TJDF=TDY=TFH=TKC=TCK, TJDF=TDY=TKC=TFH=TCK and TJDF=TDY=TFH=TKC=TCK, respectively. Therefore, hole fertilization can promote the comprehensive utilization rate of fertilizer, benefit the absorption and utilization of nutrients by halophytes, and improve soil enzyme activity.

Effects of spraying-based fertilization on S-CAT activity

Figure 6 depicts the effect of spraying fertilization on S-CAT activity under Mulched fertilization.

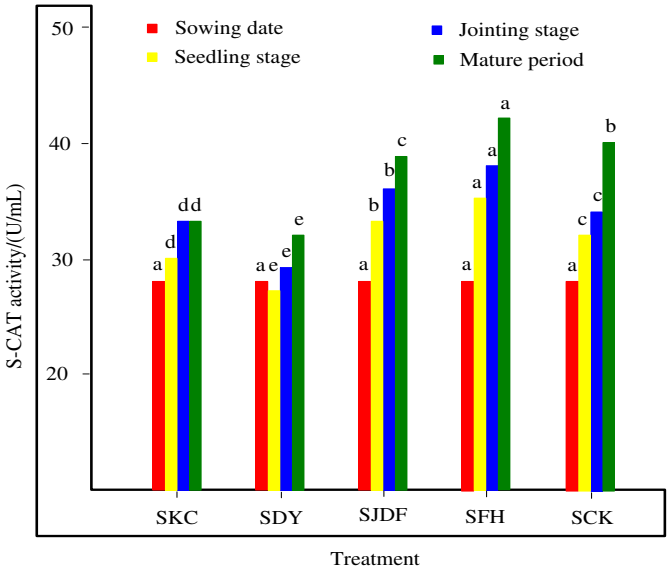

Figure 6. *Effects of spraying-based fertilization on S-CAT activity*

Figure 6 showed that the activity of S-CAT reached its peak at the ripening stage of Salicornia salsa under the spraying mode, and the activity of SFH treatment was the highest. Compared with SCK, the activity of SFH treatment increased by 9.5%, 10.5% and 4.0% at seedling stage, jointing stage and mature stage, respectively. The effect of other fertilization treatments on S-CAT activity was not obvious.

S-CAT activity was higher in seedling stage and jointing stage of Salicornia salsa than in spraying mode, but lower in ripening stage than in spraying mode. During the growth period of Salicornia salsa, there were some differences in S-CAT activity among different fertilization treatments. The activity of S-CAT at seedling stage, jointing stage and maturity stage of Salicornia salsa under different fertilization methods were SFH > SJDF > SCK > SKC > SDY, SFH > SJDF > SCK > SKC > SDY, SFH > SCK > SJDF > SKC > SDY, and the activity of S-CAT at seedling stage, jointing stage and maturity stage of Salicornia salicornis were TFH > TCK > TJDF > TKC > TDY, TFH>TCK>TJDF>TKC>TDY and TFH > TCK > TJDF > TKC > TDY. Therefore, hole fertilization can promote the utilization of fertilizer, benefit the absorption and utilization of nutrients by halophytes, and improve soil enzyme activity.

Effects of spraying-based fertilization on S-UE activity

Figure 7 depicts the effect of spraying fertilization on S-UE activity under Mulched fertilization.

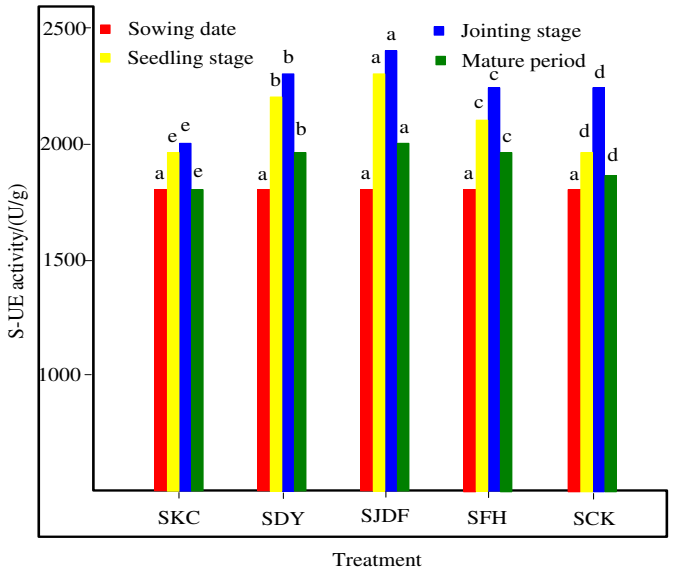

Figure 7. *Effects of spraying-based fertilization on S-UE activity*

Figure 7 shows that the peak value of S-UE activity occurs at elongation stage of Salicornia salsa under spraying mode. SJDF treatment has the greatest effect on S-UE activity. Compared with SCK, the activity of S-UE in SJDF treatment increased by 14.4%, 4.6% and 8.6% at seedling, elongation and maturity stages, respectively; SDY treatment increased by 12.0% and 2.0%, respectively; SFH treatment increased by 4.3%, 0.4% and 6.3%, respectively. The effect of SKC on S-UE activity was not obvious.

S-UE activity of Salicornia salsa was higher than that of Salicornia salicornis in the growth period. The activity of S-UE in the seedling stage, jointing stage and mature stage of Salicornia salicornis was JDF > SDY > SFH > SCK > SKC. Therefore, hole fertilization can promote the utilization of fertilizer, benefit the absorption and utilization of nutrients by halophytes, and improve soil enzyme activity.

Discussions

In this paper, the correlation between long-term different fertilization methods and soil enzyme activities in rhizosphere of halophytes was studied. The effects of different fertilization methods and different fertilization treatments on S-SC, S-CAT and S-UE enzymes in root soil during the development of Salicornia salicornis were studied. The results show that:

The activities of S-SC, S-CAT and S-UE could be promoted by mulching and fertilization at any time. Among them, film mulching combined with fertilization had the best effect, and the three enzymes activities of soil were the highest. This is because the saline soil is hot and dry in summer, and the temperature is high. Film mulching improves soil moisture and temperature, which is conducive to the absorption and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26692685

transformation of soil nutrients, thereby improving soil enzyme activity. The soil enzyme activities of plastic film mulching and fertilization treatments also increased, but the effects of the two treatments were different, which was due to the large fluctuation of temperature in the saline soil area in summer morning and evening. The soil enzyme activity was also affected by different fertilization time, and the soil enzyme activity was the highest when the soil enzyme was sampled on July 1.

The activities of S-SC and S-UE increased first and then decreased with time during the growth period of Salicornia salsa, and reached the highest level at jointing stage. During this period, Salicornia salicornis grew vigorously, its root system developed, and its nutrient demand increased, which stimulated the activities of S-SC and S-UE to increase rapidly to meet the growth needs of Salicornia salicornis. It was soil microbial activity. S-CAT activity gradually increased during the growth period of Salicornia salsa and reached its peak at maturity. Because of the maturity of Salicornia salicornis, the residue and litter of Salicornia salicornis increased in rhizosphere, which induced its activity to increase to oxidize and decompose hydrogen peroxide in soil.

From the effect of different fertilization treatments on soil enzyme activity, it can be seen that the combination of chemical fertilizer and starch-dissolving microbial fertilizer has the greatest influence on S-SC activity and S-UE activity, and the combination of chemical fertilizer and microbial fertilizer of compound bacteria has the greatest influence on S-CAT activity. The results showed that the combined application of chemical fertilizer and starch-dissolving microbial fertilizer could significantly enhance the activity of S-SC and S-UE, and the combined application of chemical fertilizer and microbial compound fertilizer could significantly enhance the activity of S-CAT, because the input of microbial fertilizer and inorganic fertilizer not only provided abundant energy for the soil, but also brought a large number of microorganisms into the soil, thus stimulated the energy metabolism of the soil. It can greatly improve soil enzyme activity. This is consistent with the research results of relevant scholars, so the combination of chemical fertilizer and microbial fertilizer can improve soil environment and soil enzyme activity.

The S-SC activity in the seedling stage and jointing stage of Salicornia salsa was lower than that in the spraying treatment, and the law of maturity was not obvious. This indicated that spraying fertilizer was beneficial to the early absorption of Salicornia salicornis root system, so the S-SC activity was higher in the seedling stage and jointing stage. The activity of S-CAT in the seedling and jointing stage was higher than that in the spraying treatment, and in the mature stage was lower than that in the spraying treatment. This indicated that the hole application was beneficial to reduce the toxic effect of hydrogen peroxide on Salicornia salicornis, which might be caused by root exudates, soil physical and chemical properties, soil environment and crop growth in different growth stages of Salicornia salicornis. As a result, S-UE activity was lower in spraying treatment than in hole application treatment during the growth period of Salicornia salsa, so hole application of chemical fertilizer could improve the effective utilization rate of nitrogen and promote the absorption and utilization of fertilizer by Salicornia salicornis. This may be due to the effects of Fertilization on soil nutrients, mineral elements, root metabolism and secretion activities. In order to reveal the effect of long-term different fertilization methods on the enzyme activity of halophyte rhizosphere soil, the halophyte was used as the research object to carry out the root bag culture on the coastal saline soil. The effects of mulching, non-mulching and no fertilization on the activities of invertase, catalase and urease in rhizosphere soil were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26692685

studied, and the effects of mulching and no fertilization on the activities of invertase in rhizosphere soil were also studied. Catalase and urease in rhizosphere soil of saline alkali soil were studied. Bacillus, Bacillus licheniformis, Bacillus amylolyticus and compound microbial fertilizer all affected the enzyme activities of the three soils. The results showed that mulching could promote the activities of S-SC, S-CAT and S-UE, and the effect of mulching and fertilization was the best at any time. The changes of soil enzyme activity were the same in the growth period. The activities of invertase and urease were the highest in jointing stage and catalase was the highest in mature stage. In conclusion, the application of plastic film mulching combined with fertilization, inorganic fertilizer and microbial fertilizer can improve soil enzyme activity, soil fertility and sustainable productivity.

Conclusions

In this paper, the relationship between long-term fertilization and soil enzyme activity in rhizosphere of halophytes was studied. A typical halophyte, Salicornia salina, was taken as the research object to study the soil enzyme activity in rhizosphere during the growth period of Salicornia salicornis under different fertilization methods and fertilization treatments. The results showed that the activities of S-SC, S-CAT and S-UE could be promoted by mulching and fertilization, and the effect of mulching combined with fertilization was the best. Different soil enzymatic activities showed different changes during the growth period of Salicornia salina. Soil invertase and soil urease activities showed a trend of increasing first and then decreasing, and soil catalase activity showed a trend of increasing gradually. There are some differences in soil invertase, catalase and urease activities under different fertilization treatments. The long-term application of organic fertilizer and chemical fertilizer can improve the content of soil organic matter, nitrogen and phosphorus nutrients, and enhance the activities of soil invertase, protease, pulse enzyme, phosphatase and catalase. In a certain control period, the transformation of soil available nitrogen and phosphorus is related to growth and development stage, soil enzyme activity and fertilization mode. Single application of chemical fertilizer is not conducive to the improvement of soil organic matter and nitrogen and phosphorus nutrients, and the enzyme activity of soil is also low. The relationship between fuel, feed and fertilizer in rural areas is quite contradictory. Crop straw is mainly used for fuel, feed and paper making. In fact, the residue in the soil every season is only crop stubble. Therefore, the long-term application of livestock manure and green manure in the medium and low yield soil is conducive to the increase of soil organic matter content and the enhancement of soil biological activity, and creates a good soil biochemical environment for the stable and high yield of crops.

Therefore, hole fertilization can improve the comprehensive utilization rate of fertilizer, promote the transformation and release of nutrients in soil, and benefit the growth and development of halophytes. Different fertilization treatments showed that microbial fertilizer combined with chemical fertilizer could improve soil environment, enhance soil enzyme activity, and provide favorable growth conditions for halophytes. Therefore, under the combination of plastic film mulching and fertilization, hole fertilization is the main treatment. Adding microbial fertilizer can improve soil enzyme activity, physical and chemical properties, and promote soil fertility level and sustainable production capacity. In the future research, we can study how to reduce the

DOI: http://dx.doi.org/10.15666/aeer/1802_26692685

transformation and release time of soil nutrients, and provide strong experimental data and theoretical reference for the research of soil enzyme activity.

(Received 3rd Sep 2019; accepted 12th Feb 2020)

Abstract. The objective of this experiment was to study the differentially expressed proteins and genes of edible lily in alpine environment, and to provide a better growth environment for edible lily. The edible lily of Heilongjiang Province, China, was selected as the object of the study. The samples were divided into two groups. The first group grew normally in the artificial climate box; the second group was treated at 4℃ for 16 hours after spraying with Abscisic Acid (ABA) hormone, and the second group included edible lily No. 1 and edible lily No. 2. The total protein of one leaf was extracted by the trichloroacetic acid-acetone method and the differential protein spots of edible lily were analyzed by DeCyder software. The leaf genes of two edible lilies were extracted based on cold-resistant gene primer design. The results showed that alpine environments could induce energy metabolism, fatty acid metabolism, photosynthesis and signal transduction of differential proteins in edible lily; exogenous ABA could promote Coscisic Rirna (COR) gene expression by activating transcription factors dependent on ABA signaling pathway, and to some extent, it promotes the expression of cold resistance genes in signal pathways independent of ABA, and improves the cold resistance of edible lily.
Keywords: *differentially expressed proteins and genes, Abscisic Acid, cold-resistant gene primer design, energy metabolism, fatty acid metabolism*

Introduction

Alpine environment is one of the main stress factors for lily growth processes. Alpine environment seriously damages Lily growth, even causing physiological imbalance of the whole lily, and bringing serious losses to production and ornamentation (Wei et al., 2017). Edible lilies are mainly distributed in the north temperate zone, the lowest temperature in winter can reach -35℃, but edible lilies can spend winter open field, adapt to the cold environment and continue to germinate and blossom in the next spring (Lu et al., 2017). In addition, they also have the ability to resist high temperature, drought and change soil salinity. However, with the deterioration of the ecological environment, the number of edible lilies has gradually decreased in recent years. Therefore, it is necessary to further protect the edible lily resources and explore the signal-induced expression of cold tolerance of Edible Lily in alpine environment. At present, there are many studies on Lily growth and yield in China. The results show that temperature and drought are the ecological factors restricting Lily regional distribution, abiotic stress directly affects Lily growth and development and yield, and even causes physiological imbalance of lily, which is the main reason for reducing Lily ornamental value (Templ et al., 2017).

The objective of this experiment was to study the differentially expressed proteins and genes of Edible Lily in alpine environment, and to provide a better growth environment for edible lily. In this paper, the differential protein analysis of edible lily and the effect of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26872701

exogenous Abscisic Acid (ABA) on cold resistance gene expression in alpine environment were used to study the differential protein and gene expression of edible lily induced by two cold tolerance signals. ABA is a signal factor of plants responding to external stresses. The content of endogenous ABA increases significantly during cold acclimation, indicating that external cold stress increases ABA levels in plants and ABA is involved in signal transduction. With the development of signal transduction pathway research, ABA has become a research hotspot. It can induce related genes in stress response, and make them up-regulated or down-regulated. The ecological balance and metabolic activity of lily were affected by external stress. The expression of differentially expressed genes and the changes of differentially expressed proteins indirectly reflected the physiological activities of lily during the same period. Lily resumed normal metabolism through self-repair and regulation. Therefore, the study of proteomics will further explore the signal transduction pathway of Lily in response to external stress. Edible lilies live in a low temperature environment. In order to adapt to cold conditions, the protein and gene expression in Lily cells will change in response to cold stress. Lily was induced by cold stress and ABA hormone. The differential proteins were identified and classified by protein spectrum identification technology. The effect of ABA on the regulation process of cold-resistant genes of edible lily under cold stress was clarified. The relationship between the changes of protein points in Lily and the adaptation of cold and low temperature environment was discussed. Inverse mechanism and further scientific basis were provided to complete the signal-induced expression of cold tolerance of Edible Lily in alpine environment.

Materials and methods

Materials

Lily was selected from Heilongjiang Province of China for food (the same bulb should be propagated with the same genotype). Sample treatment was divided into two groups: CK 0 h, i.e. the control plant grew normally in the artificial climate box; ABA + cold-treated 16 h, i.e. the lily was treated at 4℃ for 16 h after spraying ABA hormone. Sample 1 contained two kinds of Lily cultivars, edible lily 1 (10 lily leaves) and edible lily 2 (10 lily leaves), respectively. Sample 2 contained two kinds of Lily cultivars, edible lily 1 (10 lily leaves) and edible lily 2 (10 lily leaves). The mean minimum temperatures of two kinds of edible lilies collected in No. 2 Middle School were 4℃, 0℃, -10℃ and -25℃, respectively. When sampling, 50 lilies with the same growth were randomly selected, washed with distilled water, dried and cut into 0.5 cm segments. After mixing, the leaves were frozen in liquid nitrogen and stored in a refrigerator at -80℃. Then the edible lily leaves of Sample 1 were taken to extract protein. The leaves of Edible Lily in Sample 2 were taken to extract genes.

Main instruments for testing

The test instruments include: GE Amersham (USA), Second-dimension: Hofer SE600 (GE Amersham), Scanner: UMaxPowerlook 21 IOXL (GE Amersham). Leica DFC500 stereo microscope, BIO-RAD UV Gel imaging system, BIO-RAD SmartSpec Plus UV spectrophotometer, BeckMan Coulter Allegra 648 centrifuge, Illumina company's Solexa genome analyzer (Allegra), fluorescence quantitative analyzer, sterilizing pot, 54158 centrifuge, G-storm-482 PCR, TaiSite water bath pot, Microwave oven (*Figure 1*).

(a) Microscope (b)Spectrophotometer (c)Fluorescence quantitative analyzer

Figure 1. *Main instruments for testing*

Test reagent

The main reagents were solid phase pH gradient (IPG) tape (24 cm, pH 3-11), IPG buffer pH 3-11, and ammonium bicarbonate was purchased from Sigma Company. CHCA (Sigma No. 034K3707), Merck No. 1499230-935, Merck No. 56002262-009, Mass Standards Kit for the 4700 Proteomics Analyzer (AB SCIEX No. 4333604), concentrated sulfuric acid, onion ketone, acetic acid, acetic acid, beta-sparse ethanol, EASYspinPplant RNA rapid extraction kit of Adelai Company (RLT, RLT Plus, RW1, RW, RNase-free H20, PLANTaid, Genomic DNA Clearance Column and Collection Tube, RNase-free Adsorption Column and Collection Tube), Promega'sPolyATtract RNA Isolation System III with mAGnetic Stand BioTinyLated-Oligo (dT), 20×SSC M-MLV RTase Gene Synthesis Kit (5×1 st strand synthesis Buffers 5×2 st strand synthesis Buffer, dNTP Mixtures RNase Inhibitor Oligo (DT), Reverse Transcriptase (M-MLV) (200 U/mL), EcoDNA Polymerase I, E. DNA Li Gase Mixture, T4 DNA Polymerase, Tris-HCL (pH 7.6), MgCL2, DTT, ATP, T4 DNA Ligase, EDTA, SDS, phenol/chloroform/isoamyl alcohol (25:24::1).

Method

The study was conducted on edible lilies in the alpine environment. The main picking site is Gansu Province in China, located between 32°11'-42°57' north latitude and 92°13'-108°46' east longitude. The terrain of Gansu is narrow and long, and the landforms are complex and diverse. The mountains, plateaus, Pingchuan, river valleys, deserts, and Gobi are surrounded by mountains and mountains. The terrain slopes from southwest to northeast. Gansu is located at the intersection of the three plateaus of the Loess Plateau, the Qinghai-Tibet Plateau and the Inner Mongolia Plateau. The annual average temperature is 0-15°C. Taking edible lily in this area as a research example, the induced expression of lily cold tolerance signal in alpine environment was studied.

Extraction of total protein from edible lily leaves

Lily protein was extracted by trichloroacetic acid-acetone method (Shimo et al., 2017).

(1) Take a sample of about 1 g tissue, grind it with liquid nitrogen, add 45 mL TCA/acetone solution, stay overnight at -20℃, and centrifuge for 30 minutes to remove the supernatant.

(2) Add equal volume precooling acetone, centrifuge to remove supernatant, repeat this step until acetone is completely colorless; dry and precipitate at room temperature.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26872701

(3) 1.5 mL 2D pyrolysis solution was added to the dry powder of each group, and the supernatant was obtained by ice-bath ultrasonic cooling treatment (100 W, 10 s, 15 s interval, 10 times); 12 000 rpm, 4℃, 30 min.

(4) Quantitative: Bio-Rad protein assay reagent was used to quantify and stored at -80℃.

Identification of differentially expressed proteins in Edible Lily

The differential protein spots of edible lily (Liu et al., 2017) were analyzed by DeCyder software. The original mass spectrometry documents were retrieved by in-gel enzymatic hydrolysis, Ziptip desalination, mass spectrometry analysis and Mascot 2.2 software. The identified protein results (Donaldson et al., 2017) were obtained.

Primer design of cold resistance gene

Based on the existing data of DFCI Wheat Gene Index and NCBI, the primers with good performance (Ahmed et al., 2019) were designed using the conserved regions of each coding enzyme and cold-resistant gene as templates. Primers should be designed strictly according to the requirement of real-time quantitative reaction in order to obtain primers with high amplification efficiency and specificity. The primers of cold-resistant genes were designed according to the requirements of fluorescence quantitative PCR, as shown in *Table 1*.

Results

Extraction and quantification of protein from Edible Lily leaves

Using 2-D quant Kit to quantify the total protein of Sample 1 and accurately quantify the lily protein is the precondition for the follow-up study of differential proteome. SDS-PAGE single-dimensional electrophoresis was used to further verify the quantitative results. Quant Tool software analysis and visual observation showed that the results of protein display were more accurate, indicating that the quantitative results of these proteins can continue to be used in the follow-up study of differential proteins. The results of protein quantification are shown in *Table 2*.

Identification of differentially expressed protein profiles in Edible Lily

In this study, 21 protein spots were selected and identified by MALDI-TOF mass spectrometry after two-dimensional electrophoresis analysis using imageMaster 2D Elite Platnum software. Finally, 20 proteins were obtained complete peptide fingerprints, and 19 proteins were successfully identified by searching MIPS database. The identification results are shown in *Table 3*.

Functional analysis of differentially expressed proteins in edible lily under different treatment conditions

Table 3 shows that a protein can participate in different biological processes and play different roles in response to external stresses. Four differentially expressed proteins are stress response related proteins. Three proteins are involved in signal transduction, four proteins are related to energy metabolism, three proteins are related to photosynthesis response, and the other three proteins may be involved in other biological processes. In this study, stress response related proteins, signal transduction proteins and energy metabolism proteins were introduced in detail.

Changes in expression of stress-related proteins

Four differentially expressed proteins are stress response-related proteins, namely J24:LEA synthetic protein; K2:transcriptase family protein; K9:stress-induced protein. The expression of PR-107 was significantly down-regulated, while the expression of other proteins was significantly up-regulated. Protein Point K4: Some results of mass spectrometry identification of cell disease resistance protein PR-107 are shown in *Figure 2*.

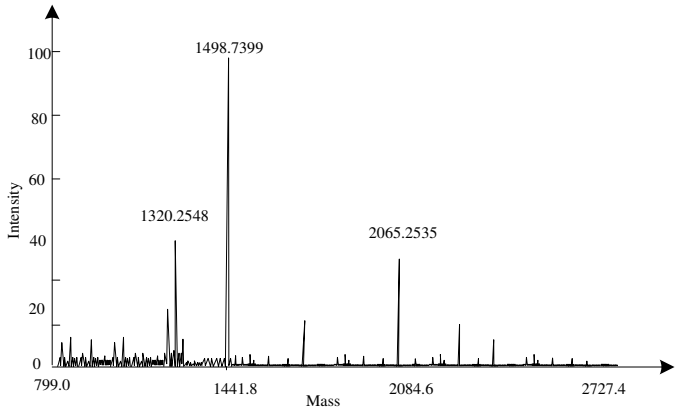

Figure 2. *Protein point K4 mass spectrometry identification partial results*

Participation in signal transduction proteins

In this study, three signal transduction related proteins were identified, namely K14: receptor protein kinase; K19: combined transporter; K20: peptide-prolylcis-trans isomerase. The expression of K14 and K19 protein was significantly up-regulated, but the abundance of the peptide-prolylcis-trans isomerase K20, which played a role in protein folding, was down-regulated under low temperature stress. K14: Some of the results of mass spectrometric identification of receptor protein kinases are shown in *Figure 3*.

Proteins involved in energy metabolism

In this study, four differentially expressed proteins, K5:ATP synthase; K6:ribose-1,5-diphosphate carboxylase/oxygenase subunit; K8:2,3-diphosphate glycerol mutase, were identified under the regulation of low temperature stress. The expression abundance of these three proteins was more than two times under cold stress and increased

DOI: http://dx.doi.org/10.15666/aeer/1802_26872701

significantly. K15 is malic deoxygenase, and its expression is significantly up-regulated. K6: Some results of the identification of ribose-1,5-diphosphate carboxylase / oxygenasemacrosubstrates are shown in *Figure 4*.

Effect of exogenous ABA on cold-resistant gene expression of Edible Lily in alpine environment

Effects of exogenous ABA on the expression of CBF and COR genes independent of ABA in edible lily under high and cold environment

The expression of TaCBFII-5.2 gene in leaf control group of two edible lily cultivars increased first and then decreased. The expression of TaCBFII-5.2 gene in leaf control group of edible lily cultivar No. 2 increased again at -25℃. The peak values above 0℃ were shown in *Figure 5a* and *Figure 5b*. Exogenous ABA treatment promoted the expression of TaCBFII-5.2 gene in the leaves of edible lily No. 1 and reached a significant level at temperatures above 0℃ ($P < 0.05$); in the leaves of edible lily No. 2, the expression of TaCBFII-5.2 gene in the ABA treatment group was higher than that in the control at 4℃, and reached a significant level ($P < 0.05$), but at temperatures below 0℃ and below. The expression of the gene in the ABA treatment group was lower than that in the control group, and the difference reached significant level at 0℃ and -25℃ ($P < 0.05$).

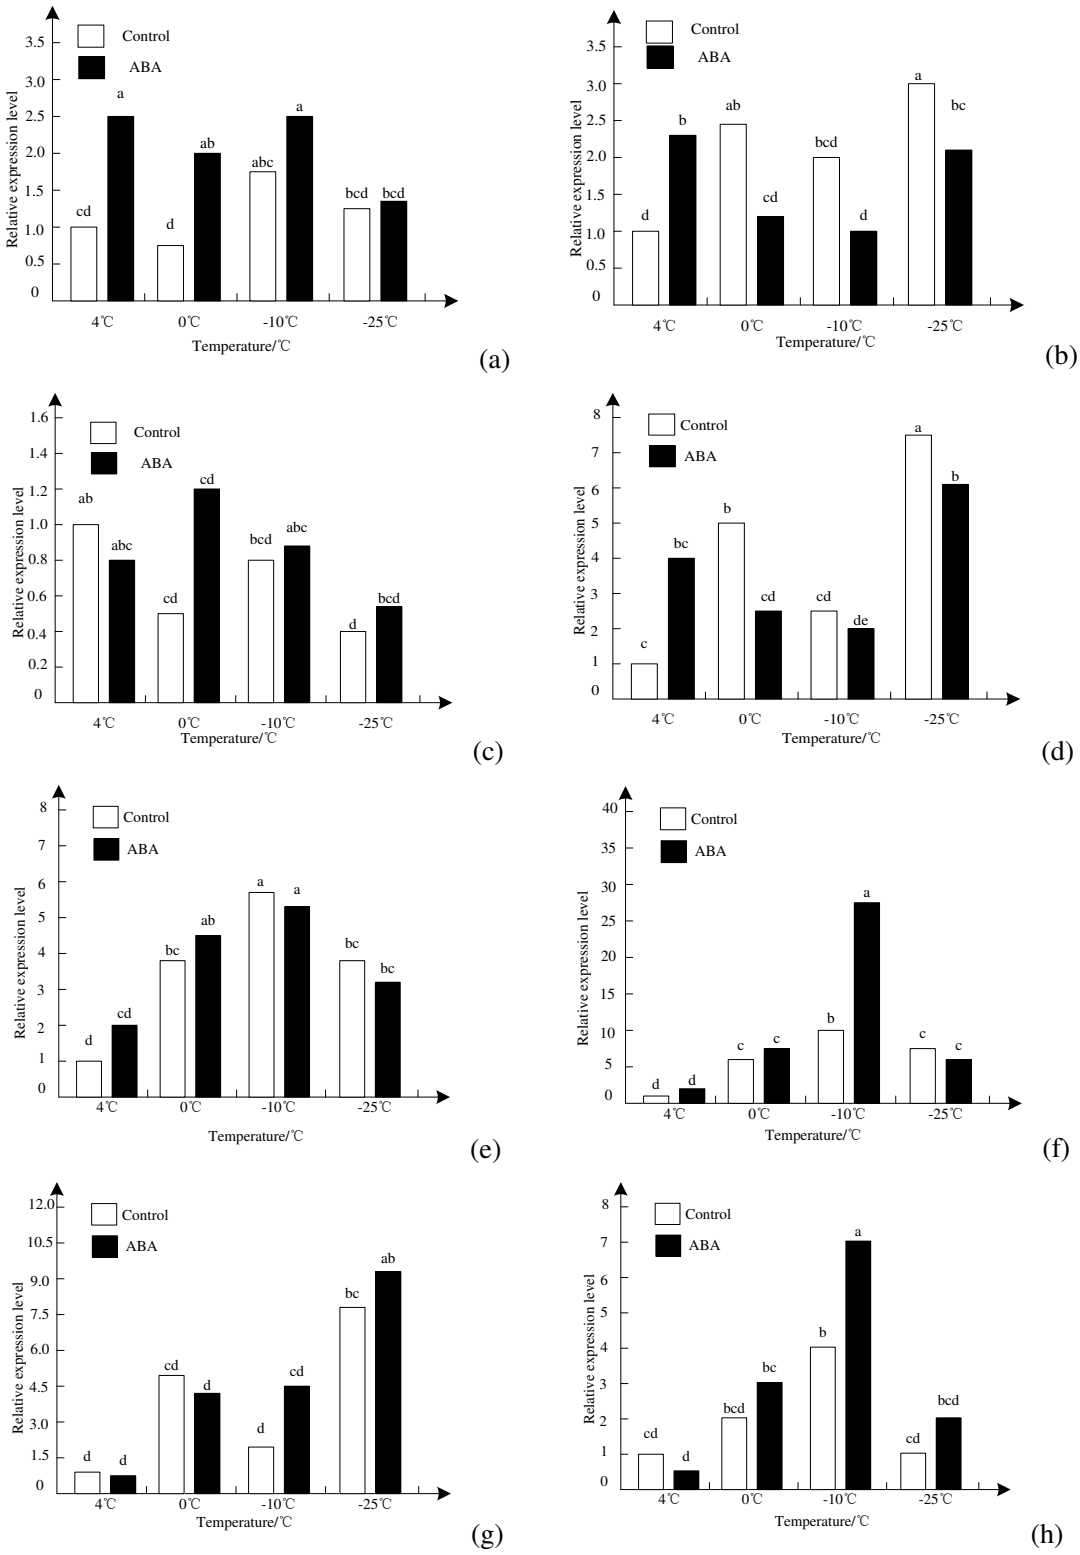

Figure 5. *Relative expressions of TaCBFII-5.2, TaWcorl5, TaWcs 120 and TaCOR39 in leaves of two edible lilies at low temperature during winter. There were significant differences in different letters of edible lily of the same cultivar ($p < 0.05$); TaCBFII-5.2, TaWcorl 5, TaWcs 120, TaCOR39 genes of edible lily No. 1 leaves were a, c, e and g respectively, and TaCBFII-5.2, TaWcorl 5, TaWcs 120 and TaCOR39 genes of edible lily No. 2 leaves were b, d, f and h, respectively*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26872701

The expression of TaWcorl15 gene in the leaf control group of edible lily No. 1 showed a downward and downward trend. As shown in *Figure 5c*, the expression of TaWcorl5 gene was inhibited by exogenous ABA at the initial stage of low temperature at 4℃, but the expression of TaWcorl5 gene was promoted after the temperature continued to decrease, but the difference was not significant. The expression of TaWcorl5 gene in the leaves of control group No. 3 showed a rising and falling trend. As shown in *Figure 5d*, exogenous ABA only promoted the expression of TaWcorl5 gene at 4℃ (< 0.05) in the early stage of low temperature, but inhibited the expression of TaWcorl5 gene at other temperatures, and reached a significant level at 0℃ (< 0.05) and -25℃ (< 0.05).

