seen (Hair et al., 1998 and Cheng, 2004). Dimensions functioned to describe the relative position between objects. The similarity of butterfly communities between urban forest locations based on the distances depicted in the two-dimensional graph (MDS) was analyzed using Statistica for Windows 6 (StatSoft, 2001).

In addition to using MDS, the similarity of butterfly communities between urban forests was also tested by cluster analysis (Krebs,1999; Ludwig and Reynold, 1988). Cluster analysis of each community was arranged hierarchically in the form of a dendrogram. Dendrograms were created using the Statistica for Windows 6 (StatSoft, 2001). Clustering employed the unweighted pair group method with arithmetic mean (UPGMA) and Euclidean distance (Lewis, 2001).

Results

Distribution of butterfly species

In four urban forests, 2 butterfly species distribution patterns based on the Morisita index were found. They are aggregate and uniform distribution patterns. Meanwhile, random distribution pattern was not found. Pattern of aggregate distribution was found in 52 species, while 4 species showed uniform distribution. Butterflies from the family Nymphalidae were found as many as 28 species and included in aggregate distribution pattern, while 2 species, namely, *Elymnias hicetas* and *Lamasia lyncides* were classified as uniform distribution. Butterflies from the family Papilionidae were obtained as many as 9 species and had a pattern of aggregate distribution, while one species, namely *Papilio demoleus*, had a regular distribution. The butterflies of the family Hesperiidae were found as many as one species with aggregate distribution and one species with uniform distribution, while all species from the family Pieridae and the family Lycaenidae were found to have aggregate distribution pattern (*Table 2*).

Structure and composition of butterfly species

The butterflies found during the study were 5 families, consisting of 56 species and 985 individuals. The butterfly families found were Nymphalidae, Papilionidae, Pieridae, Lycaenidae and Hesperiidae. The family with the most number of species (30 species) and individuals (57.26%) was Nymphalidae, followed by Papilionidae, while the family that had the least number was Hesperiidae with 2 species and 8 individuals (*Table 3*).

Butterfly species of *Parthenos sylvia salentia* were the most common species found during the study, with a percentage of 12.93%, followed by *Troides helena* and *Ideopsis vitrea oenopsis* as many as 73 individuals (7.41%) (*Fig. 3*). The fewest species found were *Elymnias hicetas*, *Lamasia lyncides*, *Papilio demoleus*, and *Taractrocera luzonensis*, each found as many as one individual (0.10%) (*Table 3*).

Based on the type of urban forest, as many as 7 species of butterflies could be found in all urban forests. The only butterflies that were found in the Kaki Dian City Forest and not found in other urban forests were 7 species, while the species *Euploea eupator* was only found in the Kenangan City Forest. Five species were only found in the Kuwil City forest and were not found in other urban forests, while the *Euthalia amanda* and *Arhopala acetes* species were only found in the Kuwil City Forest (*Table 3*).

The highest abundance of butterfly species was found in the Kuwil City Forest, as many as 295 individuals (29.95%), then followed by the Kaki Dian City Forest, which had an abundance of 282 individuals (28.63%). The urban forest that had the least number of individuals was the Kenangan City Forest with a total of 175 individuals (17.77%) (*Table 3*).

The number of butterfly families found in the Kuwil City forest, Kenangan City Forest, and Talise City Forest was 5 families, while in the Kaki Dian City Forest was only 4 families. Nymphalidae was predominantly found in all types of urban forest and was most commonly found in the Kuwil City Forest and Talise City Forest (*Fig. 4*).

Diversity of butterfly species

The highest abundance and the highest evenness index of butterfly species was found in the Kuwil City Forest, while the lowest abundance and the lowest evenness index was in the Kenangan City Forest. The highest richness index and diversity index of

DOI: http://dx.doi.org/10.15666/aeer/1802_22952314

species (H') were also found in the Kuwil City Forest, while the lowest richness index and diversity index of species were in Talise City Forest (*Fig. 5*).

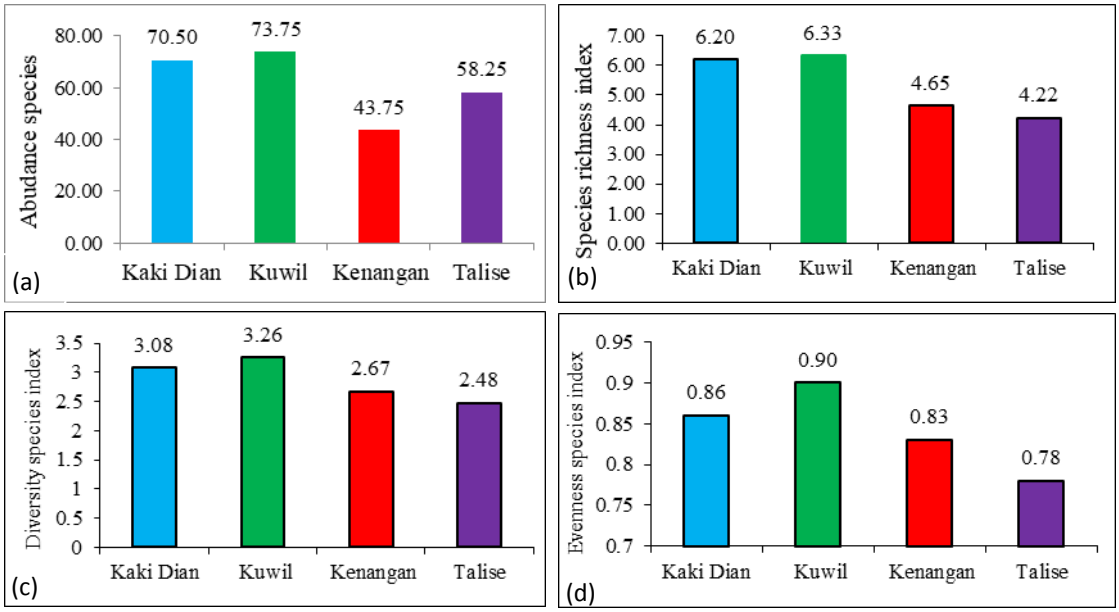

Figure 5. *The influence of urban forests types on (a) abundance, (b) richness (c) diversity and (d) evenness spescies index in North Minahasa, North Sulawesi*

Based on the categories, it was found that the species richness indices in the Kaki Dian City Forests and Kuwil City Forests were classified as high (S > 5), while the species richness indices in the Kenangan City Forest and Talise City Forest were classified as moderate (S: 3.5-5). The diversity index of butterfly species in the four urban forests was categorized as moderate (H: 1.5-3.5). Meanwhile, the evenness index of butterfly species was categorized as high because the index was greater than 0.6.

Index of species dominance

The highest dominance index of butterfly species was found in the Talise City Forest, while the lowest dominance index was in the Kuwil City Forest (*Fig. 6*). Based on the dominance index category, it was found that species dominance in the four urban forests was classified as low dominance (D < 0.5). This showed that no dominant butterfly species was found in the four urban forests.

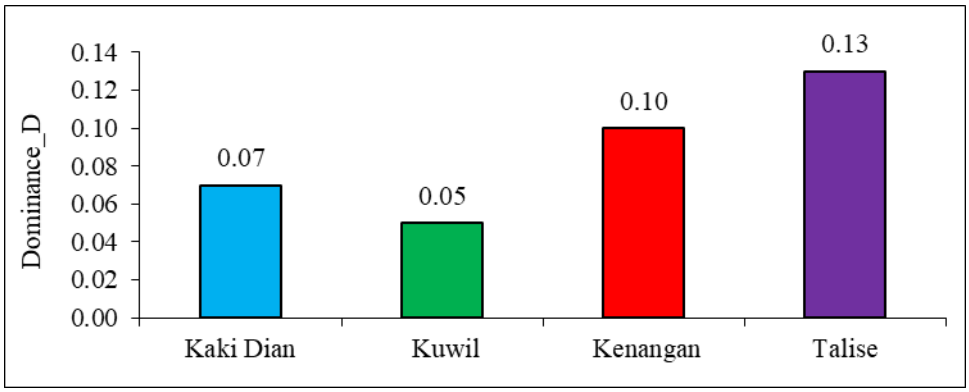

Figure 6. *Index of species dominance in four urban forests North Minahasa, North Sulawesi*

Correlation between species diversity and environmental factors

Correlation of butterfly species diversity with environmental factors showed that there was a negative correlation of species abundance, richness index, diversity index, and species evenness index with air temperature, light intensity, and wind speed (*Table 4*). The correlation of species abundance, richness index, diversity index, and evenness index of species with air humidity was positive. Dominance index was positively correlated with air temperature, light intensity, wind speed and altitude, while dominance index and air humidity showed a negative correlation (*Table 4*).

Table 4. *Correlation of butterfly species diversity with environmental factors in four urban forests North Minahasa, North Sulawesi*

Variable	Air temperature	Air humidity	Light intensity	Wind velocity	Altitude
Abundance	-0.31	0.41	-0.42	-0.56*	0.04

The similarity of the butterfly community in the urban forests

Analysis of the similarity of the butterfly community in the urban forests using MDS showed that the objects of observation, which were Kota Dian City Forest, Kenangan City Forest, and Kuwil City Forest, had a relatively close distance, while Talise City Forest had a distant point, compared to other urban forests (*Fig. 7a*). The dendrogram results from the dissimilarity matrix resulted in the Kaki Dian City Forest, the Kenangan City Forest, and the Kuwil City Forest forming one group, while the Talise City Forest separated (*Fig. 7b*).

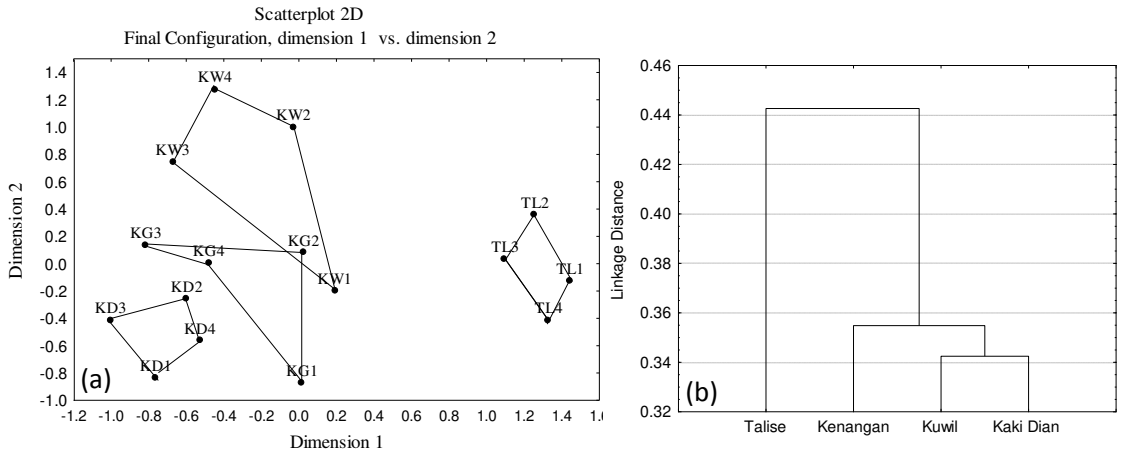

Figure 7. *Multidimensional Scaling (a), and dendrogram (b) about butterfly community similarity among urban forests in North Minahasa, North Sulawesi Utara (KD: Kaki Dian City Forest, KG: Kenangan City Forest, KW: Kuwil City Forest, TL: Talise City Forest)*

Discussion

The number of butterfly species found in four urban forest in Minahasa Regency, North Sulawesi Province, only reached 0.28% of the 20,000 species of butterflies in the world (Alarape, et al., 2015), 2.80% of about 2,000 species butterflies found in Indonesia (Peggie, 2014), and 10.19% of the 557 species of butterflies spread across Sulawesi Island (Vane-Wright and de Jong, 2003). The number of butterfly species found in this research was higher than the number of butterflies found in some butterfly diversity studies in other urban forests. Alfida et al. (2016) obtained 18 species of butterflies in Banda Aceh City Forest. Rahayu and Basukriadi (2012) found 43 species of butterflies in Sabki City Forest in Jambi City. Oktavianti (2019) found 22 species of butterflies in Pontianak City Forest, while Kumar and Rana (2018) reported 30 species of butterflies found in fragmented urban forests in Lucknow, India.

The distribution of butterfly species in four urban forests in North Minahasa Regency, in general, was classified as aggregate distribution. Aggregate distribution pattern is generally found in insects, because of their tendency to aggregate, gathering from various degrees representing the most common characteristics. D'Abrera (1990) reported that butterflies migrated in large numbers (in groups) to a certain direction to find a place that provides enough food for larval development. The aggregation of individual organisms of a population results from responding to changes in daily or seasonal weather and responding to differences in local habitat conditions (Odum, 1996).

The dominant butterfly family found in all forests was Nymphalidae. This result was similar to the results of several studies, including studies by Ramesh et al. (2010), Boonvanno et al. (2000), Sutra et al. (2012), and Koneri and Nangoy (2019). The high abundance of butterflies from the family Nymphalidae was due to the abundant number of individuals from the family throughout the world and their high ability to live. According to Vane-Wright and de Jong (2003), compared to other families, Nymphalidae is a butterfly family with the largest number of species in the world, which is about 6,500 species consisting of 13 sub-families. The butterflies from this family are generally cosmopolitan in nature.

Nymphalidae also has a tendency to be polyphage. Their polyphage nature enables Nymphalidae to be able to meet its food needs even though the main host plants are not available (Lestari et al., 2015). Sreekumar and Balakrishnan (2001) reported that many members of the family Nymphalidae are polyphage. This means that if their main host plants are not available, the butterfly can still use other plants that are suitable for feeding its larvae. Different types of flowering and host plants will invite different types of butterflies to nectar or lay eggs on the suitable host. According to Peggie and Amir (2006), the feed source of the Nymphalidae family is plants from the families Fabaceae, Annonaceae, Asteraceae, and Poaceae.

The family Nymphalidae is easily found all year round. This is because these insects are generalist. Some species of Nymphalidae do not depend on the existence of flower nectar alone. Those species are able to obtain food sources from rotten fruit and urine of other animals (Sarma et al., 2012).

Hesperiidae was a butterfly family with the fewest species and individuals found. This was because this family is small in body size and prefers moist and shady places such as forest areas. In this study, butterflies from the family Hesperiidae were found in all locations of urban forests except in the Kaki Dian City Forest. According to Amir and Kahono (2008), Hesperiidae is usually crepuscular, that is, it is active before night

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22952314

or when the light is dim. Observation of butterflies in this research was carried out since morning (7:00 pm) until late afternoon (3:00 pm). This condition caused very few encounters with butterflies from the family Hesperiidae.

Parthenos sylvia salentia species had the highest abundance compared to other species. The butterfly species is included in the family Nymphalidae. This species is found in tropical rain forests, usually around rivers. During the observation, many species were found near river basins in the Kuwil City Forest.

The next species of butterfly that had a high abundance was *Troides helena,* which belongs to the family Papilionidae. *Troides helena* is included as species protected by Government Regulation No. 7 of 1999, Decree of the Minister of Agriculture No.576/Kpts/Um/8/1980, and Decree of the Minister of Agriculture No.716/Kpts/Um1/0/1980. The species is also included in Appendix II of CITES (Convention of International Trade in Endangered Species). This means that the species is currently not included in the endangered category, but has the possibility of being endangered if the trade of the species is not regulated (Soeharto and Mardiastuti, 2003). *Troides helena* are poached for sale because of their beauty and scarcity (Noerdjito and Aswari, 2003; Nurjannah, 2010).

Differences in abundance, richness index, diversity index, and evenness index of butterfly species in four urban forests were greatly influenced by the area of urban forests and the complexity of the composition of vegetation structures making up the urban forest. The Kuwil City Forest was the location with the highest species diversity, while the lowest species diversity was in the Talise City Forest. The Kuwil City Forest is the location with the largest area (±46 ha), compared to the Kaki Dian City Forest (±37 ha), the Kenangan City Forest (±15 ha), and the Talise City Forest (±6 ha), and according to the theory of island biogeography, area is directly proportional to the diversity of species. The large size of an island will support an increase in the population size of the butterfly species due to the availability of food sources and habitats (MacArthur and Wilson, 1967). Island biogeography can be applied to fragmentation of urban forest landscapes as a model of how “islands” as small habitats can adversely affect the biodiversity of their natural habitat (Harris, 1984). Urban forest is considered an “island” in the form of habitat area that is surrounded by other areas that are not suitable for the life of species, such as residential land, offices, and plantations that are intensively processed.

The diversity of butterfly species in urban forests is also influenced by the availability of feed plants and is closely related to physical environmental factors, such as soil, water, temperature, sunlight, and biological factors that include vegetation and other animals. The distribution and abundance of plants as a source of larval feed was one of the factors that had a major influence on the survival of butterfly larvae. Nectar-producing plants also greatly affect the survival of butterflies, because the main food of butterfly is flower nectar. The more liquid nectar is available, the more butterflies come to visit the place. In the Kuwil forest habitat, there are many nectar-producing plants, such as oranges (Rutaceae), soursop (*Annona muricata*), durian (*Durio zibethinus*), gmelina (*Gmelina arborea*), Ficus sp, mango (*Mangifera indica*), *Mussaenda frondosa*, *Calliandra calothyrsus*, *Clerodendrum paniculatum*, *Ageratum conyzoides*, and *Lantana camara*. More diverse vegetation in a habitat has the potential for greater availability of feed for butterflies, compared to less diverse vegetation does (Rahayuningsih, 2012).

Another factor affecting the diversity of butterflies in urban forests in North Minahasa Regency was the availability of water. Urban forest where water flow can be found was the Kuwil City Forest and this urban forest provides a source of water for the surrounding community. The availability of water sources affects the existence of a type of butterfly, because butterflies like river banks (Amir et al., 2003). Butterflies come to the wet area to get water. Besides needing energy from their food, adult butterflies also need water in their life. Observations in the Kuwil City Forest showed that the source of water that was often visited by butterflies was sandy river banks. Glassberg (2001) argued that most species of butterflies, especially male butterflies, aggregated in moist sand or soil to absorb mineral salts and water. This behavior is called "puddling". The salt will be transferred to the female butterfly during the mating process as additional nutrient for the eggs.

Environmental factors in urban forests, such as air temperature, humidity, light intensity, and wind speed affect the diversity of butterfly species. According to Sharma and Joshi (2009), the structural complexity of habitat and vegetation diversity, including the influences of physical-chemical factors, such as air temperature, air humidity, and light intensity, was correlated with the diversity of insect species. The test results showed that species diversity was negatively correlated with air temperature, light intensity, and wind speed, whereas species diversity and wind speed was positively correlated.

Air temperature was very influential on the diversity of butterflies because these insects are poikilothermic, which means that their body temperature will increase or decrease following the temperature of the surrounding environment (Sihombing, 2002). Each butterfly species has different adaptability to temperature and humidity changes in their habitat. The temperature that can support the life of a butterfly ranges between 16 and 42 °C (Scoot, 1986), while the optimal temperature for butterflies is around 28-35 °C (Watanabe and Imoto, 2003). Based on temperature measurements in the four urban forests, it was found that the temperature in each urban forest could still support butterfly activity.

Furthermore, humidity is a very important climate factor. The correlation test found that the higher the relative humidity in an urban forest was, the higher the diversity of butterfly species in the urban forest became. Humidity can affect the breeding, growth, development, and activeness of insects. The ability of butterfly species to survive in the humidity of the surrounding air is different for each species and for each developmental stage. Air humidity can also affect the growth of host plants and indirectly affect the diversity of butterfly species (Efendi, 2009).

Light intensity influenced the diversity of butterflies. If the intensity of light was higher, the diversity of butterfly species would decrease. This was because the high light intensity caused the air temperature to rise and humidity to drop outside the range of air conditions required by a butterfly. Increased air temperature will accelerate the evaporation of body fluids and endanger the life of a butterfly. Low air humidity will affect butterflies that are large and wide-winged because the greater surface area of the body will increase the evaporation of body fluids. High light intensity also caused the volume of nectar secretions in flowers to decrease (Efendi, 2009).

Meanwhile, wind speed was negatively correlated with the diversity of butterfly species, which meant that if the wind speed got higher, the diversity of butterfly species would decrease. The results of wind speed measurements found that the lowest wind speed was in the Kuwil City Forest. Low wind speeds caused a high diversity of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_22952314

butterflies in this urban forest. High wind speed will damage the wings of butterflies, especially butterflies with broad and fragile wings, such as some species of the family Papilionidae and the family Nymphalidae, which will not last long in these conditions.

The similarity index of butterfly species between urban forests showed that the composition of butterfly species in the Kaki Dian City Forest, Kenangan City Forest, and Kuwil City Forest had many similarities, while the composition of butterfly species in the Talise City Forest did not share many similarities with the other urban forests. Species similarity between habitats is influenced by habitat characteristics, especially those characteristics related to plants as food, a place to take shelter from predator attacks, host plants to carry out their life cycle, playgrounds, and physical environmental factors, such as the presence of water flow, humidity, and weather conditions.

Conclusion

In general, the distribution of the butterfly species found (52 species) have a flocking pattern (aggregate). The butterfly species found consist of 5 families, comprising 56 species and 985 individuals. Butterfly species with the highest abundance is *Parthenos silva salentia* (29.93%). Family with the largest number of individuals is Nymphalidae (57.26%). The diversity of butterfly species which includes abundance, evenness index, richness index and the index of the highest species diversity was found in the urban forest of Kuwil. The highest domination index of butterfly species was found in the urban forest of Talise. The diversity of butterfly species is negatively correlated with air temperature, light intensity and wind speed. From the butterfly species community similarity index of urban forests, it is found that urban forests of Kaki Dian, Kenangan and Kuwil have a high similarity compared to the urban forest of Talise.

The results of this study recommend that further research on the types of plants that serve as food plants and hosts of butterflies should be done. The research period should include other seasons. It is expected that the Forestry Department of North Minahasa consider the diversity of butterflies in the management of urban forests by maintaining the habitat stability of urban forests. Habitat stability can sustain the butterfly conservation, especially *Troides Helena* butterflies which are protected and included in Appendix II of CITES (*Convention of International Trade in Endangered Species*).

Abstract. This work aims to determine the response of *Hypogymnia physodes* (L.) Nyl. (hooded tube lichen) collected in an unpolluted site (Yenice Forest in Karabük, Turkey) to stress conditions. In the present study, the effect of exposure to different heavy metals (Cd^{+2}, Pb^{+2}, and Cr^{+6}) for different durations and UV radiations dosages on lichen was examined at the physiological and molecular levels. The effects of stress conditions were determined in the case of different parameters concerning heavy metal, protein, chlorophyll, and carotenoid contents and changes in the DNA profiles. According to the results obtained that exposure to heavy metals and UV radiations leads to a physiological response in a concentration and dose-dependent manner through differences in chlorophyll, protein content in heavy metals and UV treated lichen specimen. Furthermore, changes in RAPD assay and DNA methylation analysis showed that homologous nucleotide sequences in the genome from untreated and stress conditions treated lichen specimen showed different band patterns and methylation under heavy metals and UV stress. The results determined that lichen specimen suggest as a possible bioindicator able to measure the biological effects of heavy metal pollution and damage to UV radiation.
Keywords: *lichen, UV radiations, metal uptake, chlorophyll content, DNA alteration*

Introduction

Due to population and rapid economic growth and urbanization, air pollution creates a major threat both to the environment and living organisms in the world. Environmental Protection Agency (EPA) has reported that some pollutants are poisonous, and inhaling them, in particular, can rapidly increase problems in human health (Cheloni et al., 2014; Mateos et al., 2018). Environmental pollution caused by heavy metals is one of the most serious problems at a global extent (Pescott et al., 2015; Ares et al., 2017). Among all heavy metals, cadmium (Cd^{+2}), chromium (Cr^{+3} and Cr^{+6}) and lead (Pb^{+2}), in particular, cause an ever-increasing international concern. The excessive Cr^{+6}, Cd^{+2} and Pb^{+2} concentrations in contaminated areas can give rise to a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23152338

variety of problems, which is metal toxicity to mainly humans and animals (Frohnmeyer and Staiger, 2003). Another main problem in ecotoxicology is the damage of the stratospheric ozone layer due to anthropogenic activities, which results in increased UV radiation on the surface of the Earth and causes damage to the biological system (Singh et al., 2012). Pollutants and UV radiation interrupt metabolic activities at the cellular level and damage biological molecules such as proteins and nucleic acids (Pourrut et al., 2011).

In contrast to organic pollutants, heavy metals cannot be degraded through any known biological processes (Brown et al., 2005), and thus, there remains an urgent need for remediation of contaminated areas by environmentally friendly technology. An appropriate and cost-effective method to remove pollutants and UV radiation from the environment is needed. Biological methods, instead of physical and chemical methods, enable to direct assessment of environmental stressors. Thus, information obtained from biological data can be allowed to determinate the environmental impact of global problems on biological organisms. The solution to many global problems, such as bioremediation of toxic chemicals in the environment and decreasing the effect of UV radiation will require further research on cellular and molecular biology with biological organisms (Bah et al., 2011). For instance, *Typha angustifolia* shows protein changes when exposed to Cr^{+6}, Cd^{+2} and Pb^{+2} heavy metals. Results of the study suggest that abiotic stress, such as heavy metal, temperature, drought and salt stress, induces changes in protein expression level in plants (Cho and Seo, 2005; Pandey et al., 2005). The liverwort (*Lunularia cruciate*) has been used to evaluate the effect of heavy metals on the cellular levels, including changes in the mRNA level (Basile et al., 2005). Lichen species have used to determinate the response of physiological and molecular mechanisms in stress conditions in recent years (Aras et al., 2010; Cansaran-Duman, 2011; Matos et al., 2015). Due to lichen species lack protective cuticle and roots, they can adsorb all metals directly from contaminated areas and ability to absorb in high quantity heavy metals in contaminated areas are usually used as model organisms for various purposes by the environmental area.

Damage to DNA may generate mutations, altered bases and strand breaks (Shugart and Theodorakis, 1994), and afterward, to carcinogenesis, teratogenesis and health disorders (Kurelec, 1993). Some researchers have reported that positively charged metal ions can react with negatively charged oxygen atoms located in both chains of the DNA in phosphate groups (Anastassopoulou, 2003). The DNA damage generated by environmental stress sources has been shown with various studies conducted in our laboratory (Cansaran-Duman et al., 2011; Cansaran and Aras, 2014; Vardar et al., 2014).

In recent years, some studies have shown that low UVB fluence rate is the cause of cellular changes in higher plants (Brown et al., 2005; Brown and Jenkins, 2008). It has been demonstrated that low UVB fluence rate responses involve specific receptors and appear to be photoregulatory. The changes caused by UV radiation on plant development, morphology and physiology have been observed in several studies (Mackerness, 2000; Frohnmeyer and Staiger, 2003; Jenkins, 2009; Hideg et al., 2013). Generally, energy-rich UV radiation gives rise to the formation of free radicals that damage DNA, proteins, and the damage of photosynthetic pigments (Hideg et al., 2013).

This study aimed to understand, predict and expand the knowledge of the possible biological response of *Hypogymnia physodes* lichen specimen to different types and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23152338

exposure periods of both UV and heavy metal solutions on cellular organization and physiological responses by examining bioaccumulation performance. Firstly, we evaluated heavy metal contents, chlorophyll (chl-a, chl-b, total chl, and carotenoids) and protein content in response to different heavy metal accumulation and UV radiations exposure to lichen specimen. Secondly, RAPD and MSAP-AFLP techniques were examined in *H. physodes* for possible changes in the DNA exposed to different heavy metal solutions and UV radiations. Although the capacity of heavy metal accumulation on lichen specimen has been extensively studied, only a few studies to date have shown that lichen specimen exposes to UV radiations at molecular and biochemical levels and heavy metal accumulation. This is the first manuscript examining methyl profiles in lichen specimen. Thus, this study will provide a better understanding of the molecular mechanisms of cellular protection against different stress factors on lichen species.

Materials and methods

Lichen sample and stress treatment

All procedures were carried out at Ankara University Department of Biology Molecular Systematic Laboratory and Ankara University Biotechnology Institute Central Laboratory, Ankara, Turkey. *Hypogymnia physodes* lichen specimen was selected as suitable bioindicators due to it has a large thallus surface. The lichen specimen was obtained from the unpolluted area of Yenice Forest, Karabük, Turkey in 2011 (41°10'N, 32°23'E). The sample collected from Yenice Forest was firstly washed and stored at appropriate conditions (4 °C) for a few days and sprayed distilled water. Then, the lichen specimen was sprayed constantly with distilled water in the laboratory. The sample was kept at room temperature for 2-3 h. During the treatments, thallus was placed in a climate chamber at 15 °C, exposure a photosynthetic photon flux density (PPFD) of 75 μmol m^2 s^{-1} and a 16 h photoperiod. All analytical procedures were carried out at least three replicates (n = 3).

Two different stress treatments (exposure to heavy metals and UV radiations) were applied in the study. A schematic representation of stress treatments in lichen specimen was shown in *Figure 1*. *H. physodes* was subjected to Pb^{+2}, Cd^{+2} and Cr^{+6} (30, 60 and 120 mg/L) heavy metal stress for different time periods (0.5, 1, 2, 6, 18, 24, 48 and 72 h). In brief, the stock solutions of Cd^{+2}, Pb^{+2} and Cr^{+6} (200 mg/L) were prepared by dissolving a weighed quantity in deionized water. In this study, the required concentrations were prepared from the stock solution with dilution. Lichen thallus (10 g weight) was immersed for an incubation period of 0.5, 1, 2, 6, 18, 24, 48 and 72 h. The lichen specimen was studied with three unexposed samples. The procedure followed for UV exposure; thallus sample placed in a petri dish was exposed to UV radiations at different doses of 4, 8, 12, 20 and 40 j/cm^2 (352 nm, 50 Hz, 0.60 Amps) by using dose-meter at 25 °C. Irradiation chamber BS-03 (Dr. Gröbel UV-Electronic GmbH) and dosemeter were used to lichen for determining to expose to UV radiations (UVA, UVB, UVC, daylight, UVA + UVB, UVA + day light) ratios. The control (non-stressed) group was analyzed with molecular markers and was indicated as a 'control sample'. Negative control was also used to determine the presence of any contamination.

Determination of heavy metals concentration

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23152338

The determination of heavy metal contents was performed from the previous study of Cansaran-Duman (2011). Lichen sample exposed to Cd^{+2} and Pb^{+2} heavy metals was collected at different time intervals. The sample was dried at 90 °C for 9 h and mineralization using HNO_3 and H_2O_2 (2:1, v/v) under ultrasonication. The set of standard calibration curves with good linear regression and better relative standard deviations were achieved for Cd^{+2} and Pb^{+2} metals in *H. physodes*. Cd^{+2} and Pb^{+2} concentrations of lichen sample were analyzed using Flame Atomic Absorption Spectroscopy (FAAS; Instrument PM Avarta, GBC Scientific Equipment, Australia). Standard reference material, CRM 482 Lichen (*P. furfuracea*), was used in the study to determine whether within range of the recommended values. The measured recovery % ± SD for Cd^{+2} and Pb^{+2} in the added CRM 482 reference material were 98 ± 7, 99 ± 6, 98 ± 3, respectively. The recovery was about 100% for Cd^{+2} and Pb^{+2} in the lichen sample, and the results with the CRD 482 material suggested that sample preparation and analyses were accurate. The conventional spectrophotometric method of Cr^{+6} was analyzed via 1.5–diphenylcarbazide measured at 540 nm in acid solution (APHA, 1985).

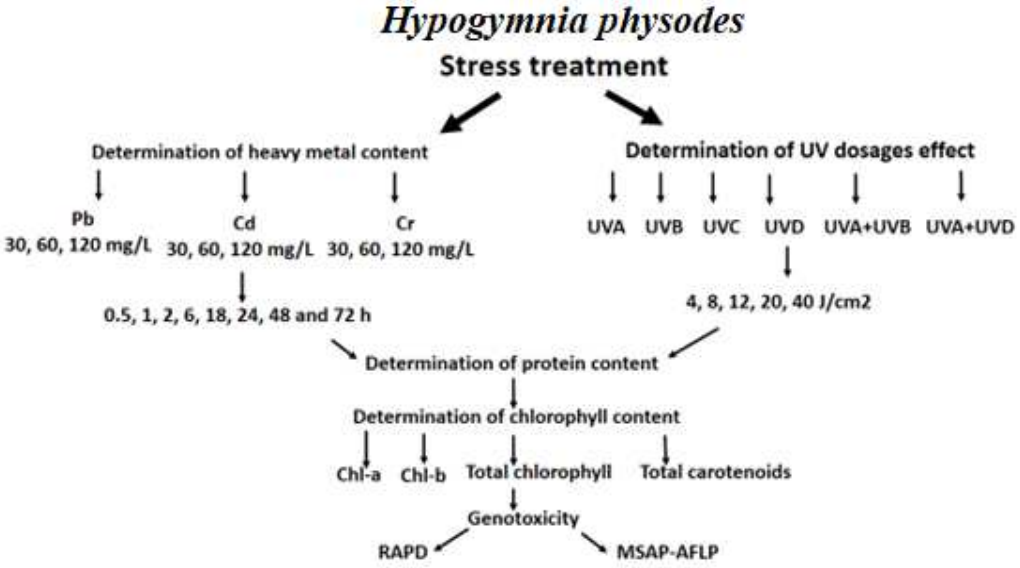

Figure 1. *A schematic representation of the treatments in Hypogymnia physodes lichen specimen. In this study evaluated three different metal stress treatments (Pb^{+2}, Cd^{+2} and Cr^{+6}) for eight different time periods (0.5, 1, 2, 6, 18, 24, 48 and 72 h) and in five different UV doses (4, 8, 12, 20, 40 J/cm^2 for UVA, UVB, UVC, daylight, UVA + UVB, UVA + daylight) in lichen sample. Also, the genotoxic effect of heavy metals and UV radiations was investigated for lichen specimen by RAPD and DNA methylation analysis*

Determination of total soluble protein content

Lichen specimen was homogenized (1:1, w/v) with 0.2 M phosphate buffer (pH 7.0). The obtained homogenate was centrifuged at 27.000 × *g* for 20 min. The supernatant was removed after centrifugation period. The total soluble protein content was determined according to the Bradford method (Bradford, 1976), using bovine serum albumin (BSA) standard. The experiments were repeated three times (n = 3).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23152338

Determination of chlorophyll contents

Unexposed lichen sample was immersed in distilled water for 5 min to obtain photosynthetic activity. Lichen specimen was exposed to Cd^{+2}, Pb^{+2}, and Cr^{+6} heavy metal solution and different UV radiations, and the chlorophyll content were determined by taking samples from this sample exposed to stress at certain time intervals (*Fig. 1*). Contents of chlorophyll a, chlorophyll b, total chlorophyll, chlorophyll a/b, and total carotenoids were spectrophotometrically determined (Metzner et al., 1965). Briefly, a 40-60 mg lichen sample was kept within 3 ml of dimethylsulfoxide (DMSO) for 1 h at 65 °C in the dark. Lichen sample kept in the dark for 1 h was centrifuged at 12000 *g* for 10 min at 20 °C. The supernatant was transferred to a fresh tube, and then, spectrophotometric measurements were taken at wavelengths of 644 (chl-a), 663 (chl-b), 452 (total chl) and 470 nm (Chls) (Ronen and Galun, 1984; Wellburn, 1994). This process was performed triplicate (n = 3). Each analysis was replicated three times.

Genomic DNA extraction and RAPD assay

H. physodes was exposed to Pb^{+2}, Cd^{+2} and Cr^{+6} (30, 60 and 120 mg/L) heavy metal stress for different periods (0.5, 1, 2, 6, 18, 24, 48 and 72 h), UV radiations and DNA of the lichen sample was extracted (*Fig. 1*). DNA extraction was performed according to the protocol defined by Aras and Cansaran (2006). Concentration and purity of the DNA extracted are measured at OD 260 and with a 260 nm/280 nm absorbance ratio by nanodrop (NanoDrop ND-1000 Spectrophotometer, Thermo Scientific, Wilmington, USA), respectively.

Primer screening for RAPD analysis was performed using 10 primers. The six of the ten primers amplified clear and reproducible bands in heavy metal stress and UV stress, respectively. PCR components were determined as follows; 200 ng genomic DNA, 2.5 µL 10X reaction buffer, 3.0 mM $MgCl_2$, 20 mM dNTPs, 0.3 mM primer, and 0.5 unit of Taq polymerase (Promega, Madison, USA), and ddH_2O was added to the final volume of 25 µL. Negative controls were used in all PCR reactions. The PCR program operated with the following steps: 95 °C for 30 s for denaturation, 36 °C for 1 min at 35 cycles for annealing step, 72 °C for 2 min for extension and a final extension at 72 °C for 10 min. PCR products were loaded on 1.5% agarose gels and run at 80 V for 4 h.

MSAP-AFLP analysis

In the MSAP-AFLP analysis was used OPC10 primer which is one of the primers giving sharp bands during RAPD analysis. The genomic DNA (200 ng) of the two stress exposed samples were separately digested with *Eco*R I/*Msp* I and *Eco*R I/*Hpa* II restriction enzymes at 37 °C for 2.0 h. Subsequently, the digested aliquot was ligated to specific adopters for examined restriction enzymes because it was applied to avoid reconstruction of restriction sites one for *Eco*R I sticky ends and other for *Msp* I or *Hpa* II sticky ends, at 20 °C for 90 min. The ligated DNA was diluted with Tris-EDTA buffer, and then the diluted products were amplified using different combinations of *Eco*R I and *Msp* I or *Hpa* II primer each with three selective nucleotides at 5′ and 3′, respectively. MSAP-AFLP analyses were conducted following the method described by Mastan et al. (2012). Briefly, selective amplifications were performed at 65 °C temperature for the first cycle, the annealing temperature was successively reduced by 0.7 °C for the other 11 subsequent cycles. The remaining 23 from 45 cycles were run at 56 °C annealing temperature. After the formamide dye added PCR product, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23152338

electrophoresis assay was run. The gels were stained with silver nitrate and scanned (Bassam et al., 1991). To test the reproducibility of the AFLP-PCR, the experiments were repeated at least twice for each primer, faint bands were not involved in this study.

Statistical analysis

The results of heavy metal content, ratio of UV radiation and total soluble protein content of the lichen specimen were evaluated by multifactor analysis of variance (univariate ANOVA) or Student's t-test followed by posthoc Tukey test as appropriate (SPSS for Windows version 11.0) to display the effects of both stress sources on the exposed lichen.

Chlorophyll a, b, total chlorophyll and carotenoids were calculated by the following equations by Shakoor et al. (2014). The experiments were repeated three times (n = 3) and then evaluated with multifactor analysis of variance (ANOVA).

Estimation of profiling scoring and data analyses for RAPD assay

The RAPD analysis of the results was evaluated by considering the number of bands, which appear in the control (non-stressed) sample. Polymorphism calculated in RAPD profiles included the disappearance and appearance bands when compared with the non-stressed sample (Atienzar et al., 1999; Liu et al., 2005). Each polymorphic DNA band on the gel was treated as an individual locus and scored for their presence (1) or absence (0). Genomic template stability (GTS%) was calculated as followed by Atienzar et al. (1999). Changes in RAPD patterns were evaluated as decreases in GTS, compare with the number of RAPD profiles exposed to a different stress condition, and profiles obtained from the control samples.

Estimation of profiling scoring and data analyses for methylation analyses

MSAP data analysis was scored reproducible bands. All the amplified bands obtained from the MSAP-AFLP analysis were divided into four methylation types based on the presence or absence of groups as indicated by Li et al. (2009). According to this classification, the bands indicating each methylation type (I, II, III, and IV) were counted and placed in their location in *Table 1*.

The percentage of methylation was evaluated as the number of methylated bands × 100 by dividing the total number of bands. The percentage of methylation polymorphism was calculated using the formula (=number of polymorphic methylated bands×100/number of methylated bands).

Table 1. *Methylation types created by the cutting ability of HPAII and MspI restriction enzymes*

Methylation type	Methylation pattern	HpaII	MspI
Type I	CCGG CCGG GGCC GGCC	Active	Active
Type II	CCGG GGCC	Active	Inactive
Type III	CCGG GGCC	Inactive	Active
Type IV	CCGG GGCC	Inactive	Inactive

DOI: http://dx.doi.org/10.15666/aeer/1802_23152338

Results

We analyzed *H. physodes* lichen specimen for three different metal stress treatments were applied (Pb^{+2}, Cd^{+2} and Cr^{+6}) in three different doses (30, 60 and 120 mg/L) for eight different periods (0.5, 1, 2, 6, 18, 24, 48 and 72 h). The same concerns exposure to UV radiations on lichen specimen examined six combinations of UV radiations (UVA, UVB, UVC, daylight, UVA + UVB, UVA + daylight) with five different doses of 4, 8, 12, 20 and 40 j/cm^2. Subsequently, in the analyzed sample, heavy metal, total soluble protein, chlorophyll a, chlorophyll b, total chlorophyll, and total carotenoids contents were measured (*Fig. 1*). The changes of DNA profile exposed to different heavy metals and UV radiations determined RAPD and DNA methylation analysis assays.

Determination of heavy metal contents in lichen specimen

The 30 mg/L Cd^{+2} metal absorption by *H. physodes* was very fast and optimum equilibrium was reached at 30 min ($P < 0.05$) (*Fig. 2; Table 2*). *H. physodes* was found to have an optimum absorption rate of 70.5% after 30 mg/L Pb^{+2} applications in 72 h ($P < 0.05$). It was noticed that 60 mg/L Cr^{+6} exposure significantly reduced (79.9%) heavy metal content in *H. physodes* (47.8 mg/L) in 72 h when compared to unexposed sample (59.8 mg/L) ($P < 0.05$). The highest absorption efficiency (94.2%) was obtained at 120 mg/L Cr^{+6} for 72 h in *H. physodes* lichen specimen ($P < 0.05$).

The highest absorption efficiency was achieved as about 92.2%, 95.1% and 95.5% using 30, 60 and 120 mg/L Cr^{+6} for 18 h, respectively. According to the results of 30, 60 and 120 mg/L Pb^{+2} application in lichen specimen, the absorption capacity percentage decreased from 43.4% to 34.5% as *H. physodes* was applied to 30 mg/L Pb^{+2} for 24 h. 60 mg/L Pb^{+2} heavy metal absorption decreased from 58.1% for 24 h in *H. physodes*. At 120 mg/L Pb^{+2}, the absorption efficiency was found to be low in *H. physodes* (59.2%) for 24 h ($P < 0.05$).

The optimum absorption capacity against 30, 60 and 120 mg/L Cd^{+2} heavy metal stress was found as 43.8% for 30 min, 63.3% for 12 h and 57.5% for 6 h in *H. physodes*, respectively ($P < 0.05$).

Table 2. *30 mg/L Cd^{+2} content of Hypogymnia physodes lichen specimen with ANOVA (Same letters in a column indicate the absence of significant differences at $P < 0.05$ by ANOVA)*

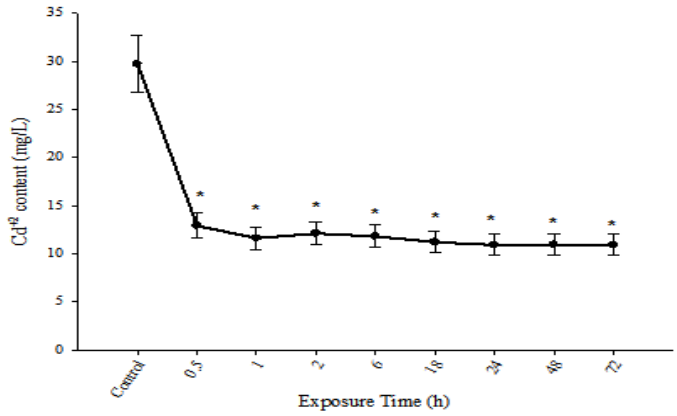

Figure 2. *The time-concentration curve of Cd^{+2} content of the stock solution that exposed to Hypogymnia physodes. (* = statistically different from control (P < 0.05) Cd^{+2} removal by H. physodes at initial Cd^{+2} concentration for 72 h*

Determination of protein content in lichen specimen

Effect of heavy metals on protein content

Protein content decreased with the increase in the concentration of heavy metals in *H. physodes* at the examined time range (30 min–72 h). Maximum protein content in *H. physodes* was increased for 30 mg/L Cr^{+6} and 30 mg/L Cd^{+2} until 30 min; however, there was a significant decrease in protein content afterward (from 60 min to 72 h) ($P < 0.05$). Protein content of lichen specimen was also significantly increased at both heavy metal stress levels (60 mg/L Cr^{+6} and Cd^{+2} heavy metals) for 30 min ($P < 0.05$). Protein content of *H. physodes* decreased all concentrations of Pb^{+2} stress when compared with the unexposed sample. The results of this study showed that the protein content of lichen specimen significantly decreased ($P < 0.05$) by 120 mg/L concentration of Cr^{+6} (*Table 3*) and Cd^{+2} at 1 h after treatment (0.023 mg/L, respectively). However, the protein content of *H. physodes* significantly decreased by 120 mg/L Pb^{+2} exposure for 1 h when compared with the unexposed lichen sample (20.73 and 19.23, 19.9 and 18.32 mg/L, respectively) ($P < 0.05$). Protein content significantly decreased after from 2 to 72 h exposure to 120 mg/L Pb^{+2}.

Effect of UV radiations on protein content

The protein content of *H. physodes* significantly decreased at 40 j/cm^2 among the other four UV radiations. Exposure to 40 j/cm^2 UVA + UVB radiations, protein content significantly decreased by 28% in *H. physodes* ($P < 0.05$), similarly after the 4, 8, 12 and 20 j/cm^2 UV radiations exposure decreased protein content of *H. physodes*. The lowest UVB radiation (4 j/cm^2) exposure was recorded as 0.0470 mg/L protein content and the highest UV radiations exposure (40 j/cm^2) was measured as 0.0157 mg/L protein content in *H. physodes* when compared to unexposed sample (0.0505 mg/L) ($P < 0.05$).

Determination of chlorophyll content

Effect of heavy metals on chlorophyll-a content

The results of the study showed that the chl-a content was significantly decreased by 30, 60 and 120 mg/L concentration of Cr^{+6}, Pb^{+2} and Cd^{+2} after 2 h exposure (15.42 and 14.46, 14.55 and 11.49 mg g^{-1}, respectively) ($P < 0.05$). 120 mg/L Cr^{+6} exposure for 2 h significantly decreased the chl-a content of *H. physodes* by 18% (0.404 mg g^{-1}) ($P < 0.05$).

Effect of UV radiations on chlorophyll-a content

In UV radiations exposure, chl-a content of the unexposed sample of *H. physodes* was determined as 2.300 mg g^{-1}. In terms of the applied stress level among all UV radiations types (UVA, UVB, UVC, daylight, UVA + daylight, UVA + UVB), the highest increase was observed at 40 j/cm^2 ($p<0.05$). After the implementation of 40 j/cm^2 UVA + UVB radiations level, the highest chl-a content increase (10.760 mg g^{-1}) was observed about 5 fold when compared to the unexposed sample (2.300 mg g^{-1}) ($p<0.05$). In contrast, exposure to UVA radiation alone at a dose of 40 j/cm^2 increased the amount of the lowest chl-a (2.742 mg g^{-1}) ($p<0.05$).

DOI: http://dx.doi.org/10.15666/aeer/1802_23152338

Effect of heavy metals on chlorophyll-b content

This study was determined the changes in chlorophyll-b content after exposure to heavy metals and UV radiations compared to the unexposed sample. The results of the study showed that chl-b content of *H. physodes* unexposed sample (1.518 mg g^{-1}) significantly decreased with 30, 60 and 120 mg/L concentration of Cr^{+6}, Pb^{+2} and Cd^{+2} after 48 h treatment ($P < 0.05$). After 30, 60 and 120 mg/L Pb^{+2} treatments, the highest decrease rate at all concentrations when compared to the unexposed specimen was determined as 0.013, 0.209 and 0.057 mg g^{-1}, respectively ($p<0.05$).

Effect of UV radiations on chlorophyll-b content

H. physodes lichen specimen was observed 1.629, 2.873, 2.659, 2.229, 2.033 and 2.853 mg g^{-1} chl-b content exposed to 8 j/cm^2 UVA, UVB, UVC, daylight, UVA + UVB, UVA + day light when compared to the unexposed sample (1.518 mg g^{-1}), respectively.

Effect of heavy metals on total chlorophyll content

Total chlorophyll content in the unexposed sample in *H. physodes* was observed as 3.818 mg g^{-1}. The optimum result of total chlorophyll content in *H. physodes* was obtained at three heavy metal exposures (Cr^{+6}, Pb^{+2}, and Cd^{+2}) and concentrations (30, 60 and 120 mg/L) after a 60 min treatment. The highest decrease rates of Cr^{+6} heavy metal among all concentrations were observed as 0.857, 1.130 and 0.583 mg g^{-1} in *H. physodes* lichen specimen, respectively ($P < 0.05$).

Effect of UV radiations on total chlorophyll content

Total chlorophyll content of *H. physodes* was observed as 4.341 and 5.394 mg g^{-1} expose to 8 j/cm^2 UVA + day light radiations. The highest content of total chlorophyll was determined as 14.923, 12.989, 12.159 and 16.010 mg g^{-1} after exposure to 20 j/cm^2 UVB, UVC, UVA + daylight, and UVA + UVB radiations, respectively ($p<0.05$). Especially, after the 20 j/cm^2 UVA + UVB radiations treatment, the maximum decrease of total chlorophyll content (16.010 mg g^{-1}) was observed in *H. physodes*, when compared to the unexposed sample (3.818 mg g^{-1}) ($P < 0.05$).

Effect of heavy metals on the ratio of chlorophyll a/b

Variations in the ratio of chlorophyll a/b were caused by increasing lichen metal content. The ratio of chlorophyll a/b in *H. physodes* exposed to 30, 60 and 120 ppm Cr^{+6} heavy metal stress showed a significant decrease after 30 min of all three heavy metal treatments ($p<0.05$). Exposed to 30 ppm Cd^{+2} and Pb^{+2} heavy metal stress in *H. physodes* lichen specimen, the treatments showed a marked increase in the ratio of chlorophyll a/b (86.02 mg g^{-1}) as a result of 18 and 24 h, respectively ($p<0.05$). After treatments, the ratio is gradually decreasing towards the lowest level.

Effect of UV radiations on the ratio of chlorophyll a/b

An increase in the ratio of chlorophyll a/b was observed after 4 j/cm^2 treatment in *H. physodes* lichen specimen exposed to UVB radiation.

Determination of total carotenoid content

Effect of heavy metals on total carotenoid content

The content of total carotenoid in the control sample of *H. physodes* was observed as 0.092 mg g^{-1}. The optimum time of after all heavy metal exposure was determined at 18 h. All examined heavy metal concentrations (30, 60 and 120 mg/L) significantly decreased total carotenoid contents in *H. physodes* when compared to unexposed sample ($P < 0.05$). The maximum change in total carotenoid content was observed as 0.056 mg g^{-1} after 18 h 120 mg/L Cd^{+2} treatment in *H. physodes* ($P < 0.05$).

Effect of UV radiations on total carotenoid content

Total carotenoid content of lichen specimen was founded a decrease expose to all UV radiations when compared to the control sample. The maximum change in total carotenoid contents was determined after 12 j/cm^2 expose to UV radiations ($P < 0.05$). The highest decrease after 12 j/cm^2 treatment was observed after UVA + UVB radiations exposure (0.070 mg g^{-1}) in *H. physodes* ($P < 0.05$).

Determination of heavy metals and UV radiations on RAPD profiles in Hypogymnia physodes

A representative example of the results obtained by RAPD analysis is shown in *Figure 3*. The concentrations measured for the DNA samples were approximately in the range of 1285–2012 ng/µl for all heavy metals and 964–2077 ng/µl for all UV radiations exposures at 260 nm/280 nm ratios between 1.64–1.97 and 1.54–1.99, respectively.

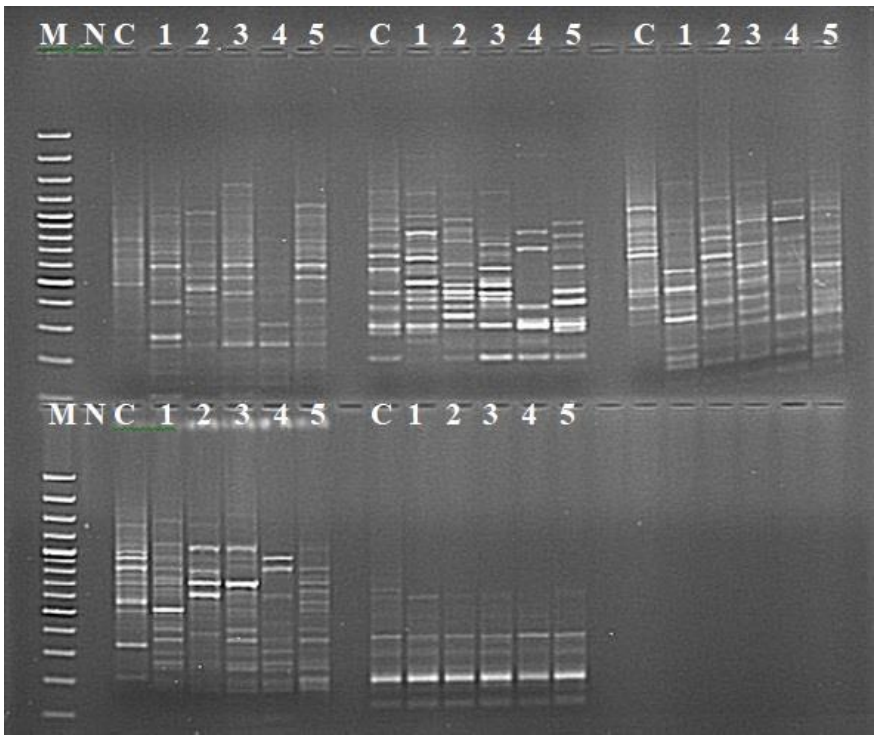

Figure 3. *The results of RAPD-PCR treating at UVB radiation in Hypogymnia physodes (top-left OPC02, top-center OPC04; top-right TubeA05, lower-left OPC07, lower-center OPC10*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

primers). (M: Marker; N: Negative control; C: Control sample (non-stressed sample); 1: 4 j/cm^2; 2: 8 j/cm^2; 3: 12 j/cm^2; 4: 20 j/cm^2; 5: 40 j/cm^2)

In RAPD analyses, some of the primers displayed significant differences in band patterns formed by loss of normal bands and appearance of new bands in the treated heavy metals and UV radiation exposure in comparison to the untreated sample profiles. The highest number of appearance and disappearance of new bands was observed at 30 mg/L Cd^{+2} concentrations with ten primers. Most of the new band appearances/disappearances were shown in Cd^{+2} contaminations (33 bands) observed in 30 mg/L Cd^{+2} contaminations. The lowest band appearances/disappearances were determined in Cd^{+2} (8 bands) and Pb^{+2} (8 bands) exposure to 30 min. The highest band appearances/disappearances in different UV radiation exposures were shown at 40 j/cm^2 exposure (42 bands).

As an analysis of the samples applied Cd^{+2} heavy metal in *H. physodes*, the highest genomic template stability (GTS%) value occurred after exposure to Cd^{+2} heavy metal stress at 72 h in all concentrations (30, 60 and 120 mg/L). 30, 60 and 120 mg/L Cd^{+2} treatment resulted in the highest GTS value of 91.1%, 85.5% and 86.6%, respectively. The lowest GTS value occurred after exposure to Cd^{+2} at 2 h in all concentrations. The lowest GTS value (63.3%, 64.4% and 70.0%) was obtained in the 30, 60 and 120 mg/L Cd^{+2} heavy metal treatment, respectively. According to this, the highest and lowest band variations were observed at 30, 60 and 120 mg/L Cd^{+2} concentrations at 2 h and 72 h, respectively. In terms of Cr^{+6} stress in *H. physodes* lichen specimen, the highest and the lowest GTS values were detected at 48 h of 30 mg/L (88.5%) and 72 h of 60 mg/L (90.6%) and 72 h of 120 mg/L (90.6%), respectively. The lowest GTS value was obtained at 30 min and 18 h in the 30 mg/L Cr^{+6} (69.7%), 2 h in the 60 mg/L Cr^{+6} (70.8%) and 1 h in 120 mg/L Cr^{+6} (78.1%). In terms of Pb^{+2} stresses in *H. physodes*, the highest GTS value was observed after exposure to Pb^{+2} at 72 h in all concentrations. 30, 60 and 120 mg/L Pb^{+2} treatments resulted in the highest GTS values of 93.0%, 93.0% and 91.3%, respectively. The lowest GTS values were obtained at 30 min, 2 h and 6 h in 30 mg/L (82.6%), 30 min at 60 mg/L (78.2%) and 30 min at 120 mg/L (80.8%) Pb^{+2} treatments.

In terms of UVA radiation stress in *H. physodes* lichen specimen, the highest GTS value (87.8%) was observed after exposure to 4 j/cm^2 UVA radiation. The lowest GTS value (76.5%) was obtained at 40 j/cm^2 UVA radiation. As regards UVA and daylight stress in *H. physodes*, the highest GTS value (88.6%) was observed after exposure to 4 j/cm^2 UVA and daylight radiations. The lowest GTS value (80.86%) was obtained at 12 j/cm^2 UVA and daylight radiations. Despite UVC stress in *H. physodes*, the highest GTS value (92.1%) was observed exposed to 4 j/cm^2 UVC radiation and the lowest GTS value (76.5%) was determined at 40 j/cm^2 UVC radiation. In terms of daylight stress in *H. physodes*, the highest GTS value (89.67%) was realized exposed to 8 j/cm^2 daylight radiation but the lowest GTS value (84.78%) was obtained at 40 j/cm^2 daylight radiation.

When all UV radiations and UVB exposure were compared, maximum changes of UV exposure were determined in UVB radiation in *H. physodes*. The significant changes were determined, such as appearances of some new bands or the disappearance of bands when compared to the control. A maximum of 28 bands disappeared among the exposed *H. physodes* with 40 j/cm^2, while in 20 j/cm^2, a maximum of 13 new bands appeared in *H. physodes* exposed to UVB radiation (*Table 4*). Also, the results showing the most variation among the different heavy metal (Cd^{+2}, Cr^{+6}, Pb^{+2}) and time arrival

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

(0.5, 1, 2, 6, 18, 24, 48 and 72 h) combinations applied to the *H. physodes* lichen species are given in *Table 5*. *H. physodes* lichen specimen for three different UV treatments were applied (UVA, UVB, UVC, UVD, UVA + UVB, UVA + UVD) in five different doses (4, 8, 12, 20 and 40 j/cm^2). The results showing the most variation among the UV radiations and doses combinations applied to the *H. physodes* lichen species are given in *Table 6*. The highest GTS value (88.4%) was observed exposed to 4 j/cm^2 UVB radiation (*Table 7*). The lowest GTS value (73.18%) was obtained at 40 j/cm^2 UVB radiation (*Table 7*). Regarding UVA and UVB stress in *H. physodes*, the highest GTS value (84.3%) was observed exposed to 4 j/cm^2 UVA and UVB radiations. The lowest GTS value (63.4%) was obtained at 40 j/cm^2 UVA and UVB radiations.

Methylation DNA and polymorphism in examined lichen specimen to different levels of stress condition

Band alterations in heavy metals and UV radiations exposure were compared with respect to the untreated control samples. 413 to 691 bands were produced in the untreated sample, and 217 bands with an average of 11 per primer were obtained in the MSAP-AFLP analysis. The total number of band alterations (a + b) was 117 bands for the Cd^{+2} heavy metal and lichen specimen stressed with UVB (*Fig. 4*).

Table 6. *H. physodes lichen specimen for three different UV treatments were applied (UVA, UVB, UVC, UVD, UVA + UVB, UVA + UVD) in five different doses (4, 8, 12, 20 and 40 j/cm^2). The highest rate of changes was observed in the *H. physodes* exposed to heavy metal stress for 6 h and UVB radiation stress for 12 and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23152338

24 h. When the results of the MSAP - AFLP analysis were evaluated based on the methylation types in the heavy metal stressed samples, the maximum level of methylation (33.3%) was observed in Type II, and the lowest level of methylation (63.3%) was seen in Type III. Type II methylation was not observed for the first 6 h and then, occurred at a rate of 34.3% at 12 h and 24 h. The rate of Type II methylation (34.3%) remained the same until the end of 12 h and completely disappeared at 24 h in Cr^{+6} heavy metal exposure in *H. physodes*.

Discussion

In our study were applied increasing Cr^{+6}, Pb^{+2} and Cd^{+2} heavy metal concentrations and UV radiations in different doses in *H. physodes* lichen specimen. Heavy metal accumulation capacities, total protein content and chlorophyll parameters constituted against stress were determined in lichen specimen. In addition, the genotoxic effect generated by heavy metals and UV radiations was investigated with RAPD and MSAP - AFLP techniques at a molecular level (*Fig. 1*). This is the first evaluation of the changes in DNA methylation and polymorphism in methylated DNA in lichen specimen under heavy metals and UV radiations stress.

Gill et al. (2015) have shown that the toxic effects of Cr^{+6} heavy metal are observed in four different cultivars of *Brassica napus* L. The study determined plant growth and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23152338

biomass ratio changed to exposure to Cr^{+6} concentrations. After Cr^{+6} application, the effect of Malondialdehyde (MDA) and Reactive oxygen species (ROS) increased, which could be an indication of cell damage in the plant. According to the results of our study also found that *H. physodes* lichen specimen was more accumulate in Cd^{+2} and Cr^{+6} heavy metals when compared to Pb^{+2} ($P < 0.05$). In our study, the damage caused by heavy metal application to lichen specimen may be due to the effects of ROS and MDA.

In another study, Fernandez et al. (1992) have indicated that fly ash, tending to be close to the source, is normally associated with the coarse fraction. This study has reported more storage Cr capacity of the samples collected around 5 km from the iron-steel factory. They have also stated that particularly *H. physodes* and *Evernia prunastri* have similar Cr accumulation ratio. Aslan et al. (2006) have reported that *H. physodes* shows high levels of Ca, Ti, Fe and Ba heavy metal accumulation collected from Ordu, province of Turkey. In our study results revealed that *H. physodes* lichen specimen showed to accumulate all heavy metals at a significant level ($P < 0.05$). Koroleva and Revunkov (2017) investigated to create a database of trace elements concentrations in the sample of the epiphytic lichen *Hypogymnia physodes* and to identify the spatial patterns of iron, manganese, nickel, cadmium, silver, lead, strontium, rubidium, and calcium in the Kaliningrad region. They stated that the lichen specimen accumulates microelements more intensively in the west of the Kaliningrad region than in its continental part, which is also due not only to a higher level of urbanization of the territory but also to the region's climatic features. Zulaini et al. (2019) investigated the accumulation of heavy metals on two types of epiphytic lichens, *Parmotrema tinctorum* and *Usnea diffracta*. They stated that *P. tinctorum* can be positively compared to *U. diffracta* for identifying the levels of heavy metals, due to the higher capability to accumulate heavy metals without affecting the internal structure. These lichen species positively responded to the heavy metal accumulation levels. Branquinho et al. (1997) have shown that they were able to determine and quantify the cellular location of Cu in lichens. They have been expected to regulate the extracellular uptake, time or concentration from conventional kinetic studies with other organisms and heavy metals. *Usnea* sp. were most sensitive to Cu uptake compare with other lichen species, since physiological changes occurred for lower supplied Cu concentrations than *R. fastigiata*. It seems that lichen specimen can accumulate much more metal elements than it needs and that accumulation is capable of high tolerance in our study. Thanks to these properties, lichens are defined as the best monitor-indicator organisms that can be used to display atmospheric heavy metal pollution (Abas et al., 2019; Benitez et al., 2019; Ramic et al., 2019). Li et al. (2009) have demonstrated comparative effects of Cd^{+2} and Pb^{+2} on biochemical response and DNA damage in the earthworm *Eisenia fetida* (Annelida, Oligochaeta). The evaluation of DNA damage in earthworms used the comet assay. As a result, it was the aim of the study to determine more detailed information on the effects of heavy metals on earthworms' organisms. When the results of our study and that of Liu et al.'s are compared, both studies clearly show that both of the examined biological organisms were affected by all heavy metal treatments. This study determined that selecting lichen specimen was important for accumulating heavy metals. As a result of this study, *H. physodes* lichen specimen could serve as biomarkers for environmental pollution. It can be used to a novel organism as an environmentally friendly and cost-effective technology for remediation of polluted sites.

Doğan and Saygıdeğer (2009) have investigated some morphological and physiological changes in *Ceratophyllum demersum* L. at different concentrations of Cd^{+2} (0, 0.01, 0.1 and 1 ml/L) effect in 96 h. They have stated that total soluble sugar and protein content are reduced by the application of Cd^{+2}. Although the amount of protein showed a decrease when compared to the controls, there was no significant correlation between protein content and heavy metals. The reason for the decrease in protein content in plants is often caused by the inhibition of protein synthesis or proteolysis triggered by ROS produced by oxidative stress. Duman et al. (2010) have investigated the biological response against Cr^{+6} heavy metal in *Ceratophyllum demersum* L. Cr accumulation, plant growth, lipid peroxidation, ion escape, photosynthetic pigmentation, protein and proline content have been investigated depending on concentration changes. They have stated a statistically significant difference between 1 mM Cr^{+6} treatment and 5-10 mM Cr^{+6} treatments. In our study, the decrease in total protein in lichen specimen was observed when compared with 60 and 120 mg/L Pb^{+2}, Cr^{+6} and Cd^{+2} heavy metals ($p<0.05$). Particularly, Cd^{+2} and Cr^{+6} heavy metals constitute a high level of damage to protein content when compared with other examined parameters in *H. physodes* ($p<0.05$). In brief, the amount of protein in lichen specimen decreased at a statistically significant level after all heavy metals application ($P < 0.05$). Our study results revealed that the respond of heavy metal stress was similar to the protein content of other study results. We evaluated the change in the protein content of *H. physodes* lichen sample exposure to UV stress. Our study results also demonstrated that total protein content in *H. physodes* lichen specimen applied with UV radiations showed an opposite relation with all samples. Reduction in total protein content was observed depending on the application dose of UVA, UVB, UVC, daylight, UVA + daylight, and UVA + UVB radiations when compared to the unexposed sample. A decrease in protein content of lichen specimen was determined up to 12 j UV dose, but further UV doses were not detected changes of protein content in lichen specimen. For this reason, lichen specimen may have a certain level of tolerance. It is very important to evaluate the protein relationship with the response given to stress conditions. Protein molecules play a significant role in the determination of mainly heavy metal stress and UV radiations exposure. If further protein-related works like proteome studies it may be used in a biomarker for environmental pollution.

A study conducted has shown the physiological change generated at a cellular extent as a result of the exposure of *Cladonia arbuscular* and *Peltigera rufescens* lichen species to mercury (Hg) (Pisani et al., 2011). The results of this study have put forward that photosynthetic pigments are sensitive to $HgCl_2$ in both species. Chl-a, -b, and carotenoids content significantly decreased in *C. arbuscula* subsp. *mitis* but only Chl-a and carotenoids significantly decreased in *P. rufescens* (Pisani et al., 2011). Chettri et al. (1998) were hypothesized that Cu was responsible for the reduced chlorophyll content of lichens growing in mining areas in which Cu, Zn, and Pb were present in the soil. Therefore, they were examined the effect of Cu, Zn, and Pb, individually and in combination, on the respective thallus metal content of the lichens *C. convoluta* and *C. rangiformis*, and the subsequent effect on chlorophyll content. They found that increasing lichen Cu content [up to 1600 μg g^{-1} dry weight (DW)] had no effect on the total chlorophyll content of *C. rangiformis*, whereas Cu concentrations exceeding 175 μg g^{-1} DW caused a decrease in total chlorophyll content in *C. convoluta*, which was 40% at 1560 μg Cu g^{-1} DW. As a result, the Cu effects on chlorophyll were reduced in the presence of Pb and Zn in both lichens, but to a lesser extent in *C. rangiformis*.

DOI: http://dx.doi.org/10.15666/aeer/1802_23152338

Metal cations appeared to be ionically bound within the cell wall in an exchangeable form with binding affinities of Pb > Cu > Zn. Similarly, Karakoti et al. (2014) found that Pb, Cu, Fe, and Cr have little effect on chlorophyll degradation in lichen *Pyxine cocoes*. Monnet et al. (2001) have observed an increase of chl-a content after applied with 10 mg/L heavy metal stress for 8 days, but then the content of chl-a decreased in ryegrass (*Lolium perenne*). Casano et al. (2015) reported that the proportion of cell walls is important for the capacity to immobilize extracellular Pb^{+2} from the photobiont layer. Therefore, the external cell wall could help to decrease the deleterious effects of Pb on chlorophyll content in a short time (24 h) exposure. Gurbanov and Unal (2018) revealed that Pb^{+2} exposure diminished the total nucleic acid quantity, which could be an important parameter for the elucidation of heavy metal tolerance mechanisms in lichens. Similarly, we observed that the contents of chl-a, chl-b and total chl in *H. physodes* were highest decreased after applied with 30 mg/L Cr^{+6}, Pb^{+2} and Cd^{+2} heavy metal concentration ($P < 0.05$). The contents of the same parameters in *H. physodes* were also significantly decreased after applied with all other 60 and 120 mg/L Pb^{+2} and Cd^{+2} concentrations ($P < 0.05$). Spectrophotometric measures were conducted to determine the carotenoid amount in *H. physodes* applied different heavy metal concentrations and UV radiations. There was a significant decrease in carotenoid amounts after exposed to 8 j/cm^2 all UV radiations in *H. physodes* ($P < 0.05$). In this study, we found that the application of heavy metals and UV exposure prevents loss of chlorophyll and carotenoid. UVA and UVB radiations together have more harmful effects, although *H. pyhsodes* may have shown quite a tolerance. Similarly, *H. pyhsodes* have been deposited at higher rate heavy metals.

Chettri et al. (1998) have indicated that the ratio of chlorophyll a/b is more sensitive to changes in the content of the lichen. They determined a marked decrease in the ratio of chlorophyll a/b, from 3.0 to 0.4 for *C. convoluta* and from 3.2 to 0.8 for *C. rangiformis*, occurred when the thallus Cu content exceeded 175 and 200 mg g^{-1} DW, respectively. Similarly, we found that there is a significant decrease with increasing treatments the ratio of chlorophyll a/b content in *H. physodes*. Larsson et al (2009) reported that the ratio of chlorophyll a/b ratio increased with increasing UVB radiation in *Xantoria aureola* lichen species at 21 °C degrees. We also found that after 4 j/cm^2 treatments, the ratio of chlorophyll a/b increase with increasing UVB radiation.

Heavy metal and UV stress toxicity have been extensively described in physiological, cellular and molecular biological aspects in the literature. The development of several PCR based techniques provides many advantages in the analysis of genetic toxicology. PCR based technique is simple, fast and capable of detecting point mutations and also a temporary alteration of DNA. Many studies have displayed that molecular technique may potentially form to detect DNA damage and mutational events in cells of different organisms. Genotoxic pollutants in the environment continue to grow rapidly, thereby stressing the need for rapid monitoring of genotoxicity in lichen species. Lichens can be used for this purpose due to the best biomonitor organism. The RAPD band profile generated after exposure to Cr^{+6}, Cd^{+2} and Pb^{+2} heavy metals in the lichen specimen was determined with the RAPD profile of the controls, differences of band number were detected. Cansaran-Duman et al. (2011) have determined the genotoxic contamination in the *Evernia prunastri* lichen species with the RAPD analyses. Körpe-Aksoy and Aras (2010) have studied eggplant seeds in a controlled setting applied to Cu^{+2} metal stress in different concentrations. The results showed that the changes in the GTS rates of the seeds that developed in different Cu^{+2}

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23152338

concentrations could be determined by generating RAPD profiles. This study significantly determined the maximum change of band intensities. The highest number of bands that appeared and disappeared was observed in the *H. physodes* lichen sample for UVB exposure. Especially, different changes in GTS rates (%) were shown in lichen specimen. Monitoring of various environmental stresses induced genotoxic effect directly on genomic DNA by RAPD analysis is mainly associated with unexposed sample and lichen treated with different stresses conditions. The changes in physiological and biochemical parameters such as shoot–root length, photosynthetic pigment contents, and antioxidative enzyme level support genomic template stability (Atienzar et al., 1999).

DNA methylation has been shown as a significant indicator of epigenetic and mutagenic effects and it causes differential gene expression, cell differentiation, chromatin inactivation and carcinogenesis in eukaryotic organisms (Xu et al., 2000; Mastan et al., 2012). The epigenetic organization of plant development can be used in production as much as an adaptation to stress since gene expression can be affected by the structure of the chromatin related to the epigenetic organization (Mirouze and Paszkowski, 2011). The level of the presence of methylcytosine can be determined with multiple approaches in many terms since there is a very appropriate technique to determine the methylation rate in the genome (Rein et al., 1997). MSAP-AFLP is a very potent technique to study the genome methylation status. The use of MSAP-AFLP assay has been useful in the detection of the tolerance level toward different environmental stresses. Therefore, biochemical and physiological assays are not enough to obtain deeper insight into the lichen stress response to biotic or abiotic stresses. In the present study, assessment of changes in DNA methylation by MSAP-AFLP in lichen specimen subjected to heavy metals and UV exposures. *H. physodes* thallus 69% methylation was determined in heavy metal stress. Similarly, 58% polymorphism was showed in methylated DNA from *H. physodes* on both stresses. According to the MSAP analysis, compared control with all stress treated; lichen specimen showed different patterns of methylation under heavy metals and UV radiations stress. In comparison to salt-untreated plants, Lu et al. (2007) have detected an increase of total methylated bands in plants exposed to 50-200 mM salt. In our study, as a result of the MSAP - AFLP analyses conducted in lichen specimen exposed to different heavy metals (Cr^{+6}, Pb^{+2}, and Cd^{+2}) and UV radiations (UVA, UVB, UVC, daylight, UVA + UVB, and UVA + daylight) stresses, serious changes of methylation were observed (*Fig. 4*).

Several studies published for determining the genotoxicity by DNA molecular markers of heavy metals exposure in cryptogams and algae so far. Sorrentino et al. (2017) were investigated by ISSR molecular markers in moss *Sphagnum palustre* for determining metal-induced genotoxicity. As a result of their study, both Cd and Pb salts showed a genotoxic effect with a dose-dependent trend. At concentration > 10^{-5} Cd also induced a general toxic effect in *S. palustre*, leading to chlorophyll degradation and moss death. The 12 primers used for the analysis provided a total of 169 reproducible bands, ten of which gave polymorphisms (appearance/disappearance of bands), indicating a clear genotoxic effect induced by the metals (Sorrentino et al., 2017). In our study, some primers showed significant differences in band patterns formed by loss of normal bands and appearance of new bands in the treated heavy metals and UV radiation exposure in comparison to the untreated sample profiles. We determined a total of 138 bands using six primers to evaluate UVB radiation samples in *H. physodes*.

DOI: http://dx.doi.org/10.15666/aeer/1802_23152338

Both *Sphagnum palustre* moss and *H. physodes* lichen species could be used as bioindicator organisms for genotoxicity.

The study evaluated the genotoxicity of MnONP in *Physcomitrella patens* a model plant system utilized for epigenetic alterations (Ghosh et al., 2018). DNA methylation pattern at the level of single cells was examined by the methylation-sensitive comet assay with HpaII and MspI. MnONP incited DNA hypomethylation in *P. patens* gametophores exposed with 20 μg/mL MnONP concentration. In this study, the highest rate of methylation was obtained in *H. physodes* lichen specimen stressed with UV exposure with Type-2 primer (28.9%).

Compared with the RAPD and MSAP - AFLP analyses, the rate of change in the methylation model in lichen sample applied with heavy metal stress showed more diversity than sample applied with different UV radiations. While sample applied with heavy metal stress had a higher GTS rate in RAPD, GTS rate was determined to decrease based on the increasing UV radiations. The effect of UV stress on DNA stability was found to be higher than heavy metal stress in lichen specimen. The stability of the methylation model applied with heavy metal stress was thought to be less than UV stress in terms of epigenetics.

Conclusion

In the present study, we examined physiological and DNA damage indicator capacity of lichen specimen that has different features than other organisms. Certain organisms, such as lichens, may have properties such as being more tolerant to some pollutants than other organisms in contaminated areas or being able to accumulate the pollutant factor. These properties of organisms are used to provide qualitative information about the level of pollution in their environment. Therefore, it should be possible to make a correlation between observing and measuring the changes in the organism and the sources of the pollutant, pollution and the intensity of the pollution. This study was shown that the use of lichen specimen could eliminate the contaminants that cause environmental pollution. Detailed presentation of possible changes generated in the DNA structure and the presentation of contamination at a molecular level were ensured with our study enriched with molecular techniques. Therefore, the effect of UV stress on lichen DNA stability was thought to be greater than genetically heavy metals. The results indicated that *H. physodes* has great potential to be used in phytoremediation exercises. In addition to the properties of this lichen, the literature data has proved their antibacterial and antioxidant activity as well as cancer cell cytotoxicity and inhibitory effects on enzymes (Song et al., 2014; Mitrovic et al., 2015; Studzinska-Sroka and Zarabska-Bozjewicz, 2019). Finally, it was possible to observe the strong mechanisms of *H. physodes* lichen specimen against stressors such as heavy metals and UV radiation, allowing it to persist under highly stressful conditions. In future studies, the investigation of the biosorption capacity to accumulate different heavy metal tolerant lichen species in laboratory work still need further research. Determination of the biological response of lichens against toxic chemicals could be useful for the treatment of wastewater with lichens. These and similar studies will contribute to the identification of DNA markers.

DEVELOPMENT OF *IN VITRO* STERILIZATION PROTOCOL FOR DO-1 (*Prunus domestica*) ROOTSTOCK

UGUR, R.

East Mediterranean Transitional Zone Agricultural Research Institute, Hacimustafa Mah. Gazi Mustafa Kemal Bulvari No: 122 (Adana Yolu Uzeri 5. Km) Onikisubat/Kahramanmaras, Turkey (e-mail: remzibey@hotmail.com; phone: +90-536-925-9915, +90-344-237-6020; fax: +90-344-237-7196)

(Received 30th Oct 2019; accepted 30th Jan 2020)

Abstract. Commercial companies have focused on clonal rootstocks free of diseases and been propagated through tissue culture for fruit seedling production lately to obtain products with higher quality and quantity. Two important stages in tissue culture are surface sterilization and *in vitro* culturing of the explants to be micro-propagated. Because *prunus* varieties which sources of explants are grown on open lands, contamination risk is higher. This study has been conducted to minimize the contamination of DO1 (*Prunus domestica*) explants by microorganisms as *prunus* rootstock for micropropagation. Several concentrations and application durations of 4 different sterilization agents ($HgCl_2$, NaClO, H2O2, and AgNO3) have been applied on the axillary buds taken from the rootstock for surface sterilization. Then, the explants have been transferred to MS nutrient media and the number of the aseptic explants was determined. Shoot and leaf regeneration have been observed on the aseptic explants 40 days after the application. While the highest aseptic explant rate (91%) was achieved with 2% NaClO application in 15 minutes, the lowest aseptic explant rate (23.33%) was achieved with 0.5% $HgCl_2$ application in ten days. Finally, the lowest contamination rate was observed in NaClO applications (18.34%) and the highest contamination rate was observed in $HgCl_2$ applications among the sterilization agents.
Keywords: *in vitro, micropropagation, prunus, rootstock, sterilization*

Introduction

Turkey is among the leading fruit producers in the world with 226.783 ha of plantation area and 2.138.393 tons of apricot, plum, peach-nectarine and almond production (FAO, 2019). These fruits are produced in different regions of the country with different climatic conditions. This situation affects the production stability of these fruit species. Therefore, the usage of suitable clonal rootstock compatible with the soil conditions of the region is very important. Recently, high quality genotypes which have been tolerant to diseases and pests, compatible with scion, adaptable to different climatic conditions, positive effect yield and fruit quality of fruit varieties have been selected as rootstock and propagated clonally in the modern horticulture (Beckman and Lung, 2003; Nimbolkar et al., 2016; Suranyi et al., 2019). Generally, clonal production through vegetative ways in rootstock improvement and rootstock production are made by cuttings and tissue culture. High numbers of plants having the same genetic structure can be produced in a quick way free of diseases and viruses during micropropagation using tissue culture. Propagation by cutting, one of classical production methods, is dependent on seasons, whereas production *in vitro* conditions is constantly possible in all season with proper explants and sub-cultural applications (Wolella, 2017). Micropropagation has become important quality criteria in terms of obtaining healthier and homogenous plants in improvement of *Prunus* rootstock breeding studies (Martinez-Gomez et al., 2005). Micropropagation techniques are commonly used in many *Prunus* species; apricot (Reighard et al., 1990; Perez-Tornero et al., 1999), almond (Ainsley et al., 2001; Choudhary et al., 2015), peach (Bhansali et al., 1990; Declerck and Karbon, 1996; Felek et al., 2015), cherry (Matt and Jehle, 2005;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23392349

Ružić and Vujović, 2008; Zarei et al., 2013) and in certain *Prunus* hybrid rootstocks (Tsipouridis and Thomidis, 2003; Felipe, 2009; Dejampour et al., 2011; Canlı and Demir, 2014). Sterilization is important *in vitro* tissue culture such as tools, equipment and nutrient medium. And besides surface sterilization of the explants, seeds, bulbs, leaves, stems, shoots, etc. taken *in vivo* such as fields, greenhouses, gardens, etc. are important (Babaoğlu et al., 2002). Obtaining aseptic explant is the first stage of tissue culture. It is also for viability of the explants taken into *in vitro* culture following surface sterilization. Microbial contamination is a serious problem in micropropagation. It causes significant number of plant losses in micropropagation (Da Silva and Kulus, 2014). Minimization of the losses are crucial for sustainability of the study (Nazary and Aghaye, 2012). Especially fungus, bacteria, viruses and yeasts cause microorganism contaminations *in vitro* culture (Omamor et al., 2007; Altan et al., 2010; Da Silva et al., 2016; Hesami et al., 2018). They cause decaying such as white, yellow and pink colonies of the nutrient medium. Another factor is which fungi are transmitted by either explant source or from the air. They may also cover the nutrient media with their grey micelles. Many researchers suggested that the main damage of these microorganisms should be defined as their nutritional competition with the explant on the medium (Nazary and Aghaye, 2012; Da Silva et al., 2016). Many activities occur during this process; slow growth of explants, necrosis formed on tissues, reduction on tissue regeneration and rooting, and their results can be disruptions leading to explant death (Mihaljevic et al., 2013). For the solution of these problems, an appropriate surface sterilization method, which varies according to the plants among the species, should be determined. Even different concentrations of chemical agents, impacts of application times within the same varieties of a single species influence the success of the surface sterilization. There are some other factors that affect performance; such as season of taking the explant, density and type of the microorganisms on the same explants but in different places (Bhojwani and Razdan, 2005; Eed et al., 2010).

Various commercial bleaches including sodium hypochlorite (NaClO), calcium hypochlorite ($Ca(ClO)_2$) and ethanol (C_2H_6O) are densely used for surface sterilization of the explants *in vitro* culture in many plant species. Besides, the chemical agents such as mercury chloride ($HgCl_2$), hydrogen peroxide (H_2O_2) and silver nitrate ($AgNO_3$) are used as disinfectants (Andreu and Marin, 2005; Arab et al., 2014). In addition, some pretreatments are carried out according to contamination, size and type of plant material prior to sterilization with chemicals. If the explant is big in size, generally the plant material is first washed under the tap water and kept in alcohol for several seconds (1 to 30 seconds) for sterilization of the plant material, which is followed by the actual surface sterilization. In case of an explant with an indented surface, 2 to 4 drops of Tween 20 may be dripped into the sterilization solution in order to benefit from diffuser and adhesive characteristics of such substance for the purpose of increasing effectiveness of the surface sterilization solution. Despite the chemical agents used in surface sterilization during *in vitro* culture studies, the establishment of the right protocol specific to using the plant material is the most important step of a successful study (Papafotiu and Martini, 2009).

There are no universal sterilization agents and nutrient medium for *in vitro* culture because rootstocks are genetically specific with regard to different components of the medium. Whereas MS (Murashige and Skoog, 1962) has been proved to be most suitable medium for successful explant development of stone fruits (almond, apricot and peach). Thus, the objective of this study was to develop on effective sterilization protocol for *in vitro* clonal prunus rootstock DO-1 (*P. domestica*). In this study, the axillary bud explants

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23392349

of DO-1 (*P. domestica*) clonal rootstock which was obtained through selection breeding program which was treated with different concentrations of four chemical agents ($HgCl_2$, NaClO, H_2O_2 and $AgNO_3$) in different time durations as well as the most favorable sterilization protocol were studied. As a result of the study, the surface sterilization protocol at the lowest contamination level and giving the least damage to the explants of DO-1 (*P. domestica*) rootstock cultures *in vitro* was obtained.

Materials and Methods

This study was carried out at the Plant Tissue Culture Laboratory of Eastern Mediterranean Transitional Zone Agricultural Research Institute, Kahramanmaras / Turkey, on April and May 2018. The study material consisted of young and healthy shoots at a length of 20 to 25 cm, which contained 10-15 buds on them, were grown in greenhouse and obtained from DO-1 (*P. domestica*) rootstock improved by Eastern Mediterranean Transitional Zone Agricultural Research Institute. The shoots were taken from the mother plant and the leaves on the shoots were cut and brought to the preliminary preparation room of the laboratory in a container full of water before taking into *in vitro* culture. The factors that dust and waste of insects which negative effect on sterilization application exist on the shoots were cleaned out with sterile water. Then, such shoots were cut at a length of 2.5 – 3.5 cm in such a way to contain one bud on each of them and the obtained explants were brought into sterile cabin in order to perform surface sterilization procedures. The explants were kept in 70% alcohol for a duration of 30 seconds in the sterile cabin as a pretreatment procedure before application of the chemical agents to be used in surface sterilization. Later on, they were rinsed with distillate water for three times in order to avoid the caustic effect of the alcohol.

When ethanol application was completed, explants were kept in solutions, which were prepared at different concentrations of 4 different sterilization agents as shown in *Table 1* for different periods. During this period, the bottle was shaken slightly in order to increase the effect of the solution on the explant surface. At the end of the awaiting duration, the sterilization solution at each application was poured down and the explants were rinsed for 3 times in sterile pure water (*Figure 1*).

Covered with roughing filter paper petri dishes were used for sterilization for a duration of 20 minutes at 121ºC at the autoclave. When surface sterilization was completed, excess water of the explants was taken with these petri dishes. After taking the first water of the explants, they were transferred to another petri and the cap of the petri was left half open in order to let it lose the water drops and the humidity on the explants. In addition, each tools used for surface sterilization (bottles, petri dishes, forceps, bistouries and the bottles full of water) were exposed to sterilization at the autoclave at 121ºC for a duration of 20 minutes. Before the autoclave process; the forceps and the bistouries were wrapped with aluminum folio and left in refrigerator bags, the caps of the bottles were strapped with autoclave band and the petri dishes were placed in autoclave bags. In addition, the forceps and the bistouries used in the sterile cabin were kept in the sterilizer in the cabin; and they were used during the study repeatedly through treatment with alcohol.

During all applications the damaged parts of the tissues as well as all the irregular and unnecessary parts were removed by the help of forceps and bistouries. The explants at the length of 2 cm and containing one bud on each of them were planted in the nutrient media

DOI: http://dx.doi.org/10.15666/aeer/1802_23392349

in such a way to keep the leaf stalks at the upper part with an angle at an amount of 45° to the nutrient media.

Table 1. *Chemicals used in surface sterilization applications and their application durations*

Treatments	Chemical agents	Application Combinations	
		Concentrations (% wv^{-1})	Durations (minute)
T1	$HgCl_2$ (Mercuric (II) chloride)	0.1	15
T2	$HgCl_2$ (Mercuric (II) chloride)	0.5	10
T3	$HgCl_2$ (Mercuric (II) chloride)	1.0	5
T4	NaClO (Sodium hypochlorite)	1.0	30
T5	NaClO (Sodium hypochlorite)	1.5	20

T7	H_2O_2 (Hydrogen peroxide)	20.0	30
T8	H_2O_2 (Hydrogen peroxide)	30.0	20
T9	H_2O_2 (Hydrogen peroxide)	40.0	10
T10	$AgNO_3$ (Silver nitrate)	0.5	30
T11	$AgNO_3$ (Silver nitrate)	1.0	20
T12	$AgNO_3$ (Silver nitrate)	1.5	10

Figure 1. *Stages of application with different chemical agents for surface sterilization to the explants*

MS (Murashige and Skoog, 1962) nutrient media supplemented with 0.5 mg/l BAP in combination with 0.1 mg/l of IBA was used for regeneration of the explants *in vitro* tissue culture. pH was adjusted to 5.6 to 5.8 with 1 N NaOH or 1 N HCI and then 30 $g.L^{-1}$ sucrose and 8 $g.L^{-1}$ agar were added into the MS medium. After addition and dissolution of agar, the nutrient media were sterilized at the autoclave at 121°C at 1.2 atmospheric pressure for a duration of 15 minutes. Clear glass bottles of 350 ml containing MS medium of 65 ml were used as culture containers. Each bottle was labeled with tags of different colors having different sterilization application information on them. All *in vitro* culture conditions were incubated at climate chamber at 16/8 light/dark photoperiod adjusted to 40 µmol m^{-2} s^{-1} light density, 25 ± 2°C temperature and 70-80% humidity (*Figure 2*).

In all different sterilization application, 15 bottles of 350 ml were placed in the testing area randomly. Sterilization data were completed in 28 days, once in 7 days. The shoot and leaf growth data were taken after 40 days for the vivid explants and the effect of different sterilization methods were investigated for plant growth *in vitro* culture. The shoot growth was measured as the length of the shoots at the end of 28-days duration. Then such data were interpreted as percentage.

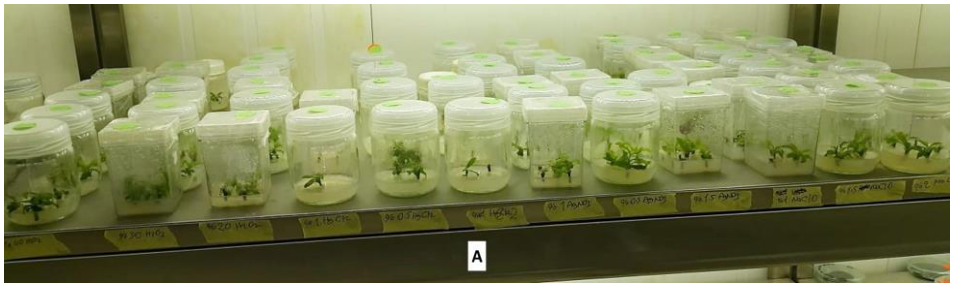

Figure 2. *An image from the climate chamber, where the explants, whose sterilization procedures have been completed, are incubated*

Data of percentage of survived explant, proliferation and shoot length, average number of leaf were analyzed by analysis of variance (ANOVA) in a completely randomized experimental design by SAS computer software (version 7.1). Significant different between means were assessed by Low Significant Different test (LSD, P≤0.05)

Result and Discussion

Table 2 shows the percentage of aseptic explant percentage at the end of applications on DO-1 (*P. domestica*) rootstock taken under *in vitro* culture through application of different doses and durations of four different chemical agents. The variations arising from the effects of different chemicals on surface sterilization may also be seen on *Table 2*.

Table 2. *Aseptic explant amount at the end of application different chemical agents (%)*

Treatments	Chemical agents	Application Combinations		Application Mean (%)	Chemical Mean (%)
		Concentrations (% wv^{-1})	Durations (minute)		
T1	$HgCl_2$	0.1	15	26.66^{d}	27.77^{c}
T2	$HgCl_2$	0.5	10	23.33^{d}	
T3	$HgCl_2$	1.0	5	33.33^{d}	
T4	NaClO	1.0	30	88.66^{a}	81.66^{a}
T5	NaClO	1.5	20	65.33^{bc}	
T6	NaClO	2.0	15	91.00^{a}	
T7	H_2O_2	20.0	30	70.00^{bc}	67.77^{b}
T8	H_2O_2	30.0	20	60.00^{bc}	
T9	H_2O_2	40.0	10	73.33^{b}

T11	$AgNO_3$	1.0	20	64.33^{bc}	
T12	$AgNO_3$	1.5	10	55.66^{c}	
LSD $_{chemical}$: 8.69**				LSD $_{application}$: 7.51*	

F** indicate P ≤ 0.01 and F* indicate P ≤ 0.05 significance level. Distinct letters in the fifth and sixth columns indicate significant differences according to LSD's test (P ≤ 0.05)

As a result, the differences among the aseptic explants obtained from application of the chemical agents) were observed to be significant at a level of 1%. It was observed that the highest aseptic explant rate was 81.66% for NaClO (sodium hypochlorite) and followed by H_2O_2 (Hydrogen peroxide) and $AgNO_3$ (silver nitrate) as 67.77% and 60.44%,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23392349

respectively. The lowest aseptic explant rate was obtained from $HgCl_2$ (Mercury chloride) application as 27.77%. Unlike to our study, Thakur et al. (2016) indicated that HgCl was a better disinfectant than NaClO during the surface sterilization stage of *in vitro* propagation of the explants (axillary buds) taken from Gisela-5 rootstock. However, it was observed in many studies that Ethanol, NaClO and Tween 20 prevent growth of bacteria and fungus when they are used as disinfectant *in vitro* culture. Even very little amounts of sodium hypochlorite ensure significant decrease in microbial population and it is rather effective disinfectant known as bacteria killer (Odutayo et al., 2007; Eed et al., 2010).