The expression of TaWcs 120 gene in the leaves of two lily cultivars increased first and then decreased. As shown in *Figure 5e* and *Figure 5f*, the expression of TaWcs 120 gene in the leaves of Lily cultivar No. 1 treated with ABA was higher than that in the control at temperatures above 0℃, while the expression of TaWcs 120 gene was inhibited at temperatures below 0℃, but the expression of TaWcs 120 gene was inhibited at temperatures below 0℃. At all temperatures, there was no significant difference between the two treatments. The expression of TaWcs 120 gene in the leaves of Lily No. 2 treated with ABA was higher than that in the control group at temperatures above -10℃, and reached a significant level at -10℃ ($P < 0.05$). The expression of TaWcs 120 gene in the leaves of Lily No. 2 treated with ABA was lower than that in the control group at late -25℃ ($P < 0.05$), but the difference between the two treatments was not significant.

The expression of TaCOR39 gene in leaves of two edible lily control groups increased first and then decreased, as shown in *Figure 5g* and *Figure 5h*. However, at the lowest temperature -25℃, the expression of the gene in the leaves of edible lily No. 1 increased to a peak. In the leaves of Lily cultivars, ABA inhibited the expression of TaCOR39 gene in the early stage of low temperature, and promoted the expression of TaCOR39 gene in the late stage of low temperature, but the difference between the two treatments was significant only at -10℃ ($P < 0.05$).

Effects of exogenous ABA on the expression of ABA-dependent transcription factor genes and COR genes in edible lilies in alpine environment

TaCBFIVd-D22, TaMYB80 and TaWabi5 are ABA-dependent transcription factors.

The expression of TaCBFIVd-D22 gene in the leaves of the control group showed a downward and downward trend. As shown in *Figure 6a*, exogenous ABA significantly inhibited the expression of TaCBFIVd-D22 gene at the initial stage of low temperature ($P < 0.05$), and increased the expression of TaCBFIVd-D22 gene at the lowest temperature, reaching a significant level at 0℃ and -10℃ (< 0.05). The expression of TaCBFIVd-D22 gene in the leaves of edible lily No. 2 increased as a whole. As shown in *Figure 6b*, exogenous ABA significantly promoted the expression of TaCBFIVd-D22 gene ($P < 0.05$) in the early stage of low temperature at 4℃, but inhibited the expression of TaCBFIVd-D22 gene when the temperature continued to decrease, reaching a significant level at 0 and -25℃ ($P < 0.05$).

The expression of TaMYB80 gene increased first and then decreased with the decrease of temperature in the control group. As shown in *Figure 6c and 6d*, exogenous ABA treatment promoted the expression of TaMYB80 gene in the leaves of edible lily No. 1. The difference between the two treatments was significant at low temperatures ($P < 0.05$). In edible lily No. 2 leaves, exogenous ABA significantly promoted the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26872701

expression of TaMYB80 gene only at 4℃ in the early stage of low temperature ($P < 0.05$), and inhibited the expression of TaMYB80 gene at other temperatures, especially at 0℃ and -25℃.

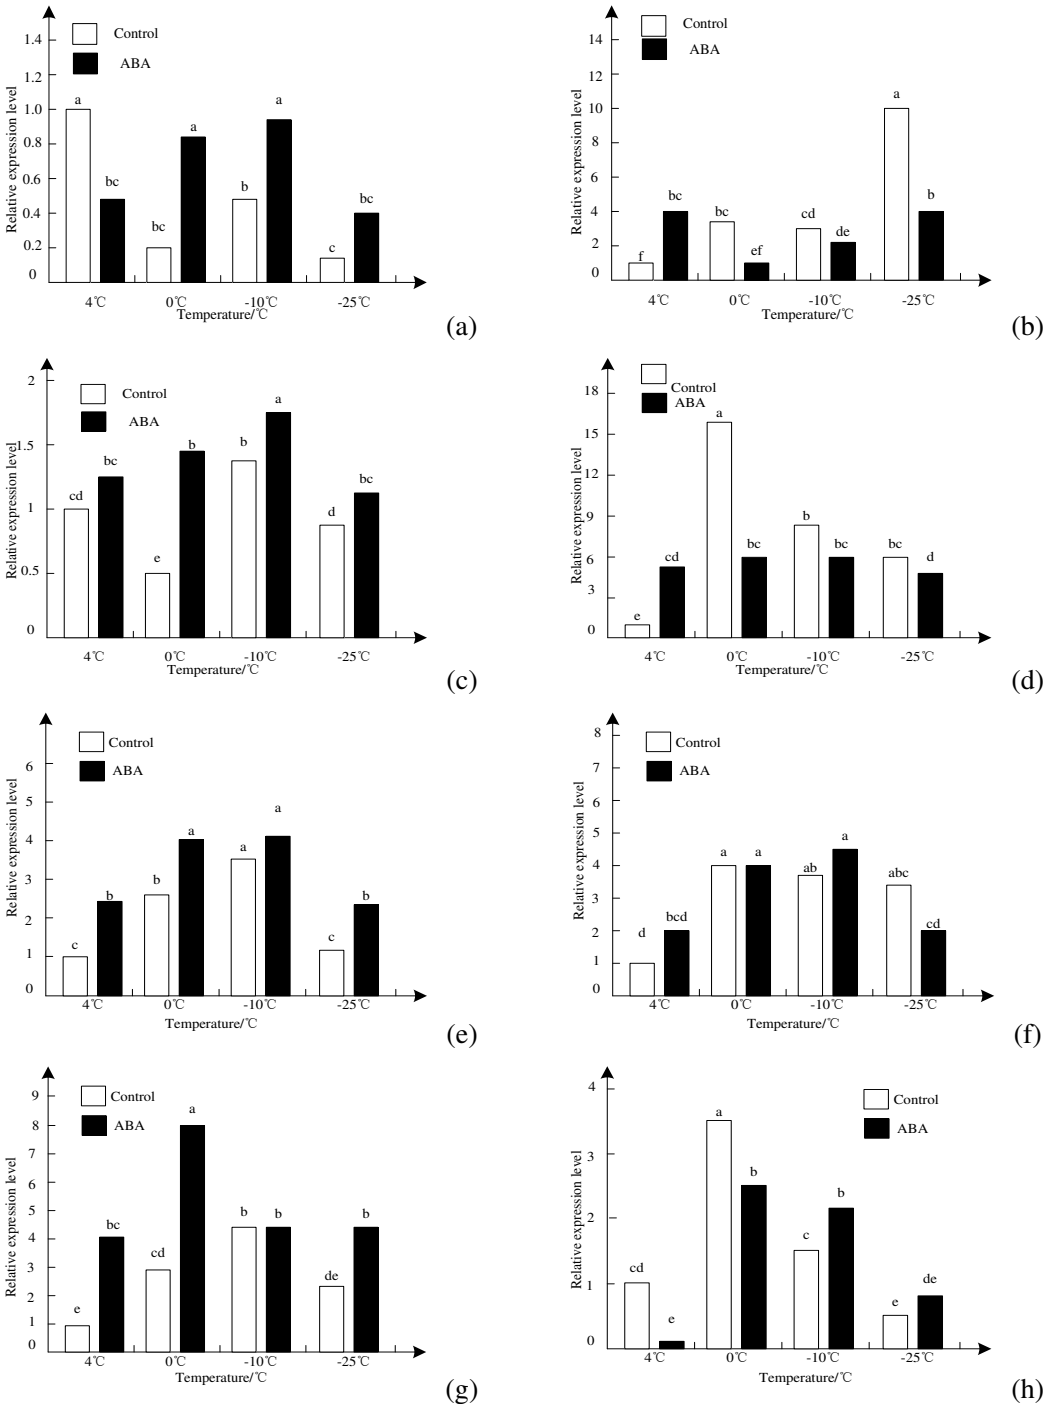

Figure 6. *Relative expressions of TaCBFIVd-D22, TaMYB80, TaWabi5 and TaWrabl7 in leaves of two edible lilies during winter. There were significant differences in different letters of edible lily of the same variety ($p < 0.05$); TaCBF1Vd-D22, TaMYB80, TaWabi5 and TaWrabl7 genes of edible lily No. 1 leaf were TaCBF1Vd-D22, TaMYB80, TaWabi5 and TaWrabl7 genes respectively; and b, d, f and h genes of edible lily No. 2 leaf were TaCBF1Vd-D22, TaMYB80, TaWabi5 and TaWra7 genes, respectively*

DOI: http://dx.doi.org/10.15666/aeer/1802_26872701

TaWabi5 belongs to the transcription factor of bZIP family. The expression of TaWabi5 gene in the leaves of two edible lily varieties increased first and then decreased. As shown in *Figure 6e and 6f*, exogenous ABA treatment promoted the expression of TaWabi5 gene in the leaves of edible lily No. 1. Except -10℃, the difference reached significant level ($P < 0.05$). In the leaves of edible lily No. 2, the expression of TaWabi5 gene reached a significant level ($P < 0.05$). Exogenous ABA promotes the expression of the gene at degree, but there is no significant difference between the two treatments, it inhibits the expression of the gene at the late stage of low temperature -25℃, and the difference is not significant.

TaWrabl7 belongs to ABA-dependent COR gene. The expression of TaWrabl7 gene in the leaves of two edible lilies increased first and then decreased, as shown in *Figure 6g and 6h*. In edible lily No. 1 leaves, exogenous ABA promoted the expression of TaWrabl7 gene, reaching a significant level ($P < 0.05$) except -10℃. In edible lily No. 2 leaves, exogenous ABA significantly inhibited the expression of TaWrabl7 gene at temperatures above 0℃, while temperature continued to decrease, and then promoted its expression at -10℃. In edible lily No. 2 leaves, exogenous ABA significantly inhibited the expression of TaWrabl7 gene. The difference was significant ($P < 0.05$).

Discussions

Functional analysis of differential proteins

Mass spectrometry analysis revealed that differential proteins were mainly involved in the balance of photosynthetic respiration, carbon, nitrogen, sulfur and energy metabolism, protein translation, protein processing, signal transduction, RNA processing and redox (Tang et al., 2017). In this study, differential proteomics of edible lily leaves under low temperature stress was studied. Twenty-one protein spots were selected and identified by MALDI-TOF mass spectrometry (Wu et al., 2018) after the analysis of protein spots with more than two-fold abundance in two-dimensional electrophoresis (2-DE) by using ImageMaster 2D Elite Platnum software. Finally, 20 proteins obtained complete skin fingerprints. These 19 proteins were successfully identified by searching the MIPS database. The identification results showed that they were involved in energy metabolism, fatty acid metabolism, photosynthesis and signal transduction. The possible physiological functions of these proteins in response to low temperature stress are discussed below.

Stress-related proteins

The Edible Lily will produce a series of proteins with protective function after being stressed by adversity. Late embryogenesis abundant proteins (LEA proteins) is one of the most important proteins (Li et al., 2017). LEA protein was first discovered in 1981. It can be enriched in the process of dehydration during the late stage of embryonic development and can improve the resistance of seeds to dehydration (He et al., 2019). Dehydration is a highly hydrophilic and molecular chaperone in the metabolic process of edible lily, which can stabilize the structure and properties of cell membranes, avoid protein denaturation caused by water shortage caused by low temperature stress, and reduce external damage to plants. A large number of studies have shown that cold stress can promote the accumulation of large amounts of LEA protein (Li et al., 2017) in plants. The expression level of LEA protein spots (J24) identified in this study was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26872701

significantly up-regulated, indicating that LEA protein played an important role in the resistance of edible lily to external stresses and reduced the damage of edible lily plants under low temperature stress. K2: transcriptase family protein; K4: cell disease resistance protein PR-107; K9: stress-induced protein, the expression of cell disease resistance protein (K4) was significantly down-regulated, and other protein expression was significantly up-regulated.

Signal transduction related proteins

When lily is stressed, plant cells receive signals, which are received by cell membrane sensors, and then transferred from cytoplasm to nucleus by a second signal molecule, such as catalytic protein kinase. In nucleus, protein kinase C and PPPC can induce Ca^{2+} and ABA pathways respectively to initiate signal transduction (Xu and Zhu, 2017). After opening the defense mechanism, it mainly includes physical structural adaptation, such as changes in lipid composition and extracellular metabolic activities, increased intercellular osmotic protective agents such as soluble sugar, proline, betaine, etc., and up-regulated synthesized antioxidants such as superoxide dismutase, pathogen defense, catalase, ascorbic acid reductase, recovery. The balance of complex biosynthesis and carbohydrate metabolism can improve the survival rate of Edible Lily in cold environment. When most signaling molecules bind to their receptors, they begin to regulate cellular behavior, including intracellular responses to metabolism, exercise, proliferation, survival and differentiation. Finally, the edible lilies were adapted to cold acclimation and resisted external stress (Jiang et al., 2017). In this study, an up-regulated protein, receptor protein kinase (K14, RLK), was identified as a signal-accepting receptor protein with a single transmembrane alpha-helix receptor. When plants respond to low temperature stress, the expression of receptor protein kinase is significantly up-regulated. It is speculated that it may be stimulated by external cold signals and participate in the process of signal transduction in cell membranes and intracellular membranes. It can transmit signals to the nucleus and inspire the expression and regulation of downstream genes. It is a series of physiological and biochemical sounds produced by plants cold stress (Yu et al., 2017). Studies have shown that active protein molecules have specific amino acid sequences and three-dimensional spatial structures, and the sequences of these genes are folded into proteins with specific structures and functions. The polypeptide prolinephthalidecis-trans isomerase CIS (K20) identified in this study has protein folding effect. It belongs to the chloroplast membrane protein, which can transmit cold signals in chloroplasts, and its expression changes directly lead to changes in the structure of chloroplast membrane.

Energy metabolism related proteins

Liu et al. (2017) showed in related research that proteins and enzymes play an important role in plant response to low temperature stress signal pathway, and the expression of genes related to these proteases are up-regulated or down-regulated. Proteins are involved in the primary and secondary metabolic processes of plants in response to stress, especially in osmotic regulators and soluble sugar soluble proteins (Liu et al., 2017). In plants, energy provides essential ATP for various life activities and intermediate metabolites for many metabolisms, so it is the basic metabolism of various life activities (Yu et al., 2018).

In this study, four differentially expressed proteins were identified, including protein points K6, K8 and K15, which play an important role in the tricuspid acid cycle and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26872701

participate in the glycolysis process of material and energy metabolism pathway. Protein point K5 is the key enzyme of oxidative phosphorylation. The increase of their expression level will promote the synthesis of downstream substances and provide essential substances and energy for edible lilies to cope with low temperature stress. At the same time, it can promote the changes of extracellular metabolic activities, restore the balance of biosynthesis and carbohydrate metabolism, and improve the survival rate in cold environment.

Effect of exogenous ABA on cold resistance gene expression

Exogenous ABA can regulate the synthesis of endogenous ABA. ABA plays an important role in ABA-dependent signal transduction pathway. Many studies have shown that ABA may activate bZIP transcription factors and regulate COR genes that depend on ABA. The activation regions of these COR genes contain ABREs. Other transcription factors such as MYC/MYB and CBF4 also play an important role in ABA-dependent stress signal transduction pathways (An et al., 2017). At present, many bZIP transcription factors, MYC/MYB transcription factor, CBF4 gene and ABA-dependent COR gene have been isolated and identified in Edible Lily and other plants. TaWabi5 gene is a bZIP transcription factor in edible lily, TaMYB80 is a MYC/MYB transcription factor in edible lily, TaCBF4 is an ABA-dependent CBF transcription factor in edible lily, and TaWrabl7 belongs to the ABA-dependent COR gene in Edible Lily (Chen et al., 2019). In this study, we found that exogenous ABA promoted the expression of TaCBF4 gene in leaves of edible lily No. 1 at the late stage of moderate and low temperatures, and exogenous ABA promoted the expression of TaMYB80, TaWabi5 and TaWrabl7 genes in leaves of edible lily No. 1, while exogenous ABA only promoted the expression of TaMYB80, TaWabi5 and TaWrabl7 genes in leaves of edible lily No. 2 at the early stage of low temperature at 0℃ or above The expression of these cold-resistant genes was inhibited when the temperature was lowered.

In ABA-independent signaling pathways, low temperature can promote the expression of CBF family transcription factors, while CBF transcription factors may cause the expression of many downstream COR genes to improve plant cold resistance. TaCBFlI-5.2 is a CBF/DREB transcription factor in edible lilies. This study found that in high-cold environment, at temperatures of -10℃ and above. Exogenous ABA promotes the expression of this gene (Lee et al., 2017). Exogenous ABA has no significant effect on the expression of COR gene independent of ABA in the leaves of two edible lilies.

Conclusions

In this paper, the differential protein of edible lily and the expression of cold-resistant gene of exogenous ABA in alpine environment were studied. The research results are as follows:

Differential protein of edible lily showed that differentially expressed protein participated in many life processes such as acceptance and transmission of stress signals, promotion of substance and energy metabolism, regulation of photosynthesis and respiration, and improved the ability of edible lily to resist external stress.

Exogenous ABA may promote COR gene expression by activating transcription factors that depend on ABA signaling pathway, and improve cold resistance of edible

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_26872701

lily. The results show that the effects of exogenous ABA on cold resistance genes in winter Edible Lily are inconsistent in alpine environment. The effect of exogenous ABA on cold resistance gene expression of edible lily may be enhanced by activating transcription factors that depend on ABA signaling pathway. The noise was more obvious in Edible Lily No. 1 than in Edible Lily No. 2. However, exogenous ABA also has some effects on cold-resistant genes in signal pathways independent of ABA, and can promote the expression of these genes to a certain extent. It can be seen that the effect of exogenous ABA on cold resistance gene expression of Edible Lily in high-cold environment is a complex process, and more mechanisms need to be further explored.

(e-mail: gaojiaojiao2019@163.com)

(Received 3rd Sep 2019; accepted 12th Feb 2020)

Abstract. At present, heavy metal pollution seriously threatens the survival and development of natural plants, so it is necessary to use a molecular marker-assisted method to select natural plant physiological genes, select good breeding, and enhance the heavy metal resistance of natural plants. Heavy metal resistance of natural plants was studied, which heavy metal resistance of rice mainly included blast resistance and stripe blight resistance. To study rice blast resistance, improved SDS extraction method was used to extract rice DNA. The obtained DNA solution could be directly used as a template to start PCR amplification. In the study of resistance to stripe blight, the varieties of stripe blight and rice were used as resistance donor parents and resistance receptor parents. The resistance of hybrid plants was identified through hybridization and backcross marker-assisted selection. The results showed that molecular marker-assisted method could identify rice germplasm resources containing Pib gene. Among 18 BC2F3 lines carrying homozygous resistance genes, the disease grade index was 16.0 at the highest level and 0.45 at the lowest level. The resistance level to stripe blight belonged to resistant. The re-harvested Indica rice had better resistance to stripe blight, which could significantly enhance its heavy metal resistance.
Keywords: *molecular markers, natural plants, physiological genes, heavy metals, rice, stripe blight resistance*

Introduction

Heavy metal pollution is in the focus of attention for the world nowadays, mostly concerning the harmfulness of heavy metals to natural plants. Natural plants are the energy, temperature, humidity, light and fresh water obtained by photosynthesis from the sun are the basic needs of plant survival, rice is one of the natural plants. On the one hand, heavy metals are permanently released into the environment and can accumulate slowly in natural plants (Gherib et al., 2017); on the other hand, most heavy metals are not essential elements of natural plants. When the content of heavy metals reaches the tolerance level of a natural plant, excessive heavy metals can destroy the structural components of natural plants, thereby threatening the survival of natural plants. As people pay more attention to the hazards of heavy metals, the remediation technology of heavy metal contaminated soil emerges. Traditional remediation methods for heavy metals have their own defects (Huang et al., 2017). Measures such as guest soil, covering soil and passivator cost a lot but have little effect. At the same time, new pollutants may be introduced to cause more serious harm. Bioremediation technology has become the mainstream remediation technology (Wang et al., 2018a) because of its advantages of wide materials, low price, strong adsorption capacity and easy management. Nowadays, bioremediation technology is taking Rhizobium of leguminous plants as a new research trend to assist natural plants to resist heavy metal stress. Although the new repair methods can overcome most of the drawbacks of traditional repair methods, the research is still in its infancy. In terms of provenance, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27032718

Rhizobium of leguminous plants in natural growth state has little or no ability to assist natural plants in resisting heavy metal uptake, while the practical application effect of leguminous plants with high resistance obtained by gene technology is not clear (Kusch et al., 2016). Whether the community of rhizobia and natural plants has the ability to activate heavy metals in the surrounding environment is not clear; besides the heavy metals absorbed by natural plants, many new problems such as whether the residual heavy metals are harmful to human beings and the environment have not been solved (Liang et al., 2017). In addition, as a new land remediation method, resistant natural plants (organisms with high accumulation and low absorption) have attracted wide attention since 1950s. With the further study at molecular level, it has been found that not only the external characteristics of plants will change under the stress of heavy metals, but also the resistance genes in natural plants response to heavy metal stress by expressing transcriptional proteins. The mechanisms and models of these natural plants have been gradually explored and applied in variety breeding, food safety and land remediation (Shah et al., 2017). In a word, in recent years, the research on heavy metal-resistant natural plants mainly focuses on the screening and marking of resistance genes, analyzing the degree of heavy metal resistance in natural plants, screening out natural plants with strong heavy metal resistance, improving the heavy metal resistance of natural plants and improving the growth status of natural plants (Wang et al., 2018b).

Natural plant resistance refers to the ability of natural plants to adapt to adversity. The acquisition of resistant materials plays a key role in elucidating the whole biological resistance research (Wang et al., 2017). It has been found that natural plants can be identified as stress-resistant by observing their living conditions under stress. They have a wide range of sources, stable heredity, and can adapt to different environments through sexual and asexual reproduction. Therefore, they have become the most common experimental material in scientific research (Wang et al., 2016), which is currently used for research. The main heavy metal-tolerant plants are Rhodiola, centipede, ryegrass and cash crops such as rice and rye. As far as the tolerance of natural plants to heavy metals is concerned, natural plants of different families and genera show different abilities. Generally speaking, woody natural plants have the best tolerance to heavy metal stress (Danilova et al., 2016). Mench et al. studied the responses of common tobacco, yellow tobacco and maize to cadmium stress. The results showed that different natural plants had different tolerance to cadmium due to different physiological metabolism, and the resistance of tobacco was stronger than that of maize. Common tobacco has stronger cadmium resistance than yellow tobacco. Mench et al. also showed that there was a positive correlation between the cadmium stress intensity and heavy metal activation ability of these two tobacco species. Therefore, the heavy metal resistance of natural plants could be analyzed by observing the tolerance of different natural plants and varieties under different concentration gradients of heavy metal stress. However, this method takes a long time and can be used to analyze the heavy metal resistance of natural plants. The observation process is susceptible to the influence of external environment (Beohar et al., 2018). In view of the fact that rice blast strains cannot be shared among the major rice-producing regions in the world, it is difficult to identify the alleles of disease-resistant genes in different rice germplasm resources. With the emergence and rapid development of DNA molecular marker technology, marker-assisted selection technology has become an effective way to select disease-resistant genes correctly. However, the recombination rate between disease-resistant genes and molecular markers varies greatly in different populations, and the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27032718

population constructed with molecular markers is often not a breeding material, which has certain limitations in practical application. In addition, because these molecular markers themselves are aimed only at genes, there may be unconnected situations in a large number of population breeding, leading to the failure of disease-resistant gene selection (Jimenez et al., 2016). Therefore, the best way is to use the disease-resistant gene sequence itself to establish the corresponding molecular markers, quickly and accurately analyze the genetic composition of individuals at the molecular level, so as to realize the direct selection of genotypes, molecular breeding, and obtain natural plants with strong resistance to heavy metals.

Heavy metal resistance of physiological genes of natural plants includes many kinds, and different kinds of heavy metal resistance of natural plants are different. Molecular marker assistant method can significantly improve the accuracy of predicting disease resistance and heavy metal toxicity, salt damage, drought resistance, dry resistance and heat resistance of natural plants. Taking rice as an example, the heavy metal resistance of rice was studied.

Materials and methods

Analysis of rice blast resistance

Test material

Choosing China as the experimental country, the tested rice materials were 122 parents or breeding intermediate materials of hybrid rice such as IRBLb-B, F-145-2 and 93-11, Shuhui 363, Shuhui 527 and D62B. IRBLb-B and F-145-2 were provided by Dr. Lei Cailin, Institute of Crop Science, Chinese Academy of Agricultural Sciences; 93-11 was an indica rice cultivar bred by Jiangsu Lixia River Institute of Agricultural Sciences. IRBLb-B and F-145-2 are monoclonal resistance Pib genetic materials bred by recurrent parents in Heigu, Lijiang New Regiment, while 93-11 does not contain Pib gene. Therefore, IRBLb-B and F-145-2 were used as resistant parents and 93-11 as susceptible parents.

The remaining 120 materials are parents or breeding intermediate materials of hybrid rice developed by Rice Research Institute of Sichuan Agricultural University in recent years. In March 2017, six hybrid combinations were prepared in Yangzhou with IRBLb-B and F-145-2 as female parents, Shuhui 363, Shuhui 527 and D62B as male parents. F1 was planted in Sichuan in the summer of the same year. In September 2017, 100 seeds of each F2 combination were selected for disease resistance test at the Rice Research Institute experimental site of Yangzhou Agricultural University.

Molecular marker-assisted selection

Firstly, Molecular marker-assisted selection (MAS) was used to link resistance genes, and DNA was extracted from resistance genes. The improved SDS method was used to extract DNA. Specific methods are as follows:

a) Take about the leaves of the tender green rice, cut them into grain-sized fragments and put them into a 2 ml centrifugal tube. Sprinkle liquid nitrogen into the tube and quickly smash it with plastic chopsticks (Hu et al., 2016).
b) 400 ml SDS buffer (1 M Tris-Hcl PH8.0, 0.5 M EDTA PH8.0, Nacl, SDS) was added to the tube, and the tube was heated for 30 min at 65 (?) C, during which

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27032718

three to four oscillations occurred, and the mixture of SDS in the tube blade was dark green.

c) Add 100 μl KAc (glacial acetic acid adjusts PH to 8.0 with NaOH) to the tube, mix evenly and insert the centrifugal tube into the ice cube, and rest for 30 min.
d) 600 μl chloroform isoamyl alcohol (24:1) was added to the tube. After homogeneous mixing, it was placed in the shaker and continued to oscillate for 30 min.
e) 8000 rpm was centrifuged for 10 min. The supernatant (about 400 l) was removed and put into 1.5 ml centrifugal tube.
f) Add 600 μl absolute ethanol which is pre-cooled at -20 ℃ and put it in the refrigerator at -20 ℃ for overnight.
g) 1200 rpm centrifugation for 15 min, discarding supernatant, visible at the bottom of the tube gray-white precipitation adherence.
h) Add 400 μl TE buffer (1M Tris-Hcl PH8.0, 0.5M EDTA), dissolve precipitation by oscillation, and keep the refrigerator in reserve at -20 ℃. The obtained DNA solution can be directly used as a template for PCR amplification.

PCR amplification

Polymerase chain reaction (PCR) amplification primers, using the Pib dominant molecular marker reported by Concetta, can specifically amplify the corresponding fragment sequence of the disease-resistant allele Pib. At the same time, using the sequenced indica rice variety 93-11 and the sequence corresponding to the Pib gene as the susceptible sequence, the polymorphism design of the disease-resistant gene Pib on the DNA sequence can specifically amplify (Salgaonkar et al., 2016). The name, sequence, location and expected size of the primers used for PCR amplification are shown in *Table 1*.

Table 1. *Primer names and sequences for PCR reactions*

Primer name	**PibdomF**	**PibdomR**	**Lys145F**	**Lys145R**

Expect size (bp)	365		803	

* represents the polymorphism of the disease-resistant gene Pib is shown below. ** represents the location of specific primer sequence in the Pib resistance gene. See GenBank accession No. AB013448 for details. *** represents the location of specific primer sequence in indica rice 93-11 corresponding to Pib gene

The primer sequence was synthesized by Yingjun Biotechnology Co., Ltd. The PCR reaction system was 25 μl, containing 2.5 μl 10×Buffer, 2.0 μl dNTP, 3.0 μl 4 $mol \cdot L^{-1}$ positive and reverse primers, 0.2 μl 4 $U \cdot \mu l^{-1}$ Taq enzyme, 3.0 μl 20 $ng \cdot \mu l^{-1}$ template DNA and 14.3 μl pure water. The procedure of PCR was as follows: pre-denaturation at 94 for 5 min, denaturation at 94 for 45 s, annealing at 55 for 45 s, extension at 72 for 1.5 min, and extension at 72 for 10 min. The amplified products were electrophoretic in 3% agarose gel, stained with ethidium bromide and photographed under ultraviolet light. When 122 parents or materials of hybrid rice and 600 F2 plants tested in early stage were detected by PCR, each sample was repeated three times.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27032718

Gel preparation and electrophoresis

The PCR products were electrophoretic by 8% polyacrylamide amide non gel. The basic procedures were as follows:

1. Clean the glass plate with deionized water and wipe it with degreased cotton dipped in absolute ethanol.
2. Insert the glass plate into the plastic pad as required, and then seal the gap in the lower part of the school with 1% agar.
3. After agar solidification, about 35 ml of collocated propylene-clozamine solution, 25 μl TEMED, 150 μl AP, were injected into the glass panels, and the comb was inserted.
4. The comb was pulled out and poured into the 1×TBE electrophoretic buffer after 30 min of standing for gel coagulation. Clear the bubbles in the sample hole (Dong et al., 2019).
5. 2 μl 6×Loading Buffer was added to the amplified products of each tube of PCR. After mixing, 1.5 l sample was injected into the dot hole with a micro-sampler.
6. Connect the electrophoresis apparatus with the electrophoresis cell, adjust the voltage to 250 V, and electrophoresis for about 2 h.
7. After electrophoresis, remove the glass plate from the electrophoresis tank and remove the gel carefully.
8. Rinse the gel two times in the steamed water and transfer it to 0.1% $AgNO_3$ solution, then put it on the shaking table and shake 12 min to dye it.
9. Remove the gel and transfer it to the distilled water for two times, then pour into the chromogenic solution for color rendering.
10. Take out the gel and wrap it with fresh-keeping film and scan the results.