It was observed that the differences between the aseptic explant rates at interactions of application with different chemical agents for different durations were statistically important. The highest aseptic explant rates were obtained from application of 2% NaClO for a duration of 15 minutes with 91.00% and 30 minutes 88.66%; and the lowest explant rates were obtained from application of 0.5% $HgCl_2$ for a duration of 10 minutes and application of 0.1% $HgCl_2$ for a duration of 10 minutes with 23.32% and 15 minutes with 26.66%, respectively.

When distribution of application combination interactions with chemical agents evaluated, the highest aseptic explant rates of the plants displayed a distribution between 60 and 70% while mercuric (II) chloride applications remained at very low levels (23 to 33%). Mihaljević et al. (2013) used different sterilization agents (NaClO, $Ca(ClO)_2$, DICA, $HgCl_2$, $AgNO_3$, H_2O_2) for surface sterilization on the axillary buds of sour cherry plant in *in vitro* propagation. The best result was indicated to be achieved from application of 1% $AgNO_3$ for a duration of 20 minutes (96.67% healthy and 3.3% contaminated bud explants). Similar to our study, the second best surviving explants obtained from 1-3% NaClO application for surface sterilization with 80%.

Table 3 shows the shoot growth [shoot length (mm)] data for the explants *in vitro* incubation after a duration of about 1 month in order to monitor the effect of four different surface sterilization agent on regeneration of the aseptic explants came from DO-1 (*P. domestica*) rootstock following *in vitro* culture.

Table 3. *Shoot lengths of aseptic explants after application different chemical agents (mm)*

Treatments	Chemical agents	Application Combinations		Application Mean (mm)	Chemical Mean (mm)

F** indicate P ≤ 0.01 and F* indicate P ≤ 0.05 significance level. Distinct letters in the fifth and sixth columns indicate significant differences according to LSD's test (P ≤ 0.05)

It was observed that the differences among the shoot lengths of the sterile explants according to the applied chemical were not statistically important. According to *Table 3*,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23392349

the highest shoot value was obtained for the explants, which were applied H_2O_2 (9.86 mm); and followed by $AgNO_3$, NaClO $HgCl_2$, and applications with 9.34 mm, 8.65 mm and 8.31 mm, respectively. The results indicate that the lowest shoot length was obtained from $HgCl_2$ application with 8.31 mm.

The highest shoot length value was observed for application of 1% $AgNO_3$ for a duration of 20 minutes (11.16 mm) and for application of 2% H_2O_2 for a duration of 15 minutes (10.86 mm) and that such interactions occurred in a way to take place in the same group statistically. The lowest shoot length values were observed as 6.56 mm for interaction of application of 1.5% NaClO for a duration of 20 minutes and as 7.60 mm for application of 0.1% $HgCl_2$ for a duration of 15 minutes.

Table 4 shows the number of leaves developed on the shoots after application of shoot surface sterilization with four different sterilization chemicals on DO-1 (*P. domestica*) rootstock. It was observed that the differences among the values of the numbers of leaves were not statistically different. As it may also be seen on the table, the highest number of leaves was obtained from H_2O_2 application as 6.54 leaves; followed by NaClO, $AgNO_3$ and $HgCl_2$ applications as 6.35, 5.92 and 5.30 leaves, respectively.

Table 4. *Average leaf numbers of the explants survived after application different chemical agents (per/explant)*

Treatments	Chemical agents	Application combinations		Application mean	Chemical mean
		Concentrations (% wv^{-1})	Durations (minute)		
T1	$HgCl_2$	0.1	15	4.56	
T2	$HgCl_2$	0.5	10	5.33	5.30
T3	$HgCl_2$	1.0	5	6.00	
T4	NaClO	1.0	30	6.93	
T5	NaClO	1.5	20	6.30	6.35
T6	NaClO	2.0	15	5.83	
T7	H_2O_2	20.0	30	6.23	
T8	H_2O_2	30.0	20	6.66	6.54
T9	H_2O_2	40.0	10	6.73	
T10	$AgNO_3$	0.5	30	4.46	
T11	$AgNO_3$	1.0	20	6.86	5.92
T12	$AgNO_3$	1.5	10	6.43	
$LSD_{chemical}$: NS				$LSD_{application}$: NS	

F^{**} indicate $P \leq 0.01$ and F^{*} indicate $P \leq 0.05$ significance level. Distinct letters in the fifth and sixth columns indicate significant differences according to LSD's test ($P \leq 0.05$)

The highest number of leaves was observed at interaction of 1% NaClO application for a duration of 30 minutes as 6.93 leaves and 1% $AgNO_3$ application for a duration of 20 minutes as 6.86 leaves. On the other hand, the lowest number of leaves was observed on the aseptic explants obtained at the interaction of 0.5% $AgNO_3$ application for a duration of 30 minutes as 4.46 leaves and 0.1% $HgCl_2$ application for a duration of 15 minutes as 4.56 leaves.

It was reported that the explants obtained from the buds of the shoots, which have completed their development, gave better results (Naghmouchi et al., 2008). Our study showed that when the explants were taken from *in vitro* culture, the season was important for the success of the surface sterilization. And especially spring season affected *in vitro* regeneration positively as the shoots taken in spring are active. It was reported that *in vitro* culturing time of the explants to be taken from woody plants (cherry rootstocks) was very

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23392349

important in terms of contaminations and that contamination was less especially in spring months and that development was faster (Fidancı et al., 2008).

Another factor affecting the shooting speed of the explants of DO-1 (*P. domestica*) rootstocks (exposed to different chemical agents) is whether the caustic effect of the chemical agent is high or not as well as the duration of keeping the explants in such chemicals. It was observed that the explants (67.77% aseptic) exposed to H_2O_2 application are distinguished for their shoot lengths and leaf numbers. And also the caustic effect of NaClO chemical, which gave the highest value of 81.66% in terms of aseptic plants, was higher and hence lower values were obtained in regeneration of the shoots.

Conclusion

Surface sterilization is first stage of *in vitro* culture and it is important for healthy and fast growth. In order to achieve this, the proper chemical agent for surface sterilization and the application duration of the chemical agent have to be determined according to some criteria; such as explant taking time of the species and varieties to be taken into *in vitro* culture, the texture of the explants (indented, puberulent, spinous, waxy, etc.) and types of the explants (leaf, stem, bud, etc.) (Mihaljevic et al., 2013; Nongalleima et al., 2014). The method, which would avoid contamination and give the least damage to the explant, has to be determined in order to avoid loss of time for the rootstocks that has to be produced *in vitro* mass micropropagation. It is necessary to achieve maximum level of regeneration speed of the explants to be source in the future.

In this study, a protocol for surface sterilization of clonal rootstock DO-1 (*P. domestica*) was developed using axillary bud explant. During sterilization protocol investigation, the highest significant survival value (91%) was recorded when disinfected with T6 (2% NaClO for 15 min). The induction, regeneration and proliferation of this explants were depending on the application combination and duration times of chemical agents that were used. The length of newly shoot varied with application chemical agents and duration times. The best length of shoot was obtained on T11 (1% $AgNO_3$ for 20 min) treatments. Whereas no differences were found between the number of leaf values of explants. Therefore, treatments of T6 (2% NaClO for 15 min) is recommended for true type and disease free plants of DO-1 (*P. domestica*).

The results of the study showed that $HgCl_2$, which has an extremely toxic effect, gave negative results in surface sterilization of plant explant in our *in vitro* studies. Although the best surface sterilization results were obtained with NaClO, the use of H_2O_2 and $AgNO_3$ also yielded positive results (*Figure 3*).

Figure 3. *Development of the aseptic plants at the incubation medium after application of different chemical agents at surface sterilization*

(Received 31st Oct 2019; accepted 30th Jan 2020)

Abstract. The cotton whitefly (*Bemisia tabaci* Genn.) is a major pest of cultivated plants in tropical and subtropical regions. In this study, the genetic diversity between populations and various biotypes of *B. tabaci* collected from Hatay, Adana, İçel, Antalya, Muğla, Aydın and Denizli provinces of Turkey were investigated using mitochondrial cytochrome oxidase subunit 1 (mtCOI) sequences. Thirty-two nucleotide variations were found in a 617 bp mtCOI sequence of the among the populations studied. Phylogenetic analysis divided the *B. tabaci* populations of Turkey into two groups clustering around the main Middle East-Asia Minor 1(MEAM1) and Mediterranean (MED) groups, (i.e. the so-called B and Q biotypes respectively). Mediterranean species were also divided into two subgroups. The populations from Aydin and Denizli provinces identified as the Qw haplotype were closely related to populations of Greece, whereas the remaining samples were identified as the Qe haplotype. This study indicated that the biotype status of the *B. tabaci* populations might have changed from year to year depending on several factors, such as insecticide resistance, host plant preferences, and climate niches to understand the factors causing changes in the biotype structure, pest populations should be monitored, and surveys must be conducted at regular intervals.
Keywords: *whitefly, biotype, MEAM1, Mediterranean, genetic variability*

Introduction

Bemisia tabaci (Genn.) is one of the most important pests of industrial plants, vegetables and cotton in tropical and subtropical regions (Brown et al., 1995). The pest was initially identified in Greece in 1889, and it has been responsible for several outbreaks in cotton. Although, its history dates back to 1928, the exact timeframe over which *B. tabaci* has caused damage to plants cultivated in Turkey is unknown (Göçmen and Özgür, 1990).

Bemisia tabaci has been reported to contain various biotypes that are morphologically indistinguishable from each other but differ according to their host sequences, fecundity, insecticide resistance and virus carrying ability (Bedford et al., 1994). Studies have shown that these biotypes can be genetically distinguished from each other using molecular methods (Frohlich et al., 1999; Bedford et al., 1994; Costa and Brown, 1991).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23512361

In terms of qualitative and quantitative characteristics, the *B. tabaci* biotypes have been differentiated based on protein (Costa and Brown, 1991; Brown et al., 1995) and nucleotide polymorphisms using random amplified polymorphic DNA (RAPD) markers (Gawell and Barlett, 1993; Lima et al., 2002; Moya et al., 2001), amplified fragment length polymorphism (AFLP) markers (Cervera et al., 2000), restriction fragment length polymorphism (RFLP) markers (Abdullahi et al., 2004), ribosomal ITS1 sequences (De Barro, 2000) and microsatellites (De Barro, 2005; Valle et al., 2013). Furthermore, biotypes can be separated by analysing gene sequences isolated from the mitochondrial DNA (mtDNA) (Frohlich et al., 1999). Currently, because of the limitations of some molecular techniques, mtCOI gene is proposed for identification of several species within the *B. tabaci* complex (Dinsdale et al., 2010). Hitherto, *B. tabaci* has been reported to form a complex comprised of at least 24 different species that cannot be separated morphologically from each other (Dinsdale et al., 2010; De Barro et al., 2011).

The diversity of *B. tabaci* biotypes in Turkey has been investigated before. Bedford et al. (1994) reported the *B. tabaci* populations as the M biotype. Göçmen and Devran (2002) studied the genetic structures of eight *B. tabaci* populations collected from Antalya with the AFLP technique and found 2 groups in relation to their hosts. Ulusoy et al. (2002) reported the presence of the B biotype in the *B. tabaci* populations in Turkey. Göçmen et al. (2004) also predicted that the B, Q and M biotypes were found in Turkey using RAPD markers. In another study Bayhan et al. (2006) reported that the *B. tabaci* populations collected from Adana, Mersin and Hatay provinces were the B biotype based on analysis of the same single gene region for all the mtCOI sequences. Karut et al. (2012) carried out a survey on pests collected from cucumber, cotton, eggplant and soybean in the 2008-2009 production seasons in the Balcalı district of Adana and reported that the *B. tabaci* populations belonged to the B and Q biotypes, with the Q biotype being the most dominant. In 2015, southwestern populations of *B. tabaci* collected from cotton fields were also studied (Karut et al., 2017). According to the above findings, to date studies have been restricted to the eastern provinces of Turkey, and there is a need to determine the distribution of whitefly biotypes in Turkey using mtCOI sequences.

In this study, *B. tabaci* populations were sampled from various cultivated plants during 2005 and 2006 from different provinces of Turkey and identified as biotypes based on the sequence analysis of mtCOI regions. The purpose of the study was to determine the species/biotype structure and genetic diversity of the *B. tabaci* populations in Turkey. Furthermore, phylogenetic analysis was conducted to clarify the relationships among *B. tabaci* populations in Turkey.

Materials and methods

Adult *B. tabaci* samples were collected from cultivated plants in the Hatay, Adana, İçel, Antalya, Muğla, Aydın and Denizli provinces of Turkey (*Table 1; Fig. 1*). At least 100 individual adults were collected from each location using a mouth aspirator and stored in 96% alcohol for DNA isolation.

DNA extraction

Total DNA was isolated from the *B. tabaci* adults by using Omega DNA isolation kit (EZNA SQ Tissue DNA Kit, D5040-02) according to the manufacturer's instructions. The DNA was precipitated in isopropanol, kept at 20 °C overnight and then dissolved in 30 µl of distilled water.

DOI: http://dx.doi.org/10.15666/aeer/1802_23512361

To identify the biotypes of the collected whitefly samples, a combination of the C1-J-2195(Primer A) and L2-N-3014 (Primer B) primer sets designed by Frohlich et al. (1999) was used to amplify a fragment of the mtCOI gene region (*Table 2*).

(Bioron), 1.25 µl of reaction buffer solution, 4 mM $MgCl_2$ and 1 µl of DNA, as described by Frohlich et al. (1999).

Polymerase chain reaction (PCR) was carried out using the following cycling parameters: an initial denaturation step at 94 °C for 2 min, and 30 cycles of a denaturation step at 94 °C for 45 s, an annealing step at 48 °C for 45 s and an extension step at 72 °C 45 s. The amplified products were separated and visualized on a 1% agarose gel containing 10 mg/l of ethidium-bromide. Amplification products of approximately 800 bp in length were re-amplified with the primers B and C (*Table 2*) using the same PCR conditions used for the nested PCR amplifications when the amplicon yield was not sufficient for direct Sanger sequencing of the initial PCR products.

Single-band PCR products with the expected fragment size (760 bp) were stored at -20 °C for sequencing. Three different PCR products derived from different individuals from each population were sequenced with the B and Q biotype control samples obtained from Dr. A. R. Horowitz.

The amplicons were subjected to DNA sequencing using the capillary Sanger sequencing platform and the Beckman 8000 CEQ Genetic Analysis System according to the manufacturer's instructions with the exception of the reaction volume which was 10 µl instead of 20 µl. Since better and clear electropherogram signals were obtained from the forward primer D than for forward primer C in the initial tests, the sequencing reactions were carried out in both directions using forward primer D and reverse primer B.

Phylogenetic analysis

The raw fluorescence data were analysed with the 'Beckman Sequence Analysis' program. The obtained sequences were manually confirmed and edited, and the sequence of each individual sample was finalized. The determination of biotype structure of the cotton whitefly populations in Turkey and phylogenetic analyses were conducted as outlined in Boykin and De Barro (2014) with curated global dataset of mtCOI sequences of Bemisia tabaci species (Boykin et al., 2017). The sequences were aligned using Clustal W implemented in the MEGAX software (Kumar et al., 2018), and the phylogenetic analysis was performed using the MEGA X program with the Kimura two-parameter model and Neighbor- Joining method with 1000 bootstrap iterations. The genetic distances were calculated using Maximum Composite Likelihood Option of MEGAX.

Results

All whitefly samples yielded a band with an expected fragment size of ~760 bp using the indicated primer pair (*Table 2*) to amplify the mtCOI fragment. The sequences were trimmed to a length of 617 bp and aligned with the CLUSTAL W program. The alignment results indicated a lack of variation among samples derived from the same populations. Samples from the same population were identified as having the same mtCOI sequences (single haplotype) and therefore were considered as homogeneous.

In contrast to the lack of variation within populations, a total of thirty-two nucleotides variants were detected in the 617 bp sequence of the analysed region among populations. All of the variable nucleotide positions involved a single base substitution with the exception of one position at which the B, Qw and Qe haplotypes had the T, A,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23512361

and C nucleotides, respectively. Furthermore, nucleotide bases in variable positions were not independent of each other. In other words, the nature of the variation at any nucleotide position in the mtCOI gene was related to the structure of the other changes. Therefore, the thirty-two different nucleotide polymorphisms identified in the studied populations did not result in thirty- two different haplotypes. Indeed, only three different haplotype groups were present in all tested individuals (*Fig. 1*). Among all haplotypes, the average nucleotide frequencies were A = 0.255, T = 0.431, G = 0.185 and C = 0.128. Hence, in light of these nucleotide values, the T + A and C + G base ratios reflected the rich A + T composition typically found in the genes of insect mitochondrial genes.

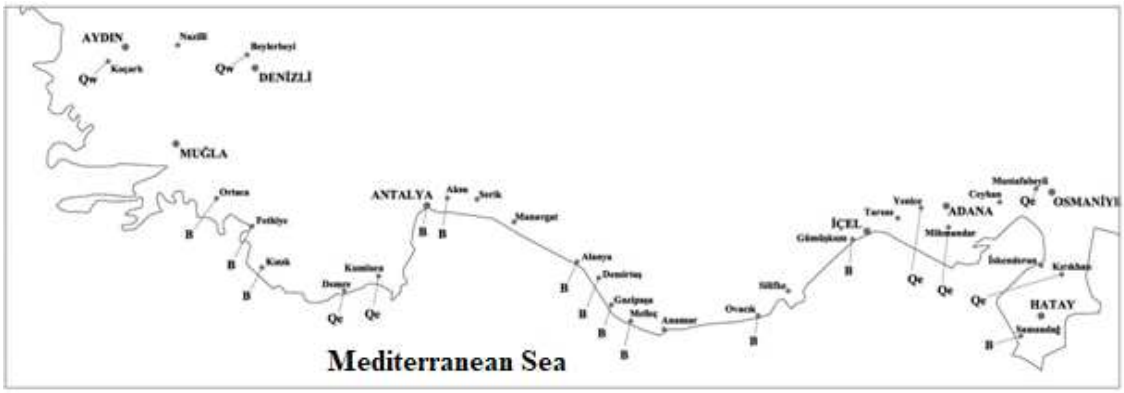

Figure 1. *The geographical distribution of the Bemisia tabaci biotypes in Turkey*

The Neighbor- Joining phylogenetic tree demonstrated that the cotton whitefly populations from Turkey were grouped into three different clusters (*Fig. 2*). When these populations were examined in relation to curated global dataset, they were grouped into two different biotypes commonly known worldwide as the B and Q biotypes which belong to the Middle East-Asia Minor 1 and Mediterranean species, respectively. Of the 20 populations analyzed eleven clustered with the B biotype in the same haplotype group (*Fig. 2*). Although the remaining nine populations were clustered with the Q biotype, the two populations collected from the Aydın-Denizli provinces (western Turkey) slightly differed from the other 7 population having Q biotype (*Fig. 2*). These two Q haplotypes were categorized with those present in Syria and Cyprus under the newly designated Qe haplotype, and the others were clustered with those present in Greece and Turkey/Aydın and Denizli province under the Qw haplotype to clearly delineate them (*Fig. 2*).

When the genetic distances of the three clusters of the Turkish populations were analyzed, they were observed to be less related to the other main group because they clustered under the main Mediterranean and MEAM1 group (*Fig. 2*). Accordingly, while the distance between the reference B biotype and Qe was 0.050, its distance to Qw was 0.055 and the genetic distance between Qe and Qw haplotypes was only 0.010. In contrast, the distances of the Turkish populations to the other world biotypes varied between 0.231 and 0.252 (*Fig. 2*). No nucleotide polymorphism was identified among all 11 Turkish populations of the B biotype. Similarly, no nucleotide polymorphism was found among the seven Qe haplotype populations or between the two Qw haplotype populations.

Discussion

The mtCOI gene region sequence was first used by Frohlich et al. (1999) to determine the biotypes of whitefly populations from different parts of the world. They were identified about 240 polymorphic nucleotides in their study. However, in our study, only 32 polymorphic nucleotides were detected. Similarly, Horowitz et al. (2003) reported limited polymorphism levels in populations collected from narrow geographical regions like our findings. Although the polymorphism level recorded in this study was low compared to that of the global populations, the mtCOI sequence information both provided sufficient data about the cotton whitefly populations in Turkey and allowed us to determine the biotypes in different regions of the country. When the geographical distribution of these biotypes was analysed, the emergence of the certain biotypes was observed intermittently rather than in a structure of spread and infestation into a geographical region. For instance, whereas the B biotype was prevalent in the Hatay/Samandağı region, the Q biotype was found in the Kırıkhan region (*Fig. 1*). Similarly, whereas the B biotype was present in the eastern region of Antalya, the Q biotype was found in the western region of the province; moreover, the B biotype was observed as the dominant population in Muğla province, which is geographically close to Antalya (*Fig. 1*).

In the current study, investigation of the biotype distribution in Turkey found that the B biotype was intermittently present in three geographical regions. The biotype could either have been introduced into Turkey from various locations and thus was still been undergoing the spreading process or could have been introduced into Turkey from only one location and not yet replaced the Q biotype in some regions. Another scenario was that the B biotype became the prevalent biotype after its introduction into Turkey, but the Q biotype started to dominate the B biotype in various geographical regions, as was observed recently. For instance, the Q biotype was identified several years after the B biotype was identified in Spain (Guirao et al., 1997). Later the Q biotype prevailed in some regions, whereas the B and Q biotypes survived together in others (Simón et al., 1999). In surveys conducted in these regions, only the Q biotype was detected (Simón et al., 2007).

In a study conducted between 2000 and 2002 in the Adana, Mersin and Hatay provinces of Turkey, the B biotype was the sole biotype present in these regions. Additionally, nucleotide polymorphisms were reported to be at a very low level among the B biotype populations which were highly homogeneous (Bayhan et al., 2006). The homogeneity of the B biotype reported by Bayhan et al. (2006) was in accordance with our findings because all populations in this study were clustered around the B biotype with 100% nucleotide sequence similarity. Since the GenBank accession numbers of the B biotypes reported by Bayhan et al. (2006) were not provided, we could not make a direct comparison between those sequences and the sequences generated in this study. The B biotype was also identified in Mersin province in 2004 (Topakçı and Göçmen, 2018). In another study carried out in the Mersin and Antakya provinces, whitefly samples collected from cucumbers, beans and tomatoes between 2007 and 2009, were identified as the B biotype (Erdoğan et al., 2011). These two studies clearly proved that the B biotype was the dominant biotype in these provinces.

In 1985, the whitefly specimens collected from cotton plants in Adana were named 'TC' and were reported to present very similar mtCOI nucleotide profiles to the Q biotype (Bedford et al., 1994). The Q biotype was determined to be rife in our study among samples collected from the Adana and Hatay regions. In this region, the presence

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23512361

of the Q biotype in the 2004 samples came to the forefront. (Topakçı and Göçmen, 2018). In addition, we have observed that this trend to continued based on samplings from among the regions. Also Karut et al. (2012) reported in their study performed in Adana that four of the 18 samples collected from cucumbers, cotton, eggplants and soya in 2008 and in only one of the 13 samples collected from the same plant species in 2009 were identified as be the B biotype; hence, the remaining samples were the Q biotype. During the 2006–2011 (except for the 2010) period, the majority of the whitefly population collected from cotton plants in Adana were identified as the Q biotype within the Mediterranean group (Karut et al., 2014).

Based on the above findings, the Q biotype may have been the local biotype in the past and then lost its dominance due to an aggressive B biotype within the region. In reference to Bayhan et al. (2006) we can speculate that the B biotype was dominant in the region and continues to spread. However, this trend has changed after 2005, when the Q biotype has started to replace the B biotype in Adana and Hatay provinces. As demonstrated in this study, the Q biotype may be in the process of becoming the dominant biotype. In a similar study, Chu et al. (2010) reported the presence of the Q (MED) biotype in the Shandong District of China: the B biotype was the dominant biotype until 2005, but the Q biotype became the dominant biotype within three years. Similar data were reported for populations in Spain; after introduction of the B biotype in the country, the Q biotype regained its dominance over the B biotype for a period of time (Brown et al., 2000; Simón et al., 2007). In another study, the Q biotype was reported to have become dominant in many regions of China partly by occupying the B biotype regions (Teng et al., 2010).

In the present study, whitefly populations collected on vegetables and cotton from Antalya province between 2005 and 2006 were identified as the B and Q biotypes. Both the B and Q biotypes were found in Antalya in 2005 (Topakçı and Göçmen, 2018). However, Erdoğan et al. (2011) reported that only the B biotype was collected from tomatoes and eggplants in Antalya province during the 2007-2009 period. Similarly, only the B biotype was reported from different districts of Antalya province in 2011 (Yükselbaba and Göçmen, 2012).

The populations collected from Aydın and Denizli provinces (Qw) were clustered within the same subgroup showed one-to-one similarity to the Greece Q biotype, and the populations collected from Adana, Hatay and Antalya provinces (Qe) were clustered within the same subgroup with the Syria and Cyprus samples. Similar findings were reported about the species and subgroups of *B. tabaci* populations collected from southwestern cotton fields in 2015 (Karut et al., 2017). In one study, the Q biotypes clustered into two subgroups under the Mediterranean main group (Dinsdale et al., 2010). The population from Turkey used by Dinsdale et al. (2010), was found to have the same evolutionary relationship with the Qe biotypes used in this study. It was observed that the samples collected from Spain, Greece and other European countries were clustered into the same subgroup of the Mediterranean main group, hence, our data are in agreement with the above-mentioned information after clarification of the Q biotype into Qe and Qw haplotypes.

The intra-population variations in all the three biotypes found in Turkey are at the zero level in terms of mtCOI. For this reason, predicting which of these populations appeared earlier in our country is impossible. However, a collected and known sample was established to show a close relationship to the Q biotype; this sample is regarded as the oldest record for our country. Based on the literature, the B biotype was first

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23512361

described between 1988 and 1989 in the USA, whereas the Q biotype was first described in Spain in 1997. However, the origin of both biotypes is known to be the Mediterranean. For this reason, the likelihood of the B biotype existing in our country before 1985 is at least as high as that of the Q biotype. Answering this question will only be possible if more variations of each biotype are investigated and revealed. For this goal, investigating these biotypes with different fingerprinting methods is a useful approach. When geographically distributed biotypes are examined, the transition zone between the B and Q biotypes will probably be the transition zone between Tarsus and Mersin from Q to B, whereas Central Antalya is likely to be a re-transition zone from B to Q.

Conclusion

Studies needs to be conducted in these regions to provide detailed information about gene exchange between the biotypes or the evolution of the biotypes into dominant species in different geographic regions. In addition, testing whitefly samples taken at regular intervals every year will be useful for monitoring how the biotypes are distributed in our southern regions, where agriculture is heavily concentrated.

Abstract. Amebiasis caused by *Entamoeba histolytica* parasite is among the worst gut diseases worldwide. The study involved detection of gut mycobiome signature of the infected subjects in a trial to improve ability to diagnose and treat this disease. The results indicated that diversity of samples slightly changed due to infection. Dendrogram indicated that the most common phyla in the human gut are Ascomycota, Basidiomycota and Zygomycota. Species *Pichia kudriavzevii*, *Candida glabrata*, *Saccharomyces cerevisiae* of phylum Ascomycota and *Rhodotorula mucilaginosa* of phylum Basidiomycota were found highly OTU abundant. Weighted unifrac diversity distances resulted in complete separation of the two groups. Differential abundance analysis indicated that four phyla, six families, nine genera and ten species showed considerable changes in gut mycobiome signatures within and among groups. Unclassified species of genus *Malassezia* (phylum Basidiomycota) showed high abundance in infected subjects as compared to healthy subjects, while families Saccharomycetaceae and Trichocomaceae, genus *Saccharomyces* and species *S. cerevisiae* showed opposite results. Linear discriminant analysis effect size (LEFSE) indicated that family Saccharomycetaceae, of which *S. cerevisiae* is a downstream taxon, can be a negative biomarker for amebiasis. In conclusion, the study provides new insights into possible use of *Saccharomyces* as a probiotic against amebiasis.
Keywords: *encystation, yeast, Crabtree effect, oxidative stress, chitin formation*

Introduction

Entamoeba histolytica parasite is among the most common causes of death worldwide (WHO, 1997). It is estimated that around 50-100 million people are infected with the disease each year. Infection can be symptomatic (dysentery or amoebic colitis) or asymptomatic, and can also be invasive (amoebic liver abscess) (Stanley, 2003; Ximénez et al., 2009; Lozano et al., 2010; Verkerke et al., 2012). Furthermore, amoebae can cause abscess in the brain, pericarditis in the heart or pleuropulmonary disease in the lung (Stanley, 2003). Infection is usually drug-treated (Ali and Nozaki, 2007), however, in severe cases surgical intervention might be necessary (Ishida et al., 2003;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23632394

Gupta et al., 2009). Amebiasis is proven to be mainly associated with water supplies contaminated with human feces resulting in 50,000-100,000 deaths reported annually, which make this protozoan parasite a significant cause of death worldwide (WHO, 1997; Soares et al., 2019).

E. histolytica parasite is transmitted via the ingestion of water contaminated with cysts. After excystation, the *Entamoeba* trophozoite divides and colonizes the colon, then, eventually produces new cysts that are excreted into the environment (Ali and Nozaki, 2007). Two major processes are crucial for the existence and cycling of these two forms of *Entamoeba*. They are encystation and trophozoite adhesion to human cells. If one of the two processes is impaired, then, existence or life cycling of the parasite will be in jeopardy. Encystation requires a number of processes including Gal-lectin production and chitin metabolism (Mi-ichi et al., 2016). Chitin in the cyst wall comprises of two chitin synthases (Chs), one of which is unique (EhCHS-1) to *Entamoeba*, while the other (EhCHS-2) resembles those in insects, fungi and nematodes (Van Dellen et al., 2006). Adhesion of trophozoites to human cells is the main event of subsequent cytopathogenic activities, contact-mediated cytolysis and phagocytosis, intestinal colonization and invasion (Eaton et al., 1970; Trissl et al., 1978; Ravdin et al., 1980; Mi-ichi et al., 2016). Phagocytosis is a mandatory process for survival of this organism, while blocking this process results in the inhibition of its proliferation and loss of pathogenicity (Hirata et al., 2007; Iyer et al., 2019). Other process for survival of *Entamoeba* is the modifications in the structure of transmembrane proteins that makes the parasite unidentified, thus, helps in escaping the host immune system (Khomkhum et al., 2019).

The human gut ecosystem contains a microbiome representing the three domains of life, with fungi—the mycobiome—predominates gut Eukarya (Rajilic-Stojanovic et al., 2007; Scanlan and Marchesi, 2008). The gut microbiome is presumed sterile at birth and the primary route for microbes to enter the gastrointestinal (GI) tract occurs via ingestion (Penders et al., 2006) of which Saccharomycetalean yeasts are the first fungi detected in the infant gut (Bliss et al., 2008). The exact relationship of host gut and its ecosystem, comprising prokaryotes, fungi, viruses and parasites, is extremely obscure (Hugon et al., 2017). The composition of the different microbiomes of the human body reflects health and disease parameters (Moyes and Naglik, 2012; Wang et al., 2014; Gouba and Drancourt, 2015; Mukherjee et al., 2015; Richard et al., 2015). Thus, studying the gut microbiota of *Entamoeba*-infected subjects might help in improving our understanding of these parameters that help in diagnosing and treating the disease more efficiently.

Although human mycobiomes have received little attention compared with bacteriomes, a number of recent articles have evidenced the importance of this organ in the whole body (Cui et al., 2013; Huffnagle and Noverr, 2013; Seed, 2014; Underhill and Iliev, 2014), especially in the gut (Ianiro et al., 2014; Kirschner et al., 2015; Suhr and Hallen-Adams, 2015). Therefore, the present study was planned to address the possible influence of human gut mycobiome on the occurrence and level of *Entamoeba* infection. The study also attempted to detect new biomarkers linked to amebiasis.

Materials and methods

Recruitment of participants and sample collection

Samples have been collected during summer 2019 from dysentery-infected subjects in four hospitals in Jeddah, KAU. An ethical approval (no. A00451) was issued by the Ministry of Health, Saudi Arabia following the regulation of the General Administration

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23632394

for Research and Studies at the Ministry of Health (registration no. 1195437) and the National Committee for Medical and Biological Ethics (registration no. H-02-J-002). Consent forms were filled by healthy and infected subjects or their relatives at sampling time. Patient's fecal samples were diagnosed by microscopic examination and positive samples were kept in iSWAB-TM Microbiome©2016 (Mawi DNA Technologies LLC. USA/Canada) to ensure the integrity of DNA required for deep sequencing. Genomic DNA was extracted using the QIAamp® DNA Mini kit (Qiagen®51306; Hilden, North Rhine-Westphalia, Germany) according to the manufacturer's instructions. DNA purity was evaluated via A260/A280 ratio using NanoDrop 7000 Spectrophotometer (Thermo Fisher Scientific, Waltham, MA, USA), and DNA integrity was checked by 1% agarose gel electrophoresis. PCR amplification of the V5-V7 region of 18S rRNA gene was performed using the universal primers SSU0817F (forward) 5′-TTAGCATGGAATAATRRAATAGGA -3′ and SSU1196R (reverse) 5′-TCTGGACCTGGTGAGTTTCC -3′. The PCR program was: initial denaturation at 95 °C for 5 min; 25 cycles of denaturation at 95 °C for 30 s, annealing at 56 °C for 30 s, and extension at 72 °C for 40 s; and final extension of 72 °C for 10 min. Amplicons were run on agarose gel (1.2%). Based on PCR results, original high-quality DNAs were shipped to Beijing Genome Institute (BGI) in China for library construction and deep sequencing on Illumina Miseq platform to recover ≥ 300 bp pair-ended reads of the V5-V7 region of 18S rRNA gene.

18S dataset processing and statistics

The ends of each read were overlapped to generate high-quality, full-length reads. The resulted sequencing data will eventually be deposited in the European Nucleotide Archive (ENA) (https://www.ebi.ac.uk/ena/submit/sra/#studies). The raw data were pre-processed to get clean data by in-house procedure as the following: (1) truncation of sequence reads not having an average quality of 20 over a 25 bp sliding window based on the Phred algorithm (Ewing and Green, 1998), (2) removal of trimmed reads having less than 75% of their original length, as well as its paired read; (3) removal of reads contaminated by adapter (default parameter: 15 bases overlapped by reads and adapter with maximal 3 bases mismatch allowed); (4) removal of reads with ambiguous base (N base), and its paired reads; and (5) removal of reads with low complexity (default: reads with 10 consecutive same base). The consensus sequence was generated by FLASH (Fast Length Adjustment of Short reads, v1.2.11; Magoc and Salzberg, 2011) in case the two paired-end reads overlapped with the following parameters: (1) minimal overlapping length: 15 bp; (2) mismatching ratio of overlapped region: < = 0.1; and (3) paired end reads without overlaps were removed.

Then, tags were clustered to OTU (Operational Taxonomic Unit) by scripts of software USEARCH (v7.0.1090; Edgar, 2010; http://drive5.com/usearch/manual/uparse_pipeline.html) as the following: (1) the tags were clustered into OTU with a 97% threshold by using UPARSE (Edgar, 2013), and the OTU unique representative sequences were obtained; (2) *de novo* chimeras were filtered out by using UCHIME (v4.2.40, Edgar et al., 2011); and (3) all tags were mapped to each OTU representative sequences using USEARCH GLOBAL. Then, the tags number of each OTU in each sample was summarized in OTU abundance table. OTU representative sequences were taxonomically classified using Ribosomal Database Project (RDP) Classifier (v.2.2; Cole et al., 2014), using 0.6 confidence values as cutoff. Silva (default) V119 database was used for species annotation (Quast et al., 2013).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23632394

OTUs were filtered as the following: (1) unassigned OTUs were removed; and (2) OTUs not assigned to the target species were removed. Then, filtered tags were clustered into OTUs to be used in downstream processing.

Alpha diversity was addressed by Shannon and Simpson indices. Both parameters were calculated by Mothur (v1.31.2; Schloss et al., 2009), and the corresponding boxplot of alpha diversity and rarefaction curve were drawn by software R (v3.1.1; https://cran.r-project.org/bin/windows/base/old/3.1.1/). Drawing rarefaction curve was based on calculating OTU numbers of the extracted tags (in multiples of 500), then, detecting the maximum depth (no. reads) permitted to retain all samples in the dataset. Sequences were extracted randomly according to the minimum sequence number for all samples, and the extracted sequences formed a new 'OTU table biom' file.

The representative sequences were aligned against the Silva core set (Silva_108_core_aligned_seqs) using PyNAST (Caporaso et al., 2010b) by 'align_seqs.py'. Then, a representative OTU phylogenetic tree was constructed using the QIIME (v1.80, Caporaso et al., 2010b) built-in scripts including the fast-tree method for tree construction. The tags with the highest abundance of each genus was chosen as the corresponding genus representative sequences, and genus level phylogenetic tree was obtained by the same way of OTU phylogenetic tree. Then, the phylogeny tree was imaged by software R (v3.1.1).

Venn diagram was drawn by Venn program of software R (v3.1.1), while differences in the relative abundances of taxa at the phylum, genus and species levels were analyzed using Metastats (Paulson et al., 2011). Benjamini–Hochberg false discovery rate (FDR) correction (Benjamini and Hochberg, 1995) was used to correct for multiple hypothesis testing where applicable.

Heat maps were generated using the package 'gplots' of software R (v3.1.1). The used distance algorithm is 'euclidean' and the clustering method is 'complete'. At phylum level, all species were used to draw the heat map and taxa of which abundance is less than 0.5% in all samples were classified as 'others'. To minimize the differences degree of the relative abundance value, the values were all log transformed.

To detect the beta diversity within and between groups, the weighted and unweighted UniFrac distances were calculated (Lozupone et al., 2011) and plotted *via* principal coordinate analysis (PCoA) using package 'ade4' of software R (v3.1.1). UniFrac uses the system evolution information to compare the composition of community species between samples. The results can be used as a measure of beta diversity. It takes into account the distance of evolution between species, and the higher the index values, the greater the differences between samples or groups. The UniFrac is divided into weighted UniFrac and unweighted UniFrac of which the weighted UniFrac considers the abundance of sequences, while unweighted UniFrac puts more emphasis on species presence or absence.

Linear discriminant analysis (or LDA) Effect Size (LEFSE) was done to determine the features (organisms, clades, operational taxonomic units, genes, or functions) explaining the differences between the two groups of subjects by coupling standard tests for statistical significance in addition to the tests encoding biological consistency and effect relevance as described (Abarenkov et al., 2010). In the LEFse tree, different colors indicate different groups. Colored node (red) indicates an important microbe biomarker in either group and the biomarker name lists in the upper right corner of the tree. The yellow nodes represent the biomarkers, which do not show any importance in either group.

Results

Statistics of gut 18S rRNA sequence datasets

Illumina MiSeq was used in analyzing a number of two healthy subjects as well as nine patients proved via microscopic examination to be infected with *Entamoeba*. The statistical analysis of gut mycobiome was done for the 11 gut mycobiome samples based on the 18S rRNA as shown in *Table 1*. The average sequence length per read was 296 bp across different samples ranging from 293 to 299 bp. Average percentages of N base and low-quality reads were as little as 0.097% and 0.00%, respectively. A total of 9,086,626 raw sequence reads were generated across subjects with an average of 1,514,437 reads per sample. While, a total of 9,050,377 clean sequence reads were generated across subjects with an average read number of 822,762 per sample. Average percentage of data utilization was as high as 99.61% (*Table 1*). The data in *Figure 1* indicates that the average number of clean reads is 791,462 across healthy subjects, while 829,717 across patients. The highest value of clean reads was given to patient 5 or P5 (1,127,017), while the lowest was given to P1 (692,848) (*Table 1*; *Fig. 1*).

Table 1. *Statistics of data generated from deep sequencing for healthy and Entamoeba-infected individuals*

Sample ID	Reads length (bp)	Raw data (Mbp)	N base (%)	Low quality (%)	Clean data (Mbp)	Raw reads	Clean reads	Read utilization (%)
H1	294:298	470.19	0.098	0	469.07	794239	792348	99.76
H2	294:297	469.35	0.096	0	467.23	794155	790575	99.55
P1	294:296	409.75	0.094	0	408.78	694500	692848	99.76

P8	295:296	446.04	0.099	0	444.03	754715	751321	99.55
P9	294:299	522.1	0.096	0	520.3	880435	877400	99.66

A total of 8,776,506 tag-linked sequences were generated across subjects with an average number of 783,091 sequences across healthy subjects and 801,147 sequences across patients (*Fig. 1*). The highest value of tag-linked sequences was given to patient P5 (1,061,387), while the lowest was given to P1 (685,566) (*Table 1*; *Fig. 1*), with an average connect percentage of 97.16%. These sequence tags were assigned to 146 eukaryotic OTUs (operational taxonomic units) across samples with an average of 60,113 sequence tags per OTU. The results for the number of observed species (S_{obs}) or number of OTUs indicated a summation of 698 OTUs for the 11 samples with an average of about 63 OTUs per sample ranging from 47 (P6) to 82 (P4) OTUs and averages of 60 and about 64 OTUs for healthy subjects and patients, respectively (*Fig. 1*). Number of OTUs in relation to relative abundance of OTUs for different healthy subjects (H) and *Entamoeba*-infected patients (P) is shown in *Figure A1* in the *Appendix*. The results in this figure complement those of *Figure 1* as P4 showed the highest number and abundance of OTUs, while P6 showed the lowest.

DOI: http://dx.doi.org/10.15666/aeer/1802_23632394

Diversity and rarefaction curve analysis

Alpha diversity analysis, as Shannon and Simpson indices, was applied to detect complexity among species and the deviation due to the disease. Shannon and Simpson values reflect the species diversity of the community at both richness and evenness levels. But Shannon index poses more weight on sequence richness, while Simpson index poses more weight on evenness. With the same species richness, the greater the species evenness, the greater the community diversity. Trend of values for the two measures likely to be opposite. The results in *Figure 2* exactly aligned with the latter statement as subject with high richness shows low evenness and vice versa. Subjects with the highest richness and lowest evenness are P2 followed by P9, while those with the lowest richness and highest evenness are P3 followed by P7 (*Fig. 2*). Overall, the results indicated that alpha diversity slightly changed due to the infection indicating an influence of the parasite on the type and intensity of the other eukaryotic microbes hosted in the gut.

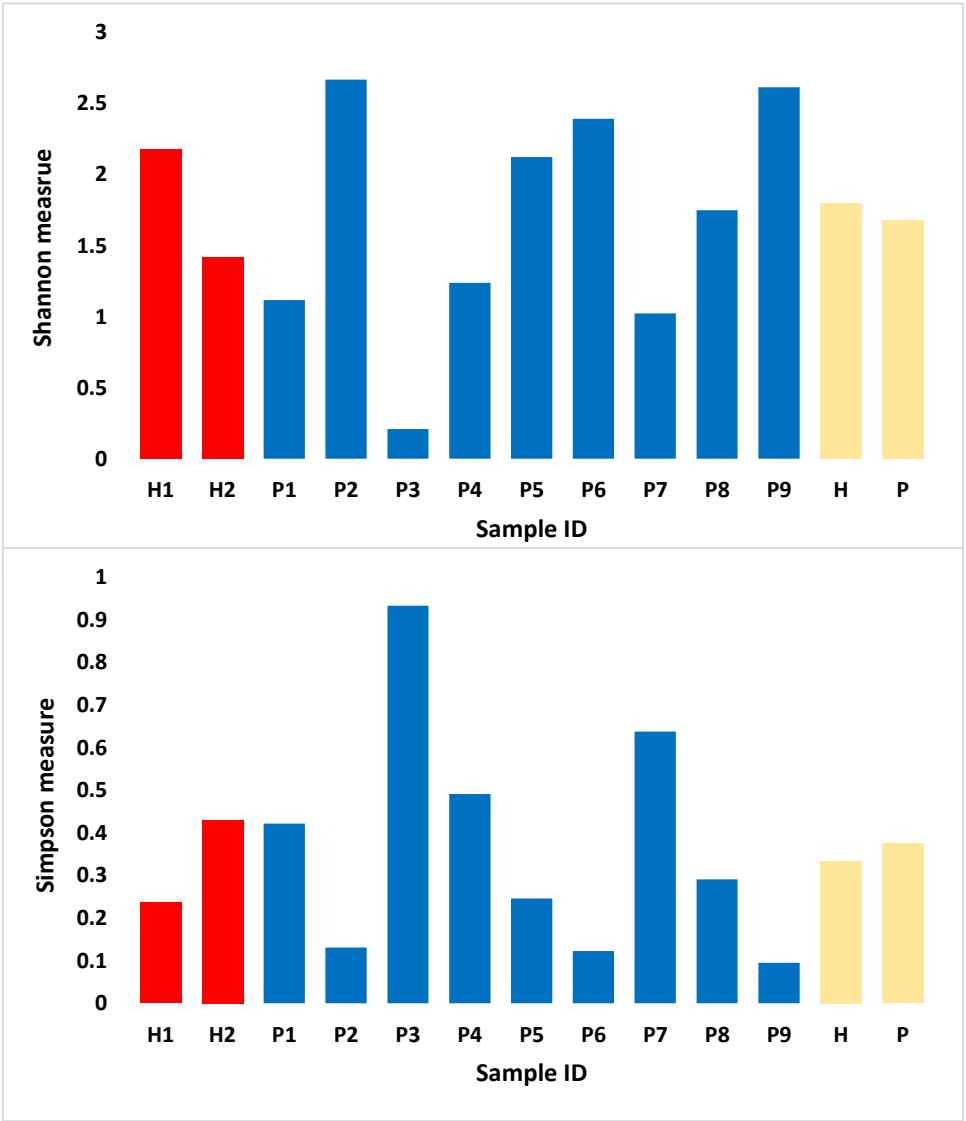

Figure 2. *Alpha diversity measures among and across healthy (H) and Entamoeba-infected (P) individuals to describe sample or group richness (Shannon index) and evenness (Simpson index). Healthy = red, Infected = blue, Mean = beige*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23632394

Principal Coordinate Analysis (PCoA) was used in order to address the differences of OTU composition in different samples and groups. PCoA summarizes factors that are responsible for this difference. When similarity between two groups is high, then, the two groups are closely located. Based on the OTU abundance information, the relative abundance of each OTU in each sample and group was calculated, thus the PCoA of OTUs was plotted (*Fig. 3*). The PCoA plot completely showed a similar tendency in the distances within and between groups. The diversity of healthy subjects was localized in the positive directions of PCoA 1 (PC1) and PC2, while diversity of patients was higher towards the negative direction of PC2, and distributed evenly in the PC1 direction. These results indicated that the gut mycobiome signatures of the two groups differed due to amebiasis.

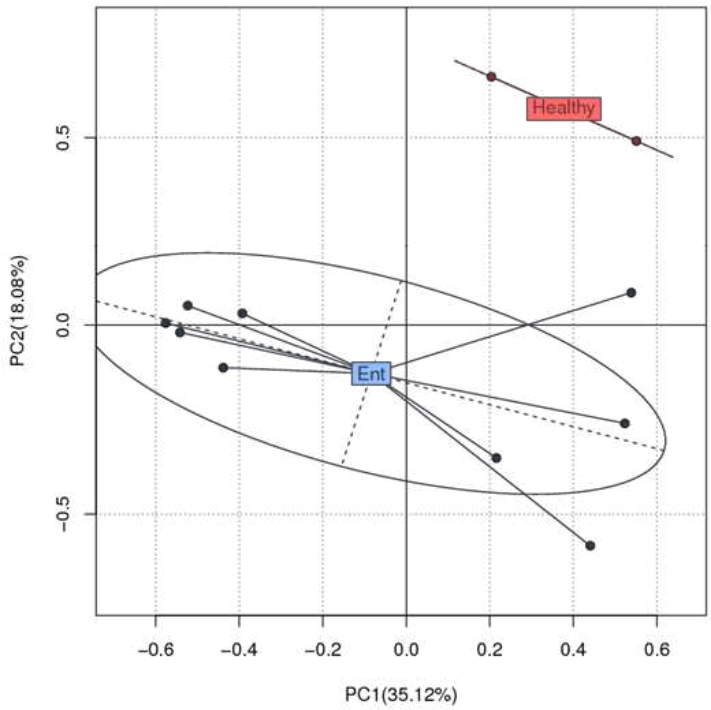

Figure 3. *PCoA based on OTU abundance of different samples. Blue box indicates samples of Entamoeba-infected patients, while red box indicates samples of healthy individuals. X-axis is the first principal coordinate and Y-axis is the second. Number in brackets represents contributions of PCoAs to differences among samples. A dot represents each sample, and different colors represent different groups. Healthy = red, Infected = blue*

Rarefaction curves based on stacked number of OTUs and number of observed species were drawn (*Fig. 4*). Stacked number of OTUs were analyzed, as rarefaction measures, in order to describe the maximum depth permitted to retain all samples in the dataset for studying taxonomic relative abundance and to evaluate if produced data is enough to cover all species in the microbial community. The point where a stacked value of a given sample approaches dropping or moving downwards (indicated by arrow in the figure) indicates the sealing at which further analysis that holds homogeneity in the datasets can be done. The more the curve continues to climb with increasing sequencing reads, the higher the complexity in samples, i.e., there still be species uncovered by the sequencing data. The rarefaction measures indicated that the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23632394

maximum number of sequence reads to be used for further analysis of taxonomy abundance is as high as ~667,000 (*Fig. 4*).

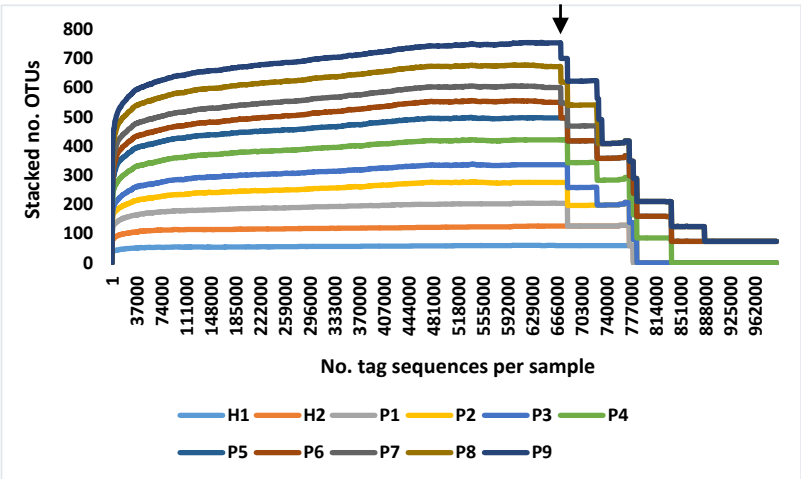

Figure 4. *Stacked number of OTU tags as rarefaction measures to describe the maximum depth permitted to retain all samples in the dataset for studying taxonomic relative abundance. The arrow indicates the suitable sample size for analyzing taxonomy abundance (~660,000 sequence reads) for healthy individuals (H) and Entamoeba-infected patients (P)*

Description of gut microbiome signatures

Description of observed species detected from OTU annotation is shown in *Table A1* (see electronic appendix). Phylogenetic tree describing taxonomic groups of oral microbiomes at the phyla and genera levels are shown in *Figure 5* and organized in *Table 2*. A phylogenetic tree is a branching diagram showing the inferred evolutionary relationships among various biological taxa based upon similarities and differences in their physical or genetic characteristics. The evolution distance between taxa is closer if the branch length is shorter. Besides the taxa composition and abundance analysis, phylogenetic tree could further clarify the species evolution relationships. The results expectedly indicated that the most common phyla in the gut are Ascomycota (11 genera), Basidiomycota (nine genera) and Zygomycota (two genera).

Six genera of Ascomycota belong to family Saccharomycetaceae, while the rest belong to separate families. The nine genera of Basidiomycota belong to nine different families, while the two genera of Zygomycota belong to the family Mucoraceae (*Table 2*). Family information of one genus of Basidiomycota namely *Tilletiopsis* is not available. Abundance of individual OTUs across samples was also studied in which OTUs with number of sequences over 100,000 were considered highly abundant (*Fig. 6*). This criterion was met for a number of 18 out of the 146 OTUs (*Table A2; Fig. 6*). These selected OTUs are OTU1-OTU15, OTU86, OTU109 and OTU130. Description of these selected highly abundant OTUs in terms of taxonomy of their phyla, genera and/or species is shown in *Table A1*. After removal of 12 non-fungal OTUs (OTU2, OTU7, OTU9-OTU15, OTU86, OTU109 and OTU130), the results indicated that the highly abundant OTUs belong to *Pichia kudriavzevii* (OTU3), *Candida glabrata* (OTU4), *Saccharomyces cerevisiae* (OTU5) and OTU6 of phylum Ascomycota and *Rhodotorula mucilaginosa* of phylum Basidiomycota.

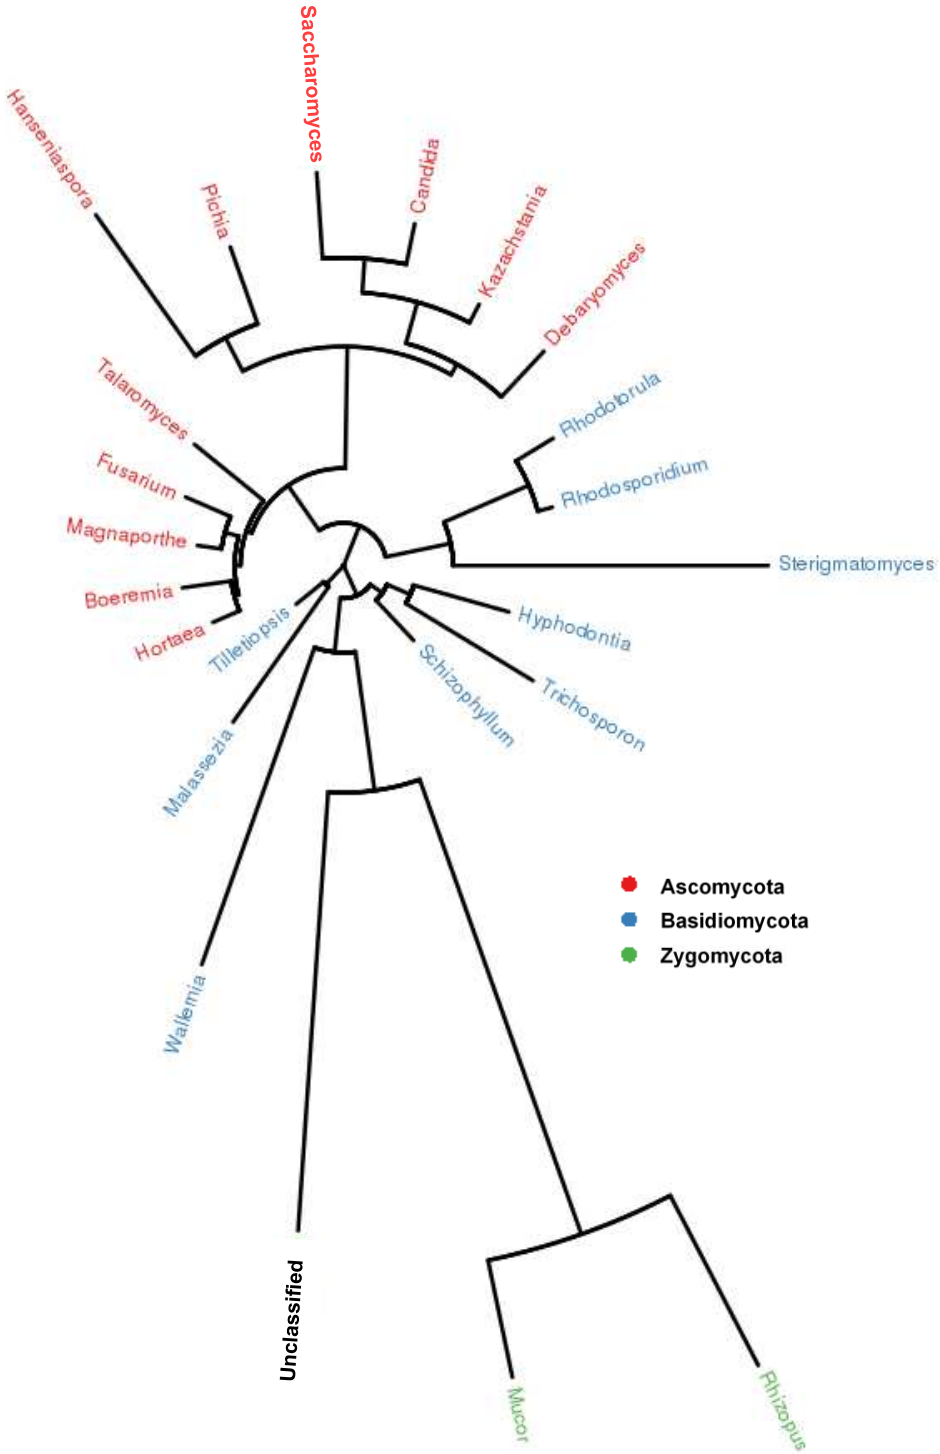

Figure 5. *Genus level phylogenetic tree of gut mycobiome across healthy individuals and Entamoeba-infected patients. Genera with the same color belong to the same phylum*

Venn diagram indicated the existence of 71 common OTUs in both groups (*Fig. 7*; *Table A3*). The number of OTUs uniquely found in healthy subjects was 11, reduced to eight after removal of non-fungal taxa representing the taxonomic groups of the phyla

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23632394

Ascomycota (5), Basidiomycota (2) and Zygomycota (1). The main taxa of Ascomycota are *Pichia kluyveri*, *Candida sake* and *Xylariales* spp., while those of Basidiomycota are *Malassezia obtusa* and unclassified genera of family Cystofilobasidiaceae and that of Zygomycota is *Rhizopus oryzae*. The number of OTUs uniquely found in healthy subjects was 64, reduced to 36 after removal of non-fungal taxa representing the taxonomic groups of the phyla Ascomycota (27), Basidiomycota (8) and Zygomycota (1).

The main taxa of Ascomycota are *Hortaea werneckii*, *Talaromyces purpurogenus*, *Debaryomyces hansenii*, *Kazachstania servazzii*, unclassified genera of the family Plectosphaerellaceae, *Hemibeltrania* sp. CL12WA, while those of Basidiomycota are *Schizophyllum radiatum*, *Hyphodontia rimosissima*, *Malassezia* spp., *Malassezia pachydermatis*, *Trichosporon coremiiforme*, *Rhodosporidium toruloides*, *Wallemia* spp. and that of Zygomycota is *Mucor racemosus*. None of these unique markers was consistent in either group in terms of existence as well as abundance. A larger number of samples might be required in order to reach a certain conclusion before we decide which of them can be considered as a biomarker for amebiasis.

The analysis of weighted and unweighted unifrac diversity distances, as a beta diversity measures, describing the overall structures of gut mycobiomes of different healthy (H) and infected (P) subjects is shown in *Figure 8*. As indicated earlier, the weighted diversity considers the abundance of the different OTUs, while unweighted diversity considers presence or absence of a given OTU. *Figure 8* indicates that analysis based on weighted unifrac diversity distances successfully resulted in complete separation between the two groups, e.g., healthy subjects (H) and *Entamoeba*-infected patients (P). However, analysis based on unweighted unifrac diversity distances resulted in no separation between the two groups although a large number of group-specific OTUs was recovered. As indicated above, these unique or group-specific OTUs were not consistently shown in all subjects of the group. Thus, no particular gut mycobiome signature was detected for either group. As this inconsistency was shown for all unique OTUs, analysis was not able to make a complete discrimination between the two groups based on the unique OTUs.

The results shown in *Figure A2,* displaying the beta diversity heat maps of weighted and unweighted unifrac diversity distances between the two groups supports the latter conclusions. A heat map is a graphical representation of data where the subject distance values contained in a matrix are represented as colors. *Figure A2* also indicated that P4 followed by P1 are the most divergent within the infected subjects (P). Gut mycobiome signature of P1 was shown to be the closest to the signatures of the two healthy subjects. However, the most closely related infected subjects in terms of gut mycobiome signatures are P5, P6, P7 and P10. The differential signatures among infected subjects might reflect the differential severity of the disease.

Differential abundance of microbes due to amebiasis

Differential abundance of microbes of different healthy (H) and infected (P) subjects was studied at the phylum, family, genus and species levels (*Fig. 9, 10, 11* and *12,* respectively). The results indicated that a number of four phyla, six families, nine genera and ten species showed considerable changes in gut mycobiome signatures within and among groups. The phyla Ascomycota and Basidiomycota were consistently shown in all subjects, albeit different in abundance, while Chytridiomycota and Cnidaria were only shown with relatively low abundances, in a single subject, e.g., P2 and H2, respectively. Therefore, no conclusions can be taken for the latter two phyla in terms of relative abundance (*Fig. 9*). The results at the family level indicated consistency in two out of the six families, e.g., Saccharomycetaceae and Trichocomaceae (*Fig. 10*). The two families belong to phylum Ascomycota. The results at the genus level indicated consistency in three out of the nine genera, e.g., *Candida* spp., *Malassezia* spp. and *Saccharomyces* spp. (*Fig. 11*). The first two genera were relatively highly abundant in the infected subjects as compared with the healthy subjects. Opposite conclusion was reached for the third genus, e.g., *Saccharomyces* spp., where it was relatively highly abundant in the healthy subjects as compared with the infected subjects (*Fig. 11*). The results at the species level indicated consistency in only one, e.g., *Saccharomyces cerevisiae*, out of the ten species (*Fig. 12*). Accordingly, it was decided to further analyze the results of the Ascomycota at the phylum level, Saccharomycetaceae and Trichocomaceae at the family level, *Malassezia* spp. and *Saccharomyces* spp. at the genus level and *Saccharomyces cerevisiae* at the species level (*Figs. 13* and *14*).

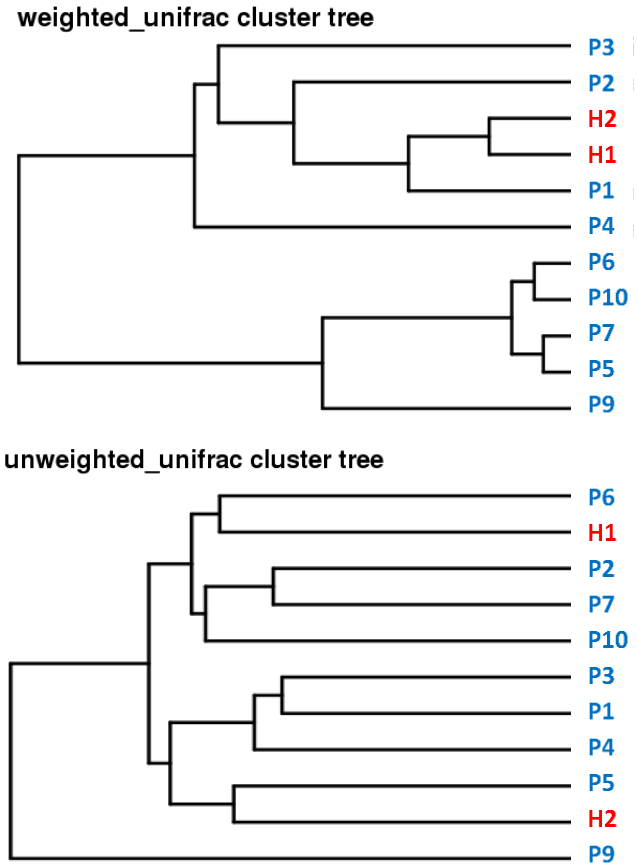

Figure 8. *Dendrogram trees describing the weighted and unweighted unifrac diversity distances among healthy individuals (H) and Entamoeba-infected patients (P). Healthy = red, Infected = blue*

Among these taxa, unclassified species of the genus *Malassezia* belonging to phylum Basidiomycota showed high abundance in infected subjects as compared with healthy subjects (*Fig. 13*), while the rest of taxa belonging to phylum Ascomycota showed opposite results (*Fig. 14*).

Linear discriminant analysis (or LDA) effect size (LEFSE) is a software that determines the entire features (organisms, clades, operational taxonomic units, genes, or functions) likely explaining differences among groups. Such features were determined by coupling standard tests for statistical significance with additional tests encoding biological consistency and effect relevance. In the present study, LEFSE was based on determining the features in the different taxa in order to detect the ones that can conclusively be considered as biomarkers for amebiasis. The analysis shown in *Figure 15* indicated that the family Saccharomycetaceae, of which *Saccharomyces cerevisiae* is a downstream taxon, is the only taxon meeting the standard criteria set of the analysis. Interestingly, there is no particular OTU specific to this family, however, the most consistent OTU with this result, e.g., OTU107, belongs to the genus *Saccharomyces*, also a downstream taxon (*Table A4*). This taxon, referring to OTU107, along with its downstream species, referring to OTU5, share a negative biomarker of amebiasis (*Fig. 15*). This result supports that generated when studying the relative abundance at the phylum, family, genus and species levels. Considering the richness of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23632394

the two OTUs (*Table A2*), we claim that OTU5, referring to *Saccharomyces cerevisiae*, is more appropriate as the new negative biomarker for amebiasis.

Discussion

Preliminary detection of the gut diseases usually involves microscopic observation with the fecal samples. Although this approach is not sensitive, it remains to be the gold standard utilized in almost all parasitological diagnostic laboratories (McHardy et al., 2014). Drawbacks of this approach arise when only few eggs exist in samples, thus, other methods such as serology-based, e.g., ELISA (Ungar, 1990), might be a better alternative. More recently, molecular approaches have been used as a promising tool for differentiating and detecting stool parasites (Tavares et al., 2011), with the first molecular study to detect mycobiome signatures published in 2008 (Scanlan and Marchesi, 2008).

Nowadays, next generation sequencing (NGS) has proven to be the ideal approach in detecting the microbiome signatures and providing an accurate figures of microbe intensity (Stensvold et al., 2010). Such high-throughput technologies are employed in detecting microbiome signatures in different human organs in relation to disease status, e.g., amebiasis (Gao et al., 2017; Jo et al., 2017). The approach is based on the use of 16S ribosomal RNA (rRNA) gene for bacteriome, while 18S or ITS (internal transcribed spacer) for fungal microbiome or mycobiome (Belda-Ferre et al., 2012; Ahn et al., 2015; Johansson et al., 2016; Zhou et al., 2016). Although, internal transcribed spacer (ITS) seems to be more appropriate than 18S rDNA for analyzing human gut mycobiome at the level of clades and species (Hamad et al., 2016), it still difficult to use it in making a proper fungal metagenomic analysis due to the absence of a well-established or rich fungal ITS database for OTU annotation (Tang et al., 2015).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23632394

There were two major issues to be considered before we approach analyzing mycobiome. The first is concerned with the influence of diet at the harvest time and the second is concerned with the lack of a database specific for mycobiome at the species level. The preliminary observation made during the analysis was the presence of a large number of non-fungal OTUs at the species level, while none at the levels of the phylum, family or genus (*Figs. 9–12*).

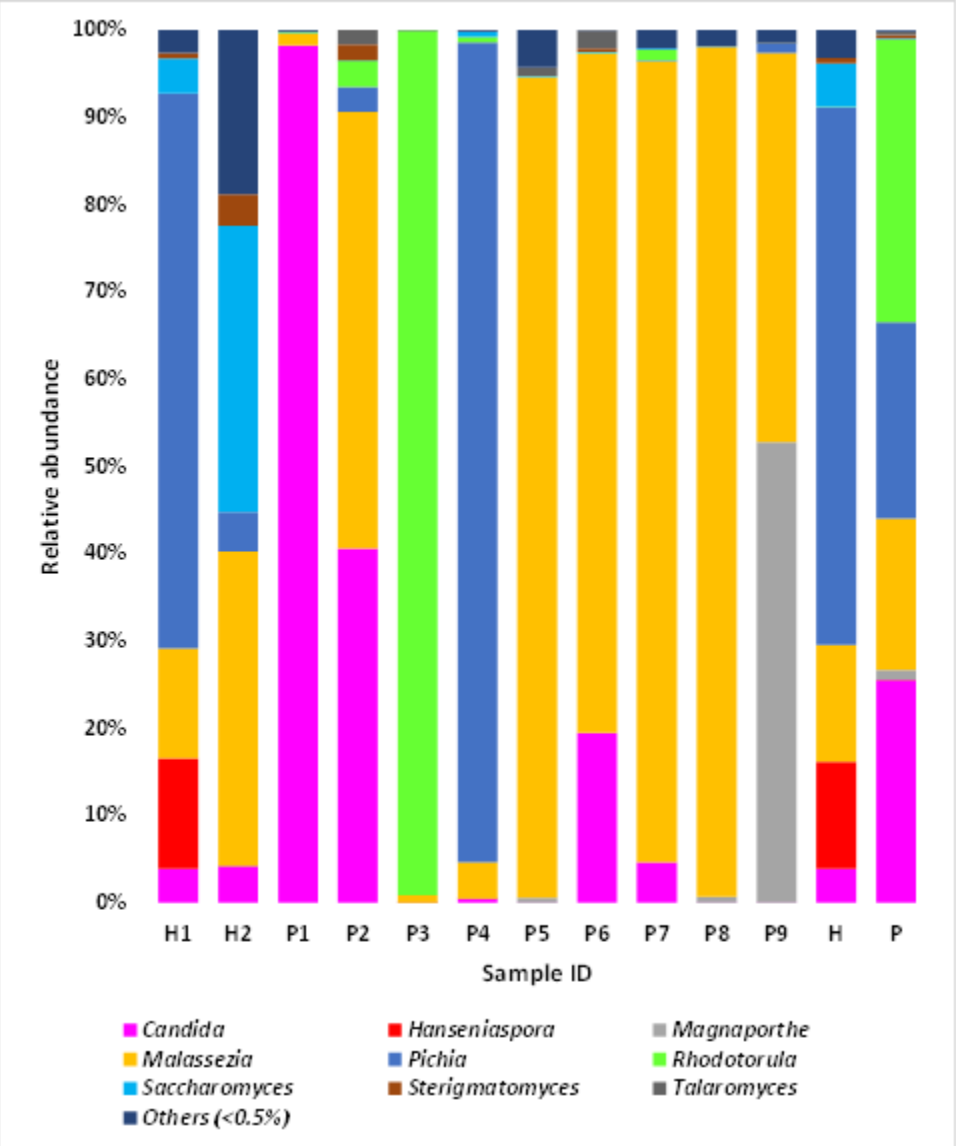

Figure 11. *Relative abundance at the genus level as measured by Metastats at the sample and group levels for healthy individuals (H) and Entamoeba-infected patients (P)*

This indicates that the data recovered at the species level requires further removal of non-fungal OTUs in order to get accurate figure of the relative abundance at the species level. *Figure 16* indicates the comparison of relative abundance of mycobiomes of the two healthy subjects at the species level before and after removal of non-fungal species. The latter are four plant species namely *Oryza sativa* (rice), *Triticum aestivum* (bread wheat), *Sesamum indicum* (sesame) and *Prunus mume* (Japanese apricot). As shown in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23632394

the figure, fungal species showed a more accurate results for their relative abundance after correcting the data (*Fig. 16*). The datasets of OTU taxonomy also required further removal of uncharacterized fungi. In addition, OTUs for a single species, genus, family, order or phylum were merged to avoid redundancy in the taxon and getting a better estimate of its relative abundance, thus, can give a better estimate of the mycobiome signature of the *Entamoeba*-infected subject. The corrected number of OTUs became 46 out of the total 146 OTUs recovered after the initial annotation step. A recent study discussed the influence of diet and the environmental factors to gut mycobiome composition, and indicated that gut mycobiome is less stable than the bacteriome, and is subject to the two factors, thus, usually changes from day to day and over time (Hallen-Adams and Suhr, 2017). David et al. (2014) further indicated that dietary-induced changes in the gut microbiome rely on the type of food consumed (either plant- or animal-based). Hugon et al. (2017) indicated that bacterial composition responds to nutrient availability, while fungal composition appears to be driven by food colonization. The latter evidences were fully supported by gut mycobiome analysis of the present study.

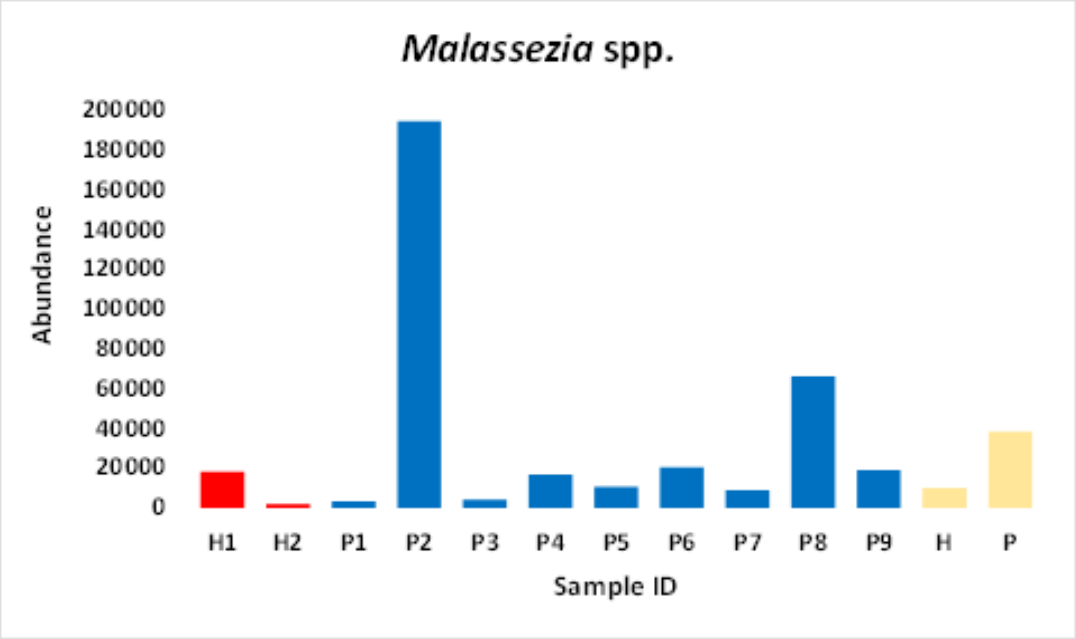

Figure 13. *High abundance of the unassigned species of the genus Malassezia spp. within or across Entamoeba-infected patients (P) as compared with healthy individuals (H)*

Based on recent molecular phylogenetic classification, the taxonomy of human gut eukaryotes includes the five major groups of Amoebozoa, Opisthokonta (including fungi), Excavata, Sar and Archaeplastida (Adl et al., 2012; Hamad et al., 2016). Fungal species, including yeasts and filamentous fungi, are considered as the most abundant group of eukaryotes in the human gut. It is likely that most fungi species represent some sort of food contamination (Rajilic-Stojanovic and de Vos, 2014), thus, their role in the human gut microbiota remains unclear. While, eukaryotic parasites, e.g., protozoa and helminths, exist in the human gut in lower abundance (Rajilic-Stojanovic and de Vos, 2014). Gut mycobiome was proven to be comprised of the four major phyla of Ascomycota, Basidiomycota, Zygomycota and Microsporidia (Moran et al., 2012; Rajilic-Stojanovic and de Vos, 2014). In the present study, only the first three phyla were detected in the mycobiomes of healthy and infected subjects (*Table 2*). Other reports indicated that gut mycobiota in healthy subjects mainly comprises Ascomycota and Basidiomycota as the most abundant phyla, and the *Candida*, *Saccharomyces* and *Malassezia* and as the most abundant genera (Ott et al., 2008; Moran et al., 2012; Hoffmann et al., 2013; Rajilic-Stojanovic and de Vos, 2014; Nash et al., 2017). The results of the present study completely align with those of the latter reports. We also found that two species of *Candida* as well as *Saccharomyces cerevisiae*, followed by *Malassezia globosa* and *Pichia kudriavzevii* are the most dominating species across subjects (*Fig. 12*). The latter species are natural, asymptomatic fungi of the human microbiome, but can become opportunistic pathogens under specific circumstances and cause candidiasis or gut microbial dysbiosis (Vogel et al., 2007; Saleh et al., 2011; Rajilic-Stojanovic and de Vos, 2014). Several other species belonging to genera *Penicillium* and *Aspergillus* have also been detected in GI tract in many researches (Scanlan and Marchesi, 2008; Gouba et al., 2013, 2014). None of the two species was detected across subject in the present study.

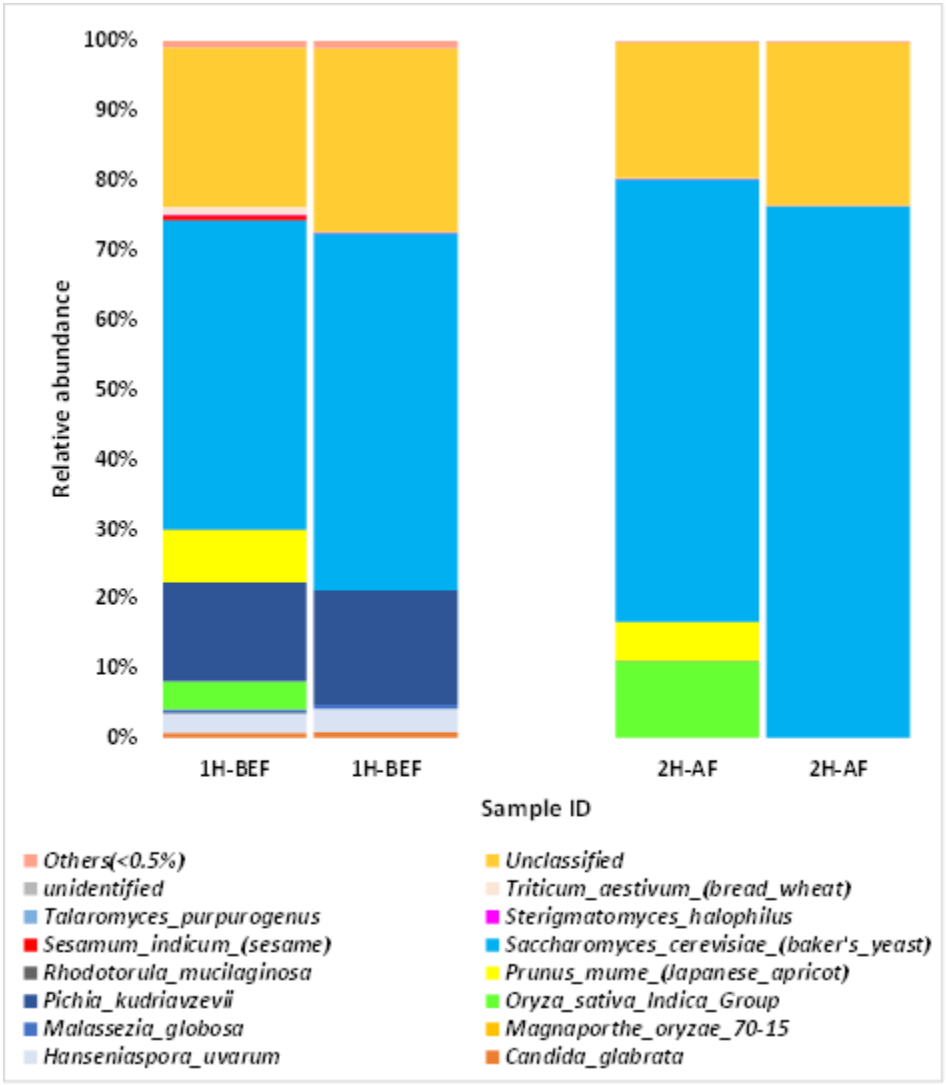

Figure 16. *Differential relative abundance of the two healthy subjects (H) before (BEF) and after (AF) removal of non-fungal information. Description of OTUs for mycobiome species is shown in Table A4*

Species of the genus *Malassezia* are well-known for the inability to synthesize their own lipids, thus, they are completely dependent on their host for nutritional needs (Gupta et al., 2004). In the present study, abundance of this genus increased in mycobiomes of the infected subjects. In other words, there is a positive relationship in the present study in the abundances of *Malassezia* and *Entamoeba histolytica*. Upon infection, *E. histolytica* was reported to exploit lipids and carbohydrates present in the colonic environment (Thibeaux et al., 2013). This indicates that lipids are available for other microbes. Therefore, there is a possibility that *E. hystolytica* be indicative of lipids available for *Malassezia* (*Fig. 17*). The latter conclusion might require further experimentation and support as genes involved in lipids metabolism were recently reported to be upregulated under growth stress in the study of RNA-Seq data of *Entamoeba* (Naiyer et al., 2019b). Expectedly, the known niche for this genus is the skin that is rich of adipose cells, while, surprisingly, it was reported in significant abundance in the gut (Gouba et al., 2013; Cano et al., 2014; Suhr et al., 2016).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23632394

Therefore, there should be other resources of lipids for this genus in the gut. There are two other groups of fungi of the phylum Ascomycota that reported to colonize the healthy human GI tract although gut is not their primary colonizer (Hugon et al., 2017). They are *Cladosporium* and yeasts of the family Dipodascaceae (e.g., *Geotrichum* and *Galactomyces*). Several evidences suggest that the majority of the fungi in GI tract are indigenous (Iliev et al., 2012; Dollive et al., 2013). Family Trichocomaceae also belongs to phylum Ascomycota and includes species *Aspergillus nidulans*, an ascomycetous fungus that is used extensively for studying processes in fungi. This species was proven to be closely related to the *S. cerevisiae* (Class: Hemiascomycetes) in several biological processes, but little is known about the family it derived from (https://www.sciencedirect.com/topics/agricultural-and-biological-sciences/trichocomaceae).

The dimorphic yeast *S. cerevisiae* is widely distributed in the environment and considered commensal upon being colonized in the gut, however, it can occasionally cause superficial and systemic infections (Byron et al., 1995; Munoz et al., 2005; De Llanos et al., 2006). This species is detected frequently in human fecal samples and abundance is directly associated with food ingestion prior to sampling (Scanlan and Marchesi, 2008). The ability of this species to grow at 37 °C makes it likely contributes to gut microbial ecology (Hugon et al., 2017). The potential for *S. cerevisiae* to persist and respond to the gut environment does not support their possible role in the gut, as its preferred niche is the open environmental (soil, air, plant matter). More recently, an article documented a protective role of *S. cerevisiae* inflammatory disorders (Jiang et al., 2017), while other article showed that *S. cerevisiae* reduces bacterial growth and colonization, and inhibits the adhesion of enterotoxigenic *E. coli* (ETEC) (Roussel et al., 2018). The gut mycobiome analysis in the present study indicated that *S. cerevisiae* proved to be a negative biomarker of amebiasis. At the relative abundance level, *S. cerevisiae* was shown to dominate in gut mycobiomes of the healthy subject. There are two possible speculations that can be reached based on the relative abundance of this species. The first is that the high abundance of *S. cerevisiae* might block the growth/spread of *E. histolytica* trophozoites by different possible ways, thus *S. cerevisiae* dominates in the healthy subjects. The second is that *E. histolytica* might propagate due to the low abundance of *S. cerevisiae*, thus, *E. histolytica* might dominate in the infected subjects. We speculate that the two species cross-talk via a number of processes basically relied on glucose level as well as growth condition (aerobic or anaerobic) in the gut, besides, the possible occurrence of oxidative stresses (*Fig. 17*).

Chitin formation is a process made by trophozoite during encystation. Chitin in the cyst wall of *E. histolytica* is synthesized by two chitin synthases, one of which is unique to it (EhCHS-1) and the other is analogue to those of insects, fungi and nematodes (EhCHS-2) (Tellam et al., 2000; Roncero, 2002; Ruiz-Herrera, 2002). In *S. cerevisiae*, chitin is produced by three specialized chitin synthases (Chs1p, Chs2p and Chs3p) (Bulawa, 1993; Choi and Cabib, 1994; Henar Valdivieso, 1999; Roncero, 2002). The first enzyme functions during cytokinesis, while the second makes the chitin in the primary septum and the third makes the bulk of cellular chitin. Yeasts transformed with the unique EhCHS-1 was proven to be functional and chitin was detected in their cells. Action of this enzyme seems to be extracellular towards the cell walls, thus, we speculate that yeast cells might compete with trophozoite for the use of the amoebic enzyme (EhCHS-1), which eventually retards the spread of the parasite by inhibiting the encystation process.

DOI: http://dx.doi.org/10.15666/aeer/1802_23632394

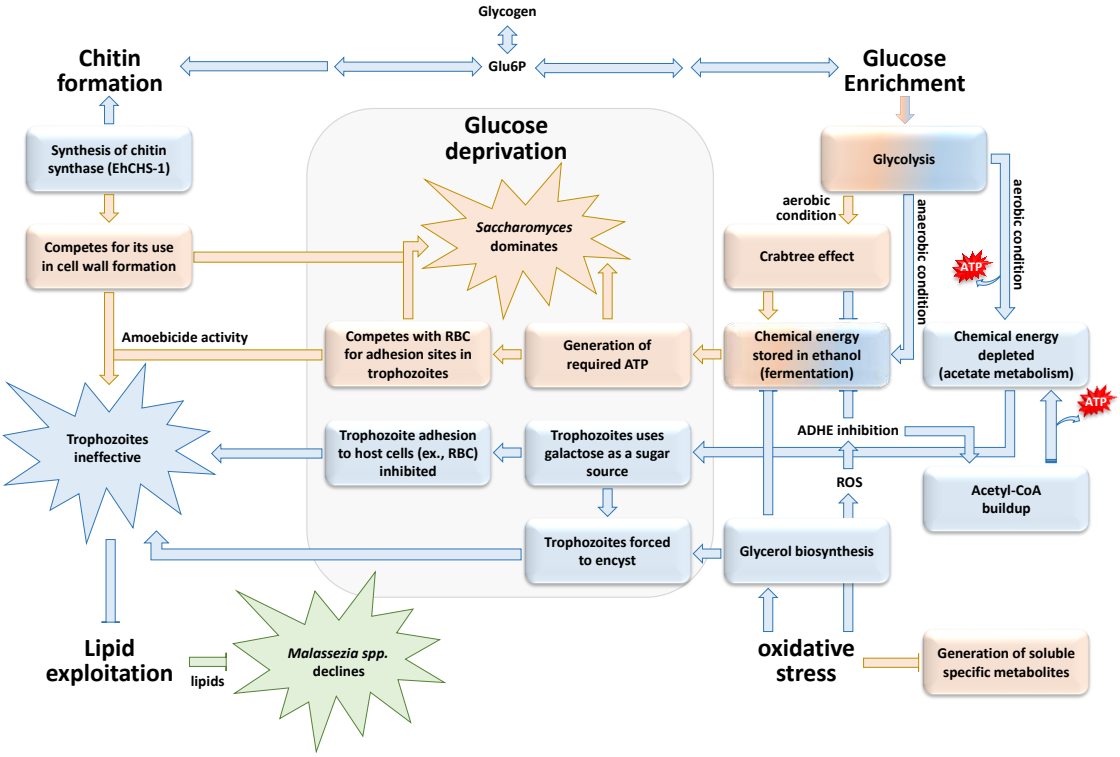

Figure 17. *Roles of the new negative biomarker for amebiasis, e.g., Saccharomyces cerevisiae. Main influence of the biomarker possibly occurs in relation to availability of glucose in the gut and/or during cell wall formation of Entamoeba histolytica. Abundance of Malassezia spp. is based on the availability of lipids proposed to be provided by E. histolytica. Cross-talking among the three taxa involves five major conditions/actions, e.g., glucose enrichment, glucose deprivation, oxidative stress, chitin formation and lipid exploitation. Processes or actions related to S. cerevisiae are shown in pink, while those of E. histolytica and Malassezia spp. are shown in light blue and light green, respectively*

It is well-established that glucose in the human gut perform four different destinations in amoebic cells (*Fig. 18*). They are glycolysis, chitin formation, fermentation and acetate biosynthesis. The first two destinations and the last two destination are very much connected by a number of redux reactions. The direction of the different reactions is dependent on the conditions at which parasite is facing, e.g., glucose level, oxygen presence, oxidative stress, etc. Glucose-6-phosphate (Glu6P) is considered as the main substrate lying upstream redux reactions of these four destinations (*Figs. 17* and *18*). Under the low level of glucose and anaerobic condition, it was reported earlier that adhesion of trophozoites to red blood cells (RBCs) were inhibited (López-Revilla and Cano-Mansera, 1982). The authors indicated that adhesion is dependent on amoebal cytoskeleton and affinity of both amoebal and RBC surface receptors. Another analysis on the effects of *Saccharomyces* on cecal amebiasis in rats indicated that the numbers of diseased rats and the severity of the infection were significantly reduced by the yeast treatment (Rigothier et al., 1990). A more recent report justified the inhibition of adhesion of trophozoite to RBCs as it indicated that pretreatment of amoebae with live yeast led to a significant reduction in the percentage of adhesion (Rigothier et al., 1994). The authors indicated that substances produced by *Saccharomyces* might compete with red blood cells, as an amoebicide, for adhesion

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23632394

sites of the trophozoite (*Fig. 17*). Other reports indicated that the reptilian parasite *Entamoeba invadens* was induced to encyst under osmotic shock, glucose deprivation, or both (Vazquezdelara-Cisneros and Arroyo-Begovich, 1984; Avron et al., 1986; Sanchez et al., 1994; Van Dellen et al., 2006). Un-organized encystation threatens trophozoite's life or it can be a reason for the inefficiency of trophozoite to cause further action in the human body (*Fig. 17*). On the other hand, *Saccharomyces* will not suffer from glucose deprivation as it can consult its saved energy in ethanol that was synthesized by fermentation and use it for regular metabolic processes rather than being forced to make irregular metabolic processes.

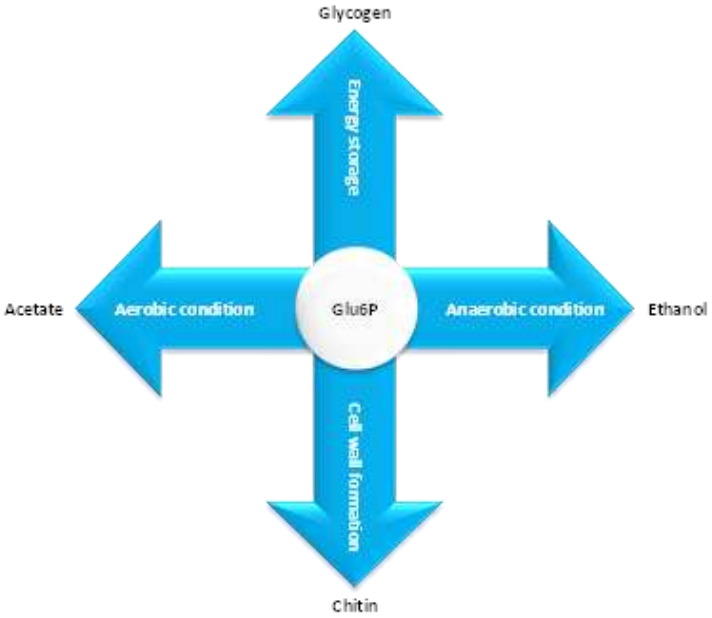

Figure 18. *Four different destinations for glucose metabolism of which Glu6P is the core molecule upstream several redox reaction based on the condition at which parasite is facing*

As a response to glucose deprivation in the human gut, trophozoite has to utilize another source of carbon such as galactose. Frederick and Petri (2005) indicated that adhesion of the trophozoites to colonic mucins and host cells occurs mainly through the abundant galactose-binding lectin on the surface of the cells, however, this adhesion is almost completely inhibited by β-D-galactose (*Fig. 17*). We speculate that utilization of galactose as a carbon source due to glucose deprivation will negatively affect the trophozoite efficiency. On the other hand, *S. cerevisiae* simply transports galactose into the cell, when glucose level is low, by galactose permease enzyme to be converted to glucose-6-phosphate (Glu-6P) that drive the reaction normally towards glycolysis (Bro et al., 2005). More recently, Naiyer et al. (2019a) indicated that aspartate might be used as energy source by *Entamoeba* under glucose deprivation due to the regulation of the gene encoding aspartate aminotransferase. Galactose was also recently reported to act in inhibiting the formation of neutrophil extracellular traps (NET) that traps trophozoites, thus, makes trophozoites invisible by host neutrophil (Fonseca et al., 2019).

Husain et al. (2012) indicated that oxidative stress also resulted in reduced level of glycolysis and ethanol production and the redirection of metabolic flux towards glycerol production and chitin biosynthesis. Reduction of glycolysis and ethanol levels indicate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23632394

the reduced stored energy required for trophozoite actions and the promotion of chitin biosynthesis can stimulate the trophozoites to encyst, thus, further retard their actions. In addition, oxidative stress induces the production of reactive oxygen species (ROS). The latter inhibits the bifunctional aldehyde/alcohol dehydrogenase (ADHE) enzyme, important during ethanol production (Nozaki and Bhattacharya, 2015), thus, results in the buildup of Acetyl CoA that is the intermediate step towards acetate metabolism and depletion of energy. Chitin biosynthesis is a further response to oxidative stress. As indicated earlier, this process enforces trophozoites to encyst, thus, no further action is taken by the microbe in the gut. *Saccharomyces boulardii* has previously been used effectively to treat rotavirus (RV) diarrhea in human enterocytes by preventing RV-induced oxidative stress (Buccigrossi et al., 2014). The study was repeated in an organ culture model using human intestinal biopsies, and results indicated that *Saccharomyces* produces soluble metabolites that prevent oxidative stress in human intestine (*Fig. 17*). Interestingly, Naiyer et al. (2019a) indicated that genes upregulated during encystation include phospholipase D as well as genes involved in meiotic division such as *MND1*, *Hop2* and *Rad52*. Meiosis was not proven in *Entamoeba*, however, earlier reports indicated the occurrence of homologous recombination (Singh et al., 2013).

Glucose is known to be converted into pyruvate through glycolysis, a metabolic pathway employed in nearly all organisms (Berg et al., 2002). In the downstream reactions, pyruvate is further degraded either through the respiration or the fermentation pathway. The first is a pathway to release or exhaust ATP, while the second is a pathway to store ATP. Under conditions of glucose enrichment, trophozoites mainly perform fermentation under anaerobic condition, while acetate biosynthesis under aerobic condition (Nozaki and Bhattacharya, 2015). Aerobic condition is accompanied by the presence of oxygen. It was reported that trophozoites produce 75% ethanol and 25% acetate under anaerobic condition, while opposite ratios under aerobic condition. The latter ratios indicate that trophozoites cannot save appropriate amount of stored energy at the form of ATP via fermentation under aerobic or oxidative stress condition (*Fig. 17*). On the other hand, some yeast species such as *S. cerevisiae* use fermentation even in the presence of oxygen, albeit glucose concentration is sufficiently high. Such *Saccharomyces* species are able to choose the proper destination for glycolysis (respiration or fermentation) under high glucose levels and aerobic conditions, a property related to Crabtree effect (Crabtree, 1929; De Deken, 1966; Postma and Verduyn, 1989; Van Urk et al., 1990; Pfeiffer and Morley, 2014), of which the direction choices are based on cell's requirement for energy. This phenomenon indicates that excess sugar availability promotes cells to ferment it rather than going through respiration or oxidative phosphorylation. Reasons for this phenomenon includes the limited membrane space that harbors the enzymes involved in oxidative phosphorylation (Hagman et al., 2013).

Conclusion

The main goal of the present study is the detection of gut mycobiome signature of *E. histolytica*-infected patients in a trial to improve our ability to diagnose and treat the disease. We suggest that the results on the discovery of new negative biomarker for amebiasis can provide new insights into the possible use of *Saccharomyces* in the future as a probiotic to treat diarrhea and downstream severity of the disease. The latter conclusion requires further experimentation way before we decide to use yeasts as a treatment in the market place.

Abstract. Extreme temperature indices (ETIs) are used to assess extreme temperature events, to further reveal possible climate impacts of El Niño-Southern Oscillation (ENSO) on temperature extremes. The primary objective of this paper is to investigate the spatial and temporal variability of ETIs, and further examine the linear and nonlinear relationships between ETIs and two ENSO anomalies including the Niño 3.4 and Southern Oscillation Index (SOI) between 1969 and 2016 in the Wei River Basin (WRB) of China. The trends of ETIs were analyzed using Mann-Kendall test and cloud model, and the relationships between ENSO and ETIs were quantified using correlation and wavelet analysis. Results showed that the ETIs had increased from 1969 to 2016. Most of the stations exhibited similar trends for each ETIs except diurnal temperature range (DTR). The trend of minimum temperature (Tmin) was larger than that of maximum temperature (Tmax). Meanwhile, the variability of Tmin in the south of WRB was more stable than in other regions. Niño 3.4 was mainly positively correlated with PC1 of ETIs, and vice versa for SOI. The results help to understand the changes in extreme temperature events and their relationships with climate anomalies, which can provide scientific references for the water resource management of the watershed.
Keywords: *extreme temperature events, linear and nonlinear relationships, cross wavelet analysis, trend analysis, cloud model, Wei River Basin*

Introduction

According to the fifth Assessment Report (AR5) of Intergovernmental Panel on Climate Change (IPCC), surface air temperature had increased for past several decades, especially since 1850. In addition to the conclusive multi-decadal warming, the global average surface temperature showed obvious inter-decadal and inter-annual variations (IPCC, 2014). The frequency and magnitude of extreme climate events had significantly increased around the world (Utsumi et al., 2011; Sun et al., 2016). Therefore, it is of great significance to understand and reveal the trends and possible climate change impacts of extreme climate events.

The increasing frequency of extreme climate events has caused severe socioeconomic losses, which has garnered widespread attention (Zhang et al., 2008; Farajzadeh et al., 2015; Ruml et al., 2017). Many previous studies mainly focused on the extreme circumstances of climate change, including the causes, intensity and frequency. For example, Jiang et al. (2019b) investigated the trends of extreme

DOI: http://dx.doi.org/10.15666/aeer/1802_23952412

precipitation indices (EPIs) for the period of 1969-2016 in the Wei River Basin (WRB). The results found that El Niño-Southern Oscillation (ENSO) exerted great impacts on the extreme precipitation events. Liu et al. (2018) analyzed the spatial-temporal change patterns of maximum and minimum temperature in the WRB. The results found that solar activity and large-scale atmospheric circulation have stronger influences on annual Tmin than annual Tmax. Tong et al. (2019) found that extreme temperature indices (ETIs) have significantly increased but the EPIs did not show significant changes in the Inner Mongolia.

Previous studies mainly investigated the spatiotemporal changes of extreme climate indices and obtained some results (Menang, 2017; Xiao et al., 2017; Agnihotri et al., 2018). However, few studies focused on the extreme climate events especially extreme temperature events in the WRB, which is the largest tributary of the Yellow River of China (Liu et al., 2017). Based on observed daily temperature data, this paper assessed the spatial and temporal variability of extreme temperature events using fourteen ETIs for the period of 1969-2016 in the WRB. The principal component analysis (PCA), Pearson's correlation, wavelet coherence and phase difference were used to explore the linear and nonlinear relationships between ETIs and typical large-scale global climate anomalies. This paper is organized as follows: material and methods are provided in the Section 2, followed by results and discussion in the Section 3, and conclusions in the Section 4.

Material and methods

Study area

The WRB is located between 33.68°N-37.39°N latitude and 103.94°W-110.03°W longitude, with basin area nearly 135,000 km^2. It originates from Gansu province, and flows through Ningxia Hui autonomous region and Shaanxi province from west to east, with length of 818 km, as shown in *Figure 1*. It can be divided into five sub-basins including the upstream, midstream and downstream of the WRB, Jing River Basin (JRB) and Beiluo River Basin (BRB). The upstream of WRB rises from the Qin Mountains with a length of 430 km. The midstream flows from Linjiacun to Xiwanyang, with length about 180 km. The downstream flows into the Yellow River from Xianyang, with length about 208 km. The JRB originates in the eastern foot of Liupan Mountain (Jiang et al., 2019b).

Due to the diversity of geological, geographical and climatic conditions, the climate of the WRB has obvious seasonal characteristics (Zou et al., 2017). The average temperature in summer is about 25°C, and below 0°C in winter. The WRB is a grain production and important economic zone in the northwest of China, especially after the establishment of Guanzhong-Tianshui Economic Zone (Chang et al., 2015). However, the climate of the WRB varied from region to region, and many extreme climate events happened in the history (Jiang et al., 2013, 2015).

Climate data

Daily temperature data from 34 meteorological stations that were downloaded from China Meteorological Administration (http://data.cma.cn/), covering the period from January 1st, 1969 to December 31st, 2016, were used to calculate the ETIs. The temperature data have passed strict quality control, the missing data and unreasonable

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23952412

data were carefully checked. The standard deviation exceeding 3 times was defined as the out-of-bound value, compared with the records of adjacent stations through manual inspection, reasonable reservation and unreasonable treatment according to absence. Two anomalies including Niño 3.4 and SOI were used as ENSO indices. The Niño 3.4 data was downloaded from Earth System Research Laboratory of National Oceanic and Atmospheric Administration (NOAA) at http://www.esrl.noaa.gov/. The SOI was downloaded from website at https://crudata.uea.ac.uk/cru/data/soi/.

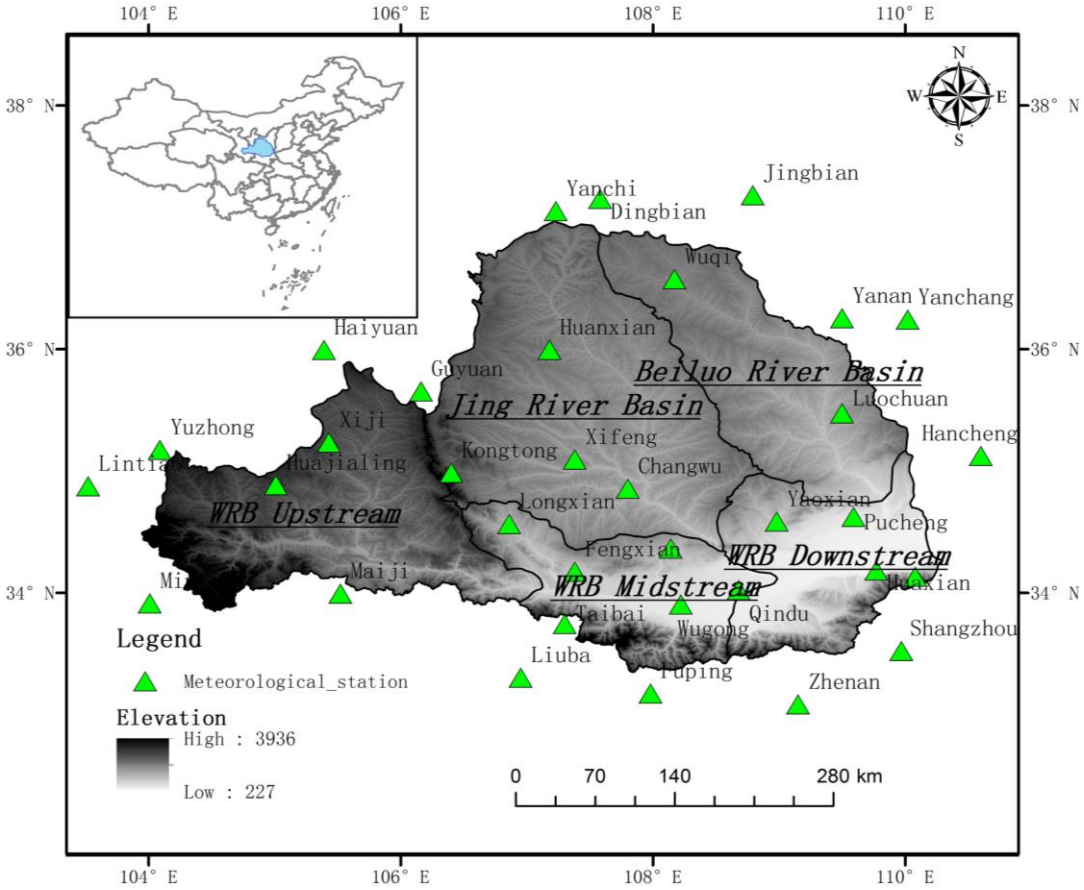

Figure 1. *Locations of the WRB and meteorological stations*

Definition and calculation of ETIs

Fourteen ETIs were defined to identify the extreme temperature events in this paper. The details of ETIs are shown in *Table 1*. These indices identify the changes of temperature in different aspects including intensity, duration and percentile, which have been widely used in previous studies (Popov et al., 2018; Jiang et al., 2017; Sun et al., 2018; Jiang et al., 2019a). A R based software named RClimDex was used to calculated the ETIs. RClimDex was based on a powerful and freely available statistical package R which runs under both Windows and Unix/Linux. It has a friendly graphical user interface and provides simple quality control process on the input daily temperature data, which has been widely used after it was developed (Almazroui et al., 2014; Jiang et al., 2018). More details of extreme climate indices and RClimDex can refer to the website at http://etccdi.pacificclimate.org/software.shtml.

DOI: http://dx.doi.org/10.15666/aeer/1802_23952412

Table 1. *Details of 14 ETIs used in the study*

Acronym	ETIs	Definitions	Units
FD0	Frost days	Annual count when daily minimum (TN) < 0°C	Days
SU25	Summer days	Annual count when daily maximum (TX) > 25°C	Days
ID0	Ice days	Annual count when TX < 0°C	Days
GSL	Growing season Length	Annual count between first span of at least 6 days with daily mean temperature (TG) > 5°C and first span after July 1 of 6 days with TG < 5°C	Days
TN10p	Cool nights	Percentage of days when TN < 10th percentile	% of Days
TX10p	Cool days	Percentage of days when TX < 10th percentile	% of Days
TN90p	Warm nights	Percentage of days when TN > 90th percentile	% of Days
TX90p	Warm days	Percentage of days when TX > 90th percentile	% of Days
WSDI	Warm spell duration indicator	Annual count of days with at least 6 consecutive days when TX > 90th percentile	Days
CSDI	Cold spell duration indicator	Annual count of days with at least 6 consecutive days when TN < 10th percentile	Days
DTR	Diurnal temperature range	Monthly mean difference between TX and TN	°C
TR20	Tropical nights	Annual count when TN > 20°C	Days
Tmax	Annual maximum temperature	Annual maximum temperature	°C
Tmin	Annual minimum temperature	Annual minimum temperature	°C

Research methodology

Non-parametric Mann-Kendall test

The non-parametric Mann-Kendall test, recommended by the World Meteorological Organization, which has been widely used to estimate the trends of time series, was used to examine the trends of the ETIs (Mann, 1945; Kendall, 1975; Du et al., 2015).

For a data series $X = \{x_1, x_2, ..., x_n\}$, the statistic *S* is calculated by *Equation 1*.

$$S = \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} \mathrm{sgn}(x_j - x_i) \quad \text{(Eq.1)}$$

where

$$\mathrm{sgn}(x_j - x_i) = \begin{cases} 1, x_j - x_i > 0 \\ 0, x_j - x_i = 0 \\ -1, x_j - x_i < 0 \end{cases} \quad \text{(Eq.2)}$$

The variance *V* is calculated using by *Equation 3*.

$$V = \frac{n(n-1)(2n+5)}{18} \quad \text{(Eq.3)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23952412

where n is the length of the data sequences, and Mann-Kendall' Z is calculated by *Equation 4*.

$$Z = \begin{cases} (S-1)/\sqrt{V}, S > 0 \\ 0, S = 0 \\ (S-1)/\sqrt{V}, S < 0 \end{cases} \quad \text{(Eq.4)}$$

The value of Z indicates the trend of series. $Z>0$ means positive trend, and vice versa for $Z<0$. Two significance levels including 1% and 5% were used to detect the statistically significant trends of ETIs.

Wavelet coherence and phase difference

Wavelet coherence (WTC) can be used to measure the part of local correlation between two data series in time and frequency domain. The wavelet transform of data series X and Y were $W_n^X(S)$ and $W_n^Y(S)$. The wavelet coherence defined by Torrence and Webster was given as follows:

$$R_n^2(s) = \frac{\left|S\left\langle s^{-1}W_n^{XY}(s)\right\rangle\right|^2}{S\left\langle s^{-1}\left|W_n^X(s)\right|^2\right\rangle S\left\langle s^{-1}\left|W_n^Y(s)\right|^2\right\rangle} \quad \text{(Eq.5)}$$

where $R_n^2(s) \in [0,1]$, and $W_n^{XY}(s) = W_n^X(s) \times W_n^Y(s)$.

The smoothing operator S of $W_n^{XY}(s)$ in numerator and wavelet power spectrum in denominator is given as follows:

$$S(W) = S_{scale}(S_{time}(W(s,t))) \quad \text{(Eq.6)}$$

$$S(W)\big|_s = (W(t,s)c_1 e^{-(t^2/2s^2)})\big|_s \quad \text{(Eq.7)}$$

$$S(W)\big|_n = (W(t,s)c_2 \Pi(0.6s))\big|_n \quad \text{(Eq.8)}$$

where S_{scale} indicates smoothing along the wavelet scale axis and S_{time} denotes smoothing in time, C_1 and C_2 are the normalized constants, Π is the rectangle function. The wavelet phase difference is given as follows:

$$\phi_n(s) = \tan^{-1}\left(\Im\left\{\left\langle s^{-1}W_n^{XY}(s)\right\rangle\right\} / \Re\left\{\left\langle s^{-1}W_n^{XY}(s)\right\rangle\right\}\right) \quad \text{(Eq.9)}$$

where $\Im\{\ldots\}$ and $\Re\{\ldots\}$ are the imaginary and real part of wavelet spectra, respectively. More details of WTC can be found at previous studies (Torrence and Compo, 1998; Grinsted et al., 2004).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23952412

Normal Cloud model

The cloud model is mainly used to reveal the uncertain transformation between qualitative concept and quantitative instance (Li et al., 2009; Qin et al., 2011; Wang et al., 2014). It has been widely used in many fields such as data mining, pattern recognition. (Li et al., 1998; Grecu and Krajewski, 2000; Zhou et al., 2015). The cloud model uses three indicators to represent its characteristics: 1) Expectation (Ex), is the expectation of cloud droplets in domain space division, 2) Entropy (En), is a measure of qualitative concept uncertainty, which is determined by the randomness and fuzziness of concepts, 3) Hyper-Entropy (He), is the entropy of entropy. More details of normal cloud model can be found in previous studies (Li et al., 2009; Qin et al., 2011).

Let U be the universe of discourse and $\tilde{A}$ be a qualitative concept in U. If $x \in U$ is a random instantiation of concept $\tilde{A}$, which satisfies $x \sim N(Ex, En'^2)$, $En' \sim N(En, He^2)$, and the certainty degree of x belong to concept $\tilde{A}$ satisfies.

$$y = e^{-\frac{(x-Ex)^2}{2(En')^2}} \quad \text{(Eq.10)}$$

Then the distribution of x in the universe U is called as a normal cloud.

Principal component analysis

As a frequently-used statistical method, the PCA obtain different orthogonal principal components by reducing the dimension of multivariate data series, and explain most of the variability of original data series through a certain number of principal components. The leading principal component (PC1) was used as a substitution for each ETIs (Singh, 2006; Jiang et al., 2014).

Results and discussion

Change patterns of ETIs in the WRB

Trends of each ETIs were analyzed using non-parametric Mann-Kendall test. The trends were classified into seven categories including positive, statistically significant positive (5% & 1%), stationary, negative, statistically significant negative (5% & 1%), to provide more knowledge of the change characteristics of the ETIs.

The trends of 14 ETIs are shown in *Table 2*, which demonstrate the proportions of positive, stationary and negative trends of 14 ETIs in 34 stations, respectively.

Figure 2 shows the spatial distributions of trends in 14 ETIs for 34 meteorological stations for the period of 1969-2016 in the WRB. All fourteen ETIs except DTR were significantly increasing trends dominated. Eight ETIs including Tmax, Tmin, SU25, TR20, TN90P, TX90P, WSDI and GSL showed increasing trends for most of the stations. Other six ETIs showed decreasing trends.

Table 2. *Trends of 14 ETIs (%)*

ETIs	Positive trend	SS (5%)	SS (1%)	Negative trend	SS (5%)	SS (1%)	Stationary trend
Tmax	94.12%	17.65%	5.88%	5.88%	0.00%	0.00%	0.00%
Tmin	82.35%	2.94%	14.71%	17.65%	0.00%	0.00%	0.00%
FD0	0.00%	0.00%	0.00%	100.00%	2.94%	91.18%	0.00%
ID0	0.00%	0.00%	0.00%	100.00%	38.24%	47.06%	0.00%
SU25	100.00%	32.35%	50.00%	0.00%	0.00%	0.00%	0.00%
TR20	91.18%	17.65%	38.24%	2.94%	0.00%	0.00%	5.88%
TN10P	2.94%	0.00%	0.00%	94.12%	2.94%	88.24%	0.00%
TX10P	0.00%	0.00%	0.00%	100.00%	8.82%	91.18%	0.00%
TN90P	100.00%	5.88%	94.12%	0.00%	0.00%	0.00%	0.00%
TX90P	100.00%	17.65%	79.41%	0.00%	0.00%	0.00%	0.00%
WSDI	100.00%	5.88%	0.00%	0.00%	0.00%	0.00%	0.00%
CSDI	2.94%	0.00%	0.00%	94.12%	14.71%	0.00%	2.94%
DTR	47.06%	5.88%	8.82%	52.94%	0.00%	14.71%	0.00%
GSL	100.00%	11.76%	79.41%	0.00%	0.00%	0.00%	0.00%

*SS denote statistically significant trends at 5% or 1%, respectively

Among 34 stations, only Changwu and Yanchi station showed downward trends in Tmax, which are located at the north and south of the JRB, respectively. Other stations showed upward trends. Three stations including Fengxiang and Wugong stations in the WRB midstream, and Luochuan station in the middle of the BRB, had significant increasing trends. Compared with Tmax, six stations had decreasing trends in Tmin. The trends of FD0 and ID0 in 34 stations were similar, with mainly downward trends dominated, and more than 90% of the stations had statistically significant decreasing trends at 5% significance level for FD0. Compared with the upward trends of SU25 for all stations, one station showed decreasing trend and two stations showed stationary trends for TR20. It is worth noting that TR20 in Minxian and Huajialing were all stationary. TX10P and TN10P showed downward trends for almost 34 stations. However, TX90P and TN90P showed upward trends. The trends of WSDI and CSDI were mainly opposite. The CSDI showed upward trends in all stations, but only several stations were statistically significant at 5% significance level for the period of 1969-2016.

Spatial distributions of Tmax and Tmin

In this study, the natural neighborhood method was used to interpolate three primary numerical characteristics in the WRB, and details are shown in *Figure 3*. Generally, three numerical characteristics have obvious and irregular spatial distributions. *Figure 3a* shows that the Tmax ranges from 25.29°C to 39.08°C, and the western WRB is lower than other regions. *Figure 3b* shows that the Tmin ranges from -23.50°C to -8.53°C, but the northern WRB is lower than that in the Guanzhong Plain. *Figure 3c* shows that the entropy values in the north and centre of the WRB are lower than those in the south and west, which indicates that the change in the north is more stable. *Figure 3d* show that the change of Tmin entropy is greater than the annual maximum. It can be concluded that the change of Tmin is more stable in the south-central region near the Qinling Mountains, but it is unstable in the north.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23952412

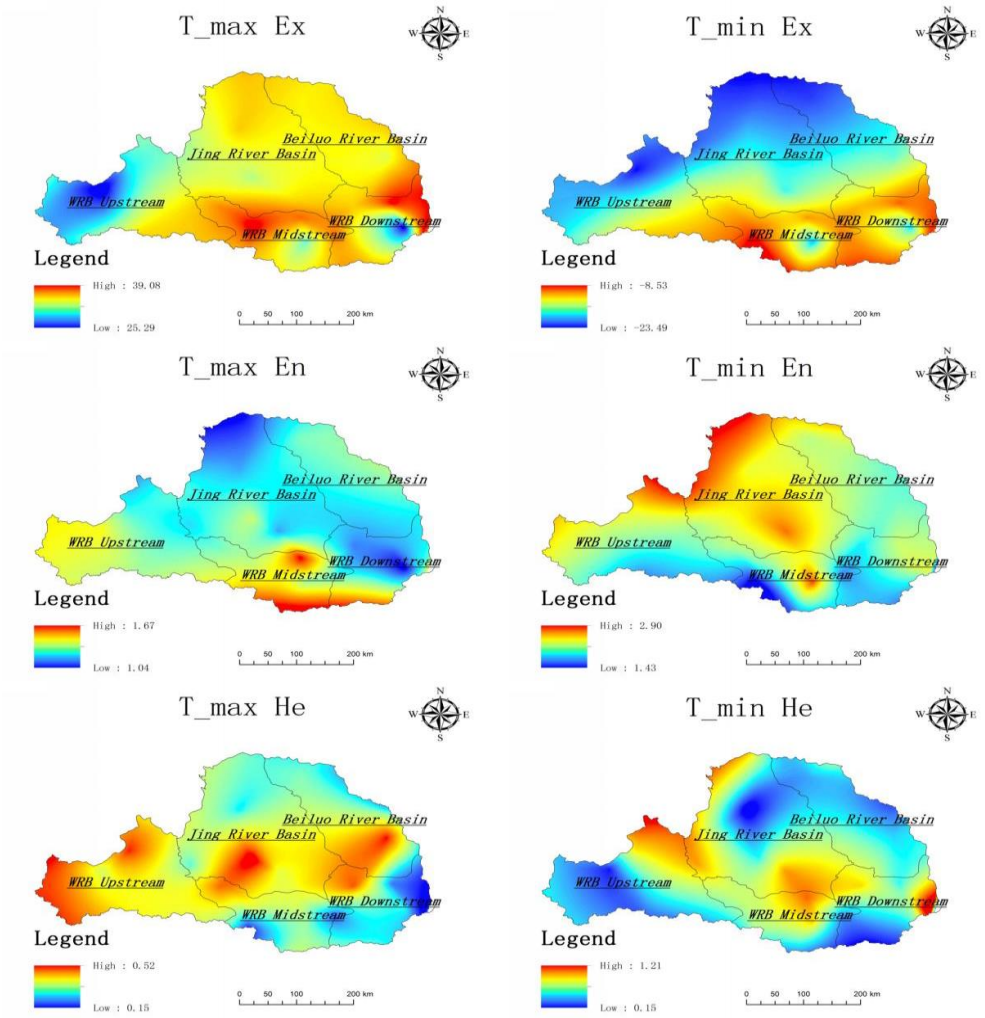

Figure 3. *Spatial distributions of three numerical characteristics in the WRB. (a)Ex of Tmax, (b)Ex of Tmin, (c)En of Tmax, (d)En of Tmin, (e)He of Tmax, (f)He of Tmin*

Ex indicates average values of Tmax and Tmin. *En* is used to react the instability of Tmax and Tmin sequences. The entropy value of Tmin is larger than that of Tmax, which indicates that the Tmin in the WRB is more unstable and scattered than that of Tmax. The standard deviations of them are calculated to further verify that the Tmin series is more uneven and unstable.

He represents the dispersion of entropy, and the larger the hyper entropy, the more the instability. Similar with entropy, the super entropy of Tmin is larger than that of Tmax, which indicates that the Tmin is more nonuniform the Tmax. In general, the Tmin variation has higher dispersion and instability than the Tmax variation in the WRB. Guanzhong Plain is the main grain production area in Shaanxi province. Annual minimum temperature changes have a negative impact on grain production. Therefore, the local government should scientifically prevent and adopt appropriate strategies to deal with this phenomenon.

The results show that generally the ETIs have similar trends for different stations, which are increasing trends dominated, as shown in *Table 2* and *Figure 2*. The cold extreme indices such as FD0 and ID0 have significant negative trends, and the warm

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23952412

extreme indices have significant positive trends. Changes in these indices indicate that extreme temperature events had mainly increased from 1969 to 2016, which is mainly consistent with previous results. For example, Zhou et al. (2011) founded that the numbers of frost days and ice days were significantly reduced in mainland China. Shi et al. (2018) found that the TR20, SU25, TX90P and TN90P had increased, but the FD0, ID0, TX10P and TN10P had decreased. The results showed that Tmax and Tmin of the JRB located in the Loess Plateau, have higher instability compared with other areas of the WRB. The results are consistent with Liu et al. (2018) who explored the maximum and minimum temperature variation in the WRB. The results found that solar activity and large-scale atmospheric circulation have stronger influences on annual Tmin than annual Tmax.

Correlation between ETIs and typical climate anomalies

PCA was used to extract the PC1 of each ETIs before correlation analysis between ETIs and two typical large-scale global climate anomalies including Niño 3.4 and SOI, because the PC1 of each ETIs represented the largest proportion of total variability.

Table 3 shows the correlation coefficients between each ETIs. The results show that PC1 of FD0 was negatively correlated with TN90P (ρ=-0.87). FD0 showed decreasing trends in 34 stations, but TN90P showed increasing trends. Thus, PC1 of FD0 and TN90P showed negative correlation. It is worth noting that there has positive correlations between typical warm temperature extremes including TX90P, TN90P, SU25, TR20 and WSDI. Similarly, there has positive correlations between typical cold temperature extremes including TN10P, TX10P, FD0, ID0 and CSDI, indicating that the warm ETIs are generally correlated with the cold ETIs. DTR and GSL also have positive correlations with warm ETIs and negative correlations with cold ETIs, except that the DTR is positively correlated with TN10P.

Table 3. *Cross correlation coefficients between different ETIs*

ETIs	FD0	ID0	TMAX	TMIN	SU25	TR20	TN10P	TX10P	TN90P	TX90P	WSDI	CSDI	DTR	GSL

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23952412

Figure 4 shows the correlation coefficients between ETIs and Niño 3.4, SOI. In general, all cold ETIs except TN10P are negatively correlated with Niño 3.4 and positively correlated with SOI, and all warm ETIs are positively correlated with SOI and negatively correlated with Niño 3.4, except TN90P, which indicated that Niño 3.4 had negative impacts on the cold EITs and positive impacts on the warm ETIs, and vice versa for SOI. Among the cold ETIs, ρ between ID0 and two typical climate anomalies was the strongest. In case of the warm ETIs, TX90P and WSDI was more strongly correlated with Niño 3.4 and SOI than other ETIs. Therefore, four ETIs including TN10P, TX10P, TN90P and TX90P were selected to analysis the nonlinear relationships between Niño 3.4 and SOI using wavelet analysis in the following section.

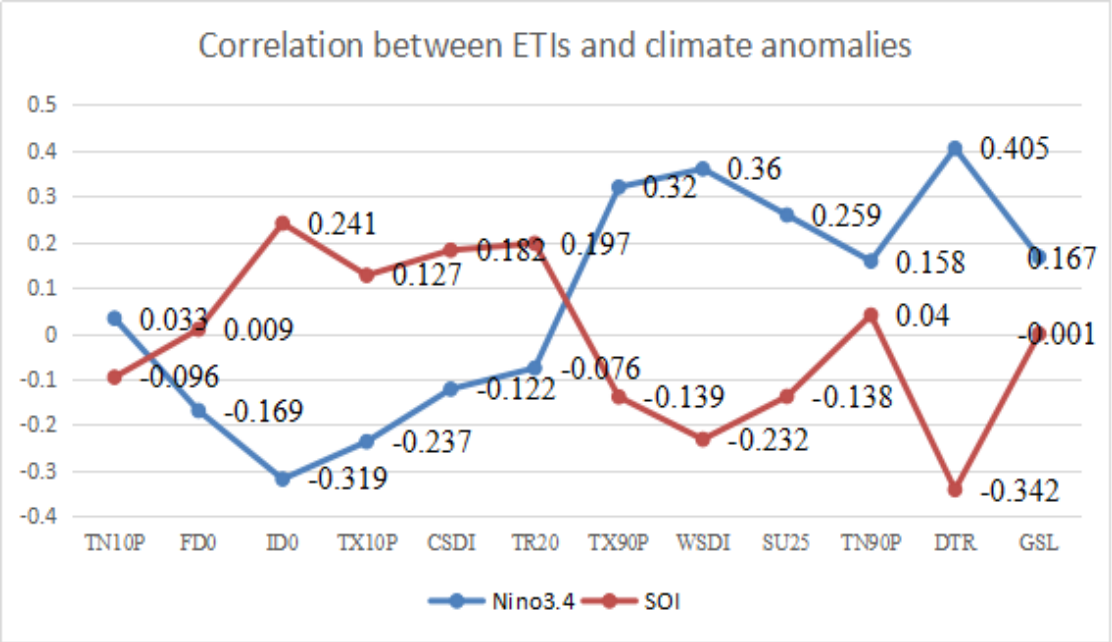

Figure 4. *Pearson's correlation coefficients between ETIs and Niño 3.4, SOI*

Wavelet analysis between ETIs and SOI

Figure 5a shows the wavelet coherence and phase difference between SOI and PC1 of TN10P. The results show that there is a 0-3 years cycle during 1969-1975 with negative correlations, a 2-4 years cycle after 2005 with a -90° phase difference and an 8-12 years cycle during 1970-1988 with a 45° phase difference. A 3 year cycle during 1995-2000 with a -90° phase difference and a 6 years cycle during 1994-1996 with negative correlations are also detected. *Figure 5b* shows wavelet coherence and phase difference between SOI and PC1 of TX10P. The results indicate that there is a 0-4 years cycle during 1995-2000, and the coherence was in-phase dominated. *Figure 5c* shows the wavelet coherence and phase difference between SOI and PC1 of TN90P. There is a 2-4 years cycle during 1990-2000, and the phase difference was 45°. The WTC analysis between SOI and PC1 of TX90P is shown in *Figure 5d*. There have a 3-6 years cycle during 1969-2016 and a 0-3 years cycle during 1985-1990, both of the coherence were dominated by anti-phase.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23952412

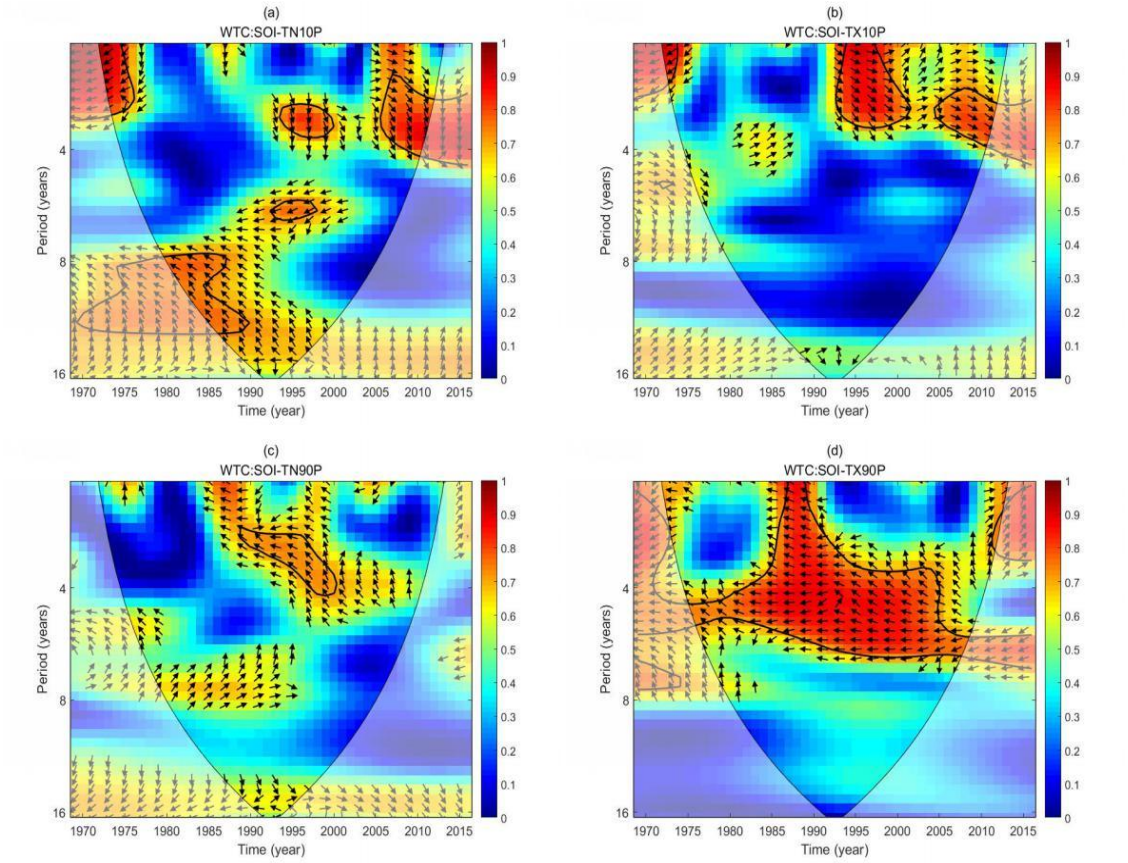

Figure 5. *WTC between SOI and PC1 of typical ETIs: (a)TN10P, (b)TX10P, (c)TN90P, (d)TX90P during 1969-2016*

Wavelet analysis between ETIs and Niño 3.4

Figure 6a shows the wavelet coherence and phase difference between Niño 3.4 and PC1 of TN10P. The results show that PC1 of TN10P is positively correlated with Niño 3.4, with a signal of 6-7 years during 1993-2003 and a 0-3 years signal during 1969-1977, it is noteworthy that half of the area are outside the cone of influence (COI), which need to be interpreted in cautious. The results also show that the Niño 3.4 leads PC1 of TN10P a quarter cycle, with a signal of 3 years during 1995-2000 and a 0-4 years signal during 2005-2016. The results also show the Niño 3.4 lags PC1 of TN10P a quarter cycle with a 12 years signal during 1970-1988, but most of the area are outside the COI. *Figure 6b* shows the wavelet coherence and phase difference between Niño 3.4 and PC1 of TX10P. There has a 2-year cycle during 1995-2000, and the phase difference was 45°. There are also statistically significant negative correlations with a 4 years cycle during 1983-1985. *Figure 6c* shows the wavelet coherence and phase difference between Niño 3.4 and PC1 of TN90P. There has a 4-year cycle during 1999-2005, and the phase difference was -90°. The WTC analysis between Niño 3.4 and PC1 of TX90P is shown in *Figure 6d*. The results show that PC1 of TX90P is positively correlated with Niño 3.4, with a signal of 4-6 years during 1980-2005 and a 0-4 years cycle during 1988-1990.

To reveal the change mechanism and potential influencing factors of ETIs in the WRB, we further investigate the teleconnections between typical ETIs and climate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_23952412

anomalies including Niño 3.4 and SOI. The results show that the correlation between ETIs and global climate anomalies is intricate, which vary in both time and frequency. However, the results of correlation between PC1 of ETIs and Niño 3.4, SOI (as shown in *Figure 4*) are consistent with the phase difference in *Figure 5* and *Figure 6*. Take TN10P and TX10p for examples, we found that the PC1 of TN10P and SOI are negatively correlated in *Figure 4*, and their phase differences are anti-phase, similarly, TX10P and SOI are positively correlated with each other and their phase differences are in-phase. The teleconnections between ETIs and ENSO indicated that the extreme temperature events might be predicted using large-scale climate anomalies as potential predictors. Previous studies have shown that the negative correlation between rainfall and SOI in the Loess Plateau is significant on the high time-frequency scale (Wang et al., 2019). However, the effects of atmospheric circulation patterns on regional temperature have been studied by many previous studies, such as Pacific Decadal Oscillation (PDO) (Newman et al., 2016; Zhang et al., 2018; Geng et al., 2019), Pacific/ North American (PNA) (Ning and Bradley, 2016), North Atlantic Oscillation (NAO) (Pokorna and Huth, 2015; Wang et al., 2017) and Arctic Oscillation (AO) (Otomi et al., 2013; Park and Ahn, 2016). Therefore, it should be better to include more global climate anomalies to predict the extreme temperature events based on their strong relationships (Loikith and Broccoli, 2012; Grotjahn et al., 2016).

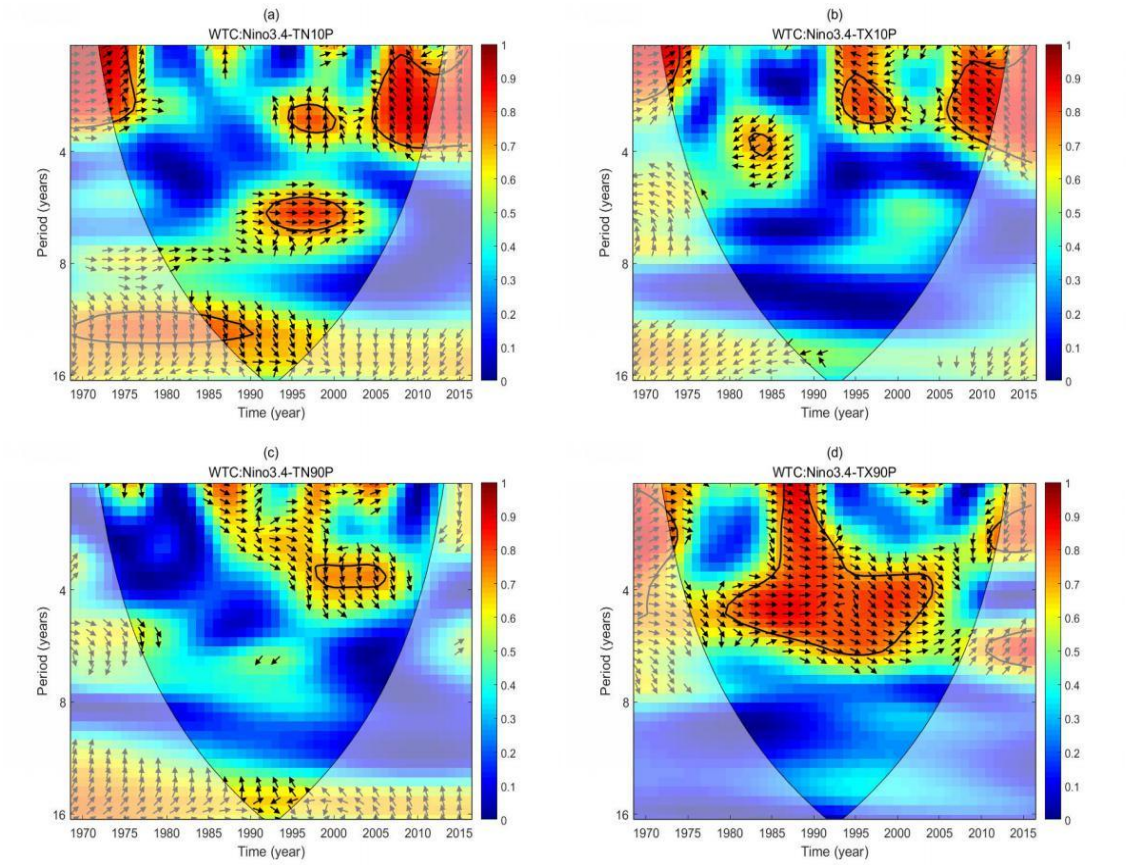

Figure 6. *WTC between Niño 3.4 and PC1 of typical ETIs: (a)TN10P, (b)TX10P, (c)TN90P, (d)TX90P during 1969-2016*

Conclusions

In this paper, fourteen ETIs were used to evaluate the extreme temperature events. The temporal and spatial variability of ETIs were analyzed using non-parametric Mann-Kendall test method during 1969-2016 in the WRB. To reveal the potential relationships between extreme temperature change and atmospheric circulation factors, Niño 3.4 and SOI were used to investigated their linear and nonlinear relationships with ETIs. The main conclusions are summarized as follows:

In general, ETIs exhibited similar variability for different stations. Eight ETIs including Tmax, Tmin, SU25, TR20, TN90P, TX90P, WSDI and GSL showed mainly increasing trends, and five ETIs including FD0, ID0, TN10P, TX10P and CSDI showed mainly negative trends. Using cloud model of Tmax and Tmin, the results showed that the geographical location has an important influence on the spatial variability of *En*, *Ex* and *He*. Tmax, Tmin and *Ex* in the middle and lower reaches are higher than the JRB and BRB, which might be caused by the rapid urbanization of Guanzhong Plain and the urban heat island effect. *En* and *He* in the middle reaches are higher, which indicates that the Guanzhong Plain is more uneven and stable than other regions, which may be due to the influence of human activities and the difference of solar activities in different regions.

Two climate anomalies including Niño 3.4 and SOI had similar wavelet coherence and phase difference with PC1 of four ETIs. The inter-decadal oscillation between Niño 3.4 (SOI) and TN10P was found at about 12 years cycle. The results of phase difference between ETIs and SOI, Niño 3.4 are mainly opposite, positive with SOI, and negative with Niño 3.4, which are consistent with the results of Pearson's correlation (*Figure 4*). It is noteworthy that the oscillations between ETIs and climate anomalies need to be interpreted in cautious because of the limited data series.

The results of this study provide a reliable estimation of extreme temperature events, which provide references for water resource management and climate planning in the WRB. In particular, the potential impacts between large-scale climate anomalies and extreme temperature events provide some scientific basis and ideas for using large-scale climate anomalies to estimate the occurrence of regional extreme temperature events. The future work will focus on the prediction of extreme climate events using multiple global climate anomalies.

Abstract. *Serriphidium quettense* of the Asteraceae family is endemic to Balochistan, Pakistan. It has been used in traditional medicine for treating gastrointestinal diseases; while also having germicidal and antibacterial properties. However, no molecular and chemical characterization was demarcated earlier. Thus this study aimed to depict the genetic variability in two mountainous populations by molecular markers. Genetic variability assessment was carried out by polymorphic bands analysis to generate a dendrogram based on Sequential Agglomerative Hierarchical and Non-overlapping (SAHN) algorithm by Unweighted Pair Group Method of Arithmetic (UPGMA) means by using Numerical Taxonomy and Multivariate Analysis System (NTSYS) Pc version 2.01 for Cluster analysis. Chemical characterization was done by evaluating Total Phenolic Content (TPC) and flavonoids. A total of 68 amplified loci with 30 polymorphic were found with an average of 11.3 and 45% polymorphism. Cluster dendrogram based on similarity coefficient ranged from 0.285 to 0.785. Chemical vaiation was assesed by Agglomerative Hierarchical Clustering (AHC) based on dissimilarity matrix as indicated by two main clusters. Cluster 1 was represented by two sub clusters exhibited more chemical variation with in Zargoon population. Overall results obtained exhibited the diverse pattern of genetic and chemical variation. In conclusion, molecular marker profiling together with phytochemical variation of total phenolic and flavonoid content in all accessions of *S. quettense* and impact of ecological diversity on genetic and chemical variation can be used as base line study. Furthermore, implementation of conservation strategies of this endemic medicinal plant is highly recommended.
Keywords: *cluster analysis, agglomerative hierarchical clustering, morphological, chemical and genetic characterization*

Introduction

S. quettense (Podlech) Ling, Bull. of Asteraceae is an important medicinal plant with different medicinal and ornamental uses. Locally it is known as Jir in Brahvi and Terkhasperah in Pashtu. This species is endemic to Balochistan and utilized abundantly by local communities and grazed by livestock. The genus *Seriphidium* is a moderate-sized genus comprising of 135 species, distributed in Europe, and temperate Asia, a few species in N. America. Ethno medicinally used for various digestive problems (Anon, 2003; Durrani et al., 2003) also exhibited significant antibacterial activities (Kakar et al. 2012). This shrub provides forage to small ruminants when other range species produce limited dry matter particularly under drought conditions. Likewise, this shrub provides many benefits to humans and animals including feed for livestock and wildlife, erosion control and industrial products. High density of survived seedlings of *S. quettense* was found under plant canopies. Maximum established

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24132423

seedlings were observed in the vicinity of adult conspecific plants. High survival rate of *S. quettense* may be due to low autumn precipitation that probably strengthen the seedlings and enable them to survive in winter season (Gul et al., 2007). Morphological markers (similar to leaf shape, plant height, color etc.) are one of the earliest markers utilized in the calculation of genetic variation. Still they are not abundantly unique and informational for the reason that the several chromosome character in the distinctive environments reasons extensive fluctuation of phenotypic qualities in individuals (Shinwari, 2011). Genetic marker is the arrangement of gene or DNA through recognized vicinity upon chromosomes and related to a unique gene or character; it may be defined as a version that can appear because of evolution or alternation of nucleotide in the genomic arrangement that may be discovered (Srivatsava and Nidhi, 2009). Molecular marker based on DNA is helping in development of beneficial plant species. DNA markers are over dependable since the phylogenetic data being exclusive and independent of age for every species, physiologic surroundings and environmental aspect (Kalpana et al., 2004). Based on PCR mostly molecular indicators RAPD is usually a conventional approach in the distinct floras (Mahmood et al., 2011; Kayani et al., 2011). PCR approach is probably the most competitive accessible DNA built techniques used for recording dissimilarities among cultivars inside species (Lakshmikumaran and Bhatia, 1998). Random amplified polymorphic DNA (RAPD) and Inter Simple Sequence Repeat (ISSR) markers were used as combined marker system for genetic variability of wild taxa (Saeed et al., 2017).

In this view, the present study was conducted to assess the genetic variability in two mountainous populations of *S. quettense* from Quetta valley Balochistan, Pakistan represented by six accessions through morphological, molecular and phytochemical profiling.

Materials and Methods

Site Selection

Two mountainous ranges of Quetta were selected for plant collection Zarghoon mountain range (3,578 masl) of high hills, steep slopes and narrow valleys and Hazarganji Chiltan National Park mountain range from 1600-3300 m asl (*Figure 1* and *Table 1*).

S. No.	Sampling sites	Site Code	Latitude (N)	Longitude (E)	Elevation (m)
Site 1	Zarghoon (ZR)	B.1	30.21	67.12	2200
		B.2	31.05	67.18	2830
		B.3	31.22	68.01	3200
Site 2	Hazarganji (HG)	C.1	30.21	66.54	1700
		C.2	30.07	65.55	2100
		C.3	30.15	66.07	2600

Plant Material

Plants were sampled during (2012-2014) from six different locations from two mountainous ranges and identified. Five replicate samples were collected from each sampling site. The voucher specimens were submitted to herbarium of Botany department, University of Balochistan Quetta for future references. Fresh and young leaves were collected and stored at ultra-low freezer at NIGAB, NARC Islamabad.

DNA Extraction and Purification

Total genomic DNA was extracted from young and fresh leaves samples of selected plants by CTAB (Cetyl Trimethyl Ammonium Bromide) method as described by Doyle and Doyle (1987) with few modifications (Saeed et al., 2015). The whole procedures including modifications are as follows:

Two to three leaves of plant material were grinded with the help of pestle and mortar, by adding 1 ml of preheated (65ºC) 2x CTAB buffer (100 mM Tris HCl (pH 8.0), 20 m Methylene Diamine Tetra Acetic acid (EDTA) with pH 8.0, 1.4 M sodium chloride (NaCl) and 1.5% mercaptoethanol. The homogenized leaf tissues were transferred to 1.5 ml eppendorf tubes and incubated at 65ºC for half an hour. An equal volume of chloroform/ isoamyl alcohol was added and the tubes were inverted gently 5–10 times, followed by centrifugation at 10,000 rpm for 10 min. After centrifugation, supernatant was transferred to a new eppendorf tube. Phenol is prepared and used as Phenol:Chloroform :Iso-amyalcohol (P:C:I) (25:24:1,v/v) to the samples to deprotenized the mixture double washed with Chloroform:Isoamyalcohol (C:I) (24:1, v/v). DNA was precipitated by adding an equal volume of 100% cold isopropanol. The DNA pellets were washed with 70% cold ethanol. The pellets were air dried and resuspended in the mixture of 40–50 µl 0.1x TE buffer. RNase were incubated at 37ºC for 30 min to remove RNA contamination and purified DNA samples were stored at -20ºC for further use. The quality of DNA was checked on a 1% agarose gel prepared in 0.5x TAE (Tris–acetate-EDTA) buffer. 1% Agarose gel stained with ethidium bromide was used to observe purified DNA along with DNA standard (50, 100 ng conc.) at 100 to 120 V for 35 min. The estimation of DNA concentration in a given samples was further checked on Biospec-Nano (230v) at ratio of 260/280 nm and values were recorded. The DNA was diluted by adding 5 µl DNA to 95 µl ddH_2O for downstream processes.

Molecular Markers Selection

For the first time for *S.quettense*10-mer RAPD (Operon USA) and 18-mer ISSR were purchased from gene link USA (*Tables 2* and *3*).

PCR Reaction

The PCR reaction for amplification was carried out in total 20 µl volume. The PCR master mix was prepared that containing, 3 mM $MgCl_2$, 1X PCR buffer, 0.2 mM dNTPs mix, 20 pmol primers, 0.01% gelatin, 1U/rxn Dream *Taq* DNA polymerase and 25 ng DNA template DNA. PCR amplification was performed using Applied Biosystems 96 well (USA), thermal cycler. For RAPD primers, PCR was programmed as mentioned below in table with initial denaturation at 94ºC for 3 min and then 36 cycles with denaturation at 94ºC for 1 min, annealing temperature at 36ºC for 1 min, extension step at 72ºC for 2 minutes and final extension for 5 minutes at 72ºC. For ISSR primers, PCR was programmed as; initial denaturation at 94ºC for 3 min and then 40 cycles with denaturation at 94ºC for 1 min, annealing temperature 56ºC for 1 min, extension step at 72ºC for 2 minutes followed by an additional final extension for 5 minutes at 72ºC (Abbas et al., 2015). Then amplified products were checked by electrophoresis in 1.8% agarose gels containing ethidium bromide (0.5µg / ml) in 1X TAE buffer. And product

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24132423

was visualized by Gel documentation system under UV light and the size of markers were estimated by comparing to the standard ladder (100 bp BIORON 0.2 mg/ml) in the gel.

Phytochemical Variation of PSMs

Flavonoids

For flavonoids estimation, method described by Ordonez et al. (2006) was used. Take 0.5 ml sample, equal volume of 2% $AlCl_3$ ethanol solution was added and incubated at room temperature for 1 h. A yellow color indicated the presence of flavonoids. After 1 h, the absorbance was measured at 420 nm with the help of spectrophotometer. Total flavonoids contents was calculated as quercetin (mg/g) equivalent equation ($Y=0.0255x$, $R^2=0.9812$) where x is the absorbance and Y is the quercetin equivalent.

Total Phenolic Content (TPC)

Total Phenolic Contents (TPC) was measured by the method of Slinkard and Singleton (1977). An aliquot of the extract was mixed with 5 ml Folin–Ciocalteu reagent (FCR) reagent (previously diluted with water 1:10 v/v) and 4 ml of sodium carbonate (7%). The tubes were vortex for 15 seconds and were allowed to stand for 30 minutes at 40ºC for color development. Absorbance was then measured at 765 nm. Total phenolic contents were expressed as mg/g tannic acid equivalent equation ($Y=0.1216x$, $R^2=0.9365$) where x is the absorbance and Y is the quercetin equivalent.

Statistical Analysis

The amplified bands were scored as 1 (present) and 0 (absent). RAPD and ISSR data were clustered and dendrograms based on similarity matrices were calculated by using Sequential Agglomerative Hierarchical and Non-overlapping (SAHN) algorithm by "Unweighted Pair Group Method with Arithmetic Mean" (UPGMA) through Numerical Taxonomy System (NTSYS) pc 2.10j (Rohlf, 1998). Plant secondary metabolites (PSMs) were analyzed statistically by using XLSTAT version (2007). Clustering were also generated based on dissimilarity matrices by using Agglomerative Hierarchical Clustering (AHC). Data were statistically studied by "Analysis of Variance" (ANOVA) differences in Phytochemical TPC and Flavonoids Significance level ($P<0.05$, $P<0.01$ and $P<0.001$) was generated among the samples of different study sites by one way ANOVA.

Results and Discussion

This is the first comprehensive report of this endemic species *S. quettense* on morphological, chemical and molecular characterization from two mountainous regions of Quetta, Balochistan.

Morphological Diversity

Morphologically *S. quettense* is a complex species difficult to distinguish from the genus Artemisia life form is Perennial. Height of this shrub may range from 30-40 cm. Habit of shrub is woody below and upright branches are herbaceous aromatic. Stem

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24132423

color vary from green to grayish green covered with densely whitish hair sometimes lack hair. Surface also varies from smooth to finely sulcate. Leaves are punctate-glandular, covered by greyish green to whitish hair. Leaf lamina is orbiculate. Upper leaves are sessile. Middle stem leaves are similar to lower but auriculate. Inflorescence based on panicles of 3-4 cm. Capitula numerous, homogamous, sessile, erect. Phyllaries green. Corolla reddish tinged to yellow. Cypsela are 0.8 mm long mostly brown in colour (*Table 4*). Present study revealed significant correlation of altitude and morphology of plants. That may be due to the differences of temperature, light intensity, change in soil properties, wind intensity or change in humidity. Earlier reported findings suggest the possibility of adaptation and variation in morphology of the plants due to change in any situations (Hovanden and Schoor, 2003). Plants can also change their morphological characters in harsh climate or weather. They were also capable to alter their characteristics in response to any biotic factors (Stenstrom et al., 2002). Earlier results revealed reduced size of *Mimulis primuloide* along low altitude that may be due to a higher competition at low altitude. Findings also explored low temperature at high-altitude resulted reduced plant size while increased size at intermediate altitude. Similarly, higher altitude decrease in growth of buds, shorter leaves length and less production of leaves (Tiwari et al., 2013).

Table 4. *Morphological Characteristics of S. quettense from Zarghoon and Hazraganji*

Sites	Stem colour	Stem surface	Shoot length	Leaf colour	Middle leaf length	Leaf lamina	Inflorescence
B.1	Green	Finely sulcate	25 cm	Green	3 cm	Orbiculate, uper sesile	Many Capitula.
B.2	Greish green	Slightly sulcate	26 cm	Green	2.5 cm	Orbiculate, uper sesile	Many sessile
B.3	Green	Slightly sulcate	30 cm	Green	2.9 cm	Orbiculate, uper sesile	Many Capitula.
C.1	Grey	Finely sulcate	28 cm	Silver green	3 cm	Orbiculate, uper sesile	Many sessile
C.2	Greish green	Smooth	27 cm	Green	3 cm	Orbiculate, uper sesile	Many sessile
C.3	Light green	Sulcate	28 cm	Silver green	2 cm	Orbiculate, to auriolat	Many Capitula.

Genetic Diversity

This is the first comprehensive report on molecular characterization and impact of ecosystem diversity on genetic diversity and chemical variation of *S. quettense*. DNA isolation was carried out without using Liquid Nitrogen. A modified protocol of Doyle and Doyle (1987) was used to extract DNA. This protocol gave a DNA with a sufficient quality to PCR reaction. This plant is also rich in polyphenolic compounds. Out of four tested ISSR and ten-mer RAPD primers on six accessions of two *S. quettense* populations, 2 ISSR and four RAPD primers exhibited polymorphic bands. (*Table 5* shows the banding pattern attained from specific primers). Combined ISSR and RAPD data revealed that total 68 loci are amplified and 30 of them were polymorphic with (44% polymorphism). Band size for ISSR ranged from 300 to 1500 bp and RAPD primers ranged from 150 to 1000 bp with an average of 11.3 bands per primer (*Figure 2*). Genetic similarity matrix was produced on the basis of combined ISSR and RAPD markers using genetic similarity coefficient. Results revealed that genetic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24132423

similarity value ranged from 0.285 to 0.785 between populations B.3 and B2. Characterized the closely related population. Mean genetic similarity also calculated as 0.53 the highest degree of genetic similarity occurred between B3 and B2 0.785 of ZR populations depicted low genetic variability within population. In contrast, lowest genetic similarity coefficient of 0.285 was found between B2 (ZR) and C3 (HG) populations, indicating high genetic variability between two mountainous sites. Overall the study revealed that in *S. quettense* genetic variability is 53% among all comparables (*Table 6*). Cluster analysis exhibited the UPGMA generated dendrogram by six accessions from two populations (*Figure 3*) showed exactly two clusters comprising of B2 B3 closely related with in ZR range and C3 cluster HG population further divided into C3, C1,and C2 clusters whereas B1 (ZR) accession also clustered with C2 indicated a different variation pattern. Morphologically *S. quettense* is a complex species difficult to distinguish from the genus Artemisia. Previously Nazar and Mahmood (2011) reported 68% polymorphism in some species of Artemisia from Rawalakot, Pakistan. Similar type of study was carried out by Hasan et al. (2009) using RAPD markers for evaluating genetic diversity of *A. capillaris* between two populations and has reported low genetic variability within the population. Whereas in present project 44% polymorphism is observed in *S. quettense*, representing less genetic diversity in isolated populations. This may also be because of over exploitation, uprooting of this significant endemic taxon due to its medicinal value and considered as a good source of fodder for livestock. Additionally, in the vicinity of the study area local communities depend mainly on many wild shrubs including *S. quettense* as a source of fuel for cooking and other purposes.

Chemical Variation

The results of Chemical variation estimated between and within population. TPC ranged from 42 mg/g to 47 mg/g within population B (Zarghoon) and 48 mg/g to 51 within population C (Hazarganji) Among the population B and C it varies from 42 to 51 mg/g general linear model ANOVA indicated that the significante diffrence P=0.03 at significant level P<0.05 (*Table 7, Figure 4*). Flavonoids also varies within and among the populations it ranges from 110 mg/g to 113 mg/g within population B (Zarghoon) and 92 to 96 mg/g within population C (Hazarganji). Among the populations it ranges from 92 to 113 mg/g ANOVA shows it is highly significant P=0.000 at significant level P<0.001 (*Table 8*). Chemical vaiation is assesed by Agglomerativ hierarchical clustering (AHC) based on dissimilarity matrix indicated two main clusters. Cluster 1 represented by two sub clusters exhibited more chemical variation with in Zargoon population (*Figure 5*).

Geographical location is the major element that may causes differences in natural climatic condition. Earlier reported research (Malencic et al., 2007) explains with the recorded climatic data that the agricultural practices of various geographical zones are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24132423

incorporating by seasonal and climatic variation. Geographical locations also have an impact on phenolic contents. The phenolic contents are also under the impact of biotic and abiotic stresses. Higher temperature inhibited the expression of flavonoid pathway genes and resulted in lower phenolic accumulation (Yamane et al., 2006; Cohen et al., 2008, 2012). The findings of this project demarcated the Total Phenolic Content (TPC) and flavonoids variation maximum among population supported by similar results that high diversity in quantities of chemical compounds was found among populations (Bottin et al., 2007). On the other hand, the mechanism behind chemical variations is still need to be studied within and among species (Pichersky and Gang, 2000). There are other factors, in addition to genetic and environmental factors that affect the chemical diversity and need to be explored (Kumar et al., 2009). Therefore, future detailed greenhouse studies are suggested to assess correlations between genetic and chemical diversities.

Conclusion

Based on our findings, it was concluded that there is an impact of ecological consequences on morphological, genetic diversity and phytochemical composition of *S. quettense*. Due to fragmented habitat and anthropogenic effects, diversity within population found to be less than between populations. Though semi-conserved and conserved regions of Zarghoon range and Hazarganji Chiltan National park still retained genetic diversity within populations, however, sustainable management plans are to be implemented. It has also been concluded that the assessment and conservation of genetic diversity through molecular markers is essential that could be used as a key to conserve genetic variability and assess environmental changes on allelic frequency. Furthermore, implementation of conservation strategies for such an important wild endemic taxa is highly recommended.

Abstract. The *Prangos platychlaena* Boiss. a wild plant belonging to the *Apiaceae* family, is a native plant of Kurdistan-Iraq. The roots, leaves, stem and flowers of the plant were collected in the Halgurd mountain of the Kurdistan region of Iraq, and extracted by petroleum ether, ethanol and water to obtain the crude extracts. Our results showed that the plant contains different phytochemicals that are distributed unequally in different parts. The chromatography technique was used for the isolation and purification of three coumarins (5,8-dimethoxy psoralen, 5-methoxy psoralen and 8-methoxy psoralen) from the parts of the flower, all compounds are new among the Prangos species. The extracts of different plant parts and isolated compounds showed anti-oxidant and anti-microbial activities against pathogenic bacteria and yeasts. These findings suggested that this plant, specially their leaves and flowers can be used for the treatment of some diseases in the future.
Keywords: *antioxidant, Erbil, bacteria, yeast, psoralen*

Introduction

Kurdistan region of Iraq is well known for the diversity of wild plants and their natural products, which have been used for a long time by its habitants as traditional medicine, fodder and for other purposes (Hamad et al., 2017). The current task is to identify the chemical compounds of the plant, facilitating its use in new medicines and may be assumed as therapies for treating many diseases with few side effects (Moradi et al., 2016). *Apiaceae* family in this aspect is regarded as one of the most important families, with its different plant species. The genus of Prangos belongs to the family of *Apiaceae*, having thirty species distributed from the Mediterranean to central Asia, seven species of them which are distributed in the Kurdistan region of Iraq, which are *P. platychlaena Boiss., P. ferulacea* (L.), *P. uloptera* DC., *P. asperula* Boiss., *P. pabularia* Lindl., *P. peucedanifolia* Fenz, and *P. carymbosa* Boiss. (Ghazanfar and Edmondson, 2013). *Prangos platychlaena* Boiss. is a perennial plant, length can reach up to 1-1.5 m. This plant is found naturally growing in the mountain of Kurdistan region, it contains

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24252443

different quantities of phytochemical compounds that have important roles in the biological activities and medicinal values of this plant.

Terpenoids in the plant may contribute against the microbial activity (Irfan et al., 2014), the alkaloid used to fight the oral intoxication (Matsuura and Fett-Neto, 2015), phenol compounds are considerably antimicrobial and the sources of antioxidants properties (Mariem et al., 2014) flavonoides and saponin compounds participate in antiviral, anti-inflammation, antioxidation and antimicrobial activities (Juca et al., 2018) (Desai et al., 2009) and tannines polyphenolic compounds are able to reduce the number of worm in the digestive tract of goat or sheep and also have great roles in the other biological activities (Wina et al., 2010). Based on the available literature the root, leaves, stem and flowers of *P. platychlaena* Bioss. has not been subjected to any investigation of this type. This is the first research performed on this species. As part of this study on the chemical constituents and their bioactivity of a different plant part of *P. platychlaena Boiss*. Thus, the work will concentrate on the chemical constituents, antioxidant and antimicrobial activities of the different plant parts.

Materials and methods

Plant collection

The different plant parts of *P. platychlaena* Boiss. were collected during June-July 2017 from the Halgurd mountain in the Kurdistan region of Iraq and shown in *Figure 1,* at the altitude of 2170 m, Dr. Abdulah Shukur, a plant taxonomist at the department of biology, College of Education/Salahaddin University, was helping for the identification of this plant.

Figure 1. *The whole plant of P. platychlaena Boiss.*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24252443

Maceration extraction

The different plant parts of the *P. platychlaena* Boiss. were collected, cleaned and shed dried at room temperature near 38 °C to constant weight and ground by grinders slowly. Dry powder of each plant part was extracted by using a solvent, with increasing polarity in the order of petroleum ether, ethanol and distilled water for three days at room temperature. The extract solution was concentrated using a rotary evaporator to obtain the crude extract.

Phytochemicals screening in different plant part of Prangos platychlaena Boiss.

Detection of terpenoid

In the test tube, a 5 ml stock solution of extract was mixed with 2 ml chloroform followed by 2 ml concentrated H_2SO_4. A reddish brown coloration has suggested the presence of terpenoids (Mujeeb et al., 2014).

Test for alkaloid

To 10 ml of the extract solution, 0.4 ml of HCl (1%) was added to a solution, followed by 6 drops of Dragendroff reagent, the brownish-red precipitate indicated the presence of alkaloids (Mujeeb et al., 2014).

Phenol detection test

Lead acetate test: Two drops of lead acetate solution (10%) was added to 2 ml of plant extract solution. The formation of a bulky white precipitate showed the presence of phenolic compounds (Singh and Bag, 2013).

Detection of flavonoid (Alkaline reagent)

In this test, two drops of diluted NaOH (10%) solution were added to the stock solution of the plant (2 ml), an intense yellow coloration showed the presence of flavonoid compounds (Hossain et al., 2013).

Detection of saponin

In this test, 10 ml of the plant extraction solution was taken in the test tube. It was shaken vigorously by hand for 2 min, the formation of stable foam indicated the presence of saponins (Mandal et al., 2013).

Tannin detection test

Two drops of $FeCl_3$ (1%) were added to the plant extract solution, the blue-black or blue- green coloration appeared as an indicator for the presence of tannin (Bankole et al., 2016)**.**

Isolation and identification of compounds in P. platychlaena Boiss.

General procedure

Normal extraction technique was applied to the dried powder of flower *P. platychlaena Boiss.* in the laboratory of the Chemistry Department of University Technology of Malaysia. Vacuum liquid chromatography (VLC) was performed using

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24252443

silica gel 60 (230-400 mesh), and gravity column chromatography (CC) was carried out using Merck silica gel 60(70-230 mesh). Silica gel aluminum sheets (Merck Kieselgel 60 F254,0.20 mm) were used for Thin layer chromatography (TLC) analysis of crude extract, fraction and isolation of pure compounds. Spots on TLC were observed under UV light at 254 nm and 365 nm, followed by spraying vanillin sulphuric acid reagent and heating at 120 °C on a hot plate for 5 min. Infrared (IR) spectra were measured using the Perkin Elmer series 1600 FT-IR spectrophotometer with a KBr pellet for a solid sample. Melting points were measured using a hot stage Leica Gallen apparatus with a microscope and were uncorrected. Nuclear Magnetic Resonance (NMR) Bruker Advance 400 Spectrometer (400/100 MHZ) was used to measure ^{1}H, ^{13}C and correlation spectroscopy (COSY) spectra by using Deuterated chloroform-d as a solvent. Mass spectral data were obtained using Gas Chromatography (GC) and Bruker Mass Spectroscopy (MS) services at the Department of Chemistry, National University of Singapore, Singapore.

5, 8- Dimethoxy psoralen (Isopimpinellin) (1)

The petroleum ether crude extract of the flower of *P. platychlaena Boiss.* (6.0 g) was subjected to silica gel VLC (285.0 g, column size:14.0 × 11.0 cm), the solvent system: n-hexane, n-hexane –chloroform, chloroform-ethyl acetate, acetone (100%) and methanol (100%) in order of increasing polarity to give 13 fractions, each fraction was subjected to TLC analysis. Finally, the single (colorless) spot showed indicated Isopimpinellin.

5-Methoxy psoralen (2)

The petroleum ether extract was partitionated from ethanol extract (2.85 g) of *P. platychlaena Boiss.* The flower was subjected to silica gel VLC column, eluted with n-hexane: chloroform: ethyl acetate: methanol: acetone in step gradient to give thirteen fractions. The fraction 4, fraction 5 and fraction 7 were selected and mixed for further purification by silica gel column chromatography, the single (colorless) spot showed indicated 5-Methoxy psoralen**.**

8-Methoxy psoralen (3)

The extract of diethyl ether (1.41 g) of *P. platychlaena* Boiss. flower was subjected to silica gel VLC, the solvent system: n-hexane, n-hexane –chloroform, chloroform-ethyl acetate, acetone and methanol in order of increasing polarity to give thirteen fractions. The 2nd fraction was used for further purification by silica gel column chromatography, the single (colorless) spot showed indicated 8-Methoxy psoralen.

Bioactivity of different plant parts of P. platychlaena Boiss.

1. Antioxidant activity (DPPH assay)

The antioxidant activity (A%) of the sample was assayed according to the method described by Giweli et al. (2012). The standard DPPH (2,2-diphenylpicrylhydrazyl) assay was carried out using 96 –well sterile micro plates. DPPH solution (0.04%) in methanol was prepared, the stock solution of the samples was prepared in methanol. 200 µL of the stock solution of sample was added to the first column and the rest of the wells were filled with 100 µL of methanol, next, 100 µL content of the first well was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24252443

transferred into the next well of the same raw of the microplate, this procedure was repeated for the following well of the same row to obtain a serial dilution of extraction. 100 µL DPPH solution was added to all well except for the blank well, while methanol (100 µL) and 100 µL DPPH solution was added to the control well. The plate was shaken for mixing the solution and incubated for 30 min in the dark at room temperature. The absorbance value of each well was measured at a wavelength of 517 nm, using a microplate reader. Ascorbic acid was used as a positive control, the DPPH radical scavenging activity at different concentrations was calculated by the following equation employed by Ahmed et al. (2015).

$$\% A = A_c - A_s / A_c \times 100 \quad \text{(Eq.1)}$$

where, %A is the percentage of antioxidant activity, A_c is the absorbance of the control and A_s is the absorbance of the sample. The lower absorbance of the reaction mixture indicated a higher free radical scavenging activity and the color of the reaction change from violet to yellow color. The IC_{50} value (mg/ml) was the concentration of the sample required to scavenge 50% of the DPPH free radical.

2. Antimicrobial activity of P. platychlaena Boiss.

Microbial strain

The in vitro antimicrobial activities of the extract and pure compound were carried out by using pathogenic bacteria such as *Pseudomonas aeruginosa* ATCC 9027, clinical *Pseudomonas aeruginosa*, *Staphylococcus aureus* ATCC 6538P, and clinical *Staphylococcus aureus*. The clinical pathogen bacteria isolated from humans were obtained from the Media Diagnostic Health Center in Erbil. While pathogenic yeast such as *Candida albicans*, and *Candida parapsilosis* were obtained from the Biology Department, College of Science, University of Salahadden-Erbil, Iraq. The yeasts were isolated from humans and identified by Dr. Hero Muhammed Ismael.

Culture media and activation of microbial strain

The medium of the Sabouraud Dextrose broth and Mueller-Hinton broth were used for the cultivation of fungi and bacteria, respectively. The inocula were prepared by transferring several single colonies of microbes into a sterile broth media and mixed together, then incubated at 37^0 C for overnight. Inoculum of the culture solution was adjusted to the McFarland scale 0.5 and confirmed by spectrophotometrical reading at 580 nm (Ginovyan et al., 2017).

Evaluation of antimicrobial activities

Antimicrobial activities of the extracts and pure compounds were assessed by the Microdilution method according to previous methods (Bacha et al., 2016; Silva et al., 2011), this was used for determining the minimum Inhibitory Concentration (MIC) of the *P. platychlaena* Boiss. The assay was carried out in 96-well sterile micro plates, then, 100 µl of nutrient broth was added to each well of the microplate. The first well was filled with 100 µl of the sample, prepared at a concentration of mg/ml. Next, by transferring 100 µl content from the first well into the next well of the same row of the microplate, after mixing the content of the well, this procedure was repeated for the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24252443

following well of the same row to obtain serial dilution, in this case, the concentration of the sample will decrease. While pure dimethyl sulfoxide and broth media were used as a negative control, whereas Ketoconazol (antifungal) and Ciprofloxacin (antibacterial) were considered as references. For each well a microbial suspension of the working solution was inoculated. The absorbance for each well was measured at 630 nm before incubation time; by using ELISA microplate reader, the microplate was incubated at 37 °C for 24 h for the growth of microbes. The absorbance was re-measured after incubation time to compare with the initial measurement. The MIC was calculated at the break point concentrations by comparing the absorbance before and after incubation time.

Statistical analysis

The antioxidant and antimicrobial activity of *P. platychlaena* Boiss. were statistically analyzed using the Kruskal- Wallis test and Dunn's multiple comparison test by Graph Pad-Prism version 7. All results arranged as mean ± SE for each property and *P* value less than 0.05 considered as statistically significant differences among them.

Result and discussion

According to the available literature, this is the first study on the phytochemical contents and bioactivity of the *P. platychlaena* Boiss.

Phytochemical screenings in different plant part of P. platychlaena Boiss.

Due to the fact that plant extracts usually occur as a combination of various types of phytochemicals and bioactive compounds with different polarities, their separation still remains a big demand for the process of isolation, identification and characterization of active compounds.

Qualitative chemical analysis was conducted by using petroleum ether, ethanol and water extract of roots, leaves, stem and flowers of the *P. platychlaena* Boiss. The data revealed the presence of terpenoids, alkaloids, polyphenols, flavonoids, saponins and tannins as major phytochemical groups and the results designated as (+) for the presence and (-) for absence of phytochemicals (*Table 1*). The results showed the diversity of phytochemical distribution in the *P. platychlaena* Boiss. plant parts.

Isolation and purification of compounds in P. platychlaena Boiss.

The structures of the isolated compounds (5,8 dimethoxy psoralen, 5-Methoxy psoralen and 8-Methoxy psoralen) from flower *P. platychlaena*, were determined by using IR, ^{1}H-NMR, ^{13}C-NMR, COSY, GC and MS spectrum.

Bioactivity of Prangos platychlaena Boiss. extract of different parts

Antioxidant content

Table 2 showed the antioxidant activity of the *P. platychlaena* Boiss. extracts, which were analyzed using the DPPH free radical scavenging method. The total antioxidant activity of the *P. platychlaena* Boiss. extracts increased with an increased concentration of the sample. The low value of IC_{50} shows the high antioxidant content. A significant difference ($P < 0.05$) was noted among the antioxidant activities of the plant parts in different solvents. It has been shown that the IC_{50} of the petroleum ether extract of *P. platychlaena* Boiss. root, leaves, stem and flower were (1.02 ± 0.04, 0.68 ± 0.01, 0.70 ± 0.03 and 0.19 ± 0.01 mg/ml) respectively, and the significant differences were increasing between root and flower parts. It was observed that petroleum ether extract of the flower of *P. platychlaena* Boiss. has higher antioxidant activity than the other parts. The activity effectiveness can be classified as follows: flower > leaves > stem > root. As well as, the IC_{50} of the ethanol extraction for root, leaves, stem and flower were (1.16 ± 0.12, 0.61 ± 0.01, 1.12 ± 0.19 and 0.67 ± 0.01 mg/ml), respectively, and the statistical analysis showed that the significant increasing of the results was present between the root and leaves parts. The data reported that extraction of the leaf parts of *P. platychlaena* Boiss. showed higher antioxidant potential than the other parts, this activity can be classified as: leaves > flowers > stem > root. While, the IC_{50} value of the water extractions of different plant part (root, leaves, stem and flower) were (1.13 ± 0.14, 0.84 ± 0.02, 0.83 ± 0.01, 0.54 ± 0.02 mg/ml), respectively, also the antioxidant values between root and flower parts were significantly increasing. This finding indicated that the flower part has a higher antioxidant potential than the other parts, this activity can be classified as: flowers > stem > leaves > root. These results showed that the plant extracts inhibited the DPPH radical but in different manners, the variation observed among the plant part extracts, may be depending on the plant part and their growth stages, and unequal distribution of the polyphenols and flavonoids which have important roles in antioxidant activities (Sylvie et al., 2014).

Table 2. *Antioxidant content (IC_{50}) of different plant parts of P. platychlaena Boiss.*

Extracts	Plant parts	IC_{50} (mg/g)

Antimicrobial activities of P. platychlaena Boiss.

The antimicrobial activity of the plant extracts was implemented against *Staphylococcus aureus* ATCC 6538P, clinical *Staphylococcus aureus, Pseudomonas aeruginosa* ATCC 9027, clinical *Pseudomonas aeruginosa*, *Candida albicans*, and *Candida parapsilosis* were studied by using the microdilution method and their potency was assessed by the corresponding MIC value, and the results are shown in *Tables 3* and 4. The petroleum ether extracts of *P. platychlaena* Boiss. for leaves showed higher activities against *S. aureus* ATCC 6538P, clinical *S. aureus*, clinical *P. aeruginosa, C. albicans,* and *C. parapsilosis*, with the lowest MIC values of 0.23, 1.16, 1.33, 0.74 and 0.87 mg/ml, respectively, these values were significantly higher than those of other parts of plant.

Table 3. *Antibacterial activities of different plant parts of P. platychlaena Boiss.*

5,8- dimethoxy psoralen			1.33 ± 0.16	2.0 ± 0.5
Ketoconazol			1.33 ± 0.16	2.0 ± 0.5

Values are mean ± SD, Symbol *,**: it means significantly with data carrying the same symbol in the same extracts and in the same pathogen

While, the MIC values of the compound 5,8- dimethoxy psoralen for both strain *S. aureus* were 1.33 and 1.43 mg/ml and for both strains of *P. aeruginosa* were 2.5 and 3.16 mg/ml, respectively, our result disagreed with those findings of Mbah et al. (2010), that concluded the 5,8- dimethoxy psoralen does not have antibacterial activities against pathogen bacteria. As well as, MIC values of the 5,8- dimethoxy psoralen for both *C. albicans* and *C. parapsilosis* were 1.33 and 2.0 mg/ml, respectively. We have not more amount of 5-Methoxy psoralen and 8-Methoxy psoralen for microbial activities. Whereas, the MIC values of Ciprofloxacin for both strains of *S. aureus* were 1.0 and 1.66, and also for both strains of *P. aeruginosa* were 1.0 and 2.33 mg/ml, respectively. While, the MIC values of Ketoconazol for *C. albicans*, and *C. parapsilosis* were 1.33 and 2.0 mg/ml, respectively. Also, when all MIC values of the extraction compared to both Ciprofloxacin and Ketoconazol, showed the extracts of this plant were close or better than antimicrobial references. All data obtained in this work, indicated that the clinical pathogen microbes are more tolerant than standard microbes that might be due to the presence of indigenous compounds resistant against the plant extracts (Mahendra et al., 2016). According to literature have not scientific research about the antimicrobial activities of *P. platychlaena* but the essential oils from the fruits of *P. ferulacea* showed antibacterial activity against *Staphylococus aureus, Eschrechia coli* and *Pseudomonas aeruginosa* (Massumia et al., 2007). Other studies revealed the methanol extract of *P. acaulis* root has potent antibacterial activity against *Streptococcus mutan* (Nosrati et al., 2018). Generally, the variation in antimicrobial activities of *P. platychlaena* Boiss. might be due to the variation in the distributions of phytochemical compounds and the quantity of phytochemicals in each of root, leaves, stem and flowers of this plant. The petroleum ether extraction for the leaves and the flower ethanol extracts of the *P.*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24252443

platychlaena Boiss. showed higher toxicity towards both bacteria and yeasts than extracts of other parts, this may be due to the presences of some compounds detected in our study, such as terpenoid, alkaloid, phenol, flavonoid, saponin and tannin, while other parts have less antimicrobial activities that may be due to the containing of less amount of the phytochemicals. The pure compound 5,8- dimethoxy psoralen, was an active compound isolated from *P. platychlaena* Boiss. having potential activity to inhibit the growth of bacteria and yeast pathogen. The differences in the susceptibility of both bacteria and yeast strains used in this work to the phytochemical compounds, may be attributed to the variation in the penetration rates of the phytochemicals through the cell wall, and cytoplasmic membrane of those organisms, one of the important properties of most compounds is causing the partition of the lipids of cell membrane of microbes and leakage of the cell contents leads to the damage of the intracellular structure of microbes (de Lira Mota et al., 2012) (Murbach Teles Andrade et al., 2013). According to literature have not scientific research about antioxidant activites of this species but in the previous years other studies conducted on other species of the same genus (Çoruh et al., 2007) have shown *Prangos ferulacea* Lindl. extracts have antioxidant properties with IC_{50} value of 0.24 mg/ml. As well as, it has been reported (Ahmed et al., 2011) that the water extracts of *Prangos ferulacea, P. heyniae*, *P. meliocarpoides* var. *meliocarpoides*, and *P. uechtritzii* display low antioxidant activities than the methanol extract of Prangos species. Also, slight antioxidant activity was observed in the fruit of *Prangos ferulacea* (L.) (Cesur et al., 2017).

Conclusion

This is the first study performed on the extract of *Prangos platychlaena* Boiss. The results revealed the presence of terpenoids, alkaloids, polyphenols, flavonoids, saponins and tannins as major phytochemical groups distributed in different plant parts of *P. platychlaena*. As well as, the three compounds (5,8 dimethoxy psoralen, 5-Methoxy psoralen and 8-Methoxy psoralen) were isolated and purified from flowers of *P. platychlaena* Boiss. and recorded for the first time in this species. The extracts and isolated compounds of this plant have shown antioxidant and antimicrobial activities against common bacteria and yeast pathogen. In conclusion, more studies are necessary to isolate and purify the active compounds and to use their antimicrobial, anti-inflammation and anticancer activities and more studies are required on the toxicology and pharmacology of crude extracts of this plant, the safety of isolated compounds should be assessed before clinical progression.

Acknowledgments. The authors thank Dr. Abdullah Shukur from the Biology department, College of Education, University of Salahadden, for helping in the identification of plant species.

Conflict of interests. The authors declare no conflict of interests.

Abstract. The study was aimed to characterize and document the wild plants of Zygophyllaceae in arid and semi-arid regions of Balochistan. The morphology, ecology and molecular characteristics and taxonomic implications of many taxa were subject to analysis. The field survey was carried out during 2017-18 in the diverse elevation zones of Balochistan selected due to the presence of the highest number of Zygophyllaceae in these regions. Morphological and molecular characterization was carried out by using, agglomerative hierarchical clustering and Principal Component Analysis. A total of 17 plants of Zygophyllaceae were documented from Sibi, Mashkaf, Noshki, Naal, Dalbandeen, Punjgur, Hingol National Park, Bella, Uthal and Quetta region. Commonly distributed taxa were *Peganum hermala* and *Tribulus terrestris*. Furthermore, seven species of *Fagonia*, five species of *Tribulus* and four species of *Zygophyllum* were also assessed. The present study documents and contributes detailed significant information of naturally occurring medicinal plants of Zygophyllaceae from diverse remote zones of Balochistan. It also provides a base line for identification of controversial taxa on morphological and molecular basis. Especially the data provided may further be utilized for novel drug development. Furthermore, the ecological distribution may be useful in management of conservation of endangered and endemic taxa.
Keywords: *Fagonia, Tribulus, Zygophyllum, Peganum, arid and semi-arid zones, PCA, AHC*

Introduction

Balochistan is the largest province comprising 44% of the total area of Pakistan. Geographical region comprised of arid to semi-arid structure ranging from cool temperate to coastal tropics. The diverse ecological conditions have an impact on the diversity of flora found. Local communities utilize wild plants as folk medicines in large amount. Selected areas are blessed by botanical diversity and endemism. Diverse taxa of the region include herbs, shrubs, and trees including evergreen Juniper forest. Aromatic, non-aromatic flowering and non-flowering plants contributes in more than sixteen hundred wild plant species. Total of 44 species are endemic to the Balochistan (Saeed et al., 2014).

The Zygophyllaceae consists of diverse habits of wild flora including succulents, herbs, undershrub, shrubs and small trees. The habitat of these plants is predominantly desert or saline areas of temperate and tropical regions around the globe (Beier et al., 2003; Bellstedt et al., 2008). *Tribulus, Fagonia, Zygophyllum* and *Peganum* considered being the main genera. Folk medicinal System is a precious resource, hence utilized as potent safe drugs (Hussain and Sher, 1998). Many members of the family are being used ethno medicinally for centuries in folk medicines. Taxa like *Peganum hermala, Fagonia indica, F. ovalifolia, F. bruguieri, Tribulus terrestris, T. longipetalus* etc traditionally used by local communities to cure fever, cough, inflammation of organs, gonorrhea, obesity, urinary tract infection (UTI) etc.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24452462

(unpublished data). Many medicinal plants extract constituted various types of chemicals, each have a property to control a variety of biological and pharmacological activities such as antimicrobial, anti-parasitic, anti-diabetic, antioxidant, anti-inflammatory and anticholinesterase. These chemicals may have a combined effect in controlling various diseases (Rates, 2001; Houghton et al., 2007).

For proper identification and standardization of crude drugs, accurate anatomical and morphological description is necessary, and this description must take into account all the diagnostic features. The evaluation of crude drug involves a number of methods such as organoleptic, microscopic, chemical, physiological and biological. Organoleptic evaluation includes shape, size, odor, taste, texture, and color of crude drug along with external marking. On the basis of gross morphology, drugs may be grouped as leaves, bark, root, rhizome, and so forth. Microscopic features such as spines, trichomes, spores, and epidermal structures may be examined which are used as diagnostic features in the identification of plant drugs (Fransworth and Soejarto, 1988; Fazal et al., 2013). As the selected plants are medicinally important and utilized in folk medicine system, their authentication is essential on morphological and molecular basis that may be utilized for novel drug discovery as a future prospect.

During the past few decades, the theoretical framework of population genetics and empirical data gathered with the help of molecular genetic methods have been widely used in conservation biology. Given a haploid nature and a low frequency of genetic recombination, molecular markers of organelle DNA have long been used for phylogenetic reconstruction at various taxonomic levels, conservation genetics, and assessing the migratory routes of species (Nite-Kang and Yong, 2014; Yong and Nite-Kang, 2015).

Molecular marker system used to assess genetic variability within and among populations. Several marker systems were being used for genetic diversity analysis. Randomly Amplified Polymorphic DNA (RAPD) markers are appropriate for DNA fingerprinting of unknown sequences and they are rapid and easy to assess, (Kernodle et al., 1993). The Inter Simple Sequence Repeat (ISSR) did not need prior sequence and was less vulnerable (Adams et al., 2003). Universal Rice Primer (URP) markers were first time used by Kang et al. (2002). These are repeated chains that were extracted of genome bank of the rice of local Korea. URP markers with suitable PCR condition, produce high polymorphs. Additionally, it has been proved that these markers are useful tools for genetic analysis in between and within species (Rashmi et al., 2008; Abbas et al., 2015). Combined marker system used to assess genetic diversity within and among the population of different wild plants which were not sequenced earlier (Saeed et al., 2015, 2017).

In this view the present study was designed to provide comprehensive information about the medicinally important and highly controversial taxa of Zygophyllaceae used in folklore from different ecological zones of Balochistan, based on morphological and molecular characterization.

Material and Methods

Study Sites

The field survey was carried out during 2017-18 in various regions viz., Quetta valley, Sibi, Mashkaf, Noshki, Naal, Dalbandeen, Punjgur, Hingol National Park, Bella and Uthal. These areas of Balochistan were selected due to the presence of high number of taxa of Zygophyllaceae (*Figure 1*).

DOI: http://dx.doi.org/10.15666/aeer/1802_24452462

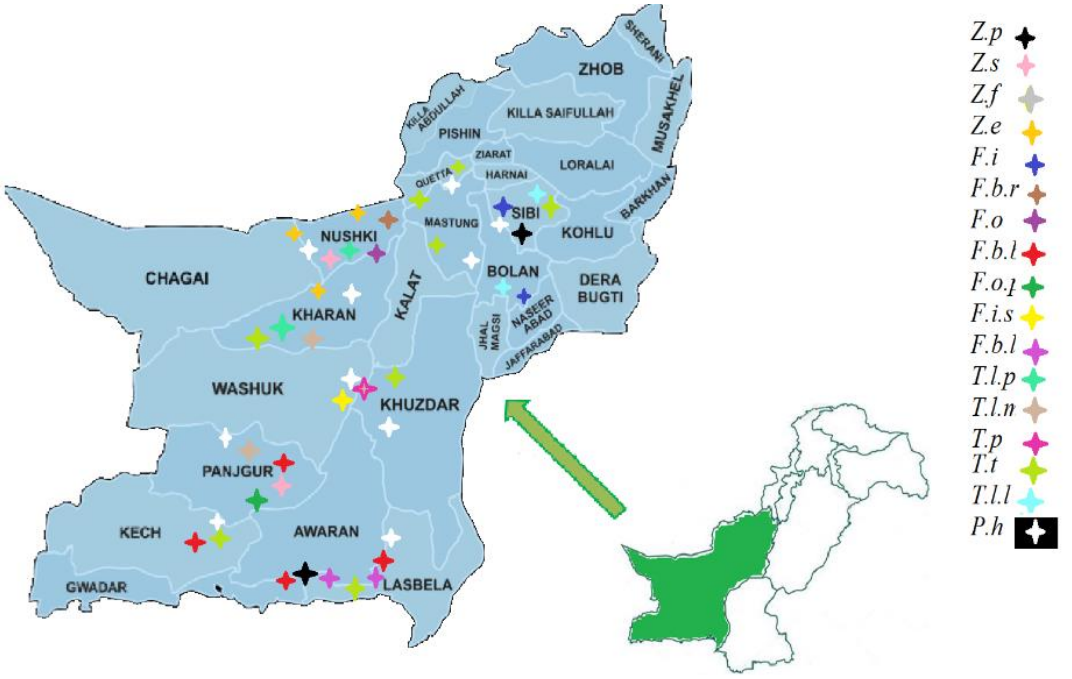

Figure 1. *Map of Balochistan (Pakistan) illustrating the sampling site areas with geographical coordinates*

Morphological Analysis

Total 58 characters were observed during the morphological analysis. Qualitative and Quantitative morphological characters were appraised and subjected to Principal Component Analysis (PCA) and Agglomerative Hierarchical Clustering (AHC).