Preparation of bacterial solution and identification of resistance to rice scar

The strains resistant to Pib gene were 05-7 (ZA13), 05-12 (ZB13), 05-3 (ZB15), 05-30 (ZC15), 05-16 (ZD7), 05-23 (ZE3), 05-2 (ZF1), 05-11 (ZG1) and so on. 122 parents of hybrid rice and 600 F2 plants tested in early stage were identified by single inoculation. The rice genotype strains were 05-12 (ZB13) and 05-30 (ZC15). The tested strains were provided by Plant Protection Laboratory of Rice Research Institute of Sichuan Agricultural University. The strain culture and the preparation of bacterial solution were carried out according to the introduced methods. Rice blast resistance (Peng et al., 2017) was determined according to the international classification criteria for rice blast resistance evaluation. The evaluation classification criteria are shown in *Table 2*.

The resistance to rice blast was analyzed according to *Table 2*. The selected samples were identified for natural induced disease resistance in the field. The infected plants were found in the field, and the disease spot length was measured to identify the level of resistance to rice blast.

Resistance to rice stripe blight

Test material

The selected indica rice varieties were selected in the "Materials and methods" section.

Table 2. *Evaluation and classification criteria*

Resistance level	Leaf plague standard	Standard of panicle neck plague
Resist (R)	0 leaf is disease-free	0 Disease-free panicle
	1 The leaf blade has brown spots and is smaller in diameter than 0.5 mm	1 Ear blast rate less than 1%
	2 Leaf blade has oval brown spot, diameter between 0.5-1 mm	3 Panicle blast rate 1% ≤ 5%
Medium anti- (MR)	3 The blade has an elliptical lesion, the center is off-white, the edge is brown, and the diameter is between 1 mm and 2 mm	
	4 The fusiform spot is between 1-2 mm and limited to two veins, and the damage area is less than 2%	
Moderate (MS)	5 Typical disease spot, damage area 3% ≤ 10%	5 The ear blast rate was 6%and 25%.
	6 Typical disease spot, damage area 11% ≤ 25%	
Susceptible (S)	7 Typical disease spot, damage area 25% ≤ 50%	7 Panicle blast rate 25% ≤ 50%
High sensitivity (HS)	8 Typical lesions, 51% 75% of the area	9 Ear blast rate 51% ≤ 100%
	9 All leaves withered to death	

Marker-assisted selection and backcross breeding

In the main season of 2017, indica rice was crossed with Dular in Yangzhou, and backcross combinations were made in Sichuan in the same winter. BC_1F_1 was sown in Sichuan in 2017 and molecular marker-assisted selection was initiated to screen plants carrying disease-resistant genes for further backcross with indica rice. In order to speed up the breeding generation and ensure the normal germination of hybrid seeds, the hybrid seeds were dried immediately after harvest, disinfected and germinated on the culture medium. BC_2F_1 seedlings were added to Sichuan in early November 2017, and BC_2F_1 plants carrying disease resistance genes were screened by molecular markers to continue backcrossing and harvesting self-crossing seeds (Chen et al., 2017). BC_3F_1 and BC_2F_2 seeds were planted in Sichuan in January 2017 after the seeds were harvested and dried, and the second season was planted. BC3F1 contains BC3F1, BC2F2, BC2F3. The plants carrying disease resistance genes were selected from BC_3F_1 and the seeds of BC_3F_1 and BC_2F_2 were harvested. BC_4F_1, BC_3F_2, BC_2F_3 and indica rice were sown in Sichuan in 2018. The disease resistance was identified and the important traits were investigated. According to the resistance and comprehensive traits, the good and the bad were selected and eliminated. Considering that the cytoplasm and backcross thicknesses of Indica Rice need to be preserved in the backcross progenies, indica rice is the female parent for each cross and backcross.

DNA extraction and molecular marker analysis DNA

The extraction method of DNA is the same as that of the above 2.1.3 section extraction method. After DNA extraction, PCR is amplified by molecular marker assisted, then glued and electrophoretic, and observed and read under ultraviolet lamp and BIORAD gel imager (Song, 2017). The band type assignment of parents is 1, Dular band type assignment is 3, F1' band type assignment is 2 and default band assignment is 0.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27032718

Evaluation of disease resistance

Natural insecticidal inoculation was used for identification. When a large number of rice planthoppers migrated to the seedlings, they were treated three times a day to make the seedlings uniformly poisoned. Before transplanting, the incidence of rice plants was investigated. In this study, two criteria for disease resistance identification were used: one was the incidence of disease, i.e. the ratio of the number of plants with disease to the total number of plants; the other was the disease grade index. According to Washio's criteria for resistance identification, the plants were divided into six grades, namely *A*, *B*, *Bt*, *Cr*, *C* and *D*. The disease grade of each inoculated plant was investigated (Sun et al., 2018), and then according to the criteria, the disease grade index was divided into six grades. The following formula calculates the disease grade index of each strain according to the disease grade.

$$B_j = \frac{(100 \times A + 80 \times B + 60 \times Bt + 40 \times Cr + 20 \times C + 5 \times D)}{Z_z} \quad \text{(Eq.1)}$$

In the formula, *Bj* represents disease grade index. *Zz* tests the total number of seedlings. *A*, *B*, *Bt*, *Cr*, *C* and *D* in the formula are calculated by substituting the number of plants with different symptoms. The resistance of inoculated seedlings can be divided into resistance (R, 0-29), moderate resistance (MR, 30-39), moderate susceptibility (S, 40-69) and high susceptibility (HS, 70-100) according to disease grade index.

Character determination

BC_4F_1, BC_3F_2 and BC_2F_3 were planted in Sichuan in the season of 2018. The parents of indica rice were planted on May 10 and transplanted on June 10. BC_4F_1 plants were planted to the full, BC_3F_2 plants were planted to 50, BC_2F_3 plants were planted to 100, with a row spacing of 16.7 cm × 26.7 cm. After heading in late August, the heading date was recorded and harvested in time after maturity. The plant height, flag leaf length, leaf angle of flag leaf (angle between base of flag leaf and main stem), panicle length of main stem, total grain number of main stem panicle, panicle curvature (angle between neck node and apex of panicle and vertical axis of panicle), 1000 of homozygous disease-resistant plants detected in BC_4F_1 population and BC_3F_2 population were investigated at harvest time. Seven agronomic traits with high heritability such as grain weight (Li et al., 2017).

BC_2F_3 strains with homozygous resistance genes were observed and evaluated in detail from heading to maturity, and excellent strains were selected. After maturation, 20 BC_2F_3 strains were selected to investigate yield traits such as yield per plant, panicle number per plant, total grains per panicle, number of solid grains per panicle, seed setting rate and 1000-grain weight, and 5 of them were selected to investigate plant height, flag leaf length, flag leaf width, flag leaf angle, panicle-leaf difference (distance between spike tip of main stem and flag leaf tip), stem. The agronomic traits included basal diameter (stem diameter at 1 cm of the main stem of stripped leaf sheath), neck diameter (axis diameter at 1 cm above the neck node), ear length of the main stem, total grain number of the main stem ear, and ear curvature. The chalky grain rate and chalkiness of rice were measured by BC_2F_3 mature seeds. Starch viscosity spectrum was measured by 3-D RVA instrument produced by Newport Scientific Instrument Company, Australia.

Results

Resistance analysis of rice blast

Anti-Pib gene spectrum

In order to verify the validity of molecular marker assisted resistance gene in this method, it is necessary to analyze whether Pib gene has any utilization value in disease resistance breeding. 16 near strains of IRBLb-B and F-145-2 were used to spray two near isogenic lines. The results of the analysis were shown in *Table 3,* using sham you 63, a common susceptible variety.

Table 3. *Analysis results*

Strain (race)	Rice material		
	IRBLb-B	F-145-2	Oil excellent63Shanyou63
05-7(A13)	R	R	S
56(A49)	R	R	S
04-25(A1)	S	R	S
04-15(A1)	S	R	S
04-1(A15)	R	R	S
05-12(B13)	R	R	S
05-3(B9)	S	S	S
04-27(B15)	S	R	S
04-10(B13)	R	R	S
05-29(B31)	R	S	S

R means disease resistance, S means disease susceptibility. Among the 10 tested strains, IRBLb-B and F-145-2 were resistant to 6 and 8 strains respectively, and the resistance frequencies were 60% and 80%, respectively. The difference of resistance frequencies between them was 20%. This indicated that Pib gene had good utilization value in disease resistance breeding, that is, the molecular marker of resistance genes in rice had strong validity

Pib molecular marker assisted selection of rice blast resistance breeding

In this paper, 600 F-2 strains derived from IRBLb-B and F-145-2 hybridization were amplified by using the molecular marker-assisted method. The amplification results are shown in *Table 4*.

From *Table 4,* 185 homozygous plants of Pib gene were screened out from 600 F2 plants. At the same time, 600 F2 plants were used as materials to investigate the relationship between Pib gene and disease resistance in the field. The results showed that all Pib homozygous and heterozygous plants were resistant to the disease, while all Pib-free plants were susceptible to the disease. The results showed that the existence of Pib gene was consistent with the field resistance and the Pib gene was dominant.

Application of Pib molecular markers in germplasm resources identification

As we all know, germplasm resources (including wild and domesticated species) play an important role in both production practice and scientific research. In order to verify the consistency of Pib gene molecular markers with blast resistance, 122 hybrid rice parents or materials were tested by single race inoculation with blast fungus strains

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27032718

05-12 (ZB13) and 05-30 (ZC15). The results of Pib molecular identification are shown in *Table 5*. At the same time, the parent material is the basis of cultivating new crop varieties. Two pairs of dominant molecular markers Pibdom and Lys 145 were used to detect 122 parents or materials of Hybrid Rice by PCR. The results of PCR amplification were shown in *Figure 1*.

Table 4. *Molecular test of Pib gene and its resistance to rice blast in the field*

Hybridized combination	Disease resistance response	Number of pure plants with Pib gene	Number of hybrid plants with Pib gene	Number of plants without Pib gene

Total		185	254	158

In the field resistance identification, 3 plants did not get results because of death

Table 5 shows that only 22 of 157 rice varieties contain the blast resistance gene Pib, while most varieties do not. The results showed that the molecular marker-assisted method could quickly and accurately identify rice germplasm resources containing Pib gene, and provide effective methods and scientific basis for selection of resistant parents in blast resistance breeding. At the same time, it can be seen from *Figure 1* that the dominant molecular marker Pidom can specifically amplify a fragment about 350 bp in size, and the dominant molecular marker Lys145 can specifically amplify a fragment about 800 bp in size. In *Figure 1,* it can be seen that only 7 parents or materials of 122 hybrid rice contain blast resistance. Pib gene was not found in other parents or materials of hybrid rice.

Table 5. *Molecular identification of Pib gene in rice varieties from different countries*

Resistance test of rice stripe blight

Molecular marker assisted effect

In order to verify the effect of molecular marker-assisted resistance to rice stripe blight, a practical test and analysis are needed. The results are shown in *Table 6* and *Figure 2*.

From *Table 6,* it can be seen that this method can better label the gene of rice stripe blight, and can accurately reflect the positive and reverse sequence of the gene and the

DOI: http://dx.doi.org/10.15666/aeer/1802_27032718

location of the clone. At the same time, from *Figure 2,* it can be seen that most of the amplification results of BC_3F_1 are the same as those of all the selected individuals, which indicates that other rice bodies have the same amplification results. It also contains the stripe blight gene.

Table 6. *Analysis of marker results*

Tab	Forward sequence	Reverse sequence	Where the clone is located

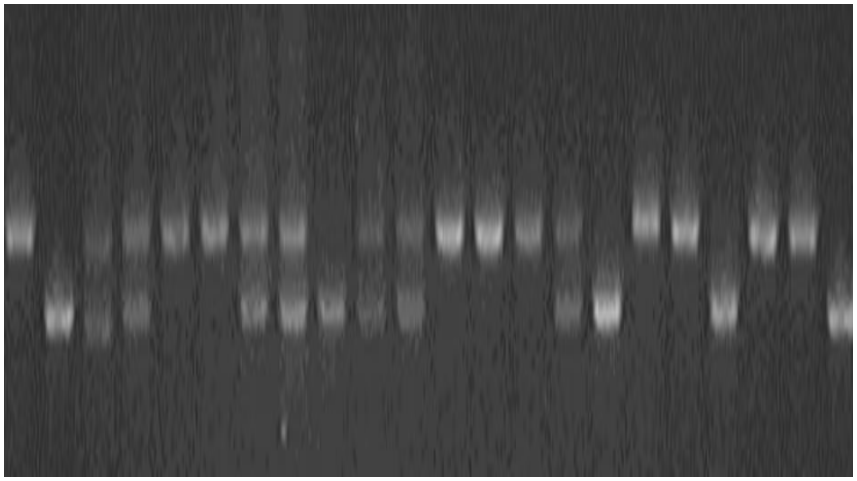

Figure 2. *Amplification results*

Molecular marker-assisted selection of backcross transfer stripe blight resistance genes

Marker-assisted selection (MAS) breeding was carried out according to the technical route. The acquisition of each backcross generation population and individual plant carrying disease-resistant genes was shown in *Table 7*.

Table 7. *Detection of disease resistance per plant*

For generations	Plant coefficient	Number of plants detected	Number of plants carrying resistance genes	B/A%
BC_1F_1	1	13	5	38.46
BC_2F_1	3	9	5	55.56
BC_3F_1	5	331	51	15.41
BC_4F_1	52	1297	407	31.38
BC_2F_2	4	139	17	12.23
BC_3F_2	51	1066	218	20.45

The BC_nF_1 population was detected as a hybrid plant with disease resistance gene, and the BC_nF_2 population was detected as a homozygous plant with disease resistance gene

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27032718

From *Table 7,* it can be seen that with the increase of backcross generations, backcross and inbred population gradually expanded. A total of 407 plants containing heterozygous resistance genes were obtained by BC_4F_1 and 218 plants containing homozygous resistance genes were obtained by BC_3F_2. It is hopeful to select new lines with good disease resistance from these offspring. After marking resistance genes by molecular marker-assisted method in this paper, the effect of selecting rice breeding is better.

Identification of resistance to stripe blight

The resistance of BC_2F_3 strains with homozygous resistance genes and their parents to natural insects was identified. The incidence and disease grade index of rice were investigated after the disease condition was stable. The results were shown in *Table 8*.

Table 8. *Results of the survey*

Strain number	Disease grade index	Plant incidence rate	Resistance level
E1	5.20	11	R
E2	0.45	2	R
E3	3.80	8	R
E4	0.61	2	R
E5	3.00	4	R
E6	16.00	31	R
E7	10.20	14	R
E8	8.80	12	R
E9	3.80	5	R
E10	10.00	14	R
E11	5.85	8	R
E12	3.61	6	R
E13	8.00	9	R
E14	6.80	9	R
E15	8.80	12	R
E16	10.90	16	R
E17	4.60	6	R
E18	10.60	15	R
CK	85.00	85	HS

From *Table 8,* it can be seen that the incidence rate of indica rice is 85%, the disease grade index is 85.0, and the resistance level belongs to high susceptibility. Among 18 BC_2F_3 lines carrying homozygous resistance genes, the highest disease grade index is only 16.0, and the lowest is 0.45. The resistance level to stripe blight belongs to resistance level, which indicates that the resistance level to stripe blight is assisted by molecular markers in this paper. Later, the re-harvested indica rice had better resistance to stripe blight.

Discussion

With the development of industrial and agricultural production, the discharge of three wastes, the exploitation and utilization of minerals, sewage irrigation and the use of pesticides, herbicides and fertilizers have seriously polluted the soil, water quality

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27032718

and atmosphere, resulting in environmental deterioration and causing immeasurable harm to society, economy and human beings. Excess heavy metals can hardly be eliminated once they enter the environment, especially in the soil. In addition, there is a trend of organic in the organism, so heavy metal pollution has a greater hazard. Through actual investigation and analysis, it is found that many heavy metals are essential trace elements for natural plants, and play a very important role in the growth and development of natural plants. However, when the amount of heavy metals in the environment exceeds the even-critical point, it will have a certain toxic effect on plants. In light of this, the lower processes in plants will be disordered, growth and development will be inhibited, and the heavy metals will change the genes in plants, leading to a variety of diseases in plants and eventually leading to plant death. Taking rice as an example, the main heavy metal resistance in rice was blast resistance and stripe blight resistance. Therefore, molecular marker-assisted method should be used to label rice blast resistance and stripe blight resistance, so as to shorten breeding years, improve the selection efficiency, enhance the heavy metal resistance of natural plants, and promote the growth and development of natural plants.

The significance of marker-assisted genes was found through the above studies. Molecular marker-assisted selection (MAS) is an important means of crop breeding, which uses molecular markers closely linked to target genes to select genotypes, and is not affected by environmental conditions. MAS can shorten breeding years and improve selection efficiency. However, the recombination rate between target traits and markers is different in different populations, and often the target traits are not breeding populations. Therefore, in practical application, the recombination rate of molecular markers and target traits for assisted selection must be low, so it is greatly limited. Therefore, the best way is to use the resistance gene itself to establish the corresponding molecular markers. Cloning of disease-resistant genes provides the possibility of establishing such markers. Wang established the molecular marker of Pi-ta gene based on the PI-ta gene which has been cloned. These markers were successfully applied to rice blast resistance assistant breeding. This kind of marker is defined as functional gene-assisted selection. The molecular marker of Pib gene mentioned in this paper is based on the disease-resistant gene Pib itself. It is of great significance to select target genes accurately by using these markers, to speed up the screening of resistant sources, to identify resistant genes and to breed rice varieties with high resistance (Li et al., 2017).

Studies on the marker-assisted gene of rice Pib show that previous scholars could only detect whether the material contained the disease-resistant gene Pib when using the dominant molecular marker Pibdom molecular detection, and could not directly determine the homozygous disease-resistant gene Pib material. If homozygous plants are to be selected, they need to be differentiated by several generations of field resistance identification, which is time-consuming and vulnerable to environmental impact without accurate results. In this paper, a set of molecular markers of resistance gene Pib itself was established by using dominant molecular markers Pibdom and Lys 145 for molecular detection. Combined with Yangzhou Jiadai, homozygous plants containing resistance gene Pib could be selected in F2 generation of hybrid isolation within one year, and the results were identical through field resistance identification. The results showed that the homozygous plants containing Pib gene could be selected quickly and accurately by using this set of molecular markers, which could simplify the complicated identification of resistance in the field. Most parents and combinations of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27032718

hybrid rice currently used in production are not resistant to rice blast. Pib gene is a major disease resistance gene, which is a good choice in disease resistance breeding. By using these molecular markers, the blast resistance gene Pib can be quickly and accurately selected from numerous rice resources. The parents selected by this marker can transfer Pib resistance gene into rice varieties by conventional hybridization breeding method to produce resistance. At the same time, other resistance genes and Pib genes can be aggregated into the same fine varieties by MAS technology to produce durable resistance and to maintain the best varieties to the greatest extent. By using STS and SSR markers OSR20, OSR32, RM213, RM207 and RM262 closely linked to disease resistance genes, Chen Xuewei et al. tracked and screened rice blast resistance genes. Pi-d(t)1, Pib and Pi-ta2 were aggregated into G46B. In a relatively short time, relatively durable resistant strains of several physiological races were developed. Our laboratory is using this kind of molecular marker to polymerize Pib and Pi-ta multiple blast resistance genes, so as to further use Pib gene to breed persistent resistant varieties and lay the foundation for the ultimate goal of rice disease resistance breeding.

At the same time, the resistance of rice stripe blight was studied. It was found that this method could improve the resistance of rice stripe blight. It was found that Dular had strong resistance to stripe blight, but its agronomic morphology was not good. In practical application, because of rice hybridization, the characters of both donor and recipient are quite different, and they are severely separated in the lower generations of backcross, so it is difficult for the characters to return to the status of recipient parents. Fertility and character segregation still existed in the offspring of Indica Rice crossed with Dular to BC_4F_1 in this experiment. This needs to be solved by increasing the number of backcross to break the linkage between unfavorable trait genes and good trait genes, or by enlarging backcross population and increasing selection pressure. Indica rice is a semi-erect panicle variety. If the erect panicle-type indica rice varieties with resistance to stripe blight, such as Zhendao 88, Zhendao 99 and Xudao 3, were selected or bred in recent years as resistant donor parents, the speed of backcross improvement might be accelerated. Of course, this is only considered from improving the resistance of recipient parents by backcrossing, so that the comprehensive traits of offspring can be completely restored to the status of recipient parents. If we want to breed new varieties resistant to stripe blight, we need to increase the character differences between donor and recipient parents, which is more conducive to enriching variation and breeding varieties beyond recipient parents. If five BC_2F_3 lines of Indica Rice crossed with Dular were screened out in the experiment, their yield would be much higher than that of Indica rice. In conclusion, this method can significantly enhance the resistance to heavy metals and promote the healthy growth of rice after analyzing the marker-assisted heavy metal resistance of rice.

Conclusions

In order to enhance the heavy metal resistance of natural plants and improve the survival and development ability of natural plants, it is necessary to use molecular marker-assisted method to label heavy metal resistance genes of natural plants, select natural plants, accelerate the speed of crop improvement and improve the level of crop improvement. In this paper, rice was taken as an example for specific analysis. Through practical analysis, it was found that rice heavy metal resistance was mainly composed of blast resistance and stripe blight resistance. Molecular marker-assisted method was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27032718

needed to label rice blast resistance genes and stripe blight resistance genes. Higher resistant rice was selected to improve rice quality. It was found that the molecular marker of rice resistance gene could retain the basic characteristics of rice and enhance the heavy metal resistance gene of rice, which plays a new role in production, and breeding new disease-resistant varieties. Due to the limited time, this paper only chooses rice as the research object, which has one-sidedness, so more natural plants need to be selected as the research object, which lays the foundation for the research of heavy metal resistance genes in natural plants.

(Received 3rd Sep 2019; accepted 12th Feb 2020)

Abstract. This study revealed intraday variation of chlorogenic acid (CGA) and synthesis mechanism in leaves of *Eucommia ulmoides* Oliver by investigating relation of CGA content in leaves and the light intensity. CGA was quantified by High performance liquid chromatography (HPLC) with diode array detection (DAD). Illumination intensity was determined by portable photosynthesis system. It was shown that CGA content in leaves enhanced with the increase of light intensity and the highest point of CGA content in leaves got behind the highest point of illumination intensity. The fact that dark spots of blue formazan appeared in leaves which had been illuminated by sun light and were treated with nitroblue tetrazolium (NBT) showed that sunlight induces $O_2^{\cdot-}$ production in leaves. In addition, CGA possessed higher antioxidant activity and free radical scavenging activity in vitro experiment. DPPH radical scavenging activity was 2.43 ± 0.092 times of vitamin C equivalents (molar ratio), and ABTS radical cation scavenging activity was 3.61 ± 0.14 time of trolox equivalents (molar ratio), and reducing powers was 3.40 ± 0.11 times of vitamin C equivalents (molar ratio). In plant cells, free radicals produced by photo oxidation can damage the cells, and however, CGA can protect cells by eliminating free radicals. This may be the mechanism of the synthesis of chlorogenic acid in plants.
Keywords: *chlorogenic acid, Eucommia ulmoides Oliver, oxygen free radical*

Introduction

Eucommia ulmoides Oliver (*E. ulmoides*) is a traditional medicinal plant of China, and is also one of the main sources of chlorogenic acid (CGA). The pharmacological functions of CGA have been studied extensively. Potentially beneficial properties to human such as antimicrobial, antiinflammatory, antioxidant, anticancer, antiviral, hepatoprotective activities, antihypertension and protection against UV radiation have been attributed to CGA in vitro (Bhattacharyya et al., 2014; Chen et al., 2010; Shao et al., 2015). In plants, CGA performs anti-oxidant functions, and increased CGA accumulation is also associated with increased UV-protection (Cle et al., 2008; Doring and Petersen, 2014; Mudge et al., 2016). In this paper, the effect of illumination intensity on produce of CGA in leaves of *E. ulmoides* was investigated.

The quantitative determination methods of CGA have been reported, including gradient HPLC method, new flow injection chemiluminescent method, nano-LC-ESI mass spectrometry and electrochemical sensor (Hu et al., 2009; Santos et al., 2011; Wang et al., 2007; Zhang et al., 2007). However, a rapid, reliable and convenient determination of CGA is required. High performance liquid chromatography (HPLC) with diode array detection (DAD), more common and less costly, currently represents the most prevalent and reliable analytical method for the characterization of compounds, which need to be simultaneously acquired of chromatograms at any wavelength accompanied by the absorption spectrum of each eluted band and verified

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27192725

of separation quality with peak purity analysis (Huang et al., 2015; Luo et al., 2011; Sriseadka et al., 2012; Zeraik and Yariwake, 2010). Consequently, a normally manageable HPLC-DAD process was proposed in this research.

Materials and methods

Materials

Fresh leaves of *E. ulmoides* were obtained in campus of Henan University in summer and ground into dry powder, followed by sieving through 200 mesh screen to control the particle size.

Reagents

1,1-diphenyl-2-picrylhydrazyl (DPPH) and 2,2'-azinobis-(3-ethylbenzthiazoline- 6-sulphonate (ABTS) were purchased from Sigma Chemical Co. Trolox was purchased from MP Biomedicals. Nitroblue tetrazolium (NBT) and CGA were purchased from Bomei Biotechnology Co. Methanol was chromatographically reagent grade. All other chemicals used in this study were of analytical reagent grade.

Determination of sunlight intensity

Sunlight intensity and temperature of leaves were determined by portable photosynthetic apparatus (LI-6400XT, LICOR USA) in a clear day.

Determination of CGA in leaves

CGA in leaves was separated and quantified using a Waters HPLC (Milford, Massachusetts, USA) equipped with a Waters1525 pump, a Waters 2707 autosampler, and Waters diode array detector 2998. Breeze Software was used for the data processing. C18 column (Waters, 250 × 4.6 mm i.d., 5 μm particle size) was used to identify CGA. The chromatographic separation was operated with solvent A (MeOH) and B (water). The separated flavonoid peaks were identified by comparing the retention time of individual standards. The optimum procedure elution used in this study was as follows: a gradient of 70-30% A (0-15 min), 30-70% A (15-20 min). The samples were injected automatically (20.0 μL). The column and guard column were controled at 30 °C and a 1.0 mL min^{-1} flow rate was applied, and the CGA were scanned from 210 to 400 nm in HPLC.

O_2^- localization in situ

Fresh leaves from control (dark-treated leaves) and light-treated leaves were excised and immersed in a 0.1% solution of nitroblue tetrazolium (NBT) in 50 mM Kphosphate buffer (pH 6.4), containing 10 mM Na-azide, and were vacuum-infiltrated for 5-10 min and illuminated until appearance of dark spots, characteristic of blue formazan precipitates. Leaves were bleached by immersing in boiling ethanol (Romero-Puertas et al., 2004).

Analytical method of antioxidant capacity

The antioxidant capacity of CGA was determined by the Thermo Multiskan GO (Thermo Fisher Scientific Oy, Finland) (Shown as *Table 1*). The free radical scavenging

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27192725

activity was evaluated using the 2.2-diphenyl-1-picrylhydrazil (DPPH) assay and the absorbance values were measured at 518 nm and converted into the percent antioxidant activity (AA) using the following formula: AA% = [(absorbance of the control - absorbance of the sample) / absorbance of the control] × 100, The Vitamin C equivalents (VCEs) values of CGA were calculated from a linear regression of the AA of Vitamin C (VC, ascorbic acid); the scavenging activity against 2,2'-azino-bis(3-ethylbenzo thiazoline)-6-sulfonic acid (ABTS) radical cation was measured by the method that ABTS radical cation was produced directly by reacting ABTS solution with potassium persulfate and allowing the mixture to stand for 12-16 h in dark at the room temperature and prior to beginning the assay, and ABTS solution was diluted with methanol to an absorbance of at 734 nm, and then sample solution was added to ABTS solution and read at 734 nm after mixture and 30 min incubation at room temperature, and then The trolox equivalents (TEs) values of CGA were calculated from a linear regression of the AA of trolox equivalents; the determination of reducing powers of CGA was changed according to the method described by Ozsoy: 0.1 ml VC (20-100 μg/ml) and 0.1 ml CGA (20 μg/ml) were mixed with an equal volume of 0.2 M phosphate buffer (pH 6.6) and 1% potassium ferricyanide and then incubated at 50 °C for 20 min, and then 0.25 ml of 1% trichloroacetic acid was added to the mixture to stop the reaction, and then the mixture was centrifuged at 3000 g for 10 min, and the supernatant (0.25 ml) was mixed with 0.25 ml distilled water and 0.1% $FeCl_3$ (0.5 ml) and then the absorbance was measured at 700 nm, and the VCEs values of CGA were calculated from a linear regression of the AA of Vitamin C (Du et al., 2009; Dudonne et al., 2009; Ma et al., 2017; Ozsoy et al., 2008; Reis et al., 2015; Zengin et al., 2015).

Table 1. *Antioxidant capacity of chlorogenic acid (CGA)*

	VCEs (mass ratio)	**VCEs (molar ratio)**	**TEs (mass ratio)**	**TEs (molar ratio)**
DPPH radical scavenging activity	1.21±0.046	2.43±0.092	-	-
ABTS radical cation scavenging activity	-	-	2.55±0.099	3.61±0.14
Reducing powers	1.69±0.054	3.40±0.11	-	-

VCEs: vitamin C equivalents; TEs: trolox equivalents

Statistical analysis

Results were described as means ± standard deviation (SD) of three measurements. Statistical analysis was carried out using Student's t-test and significant difference was statistically considered at the level of $p < 0.05$.