Molecular Analysis

This study was carried out using three different marker systems namely, RAPD, ISSR and URP's (*Table 1*). Combined markers RAPD, ISSR and URP were used to amplify for cluster analysis.

DNA Extraction

Genomic DNA was isolated by using CTAB (Cetyl Trimethyl Ammonium Bromide) Doyle and Doyle (1987). Quantified on a spectrophotometer at 260 nm and Checked DNA Quality on 0.8% gel by electrophoreses.

PCR Amplification

PCR reaction for amplification was carried out. Total 20 µl volume reaction was prepared. Enzynomics 2X TOPsimple DyeMIX-nTaq, Master Mix was used. PCR mixture contains 5 µl Master Mix (2X), 0.4 µl Primer (5 pmol/ µl), 4 µl DNA template (0.1 ng/µl). PCR amplification was performed using thermal cycler (Applied Biosystems 96 well USA). For RAPD primers, PCR was performed with initial denaturation at 94ºC for 4 min, Denaturation 94ºC for 4 min and then 36 cycles with annealing temperature 33ºC for 1 min, extension step at 72ºC for 2 minutes. An additional extension step for 7 minutes at 72ºC in the final cycle was also added. For

DOI: http://dx.doi.org/10.15666/aeer/1802_24452462

URP primers, cycles increased to 40. ISSR primers performed 40 cycles. The amplified products were checked by electrophoresis in 1.8% agarose gels. Gel stained with ethidium bromide (0.5 µg / ml) in 1X TAE buffer. The product was visualized by Gel documentation under UV light and the size of markers were estimated by comparing to the standard ladder (100 bp BIORON 0.2 mg/ml) in the gel.

Gel Analysis by Software

Then amplified products were checked by electrophoresis in 1.5% agarose gels in 1X TAE buffer. Further gel was stained in ethidium bromide. The product was visualized by Gel documentation system under UV light and the size of markers was estimated by 100-1500 bp DNA ladder (RTU) containing orange G & xylene cyanol FF tracking dyes in the gel. Gel analysis was carried out by using UVI-Soft UVI-Band Map. Similarity coefficients Nie & Li (Dice) were performed by UPGMA. Dendrogram generated based on homology.

Results

In this project seventeen wild species of Zygophyllaceae were reported from diverse and remote ecological zones of Balochistan including endemic taxa (*Figure 2*). Voucher specimen of all collected species was submitted in www.openherbarium.edu. Geographical coordinates of these plants at their existing habitats were recorded and the Phenology (flowering period) of the taxa was also recorded (*Table 2*).

Table 2. *Geographical coordinates, soil type and phenology of selected Taxa of Zygophyllaceae*

Morphological Analyses

Morphological evaluation of 17 taxa of Zygophyllaceae found in study area was carried out by total of fifty-nine morphological characters. Out of which thirty-one were qualitatively measured and twenty-eight were quantitative characters.

Qualitative Analyses

Life cycle

Studied taxa exhibited different life cycles. All the taxa of *Tribulus* were annual except the *T. pentandrus* was biannual. Perennial taxa were *P. hermala*, *Z. fabago, Z. propinquum, Z. eurypterum* and *F. bruguieri* var. *laxa. F. indica* var. *schweinfurthii* and *F. indica* were annual herbs all other taxa of *Fagonia* were Bi-annual.

Plant nature

Plant nature varied in all studied species of Zygophyllaceae. *T. longipetalus* subsp. *pterophorus* and *T. longipetalus* subsp. *macropterus* were prostrate-erect. *T. longipetalus* subsp. *longipetalus, T. terrestris, T. pentandrus, F. bruguieri* var. *rechingeri, F. bruguieri* var. *bruguieri* were prostrate in nature. *Z. simplex* was the only taxa having sub-erect plant nature. *F. ovalifolia* subsp. *pakistanica* was unique in nature i.e. Procumbent. *F. indica* var. *schweinfurthii* was ascending in nature. *F. indica* was decumbent and *F. olivieri* was sub-prostrate. All remaining were erect in nature.

Plant surface

Plant surface of *T. longipetalus* subsp. *macropterus* and *T. pentandrus* were densely hairy while *T. longipetalus* subsp. *longipetalus, T. terrestris* and *Z. propinquum* were sparsely hairy. *F. bruguieri* var. *laxa* was sparsely glandular whereas *F. indica* var. *schweinfurthii, F. olivieri* and *F. bruguieri* var *bruguieri* were glandular. Other taxa had glabrous plant surface.

Hair shapes

Hair shapes of *T. longipetalus* subsp. *pterophorus, T. longipetalus* subsp. *macropterus*, *T. longipetalus* subsp. *longipetalus*, *T. terrestris*, *T. pentandrus, Z. propinquum* and *F. ovalifolia* subsp. *pakistanica* were glandular.

Trichome stalk

In most of the taxa trichome stalk were absent while present only in all genera of *Tribulus.*

Stem nature

Nature of the stem varies from woody to herbaceous in selected taxa of Zygophyllaceae. *Z. eurypterum* was characterized in woody stem nature. All genera of *Tribulus, P. hermala* and *Z. simplex* were having herbaceous stem. The stem in all genera of *Fagonia* were woody at the base.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24452462

Stem outline shape

Significant variations were found in stem outline shape of different taxa of Zygophyllaceae. *T. terrestris, T. pentandrus, P. hermala* and *Z. propinquum* were terete outline shape of stem. *Z. fabago*, *Z. simplex* and *Z. eurypterum* were striate. *F. indica* var. *schweinfurthii* and *F. indica* were terete and striate, while all other were quadrangular.

Stipule

Stipule was present in selected taxa of Zygophyllacae. Nature of stipule varies within the selected taxa. Stipule of *T. pentandrus* was bristles while other four genera of *Tribulus* and *Z. eurypterum* were foliaceous. Stipule nature of *P. hermala* was also bristles. *Z. fabago, Z. propinquum* and *Z. simplex* stipule were scarious and all the *Fagonia* species have spinescent stipule nature.

Leaves/leaflets arrangement

Leaves/leaflets arrangements were alternate in *T. longipetalus* subsp. *pterophorus* and *F. indica* var. *schweinfurthii,* whereas all other taxa were having opposite Leaves/leaflets arrangements.

Leaf-blade\leaflets

Leaf-blade\leaflets of all the studied taxa of *Tribulus* were in paired while other taxa leaves were not paired.

Leaf structure

Variation was found in leaf structure of studied taxa. Leave of *T. longipetalus* subsp. *pterophorus* was paripinnat abruptly. Leave structure of *T. longipetalus* subsp. *macropterus, T. longipetalus* subsp. *longipetalus, T. terrestris, T. pentandrus, Z. propinquum* and *Z. fabago* were bifoliate. *P. hermala and Z. eurypterum* leaves were found simple. *Z. simplex* leaves succulent. *F. bruguieri* var. *laxa* leaves was trifoliate below and unifoliate above. All other taxa of *Fagonia* were had unifoliate leaf structure.

Leaf petiole

Leaf petiole showed variation among all selected taxa. *Z. fabago, Z. propinquum, Z. eurypterum, F. ovalifolia* subsp. *pakistanica, F. bruguieri* var. *bruguieri, F. bruguieri* var. *laxa, F. indica* var. *schweinfurthii, F. indica* and *F. olivieri* were petiolate. *T. terrestris* was sub-sessile while other taxa were sessile.

Leaf\leaflet shape

Leaf\leaflet shape also showed variation in all studied taxa. *T. terrestris* had ovate shape. *T. longipetalus* subsp. *pterophorus, T. longipetalus* subsp. *macropterus, T. longipetalus* subsp. *longipetalus, T. pentandrus* and *Z. simplex* shape were oblong. *Z. propinquum* was semi-cylindrical. *P. hermala, F. bruguieri* var. *rechingeri, F. olivieri* and *F. bruguieri* var. *bruguieri* were found in lanceolate shape. *F. indica* was ovoid, *F. indica* var. *schweinfurthii* was trifoliate, *F. bruguieri* var. *laxa* was linear lanceolate, and *F. ovalifolia* subsp. *pakistanica* was oblanceolate shape leaflets.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24452462

Leaf apex

Leaf apex of *P. hermala, F. indica var schweinfurthii* and all taxa of *Tribulus* were acute. *Z. fabago* was oval apex. *Z. propinquum* and *Z. simplex* had obtuse apex. *Z. eurypterum* was found with spathulate, *F. ovalifolia* sub sp *pakistanica* was minutely mucronate. *F. bruguieri* var. *rechingeri, F. bruguieri* var. *bruguieri, F. bruguieri* var. *laxa, F. indica* and *F. olivi*eri had mucronate apex.

Sepal shape

Shape of sepal of *F. bruguieri* var. *rechingeri, F. bruguieri* var. *laxa* and all species of *Tribulus* were lanceolate. *P. hermala* had linear sepal shape. *Z. simplex* was elliptic-oblong, *F. olivieri* was oblong. Whereas ovate sepal shape were found in *F. indica, F. indica* var. *schweinfurthii*, *F. bruguieri* var. *bruguieri*, *F. ovalifolia* subsp. *pakistanica*, *Z. propinquum, Z. fabago* and *Z. eurypterum.*

Sepal apex

Sepal apex was obtuse in *Z. fabago* and *Z. propinquum,* retuse in *Z. eurypterum* and acute in all remaining taxa.

Sepal surface

Sepal surface varies from glabrous to hairy. Sepal surface of *T. longipetalus* subsp. *longipetalus* was sparsely hairy. *F. ovalifolia* subsp. *pakistanica*, *F. indica* and *F. olivieri* had glandular sepal surface. *T. longipetalus* subsp. *pterophorus, T. longipetalous* subsp. *macropterus, T. terrestris, T. pentandrus* and *F. indica* var. *schweinfurthii* were having hairy sepal surface. While all other remaining taxa sepal were having glabrous surface.

Sepal and petal persistence at fruit maturity

Sepal in *T. longipetalus* subsp. *pterophorus*, *T. longipetalus* subsp. *macropterus*, *T. longipetalus* subsp. *longipetalus, T. terrestris¸ T. pentandrus, P. hermala, Z. propinquum, Z. simplex, F. bruguieri* var. *rechingeri, F. bruguieri* var. *laxa* and *F. indica* were persistent at the time of maturity. While in other taxa it was not persistent. Petals in all the studied taxa were not persistence at the time of fruit maturity.

Petal shape

Petal shape varies in these studied taxa. Obovate shape of petal was found in *T. longipetalus* subsp. *pterophorus, T. longipetalus* subsp. *macropterus, T. longipetalus* subsp. *longipetalus, T. terrestris, Z. fabago, Z. eurypterum, F. ovalifolia* subsp. *pakistanica* and *F. indica* var. *schweinfurthii. T. pentandrus* and *P. hermala* were oblong. *Z. propinquum, Z. simplex, F. bruguieri* var. *rechingeri, F. bruguieri* var. *bruguieri, F. bruguieri* var. *laxa, F. indica* and *F. olivieri* were spathulate.

Petal colour

Petal colour of all studied taxa showed variation. Petals of *P. hermala, Z. propinquum* and *Z. simplex* were yellowish white. Petal of *Z. fabago* was yellowish above orange at the base and *Z. eurypterum* was pale white. *F. ovalifolia* subsp. *pakistanica* and *F. bruguieri* var *bruguieri* were light pink in colour. *F. bruguieri* var. *rechingeri* was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24452462

purple, *F. bruguieri* var. *laxa* was pale pink *F. indica* var. *schweinfurthii* pinkish purple and *F. olivieri* was pinkish white. Petals of all species of *Tribulus* were yellow in colour.

Petal apex

Retuse petal apex was found in *Z. fabago.* In *Z. propinquum* it was reported spathulate/margin serrate. *Z. simplex* was having serrate margin apex. The apex of petal *T. longipetalus* subsp. *pterophorus, T. longipetalus* subsp. *macropterus, T. longipetalus* subsp. *longipetalus* and *T. terrestris* were clawed. While in remaining taxa obtuse petal apex were found.

Ovary surface

Ovary surface was hairy in all selected species of *Tribulus* and as well as all selected species of *Fagonia*. While the surface glabrous in *P. hermala* and all selected species of *Zygophyllum*.

Fruit type

Fruit type of *T. longipetalus* subsp. *pterophorus, T. longipetalus* subsp. *macropterus, T. longipetalus* subsp. *longipetalus* and *T. terrestris* were schizocarpic. Fruit of *Z. eurypterum* was capsule oblong-sherical. Loculicidal capsule type of fruits was found in all the other remaining taxa.

Fruit surface

Fruit surface in *P. hermala, Z. fabago, Z. propinquum* and *Z. eurypterum* were glabrous. *Z. simplex* fruit surface was regulose. While all the other studied fruits type surface was Hairy to sparsely hairy.

Fruit shape

Fruit shapes vary in all selected studied taxa of Zygophyllacae. Shape of fruits in all species of *Fagonia* was pyramidate and not winged. *Z. eurypterum* was oblong-spherical and winged. *Z. simplex* fruit shape was oblong and not winged. *Z. propinquum* fruit was oblong pyramidate and not winged. *Z. fabago* was oblong-cylindric and not winged. Fruit shape of *P. hermala* was found trigonous and not winged. *T. terrestris* was also not winged and sub spherical. All other four species were winged and discoid.

Seed shape

Seed shape in all species of *Tribulus* and *P. hermala* were triangular. *Z. eurypterum* seed shape was reniform. *Z. fabago, Z. propinquum* and *Z. simplex* was oblong/compressed. Seed shape of *F. indica* var. *schweinfurthii, F. indica* and *F. olivieri* was broadly oblong. While oblong shape type of seeds were reported in three species of *Fagoina* i.e *F. ovalifolia* subsp. *pakistanica, F. bruguieri* var. *bruguieri* and *F. bruguieri* var. *rechingeri.* However seeds of *F. bruguieri* var. *laxa* were obovoid.

Quantitative Analysis of Morphological Characters

Morphological characterization was also performed on the basis twenty-eight quantitative characters in seventeen species of Zygophyllaceae. Quantitative characters were further subjected to analyses through Principle component analyses (PCA).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24452462

Principle Component Analyses (PCA)

Eigenvalues

Out of 16 principal components (PCs), three viz. PC-1, PC-II, PC-III, PC-IV, PC-V and PC-VI had Eigen values >1 and contributed for 89.41% of total cumulative variability among different species (*Table 3*). The contribution of PC-I towards variability was highest (35.96%), PC-II contributed (15.42%), PC-III showed (13.72%) variability, PC-IV gives (13.28%), PC-V and PC-VI (6.05% and 4.92%) variability, respectively.

Table 3. *Eigenvalues of Principle component analyses*

	F1	F2	F3	F4	F5	F6
Eigenvalue	10.069	4.319	3.843	3.719	1.707	1.379
Variability (%)	35.960	15.424	13.725	13.281	6.095	4.924
Cumulative %	35.960	51.384	65.109	78.390	84.485	89.409

The PC-I showed 17 positive factor loadings (*Figure 3*) for Plant length, Petiole, Flower pedicle, Sepal length, Sepal width, Petal length, Petal width, Stamens number, Filament length, Style number, Style length, Stem internode, leaf length, leaf width, Fruit length, Fruit width, Fruit wings size, Fruit pedicel, Seed length, Seed width. PC-II indicated 15 positive factor loading for stipule width, Leaf-blade\leaflets no, flower pedicle, sepal length, Petal length, Petal width, Sepal No, Stamens number, Style number, Fruit width, Fruit wings size, Mericarp edge no, Fruit pedicel, Seed length. Quantitative characters which contributed 17 positive factor loadings towards PC-III were Plant length, Stipule width, Leaf-blade\leaflets no, Petiole, Sepal width, Petal No, Filament length, Style number, Stem internode, leaf width, Fruit length, Fruit width, Fruit wings size, Mericarp edge no, Number of fruit locules, Seed Length, Seed width. Plant length, Stipule width, Leaf-blade\leaflets no. leaflet petiole size, Petiole size, Sepal length, Petal length, Petal No, Sepal No, Stamens number, Filament length, Style number, Style length, Stem internode, leaf length, leaf width, Mericarp edge no, Number of fruit locules, Fruit pedicel were contributed 20 positive factor loadings towards PC-IV. 19 positive factor loadings towards PC-V were Plant length, Stipule length, Leaf-blade\leaflets no, leaflet petiole size, Petiole size, Flower pedicle, Sepal length, Sepal width, Petal width, Petal No, Sepal No, Filament length, Style length, Stem internode, leaf width, Fruit length, Fruit width, Fruit wings size, Mericarp edge no., and PC-VI included 17 positive factor loadings Plant length, Stipule length, Leaf-blade\leaflets no, leaflet petiole size, Petiole size, Flower pedicle, Sepal length, Petal length, Petal width, Stamens number, Style number, Fruit length, Fruit width, Number of fruit locules, Fruit pedicel, Seed size Length, Seed width.

Cluster Analysis

Clustering of studied taxa based on quantitative characters only is presented in (*Figure 4*). Cluster analysis grouped all taxa into 3 clusters which are further divided as Cluster-I comprised T.l.p, Cluster-II comprised of 15 taxa which are further divided into sub clusters a & b. Cluster a comprised of P.h and Z.s. Cluster b further divided into c & d. Cluster c comprised of Z.e. Cluser d have two more groups e and f. Cluster e comprised of T.t. Z.p. Z.f. T.l.m and T.l.l. while cluster f comprised of all *Fagonia* species. Cluster-III comprised of T.p.

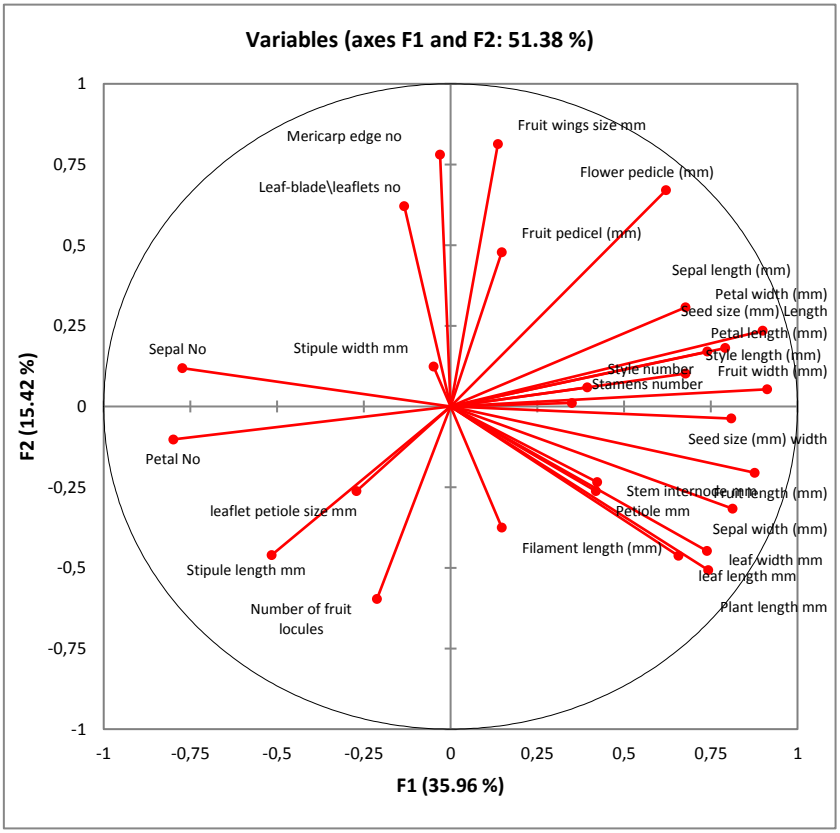

Figure 3. *Correlations chart of 17 taxa of Zygophyllaceae plotted according to the first two principal components, obtained from morphological and quantitative traits*

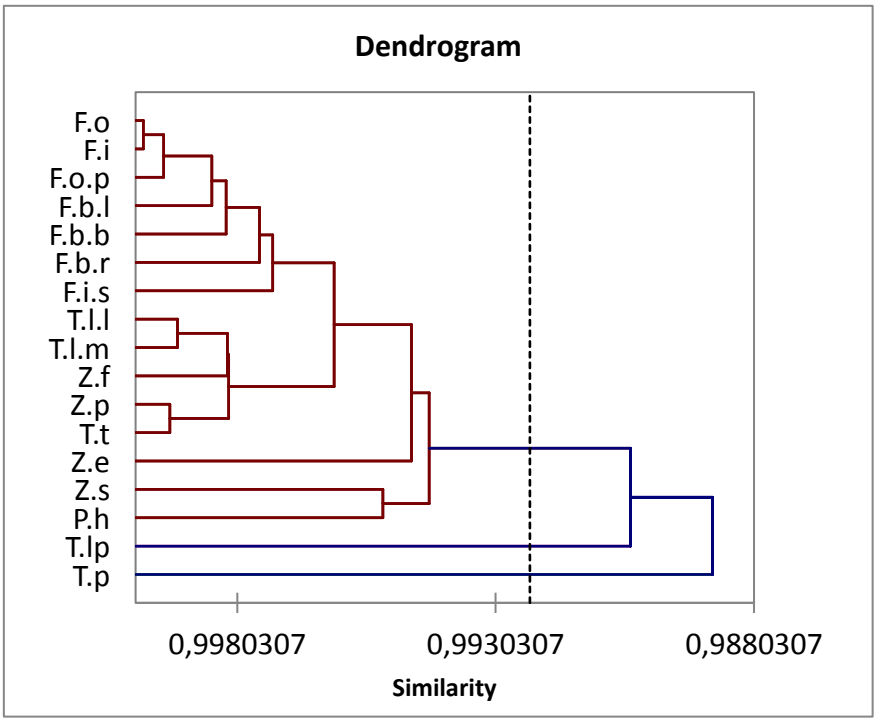

Figure 4. *Tree diagram based on 28 quantitative characters in all selected taxa of Zygophyllaceae*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24452462

Molecular Characterization

Using different molecular markers may target different regions of genome and could help in removing errors for the detection of polymorphism. Out of forty-one tested primers, thirty two RAPD and five ISSR revealed polymorphism, and exhibited reproducible bands among all selected taxa of Zygophyllaceae. The URP's did not give amplification in selected taxa. These taxa were not characterized earlier by different markers combination so this study would give the amended pattern of genetic variation.

Dendrogram based on molecular data grouped all genera into three main clusters A, B and C (*Figure 5*). Cluster A grouped into four sub-clusters a,b,c,d. Cluster a comprised of three species i.e *T. longipetalus* subsp. *longipetalus*, *T. longipetalus* subsp. *pterophorus* and *T. longipetalus* subsp. *macropterus*. Cluster b comprised of four species i.e *P. hermala*, *Z. simplex*, *Z. propinquum* and *Z. fabago*. Cluster c comprised of *F. olivieri*, *F. bruguieri* var. *rechingeri*, *F. bruguieri* var. *bruguieri.* Cluster comprised of *T. terrestris* and *T. pentandrus*. Cluster B having sub-clusters f and e contained *Z. eurypterum*, *F. indica*, and *F. indica* var. *schweinfurthii* while on cluster C *F. bruguieri* var. *laxa* collected from Uthal (Zero point) and Hingol National Park both plants were identified with same species showing interspecific diversity that may be due to change in elevation.

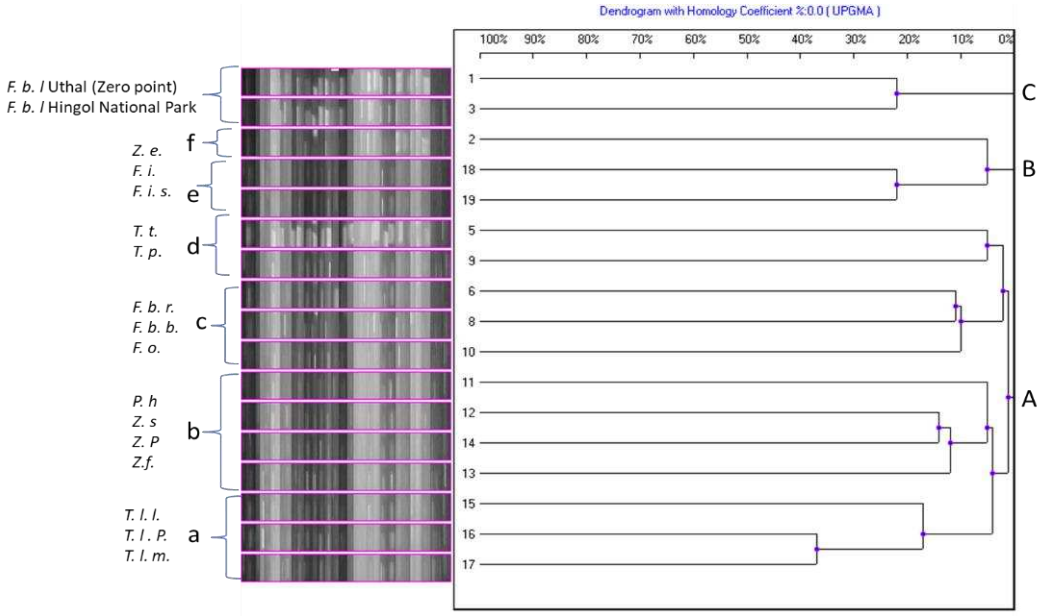

Figure 5. *Cluster analysis UPGMA based on Homology Coefficient among taxa of Zygophyllaceae generated by combined tested markers*

Discussion

Ecological Distribution

The species of Zygophyllaceae are widely distributed in scattered populations usually at diverse ecological zones from low to high elevations in Balochistan Pakistan. Earlier reported by Ghafoor (1974) that the plants are widespread in tropical, subtropical and warm temperate, often in drier areas and represented by 8 genera and 22 species. The present study revealed that *P. hermala* is widely distributed in all studied

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24452462

sites. From high-elevation to low-elevation zones, High elevation includes Quetta, Naal, Noshki, Low elevation includes Uthal, Hingol National Park, Mushkaf, Sibi. Environmental conditions play a key role in determining the distribution and functional distinctiveness of the species occupying a particular region (Ricklefs and Latham, 1992; Noman et al., 2012). Previously, few ethnobotanical and phytochemical studies of Zygophyllaceae were reported from Balochistan by Tareen et al. (2010), Perveen and Qaiser (2008), Zaidi and Crow (2005) and Manzoor et al. (2017). *F. ovalifolia* subsp. *pakistanica* is the Endemic species to Pakistan collected from Panjgur (Ghafoor, 1974). *F. bruguieri* was earlier reported from Johan and Kalat area of Balochistan by Goodman and Ghafoor (1992) whereas in present study three sub.species of *F. bruguieri* i.e. *F. bruguieri* var. *rechingeri* from Noshki sandy Rocks, *F. bruguieri* var. *bruguieri* were collected from Panjgur, *F. bruguieri* var. *laxa* were found from Hingol National Park and Uthal. *F. indica* var. *schweinfurthii* were collected from Naal. *F. indica* were collected from Mushkaf earlier reported in plant biodiversity of Dureji in southern Balochistan Province by Perveen and Qaiser (2008). *F. olivieri* were collected from Noshki, Near Janglat area, *T. terrestris* were collected from Quetta, Mushkaf, Lasbella and Noshki earlier Goodman and Ghafoor (1992) reported from Kalat and Khuzdar. *T. longipetalus* subsp. *pterophorus* were collected from Noshki. *T. longipetalus* subsp. *macropterus* from Panjgur, *T. longipetalus* subsp. *longipetalus* from Sibi and Mushkaf, *T. pentandrus* were collected from Naal area. *Z. fabago* were found from Quetta earlier also reported by Zaidi and Crow (2005) from Quetta. *Z. eurypterum* from Dalbandeen and Noshki Goodman and Ghafoor (1992) earlier reported from Mastung, Naal and Kharan. *Z. simplex* collected from Punjgur, Naal and Noshki. *Z. propinquum* were found in Hingol National Park and Mushkaf earlier work has been done on *Z. propinquum* from Dureji in Southern Balochistan by Perveen and Qaiser (2008). Manzoor et al. (2017) also collected *Z. propinquum* from Hub District Balochistan. It was observed that the studied sites most dominated plants were succulents, often xerophytic and spiny as the area were mostly deserted. The areas have dry and warm climatic conditions, with low rate of precipitations.

Morphological Characterization

Morphological characters play an important role identification and documentation of the taxa. Earlier different studies were conducted explaining morphological identification of different taxa. Pollen morphology of the family has also been examined by Perveen and Qaiser (2006). Sheahan and Cutler (1993) investigated the vegetative anatomy of 37 species in 19 genera of Zygophyllaceae. In present study based on 57 morphological characters were recorded to study the interspecific relationships between taxa present in Balochistan, Pakistan. Plants of Zygophyllaceae reported earlier for its great medicinal importance so the morphological characterization leads towards the validation of taxa used in folk medicines. The results of cluster and principal component analysis revealed that all collected species of *Fagonia* form a well-distinguished group earlier also reported by Kadry (2012). *Fagonia* species indicated the *F.o* and *F.i* closely related and clustered with *F.o.p. F.b.l, F.b.r, F.i.s*. *Tribulus* genus was also reported from the region. Previously El-Hadidi (1975, 1977) classified the species of *Tribulus*. Mohamed (2006) studied seed morphology, proteins and Iso-enzymes in *Tribulus*. Kadry (2012) also characterized different species of *Tribulus*. In present study *T.p* clustered separately. Its closed group was *T.l.p*. while *T.l.l* and *T.l.m* were clusterd together. Its closed group was *T.t.* Van Zyl (2000) presented morphological analysis of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24452462

the genus Zygophyllum in South Africa. Kadry (2012) also characterized different species of Zygophyllum. *Z.p*. grouped with *Z.f, Z.e* grouped separately, may be because of its diverse habit, plant height and woody stem. *Z.s* grouped with *P.h*. In some previous reports, *Peganum* was placed in a distinct family (Takhtajan, 1969; El Hadidi, 1975). However, Takhtajan (1980) and El Hadidi and Fayed (1995) placed it in Zygophyllaceae. Kadry (2012) grouped *Peganum* with species of Zygophyllaceae as in present study. Shamso et al. (2013) concluded *Zygophyllum* and *Fagonia* linked in one group based on many characters.

Molecular Characterization

The molecular analysis confirmed the characterization of different genus of Zygophyllaceae. Earlier characterizations with in different genera of Zygophyllacae have been reported from many regions of the world. Al-Arjany et al. (2014) worked on molecular diversity among three genera of Zygophyllaceae they displayed the genetic relationships between *Zygophyllum*, *Tribulus* and *Fagonia* species. Their work is in agreement with the present work here we also included *Peganum* with these three genera. All species of *Fagonia* has different pattern as they give amplification on very different pattern. To the knowledge of the authors no earlier work has been reported on the characterization of *Fagoina* species. Bakatoushi and Ahmed (2017) represented the genetic diversity in different wild populations of *Peganum* from desert of Egypt. Molecular analysis of present data of *Fagonia* exhibited no amplification in two species by the selected markers that may be due to varying base pair patterns. Similar findings were earlier reported by Al-arjany et al. (2014). Thus these two species need to be studied with additional diverse molecular markers. As the *F. ovalifolia* var. *pakistanica* is the endemic taxa of the region no earlier report has been found. No molecular characterization data on *Peganum* has been reported earlier from the region. Patil et al. (2014) characterized three species of *Tribulus*. Hammad and Qari (2010) worked on twelve populations of *Zygophyllum* and explained the genetic diversity. Wu et al. (2015) characterized different species of Zygophyllaceae. Few reports also explained the molecular characterization of Zygophyllaceae by Godoy-Bürki et al. (2018) and Kadry (2012). Finding of present study is in agreement with earlier reported work. Molecular characterization plays an important role in characterization of taxa at inter specific and infraspecific level. As these important plants used in folk medicines their authentication is very important. Furthermore, molecular characterization for evaluating genetic diversity has widely been used in conservation biology.

Conclusion and Recommendations

The selected zones of Balochistan have diverse distribution of different genera of Zygophyllaceae. These plants are well adapted in suitable habitats and soil types of these regions. Enormous morphological and molecular markers provide a better understanding in authentication of some controversial taxa that could further be exploited for a novel drug discovery. Furthermore, the unsustainable utilization of these taxa may cause a serious decline. It is thus recommended that conservation strategies must be implemented including cultivation techniques of theses significant medicinal plants to fulfill the needs of local and International herbal market.

Abstract. The present work is an effort to determine the best and easiest method of producing plant of *Prosopis cineraria* from branch cutting. The root initiating hormones IBA were used for vegetative propagation of *Prosopis cineraria.* The results of this research well help in reducing the size of shoot being used in vegetative propagation. It will also reduce the plant genotypic variability and will help to ensure increased germination percentage by determining the best dose of root initiating hormones and different cutting sizes. Sprouting percentage is very important to predict the behavior of the tree if any species is to be propagated by asexual method of shoot cutting. Overall 15.24 cm cutting at open air was found best (2.38 C) in all the treatments, but it sprouted maximum in growth regulator IBA (3.71 A). Production of more number of leaves is also an important factor in determining the fodder value of the plant. Under the individual factor highest number of leaves (4.21 A) was produced by the 15.24 cm cuttings with IBA and least was produced by the 5.08 cm cutting in open air. The number of leaves produce was higher in 10.16 cm cuttings with (3.44 A) in polythene sheet compared to open air. Plant height showed its peak value (2.21 A) in 15.24 cm cutting with provided IBA and least height (1.23 C) was noted in 15.24 cm cutting without growth regulator. The second peak value was observed (1.78 B) in 5.08 cm cutting followed by (1.75 B) in 10.16 cm cutting. Root length indicated its peak value (2.18 A) in 15.24 cm cutting with provided IBA and least height (1.19 B) was noted in 15.24 cm cutting.
Keywords: *variability, vegetative, growth regulator, IBA, sprouting*

Introduction

Prosopis cineraria (L.) belongs to the (Family Fabaceaea) which is extraordinary versatile tree species of Cholistan Desert. This tree is locally called Jhand which holds the vital place in rural bargain in the southern region of the Punjab, Pakistan. The genus *Prosopis* contains about 44 species of shrubs and trees scattered mainly in the dry regions of the Southwest part of Asia, Africa and generally America from the western North America to Patagonia (Liu et al., 2012; Puri and Kumar, 1995). Therefore all the parts of this tree are useful, it is also known as "wonder tree" and "king of desert". It is a small, irregularly forked and thorny tree which is about 5-10 m in height. It has uneven, thick and grey bark with the deep gaps. Roots are very bottomless; the tap root of *P. cineraria* may enter perpendicularly nearly about 20 m or more (Mahoney, 1990; Preek et al., 2015). *Prosopis cineraria* are an imperative member of the arid, semiarid

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24632474

environments of the sub-tropical and tropical area around the world (Sushant et al., 2010). Maximum species of the *Prosopis* originate in the Americas, and the only four species of *Prosopis*is arising outside the America, in region like Southwest Asia and Africa (Atalano et al., 2008).

In Pakistan this species *is* found wildly and well adopted to the semiarid and arid condition of the Pakistan may be due to their well-developed and extensive tap root system, which reaches nearly to the length of 20 m habitually reaching out to the ground resources of the water (Gehlot et al., 2008). It becomes an important factor of the desert Ecosystem in the Pakistan as the biomass producer and as leguminous tree which enriches the desert soil, fixes atmospheric nitrogen and offers a green coverage. It donates to ecological constancy of the region and providing the wide support to human beings, nutrient deficient soils and the livestock (Chaudhry and Castle 2011). Furthermore, this plant species also provide remaining fuel wood for cooking and the heating in utmost households and restoration of despoiled lands in the arid and semiarid areas (Oduor and Githiomi 2013). All the closely related species of *Prosopis* keeps the similar morphology and their identification can be difficult, especially in the absence of fruit and flowers. In adding, the environment can have wide ranging effects on plant form, growth and leaf characteristics (Pasiecznik et al., 2001), and closely related species of *Prosopis* are known to crossbreed readily (Hunziker et al., 1986; Chaudhry, 2011).

Prosopis cineraria are one of the highly valued plant in the native system of medicine. It is also known to possess antibacterial, anthelmintic antifungal, anticancer antiviral and many other pharmacological qualities (Malik and Kalidhar, 2007). *Prosopis cineraria* an evergreen or nearly so, it forms an open crown and has thick, uneven grey bark with profound gaps (Rajesh et al., 2012). Its slim, glabrous and armed branches with prickles of 3-4 cm length, that is slightly compacted, straight and scattered. Flower is in the form of axillary spines with 7-11 cm length, either lonely or in terminal panicles. Flowers have yellow corolla, attracting a bulk of insects including great number of *Apis florae* and various other wild bees in December and April months (Gorain et al., 2012). It possesses bipinnately compound leaves, alternate in organization. The leaflets are 15–18 pairs, and designed rectangle with an entire margin, apiculate apex, obtuse base, glabrous surface, reticulate venation, petiolate, and the petiole is 0.5-4 cm long. The typical leaf size is 2.5 cm (length) and 1 cm (breadth). Morphologically, fresh leaves are green in colour, and are odorless with a bitter palatability (Dharani et al., 2011). The general phenological phase of Jhand, mainly flowering and fruiting will be in May-June of summer season. New leaf formation due to high protein content during end of summer (June-August) guarantees the availability of fodder to the livestock in severe summer period (Raj and Hooda, 1994; Chaudhry and Castle 2011). Their wood is valuable for making cart, house construction and agricultural tools (Gupta et al., 1998; Preek et al., 2015).

Existing shrinkage of forest area is due to some obvious factors. Clearing of forest for cultivation of farm crops and for fuel wood are among major factors. Our forest department, despite of their tiresome efforts are ineffective to raise the forest area even by 1% (FAO 2004). At this stage Pakistan is capable in forest resource even to meet growing local demand of wood. Pakistan is an agrarian country; the existing forests cover is only 4.8% of its area. This is very low as compared to desired ratio of 25% which is declared for sustained economic development and to encounter the wood demand of a country. The use of cutting is the best vital method for reproducing new

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24632474

plants. During the favourable situation cutting any isolated plant part that for rebirth will produce new plant similar to the parent plant (Singh et al., 2015). In this situation agro-forestry is best solution where the forest land cannot increase. In this way we can not only produce extra amount of wood to meet our domestic demands but can also complete the goals of exports for our valued wood product. It has been estimated that of our 10% farmland area can be brought under agro forestry without destroying of our farm crops.

In our land just about concerning 330 million timber standing throughout the entire farmland with the standing up with the amount of 70 million m^3 (Qurashi, 1998; Kaushik and Kumar, 2003; FAO 2004). The vegetative reproduction has been one response. The capability to harness bigger genetic characters through the asexual reproduction is being observed in various forest tree development plans. This method of reproduction is fast becoming a very vital nursery controlling tool because of reduced time requirement for cutting of larger trees to root and grow (Hudson, 1997; Singh et al., 2007). The present work is best and easiest method to determine the method of producing plant of *Prosopis cineraria* from branch cutting. The root initiating hormones IBA were used for asexual propagation of *Prosopis cineraria.* The results of this research will play an important role in reducing the size of shoot being used in asexual propagation and it will also reducing the plant genotypic variability and will help to ensure increased germination percentage by determining the finest amount of root initiating hormones. The research was conducted to check the propagation potential in shoot cuttings of *Prosopis cineraria* collected from various locations in Cholistan desert. To check the individual effects at various concentrations of growth hormone like IBA in inducing the root formation in *Prosopis cineraria* cuttings. To relate the propagation potential of various sizes of cuttings as a growing stocks.

Materials and methods

The research work was carried out in the nursery area, Department of Forestry, Range and Wildlife Management, The Islamia University of Bahawalpur during the last week February in 2015. The site is located at the latitude 36°-26”N and longitude of 73°-06”E. Altitude of site is 184.4 m. Different sized cuttings of *Prosopis cineraria* were collected from a healthy tree of *Prosopis cineraria* from the various locations of Cholistan desert.

Collection of plant samples

Selection of tree was done on following phenotypic qualities.

(1) The age of tree should be between 20-25 years. (2) The plant which is selected should be disease free, with leaves and branches. (3) The selected plant should have more and straight bole. Approximately one year old branches of thumb thickness were selected.

Size of cutting

Cutting of three sizes i.e. 5.08 cm, 10.16 cm and 15.24 cm were prepared. While preparing, the cuttings were taken to avoid that the bark may not get damaged. Flush cutting was done to avoid the peeling away of the bark. A slanting cut was given on the upper end of cutting to avoid fungal attack. The cuttings were dipped in bleach solution carefully prepared at a ratio of 1: 4 in water. Cuttings were planting in polythene bags

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24632474

(6 cm × 18 cm). These polythene bag were filled with silt, sand and clay in equal ratio, which acted as the rooted medium.

Application of IBA

Treating with root initiating hormone, the root initiating hormones, Indole butyric acid (IBA) were used in 4000 ppm. Basal 1/3 portion of cutting were dipped in the root initiating hormone solution for 16 h (Ram et al., 2013).

Data collection

Three parameters were studied along with their interaction. Following six treatments were applied to different cuttings. Only 15.24 cm cuttings were applied to the root initiating hormones, Indole butyric acid (IBA) in open air to check its effect on different growth parameters. Cuttings of different sizes 5.08 cm and 10.16 cm in pen air and under Polythene sheet were used. Cuttings were observed daily but the measurement were taken after every 7 days interval. The last reading was taken after sixty days. Data on Sprouting percentage, Number of leaves, Plant height and Root length were recorded during experiment.

Statistical analysis

Experiment was carried out according to CRD (Complete randomized design) (Steel et al., 1997).

Results and discussion

The present work was an effort to determine the best and easiest method of producing plants of *Prosopis cineraria* from branch cuttings. The root initiating hormone lndole butyric acid was applied on the branch cuttings of *Prosopis cineraria*. This research was an effort to reduce the size of shoot being used in vegetative propagation. This method reduces the plant genotypic variability.

Sprouting percentage

Sprouting percentage always plays an important role for a good future crop. If there is more sprouting it means the cultural practices you are doing and planting material used is satisfactory. Environmental conditions are also important for good sprouting. High sprouting percentage is the primary requirement for a good nursery business. Sprouting percentage is very important to predict the behaviour of the tree if any species is to be propagated by asexual method of shoot cutting. Good sprouting percentage is a perquisite for a healthy future crop stand. Analysis of variance for the sprouting per outing are given *Table 1* and the comparison of means for the factors like cutting size and Growth hormones are given in *Table 1* and overall sprouting % age given in *Table 1*. From the results of the sprouting percentage it is clear that 15.24 cm cutting under growth regulator IBA gave the best result with sprouting. Overall 15.24 cm cutting at open air was found best (2.38 C) in all the treatments as shown in *Table 1* but it sprouted maximum in growth regulator IBA (3.71 A) as shown in *Table 1*. 10.16 cm cuttings were also good (3.12 B) in polythene sheet as shown in *Table 1,* but showed less sprouting than 15.24 cm. 5.08 cm cutting showed good sprouting in polythene and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24632474

it was even lower in open air as shown in (*fig. 1*). Our findings are in the line of Ngo Mpeck et al. (2003), Wang et al. (1997) and Edson et al. (1991). Cuttings were observed very carefully and after 30 days sprouting percentage was calculated by (Mebrahtu and Hanover 1990).

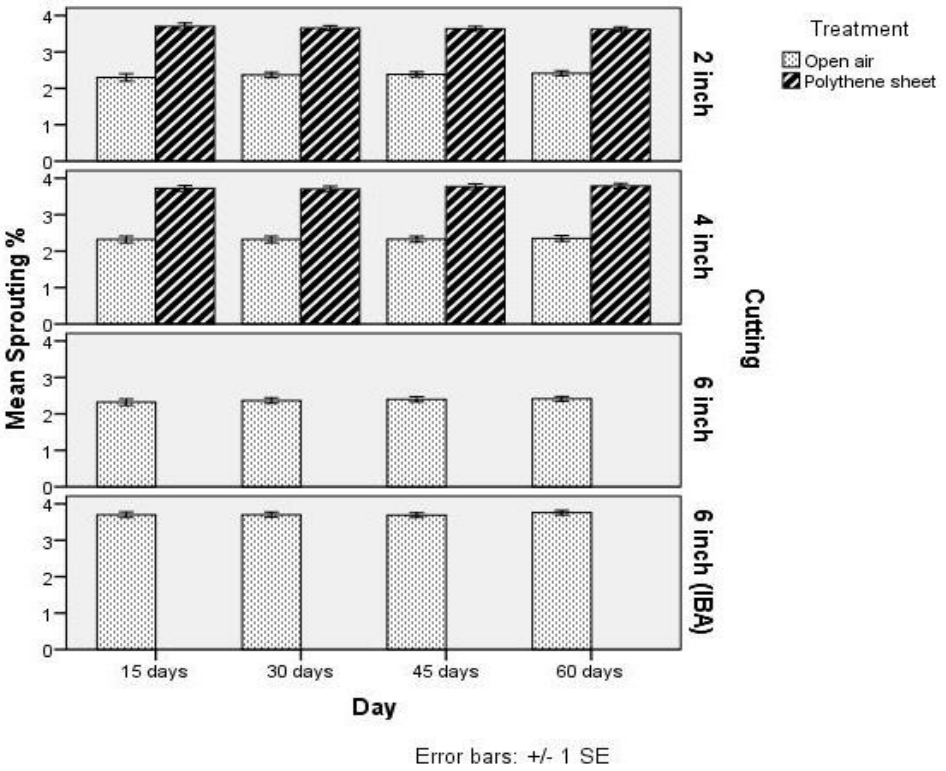

Figure 1. *Sprouting percentage as affected by different cutting sizes*

Table 1. *Comparison between open air and polythene sheets regarding number of leaves, sprouting percentage, height (cm) and root length (cm) for overall data*

Parameter	Treatment	N	Mean	SD	SE	t-value	Prob
No. of leaves	Open air	1005	3.04	0.958	0.030	-19.37**	0.000
	Polythene sheet	571	3.93	0.684	0.029		
Sprouting %	Open air	1005	2.77	0.857	0.027	-22.81**	0.000
	Polythene sheet	571	3.70	0.611	0.026		
Height (cm)	Open air	1005	1.51	0.516	0.016	-30.72**	0.000
	Polythene sheet	571	2.22	0.253	0.011		
Root length (cm)	Open air	1005	1.50	0.497	0.016	-30.68**	0.000
	Polythene sheet	571	2.16	0.166	0.007		

** = highly significant (P < 0.01); N = number of observations; SD = standard deviation; SE = standard error

Number of leaves

The number of leaves is important for the good growth of plants, if a plant has more leaves it means the plant will utilize the sunlight in a more efficient way and the plant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24632474

overall will be healthy. Number of leaves also determines the growth of plants at nursery stage. The plant having more leaves are more vigorous in their growth and are stable than the plants having less number of leaves. Production of more number of leaves is also an important factor in determining the fodder value of the plant (Rafay et al., 2013). After 15 days under the individual factor highest number of leaves (4.21) was produced by the 15.24 cm cuttings with IBA as shown in *Figure 2* and least was produced by the 5.08 cm cuttings in open air. Number of leave was produce (3.44) more in 10.16 cm cutting in polythene sheet as compared to open air as shown in *Table 1*. Different scientists observed that 15.24 cm cuttings growth is better and produce more number of leaves in plastic tunnels (Pomper et al., 2002). After 30, 45 and 60 days highest numbers of leaves were produces by the 15.24 cm cutting as shown in *Figure 2* with growth hormone IBA in open air and the least number of leaves were produced by the 5.08 cm cutting in open air. In 10.16 cm cutting number of leaves are more as compared to 5.08 cm cutting in polythene sheet. Other scientists observed that under plastic sheets 15.24 cm cutting showed better growth and produce more number of leaves (Rafay et al., 2013).

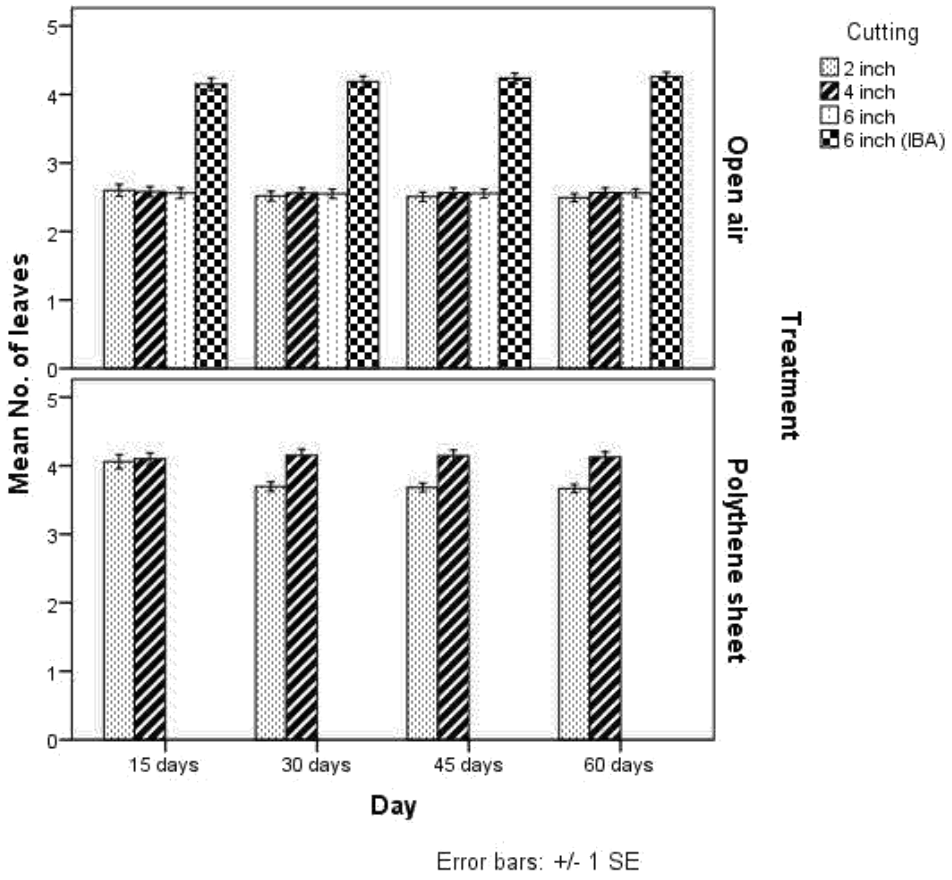

Figure 2. *Mean comparison of leaves in different cutting size*

Plant height (cm)

Plant height is measured in order to determine the total length of the plant (Root and Shoot). Plant height in open air after fifteen days showed its peak value (2.20 A) in 15.24 cm cutting with provided IBA and least height (1.23 C) was noted in 15.24 cm

DOI: http://dx.doi.org/10.15666/aeer/1802_24632474

cutting without growth regulator. Second peak value (1.19 B) in 5.08 cm cutting followed by (1.19 B) in 10.16 cm cutting. Plant height in polythene sheet after fifteen days showed its peak value (2.20 A) in 10.16 cm cutting and least height (1.20 A) was noted in 5.08 cm cutting. 10.16 cm cutting was noted to be highly significant as given in *Figure 3*. Plant height in open air after thirty days showed its peak value (2.20 A) in 15.24 cm cutting with provided IBA and least height (1.19 B) was noted in 10.16 cm cutting. Second peak value (1.22 B) in 15.24 cm cutting without growth regulator followed by (1.20 B) in 5.08 cm cutting. Plant height in polythene sheet after thirty days showed its peak value (2.22 A) in 5.08 cm cutting and least height (2.20 A) was noted in 10.16 cm cutting. 5.08 cm cutting was noted to be highly significant as given in *Table 1*. Plant height in open air after forty five days showed its peak value (1.52 A) in 15.24 cm cutting with provided IBA and least height (1.19 B) was noted in 10.16 cm cutting. Second peak value (1.23 B) in 15.24 cm cutting without growth regulator followed by (1.22 B) in 5.08 cm cutting. Plant height in polythene sheet after forty five days showed its peak value (2.25 A) in 5.08 cm cutting and least height (2.19 A) was noted in 10.16 cm cutting. In these factors the factor A of 5.08 cm cutting was noted to be highly significant as given in *Table 1*. Plant height in open air after sixty days showed its peak value (2.21 A) in 15.24 cm cutting with provided IBA and least height (1.21 B) was noted in 10.16 cm cutting. Second peak value (1.25 B) in 15.24 cm cutting without growth regulator as well as (1.25 B) in 5.08 cm cutting. In these factors the factor A was found to be highly significant as given in *Table 1*. Plant height in polythene sheet after sixty days showed its peak value (2.26 A) in 5.08 cm cutting and least height (2.20 A) was noted in 10.16 cm cutting. 5.08 cm cuttings were noted to be highly significant as given in *Table 1* (*Figs. 4* and *5*).

Root length (cm)

Root is the basic organ, which plays a vital role in the plant development. Roots not only provide anchorage to the plant but also absorb important nutrients which are essential for the growth of the plant. A root goes deeper into the soil and explores the soil mass for more and more nutrients. Root length determines the growth of the plant. The plants having healthy and more vigorous roots are healthier than those with weak root system. Good plant root system developed at the early stages of plat growth is the prerequisite for the good survival percentage of the crop. Analysis of variance for the root length in open air taken after 15 days and mean comparison of 5% level of significant is given in the *Table 1*. Analysis of variance for the root length in polythene sheets taken after 15 days and mean comparison of 5% level of significant is given in the *Table 1*. Root Length in open air after fifteen days showed its peak value (2.14 A) in 15.24 cm cutting with provided IBA and least height (1.19 B) was noted in 5.08 cm cutting as shown in *Table 1*. After that (1.20 B) value was recorded in 10.16 cm cutting as well as in 15.24 cm cutting without growth regulator. Root Length in polythene sheet after fifteen days showed its peak value (2.14 A) in 10.16 cm cutting and least height (2.14 A) was noted in 5.08 cm cutting (*Fig. 6*).

peak value (2.17 A) in 15.24 cm cutting with provided IBA and least height (1.20 B) was noted in 10.16 cm cutting. After that (1.21 B) value was recorded in 5.08 cm cutting as well as in 15.24 cm cutting without growth regulator. Root Length in polythene sheet after thirty days showed its peak value (2.16 A) in 5.08 cm cutting and least height (2.14 A) was noted in 10.16 cm cutting. Analysis of variance for the root length in polythene sheets taken after forty five day and mean comparison of 5% level of significant is given in *Table 1*. Root Length in open air after forty five days showed its peak value (2.20 A) in 15.24 cm cutting with provided IBA and least height (1.21 B) was noted in 10.16 cm cutting. After that (1.22 B) value was recorded in 5.08 cm cutting as well as in 15.24 cm cutting without growth regulator. Root Length in polythene sheet after forty five days showed its peak value (2.18 A) in 5.08 cm cutting and least height (2.14 A) was noted in 10.16 cm cuttings. Root Length in open air after sixty days showed its peak value (2.22 A) in 15.24 cm cutting with provided IBA and least height (1.21 B) was noted in 10.16 cm cutting. After that (1.25 B) value was recorded in 15.24 cm cutting without growth regulator followed by (1.23) in 5.08 cm cutting. Root Length in polythene sheet after sixty days showed its peak value (2.20 A) in 5.08 cm cutting and least height (2.16 A) was noted in 10.16 cm cutting. Jhand is a desert tree species and it is a difficult species to root unlike *Teerminalia chebula* which sprouted after 30 days (Jose and thomas 1998). Best rooting was observed in IAA, which is in contradiction with the other scientists who found IBA, the most effective auxin (Palanisamy et al., 1998; Reddy et al., 1998; Hee et al., 1997; McGuigan et al., 1996; Wang et al., 1997).

Conclusions

Indole Butyric Acid (IBA) was used to determine the different parameter including the sprouting percentage, number of leaves, plant height and root length. In open air experiment, 15.24 cm cuttings showed excellent results. Maximum number of leaves during air experiment by using 15.24 cm cuttings were 4.21 A. similarly sprouting was maximum at 3.71 A in open air. Best height was obtained from 15.24 cm cuttings with 2.21 A. Root length at 2.18 A for 15.24 cm cuttings were maximum. During open air experiment it was observed that numbers of leaves were reduced with the reduction in cutting size. While under polythene sheet at 3.44 A maximum number of leaves was produced by using 10.16 cm cuttings. Maximum heights were obtained from 15.24 cm cuttings with 2.21 A. minimum height was shown from 15.24 cm cuttings without regulator. So these treatments showed best result for maximum growth, sprouting, heights and number of leaves of *Prosopis cineraria*. We can get desired plant by applying these conditions on our nursery to ensure better results in future.

(Received 9th Aug 2018; accepted 31st Oct 2019)

Abstract. Nematicidal activities of some plant extracts were assayed against *Meloidogyne incognita.*. Six different medicinal plants were collected from Swat valley of Pakistan. Plants were moderately washed with tap water in order to remove various impurities like dust, dirt and adhering materials. The plants were shade dried and powdered. Aqueous Methanolic extraction of the dried powdered samples were carried out through cold percolation technique followed by removal of the solvent using vacuum rotary evaporator under controlled temperature. The methanolic crude extracts were further fractionated using different polarity solvents n-hexane, chloroform, ethyl acetate, and n-butanol. Methanolic extracts were screened for egg hatchability and nematicidal activity against second stage juveniles of *M. j incognita.* in the laboratory under the microscope. The nematode eggs and juveniles were exposed 24, 48 and 72 hrs in different concentrations (10, 100, 1000 ppm) of plant extracts. The plant extracts of *Acacia modesta* (roots), *Segeratia thea* (leaves), and *Celtis caucasic* (aerial part) exhibited highly promising mortality of more than 60% after 72 hrs exposure. There was a gradual decrease in egg hatching with increase in extract concentration of *Acacia modesta* (roots), *Segeratia thea* (leaves), and *Celtis caucasic* (aerial part) were found to be the most effective in reducing egg hatching. Larval mortality were strongly influenced by concentration of extract, plant species and duration of period.
Keywords: *Segeratia thea, methanolic extraction, larval mortality, Acacia modesta, juveniles*

Introduction

Root-knot nematode, *Meladogyne incognita.* is one of the major plant- parasitic nematodes adversely affecting the quantity and quality of the major crops. Plant parasitic nematodes are the main pathogens on most food crops and without adequate control cause loss of yield and quality. Yield losses due to plant parasitic nematodes have been reported to be $100 billion worldwide annually (Sasser and Freckman, 1987). Root-knot nematodes (*Meloidogyne* species) infect almost all types of plants and cause considerable damage (Adekunle and Akinlua, 2007). Root knot nematode larvae infect plant root causing the development of root knot galls that affect the plant's photosynthetic process and nutrient uptake (Eisenback and Triantaphyllous, 1991).

Nematodes are difficult to control because of their high rate of reproduction and wide host range, while females are capable of producing up to one thousand eggs/female (Natarajan et al., 2006). Plant–parasitic nematodes are documented as the causes of serious yield losses on a wide range of crops (Javad et al., 2006). Current study shows that *M. incognita.* is the species which cause serious problem in various agricultural crops.

DOI: http://dx.doi.org/10.15666/aeer/1802_24752482

Although chemical nematicides hold major role in nematode control but it is expensive and is economically viable only for high value crops and create a potential hazard to the environment and human health (Tsay et al., 2004). This issue has stimulated research on nematode management through natural products with nematicidal activity such as root exudates, plant volatile compounds (Linford et al., 1938), endophytic bacteria (Vetrivelkalai et al., 2010) and plant extracts (Muniasamy et al., 2010; Pavaraj et al., 2010). A wide variety of plant species, representing 57 families have been shown to exhibit nematicidal compounds (Sukul, 1992), which includes isothiocynates, thiophenics glycosides, alkaloids, phenolics and fatty acids (Gommers, 1973). Nematicidal phytochemicals are generally safe for the human health and environment (Chitwood, 2002). Hence, the present study has been carried out to evaluate some plant extracts for their nematicidal properties against root-knot nematode *M. incognita.*.

Material and methods

Several hundred plants wildly grow in Swat valley and adjacent areas. Due to their socioeconomic, agricultural and pharmacological potential they are very popular in the native people. *Debregeasia saeneb* aerial part (stem + leaves), *Celtis caucasica* aerial part (stem + leaves), *Acacia modesta* (roots & bark), *Segeretia thea* (leaves), *Isodon rugosus* (roots), *Buxus papillosa* (leaves + stem + roots) were used in the study. The plants samples were collected from different regions of district Swat and district Upper Dir (*Figure 1*). The collected species were moderately washed with tap water to remove various impurities like dust, dirt and adhering materials. Then were shade dried until complete dryness of the plant material was achieved. The dried samples were grinded by using electrical grinder. The powdered samples were extracted in aqueous methanol followed by removal of the solvent using vacuum rotary evaporator under controlled temperature.

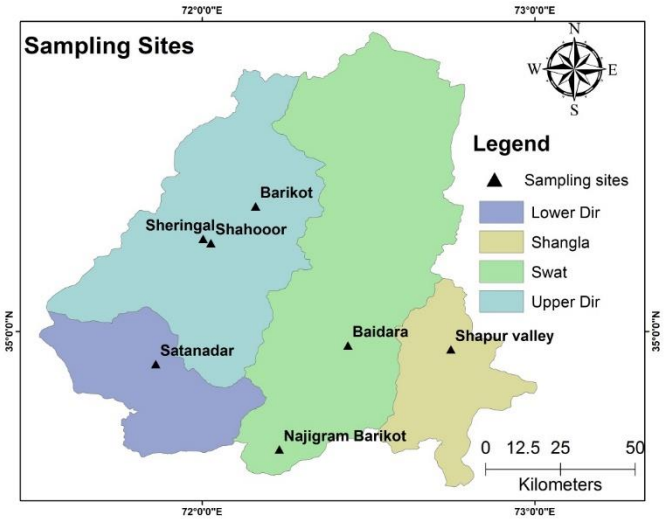

Figure 1. *Map of the sampling sites*

The methanolic crude extracts were further fractionated using different polarity solvents n-hexane, chloroform, ethyl acetate, and n-butanol in separating funnel. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24752482

crude extracts and their respective fractions were then dissolved in 5% aqueous DMSO to prepare stock solution. Different concentrations of plant extracts (10, 100, 1000 ppm) were prepared from the stock solution using 5% aqueous DMSO. For obtaining of egg masses and larvae pure culture of *M. incognita.* were collected from the roots of infected *Red duranta* plant. Plant roots were washed well to remove soil and debris. Then infected roots were cut into 2-3 cm pieces. Root pieces were placed in a blender. Enough water was added to cover the roots and blended for 15 –20 sec at low speed. The suspension was poured through the sieves 25 µm, 36 µm, 63 µm, 100 µm. The top sieve (100 µm mesh) was used to retain debris, washed with tap running water.

Eggs on the 500 mesh sieve are gentle washed under a slow stream of cold tap water. The eggs were collected from the 500 mesh sieve into a beaker. The egg suspension was brought to a known volume to determine the number of eggs per millilitre. 1 ml of the egg suspension was used in counting plate with the plant extract and was kept at room temperature for 24, 48 and 72 hrs for egg hatchability test. The nematodes eggs were exposed to 10, 100 and 1000 ppm of each plant extract for 24, 48 and 72 hrs. Four plant extracts exhibited highly promising mortality rates of more than 60% after 72 hrs of exposure ($P<0.05$).

Rest of the egg suspension was stored in saline solution in refrigerator. For the juveniles study the freshly extracted egg suspension was kept in incubator at 24°C for 4 days to let the eggs hatched and get the second stage juveniles. Effect on egg hatching was evaluated on mature uniform size eggs of *M. incognita.* were suspended in the extract, 5% aqueous DMSO (control) and nemacur (nematicide) replicated three times in counting plates. The counting plates were kept at room temperature. Observations were recorded on number of eggs hatched after 24, 48, 72 hrs. For effect of % mortality freshly hatched J_2 of *M. incognita.* were placed in each dilutions and control, replicated three times in counting plates. The plates were kept at room temperature. Mortality of larvae was calculated as a percent of total larvae suspended (Cayrol et al., 1989).

$$\% \text{ egg hatching} = \text{No. of hatched eggs} / \text{Total No. of eggs} \times 100$$

$$\% \text{ Mortality} = \text{No. of dead juveniles} / \text{Total No. of juveniles} \times 100$$

Statistical analysis

All the data were analysed using 2-way factorial experimental design at 5% level of significance, using statistical package Statistix. The letters showing a, b and c with the mean values shows that the means are significantly different from each other.

Results and Discussions

% Egg Hatchability of Plant Methanolic Crude Extracts

A gradual decrease was observed in egg hatching with increase in plant extract concentration (*Table 1*). Abdalla et al. (2008) reported that methanol and hexane extracts of the 27 samples were screened for nematicidal activity against second stage juveniles of *M. incognita* in the laboratory. The present study revealed that plant extracts of *Acacia modesta* (roots), *Segeratia thea* (leaves), *Isodon rugosus* (roots), *Celtis caucasica* (arial part) were found to be most effective in reducing % egg

DOI: http://dx.doi.org/10.15666/aeer/1802_24752482

hatching. Plant extracts of *Boxus papillosa* (leaves, stem and roots), *Acacia modesta* (bark) and *Debregeasea saeneb* proved to be less effective against *M. incognita*.

Table 1. *Effect of different concentrations of plant crude extracts on %egg hatchability in the root-knot nematode, Meloidogyne incognita*

Plants	Exposure time hours	% of egg hatching at different dilutions (ppm) of plant extract

% Mortality of Plants Methanolic Crude Extracts

The methanolic crude extracts of *Acacia modesta* (Roots), *Segeratia thea* (leaves), *Isodon rugosus* (roots) and *Celtis caucasica* (aerial part) exhibited mortality more than 50% after 72 hrs exposures (*Table 2*). Pavaraj et al. (2012) observed the plant extracts effect on egg hatching of nematode and mortality of the second stage juveniles of *M. incognita in vitro* after 24, 48 and 72 hrs of exposure. Similar results were observed in the current work from crude extracts of *Segeratia thea* (leaves) and *Celtis caucasica* (aerial part) exhibited 74.5 and 87.3% of larval mortality, while undiluted root extracts of *Acacia modesta* and *Isodon rugosus* exhibited 69 and 54% of larval mortality each at 1000 ppm concentration after 72 hrs of exposure, respectively. Egg hatching inhibition

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24752482

and larval mortality decreased with decrease in the concentration of the extracts. Juvenile mortality increased parallel to an increased time of exposure. The potential of using plant extracts in controlling plant parasitic nematodes has been shown by several authors (Adegbite and Adesiyan, 2005; Opareke et al., 2005; Orisajo et al., 2007; Abbasi et al., 2008). Extracts from *Segeratia thea* and *Celtis caucasica* were the most toxic compared to other plant extracts (*Table 2*). The nematicidal effect of the tested crude extracts may probably be because of higher content of certain oxygenated compounds which are considered to possess lipophilic properties that allow them to dissolve the cytoplasmic membranes of nematode cells and their functional groups interfering with enzyme protein structure (Knoblock et al., 1989).

In *Acacia modesta* (roots) among all the four fractions the chloroform and ethyl acetate fractions exhibited highly mortality rates of 68.13 and 70%, respectively after 72 hours exposure (*Table 3*). In *Segeretia thea* (leaves) the chloroform and ethyl acetate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24752482

fractions exhibit high mortality rates of 74.14 and 75.16%, respectively after 72 hours exposure (*Table 4*). *Celtis caucasica* (aerial part) fractions caused larval mortality at the rate of n-hexane 84, chloroform 86, and ethyl acetate 88% after 72 hours of exposure at 1000 ppm (*Table 5*). While *Isodon rugosus* (roots) ethylacetate fraction showed highly mortality rates of juveniles at 55% after 72 hours exposure time at 1000 ppm concentration (*Table 6*). All the means regarding concentration level were significantly different among each plant extract. The nematicidal effect of ethyl acetate and chloroform fractions are may be due to the presence of nematicidal compounds isothiocynates, thiophenics glycosides, alkaloids, phenolics and fatty acids (Gommers, 1973).

Abstract. This paper presents the results of a study on the main reasons for the transformation of wetland ecosystems in the Delta of the Ili River in the period of 1979-2014. The study results are shown based on the analysis of multi-temporal satellite data Landsat, dynamics of hydrological regime of the river Ili, climate conditions and features of economic activities of the local community, as well as fieldwork in the study region. Analysis of area changes of main types of hydromorphic and semi-hydromorphic ecosystems of Delta river Ili in high and medium on water discharge in the following (1979, 1993, 2000, 2010, and 2015) years. Increasing water consumption in China and in Kazakhstan part of the Ili-Balkhash basin due to the development of the agrarian and municipal sectors of economy especially in China, significantly exceed increasing flow of Ili River, caused by regional warming in the catchment part of Ili River Basin. The global warming has intensified the degradation of glaciers in mountain catchment areas of Ili River, this in the near future threatens with a decline in river flow and as a consequence lead to the deterioration of delta ecosystems and the desiccation of lake Balkhash similarly to the ecological disaster of the Aral Sea. Analysis of long-term (from 1970 to 2013) climatic data from three meteorological stations demonstrated a trend of the regional increase of average annual air temperature by 1.4 °C and decreasing of average annual precipitation by 10 mm. These factors also contribute to the transformation process of hydromorphic ecosystems.
Keywords: *Ili-Balkhash basin, Ili Delta, hydrology, ecosystem transformation, climate warming and anthropogenic pressure*

Introduction

The processes of landscape degradation in river deltas in connection with regulation of runoff, in recent years has given more consideration (Hajdarov, 1968; Magasheva, 1977; Plisak, 1981; Starodubtsev et al., 1978). Similar works were carried out during the filling of Kapchagai reservoir from 1969 to1989 on the middle stream of river Ili, which provides nearly 80% of the water inflow into the largest inland water body in Kazakhstan - Lake Balkhash (Evstifeev et al., ND; Sovolova and Zhelnova, 1984; Plisak and Ogar, 1985). Ili is the most abounding in water river of South-East Kazakhstan. More than 3 million people live in the basin, and over many years a large industrial and agricultural complex was formed, which occupies an important place in the socio-economic life of the country.

The lower reaches of river Ili from Kapshagai ravine to the estuary, lies in the western part of the Balkhash flat depression. Modern Ili Delta geomorphologically enters into its composition and covers an area about 8000 km^2, as well as it is currently the largest River Delta in Central Asia. The Delta is represented as mosaics of zonal-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24832498

desert and intrazonal-floodplain-lowland hydromorphic biocenoses. This latter is distinguished by high biological productivity and cenotic biodiversity in the delta that are crucial for the conservation of some rare and endangered species and populations of animals and plants, as well as the unique wetland ecosystems (Jensen et al., 1987; Frazier et al., 2003). Ili Delta and the southern part of Lake Balkhash were declared as wetlands of international importance and included in the list of the Ramsar Convention in February 2012 (Du et al., 2014).

Since the 1970s, due to a sharp increase in water consumption and construction of reservoirs in Kazakhstan, and then in the Chinese part of the River Ili Basin, the runoff was significantly reduced in the lower reaches. This led to a sharp deterioration of water cut of floodplain and wetland areas and aridization of hydromorphic landscapes with the expansion of zonal, desert-like ecosystems (Tso and Mather, 2009). Quite a large number of articles are published on the threatening ecological situation in the Ili-Balkash basin, which is a reminder to the well-known catastrophe of the Aral region (Kanika et al., 2013; Congalton and Green, 1999; Neasset, 1996; Cherednichenko et al., 2010). However, volume of standard observations that were conducted previously was sharply reduced in 1990s, in particular, part of weather stations and gauging stations has been closed and field scientific studies are almost stopped (Vilesov et al., 2006). Currently, it is very little data on the current environmental state of the Basin in general and the modern Delta of the Ili River. In view of this, the aim of the study that had been done in 2008-2015, was to examine the main trends in the transformation of wetland ecosystems of the Ili River in relation to the regulation of river flow, regional climate changes, and anthropogenic impacts on the delta biocenoses.

Methods

The methods and multi-temporal remote sensing data were used in this study taking into account the large area of the Ili River Delta. Multi-temporal comparative analysis of biocenoses and classification of main studied biocenoses were based on the Landsat series: Multispectral Scanner (MMS); Thematic Mapper (TM); Plus Enhanced Thematic Mapper (ETM+) and Operational Land Imager (OLI), which are widely used in the world in the investigations of wetlands and delta ecosystems (Burlibaev et al., 2004, 2011). The time interval of used satellite images based on the changes of Ili Delta over the past 36 years due to fluctuations of average annual runoff from the relatively water-short years (1979, 1993, 2015) to an average water year (2000) and abnormally high 2010. These satellite images are in open access (http://earthexplorer.usgs.gov) *Table 1*. In selecting of satellite images all standard quality criteria (minimum cloudiness, image clarity and comprehensive coverage of the study area) was taken into account, as well as date of images, which were focused on the full-flowing months: June and July. In addition to remote data a complex fieldwork was carried out in 2008-2015 and during the fieldwork data were collected on land cover, features of terrestrial and aquatic landscapes on 382 representative points from different types of biocenoses.

Data from the gauging station “The tract Kapshagay” which is located on 37 km below the Kapshagai hydropower plant (44° 7’ 48.21” N; 76°59’ 12.98” E) and gauging station 164 which located in 164 km further upstream of Kapshagai hydropower plant (43°51’ 20.00” N; 79°11’ 53.38” E) were used to analyze dynamics of hydrological regime of the lower reaches of the Ili River for the period of 1950 to 2013.

Apart from runoff, the fluctuations of weather conditions also have a significant impact to the delta. An analysis of average annual fluctuations of air temperature and precipitation for the period of 1970-2012 was made based on the data of the weather stations Aul-4 and Kuigan, which located in the Delta (*Fig. 1*). Long-term runoff and climate data were purchased from the National Hydrometeorological Service "Kazhydromet". Influence of various forms of economic and human activities to the delta ecosystem were also taken into account.

Preprocessing satellite data

To eliminate the radiometric, geometric and atmospheric distortions, all used satellite images have passed preliminary processing in accordance with conventional methods of Remote Sensing (Starodubtsev and Truskavetskij, 2007). The spatial resolution of images was unified to 30 m. As single geographic coordinate system the Universal Transverse Mercator (UTM) was used.

Classification

Classification of hydromorphic and semi-hydromorphic ecosystems were carried out by using algorithm-supervised classification «Maximum Likelihood» as the most reliable and widely used algorithm for classifying the environment (Kanika et al., 2013; Hajdarov, 1963). For improving results and minimizing errors of classification ecosystems in 1979-1993 soil cover and geobotanical maps of 1981-1985 were used. For visual adjustment of boundaries of anthropogenic objects as ancillary data high-resolution satellite images on Google Earth mode were used.

Accuracy of the classification

The accuracy of classification of ecosystems was estimated based on multinomial algorithm, known under the name «confusion matrix». Matrix differences is a static analysis, which uses cross-tabs to display the degree of difference between the classes obtained by supervised classification and a set of field data in reference points, which carry a more accurate information (Congalton and Green, 1999). Thus, the overall accuracy and accuracy of "producer" and "user" classification results of multi images from 1979 to 2014 (*Table 2*) have been calculated. Final accuracy of the derived class has been assessed by the Kappa coefficient, which is calculated by:

$$K = \frac{N\sum_{i=1}^{n} x_{ii} - \sum_{i=1}^{r} x_{i+}x_{+i}}{N^2 - \sum_{i=1}^{r} x_{i+}\, x_{+i}}$$

where x_{ii}- is the diagonal elements of the matrix's errors; x_i + - is the total number of pixels in line; $x + i$ – is the total number of pixels on the column; N- is the total number of pixels in the matrix; n - is the number of classes (Neasset, 1996).

Results and discussion

The dynamics of hydrological regime and weather conditions in Ili River Delta 1950-2013

Since the 1970s there have been a trend in the reduction of average annual runoff of river Ili, primarily because of intensive building of irrigation systems and hydropower objects, both in China and in the Kazakh part of the Ili-Balkhash basin. It is known that due to the location of the main catchment area and hydrological regime, Ili River has a predominantly glacier-snow feeding. The riverhead of Ili is located at an altitude over 4000 m in the Tien-Shan mountain and numerous tributaries that considerably influence hydrological regime also have large catchment areas in mountains Zailiyskiy and Zhetysuskiy Alatau.

The annual runoff of Ili River before the building of Kapchagay hydropower plant was observed based on long-term data for the period of 1950-1969: spring flood in April-May, with an average monthly runoff of 455 m^3/s; three-month summer flood with an average monthly runoff 900 m^3/s and seven-month autumn and winter low-water period with an average monthly runoff of 321 m^3/s. Maximum monthly average runoff was observed about 950 m^3/s in July during the most intensive melting the of snowfields and glaciers (*Fig. 2*). Runoff begins to decline in September due to decrease in air temperature. Runoff begins to decline in September due to decrease in air temperature. Precipitation of the autumn period had no significant effect on volume runoff of Ili River and slump of runoff continued. Minimal value of runoff of the described period was around 200 m^3/s. and observed in winter months.

On average for the period of 1950-1969, the annual value of flow of Ili River from China to Kazakhstan was 12.47 km^3 with an average runoff of 395.42 m^3/s on the gauging station Dubyn. On the gauging station of Kapchagay it was increased until 14.9 km^3 with an average runoff of 473/516 m^3/s at expense of water inflow from Kazakhstan part of the Ili-Balkash basin. A significant reduction of Ili River runoff occurred from 1969, caused by the filling of Kapchagay reservoir since September 1969 and by increased water consumption due to irrigation in China and Kazakhstan. Before the building of hydropower plant the annual average runoff was 516 m^3/s, during the filling time (1970-1987) of Kapchagay reservoir it decreased by 28.2% to 370.2 m^3/s. At the same time, in the gauging station "164" the annual average runoff of Ili River was equal to 442 m^3/s. After the 1970s, the water runoff in the lower stream of river Ili never surpassed the runoff of the middle stream (*Fig. 3*).

The hydrological and atmospheric thermal conditions in the lower reaches of the river including the delta also changed dramatically with the beginning of the filling of Kapshagay reservoir. In seventeen years, there was a sharp more than 48% reduction of summer runoff and increased winter month runoff by 28% (*Fig. 2*). Winter floods have arisen that were not peculiar to Ili River, conditioned by increasing of water releases due to growth of energy needs during the cold season. Therefore, in winter the waves with a height up to 0.5 m from the Kapshagay power plant reached the upper reaches of the delta that caused ice drift, congestion and numerous spillages, which adversely affected biocenoses, especially the fauna. Despite the artificial discharges in May, spring floods did not achieve the scale of the former natural runoff of Ili River (*Fig. 2*).

In the following twenty-five years (1988-2013) in the same Kapshagay gauging station the annual average runoff of the Ili River has increased again to 466 m^3/s however, without attaining the previous amount (*Fig. 2*). The dramatic reasons of increasing runoff

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24832498

to 47.6-60 m^3/s are the result of regional warming. By results of investigation of glaciers from 1955 to 2004, the area of glacier systems of Kazakhstan part of Ili River Basin has decreased by 38.5%, from 926.13 to 570.15 km^2 (Vilesov et al., 2006). At the same time, due to the profound social and economic transformations in the 1990s and 2000s, the area of irrigated agriculture and water consumption have been reduced overall at the Kazakhstan part of the Ili-Balkhash basin (Burlibaev et al., 2011).

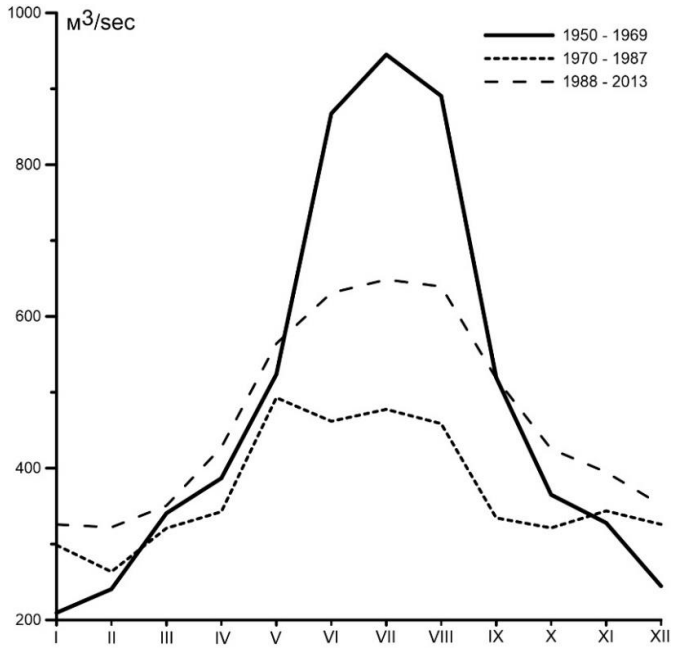

Figure 2. *Monthly average runoff before building Kapchagay hydroplant 1950 -1969; during the filling time 1970-1987; after filling of Kapchagay reservoir 1988-2013; according to Kapchagai gauging station*

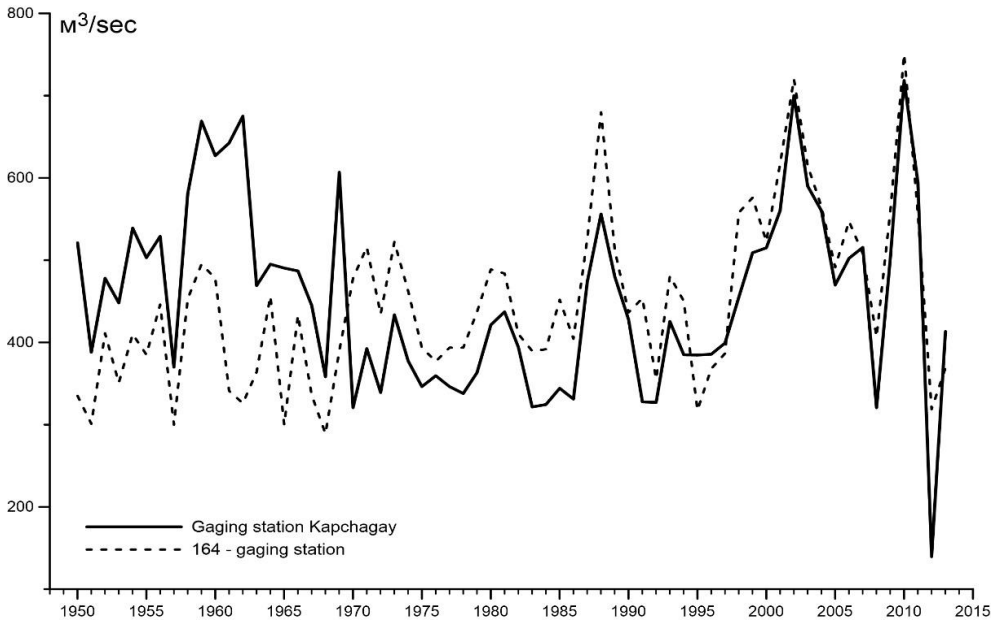

Figure 3. *Combined schedule of annual runoff of average annual water content of Ile River in alignment of gauging station Kapshagai and gauging station 164 (1950-2013)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24832498

An intensive construction of hydro-economic facilities in the Ili River Basin is accompanied by increasing water losses due to evaporation and filtration. After filling the Kapshagay reservoir 1.5-2.3 km^3 of water was lost annually for evaporation and filtration. In lower and middle reaches of the Ili River with the Kapshagay reservoir a series of large irrigation massifs were activated causing large water losses in Shengeldy, Akdaly, Kerbulak and Karoi. Besides, unjustifiably high water consumption caused by the imperfection of irrigation systems with an efficiency coefficient of 0.59 (Burlibaev et al., 2004) and, in our opinion, cultivation of hydrophilous crops as rice and alfalfa was an unfortunate choice.

Thus, area of irrigated lands at 1986 in the Ili River Basin in Kazakhstan's part was 369.6 thousand ha, and by 2000 it was reduced until 299.2 thousand ha due to radical social and economic collision in Kazakhstan. In contrast, water consumption in the Chinese part of the basin increasing rapidly, where large hydraulic works had been built and continued to be built for intensively developing industrial and agricultural sectors, as well as a growing population of Xinjiang Uygur Autonomous Region (Burlibaev et al., 2004).

Analysis of satellite images shows the area of irrigated land on the Chinese side has reached 465 500 ha already in 2007 and the annual water withdrawal from the Ili River in China has increased from 1.4 to 4.0 km^3 (Starodubtsev and Truskavetskij, 2007). In the coming years active construction of water facilities in the Chinese part of the Ili River basin will continue, and this creates a serious problem of water scarcity, desertification of ecosystems in the South-East of Kazakhstan and, as a consequence, water sharing between China and Kazakhstan at government level.

The climate-geographical conditions and soil characteristics of much of the Kazakh part of the Ili River Basin refers to the northern deserts and semi-deserts and historically used as natural pastures for livestock and in particular for irrigated agriculture. Location of the delta in the center of Eurasia determines the continental climate with large daily temperature range and seasonal temperature. The highest average monthly air temperature is 25-27 °C observed in July, with an absolute maximum of 44-46 °C; the lowest average monthly temperature is -13-15 °C observed in January, with an absolute minimum of - 45 °C.

The amount of positive annual temperatures above 10 °C reaches to 3500 °C that is the cause of high evaporation around 1000 mm/year in the delta area and Balkhash Lake and extra-arid climate. The average annual precipitation in the delta during 1970-2012 was little less than 160 mm/year, with a range of 80-260 mm/year that is about 13% of total evaporation. According to our data in the summer, the humidity can vary between 25 and 30% in the course of day and content of moisture in the soils at depth of 12-24 cm can vary between 1-2%. Hence, hydrological regime of the Ili River has a determinative importance on the state of intrazonal hydromorphic biocenosis of delta and the conservation of Balkhash Lake.

The negative anthropogenic impacts on the delta biocenoses

The lower reaches of the Ili River from the Kapshagai gorge to estuary occupies the western part of the Balkhash flat depression with an area of more than 20 000 km^2 (Hajdarov, 1968). Geomorphologically situated in the lower reaches the modern Ili Delta it covers an area about 7,000 km^2. On the top of the modern delta, about 120 km from the shore of Balkhash Lake, Ili River divides into many deltaic channels, which form three major hydrographic systems: Toparsky, Ilisky and Zhidelinsky (*Fig. 1*). Each

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24832498

of them, in its turn divides into smaller channels. Large part of the delta occupies the vast depressions between channels bounded by hilly sands that are flooding forming a shallow lakes and marshes.

Flat relief of the Balkhash depression and granulometric soil structure: light clay loams, loamy sands, fine-grained sands, as well as significant fluctuations of water content of the Ili River caused the variability of hydrographic system: some of the streams and channels are silting and disappear, others are increasing and new ones appear.

The system of lakes and swamps of deltaic territories are also very dynamic. The study area of the Ili Delta varies with the largest species and cenotic diversity in the region, with the presence of fertile land, rich natural pastures and hayfields, with an extensive hydrographic network of lakes, canals and sleeves with commercial fish fauna and bird colonies. It has been under intense economic use from the beginning of the formation of the modern delta over the years. This has led to a violation of the integrity of plant communities and caused great damage to the rich fauna of the region. With regard to vegetation this is reflected in a simplified structure of the communities, in impoverishment of their species composition, in reducing or complete disappearance of the most valuable indigenous species, in increasing the number and biomass of secondary species (including fault indicators, etc.), in reducing the role of perennial species and in increasing the specific value of annual plants. Negative processes are caused by unsystematic livestock grazing, uncontrolled burning of low productivity grass and last year's reed beds, as well as by cutting riparian and saxaul forest during harvesting for the winter. The number of livestock in the delta area reached 101.7 thousand units, sheep and goats account for - 50.8%, cattle - 38.4%, and horses - 10.8%. Negative delta transformation of biocenosis are particularly strongly expressed in the vicinity of settlements, livestock sheds on distant pastures and close to water bodies. Restoration of vegetation in desert is going slowly, due to the harsh climate, soil poverty, poor water content and high salinity of groundwater. Therefore, floristic diversity is reduced now almost on the entire territory, and for its restoration requires different phytomeliorative events. Vertebrate fauna of the region has about 345 species, that includes 33 rare and endangered animals, which are also under threat from poaching, habitat degradation, disturbance growth at the moment. The load on the ecosystem of the delta from huge number of tourists, hunters and fishermen on private cars, motorcycles and water transport is practically not regulated, especially those that are heavily influencing on floodplain, riparian and wetland biocenoses and vertebrate fauna as well.

Pollution of surface water and terrestrial ecosystems by various pollutants, household, industrial, agricultural effluents and emissions are increasing. Violation of hydrological and hydrochemical regime of the Ili River has a particularly devastating impact on the floodplain and deltaic wetland ecosystems.

Regional climate change in the study region from 1970-2013

Precipitation regime in the study area has been considered with 2 meteorological stations for the period of 1971-2013. In the annual course precipitation maximum occurs in spring months (April-May) and secondary maximum was observed in the fall. The minimum amount of precipitation falls in August and September, as well as in January and February across the study area. In general, rainfall throughout the year dominates in the warm period. Taking into account high evaporation in the delta region, long-term fluctuations in average precipitation sums cannot play a decisive role. An analysis of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24832498

linear trend in temporary course of annual precipitation sums and precipitation sums for warm and cold periods on both considered meteorological stations have shown weak trends. The maximum positive value 1.5 mm/10 years of the linear trend coefficient had been observed at Bakanas meteorological station. The character of changes in precipitation during the warm period of the year roughly corresponds to the annual. A negative trend (minus 1.2 mm/10 years) was noted in Bakanas. In the cold season there is a weak positive trend (3-6 mm/10 years) or sometimes it is not possible to observe them at all.

At the same time, the main volume of the Ili River flow is formed by precipitations in the catchment part of the basin, which is situated in the mountains at an altitude of over 2,000 m, where the average annual rainfall is equal to 900-1100 mm. For example, 2010 was an abnormally high-water year for the Ili River, according to Shymbulak (2300 m. above sea level) and Myn Zhylki (3100 m above sea level) meteorological stations, which are located in the valley Maloalmatinskoe in Zailiysky Alatau, that fell on 50% of precipitation more than the average annual rainfall for the period 2000-2009.

An analysis of the linear trend in temporary course of annual precipitation shows that despite the great variability of precipitation from year to year in considered period (1971-2013) trends are expressed weakly, but in general, the average annual amount of precipitation decreased to 10 mm according to Bakanas and Kuigan weather stations for 44 years (*Fig. 4*).

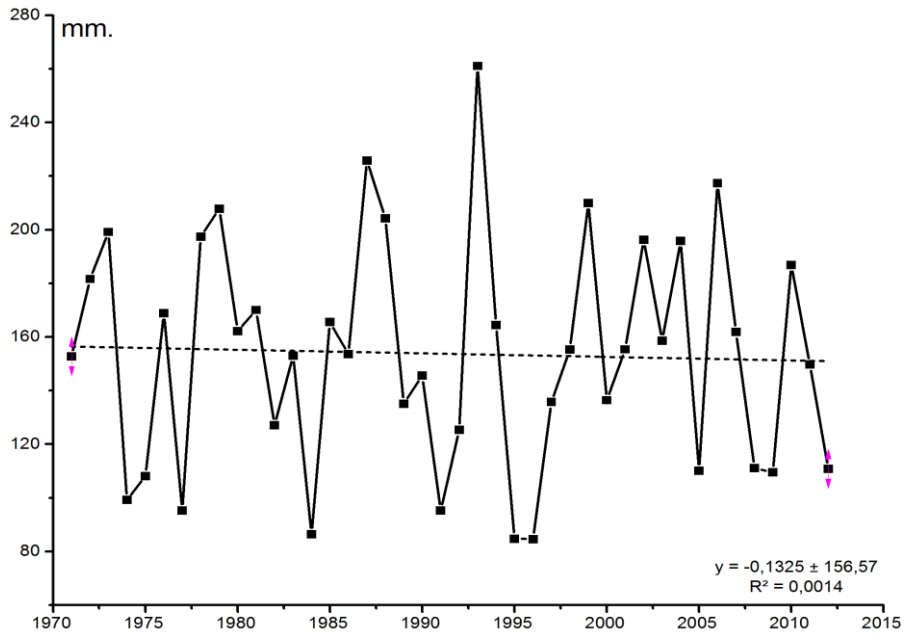

Figure 4. *Average annual amount of precipitation in Bakanas and Kuigan meteorological stations*

The main characteristics of temperature regime are average annual and average monthly air temperature, as well as absolute maximum and absolute minimum. Deviations of the actual temperature from its long-term average (norm) give an idea about temperature variation. Long-term data (1970-2013) on the air temperature provided by Bakanas and Kuigan weather stations (*Fig. 5*) were the source material for the study.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24832498

The annual course that is ordinary for a continental climate, when the warmest month is July and the coldest - January, is typical for the whole territory. The average monthly air temperature can vary significantly from year to year. Therefore, in addition to the monthly values in the description of the climatic conditions it is important to have data on their variability. The highest interannual variability is possessed by the winter months, and the smallest by the summer months. So the long-term average air temperature in January may vary from -7.3 °C to -14.6 °C, and in July from 23.8 °C to 26.0 °C. Variability of air temperature fluctuates during the winter months from 3.7 °C to 5.1 °C, and in the summer months from 1.0 °C to 1.5 °C.