Result and discussion

The CGA peaks were identified by their UV/DAD spectra due to their characteristic UV spectral pattern (Band I, λ max around 320 nm and Band II, λ max around 220 nm) in *Figure 1*. The absorption spectrum of each eluted band of leaves of *E. ulmoides* at any wavelength was consistent with that of CGA standard (*Fig. 1a* and *b*). Practically, UV/DAD scanning of herbal medicines without grinding makes CGA determination much more convenient.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27192725

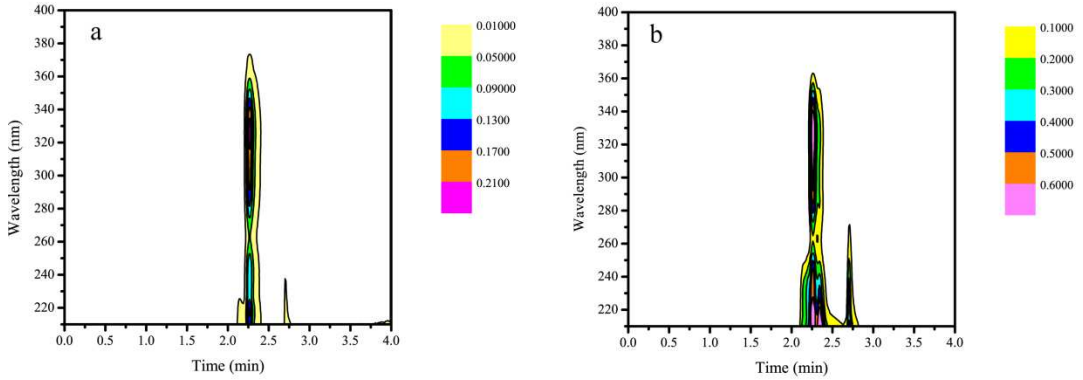

Figure 1. *HPLC-UV/DAD of chlorogenic acid (CGA). a: CGA standard, b: leaves of E. ulmoides*

Under clear day solar radiation condition, the change of CGA content in leaves of *E. ulmoides* with the illumination intensity was shown in *Figure 2*. The highest CGA content in leaves appeared at the decrease point of illumination intensity (14:00) but not the top of illumination intensity (12:00). And then CGA content in leaves dropped fast with illumination intensity after 14:00.

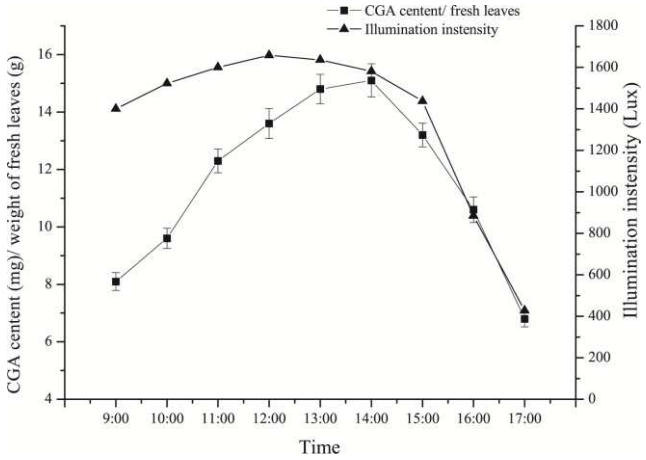

Figure 2. *Intraday variation of chlorogenic acid (CGA) content in leaves of E. ulmoides*

Fresh leaves of *E. ulmoides* had been illuminated by sun light and then were treated with nitroblue tetrazolium (NBT). In *Figure 3,* the dark spots of blue formazan appeared in leaves, while no dark spots appearing in the control (leaves in dark). This showed that sunlight induces $O_2^{\cdot-}$ production in leaves.

CGA performed higher antioxidant capacity: DPPH radical scavenging activity was 2.43 ± 0.092 times of VCEs (mmol/mmol), and ABTS radical cation scavenging activity was 3.61 ± 0.14 time of TEs (mmol/mmol), and reducing powers was 3.40 ± 0.11 times of VCEs (mmol/mmol).

In plant, reactive oxygen species (ROS) are involved in plant responses to various biotic and abiotic stresses (Ma et al., 2012; Wang et al., 2013; Qi et al., 2018). Plants requires light for photosynthesis, but absorption of too much light can lead to photo-oxidative damage to the photosynthetic apparatus, and then this phenomenon occurs due

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27192725

to imbalances which result from the overproduction of ROS (Chung et al., 2015; Ramabulana et al., 2016). However, accumulation of ROS can damage various cellular components such as proteins, nucleic acids, carbohydrates, and unsaturated lipids (Yu et al., 2018). Here, increased illumination intensity accelerated photooxidation reaction rate, which lead to enhancement of ROS level in cells. And then ROS heightened the content of CGA in the cell by increasing the expression of the genes related to the biosynthesis of CGA, which was completed over a period of time. Probably, this was why the top CGA content in leaves was late for a few hours than illumination intensity.

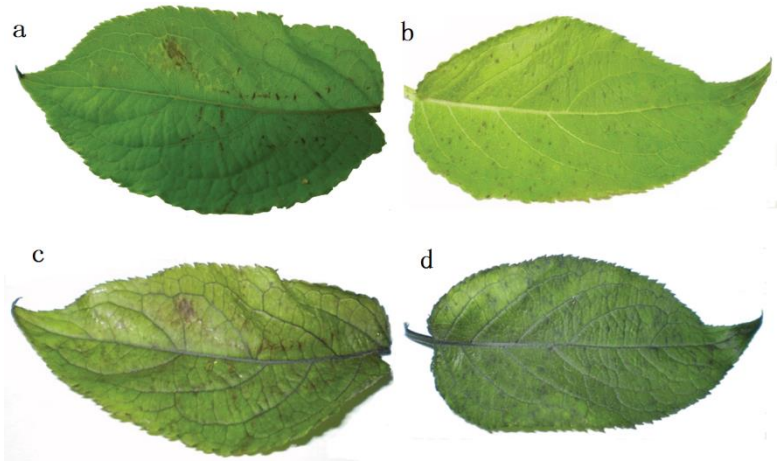

Figure 3. *$O_2^{\cdot-}$ localization in situ of fresh leaves of E. ulmoides. Control leaf and sample leaf illuminated by sun light were treated with NBT and then bleached by immersing in boiling ethanol; a: control leaf; b: sample leaf c: control leaf treated by boiling ethanol; d: sample leaf treated by boiling ethanol*

In plant cells, free radicals produced by photo oxidation can damage the cells, and however, CGA can eliminate free radicals, which can protect cells. This may be the mechanism of the synthesis of chlorogenic acid in plants.

Abstract. In the process of oil exploitation, refining, storage, transportation and use, due to the limitations of technological level and treatment technology, a large amount of petroleum-containing wastewater and waste residue are inevitably discharged into the soil, thus affecting the whole soil ecosystem. In this paper, an ecological remediation method for petroleum contaminated soil based on microbial degradation is proposed. The natural biodegradation of petroleum contaminants in soil is discussed. The types of degrading microorganisms and their degradation mechanisms for saturated hydrocarbons and aromatic hydrocarbons are introduced, and the chemical composition of petroleum and the number of microorganisms in the soil are analyzed. The effects of nutrients, oxygen supply, temperature, humidity and pH on the degradation efficiency of petroleum are studied, and the in-situ soil ecological remediation is carried out after the degradation of pollutants. Experiments show that the ecological remediation of petroleum contaminated soil based on microbial degradation can be more thorough in essence. This method has the advantages of requiring only a low time investment, being, low cost, simple and effective, and having a good remediation effect and no secondary pollution.
Keywords: *ecological remediation method, natural biodegradation, soil ecological remediation, degradation efficiency, chemical composition*

Introduction

Petroleum is a complex mixture of thousands of substances with different chemical properties, including saturated hydrocarbons, aromatic hydrocarbons, asphaltenes, resins and so on. Pollution and omission accidents in the process of oil exploitation, smelting, use and transportation, as well as the discharge of oily wastewater, sewage irrigation, volatilization of various petroleum products and falling of incomplete combustion materials, have caused a series of soil pollution problems. Especially the crude oil produced in the process of oil exploitation has become a significant source of mineral oil pollution in soil.

With the rapid development of the petroleum industry, the contamination of soil by petroleum pollutants is becoming more and more serious. Many studies have shown that some petroleum hydrocarbons have carcinogenic, teratogenic and mutagenic effects on humans and other mammals after they enter the animal body. It is difficult to remove petroleum hydrocarbons when they enter the soil, which will lead to changes in soil properties, even groundwater pollution and other major ecological crises. The serious pollution of soil will lead to the accumulation of some petroleum hydrocarbons in grain, affect its quality, and endanger human health through the food chain. Finding out how to effectively remediate petroleum contaminated soil has become a global environmental problem.

(1) Rapid pyrolysis technology will be used to remediate the soil. The effects of remediation related to pyrolysis parameters, oil recovery rate and its possible formation pathway, as well as the physical and chemical properties of the remediated soil and its suitability for planting are systematically studied. However, this method cannot degrade petroleum pollutants and remediate soil very well, and there are some shortcomings such as troublesome process and time-consuming (Li et al., 2018).

(2) The technology of supersulphate bioaugmentation foam spray is put forward, and used to accomplish the purpose of removing total petroleum hydrocarbon (TPHS) from diesel petroleum contaminated soil. The penetration/unsaturated hydraulic conductivity of unsaturated soils increased with the use of foam remedies. The mixture of sulfate and surfactant solution penetrates the soil faster than peroxide, but it does not make the soil moisture and dryness to an average effect (Bajagain et al., 2018).

(3) Based on the distribution mechanism of cell temperature in soil, the energy efficiency and distribution mechanism of EKR process are proposed. To some extent, the transformation mechanism of Cr6 + and Cr3 + in EKR process is discussed. Through this transformation mechanism, the regularity of chromium fractionation in soil is obtained, so that the degradation of soil is optimized. Although it had the function of post-transformation distillation, it cannot make remediation of soil well (Fu et al., 2017).

In this paper, an ecological remediation method for petroleum contaminated soil based on microbial degradation is proposed. According to the way of microbial degradation, the essential remediation of petroleum contaminated soil is fundamentally carried out. This method has the advantages of simple, effective, time-consuming and good soil remediation.

Material and methods

Materials

Chemical reagents: $M_gSO_4 \cdot 7H_2O$, NH_4NO_3, $CaCl_2$, $FeCl_3$, KH_2PO_4, KCl, HCl, $C_4H_4KNaO_6$, $CHCl_3$, etc., which are all analytical pure.

Additives: chicken manure, chicken manure soil, etc.

The test site is located about 20 kilometers northwest of Daqing oil field, Heilongjiang Province, China (45°46′-46°55′N, 124°19′-125°12′E). For loess, the test depth is 0-15 cm, and the maximum thickness is 50 cm. There are 2-10 mm gravels in the soil. The wet bulk density of the soil is 1.821 g/cm^3. The natural water content is 9.18%. The pH is 8.4; the nitrate content is 55.3 mg/kg, and the oil background content is 1.3-4.6 mg/kg. The experimental water is local shallow groundwater with pH of 8.2 and TDS of 420.5 mg/L. The crude oil produced in the test site is 2400 m underground.

Testing glassware: 150 mL, 250 mL triangle bottle with plug, 125 mL, 1000 mL grinding fine-mouth reagent bottle, various types of bacteria culture tube, Petri dish, rubber plug, 2SL plastic barrel.

Main instruments: QZD-1 electromagnetic oscillator, KQ218 ultrasonic cleaner, biothermostat incubator, high-speed centrifuge, high-pressure steam sterilizer, sterile laboratory, biochemical incubator, shaker incubator, Leica biomicroscopy, 752N ultraviolet-visible grating spectrophotometer, pH meter (pHB-3), DDB-303A conductivity meter, electrothermal drying chamber and various glass instruments for chemical analysis, etc.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27272746

Chemical analysis test methods: ultraviolet spectrophotometry is used for analysis of petroleum and NO_3, reagent colorimetry for NH_4, pHB-3 type of pH meter for pH testing, DDB-303A type of conductivity meter for calculation of TDS. Using the above experimental materials, chemical reagents were used to sample the oil-contaminated soil. *Figure 1* shows a sample of oil-contaminated soil.

Figure 1. *Oil contaminated soil samples*

The relevant data obtained are processed by SPASS18.0 statistical software, and the measured data are represented by $(\bar{x} \pm s)$, and the average values of multiple samples are compared by variance analysis method. When there are differences between groups, the average values of multiple samples between groups are pairwise. The average values of the corresponding samples in each comparison group are equal. The test is carried out by LSD-t. If the average value of the corresponding samples in each comparison group is not equal, the Dunnett-T3 test is used. $P > 0.05$ indicated that there was no significant difference.

Sources and hazards of petroleum contaminated soil

(1) Mode of production

Petroleum pollutants (Varjani et al., 2017) are products of oilfield development and petroleum processing. Every link of the petroleum industry may produce petroleum pollutants, of which drilling, oil recovery, transportation, emissions and accidents are the main links. Drilling wastewater and oil-bearing mud containing petroleum pollutants are produced during drilling in oilfields, mainly from oil pollution on flushing surface equipment, loss of drilling mud and leakage of mud circulation system. During the period of oil production, oil production wastewater will be discharged from normal production operation, well washing wastewater will be discharged from well washing, dewatering treatment of crude oil will produce wastewater, and overhaul of equipment will also produce oily wastewater. Accident pollution includes natural and human factors. Natural accidents include blowout and equipment failure. When vehicles are used for transportation, crude oil leakage is caused by traffic accidents caused by landslides, avalanches, floods and gales. Man-made accidents refer to the destruction of oil production equipment and pipelines caused by various man-made factors, and the pollution caused by the rollover of crude oil transport vehicles caused by man-made traffic accidents, etc. Investigations show that the oil content of most soils collected in the 100 m range around oil wells in Shengli and Daqing oilfields is higher than the national standard threshold (500 μg/g). In addition, oil sludge from oil tanks, sedimentation tanks, sewage tanks and sediment from oil transfer stations and combined stations in oilfields can also pollute the soil, causing the oil content in the soil to exceed the standard seriously.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27272746

Harmful to soil ecological environment

Petroleum pollutants rank eighth among 48 hazardous wastes in China (Sharma et al., 2018). After petroleum pollutants are discharged into soil, soil structure is destroyed, soil permeability is affected, soil organic matter composition and structure are changed, and soil quality is reduced. Petroleum hydrocarbons accumulated in soil, mostly macromolecule compounds, form a layer of mucosa on plant roots, hinder root respiration and absorption, and even cause root decay. Petroleum pollutants often accumulate in the soil surface, and the soil surface is the most developed area of crop root system, so the degree of soil pollution directly affects the growth of crops. As oil contaminates the soil, it also causes pollutants to enter the grain, causing the accumulation and amplification of pollutants. It not only affects the quality of food, but also makes oil pollutants enter the food chain, endangering human health. In the process of infiltration into the soil, oil also diffuses along the surface, erodes the soil layer, makes it saline-alkali, asphalt, hardening, and migrates to the deep part of the soil under the action of gravity. Because of the strong viscosity of petroleum pollutants, they will form a small range of high concentration pollution in a short time.

Ecological remediation of petroleum contaminated soil based on microbial degradation

Bioremediation technology (Fruchter, 2017) is a new clean technology developed on the basis of biodegradation. It is the development of traditional biological treatment methods. Compared with physical and chemical remediation of contaminated soil, it has the advantages of low cost, no damage to the soil environment needed by plant growth, safe oxidation of pollutants, no secondary pollution, good treatment effect and simple operation. Bioremediation can accelerate the rate of natural biodegradation by optimizing environmental factors. It is an efficient, economical and ecologically affordable clean technology. At present, there are two main types of bioremediation technologies for petroleum hydrocarbon contaminated soil: one is microbial remediation technology, which can be divided into in situ bioremediation and heterotropic bioremediation according to the location of remediation; the other is phytoremediation.

In situ bioremediation and ectopic bioremediation technology

In situ treatment method is to treat contaminated soil in situ. During the treatment period, the soil is basically undisturbed. The most common method of in-situ treatment is to biodegrade the water saturated area of the soil. In addition to adding nutrients and oxygen sources (mostly hydrogen peroxide), microorganisms should be introduced to improve the biodegradability. Sometimes, a group of wells are dug in the contaminated area and injected directly into the appropriate solution, so that microorganisms in the water can be introduced into the soil. After some treatment, groundwater can be recovered and recycled, and soil amendment can be added before groundwater is recycled. It is impossible to remove most PAHs (polycyclic aromatic hydrocarbons) effectively by in situ treatment within a certain period of time, and this method has some limitations due to the influence of temperature and soil type. Ectopic bioremediation mainly includes field treatment, prefabricated bed treatment, composting treatment, bioreactor and anaerobic biological treatment.

DOI: http://dx.doi.org/10.15666/aeer/1802_27272746

Field treatment method

In recent years, there have been many studies on Bio-treatment of petroleum hydrocarbon contamination (Jupp et al., 2017; Wu et al., 2017), among which soil tillage treatment is a common method for field treatment of soil contamination. Polluted wastes are applied to the soil, and the optimum values of oxygen, water and pH are maintained through fertilization, irrigation and lime addition. Tillage is carried out to improve soil ventilation and ensure the degradation of pollutants in polluted wastes and underlying soil layers. Most of the microorganisms used in the degradation process are indigenous microorganisms, but domesticated microorganisms need to be introduced to improve the effect.

Prefabricated bed method

The biggest drawback of soil tillage treatment in field treatment is that pollutants may migrate from the treatment area. The design of prefabricated bed can minimize the amount of pollutants migration because of its filtrate collection and emission control system. The bottom of the prefabricated bed is low permeability material, such as high-density polyethylene or clay. Contaminated soil is transferred to prefabricated bed, pH is adjusted through fertilization, irrigation, and sometimes microorganisms and surfactants are added to make it most suitable for pollutant degradation.

Piling treatment method

Soil piling treatment (Selvi et al., 2017) is to excavate contaminated soil from contaminated areas, prevent contaminants from spreading to groundwater or larger areas, transport it to a treated site (layout of seepage prevention bottom, ventilation pipelines, etc.) and pile it up to form a rising slope, and carry out biological treatment. Piling is a new alternative technology in bioremediation technology.

Bioreactor method

Bioreactor method (Ming et al., 2017) is to treat contaminated soil in a special reactor. Bioreactor is usually built on site or in a specific treatment area, usually in horizontal drum and elevator shape, with two types of gap and continuous. Because the reactor can completely mix the soil with microorganisms and other additives such as nutrients, surfactants and so on, and can control the degradation conditions well, the treatment speed is fast and the effect is good. The process of bioreactor treatment is as follows: firstly, the soil is dug out and mixed with water to form mud, and then transferred into the reactor. In order to improve the degradation rate, domesticated microorganisms are often isolated from the soil previously treated by the reactor and added to the soil prepared for treatment.

Anaerobic bioremediation method

Aerobic remediation technologies such as bio-layer, composting and soil slurry reactor have been developed for the remediation of petroleum hydrocarbon-contaminated soils. However, when some degrading bacteria are isolated, some degrading bacteria are accompanied by products with high ecological risk. Recent studies have shown that anaerobic microbial remediation technology characterized by anaerobic reductive dechlorination has great potential.

Biodegradation of petroleum pollutants in soil

After petroleum pollutants enter the soil, they can be transformed and degraded through three natural ways: volatilization, autoxidation and degradation. The latter mainly includes biodegradation (Chandrangsu et al., 2017), photolysis and mechanical degradation, which is a very slow process. The ultimate fate of petroleum pollutants in the environment is that they are degraded by microorganisms, and thee photolysis is very small. When petroleum pollutants enter the environment, various microorganisms will participate in their biodegradation process. As nutrients, pollutants are absorbed and transformed into organic components in microorganisms or reproduced into new microorganisms. The rest is oxidized and decomposed into simple organic or inorganic substances such as methane, carbon dioxide and water by microorganisms. Petroleum pollutants are biodegraded by aerobic respiration, anaerobic respiration and fermentation after they enter the cell membrane of degrading microorganisms. In aerobic respiration, organic matter is oxidized to carbon dioxide, water and other final products, and the electron acceptor is atomic oxygen; in anaerobic respiration, other inorganic substances are used as electron acceptors, and organic matter is oxidized to methane, sulfate is reduced to sulfide, nitrate is reduced to N_2 or ammonia; the fermentation process does not depend on oxygen, but on the presence of oxygen. As electron acceptors, the final products are carbon dioxide, acetic acid, alcohol, propionate and so on. Generally, biodegradation of petroleum substances is mainly accomplished by aerobic degradation.

In soil, bacteria (Papale et al., 2017) are dominant decomposers, followed by fungi. Different petroleum degrading bacteria have different degrading ability for different hydrocarbons in pollutants. Most petroleum degrading bacteria can degrade only one or several hydrocarbons. Among them, long-chain n-alkanes in petroleum hydrocarbons can be utilized by most petroleum-degrading bacteria, while short-chain alkanes and aromatics can only be degraded by a few bacteria. The proportion of hydrocarbon-degrading bacteria in the total heterotrophic population varies greatly. So far, more than 200 kinds of hydrocarbon-degrading microorganisms have been known.

Biochemical principle of petroleum degradation by microorganisms

It is a very complicated process that petroleum pollutants are degraded by assimilation after they enter the cells of degrading microorganism (Barp et al., 2017). Under aerobic conditions, mainly under the catalysis of oxygenase, molecular oxygen is combined into the matrix to form oxygen-containing intermediates, and then converted into other substances. In the degradation of alkanes, one oxygen atom in O_2 is bound, while in the degradation of aromatics, two oxygen atoms are bound. Since petroleum is a mixture of hydrocarbons, the degradation of petroleum can only be accomplished by the interaction of various microorganisms.

When the degradation of petroleum pollutants by microorganisms are caused by intracellular enzymes, the whole process of microbial degradation can be divided into the following three steps:

(1) Compounds are adsorbed on the surface of microbial cell membrane, which is a dynamic equilibrium process.

(2) Compounds adsorbed on the surface of cell membrane enter the cell membrane (when the biomass is constant, the penetration rate of the compound to the cell membrane determines the amount of the compound penetrating the cell membrane).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27272746

(3) Enzymatic reactions occur when compounds entering microbial cell membranes bind to degrading enzymes, which is a fast process. The metabolic pathways and mechanisms of microorganisms to different hydrocarbons in petroleum pollutants are different. The following are mainly discussed.

Biodegradation of saturated hydrocarbons in petroleum

Straight-chain alkanes: it is generally believed that saturated hydrocarbons (Pattison et al., 2018) are first oxidized to alcohols under the action of microorganisms, alcohols are oxidized to corresponding aldehydes under the action of dehydrogenase, and then oxidized to fatty acids through the action of aldehyde dehydrogenase. The oxidation pathways include single-end oxidation, double-end oxidation and sub-end oxidation. After converting to the corresponding fatty acids, one form of conversion is to directly undergo the subsequent β-oxidation sequence, i.e. to form carboxyl groups and to shed two carbon atoms; the other is to undergo the ω-hydroxylation of fatty acids to form ω-hydroxy fatty acids, which are then oxidized to dicarboxylic acids with the participation of non-specific hydroxylase, and finally experienced the final β-oxidation sequence. Fatty acids are degraded into acetyl coenzyme A by β-oxidation, which enters the tricarboxylic acid cycle, decomposes into CO_2 and H_2O and releases energy, or enters other biochemical processes. Alkanes can also be dehydrogenated directly to form olefins, which can be further oxidized to alcohols and aldehydes through enzymatic catalysis, and finally to fatty acids, which can be further decomposed according to the sequence of β-oxidation; or alkanes can be oxidized to alkyl hydrogen peroxide and then directly converted to fatty acids.

Branched alkanes: the degradation mechanism of branched alkanes by microorganisms is basically the same as that of straight alkanes. Compared with n-alkanes, the presence of branched chains increases the resistance of microbial oxidation and degradation. The main part of oxidation and decomposition occurs on the straight chain, and it is difficult to oxidize near the end of the side chain. The degradation of branched alkanes can be carried out through α-oxidation, ω-oxidation or β-base removal pathway. Generally speaking, the degradation rate of hydrocarbons with branched chain structure is slower than that of straight chain hydrocarbons with the same carbon number, because the branched chain of alkanes reduces the decomposition rate.

Naphthalene: Naphthalene accounts for a large proportion of petroleum fractions. Its biodegradation principle is similar to that of sub-terminal oxidation of alkanes. First, naphthenols are oxidized by mixed-function oxidase (hydroxylase), then dehydroketones are oxidized to esters, or fatty acids are formed by direct ring opening. Taking cyclohexane as an example, its biodegradation mechanism is as follows: cyclohexane is hydroxylated by oxidase to form cyclohexanol, which dehydrogenates to ketone, then oxidizes further. An oxygen atom inserts into the ring to form ester, ester opens, and hydroxyl at one end is oxidized to form aldehyde group, then oxidized to form carboxyl group, finally, dicarboxylic acid is further metabolized by β-oxidation.

Monocyclic aromatic benzene and short-chain alkylbenzene are metabolized to catechol and substituted catechol through the intermediate process of diol under the action of dehydrogenase and redox enzyme. The aerobic degradation of benzene is the formation of cis-dioxyl compounds by introducing two hydroxyl groups into the benzene ring, and then deoxidized to form catechol.

Catechol (Du et al., 2017) can be cleaved in two ways: between two hydroxyl groups; between hydroxyl carbon atoms and non-hydroxyl carbon atoms.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27272746

There are two ways to degrade toluene, ethylbenzene and xylene: oxidation of methyl or ethyl groups on benzene rings to form carboxyl groups, then removal of carboxyl groups, and introduction of two hydroxyl groups to form catechol under the action of hydrogenase; direct oxidation of benzene rings to connect two hydroxyl groups, and further oxidation.

Polycyclic aromatic hydrocarbons (PAHs) are very difficult to degrade. The degree of degradation is related to the solubility of PAHs, the number of rings, the type of substituents, the position of substituents, the number of substituents and the properties of heterocyclic atoms. Biodegradation of polycyclic aromatic hydrocarbons (PAHs) begins with the progressive degradation of pyruvic acid and CO_2 by hydroxylation of the first ring, followed by the decomposition of the second ring in the same way. Prokaryotic and eukaryotic microorganisms have the ability to oxidize aromatic hydrocarbons, but the mechanisms of aromatic hydrocarbon oxidation by bacteria and fungi are different. Bacteria produce dioxygenase, which combines the two oxygen atoms of molecular oxygen with the substrate by the catalysis of dioxygenase to oxidize aromatic hydrocarbons into cis-structured diols, and cis-diols break the aromatic ring into catechols under the catalysis of another peroxidase. Fungi, on the other hand, can oxidize aromatic hydrocarbons to trans-dihydrodiphenols by catalysis of monooxygenase and cyclohydrolase. Different metabolic pathways have different intermediates, but the common intermediates are catechol, 2,5-dihydroxybenzoic acid and 3,4-dihydroxybenzoic acid. These metabolites are degraded through similar pathways, i.e. the breaking of carbon bonds. On the one hand, the metabolites can be utilized by microorganisms to synthesize cell components, on the other hand, they can also be oxidized to CO_2 and H_2O.

Influencing factors of microbial degradation of petroleum pollutants

Chemical composition and environmental factors of petroleum are the most significant factors affecting biodegradation in soil. Environmental factors include microbial species and quantity in soil, nutrient elements in soil, oxygen supply, temperature, humidity, pH value and so on.

Chemical composition of petroleum

The degradability of petroleum products varies with their composition. Petroleum compounds are mainly composed of saturated hydrocarbons, aromatics, nitrogen sulfur oxides and asphaltene. Petroleum compounds can be classified into thousands of chemical systems according to the length of carbon chain (Schmidbaur and Schier, 2017) and whether they form straight chain, branched chain, ring or aromatic hydrocarbon structure (Sinsabaugh et al., 2017). The degree of biodegradation of various hydrocarbons is different, and the degradation rate is mainly determined by the number of carbon and its functional groups. Among the components, saturated hydrocarbons are the most easily degraded, followed by aromatic compounds with lower molecular weight, while aromatic compounds, resins and asphaltenes with higher molecular weight are extremely difficult to degrade. Among saturated hydrocarbons, straight-chain alkanes are the most easily degraded, while branched-chain alkanes are more difficult to be degraded by microorganisms. The presence of branched-chain enhances the corrosion resistance of alkanes, and the more and larger the branched-chain is, the more difficult it is to be degraded by microorganisms. In aromatic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27272746

hydrocarbons, dicyclic and tricyclic compounds are easily degraded. The degradation order of aromatic compounds generally decreases with the increase of aromatic rings and alkyl substituted side chains. The biodegradability of polycyclic aromatic hydrocarbons decreases in the following order: triaromatic steroids, yield series, phenanthrene series and naphthalene series. Cycloalkanes and aromatic hydrocarbons with more than four rings, or compounds containing tar and asphaltene components, have a slower biodegradation rate. A large number of these substances remain in the final products of biodegradation and become the main residual substances after degradation.

Generally, medium-length alkanes degrade rapidly, while longer-chain alkanes are not easy to degrade. Compounds with relative molecular weight more than 500 cannot be directly used as carbon source for microbial growth (Han and Currell, 2017). Generally speaking, C10-C22 compounds in alkanes and aromatics are the least toxic and most easily degraded. C1-C6 volatilizes rapidly, mainly in the form of gases in the environment, and short-chain hydrocarbons are degraded by a small number of microorganisms because of their relatively stable structure. Hydrocarbons above C22 are poorly water-soluble, usually in the form of gases. In the case of solid, the degradation of microorganisms is very limited; with the increase of relative molecular weight, the biodegradability decreases. Because of the difference of biological stability, the degree of biodegradability of petroleum components is very different, and the environment of microorganisms in the same polluted area is also quite different.

Microbial species and quantities

As the executor of petroleum biodegradation, the number and species of microorganisms are the important factors affecting the efficiency of petroleum biodegradation. Environmental conditions affect the biodegradation of organic pollutants (Lee et al., 2017), generally by affecting the activity of microorganisms. Different microorganisms have different ability to degrade petroleum hydrocarbons, and the same strain has different ability to utilize different hydrocarbons. In the petroleum contaminated soil environment, the more the number and species of petroleum-degrading microorganisms are, the faster the degradation rate is. Petroleum pollution can induce the growth of oil-degrading microbial population. The number of oil-degrading microbial population is less than 0.1% in non-oil-polluted areas, but the proportion and quantity of oil-degrading bacteria in the polluted areas have increased significantly. The more serious the pollution is, the more bacteria there are. The results show that the number of microorganisms is an important factor affecting the oil degradation efficiency. Within a certain range of oil concentration, the petroleum degradation efficiency of microorganisms is not affected by other factors.

Oxygen supply and nutrition in soil

Adequate oxygen content in soil has an important influence on degradation efficiency. The initial process of microbial degradation of petroleum pollutants is the oxidation of matrix by oxidase (Naafs et al., 2017). First of all, oxygen must be involved. That is, under the catalysis of oxygenase, oxygen is added into the matrix to form an intermediate product containing oxygen. In theory, the amount of oxygen required for degradation is about 3.5 times the mass of hydrocarbons. Under anaerobic conditions, although some microorganisms may react to degrade petroleum pollutants, it

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27272746

is much slower than that under aerobic conditions, and there are few kinds of microorganisms that can degrade hydrocarbons. Experiments show that under anaerobic conditions, the degradation rate of pollutants is less than 5% after 233 days, while under aerobic conditions, the degradation rate of some hydrocarbons is increased, and the degradation rate of some hydrocarbons is more than 20% after 14 days.