Temperatures of warm period of the year, especially in the summer are fairly stable, and its interannual variability is minimal in comparison with other months of the year. The absolute maximum of temperature was recorded in Kuigan meteorological station (46 °C) in 1983, and at Bakanas meteorological station (45 °C) in 1997. The absolute minimum of air temperature was observed in 1969 and amounted minus 43 °C in Bakanas and (minus 41 °C) in Kuygan. The daily amplitude, that is the difference between the daily maximum and minimum of temperature gives an idea of the weather variability. Its highest values are confined to the warm period (April-September) and constitute 13.1-19.3 °C (Bakanas), and the lowest - in winter (December-February) – are 8.2-12.2 °C (Bakanas). The daily amplitude in clear weather is much greater than in cloudy. In the high water year 2010 the average monthly air temperature for January-September was near normal in the study area, almost all the months were warm, with the exception of February and July. January was very warm and the average monthly air temperature at all stations was above the long term average 3.8-4.3 °C. February was abnormally cold with temperatures below the long term average 1.6-4.3 °C and in July air temperature was 23.7-24.4 °C, so that was lower by 1.1-1.3 °C than the average of long term average values. The air temperature in other months fluctuated within normal limits. An analysis of factual material on the air temperature and precipitation for 2010 and 2011 have shown that the positive trend in the annual air temperature and in annual precipitation sum, that identified material for many years (1971-2008) is preserved (*Fig. 5*).

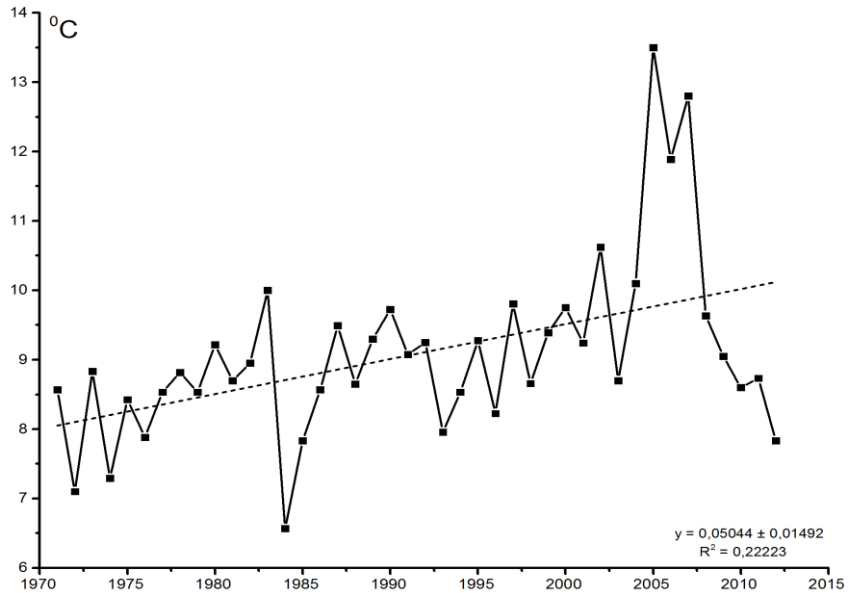

Figure 5. *The graph of long-term dynamics of average annual temperature at Bakanas meteorological station*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24832498

Monitoring of Ili Delta for 1979-2015 on satellite images

Reducing the average annual runoff in lower reaches of the Ili River from 472 m^3/s (1948-1969) to 361 m^3/s (1970-1986) and the lowering of water level by 1-1.5 m, as well as changes in the natural hydrological regime of water releases by Kapshagai hydropower plant significantly worsened the flooding of the delta region of the river. Additionally, it was the reason for the drying of many flowing and stagnant lakes, reducing the area of reed massifs, salinization of soils and desertification of shores. Thus, these negative processes extend from the least watered peripheral part of the delta, which is adjacent to the coast of the Balkhash, to its top.

To identify the features of the dynamics of intra-zonal ecosystems depending on the water content of the river in different years, areas of hydromorphic ecosystems (meadows, reed, aquatic) were defined in dry years (1979, 1993, 2015), in a year with average water flow (2000) and in a year abnormally abounding in water (2010). As the analysis of satellite images show, significant amplitude of fluctuations of the delta watering have caused corresponding dynamic changes in the area of hydromorphic ecosystems, the total area and the relation between them have varied in a wide range (*Table 3*). Specially marked dynamics in changing the wetland area attracts attention. So according to Hydroproject the total delta area of the Ili River was 7740 km^2 in 1948, and 841 km^2 of them accounted for an open water surface of delta lakes and ducts (Hajdarov, 1963). And 50 years later, in 2000 lakes and ducts area on the basis of our data, has decreased by 36% and amounted to 540 km^2. However, after 2010 the abnormally high-water year the open water of lakes and ducts enormously increased, reaching 1177.7 km^2.

Table 3. *Areal ratio of hydromorphic Ili Delta ecosystems (km^2)*

Date of space images	1979		1993		2000		2010		2015	
	1978	1979	1998	1993	1999	2000	2009	2010	2014	2015
The average annual water content on of Ili River at "Tract Kapchagai" gauging station	337.9	363.2	327.1	425.5	509.0	515.0	503.0	718.5	220.0	No available data
Aquatic ecosystems	438.0		393.7		540.4		1177.7		539.9

Reed ecosystems	1771.0		1669.2		2630.9		3027.3		2430.0	
The total area of hydromorphic ecosystems	3538.6		2817.9		3784		4367.9		4325.6	

The study of the temporal dynamics of the transformation of the delta ecosystems by satellite images revealed the following changes (*Fig. 6*):

1979

Analysis of satellite imagery that was made during the filling of Kapchagai reservoir showed pronounced negative changes of hydromorphic and semi-hydromorphic ecosystems. Low water period in lower reaches of the Ili River continued from 1970 to 1986. This caused desiccation of the major large delta lakes of the Zhideli system: Blue, White and Kaldayakskoe with a total area of 11; 3.5 and 45 km^2, respectively. Most ducts of the Zhideli system has been lost. Zhideli duct and its secondary ducts on the right side, such as Shybykty, Kertyubel, Zhalasar, Ketpenkaldy and partially Arystan

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24832498

ducts that feed the eastern part of the delta and their surrounding hydromorphic ecosystems strongly have become shallow. Unique Topar lake system has undergone a massive transformation and drying, where the water content of major ducts such as Topar I (Suminka) and Topar II did not exceed 1.4% of the Ili River flow. This is explained by a weak elaboration of Topar riverbed and its great fragmentedness due passive follow to local relief. The total water surface area of the Topar system was 120 km^2 in 1979, that is 220 km^2 less than in 1948. There has also been drying up of lakes and Topar side ducts such as Balatopar, Kishpa, Aksyir, Koktal that filled inter-ridge depressions before.

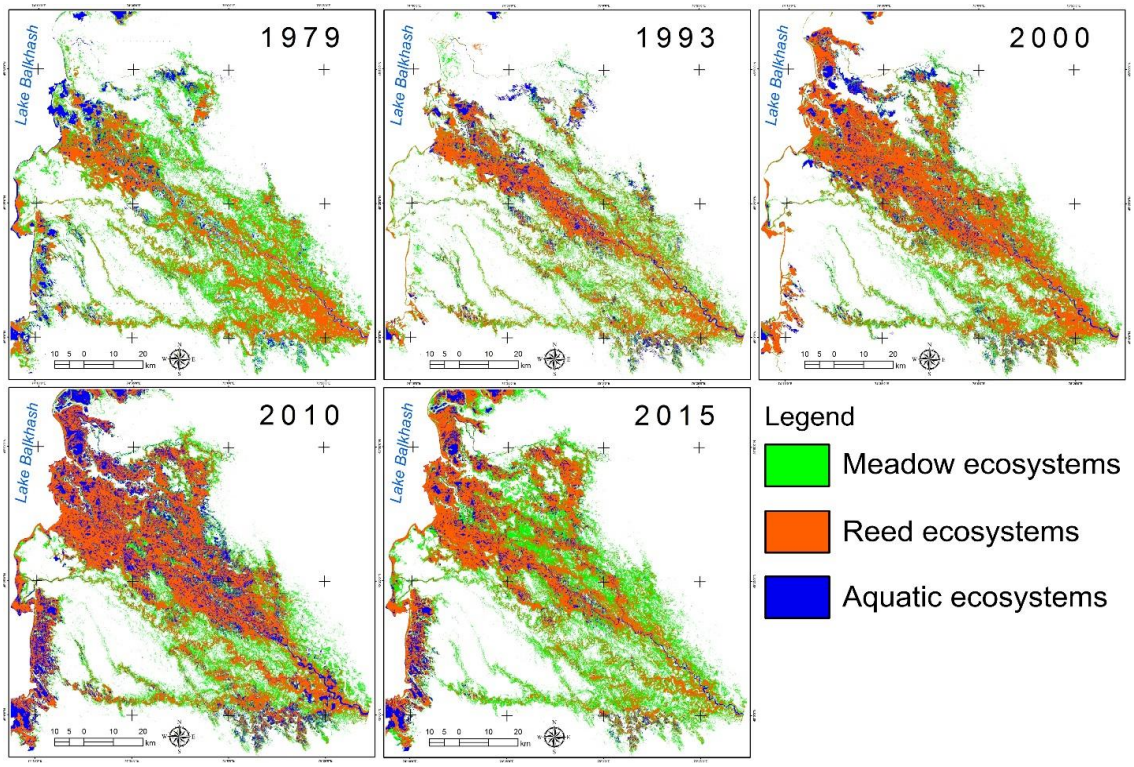

Figure 6. *Dynamics of area change of major ecosystems in the Ili Delta in 1979-2015*

1993

Despite the sharp decrease the area of irrigated land in the Kazakh part of the Ili basin in the 1990s there was a three-year water shortage during 1990-1992. The average water flow rate was 327.4 m^3/s and this led to sharp deterioration of general status and reducing the area of hydromorphic and semi-hydromorphic ecosystems for 720 km^2 in comparison with 1979. Such a sharp drop in runoff in lower reaches of the Ili River is explained by artificial changes in the hydrological regime by the Kapshagai hydropower plant. As a result, the level of the reservoir has increased by 23.5 cm during the period of 1990-1993, and the water surface area has increased from 1150 km^2 to 1244 km^2.

The sharp decline in the average annual runoff in lower reaches of the Ili River from 503 m^3/s to 327.4 m^3/s and the reduction of the level of Balkhash Lake by 25 cm from the nominal level 341.30 m occurred. This has led to the drying up of the aquatic, particularly coastal ecosystems and to the subsequent large-scale desertification of the Ili Delta's hydromorphic and semihydromorphic ecosystems, which is clearly observed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24832498

in the picture in 1993. It should be highlighted that the total disappearance of lake systems - former bays of Balkhash Lake, were previously a part of the Topar system. The largest of them are Semizkol, Akkol, Bogatoe and Abishkol with the total area of 39.4 km^2, which had links with Aksiyr ducts from the Topar system in the 40-ies of the last century. Reducing the level of Balkhash Lake as in 1979 has led to the drying up of the major lakes of Zhideli System such as - Sinee, Beloe, Kaldayakskoe and Nauryzbaevskoe. Moreover, it has led to extended arm of large bays Majtán and Balakashkan, which penetrated into the delta for 10-15 km. Desertification of hydromorphic and semi-hydromorphic biocenoses took place on the periphery of the Zhideli system, especially in the eastern part. In the full-flowing years the lake, such as Erimbay dominated by flowing, where the runoff is carried out during the whole year.

2000

The annual average runoff of Ili River increased from 360 m³/s up to 430 m³/s in the period from 1993 to 2000. This has led to the expansion of the area of hydromorphic ecosystems, including reed community and meadow-bog cenoses in the northern periphery of the Zhideli system. Thus, the runoff increase on 19.5% has increased the area of hydromorphic and semi-hydromorphic ecosystem to 966 km^2. The proportion of aquatic ecosystem is also increased to 146.7 km^2 due to flooding and restoration of large deltaic lakes - Sinee, Beloe and Nauryzbaevskoe, which had dried during the period of 1979-1993.

At the same time, further drying processes and increase in the areas of desertification occurred in the Topar system. Increasing the level of Balkhash Lake to the mark of 341.54 m above sea level is not particularly wag on coastal lake systems (Semizkol, Akkol, Bogatoe and Abishkol), which are mainly recharged by groundwater inflow from the Balkhash.

2010

The average runoff of the Ili further increased and reached 538.6 m³ in the period of 2001-2010. The record for 2010 and the last 60 years of water content observing notices difference, because the water content reached 718.5 m³/s. This led to a significant increase in the area of all hydromorphic ecosystems, especially in the central and peripheral parts of the Zhidelinsk system and in a lesser degree, the first time after the 60s, in the Ili duct system where flooding phenomenon was detected. Appreciable growth of hydromorphic biocenosis was also observed at the head of the most abounding Topar system, where the total water surface area was 284 km², where the total water surface area was 284 km² not reaching the index in 1948, it achieved only 63 km².

In 2010, in the Ili River basin three waves of flood occurred - winter 411 m³/s (from October to February), spring 739 m³/s (from March to May), summer 1155 m³/s (from June to September), which is typical for a river with glacial feeding. Due to the significant increase in the water content of the River Ili and its tributaries, in many areas of the lower reaches, in the delta, spills and floods formed, which significantly changed the water regime and environmental conditions in aquatic and semi-aquatic ecosystems of the territory.

DOI: http://dx.doi.org/10.15666/aeer/1802_24832498

2015

Since the 12th May 2014 the Ili River runoff on the Kazakh-Chinese border sharply fell, from 291 m³/s to 90 m³/s. The level of water in the Kapchagai reservoir decreased by 113 cm. Throughout the more than a century of instrumental hydrological observations of such flow reduction.

This caused a sharp reduction in the area of reed communities of the Zhideli system, firstly in the place of head part. In the middle and in the peripheral part the reed plant communities were preserved. In the Topar system drying of meadow and marsh phytocenoses was observed. Drying processes spread from the head of the Delta to the periphery, to the north direction. Based on an analysis of satellite images, it can be concluded desertification processes in most parts of the delta, particularly in the central regions of the Zhidelinsk system was expressed. Compared with 2010 semi-hydromorphic ecosystem area decreased by 555 km² and reed area by 597 km², which shows the extent of ongoing desertification processes. Reduction of aquatic ecosystems is observed at the head of the delta, where significant drying of large lakes occurred (*Table 4*).

Table 4. *Change of area ratio in Zhideli system delta lakes*

Year	Lake name					
	Siniy	**Belyiy**	**Kaldayakskie**	**Nauryizbaevskoe**	**Asaubay**	**Kokol**
2010	10.84	2.52	38.51	8.68	9.22	17.87
2015	9.32	2.18	17.08	3.58	5.27	8.19

Conclusion

In summary, it is supposed that the main anthropogenic factors that have a significant, often negative, impact on intrazonal half and hydromorphic ecosystems downstream of the Ili River include:

1. Regulation of water flow and decrease in water availability considering Ili River and its tributaries in China and Kazakhstan, in spite of the total increase in river flow due to degradation of glaciers in mountainous areas of the catchment basin of Ili.
2. Economic activities of the local population, as well as leisure travelers, hikers, hunters, fishermen, etc., adversely affecting the landscape, flora, plant communities, fauna and habitats of animals.
3. There is an urgent need to develop and implement a program of rational use of water resources of Ili-Balkash basin, including the modernization of irrigation systems, as well as the introduction of drought-resistant agricultural crops, water-saving technologies in the industrial and utilities sector.
4. Pollution of surface and ground water and terrestrial ecosystems with various pollutants, household, industrial and agricultural effluent sand emissions.
5. Related to the global and regional climate changes that lead to a marked increase in the average annual air temperature and reduction the number of drop-down in the region of precipitation, increase desertification process.

All of these factors which are strong and continuously increasing under human impacts since the early 70s and make less noticeable climatic changes, put unique

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24832498

ecosystems of the lower reaches of the Ili River, including its delta and Lake Balkhash, in a position that is more and more difficult to resolve causing to face the ecological crisis very reminiscent of the Aral Sea catastrophe. Naturally, the importance of each of these factors varies for different types of ecosystems. Anthropogenic factors are less effecting to the desert biocenosis remote from populated areas and water bodies. Because of the extra arid climate, they are not used for commercial purposes and are not visited by tourists. Their condition is determined mainly by climatic geographical features of the territory, whereas state hydromorphic delta ecosystems depends mainly on the factors of human nature.

At the same time, the state of soil and vegetation, especially wetlands, mainly determined by the water content of the Ili, and the condition of the animal world, especially commercial species of vertebrate fauna, by environmental services. Considering the continuously growing water demand, both in the Kazakh and especially in the Chinese part of the Ili basin, one should expect a significant further reduction of the hydromorphic ecosystems deltaic areas. The hydrographic Zhideli-Kogalinsk network system has the best prospects for the partial preservation of the unique intrazonal ecosystems.

Solving the problem of maintaining the water content in the lower reaches of the Ili River at an acceptable level is impossible without intergovernmental agreement between China and the RK on water allocation and a cardinal restructuring of irrigation and water distribution systems.

(Received 28th May 2019; accepted 11th Oct 2019)

Abstract. The production of acid mine drainage (AMD) is among the factors responsible for much of the degradation of water and soil resources and the disruption of biodiversity in the environment. Several studies have shown that organisms (either macro or micro) present at sites contaminated with AMD have the potential to bioaccumulate heavy metals and hence stimulate their application in bioremediation processes. Algal strains are not an exception to those organisms found in AMD. This review was aimed at examining the heavy metal remediation of AMD using algae, remediation properties of algae and different algal-based methods used in heavy metal remediation of AMD. Algal strains such as *Spirulina* sp., *Chlorella* spp., *Scenedesmus* spp., *Cladophora* spp., *Oscillatoria* spp., *Anabaena* spp. and *Phaeodactylum tricornutum* act as "hyper-accumulators" and "hyper-adsorbents" with a high selectivity for different elements from AMD. However, algae-based methods of abating AMD are not the ultimate solution to the problem and there is room for more studies. The current study suggests further attention to phycoremediation individually and synergistically with sulphate-reducing bacteria.
Keywords: *bioremediation, hyperaccumulation, phycoremediation, phytoremediation, sulphate-reducing bacteria*

Abbreviations: AMD: acid mine drainage, HRAP: high-rate algal ponds, SRB: sulphate-reducing bacteria, ATS: algal turf scrubber, PIMR: pipe inserted microalgae reactor

Introduction

Industrialisation has brought immense development and economic improvement to most countries of the world. Despite the positive impact of industrialization, it also has negative effects on the environment and biodiversity. Acid mine drainage (AMD) is one of the negative consequences of industrialisation. The mining of gold (Au), copper (Cu), nickel (Ni) and other minerals are associated with AMD, which may have adverse effects on human and animal health as well as the environment (Azapagic, 2004). Conventional approaches to remediation and other active and passive technologies have been adopted to neutralise the threat of AMD. However, they have been found to have many drawbacks, including high cost of application and further and unforeseen environmental damage. The option of using green technologies in remediating AMD has been researched and applied in many countries, and offers much promise for a cleaner and safer environment (Galiulin and Galiulina, 2003, 2008; Koptsik et al., 2014; Cunningham and Ow, 1996; Nowack et al., 2006; Prasad and Freitas, 2003). These green technologies involve, among others, the use of algae that offer solutions without causing any adverse effects on the environment.

The process of using macro- and microalgae to remediate AMD and other contaminated environments is termed phycoremediation. Kalin et al. (2006) state that the use of algae as decontaminating agents provides some advantages, including low costs of operation, easy manipulation, lack of pollution, relatively simple recovery of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24992512

the metal contaminants for recycling and not constituting a source of secondary waste. The accumulated heavy metals can be recovered after the growth of algae in the contaminated environment by separating the algal biomass from the water. The separated algal biomass is dried and the heavy metals are recovered by converting the heavy metals into oxides or other recoverable salts. In addition, the separated algal biomass can either be sequestered or stored for future purposes or disposed of in municipal waste landfills to reduce its environmental footprint (Edmundson and Wilkie, 2013).

Compared to the conventional method of remediation, phycoremediation has been shown to be less costly, less energy consuming and with no generation of sludge (Ghosh and Singh, 2005; Abdel-Raouf et al., 2012). In phycoremediation, macro- or microalgae are used for the removal or biotransformation of pollutants from wastewater (Ahmad et al., 2013). Algae of the genera *Chlorella*, *Chlamydomonas*, *Spirulina*, *Scendesmus*, *Nostoc* and *Oscillatoria* have been used in wastewater treatment over the last few decades (Dubey et al., 2011; Sharma and Khan, 2013). It was assumed that microalgae are versatile in converting contaminants into a non-hazardous material, making the treated water fit for reuse or discharge into receiving water bodies (Rao et al., 2011). Algae-based treatment can be used in combination with secondary treatment where microorganisms work in symbiosis with algae cells for effective treatment.

The remediation of AMD by using algae has been the focus of many studies since the ability of algae to adsorb and actively transport heavy metals through the cellular tissues was identified (Stevens et al., 2001; Malik, 2004; Das et al., 2009; Mehta and Gaur, 2005). The transported heavy metals can be intracellularly immobilized by metal-binding peptides found in the vacuoles of the cells and stored in the cytoplasm through the synthesis of polyphosphate bodies (Pawlik-Skowrońska, 2001; Priya et al., 2014). Nishikawa et al. (2003) point out that algal cells are composed of electron-dense bodies made up of polyphosphate that are capable of accumulating metals and protecting algal cells from metal toxicity. Irrespective of the ability of algae to remediate water contaminated by heavy metal, the species of algae prospected to be used in bioremediation of heavy metals in AMD must be able to tolerate highly concentrated mixtures of distinct heavy metals. In this review, heavy metal remediation of AMD is examined. In addition, the heavy metal remedial properties of algae and the different methods involving algal strains in heavy metal remediation of AMD are reviewed. Topics under discussion include remediation properties of algae and an overview of different algal-based methods used in heavy metal remediation of AMD.

Heavy metal remediation of acid mine drainage using algal strains

Intense mining leads to the production of AMD, which has detrimental effects on the environment – hence the need to control and possibly manage the waste and acidic water produced by mines. Conventional treatment methods have been widely researched and applied in the remediation of AMD (Gazea et al., 1996; Robinson and Robb, 1995; Ghosh and Singh, 2005; Abdel-Raouf et al., 2012). A medium-sized mining operation may spend over US$70 000 annually on the cost of lime alone, making conventional treatment methods expensive (Gazea et al., 1996; Robinson and Robb, 1995; Ghosh and Singh, 2005; Abdel-Raouf et al., 2012).

Harris and Ramelow (1990) point out that research has been done on the use of algal strains in bioremediation but the main focus has been the metal ion accumulation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24992512

abilities of some algae species from solutions. McKnight and Morel (1980) report that complex metal ions forming chelatins and polysaccharides produced in algae strains have been extensively studied to enhance the knowledge of heavy metal remediation by algae. Shiraiwa et al. (1993) discovered the ability of certain strains of algae to increase the alkalinity of the medium as a by-product of their inorganic carbon accumulating mechanism. However, the use of this alkaline production by algae in precipitation of metals in AMD has not been widely reported.

Some researchers have shown that direct treatment of AMD with an algal culture has a short period of effectiveness and the sustainability of this direct treatment is poor (Wallace et al., 1997; Boshoff et al., 1996). Cu, lead (Pb) and zinc (Zn) are toxic to algal species such as *Spirulina* sp. when the accumulated concentrations of these metals exceed 7 μmol/g (Payne et al., 1999). Van Hille et al. (1999) developed a system that separates the growing culture of algae from the untreated effluent to help solve the problem of heavy metal toxicity in *Spirulina* sp. The system combines the principles of passive treatment with simple, low-cost reactors associated with active treatment methods. Furthermore, Van Hille et al. (1999) utilized the alkalinity produced by the alga *Spirulina* sp. in a continuous system and found that the alkaline environment elicited by the algal strain enhanced heavy metal precipitation. According to their findings, the primary treatment process consistently removed between 80 and 95% of Zn (7.16 mg/l), over 99% of iron (Fe) (98.9 mg/l) and Pb (2.35 mg/l) within 14 days. Van Hille et al. (1999) further discovered that the combination of the primary and secondary treatments enhanced the removal of over 95% of all metals tested as well as a 90% reduction in sulphate concentration.

Recently, Oberholster et al. (2018) grew *Microspora tumidula*, *Oedogonium crassum* and *Klebsormidium klebsii* previously established by Oberholster et al. (2014) under laboratory conditions for 192 h to determine their bioaccumulation of sulphur (S) and other important algal growth elements such as calcium (Ca), magnesium (Mg) and phosphorus (P) from AMD water and treatment constructed wetland water in the vicinity of the Boesman Spruit (stream) near the town of Carolina in the Ermelo coalfield in South Africa at different pH values. They observed that *Microspora tumidula* showed the highest bioaccumulation of S and P at a pH of 5 and *Oedogonium crassum* showed the highest bioaccumulation of Ca and Mg at a pH of 7. The accumulation efficiency of Mg by all three macroalgal species increased significantly with an increase in the pH. *Oedogonium crassum* and *Klebsormidium klebsii* showed very little increase in chlorophyll A (mg g^{-1} fw) and ash-free dry weight (mg g^{-1} AFDW) when compared to the species *M. tumidula* at all four pH ranges. In conclusion, their study established *Microspora tumidula* as a good candidate for use in a biological hybrid system for treating sulphur-rich AMD.

Remediation properties of algal biomass

The removal of heavy metals and sulphates by algae is believed to be very flexible and depends on the type of metal, the taxon of the alga and the age of material to be removed (Novis and Harding, 2007). Studies have shown that the removal of heavy metals and other contaminants by algae is influenced by seasons (Elbaz-Poulichet et al., 2000; Brake et al., 2004). The seasons influence the availability of light and temperature range, and this can in turn affect the rate of bioremediation by algae because of their sensitivity to light intensity and temperature.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24992512

The common mechanisms used by algae in the remediation process are absorbency and adsorbency. Heavy metal remediation is dependent on the species of algae. The algae feed on the nutrient elements during the process of heavy metal removal and there is an increase in their biomass. Some of these heavy metals adhere to the surface of algae (adsorbency) and others are taken up into the inner cells (absorbency) of the algae. An aqueous solution is required by algae in the removal of a low concentration of metal ions and the bioaccumulation of these metals in their cells (Afkar et al., 2010; Chen et al., 2012; Kumar and Gaur, 2011; Mehta and Gaur, 2005). The heavy metals are bioaccumulated in the cell vacuoles, intercellular spaces and cell wall (Afkar et al., 2010; Chen et al., 2012; Kumar and Gaur, 2011; Mehta and Gaur, 2005), as shown in *Figure 1*. Vymazal (1984) observed that *Cladophora glomerata* and *Oedogonium rivulare* are among the species used to continuously remove cobalt (Co), Ni, Pb, cadmium (Cd), manganese (Mn), Fe, chromium (Cr) and Cu from wastewater. The ability and extent of heavy metal removal by algae is believed to vary from strain to strain (Al-Shwafi and Rushdi, 2008). Mehta and Gaur (2005) discovered that dead algae biomass adsorbs more heavy metals than living ones. Pawlik-Skowrońska (2001) observed that the freshwater algae *Stigeoclonium* spp. can thrive well and effectively remove Zn in mining water containing a high concentration of Zn.

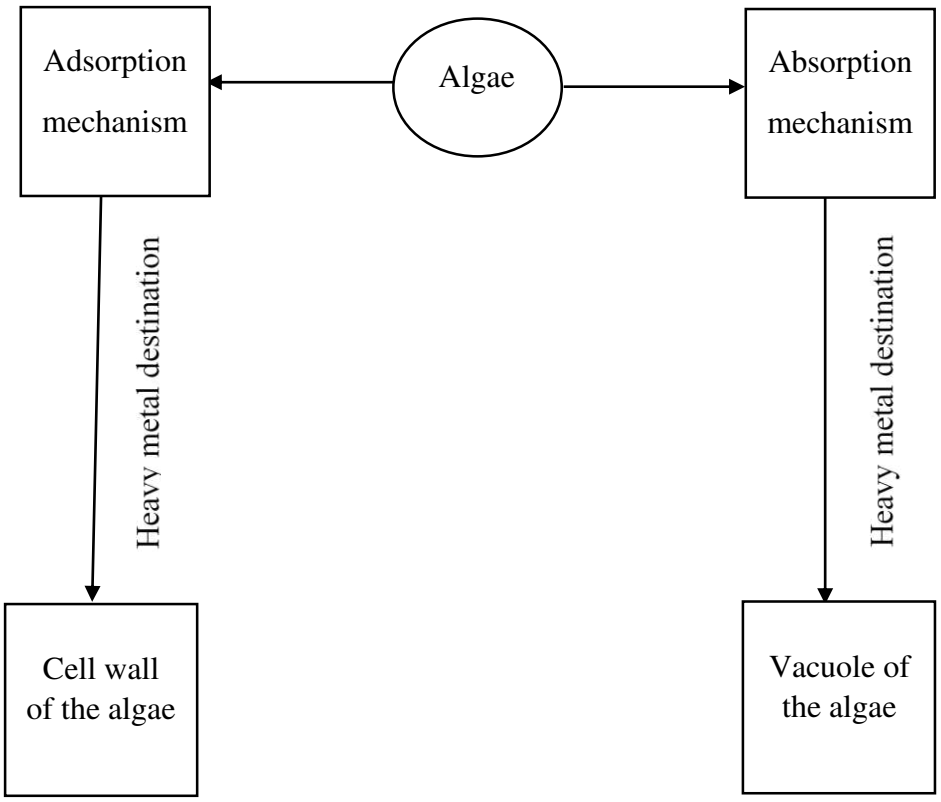

Figure 1. *Mechanisms of heavy metal remediation and their destination in algae*

Living algae accumulate trace metals intracellularly through active biological transport (Ajjabi and Chouba, 2009; Kiran and Thanasekaran, 2011). The synergic activity of different types of algae, along with their multilayer cell walls, makes them a suitable adsorbent for heavy metals (Bilal et al., 2013; Gupta et al., 2015; Wang and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24992512

Chen, 2009). Algae can survive in both fresh and marine brackish waters and are among the most commonly found photosynthetic eukaryotes (Ioannis and Kyzas, 2015). Bishnoi and Pant (2004) discovered that Spirogyra algal species were able to remove Cu (II) with an efficiency of 58 to 85% at an initial concentration of 20 mg/l after 30 min. Furthermore, Pavasant et al. (2006) found that *Caulerpa lentillifera* (a dried green macroalga) was also effective in the removal of multiple metals in an aqueous solution through adsorbency. Other algae such as the brown alga *Turbinaria ornate* and the green alga *Ulothrix zonata* were also found to be very effective adsorbents in the removal of heavy metals (Nuhoglu et al., 2002; Vijayaraghavan and Prabu, 2006; Djati et al., 2016). Regarding the tolerance of *Ulothrix* sp. LAFIC 010 (Chlorophyta) for a high concentration of metals from ACD in Brazil, Massocato et al. (2018) found that the algae accumulated Mn and Ni in their cell walls and vacuole respectively.

Microbial sulphate reduction generates alkalinity and this promotes the bioremediation of acid mine drainage through the formation of metal sulphides that allows for the precipitation of metals from the solution. Acid mine drainage environments are known to be deficient of natural carbon (Koschorreck, 2008), and the addition of suitable carbon sources promotes the activity of sulphate-reducing bacteria (SRB) (Zhang et al., 2017). For SRB to survive and for their better growth, nutrients such as yeast extract and tryptone are absolutely necessary (Zhang et al., 2017). Kiran et al. (2017) state that the most studied bioremediation for heavy metals removal is based on SRB which cause metal sulphide precipitation and hence the removal of the metals from the contaminated environment. The use of SRB to remove heavy metals was successful on a large scale for heavy metal removal at low pH values, stable sludge, very low operating costs and minimal energy consumption. Based on this, SRB could provide an on-site alternative treatment method for AMD; however, they may not be suitable for sites with low temperatures such as those in extreme winter conditions (Sheoran et al., 2010).

The use of SRB for the remediation of the contaminated environment has the weakness of long residence times that can last for weeks. Furthermore, a constant supply of organic substrates and the use of large steel bioreactors are required for them to be effective (White et al., 1997; Sheoran et al., 2010). SRB also require time to grow and reach the critical population growth level to work effectively. This can be a cost of remediation. However, the greatest advantage of using SRB to remediate the environment is their ability to remove both metals and sulphates simultaneously. This is not common when the traditional chemical remediation process is used (Kiran et al., 2017).

Overview of remediation methods of acid mine drainage using algal strains

Various policies, regulations and standards have been suggested in many countries to prevent the threat of AMD to human health and the environment, to reduce the concentrations of the pollutants and to develop cost-effective technologies that will enhance AMD remediation (Fan, 1996). This is due to the challenge that AMD has imposed on most countries of the world (Nriagu and Pacyna, 1988). The conventional treatment methods which are based on either separation (such as precipitation, adsorption and filtration) or reaction have shown many weaknesses, such as low removal capacity, lack of selectivity and intolerance to organic substances.

The high-rate algal pond (HRAP) system is believed to be the most frequently used method for remediating AMD (Oswald, 1998; Mehrabadi et al., 2015). In addition, the algal turf scrubber (ATS) was also developed to remediate AMD and polluted groundwater. The ATS method involves the application of suspended biomass of cyanobacteria such as S*pirulina, Oscillatoria, Anabaena* or consortia of species or common green algae species such as *Chlorella, Scenedesmus, Cladophora* (Craggs et al., 1996; Adey et al., 1996). These methods were found to be effective in the removal of heavy metals and organic compounds such as chlorinated and aromatic organic compounds to acceptable levels in AMD or any other industrial wastewater (Craggs et al., 1996; Adey et al., 1996).

Toumi et al. (2000) reported that the HRAP has a higher removal rate per unit volume per day. Tested on urban polluted water with lower ion concentrations of Zn, Cu and Pb, the HRAP was found to be 10 times more efficient in removing Cu compared to the waste stabilization pond system. Furthermore, high pH values enhanced metal precipitation and effective algal photosynthesis. Rose et al. (1998) reported the formation of a patent ATS formed from a combination of HRAP and SRB. This process involves the direct addition of AMD into HRAP with a high pH value to enhance the precipitation of heavy metals, followed by the recovering of HRAP biomass which is used as a carbon source for SRB (Perales-Vela et al., 2006). However, these methods had challenges in maintaining a dynamic equilibrium between algae net oxygen production, bacterial respiration due to low light penetration, rich microalgal biomass, climate conditions and proper mixing (Fallowfield and Garret, 1985).

Phillips et al. (1995) suggest non-agitated algal ponds as a remedy for the challenges faced with constructed wetland technologies in enhancing the effective removal of Mn and stability of a neutralizing pH. They show that consortia of algae and cyanobacteria can reduce Mn concentrations effectively to an environmentally safe level. The work done by Perales-Vela et al. (2006) also shows that Mn can be removed through biomass adsorption, high pH precipitation and immobilization. All these findings provide a promising future for the treatment of AMD and wastewaters through algae bioremediation.

Dinardo et al. (1991) state that the history of the ability of aquatic plants to remove heavy metals efficiently from contaminated AMD water dates back to 1973. Since then, several algae strains have been successfully used in the removal of heavy metals from AMD or wastewater but most of the work was completed during a batch process in which microalgal species were grown. Wang et al. (2016) state that algae can produce oxygen at a lower cost and also be effective in phycoremediation.

Algae play an essential role in the bioaccumulation of heavy metals in wetland remediation of AMD. Zagury et al. (2007) state that this role of algae makes it possible to design passive bioreactor systems for the remediation of AMD. A passive bioreactor system is based on a similar principle as a large activated carbon filter where AMD comes into the surface area, percolates through a specially constructed barrier layer and exits the system from below. The major components of this bioreactor, especially the initial stage, include algae. *Spirulina* spp. was discovered to be useful in remediating AMD because they were able to absorb various heavy metals rapidly through direct contact with the AMD effluent stream and reached saturation within 30 min (Van Hille et al., 1999; Balaji et al., 2014). Furthermore, it was observed that *Spirulina* spp. exhibited toxicity after the period of saturation but continued to generate an alkaline environment capable of reducing the acidity of AMD through the production of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_24992512

inorganic bicarbonate salts. Species of both micro- and macroalgae have been identified as useful in phycoremediation. A *Chlorella* strain that was capable of sustaining growth at 11.24 mg of Cd^{2+}/l was analysed in a marine screen and was found to have a removal efficiency of 65% when exposed to an amount of 5.62 mg of Cd^{2+}/l (Matsunaga et al., 1999). Furthermore, *Chlorella* and *Scenedesmus* strains were analysed in a batch process at 20 mg Cr^{6+}/l and were found to have removal efficiencies of 48% and 31% respectively (Travieso et al., 1999).

Algal biomass was observed to accumulate heavy metals in the work done by Freitas et al. (2011) on the biosorption of heavy metals by algal species in AMD from coal mining in Brazil. They further observed that the algal biomass' capabilities to absorb the heavy metals were Fe > Al > Ca > Mg > Zn > Mn > Cu in all the sampling sites. Algal genera such as *Microspora, Eunotia, Euglena, Mougeotia* and *Frustulia* survived in the AMD environment and *Microspora* was the most dominant (Freitas et al., 2011). A hybrid system comprising a pipe inserted microalgae reactor (PIMR) and an active treatment unit for the removal of Fe from AMD was used by Park et al. (2013) to study the removal of heavy metals by algal species. Fe can hinder the growth of algae and lipid formations which can limit the ability of algal biomass to remove heavy metals in AMD, hence the need to remove the element in the hybrid system. Furthermore, in the study carried out by Park et al. (2013), *Nephroselmis* sp. was observed to be effective in removing heavy metals and had a strong tendency to grow with pre-treated AMD. Based on the ability of the algal species to grow well and also remove heavy metals, PIMR was suggested to be more effective in removing heavy metals and enhancing the growth of algal species. PIMR was found to be more protective than HRAP and SRB in protecting the algal species against environmental contaminants. However, the HRAP system has more treatment capacity and heavy metal removal than the PIMR system.

At least 14 algal species and their ability to take up heavy metal contaminants from AMD and other pollution sources were reviewed by Ben and Baghour (2013), and were found to hyperaccumulate or hyperabsorb heavy metals with high selectivity for different metals. Furthermore, the results of a few studies regarding the use of some microalgae species for AMD bioremediation were compiled by Das et al. (2009). The removal efficiencies of heavy metals and sulphates which are the main contaminants in AMD, operating conditions and the growth methods used to achieve the results, and the effectiveness and possibility of algae technology for AMD bioremediation are contained in *Table 1*. Cu, Zn, Fe, Pb, Ni, Mn and sulphates, under a known pH range, can be removed by microalgae. This knowledge about microalgae enhances the possibility of modifying phycoremediation of the algal biomass to suit specific pollutant conditions, alongside both uptake limits and specificity through genetic engineering of algal species.

Since the early 1990s, passive water treatment systems where algae remove heavy metals from AMD or other contaminated wastewater as a common component have been used. Although the algal biomass has been proven to be efficient in removing both organic and inorganic pollutants, there is a need for more studies to explore its full potential with the development of innovative technologies. Such innovative technologies could include gene modification technology. This technology involves identifying specific genes responsible for producing metal-chelating proteins and enhancing this capability in algal strains.

Table 1. *Summary of the use of some algal species in acid mine drainage bioremediation (adapted from Das et al., 2009)*

Algal strains	Remediation role	Achieved results	Growth method	Reference
Blue-green algae – cyanobacterial mat		Removal of 2.59 g of Mn/day/m^2	Oxidation pond	Phillips et al. (1995)
Spirulina sp.	Metal adsorption, re-alkalization, nutrient for SRB (dead biomass)	(i) Removal of Fe (up to 100%), Zn (86-98%), Cu (38-76%), Pb (40-78%) at retention time of 10 days (ii) Rise of pH from 3 to 8.5 for a biomass loading of 3 mg/mL chlorophyll A	HRAP (high-rate algal pond)	Rose et al. (1998)
Spirulina sp.	Alkalinity generation and metal precipitation	(i) pH rise from 1.8 to 8.18 (ii) Reduction of sulphates (SO_4) 89%, Fe 99%, Pb 95%, Zn 93%, Cu 94%	Bench scale anaerobic digester, primary and secondary treatment	Van Hille et al. (1999)
Mixed algal population	Soluble EPS as carbon source for SRB	Up to 57% of sulphates (SO_4) and 52% COD removal by mixed SRB	HRAP	Molwantwa et al. (2000)
Eunotia exigua and *Pinnularia obscura*	Primary production	Chlorophyll A (Chl A) Content 52-72 mg/m^2	Mining lake	Koschorreck et al. (2002)
Spirulina spp.	Dead biomass as nutrient for SRB	150 mg SO_4 removal/g algal biomass/day	Bench scale anaerobic upflow reactor	Boshoff et al. (2004)
Blue-green algae (predominantly *Oscillatoria* spp.) – microbial consortium	SO_4 removal, metal precipitation by consortium	(i) pH increase from 2.93 to 6.78 (ii) Reduction of SO_4 29%, Fe 95%, Pb 88%, Zn 86%, Cu 97%, Co 83%, Ni 62%, Mn 45%.	Bench scale test cell	Sheoran and Bhandari (2005)
Chlorella ellipsoidea	Bioremediation potential		In-situ test using limnocorrals	EPA (2005)
Eunotia exigua and *Chlamydomonas* sp.	Enhance primary production, thereby SRB growth	Reduction of Fe from 14 mg/L to 0.2 mg/L and SO_4 from 344 mg/L to 124 mg/L	Microcosm experiment	Fyson et al. (2006)
Ulothrix spp.	Metal absorption	Absorption of Cu 3500 mg/L and As 500 mg/L	AMD, Sar Cheshmeh copper mine	Orandi et al. (2007)

The knowledge of the use of algae and their ability to remove heavy metals is widely accepted and growing fast. However, significant contributions are yet to be made in light of the success of passive systems used in the remediation of AMD. Many researchers have focused on the production of biofuel or biodiesel from algal sources. This has taken the attention of most researchers away from the potential value of algae in phycoremediation which presents a promising solution in AMD remediation. Das et al. (2009) encourage the use of *Lepocinclis* sp. and *Klebsormidium* sp. in the treatment of AMD because they showed promising features in terms of their growth and distribution. Furthermore, the use of a consortium of algae and fungi has been encouraged, either used individually or as a group, as they offer the advantage of working in symbiosis and synergy. However, this consortium of algae and fungi could bring the challenges of high heavy metal concentrations, acidity, low availability of organic carbon and phosphates because these factors affect the growth of both organisms. This can be a setback to the success of using this consortium of algae and fungi in treating AMD because it contains high levels of heavy metals with a very low pH.

Conclusion

Many studies have indicated the effectiveness of phycoremediation of AMD and its potential for future applications, as shown in this current review. It is also evident from this review that passive systems involving the use of algal biomass have achieved commendable results; however, they are not the ultimate solution to the problem of AMD. Consequently, there is a need for further studies on effective remediation of AMD to provide more solutions to the environmental problem caused by this scourge. It is believed that each AMD tailing site has unique chemical characteristics and compositions that require a unique way of remediation.

Therefore, a conclusive study will require evaluation of various algae species, their removal mechanisms and growth, pH, temperature, residence time and flow rate of the AMD to enhance the success of AMD remediation using algae species. Some algae species are known as extremophiles because they can thrive well in unusual and extreme environmental conditions. As a result, there is a need to study in detail their adaptability to be used in phycoremediation processes, especially for AMD. However, algae as sources of oxygen have some weaknesses such as their unpredictable response to a complex changing environment or wastewater when compared to conventional wastewater treatment plants. Furthermore, the opacity of the medium, solar radiation, rise of nutrients, temperature, season and ecological succession, and other major environmental factors are not easily understood and require careful monitoring to ensure the success of the process.

This current review suggests that more studies should be done on different aspects of phycoremediation and SRB approaches, and possibly a combination of the two approaches in the remediation of AMD. This should range from identifying and developing simple, effective physical barrier materials to advanced genetic research suitable for AMD.

Abstract. In order to realize the evaluation of hazardous chemicals disposal sites in the Kuluktag region of Xinjiang, China, this paper conducted a numerical simulation study of the circulation of groundwater in the carrier of nuclide migration. Based on the hydrogeological survey in the field, a hydrogeological conceptual model of regional groundwater flow and a three-dimensional numerical model of regional groundwater flow were established. The finite difference method was applied to obtain the flow velocity and characteristics of groundwater under various scenarios. By analyzing the sensitivity of the structure of water-containing medium and its parameters, this paper aims to explore the impact of the uncertainty of precipitation, water-containing medium structure and its parameters on the flow velocity and direction of regional groundwater, simulate the change of flow velocity and direction of groundwater in the study area, and predict the groundwater circulation rules in the long run measured in the unit of 10,000 years.
Keywords: *Kuruktag, hydrogeological conditions, groundwater circulation model, nuclide migration, numerical simulation*

Introduction

As groundwater is the carrier of nuclides migration, the quantitative evaluation of groundwater flow and migration of nuclide in underground complex geological bodies is critical to the evaluation and selection of disposal sites. Research and discovery on hydrogeology, groundwater circulation and nuclides migration evaluation is one of the hottest research topics on disposal site evaluation (Kolbe et al., 2016; Post et al., 2019; Cao et al., 2016; Tatti et al., 2019; Zhou et al., 2013; Jiang et al., 2018).

In recent decades, numerical simulation has been carried out extensively to analyze groundwater flow in various areas. Kihm et al. (2007) predicted the relationship between groundwater flow and land deformation using three-dimensional numerical simulation. Blessent et al. (2011) conducted fluid flow and solute transport model in discretely-fractured crystalline bedrock for nuclear-fuel site. Tatti et al. (2019) built numerical model of the contaminated low permeability layers based on groundwater Circulation Wells. Pétré et al. (2019) analyzed the regional groundwater flow system of the transboundary Milk River Aquifer using numerical modeling. Mengistu et al. (2019) employed the numerical simulation to evaluate groundwater monitoring network of the Moab Khutsong deep gold mine.

This article makes full use of existing data, including geological, hydrogeological, groundwater dynamic data and satellite imagery, combined with field hydrogeological surveys to analyze regional hydrogeological conditions and groundwater distribution characteristics, including aquifer media system structure, boundary conditions, characteristics of groundwater flow field, hydraulic connection between different water-bearing units, and characteristics of groundwater recharge and discharge (Chang et al., 2001).

DOI: http://dx.doi.org/10.15666/aeer/1802_25132538

According to the survey of stratigraphic lithology in combination with the analysis of groundwater dynamic field, geological structure and hydrogeology in the Kuruktag region of Xinjiang, the model of regional groundwater circulation is established, and the numerical model of three-dimensional groundwater flow is constructed to obtain the parameters related to the aquifer system. Based on the existing research results and risk assessment experience at home and abroad (Kendall, 1998; Singleton et al., 2005), the groundwater flow numerical model is used to simulate the spatial and temporal distribution characteristics of groundwater flow under various scenarios, and the influence of the uncertainty of geological medium structure and parameters on groundwater flow is studied and explored. The variation rules of regional groundwater flow under long-term scale could be predicted through the mechanism and pattern of groundwater flow.

(1) We use GIS (Geographic Information System) technology to integrate a large number of regional scale data (including geology, topography, spring location, and well information) into hydrogeological information data. The method not only accurately describes the hydrogeological conditions of the study area, improving the data management and efficiency, but also provides necessary data to support the establishment of regional groundwater models.

(2) Due to the large-scale work area and the difficulties determining hydrogeological boundaries, SRTM DEM (the digital elevation model) data is used for hydrological space analysis, that is, the extraction of digital river network and the division of the drainage basin, so as to grasp the boundary of the whole basin. On the basis of hydrological analysis, the model boundary is determined according to the hydrogeological conditions, flow conditions and replenishment relationship of the work area.

(3) According to the stratigraphic age and lithology, the regional groundwater permeability coefficient is divided. At the same time, considering the strong heterogeneity of the work area, the faults are separately characterized in the model to analyze the impact of faults on groundwater flow.

(4) We aimed to establish a regional groundwater flow model by MODFLOW (Visual MODFLOW 2000 software), and correct the model through the measured groundwater water level so that the regional groundwater model can reflect the real groundwater flow field more accurately.

Hydrogeology introduction

Natural geographical conditions

Topography

The western part of the work area is Bosten Lake by an altitude of about 1,050 m, and the eastern part gradually becomes mountainous. On the north side of the east is the Qoltag Mountains, and on the south side is the Kuruktag Mountain interspersed with the mountain basins. The eastern part of the work area is mainly the Nanhu Gobi. The north side of the work area is the Turpan Basin, and the south faces the Lop Nurdriedbasin. Lop Nur, the lowest plutonium in the Tarim Basin, is a modern dried-up salt lake with an area of 10,350 km^2. Its outer zone is the vast Taklimakan Desert in the west; the eastern part is the Beishan and the Aqike Valley; the alluvial fan and dune of the Altun Mountains is in the south, and the low hills of Kuruktag in the north. There are large areas of Yadan or wind-eroded mounds and terraces in the north, west and east of Lop Nur. Lop Nur is an endless salt-desert plain with a slope of only 0.04%. The surface presents different forms of salt crust, which often exhibits micro-topography such as ploughing land and cracks.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25132538

The salt crust is hard and sharp, and the height of the undulation varies from 10 to 60 cm approximately (Xia, 2007). The surface elevation of the work area is shown in *Figure 1*.

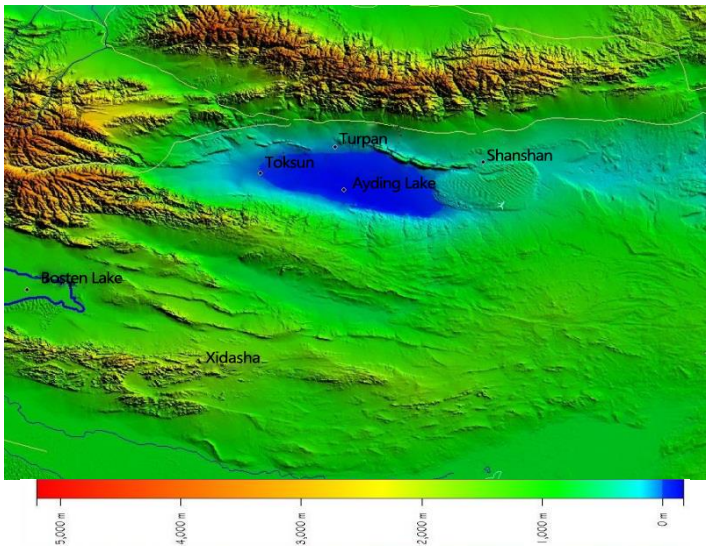

Figure 1. *Work area elevation*

Meteorology and hydrology

The work area belongs to the arid area of the northwest inland. The average annual precipitation is less than 60 mm, and the most rainfall is concentrated in the summer. The average annual precipitation of Kumish and Tokson in the west of the work area is 61.6 mm and 9.2 mm; 26.3 mm of Shanshan and 56.9 mm of Hami in the north; 47.8 mm of Ruoqiang and 42.9 mm of Milan in the south.

Lop Nur in the south-central part of the work area is located at the lowest recess in the eastern end of the Tarim Basin and surrounded by mountains to the north, east and south of the typical continental arid climate, which means that the region considered to be dry. For example, the average annual precipitation of Tieqianlike is less than 20 mm, however the annual average evaporation is up to 2,600 mm with 10.6 °C as the annual average temperature and 26.7 °C of the average temperature in July, -9.5 °C in January. There is a lot of wind in the area, and the prevailing wind direction is NE (SDIC Xinjiang Lop Nur Potash Co. Ltd, 2006).

Geological introduction

The northern part of the work area is the Turpan-Hami Basin. The Turpan-Hami Basin is an intermountain basin in the eastern section of the Tianshan fold mountain range. It is a Mesozoic and Cenozoic sedimentary basin that occurred and developed on the basis of the returning slanting slope of the Hercynian period. The layer thickness is 5,000-6,000 m with the maximum of 8,700 m. The southern part of the basin is about 2000 m above sea level. They are composed of Upper Paleozoic volcanic rocks, volcanic clastic rocks and rammed rocks. The pier uplift divides the Turpan-Hami basin into east and west Quaternary sedimentary basins, and the western part is the Turpan Basin, with an area of about 21,000 km^2. The structural pattern of the Tu-ha Basin is shown in *Figure 2* (Chen, 1993).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25132538

The central and western part of the work area is the Kuruktag region, and the structure of the area is shown in *Figure 3*. Most of the Sinian and Paleozoic caprocks were constructed with carbonate platforms and clastic rocks. The total thickness is up to 8,000 m, and the maximum thickness reaches 14,000-15,000 m. When the Tertiary continental clastic sediments are developed, the thickness of the caprock is greatly reduced to only 100-200 m. Due to the different neotectonic movements, the geomorphology of the area is in a relatively young development stage, especially in the northwest, where many high and steep mountains are formed. There is a clear topographical difference between the area and the north of the CazelTaga (geosyncline) and the Tarim Basin (Lot) in the south (Chen, 1966; Feng et al., 1994).

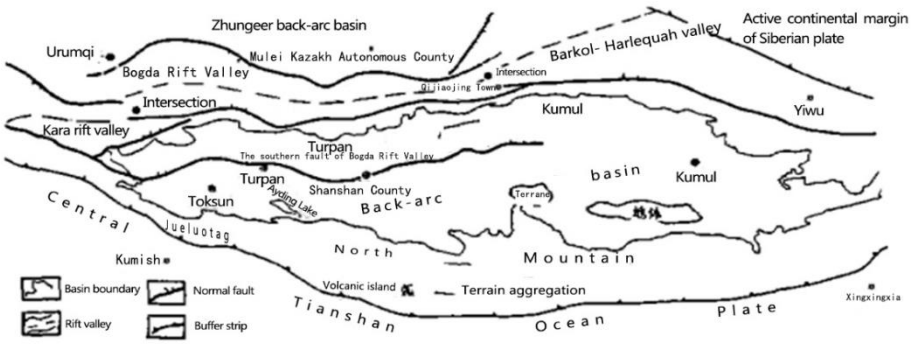

Figure 2. *Tectonic framework of the Tu-ha basin and its adjacent area*

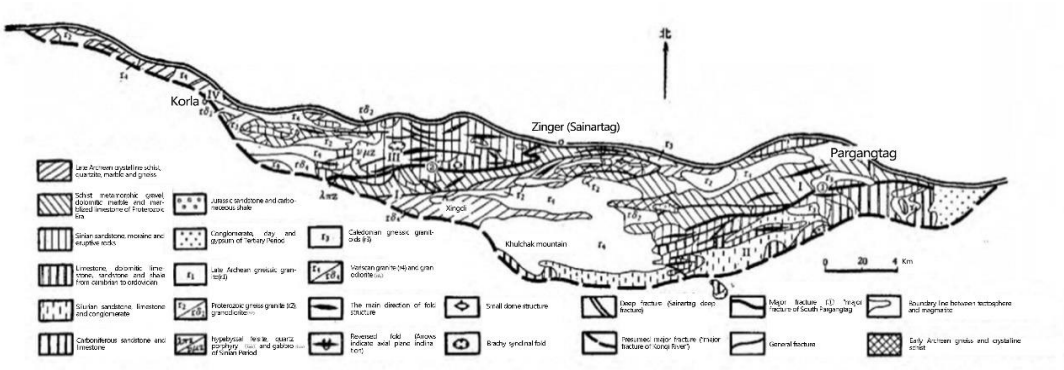

Figure 3. *Tectonic sketch of the Kuruktag*

Stratum

The Paleozoic and pre-Paleozoic clastic rocks, magmatic rocks and carbonate rocks are widely distributed in the Kuruktag Mountains. There are thin Quaternary loose stratums distributed in the piedmont strips and local inter-mountain basins. The Tertiary clastic rocks are mainly distributed in the denudation platform and the inter-mountain depression in the northeastern part of the Lop Nur Basin. The formation is generally gentle, and the lithology is mainly mudstone, sandy mudstone, sandstone and glutenite. The Quaternary loose sediments are mainly distributed in the lake basin and its surrounding low-lying areas. The thicker Quaternary alluvial sand and gravel stratums are distributed in the sloping plains of the Altun Mountains in the south and the Aqike Valley in the east.

Tectonics

(1) Fracture

There are three lithospheric faults within the work area, and two shell faults, and more general faults. According to its distribution direction, it can be roughly divided into three groups: the north-north-east fault, the near east-west fault and the north-east-east fault, among which the north-east-east fault is the most developed. The near east-west basal-type fault developed in the Altun Mountains is mostly spread in a sleek shape in a large scale. The main compresso-shearing structure with water-resistance controls the boundary between the bedrock mountain and the basin. The northwestward fault constitutes a conjugated fault zone, which develops in the Kuruktag, Beishan and Aqike Valleys (The Second Hydrogeology Engineering Geology Brigade of Xinjiang Geology and Minerals Bureau, 2003). It extends far with a large scale, and it is regarded as left-handed compresso-shearing, which controls the northern boundary of the dried-up Lop Nur salt lake. Across the dried-up Lop Nur salt lake, the fault divide it into several units, and along the fault the spring points are distributed (Shi et al., 2017).

(2) Fold

There is a large number of folds in diverse forms mainly developed in the Kuruktag and Beishan areas. Among them, the large-scale Beishan fold belt with complex folds is generally north-east-east and north-eastward directed. The fold belt in Kuruktag region is small and omnidirectional in axial direction. In the red clay castle in Luobei, there is a new generation of anticline development.

(3) Joint fissures

In the Kuruktag and Beishan areas, there are common joint fissures in the rock, and the dense belts are mostly distributed on both sides of the fault. The development of joint fissures in brittle rocks such as limestone and granite are significantly higher than those of soft rocks.

Regional hydrogeological conditions

Division of groundwater systems

Based on the viewpoint of groundwater system theory, the complete groundwater migration space with relatively independent recharge, runoff and excretion is divided into six groundwater first-level systems in the region, and then according to aquifer characteristics, recharge conditions, hydrodynamic characteristics and groundwater quality, characteristics, several secondary systems (sub-zones) can be divided (Lei et al., 2019).

Regional groundwater circulation characteristics

Atmospheric precipitation in the mountainous area is transformed into bedrock fissure water and surface water in the Altun Mountains and Kuruktag and Beishan. Part of the bedrock fissure water is transferred to deep circulation water to the deep subsurface, and the other part along the valley or the front of the mountain to replenish surface water as spring. The surface water flows out of the mountain, passing and then enters the Altun Mountains and Kuruktag and the sloped gravel plains of the Beishan

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25132538

Mountain and the front edge of the mountain depressions are turned into springs along the faults and then converted into surface water. It is supplied in the form of lateral replenishment to the Acoch Valley, the Peacock River Delta and the Tarim River Delta alluvial plain, and then to the Lop Nur Lake Plain (Shao et al., 2017). In this migration process, it is excreted by water surface evaporation, phreatic evaporation, plant transpiration and artificial mining. In the vertical direction, the groundwater system is relatively stable and moves upwards and downwards. The water alternates in a mixed type, and the middle and deep layer confined water heads are relatively more. High, the shallow confined water is replenished through faults or relative water-repellent layers, and the shallow confined water is replenished for diving. During this process, the groundwater forms a dynamic equilibrium and the property of water changes from HCO_3-Ca•Mg to SO_4. • Cl-Ca•Na, which eventually becomes Cl-Na; in the vertical direction, it also changes from SO_4-Ca•Mg to SO_4•Cl-Ca•Na, eventually it becomes Cl-Na, and then after long-term evaporation and concentration, a highly mineralized potassium-rich brine is formed (Jiao et al., 2004; Liu et al., 1999; Lei et al., 2019; Wang, 2016).

Simulation analysis of regional groundwater flow patterns

Due to the development of today's groundwater modelling technology and the rapid improvement of computer technology, groundwater numerical model has become an important tool for quantitative study of groundwater movement rules, and plays an increasingly important role in solving specific hydrogeological problems. So far, only through the model, can data from different methods (such as geophysical exploration, drilling, surveying, monitoring, remote sensing, etc.) be put into a unified system for data integration and management, and whether there is any existing contradiction between them. If there is some prior understanding of hydrogeology, it can be analyzed by means of modelling whether the data is consistent with our understanding, which is extremely essential. In the process of comprehensive processing of hydrogeological data by modelling, the sufficient and absent hydrogeological information can be found respectively, which leads to the further exploration of the lacking information. Therefore, the model is also an important means to help deploy further field surveys, and place limited investment on the situations in need of data. We have many assumptions about the flow, excretion, and recharge of groundwater. An effective way to test whether these assumptions are correct is to put the hypothesis into the model and compare the results of the model with the reliable measured results. In this way, we can understand more about hydrogeological conditions.

Groundwater flow is a complex geological process, which means that we cannot directly observe where the groundwater flows to, how fast the water flows, and the spatial variation of aquifer hydrogeological parameters. To comprehend the spatial distribution of groundwater in the ground, the characteristics of groundwater flow and its dynamics over time, scientists have conducted a large number of field surveys and studies in order to master the distribution characteristics and rules of groundwater flow in time and space. Nevertheless, this scientific problem still cannot reach a satisfactory solution for a long time. One of the main reasons is the heterogeneity of the aquifer structure and the uncertainty of its parameters. Because people can only analyze and study aquifer systems based on limited geological and hydrogeological

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25132538

exploration data. The hydrogeological community has been seeking for a theory and method that can more reasonably describe the distribution of aquifer system parameters. Therefore, the use of numerical model of three-dimensional groundwater flow to describe the spatial variation characteristics of aquifer structure and groundwater flow rules is the current research trend in the field of hydrogeology.

This paper focuses on the simulation analysis of the groundwater flow pattern in the work area, so as to take in the mode and flow characteristics of regional groundwater circulation.

Mathematical models and numerical methods

The numerical method has the rules of groundwater flow that can be characterized by complex hydrogeological conditions, artificial activity conditions, irregular boundary conditions, and a series of time variables. After the 1970s, with the development and popularization of computers, numerical methods have been successfully used to simulate groundwater movement and groundwater resource evaluation. The previous numerical simulation research and application of groundwater flow has two distinct features: first, most models discuss numerical algorithms and computational formats, and the processing of boundary conditions is too simple and often insufficient. Many models use artificial boundaries. Whether the artificial boundary selection is reasonable or not will affect the flow pattern of groundwater. The artificial boundary is not a problem in the simulation process. The local parameters can be adjusted to make the calculated value and the measured value reach the expected target. When forecasting, the hydraulic head of the original artificial boundary is generally not given and can only be treated as a known boundary. Second, most studies rely on the two-dimensional model, although in recent years, the use of three-dimensional model has increased, but in practice, few three-dimensional models are adopted with few vertical stratifications in the model. More models use idealized research fields and units (rectangular domain regular hexahedron), depending on the aquifer as a horizontal layer. The calculation unit is too idealized and the aquifer is horizontally layered, which is far from the actual distance, bringing about difficulties to reasonably characterize the actual spatial structure changes of the aquifer (Xue et al., 2018).

In this paper, the three-dimensional finite difference model is used to simulate groundwater flow, and the spatial and temporal distribution characteristics of regional groundwater flow are analyzed, and the influencing factors are studied and analyzed.

Mathematical model of three-dimensional groundwater flow

According to the three-dimensional hydrogeological conceptual model of groundwater flow, the unsteady three-dimensional mathematical model of groundwater flow in the regional aquifer system can be described as follows:

$$\frac{\partial}{\partial x}\left(Kxx\frac{\partial H}{\partial x}\right)+\frac{\partial}{\partial y}\left(Kyy\frac{\partial H}{\partial y}\right)+\frac{\partial}{\partial z}\left(Kzz\frac{\partial H}{\partial z}\right)=\mu s\frac{\partial H}{\partial t}+W \quad (x,y,z)\in D \quad \text{(Eq.1)}$$

Initial conditions:

$$H(x,y,z,0)=H_0(x,y,z) \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25132538

Boundary conditions:

$$\begin{aligned} &H(x,y,z,t)|_{\Gamma 1} = H(x,y,z) \\ &H(x,y,z,t)|_{\Gamma 2-1} = Z \\ &Kzz\frac{\partial H}{\partial z}|_{\Gamma 2-1} = \varepsilon' - \mu_d \frac{\partial H}{\partial t}|_{\Gamma 2-1} \\ &Kzz\frac{\partial H}{\partial z}|_{\Gamma 2-2} = 0 \end{aligned} \quad \text{(Eq.3)}$$

where: xyz - Cartesian axis; t - time; H - known hydraulic heads; *KxxKyyKzz* - the main permeability coefficient in the direction of the coordinate axis; μs - specific storage; μ_d - gravity specific storage; W - the flow rate per unit volume of the well, taking a negative sign when pumping; $\Gamma 1$ - the Dirichlet boundary; $\Gamma 2-1$ - the boundary of the phreatic surface; $\Gamma 2-2$ - zero flow boundary; ε' - recharge amount of precipitation infiltration.

Numerical methods

The basic idea of the finite difference method is to replace the continuous vadose zone with a set of finite discrete points in the Vadose zone, as well as replacing the derivative approximated by the difference quotient at the discrete point, and condition the differential equation and its solution as an unknown function. The approximation of the discrete points is an algebraic equation of unknown quantity, and then the difference equation is solved, and then the approximation of the solution of the differential equation at discrete points is obtained.

The method is based on a continuity equation for groundwater flow according to which, the differences between the water flows into and out of a computing element is equal to the change in the water storage capacity of the unit.

The groundwater continuity equation can be expressed as:

$$\sum Q_i = SS \cdot \Delta h \cdot \Delta v \quad \text{(Eq.4)}$$

where: Q_i - the amount of water flowing into or out of the calculation unit per unit time; SS - the storativity of the aquifer; Δh - changes of the hydraulic head per unit time; Δv - the volume of the computing element.

After the Vadose zone is split and separated, the computing element can be determined according to the continuity equation and the Darcy formula:

$$\begin{aligned} &\sum Q_i = SS \cdot \Delta h \cdot \Delta v \\ &Q = K \cdot \omega \cdot \frac{h}{L} \end{aligned} \quad \text{(Eq.5)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25132538

The flow into the unit (i, j, k) by the computing element (i, j-1, k) in the row direction can be obtained as:

$$q_{i,j-1/2,k} = KR_{i,j-1/2,k}\Delta c_i \Delta v_k \frac{(h_{i,j-1,k} - h_{i,j,k})}{\Delta r_{j-1/2}} \quad \text{(Eq.6)}$$

where: $q_{i,j-1/2,k}$ - the flow through the interface between the grid points (i, j, k) and (i, j-1, k) ($L^3\ T^{-1}$); $KR_{i,j-1/2,k}$ - the permeability coefficient (LT^{-1}) between the grid point (i, j, k) and (i, j-1, k); $\Delta c_i \Delta v_k$ - cross-sectional area (L^2); $h_{i,j-1/2,k}$ - the value of the hydraulic head at the grid point (i, j-1, k); $h_{i,j,k}$ - the value of the hydraulic head at the grid point (i, j, k); $\Delta r_{j-1/2}$ - the distance (L) between the grid point (i, j, k) and (i, j-1, k).

Groundwater flow through the other five interfaces can be analogized. For example, the groundwater flow rate from the grid point (i, j + 1, k) to (i, j, k) in the row direction is:

$$q_{i,j+1/2,k} = KR_{i,j+1/2,k}\Delta c_i \Delta v_k \frac{(h_{i,j+1,k} - h_{i,j,k})}{\Delta r_{j+1/2}} \quad \text{(Eq.7)}$$

Similarly, it can be concluded in turn:

$$q_{i+1/2,j,k} = KC_{i+1/2,j,k}\Delta r_j \Delta v_k \frac{(h_{i+1,j,k} - h_{i,j,k})}{\Delta c_{i+1/2}} \quad \text{(Eq.8)}$$

$$q_{i-1/2,j,k} = KC_{i-1/2,j,k}\Delta r_j \Delta v_k \frac{(h_{i-1,j,k} - h_{i,j,k})}{\Delta c_{i-1/2}} \quad \text{(Eq.9)}$$

$$q_{i,j,k+1/2} = KV_{i,j,k+1/2}\Delta r_j \Delta c_i \frac{(h_{i,j,k+1} - h_{i,j,k})}{\Delta v_{k+1/2}} \quad \text{(Eq.10)}$$

$$q_{i,j,k-1/2} = KV_{i,j,k-1/2}\Delta r_j \Delta c_i \frac{(h_{i,j,k-1} - h_{i,j,k})}{\Delta v_{k-1/2}} \quad \text{(Eq.11)}$$

The above formula shows the groundwater flow through the six interfaces of the computing element (i, j, k), and the grid spacing and the permeability coefficient are combined into one variable as the hydraulic conductivity coefficient:

$$CR_{i,j-1/2,k} = KR_{i,j-1/2,k}\Delta c_i \Delta v_k / \Delta r_{j-1/2} \quad \text{(Eq.12)}$$

Applying the hydraulic conductivity to *Equations 6* to *11,* it can be concluded that:

$$q_{i,j-1/2,k} = CR_{i,j-1/2,k}(h_{i,j-1,k} - h_{i,j,k}) \quad \text{(Eq.13)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25132538

$$q_{i,j+1/2,k} = CR_{i,j+1/2,k}\left(h_{i,j+1,k} - h_{i,j,k}\right) \quad \text{(Eq.14)}$$

$$q_{i-1/2,j,k} = CC_{i-1/2,j,k}\left(h_{i-1,j,k} - h_{i,j,k}\right) \quad \text{(Eq.15)}$$

$$q_{i+1/2,j,k} = CC_{i+1/2,j,k}\left(h_{i+1,j,k} - h_{i,j,k}\right) \quad \text{(Eq.16)}$$

$$q_{i,j,k-1/2} = CV_{i,j,k-1/2}\left(h_{i,j,k-1} - h_{i,j,k}\right) \quad \text{(Eq.17)}$$

$$q_{i,j,k+1/2} = CV_{i,j,k+1/2}\left(h_{i,j,k+1} - h_{i,j,k}\right) \quad \text{(Eq.18)}$$

These formulas are used to calculate the groundwater flow inflows from the six boundary faces of the unit (i, j, k). In addition, the effects of other various external sources and sinks on the calculation unit, such as rivers, ditches, production wells, and injection wells, evapotranspiration, etc. need to be considered. The quantity of these sources and sinks into the unit can be calculated by a formula:

$$a_{i,j,k,n} = p_{i,j,k,n}h_{i,j,k} + q_{i,j,k,n} \quad \text{(Eq.19)}$$

where: $a_{i,j,k,n}$ - the replenishment of the nth external source pair calculation unit (i, j, k) (L3 T-1); $q_{i,j,k,n}$, $p_{i,j,k,n}$ - constant, the unit is (L2 T-1), (L3 T-1).

Considering the six adjacent grid points of the calculation unit and all the sources and sinks contained in the unit, the continuity equation (*Eq. 4*) can be calculated as:

$$\begin{aligned} &q_{i,j-1/2,k} + q_{i,j+1/2,k} + q_{i-1/2,j,k} + q_{i+1/2,j,k} + q_{i,j,k-1/2} + q_{i,j,k+1/2} + \sum_{n=1}^{N} a_{i,j,k,n} \\ &= SS_{i,j,k}\frac{\Delta h_{i,j,k}}{\Delta t}\Delta r_i \Delta c_j \Delta v_k \end{aligned} \quad \text{(Eq.20)}$$

where: $SS_{i,j,k}$ - the storativity of the computing element (L^{-1}); $\frac{\Delta h_{i,j,k}}{\Delta t}$ - a differential approximation of the partial derivative of the hydraulic head for time; $\Delta r_i \Delta c_j \Delta v_k$ - the volume of computing element (L^3).

Substituting *Equations 13–18* and *19* into *Equation 20* yields:

$$\begin{aligned} &CR_{i,j-1/2,k}\left(h_{i,j-1,k} - h_{i,j,k}\right) + CR_{i,j+1/2,k}\left(h_{i,j+1,k} - h_{i,j,k}\right) + CC_{i-1/2,j,k}\left(h_{i-1,j,k} - h_{i,j,k}\right) + \\ &CC_{i+1/2,j,k}\left(h_{i+1,j,k} - h_{i,j,k}\right) + CV_{i,j,k-1/2}\left(h_{i,j,k-1} - h_{i,j,k}\right) + CV_{i,j,k+1/2}\left(h_{i,j,k+1} - h_{i,j,k}\right) + \\ &P_{i,j,k,n}h_{i,j,k} + Q_{i,j,k,n} = SS_{i,j,k}\frac{\Delta h_{i,j,k}}{\Delta t}\Delta r_i \Delta c_j \Delta v_k \end{aligned} \quad \text{(Eq.21)}$$

The partial derivative of the hydraulic head to time is approximated by the difference quotient:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25132538

$$\frac{\Delta h_{i,j,k}}{\Delta t} \approx \frac{h_{i,j,k}^{m} - h_{i,j,k}^{m-1}}{t_m - t_{m-1}}$$

Then all the flows are based on the end time t_m of a certain time period, then *Equation 21* becomes:

$$CR_{i,j-1/2,k}\left(h_{i,j-1,k}^{m} - h_{i,j,k}^{m}\right) + CR_{i,j+1/2,k}\left(h_{i,j+1,k}^{m} - h_{i,j,k}^{m}\right) + CC_{i-1/2,j,k}\left(h_{i-1,j,k}^{m} - h_{i,j,k}^{m}\right) +$$
$$CC_{i+1/2,j,k}\left(h_{i+1,j,k}^{m} - h_{i,j,k}^{m}\right) + CV_{i,j,k-1/2}\left(h_{i,j,k-1}^{m} - h_{i,j,k}^{m}\right) + CV_{i,j,k+1/2}\left(h_{i,j,k+1}^{m} - h_{i,j,k}^{m}\right) +$$
$$P_{i,j,k,n}h_{i,j,k}^{m} + Q_{i,j,k,n} = SS_{i,j,k}\frac{h_{i,j,k}^{m} - h_{i,j,k}^{m-1}}{t_m - t_{m-1}}\Delta r_i \Delta c_j \Delta v_k \qquad \text{(Eq.22)}$$

The above equations are iteratively solved. At the beginning, the unknown computing element to each hydraulic head is assigned to the initial head or the estimated head, and the result of each iteration is used for the next calculation.

According to the difference equation, the matrix form of the system of equations can be concluded:

$$[\mathrm{A}]\{\mathrm{h}\} = [\mathrm{q}]$$

where: [A] - the coefficient matrix of the hydraulic head; - the requested matrix of the hydraulic head; [q] - All absolute terms and known terms contained in each equation.

In MODFLOW, the coefficient matrix and the right term are gradually established by each software package. Finally, MODFLOW solves by iteration based on these two matrices.

Software for realizing numerical simulation of 3D flow

Visual MODFLOW 2000 software was used to build a finite difference model for groundwater flow and particle migration in this workspace. Visual MODFLOW is the most complete and user-friendly 3D groundwater flow and contaminant transport simulation software for practical applications. This complete integrated software combines MODFLOW, MODPATH and MT3D with an intuitive and powerful graphical user interface to easily determine the size of the simulation area, select parameter units, set model parameters and boundary conditions, and run model simulations (MT3D, MODFLOW, and MODPATH), correcting the model and visualize the model mesh, inputting parameters and results in the form of sections and plans.

Regional groundwater flow modelling

Model boundary

On the account of the large-scale work area and the difficulties of hydrogeological boundary to be determined, first, the SRTM DEM data is used for hydrological space analysis, digital river network extraction and watershed division, so as to have a brief knowledge of the boundary in terms of the whole basin. The DEM elevation map of the work area is shown in *Figure 1*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25132538

SRTM is the abbreviation of The Shuttle Radar Topography Mission, which was completed in February 2000. Most of its data is located between 60° north latitude and 56° south latitude, covering 80% of the continent. SRTM includes two resolutions: SRTM1, only covering the continental United States with a resolution of 1 s of arc; SRTM3, with global coverage and a resolution of 3 s of arc. Due to the areas without data in SRTM DEM database, the CGIAR-CSI SRTM3, the SRTM DEM product processed by CIAT (International Tropical Agriculture Center) can also be used, which has released the latest V3 version recently with two formats named as arc-formatted ASCII and GeoTIFF. The CGIAR-CSI SRTM3 DEM in GeoTIFF format downloaded from CIAT, which is referred to as SRTM3 DEM, is used in this study. The SRTM3 elevation reference is the geoid of the EGM96 and the planar reference is WGS84. SRTM3 has an accuracy of 3 s arc, which divides the area of 1 square degree into 1,200 × 1,200 small areas, each small area is 3 s (90 m × 90 m) in size, and each small area has a value representing the elevation of the center of the area. The SRTM3 DEM data is equivalent to 1:250,000 scale map data. The 3D perspective of the work area is shown in *Figure 4*.

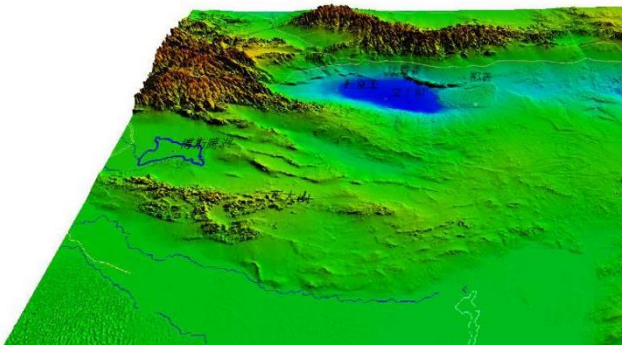

Figure 4. *Three-dimensional view of the work area*

Hydrological analysis is an important aspect of DEM data applications. The use of DEM to generate catchment basins and water flow networks to analyze surface water flow conditions is an important application as well as the great significance for comprehension of the shape of the Earth's surface. The main content of surface hydrological analysis based on DEM is to use hydrological analysis tools to extract the flow direction, the cumulative amount of flow, the length of water flow, the river network (including the classification of river networks, etc.) of the surface water runoff model, and the division of the watershed in the work area. By extracting these basic hydrological factors and basic hydrological analysis, the process of water flowing can be redisplayed on the surface of the DEM, contributing to the hydrological analysis process eventually.

The hydrological analysis mainly constitutes the direction of surface water flow in the region and the possible surface watersheds in each basin. Therefore, the analysis core is placed on the extraction of river networks and the division of watersheds.

The basic flow of extracting digital river network and watershed based on DEM data is as follows (Wang et al., 2018):

(1) DEM data preprocessing. Before extracting the digital river network of the watershed by using DEM data, the data is supposed to be preprocessed to eliminate the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25132538

invalid data area existing in the DEM. In addition, since the DEM data itself often has a lot of depressions and plane ground, as a result, the DEM data such as the determination of the DEM data and the filling of the depression and the lifting of the ground must be pre-processed, after the valid DEM data is available in order to obtain effective DEM data for river network water extraction.

(2) The grid flow direction is determined. After the pre-processed valid DEM data is in hand, the flow direction of each raster in the data can be determined. The method of judging the flow direction mainly includes a multi-flow method and a single flow method. As specified, the single flow method is so simple and convenient that it can be extensively used, among which D8 is the most widely used one. The D8 method assumes that there are only eight possible flow directions in the water flow in a single grid, that means, the water flow will flow into the eight adjacent grids. It uses the steepest slope method to determine the direction of the water flow, that is to calculate the distance weight difference between the center grid and each adjacent grid (i.e., the grid center point drop divide the distance between the gridcenter points) on the 3 × 3 DEM grid, the grid with the largest distance drop is the outflow grid of the center grid, which is the flow direction of the center grid.

(3) Determination of the water flow accumulation matrix. Based on the determined water flow direction data, the upstream water supply area range of each grid unit is accumulated, which means to determine the specific upstream grids flow direction to be cumulatively directed to the grid unit.

(4) Drainage networks extraction. Set the catchment area threshold to the flow accumulating grid according to the threshold value, then the river network grid network map of the area can be obtained to generate a digital drainage network.

(5) Watershed division. The drainage basin collects all kinds of precipitation divided by watersheds. It determines all the grids that are interconnected and in the same basin by analyzing the water flow direction data. The first step of determination of the drainage basin is to determine the location of the outlet at the edge of the analysis window that is to say, in the division of the drainage basin, the outlets of all drainage basins are at the edge of the analysis window. When the location of the water outlet is determined, the determination of the collection area of the drainage basin is similar to that of the contribution area of the depression, equal to the location of all upstream grids flowing into the outlet.

After the GIS hydrological space analysis, the river network and watershed model of the work area can be obtained, as shown in *Figure 5*.

It is better to build the regional groundwater model with the natural hydrogeological boundaries as far as possible from a holistic perspective. It is assumed that the watershed at the surface drainage basin is also a ground watershed, so the surface watershed of the drainage basin obtained by hydrological space analysis is treated as a groundwater watershed with a zero flux boundary. However, due to the asymmetry of precipitation recharge and topography, the watershed of surface water and surface water is inconsistent, but the impact on groundwater simulation in large areas is acceptable.

Based on the analysis results, the model boundaries are generalized as follows:

- West Bosten Lake is a type of head boundary.
- The eastern part is the lateral replenishment boundary, defined as the Neumann boundary.
- The northern part of Aidin Lake is defined as Dirichlet head boundary.
- Southern Lop Nur is the evaporation boundary.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25132538

- The other boundary is the flux boundary.
- The vertical top boundary of is the phreatic boundary, and the model is divided to the surface, directly accepting the recharge of atmospheric precipitation and evaporation and drainage, leading to a definition as the flux boundary in the form of source and sink items in the model.
- The vertical bottom boundary is the Neumann confining boundary (zero flux boundary).

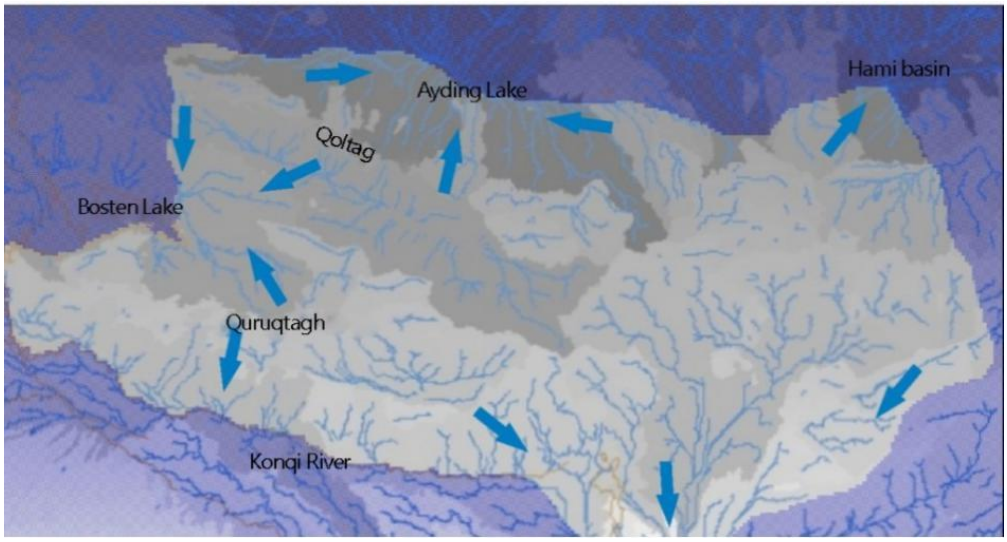

Figure 5. *Work area hydrological space analysis results*

Model splitting

The work area is divided by a rectangular hexahedron (the upper and lower planes are not necessarily parallel).

The model is discretely divided into 160 rows and 285 columns, each of which has a length and width of 2 km (*Fig. 6*). The vertical model is divided into three layers, each of which has a constant thickness. The thickness of the three layers is 0-1,000 m, 1,000-1,800 m, 1,800-2,600 m from the top to the bottom, and each layer is not horizontally distributed. The vertical division into three layers is the most simplified way of performing three-dimensional numerical simulation. As the geological survey of the work area is deepened, it will be continuously improved to accurately describe the spatial distribution of the aquifer. The bottom of the model is 2,600 m below the surface of the submerged surface. It is assumed that the groundwater is mainly horizontally flowing at this depth.

The total model is split into 136,800 units in total, of which 79,356 are effective and 57,444 are invalid ones.

Aiming at solving the problem of insufficient terrain data of large-area model, SRTM DEM data is used to establish groundwater space model, and high-precision surface elevation characterization can effectively improve the calculation accuracy of groundwater model phreatic evaporation.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25132538

Parameter partitioning

(1) Horizontal permeability coefficient

The horizontal permeability coefficient division is mainly conducted according to the 1:2.5 million scale geological map of the working area, as shown in *Figure 7*, mainly considering the dominant hydrogeological features, including granite, shale, clasticrocks, Quaternary sediments, etc. It is divided into different coefficient partitions and reflected in the model to obtain a heterogeneous parameter model. The consideration of heterogeneous characteristics is more in line with the actual hydrogeological conditions and can better reflect the groundwater flow conditions in the area.

It could be reduced to three parameter partitions: high permeability performance partition (K1), medium permeability performance partition (K2), and low permeability performance partition (K3). The permeability coefficient parameter partitioning is discontinuous, and each partition contains several units in the model, as shown in *Figure 8*.

According to the research results of the permeability coefficient of the predecessors in the work area (see *Table 1*), combined with the characteristics of the regional groundwater model, the basic values of the three partition permeability coefficients are defined in *Table 2*.

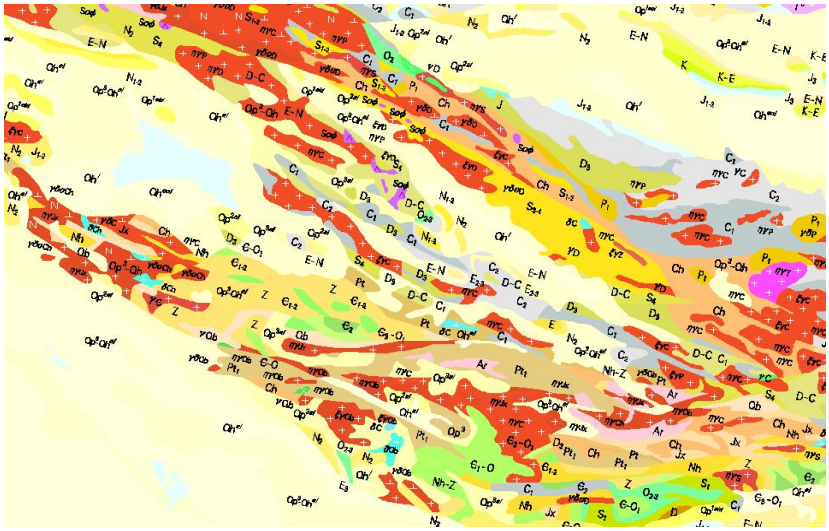

Figure 7. *Geological map of work area*

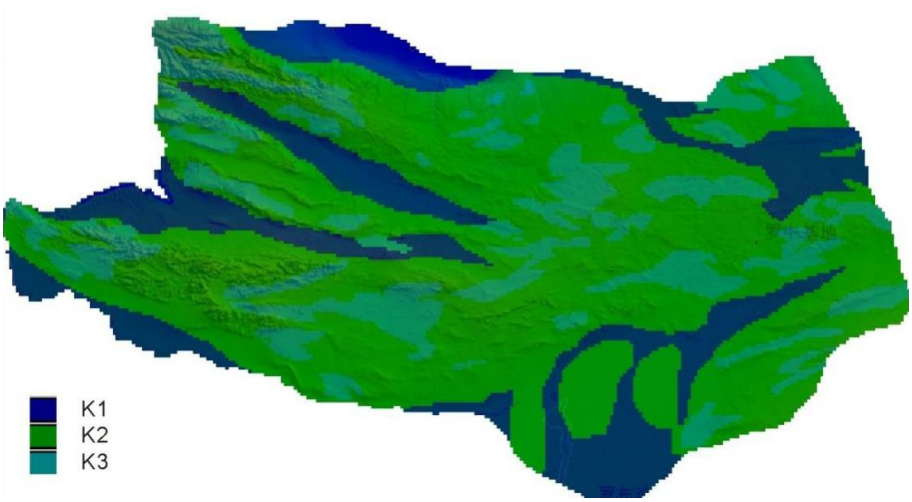

Figure 8. *Horizontal permeability coefficient partition map*

Table 1. *Permeability coefficient of work area*

Groundwater location and type	Permeability coefficient value (m/d)
Peacock river alluvial delta pore water	0.14–5.73
Aqike valley unit	0.621–4.49
Luobei concave ground pores and intercrystalline pore water	0.5–80
Lop Nur dry salt lake pores and intercrystalline pore water	< 1.0

Table 2. *Partition values of each permeability coefficient of the model*

Partition	Permeability coefficient value (m/d)
K1 High permeability performance partition	2.0
K2 Medium permeability performance division	0.26
K3 Low permeability performance zone	0.004

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25132538

The permeability coefficient values for each partition will be scaled up or down during multiple scenario simulations to analyze the uncertainty of the parameters.

(2) Vertical permeability coefficient

The vertical permeability coefficient partition is consistent with the horizontal permeability coefficient partition. According to the geological conditions and empirical values of the working area, the ratio of the vertical permeability coefficient to the horizontal permeability coefficient in the model is 0.25, and the trial calculation is carried out in the model.

(3) Precipitation

The average annual precipitation of the working area is shown in *Table 3,* and the precipitation parameters can be divided according to different regions.

Table 3. *Annual average precipitation statistics of the work area*

Area	Statistical time period	Annual average precipitation (mm)
Milan	2,004-2,005	42.9
Lop Nur Town	2,005	29.3
Kumish	2,001-2,005	61.6
Toksun	2,001-2,005	9.2
Yan Shan	2,001-2,005	29.3
Hami	2,001-2,005	56.9
Qarkilik	2,001-2,005	47.8

According to the "95" national key scientific and technological research project, the effective precipitation infiltration rate of the Hexi Corridor area (climate condition which is similar to that of the Lop Nur area) is 30-50%. Depended on the previous research results, the infiltration recharge of atmospheric precipitation in different depths of Luobei depression is shown in *Table 4*.

Table 4. *Recharge of atmospheric precipitation infiltration in different depths of Luobei depression*

Groundwater depth (m)	1.0-1.5 m	1.5-2.0 m	> 2.0 m
Rainfall infiltration coefficient	0.235	0.15	0.11

According to different rainfall infiltration coefficient and precipitation, the rainfall infiltration in each region can be obtained.

Calculation formula:

$$Q\ drop = A \bullet \beta$$

where: Q drop - atmospheric precipitation infiltration recharge (10^4 m^3/a); A - year effective precipitation; B - effective precipitation infiltration coefficient.

The effective precipitation infiltration in each region can be determined by model identification.

Regarding the formula of the evaporation law of diving, we use the empirical formula (index formula) obtained in the article Study on water transport and equilibrium factors of the aeration zone in the middle reaches of the Heihe River in Gansu Province (internal data from Second Hydrogeological Institute of Gansu Province, 1995):

$$\varepsilon = \varepsilon_0 \cdot e^{-bD}$$

where: ε - diving evaporation intensity; ε_0 - water surface evaporation intensity; D - diving depth; b - Experience factor (related to soil quality), determined by model identification.

Numerical simulation and correction of regional groundwater flow

Due to the large scope of the work area in remote areas in the northwest, the researches on hydrogeological work area are relatively less, so there is a lack of dynamic data required for the simulation of groundwater unsteady flow, such as long-term water level observation data, monthly precipitation, monthly evaporation, etc., so the use of multi-year average data in the study for stable flow simulation, focusing on the characteristics of the water cycle in the work area.

Stable flow simulation

On the strength of average data of multiple years, the permeability coefficient is taken as a basic combination for steady flow numerical simulation. The simulation results are shown in *Figure 9*.