The most basic limiting factor for microbial growth is the lack of appropriate energy sources. There are at least 11 macronutrient and micronutrient elements (N, P, K, Na, S, Ca, Mg, Fe, Mn, Zn, Cu) necessary for microorganisms in the soil. These elements must maintain a certain amount, form and proportion in order to maintain the growth of aerobic bacteria. The other micronutrient elements necessary for several anaerobic bacteria include Ni and Co. Lack of nutrients inhibits microbial degradation of petroleum hydrocarbons. Most microorganisms are heterotrophic and use certain organic matter as energy source. In petroleum contaminated soils, organic carbon is usually high, while N and P are relatively deficient. If m(C):m(N):m(P) does not reach the required proportion of bacterial metabolism, the metabolic rate of bacteria will be limited, thus restricting the degradation of organic pollutants. Therefore, adjusting the proportion of essential nutrients is a necessary condition for the smooth degradation process. The results show that close to 100:10:1 is the most suitable ratio for hydrocarbon biodegradation.

Soil temperature

Soil temperature also affects degradation efficiency. Temperature can directly affect the growth, reproduction and metabolism of microorganisms, and the biochemical reaction accords with the general law of chemical reaction rate, that is, the higher the temperature is, the faster the reaction rate is. The results show that the effect of soil temperature (T) on the rate constant (k) of biological reaction is in accordance with the following relationship:

$$k = 3145\exp(-5233/T) \quad \text{(Eq.1)}$$

In the aerated zone, the half-lives of petroleum pollutants at 5 ℃, 10 ℃, 20 ℃ and 30 ℃ are 1499 d, 1075 d, 572 d and 317 d, respectively. The results show that microorganisms can degrade at -72 – -2 ℃; the number of microorganisms increases and the degradation rate increases with the increase of temperature at -10-0 ℃; the degradation rate of n-alkanes can be doubled at 20-30 ℃, and the degradation rate of heavy oil and light oil can be decreased by 50-60% and 0-40% respectively, when the temperature decreased from 20 to 10 ℃. Temperature affects the degradation of petroleum organisms mainly in the following two aspects: the effect of temperature on enzymes in microorganisms and the effect of temperature on petroleum properties.

The effect of temperature on enzymes in microorganisms: because microorganisms are accompanied by complex biochemical reactions in the process of degradation of organic substances, the biodegradation of these organic substances actually needs to be carried out under the catalysis of enzymes produced in microorganisms, and temperature is an important dominant factor in the kinetics of enzymatic reaction. The catalytic activity of each enzyme can only be brought into play within a certain temperature range, and beyond a certain temperature range, the activity of the enzyme will be inhibited or even cause the inactivation of the enzyme. The activity of microbial

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27272746

enzymes can be reduced by too low temperature, and the degradation rate of hydrocarbons can be accelerated and the maximum value can be achieved by increasing temperature. The appropriate temperature is generally 15-35 ℃. The toxicity of hydrocarbons will increase when the temperature is higher, which will affect the degradation and biological activity of hydrocarbons.

The influence of temperature on petroleum properties: temperature also affects the physical and chemical properties of petroleum, and ultimately affects the interaction between microorganisms and petroleum molecules, thus changing the process and rate of biodegradation. When the temperature is low, the membrane toxicity of hydrocarbons is small, the oil viscosity is high, the volatility decreases, the start-up of biodegradation lags behind, and the rate decreases. With the increase of temperature, the membrane toxicity of hydrocarbons increases, and the emulsification degree of oil increases. In addition, the microbial activity needs liquid water, so the degradation temperature should be at least above the freezing point of water (Wu et al., 2018).

Soil moisture and pH value

Water is an indispensable nutrient for microbial life activities. Microorganisms cannot survive without water, and let alone degrade petroleum pollutants. In addition, organic matter must be water-soluble in order to be utilized by microorganisms. Water is also closely related to redox potential and solubility of compounds. The results are important factors affecting petroleum degradation. Soil moisture varies in depth, soil moisture is too low, microorganisms cannot get enough water supply, cell activity is inhibited, and metabolic rate is reduced; but excessive soil moisture will hinder air permeability and oxygen supply. The results showed that the maximum soil water holding capacity is 25-85%, which is the most suitable time for microorganisms to survive, and the best soil water holding capacity is 30-90% for petroleum pollutants degradation.

Most heterotrophic bacteria and fungi which can degrade petroleum pollutants prefer neutral environment. The suitable pH value of many soil microorganisms is 6-8. Excessive or low pH value will affect the degradation ability of microorganisms. The optimum pH values of hydrocarbons and polynuclear aromatic hydrocarbons are 7.5, 7.5-7.8, respectively. The optimum pH values of most bacteria are slightly greater than 7. The degradation rate of petroleum in neutral soil is twice as fast as that in acidic soil (pH 4.5) or alkaline soil (pH 8.5).

Results

The main mechanism of microbial remediation technology is that petroleum hydrocarbons are directly involved in the biochemical reaction of microorganisms. The development and research of microbial remediation technology for degradation of contaminants in soil by metabolic process has attracted extensive attention of scholars at home and abroad. At present, more than 100 genera and 200 species of microorganisms are known to degrade hydrocarbons in petroleum. They belong to bacteria, actinomycetes, fungi, yeasts and algae. Geological microecology technology is a comprehensive remediation technology which makes full use of the optimization of in-situ microbial flora, supplemented by physical and chemical methods and combined with geological environment. In the past, most of the research materials reported are indoor studies. This study is carried out in situ soil remediation experiments in the field,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27272746

and achieves good results, which provides technical support for the popularization and application of this technology, and has important practical significance.

Experimental steps

The crude oil obtained in the test area is used as carbon source (pollutant). The strains and flora of petroleum-degrading soil in the test area are selected and cultured in a large scale. According to the inoculum amount used in the test, sufficient bacterial liquid preparations are cultured, and a large number of bacterial flora for the test are grown through microscopic examination. According to the calculation, a certain amount of oil is evenly mixed into the surface layer of soil in the test area at a depth of 15 cm. The microorganisms that degrade petroleum compounds can be divided into bacteria, fungi and algae according to their biological types (as shown in *Table 1*).

Table 1. *Microbial composition of oil contaminated soil*

Soil sample	Germ		Fungus		Actinomyces	
	10^5CFU (g)	**Percentage composition (%)**	**10^3CFU (g)**	**Percentage composition (%)**	**10^3CFU (g)**	**Percentage composition (%)**
CK	33 ± 8b	94.25	3 ± 1c	0.08	176 ± 55a	5.10
PCS-1	297 ± 35a	98.88	27 ± 4a	0.08	9 ± 3b	0.03
PCS-2	193 ± 49a	99.92	12 ± 3b	0.08	3 ± 1b	0.02

According to the soil weight of the test layer in the test area, 4.3% chicken manure and 50% chicken manure are evenly mixed as additives. The amplified culture liquid is evenly inserted into the test area according to the 3% spray tillage, and then the nutrient solution of nitrogen, phosphorus, calcium, magnesium, sulphur and iron is adjusted uniformly according to the proportion of the medium. The water content of the soil layer is about 20% with the local groundwater regulation test. Agricultural plastic film is covered in the test area for heat preservation, moisturizing, rainproof and so on. Within a certain time interval, the sampling method is to take the sample with same depth soil (15 cm) at five different points in the shape of plum blossom in each area, and then mix it thoroughly and test it with 4-point sampling method. After sampling, the experimental layer of the tillage test area is aerated by the storm air and supplemented with a certain amount of water to ensure that the soil's water content in the test area is about 20%. The amount of petroleum added into the control area is basically the same as that in the experimental area, but not in the other areas, which is regarded as natural degradation. There is no substance added to the blank area as a monitoring sample. Three areas are sampled at the same time and tested components are petroleum content, pH, soil soluble salt, water content, NH_4, NO_3 and so on. At the same time, the surface temperature and soil temperature are monitored. After the completion of the test period, samples are taken from the lower part of the test layer in each district. The test results are shown in *Table 2.*

Experimental result

In this paper, Matlab simulation tool was used to simulate the oil content and removal rate of soil, the degradation rate of organic matter in oil pollution samples with different water content, the degradation rate of petroleum by microorganisms and the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27272746

degradation characteristics of n-alkane in oily soil under the environment of Microsoft Windows XP operating system, Intel (R) Celeron (R) 2.6 GHz processor and 24 GB memory.

Removal rate of petroleum from soil

From *Table 2* it can be seen that the implementation of in-situ micro-ecological remediation technology for petroleum contaminated soil has certain effectiveness through field experiments. In the early stage of the experiment (0-7 d), the added optimum bacterial solution does not play a role. That is to say, when indoor optimum bacterial solution is applied in the field, it needs an adaptation period or a lagphase of bacteria. The optimum period of this experiment is about 7 days. Later, the proliferative phase (logarithmicphase) is entered. *Table 1* shows that the removal rate is over 80% after the 11th day of the experiment, that is, after the adaptation period. The sample is slightly higher because of the sampling location and heterogeneity. However, the removal rate is over 68% at the 16th day of the experiment, and 84.3% at the 32nd day of the experiment. The oil content of the soil in the control area does not change much, except that the two abnormal low values are less than 10%, which indicates that the degradation of oil in the soil is slow under natural conditions. The test data of 16 and 21 days of the two abnormal low values may be caused by the uneven oil content in the soil, and also reflects the heterogeneity and complexity of soil material composition. The blank area reflects the oil content in the soil without adding any substance, but in the later stage of the experiment, the oil content increases because of the adjacent of the test area and the control area, as well as the contamination of the area by rainfall and artificial sampling.

Table 2. *Testing results of changes of oil content and removal rate with time in soils of different areas*

Sampling date (month/day)	8/19	8/23	8/26	8/30	9/4	9/9	9/14	9/20

Controlling factors of geological microecological remediation technology

Geological microecology technology is an in-situ remediation technology which changes macro-environment by micro-effect. The key to the application of this technology is the combination and regulation of microorganisms and geological environment. The main controlling factors are improvement of temperature, water, oxygen, nutrient elements and geological environment.

(1) Regulation and control of soil temperature

Temperature is one of the important factors affecting the growth and survival of bacteria, and the activity intensity and biochemical function of bacteria are related to it. Excessive or low temperature can inhibit growth or cause bacterial death, and moderate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27272746

temperature can accelerate the biochemical reaction rate in bacterial cells. Most of the microorganisms we used are mesophilic microorganisms (13-45 ℃), and the optimum growth temperature is 25-38 ℃. How to control the temperature is the key to the test effect. Therefore, agricultural plastic film is used for thermal insulation in the test area, and grass curtain is used to cover the night after September because of the obvious drop in temperature.

(2) Analysis of soil pH, water content, soluble salt, NH_4 and NO_3 content

Firstly, the effect of soil dryness and wetness on the degradation rate of oil pollution.

Under different water content conditions, the degradation characteristics of petroleum contaminated soil samples with 100 g/kg petroleum pollutant concentration by microorganisms are shown in *Figure 2*.

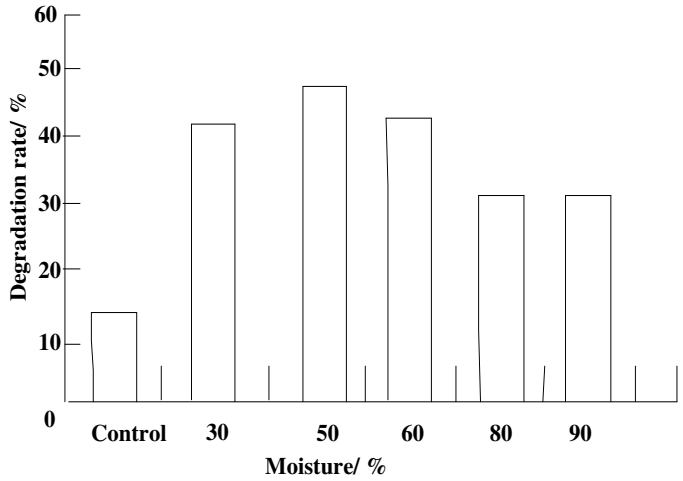

Figure 2. *Degradation rate of organic matter in oil pollution samples with different water contents by microorganisms*

Figure 2 shows that the water content of petroleum contaminated samples has a significant effect on the petroleum-degrading ability of oil-loving microorganisms. When the water content is less than 50%, the ability of microorganism to degrade petroleum increases with the increase of water content; however, when the water content is higher than 50%, the ability of microorganism to degrade petroleum begins to weaken gradually with the increase of water content. In fact, microorganisms in soil need water to maintain their basic metabolism. If the soil water content is too low, microorganisms will not get enough water supply, and cell activity will be inhibited, resulting in a decrease in its metabolic rate; while excessive soil moisture will hinder air permeability and oxygen supply. According to the conditions required for microbial activity, the degradation of petroleum hydrocarbons is more advantageous in the range of 30-80% of the maximum water holding capacity of soil. When the water content is less than 30% or more than 90%, the activity of petroleum hydrocarbon-degrading bacteria will be adversely affected. This phenomenon shows that the growth and reproduction of microorganisms need certain water conditions, and water is necessary for some enzymes of microorganisms; however, excessive water will prevent

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27272746

microorganisms from effectively contacting with oxygen, resulting in microbial hypoxia and inhibiting the ability of microorganisms to degrade petroleum.

Secondly, the effect of adding H_2O_2 on the degradation of petroleum pollution.

Microorganisms continuously consume dissolved oxygen in petroleum hydrocarbon degradation process, so that the concentration of dissolved oxygen decreases. In this study, H_2O_2 is added to the sample, which is decomposed to supplement the dissolved oxygen consumed by microorganisms. In order to maintain the dissolved oxygen in the sample, a certain amount of H_2O_2 is added every day. At the same time, because of the strong oxidation of hydrogen peroxide, if the amount of hydrogen peroxide is too high, it will inhibit the growth of microorganisms. Therefore, this study determines that the upper limit of adding H_2O_2 is 0.5 ml/d. In the process of experiment, under the best conditions of other factors, for the sample 1-4 containing 100 g/kg oil-polluted soil, 0.1 ml, 0.2 ml, 0.5 ml and 0.6 ml of H_2O_2 are added. And the degradation characteristics of petroleum contamination by microorganisms are shown in *Figure 3*.

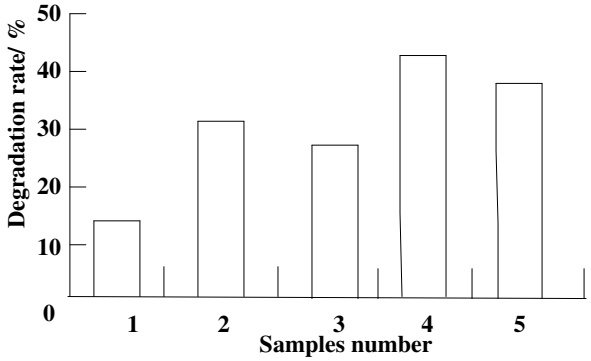

Figure 3. *Effects of microorganisms on petroleum degradation rate under different conditions of H_2O_2*

It can be seen that the influence of oxygen content on the ability of microorganisms to degrade petroleum is also relatively large. With the addition of H_2O_2, the activity of microorganisms is gradually strengthened and the degradation ability is gradually improved. When H_2O_2 is added to 12 ml in 24 days, the degradation efficiency reaches its maximum value. Moreover, it can be seen from the determination of microorganisms in oily soil that the number of living bacteria in test samples increases with the addition of H_2O_2, and the number of living bacteria in test samples increases gradually. Increase of the number of living bacteria will inevitably accelerate the degradation rate of petroleum pollutants. In addition, the pH value of slurry can be maintained stable without obvious change with the addition of H_2O_2. In the absence of electron acceptor, microbial oxidation of fatty acids is difficult and hydrocarbon contaminants cannot be completely oxidized, which results in the accumulation of some short-chain fatty acids in the test samples and the decrease of pH value. If sufficient electron acceptors are provided, microorganisms will completely oxidize hydrocarbons to CO_2 and H_2O, thus keeping the pH value of the sample stable. This is conducive to the growth and reproduction of microorganisms, enhancing their activity, and leading to the degradation of microorganisms more obvious.

Thirdly, the degradation characteristics of alkanes under different N/P ratios.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27272746

Under different N/P ratios, the relative content of residual alkanes after degradation of petroleum contaminated samples with 100 g/kg contamination by microorganisms is shown in *Figures 4* and *5*. *Figures 4* and *5* show that the residual content of n-alkanes and iso-alkanes with various carbon numbers is the least when the ratio of N to P is 10:1 under different N/P ratios, while the residual amount of n-alkanes and iso-alkanes is higher under other N/P ratios. Quality can effectively enhance the degradation ability of microorganisms and promote oil-loving microorganisms to effectively degrade alkanes in petroleum. It also reflects that oil-loving microorganisms have a relatively balanced degradation of n-alkanes in the range of C16-C21, however, oil-loving microorganisms are selective for the consumption of isoparaffins in the range of C15-C20. The degradation rates of C16 isoprene, Pr and Ph are significantly lower than those of C15, C18 isoprene, Pr2 and MP isoalkanes. The characteristics of selective degradation show that Pr, Ph are difficult to degrade, and the stability of Pr and Ph can also be utilized, so that Pr and Ph are used as molecular markers for the degradation of petroleum pollutants.

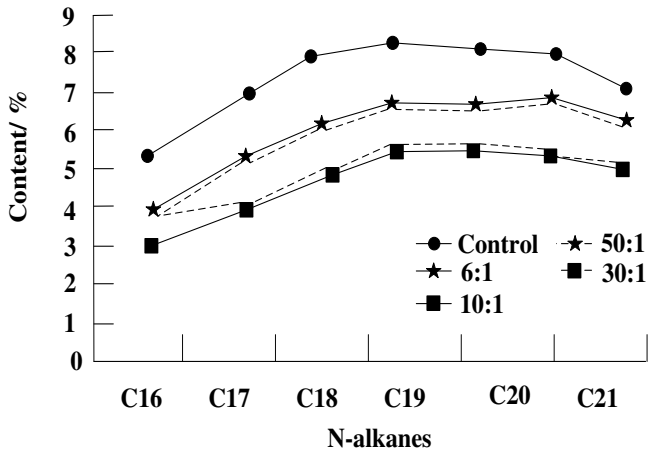

Figure 4. *Degradation characteristics of n-alkanes in oily soil under different nutrient conditions*

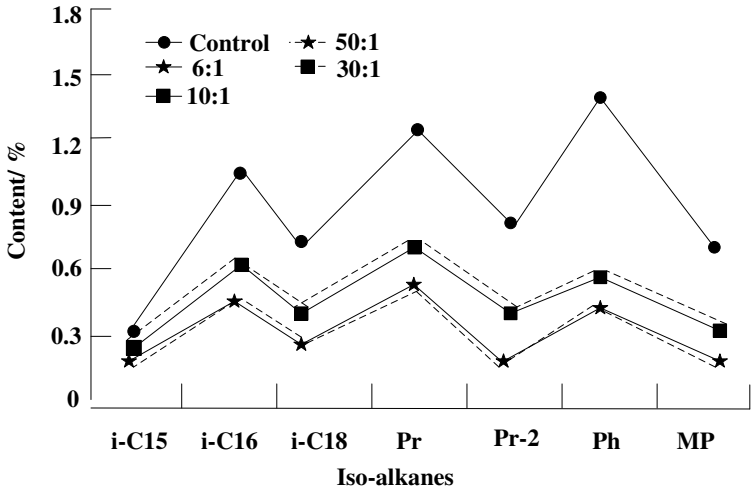

Figure 5. *Degradation characteristics of isoalkanes in oily soil under different nutrient conditions*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27272746

The pH of the environment has a certain influence on the life activities of microorganisms. It can cause the change of cell membrane charge, affect the absorption of nutrients and the activity of enzymes, and change the availability of nutrients and the toxicity of harmful substances in the environment. The survival of each microorganism has a certain range of pH value and the optimum pH value. The optimum pH value of most bacteria is 6.5-7.5, and that of actinomycetes is 7.5-8.0. Fungi can grow and develop in a wide range of pH. For example, fungi can grow at pH below 3 and above 9, and the optimum is 5-6.

Effect of test process on lower soil in test area

Table 3 is to test the contents of oil, pH, water content, soluble salt, NH_4 and $N0_3$ in different depths of the lower part of the test area after the completion of the test. From the test results, it can be seen that the oil content in the lower part of the test layer does not increase significantly. Compared with the control and blank areas, it shows that the oil in the soil of the experimental layer has not diffused downward or has been degraded. From the contents of pH, water content, soluble salt, NH_4, NO_3, it can be seen that they are different from the control area and blank area. That is to say, some soluble nutrients such as nitrogen and phosphorus enter the lower soil layer with water. In the future, this kind of remediation work is of great significance to the requirements of water quantity and soluble nutrients and the adding methods.

Table 3. *Test for soil pH, water content and soluble salt, NH_4, NO_3 content changing with depth in each area after the experiment*

Different depths	Petroleum (mk/kg)	pH	Water content (%)	Soluble salt (Ms/cm)	NH_4 (mol/L)	NO_3 (g/cm^3)
Test area 20-25	61.9	7.8	14.04	821.5	70.0	246.4
30-35	102.2	8.0	15.27	612.0	5.0	242.7

30-35	36.55	8.7	10.58	80.2	1.5	32.7
45-50	36.95	8.5	14.09	171.2	1.5	31.6

Discussion

Oxygen supply has become one of the important regulators in the process of bacterial degradation of petroleum pollution. The amount of oxygen supply can affect the activity of many enzymes and cell respiration in microbial cells, and control the growth of microorganisms and the ability to degrade petroleum pollution. Generally, 1.02 g petroleum per 3.5 g of oxidation is required, which can be degraded rapidly only under sufficient oxidation conditions. In this experiment, the supply of soil oxygen is regulated from four aspects. Firstly, the soil is fully tilled and the experimental layer is tilled after each sampling, which is fully mixed with the atmosphere. The second is to ensure that the tested soil has a certain water content and oxygen provided by water. In addition, chicken manure is used as an additive, which is not only cheap and easy to obtain, but also can supplement nutrients, and the soil of the experimental layer is improved to increase the fluffy and permeability, so that oxygen in the air is easy to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27272746

enter. Finally, the added nutrients of NH_4O_3, KH_2PO_4, K_2HPO_4, NO_3, etc., not only increase the nitrogen source, but also the sources of oxygen.

Nutrient elements are the active components of microbial cells, enzymes, substance transport systems and the energy required to provide physiological activities. Microbial cells are mainly composed of C, H, O, N, P and so on, in which C and H come from petroleum pollutants. Oxygen comes from water and air and other regulated sources of oxygen. The trace elements of N and P as well as S, K, Ca, Mg and Fe need to be supplemented and regulated as nutrients, and chicken manure from local chicken farms is as additive to supplement other biotin and nutrients. *Table 2* shows the changes of soluble salts, NH_4 and NO_3 contents with the test process. It can be seen that the test area is supplemented various nutrient elements on August 21, reflecting the process of utilizing, degrading and transforming petroleum and various elements with the microbial activities in the test process. This process verifies that the nutrient elements added in the regulation and control of this experiment are appropriate. The control area and blank area reflect the natural content change, and the rainfall makes the content decrease.

Conclusions

(1) Based on the preliminary experimental study on in-situ microecological remediation of petroleum contaminated soils, the soil temperature, water, oxygen, nutrients and geological environmental factors in the test area are regulated by optimizing in-situ (indigenous) microbial flora and combining physical and chemical methods with geological environment. The experiment of degradation and remediation of man-made petroleum contaminants in soil shows that the average content of oil in soil is 2318.5 mg kg^{-1}. After 11-32 days of in-situ microecological remediation, the removal rate of petroleum in soil can reach 68.47-84.30%. The oil content of artificial filling in the soil of the control area does not change much, basically less than 10%, indicating that the degradation of oil in the soil is slow under natural conditions. The validity of geological microecological remediation technology for petroleum pollution remediation is verified, and the feasibility of its popularization and application is explored.

(2) It is concluded that the best season for using microecological restoration technology in this area should be from late June to early September every year, and soil temperature can be kept above 25 ℃ through regulation.

(3) It is proved that the nutrients added in the experiment and the improvement of soil environment are moderate, and the method is feasible.

The experimental process preliminarily verifies that the geo-microecological remediation technology is effective and feasible in the field in situ soil's oil pollution remediation experiment. It has the advantages of simple treatment method, low cost, good remediation effect, little environmental impact, no secondary pollution, and in situ remediation. Although it is an experimental study and needs to be improved for large-scale field restoration, it can be achieved through continuous efforts. It can not only effectively remediate soil, aeration zone and prevent and control oil pollution of groundwater in situ, but also increase soil fertility and improve soil environment. It is of great significance to remediate contaminated soil and increase crop production. It is also one of the effective methods to remediate and control oil pollution in large areas of soil fundamentally, having certain practical application value. In this paper, the ecological restoration of soil oil pollution is studied, but the application of the technology to the ecological restoration of heavy metal soil pollution is still to be verified.

(Received 3rd Sep 2019; accepted 12th Feb 2020)

Abstract. As heavy metal pollution in the soil is becoming more and more serious, a solidification remediation method considering environmental carrying capacity is proposed. Firstly, the index system for soil environmental carrying capacity is constructed to obtain an evaluation method and grade soil carrying capacity, in order to be able to take the evaluation results into account. According to the soil remediation standard, the method of solidification remediation is used to remediate the heavy metal pollution in soil. The method first measures the soil sample and adds water to the mixture based on the results of measurement; excavates the soil and sprinkles the mixture with water; mixes the mixture until the color and moisture are uniform; smoothes and regularly compacts the toppled soil to solidify the contaminated elements in the soil. In order to remedy the contaminated soil, the organic and inorganic pollutants in its solid phase are transferred into the liquid phase by ethylenediamine tetraacetic acid (EDTA) reagent. The experimental results show that the average reduction rate of soil contaminated elements is 95.86% after remediation by the proposed method, and this method can effectively remediate the various forms of heavy metal contaminated elements in soil.
Keywords: *evaluating indicator, comprehensive evaluation value, range standardization, data preprocessing, expert evaluation method*

Introduction

In recent decades, with the rapid development of China's industry, heavy metals have been widely used in production. However, with the adjustment of industrial structure and the implementation of policies such as "retreat into three" and "retreat to the city and enter the park", a large number of industrial and mining enterprises have been shut down and relocated. "Retreat into three" is the phenomenon that the original plant land is re planned as residential land. Many industrial enterprises in the old urban area move to the industrial park, suburb or development zone. This process is called "retreat to the city and enter the park". According to the data released by the State Environmental Protection Administration in 2013, from 2006 to 2012, there were nearly 100,000 industrial relocation sites in China (Matos et al., 2017). Due to the extensive environmental safety management model, the disorderly discharge or leakage of industrial wastewater and the stacking of metal slag, a large number of heavy metal contaminated sites have been produced, which has exerted tremendous pressure on the subsequent land development and utilization.

Land resources are the basic guarantee for human survival and development, sustainable utilization of ecological environment and regional economic construction. In recent years, with the rapid development of urbanization in China, there are many problems such as environmental pollution and shortage of resources. There is a "one more

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27472760

and three less" phenomenon: more land resources, less per capita, less high-quality arable land and less arable land reserve (Liu et al., 2018). Therefore, according to the regional population, economy, industry, agriculture, city, transportation, energy, environmental management, industrial environmental governance, urban environmental governance and other factors, this paper establishes a comprehensive evaluation model of environmental carrying capacity (Chen and Li, 2018) to evaluate the level of soil environmental carrying capacity in the region, which provides scientific basis for strengthening the scientific management of regional land resources, protecting the ecological environment, improving the productivity of regional soil cultivated land and ensuring human health.

Heavy metal pollution has the characteristics of wide pollution range, long duration, hidden pollution, and cannot be degraded by microorganisms. It directly or indirectly endangers human health and life (Tian et al., 2017). With the continuous transformation of regional economy and the constant adjustment of economic structure, enterprises located in urban areas began to "retreat to the city and enter the park". A number of enterprises with high pollution and low productivity are facing relocation, transformation or elimination. The polluted soil left behind must be repaired before it can be transferred and redeveloped.

The remediation of heavy metal contaminated soils has been a hot topic both at home and abroad. Wang et al. (2016) focuses on the application of remediation methods for heavy metal contaminated soil, but the remediation of heavy metal contaminated soil is not carried out under the premise of considering the environmental carrying capacity. Rutskii et al. (2017) only described the remediation of pollution elements Cu and Pb in detail, however, it does not show that the method adopted has the effect of remediation for most of the contaminated elements. Yang et al. (2016) uses a variety of chemical reagents to transfer organic and inorganic pollutants from the solid phase of contaminated soil to liquid phase fluid, but this process is only carried out once, and the data obtained from heavy metal pollution of soil are not accurate.

In this paper, physical, chemical and biological methods (Lü et al., 2017) are used to remediate heavy metal contaminated soils through the following ways: (1) reducing the concentration of heavy metals in soil by dilution; (2) changing the form of heavy metals to fix or passivate them, and reducing their mobility and bioavailability in the environment; (3) removal of heavy metals from soil. The domestic soil remediation industry is still in its infancy and growing stage. Most of the pilot projects are site pollution control in urban relocation plant areas. There are many cases of organic pollution remediation, few cases of heavy metal pollution remediation, and many heavy metal technologies are still in the laboratory research stage (Chen et al., 2017). Based on the index system of soil environmental carrying capacity, the evaluation method and grade of soil environmental carrying capacity are obtained, and the solidification remediation method of soil heavy metal pollution is studied considering the effect of environmental carrying capacity. This method first determines the soil sample and adds water to the mixture on the basis of the measured results; excavates the tested soil and sprays the mixed material with water; mixes the mixed soil until the color and moisture are uniform; smoothes the overturned soil, and regularly rolls the soil to make it uniform. Polluted elements in soil are solidified, organic and inorganic pollutants in the solid phase of contaminated soil are transferred to liquid phase fluids by chemical reagents to achieve the purpose of remediation of contaminated soil (Wang et al., 2016). According to the above analysis, the soil treated by this method has been significantly improved, and a variety of heavy metal pollution elements have been effectively repaired.

Material and methods

Establishment of evaluation index system for soil environmental carrying capacity

In order to objectively, comprehensively and scientifically evaluate the status of soil carrying capacity, when studying and determining the evaluation index system of soil carrying capacity and its evaluation method, we should follow the scientific principles of selecting evaluation index, determining index weight, the scientific principle of calculating and synthesizing index, the dynamic principle of the change of soil carrying capacity in time and space, and the feasibility principle based on regional sustainable development (Rutskii et al., 2017).

According to the five principles of index selection, an index system for evaluating soil environmental carrying capacity in Liaoning province is established, with 522 indexes (Yang et al., 2016). Specific indexes are shown in *Table 1*.

Table 1. *Evaluation index system of soil environmental bearing capacity*

Project level	Factor layer	Index layer	Company
Pressure	Population economy	Population density	Ten thousand people/km^2
		Natural population growth rate	%
		Per capita GDP	Ten thousand yuan
		The proportion of output value of secondary industry	%
	Industry	Emission intensity of industrial smoke and dust	Tons/km^2
		Discharge intensity of industrial wastewater	10,000 tons/km^2
		Discharge intensity of industrial solid waste	10,000 tons/km^2
	Agriculture	Use strength of chemical fertilizer	10,000 tons/km^2
		Pesticide use intensity	Tons/km^2
	City	Domestic sewage discharge	10,000 m^3
		Domestic waste emissions	Ten thousand tons
	Transportation, energy	Ten thousand yuan GDP energy consumption	Ton standard coal
		Highway passenger transport intensity	Ten thousand people/km^2
	Environmental management	Proportion of environmental protection input to GDP	%
Response	Industrial environmental governance	Achievement rate of industrial wastewater discharge from key pollution sources	%
		Comprehensive utilization rate of industrial waste	%
	Urban environmental governance	Urban domestic sewage treatment rate	%
		Harmless treatment of municipal domestic waste	%

Evaluation method of bearing capacity

Select the data provided by Google dataset search dataset as the data source of the experiment. Google dataset search data set can be regarded as a one-stop data set, which contains massive data of different sizes and types from NASA, propublica and other sources. The data source is comprehensive, so the data set has strong

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27472760

application value. In this database, six datasets are selected as the experimental data. The datasets involve image and other fields, and contain 150000 kb different data groups. In order to facilitate evaluation, the above basic data is standardized by the range standardization method (Li et al., 2015), that is, the data is dimensionless and unified by an order of magnitude. Soil environmental assessment indexes are divided into favorable indexes and unfavorable indexes. According to the different types of indexes, standardized treatment is carried out according to the formula. Among them, the higher the favorable index is, the better the soil bearing capacity is, and the lower the unfavorable index is, the better the soil bearing capacity is (Wang et al., 2015).

$$P = \left(X_i - X_{\min}\right) / \left(X_{\max} - X_{\min}\right) \quad \text{(Eq.1)}$$

$$Q = 1 - \left(X_i - X_{\min}\right) / \left(X_{\max} - X_{\min}\right) \quad \text{(Eq.2)}$$

where P represents favorable index after standardization; Q represents the disadvantageous index after standardization; X_i represents the measured value of an index; $X_{\max}$ represents the maximum value in the statistical range of an index; $X_{\min}$ represents the minimum value in the statistical range of an index.

Because of the coexistence of quantitative index and qualitative index in the evaluation index of soil environmental carrying capacity (Liu et al., 2018), this paper uses expert evaluation method to determine the weight of each evaluation index. Five experts scored the importance of each indicator, obtained the scoring results, and calculated the average value of each indicator. According to the standardized results of *Equations 1* and *2*, the weight of each indicator is allocated after the implementation of inspection as shown in *Table 2*.

Computation of comprehensive evaluation value

The final comprehensive evaluation value is calculated by multiplying the dimensionless utility value of an index in the terminal index by the corresponding weight of the index to the target layer (Yu et al., 2015), which is expressed by the following formula:

$$Y = \sum_{i=1}^{n} X_i P_i \quad \text{(Eq.3)}$$

In the formula, Y is the total score of soil carrying capacity, P_i is the utility value of the i-th index and X_i is the weight of the i-th index to the target.

Criteria for evaluating soil environmental bearing capacity

According to the comprehensive score of soil carrying capacity of cities in the provincial capital city group, this study formulates five bearing capacity grades (Girsowicz et al., 2018), as shown in *Table 3*.

Based on the above assessment results of soil environmental carrying capacity and soil remediation standards, the following remediation schemes are adopted to remediate heavy metal pollution in soil.

Table 3. *Criteria for evaluating soil environmental carrying capacity*

Interval value of soil bearing capacity	Grade of bearing capacity	Representation state
<0.2	Ⅰ	More weak bearing capacity
0.2-0.4	Ⅱ	Weak bearing capacity
0.4-0.6	Ⅲ	General bearing capacity
0.6-0.8	Ⅳ	Strong bearing capacity
>1.0	Ⅴ	More strong bearing capacity

Standards for soil remediation

Remediation standard

Secondary development of sites requiring remediation is carried out. Remediation criteria are selected according to different development projects. This paper mainly assumes that the secondary development project is commercial land. Then, after the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27472760

demonstration of industry experts, the standard of site excavation and remediation is the commercial land standard in the secondary standard of Soil Environmental Quality Standard (GB 15618-2008) (Arenaslago et al., 2018), i.e. the standard values of C_r, C_u, N_i, P_b and Z_n are 800, 500, 200, 600 and 700 mg/kg, respectively.

Scheme of solidification remediation

The solidification method solidifies contaminated soil with solidifying agent, which reduces the mobility and bioavailability of contaminated molecules. The selection of solidifying agent is very important for the remediation of contaminated soil by solidification method.

Flow chart of solidification remediation process

Figure 1 is the flow chart of solidification remediation. It can be seen from the figure that: (1) the moisture content of the soil sample in the field is measured to determine the water content of the mixture; (2) earthwork excavation; (3) material distribution; (4) mixing: dry mixing for 3-4 times, and spraying water solution containing stabilizer on the mixture; mixing twice more carefully and turning the bottom "plain soil" up each time without loosening the underlying stratum; the mixture has uniform color without gray strips, ash and flower surface, no coarse and fine particle nests, and suitable moisture content; (5) shaping: preliminary scraping and shaping, straight line section from both sides to the center, return to scraping if necessary, pay attention to the flat seam.(6) rolling: Rolling requires following the paving closely with no wheel tracks, generally rolling first slow and then fast, first light and then heavy; (7) Maintenance; (8) Testing: testing dry density and moisture content, calculating whether the compaction coefficient meets the requirements (Yan et al., 2015).

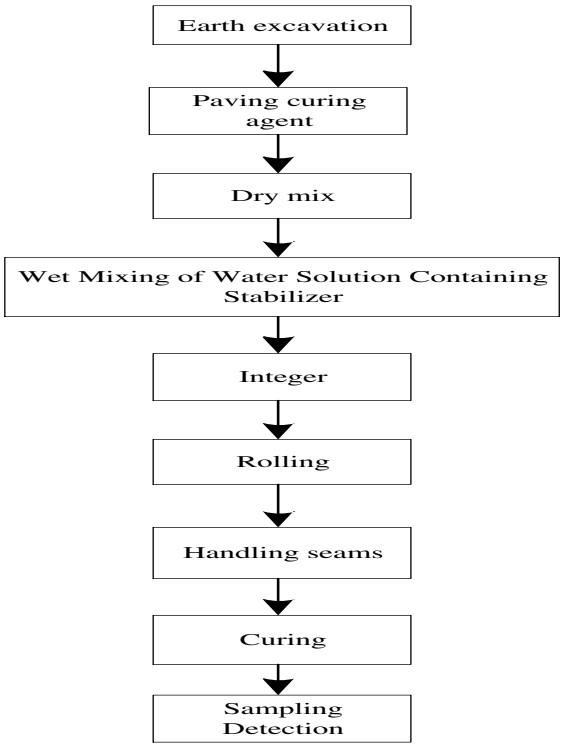

Figure 1. *Flow chart of solidification remediation*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

Content analysis of soil leaching solution for remediation

Leaching is the main way for harmful substances from solid waste to enter the environment (Li et al., 2017). Leaching experiment is a laboratory simulation of leaching process. Its purpose is to assess the environmental risk of different solid waste under different treatment environments and treatment modes. According to the current management needs and disposal methods of solid waste in China, in the standard experimental study, there are two hypothetical scenarios: non-standard landfill treatment of industrial solid waste, waste accumulation, land use of wastes after innocuous treatment (Xiao et al., 2017); 5% of industrial wastes or harmless wastes enter sanitary landfills and are combined with 95% of municipal wastes. In the first scenario, nitric acid sulfate solution is used as extractant to simulate this adverse environmental factor. In the second scenario, acetic acid buffer solution is used as extractant.

When sulfuric acid nitric acid solution is used as leaching agent, its acidity is helpful for metal leaching, but it has no buffer capacity, and the leaching amount of metal is very low. If the content of any hazardous substance in leaching liquor exceeds the standard value of leaching toxicity in "Hazardous Waste Identification Standard of Leaching Individual Identification" (GB5085.3-2007), it is determined that the solid waste is a hazardous waste with leaching toxicity characteristics.

When acetic acid buffer solution is used as leaching agent, the complexation effect on metal leaching is obvious, and the acidity of the system changes slightly after leaching (Ma et al., 2017), and the amount of metal leaching is very high.

These two extractants have their own advantages and disadvantages in remediation of heavy metal pollution in soil, but EDTA is often used as a leaching agent for heavy metal pollution in soil and as an amendment for the bioavailability of heavy metals in soil (Zhang, 2018). Soil elution is to transfer organic and inorganic pollutants in the solid phase of contaminated soil to liquid phase fluid by chemical reagents, so as to achieve the purpose of remediation of contaminated soil. In this paper, EDTA is used as soil eluent, and the hydrolysis stability is high in the range of high temperature and wider pH value.

Results

Analysis of remediation effect of different methods on heavy metal contaminated soil

In order to verify the best remediation effect of the proposed method for heavy metal contaminated soil, on the premise of sufficient soil environmental carrying capacity. The experiment was carried out under the hardware conditions of Intel core-m480i5cpu @ 2.67 GHz, 4 GB memory, 32-bit operating system and windows 7 version. And the simulation data set my sea is selected as the basic data set, and the data is analyzed by the online data anal ysis software MOA (an experimental tool for massive online analysis). The effects of chemical leaching, cement kiln co-disposal, phytoremediation (Bennabi et al., 2017) and the proposed method on remediation of heavy metal contaminated soil are compared, as shown in *Table 4*.

Table 4 shows that after the remediation of heavy metal contaminated soil by the proposed method, the content of various contaminated elements has been greatly reduced. The average reduction rate of the content of contaminated elements after remediation is 95.86%, which is higher than that of the contaminated elements removed by other methods.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27472760

Table 4. *Comparison of reduction rates of contaminated elements after remediation of heavy metal contaminated soil*

Repair Technology	Reduction ratio of Cr content%	Reduction ratio of Cu content%	Reduction ratio of Ni content%	Reduction ratio of Pb content%	Reduction ratio of Zn content%
Chemical elution	83.22%	89.19%	88.33%	90.02%	87.54%
Co-disposal of cement kiln	88.49%	85.32%	86.13%	88.96%	81.23%
Phytoremediation	90.22%	91.32%	89.01%	88.39%	88.14%
The method in this paper	95.32%	97.19%	96.33%	94.56%	95.92%

In order to make the data comparison in *Table 4* more intuitive, a column chart is constructed to analyze the content of pollutant elements reduced by various methods, as shown in *Figure 2*.

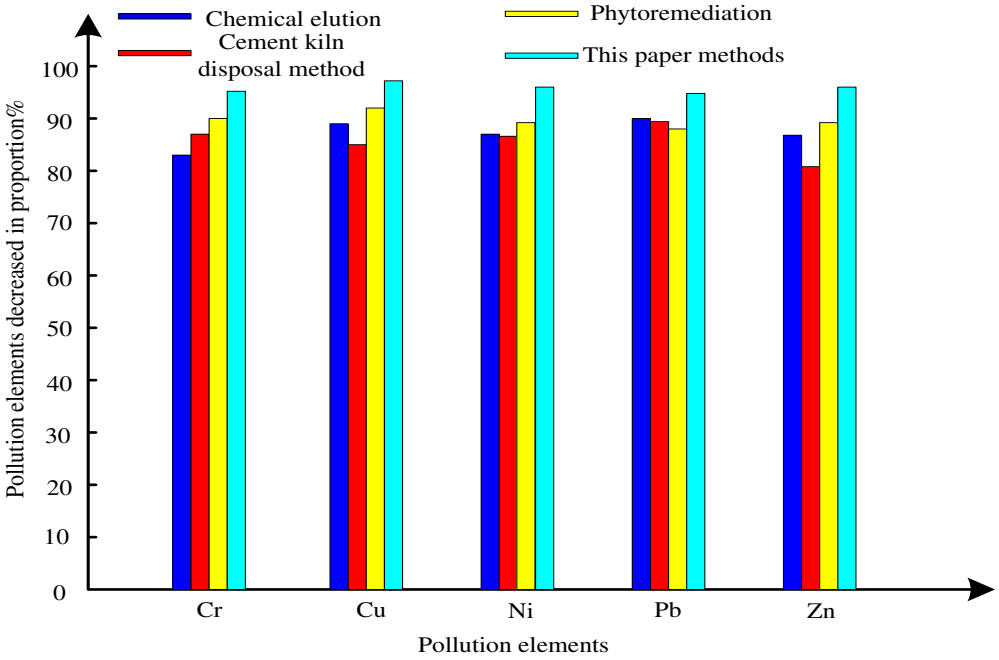

Figure 2. *Percentage decrease of various pollutant elements after remediation of heavy metal land pollution*

As can be seen intuitively in *Figure 2,* the method in this paper has the highest removal rate of various pollutant elements in all comparison methods, so the method in this paper has the best effect on remediation of heavy metal pollution in soil by considering environmental carrying capacity.

Morphological analysis of heavy metals removal

In order to verify the remarkable effect of DETA extractant on remediation of heavy metal pollution in soil, the morphological analysis model of heavy metal removal is constructed. The precipitation of 0.2 mol/L citric acid and 0.05 mol/L EDTA is analyzed after washing once and five times, respectively, in order to find out the mechanism of removing copper and nickel from soil by the eluent, as shown in *Table 5*.

	Residual state	183.3111	45.1	19.81	763.903	26.92	14.66

In *Table 5,* the removal rates of five forms of copper and nickel by citric acid and EDTA at one and five leaching times show that the removal rates are almost exchangeable> residual> carbonate-bound> iron-manganese oxide-bound> organic-bound, which are related to the content of the original forms of heavy metals in soil. The main forms of copper removal by citric acid and EDTA are exchangeable, carbonate-bound and iron-manganese oxide-bound and the removal rates are above 60%, while the removal rates of organic and residual states are generally low. The data in the observation table show that the removal rates of various forms of contaminated elements by citric acid are weaker than EDTA. Therefore, the removal rate of various forms of contaminated elements is very high by the proposed method.

Comparison of remediation techniques for different heavy metal contaminated elements

In order to verify the best effect of the proposed method on remediation of heavy metal contaminated soil, the heavy metal contaminated soil area in the suburb of a city is selected as the experimental area, the range value of soil environmental carrying capacity is 0.6-0.8, and the soil environmental grade is grade IV. Taking the carrying capacity as the consideration factor, chemical leaching method, cement kiln co-treatment method and phytoremediation and the method in this paper are used to make compare. *Table 6* is a comparative table of four methods.

As can be seen from *Table 6,* the proposed method has mature technology, the lowest cost of remediation, the highest efficiency of remediation, and little impact on the environment. Therefore, the effect of the proposed method on remediation of heavy metal pollution in soil is remarkable.

Table 6. *Comparison of remediation methods for different heavy metal contaminated soils*

Repair technology	Technical maturity	Repair unit price	Repair efficiency	environmental effect	Advantage	Shortcoming
Chemical elution	More mature	2000-3000	Higher	Less	Disposable compound contaminated soil, safe operation	Not suitable for soils with high clay content
Co-disposal of cement kiln	Test phase	800-1000	Commonly	Less	Disposal cost is relatively low and operation is simple and safe	Limited by cement production and emission
Phytoremediation	Test phase	It depends	Low	Less	Polluted soils need not be excavated and the cost of disposal is low	Remediation takes a long time and plant screening is difficult
The method in this paper	More mature	500-800	High	Less	The disposal cost is low, the disposal quantity is large, the operation is simple and safe	No pollutants were removed from the soil

Analysis of soil remediation capacity and environmental bearing capacity

In order to verify that the proposed method can improve the soil environmental carrying capacity, the improvement of soil carrying capacity after remediation of heavy metal contaminated soils in mountainous, plain, plateau, basin and hilly areas is compared, as shown in *Figure 3*.

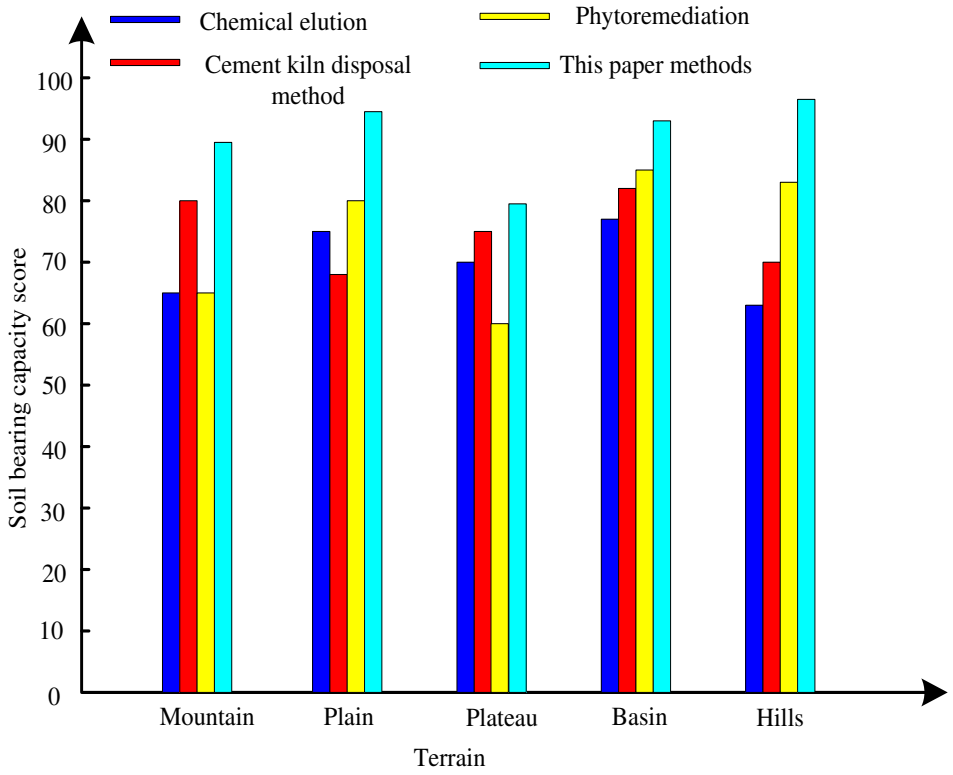

Figure 3. *Score of soil carrying capacity after remediation of heavy metal contaminated soil*

DOI: http://dx.doi.org/10.15666/aeer/1802_27472760

The comparative results of soil remediation capacity of different methods are shown in *Table 7*.

Table 7. *Comparison of soil remediation capacity*

Terrain	Soil remediation capacity/m^3.s				Standard for element content of soil pollutants			
	Chemical elution	Cement kiln disposal method	Phytoremediation	The method in this paper	Chemical elution	Cement kiln disposal method	Phytoremediation	The method in this paper
A mountain country	15	12	13	24	Excessive content	The content is up to the standard	The content is up to the standard	The content is up to the standard
Plain	18	11	16	28	The content is up to the standard	Excessive content	The content is up to the standard	The content is up to the standard
Plateau	10	15	15	29	Excessive content	Excessive content	Excessive content	The content is up to the standard
Basin	20	17	15	31	Excessive content	Excessive content	The content is up to the standard	The content is up to the standard
Hill	20	16	12	33	The content is up to the standard	The content is up to the standard	Excessive content	The content is up to the standard

Remediation time and cost analysis of heavy metal contaminated soil

In order to verify that the proposed method can reduce the repair time-consuming and reduce the cost, the repair time and cost of the five topographies mentioned above are compared. The results are shown in *Table 8*.

Table 8. *Comparison of soil remediation time and cost*

Terrain	Repair time (days)				Repair cost (10,000 yuan)			
	Chemical elution	Cement kiln disposal method	Phytoremediation	The method in this paper	Chemical elution	Cement kiln disposal method	Phytoremediation	The method in this paper
A mountain country	1	1.5	1	0.5	1.3	1.2	1.4	0.9
Plain	0.5	1.5	1	0.5	1.5	1.6	1.6	1.1
Plateau	2.5	3	2.5	1	2.6	2.4	2.4	1.5
Basin	2	2.5	2	1	1.6	1.9	1.8	1.1
Hill	1.5	1.5	1.5	1	1.4	1.6	1.6	1.2

Analysis of the data in *Table 8* shows that the method in this paper has the shortest time and the lowest cost to repair the five topographies.

Discussion

Heavy metal pollution refers to the fact that the content of heavy metals in soil is much higher than its background value, which leads to the deterioration of the original function of the soil. The main pollution in urban soils comes mainly from human activities. Heavy metal wastes are produced in heavy industries such as metal smelting and processing, fur and products processing, glass manufacturing, printing and dyeing, electronic component manufacturing and other light manufacturing industries, as well as in the process of garbage disposal in people's daily life and medical activities.

Based on the above-mentioned environment, this paper firstly constructs the index system of soil environmental carrying capacity and the standard of soil remediation, and uses the method of curing remediation to fix the heavy metal pollution in soil. According to the above experimental results, we can see that:

Figure 3 shows that when five topographies are restored by four different methods, only the proposed method can get the highest score of soil bearing capacity. Because of the sparse vegetation and serious soil erosion in the plateau area, it is more difficult to repair the heavy metal contaminated soil. Therefore, the land carrying capacity score of the proposed method in the plateau topographic area is only 80 points. *Table 7* shows that chemical leaching method, cement kiln treatment method and phytoremediation method are not effective in soil remediation, and the content of contaminated elements in the remediated soil still exceeds the standard, while the method in this paper has the highest remediation ability in all methods, and the content of contaminated elements in the remediated soil does not exceed the standard.

Through the analysis of the above data, it can be seen that the moire method effectively improves the traditional method, and can effectively repair various forms of heavy metal pollution elements in the soil.

Conclusions

The main characteristics of heavy metal pollution in urban soils are long duration, concealment, hysteresis and irreversibility. Based on the index system of soil environmental carrying capacity, the evaluation method and grade of soil carrying capacity are obtained, and the soil environmental carrying capacity is assessed. The evaluation results are taken into account and the technology of solidification and remediation is used to remediate urban heavy metal pollution. Metal contaminated soil makes the remediated soil have a certain strength, which is conducive to rational utilization and disposal in the subsequent commercial development. At the same time, EDTA leaching solution used in the proposed method can remove various forms of heavy metal contaminated elements very well. Using the proposed method to solidify and treat soil not only can control soil pollution, but also can play a solid role in the soil, making the foundation more solid. Therefore, the proposed method has the best effect on remediation of heavy metal contaminated soil.

Although the method in this paper is effective, more environmental factors should be considered, such as water, weather and so on. In the future, this paper will focus on the influence of these factors on the remediation of heavy metal pollution in soil.

SPATIAL VARIABILITY IN GREENHOUSE GAS FLUXES FROM A TEMPERATE FRESHWATER MARSH IN CHINA: EFFECTS OF SOIL MOISTURE, ANIMAL ACTIVITIES AND LAND USE

BAO, T.[1, 2] – ZHU, R. B.[1*] – WANG, P.[1] – FANG, Z. Y.[1] – LI, B. K.[1] – GAO, Y. S.[1] – XU, H.[3]

S1. Study Area

The Shengjin Lake Wetland National Nature Reserve (116° 55′ E-117°15′ E, 30° 15′ N-30° 30′ N) is located at the junction of Dongzhi County and Guichi district in Anhui Province and in the Middle-Lower Yangtze Plain near the Yangtze River. The Shengjin Lake is an important flood storage/discharge reservoir and a natural fishing ground, and it is surrounded by diverse terrains with curving lakeshore lines. Topographically it can be divided into three parts: the upper lake, the middle lake and the lower lake. At present, there are 13 towns and 46 villages around the lake with total population of about 80,000 (Jiang et al., 2007). Most of the villagers depend on the cultivation of cotton and rice on the plain around the lake. Grazing livestocks in the lake marsh and fishery resource from the Shengjin Lake are also essential food sources for the local residents (Fox et al., 2013).

The Shengjin Lake Marsh (SLM) has similar hydrological and ecological features to other Chinese wetlands in mid-latitudinal area. The marsh around the lake has diverse vegetation types including *Artemisia lavandulaefolia DC*, *Artemisia scoparia Waldst* and *pinus massoniana* (Lu and Liu, 2011; Bernal and Mitsch, 2012; Yang et al. 2015). Human activities including the land use conversion and aquaculture, and natural disturbances have intensively affected the local environment (Yang et al., 2015). This marsh is a natural colony for over 100 species of migratory birds to overwinter and breed (Lu and Liu, 2011). The common species of waterbirds include bean goose *Anser fabialis*, greater white-fronted goose *Anser albifrons*, lesser white-fronted goose *Anser erythropus*, swan goose *Anser cygnoides* and tundra swan *Cygnus columbianus bewickii* (Zhang et al., 2015). Migrant birds play an important role in the nutrient cycling in the ecosystems, and their activities strongly influence the physical and chemical properties for the marsh soils, which might lead to be generally high in soil organic carbon, total nitrogen and total phosphorus levels (Lu and Liu, 2011; Zhu et al., 2014a, b). Overall the marsh has been experiencing human disturbance from the conversion of land use, and natural disturbance from waterbirds, drought and flooding (Lu and Liu, 2011).

S2. Investigation Sites and Experimental Design

(i) The upland marsh area: During the rain season in July 2013, the lake water level rose up to the highest, and the marsh was formed along the lakeshore. The total 14 stations (sj1-1 to sj1-14) for GHG flux observations were set up from the dry to waterlogged marsh areas along the lakeshore transect.

(ii) The lowland marsh area: A large flooded land area was exposed with the decrease in the lake water level during the dry season in December 2013. We selected a long transect from the upland to the lowland, and then to a small island along the lakeshore. The middle lowland was exposed only during the dry season in winter, and the upland and the island were both exposed areas throughout the year.

(iii) The marsh sites disturbed by animal activities and land use: Four disturbed areas including waterbird active area (BA), poultry active area (PA), landfill (LF) and farmland (FD), were identified as the observation areas for GHG fluxes. The waterbird active area was located near the transect. A great number of migrant birds flew to the lake marsh to live through the winter, and their guano could be seen everywhere in the exposed marsh. The poultry active area was located in the northwest of the marsh. A lot of geese and ducks often went into the area, and their fertile excreta deposited into the marsh soils. The ground surface in the poultry and waterbird active areas had sparse vegetation due to the tramp of the animals and the input of high nutrients from their excreta. The landfill was a bog with the soft peat and a large amount of garbage. The marsh exposed in summer was transformed into the farmland where winter wheat grew, resulting in soft soil texture and low soil moisture. Two repetitions were made at each station. The soil physiochemical properties at all the microsites were summarized in ***Table S1*** and ***Table S2***.

Note: TOC, TN, TC, TS, Mc indicate total organic carbon, total nitrogen, total carbon, total sulfur and soil moisture respectively. The measured soil physical and chemical properties at the upland marsh transect sites with the same suffix letter (a, b, c or d) are not significantly different from one another (LSD, $P<0.05$).

S3. Determination of GHG Concentrations and Flux Calculation

The CH_4 concentration was tested by gas chromatography (Shimadzu GC-12A, Japan) with flame ionization detector (FID), and the column and detector temperatures were 80 and 200 °C, respectively. The N_2, H_2 and air flow rates were 40 ml min^{-1}, 35 ml min^{-1} and 350 ml min^{-1}, respectively (Zhu et al., 2009a, b). The N_2O concentration was determined by the gas chromatography (GC-HP5890, USA) with the ^{63}Ni electron capture detector (ECD). The Ar-CH_4 (95:5) was used as the carrier gas, and the flow rate was 30 ml min^{-1}; the column and detector temperatures were 85 and 330 °C, respectively. The back flush time was 2.80 min and the volume of the sample injector is 1.7 ml (Chen et al., 2013). The CO_2 concentration was determined equipped with the gas chromatography (GC) with thermal conductivity detector (TCD) (Shimadzu GC-14B, Japan) and 80/100 mesh Chromosorb 102 column. The oven, injector and detector temperatures were 60, 100 and 60 °C, respectively. The carrier gas (H_2) had a flow rate of 80 ml min^{-1}. The variance coefficient for standard samples was within 0.2-0.5% in 24 h (Zhu et al., 2009a, b).

The GHG fluxes were calculated using a linear least squares fit to the four points in the time series (0, 10, 20, and 30 min during the time of chamber closure) of

concentrations with an average chamber temperature. The least squares regression lines "headspace GHG concentrations versus time" were first visually inspected for abrupt changes in the direction of the flux, resulting from disturbances such as the leakage of the chamber or disturbances of soils during sampling. The correlation coefficient R^2>0.95 for the linear regression was used as a quality check for the measurement. If the fluxes are low, the random error of the measurement can be larger than the change in GHG concentrations between two sampling points. Discarding these fluxes based on low R^2 values would lead to an overestimation of the overall fluxes. Some low GHG fluxes were included regardless of their R^2 value. For the gas fluxes, positive values indicate net emission to the atmosphere, and negative values indicate net uptake from the atmosphere.

Abstract. The greenhouse gas (CH_4, N_2O and CO_2) fluxes from Shengjin Lake Marsh (SLM) were *in situ* investigated at the undisturbed sites and the disturbed sites by animal colonization and human activities. Overall the CH_4 emissions from the wet sites were one order of magnitude higher than those from the mesic or dry sites, whereas higher N_2O emissions and net CO_2 uptake occurred at dry sites rather than at mesic and wet sites. Soil moisture was the predominant factor controlling the spatial variability in marsh CH_4 and N_2O fluxes and NEE at undisturbed sites. Mean CH_4 fluxes from migrating water bird and poultry active areas showed no statistically significant differences from the undisturbed sites, but their activities significantly increased N_2O emissions and decreased marsh CO_2 sink, with the highest N_2O fluxes (mean 49.5±11.9 μg N_2O m^{-2} h^{-1}) in poultry active areas. The conversion of the marsh into agricultural field and landfill did not significantly change CH_4 and N_2O fluxes, but significantly decreased CO_2 sink. Our results revealed that the accurate evaluation of GHG budget for the SLM and other similar temperate wetlands should involve soil water regimes, water bird colonization and human-induced influences.
Keywords: *CH_4 flux, N_2O flux, NEE, Shengjin Lake Marsh, temperate wetland*

Introduction

Atmospheric carbon dioxide (CO_2), methane (CH_4) and nitrous oxide (N_2O) are key radiatively active greenhouse gases (GHGs) (Ravishankara et al., 2009). Natural wetlands play a critical role in the global GHG budgets due to the storage of a large amount of carbon and nitrogen (Post et al., 1982), the high temperature sensitivity of microbial respiration, and nitrogen mineralization (Davidson and Janssens, 2006; Song et al., 2009). The wetlands are one of important sources for atmospheric GHGs (Jungkunst and Fiedler, 2007; Marani and Alvala, 2007; Song et al., 2009). For example, natural wetlands present the largest single CH_4 source, accounting for more than 75% of natural CH_4 source and more than 20% of the global CH_4 source (Kirschke et al., 2013). Global wetland ecosystems also contribute considerably to N_2O budget although sometimes the N_2O emissions from the wetlands are very low (Martikainen et al., 1993; Xu et al., 2008). Therefore, it is necessary to conduct the research about GHG fluxes from the wetlands in different climatic zones.