There are multiple groundwater flow systems in the area by the regional groundwater flow field. In the vicinity of the Turpan Basin in the northern part of the work area,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25132538

groundwater mainly flows from the Qoltag Mountain and the eastern side of the basin to the Aiding Lake; the southwestern side of the Qoltag Mountain and the northwest side of the Kuruktag are collected from the Bosten Lake; the groundwater in the south of Kuruktag mainly flows along the Peacock River to Lop Nur; the groundwater in the northeastern part of the working area flows from the west and south to the sand lake in the Hami Basin; the eastern part of the working area receives the lateral recharge of the downstream of the Shule River and flows to Lop Nur (Zhu et al., 2001).

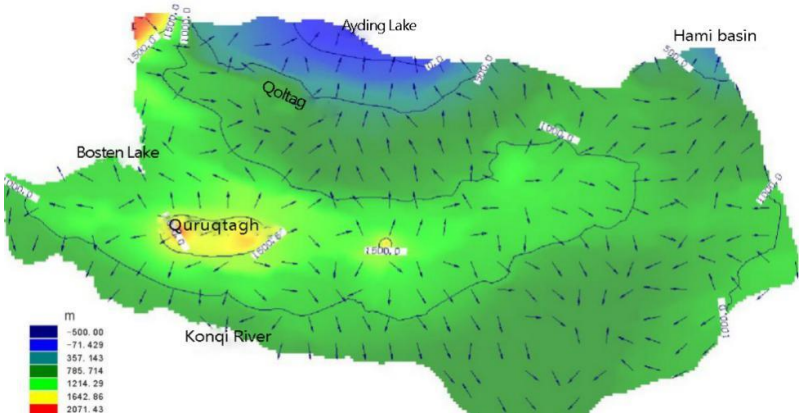

Figure 9. *Basic model steady flow field*

Model adjustment

Due to the lack of water level observation data in the working area, the groundwater heads formed by interpolation of some measured groundwater data in the area are compared with the simulated preliminary flow field, and the differences are analyzed. The parameters in the model are then adjusted according to the hydrogeological conditions of different locations. The adjusted and simulated flow field and the measured value interpolated flow field are shown in *Figure 10*.

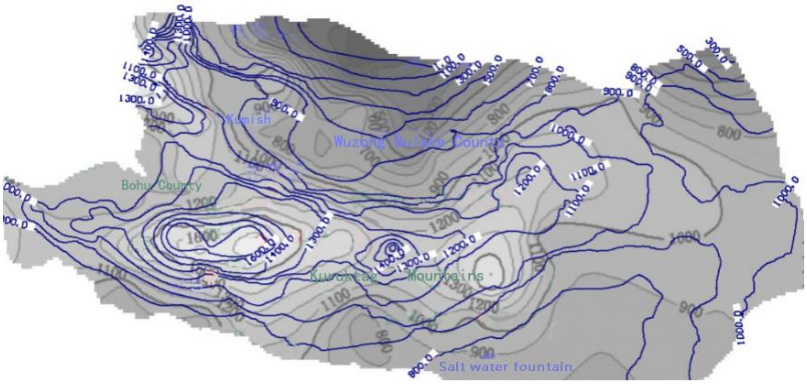

Figure 10. *Comparison of measured and simulated groundwater level contours (blue line-analog value, black-measured value)*

It can be seen from *Figure 10* that the simulated flow field is consistent with the measured flow field as a whole, but there are certain differences in some parts mainly resulting from the following reasons:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25132538

(1) Insufficient measured groundwater level data causes local distortion of the interpolation flow field, which cannot fully represent the real groundwater flow field. The work area is over 100,000 km^2, but there are only a few dozen groundwater data for interpolation, especially in the eastern part of the work area, with fewer interpolation points. Taking the northern part of Dongshuiquan as an example, there is a high water point in the measured interpolation flow field, but in fact it is not the highest point of the surrounding elevation, and there is no other water supply, just because there are no other interpolation points nearby.

(2) On the account of large working area but less relevant geological and hydrogeological information, the model based on the water quantity information cannot completely simulate the local and detailed groundwater flow characteristics in the area. The lack of basic data in the work area, the characterization of geological structures and the treatment of source and sink items such as precipitation and evaporation are not able to reach high standards, giving rise to the lack of ability to characterize small cycles in local areas such as small basins in the mountains.

Although there is a lack of local details and precision, the model initially depicts the unaffected characteristics of groundwater flow with the overall regional perspectives which can support the analysis of regional groundwater circulation.

Multi-scenario particle tracer simulation analysis

In order to analyze the particle migration in key areas of the work area, the MODPATH software was used to simulate the particle tracing under multiple scenarios with comprehensive consideration of the uncertainty of the parameters.

MODPATH is a convection transmission simulation software that can acquire groundwater model and simulation result data from MODFLOW and calculate the particle migration trajectory. MODPATH uses a semi-analytical solution for particle tracking to calculate groundwater migration routes and flowing time. The method assumes that the velocity components in each direction of each grid cell vary linearly in their own coordinate direction, allowing us to get an analytical expression that describes the streamlines within the grid cell. Given any initial position of the mass point in the cell, the coordinates of other points on the streamline within the cell and the time interval between the groundwater masses passing through the two points can be calculated.

Through the graphical interaction interface of MODPATH, the user can use the mouse to click to set the particle point and demonstrate of the particle migration. Most particle migration simulation software requires post-processing to get the route and time visualization results, however it can be calculated and displayed simultaneously on the MODPATH. MODPATH also provides a variety of data display functions for any selected model layer and time step, such as displaying the water head contour, the drop contour, and the flow rate and direction.

It is assumed that the nuclide is the ideal particle, that is to say, the program module can be used to conveniently simulate the migration trajectory of the nuclide particle under different scenarios without consideration of the reaction of the nuclide-water-rock.

According to the research geological map, three large-area granite areas located in the eastern and central parts of the work area were selected for particle tracing simulation. The position of the tracer particles is shown in *Figure 11*. In the central region of each granite zone, 20 particles were placed on a circumference with a radius of 5 km. The particles in the simulation are shown in green and the migration trajectory is shown in red.

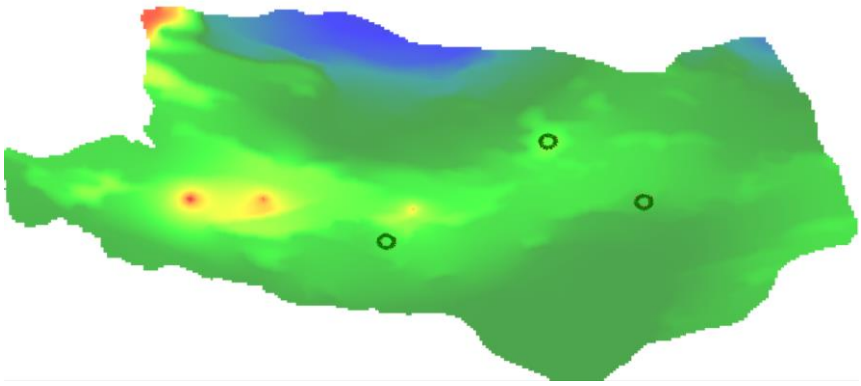
Figure 13. *Scenario 1 particle migration simulation results*

Scenario 2

Scenario 2 considers the variation trends of particle migration when the permeability coefficient of granite is reduced to half. The partition values of the permeability coefficient used are shown in *Table 8*, and the simulation is performed for 10,000 years. The results of particle tracing are shown in *Figure 14*.

Table 8. *Scenario 2 permeability coefficient partition value*

Partition	Permeability coefficient value (m/d)
K1 High permeability performance partition	2.0
K2 Medium permeability performance partition	0.26
K3 Low permeability performance partition	0.002



Particle migration trajectory in 10,000 years

Figure 14. *Scenario 2 particle migration simulation results*

Scenario 3

Scenario 3 considers the trends of particle migration change when the precipitation is doubled, and simulates it for 10,000 years. The results of particle tracing are shown in *Figure 15*.

Conclusion

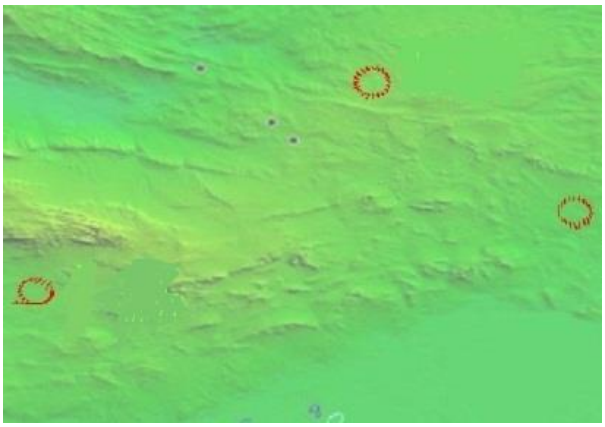
By analyzing the hydrogeological conditions of the Kuruktag region in Xinjiang, including the structure and boundary conditions of the aquifer system, the characteristics of the groundwater flow field, the hydraulic connection between different water-bearing units, and the relation between groundwater and surface water, the characteristics of the groundwater recharge and discharge, etc. are analyzed from the perspective of groundwater dynamics.

By adopting the combination of groundwater dynamics and field hydrogeological surveys and analyzing the hydrogeological conditions in the work area, the hydrogeological conditions are relatively simple, focusing on weakly water-bearing, low-permeability, slow flow rate, and relatively closed areas. Based on the above preparations, the simulation study of regional groundwater flow can be carried out, besides, the variation rules of regional groundwater flow under long-term scale is able to be predicted.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25132538

Owing to the insufficient basic data and high uncertainty of large-scale model, the simulation of the groundwater flow of the model under multiple conditions and multiple scenarios by means of multi-scenario analysis. The study mainly considers the influence of permeability coefficient, precipitation change and fault on groundwater flow. Additionally, the particle tracing simulation is performed in three granite areas located in the eastern and central parts of the work area with six scenarios carried out by MODPATH to figure out the trajectories of nuclide migration in varied periods, reflecting the influencing factors and regularity of groundwater flow change and nuclide migration.

In order to comprehensively analyze and evaluate the particle migration conditions in multiple scenarios, the particle migration trajectories of the four scenarios are superimposed by 10,000 years of migration time respectively. The results of particle tracing are shown in *Figure 17*.



Superimposed particle migration trajectories in 10,000 years (4 scenarios)

Figure 17. *Comprehensive analysis of particle migration simulation in four scenarios*

From the above superposition results, the trends of particle migration in each simulation period can be analyzed as follows: The migration of particles in the three regions is not large in 10,000 years, mainly moving along the direction of groundwater flow, and the migration length is 2 to 5 km.

With the help of comprehensive analysis of particle motion in three regions under different scenarios in different periods, from the perspective of hydrogeology, the following conclusions can be drawn: the particle motion changes little under various scenarios, and the groundwater flow is stable subject to external conditions. The interference is small, the groundwater flow rate is relatively slow, and the particle migration speed is small.

Recommendations for future studies: (1) Due to scarce monitoring data of groundwater level, the interpolation of flow field would be distorted, which cannot represent the real flow field. To further correct the results of numerical simulation, the monitoring data of groundwater level should be enriched, and more hydrological drill holes are proposed to be set. (2) As the carrier of underground nuclide migration, groundwater should be defined as the circulation process. Numerical simulation of groundwater circulation is suggested to be conducted in the area with abundant monitoring data. Taking the petrological and hydrological conditions into consideration, the long-term groundwater circulation is able to be predicted.

Abstract. This research was carried out in Van-Gevaş in 2015 and 2016 with three replications according to the Divided Parcel Trial Design that was divided into random blocks. The experiment involved 2 bean varieties (Aras-98 and Seker-90) x 4 phosphorus dose (0.0, 40.0, 60.0 and 80.0 kg ha^{-1}) x 4 zinc dose (0.0, 10.0, 25.0 and 50.0 kg ha^{-1}) x 3 repetition = 72 parcels were planned and examined. In the experiment, 4 different phosphorus (P) doses were applied to the subparcels as TSP (P2O5) fertilizer. and to gold sub-parcels 4 different zinc (Zn) doses were applied as zinc sulfate (ZnS04.7H20) fertilizer. Two bean varieties used in the study on the effect of phosphorus and zinc doses on plant height (cm), the number of pods per plant (units of plant^{-1}), number of branches (plant^{-1}), seed yield (kg ha^{-1}), harvest index (%) and the effect of protein (%) on grain was also investigated. According to the results obtained in 2015 and 2016, the highest grain yield was obtained from Sugar-90 beans. In the first year, the highest grain yield was obtained from 3380.00 kg ha^{-1} and 40.0 kg ha^{-1} phosphorus and 10.0 kg ha^{-1} zinc, while in the second year 4250.70 kg ha^{-1} was obtained in the same phosphorus and zinc dose. As a result, it has been determined that due to degradation in the phosphorus balance in soil, the efficiency of utilization of zinc in plants affects the yield and quality characteristics.
Keywords: *bean, number pods, interaction, grain yield*

Introduction

For many thousands of years, legume grains have had a very important place in human nutrition. In cases where animal proteins cannot be provided in suffiecient amount, the deficiencies are met from these plants (Adak, 2014). These plants are rich in vitamins and also minerals such as iron, phosphorus, calcium and potassium, as well as dietary fibers (Pekşen and Artık, 2005). It form in nutrition programs together with cereals a very good group (McPhee and Muehlbauer, 2002). Especially together with high lysin content, cholesterol rates are very low. In human nutrition, edible grain legumes contain 22% of proteins and 7% of carbohydrates. 18-31.6% of the leguminous protein is an important and inexpensive source for solving nutritional problems in the body (Adak et al., 2010; Altunkaynak, 2018). In terms of cultivation and production in the world, this is an important genus in the family of beans. Dry and fresh consumption is common. Around 29 million hectares of land is cultivated in the world. The total production amount is 23 million tons and the yield per hectare is 8000.00 kg (FAO, 2015). In our country, bean cultivation area is 848 thousand ha, 220 thousand tons production and 2590.00 kg ha^{-1} yield is obtained (TÜİK, 2018).

Cultivation, irrigation, fertilization and harvesting are very important in bean production. Fertilization has an important place in these cultural applications. The fact that they fix the free nitrogen of air due to the rhizobium bacteria found in the roots of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25392553

legumes reduces their need for nitrogenous fertilizers. In this case, in the case of deficiencies such as phosphorus and zinc, it increases the importance of the nutritional elements affecting other yield parameters, in particular efficiency. In terms of legumes, phosphorus is an important macro element. This need must be eliminated by fertilization with sowing (Togay and Anlarsal, 2008). The greatest benefit of phosphorous fertilizers is the increase in the quality of the grain and the availability of nitrogen by increasing nodulation and nitrogenase activity (Arıoğlu, 1989).

Another important plant nutrient is zinc, while various enzymes operating in the plant are the building blocks of some hormones in tissue development, the deficiency of zinc leads to the decrease of tryptophan hormone level and protein synthesis is disrupted. In addition, free amino acid accumulation in plants adversely affects grain quality (Yalçın and Usta, 1990).

The height of elements such as phosphorus and zinc in the soil does not always mean that they will be taken and used by plants. In soil, pH, salinity and the amount of other elements are important factors affecting plants. As a result, deficiencies in plants cause significant reductions in yield and quality (Togay and Anlarsal, 2008).

With this study, it was aimed to determine the effect of phosphorus and zinc fertilizers on yield and yield components of beans grown in our region, and as well as to investigate the interactions between P and Zn micronutrients.

Materials and Methods

The research was conducted in Van-Gevaş District (38.2978° N, 43.1055° E) between the years of 2015-2016 (*Figure 1*). In the experiment, two bean varieties (Aras-98 and Şeker-90) were used as plant material. The varieties are registered at the East Anatolian Agricultural Research Institute are white and coarse in color (Şehriali, 1988). Climate data for the years of research and the average for many years are given in *Table 1*.

Figure 1. *Place of trial (Van-Gevaş)*

The total amount of precipitation during the period from May to September in 2015, when the experiment was conducted, was 43.6 mm. In 2016, it was observed that this amount was more than 2015 with 73.3 mm. The average temperature was 18.5°C in the

DOI: http://dx.doi.org/10.15666/aeer/1802_25392553

first year. This value was measured as 17.9°C in the second year of the experiment. The average humidity was lower in the first year (42.4%) than in the second year (50.5%).

*Van Commodity Exchange was conducted in soil analysis laboratories, 2015

The experimental soils are slightly alkaline and the organic matter levels are moderate. It was found that the soil was low in lime, poor in phosphorus and zinc and rich in potassium.

The research was established according to the experimental design of Divided Parcels Divided into Randomized Blocks with 3 replications. The trial area, which was driven deeply in the last spring, was completed in April with a second surface version and disc harrow. Seed planting was carried out in the first week of May, in 5 rows per parcel. The distance between the rows in the parcels was 40 cm. The area of a parcel was 2.0 m x 4.0 m = 8 m². In the study, the varieties in the main parcels were Aras-98 and Seker-90, phosphorus (18-19% P_2O_5) doses in sub-parcels and zinc (Zn) sulphate doses ($ZnS0_4.7H_20$) were applied to the six parcels in the same test design. The amount of seed to be taken into the parcel was determined to be 45 seeds per m^2 21% Ammonium Sulphate $(NH4)_2SO_4$ fertilizer was placed in the soil with 20.00 kg of pure nitrogen per hectare evenly to each parcel. Trial parcels; 1 The first foliation period, 2 with branching, 1 before flowering, 1 flowering period, and 1 bean binding period in including was irrigated 6 times in total. (Engin, 1989). In this study, the effect of increasing Zinc (Zn) and Phosphorus (P) doses on plant height, number of pods per plant, grain yield, harvest index (Harvest index = Grain / Plant stalk ratio), thousand seed weight and protein ratio in two bean varieties were investigated. In the study, two bean varieties were treated in 4 different doses (0.0, 10.0, 25.0, 50.0 kg ha^{-1}) in the form of Zinc $ZnSO_4.7H_2O$ and in 4 different doses (0.0 (control), 40.0, 60.0, 80.0, kg ha^{-1}) in the form of phosphorus P_2O_5. Each row of 5 parcels on each side of each row and 50 cm within the row of plants in the row

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25392553

as the edge of the effect was excluded from the observation (Ceylan and Sepetoğlu, 1979). All observations were made on an area of 1.2 m x 3 m = 3.6 m². The data obtained after trial in terms of yield and yield components were used in determining the differences of split parcel design with the variance analysis method. In the determination of different groups Duncan (5%) multiple comparison test was utilized with Costata and Mstatc software (Düzgüneş et al., 1987).

Results

Plant Height (cm)

According to the data obtained at the end of the research in 2015, the interactions of year, variety, phosphorus, zinc doses, variety x phosphorus, variety x zinc, variety x phosphorus and variety x phosphorus x zinc doses were significant and phosphorus x zinc interactions were not statistically significant. In 2016, other differences between plant height averages were significant (*Table 3*).

Table 3. *Bean varieties in the groups and averages related to the height of the plant**

According to the data obtained at the end of the experiment; In 2015 and 2016, the average plant height was 46.68-65.12 cm with Aras-98 cultivar, while the Sugar-90 variety was higher with 50.93- 60.04 cm. The plant height values obtained from the Seker-90 variety in both years of the experiment were found to be higher than that of the Aras-98 variety (*Table 3*).

According to the data obtained, average plant height values obtained from different phosphorus doses ranged from 54.62-44.77 cm in 2015 and from 70.53-56.16 cm in 2016. In

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25392553

the first year of the experiment, the highest plant height (54.62 cm) was obtained in Sugar-90 from 60 kg ha^{-1} phosphorus dose. The lowest plant height value was determined at a dose of 0 (control) applied to Aras-98 cultivar with 45.20 cm. In 2016, the plant height average values ranged from 56.16 to 70.53 cm. The highest plant height values (70.53 cm) were obtained from 60.00 kg ha^{-1} phosphorus dose applied to Aras-98 cultivar, 56.16 cm with the lowest value was obtained from parcels belonging to sugar-90 cultivar of not phosphorous.

As shown in *Table 2*, plant height average values obtained from different zinc doses changed between 51.32-47.73 cm in 2015 and 67.82-60.26 cm in 2016. In the first year of the experiment, the highest plant height value was obtained from Sugar-90 varieties with 54.07 cm and 25.00 kg ha^{-1} zinc. The lowest value was determined in Aras-98 cultivar, which does not apply zinc dose, which is measured as 43.65 cm.

The highest plant height (56.22 cm) value in the first year in terms of zinc x phosphorus doses applied in the research; It was obtained from 25.00 kg ha^{-1} zinc x 60.00 kg ha^{-1} phosphorus dose applied to Sugar-90 bean variety, and the lowest value was obtained from the P3 phosphorus dose and non-zinc parcels with 42.02 cm (*Table 3*).

Number of Pods (number / plant)

As seen in *Table 4*, there were differences in the number of pods in the experiment. In the first year of the experiment on the average number of pods; Interactions between year, variety, zinc doses, type x phosphorus and phosphorus x zinc dose interactions were significant, some x phosphorus x zinc doses were considered statistically insignificant. In the second year of the experiment, cultivar, zinc, phosphorus, Zn x P, Ç x Zn and Ç x Zn x P interactions were found statistically significant.

DOI: http://dx.doi.org/10.15666/aeer/1802_25392553

The average number of pods obtained at the end of the study was 9.48 in the first year and 13.41 in the second year. According to the results, the average number of pods per year was determined to be 10.21-14.35 in Seker-98 cultivar and 8.75-12.45 in Sugar-90 cultivar, respectively (*Table 4*). According to the data obtained, the interaction of the first year varieties x phosphorus doses on the average number of pods was statistically significant and the second year was insignificant. The highest number of pods was obtained from Aras-98 bean varieties with 10.8 pieces at 60.0 kg ha^{-1} phosphorus dose, while the lowest value was obtained from 00.0 kg ha^{-1} phosphorus dose in Sugar-90 cultivar with 8.11 pieces. According to these results, it was seen that increased phosphorus doses increased the number of pods in the plant up to a certain point. According to the data obtained at the end of the study, it was observed that the correlation was statistically significant on the average number of pods per day. The highest number of pods was obtained from 10.00 kg ha^{-1} zinc and 40.00 kg ha^{-1} phosphorus application per decare with 11.05 pcs in the first year. The lowest value was obtained with 0.33 doses of both fertilizer doses. The highest number of pods obtained in the second year of the experiment was obtained from 16.73 number pods of 60.00 kg ha^{-1} phosphorus and 10.00 kg ha^{-1} zinc dose. The lowest value was found in 9 doses with 9.91 pieces (*Table 4*). According to the data obtained in the second year of the experiment, the interactions between the number of phosphorus x zinc doses considering the average number of pods were statistically significant and the first year was insignificant. The highest average number of pods was 18.04 and was obtained from 60.00 kg ha^{-1} phosphorus and 10.00 kg ha^{-1} zinc dose applied to Aras-98 bean cultivar. The lowest value was measured in the control parcel with Sugar-90 cultivar with 9.37 units (*Table 4*).

Number of Branches (pieces / plant)

In the study carried out in 2015-16 years, year, variety, phosphorus doses, variety x phosphorus doses and phosphorus x zinc doses interactions were found statistically significant considering the average number of branches in bean varieties in the first year. In the second year of the experiment, the effect of varieties on the average number of pods was found statistically significant (*Table 5*).

According to the results obtained in the experiment, the average number of branches in the first year was 4.33 and in the second year it was 5.24. The number of branches among the varieties were obtained from Aras-98 variety with 4.78-5.78 units, respectively. Sugar-90 varieties (3.88-4.70) branching was detected in a lower number (*Table 5*).

According to the results obtained, the first year on the number of branches was statistically significant and the second year was insignificant. According to the results obtained from the experiment, the highest average number of branches was obtained from the 40.00 kg ha^{-1} phosphorus dose applied to the Aras-98 variety. The lowest value was obtained from the control (0 dose) of Sugar-90 variety with 3.59.

As seen in *Table 5*, the effect of P x Zn interaction on the average number of branches was found significant ($p<0.01$). The highest average number of branches was obtained from 4.67 pieces and 40.00 kg ha^{-1} phosphorus x10.00 kg ha^{-1} zinc dose. The lowest value (3.89) was measured in the application of 60.00 kg ha^{-1} phosphorus x 25.00 kg ha^{-1} zinc dose.

Harvest Index (%)

In the study conducted between 2015-16 years; It was statistically determined that other factors other than the varieties on the harvest index of zinc x phosphorus fertilizer application were insignificant (*Table 6*).

According to the results obtained in the study, the harvest index was found to be 41.89-41.91% in the Aras-98 variety and 45.67-46.18 % in the Ç2 (Şeker-90). In this study; phosphorus and zinc fertilizer doses were not found to be very effective on the harvest index. Harvest index = Grain / Plant stalk ratio is calculated with the formula.

Grain Yield (kg ha^{-1})

In 2015 and 2016, the effect on average grain yield of different phosphorus and zinc doses in dry bean varieties year, variety, phosphorus, zinc, variety x phosphorus, variety x zinc, phosphorus x zinc and cultivar x phosphorus x zinc interactions were found statistically significant (*Table 7*). The mean grain yields obtained at the end of the experiment were 2320.71 kg ha^{-1} in the first year and 2518.90 kg ha^{-1} in the second year.

According to the data, the average grain yield of Aras-98 bean varieties was 1449.80-2174.40 kg ha^{-1} in years, and in Sugar-90 variety 2308.70-2863.00 kg ha^{-1} (Das et al., 2005) in the study carried out in Erzurum. The yield of Yakutiye-98 and Aras-98 varieties were determined as 1842.00 and 1944.00 kg ha^{-1}, respectively. The effect of

DOI: http://dx.doi.org/10.15666/aeer/1802_25392553

phosphorous fertilizer on average grain yield in beans was found statistically significant. The highest grain yield in both years of the experiment was obtained from a dose of 60.00 kg ha^{-1} phosphorus in Sugar-90 cultivar with 2465.10-3468.50 kg ha^{-1}, respectively. The lowest value is determined as 1209.80-2000.00 kg ha^{-1} in parcels with no fertilizer (*Table 7*). In parallel with the increasing phosphorus doses, the average grain yield of the varieties was increased up to 60.00 kg ha^{-1} phosphorus dose and the yields of grain decreased.

As shown in *Table 7*, the effect of zinc doses on average grain yields in bean varieties was found significant. The highest grain yields obtained from the experiment were obtained from the application of 2340.00-4416.60 kg ha^{-1} and 25.00 kg ha^{-1} zinc dose in Sugar-90 bean cultivar by years. The highest grain yields obtained from the experiment were obtained from the application of 2340.00-4416.60 kg ha^{-1} and 25.00 kg ha^{-1} zinc dose in Sugar-90 bean cultivar by years.

The effect of phosphorus and zinc on the average grain yield in beans was found significant ($p<0.01$). The highest average grain yield was obtained in 2548.80-3304.80 kg ha^{-1} and 60 kg ha^{-1} phosphorus and 25.00 kg ha^{-1} zinc in both years of the experiment. The lowest value was obtained from the fertilizer-free parcels with 1425.50 kg ha^{-1} in the first year and from the parcel applied 40.00 kg ha^{-1} phosphorus in the second year (*Table 7*).

The effect of phosphorus and zinc fertilizer doses on mean grain evolution was found statistically significant. The highest average grain yield was obtained from the Sugar-90

Crude Protein Content (%)

At the end of the study, it was found that the effects of type x zinc and phosphorus x zinc doses on the crude protein content were statistically significant. As of years, the protein ratio was obtained from Seker-90 variety with 22.48-12.08%, respectively. Lower crude protein ratios were obtained from Aras-98 variety (22.45-22.04%) (*Table 8*).

The effect of different zinc doses on average crude protein ratios was found statistically significant in every two years when seen in *Table 8*. The highest crude protein content (24.20-23.96%) was obtained from Sugar-90 bean cultivars of 25.00 kg ha^{-1} zinc fertilizer while the lowest values (20.95-21.79%) were obtained from the fertilizer application of the same type.

The effect of phosphorus doses on the average crude protein ratio was found significant ($p < 0.01$). The highest values were obtained from 23.56 to 23.26% crude protein ratios and 60.00 kg ha^{-1} phosphorus dose in 2015-2016. The lowest value was

found in the first year without fertilizer with a rate of 21.23% and with a rate of 80.00 kg ha^{-1} phosphorus with 21.98% in the second year (*Table 8*).

Discussion

These results of plant height values in the second year were significantly higher than the first year. In the first trial year, due to lack of precipitation, the decrease in the plant output and the decrease in the time between the output and the maturation caused the plant height values to decrease. This difference is thought to be caused by the climate in terms of plant height values (Elkoca and Kantar, 2003). This difference between years is thought to be due to the effect of climate factors as well as phosphorus fertilizer applied. It is stated that phosphorus, like nitrogen, increases the root, stem length, seed production, seed quality and resistance to diseases (Marschner, 1995; Hussein and Alva, 2014). Many research studies (Shrotriya, 1998; Bokhtiar and Sakurai, 2005; Pholsen and Sormsungnoen, 2005; Bayu et al., 2006; Barros et al., 2007; Alatürk, 2012) on fertilization obtained similar results as this study. In similar studies, increased fertilization of leguminous crops indicated that zinc fertilization increased plant height (Sing and Saxena, 1986; Togay and Anlarsal, 2008). In the second year of the experiment, the interaction effect between doses was statistically insignificant. In similar studies Tisdale and Nelson (1966), reported that phosphorous fertilizers added to phosphorous-rich soils make it difficult for the plants to uptake other nutrients, especially zinc, resulting in zinc deficiency in the plants grown in these parcels.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25392553

Similarly, Bayraktar (1966) also stated that when excess phosphorus is present in the soil or when more phosphorus is supplied to the plant, excess phosphorus prevents the extraction of 67 micro elements such as zinc and iron.

In a similar study conducted by Elkoca and Kantar (2004), the number of pods ranged from 3.5-4.2, indicating that this feature showed a wide variation according to the types and lines. Legumes in plants are the most effective group of phosphorus in the soil (Altın et al., 2005; Batıca et al., 2017). Turunko and Mohammed (2014), in Ethiopia's Arbe Minch agricultural enterprise using Red Wolaita varieties; 5 different doses of phosphorus (00.00, 10.00, 20.00, 30.00, 40.00 kg ha^{-1}) growth, dry matter and yield components were investigated. As a result, the most suitable phosphorus fertilizer dose was 20.00 kg ha^{-1}. In another similar study, it was noted that the leaf area of beans increased significantly with the increase of phosphorus dose from 25.00 kg ha-^{1} to 75.00 kg ha^{-1} (Veeresh, 2003). According to these results, increasing doses of phosphorus in low zinc doses caused increases in the number of pods up to a certain point. Lonergan et al. (1982) obtained higher yields than plants in low Zn and high P conditions. In contrast, an antagonist effect also occured, resulting in reduced yields (Ozanne, 1980). As the reason for these results; Besides to the environment and genotype, high doses of phosphorous fertilizers are thought to result in yield losses due to reduced zinc uptake (Ozanne, 1980).

Unlike nitrogenous fertilizers, the effect of phosphorus fertilizers remains limited on the number of branches depending on the environment and genetic structure. It is thought that this difference in average number of branches due to years is due to insufficient quantity and distribution of rainfall in the first year as well as genetic factors (Elkoca and Kantar, 2003). Like the number of pods, the number of branches also show a very wide variation depending on the variety and lines (Elkoca and Kantar, 2004). In spite of increasing doses of phosphorus, it is thought that zinc use efficiency and number of branches decrease (Ozanne, 1980).

In the studies conducted by some researchers, it has been observed that these effects vary widely. It is thought that this difference is caused by environment, genotype and cultural practices. Gangwar and Singh (1986) showed in their study, that the rate of harvest index of zinc fertilizers increased the maximum rate of foliar applied fertilizers. Azad et al. (1993), reported that zinc fertilizers increased the rate of harvest index up to a certain dose and then decreased. In this study, it is observed that zinc fertilizer increased the ratio of harvest index by 15.00 and 30.00 kg ha^{-1} and then it started to decrease.

Climate factors are undoubtedly the most important factors in determining the fate of agricultural production. It is thought that this difference between years is mainly due to the fact that the precipitation amount (43.6 mm) and distribution in the first year is lower and insufficient compared to the second year (73.33 mm) (*Table 1*). The balance of soil water in beans is very sensitive to flowering period. Fluctuations in this period are reported to cause 20% yield losses in yields (Elkoca and Kantar, 2003). In the second year fertilizer doses were used more effectively with rainfall in the development periods of the plant. In the first year, the average temperature were recorded higher than in the second year, especially in flowering and pollination periods of the plant in other developmental according to the periods.

The grain yield in beans is dependent on other genetic-based variations, particularly earliness in various environmental conditions (Dreyer and Wielpütz, 1998). Similar studies have shown that phosphorus promotes flowering and pod formation in the plant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25392553

(Araújo et al., 2000). In the experiment, it can be said that the difference between the first year and the second year zinc doses was due to the fact that the phosphorus in the first year inhibited the uptake of zinc more than in the second year. In the second year, it is thought that the climate is more suitable and fertilizers may be taken more uniformly (Toğay and Anlarsal, 2007). In many studies, it has been reported that phosphorus and zinc fertilizers are used together and that the efficiency of phosphorus zinc decreases the efficiency and quality decreases (Ozanne, 1980; Lonergan et al., 1982). In a similar study, it was reported that environmental and genetic factors were effective on the average grain yield in lentils (Islam et al., 1989).

Many previous studies have shown that the protein content of beans varies between 17.40% and 28.00%. It has been reported that bacterial applications, especially nitrogen fertilization, increase this rate (Tajini et al., 2012; Bulut, 2013; Özturan and Akman, 2017). The effect of zinc fertilizer on crude protein content was found to be important due to environmental and genotypic factors. Similar results were obtained in other studies conducted on legumes (Toğay and Anlarsal, 2008). Zinc is an active element in biochemical events and has a biological interaction. When used in combination with phosphorus, a decrease in the uptake by plants occurs. The most important element limiting the use efficiency of zinc by plants is phosphorus. Especially in the case of phosphorus poor soils, where the need for excess phosphorus is met, the use of zinc decreases. Disruptions in phosphorus and zinc balance in the plant cause disruptions in the cell and some parts of the cell (Das et al., 2005; Khorgamy and Farnis, 2009; Salimpour et al., 2010).

Conclusion

In this study carried out in Van-Gevaş, the effect of different phosphorus and zinc doses on the yield and yield components of dry bean varieties were investigated. Although these factors have changed over the years, they have provided important information about yield and yield components. The results of the decrease in zinc utilization efficiency in high phosphorus doses have emerged in yield and quality parameters. Especially in our city where zinc deficiency is seen too much, and especially before planting other plants, soil analysis should be conducted before planting. In view of these results, phosphorus fertilization should be done between 10.00-30.00 kg ha^{-1} zinc and 20.00-80.00 kg ha^{-1}. The grain yield which is close to Turkey's on average or above on a yearly basis may be interrelated with zinc and phosphorus deficiency in the soil, which is thought to reduce the yield and quality losses.

Abstract. In this study the treatments were carried out as follows: Control; Full dose of NPK containing 6 g ammonium sulphate (20.5%N) + 4 g calcium super phosphate(15.5%P_2O_5) + 3 g potassium sulphate (48.5%K_2O) to 8 kg soil in the pot; Half NPK dose; Half NPK dose + 50 ppm (HA); Half NPK dose + 100 ppm(H.A.); Half NPK dose + 150 ppm (H.A.); as well as (H.A.) at 50,100 and 150 ppm. The obtained results showed that most treatments resulted significantly taller plants, higher branch and leaf plural, wider leaf area compared to control with $^1/_2$ NPK + 150 ppm (H.A.) treatment providing the best results as this treatment gave also the high significant. Additionally, this treatment caused significantly the earliest flowering with the longest flower stem, widest flower diameter, number of flowers per plant as well as the heaviest fresh and dry weight of flowers. Most treatments gave significantly higher total chlorophyll in the leaves than the control with the superiority of the treatment of $^1/_2$ NPK + 150 ppm (H.A.) followed by the treatment of NPK alone with non-significant differences in between. N ratio in the leaves significantly increased over control in most treatments and especially for the treatment of $^1/_2$ NPK + 150 ppm (H.A.). P ratio in the leaves were significantly the highest as a result of the NPK treatment with no other additives. While the highest K ratio resulted from the treatment of either 100 or150 ppm (H.A.) without significant differences in between. However, the treatment of ½ NPK + 150 ppm (H.A.) is recommended to obtain high quality plants.
Keywords: *potassium humate; N, P and K fertilization; chemical fertilization; Erantheumum pulchellum*

Introduction

Chemical fertilization provides nutrients optimal for plant growth and development. The essential nutrients in the fertilizers are nitrogen, phosphorous and potassium (NPK). The most important major nutrient is nitrogen (N) which partakes in many compounds in the plant such as amino acids, proteins, chlorophylls, hormones, alkaloids and enzymes. Phosphorus (P) partakes in phospholipids, DNA, RNA and metabolism of fats. Potassium (K) regulates water condition within the plant cell and water loss by transpiration as a catalyst and condensing agent of complex substances through its active properties (Devlin, 1975) and potassium has a main role in plant metabolism such as photosynthesis, translocation of photosynthates, water relation as well as enzyme activation. Although, potassium is not a constituent of any plant structures or compounds, but it plays a part in many important regulatory roles in the plant, i.e. osmo-regulation process, regulation of plant stomata and water use, translocation of sugars and formation of carbohydrates, energy status of the plant, the regulation of enzyme activities, protein synthesis and many other processes needed to sustain plant growth and reproduction (Hasio and Lauchli, 1986).

Humic acid (HA), called humin materials widely consists of a part of soil organic matter (65-70%) (Stott and Martin, 1990). It is a potential natural resource that can be utilized to increase growth, nutrient availability and yield (Sharif et al., 2002). It has direct and indirect effects on plant growth due to roles of humic acid (Pal and Biswas, 2005). Humic acid treatments improve soil aggregation, structure, water permeability, air conditioning, fertility, moisture-holding capacity. It constitutes a stable fraction of carbon (C), thus regulating the carbon cycle and releasing of nutrients, including N, P and S (Stevenson,1994) and improving nutrients uptake and hormonal effects (Nikbakht et al., 2008).

Erantheumum pulchellum Andrews (syn Daedalacanthus nervosum R) blue sake

The 7.5 to 15.3 cm-long flower spikes are borne above the large, rounded and prominently veined leaves. Leaves are large, dark green, simple, opposite and leaf blade length arrives 5 to 10 cm. Fruit shape is oval and its length is less than 12.5 cm. It is used in flower beds. It is popular with gardeners because of the spikes of flowers that are bright gentian blue - an unusual color in the tropics (Edward, 1999) as illustrated in *Figure 1*.

Figure 1. *Erantheumum pulchellum Andrews plant*

The aim of this work was to study the effect of (NPK) nitrogen, phosphorus and potassium and humic acid (HA) on the growth, flowering and chemical composition of the plant and try to obtain the synergistic effect of HA to partly replace the risk of pollution to environments by chemical fertilization. Hence there was no need for the treatment of NPK (full dose) + HA.

Martials and methods

A series of pot experiments in the open field were conducted during 2014/2015 and 2015/2016 seasons in Hort. Dept., Agric. Fac., Kafr El-Sheik Univ. Egypt. The site is located at 31°07 N latitude and 30°57 E longitude with an elevation of about 6 m above mean sea level. The climatic conditions of the study area are provided in *Table 1*.

The aim was to study the effect of N, P and K fertilization and humic acid foliar spray on the growth, flowering and chemical composition of a local variety of *Eranthemum pullchellum* Vahl R.BR. The cuttings of one-year-old plants of 10 cm length were planted in 20 cm diameter clay pots filled with about 8 kg clayey soil as one plant/pot commencing on the 1st September till September of the next year. The plants were treated as follows: 1-Control, 2-Full dose of NPK containiing 6 g ammonium sulphate (20.5% N) + 4g calcium super phosphate (15.5%P2O5) + 3 g potassium sulphate (48.5% K2O), 3-Half NPK dose, 4- Half NPK dose + 50 ppm humic acid (HA), 5- Half NPK dose + 100 ppm humic acid (HA), 6- Half NPK dose + 150 ppm humic acid (HA), 7- 50 ppm humic acid (HA), 8- 100 ppm humic acid (HA) and 9- 150 ppm humic acid (HA). The treatments were replicated three times involving 9 plants in a complete randomized design. NPK fertilizer was drench-applied as calcium super phosphate at preparing the soil, while N and K were monthly applied after one month from planting. HA was foliar applied monthly after one month from planting as the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25552567

plants were run-off sprayed. The watering was every three days at summer and weekly in winter. The following data were recorded after one year, plant height (cm), number of branches, number of leaves/plant, leaf area as mean of 3 leaves in the middle part of the plant (cm^2) by using CI-202 portable laser leaf area meter (cidb10-science) made in USA, WWW.CID-INC.COM, fresh and dry weights of vegetative parts per plant (g), root length of the longest root (cm), fresh and dry weight of the roots per plant (g) after removing soil by water, flowering date (days) as the first flower showed color on the plant, number of flowers per plant, diameters of flower (cm), fresh and dry weights of flowers/plant (g) and flower stem length (cm). As for chemical composition total chlorophyll in leaf of the middle part of the plant was carried out according to Minolta chlorophyll method SPAD-SO (Yadava, 1986). Nitrogen% was determined by modified micro Kjeldahle method as described by Black (1983)

Phosphorus was determined colorimetrically as the method described by King (1951) while, potassium was estimated using the flame photometer according to Jackson (1967). Means of treatments were compared by Duncan' s multiple range test (Duncan, 1955) at a level of 5% probability according to Sendecor and Cochran (1980).

Results

Effect of treatments of NPK and humic acid on vegetative growth, flowering and chemical composition parameters of the plants

A. Vegetative growth, plant height, No. branches, No. leaves and leaf area

Data presented in *Table 2* showed that in most cases treatments of NPK and humic acid significantly increased plant height and gave more branches than the control in both seasons. The significantly tallest plants and highest number of branches in the first season resulted from the treatment of $^1/_2$ NPK + 150 ppm humic acid. In the second season, this treatment extended the simulative effect in addition to the treatment of NPK alone without significant differences in between.

The same table revealed that most treatments gave significantly more leaf number and widest leaf area per plant compared to control in the two seasons with the superiority of treatment of $^1/_2$ NPK + 150 ppm humic acid in both seasons. In the second season, this treatment was partaken with the treatment of $^1/_2$ NPK + 100 ppm humic acid (HA) and NPK alone without significant differences.

B. Fresh and dry weight of vegetative parts

Data presented in *Table 3* revealed that most treatments gave significantly heavier fresh and dry weights than control in the two seasons. The significantly heaviest fresh and dry weight in the first season resulted from the treatment of $^1/_2$ NPK + 150 ppm humic acid (HA). In the second season, this resulted from the treatment of NPK and the treatment of $^1/_2$ NPK + 150 ppm humic acid (HA) without significant differences.

C. Root parameters

Data of the root length No. roots/plant fresh and dry weight of roots are presented in *Table 4*. Data exhibited that most treatments significantly increased root length over control in the first season as the significantly longest roots and highest roots number/plant resulted from the treatment of $^1/_2$ NPK + 150 ppm humic acid (HA)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25552567

followed by the treatments of $^1/_2$ NPK + 50 ppm humic acid (HA), treatment of $^1/_2$ NPK + 100 ppm humic acid (HA) without significant differences. In the second season, all treatments significantly increased root length when compared to the control and the significantly longest roots resulted from the treatment of $^1/_2$ NPK + 150 ppm humic acid (HA) followed by the treatment of NPK alone without significant differences.

Data showed clearly that most treatments gave significantly heavier fresh and dry weight of roots than the control in both seasons. The significantly heaviest value of roots weight resulted from the treatment of $^1/_2$ NPK + 150 ppm humic acid (HA), followed with non- significant differences by the treatment of NPK alone. The results were similar in the second season but the significantly highest value resulted from the treatment of NPK alone followed with non-significant differences by the treatment of ½ NPK + 150 ppm humic acid (HA).

D. Flowering characters

Data presented in *Table 5* showed that the precocity of flowering in both seasons was for the treatment of 1/2 NPK + 150 ppm humic acid (HA) followed by NPK alone with non-significant differences. The previous promotive effect of these treatments was extended to the other flowering parameters. The stimulatory effect of NPK on flowering is well known as nitrogen is a main constituent of chlorophyll leading to effective characteristic as flower stem length, flower diameter, number of flowers per plant and fresh and dry weights of flower registering the significantly highest values when compared to control and other treatments. A few exceptions were gained for the treatment of 1/2 NPK + 100 ppm humic acid giving values close to the previous treatments in the criteria of fresh and dry weights of flower.

E. Chemical composition of plants

Data of the effect of NPK treatment and humic acid on total chlorophyll, nitrogen, phosphorus and potassium ratio are presented in *Table 6,* as revealed the significantly highest values of total chlorophyll resulted from the treatment of ½ NPK + 150 ppm

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25552567

humic acid (HA) followed by the treatment of NPK alone. with non- significant differences. It is apparent that most treatments of either NPK + humic acid or NPK alone increased total chlorophyll in the leaves of plant over control in both seasons. The superiority was for the treatments of 1/2 NPK + 150 ppm humic acid followed by the other treatments of NPK alone or with humic acid with non-significant differences in most cases.

Table 4. *Effect of NPK and humic acid treatments on some rooting characters and fresh and dry weight roots of Erantheumum pulchellum Andrews in two seasons*

Mean	32.33	27.93	21.09	4.89

Means within a column having the same letters are not significantly different according to Duncan's multiple range test

The results presented in *Table 6* showed that most treatments gave significantly higher N percentage than control in both seasons. The utmost highest values resulted from the treatments of NPK alone and 1/2 NPK + 150 ppm humic acid (HA) with non-significant differences in between. A somewhat similar trend was obtained for phosphorus percentage (P%) with an exception for the treatment of 1/2 NPK + 100 ppm humic acid giving values which non- significantly differ from the treatment of either NPK alone or 1/2 NPK + 150 ppm humic acid.

For potassium percentage (K %) a similar trend was obtained. but the treatment of 1/2 NPK + 100 ppm humic acid gave a value which did not differ from the treatments of NPK alone and 1/2 NPK + 150 ppm humic acid.

Discussion

The aforementioned results showed that the treatment of 1/2 NPK + 150 ppm humic acid gave the best vegetative growth characters in both seasons followed by the treatment of NPK alone in a few cases. This may be due to the synergistic effect of NPK and humic acid. Nitrogen stimulates stronger green growth, which provides healthy stems and leaves. Phosphorus is a vital nutrient involved in stimulating and enhancing bud development. Potassium plays a main role in plant metabolism as well as enzymes activation for formation of carbohydrate, energy status of the plants, which strengthen the stem. This coincides with the results of El Sallami (2002) on *Chorisia speciosa, Leucaena leucocephala* and *Prosopis juliflora*, and El-Naggar and El-Nasharty (2009) on amaryllis and Dubey et al. (2017) who mentioned that NPK fertilization treatments significantly increased plant height, number of leaves and suckers per plant. For humic acid, it helps in improving respiration in the growing medium and increasing the water holding capacity (Dorer and Paecock, 1997) in addition to the production of hormone-like activities that improved photosynthesis, phosphorylation, protein synthesis and various enzymatic reactions. However, it reduces inputs of chemical fertilization and minimizes environmental risks (Koreish et al., 2004). It supplies soil with carbon, microbes, increases cell membrane permeability, respiration, photosynthesis, oxygen and phosphorus uptake and helps chelation, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25552567

improves the effects of mineral fertilizers (Henry, 2011). Atiyeh et al. (2002) reported that the combined application of humic acid and macronutrients helps to transport vital sugars through plant membranes, promotes cell division, cell wall formation, and acts as an enzyme activation in protein.

Table 6. *Effect of NPK and humic acid treatments on chemical composition of Erantheumum pulchellum Andrews leaves in two seasons*

Treatments	Total chlorophyll (SPAD)	Nitrogen (%)	Phosphorus (%)	Potassium (%)

Stimulatory effect of the treatment 1/2 NPK + 150 ppm humic acid followed in some cases by NPK alone on the fresh and dry weight of the plant is a reflection of the better growth attributes mentioned before. It is well known that nitrogen forms about 40-50% of dry matter of the plant. Phosphorus has a vital role in photosynthesis and respiration while potassium plays a very important role in regulation of photosynthesis, respiratory rate and increases protein synthesis (Csirzinsky, 1999). This coincides with the results of Hendawy (2008) on *Plantago arenaria* and Sakr et al. (2018) on *Pelargonium graveolens.*

Regarding the promotive effect of humic acid, it affects growth through producing hormone analogues or growth regulators (Albayrak and Camas, 2005). Moreover, Sathiyabama and Selvakumari (2001) mentioned that application of 10 kg/ha humic acid, along with 75% of the recommended NPK dose was found to significantly influence production of green matter of Amaranthus.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25552567

The mentioned results, concluded that the rooting parameters (root length, root number and fresh and dry weighs of roots) significantly responded to the treatment of $^1/_2$ NPK + 100 ppm humic acid and then in a few cases to the treatment NPK alone. This is explained in the view that nitrogen stimulates vegetative growth, which reflects on better root growth. Root stimulating fertilizers are often higher in phosphorus as it helps strengthen young roots and give them a strong start (Ayemi et al., 2017). As for humic acid which includes microorganisms capable of producing plant growth regulators such as auxins, gibberellins, cytokinins, etc. and also buffers the hydrogen ion (pH) concentration of the soil as attained by several workers as Mohammad Ipour et al. (2013) on pot marigold and Boogar et al. (2014) on *Petunia hybrida.*

The stimulatory effect of NPK on flowering was well known as nitrogen is a main constituent of chlorophyll leading to effective photosynthesis process with more carbohydrates necessary for flowering. Phosphorus is the element most responsible for stimulating stronger bud and flower development (Ayemi et al., 2017) and potassium is vital to several areas of plant growth as photosynthesis and metabolism, etc. including drought tolerance, disease resistance, stem strength, improved texture, colour and photosynthesis. Ahmed et al. (2010) reported that NPK treatments increased number of flowers per plant, fresh and dry weights of flower reached maximum with 15:20:10 NPK application in African marigold and 15:10:10 in French marigold. Similarly, were the results of EL-Naggar et al. (2016) on *Anthurium andreanum* and Ayemi et al. (2017) who demonstrated that Gerbera cv Ruby Red responded to NPK fertilization treatments in terms of number of flowers per plant, days to first flower appearance, flower diameter, stalk length and diameter and vase life of flowers.

The simulative effects of humic acid on plant growth was previously discussed and are supported by the findings of Dudley et al. (2004) on *Zinnia elegans* (Memon et al., 2014) on *Petunia multiflora*. As for the synergistic effect of humic acid due to partitioning of NPK with it, Ibrahim et al. (2014) mentioned that the significantly highest values of enhanced growth, flowering and quality of wild garlic plants, resulted from the treatment of 2 ml humic acid + 1 g/pot NPK (10:10:10).

Briefly it is a must to maximize from the synergistic effect of humic acid to reduce the risk of chemical minerals on environment as well as their high costs from the economical point of view as the treatment of $^1/_2$ NPK + 150 ppm humic acid seems to be the best in this concern. Moreover, the application of humic acid alone gave close values or even less than control in all studied characters as failed to compensate the effect of NPK at anyhow.

This is logical since nitrogen is a main constituent of chlorophyll molecule and has a great role to form protein, which affects forming of chlorophyll. Also, phosphorus is vital in photosynthesis and respiration. Potassium affects many functions in plant like regulating photosynthesis, respiratory rate and increases protein synthesis by Hasio and Lauchi (1986).

The data in *Table 6* were in agreement with the findings of the synergistic effects of humic acid due to its beneficial effects associated with elevated tissue concentration of macronutrients. This was attained by Boogar et al. (2014) on *Petunia hybrida L* and Ibrahim et al. (2014) on *Tulbaghiavi oleracea* L and Sakr et al. (2018) on *Pelargonium graveolens*.

The results were a reflection of the promotive effect of NPK and humic acid on the various vegetative, rooting and chlorophyll characters leading to more accumulation of dry matter in the leaves. These results were confirmed by the findings of Darwish

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25552567

(2008) on *Casuarina glauca* and Sayed et al. (2010) on *Vinca rosea* c.v Major who indicated that all NPK treatments increased the leaf content of chlorophyll a and b and N, P and K %.

Humic acid helps the soil to retain the nutrients making plants healthier and less susceptible to insect and disease problems (Henry, 2011). These results were supported by those of Ibrahim et al. (2014) on *Tulbaghiavi oleracea* L. who mentioned that application of humic acid at 9 cm/l as soil drench increased chlorophyll (a) and (b), content, N, P and K% in the leaves compared to untreated plants.

Conclusion

From the aforementioned results, it is recommended to fertilize the *Erantheumum pulchellum* plant with half dose of NPK (3 g ammonium sulphat 2 g calcium super phosphate + 1.5 g potassium sulphat) plus spraying plants with 150 ppm humic acid for each/pot to minimize the risk of the pollution due to chemical fertilization. Calcium super phosphate should be applied at preparing of the soil while N and K as well as spraying humic acid should be applied monthly during the growing season to obtain the high quality vegetative, rooting and flowering characteristics of the plants.

Abstract. Several heavy metal ions including chromium(II), nickel(II), copper(II), zinc(II), cadmium(II), and lead(II) have gained attention due to their common occurrence in recent years. At medium-high temperatures, rice plant stalk (*Oryza sativa* L.) biochar, cassava stalk (*Manihot esculenta Crantz*) biochar and reed stalk (*Phragmites Trin.*) biochar automatically undergo pyrolysis, and the resulting biochar can be used as an adsorbent of heavy metal ions. While maintaining the pH and temperature of the solution and the dosages of biochar, the adsorption capacity of heavy metal ions in biochar under different treatment times (1 h, 6 h, 12 h, 24 h, 48 h, 72 h, and 96 h) were assessed. The physical and chemical characterization of the biochar was also performed. In this article, biochars produced from two common grain crop stalk (rice plant and cassava) and cash crop stalk (reed) were estimated as potential adsorbents for the removal of heavy metal ions from the contaminated solution.
Keywords: *agricultural residues, stalk biochar, heavy metal solution, removal efficiency, potential adsorbent*

Introduction

Biochar products are obtained by the pyrolysis of biomass energy materials under high temperatures (300-900°C) in environments with limited oxygen content (Ahmad et al., 2012), and have been used in agricultural soil improvement. Depending on the porous structure, biochar can be considered anadsorbent and water-retaining admixture material. A large amount of material from agricultural production and industrial processing can be used as biochar raw stock due to its abundance and low cost (Inyang et al., 2016). In the harvest season especially, many agricultural residues are produced, such as rice, wheat, corn and peanut. Processing abundant biomass into biochar by pyrolysis in anaerobic conditions not only greatly reduces the volume, but also improves the value (Abdelhadi et al., 2017). Typical biological carbon has high cation exchange ability (CEC) and alkalinity. With increasing biological soil activity, biochar improves soil properties, ultimately giving potential to increase agricultural yield (Chun et al., 2004). Biochar may also affect the bioavailability of heavy metals in soil and the accumulation of heavy metals in soil-grown plants. However, previous studies have not shed much light on the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25692579

effects of biocarbon on heavy metals in soil (Chen et al., 2011). Unlike most biodegradable organic and inorganic pollutants, heavy metals cannot be biodegraded and accumulated through the food chain (Inyang et al., 2016). In recent years, more attention has been paid to biological carbon, because of its role in ecological restoration, such as carbon sequestration, soil fertility improvement and soil restoration. Recent literature provides evidence that it has the ability to hold organic and inorganic pollutants in soil (Inyang et al., 2016). Therefore, biochar is considered to be a new type of remediation agent that can help to repair heavy metal soil pollution (Liu and Zhang, 2009).

Water is an important part of human ecological environments. Human health is harmed by the contamination of drinking water, agricultural products, and aquatic products with heavy metals. Owing to the characterization of heavy metal pollutants as being non-degradable, cumulative, and potentially harmful, heavy metal pollution of water has attracted more attention. In light of research results for the application of biochar, multi-aperture, specific surface area, cationic exchange ability, high stability, and other characteristics were considered. Biochar use as an adsorbent material for metal contaminated water treatment has important application prospects (Meng et al., 2014). Researchers found that biochars produced by anaerobic digestion had higher adsorption capacity to heavy metals (Inyang et al., 2011, 2012). Cellulosic biomass waste from agricultural and forestry production are usually used as the raw materials for biochar processing (Keiluweit and Kleber, 2009).

In China, reed is a common cash crop that is often used as the raw material for paper production. Owing to the ability of adsorption and enrichment of heavy metals, reed could be used for wastewater treatment and as a landscape plant in constructed wetlands (Hou et al., 2016). Cassava and rice are common food crops and the residues account for a large proportion of agricultural waste in tropical areas (Deng et al., 2014; Huang et al., 2018). Biochar production from these three stalk materials has been reported (Huang et al., 2017; Edhirej et al., 2017; Li et al., 2018). Therefore, this paper mainly compared the different adsorption capacities of heavy metals by biochars using rice plant stalk, cassava stalk, and reed stalk as raw materials for biochar. The aims of this study were: (1) to examine the physical and chemical characteristics of biochars, (2) to examine the surface and pore characterization of biochars, and (3) to examine their adsorption capacity of common heavy metals.

Materials and methods

Biochar preparation and characterization

The biochars that were texted were made of rice plant stalk, cassava stalk, and reed stalk material. The raw materials used in this study were collected in Fuping County, China. The sorption ability of the biochar was enhanced by pulverization prior to pyrolysis (Tong et al., 2011). In order to do this, the stalk were initially cut to 25 mm pieces with an electronic chipper and then these were cut in a 5 mm cross-cutting mill. The material was dried at 60°C for constant weight before pyrolysis (Sevilla and Fuertes, 2009). Studies have shown that when the carbonization temperature reaches 500°C, the carbon yield biomass is essentially stable (Bridgwater, 2007). Thus, all biochar from this study was produced at a temperature of 550°C for 4 h. Only the small particles that passed through a 0.5 mm sieve were used in the experiments described below.

Ash content was determined by combusting the biochar at 750°C for 6 h in open crucibles on a dry weight basis (105°C for 18 h under argon). A CHN elemental analyzer

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25692579

(Flash EA 1112, Thermo Finnigan) was used to determine the carbon (C), hydrogen (H), and nitrogen (N) contents of all biochars. Oxygen content was calculated according to *Eq. 1*. Elemental composition was measured in duplicate, and in this paper, the averaged data was used for analysis. Biochar SEM images were obtained by FEI Q45 scanning electron microscop (FEI, USA). The pH of the biochar was measured in a 1:10 ratio of biochar suspension in deionized water. To determine the concentrations of heavy metals in the biochar, each of the 0.1 g of biochar samples was dissolved in 3 mL of HNO_3 (65%), 9 mL of HCl (37%), and digested for 1 h. The digestion solution was poured into 50 mL flask and diluted with deionised water to reach the tick mark (Pundytė et al., 2011; Baltrėnaitė et al., 2016). The concentrations of heavy metals in the solution were determined by ICP-MS (Agilent 7700e, USA).

Metal adsorption experiments

All chemical reagents were of analytical grade. Heavy metal solution (10 mg/L) of Cd, Cr, Pb, Cu, Zn, Ni was prepared. The mixed solutions made to have a pH 7.0±0.1 which was adjusted by the addition of nitric acid or sodium hydroxide solutions. For adsorption efficiency investigation, 50 ml centrifuge tubes were filled with a heavy metal solution into which 0.01 M $CaCl_2$ and 0.2 g/L NaN_3 were added to maintain a constant ionic strength and to inhibit microbial activities. 0.5 g of biochar per sample were added to the test solutions. Other scholars who studied the equilibrium adsorption time in similar biochars found the time to be around 24 h (Deng et al., 2014; Huang et al., 2018). In order to compare the adsorption effects of the three kinds of biochar, the experimental adsorption time was set to 1 h, 6 h, 12 h, 24 h, 48 h, 72 h, and 96 h. Heavy metals mixed without biochar and biochar with the addition of double distilled water were used as blank controls. All tubes were agitated in the dark at 180 rpm at 25°C. After the adsorption completed, samples were centrifuged for 10 min at 5000 rpm, and the supernatant was then filtered through a 0.45 μm membrane. The removed amount was determined by measuring concentration differences of heavy metals before and after the adsorption experiment (Hou et al., 2016).

Evaluation method

Oxygen content of biochar was calculated according to *Eq. 1*.

$$O = 100 - (C + H + N + \text{ash}) \quad \text{(Eq.1)}$$

where O is the oxygen content of the biochar; C, H and N are the carbon, hydrogen, and nitrogen contents of the biochar, respectively; ash is the ash content of the biochar.

Data processing

The adsorption capacity of biochar (q_t) was calculated by *Eq. 2*:

$$q_t = \frac{(C_{i0} - C_{if}) \times V_0}{m_f} \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25692579

where C_{i0} and C_{if} are the initial and final concentrations of the tested solution ($mg \cdot L^{-1}$), respectively; V_0 is the volume of the tested solution volume (ml); m_j (g) is the weight of the biochar; j refers to the different biochars.

Data analysis

ANOVA test was performed at 95% level using SPSS 22 (IBM SPSS Statistics, Version 22) which tested for the significance of the differences between treatments.

Results and Discussion

Characterization of the biochars

The physicochemical properties of the three different biochars are shown in *Table 1*. We found that all the biochars were alkaline (pH > 10). This observed higher pH of the three biochars is an indication that they may have potential to ameliorate and neutralize soil acidity, which can be an important component in the mobility of heavy metals. The ash content of rice plant stalk (40.00%) was higher than that of cassava stalk (9.85%) and reed stalk (15.75%). The ash content of the three biochars is consistent with the productivity trend, rice plant stalk (43.19%), cassava stalk (23.13%) and reed stalk (24.27%), respectively. Ash is made up of solid inorganic substances, which are the residual mineral elements that remain after burning the stalk material, such as sodium, potassium, calcium, magnesium, phosphorus, and iron. The ash content shows the selective absorption and accumulation of minerals by different plants. Higher ash content indicates that rice plant can absorb more mineral elements, which creates favorable conditions for biochar to absorb heavy metals. The productivity of the three biochars are 43.19%, 23.13% and 24.27%, respectively. The productivity of biochars is consistent with the ash content.

Table 1. *Physicochemical characteristics of the three different biochars*

Physicochemical characteristics	Biochar		
	Reed stalk	***Cassava stalk***	***Rice stalk***
pH	10.55	10.24	10.94
Conductivity ($\mu S \cdot cm^{-1}$)	677	1313	911
TC (%)	65.82±14.62	59.12±10.81	39.23±5.28
Ash content (%)	15.75±0.36	9.85±0.42	40.00±2.08
Productivity (%)	28.53±2.57	31.05±1.69	41.71±0.61
C (%)	61.93±0.98	64.30±0.32	41.05±0.44
H (%)	1.65±0.07	1.61±0.05	1.12±0.02
N (%)	0.73±0.09	1.53±0.11	1.36±0.09
S (%)	0.69±0.27	0.50±0.17	0.35±0.02
O (%)	19.94±0.97	22.71±0.41	16.47±0.49
C/N	85.07±10.13	42.13±2.87	30.15±1.96
H/C	0.027±0.001	0.025±0.001	0.027±0.000
O/C	0.32±0.02	0.35±0.01	0.40±0.02
(N+O)/C	0.33±0.02	0.38±0.01	0.43±0.02

Chemical composition of the three biochars is shown in *Table 1*. Rice stalk biochar contained lower concentrations of C, H, O, and S than cassava stalk and reed stalk biochar. This might be related to the different cellulose content of each feedstock.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25692579

Previous study found that the C content was higher in hardwood than stover (Park et al., 2016). The lignin content in the raw material biomass directly affects the total carbon content of the biochar. While the N content of reed stalk was the least (0.73%), it was probably related to the accumulation of N in plants. In addition, the higher content of hydrogen and oxygen for cassava stalk and reed stalk revealed that more activated sites were available and stable carbon-oxygen complexes existed on the surface of cassava stalk and reed stalk as opposed to rice plant stalk (Guerrero et al., 2005; Tong et al., 2011). The degree of carbonization can be described by the molar H/C ratio, where H is primarily associated with plant organic matter (Tong et al., 2011). Compared to activated carbon (AC) with H/C ratios of 0.12 and 0.256 (Chen et al., 2011; Xu and Zhao, 2013), the observed H/C ratios of 0.027, 0.025, and 0.027 for rice stalk biochar, cassava stalk biochar and reed stalk biochar, respectively, indicate that these biochars are strongly carbonized and are consistent with high amounts of aromatization.

These low H/C ratios suggest that the biochars contain low amount of organic plant residues. The molar oxygen to carbon (O/C) ratio of biochar has been used as a surrogate for surface hydrophilicity since it is indicative of polar-group content, most likely derived from carbohydrates. Based on this assumption, rice plant stalk (0.4) is likely to be more hydrophilic than cassava stalk biochar (0.35) and reed stalk biochar (0.32), as it has a higher O/C ratio. (N+O)/C ratios of rice stalk biochar, cassava stalk biochar and reed stalk biochar were 0.43, 0.38 and 0.33, respectively. The lower O/C and (N+O)/C ratios indicated an increase in aromaticity and a reduction in polarity. Hydrophobic carbon can provide more sorption domains for HOCs (Teixidó et al., 2011; Yang et al., 2011). Different plant types affect the reduction of mass (Keiluweit and Kleber, 2009). The reduction in biomass weight of cassava stalk and reed stalk are more than that of rice stalk. The weight of dry rice stalk biomass, cassava stalk, and reed stalk decreased 2.32, 4.32, and 4.12 times during the production of biochar, respectively.

For rice stalk biochar, ash content and TC had a significant effect at 95% level ($p < 0.05$), C and (N+O)/C had a significant effect at 95% level ($p < 0.05$). For cassava stalk biochar, ash content led to a significant increase in N and C/N. N and C/N had a significant effect at 95% level ($p < 0.001$) and O/C and (N+O)/C had a significant effect at 95% level ($p < 0.05$). For reed stalk biochar, C and O had a significant effect at 95% level ($p < 0.001$), and C and (N+O)/C had a significant effect at 95% level ($p < 0.05$). C and O/C had a significant effect at 95% level ($p < 0.001$), and O and (N+O)/C had a significant effect at 95% level ($p < 0.05$). The O and O/C of the three biochars were all significantly correlated at 95% level ($p < 0.05$).

Surface characterization

Scanning electron microscope images (*Fig. 1*) indicated that three biochar samples consisted of small 1–20 μm diameter pores. The pores of cassava stalk biochar were larger than that of rice stalk biochar. And the pores of reed stalk biochar were the smallest. SEM imaging showed that heat-treated stalk retained its original stalk pores structure.

The strong sorption ability of biochars may be attributed to their surface properties, which is inherited from the feedstock materials. Obvious microporous structures were observed after carbonization of the three substances. The average pore size of the rice biochar was the smallest (1.0 μm–4.2 μm) followed by reed stalk biochar (3.5 μm-4.4 μm), and cassava stalk biochar (7.0 μm–20.0 μm). Within the same field of vision, the pore arrangement of cassava stalk biochar was more compact and the reed stalk biochar had the least number of pores.

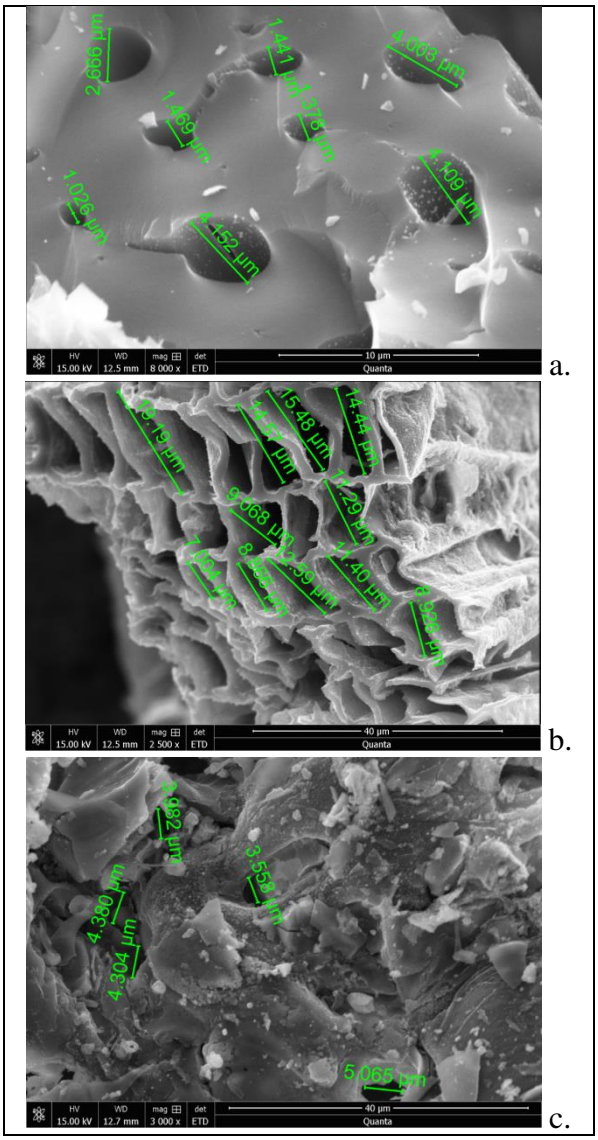

Figure 1. *Scanning electron microscope images of biochar (a. reed stalk biochar, b. Cassava stalk biochar, c. rice stalk biochar)*

Capacity of heavy metal adsorption for three biochars

The capacity of adsorpion of heavy metals q_t (*Eq. 2.*) by three types of biochar is shown in *Fig. 2*. The temperature, pH, dosage of biochar were kept the same. Within the entire experimental adsorption time range, the amount of heavy metal adsorption of the three biochars all showed an increasing trend with the increase in adsorption time. During the entire adsorption process, cassava stalk biochar had the largest cumulative adsorption of heavy metals. When the adsorption time was at 1 h, the reed stalk biochar had a stronger adsorption capacity for various heavy metals than the rice stalk biochar. At other adsorption times, the cumulative adsorption of various heavy metals by rice stalk biochar was higher than that of reed stalk biochar. There are some differences in the adsorption capacity of the three biochars for each of the different heavy metals. For example, cassava stalk biochar had stronger adsorption capacity for Cr, Cu, and Pb than the other two biochars. Their adsorption amounts accounted for 49.17%, 70.56%, and 65.27% of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25692579

total adsorption of the three heavy metals, respectively. Rice stalk biochar showed good adsorption capacity for Zn, and its adsorption amount accounted for 51.67% of the total adsorption. The final adsorption amount of rice stalk biochar for Ni and Cd was higher than that of cassava stalk biochar. However, the contribution of cassava stalk and rice stalk biochar to the adsorption of Ni and Cd was not much different. For example, rice stalk biochar adsorption contribution rates of Ni and Cd were 36.66% and 36.69%, respectively, and cassava stalk biochar adsorption contribution rates of Ni and Cd were 34.81% and 35.64%, respectively.

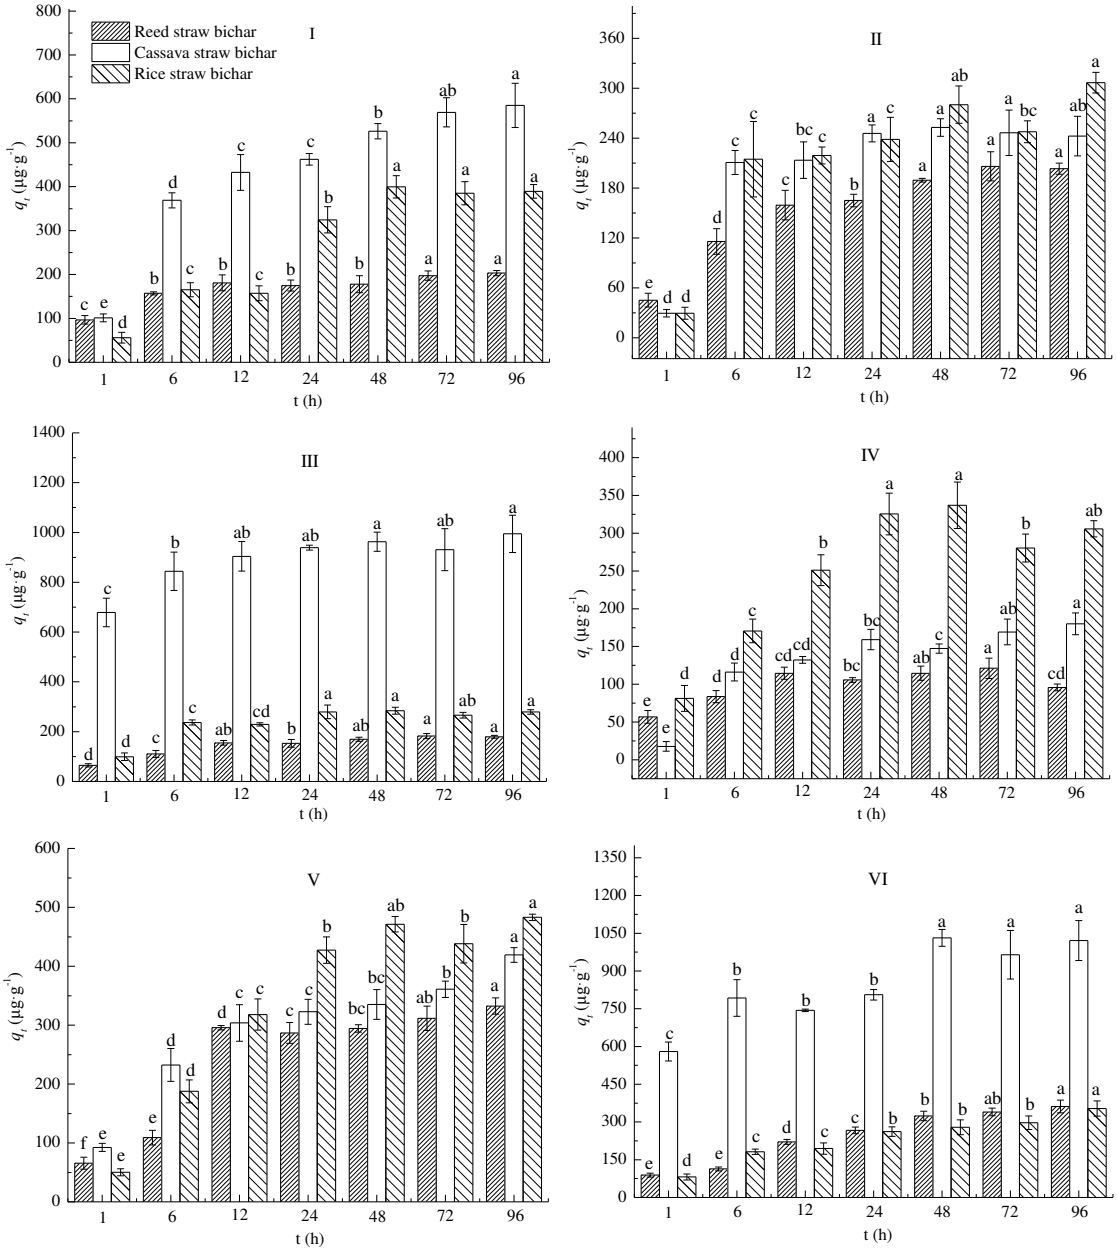

Figure 2. *Effect of biochar concentration on heavy metal adsorption efficiency for three different biochars. I, II, III, IV, V, and VI represent Cr, Ni, Cu, Zn, Cd, and Pb, respectively. Bars indicate standard errors. Lowercase letters indicate significant differences in heavy metal adsorption capacity of the same biochar at different adsorption times ($p < 0.05$)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25692579

As the contact time increased, available adsorption sites became occupied, followed by an increase in adsorption capacity of heavy metals and a decrease in adsorption efficiency. Research has shown that biochars with higher O content and more acidic surface sites have higher CECs (Harvey et al., 2011). High carbonization temperatures (> 400°C) also promote the formation of graphene structures in biochars, which favor electrostatic attraction sorption mechanisms (Keiluweit and Kleber, 2009). High temperature pyrolysis can remove aliphatic groups and form surface functional groups that have strong adsorption ability, increasing the adsorption and fixation strength of biochar for heavy metal ions.

The correlation analysis of the adsorption test data shows that when the adsorption time does not exceed 6 h, the amount of Cr, Zn, and Cu adsorbed by the biochar of reed stems and the amount of Ni, Cu, Zn, and Pb adsorbed by the biochar of cassava stalks was significantly related to the adsorption time ($p < 0.05$). When the adsorption time did not exceed 12 h, the amounts of Cr and Cd adsorbed by cassava stalk biochar and Zn and Cd by rice stalk biochar were significantly related to the adsorption time ($p < 0.05$). When the adsorption time was at 24 h, the amount of Cd adsorbed by reed stalk biochar increased significantly with the increase in the adsorption time ($p < 0.05$). When the adsorption time was less than 48 h, the adsorption amount of Ni and Pb by reed stem biochar was positively correlated with the adsorption time ($p < 0.05$).

In addition, there are some other notable adsorption phenomena. Within 6-48 h, the adsorption amount and adsorption time of Cr by reed stem biochar was not significant ($p > 0.05$), and the adsorption amount of Zn within this adsorption time range was not significant ($p > 0.05$). The adsorption amount of Cr at 72 h and 96 h was significantly correlated with adsorption amount at 48 h ($p < 0.05$), but there was no correlation between the adsorption amount at 72 h and 96 h ($p > 0.05$). The result shows that the adsorption amount of Cr by reed stalk biochar falls within 6 h of adsorption time, and the adsorption amount increases rapidly with adsorption time. The adsorption amount from 6-48 h does not increase or increases very slowly with the adsorption time. Once a certain adsorption amount was reached, the adsorption amount stabilized itself from the time points of 72-96 h.

The adsorption of Ni (II) and Zn (IV) by cassava stalk biochar was not significant at 6 h and 12 h ($p > 0.05$). The adsorption amount of these two heavy metals did not increase during this adsorption time. Ni (II) adsorption increased at 12 h and 24 h ($p < 0.05$), but stabilized at 24-96 h. The adsorption amount of Zn (IV) increased from 12 h to 48 h ($p < 0.05$) and the adsorption amount was stable after 48 h. The adsorption amount of Cu (III) gradually stabilized after 12 h. The adsorption amount of Pb (VI) stabilized from 6 h to 24 h, increased from 24 h to 48 h, and then stabilized again.

Based on the above analysis, cassava stalk biochar and rice stalk biochar can achieve high adsorption efficiency for six heavy metals in a relatively short time (that is, an adsorption time less than 12 h). The adsorption of the heavy metal Cd (V) by reed stalk biochar reached its highest level within 24 h of adsorption time, but its final adsorption amount was lower than that of cassava stalk biochar and rice stalk biochar. The reed stalk biochar adsorbed heavy metals Ni (II) and Pb (VI) only after 48 h, and the final adsorption of Ni (II) was lower than that of rice stalk and cassava stalk biochar. The final Pb (VI) adsorption amount by reed stalk biochar was basically the same as that of rice stalk, indicating that compared with cassava stalk biochar and rice stalk biochar, reed stalk biochar has poor adsorption capacity and poor adsorption strength for these six heavy

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25692579

metals. For reed stalk biochar, it may take longer to adsorb the same amount of heavy metals as the other two biochar types in this study.

Higher quantities of biochar minerals are produced at higher temperature ranges (350-600℃). Most of the biochar minerals produced at high temperatures are insoluble and are slowly released during the adsorption process, forming precipitate with heavy metals (Inyang et al., 2011). Higher specific surface area and pore volume can physically adsorb heavy metal ions on the surface of biochar and in its pores. The surface of biochar is often negatively charged and can attract positively charged metal ions (Patra et al., 2017).

The three biochar raw materials used in this study were primary stalk residues from agricultural and forestry production. In China, a large amount of agricultural and forestry production residues provide feasibility for biochar production. Biocharing technology not only efficiently treats biomass waste, but also produces by-products such as biochar and bio-oil which both have a higher utilization value.

Studies have shown that adding a certain amount of biochar to heavy metal contaminated soils usually has the effect of improving pH in acidic soils, increasing soil nutrient content and its effectiveness. Biochar can increase the pH of acidic soil by increasing the alkaline saturation of the soil, reducing aluminum levels, thereby reducing the transportable forms of heavy metal ions (Zhao et al., 2015). Adding biochar can increase soil available P, available K, organic matter, total N, total P, and total K to different degrees. First, biochar contains mineral nutrients such as N, P, K, etc., which can be directly applied to soils in order to increase soil nutrient content (Yuan et al., 2011). Second, biochar can also significantly increase the available content of major cations such as K, Mg, and Ca in the soil, provide essential nutrients for plant growth, and improve soil nutrient effectiveness (Lehmann et al., 2003). Third, the strong adsorption and structural characteristics of biochar have a retention effect on water-soluble nutrients in the soil, effectively reducing soil nutrient leaching-loss, slowly and continuously releasing nutrients, and enhancing effective soil nutrient content (Angst and Sohi, 2012). In summary, the application of stalk-based biochar in the restoration of contaminated land is very significant. Not only is the biomass waste used efficiently, but it can also achieve carbon sequestration, improve soil structure and soil fertility.

Conclusions

Excellent removal of heavy metals from soil results from the advantageous physical and chemical characteristics of biochar. Due to the fact that heavy metal removal mechanisms vary with respect to different biochars and metal contaminants, the interest in understanding adsorption processes and the removal efficiency of various pollutants by different types of biochar has increased in recent years. For certain heavy metals, the suitable biochar repairer is different. For Cu, Pb, and Cr, cassava stalk biochar should be chosen as the adsorbent. For Zn, rice stalk biochar is more suitable for treatment, because of the stability of the heavy metal adsorption efficiency. For Ni and Cd, cassava stalk biochar and rice stalk biochar are more suitable as adsorbents than reed biochar.

The soil system is more complex than just a mixed solution of heavy metals. In this experiment, we initially obtained the heavy metal ion adsorption effect for different types of biochar under different adsorption time conditions. The types of biochar with specific adsorption capacity for different heavy metals were summarized. The simulation and calculation of heavy metal chemical conversion processes, heavy metal ion infiltration,

DOI: http://dx.doi.org/10.15666/aeer/1802_25692579

and diffusion processes in the soil solution will be carried out in the future. The application of biochar for the remediation of contaminated land will soon become an effective treatment rapidly used across the world.

(Received 23rd Jul 2019; accepted 12th Feb 2020)

Abstract. This research was conducted under the ecological conditions of Van-Gevaş, Turkey in 2015 and 2016 in three replications according to the Random Parcel Trial Pattern. This study is a flowerpotting trial investigating the effects of copper (Cu) and zinc (Zn) doses applied in increasing amounts to the bean plant grown in the hydroponic system. Four different copper doses (0-200-400-800 mg Cu kg^{-1}) and four different zinc doses (0-2.5-5.0-10.0 mg Zn kg^{-1}) were applied. This study was conducted in drybean varieties on different doses and interactions of Cu and Zn; characteristics such as plant height, number of pods in the plant, number of branches, grain yield in the plant, harvest index and protein ratio were examined. According to the results of the research, while the of 400 mg kg^{-1} Cu and 5.0 mg kg^{-1} Zn dose applied to Yakutiye-98 variety in the first year increased the seed yield (36.32 g $plant^{-1}$) in the plant; in the second year, 200 mg kg^{-1} Cu applied to Yakutiye-98 variety and 5.0 mg kg^{-1} Zn increased the yield (28.45 g $plant^{-1}$). In general copper-zinc interaction; Co-administration of Cu and Zn doses led to increases in yield and yield parameters of bean varieties compared to the separate administration of these doses and was found statistically significant at 1% level.
Keywords: *dry beans, hydroponics, copper, zinc, fertilizer, grain yield*

Introduction

High content of protein in the composition of grains between 22-30% is sufficient by carbohydrates; bean is an important legume plant as it is rich in potassium, calcium, magnesium and phosphorus and also has various vitamins. It is in the first place among legumes in terms of cultivation and production in the world. Dry and fresh consumption of bean is very common. Around 29 million hectares of land is cultivated in the world. The total production is 23 million tons and the yield per hectare is 800 kg (FAO, 2017). In Turkey, bean cultivation area is 848 thousand ha, 220 thousand tons of production and 2590.00 kg ha^{-1} yield is obtained (TUİK, 2018).

As the world population increases rapidly, food consumption is increasing accordingly. This brings about an urgent need for increasing the production together with the need for vegetable protein sources. In order to increase production in existing agricultural areas, grain yield per unit area should be increased. For this reason, it is very important to apply the macro and micro nutrients in sufficient doses considering the interactions with each other as well as technical agricultural practices.

Copper (Cu) and zinc (Zn) are absolutely essential micro nutrients for plants. However, although it is necessary for the life of living things, high doses cause toxic effects on plants and other living things. Although high concentrations of Cu and Zn is toxic, they are part of molecules that play a key role in photo-synthetic electron transport and enzyme activation (Raven et al., 1999).

Copper is a micro nutrient in plants and it is required for respiration, protein synthesis and chlorophyll production. Indeed, it is very effective in protein and carbohydrate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25812598

metabolism. It is an important trace element due to its role in carbohydrate and lipid metabolism through influencing enzyme activity in plants (Kacar and Katkat, 2006). Activation and electron transfer of many oxidase enzymes are carried out by copper (Cu). In particular, the role of copper in the symbiotic nitrogen fixation in legume plants as the subject to this study is important (McCauley et al., 2009). In addition, Cu is an effective element in plant resistance against fungal diseases and in controlling plant moisture (Plaster, 1992).

Copper is present in the soil attached to organic materials, manganese (Mn) and iron (Fe) oxides. As a matter of fact, copper deficiency can be seen in soils rich in organic matter and ready pit soils containing more than 50% organic matter because organic matter holds copper very strongly. In addition, silicates contain copper, which changes and dissolves in weak amounts. Washing of sandy soils also causes copper deficiency. In the absence of copper in the young leaves of plants, chlorosis necrosis such as jaundice is seen, development is stunted, maturation is late and sometimes due to the excess color matter the coffee color symptoms are detected. However, in copper deficiency, plants are particularly vulnerable to fungal diseases caused by fungi. Carbohydrate content in Cu deficiency is very low in the plant. In addition, it was found that the nodule formation in legume plants was interrupted and a small amount of N was fixed (McCauley et al., 2009; Bolat and Kara, 2017).

Copper concentration in clean soils that are not polluted in nature varies between 2-40 ppm, while in dirty soils this value can increase up to 1000 ppm (Sönmez et al., 2006a). Toxic effects occur when the amount of copper in the soil is high and it is difficult for plants to take iron up. Therefore, symptoms of chlorosis appear to be iron deficiency. Another disadvantage of the excess copper in plants is the slowdown of root and shoot development. Also, it's excess in the soil affects the uptake of molybdenum negatively (Bolat and Kara, 2017).

If the amount of copper (Cu) in the dry matter weight of the plant is more than 15-30 mg Cu kg^{-1} toxic effects occur. Copper toxicity in the plant generally occurs in the root region and causes some degradation of the plant's physiological properties such as protein synthesis, photosynthesis, respiration, ion exchange and cell membrane structure (Sossé et al., 2004).

Heavy metal pollution is generally seen in soils with physical, chemical and biological degradation. Copper pollution is caused by natural disasters such as earthquakes, volcanic eruptions and floods as well as anthropogenic activities such as industrial, urban, mining and pesticide use in agriculture and the use of sewage wastes as fertilizers (Karaca and Turgay, 2012; Dağhan and Öztürk, 2015). It is known that copper fertilizers, copper-containing fungicides and pesticides are used more and more widely than necessary in recent years especially against the fungal factors that are defective in agricultural areas. As a matter of fact, it has been reported that Cu content is close to the critical toxicity limit in the Mediterranean Region soils of Turkey and Cu content is above the critical limit in 8% of greenhouse soils (Kaplan, 1999).

Zinc (Zn) plays a role in the metabolism of certain hormones such as auxin, which provides the formation of shoots, and it is also important for the activity of various enzymes that occur in the plant (Marschner, 1997; Kaya et al., 2018). Zinc is one of the micro nutrients that is essential for plants in small amounts.The effect of zinc in plants is similar to magnesium (Mg) and manganese (Mn). Zinc enzyme activation is directly effective in the formation of product quantity and quality due to its effect on photosynthesis, respiration and biological membrane stability (Rout and Das, 2003). At the same time, zinc which acts on

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25812598

nitrogen (N) metabolism in plants, is effect in the formating of starch and ripening of seed (McCauley et al., 2009).

Zinc is present in the soil in the form of oxides in silicate minerals, bonded to clay minerals or in combination with organic matter. While the Zn concentration in the soil varies between 10-300 ppm, it is reported that the Zn concentration that can be taken by plants varies between 3.6-5.5 ppm (Öktüren Asri and Sönmez, 2006). Zinc toxicity in plants generally occurs above 400 ppm. Root and shoot growth of plants exposed to zinc toxicity weakens, roots become thin, young leaves curl and signs of chlorosis appear. In addition, cell growth and elongation are interrupted, cell organelles are broken down and chlorophyll synthesis is reduced (Rout and Das, 2003; Öktüren Asri and Sönmez, 2006). The zinc in the soil occurs in complex compounds that do not dissolve in time. This bonding of zinc (Zn) also affects the high soil pH. In contrast, the solubility of zinc compounds increases as the soil gains an acidic character. Zinc poisoning due to excess zinc in the soil is a very rare condition in plants. Likewise, the zinc content of plants grown in soils close to mineral deposits can be quite high. When the Zn concentration is high, the root and leaf growth of the plant is significantly weakened. In addition, the nitrogen, phosphorus and iron uptake rate of the plant decreases (Bolat and Kara, 2017).

Zinc deficiency is generally found in soils with high alkaline pH and alkaline plants with high basic character (Marschner, 1997; Bolat and Kara, 2017). In Zn deficiency, carbohydrate, protein and auxin metabolism is damaged due to the decrease in enzyme activity. The most obvious symptom of zinc deficiency in plants is a dwarf development and small leaf formation caused by deterioration of auxin metabolism and especially decrease in IAA synthesis (Kacar and Katkat, 2006; Kaya et al., 2018). In addition, chlorose-like necrosis appear between the veins of the leaves. The veins of such leaves may be green, the color of the parts between the veins are yellowish green, yellow or white. Leaf formation in plants decreases, leaves become sparse, top shoots die and early foliage is seen (Plaster, 1992).

It is reported that the amount of tryptophan in zinc deficiency in legume plants is decreased, protein synthesis is stopped and the quality of the product is adversely affected due to the accumulation of free amino acids (Yalçın and Usta, 1990; Toğay and Anlarsal, 2008).

Zinc deficiency not only limits crop yield but also lowers product quality. As a matter of fact, the lack of zinc in agricultural areas is quite common in recent years. Because, 30% of agricultural land in the world 83%, if in Turkey; It has been determined by studies that it contains less than 0.5 ppm Zn and it is reported that zinc deficiency is at significant levels in agricultural areas (Yağmur and Aydın, 2013).

In this study, the effect of increasing Cu and Zn doses and different dose application interactions on yield and yield characteristics of bean cultivars, a legume plant, was investigated. Bildirici et al. (2016) conducted different researches on the effect of heavy metals on beans in Van and its soils. They determined the relationships between some growth parameters and micro nutrients (Zn, Cu, Mn, Mg, Pb, Co, Cd and Fe). In line with this information; The aim of this study was to investigate the effects of copper (Cu) and zinc (Zn) nutrients and their interactions on the yield and yield components of bean plants grown hydroponically in the unheated greenhouse of Gevaş Vocational School of Yüzüncü Yıl University.

Materials and Methods

This research was conducted in Turkey's Van province in 2015 and 2016 in three replications according to the Random Parcel Trial Pattern. The trial was carried out with hydroponic system in the un-heated greenhouse of Yüzüncü Yıl University in Gevaş District of Van. In the experiment, Göynük-98(Ç1) and Yakutiye-98(Ç2) bean varieties registered in 1998 were used as plant material. These varieties are among Turkey's proprietary 12 varieties of beans. It is white and coarse colored and registered to Eastern Anatolia Agricultural Research Institute (Şehirali, 1988).

Cocopeat, which is rich in organic matter, was preferred as soil material in order to see the effects of copper (Cu) and zinc (Zn) doses applied to bean cultivars. Its properties and nutrient content are given in *Table 1*.