At present, net GHG fluxes have been extensively measured at a number of sites of global wetlands to better understand the relationships between GHG fluxes and environmental parameters (Jungkunst and Fiedler, 2007; Marani and Alvala, 2007; Song et al., 2009). China is home to the world's fourth largest wetland area (Wang et al., 2012), and *in situ* GHG flux observations have covered the wetlands in Northeast China (Ding et al., 2004; Ding and Cai, 2007; Song et al., 2009), the Tibetan Plateau (Chen et al., 2008; Song et al., 2015; Wei et al., 2015), Inner Mongolia (Duan et al., 2005; Wang et al., 2009), coastal salt marshes (Song and Liu, 2016), and the Middle-Lower Yangtze Floodplain (MLYP) wetlands including the freshwater marshes in Poyang Lake and Taihu Lake (Xing et al., 2005; Wang et al., 2006; Hu et al., 2016). Observations suggest that the wetlands showed the micro- and macro-scale spatial pattern of GHG release (Kato et al., 2011; Song and Liu, 2016; Wei and Wang, 2017), and soil physicochemical properties, soil microbial community structure, vegetation coverage and warming climate are important factors affecting wetland GHG fluxes (Johansson et al., 2006; Wei and Wang, 2017). The MLYP is characterized by dense human population and rapid economic development, which both impose unprecedented pressure on the wetland ecosystems, and has caused serious wetland degradation (Zhou et al., 2010). In addition, the MLYP wetland is an important wintering habitat and stopover site for migrating waterbirds on the East Asia-Australia Flyway (Fang et al., 2006). Environmental variables, animal colonization and human activities might lead to spatial variability in GHG emissions from the MLYP wetland. A better understanding of the spatial patterns in the GHG fluxes and their controlling factors is crucial to accurately estimate the regional and global GHG budgets from wetlands (Song et al., 2009; Kirschke et al., 2013; Wei and Wang, 2017). Nevertheless, the data about GHG fluxes are still lacking in the MLYP wetlands, and especially effects of animal colonization and human activities on GHG fluxes are highly neglected.

The Shengjin Lake Marsh (SLM), as a natural freshwater wetland, is located in the MLYP with temperate monsoon climate and an evident distinction between rainy and dry seasons in the precipitation. Part of the marsh is often converted into farmlands including paddy fields or wheat lands with the drawdown of water level. This marsh also provides an important natural colony for some migrant waterbirds to overwinter and breed, and a natural raising area for the poultry including ducks and gooses (Lu and Liu, 2011). The natural disturbances due to flood and drought, animal colonization and human activities have intensively affected the local environment (Yang et al., 2015). However, effects of these natural and anthropogenic factors on GHG fluxes to date have not been investigated in the SLM. During summer and winter in 2013, the SLM was selected as study area, and CH_4, N_2O and CO_2 fluxes were simultaneously observed at the upland and lowland marsh areas, and the marsh sites disturbed by animal colonization and land use. Our objectives were (1) to study spatial variability in GHG fluxes from the marsh; (2) to investigate the effects of soil moisture on GHG fluxes; (3) to examine the effects of animal activities and land use on GHG fluxes. This is an important attempt to reasonably evaluate the importance of soil moisture, animal activities and land use in the GHG budgets in the MLYP wetland.

Materials and methods

Study area

The Shengjin Lake Wetland National Nature Reserve (116° 55′ E-117°15′ E, 30° 15′ N-30° 30′ N) is located in the Middle-Lower Yangtze Plain (*Fig. 1*). The wetland covers an area of approximately 133 km^2 in the rain season and only 33 km^2 in the dry season. This area has a temperate monsoon climate with a hot and humid summer, and a cold and dry winter; its mean annual air temperature and precipitation is about 16.1°C and about 1600 mm, respectively (Xu et al., 2008). Topographically the Shengjin Lake can be divided into three parts: the upper lake, the middle lake and the lower lake. The marsh around the lake has diverse vegetation types including *Artemisia lavandulaefolia DC*, *Artemisia scoparia waldst* and *Pinus massoniana* (Lu and Liu, 2011; Yang et al., 2015). It is a natural colony for over 100 species of migratory birds to overwinter and breed (Lu and Liu, 2011). The common species of waterbirds include bean goose *Anser fabialis*, greater white-fronted goose *Anser albifrons*, lesser white-fronted goose *Anser erythropus*, swan goose *Anser cygnoides* and tundra swan *Cygnus columbianus bewickii* (Zhang et al., 2015). Overall the Shengjin Lake Marsh (SLM) has been experiencing the disturbance from human activities, poultry raising and natural disturbances from waterbirds, drought and flooding (Jiang et al., 2007; Lu and Liu, 2011; Fox et al., 2013).

More information was given in *S1 for Electronic Appendix*.

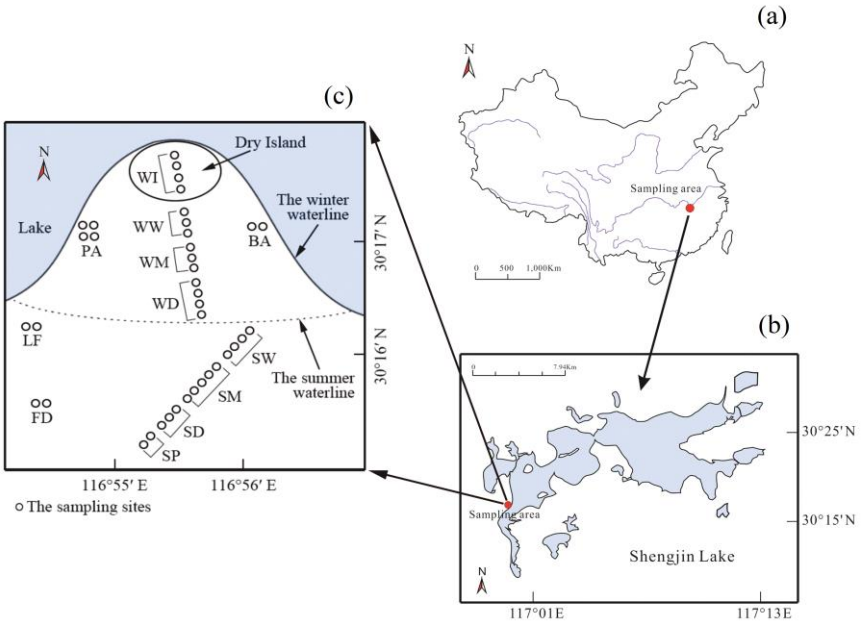

Figure 1. *(a) The red dot indicates location of the investigation area in China. (b) The topographic feature of Shengjin Lake and the red dot indicates location of the investigation area in Shengjin Lake. (c) The location of the investigation sites for the SLM in the summer and winter. SD, SM, SW and SP represent the dry, mesic and wet marsh sites, and paddy field sites in the summer, respectively; WD, WM, WW and WI represent the dry, mesic and wet marsh sites, and the island marsh sites, respectively, in the winter; BA, PA, LF and FD represents water bird active area, poultry active area, landfill and farmland, respectively. In the summer, the lake water level rose up to the highest, and the marsh formed along the summer waterline. In the winter, a large flooded land area was exposed with the decrease in the lake water level and the marsh formed along the winter waterline*

Investigation sites and experimental design

To test effects of soil moisture, waterbird colonization and human activities on the spatial variability in GHG fluxes from the SLM, a series of the flux observation sites were established within the following three areas located on the western shore of the upper lake as illustrated in *Fig. 1*:

(i) The upland marsh area: In summer, the lake water level rises up to the highest along the shore. In July 2013 (From July 1st to July 30th), a total of 14 stations (sj1-1 to sj1-14) for summer GHG flux observations were set up from the wet to dry marsh areas along a transect. These stations were further divided into four types of sites according to soil water regime: (a) wet site (SW), which were near the lake with almost no vegetation; (b) mesic site (SM) with few vegetation; (c) dry site (SD) with the extensive vegetation; and (d) paddy site (SP), which was located at the uppermost locality of the transect with changing water levels. Two repetitions of GHG flux measurements were made at each station.

(ii) The lowland marsh area: A large flooded land area was exposed in winter with the drawdown of water level. In December 2013 (From December 1st to December 30th), we selected a long transect from the upland to the lowland, and then to a small island along the shore. A total of 14 stations (sj2-1 to sj2-14) along the transect were set up for GHG flux measurements. These stations were divided into four types of sites as follows: (a) dry marsh site (WD); (b) mesic marsh site (WM); (c) wet marsh site (WW); (d) dry island marsh site (WI). Two repetitions were made at each station.

(iii) The marsh sites disturbed by animal activities and land use: In December 2013, a total of 10 stations were set up in the disturbed areas for GHG flux measurements. These stations were divided into four types of sites: waterbird active site (BA, two stations), poultry active site (PA, four stations), landfill (LF, two stations) and farmland (FD, two stations). Two repetitions were made at each station. In *Electronic Appendix*, more detailed information was given in *S2*, and soil physiochemical properties at all the stations were summarized in *Table S1* and *Table S2*.

In-situ GHG flux measurements

The GHG fluxes from all the stations were measured in the SLM during two sampling campaigns (July, 2013 in the summer, and December, 2013 in the winter) using a static chamber technique (Hutchinson and Mosier, 1981; Zhu et al., 2014a,b). Open-bottomed clear plexiglass chambers (50 cm×50 cm×50 cm) were placed on the PVC collars installed at the measurement sites. The collars enclosed an area of about 0.25 m^2 and were inserted into the soils to a depth of about 5 cm. The use of flux collars ensures that flux chambers are well sealed since the chambers fit into a water-filled notch in the collars. The average chamber height was 45 cm above the ground, which met the minimum required without influencing gas diffusion patterns under normal atmospheric pressure (Hutchinson and Mosier, 1981).

During gas flux measurements, upon enclosure of the cover chambers, headspace gas samples were collected at 0, 10, 20 and 30 min intervals with a double ended needle connected to pre-vacuated glass vials (18 mL) with butyl rubber septa. For each gas flux measurement, a total of four samples were withdrawn from each chamber after enclosure. Internal air temperature inside the chambers was simultaneously measured using a thermometer installed on the chamber. Ground temperature (GT) and soil moisture (Mc) were measured before and after the gas sampling. The order of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27612780

measurements was varied to ensure that the measuring time did not bias the results, resulting in two replicate measurements per station.

Net ecosystem exchange (NEE), defined as net ecosystem CO_2 flux under light conditions, was measured by the change in CO_2 concentrations in transparent chambers (Ström et al., 2007). In summer 2013, immediately following NEE measurements, ecosystem respiration (ER) was measured by the same procedure after darkening of the chamber covered by three layers of thick black cloth. Marsh ER includes soil and vegetation respiration, and photosynthesis was calculated as the difference between NEE and dark respiration (Ström et al., 2007).

Determination of GHG concentrations and flux calculation

The methods of analyzing GHG concentrations and flux calculation are described in detail in our previous papers (Zhu et al., 2014a,b; Bao et al., 2018a,b). In brief, N_2O, CH_4 and CO_2 concentrations were analyzed using gas chromatography equipped with a ^{63}Ni electron capture detector, a flame ionization detector and a thermal conductivity detector, respectively (GC-HP5890 II, USA; Shimadzu GC-12A, Japan; Shimadzu GC-14B, Japan). Net GHG fluxes were calculated using a linear least squares fit to four points in the time series of concentrations with an average chamber temperature. The least squares regression lines "headspace GHG concentrations versus time" were first visually inspected for abrupt changes in the direction of the flux, resulting from disturbances such as the leakage of the chamber or disturbances of soils during sampling. The correlation coefficient $R^2>0.95$ for linear regression was used as a quality check for the measurement. If the fluxes are low, the random error of the measurement can be larger than the change in GHG concentrations between two sampling points. Discarding these fluxes based on low R^2 values would lead to an overestimation of the overall fluxes. Some low fluxes were included regardless of their R^2 values. For the gas fluxes, positive values indicate net emission to the atmosphere, and negative values indicate net uptake from the atmosphere. More information was given in *S3 for Electronic Appendix*.

Environmental variables and general soil properties

Altogether 41 soil samples (3 samples were taken at each station except sj1-1 only 2 samples) in summer and 48 soil samples (2 samples were taken at each station) in winter were taken along with the same stations where GHG fluxes were measured. All the soil samples were air-dried, milled and screened using the 200 mesh sifter for the detection. Soil gravimetric moisture content (M_C) was determined by drying the soil at 105°C for 12 h. M_C was calculated as: M_C=the weight of the lost water/dry soil weight×100%. The pH was determined in distilled water and in 1M KCl solution (soil: solution ratio=1:3). Total organic carbon (TOC) was analyzed from the dry soil by the potassium dichromate volumetric method with an analytic error of 2.5%. Total carbon (TC), total nitrogen (TN) and total sulfur (TS) were determined using vario MACRO CHNS analyzer. The NH_4^+-N and NO_3^--N were determined by an ion-selective electrode method with an analytical error of <5.0%, and total phosphorus (TP) was determined by ultraviolet visible spectrometry (UV-2450, Shimadzu, Japan) with an analytical error of <2.0% (Zhu et al., 2009).

Statistical analysis

Microsoft Excel 2013 and SPSS 20.0 are used to make the statistical analysis of the data under the Windows 10 environment. For each station, we used standard error (SE) to estimate the uncertainty of the individual fluxes. The individual fluxes and their associated uncertainty were then averaged for each type of marsh site. All the data for GHG fluxes were expressed as mean ± SE. We used the coefficient of variance (CV) of those flux as a measure of intra-site spatial variability. The statistically significant differences between the means for each type of sites in the upland, lowland and disturbed marsh areas were tested using Fisher's Least Significant Difference (LSD, $P<0.05$) tests. We used the Principal Component Analysis (PCA) as a multivariate exploratory technique to explain the main factors affecting spatial variability in GHG emissions at the undisturbed and disturbed sites. To find factors causing spatial variability in the fluxes, the correlations of GHG fluxes with environmental variables were tested separately for all the types of sites using Spearman's rank order correlation. A univariate exponential function model (*Eq.1*) was fitted for the relationship between ER and soil temperature:

$$ER=\beta_0 e^{\beta_1 T} \quad \text{(Eq.1)}$$

where ER is ecosystem respiration (mg CO_2 m^{-2} h^{-1}), T is mean soil temperature (ºC), and β_0 and β_1 are the constants fitted with the least squares technique. The Q_{10} value was calculated as (*Eq.2*):

$$Q_{10}=e^{10\beta_1} \quad \text{(Eq.2)}$$

In all analyses where $p<0.05$, the factor tested and the relationship were considered statistically significant. Although our data might represent a rough estimate of GHG fluxes, we still used the GWP (Global Warming Potential) as a conversion factor to evaluate the impact of the SLM on the greenhouse effect. Based on a 100-year time frame, the GWPs of CH_4 and N_2O are, respectively, 25 and 298 times higher than that of CO_2 (Ravishankara et al., 2009). The net GWP were calculated by taking mass factors, 1 for CO_2, 25 for CH_4, and 298 for N_2O.

Results

Environmental variables in the marsh

The soils at the upland marsh transect were slightly acid with the pH of 5.2-6.1, and soil moisture decreased from the lowland to the upland marsh with the range of 17%-59% (*Table S1* and *Table S2*). Ground temperatures showed no significant differences between four types of sites in summer or in winter (*Fig. 2*). TC, TOC and TN levels in the soils showed no significant differences. The TC and TOC levels were very close to each other (average 1.24% and 1.13%), and they showed a significant correlation ($R=0.941$), indicating that soil carbon in the marsh mainly existed as organic carbon. Soil organic carbon content (average 2.62%) at the lowland marsh was almost twice higher than that at the upland marsh (average 1.13%). Soil NO_3^--N contents were one to two orders of magnitude higher than NH_4^+-N contents at upland or lowland

marsh transects. Soil NO_3^--N contents in landfill, poultry and waterbird active areas and farmland were evidently higher than those in non-disturbed marsh areas, and extremely high NO_3^--N occurred in poultry active soils (1143.4 μg g^{-1}). In addition, soil moisture showed evident differences with the range of 19%-73% between the types of marsh sites due to effects of animal activities and land use.

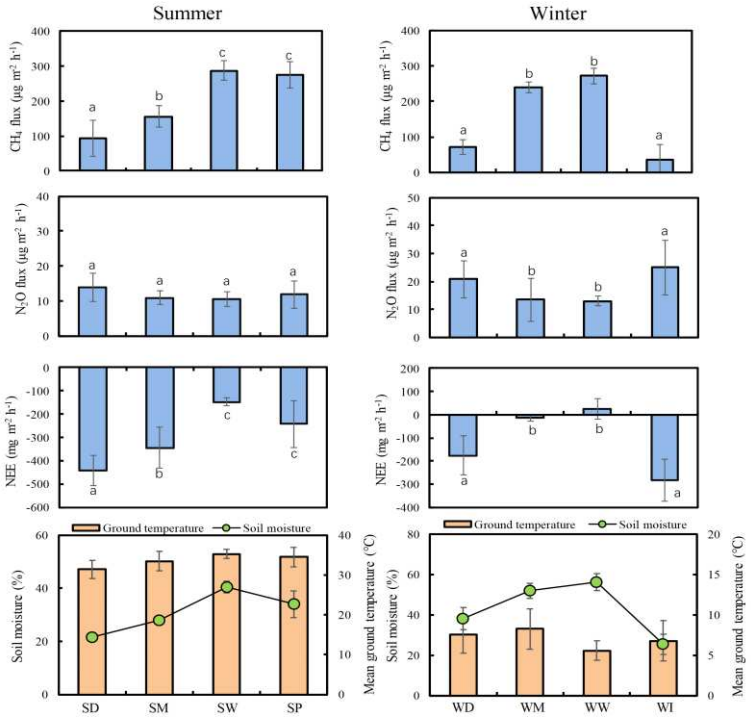

Figure 2. *Spatial variability in CH_4, N_2O and CO_2 fluxes from the SLM transects during the summer and winter. The given data are the mean values at each site in the marsh, and the vertical bars indicate standard errors of GHG fluxes. (a) In the summer, SD (n=6), SM (n=10), SW (n=8) and SP (n=4) represent the dry, mesic and wet marsh sites, and paddy field sites, respectively; (b) In the wintertime, WD (n=8), WM (n=6), WW (n=6) and WI (n=8) represent the dry, mesic and wet marsh sites, and the island marsh sites, respectively. The different lowercase letters (a, b, c) indicate statistically significant differences between the mean values (Fisher's LSD, $P < 0.05$)*

CH_4 fluxes

The wet marsh sites SW and WW showed strong CH_4 emissions with the mean fluxes of 287.3±51.1 μg CH_4 m^{-2} h^{-1}, and 271.2±21.1 μg CH_4 m^{-2} h^{-1}, respectively. Dry marsh sites SD and WD showed net weak CH_4 emissions with the mean rates of 93.9±27.8 μg CH_4 m^{-2} h^{-1} and 70.1±20.7 μg CH_4 m^{-2} h^{-1}, one order of magnitude lower than those from the mesic and wet sites, whereas the lowest CH_4 emission occurred at the dry island site WI (*Fig. 2*). The paddy site SP showed strong CH_4 emission (275.8±37.7 μg CH_4 m^{-2} h^{-1}), comparable to the sites SW and WW, but significantly higher than those at the sites SM and SD (*Table 1*). Overall the fluxes from waterbird active area (148.3±51.5 μg CH_4 m^{-2} h^{-1}) and landfill (98.8±28.9 μg CH_4 m^{-2} h^{-1}) were higher than those from poultry active area (64.4±44.3 μg CH_4 m^{-2} h^{-1}) and farmland (20.0±105.0 μg CH_4 m^{-2} h^{-1}) although their mean fluxes showed no statistical significant differences (*Fig. 3*).

The measured GHG fluxes at marsh site types with the same suffix letter (a, b or c) are not significantly different from one another (LSD, $P< 0.05$). Marsh ER was not observed in 2013 winter

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27612780

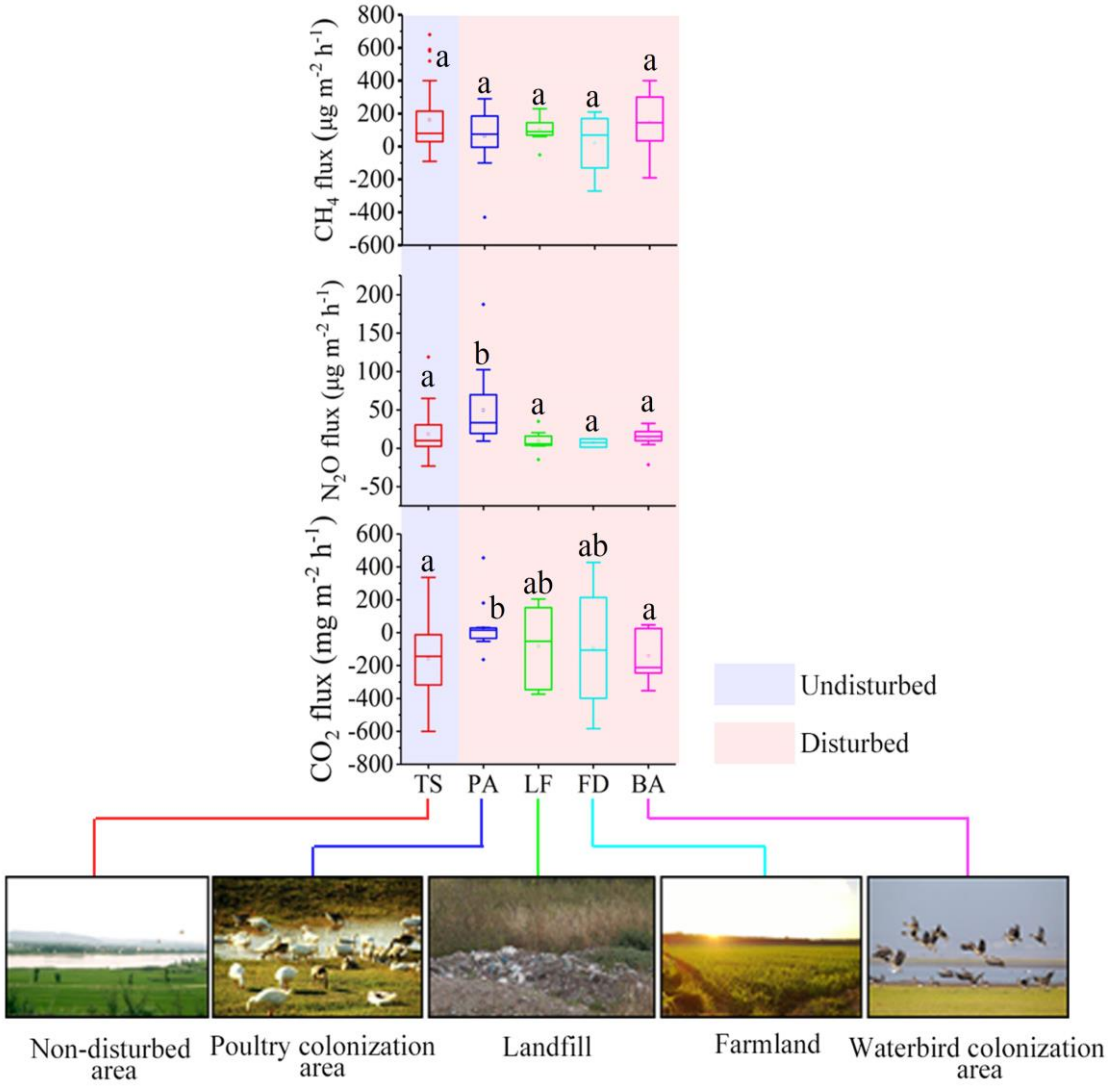

Figure 3. *Comparisons of CH_4, N_2O and CO_2 fluxes from different non-disturbed and disturbed marsh areas. TS (n=56), PA (n=8), LF (n=4), FD (n=4) and BA (n=4) represent non-disturbed site, poultry colonization area, landfill, farmland, and waterbird colonization area, respectively. The different lowercase letters (a, b) indicate statistically significant differences between the mean fluxes (Fisher's LSD, $P < 0.05$)*

The PCA analysis showed that the environmental variables in the first two components explained 71.0% and 87.2% of the cumulative variance of the CH_4 fluxes at the undisturbed and disturbed marsh sites, respectively, and soil moisture was the predominant factor affecting spatial variability in CH_4 emission (*Fig. 4*). The CH_4 fluxes showed a significant positive correlation with soil moisture at the undisturbed or disturbed marsh sites. When the data at all the observation sites were combined, CH_4 fluxes showed a strong positive correlation (P=0.000) with soil moisture (*Table 2*). The TN, NH_4^+–N did not significantly affect CH_4 emissions at the undisturbed sites, whereas they showed a significant positive correlation with CH_4 emissions at the disturbed marsh sites.

N_2O fluxes

The dry marsh sites SD and WD showed strong N_2O emissions with the mean fluxes of 13.9±2.1 μg N_2O m^{-2} h^{-1} and 20.8±6.7 μg N_2O m^{-2} h^{-1}, respectively, whereas the mesic sites SM and WM and wet sites SW and WW presented weak N_2O emissions (*Fig. 2*). The mean fluxes from SM (11.0±2.0 μg N_2O m^{-2} h^{-1}) and WM (13.4±7.6 μg N_2O m^{-2} h^{-1}) were comparable to those from SW (10.6 μg N_2O m^{-2} h^{-1}) and WW (13.0±1.7 μg N_2O m^{-2} h^{-1}). High emission (25.1±9.8 μg N_2O m^{-2} h^{-1}) occurred at the site WI, corresponding to the lowest soil moisture (*Fig. 2*). Overall the highest N_2O fluxes (mean 49.5±11.9 μg N_2O m^{-2} h^{-1}) and slightly enhanced fluxes (mean 14.1±3.9 μg N_2O m^{-2} h^{-1}) occurred in poultry and waterbird active areas, respectively (*Fig. 3*). The landfill site LF (mean 8.9±5.1 μg N_2O m^{-2} h^{-1}) and farmland site FD (mean 5.2±2.8 μg N_2O m^{-2} h^{-1}) showed relatively low N_2O fluxes, comparable to the undisturbed sites (mean 8.7±4.2 μg N_2O m^{-2} h^{-1}).

The PCA analysis showed that environmental variables in the first two components explained 72.2% and 87.9% of the cumulative variance of the N_2O fluxes at the undisturbed and disturbed marsh sites, respectively, and soil NO_3^--N contents and soil moisture were the predominant factors affecting spatial variability in N_2O emission (*Fig. 4*). The N_2O fluxes showed a significant negative correlation with soil moisture at the undisturbed or disturbed marsh sites. Almost no statistically significant correlations were obtained between N_2O fluxes and other environmental parameters at the undisturbed marsh sites. However, a strong positive correlation occurred between the fluxes and NO_3^--N contents at the disturbed sites, but the weak negative correlations between the fluxes and TOC, TN and NH_4^+-N (*Table 2*), indicating that animal-derived NO_3^-–N input significantly enhanced N_2O emissions from the SLM.

NEE and ER

NEE between dry, mesic and wet marsh sites showed a significant difference ($P<0.05$), and the maximum mean CO_2 uptake occurred at the dry sites SD and WI (-443.6±17.0 mg CO_2 m^{-2} h^{-1} and -284.7±90.1 mg CO_2 m^{-2} h^{-1}, respectively) (*Table 1*). The marsh experienced a net gain of CO_2 in the summer or in the winter (*Fig. 2*). Overall net CO_2 emission occurred in the poultry active area (29.1±33.2 mg CO_2 m^{-2} h^{-1}), whereas waterbird activity area (-140.0±41.9 mg CO_2 m^{-2} h^{-1}), landfill (-82.6±86.6 mg CO_2 m^{-2} h^{-1}) and farmland (-92.2±210.9 mg CO_2 m^{-2} h^{-1}) showed weak CO_2 uptake compared to the non-disturbed marsh areas (*Fig. 3*). The marsh NEE had a strong positive correlation with soil moisture at both the undisturbed and disturbed sites, and soil moisture played a more important role in explaining the spatial variability in net CO_2 fluxes (*Fig. 4* and *Table 2*).

The mean ER rate at the dry site (1106.9±109.7 mg CO_2 m^{-2} h^{-1}) was greatly higher than those at the mesic (674.9±210.8 mg CO_2 m^{-2} h^{-1}) and wet (694.2±420.1 mg CO_2 m^{-2} h^{-1}) sites (*Fig. 5a* and *Table 1*). Marsh ER showed a significant negative correlation with soil moisture ($P<0.05$). However, the pattern of ER appeared to follow soil temperature with a strong, positive exponential correlation ($R^2=0.57$, $P<0.05$) and the Q_{10} value of 8.7 (*Fig. 5b*). Summertime photosynthesis (Pg) rates at the dry, mesic, paddy and wet sites averaged 1550.4±126.7 mg CO_2 m^{-2} h^{-1}, 1020.4±202.8 mg CO_2 m^{-2} h^{-1}, 1286.2±386.2 mg CO_2 m^{-2} h^{-1} and 820.4±341.6 mg CO_2 m^{-2} h^{-1}, respectively, and showed a large spatial variability between the types of sites (CV=8.2%, 19.9%, 30.0% and 41.6%, respectively). The Pg rates at the dry marsh

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27612780

(1550.4±126.7 mg CO_2 m^{-2} h^{-1}) and paddy sites (1286.2±386.2 mg CO_2 m^{-2} h^{-1}) were significantly higher than those at the mesic (1020.9.4±202.8 mg CO_2 m^{-2} h^{-1}) and wet marsh sites (820.4±341.6 mg CO_2 m^{-2} h^{-1}) (*Fig. 5a*).