Table 1. *Some physical and chemical properties of Cocopeat**

Soil Properties	Values
pH	5.5-6.5
Cation exchange capacity (meq/100g)	64-130
Electrical transmission (EC)	0.5-1.0 mS/cm
Compression ratio	5:1
Color	Light brown-dark brown
Appearance	Short fiber and granular
Fiber	25%
Fiber length	3-30 mm
Particle size	0.1-9 mm
Water holding capacity	9 times dry weight
Total porosity	96%
Composition (% by dry weight)	
Organic matter	94-98
Organic carbon	45-50
Lignin	65-70
Cellulose	20-30
N	0.30
K2O	0.90
P2O5	0.05
CaO	0.40
C : N rate	80 : 1

*Gül, 2008

The micro nutrients subject to the study are copper (Cu) and zinc (Zn). $CuSO_4 \cdot 5H_2O$ copper sulfate as Cu source; $ZnSO_4 \cdot 7H_2O$ zinc sulfate solution was applied homogeneously to the pots before sowing (Eren and Mert, 2016). Cu and Zn doses applied in the experiment were determined by taking into consideration the averages and upper limits reported by Lindsay (1978).

The research was established with randomized plot design with 3 replications. Before sowing the pots; 4 different levels of copper dose [0 mg kg^{-1} (Cu1), 200 mg kg^{-1} (Cu2), 400 mg kg^{-1} (Cu3), 800 mg kg^{-1} (Cu4)] in copper sulfate ($CuSO_4 \cdot 5H_2O$) format and 4 different levels of zinc dose [0 mg kg^{-1} (Zn1), 2.5 mg kg^{-1} (Zn2), 5.0 mg kg^{-1} (Zn3), 10.0 mg kg^{-1} (Zn4)] in zinc sulfate ($ZnSO_4 \cdot 7H_2O$) were determined. The main reason for the high application of copper doses is the widespread use of Cu-containing pesticides, especially in agricultural pesticides. In addition to this, to observe the possible effects of copper toxicity and the effects of copper-zinc interactions on beans

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25812598

due to the increase in the use of sewage residues such as sewage sludge as fertilizer in plant production. The experiment subjects consisted of 2 bean varieties and 4 different application doses for each element.

In this study, 540 g of cocopeat was placed in 3 liter pots with a diameter of 16.5 cm and a depth of 19.0 cm. In the experiment, seed sowing process was made 1 week after the copper application for the incubation of the copper given to the pots. Bean varieties seeds were sowed in the first year on 07.05.2015 and the second year on 10.05.2016 with one plant per flowerpot. Irrigation and fertilization of the test pots were carried out evenly and homogeneously after the exit. In the research, the macro and micro basic nutrients required by the plant were prepared as separate solutions (Buttaro et al., 2012; Di Lorenzo et al., 2013). In the preparation of the nutrient solution, Tangolar et al.'s work (2017) on the soilless culture system was used. The applied nutrient solution mixture was prepared in 150 ppm nitrogen (N) as NH_4NO_3; 20 ppm phosphorus (P) as H_3PO_4; 100 ppm potassium (K) as K_2SO_4; 15 ppm magnesium (Mg) as $MgSO_4$; 10 ppm sulfur (S) sulphate in the form of compounds; 5 ppm iron (Fe) as Fe-EDDHA; 3 ppm manganese (Mn) as $MnSO_4$ format; It was formed of three different solutions in 0.4 ppm boron (B) as H_3BO_3 and 0.05 ppm molybdenum (Mo) as $NH_4Mo_7O_{24}.4H_2O$. The plants were periodically fertilized once a week by introducing these three nutrient mixtures into the system. In both years of the study, the application of nutrient solution was started when the plants had 4-5 leaves and 1.0 mL of plant^{-1} from macro nutrient solution and 0.5 mL of plant^{-1} from micro nutrient solution were applied. The pH value of the deionized water used in this study was determined as 7.45 and electrical conductivity as 0.667.

In the experiment, harvesting was carried out on 4 October in 2015 and on 22 September in 2016 based on the physiological yellow maturity of the beans. The plants were harvested after 120-130 days of ripening period and the following characteristics were examined in comparison of the applications;

Plant height (cm), number of pods (number of plant^{-1}), number of branches (number of plant^{-1}), grain yield in the plant (g plant^{-1}), harvest index (%) and protein content (%) characteristics were measured (Yağmur and Aydın, 2013; Tangolar et al., 2017).

In the study, randomized experiment design variance analysis method was used in statistical evaluation of the effects of different doses of Cu and Zn applications on yield and yield components of plant and interactions of nutrient concentrations. In determining different groups; Duncan's (5%) Multiple Comparison Test (Düzgüneş et al., 1987), Costat and Mstatc package programs were used.

Results

Plant height (cm)

According to the data obtained at the end of the research, in year 2015, varieties, copper (Cu) doses and varieties x copper (Cu) interactions were significant; zinc (Zn), cultivar x zinc (Zn), copper x zinc and Ç x Cu x Zn interactions were statistically insignificant. In 2016, except for cultivar x copper (Cu) and Cultivar x Cu x Zn interactions, other differences between plant averages were significant (*Table 2*).

As shown in *Table 2*, the average plant height in 2015 and 2016 was obtained as higher in Göynük-98 (Ç1) cultivar (with 50.82-44.86 cm), compared to Yakutiye-98 (Ç2) cultivar. The average plant height values obtained from different copper doses in the experiment varied between 53.08-45.14 cm in 2015 and 46.19-41.39 cm in 2016.

*The difference between the averages indicated by the same letters is not significant at 5% level. Cu: Copper Dose, Zn: Zinc Dose, Ç1: Göynük-98, Ç2: Yakutiye-98, Avg.: Average, ÇxCu: Variety x Copper Dose Interaction, Ç x Zn: Variety x Zinc Dose Interaction, Cu x Zn: Copper x Zinc Dose Interaction

According to the results of the research, the plant height in the averages of in 2015 and 2016 and both year averages was obtained from the applications of 400 mg kg^{-1} Cu3 applied, respectively to Göynük-98 variety with 53.08-46.19 cm.

In the first year of the experiment, the lowest plant height was determined as 45.14 cm with 800 mg kg^{-1} Cu4 dose applied to Yakutiye-98 cultivar. In the second year, the low plant height was 41.39 cm and it was obtained from Göynük-98 variety without copper application.

It was determined that the plant height value was higher in plots with 5.0 mg kg^{-1} zinc dose applied to Göynük-98 cultivar (52.27-48.51 cm) in both years of the experiment. The shortest plant length was measured in Yakutiye-98 cultivar, where a dosage of 41.60 cm and 2.5 mg kg^{-1} zinc was applied. In similar studies on legumes, they reported that increased zinc fertilization increased plant height (Togay and Anlarsal, 2008).

In terms of zinc x copper doses applied in the study, the interaction effect between the doses in 2015 was found to be statistically insignificant. In 2016, the effect of the interaction between 5.0 mg kg^{-1} zinc dose and 800 mg kg^{-1} copper doses applied to Göynük-98 bean variety was found to be statistically significant in terms of plant height (51.15 cm) (*Table 2*).

It is known in the studies on legumes that increasing doses of zinc fertilization increases the plant height to a certain extent. However, this difference between years is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25812598

thought to be due to the effect of climate factors as well as the usefulness of copper applied. As a matter of fact, the expected benefit from fertilizing in terms of yield and quality in crop production depends on the application of the right fertilizer source at the right time, with the right methods and appropriate quantities.

Number of pods (pieces / plant)

According to the results of the experiment, there was a difference between the number of pods between the years. On average number of pods in 2015 copper and zinc doses, varieties x copper and varieties x zinc dose interactions were significant, varieties, copper x zinc and varieties x copper x zinc interactions were statistically insignificant. In 2016, varieties, copper, zinc, copper x zinc interactions were found to be statistically significant.

The average number of pods obtained as a result of the research was counted as 14.12 in the first year and 9.31 in the second year. According to the results obtained, the average number of pods in years for Göynük-98 variety, was respectively, 14.04-9.93 in the other varieties of Yakutiye-98 variety was determined as 14.20-8.71 (*Table 3*).

*The difference between the averages indicated by the same letters is not significant at 5% level. Cu: Copper Dose, Zn: Zinc Dose, Ç1: Göynük-98, Ç2: Yakutiye-98, Avg.: Average, ÇxCu: Variety x Copper Dose Interaction, Ç x Zn: Variety x Zinc Dose Interaction, Cu x Zn: Copper x Zinc Dose Interaction

According to the data obtained, the interaction of varieties x copper doses in the first year was statistically significant and the second year was insignificant on the average

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25812598

number of pods. The highest number of broad beans was obtained from Yakutiye-98 bean cultivars with 16.30 doses of 400 mg kg^{-1} Cu3, and the lowest value was obtained from 0 mg Cu kg^{-1} Cu1 control dose in Yakutiye-98 cultivars with 12.57 units. According to these results, increasing doses of copper increased the number of pods per plant up to a certain point and then decreased.

In the study, the interaction of copper x zinc doses on the average number of pods was found statistically insignificant in the first year and significant in the second year. The highest number of pods was obtained in the first year with 16.36 units of 400 mg Cu kg^{-1} Cu3 and 5.0 mg Zn kg^{-1} Zn3. The lowest value was obtained from 0 doses of both application doses with 11.13 units (*Table 3*). In the second year of the experiment, the highest number of pods was obtained from 11.34 units of 200 mg Cu kg^{-1} Cu2 and 10.0 mg Zn kg^{-1} Zn4. The lowest value was determined in doses of 7.93 with 0 (*Table 3*). According to these results, increased zinc doses at low copper doses increased the number of pods per plant. It is known that where copper and zinc fertilizer are used together, copper x zinc decreases the efficiency of use and causes decrease in yield and quality.

Number of branches (pieces / plant)

In 2015, it was found that the number of branches, beans, zinc doses, varieties x zinc doses and copper x zinc doses interactions on the average number of branches were statistically significant. In the second year of the experiment, the effect of all application doses and interactions on the average number of branches in bean cultivars was found to be statistically insignificant (*Table 4*).

*The difference between the averages indicated by the same letters is not significant at 5% level. Cu: Copper Dose, Zn: Zinc Dose, Ç1: Göynük-98, Ç2: Yakutiye-98, Avg.: Average, ÇxCu: Variety x Copper Dose Interaction, Ç x Zn: Variety x Zinc Dose Interaction, Cu x Zn: Copper x Zinc Dose Interaction

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25812598

According to the results obtained in the experiment, the average number of branches was 6.48 in the first year and 4.69 in the second year. The number of branches among the bean varieties was obtained from 5.83-4.58 plant^{-1} and Göynük-98 varieties, respectively. In the Yakutiye-98 variety, a higher number (7.12-4.80) of branching was detected (*Table 4*). According to the results obtained on the average number of branches in the first year Ç x Zn interaction was statistically significant, the second year was found to be insignificant. According to the results obtained from the experiment, the highest average branch number was obtained from 2.5 mg kg^{-1} Zn2 dose applied to Yakutiye-98 cultivar. The lowest value was obtained from the control (0 dose) application of Göynük-98 variety with 5.53 units (*Table 4*).

As shown in *Table 4*, the effect of Cu x Zn interaction on the mean number of branches was significant ($p<0.01$). The highest average number of branches was obtained from 7.03 Zn4 dose of 200 mg kg^{-1} Cu2 x 10.0 mg kg^{-1}. The lowest value was measured with 5.40 units of 200 mg kg^{-1} Cu2 x 0 mg kg^{-1} Zn1 control dose.

Harvest index (%)

It was determined that the factors other than cultivars, copper doses, varieties x copper dose interactions were insignificant on the harvest index of bean cultivars in 2015.

In 2016, the effect of varieties, copper and zinc doses, cultivar x zinc and Ç x Cu x Zn interactions on harvest index averages were found to be statistically significant (*Table 5*).

Table 5. *Groups and averages of harvest index in bean varieties(%)**

*The difference between the averages indicated by the same letters is not significant at 5% level. Cu: Copper Dose, Zn: Zinc Dose, Ç1: Göynük-98, Ç2: Yakutiye-98, Avg.: Average, ÇxCu: Variety x Copper Dose Interaction, Ç x Zn: Variety x Zinc Dose Interaction, Cu x Zn: Copper x Zinc Dose Interaction

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25812598

According to the results obtained at the end of the research, harvest index was found to be 38.83-39.38% in Ç1 (Göynük-98) and 44.03-44.07% in Ç2 (Yakutiye-98). In this research, the highest harvest index average was obtained from Ç2 according to the results of both years. It is thought that this difference, which occurred a little between the years, is due to environmental factors, genotype and cultural practices.

In the study, average harvest index values obtained from different copper doses applications varied between 42.97-39.95% in 2015 and 42.93-40.6% in 2016 (*Table 5*). According to the results of the study, the highest harvest index in 2015 and 2016 and the average of both years was obtained from 200 mg kg^{-1} Cu2 dose applied to Ç2 (Yakutiye-98) with 44.90-45.51%, respectively. In the first year of the experiment, the lowest harvest index value was found to be 800 mg Cu kg^{-1} Cu4 administered to Ç1 with 36.67%. In the second year, the lowest harvest index was obtained from the parcel without copper applied to Ç1 with 38.26%. Eren and Mert (2016) investigated the effect of increasing Cu applications on the growth and development of plants and found that the lowest plant dry weight of the plants was 2.28 g $plant^{-1}$ and 800 mg Cu kg^{-1} application and control application.

As it can be seen in *Table 5*, zinc (Zn) and Ç x Zn dose interactions on the average harvest index were found to be statistically insignificant and significant in the second year. According to the results obtained from the experiment, the highest harvest index was obtained from the dose of 5.0 mg kg^{-1} Zn3 applied to Ç2 (Yakutiye-98) with 42.21%. The lowest value was obtained from control (0 dose) application of Ç1 (Göynük-98) with 37.66% (*Table 5*). In the study, it was observed that increasing the dose of Çx Zn increased the harvest index up to a certain point. Taban and Alpaslan (1996) from the soil to the corn plant; in a similar study by applying 0, 2.5, 5.0 and 10.0 mg Zn kg^{-1}, the highest increase in dry weight (67.3% increase) was obtained from the dose of 5.0 mg Zn kg^{-1} applied to flowerpot-1 with 14.96 g.

According to the results, the effect of cultivars x Cu x Zn interactions on the harvest index was statistically insignificant in the first year and was significant in the second year. The average harvest index values were 34.51-48.03% in 2015 and 34.85-46.56% in 2016 (*Table 5*). In the second year, the highest harvest index was obtained from interaction of doses of 400 mg Cu kg^{-1} Cu3 x 5.0 mg Zn kg^{-1} Zn3 applied to Yakutiye-98 cultivar with 46.56% (Z2 x Cu3 x Zn3). The lowest value of 34.85% Göynük-98 variety was obtained from the application of 800 mg kg^{-1} Cu4 x Zn1 control (0 dose) (*Table 5*).

Grain yield in the plant (g / plant)

On the average seed yield in bean plant of different phosphorus and zinc doses in 2015 and 2016 research years; cultivar, copper, zinc, cultivar x copper, cultivar x zinc, copper x zinc and cultivar x copper x zinc interactions were found to be statistically significant (*Table 6*). Average seed yields in per plant obtained at the end of the experiment were measured as 23.49 g $plant^{-1}$ in the first year and 18.72 g $plant^{-1}$ in the second year.

According to the results, average seed yield of Göynük-98 bean cultivar was 19.35-16.87 g $plant^{-1}$ over the years, while it was 27.63-20.58 g $plant^{-1}$ in Yakutiye-98 cultivar. Düzdemir and Akdağ (2001) in their study; reported that the mean seed yield in the plant was between 10.20-27.40 g $plant^{-1}$. In the study of by Bildirici and Baran (2018) in under the ecological conditions of Van-Gevaş, the seed yields of Akman-98 and Göynük-98 varieties were determined as 9.82-13.44 g $plant^{-1}$, respectively. Seed

*The difference between the averages indicated by the same letters is not significant at 5% level. Cu: Copper Dose, Zn: Zinc Dose, Ç1: Göynük-98, Ç2: Yakutiye-98, Avg.: Average, ÇxCu: Variety x Copper Dose Interaction, Ç x Zn: Variety x Zinc Dose Interaction, Cu x Zn: Copper x Zinc Dose Interaction

The effects of copper fertilizer on average seed yield in the plant of beans were found to be statistically significant. The highest seed yield was obtained from the doses of 31.27-23.83 g plant^{-1} and 200 mg kg^{-1} Cu2 in Yakutiye-98 cultivars in both years of the experiment. The lowest value for years 17.84-13.69 g plant^{-1} and 0 fertilizer dose of copper and copper (800 mg kg^{-1} Cu4) dose was determined in the parcels applied (*Table 6*). As seen in *Table 6*, the effect of zinc doses on average seed yields of bean cultivars was found to be significant. Average highest seed yields obtained in the experiment over the years for Yakutiye-98 bean cultivar 30.61-22.87 g plant^{-1} and 5.0 mg Zn kg^{-1} Zn3 dose was obtained from the application. The lowest yield values (25.42-15.10 g plant^{-1}) in 0 zinc dose (Zn1) was measured in Göynük-98 bean cultivar.

The effect of copper and zinc doses on the average seed yield of beans was significant ($p< 0.01$). The highest average seed yield in both years of the study was obtained from 28.72-23.92 g plant^{-1}, 200-400 mg kg^{-1} copper and 5.0 mg kg^{-1} Zn3 zinc, respectively. The lowest yield value in two years 16.76-14.08 g plant^{-1}, respectively with 0 copper and zinc fertilizer dose was obtained from parcels (*Table 6*). The effect of copper and zinc fertilizer doses on average seed yield of bean cultivars was found to be statistically significant in both years. The highest average seed yield was obtained from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)

Yakutiye-98 cultivar in 36.32-28.45 g plant^{-1} and 400 mg kg^{-1} Copper (Cu3) x 5.0 mg kg^{-1} Zinc (Zn3) application in two years. Low values 12.01-10.85 g plant^{-1} were obtained from Ç1 (Göynük-98) variety, in the cases of 0 dose and 800 mg kg^{-1} copper-zinc dose (Cu4 x Zn4) applications (*Table 6*).

Crude protein content (%)

As a result of the research, the interactions of the varieties, varieties x zinc, varieties x copper doses and copper x zinc doses were found to be statistically significant on the crude protein content of the grains obtained. Protein ratio by years are as follows: while Göynük-98 variety was obtained with 21.93-22.01%, 22.06-21.45% protein ratios were obtained from Yakutiye-98 variety (*Table 7*).

*The difference between the averages indicated by the same letters is not significant at 5% level. Cu: Copper Dose, Zn: Zinc Dose, Ç1: Göynük-98, Ç2: Yakutiye-98, Avg.: Average, ÇxCu: Variety x Copper Dose Interaction, Ç x Zn: Variety x Zinc Dose Interaction, Cu x Zn: Copper x Zinc Dose Interaction

The effect of different zinc doses on protein ratios in beans was found to be statistically significant in both years. The highest crude protein content by years with 5.0 mg Zn kg^{-1} was obtained from Göynük-98 bean cultivar with 23.25-22.74%, the lowest values were obtained from 0 dose application of 20.47-20.95%.

As shown in *Table 7*, the effect of copper doses on average crude protein ratios in beans was significant in 2015-16 ($p < 0.05$). The highest crude protein content was obtained from 200-400 mg kg^{-1} copper applications with 22.15-22.32%. The lowest value was found to be 800 mg Cu kg^{-1} copper (Cu4) with 21.19-21.60% (*Table 7*).

Discussion

In addition, plant height values were lower in both cultivars in the second year than in the first year. According to the first year of the experiment, due to the high average temperature and the lack of moisture due to the decrease in the time from the output to ripening caused the plant height values to decrease. It is thought that this difference is caused by climate in terms of plant height values between years (Elkoca and Kantar, 2004). It is thought that this difference between the years is due to the effect of climate factors as well as the usefulness of the applied copper. Çopur and Sarı (2012) in the study of the effect of $CuSO_4.5H_2O$ on the growth of cucumber seedlings concluded that applications are significant in terms of seedling length. Seedling height of 9.53 cm of the highest seedlings with copper sulfate 4000 + 4000 mg / l were detected in the application. Zengin and Munzuroğlu (2004) investigated the effects of mercury, copper, cadmium and lead on the amount of growth hormone cytokine in bean seedlings. In their study, control seedlings and seedlings grown in 0.1, 0.2 and 0.3 mM $CuCl_2$ solutions were measured the cytokine content of 1.83x10-7, 4.42x10-7, 3.77x10-7, 3.66x10-7 and 3.55x10-7 M, respectively. They stated that growth is supported up to a point, increasing the dose of copper decreases the cytokinin level of the seedlings and this situation occurs due to increase in copper concentration. These results are consistent with our findings.

Yağmur and Aydın (2013) applied 10, 20 and 30 mg Zn kg-1 (ZnSO4.7H2O) in the soil and in addition 0.1%, 0.2% and 0.3% ZnSO4.7H2O solution to the leaves in lettuce cultivation. The highest plant height (22.25 cm and 21.10 cm) was obtained from applications of 20 mg kg-1 zinc to the soil and 0.2% zinc to the leaves. The results obtained support our study.

Elkoca and Kantar (2004), in a similar study conducted by the number of pods between 3.5-4.2 on this variety showed a wide variation according to the variety and lines. Sönmez et al. (2006b) applied 1000 and 2000 mg Cu kg^{-1} yield in tomatoes grown in the greenhouse yield, fruit number, dry root weight and plant height were reported to decrease with the amount of Cu in the soil. This study supports our findings. In a similar study Yağmur and Aydın (2013) applied Zn in the form of 0.1%, 0.2% and 0.3% $ZnSO_4.7H_2O$ solution from the leaf in addition to 10, 20 and 30 mg Zn kg^{-1} ($ZnSO_4.7H_2O$) doses. As a result of the research, they were obtained the highest plant height (22.25 cm and 21.10 cm) by applying 20 mg kg^{-1} zinc to the soil and 0.2% Zinc dose to the leaf. The results obtained from these studies are in parallel with the findings of our research.

It is thought that this difference in average number of branches over the years is due to the differences in the amount of humidity and temperature in the greenhouse as well as genetic factors (Elkoca and Kantar, 2004). Babagil et al. (2011) stated that they measured the maximum number of branches in 3.1 beans-1 and Yakutiye-98 cultivars in their study with 6 bean cultivars under Erzurum conditions. Kumar et al. (1993) reported that zinc doses applied to the soil between 0 and 5 kg da^{-1} increase the yield and decrease at the next doses. Similar results have been obtained in many studies (Azad et al., 1993; Yağmur and Aydın, 2013). Unlike nitrogenous fertilizers, the effect of micro nutrients on the number of branches depends on the environment and genetic structure. In the study, increasing dose of Cu x Zn increased the number of pods per plant up to a certain point. Wang et al. (2016) in a similar study conducted in China on Indian beans; reported that Cu and Zn interactions applied at low concentrations in the soil caused a slight increase in the growth of the plant, whereas high concentrations

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25812598

showed a significant decrease in plants height and biomass. We can assume that the interaction of Cu and Zn is clear. Zn, Cd and Cu interactions related to the similar results have been reported about the interactions (Chizzola and Mitteregger, 2005; Chaoui et al., 2017).

Gangwar and Singh (1986), in their studies of zinc fertilizer increases the rate of harvest index rate has been reported that the maximum rate is taken from the applied foliar fertilizer. Azad et al. (1993) reported that zinc fertilizers increased the harvest index rate up to a certain dose and then decreased. In this study, it was observed that zinc fertilizer increased the harvest index rate up to 2.5 and 5.0 mg Zn kg^{-1} and then started to decrease. MacFarlane and Burchett (2002), in their study applied an increasing doses from 100 μg Cu g^{-1} to 400 μg Cu g^{-1} reported a reduction in total plant biomass and a decline in root growth. Therefore, similar results were obtained in this study as in many fertilization studies (Pholsen and Sormsungnoen, 2005; Barros et al., 2007). According to some other studies, it has been reported that the green parts and grain contents of wheat plant increase with Zn application and this increase varies according to varieties (Helaloğlu et al., 1997). Many of these studies support our findings.

It is known that there is an antagonistic effect between Cu and Zn ions (Aktaş, 1991; Chizzola and Mitteregger, 2005). Wang et al. (2016) stated that Cu and Zn interactions applied at low concentrations in the soil caused a slight increase in the growth of the plant, whereas a significant decrease in plant height and biomass was observed in high concentrations. The most important factor in determining fate of crop production is undoubtedly the growing conditions and climate factors. It is thought that this difference between years is mainly due to the fact that the average temperature and distribution in the first year(21.3 ^{o}C) is higher compared to the second year (17.90 ^{o}C). In addition, the bean is very sensitive to the water balance in the soil during the flowering period. It has been reported that fluctuations in this period cause 20% yield losses in grain yield. In the first year of the research, the average temperature has been identified to be higher than the second year, especially during the flowering and pollination periods (Elkoca and Kantar, 2004). Seed yield in bean plants shows dependence on earliness of different environmental conditions in genetic variations. In the study, it was observed that the average seed yield of varieties increased up to 200 mg kg^{-1} copper dose in parallel with the increasing copper doses, and it caused decreases in seed yield in subsequent doses (Wang et al., 2016). Sönmez et al. (2006b) 1000 and 2000 mg Cu kg^{-1} applied to the soil in greenhouse grown tomatoes; reported that yield, fruit number, dry root weight and plant height decreased with high Cu doses such as. This study supports our findings. It is estimated that the difference between the first and second year zinc doses of the study is due to the fact that copper inhibits the zinc uptake more than the second year.

In the first year, it is estimated that fertilizers are used more beneficially due to the favorable conditions of the average temperature and climate (Taban et al., 1997; Toğay and Anlarsal, 2008). In studies where copper and zinc fertilizer are used together, it is known that copper x zinc increases the efficiency of use, decreases soil pH, increases total N and P intake and has a positive effect on yield and quality (Sönmez et al., 2006a). In this study, it has been found that increasing doses of Ç x Cu x Zn increases the seed yield up to a certain point (Wang et al., 2016). Sonmez et al. (2006a) found that the effect of Cu applications on soil, which Zn contents was increased by 5% was significant. This study in bean is in agreement with the results of many researchers.

In many studies, it has been determined that the protein content of bean grains varies between 17.40% and 28.00% according to the varieties and applications. It was stated that bacterial applications, especially nitrogen fertilization, increased this rate (Tajini et al., 2012). The effect of zinc fertilizer on crude protein content was found to be important depending on environmental and genotypic factors. Similar results have been obtained in other studies conducted on legume plants (Toğay and Anlarsal, 2008). Zinc is an active element in biochemical processes as well as has a biological interaction. When zinc (Zn^{++}) is used together with copper (Cu^{++}), an increase in uptake occurs by plants (Sönmez et al., 2006a; Wang et al., 2016). According to some other studies; Leaf and soil zinc sulphate applications to watermelon, grapes, wheat, lentils, spinach have been found to have a positive effect on quality components yield, yield components of different crop plants, vegetative growth and development (Kaya et al., 20018).

Conclusion

In this study carried out as a greenhouse experiment in Van-Gevaş ecological conditions, the effect of different copper-zinc dose and applications and interactions on the yield and yield characteristics of dry bean cultivars grown in soilless systems were investigated. Although these factors have changed over the years, they have provided important information in terms of yield and yield components. The use of zinc at increasing copper doses and the decrease in efficacy and it has been seen decline in yield and quality parameters too. Soil analysis should be done before sowing in culture plants, especially legumes, in our province where zinc deficiency is seen too much. Based on these results, in case of deficiency, copper fertilization between 2.5-5.0 mg Zn kg^{-1} zinc and 200-400 mg Cu kg^{-1} can be performed. It is known that copper zinc increases usage efficiency, decreases soil pH, increases total N and intake P contents, and has a positive effect on yield and quality. However, it should not be ignored that it may have toxic effects in overuse. In general, the interaction of copper-zinc concentrations examined did not reach the degree of toxic effect in the plant.

As a result, co-administration of copper-zinc interactions, 400 mg kg^{-1} Cu and 5.0 mg kg^{-1} Zn doses resulted in an increase in yield and yield parameters in bean compared to the separate administration of these doses and was found to be statistically significant at 1% level. It is thought that this study will contribute to the new studies to reduce the yield and quality losses that may occur due to Zn deficiency, Cu excess or interactions in agricultural soils.

Abstract. Physiological responses of plants against biotic and abiotic stresses limit plant cultivation. The present study was designed to investigate the changes in polyphenol and protein content and photosynthetic response in different olive cultivars under influence of saline conditions. For this, the effects of different sodium chloride (NaCl) salinity levels (0, 75, and 150 mM) on physiological and biochemical parameters of *Olea europaea* L. cultivars (Gemlik, Kilis Yaglık, and Nizip Yaglık) were investigated. The highest total chlorophyll content was obtained under 75 mM salinity level while the lowest one was determined under 150 mM salinity. With respect to the cultivars, the highest chlorophyll content was found in Kilis Yaglık cv. whereas the lowest value was obtained from Gemlik. However, flavonoid content was determined to be highest under 150 mM but lowest under 75 mM salinity level. Regarding cultivars, total flavonoid content was ascertained for Gemlik cv. while it was lowest for Kilis Yaglık cv. Accordingly, it can be deduced that salinity decreased the chlorophyll content and cultivars showed different reactions against salinity and its doses. In addition, it influenced total phenolic and protein content in small quantities except for flavonoids which were differently synthesized against salinity levels.
Keywords: *Gemlik, Kilis Yaglık, Nizip Yaglık, olive cultivar, salt stress, phenolic content, flavonoid content*

Introduction

Historically, plants have been extensively used for medicinal, nutritional, flavoring, cosmetic and industrial purposes. Of those plants, *Olea europaea* L. belonging to the *Oleaceae* family is one of the most widely grown fruit crops in the countries of the Mediterranean basin and Turkey is one of the important producer and stakeholders of olive and olive oils. Origin and homeland of olive tree is considered to be the eastern Mediterranean Basin, Syria, central Mesopotamia and Anatolia. The existence of a large number of native wild olive trees in Anatolia reinforces this theory. Archaeological studies revealed that olives were cultivated and evolved in the Mediterranean Basin about 6000-7000 years ago and it then moved on and spread initially in the Aegean, later on in the central and western Mediterranean, and from there it spread to the other places (Ozkaya et al., 2009; Zohary et al., 2012; Breton et al., 2012; Kostelenos and Kiritsakis, 2017). *Olea europaea* L. has many cultivars and genotypes widely distributed in the southern parts of Turkey near Syrian border which is a semi-arid part. In this region, it is possible to see the sub-varieties and rich biological diversity of the species. The cultivars (cv. Gemlik, Kilis Yaglık and Nizip Yaglık) herein are the most commonly cultivated olive tree in this part.

Stress in plant cultivation is defined a number of regressions resulting in low yield and decline plant growth due to abiotic stress (salinity, drought, nutrient deficiencies or excesses, heavy metals, low and high temperatures, air pollution, radiation) and biotic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25992610

stress (bacteria, fungus, viruses etc. and pests). Drought and salinity are the most important abiotic stress factors that limit agricultural production in the world. Approximately 45% of the world's agricultural land is constantly exposed to drought stress, while about 6% of the world's surface is suffering from salinity (Asraf and Foolad, 2007). Salinity is one of the important environmental abiotic stresses that adversely affect plant growth, yield, quality and soil fertility (Ozturk et al., 2004; Debez et al., 2004; Zehtab-Salmasi, 2008). Under natural climatic conditions, plants are routinely subjected to the environmental conditions, which affect plants growth, development and subsequently or consequently primary or secondary metabolite contents but the effects depend on the type, duration and magnitude of abiotic or biotic factors. Plants in general have given various biochemical and physiological responses to the biotic or abiotic stress (Bray et al., 2000). Physiology and biochemistry of plants such as photosynthesis, protein synthesis and energy and lipid metabolism are affected by salinity and that may result growth inhibition, fading or death of plants (Hamouda et al., 2015; Ahmad et al., 2016). Results such as toxicity, deterioration in mineral metabolism, consequently decline in productivity and yield can be observed in the biochemical and physiological processes of plants due to detrimental effects of high salinity. However, plant behavior can change with respect to the secondary metabolite synthesis, production, secretion, and storage during onset and development of salt stress or drought stress (Khalid and Da Silva, 2010; Ozkan and Kulak, 2013). Irrigation with saline water may effect growth of plants. In salinity exposed plants a significant reduction of shoot elongation and Na accumulation, an enhancement of cells area and a thickening of epidermis, cuticle, hypodermis and outer mesocarp were observed. These alterations could be considered that plant protection against stress factors. So it must be applied a proper irrigation management with saline water for fruit production and olive tree quality (Moretti et al., 2018).

In some areas it is important to estimate the effects of irrigation-induced salinity on olive oil phytochemicals and bioactivities because of irrigation with recycled wastewater or salty groundwater. Effect of saline water irrigation on tree physiological parameters in different olive varieties at various salinity levels have been examined by many researchers. In this context, they have examined tree growth, fruit and oil yield, tree nutritional status, oil content and fruit characteristics, mechanisms of salt tolerance in olives and differences among cultivars in these studies (Chartzoulakis et al., 2006; Melgar et al., 2009; Ben-Gal, 2011; Kchaou et al., 2013; Moretti et al., 2018; Trabelsi et al., 2019; Tietel et al., 2019). Olive trees are able to resist water and salt stresses. Decreasing in total chlorophyll content, leaf water potential and photosynthetic gas exchange are observed in rainfed olive trees during drought. But half of their photosynthetic activity of olive leaves are permanently lost during to drought without irrigation and after being exposed to severe water or salt stress, they are unable to recover their whole photosynthetic capacity. However, they were not able to totally recover their physiological performance after re-watering (Tabelsi et al., 2019).

Leaves and roots of different pistachio rootstocks have given different physiological responces to salinity. Therefore, improving salt-tolerant genotypes are important for cultivation (Akbari et al., 2018).

Phenolic compounds are synthesized in plants via the shikimic acid metabolic pathway and endogenously controlled process during developmental differentiation. But their biosynthesis can be regulated by exogenous and stress factors such as light, temperature, drought, salinity, cold etc. (Crozier et al., 2006; Waśkiewicz et al., 2013).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25992610

Phenolic compounds play an important role in scavenging free radicals and protect plants against the damaging effects of reactive oxygen species due to salt and drought stresses (Petridis et al., 2012; Waskiewicz et al., 2013). On the other hand salt stress has effects on the lipid and phytochemicals and it has increased polyphenol contents of olive oil. The increased levels of polyphenols in response to increasing salinity level show that exposure to salinity probably due to stress response to high salt levels. Polyphenol augmentation of olive oil was previously reported in response to various tree stress conditions involving, e.g., water, salinity, and drought (Artajo et al., 2006; Ben Ahmet et al., 2012; Tietel et al., 2019).

Southeast part of Turkey has major agricultural areas for crop production. Most of these crops are grown under dry conditions. With the development of irrigation systems, irrigation has become widespread in this region in recent years. Salinity problems arise with the irrigation of the orchards. Pistachios and olives are the most grown crops in this region. Kilis Yaglik, Nizip Yaglik and Gemlik olives are widely grown olive cultivars. Thus, present study was designed to investigate the alterations in polyphenol and protein content and photosynthetic response in three important and widely cultivated olive cultivars in response to the saline conditions.

Material and Methods

Plant material

The study was conducted with three cultivars of olive common in the study region (Kilis, Turkey), namely Gemlik, Kilis Yaglık and Nizip Yaglık.

Growth conditions and salt treatment

The present study was carried out according to the method with slight modifications (Demiral et al., 2011) differing with cultivars and stress exposure time. In the study, three olive cultivars (Gemlik, Kilis Yaglık and Nizip Yaglık) were used. The experiment was conducted using irrigation water with 2 different salinity levels (75 and 150 mM). The salinity levels were adjusted by the addition of appropriate amounts of NaCl to half-strength Hoagland's solution. The experiments were conducted in pots and arranged as a factorial, using a randomized complete design with three replications and one plant per pot. The seedlings were grown for one month using half-strength Hoagland's solution before the application of saline solutions to the plants were subjected. Experiments were conducted in a greenhouse with a 14-hour photoperiod and lasted 4 months (August-December). Mean temperature and relative humidity were 26-30^{o}C during day and 16-20^{o}C at night, 60%, respectively. All plants were irrigated twice week with half-strength Hoagland solution. Before the flowering period, uniform sized leaves were detached from the same plant parts and immediately stored -80^{o}C until analysis. The soil mixture was included with soil: peat: perlite (3:1:1).

Preparation of extracts

The air-dried and finely powdered leaves of olive cultivars (5 g) were stirred with 100 ml of pure methanol for 30 min, respectively. Extraction was carried out using maceration at room temperature for 24 h followed by filtration through Whatman No.4 filter paper. The extracts were then concentrated in vacuo at 40^{o}C using a Rotary evaporator. Then the extracts were preserved in sealed vials at 4^{o}C until further analysis.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25992610

Photosynthetic pigment and total protein determination

The contents of chlorophyll a, chlorophyll b and total chlorophyll a + b in the leaves were determined, according to the method of Arnon (1949). Protein content in the crude extracts was determined after TCA precipitation according to the method of Bradford (1976), using bovine serum albumin (BSA) as a standard. The measurements were done using three replicates corresponding to the five samples for each replicate.

Determination of total phenolic content

Total phenolic content was determined according to the Folin-Ciocalteu reagent method (Singleton et al., 1999). The amount of total phenol was calculated as mg/g (Gallic Acid Equivalents) from calibration curve of Gallic acid standard solution (R^2=0.9993). An aliquot of each sample (0.1 ml) was diluted to 1 ml with distilled water. Briefly, 0.5 ml of Folin-Ciocalteu reagent (1:1 v/v) and 1.5 ml of 20% (w/v) sodium carbonate were added to the diluted sample solution, and the mixture was then vortexed and allowed to stand for 2 hours at room temperature for color development. The volume was completed to 10 ml with distilled water and their absorbance was measured at 765 nm (Evolution 201 UV-Visible Spectrophotometer).

Determination of total flavonoid content

The flavonoid content was determined by aluminum chloride method using quercetine as a reference compound (Kumaran and Karunakaran, 2006). This method based on the formation of a complex flavonoid-aluminum. The amount of total flavonoid was calculated from calibration curve of quercetine standard solution (R^2=0.9815). 1ml of olive leaf extracts or standards catechol solution (500 µg/ml) was added to 4 ml distilled water and 0.3 ml of 5% $NaNO_2$ was added. After 5 minutes, 0.3 ml of 10 % $AlCl_3$ was added. After 6 min, 2 mL of 1 mol L- NaOH was added and final total volume was completed to 10 mL with distilled water. Afterwards the absorbance of the mixture was measured at 510 nm.

Statistical analysis

Three replications were used for each treatment. Data were expressed as mean. The experiments were arranged as a split plot design with three MSTAT-C statistical program was used to determine statistical significance levels and the differences between individual averages were considered to be statistically important at $p<0.01$. Herein, one-way variance analysis followed by post-hoc tests of Duncan and regression analysis was performed to determine the differences between the cultivars and applied doses of salt.

Results

Photosynthetic pigment content

Leaf chlorophyll a, chlorophyll b, and total chlorophyll content in relation to salt stress effects are collectively represented in *Table 1* and *Table 2*. Determination of chlorophyll content in plants is an important indicator for photosynthesis capacity. The effects of different concentration of saline conditions on photosynthetic pigments were statistically significant ($P\leq0.01$). There were also statistically significant differences

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25992610

associated with different olive cultivars and concentration levels of sodium chloride (P≤0.01). The highest content of photosynthetic pigments was determined in 75 mM whereas the lowest content was ascertained in 150 mM NaCl concentration. Chlorophyll a content was the highest at 75 mM concentration in Nizip Yaglık cultivar, the lowest at Gemlik cultivar control group. Chlorophyll b content was the highest at 75 mM concentration in Kilis Yaglık cultivar, the lowest at 150 mM concentration in Gemlik cultivar.

Polyphenol and protein content

In the current study, the effects of different NaCl concentration did not elicit any statistical significant changes in relation to the cv. Gemlik, Nizip Yaglık and Kilis Yaglık but total flavonoids were differently influenced with salt application (*Table 3* and *Table 4*). Even different salt concentration did not induce any statistically significant differences associated with total phenolic content; the highest total phenolic content was ascertained in 150 mM for both cv. Nizip Yaglık. Total flavonoid content decreased with increasing salt concentration in cv. Gemlik. The effects of salt concentration and cultivars were statistically significant in terms of flavonoid content.

DOI: http://dx.doi.org/10.15666/aeer/1802_25992610

Flavonoid content increased an all cultivars with salt stress. The difference concerned with respect to the concentration was statistically significant at $p< 0.01$. The highest content was determined at 150 mM concentration.

Effects of cultivars and salinity concentration

The effects of different NaCl concentration and cultivars on chlorophyll a, chlorophyll b, total chlorophyll, polyphenol and protein content in olive leaves are shown *Table 5*. Cultivars have given different response to salinity. While there was no statistical difference between the total phenol and protein contents, total chlorophyll, chlorophyll a and b content and total flavonoid content were significant. Accordingly, the highest total chlorophyll, chlorophyll a and chlorophyll b content were observed in Kilis Yaglık cultivar and lowest in Gemlik cultivar. In terms of total flavonoid content, Gemlik cultivar was the highest and Kilis Yaglık cultivar was the lowest content. According to the results, while Gemlik was the most and Kilis Yaglık the least affected

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25992610

cultivar to salinity. The high flavonoid in the Gemlik cultivaris due to the fact that the cultivar has developed a defense mechanism against salinity.

When the salt concentrations were evaluated, no statistically significant difference was observed between the total phenol and protein contents, but total chlorophyll, chlorophyll a and b content and total flavonoid content were found to be significant. Accordingly, the highest total chlorophyll, chlorophyll a and chlorophyll b content were observed at 75 mM and the lowest 150 mM concentrations. In terms of total flavonoid content, the highest content was determined at 150 mM and the lowest 75 mM concentrations. Consequently, the effect of salt stress was most at 150 mM concentration. As in cultivars, the high content of total flavonoid at 150 mM shows the effect of the dose level.

Discussion

Cultivars have given different response to salinity in the study. The highest total chlorophyll, chlorophyll a and chlorophyll b content were observed in Kilis Yaglık cultivar and lowest in Gemlik cultivar. It is concluded that Kilis Yaglık variety is more resistant to salt than others. Olives give some physiological and biochemical responces to salinity such as decreasing photosynthesis, stomatal and mesophyll conductance, leaf starch, Rubisco carboxylation rate, actual PSII efficiency etc. (Munns, 1993; Ben Ahmed et al., 2008; Mousavi et al., 2008; Tattini and Traversi, 2009; Remorini et al., 2009). Growth inhibition is a common effect of salinity but in olive tree mechanism of salt effects are prevention of salt translocation, decreasing its transport (Tattini, 1994; Tabatabaei, 2006; Cimato et al., 2010). In the recent studies, physiological, epigenetic, genetic regulation, water status, biochemical and molecular mechanism in olive cultivars under salt stress have been examined and revealed (Abdallah et al., 2018; Trabelsi et al., 2019; Mousavi et al., 2019).

Physiological parameters like Na accumulation in shoots, decrease in shoot elongation, reduction of maximum photosynthetic efficiency to NaCl treated plants demonstrate that treated plants perceive the stress (Loreto et al., 2003; Kchaou et al., 2013; Koubouris et al., 2015).

Leaf chlorophyll (a, b) and total chlorophyll content in various olive cultivars were reported to decline when exposed to the saline conditions (Atia, 2002; Melgar et al., 2008; Shaheen et al., 2011). Halophyte plants demonstrate more protective mechanisms against salt stress concerned with chlorophyll content. Salt at higher concentration in apoplast of cells leads to the ionic toxicity, cellular disequilibrium and hyper osmolality

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25992610

and as a result, induction of oxidative stress by increasing formation of reactive oxygen species which causes chlorophyll degradation (Sevengor et al., 2011).

High salt concentrations bring about many problems in the plant cell. These stages are water stress, damages caused by ion toxicity due to high concentration of Na and Cl ions in the cell and degradation of Ca and K ions in the cell as a result of Na and Cl accumulation (Marschner, 1995; Borsani et al., 2003; Xue and Liu, 2008). High salt concentrations negatively affect parameters such as green parts, root development, water use efficiency and root/stem ratio and K/Na and Ca/Na ratios were found higher in salt resistant plant species (Grewal, 2010).

Differences in salt tolerance are reported among olive tree cultivars. Salinity reduces photosynthesis and stomatal conductance more in salt tolerant than in salt sensitive cultivars according to gas exchange measurement (Tattini et al., 1997). Most of these cultivars such as Manzanillo, Chemlali, Arbequina, Mission, Leccino, Koroneiki, Mastoidis, Frantoio, Cipressino, Allora and Zard response to salinity by decreasing stomatal conductance and photosynthesis (Chartzoulakis et al., 2006; Tabatabaei, 2006; Ben Ahmed et al., 2008; Mousavi et al., 2008; Melgar et al., 2008, 2009; Remorini et al., 2009; Tattini and Traversi, 2009; Tattini et al., 2009; Kchaou et al., 2010). Chétoui variety is moderately sensitive to both drought and salt stress, although it has greater ability to tolerate water depletion. The most significant changes were observed under the salinity stress condition. Under both stress conditions, a greater growth reduction observed due to reduction of all photosynthetic parameters like the integrity of photosystem II and leaf nitrogen content (Abdallah et al., 2018).

Phenolic compound are essential indicators in determination of olive quality. Olive leaves phenolic compounds are significantly influenced by many factors such as genetic factor, harvest time, color, and age (Ranalli et al., 2006). Phenolic components are significant elements in struggle against abiotic and biotic stress factors (Ruiz and Romero, 2001). Phenolic compound biosynthesis and accumulation was stimulated in response to the abiotic and biotic stress factors (Naczk and Shahidi, 2004). However, studies on different species and genotypes have also shown that there may be decreases in total phenolic content with increasing stress factors. Flavonoid content increased and then lipid peroxidation decreased and a negative correlation was reported between lipid peroxidation and flavonoid content under saline conditions (Chutipaijit et al., 2009). Flavonoids have been reported to increase the plant's ability to tolerate stress through affecting physiological performance (Chutipaijit et al., 2009).

It has been reported that the increase in salt doses may affect the amount of free amino acids, although it may lead to reductions in total protein content. Increased acidic and alkaline protease activity increases the amount of free amino acids and provides resistance to stress conditions (Parida et al., 2004).

Conclusion

As a result, the amount of chlorophyll in the leaves of the olive cultivars decreased with salt stress. Cultivars demonstrated different responses in relation to the salt stress and chlorophyll content. Moreover, while the salt application did not elicit any significant change in terms of total phenolic content, total flavonoid content increased with increasing salt stress. With respect to growth parameters the highest total chlorophyll, chlorophyll a and chlorophyll b content were observed in Kilis Yaglık cultivar and lowest in Gemlik cultivar. It is concluded that Kilis Yaglık variety is more

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_25992610

resistant to salt than others and Gemlik was the most and Kilis Yaglık the least affected cultivar to salinity. The high flavonoid in the Gemlik is due to the fact that the cultivar has developed a defense mechanism against salinity.

According to the findings of the study, the salt conditions affected the crops at different doses. In addition, the responses of cultivars have been different against salt concentration. Cultivars may develop a defense mechanism against saline conditions through biosynthesizing polyphenols in different amounts. However, chlorophyll content was adversely influenced and consequently, photosynthesis yield is expected to decline under saline conditions.

For further studies, to discriminate the cultivars for their response, enzymatic antioxidant systems of the plants and responsive responses proteins or genes can be revealed. In addition, the results should be compared with the multi-successive year field studies.

Acknowledgement. The current study was a part of MSc thesis "Defense Strategy of Some Olive Cultivars against Salt Stress" written by Sekvan Demir.

(Received 27th Jul 2019; accepted 30th Jan 2020)

Abstract. Microorganisms are the preferred source of enzyme applicable to a variety of industries, such as food, paper, detergent, and energy. In this study, amylase enzymes were explored for the first time in the springs of Shahdara, Islamabad, Pakistan. 22 out of 28 bacterial isolates showed amylase activity from which the three best amylase producing isolates (S5, S13, and S17) were selected for further studies. These isolates were identified as *Bacillus spp* and *Clostridium spp* using microscopic, biochemical, and molecular-based (16S rRNA) approaches. Phylogenetic analysis further revealed that strains (S5, S13, and S17) have 97% similarity with *Paraclostridium benzoelyticum, Bacillus subtilis,* and *Bacillus tequilensis,* respectively. The maximum amylase production of *Bacillus subtilis* and *Paraclostridium benzoelyticum* was observed at pH 5 and 55 °C whereas that of *Bacillus tequilensis* was at pH 8 and 55 °C. Similarly, the highest activity of amylases from each strain was found at 55 °C in common, but in different pH conditions (at pH 5 for *Paraclostridium benzoelyticum* and *Bacillus subtilis* and at pH 6-8 for *Bacillus tequilensis*). Our study represents that Shahdara springs have beneficial microbial reservoirs producing acidic and thermostable amylases, having great importance to various bio-industrial applications.
Keywords: *thermostable amylase, Shahdara springs, Bacillus spp, Clostridium spp, 16S rRNA gene sequencing*

Introduction

Microbial enzymes are preferred natural sources to animals and plants due to the ease of cultivation, shorter generation time, low cost, and feasibility for human consumption. Microorganisms, which synthesize the microbial enzymes, are found in different sources including extreme sites such as springs, salt mines, and deserts. Among them, springs are considered the best natural source of microbial enzymes. It provides suitable environments for various extremophiles including thermophiles, acidophiles, and alkaliphiles that produce extremophilic enzymes (Sen et al., 2010), which collectively have attracted researchers' attention (Ali et al., 2013; Tango and Islam, 2002). The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26112620

extremophilic enzymes gathered from springs, in particular, have a great potential for many industrial applications because of their diversity and unique enzyme activity (Gopinath et al., 2017; Li et al., 2012; Singh et al., 2016).

Among these enzymes, amylases, which can be used to hydrolyze starch into dextrin and small polymers of glucose, are the most widely used enzymes in various industries, taking the first place in the global enzyme market (25-33%). Amylases have replaced acidic hydrolysis and chemical catalysts for starch degradation which is available in huge amounts in waste reservoirs (Sen et al., 2014). Amylases have many applications in the food and pharmaceutical industries such as production of fruit juices, bread making, glucose syrups and alcoholic beverages (Wajeeha et al., 2011). Amylases are generally classified into 1) endoamylases (α-amylases), 2) exoamylases (β-amylase, glucoamylase), and 3) debranching enzymes (pullulanase, isoamylase) based on their modes of action to generate glucose, maltose, malto-oligosaccharides, and dextrins (Kim and Toldrá, 2016; Suriya et al., 2016). Amylase enzymes have diverse bio-industrial applications which demand large scale exploration of these enzymes in extreme reservoirs (de Souza and de Oliveira Magalhaes, 2010; Parmar and Pandya, 2012; Patel et al., 2018). Pakistan is particularly gifted with a number of extremophilic environments. Several hot springs, salt mines, deserts, glaciers, marine brine pools, and hydrothermal vents are present in various localities of Pakistan e.g., novel strains producing hydrolytic enzymes were isolated from hot springs and salt mines in Pakistan (Roohi et al., 2012, 2014; Zahoor et al., 2016). We are still exploring different microbial reservoirs to characterize novel extremophilic enzymes from sources such as hot springs, glaciers, deserts, salt mines, and coal mines located at Pakistan. Although there are few reports regarding microbial explorations in these areas, there is still a lot of work needed to identify novel microbial sources of bio-industrial importance (Afridi et al., 2019; Ali et al., 2016; Shah et al., 2017). Here, we report new amylase producing bacterial strains taken from the Shahdara springs located in the hilly area of Margalla-Islamabad-Pakistan. The Shahdara springs have been explored for microbial flora, however, these springs have been rarely investigated for microbes producing enzymes. Total of 28 bacteria were primarily isolated from the Shahdara springs and screened for the amylase activity. The three best amylase producing bacteria were selected out of 22 amylase producers to check its growth and activity under different physical factors like pH and temperature.

Materials and methods

Specimen collection and enrichment of bacterial isolates

Freshwater samples (n = 25) were collected from different locations in the springs of Shahdara valley, Islamabad (31° 37’ 16.0068” N and 74° 16’ 56.5104” E) in 2018. Temperature and pH at the time of sampling collection was approximately 22ºC and 7-8, respectively. The samples in sterilized bottles were immediately transported to the microbiology laboratory of Kohat University of Science & Technology (KUST), Kohat and preserved at 4 °C until further use. The bacterial isolation was carried out through a standard serial dilution technique. Moreover, enrichment was done using 2 ml of bacterial culture into 10 ml of LB broth and incubated at temperatures 40, 50, 55 and 60 °C for 24 h. After that, 100 µl of samples were diluted and spread onto LB agar and nutrient agar. The plates were then incubated at temperatures 40, 50, 55, and 60 °C for 24 and 48 h. The bacterial isolates were further purified based on colonial morphology.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26112620

Screening and identification of amylase producing bacteria

All the isolated colonies were further streaked on the spot method on a starch agar plate and were incubated at 37 °C for 24 h. The incubated plates were checked for amylase activity by adding 1% iodine and 2% potassium iodide solution. The isolate that survived and produced a clear zone around the colony was considered as an amylase producing bacteria. Bacterial isolates giving the largest clear zones were taken for further studies. The bacterial isolates were characterized according to the standard procedure based on morphological and biochemical tests for initial identification that were further identified by 16S rRNA gene sequencing (Sen et al., 2014). Therefore, for molecular identification, bacterial DNA was extracted using Gene Jet Genomic DNA Purification Kit. Genomic DNA samples were subjected to PCR for the amplification of the 16S rRNA gene using universal primers (5-GGAGGCAGCAGTAGGGAATA-3) and (3-TGACGGGCGGTGAGTACAAG-5). The PCR conditions were set as initial denaturation (94 °C for 6 min), followed by annealing temperature (56 °C for 40 s) and extension (72 °C for 50 s). The final extension was performed at 72 °C for 3 min for a total of 35 cycles. The PCR amplified product was sequenced using the commercial service of Advance Bioscience International (ABI). The sequence was BLAST searched on EZ-Biomedical server to get the exact nomenclature of the isolates. The phylogenetic tree was constructed with MEGA 6 using the neighbor-joining method with a bootstrap value of 1000.

Optimization of bacterial growth and amylase production

The selected amylase producing bacterial isolates were optimized by the following factors such as pH and temperature in liquid media. The liquid medium was contained of starch peptone (10 g/l each), yeast extract (20 g/l), KH_2PO_4 (0.10 g/l), $CaCl_2.2H_2O$ (0.10 g/l), $MgSO_4.7H_2O$ (0.50 g/l) and $FeSO_4.7H_2O$ (0.02 g/l) to evaluate amylase production. The effect of pH on bacterial growth and production was conducted in a flask containing the above liquid media by maintaining pH range of 3-11. While the effect of temperature was checked by incubating at different temperature ranges from 35, 45, 55, 65 and 75 °C. The turbidity of bacterial culture was measured by spectrophotometer at 540 nm as amylase produced.

Bernfeld (1995) method is used to determine the activity of amylase (Bernfeld, 1995). The assay was performed in a test tube using enzyme extract (1 ml), 0.05 M sodium phosphate buffer (1 ml) at pH 7.0 and 1% starch (1 ml). The mixture was then incubated at 55 °C for 15 min followed by the addition of 1 ml of DNS reagent to stop reaction. The optical density of color produced was reported by spectrophotometer at 540 nm using maltose as standard. One unit of enzyme was defined as the amount of enzyme requires releasing one µmol of reducing sugar per minute by applying the following formula reported in literature (Singh et al., 2015):

$$\text{Amylase Activity}(\text{IU/ml/min}) = \frac{\text{Activity of enzyme} \times 1000}{\text{Molecular weight of maltose} \times \text{Incubation time}}$$

Partial purification of amylase

Ammonium sulfate precipitation method was used to partially purify crude amylase enzyme. The precipitation mixture was centrifuged at 4000 rpm at 4 °C for 30 min. The supernatant was discarded and protein pellet was dissolved in 5 ml of phosphate buffer and store at 4 °C for further analysis.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26112620

Electrophoretic amylase separation

The Laemmle method was used to determine the purity and molecular weight of partially purified amylase on 12% (w/v) Sodium dodecyl polyacrylamide gel electrophoresis (SDS-PAGE) under reducing conditions. The enzyme was taken in eppendorf tube and loading dye was added. The solution was mixed gently. Both were heated in a water bath for 5 min. The protein sample was loaded in each well along with standard protein ladder. The process was performed for 120 min at 120 V until the bromophenol blue reached to the bottom of the gel. Coomassie Brilliant blue solution was used to stain the gel for 30 min and the gel was de-stained for 2.5 h.

Characterization of partially purified amylase

The activity of amylase enzyme was determined using a buffer of different pH range from 3 to 11. Similarly, the temperature effect was studied by incubating at 35, 45, 55, 65, 75 °C and amylase activity was measured as per the assay procedure.

Statistical analysis

All assays were performed in triplicate (n = 3) and their means and standard errors were statistically analyzed using Graph Pad Prism Software.

Results

Isolation and screening of amylase producing isolates

In current study, total 28 bacterial isolates were isolated on the basis of their morphology using spread plate technique from Shahdara valley Islamabad, Pakistan. These isolates were further screened for their amylase activity on the basis of sizes of clear zones by applying 1% iodine solution using starch agar media. Among these, 22 isolates showed amylase activity ranged from a small to large zone around the bacterial colony (*Fig. 1A, B*). The amylase activities based on clear zones around the colonies are also reported in previous literature (Padhiar and Kommu, 2016). On the basis of their maximum amylase activity on specific conditions, the strains such as S5, S13, and S17 were selected to proceed further for onward characterization.

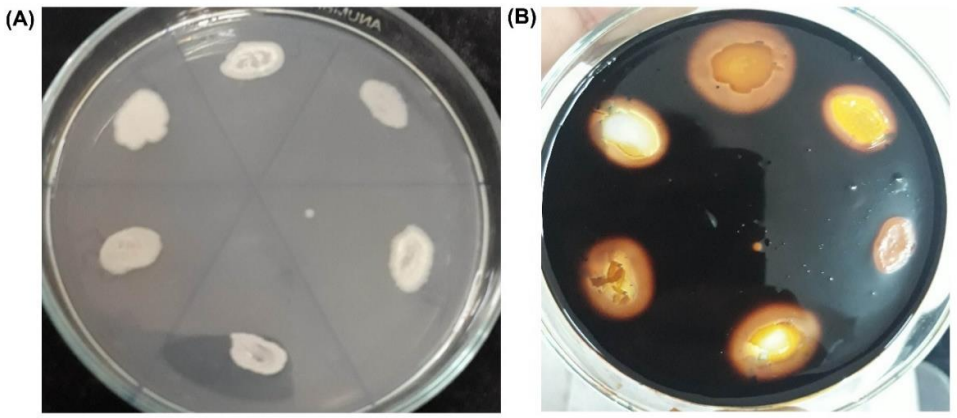

Figure 1. *Amylase activity test. (A) Bacterial zone before addition of iodine and potassium iodide solution. (B) clear zone around the colonies after addition of iodine and potassium iodide solution*

DOI: http://dx.doi.org/10.15666/aeer/1802_26112620

Morphological and molecular identification of the selected isolates

The selected bacterial isolates were further subjected to gram staining and were observed as gram-positive rods and positive for spore staining. Based on their morphological and biochemical tests, the isolates were identified as *Bacillus* and *Clostridium spp* as described in *Table 1*. Moreover, 16S rRNA gene sequencing for these isolates revealed that the isolate S5, S13, and S17 have 97% similarity with *Paraclostridium benzoelyticum*, *Bacillus subtilis* and *Bacillus tequilensis* respectively using phylogenetic analysis (*Fig. 2A-C*).

Analysis of bacterial growth and amylase production

The selected isolates were subjected to variable temperature and pH, in order to evaluate optimum bacterial growth as well as optimum amylase production. Among them, the *Paraclostridium benzoelyticum* strain S5 given the highest growth at pH 7 while the highest production of amylase at pH 5. The growth and production were also checked for *Bacillus subtilis* strain. It was observed that the maximum growth and optimum production of amylase enzyme were at the same pH, i.e. pH 5. However, *Bacillus tequilensis* showed the optimum growth at pH 6 and amylase production at pH 8. In addition, the temperature effect on the growth and production of all selected isolates were also checked. It was observed that the optimal temperature for growth of *Paraclostridium benzoelyticum* was 45 °C and obtained a maximum yield of amylase at 55 °C. However, for the *Bacillus subtilis* and *Bacillus tequilensis*, the optimum temperature of bacterial growth and yield was the same and reported as 55 °C (*Fig. 3A-F*).

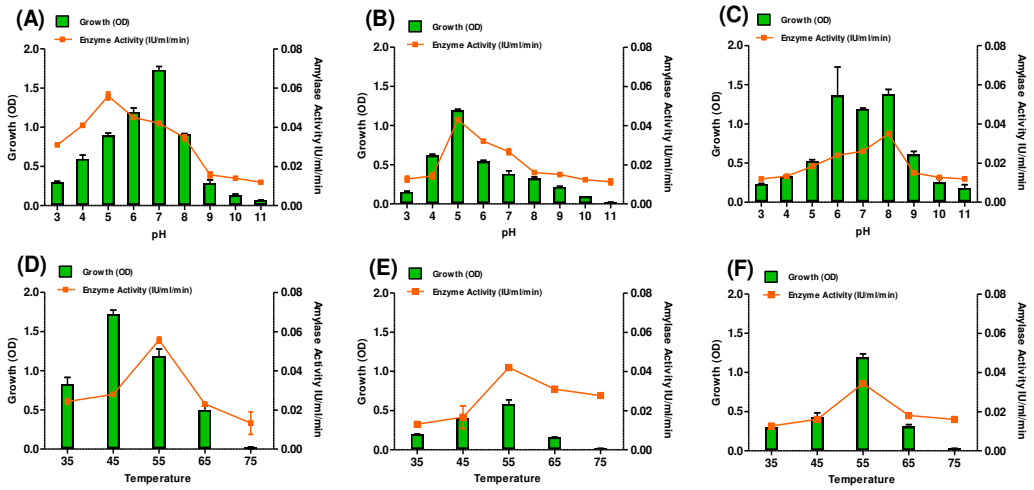

Figure 3. *Effect of pH and temperature on bacterial growth and amylase production. (A and D) growth and amylase production of isolate S5, (B and E) growth and amylase production of isolate S13, (C and F) growth and amylase production of isolate S17 at different pH and temperature*

SDS-PAGE analysis and activity of amylase enzymes

Partial purification of amylase enzymes was performed using 80% saturation of ammonium sulfate. The pellet was separated by SDS PAGE and the amylase enzymes of the strain *Paraclostridium benzoelyticum* (S5), *Bacillus subtilis* (strain S13) and *Bacillus tequilensis* (S17) had the molecular weight of 35 kDa, 37 kDa, and 36 kDa, respectively (*Fig. 4*).

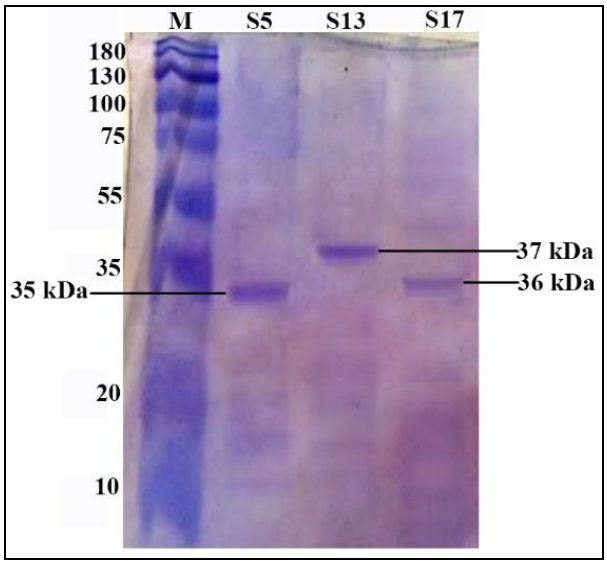

Figure 4. *SDS-PAGE analysis of partially purified amylase enzymes extracted from isolates S5, S13, and S17*

In order to find optimum conditions for amylase activity, the product of selected isolates was subjected to a gradient range of pH and temperature. The highest activity of amylase for both species *Paraclostridium benzoelyticum* strain (S5) and *Bacillus subtilis* strain (S13) was at pH 5. However, for *Bacillus tequilensis* strain (S17), the optimal pH for amylase activity was found in the ranges of pH 6-8. Moreover, the maximum amylolytic activity of all the three isolates was reported at the same temperature, i.e. 55 °C (*Fig. 5A, B*).

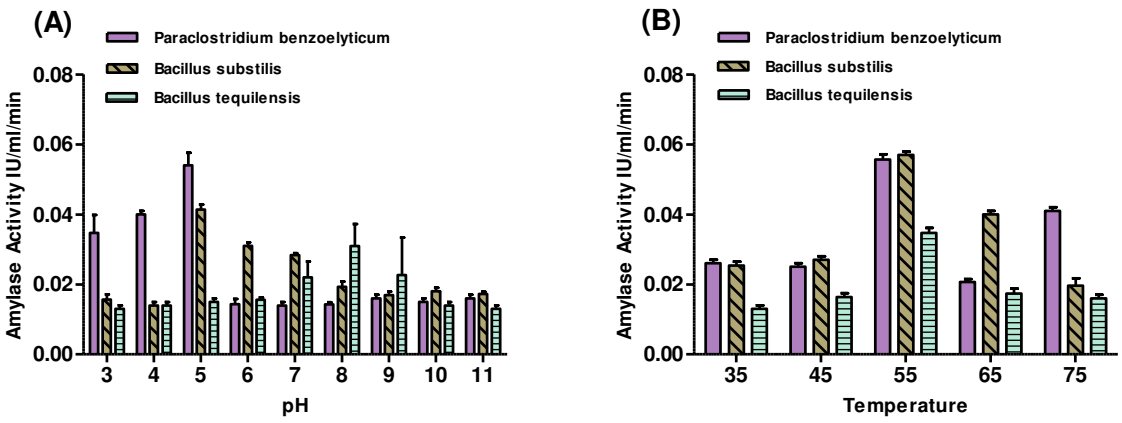

Figure 5. *Effect of pH and temperature on amylases activity of selected bacterial isolates. (A) pH effect on amylase activity, (B) temperature effect on amylase activity*

Discussion

Amylases are the most widely used enzymes in different industries for manufacturing purposes. In the food industry, amylase enzymes play a significant and leading role in hydrolysis of starch into dextrins and small polymers of glucose. In addition, amylases are widely applicable to other industries such as textile and pulp (Gupta et al., 2003). Microbial sources, for examples, bacteria, and fungi, are the most preferred sources to harvest amylase enzymes due to the ease of cultivation, shorter generation time, smaller space requirements and efficient purification procedures (Burhan et al., 2003). In this study, the amylase producing bacterial isolates are explored for the first time in the rarely explored Shahdara springs, Pakistan. In total, 28 bacteria were isolated and among these, 22 bacterial isolates showed amylase activity ranged from small to large zone around the bacterial colony. Three best amylase producing strains, S5, S13, and S17, were selected for onward characterization based on their high amylase activity, in other words, starch degradation potentials, as depicted in *Figure 1A-B*. The morphological and biochemical characteristics revealed differences in bacterial diversity of Shahdara springs. 16 sRNA gene sequencing provided the precise identifications of microbes, revealing that the three selected strains S5, S13 and S17 are *Paraclostridium benzoelyticum, Bacillus subtilis* and *Bacillus tequilensis*, respectively. The amylase enzymes collected in the pellet after ammonium sulfate precipitation was separated by SDS PAGE and three bands of similar sizes ranging from 35 kDa to 37 kDa were obtained on the gel. The molecular sizes of the amylases in the literature varied mainly depending on the microbial sources from which enzymes were purified. We have reported the bacterial amylase from a different source such as salt mines of Karak, which had a molecular weight of 50 kDa (Shah et al., 2017).

Intriguingly, temperature and pH conditions for the highest bacterial growth did not always correspond to those of the highest amylase yield. The best bacterial growth and amylase yield of *Paraclostridium benzoelyticum* (S3) were at pH 7 and 5. *Bacillus tequilensis* (S17) also revealed the maximum growth and enzyme production at different pH values, 6 and 8. Similar results in the same species were reported by Khan and Gupta (2011) They reported the best growth and enzyme production of *Bacillus tequilensis* were achieved at pH 7 and 10, respectively (Khan and Gupta, 2011). However, the *Bacillus subtilis* (S13) showed the best growth and amylase production at the same pH 5 (*Fig. 3A-F*). In the previous work of our laboratory, the same condition for optimum growth and enzyme production of proteases produced by *Pseudomonas aeruginosa* strain collected from coal mines was reported (Afridi et al., 2019). Taken together, these results indicate that there is no direct relationship between the growth and production of enzymes.

In a similar fashion, the effect of temperature on amylase production and bacterial growth was evaluated as well. It is characterized that the *Bacillus subtilis* and *Bacillus tequilensis* strains have the maximum growth and enzyme production at the same temperature, 55 °C. However, *Paraclostridium benzoelyticum* strain grew well at 45 °C, whereas the optimum temperature for enzyme production was 55 °C (*Fig. 3A-F*). The amylase enzymes activity has also been reported for *Bacillus sp. WA21* at 55 °C which is supported here by our findings (Wajeeha et al., 2011).

Furthermore, the amylase activity of the three isolates was studied on various pH and temperature conditions. The two isolates, *Bacillus subtilis* (S5) and *Paraclostridium benzoelyticum* (S13), showed the highest amylase activity in the same conditions, pH 5 and 55 °C (*Fig. 5A, B*). This revealed the acidic and thermophilic nature of the amylase

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26112620

enzymes produced by these bacteria. The third isolate *Bacillus tequilensis* (S17) had the highest amylase activity at the same temperature, but the optimum pH was in a range of 6-8. These unique acid-stable and thermo-stable amylases can be used in unavoidable acidic and high temperature conditions frequently occurred in fermentation, food processing, and pharmaceutical manufacturing. Together, this study revealed that Shahdara springs are the rich source of microbial enzymes of diverse nature and of biotechnological importance.

Conclusion and future studies

In total, 22 amylase producing bacteria were isolated from the rarely explored Shahdara springs and the three best producers were identified and characterized as *Paraclostridium benzoelyticum* (S5), *Bacillus subtilis* (S13) and *Bacillus tequilensis* strain (S17). The two isolates *Paraclostridium benzoelyticum* (S5), and *Bacillus subtilis* (S13) have surprisingly revealed the same optimum conditions for amylase enzymes activity such as pH 5 and temperature 55 °C. This revealed the acidic and thermophilic nature of amylases produced by these isolates which can be of high importance at acidic and high temperature operational conditions in bio-industrial applications. On the basis of previous studies, it has been recommended that most of the springs located in Pakistan, possessed valuable bacterial flora that need to be explored for enzymes using metagenomics-based approaches for various bio-industrial applications.

Abstract. Evaluation of compatibility and stability of cultivars under different environmental conditions is a particular interest in crop breeding programs. In order to evaluate the seed yield stability of advanced chickpea genotypes under tropical and subtropical rainfed areas of Iran, 18 advanced chickpea genotypes and two check varieties (Adel and Azad) were studied in terms of randomized complete block design (RCBD) with three replications in four locations including Gachsaran, Gonbad, Khorramabad and Ilam using GGE biplot analysis during three growing seasons (2014-2017). Results of GGE biplot analysis and which-won-where pattern revealed that the genotype G13 was the most stable genotype for Khorramabad, Gachsaran and Gonbad while it was genotype G12 for Ilam. According to average tester coordinate (ATC), the genotype G13 was the most stable one across average test environment. The genotype G13 was also determined as a stable and high yielding genotype among all investigated genotypes and environments. Based on the average yield and Shukla Stability Index, as well as the mean of yield to maximum or Superiority Index (SI), G12, G13 genotypes were superior to the other genotypes in all regions with warm climate and thus be recommended.
Keywords: *adaptation, environment, GGE biplot, interaction, promising line, superiority index*

Introduction

The chickpea (*Cicer arietinum* L.) is a self-pollinated, diploid, and annual plant (2x=2n=16). After peas and beans, it is the most important legume in the world (Varshney et al., 2013). The main countries producing chickpeas in the world are India, Pakistan, Turkey, Iran and Australia, respectively (Gan et al., 2005). The area under cultivation of chickpea in Iran is 650 thousand hectares and its annual production is about 350 thousand tons (Kanouni et al., 2016). Iran ranked seventh in the world for chickpea production after India, Australia, Turkey, Myanmar, Pakistan and Ethiopia (FAO, 2012). Farmers who grow chickpea need cultivars with high yields and maintain desirable qualities in a wide range of environmental conditions throughout the years (Zali et al., 2007; Tabrizi, 2012). The genotype by environment interaction (GEI) is the reaction of a variety to the changes in the environments (Yan et al., 2000). This interaction is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26212636

important to plant breeding researchers and is one of the complexities of breeding programs for the preparation of a high-yielding and sustainable genotype (Yan et al., 2010; Karimizadeh et al., 2016). The GEI indicates a different sensitivity to environmental conditions, which means that the best genotype in an environment is not necessarily the best genotype in another environment (Farshadfar, 1998). Stability analysis is the most important method used to find out the nature of the GEI. Therefore, stable and compatible cultivars can be identified by using this analysis. Different methods have been proposed to investigate the GEI and the determination of stable genotypes, which include univariate and multivariate parametric and nonparametric methods (Dehghanpour et al., 2007; Mohammadi et al., 2012). The GGE biplot method is one of the multivariate methods for evaluating and interpreting the pattern response of cultivars, environments and their interaction (Gabriel, 1971). In the GGE biplot method, the effect of the genotype and the G×E are not separated and selection of cultivars with yield stability is based on both effects (Yan et al., 2000). What is important in assessing genotypes in different environments is that the environmental effect is very large in most cases, but not exploitable, thus eliminating the environmental impact of the data and focusing on the effects of genotype (G) and the G×E are important (Yan and Kang, 2002). Only effect of the genotype and the G×E are important to select the lines with stable yield. The main point is that the two mentioned effects should be considered together (Yan, 2001). The GGE biplot method examines these two effects graphically (Yan, 2001). This method has been identified to be useful and applicable by numerous researchers for different crops for analyzing regional test data. Employing the GGE biplot method for selecting suitable chickpea cultivars (Kanouni et al., 2007; Zali et al., 2007; Farshadfar et al., 2012, 2013; Mostafavi et al., 2013; Pourdad and Jamshidi-Moghaddam, 2013; Shiri and Bahrampour, 2015), canola (Zali et al., 2016; Jabbari et al., 2019; Kheybari et al., 2019), bread wheat (Omrani et al., 2017), lentil (Karimzadeh et al., 2013), durum wheat (Mohammadi et al., 2016; Karimzadeh et al., 2019) for Iranian germplasm has been reported.

The present study aimed to investigate the GEI using GGE biplot methodology in chickpea genotypes to obtain high yielding cultivars, which are adapted with climatic conditions in tropical and subtropical regions of Iran.

Materials and Methods

Description of the trials

The plant materials used in this study were 18 advanced chickpea lines with two local check varieties (Adel and Azad) grown for three years (2014-2017) at each of four different locations in Iran. Geographical characteristics and soil properties of the test environments are presented in *Table 1*. These plant materials used in national chickpea breeding program for rainfed areas of Iran are provided from the International Centre for Agricultural Research in the Dry Areas (ICARDA) chickpea international breeding program. Genotype names and their pedigrees are presented in *Table 2*.

Seed density for each genotype was 50 seed per m^2 and planting was done using experimental planter's machine. Sowing date of all experiments was November 15. Each plot consists of five plant rows, 6 m length with row space of 25 cm. Therefore, the size of each plot was 7 m^2. Fertilizers were applied 100 kg ha^{-1} of ammonium phosphate as triple super phosphate at planting time, and 35 kg of urea during field preparation. No disease was shown during growth period. Weed control and thinning of plants were done

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26212636

by hand during the experiments. To avoid the marginal effects, 25 cm from the beginning and end of the rows of each experimental plot was removed. Then 5 m^2 of each plot were harvested at physiological maturity of each genotype and finally seed yield of each plot was weighted. Weather data of the test site locations during the experiments are presented in *Table 3*.

Statistical analysis

The experimental design in all locations was a randomized complete block design with four replicates. Outliers were firstly detected using Grubb's test (Grubbs, 1969) before variance analysis. Then the normality of seed yield data was checked by the Shapiro-Wilk test (Shapiro and Wilk, 1965). To test the uniformity of the variance of experimental errors, the Levene test (Leven, 1960) and Bartlett's test (Bartlett, 1937) were employed. Combined analysis was performed by SAS 9.1 software package. Graphical stability analysis was performed using GGE biplot software version 6.3 (Yan, 2001).

Model 1 based on singular value decomposition (SVD) of tester-centered data of the first two principal components was chosen to construct various biplots. This model is used for dataset in which all testers have the same unit, such as a genotype-by-environment table of a single trait like seed yield in this study.

The model is: $Yij - u - \beta j = gi1\ e1j + gi2\ e2j + \varepsilon ij$; where: Yij is the performance expected seed yield of genotype (entry) i in location (environment) j; μ is the overall mean of the observations; βj is the main effect of location j; g1i and e1j are the primary scores for the ith genotype in the jth environment, respectively; gi2 and e2j are the secondary scores for the ith genotype in the jth environment, respectively; and εij is the residual not explained by primary and secondary effects (Yan and Kang, 2002). Therefore, biplot in the GGE biplot model is generated by the simple dispersion of g1i and gi2 for genotypes and e1j and e2j for environments, via singular value decomposition, in accordance with the equation $Yij - \mu - \beta j = \lambda 1 \xi i1 \eta 1j + \lambda 2 \xi i2 \eta 2j + \varepsilon ij$, where λ1 and λ2 are the largest eigenvalues of the first and second principal components, PC1 and PC2, respectively; ξi1 and ξi2 are the eigenvalues of the ith genotype for PC1 and PC2, respectively; and η1j and η2j are the eigenvalues of the jth environment for PC1 and PC2, respectively (Yan and Kang, 2002).

Superiority Index (SI) was calculated using YREM which refers to "Yield relative to the maximum". The output is the average YREM of each genotype across environments. It is a [0,1] superiority index, the larger the value of a genotype the more superior it is (Yan, 1999).

Results and Discussion

Before combined analysis of data, the results of the Levene's Test (1.35^{ns}) and Bartlett's test (11.53^{ns}) to ensure the uniformity of the experimental errors in the test environments showed that there is a uniformity of error among the variances of the experimental errors. Therefore, combined analysis can be carried out. Combined analysis of variance showed that there was a significant difference between the genotypes in terms of seed yield at a probability level of 0.05. The G×E was also significant (*Table 4*). The significance of the G×Y×E indicated that the mean seed yield of chickpea genotypes was different across different locations. Therefore, stability analysis could be used to identify genotypes or stable genotypes. This model is suitable for a series of data that have the same units as the genotype table in the environment for a trait, such as the seed yield in this study.

Graphical analysis of chickpea genotypes by GGE biplot method showed that the first two components explained 62.5% of variations in seed yield in different environments. 32.9% of these variations belonged to the first component, and 29.6% belonged to the second component. According to Yan and Kang (2002), if GGE biplot methodology can

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26212636

explain at least 60% of the variance of the total data, it can be applicable and useful for evaluating mega environments.

Table 4. *Combined analysis of seed yield in chickpea genotypes across different environments*

S.O.V	Df	MS
Year (Y)	2	4816696.8^{ns}

CV%	19.38	

ns * and **: non-significant, significant at 5% and 1% probability level, respectively

Total variance percentages, as well as the percentage of the first and second components in Maqbool et al. (2015) study, were 98.61%, 87.67%, and 10.49%, respectively. In Kanouni et al. (2016), the values were, 66.43%, 43.09% and 23.34%, and in Usefi et al. (2017) they were 75%, 46%, and 29%, respectively. *Table 5* illustrates the variance values explained by genotype, environment, and G×E. Accordingly, 2.15% of the total variance, as explained by the first two components of the biplot analysis was related to the genotype (G), 92.02% was related to the environment (year and location), and 5.83% was related to the G×E. In Farshadfar et al. (2011) conducted on the stability of chickpea cultivars, 2.48% of the total variance was related to the genotype, 86.44% was related to the effect of the environment, and 11.08% was related to the G×E, which are with consistent with the results of the present research. Gauch and Zobel (1996) concluded that the large environment main effect, however, is not relevant to cultivar evaluation. Only G and G×E are relevant to cultivar evaluation. Therefore, for cultivar evaluation, it is essential to remove E from data and to focus on G and G×E. Thus, large environment main effect reported in this study was in accordance with previous studies. Another important point in cultivar evaluation and stability analysis is that G and G×E must be considered simultaneously to make any meaningful selection decisions (Yan and Kang, 2002).

Table 5. *Relative magnitude of the genotype, environment and their interaction based on two first components of biplot analysis*

S.O.V	SS	Percentage of total variance
Genotype (G)	1591434	2.15

G×E	4317009	5.83
Total	74005918	

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26212636

Assessment of test environments showed that the highest seed yield was obtained in Khorramabad, and the lowest was in Gachsaran. Also, Gonbad has highest, and Khorramabad the lowest coefficient of environmental variations among testers. In terms of heritability of the test environments, Gonbad and Gachsaran have the highest values, indicating the power of differentiation of these regions in the discriminating of genotypes in terms of stability (*Table 6*).

Table 6. *Mean yield, heritability and coefficient of variations of the test environments*

Test environment name	Mean Yield (kg ha^{-1})	Standard Error	Heritability	CV (%)
Gachsaran	1029.065	115.891	0.668	11.26
Gonbad	1241.449	174.349	0.723	14.04
Ilam	1136.55	142.364	0.637	12.53
Khorramabad	2353.557	238.292	0.459	10.12

The heritability values reflect the variation detected among the genotypes, which will be greater when increase the environment discriminating ability (Cravero et al., 2010).

Fig. 1 shows a biplot graphical analysis and a which-won-where pattern of 20 genotypes of chickpea based on the mean seed yield in four environments examined. The visualization of the which-won-where pattern is important in multi-environmental data to study the possibility of having large environments in a region. The biplot polygon diagram is the best way to visualize the patterns of G×E and to correctly interpret a biplot (Yan and Tinker, 2006). Accordingly, G13 was the most stable one in Khorramabad and Gachsaran, and G12 was the highest yielding and most stable one for Ilam (*Fig. 1*). This conclusion can also be obtained from drawing specific biplots for each location (*Figs. 2, 3, 4, and 5*). In other words, the G13 in Khorramabad, Gachsaran and Gonbad, and G12 in Ilam have a specific adaptability to the locations.

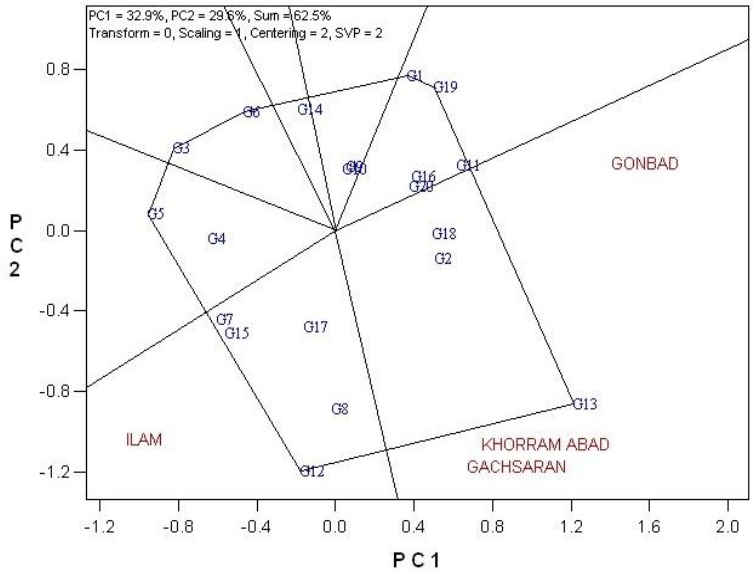

Figure 1. *Which-won-where pattern biplot based on seed yield of chickpea genotypes in different test environments*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26212636

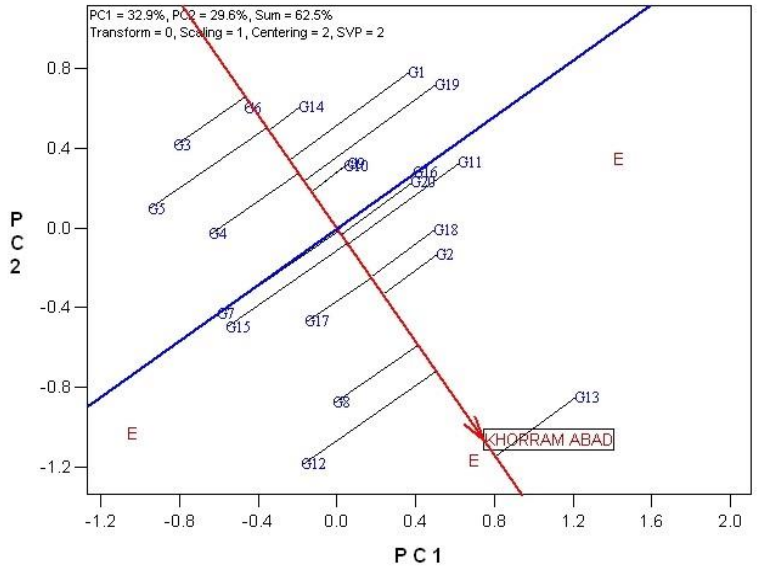

Figure 2. *Ranking of all genotypes and determination of specific adaptability in the Khorramabad test environment*

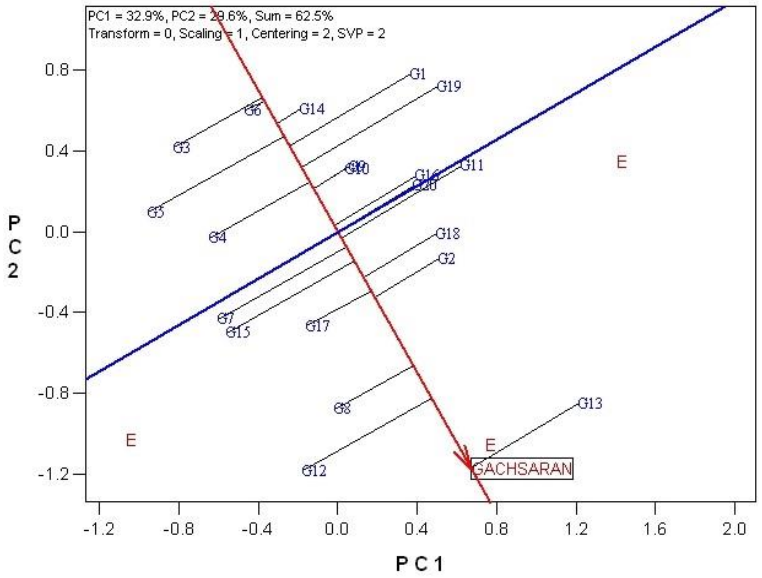

Figure 3. *Ranking of all genotypes and determination of specific adaptability in the Gachsaran test environment*

Also, genotype G5 at the left side of the biplot had the lowest seed yield and stability among the genotypes tested. In *Figs. 2, 3, and 4,* the red axis, indicates the mean yield of genotypes (G) and the perpendicular blue axis indicates the G×E. Thus, from the right side of the biplot to the left, the genotype yield decreases. The best genotype is a genotype that is inclined to the positive end of red axis and its vertical distance is shortest from this line. Genotypes with the shortest distance from the center have more stability (Yan and Kang, 2002).

DOI: http://dx.doi.org/10.15666/aeer/1802_26212636

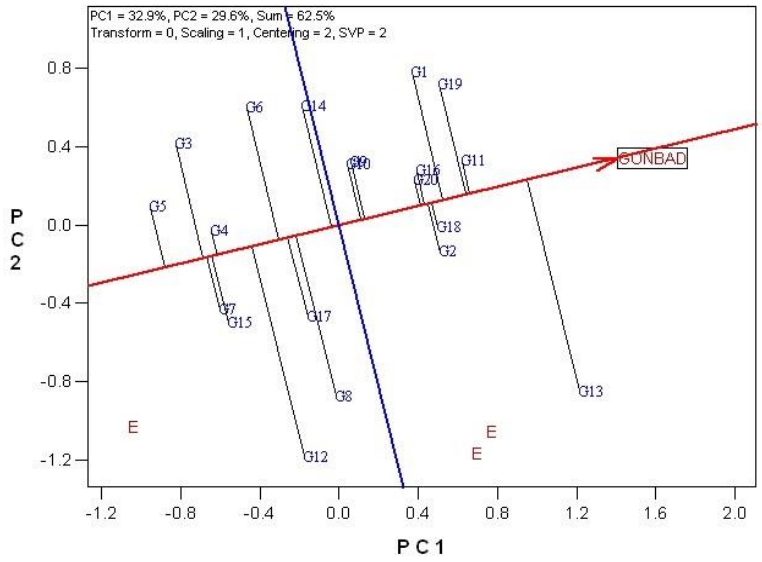

Figure 4. *Ranking of all genotypes and determination of specific adaptability in the Gonbad test environment*

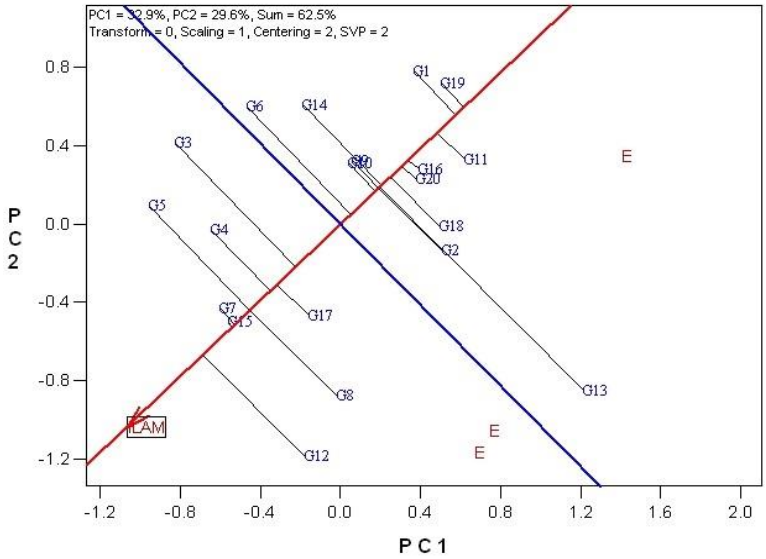

Figure 5. *Ranking of all genotypes and determination of specific adaptability in the Ilam test environment*

To examine the stability and yield of genotypes the Average Environment Coordination (AEC) was used (*Fig. 6*). In this biplot, the horizontal axis with an arrow moves from the origin of the coordinates (Yan et al., 2000). The images of genotypes on this axis represent approximately their yield. This axis is called the average environment axis. The results of the biplot (*Fig. 6*) showed that G13 was the most efficient and stable genotype in the average environment of all test environments. The vertical axis, originating from the coordinates of the past and perpendicular to the average environment axis indicates the G×E and determines the stability of the genotypes. How much vertical distance is highest from red line, represents unstable mean yield. One of the features of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26212636

GGE biplot analysis is based on the analysis of the main components is genotype-based scaling, and using the same unit for both horizontal and vertical axes, which allows more accurate examination of genotypes. This feature can be used to show the average of genotype and stability simultaneously (Farshadfar et al., 2011). The common unit for the mean yield and stability allows both criteria of yield and stability can be combined and conceptualized into a single criterion. The display of average genotype and stability of genotypes can be possible through drawing an axis that passes through the biplot and the average environment (small red circle on the axis). The images of the signs of genotypes on this axis are estimations of their mean yield (Yan and Kang, 2002). The correlation coefficient between this ranking and the average genotype yield was 0.927, indicating an appropriate explanation of the average genotypes on the average environment axis. Direction of red arrow displays a higher average. The blue vertical axis provides an estimate of the interaction and stability of the genotypes, and distance from the source (the intersection with the red axis) is a criterion for the variability or instability of genotypes. Moreover, the vertical blue axis, perpendicular to the red axis, provides an estimate of the interaction and stability of the genotypes, and the distance from the origin, (the intersection with the red axis) is a criterion for variability or instability of genotypes.

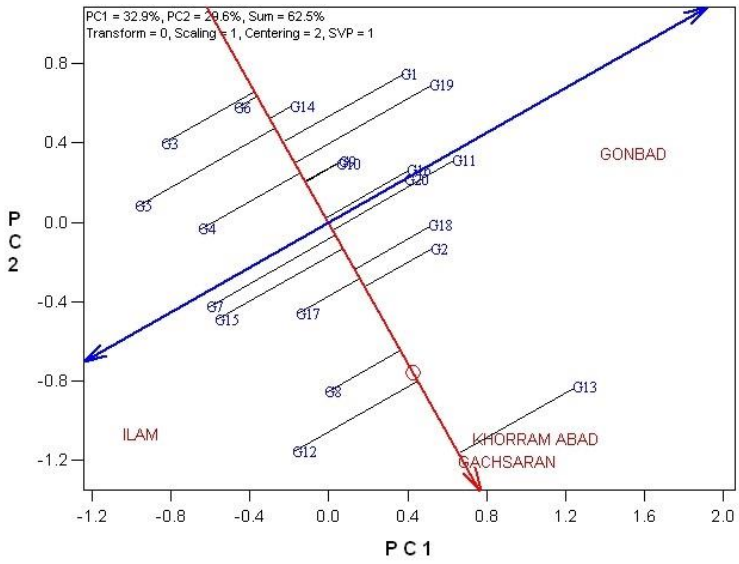

Figure 6. *Average Environment Coordination (AEC) of seed yield stability in chickpea genotypes using GGE biplot analysis in different test environments*

The stability criterion determined by the G×E is only useful when considered together with the mean yield (G) (Yan, 1999). For example, in *Fig. 6* it seems that G4 is more stable than G13 because it is less close to the average environment vector, but is not desirable because it has a much lower yield than G13. Kang (1993) and Yan (1999) concluded that stability is a non-dimensional value which displays a high-yield value better, but displays a low-yield value worse. Eskridge (1996) concluded that stability is less inherited than mean yield. Therefore, stability, along with the mean yield, are useful, and the GGE biplot methodology converts it to a benchmark that can be evaluated graphically (Yan et al., 2000).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26212636

Fig. 7 shows the biplot of comparison different test environments with the ideal test environment, and vector display of the interaction between them based on the seed yield of the chickpea genotypes using the graphical GGE biplot analysis. For this purpose, the origin of the linear coordinates is connected to the point of the average environments and continues to the sides. The best environment is the environment that is closer to the center of the circles. Since the comparison of genotypes in this biplot is not indicated, they are shown with small circles. Based on this biplot, Gachsaran and Khorramabad regions had higher representation and differentiation than Gonbad and Ilam in terms of differentiation and discriminating of the genotypes. In fact, the length of each test environment estimates the standard deviation within each environment. The longer the test environment, the more power of differentiation and representativeness of that environment (Yan and Kang, 2002).

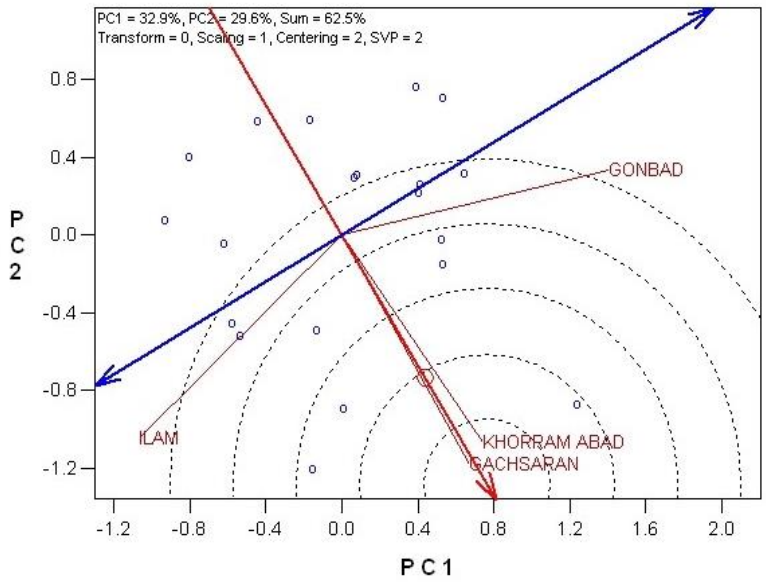

Figure 7. *Biplot for comparison environments with the ideal environment and vector display of the interaction between them based on seed yield of chickpea genotypes*

Table 7 shows the correlation coefficients between different environments. As *Table 7* illustrates, there is no significant positive correlation between each environment, in other words the effect of the year was different during the three years of the experiment. The GGE biplot method is also used to separate of similar environments from non-similar (Navabi et al., 2006).

Table 7. *Correlation coefficients among different test environments*

Location	Gachsaran	Gonbad	Ilam	Khorramabad
Gachsaran	1			
Gonbad	0.106	1		
Ilam	0.064	-0.281	1	
Khorramabad	0.176	0.100	0.023	1

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26212636

In fact, in the fitted model of GGE biplot, the cosine of the angle between any two environments approximates their correlation coefficient between them (Yan and Kang, 2002). In this study, Gachsaran and Khorramabad have a close angle between their vectors, therefore, they should be correlated. Indeed, the correlation coefficient between them is 0.176 because the model is not 100% fitted. Yan and Kang (2002) concluded that the cosine of the angles does not precisely translate into correlation coefficients, since the biplot does not explain all of the variation in a dataset.

Fig. 8 shows the biplot of comparison of all genotypes with the ideal genotype. The red circle on the red axis represents the ideal hypothetical genotype that has the highest yield and stability among all genotypes and environments. In practice, however, such a genotype does not exist, but the ranking of other genotypes is estimated based on this ideal genotype (Yan and Kang, 2002). Accordingly, G13 was identified as a stable and high yield genotype among all genotypes and environments (*Fig. 8*). The correlation coefficient was calculated between the average genotypes and their distance on the biplot as -0.903, indicating a proper explanation of the biplot of comparison of the genotypes with the ideal genotype. Moreover, the results of this biplot were consistent with the results of the biplot of the average environment (*Fig. 6*).

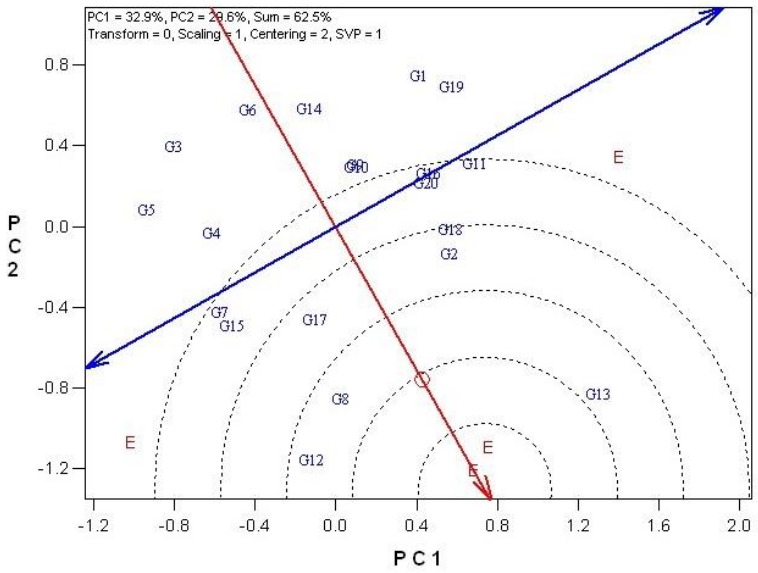

Figure 8. *Biplot drawn based on genotype-focused scaling for comparison of chickpea genotypes with an ideal genotype*

Fig. 9 shows the mean seed yield of chickpea genotypes versus the deviation of their stability (Shukla's Stability Index). Accordingly, genotypes G13 and G12 were superior to the other genotypes.

Fig. 10 displays the mean seed yield in relation with the maximum seed yield (YERM) or Superiority Index of seed yield of chickpea genotypes versus the deviation of the stability of the superiority index. Accordingly, genotypes G13 and G12 were superior to other genotypes in all regions of the study. This criterion, which was first suggested by Yan (1999), is a superiority index based on (0 and 1), so that the larger its value, the more stable its genotype.

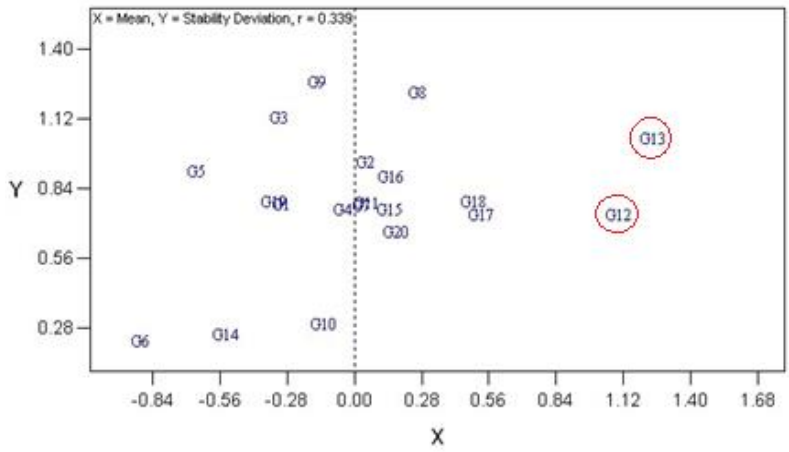

Figure 9. *Shukla's Stability Index and Mean yield in chickpea genotypes*

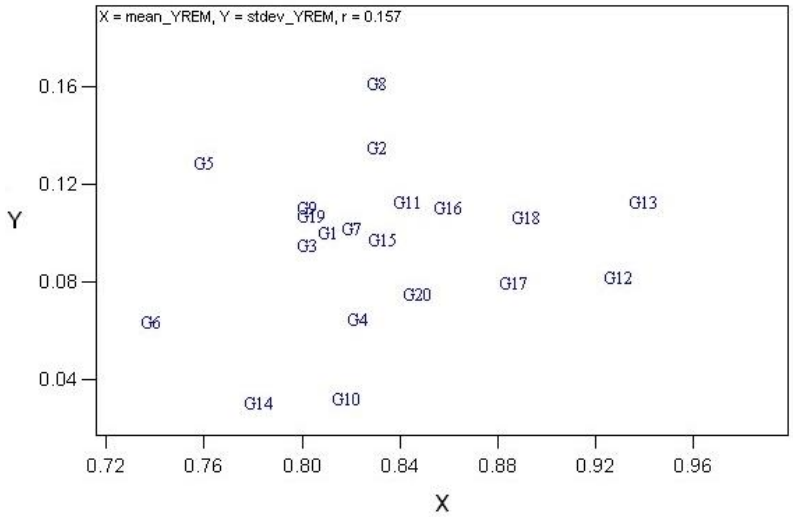

Figure 10. *Mean yield of superiority index for each chickpea genotype in all test environments*

Concurrent selection for yield and stability is one of the most important considerations in breeding plans (Yan and Kang, 2002). GGE biplot analysis with a user-friendly graphical interface can analyze different kinds of two-way data and provide a quick and complete understanding of the relationships between genotypes, environments, and their interactions. In this regard, the results of a study by Farshadfar (2011), investigating phenotypic stability evaluation in 17 chickpea genotypes in five research stations in Iran using the GGE biplot methodology, pointed up that the environment explained 86.44%; the genotype 2.48%; and the G×E 11.8% of the total variations of G + E + GE equation. The overall biplot analysis revealed three large environments from five research sites for chickpeas in Iran. Sabaghpour (2010) used GGE biplot in studying the stability of seed yield in 16 chickpea genotypes in autumn crop under rainfed conditions for three years. They also analyzed the two sites of Gachsaran and Gonbad separately and examined the interaction between year and location as well as genotype and year.

DOI: http://dx.doi.org/10.15666/aeer/1802_26212636

Conclusion

One of the main subjects among plant breeders is to understand the concept of the relationship between crop yield and environment. Analysis of the G×E is one of the substantial issues in plant breeding, which is very important in the development and expansion of new cultivars. In this experiment, G×E of advanced chickpea genotypes in tropical and subtropical rainfed regions in Iran were investigated. The main effects of genotype and environment as well as the G×E were significant and the environment caused the most variations in seed yield. The highest mean seed yield of chickpea genotypes was observed in Khorramabad (2353.557 kg ha^{-1}) and the lowest was observed in Gachsaran (1029.065 kg ha^{-1}). GGE biplot analysis and which-won-where pattern of 20 genotypes showed that G13 was the most stable genotype for Khorramabad, Gonbad and Gachsaran, and G12 was the highest yielding and most stable and suitable genotype for Ilam. Based on the average environment coordinates, G13 was the highest yielding and most stable genotype in the average environment. Based on the biplot of comparison of all genotypes with the ideal genotype, G13 was identified as a stable and top-yielding genotype among all genotypes and environments. Based on the mean seed yield and Shukla's Stability Index, as well as the mean yield in relation with maximum or Superiority Index, G13 and G12 are superior and more stable than all other genotypes in the whole tropical regions in southern area of Iran; hence they are well recommended. Also, evaluation of the qualitative traits of the genotypes studied in this experiment can be recommended for future research.

(Received 5th Aug 2019; accepted 28th Nov 2019)

Abstract. The experiment was conducted to investigate the effects of poultry manure (without Poultry manure A_0, 2% poultry manureA_1 and 4% poultryA_2), bio-fertilizers (not inoculation corms by bacteria B_0, inoculation corms by bacteria *Azospirillum brasilense* B_1, and inoculation corms by *Bacillus subtilis* B_2) and type of irrigation (tap water C_1 and magnetic water treated by 500 gauss C_2) on cut flowers and vase life of Gladiolus flowers Cartago cultivar in two seasons (autumn 2016 and spring 2017) The field experiment was laid down in a factorial 2*3*3 in Split plot Randomized Complete Block Design (RCBD) with three replications and seven plants for each treatment. Results showed a significant increase in vegetative growth (Plant height, Leaf dry matter, Leaf chlorophyll intensity, N, P and K concentration in the leaves) and flower quality (number of days to flowering, anthocyanin concentration in petals (mg.100 g^{-1}), basal floral diameter and vase life), these due to effect of plants with 2% poultry manure, inoculation by bacteria and irrigation with magnetic water. Decreasing in vegetative and flowering characteristics was also observed, when Poultry manure was used at 4% rate and without inoculation by bacteria and irrigation by tap water. But the magnetic water reduced the negative effect.
Keywords: *Azospirillum, Bacillus, cut flower, soil media, irrigation*

Introduction

Gladiolus (*Gladiolus hybrida* L.) belonging to family Irridaceae, it is a monocotyledonous, perennial bulbous flowering plant (Manning and Goldblatt, 2008). are one of the most important flowering plants that are used worldwide for cut flowers production, as they rank among of the top ten best cut flowers due to their different shapes, dazzling colors, varying sizes and excellent vase life. There is a considerable demand in both domestic and export production (Ali et al., 2014). For an amount of 16 million dollars, 60 million gladiolus spikes were sold in the United States of America (Sajjad et al., 2014). The success of gladiolus cultivation depends on many factors like soil fertility, irrigation, planting time, planting density, plant protection, plant growth regulators and some chemicals, these may play major role towards increasing production and quality of gladiolus. But, biofertilzers have positive impact on availability of nutrients (Bhalla et al., 2006). Organic fertilizers including farmyard manure, and poultry manure, sheep manure may be used for the crop production as a substitute of the chemical fertilizer because the importance of the organic manures cannot be overlooked. In recent year organic matter as a suitable source of nutrients to the soil has been replaced by chemical fertilizers that positively affect both the chemical and physical properties of the soil such as soil structure (Bot and Benites, 2005).

The emphasis is now focused on the use biofertilizers like Azotobacter, Azospirillium and phosphate solubilizing bacteria (PSB). Species of Bacillus is known to promote plant growth. The principal mechanisms of growth promotion include production of growth

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26372655

stimulating phytohormones, solubilization and mobilization of phosphate, siderophore production, production of antibiotics, inhibition of plant ethylene synthesis, and induction of plant systemic resistance to pathogens (Gutiérrez-Mañero et al., 2001). Azospirillum is a symbiotic N-fixing bacterium. Azotobacter and Azospirillum fix atmospheric nitrogen when inoculated to plants, which help to save the application of N-fertilizers to an extent of 20-25 percent (Chaitra and Patil, 2007).

The magnetic water technology is wide studied subject throughout the world, especially in major countries like China, USA, and Australia (Hozayn and Qados, 2010). A magnetic field is an unpreventable environmental factor for plants in the soil. However, its impact on plant growth (Eşitken and Turan, 2004). Magnetic treatment results in changes in structure of the water, such as changes the formation of clustering structures from linear and ring hydrogen-bound chains of molecules, the magnetic interaction between these clustering structures and increasing polarization effects of water molecules (Pang and Deng, 2008). Magnetic fields have a positive effect on plant characteristics such as seed germination, seedling growth, agronomic traits and seed yield (Aladjadjiyan, 2002; Tahir and Karim, 2010).

The postharvest longevity of flowers has a critical importance in determining the value of the crop. Cut flowers are highly perishable commodities and are highly vulnerable to postharvest losses. It is estimated that nearly 70% of the potential lasting quality of cut flowers is pre-determined at harvest while postharvest factors influence 30% of the quality. In cut flower trade, it is very important to maintain freshness and original colors of flowers for the longer period, throughout the postharvest chain. Harvesting of flowers at an optimum stage of bud development (Kumari, 2014).

The aim of this study is to determine the effect of various amounts of poultry manure, bio-fertilizer and magnetic water processor on the growth characteristics and flower quality of gladiolus plants of the Cartago cultivar.

Materials and methods

The experiment sites

The experiment was conducted at the College of Agricultural Engineering Sciences, Sulaimani University, Kurdistan, Iraq in greenhouse for two seasons first period in 7th of October 2016 to May 2017 (autumn), second study in 5th of March 2017 to August 2017 (spring). The area is located at 35° 3214" N, 45° 2197" E, and an altitude of (743.40 M) above sea level, with GPS reading.

The experiment was conducted to investigate the effects of poultry manure, (A_0 without poultry manure, A_1 poultry manure at 2% of soil weight, A_2 poultry manure at 4% of soil weight), biofertilizers (B_0 without inoculation, B_1 inoculation by *Azospirillum brasilense*, B_2 inoculation by *Bacillus subtilis*) and water processor magnetic (C_1 irrigation by tap water, C_2 irrigation by magnetic water) and its impact on the vegetative and flower quality of *Gladiolus hybrida*. These treatments were randomized in a split plot design with three replicates, were irrigation types contributed as the main plots, while interaction of poultry manure and biofertilizers (A*B) were distributed in the sub plots.

The magnetic water treatment was conducted by passing the irrigation water through magnetic flux densities 500 Gauss. A local magnetic device is special magnets spaced a part and parallel to the length of water carrying copper pipe.

Planting the corms

Planting the corms in the plastic bags (4 kg size) were filled from the soil agriculture consisting of the three levels, first was consisting of soil and Peatmoos in equal proportions. The second media was composed of the soil and Peatmoos in equal proportions plus poultry manure at 2% and the third level was consisting of soil and Peatmoss in equal proportions with 4% of poultry manure based on soil weight. Analysis of the physical and chemical properties of three soil media is shown in *Table 1.*

Table1. *The main physical and chemical properties of three soil media*

Soil properties	Units	Without poultry manure	2% poultry manure	4% poultry manure
Sand	%	34.40	30.40	32.40

Data were analyzed in the Central Laboratories of College of Agriculture, University of Baghdad

Source of the corms

The corms of gladiolus var. Cartago were brought from the company of stoop flower bulbs in Holland. Healthy and uniform size 10-12 cm corms are divided in to three groups the first group dipped in the distillates water, second group were dipped in the solution which contain *Azospirillum brasilence* and the third group were dipped in the solution which contain *Bacillus subtilis* for half an hour and dried in shade for 30 min before planting.

Planting one corm in the plastic bags in 8 cm depth (Greving, 1987). Agricultural practices were carried out for all replications, such as weeding and hoeing the surface of the soil, in order to ventilate. Ventilation of the greenhouse was done by opening the doors and slots. Also, air cooler and heater were used to adjust the temperature in the greenhouse in both high and low temperature conditions. Atmospheric condition inside

DOI: http://dx.doi.org/10.15666/aeer/1802_26372655

the greenhouse had been measured by recording maximum and minimum temperatures and relative humidity.

Experimental parameters

The experimental parameters are presented in *Table 2.*

Table 2. *Study parameters*

Parameters	Methods
Plant height (cm)	Measured from the soil surface to the end of the flower spike length
Leaf dry mater (%)	Dry matter (%) = $\frac{\text{dry weight of leaves}}{\text{fresh weight of leaves}} \times 100$
Chlorophyll (spad unit)	Portable chlorodhyll meter CCM-200 plus. OPTI-SCIENCES
Nitrogen concentration in leaves (%)	Micro-Kjeldahl (Page et al., 1982)
Phosphorus concentration in leaves (%)	Spectrophotometer at (882 ηm) wavelength (Olsen et al., 1982)
Potassium concentration in leaves (%)	Flame Photometer (Page et al., 1982)
Number of days for flowering (day)	We have counted the days from the first day of planting unit the first appearance of the basal floret's color
Anthocyanin concentration in flower petals (mg.100 g^{-1})	Spectrophotometer (Ranganna, 1977) method
Basal floral diameter (cm)	Digital caliper vernier
Vase life (day)	Measured by the number of days after harvesting the flower as until ¾ of the florets are wilted

Preparation of bacterial inoculants

Pure isolated bacteria were taken from the laboratories of the Agricultural Research Center- Baghdad- Zaafaraniyah associated to the ministry of Science and Technology, Iraq.

Inoculants corms by bacteria Azospirillum brasilense and Bacillus subtilis

- Preparation of 1 L of nutrient solution, 25 g of nutrient broth was dissolved in one litter of distilled water and sterilized by using autoclave with the pressure of 1.5 bar at temperature 121 °C for 15 min before adding bacteria.
- Adding 6 cm^3 of bacteria to the cultural media (liquid nutrient broth) and shaken for 15 min.
- Then the bacterial culture putted in an incubator at 28 °C for 72 h.
- After inoculation period 3 g of sugar and 2 g of Arabic gum were added to the bacteria suspension shake it for 30-60 min. The bacteria inoculants ready to use.

Description of the experiment

The field experiment was carried out based on the Split plot randomized complete block design (RCBD) with three replications and seven plants for each treatment. The data were analyzed by a computer program Statistical Analysis System (SAS) and the comparisons among means were carried out by the least significant difference (L.S.D) at $P \leq 0.05$ (*Table 2*).

Results

Effect of poultry manure, bio-fertilizers and magnetic water and their interaction on the plant height (cm)

Table 3 illustrates that using A_1 treatment which is 2% of poultry manure has a significant effect on plant height 124.74 and 139.58 cm for autumn and spring respectively compared to control A_0 120.26 and 134.68 cm. In addition, it was noticed that plant height after using A_1 was significantly different as compared to using 4% of poultry manure A_2 98.38, 133.91 cm for both seasons respectively.

Regarding the inoculation of gladiolus corms with bacteria *Azospirillum brasilense* and *Bacillus subtilis*, the maximum plant height values are 116.89, 117.11 and 138.85, 137.15 cm in autumn and spring respectively. These results are significantly different from control B_0 (without inoculation by bacteria), which are 109.38 and 132.16 cm in both seasons. With regard to irrigation, using magnetic water C_2 significantly increases plant height 118.07, 138.08 cm as compared to C_1 which gave 110.85, 134.02 cm in autumn and spring season respectively. The significant effect of interaction of organic matter, bio-fertilizers, and magnetic water on plant height of gladiolus shown in the same table, the highest plants 132.88, 145.90 cm were achieved from $A_1B_1C_2$ for both seasons, respectively. While the lowest plant height 93.49 cm was noticed from $A_2B_0C_1$ in the autumn and 128.94 cm from $A_0B_0C_1$ in the spring.

Effect of poultry manure, bio-fertilizers and magnetic water and their interaction on leaf dry matter %

Table 4 shows that planting the corms in medium containing 2% of poultry manure A_1 has a significant effect on leaf dry matter. The highest value 24.54, 26.95% were found from A_1 for autumn and spring respectively, while the lowest value 20.84% was achieved from A_2 in the autumn and 22.71% was found from A_0 in spring. Inoculation of gladiolus corms with *Azospirillum brasilense* B_1 significantly affected the percentage of the leaf dry matter which were 22.94, 25.71% for both seasons. Also, the inoculation by *Bacillus subtilis* B_2, significantly affected the percentage of the leaf dry matter 23.57, 25.69% as compared to control B_0 20.50, 21.89% for both seasons respectively.

A is poultry manure, A0 without poultry manure, A1 application of poultry manure at 2% of soil weight, A2 application of poultry manure at 4% of soil weight. B is bio-fertilizers, B1 is inoculation by bacteria *Azospirillum brasilense,* B2 is inoculation by bacteria *Bacillus subtilis,* C is type of irrigation, C1 is irrigation by tap water, C2 is irrigation by magnetic water

Irrigation by magnetic water C_2 has a significant effect on the leaf dry matter 23.71, 26.62%, while irrigation by tap water C_1 gave 20.97, 22.24% for both seasons, respectively. The significant effect of interaction of poultry manure, bio-fertilizers and magnetic water on leaf dry matter percentage in the autumn shown in the same table. The maximum leaf dry matter value 27.20% in autumn was found from $A_1B_2C_2$, while the minimum leaf dry matter value 17.79% was observed from $A_2B_0C_1$. However, the highest value in the spring (30.46%) was achieved from $A_1B_1C_2$ and the lowest value 17.90% was found from $A_2B_0C_1$.

Effect of poultry manure, bio-fertilizers and magnetic water and their interaction on the leaf chlorophyll intensity (spad unit)

Table 5 shows the significant effect of using poultry manure on the leaf chlorophyll intensity of gladiolus plant var. Cartago. In both seasons, the maximum leaf chlorophyll intensity 58.18, 58.08 spad unit were noticed from A_1 treatment, while the minimum leaf chlorophyll intensity 50.53, 47.43 spad unit were achieved from A_2 treatment for both seasons respectively.

Effect of poultry manure, bio-fertilizers, magnetic water and their interaction on the concentration of potassium (%) in the leaves

The data in *Table 8* showed the maximum potassium concentrations due to application of poultry manure at 2% percentage A_1 which were 3.24, 2.95% significantly differed with A_2 resulted 2.55, 2.34% for both seasons respectively. However, the significant effect of bio-fertilizers was noticed with B_1 and B_2 in two seasons without significant differences between them. The highest potassium concentrations 3.19, 2.99% were found from both *Azospirrilum brasilense* B_1 followed by *Bacillus subtilis* B_2 which gave 2.92, 2.65% and the lowest potassium concentrations 2.28, 2.12% were resulted from two control B_0 respectively.

Irrigation by magnetic water resulted increasing of potassium concentrations by giving 3.21, 2.92% for C_2 as compared to C_1 which gave 2.37, 2.25% for both seasons respectively.

The interaction between poultry manure, bio-fertilizers and magnetic water on the potassium content in gladiolus leaves was statistical difference in both seasons. The highest concentrations 4.19, 3.81% were achieved from $A_1B_1C_2$, while the lowest concentration 1.83, 1.83% was noticed from both treatments $A_2B_0C_1$.

Effect of poultry manure, bio-fertilizers, magnetic water and their interaction on the number of the days for flowering of Gladiolus

Table 9 shows that the numbers of the days required for flowering for gladiolus var. Cartago were affected significantly by application of poultry manure. The use of A_1 resulted of decreasing of the number of the days for flowering 123.95, 84.89 significantly as compared to A_2 treatment which flowered after 132.93, 89.19 days for both seasons, respectively. However, the lowest number of the days for flowering affected by inoculations with both bacteria B_1 125.55, 85.25 days and B_2 128.28, 85.99 days as compared to control 130.37, 89.96 days for two seasons, respectively.

Irrigation by magnetic water caused decreasing of the number of the days for flowering by giving 125.63, 85.33 days for C_2 as compared to C_1 which gave 130.50, 88.81 days for two seasons, respectively.

However, the interaction between poultry manure, bio-fertilizers and magnetic water on the number of the days for flowering was found to be significant. In the autumn the minimum numbers of the days required for flowering 120.73, 120.96, 120.99 days were found from $A_1B_0C_2$, $A_1B_1C_2$, $A_1B_2C_2$ without any significant differences between them, while all of them differed significantly with control $A_0B_0C_1$ 139.18 days. However, in the spring the lowest number of the days required for flowering 82.11, 83.72 days were obtained from $A_1B_1C_2$ and $A_1B_2C_2$, while the highest number of the days required for flowering 93.83 days was achieved from $A_0B_0C_1$.

Effect poultry manure, of bio-fertilizers, magnetic water and their interaction on the anthocyanin concentration in flower petals (mg.100 g^{-1}) of gladiolus

Table 10 explains that poultry manure applications A had significant effect on the anthocyanin concentration in flower petals of gladiolus var. Cartago. The highest concentrations 21.99, 19.27 mg. 100 g^{-1} were found from A_1, whereas the lowest concentrations 15.93, 13.40 mg. 100 g^{-1} were obtained from A_2 for both seasons respectively.

Table 10. *Effect poultry manure, of bio-fertilizers, magnetic water and their interaction on the anthocyanin concentration in flower petals (mg.100 g^{-1}) of gladiolus in two seasons*

B is bio-fertilizers, B1 is inoculation by bacteria *Azospirillum brasilense,* B2 is inoculation by bacteria *Bacillus subtilis,* C is type of irrigation, C1 is irrigation by tap water, C2 is irrigation by magnetic water

Also, the significant effect of bio-fertilizers on anthocyanin concentration in flower petals was shown in the same table. In the autumn the maximum value 20.48 mg. 100 g^{-1} due to inoculation by B_2, while the minimum value 16.81 mg. 100 g^{-1} was found from control. In the spring there were not significant differences between inoculations of $B_1$and B_2 which gave 16.39, 17.87 mg. 100 g^{-1} whereas both of them differed significantly with control 13.85 mg.100 g^{-1}.

Irrigation by magnetic water C_2 caused increasing of anthocyanin concentration in flower petals which gave 19.50, 18.94 mg.100 g^{-1} as compared to irrigation by tap water C_1 which achieved 17.90, 13.12 mg.100 g^{-1} for both seasons, respectively.

However, the interaction between poultry manure, bio-fertilizers and magnetic water on the anthocyanin concentration in flower petals had significant differences. In the autumn the highest concentration 25.53 mg.100 g^{-1} was noticed from $A_1B_2C_2$ followed

by $A_1B_2C_1$ which gave 23.49 mg.100g^{-1}, while the lowest concentration 13.94 mg.100g^{-1} was achieved from $A_2B_0C_1$. Also, the interaction of three study factor affected significantly in the spring, the maximum concentration 24.76 mg.100 g^{-1} was found from $A_1B_2C_2$ followed by $A_1B_1C_2$ which gave 22.17 mg.100 g^{-1} while the minimum concentration 9.46 17 mg.100 g^{-1} was obtained from $A_2B_0C_1$.

Effect of poultry manure, bio-fertilizers, magnetic water and their interaction on the basal floral diameter (cm) of gladiolus

Results shown in *Table 11* indicates that the application of A_1 gave highest values in two seasons 12.16, 10.44 cm were noticed from both A_1, while the lowest values 8.76, 8.86 cm were obtained from both A_2 respectively. Moreover, the floral diameter was affected significantly by inoculations the corms by B_1 and B_2. The maximum floral diameter 11.33, 10.32 cm were found from B_1 followed by B_2 which gave 11.09, 9.97 cm those two treatments varied significantly with both control 9.07, 8.23 cm for two seasons respectively.

The irrigation by C_2 caused increasing in floral diameter in two seasons by giving 11.01, 10.17 cm were found from C_2 as compared to C_1 which gave 9.89, 8.84 cm respectively. However, the interaction between poultry manure, bio-fertilizers and magnetic water gave statistical differences on lower floral diameter. The highest values in the autumn 13.73, 13.54, 13.01 cm were obtained from $A_1B_2C_2$, $A_1B_1C_2$, $A_1B_2C_1$, while the lowest value 7.58 cm was noticed from $A_2B_0C_1$. In the spring the maximum floral diameter 12.19, 11.99 cm were obtained from $A_1B_1C_2$, $A_1B_2C_2$, whereas the minimum floral diameter 6.96 cm was found from $A_2B_0C_1$.

Effect of poultry manure, bio-fertilizers, magnetic water and their interaction on the vase life (day) in magnetic water of gladiolus

The effect of poultry manure on the number of the days for vase life of gladiolus var. Cartago is shown in *Table 12*. The highest number of the days 12.12, 9.83 day were noticed from A_1 application for both seasons, while the lowest number of the day 8.88 day in the autumn was obtained from A_2 application and 8.18 day in the spring was noticed from A_0.

However, the inoculation of gladiolus corms with bio-fertilizers significantly affected flowers vase life. The highest vase lives 11.04, 10.45 days were obtained with B_2, B_1 inoculation in the autumn respectively, whereas the lowest vase life 8.85 day was found from B_0. In the spring the highest vase lives 9.62, 9.54 days were found from B_1, B_2, while the lowest vase lives 7.66 days was achieved from B_0. The irrigation by magnetic water caused increasing of vase life significantly. The 11.05, 9.35 day achieved from C_2 as compared to C_1 which gave 9.17, 8.53 day for both seasons, respectively.

Discussion

The reason for the difference of plant height in autumn and spring seasons *Table 3* might be that clay percentage in soil media A_1 is 37.6 compared to soil media A_2 is 21.6 as it is shown in *Table 1*. This effect may be attributed to the physical properties of some ions adhere on the clay soil particles (Mazhar, 2010).

Regarding the inoculation of gladiolus corms with bacteria *Azospirillum brasilense,* it gave the maximum plant height and there were not significant differences with inoculation by *Bacillus subtilis,* while both of them are different from treatment without bacteria. This result is similar to what was obtained by Ali et al. (2014) as they reported that the vegetative growth improved after the application of bacteria *Azospirillum*. Moreover, a significant difference in vegetative growth was observed after using Azotobacter and Phosphate Solubilizing Bacteria (PSB) on growth of gladiolus by Srivastava and Govil (2005). Using magnetic water can improve plant height as it increases the ability of soil to get rid of salt, and it helps to better assimilate nutrients in plants during vegetative growth.

In this study, dry matter percentage in Gladiolus leaves were significantly affected by the application of 2% poultry manure in soil media (*Table 4*). These results could be due to efficient nitrogen availability which led to the improvement of vegetative growth (Shah et al., 2016). Nitrogen as an essential component of protein, nucleic acid and many important substances like chlorophyll, which are required for vegetative growth and might be responsible for the increase in dry matter accumulation in leaves. The soil bacteria belonging to the genera *Bacillus* is more common. The major microbiological means by which insoluble phosphorus compounds are mobilized by the production of organic acids, accompanied by acidification of the medium. The organic and inorganic acids convert tricalcium phosphate to di- and monobasic phosphates with the net result of an enhanced availability of the element to the plant (Yazdani et al., 2009).

The magnetic field can increase ions mobility and ions uptake which leads to a better photo stimulation and growth (Pietruszewski, 1999). Moreover, magnetic field has the ability to change water properties. Thus, this results in the increase of chlorophyll content which leads to increase in fresh weight of leaves and might cause nutrient accumulation in the leaves.

Effects of the interaction $A_1B_1C_2$ on chlorophyll intensity might be due to effects of each factor on all vegetative growth characteristics of Gladiolus var. Cartago, and it was clearly compact with the high concentration of nitrogen in leaves for both seasons 3.63, 3.40% that is shown in *Table 6,* which had major role of increasing photochemical reduction. These results are close with findings of Al-Khazan et al. (2011) that noticed that photosynthetic pigment and nutrient content of *Simmondsia chinensis L.* enhanced when irrigated by magnetic water. Atak et al. (1997) suggested that the increase of photosynthetic pigments was due to an increase in cytokinin synthesis and this plays an important role on chloroplast development. Magnetic fields are known to induce biochemical changes and affect photo pigments (Dhawi and Al-Khayri, 2009).

Tables 6–8 illustrated that A_1 had significant effect on nutrient concentration in leaves of gladiolus. This may be due to poultry manure which is an excellent organic fertilizer, as it contains high nitrogen, phosphorus, potassium and other essential nutrients (Garg and Bahl, 2008). The addition of organic fertilizers gives the plant an opportunity to provide more efficiently in the nutrients needed by nitrogen that enters into the composition of a number of important organic compounds in the biological processes in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26372655

the plant. It also involves into the synthesis of nucleic acids such as DNA, RNA and helps the building of important proteins that increase division and elongation of cells.

Although, the inoculation corms of Gladiolus var. Cartago by each *Azospirrilum brasilense* and *Bacillus subtilis* had significant differences in nutrient content in leaves as compared to treatment with control. These results are accordance with (Orhan et al., 2006) who investigated two Bacillus strains OSU-142 (N2-fixing) and M3 (N2-fixing and phosphate solubilizing) that were tested alone or in combinations on organically grown primo cane fruiting raspberry (cv. Heritage). It was found that bacterial treatment improves nutrient uptake and increase most nutrient element contents P, Ca, Fe, Mn and K in leaves.

Third factor that caused of increasing nutrient element concentration in leaves was irrigation by magnetic water. These results agree with findings of Al-Ma athidi (2006) who investigated the effect of magnetic water on *Gerbera jamessonii* which caused to increasing of nitrogen and magnesium availability in soil solution (Hashemabadi et al., 2015; Abdelaziz and Abdelrazig, 2014).

As indicated in *Tables 9–12,* treatment A_1 had significant effects on most flower characterizes (Number of the days for flowering, anthocyanin concentration in petals, basal floral diameter and vase life) of gladiolus var. Cartago. The results were on line with Jha (2011) findings that the farm yard manure10 t. ha^{-1} with 75% RDF gave significant effect on the reducing the number of the days for spike emergence of gladiolus cultivar candyam. In this study, the use of 4% did not have significant effects on the flower attributes which may be because of effects of high Electrical conductivity of A_2 which 2.91 was higher than A_1 1.70 which might be due to the presence of more salts in the poultry manure at the rate A_2 as shown in *Table 1*.

The bio-fertilizers inoculation gave significant effects on most flowering characterizes as compared to control. The data in *Table 9* indicated that the number of the days required to opening of basal floret was significantly reduced with the inoculation of *Azospirillum barasilense* and *Bacillus subtilis* in two seasons. These results were in close with findings of Singh (2009). The study was carried out to use bio-fertilizers in combination with nitrogen on growth and flowering of Gladiolus, to see the effect of Bacillus and Pseudomonas strains on growth and flowering of gladiolus cultivar American Beauty. Significant increase in spike length, and number of florets per spike and floret diameter was recorded under levels of nitrogen, bio-fertilizers, Bacillus, Pseudomonas strains and their combinations.

Moreover, irrigation by magnetic water caused improvements in flower quality. The reason for the positive effects of magnetized water could be due to the fact that the magnetic field is dependent on changes in the physical and chemical properties of water, including reducing surface tension, viscosity and water density, making it lighter and easier to absorb. The results were close with findings of Al-Maathidi (2006) in the study of using magnetized water on *Gerbera jamesonii.*

Regarding of vase life, the biofertilizers regulate nutrient uptake process and prolonged vase life phenomenon. Bekheta and Mahgoub (2005) concluded that the increase in nitrogen level lead to change in amino acids quantity and specific proteins in carnation plants. Plants treated with microbial inoculations showed more sugar contents.

Conclusion

The study discusses that the poultry manure at the rate of 2% of soil weight improves vegetative growth of Gladiolus (*Gladiolus hybrida*) as well as flower characteristics. Moreover, inoculation by *Azospirillum brasilense* and *Bacillus subtilis* increases the plant height, chlorophyll intensity, N, P, K uptake and flower quality in autumn and spring seasons. Since the soils of Sulaimani farms are suffering from organic matter deficiency, application of animal residue as poultry manure is used as it improves organic matter content. Furthermore, using biofertilizer is safer than chemical fertilizer to decrease soil pollution, and it costs less. It is clear that the irrigation with magnetic water and using bacteria Azosperilum spp. can improve flower production and reduced salinity of the soil. It is recommended for future researches to study the different type of bacteria and mycorrhiza with organic matter.

Abstract. The alternative to the traditional method for heavy metal uptake is biosorption. The potential of *Spirulina sp.* for biosorption of waste effluent was examined. In this study, morphology and molecular features of microalgae *Spirulina sp.* isolated from Koya city were identified on. The rate of biosorption of cadmium (Cd^{+2}) and lead (Pb^{+2}) were studied by using a spectrophotometer. The optimum uptake for both metals Cd^{+2} and Pb^{+2} showed at low metal concentration of 100 mgl^{-1} 88.8% and 93.6%, respectively. *Spirulina sp.* showed the ability to remove metals at all pH values 38.1% and 85.8% for Cd^{+2} and 34.6% and 88.4% for the Pb^{+2} with maximum uptake at 30 °C 85.7% for Cd and Pb optimum uptake was 88.4%. Optimum removal showed at agitation rate 150 rpm 87.1) in Cd^{+2}, and Pb^{+2} optimum adsorption at 150 rpm was 89.9%. Both metals showed optimum adsorption at 1.5 g l^{-1} of algal biomass, Cd^{+2} removed 86.7%, and Pb^{+2} 89.2%. Pb^{+2} showed the best performance for metal biosorption.
Keywords: *metal uptake, algal biomass, temperature, agitation rate, pH*

Introduction

Microalgae include those chlorophyll-bearing organisms that are thalloid (Vashishta et al., 2002). Nearly 75% of algal species are microalgae that contribute 30-40% of oxygen to the atmosphere (Ponuswamy et al., 2013). They are the primary producers who switch water and carbon dioxide into carbohydrates and oxygen in the presence of the sun (Chisti, 2008). Microalgae biomass is often measured with a concentration of chlorophyll and can provide a useful index of potential production.

Cadmium (Cd^{+2}) is a chemical element that involves different machinery to induce its harmful effect on many biological activities in humans, animals, and various other organisms. In humans, the adverse effect of Cd^{+2} is not only limited to the kidney and bone, but it includes nearly every organ and tissue where it accumulates, which argues the need for public health measures aimed at reducing exposure. There are many ways in which this heavy metal can be suppressed in its activities, forming the prospect for reduced metal toxicity involving Cd^{+2} (Hogan, 2010; Sharma et al., 2015).

Lead (Pb^{+2}) is number two on the "Top 20 List" of toxic and hazardous substances of the ATSDR. Pb^{+2} accounts for the majority of pediatric heavy metal poisoning (Roberts, 1999). Pb^{+2} occurs in many forms worldwide in natural sources and is one of the most commonly and uniformly distributed trace metals (Jackson et al., 2005). Pb^{+2} creates several adverse effects in both males and females on the reproductive system. Common impacts shown in males involve decreased libido, unusual spermatogenesis (decreased motility and number), chromosomal harm, infertility, abnormal prostatic function, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26572668

serum testosterone alterations. Women, on the other hand are more prone to infertility, miscarriage, premature membrane rupture, pre-eclampsia, pregnancy hypertension, and premature delivery (Flora et al., 2011). Also, during gestation, the direct influence of Pb^{+2} on the developmental stages of the fetus was registered (Saleh et al., 2009; Flora et al., 2012). Hasson (2018) measured concentrations of some heavy metals in various imported and locally produced vegetable crops in Baghdad city, including root crops and the daily intake of four main heavy metals (Cd, Cu, Zn, and Pb) had been estimated, which revealed a high consumption of Cd^{+2} (310 and 372 μg per day) for imported and local vegetables that affect human health. Because of multiple anthropogenic activities, heavy metals are released into the fairway. Their therapy is of particular significance since heavy metals are non-biodegradable and cause environmental damage due to their poisoning to many crops, livestock, and microorganisms in the aquatic environment (Sadettin and Donmez, 2007; Kaplan, 2013; Salih et al., 2017). Traditional methods for the removal of dissolved heavy metal ions involve chemical precipitation, electrochemical treatment, chemical oxidation and reduction, ion exchange, filtration and evaporative recovery (Aksu et al., 2002). Biosorption of heavy metals by microalgae is generally a biphasic process involving adsorption by materials associated with extracellular cells, such as polysaccharides and cell wall components (Roy et al., 1993; Das et al., 2008).

Materials and methods

Sampling and cultivation

Microalgae sample was isolated along Taq-Taq river in Koya city during May-September 2018, Water samples were taken from a depth between 10 and 50 cm from the bottom (Prasad et al., 2013) and plated Blue-green 11 medium (BG11) as described by Allen (1968) and Oswaled (1988). The cultures were incubated at pH 7.8 and 28 ℃ under constant light 800Lx. Two weeks later, following the growth of colonies on the agar media, the colonies were removed with pasture micropipettes and gently blown into the liquid medium, then incubated at 28 ℃, 800 Lx, and pH 7.8.

Morphological and molecular identification of algae

After a 15-days single colony removed and examined under a light microscope for identification purposes based on their morphology as described by Prescott (1963), Desikachary (1968), Rippka (1988) and Holt et al. (1994). Further identification was performed by polymerase chain reaction (PCR) to confirm algal genera.

Extraction of DNA

Genomic DNA extraction was performed using a commercial extraction kit (Thermofisher, USA) according to the manufacture's instruction. DNA samples were then checked for their quantity and quality using Bio-photometer (Eppendorf, German).

PCR amplification and DNA sequencing

The targeted region of 16S rRNA of algae amplified by PCR using universal primers, forward primer A8F (5- AGAGTTTGATCCTGGCTCAG-3), and the reverse primer A1492R (5- TACGGCTACCTTGTTACGACTT- 3). Primers were previously used by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26572668

Ponnuswamy et al. (2008). A total of 50 µl volume of the reaction mixture was prepared, which contained 40–55 ng DNA, 100 mM of each primer, 0.05 U/µl Taq DNA polymerase, 4 mM MgCl2, and 0.4 mM of each dNTP.

ABI 3130XL genetic analyzer (USA) was employed to find the order of the nucleotides of 16S rRNA for the algae sample. The PCR products were cut from the agarose gel and utilized as a base of DNA template for sequence-specific PCR amplification and sent for nucleotide sequencing analysis to the private medical genetic laboratory in Intergene Genetic Center, Ankara, Turkey.

Preparation of biomass

Spirulina sp. biomass initially dried from moisture on an aluminium tray, kept in the oven at 80 ℃ for 24 h, after cooling, this material was subjected to sieve analysis.

Chemicals

Cadmium nitrate tetrahydrate ($Cd(NO_3)_2 \bullet 4H_2O$) and lead nitrate ($Pb(NO_3)_2$) were used to prepare 1000 mg l^{-1} inventory metal ion solutions that were diluted to produce metal ion alternatives for adsorption. Before the microorganisms were mixed, the pH value of each metal solution was adapted with 1 mol l^{-1} NaOH to the appropriate value (Fan et al., 2008).

Batch experiments

Batch experiments were performed at different initial metal concentrations 100-500 mgl^{-1}, pH 6.5-8.5, temperature 20-40 ℃, agitation speed from zero-200 rpm, and biosorbent dosage 0.3-1.5 gl^{-1} according to Aksu (2005). The rate of biosorption was read using spectrophotometer at 540 nm for Cd^{+2} and 530 nm for the Pb^{+2}. Metal containing medium was used as blank (control medium contained both metals and solution without biosorbent to observe any reaction of the solution with metals). Each experiment was carried out in triplicate. The yield of biosorption was determined (*Eq. 1*) by the formula below (Blanco et al., 1999; Aksu, 2005):

$$Biosorption\ \% = (Co) - (C).100/Co \qquad \text{(Eq.1)}$$

C_o - Initial metal concentration, C - Final metal concentration.

Statistical analysis

The test results were statistically analyzed with a one-way variance analysis (ANOVA) followed by a Tukey post hoc test ($P \leq 0.5$) to assess significant differences between the experimental classes.

Results

Morphological and molecular identification of algal strain

After observation under the microscope at different magnifications and according to the guide of taxonomic, in the isolated and purified samples trichomes width without akinetic and heterocyst, cell length, pointed calyptras, type of coil and helix shape (*Fig.*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26572668

1) were observed and identified as *Spirulina* according to Ciferri (1983), Rippka (1988), Tomasseli (1997) and Prasal et al. (2013).

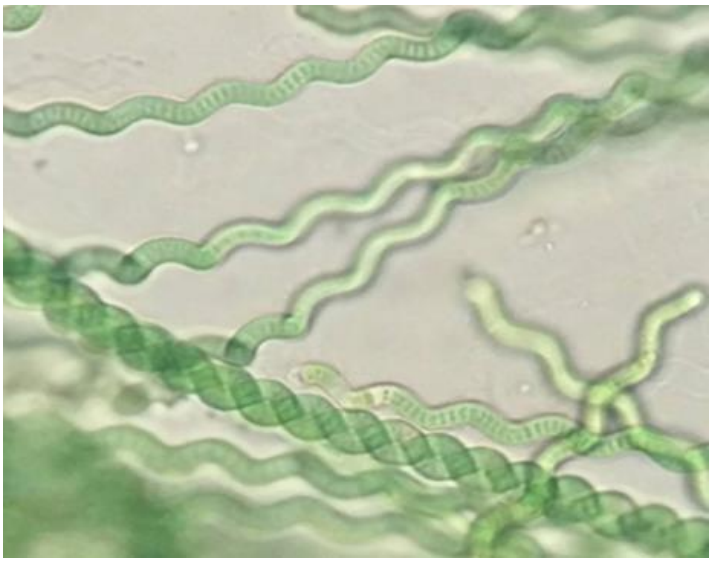

Figure 1. *Microscopic observation of Spirulina sp.*

By molecular examination, the sequence from 16S rDNA of algae specimen was made of 1200-1400 bp (amplified fragment was 1468 bp, also after testing some non-nucleotides were removed, linked to the character of the sequencing assessment) and then placed to BLAST compared to other stored algae sequence genus from the Gene Bank database. The primary sequence analysis using a universal primer of the observed specimen disclosed that algae from Koya city belong to the *Spirulina sp.* genus. Its rDNA conforms to the same rDNA sequence fragment symbol required at the Gene Bank in the National Center for Biotechnology Information (NCBI), pairwise analysis of the algae specimen is shown in *Figure 2.*

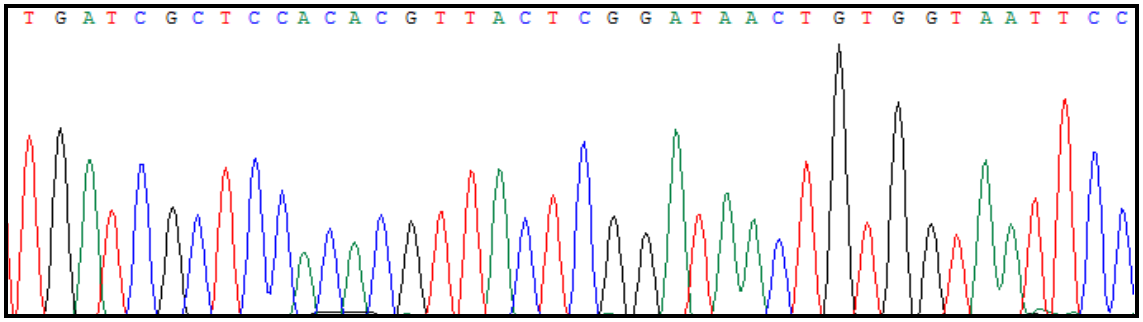

Figure 2. *The partial sequencing result of 16S rDNA of Spirulina sp.*

Effect of Cd and Pb concentrations on biosorption

Figures 3 and *4* showed the effect of initial metal ion concentration (Cd^{+2} and Pb^{+2}) ranging from (100-500 mg l^{-1}). Optimum removal showed during 15 h, and the rapid removal showed at hour 3; by increasing metal concentration, the biosorption process decreased. In the case of Cd^{+2}, the optimum adsorption (88.8%) was recorded at a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26572668

concentration of 100 mg l^{-1}, while high removal of Pb^{+2} was (93.6%) at the same concentration. Increasing concentration of both metal ions led to a decline in adsorption, indicating saturation of all the binding sites on the algal surface. The result showed that there were no significant differences between heavy metal concentration with Cd^{+2} (*p*-value = 0.0936) and Pb^{+2} (*p*-value = 0.0981).

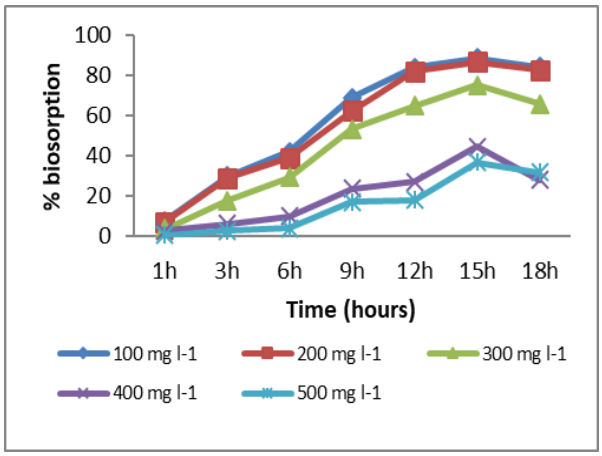

Figure 3. *Effect of metal Cd^{+2} concentration on biosorption process (pH 7, 35 °C, 100 rpm)*

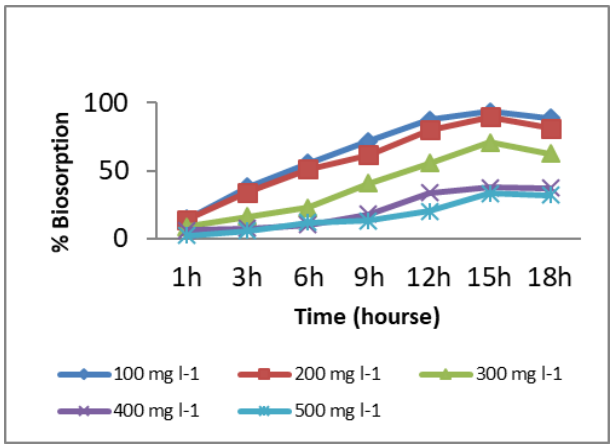

Figure 4. *Effect of metal Pb^{+2} concentration on biosorption process (pH 7, 35 °C, 100 rpm)*

Effect of pH on biosorption of Cd and Pb by Spirulina sp.

The pH is an important factor in biosorption processes. To find an appropriate pH for *Spirulina sp.* efficient heavy metal biosorption, studies were conducted at five distinct original pH values (6.5, 7, 7.5, 8, 8.5), *Spirulina sp.* showed ability to remove metals at all pH values 38.1% and 85.8% for Cd^{+2} and 34.6% and 88.4% for the Pb^{+2}. The Statistical analysis showed significant differences among pH and adsorption percentage of both Cd^{+2} and Pb^{+2} ions. A significant correlation had been recorded among pH degree change with both Cd^{+2} (*p*-value = 0.0039) and Pb^{+2} (*p*-value = 0.0065), which means with increasing pH, the adsorption percent increased, and the peak of adsorption percent was reached to 85.8 for Cd^{+2} and 88.4 for Pb^{+2} ion. The optimum removal showed at pH 8 (Cd^{+2} 85.8% and Pb^{+2} 88.4%) as shown in *Table 1*.

Effect of temperature on biosorption of Cd^{+2} and Pb^{+2} by Spirulina sp.

To find an appropriate temperature for *Spirulina sp.*'s on efficient heavy metal adsorption, studies were conducted at five distinct temperature values (20, 25, 30, 35, and 40 °C) as shown in *Figures 5* and *6*. Rapid removal showed in first hour at 20 °C. Optimum removal of Cd^{+2} showed at a temperature of 30 °C (85.7%), and for Pb^{+2}, optimum removal was (88.4%) at the same temperature. The effect of temperature showed significant differences among temperature and adsorption percentage of both Cd^{+2} and Pb^{+2} ions. Significant differences had been stated related to temperature change in both Cd^{+2} (p-value = 0.025) and Pb^{+2} (p-value = 0.0248) biosorption.

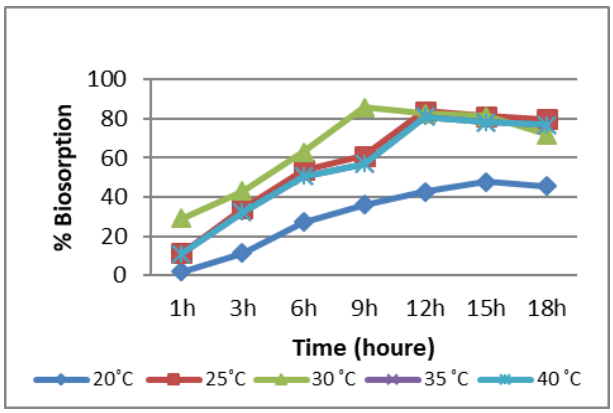

Figure 5. *Effect of temperature on Cd^{+2} adsorption C_0- 200 mg l^{-1}, pH 8, 100 rpm*

DOI: http://dx.doi.org/10.15666/aeer/1802_26572668

Effect of agitation rate (rpm) on biosorption of Cd^{+2} and Pb^{+2} by Spirulina sp.

The effect of agitation rate on Cd^{+2} and Pb^{+2} adsorption by *Spirulina sp.* is shown in *Table 2*. At equilibrium, metal uptake increases with an increase of agitation rate - rpm (unshaken to 150 rpm), and the optimum removal showed at rpm 150 (87.1%) in Cd^{+2} and Pb^{+2} showed optimum adsorption at 150 rpm (89.9%). The adsorption process decreased with 200 rpm. The *p*-value of Cd^{+2} (*p*-value = 0.469) and Pb^{+2} (*p*-value = 0.5031) that showed no significant correlation between rpm, in spite of increasing rpm, the adsorption percent of Cd^{+2} and Pb^{+2} ions were not changed significantly.

Table 2. *Effect of agitation rate on biosorption of Cd^{+2} and Pb^{+2} by Spirulina sp. (200 mg l^{-1} initial metal concentration (C_0), pH 8, 30 °C)*

Effect of algal biomass on biosorption of Cd^{+2} and Pb^{+2} by Spirulina sp.

The effect of biomass on Cd^{+2} and Pb^{+2} ion removal is indicated in *Figures 7* and *8*. At equilibrium, metal uptake increases with an increase in biomass from 0.3 to 1.5 g l^{-1}. Optimum removal showed during 6 h in a biomass of 1.5 g l^{-1}, rapid removal showed at 1 h in a biomass of 0.3 g ml^{-1}. Both metals showed optimum adsorption at 1.5 g l^{-1} of algal biosorbent 86.7%, of Cd^{+2} and 89.2% of Pb^{+2} were removed.

The result showed significant differences among algal biomass and adsorption percent of both Cd^{+2} and Pb^{+2} ions. The *p*-value for both Cd^{+2} (*p*-value = 0.0095) and Pb^{+2} (*p*-value = 0.0036), means with increasing of algal biomass, the adsorption percent increase and the peak of adsorption percent was reached to 86.7 for Cd^{+2} and 89.2 for Pb^{+2} ion.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26572668

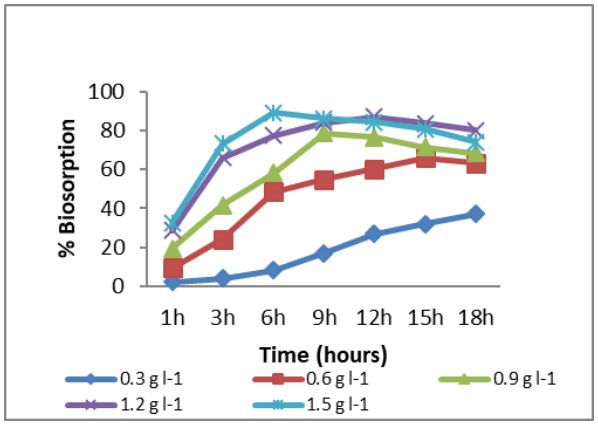

Figure 8. *Effect of biosorbent dosage on Pb^{+2} adsorption (200 mg l^{-1} initial metal concentration, pH 8, 30 °C, 150 rpm)*

Scanning electron microscopy (SEM) analysis

The biosorbent morphology, which is cell/filamentous algae-binding-Pb^{+2} and Cd^{+2}, was examined using SEM with 200x magnification to demonstrate the porous places of cell/filamentous algae as seen in (*Fig. 9a, b, c*) illustrate the efficient binding with Cd^{+2} and Pb^{+2}, respectively. However, in composites with a greater content of Cd^{+2} and Pb^{+2}, the particles are often abnormal in form and circular in the preparing of irregular surface, this distinctive shift in the analyzed SEM pictures highlights the existence of Cd^{+2}.

Discussion

Isolated and purified microalgae strain observed under microscope and culture showed filamentous spiral-shaped microalgae that were identified as *Spirulina sp.* and the strain was confirmed by using molecular identification. The same characteristics showed by isolated *Spirulina* from (Koya city). In many cases, the selection of efficient organism is known to be essential tools in the successful treatment of wastewater effluents rich in toxic compounds such as Cd (II) and Pb (II) in textile industry effluents. Microalgae were proposed as perfect candidates for the wastewater treatment system. In the present research, *Spirulina* strain was used as biomass for Cd^{+2} and Pb^{+2} adsorption process under various initial metal concentrations, pH, biosorbent dosage, temperature, and agitation velocity. In the experiments, it was showed that there are different factors affecting the biosorption of heavy metals by *Spirulina sp.* The present results were in agreement with Gupta and Rastogi (2008), Kőnig-Péter et al. (2015). Al-Homaidan et al. (2015) and Palaniswamy and Veluchamy (2017). As shown in the results, Pb^{+2} biosorption was more prominent than Cd^{+2} biosorption. Similar results were obtained by Domínguez-Bocanegra et al. (2013), who reported that Pb^{+2} biosorption was more prominent than Cd^{+2} and nickel. By increasing the original metal concentration, the proportion of biosorption of metal ions reduced (*Figs. 3* and *4*) same result was obtained by Abdel-Aty et al. (2013).

The fast adsorption of the metals shows that the sorption method may be ionic where the acidic (anionic) dye molecules bind to the multiple strongly loaded organic functional groups present on the biomass surface (Gulnaz et al., 2004).

pH is one of the most significant parameters affecting original adsorption frequency and ability; the optimum pH was 8 (*Table 1*). This phenomenon is due to the nature of the chemical interaction of each heavy metal with algal cell walls. Hydrogen ion also functions as a bridging ligand between the cyanobacterial cell wall and the heavy metal molecules, and the results were in agreement with Abdel-Aty et al. (2013) who confirmed that the biosorption of Cd (II) and Pb (II) was increased with increasing the pH value and disagreed with Kőnig-Péter et al. (2015) who stated that the biosorption process was successful at pH 5–6 for Pb(II) and pH 4−6 for Cd(II) adsorption. Metals biosorption on *Spirulina sp.* has been researched at various temperatures of 20-40 ℃, and the optimum temperature for adsorption of metals showed at 30 ℃ and the lowest adsorption at 20 ℃ (*Figs. 5* and 6). However, temperature variation in comparisons had an important impact on the removal of Cd^{+2} and Pb^{+2} of *Spirulina sp.* The results of this investigation were in agreement with Donmez et al. (1999), Dhargalkar (2004) and Kőnig-Péter et al. (2015). To determine the impact of agitation velocity on metal adsorption, a series of studies at distinct agitation degrees (unagitated – 200 rpm) were conducted and shown in *Table 2* indicating that the degree of agitation positively affected the sorption process rise in agitation rate biosorption of metals improved optimum adsorption at 150 rpm with agitation levels greater than 200 rpm. This relates to the weakening interaction between the sorbent locations and the metal ion described by the Van-der Waals interaction Anwer and Abdullah (2017) when they study the effect of agitation rate on direct Blue nine adsorption using baker's yeast.

Figures 7 and *8* showed the effect of biosorbent dosage to remove heavy metal, Optimum removal showed in biomass 1.5 at 6 h, fast removal showed in biomass 0.3 at 1 h. By increasing biosorbent dosage adsorption of biomass increased due to increase in the region and the accessibility of more biosorption locations (Mane et al., 2007). After

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26572668

biosorption process ended the algal biomass accumulated and used for further study which was desorption experiments.

However, in composites with a higher content of Cd^{+2} and Pb^{+2}, the particles are mainly abnormal in form and circular in the preparation of a rougher surface, this distinctive shift in the analyses SEM pictures highlights the existence of Cd^{+2} and Pb^{+2} in the cell/filamentous algae surface this result is agreed with Salih et al. (2017).

Conclusion

Biosorption of heavy metals (Cd^{+2} and Pb^{+2}) increased by increasing biosorbent (*Spirulina sp*.). This study shows that isolated *Spirulina sp.* deserves attention as biosorbent, which can be utilized in the treatment of wastewater effluents containing heavy metals before the treatment, and the technique can be modified further to make it applicable on a large scale to clean up heavy metal contamination using dried biomass of *Spirulina* sp. In most of the studies that done previously by researchers spirulina cells were purchased in the dried form while in our research we isolated spirulina from different site of Koya city which was not conducted before, and cultured Spirulina sp. by using different parameters to obtain high rate of biomass in lab.

Abstract. In order to reveal the correlation between long-term different fertilization methods and soil enzyme activity in rhizosphere of halophytes, Salicornia salina was selected as the research object and cultured in root bags in coastal saline soil. The effects of plastic film mulching, non-plastic film mulching and non-fertilization on invertase, catalase and urease activities in rhizosphere soil of Salicornia salsa during its growth period were studied, while the effects of plastic film mulching and non-fertilization on the activities of invertase, catalase and urease in the rhizospheric soil of Salicornia salicornis were also investigated. Bacillus, Bacillus licheniformis, Bacillus amylolytica and compound microbial fertilizers had effects on the activities of three soil enzymes. The results showed that the activities of S-SC, S-CAT and S-UE could be promoted by mulching and that fertilization at any time, and the effect of mulching combined with fertilization was the best. Soil enzyme activity showed the same change pattern during the growth period of Salicornia salina. The highest activity of soil invertase and urease occurred at jointing stage, and the highest activity of soil catalase occurred at maturity stage. Compared to spraying treatment, adding compound microbial fertilizer could increase catalase activity by 6.3% and 4.0% at different stages, while adding Bacillus amyloliquefaciens microbial fertilizer, the activity of sucrase and urease increased by 20.7% and 18.6%, respectively, and 21.8% and 4.6%, respectively in different periods. In conclusion, the application of plastic film mulching combined with fertilization, inorganic fertilizer and microbial fertilizer can improve soil enzyme activity and soil fertility, and enhance the sustainable productivity of soil.

Introduction

Soil is a living ecosystem, containing various soil enzymes. They play an important role in the process of soil material circulation, energy and nutrient transformation (Tang et al., 2016). The activity of soil enzymes is one of the biological indicators to characterize soil biological activity, soil fertility level and soil quality. Nature and environmental conditions are closely related, and are regarded as sensitive indicators of soil ecosystem change (Cunha et al., 2017). Soil enzymes are proteins that catalyze soil biochemical reactions, mainly from soil microorganisms and plant roots, and also from soil animals and plant residues (Cheng et al., 2016), which are one of the most active organic components in soil components. Plant rhizosphere is the place where plant roots grow and develop, absorb nutrients and metabolize. It is also an important interface between plant and soil environment (Nawaz et al., 2016). The effect of plant living roots on soil enzyme activities is reflected in two aspects. On the one hand, plant roots can secrete extracellular enzymes; on the other hand, they may also be root thorns. It stimulates the activity of soil microorganisms. It is more sensitive to the soil environment and more responsive to the soil environment. Rhizosphere is also the most active micro domain of soil chemical and biological properties, and its importance has been widely recognized. Soil enzyme activity,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26692685

as a quick-acting index to measure the rhizosphere micro-ecological environment, has been widely used in the study of soil ecological environment. Therefore, the study of soil enzyme activity is of great significance to the formation, evolution, and improvement of soil fertility and the material cycle process of soil ecosystem (Fan et al., 2016).

Soil invertase (S-SC), catalase (S-CAT) and soil urease (S-UE) activities play an important role in evaluating soil fertility. Among them, S-SC activity reflects the intensity of soil respiration and carbon transformation (Van et al., 2017), and has been widely used to characterize the intensity and direction of soil carbon cycle and biochemical activity. S-CAT is an indicator of aerobic microorganisms. It can effectively promote the decomposition of harmful substance hydrogen peroxide, which is related to the redox capacity of soil and the transformation rate of soil organic matter (Chen et al., 2018). The activity of S-UE represents the abundance of soil nitrogen and is closely related to the transformation of nitrogen in soil. Therefore, the activity of S-UE is commonly used to characterize soil nitrogen status (Liu et al., 2016). At present, there are a lot of reports about the effect of organic fertilizer on soil enzyme activity. Fertilizer application is the way to apply fertilizer to soil. The basic requirements of scientific fertilization methods are as follows: to apply fertilizer to the soil layer which is easy to absorb by the root system of the crop as far as possible, to improve the utilization rate of chemical fertilizer; to select the appropriate location and to reduce fertilizer fixation, volatilization and leaching. Fertilization methods vary with different crops, fertilization loss and fertilizer properties. The most commonly used methods are artificial spraying, acupoint application, rotation, radial fertilization and external fertilization. According to the planting mode of Salicornia salsa, artificial spraying and hole fertilization (Ma et al., 2016) were used in the fertilization process, and after fertilization, sowing was conducted. Microbial fertilizer is applied in the same hole as seed fertilizer. The mixed strains were Bacillus subtilis, Bacillus licheniformis and Bacillus amyloliquefaciens.

Halophyte is a kind of natural plant flora (Poeplau et al., 2016) which grows on saline soil with certain salt resistance. Phytoremediation on saline-alkali soil is a feasible method to solve the problem of saline-alkali land utilization. Therefore, the research on the phytoremediation of saline-alkali soil by plant rhizosphere has received extensive attention. The strong salt and barren tolerance of coastal halophytes may also be related to their rhizosphere soil enzymes. The rhizosphere soil enzymes of halophytes may be one of the most direct characteristics of coastal halophytes to rapidly absorb, utilize soil nutrients and adapt to saline environment (Zhao et al., 2016). The research of plant rhizosphere is very limited, especially the soil enzyme activities of these plants are seldom concerned. Studying the soil enzyme activities of coastal halophytes will help to protect the resources of Halophytes in these areas, and provide a theoretical basis for the restoration and utilization of these plants in coastal saline soil. Based on this, the correlation between long-term different fertilization methods and soil enzyme activities in rhizosphere of halophytes was studied. The activities and dynamic changes of S-SC, S-CAT and S-UE in rhizosphere of five fertilization treatments under artificial spraying and hole application during the growth period of halophyte Salicornia salina were mainly studied in order to clarify different microorganisms. The intrinsic relationship between fertilizer and soil enzyme activity provides theoretical basis for rational fertilization, soil improvement and seeking the best growth environment for stable and high yield of halophytes. In order to reveal the correlation between long-term different fertilization methods and soil enzyme activity in rhizosphere of halophytes, Salicornia salina was selected as the research object and cultured in root bags in coastal saline soil.

Materials and Methods

Halophytes and soils

Generally speaking, the basic conditions for plant growth are: moderate sunshine, air and water. The five essential elements of plant life are: sunlight, temperature, water, air and nourishment, which are the lifeline of plants. Temperature has a great influence on the growth and development of plants. Plants need different and appropriate temperatures in different growth periods and development stages; water is an important part of plants; oxygen, nitrogen and carbon dioxide in the air have a great impact on plant life; plants need a lot of nutrients, including carbon, hydrogen, oxygen, nitrogen, phosphorus, potassium, calcium, sulfur, magnesium, iron and other 10 kinds of elements. Air affects the lives of animals and plants. The photosynthesis of plants needs carbon monoxide, and the respiration of animals needs oxygen. Only under light conditions can plants carry out photosynthesis, produce organics and store energy every day. Light plays a decisive role in plant physiology and distribution. Some plants can grow well only under strong light, such as wheat, corn, etc.

Salicornia salina, a typical halophyte in northern coastal areas of China, was selected to adapt to the coastal saline soil environment. Salicornia salina is a salt-accumulating halophyte (Xu et al., 2017). Seeds of the tested plants were collected in the coastal area of Dagang, Tianjin, in October 2016. The coastal saline soil with natural distribution of halophytes was selected for the tested soil, and the basic properties of the soil were shown in *Table 1*.

Table 1. *Main properties of soils used*

Soil properties	Littoral rock and soil
PH value	8.52
w(Total salt) ($g \cdot kg^{-1}$)	12.72
w(CO_3^{2-})($g \cdot kg^{-1}$)	0.08
w(HCO^{3-})($g \cdot kg^{-1}$)	0.17
w(CI^-)($g \cdot kg^{-1}$)	7.15
w(SO_4^{2-})($g \cdot kg^{-1}$)	0.75
w(Na^+)($g \cdot kg^{-1}$)	2.63
w(K^+)($g \cdot kg^{-1}$)	1.50
w(Ca^{2+})($g \cdot kg^{-1}$)	1.49
w(Mg^{2+})($g \cdot kg^{-1}$)	0.20
w(Quick-actingN) ($mg \cdot kg^{-1}$)	30.18
w(Quick-actingP) ($mg \cdot kg^{-1}$)	12.63
w(Quick-actingK) ($mg \cdot kg^{-1}$)	384

Root bag culture and sample collection of plants

The experiment began on May 9, 2017. Firstly, the soil was collected, dried, crushed and fully blended, grinded over 0.2 mm sieve, and then added distilled water to the soil water content of 140 $g \cdot kg^{-1}$ for reserve. The potted root bag method was used to simulate the experiment (Gu et al., 2016). All the experiments were carried out in greenhouse. The nylon mesh yarn with 30 μm aperture was sealed with a plastic sealing machine to form a root bag with a diameter of 3 cm and a height of 15 cm. The root bags of Salicornia salicornis could not grow out. Each root bag was filled with 240 g of prepared soil (Chen et al., 2017). The same soil was also put into a basin with a height

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26692685

of 40 cm and a diameter of 30 cm, and then one of the prepared root bags was buried in the center of the basin. Fifteen dew-white seeds of Salicornia salsa were planted in each root bag, and six seedlings were retained in each root bag after emergence. Water every 15 days during the growth period, and pour the same amount of distilled water 3 L for each treatment, and do not do any other treatment. After 100 days of plant growth, 12 pots with similar seedling emergence and growth were selected for sampling, i.e. 12 replicates. When all the roots of Salicornia salsa were observed to be fully filled with root bags, the soil below 2 cm in the root bags was taken as rhizosphere soil, and the soil samples were dried in shade to be tested.

Fertilizer for test and test design

There are three kinds of fertilization methods: film-covered fertilization (CF), film-covered non-fertilization (C), non-film-covered fertilization (F) (Gschwendtner et al., 2016), and non-mulching and non-fertilization (CK) as control. Samples were taken for 15, 30 and 45 days after treatment. There are 10 treatments in the fertilization process, and the different treatment schemes are shown in *Table 2*.

Table 2. *Test design scheme*

Serial number	Code	Handle	Consumption/ g
1	SCK	Manual application of chemical fertilizer	1.5
2	TCK	Point application of chemical fertilizer	1.5
3	SKC	Manual Spraying of Chemical Fertilizer + Microbial Fertilizer (Bacillus subtilis)	1.5+3.0
4	TKC	Point Application of Chemical Fertilizer + Microbial Fertilizer (Bacillus subtilis)	1.5+3.0
5	SDY	Manual fertilization + microbial fertilizer (Bacillus licheniformis)	1.5+3.0
6	TDY	Point Application of Chemical Fertilizer + Microbial Fertilizer (Bacillus licheniformis)	1.5+3.0
7	SJDF	Manual fertilization + microbial fertilizer (Bacillus amylolytica)	1.5+3.0
8	TJDF	Point Application of Chemical Fertilizer + Microbial Fertilizer (Bacillus amyloliquefaciens)	1.5+3.0
9	SFH	Manual Spraying of Chemical Fertilizer + Microbial Fertilizer (Compound Bacteria)	1.5+3.0
10	TFH	Point Application of Chemical Fertilizer + Microbial Fertilizer (Compound Bacteria)	1.5+3.0

According to the characteristics of rapid cooling and unstable temperature in saline soil area in the morning and evening, fertilization treatment was carried out in June 20, July 1 and July 10, respectively. The test chemical fertilizer was Stanley slow-release mixed fertilizer ($N:P_2O_5:K_2O$=26:12:10) (Liu et al., 2016). The microbial fertilizer was organic fertilizer plus 10% bacteria (bacteria 2×10^{10}cfu/g) and organic matter content was 40.857% (Li et al., 2017). The tested strains were Bacillus subtilis, Bacillus licheniformis and Bacillus amyloliquefaciens (Gong et al., 2017), which were preserved by the Biochemical Laboratory of Institute of Applied Chemistry, Shanxi University.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)

Artificial spraying

Artificial spraying is the way of evenly spreading fertilizer on the field (Duan and Liu, 2019), which belongs to topsoil fertilization and mainly meets the needs of shallow root distribution at seedling stage. This method is commonly used in the application of base fertilizer to uncultivated crops or in the topdressing of densely planted grain crops (Wang et al., 2018). Artificial spraying combined with soil tillage measures can increase the uniformity of soil and fertilizer mixing, which is conducive to the extension of crop roots and early absorption.

Point application

Point application can be made by opening hole fertilizer in the designated planting position or termination of the crop, or in the seedling stage, per plant or between two sides of the plant during the crop growth period (Zhou and Lin, 2016). Point fertilizer is usually 5-10 cm deep and covered with soil after application. Point application is a more centralized method of chemical fertilizer application, avoiding damage to the root system. Generally, less chemical fertilizer is applied, and the appropriate position and depth are maintained with the root system of crops. After fertilization, irrigation is combined before covering soil, and the effect of chemical fertilizer application is better.

Determination of nutrients and active enzymes in soil

Soil samples are used for the determination of various indicators after indoor shade drying. Soil nutrient determination methods: Kjeldahl method for total nitrogen, HCl-HF method for digestion of total phosphorus, anti-colorimetric method for molybdenum and antimony, alkali hydrolysis diffusion method for available nitrogen and Bray1 method for available phosphorus.

The activity of S-SC (soil sucrase) was determined by the colorimetric method using 3,5-Dinitrosalicylic acid as the chromogenic agent (Song et al., 2018). S-SC can enzymatically hydrolyze sucrose to produce glucose and fructose. The hydrolyzed sucrose can form colored compounds with 3,5-Dinitrosalicylic acid. The content of glucose can be determined by colorimetry. The activity of S-SC was expressed by the quality of soil glucose (mg) 1 g after 24 hours (Hicks et al., 2017).

The activity of S-CAT was determined by titration with 0.1 $mol \cdot L^{-1}$ KMnO4 using hydrogen peroxide as matrix, and the activity of S-CAT was expressed by the amount of 0.1 $mol \cdot L^{-1}$ KMnO4 consumed by 1 g of dry soil after 20 minutes of incubation.

The activity of S-UE (urease) was determined by urea residue method. S-UE can hydrolyze urea into ammonia, water and carbon dioxide. After incubating fresh soil and urea at 37℃ for 5 hours, the urea residue was determined and the activity of S-UE was estimated. The activity of S-UE was expressed by the mass (mg) of urea nitrogen reduction per unit time.

Data processing

Microsoft Excel 2016 and SPSS 22.0 were used to analyze the test data. The determination of s-ue (urease) activity by urea residue method is improved on the basis of research method: take 1 g soil (rhizosphere soil stored at -20℃) and add 9 ml sterile water, mix it with vortex, take 200 μl soil suspension respectively and add it into 50 ml sterilized medium (Ca-P, Fe-P and Al-P liquid medium), culture it in 160 r min^{-1} shaking bed at 30℃ for 9 days, and take 5 ml soil suspension every 1 day. After

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26692685

centrifugation at 4000 r min^{-1} and 4℃ for 10 min, the supernatant was taken to determine the effective phosphorus content and pH. The treatment was repeated 3 times.

Results

Effects of different fertilization periods and modes on soil enzyme activities in the rhizosphere of Salicornia Salsa

In order to verify the effect and feasibility of the method in this paper, an experiment is set up for verification. The soil culture dish diagram of the experimental plant is shown in *Figure 1*.

Figure 1. *Dish chart of experimental plant soil*

Effects of different fertilization periods and modes on S-SC activity of Salicornia salsa rhizosphere

Table 3 describes the effects of different fertilization stages and modes on S-SC activity in the rhizosphere of Salicornia salina.

Table 3 showed that both fertilization and mulching methods were beneficial to the improvement of S-SC activity in Salicornia salina rhizosphere soil. The effect of film mulching combined with fertilization was the best, and the S-SC activity was significantly higher than that of non-film mulching and non-fertilization, showing significant difference. Among them, S-SC activity was the highest on June 20 when the fertilizer was applied with plastic film for 15 days. The S-SC activity of mulching treatment and fertilization treatment also increased, but the effect of the two treatments was different. The S-SC activity of mulching treatment was the highest at 15 days of sampling on July 1, and the S-SC activity of fertilization treatment was the highest at 45 days of sampling on July 1. Soil S-SC activity was also affected by different fertilization stages, which showed that the S-SC activity was the highest in the treatment on July 1. The S-SC activity of each treatment was higher in the 15-day sampling on June 20. The S-SC activity of each treatment was higher in the 45-day sampling on July 1. The S-SC activity of each treatment was higher in the 45-day sampling on July 10. The S-SC active phase of each treatment was the highest in the 45-day sampling on July 10.

Table 4 shows that both fertilization and mulching methods are beneficial to the improvement of S-CAT activity in Salicornia salina rhizosphere soil. The effect of combined application of film mulching and fertilizer was the best, and the activity of S-CAT was significantly higher than that of non-film mulching and non-fertilization, showing a significant difference. The S-CAT activity was the highest on June 20 when the treatment of plastic film mulching fertilization was sampled for 15 days. The S-CAT activity of plastic film mulching treatment and fertilization treatment also increased, but

DOI: http://dx.doi.org/10.15666/aeer/1802_26692685

the effect of the two treatments was different. The S-CAT activity of the two treatments was the highest when they were sampled for 15 days on July 1. Different fertilization time also affected the activity of S-CAT, which was the highest in the treatment on July 1, and it was found that the activity of S-CAT was higher in the treatment on the 15th day of sampling.

Effects of different fertilization periods and manners on S-UE activity in rhizosphere of Salicornia salsa

Table 5 describes the effects of different fertilization periods and modes on S-UE activity in the rhizosphere of Salicornia salina.

Table 5 shows that both fertilization and film mulching are beneficial to the improvement of S-UE activity in Salicornia rhizosphere soil. The effect of film mulching combined with fertilization was the best, and the S-UE activity was significantly higher than that of non-film mulching and non-fertilization, showing significant difference. The S-UE activity was the highest on July 1st when the film mulching treatment was taken for 15 days. The S-UE activity of mulching treatment and fertilization treatment also increased, but the effect of the two treatments was different. The S-UE activity of mulching treatment was the highest at 30 days of sampling on July 1, and the S-UE activity of fertilization treatment was the highest at 15 days of sampling on July 1. The activity of S-UE was also affected by different fertilization periods. The highest activity of S-UE was observed on July 1. At the same time, it was found that the activity of S-CAT was higher in different fertilization methods at different time.

Effects of point fertilization on soil enzyme activity

Effect of point fertilization on S-SC activity

Figure 2 depicts the effect of hole fertilization on S-SC activity under plastic film mulching. Different lower-case letters in the picture showed significant difference ($P < 0.05$), and the following is no longer repeated.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26692685

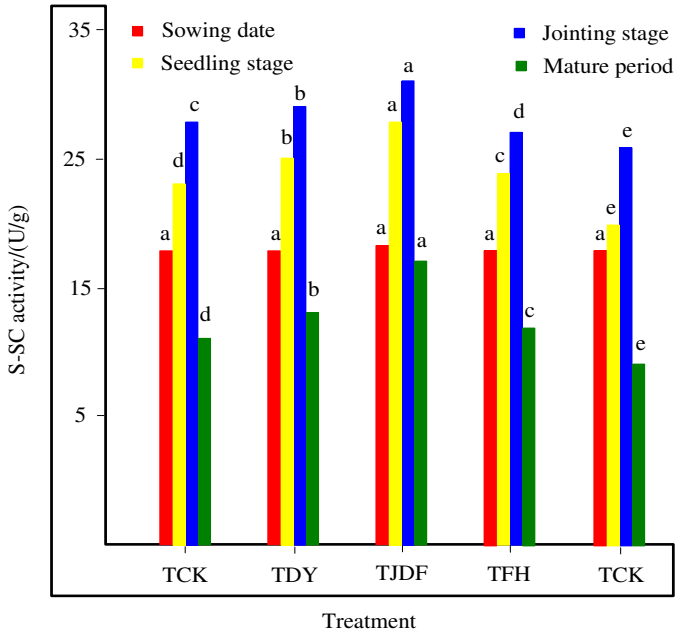

Figure 2. *Effects of point-based fertilization on S-SC activity*

Figure 2 shows that the S-SC activity of Salicornia salicornis showed the same change rule during its growth period, and reached the maximum at jointing stage, then decreased gradually. The activity of S-SC was higher than that of control, and TJDF had the greatest influence on S-SC activity. Compared with the single application of chemical fertilizer (TCK), the enzymatic activities of TJDF treatment increased by 41.9%, 20.7% and 68.0% at seedling stage, jointing stage and maturity stage, 15.1%, 8.7% and 16.6% in TKC treatment, 23.7%, 12.8% and 33.1% in TDY treatment, 17.3%, 4.1% and 23.2% in TFH treatment, respectively. It can be seen that the increase of S-SC activity can be promoted by applying microbial fertilizer. Among them, microbial fertilizer combined with chemical fertilizer (Bacillus amylolytica) has the most obvious effect, followed by microbial fertilizer combined with chemical fertilizer (Bacillus licheniformis).

Effects of point-based fertilization on S-CAT activity

Figure 3 depicts the effect of hole fertilization on S-CAT activity under plastic film mulching.

Figure 3 shows that the activity of S-CAT increases gradually during the growth period of Salicornia salsa. The highest value occurs in the mature stage. The fertilization treatments mainly based on hole application show that TFH treatment has the most significant effect on the activity of S-CAT. Compared with TCK, the activity of S-CAT increased by 7.6%, 9.0% and 6.3% at seedling stage, jointing stage and mature stage, respectively. Therefore, the application of microbial fertilizer can improve the activity of S-CAT, and the effect of microbial fertilizer combined with chemical fertilizer (compound bacteria) is the most obvious. Other fertilization treatments inhibited S-CAT activity.

DOI: http://dx.doi.org/10.15666/aeer/1802_26692685

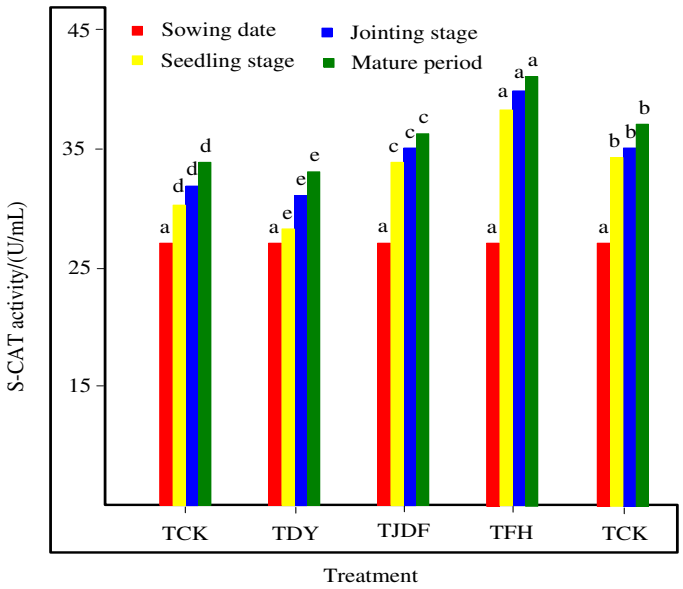

Figure 3. *Effects of point-based fertilization on S-CAT activity*

Effects of point fertilization on S-UE activity

Figure 4 depicts the effect of hole fertilization on S-UE activity under plastic film mulching.

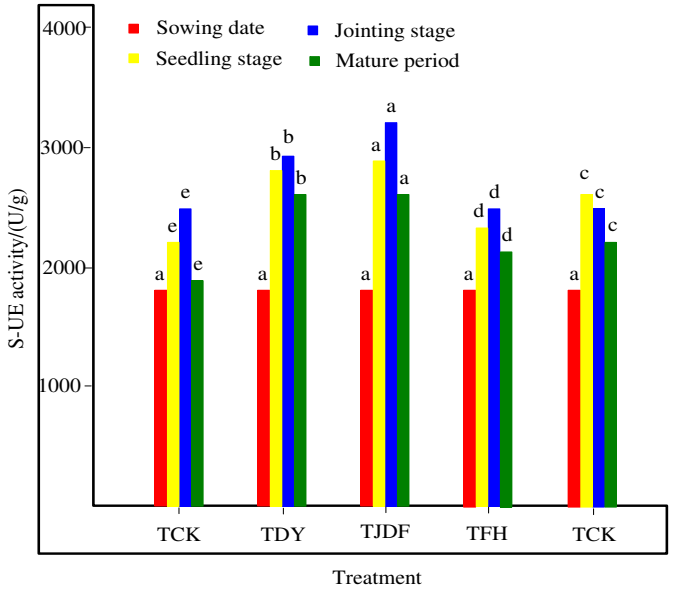

Figure 4. *Effects of point-based fertilization on S-UE activity*

Figure 4 shows that the activity of S-UE increases first and then decreases during the growth period of Salicornia salina, and reaches its peak at jointing stage. Among them, TJDF treatment had the greatest effect on S-UE activity, which increased by 15.8%, 30.4% and 21.8% at seedling stage, jointing stage and maturity stage, compared with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26692685

TCK alone, while TDY treatment increased by 12.7%, 19.7% and 19.9% respectively. Therefore, the increase of S-UE activity can be promoted by applying microbial fertilizer, the most significant effect is the combination of chemical fertilizer and microbial fertilizer (Bacillus amyloliquefaciens), followed by microbial fertilizer (Bacillus licheniformis).

Effects of fertilizer application on soil enzyme activities

Effects of spraying-based fertilization on S-SC activity

Figure 5 depicts the effect of spraying fertilization on S-SC activity under mulched fertilization.

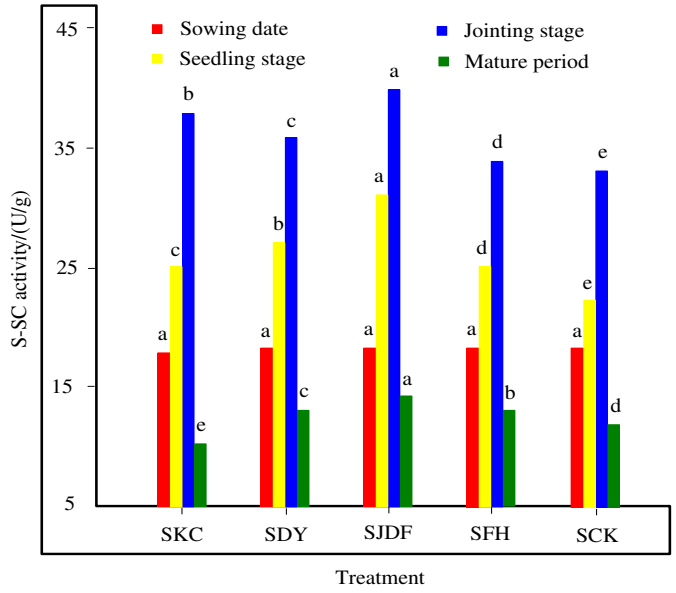

Figure 5. *Effects of spraying-based fertilization on S-SC enzyme activity*

From *Figure 5*, we can see that S-SC activity reached the highest level at jointing stage of Salicornia salsa under spraying mode, and then decreased gradually. Among them, SJDF treatment had the highest enzymatic activity, which increased by 37.4%, 18.6% and 22.9% at seedling stage, jointing stage and maturity stage, respectively, compared with SCK treatment; the enzymatic activity of SKC treatment increased by 11.6%, 12.5% and 2.5%, respectively; the enzymatic activity of SDY treatment increased by 19.3%, 6.9% and 14.8%, respectively; and the enzymatic activity of SFH treatment increased by 19.3%, 6.9% and 14.8%, respectively. They increased by 10.0%, 2.9% and 18.9%, respectively.

S-SC activity of Salicornia salina in seedling and jointing stage was lower than that in spraying mode, but there was no significant difference at maturity stage. During the growth period of Salicornia salsa, the fertilization methods were different, and the activity of Salicornia salicornis was different among different fertilization treatments. The activity of S-SC in seedling stage, jointing stage and ripening stage of Salicornia salsa under different fertilization methods were SJDF > SDY > SKC > SFH > SCK, SJDF > SKC > SDY > SFH > SCK, SJDF > SFH > SDY > SCK > SKC, while the activity of S-SC in seedling stage, jointing stage and ripening stage was