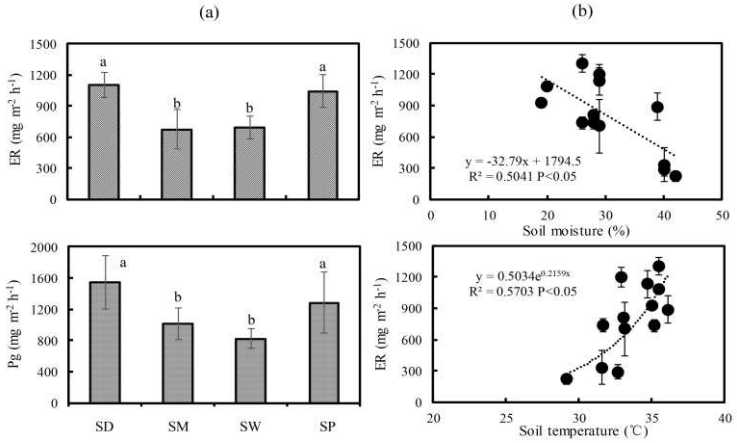

Figure 5. *(a) The ecosystem respiration rates (ER) and gross photosynthesis (Pg) from the marsh transect sites during the summertime. The different lowercase letters (a, b) indicate statistically significant differences between means (Fisher's LSD, P < 0.05); (b) The relationship between ER and soil moisture, soil temperature at the marsh transect sites. If the overall regression is significant at P<0.05, regression lines and r values are given*

Correlation between GHG fluxes and global warming potential

The N_2O and CH_4 fluxes from different types of marsh sites showed a significant negative correlation, i.e. so-called ''trade-off effect". The significant positive relationships occurred between CH_4 flux and ER, NEE, whereas N_2O fluxes showed a significant negative correlation with NEE (*Fig. 6*). The average CH_4 and N_2O fluxes are 178.8 μg m^{-2} h^{-1} (n=76) and 15.2 μg m^{-2} h^{-1} (n=76), respectively, and their fluxes are equivalent to 4.5 mg CO_2 m^{-2} h^{-1} and 4.5 mg CO_2 m^{-2} h^{-1}, respectively. However, net mean CO_2 flux from the marsh is -212.6 mg m^{-2} h^{-1}. A GWP-negative process strongly dominates when N_2O, CH_4 and CO_2 fluxes from the marsh are combined in terms of their relative GWPs. Overall the SLM is still a large "carbon sink".

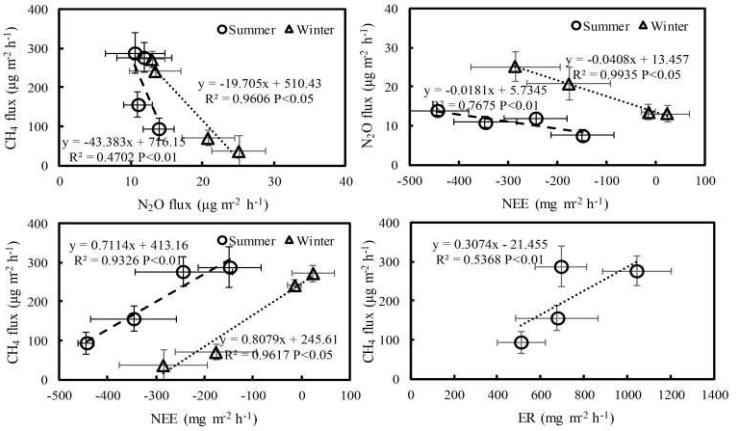

Figure 6. *Correlations between CH_4 flux, N_2O flux, NEE and ER from different types of marsh sites*

Discussion

Effects of soil moisture on spatial variations of GHG fluxes

Overall our statistical analyses showed soil temperatures and soil nutrient variables were not predominant factors affecting marsh CH_4 and CO_2 fluxes at the undisturbed sites (*Table 2*). Soil moisture (Mc) had a significant difference among the sites due to the drawdown of lake level and the differences in topography, slope and hydrology, which influenced the magnitudes and variations of GHG fluxes at spatial scale (Ding et al., 2002; Song et al., 2009). Mc showed a significant positive correlation with CH_4 fluxes and NEE, but a significant negative correlation with N_2O (*Fig. 4* and *Table 2*). This indicated that marsh soil moisture regulated spatial variability in marsh GHG fluxes. Soil water regime is widely recognized as the fundamental factor in regulating small-scale variation in CH_4 emissions from the wetlands, given water regime can directly affect the anaerobic condition, which is necessary for CH_4 production (Christensen et al., 2003; Wang et al., 2008; Wei and Wang, 2017), whereas low soil moisture make O_2 diffuse into soil to oxidize CH_4 into CO_2 (Song and Liu, 2016; Bao et al., 2018a). Therefore the decrease in soil moisture inhibited marsh CH_4 production. N_2O is an intermediate product of soil nitrification and denitrification processes, and soil moisture might have an important effect on N_2O production through its effects on nitrification and denitrification processes (Granli and Bockman, 1994). In this study, N_2O fluxes showed a significant positive correlation with soil NO_3^--N contents, indicating that denitrification might be the main process responsible for marsh N_2O emissions. Furthermore increasing soil moisture could cause high anaerobic condition and low O_2 availability, and most of N_2O can be reduced to N_2 via denitrification, which might cause the decrease in N_2O emissions from the wetlands (Kato et al., 2011; Zhu et al., 2014b; Bao et al., 2018b). The lowering of water table could increase the volume of modestly aerated soil, thus increased the proportion of N_2O production in either of nitrification and denitrification (Kato et al., 2011; Chen et al., 2013). The incomplete denitrification releases N_2O, which might be favorably produced in marsh soil at well-drained, aerated marsh sites (Granli and Bockman, 1994; Scaroni et al., 2014). Therefore higher N_2O emissions occurred at the dry marsh sites SD, WD and WI in the SLM.

On the other hand, the decrease in soil moisture might stimulate carbon sequestration in the marsh (*Fig. 2*). Stronger plant photosynthesis occurred at the site SD than SM and SW (*Fig. 5a*), which might be due to higher vegetation coverage at the dry upland marsh (Lu and Liu, 2011; Yang et al., 2015). Soil moisture directly affected the distribution of soil microbial communities and marsh vegetation, thus influenced ecosystem respiration (Llstedt et al., 2000). Previous studies indicated that the Pg rates were the highest in dry tundra marsh with smaller differences in net CO_2 exchange whereas the ER rates were limited, therefore the dry marsh showed much higher net CO_2 uptake (Dagg and Lafleur, 2011). In the SLM, the decrease in soil moisture stimulated ER rates instead of limiting ER (*Fig. 5b*). The increase in net CO_2 uptake at the dry marsh sites showed that plant photosynthesis might surpass ER with the drawdown of lake water level. Similarly, plant photosynthesis, rather than the mineralization of organic matter, played a more important role in net CO_2 flux at the dry marsh site (Del Giorgio et al., 1999; Huttunen et al., 2003). Therefore plant photosynthesis might dominate CO_2 exchange across air-soil interface in the SLM. In addition, a strong, positive exponential correlation between ER and soil temperature

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27612780

showed a positive feedback of ER to current warming climate. Climate warming might decrease CO_2 sink through the increase in ER (Davidson and Janssens, 2006; Zhu et al., 2014a). The Q_{10} value of 8.7 in the SLM was much higher than the range (1.3-5.6) for different biomes of the world (Davidson and Janssens, 2006), indicating a greater temperature sensitivity to ER.

Effects of animal activity and land use on GHG fluxes

Overall the mean CH_4 fluxes from waterbird and poultry active areas showed no statistical significant differences ($p>0.05$) from the undisturbed sites (*Fig. 3*).The fluxes from waterbird (148.3±51.5 μg CH_4 m^{-2} h^{-1}) and poultry (64.4±44.3 μg CH_4 m^{-2} h^{-1}) active areas were lower than those from dairy cow feeding yards (358.3 μg CH_4 m^{-2} h^{-1}), dairy cow collecting yards (429.2 μg CH_4 m^{-2} h^{-1}), and pig loading areas (158.3 μg CH_4 m^{-2} h^{-1}) (Misselbrook et al., 2001), which might be related with low soil moisture, especially in poultry active area (Mc<30%, *Table S2*). Lower soil moisture might greatly increase marsh CH_4 consumption (Gulledge and Schimel, 1998). However, net CO_2 emission occurred in the poultry active area (29.1±33.2 mg CO_2 m^{-2} h^{-1}), whereas waterbird activity area showed weak CO_2 uptake compared to non-disturbed marsh areas, indicating that poultry activity could decrease marsh CO_2 sink, even convert a marsh site from CO_2 sink into a net source. Similar results also occurred in the tundra marsh disturbed by marine animal activities (Zhu et al., 2014a).

The N_2O fluxes from poultry (mean 49.5±11.9 μg N_2O m^{-2} h^{-1}) and waterbird (mean 14.1±3.9 μg N_2O m^{-2} h^{-1}) active areas were comparable to or even greater than those from the farm yards used by livestock (11.8-27.5 μg N_2O m^{-2} h^{-1}) (Misselbrook et al., 2001), and from some temperate extensive pastures or rangelands (0-26.6 μg N_2O m^{-2} h^{-1}) (Phillips et al., 2007), and those from heavily fertilized agricultural systems and tropical forests (23.6-83.3 μg N_2O m^{-2} h^{-1}), which are the two largest N_2O sources worldwide (Perez et al., 2001). Similar results also occurred in tundra marsh sites disturbed by seabird activities (13.3-57.4 μg N_2O m^{-2} h^{-1}) (Zhu et al., 2012, 2013). The high N_2O emissions from poultry or waterbird active areas might be modulated by soil physical and chemical processes associated with animal activities: continuous N input from animal excreta and animal tramp (Zhu et al., 2012). Significantly elevated NO_3^-–N concentrations occurred in animal-disturbed marsh soils as compared with undisturbed soils (*Table S2*). A strong positive correlation between N_2O fluxes and soil NO_3^-–N contents confirmed that animal-derived NO_3^-–N input had an important effect on spatial variability in N_2O fluxes (*Fig. 4* and *Table 2*). Therefore, animal activity and the deposition of their excreta significantly enhanced N_2O emissions in the SLM.

During the conversion of the marsh into paddy fields, human tillage and the rice plants with well-developed aerenchyma might lead to the increase in CH_4 emission (Cai et al., 1997). The plants with well-developed aerenchyma are important in determining net CH_4 fluxes from some wetlands (Bass et al., 2014; Bao et al., 2018b). However, net CH_4, N_2O and CO_2 fluxes from agricultural field site FD were comparable to the undisturbed sites (*Fig. 3*), indicating that the conversion of the marsh into agricultural fields did not significantly change GHG emissions. Landfill gas is mainly composed of CH_4 and CO_2, which is generated during decomposition of the solid waste (Sharma et al., 2011). The landfill did not change CH_4 and N_2O fluxes, and slightly decreased CO_2 uptake compared to non-disturbed marsh areas (*Fig. 3*). GHG fluxes from the landfill were lower than those reported from sanitary landfills (Bogner et al., 1995; Rinne et al., 2005; Kormi et al., 2017). Generally landfill GHG emission estimates are highly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27612780

uncertain because factors influencing gas emission and mitigation are site specific (Boeckx et al., 1996). Landfill GHG emissions can range over six orders of magnitudes (Lando et al., 2017). The ambient and soil moisture had an important effect on GHG production from the landfill (Rinne et al., 2005). During the study period, very high soil moisture (68%-73%, *Table S2*) might stimulate CH_4 and CO_2 emissions, but decrease N_2O production from the landfill (*Fig. 3*).

In summary, correlation analyses revealed that GHG fluxes from the disturbed marsh sites were involved in more complicated factors than from undisturbed sites (*Table 2*). Significant positive correlations ($p<0.05$) between net CH_4 and CO_2 fluxes and soil moisture, soil nutrients indicated that their fluxes might be modulated by soil physical and chemical processes associated with animal activities (Zhu et al., 2012, 2013). Negative correlations were generally observed between N_2O emissions and soil moisture, nutrient variables TOC, TC, TN and NH_4^+ at the disturbed sites and all the combined sites (*Fig. 4* and *Table 2*), which was different from some previous studies (Chen et al., 2011; Sun et al., 2014). One possible reason was related to the interaction of vegetation and microorganism (nitrifiers and denitrifiers) during N_2O production (Sun et al., 2014). N_2O production might be partly inhibited as the available N was significantly competed by both vegetations and microorganisms in *Artemisia lavandulaefolia DC* and *Artemisia scoparia waldst* community (Lu and Liu, 2011; Yang et al., 2015), which partly contributed to the difference in N_2O emissions at spatial scale. Overall the PCA analysis showed that soil moisture was the predominant factor affecting spatial variability in marsh GHGs fluxes from the undisturbed and disturbed sites in the SLM (*Fig. 4*). This preliminary study only provided short summertime or wintertime GHG fluxes from agricultural field or landfill in the SLM, and effects of animal activities and land use on marsh GHG emissions need to be further confirmed in the future.

Implication of marsh GHG evaluation

The SLM, as a typical natural freshwater wetland in the Middle-Lower Yangtze Plain, is involved in effects of complicated factors including environmental variables, human activities and waterbird colonization (Lu and Liu, 2011; Yang et al., 2015; Zhang et al., 2015). The coefficients of variance (CV) of CH_4, N_2O and CO_2 fluxes were relatively small (<100%) within the same type of sites. However, their fluxes showed significant differences among the sites, indicating that to assess the regional GHG budget precisely, measurements should be designed at fine scales and environmental heterogeneity should be considered in the marsh. In addition, the study area has a temperate monsoon climate with an evident distinction in precipitation between rainy and dry seasons. This could lead to soil moisture changes, dry-wet alternation and wetland extent dynamics, and cause the ‘‘trade-off effect” of N_2O and CH_4 fluxes and carbon sequestration in the marsh (Cai et al., 1997; Ding and Cai, 2007). Effects of soil moisture changes on ‘‘trade-off effect” of N_2O and CH_4 fluxes need to be used for accurate evaluation of net GWP in the SLM. In summary, there still remains a large uncertainty regarding the evaluation of GHG budgets in the SLM. The GHG budget evaluation for the SLM and other similar MLYP wetlands should be involved in soil water regimes, waterbird colonization and human-induced influences.

Conclusions

We revealed effects of soil moisture, animal activities and land use on GHG fluxes from the SLM based upon *in situ* flux measurements. Overall CH_4 emissions from the dry marsh sites were much lower than those from wet or mesic sites, vice versa for N_2O emissions and NEE. Soil moisture was the predominant factor controlling the spatial variability in marsh CH_4 and N_2O fluxes and NEE at undisturbed sites. Correlation analyses revealed that GHG fluxes from the disturbed marsh sites were involved in more complicated factors than from undisturbed sites. The mean CH_4 fluxes from waterbird and poultry active areas showed no statistically significant differences ($p>0.05$) from the undisturbed sites, but animal activities increased N_2O emissions, decreased marsh CO_2 sink, even convert into a net CO_2 source. The conversion of the marsh into agricultural field and landfill did not significantly change GHG emissions compared to non-disturbed marsh areas. To assess the regional GHG budget precisely, measurements should be designed at fine scales and environmental heterogeneity should be considered in the marsh. This study only provided short summertime and wintertime GHG fluxes, and long-term and high-frequency observations are needed to accurately quantify GHG budgets in the SLM. Continued investigations into the dynamics of GHG fluxes as well as mechanisms of GHG production in natural wetland, with an emphasis on temporal variation are essential in the future.

Abstract. *Haloxylon persicum* is a desert shrub with economic and ecological importance for arid zones in Saudi Arabia. It has a vital role in the protection of Unaizah and Buraidah, two large cities, and their surrounding from the dangerous mobile sand dunes and without it, the area could be covered by these dunes in a few years. The current study aims to analyze the floristic, vegetation structure and size structure of *H. persicum*. Eighteen stands were selected along the north and south of the study area with 20 m^2 each. At each stand, the vegetation inventory including plant species abundance percentage and size structure for *H. persicum* were estimated. Three plant associations; *H. persicum-Plantago boissieri*, *H. persicum-Stipagrostis plumose* and *H. persicum* were identified. Analysis of *H. persicum* size structure frequency was skewed towards medium size classes in all populations and the early life stages such as juvenile and the seedling recruitment was extremely limited. These results indicated that the populations of *H. persicum* are threatened by aridity and human impacts. Therefore, efforts are required to minimize uncontrolled exploitation. Finally, *in situ* and *ex situ* conservation of *H. persicum* populations are strongly recommended.
Keywords: *human impact, managed area, population demography, seedling recruitment, size structure*

Introduction

Sand dunes are one of the largest arid terrestrial ecosystems in Saudi, covering huge area of land surface (Reynolds et al., 2007). This sandy arid dry land is a fragile ecosystem component and one of the most sensitive areas to climate change and human activities, because the rare of rainfall and high evapotranspiration (Huang et al., 2015). Conversely, there are a lot of groundwater under these sand dunes due to the seeping of the rainfall water through the sand layers and stored against the evapotranspiration. These quantities of underground water are often an important water source for perennial plants and can be used for cultivation of farms (Cui and Shao, 2005; Naumburg et al., 2005; Imada et al., 2008). Moreover, the dynamics and the availability of the groundwater plays an important role in defining vegetation composition and distribution (Naumburg et al., 2005; Elmore et al., 2006), and in driving the vegetation dynamic and shifting the interactive balance between wooden species and herbaceous plants (Cooper et al., 2006; Holzapfel et al., 2006; McCluney et al., 2012). The unsustainable exploitation of groundwater associated with rapid population expansion and socio-economic development in these regions has aggravated the fluctuation of the groundwater table and influenced the availability of groundwater to desert shrub plants

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27812794

(Wang et al., 2011; Orellana et al., 2012). Declining or shifting the area of vegetation will decrease the diversity of plant associations and the stability of sand dunes this can consequently result in covering of the cities and productive farms by sands (Naumburg et al., 2005; Padilla and Pugnaire, 2007).

H. persicum is one of the most characteristic communities inhabit the Nafud habitat (flat sand seas with high sand dune) and characteristically occupies deep sand on the shoulders of sand dunes and shallow hollows of center Saudi (Schulz and Whitney, 1986). It nearly corresponds to the *Calligonum comosum* and *Artemisia monosperma* shrubland. *H. persicum* is an important plant for binding the mobile sand and shelter for many other plant associations which increasing the plant diversity (Brown and Porembski, 1998; El-Sheikh et al., 2010). Removal of *H. persicum* and *Calligonum comosum* for using as fuel and *Stipagrostis* by heavy gazing are common anthropogenic practices in Al-Qassim area. Therefore, people are managed this area at Unaizah from long time ago. Because, this managed area is the main reason for saving Unaizah and Buraydah cities and farms against the common dangerous sandy storms with strong mobile sand dunes. Without a dominant *H. persicum* and its associations, the area will be covered by mobile sand dunes in few years. However, there have been only few studies on the status of woody vegetation such as (Alatar et al., 2015). Therefore, understanding the mechanisms underlying the size, shape and dynamics of the geographic distributions of various species remains a key challenge (Pennisi, 2005; Gaston, 2009).

However, the present study aims to: 1- analysis the floristic and vegetation structure of managed area, 2- examine the status of *H. persicum* size structure if the population grow or decline after the long period of protection, and 3- analysis the ecological relations of *H. persicum* with edaphic and dominant anthropogenic factors.

Materials and methods

Study area

Al-Ghada managed area is located in Nafud Al-Shuqayyqah 'sandy arc'. It is located in the center of Al-Qassim area, south-west of Unaizah city and south of Wadi Al-Rumah valley between 43°-44° E 25°-26° N, lat. 630-724 meters above sea level (*Figure 1*). It is surrounded by sand dunes from the north and the west called the sands of Ghamis. The presence of *H. persicum* on the deep sand habitat, often in the form of low sand dune and extended to covering large area with low cover and it only scattered hummocks are to be seen in the landscape. There are associated few sub-shrubs, perennial grasses and annuals indicate a shallow ground water table fed by percolation.

According to the data of the meteorological station in Qassim region, the study area is located in the arid regions of Saudi Arabia. The climate is mildly moderate as the temperature reaches 20.0°C around the day during winter season and at night it is cold as the temperature drops to 6.0°C. Daytime temperatures reach up to 44°C and at night 27°C in the summer season.

Sample stands

A total of 18 stands in the north and south sector of the managed area were selected to covering all variations of habitats and vegetation structure. To analyze floristic and vegetation structure, in each stand plants were collected, identified and classified into

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27812794

their different life forms and chorotypes were recorded. Identification of plant species were conducted based on available references (Collenette, 1985, 1998, 1999; Chaudhary, 2001). Plant species cover were estimated in each stand as abundance percentage according to Kent (2012) and Canfield (1941).

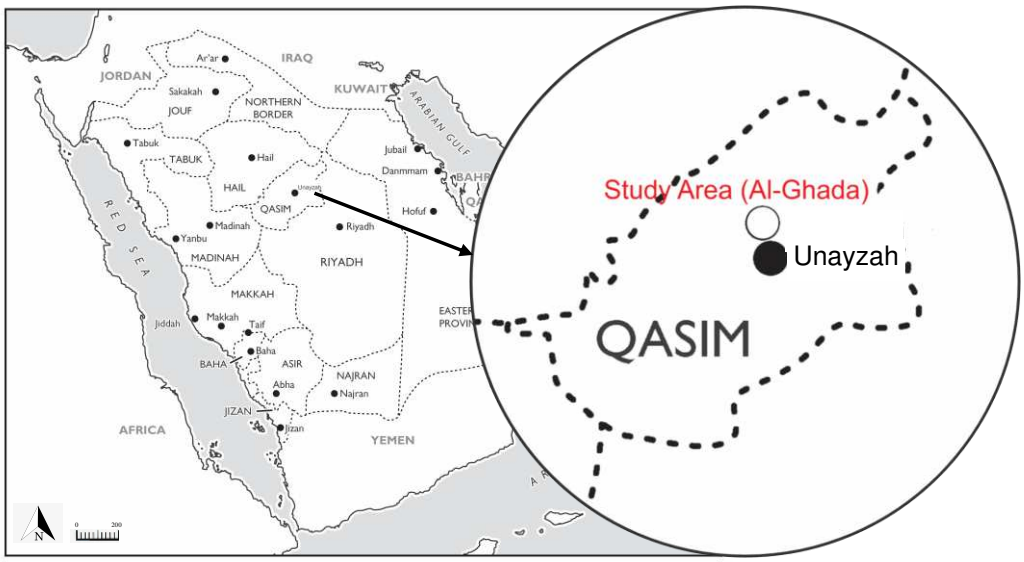

Figure 1. *A map showing the study in site at Unaizah area (Source: Ministry of Petroleum and Mineral Resources, Saudi Arabia)*

Soil analysis

Eighteen soil samples were collected; one from each stand from 0 - 50 cm depth. Soil texture (sand, silt and clay) was analyzed by Hydrometer method (Allen, 1989). The percentage of total organic matter was determined by loss of ignition of soil at 550°C for 2 hours. The prepared soil water extract (1:5) was used for further chemical analysis. Soil reaction (pH) measured by pH-meter and electrical conductivity (EC in mS cm^{-1}) was measured by conductivity -meter. The soil content of nutrient elements (N, P, K, Ca, Mg, Na and Fe) was estimated by using Inductively Coupled Plasma Optical Emission Spectrometry (ICP MSEOS 6000 Series, Thermo Fisher Scientific) method. All these methods are outlined in Allen (1989).

Data analysis

The numerical classification analysis TWINSPAN using two-way indicator species analysis (Hill, 1979b) were applied for plant species cover in 18 sample studied i.e matrix of 18 stand x 35 species cover values; and Detrended Correspondence Analysis (DCA) using DECORANA software (Hill, 1979a; ter Braak and Smilauer, 2002) was applied on the same data to obtain a graphical representation of the ecological structure of the vegetation groups identified using TWINSPAN. The second matrix of 18 stand X 35 species cover values X soil variables was using for detecting the correlations of the derived vegetation groups with environmental data, Canonical Correspondence Analysis, 'CCA', according to ter Braak and Smilauer (2002).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27812794

Species richness of each vegetation group was calculated as the average number of species stand^{-1}. Simpson index following the equation $C = \sum_{i=1}^{s} p_i^2$ as an indicator for the relative dominance concentration and Shannon-Wiener index following the equation $\hat{H} = -\sum_{i=1}^{s} p_i \log p_i$ were calculated for each stand on the basis of the relative cover (pi) of *i*th species (Pielou, 1975; Magurran, 1988). The correlation between the ordination axes on one hand and soil variables on the other hand were estimated by Pearson's simple linear correlation coefficient (r). Moreover, the relations between species diversity indices and soil variables were tested. The variation in species diversity, soil variables and stand characters in relation to vegetation group was assessed by one-way analysis of variance SPSS 20.0 software, IBM, Chicago, IL.

Plant size structure analysis

The size of *H. persicum* individuals were counted by their height (H) and average crown diameter (D) were measured (based on 3-diameter measurements/individual) and their average of H and D were calculated in each stand. The size index H+D/2 was calculated (modified Crisp and Lange, 1976). This obtained value used for calculation the size frequency distribution category of *H. persicum*. The frequency of each category is calculated separately as a percentage frequency and drawing graphically. Density of *Haloxylon persicum* in the studied area was calculated as the number of individuals/ha. Finally, the mean and coefficient of variation of density, height, diameter, and size index of *H. persicum* were calculated.

Results

Floristic diversity

A total of 35 plant species belonging to 12 families were collected from the studies stands. The most represented families in the study area were Poaceae and Caryophyllaceae (21% each), Boraginaceae (18%) and Geraniaceae (7%). The most prominent life forms (*Figure 2a*) were annual herbs (61%), sub-shrubs (12%), annual grasses (9%), perennial herbs (6%), perennial grasses (6%) and shrubs (6%). The dominant chorotypes were the Saharo Arabian region represented by 12 species (41%) followed by the Mediterranean-Irano Turanian-Saharo Arabian (17%), the Saharo Arabian-Somali Masai (14%) and the Saharo Arabian-Irano Turanian (10%) (*Figure 2b*).

Multivariate analysis

The dataset formed in this study consisted of 18 studied stands and 35 species. TWINSPAN analysis of this dataset generated a dendrogram divided it into three vegetation groups (plant communities) at the second level. Characterization and nomination of these groups were assigned based on the dominant and subdominant species in each group as follows: vegetation group (VG) I: *H. persicum-Plantago boissieri*, VG II: *H. persicum- Stipagrostis plumosa*, VG III: *H. persicum*. Further CCA and DCA analysis confirmed the separation of these plant communities generated by TWINSPAN and reveals a great relationship between topographic aspects and environmental gradients in Ghada managed area (*Table 1* and *Figure 3a,b*). The association VG I: *H. persicum-Plantago boissieri* mostly inhabits on the north sector of managed area (75%) of total stands and the association II: *H. persicum- Stipagrostis plumosa* inhabits mostly on the south zone (57%) of total stands. On the other hand, the association III *H. persicum* is completely inhabited on the north sector of the managed area (*Table 2*).

Correlation analysis

The relation between the environmental variables and ordination axes was done by CCA application (*Table 2* and *Figure* 4). The separation of stands along the AX-1 is affected positively by species number, richness, evenness, Mn and negatively by Simpson index (*Table 2* and *Figure 4a*). The species number, Mn and Fe are positively correlated with the AX-2. The distribution of *H. persicum* are located on the lower negative side of the AX-1 and correlated with EC, Na, Clay and Ca content (*Figure 4b*).

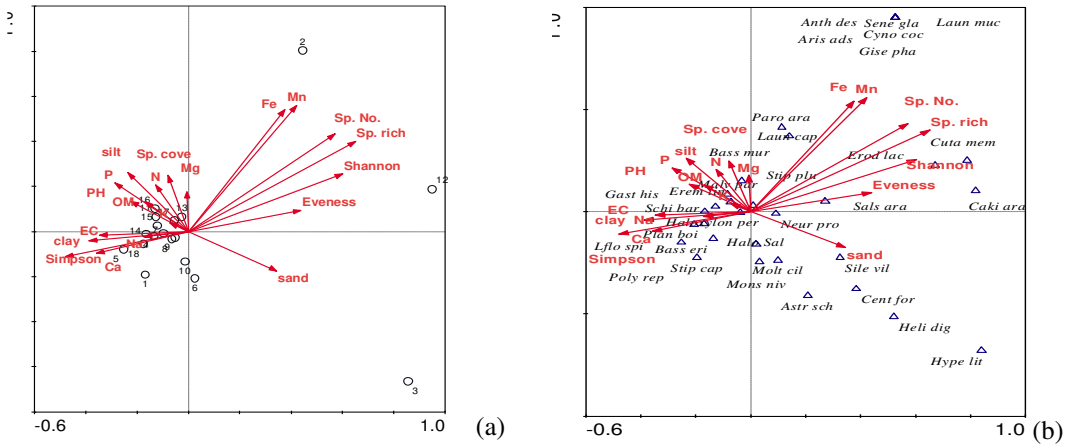

Figure 4. *CANOCO ordination biplot with environmental variables (arrows); 18 stands (a) represented by circles and 35 abundant species (b) represented by triangles with the first four letters of genus and three letters of species name. Fullanames of the abundant species are available in Table 1*

Species number and species richness are correlated positively by Fe and Mn and negatively by clay content. Species evenness and Shannon index are correlated positively by sand and negatively by silt, Na and P but the Simpson index are correlated vice versa by these element contents (*Table 3*).

Soil-plant association characteristics

The association of VG I: *H. persicum-Plantago boissieri* had the high values of species cover, silt and clay and lower values sand, Fe and Mn content (*Table 4*). The association of VG II: *H. persicum- Stipagrostis plumosa* had the highest values of Simpson index, organic matter, pH, EC, K, Mg, Na, N, Fe and lower in species cover, species number, species richness, species evenness and Shannon index. On the other hand, the association of VG III *H. persicum* had the highest values of species number, richness, evenness, Shannon indices, sand, Fe, Mn and lower values of Simpson index, silt, clay, organic matter, pH, EC, K, Ca, Mg, Na, N and P content.

H. persicum size structure

The northern part of the studied area is characterized by high density number and lower values of plants' height, diameter, height/diameter ratio and size index as compared to the southern region of the studied area (*Table 5*).

The size structure of *H. persicum* individuals in the northern sector and in all over the study managed area showed an inversed-J shape approving that there is a growth of individuals toward the medium individuals which constitutes the highest percentage (*Figure 5*). On the other hand, the size structure frequency of *H. persicum* growing in the southern sector of the study area showed a bi-modal pattern of growth indicating

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27812794

that there is equal of juvenile and medium individuals age (*Figure 5c*). This could be considered as an indicator of dangers threatens the *H. persicum* individuals in the southern studied area.

Table 5. *Demographic analysis of Haloxylon persicum in the study area*

Discussion

Topography and land forms significantly influence the growth, existence and distribution of different plant life forms in arid and semi-arid regions (Kassas and Girgis, 1964; Zohary, 1973; Shaltout et al., 2010) such as the managed area of Unaizah; the studied area. The results obtained in this study indicated that the dominant life form in the study site is annual herbs. This dominance of annual herbs could be attributed to the abundance of water during rainy seasons which supporting the growth of such plants on these *H. persicum* Nabkhas. Moreover, these Nabkhas are considering as shelter for many therophytes because it is modified the soil substrates by retain with rainfall under soil surface (Schulz and Whitney, 1986; Shaltout and Mady, 1996; Hosni and Hegazy,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27812794

1996; Shaltout et al., 2010). However, this water is adequate to support the growth of sub-shrubs e.g. *H. persicum*; therefore, the existence of such plants may be due to their adaptation to the harsh conditions exist in the study site (Alatar et al., 2012). The composition of vegetation life forms in the study area showed a typical pattern of the desert flora dominated by xerophytes and chamaephytes. The same pattern of vegetation was observed in different desert habitats among different parts of Saudi Arabia (Collenette, 1985, 1998, 1999; El-Demerdash et al., 1994; Chaudhary, 2001; Al-Turki and Al-Olayan, 2003; Fahmy and Hassan, 2005; El-Ghanim et al., 2010). In general, there is a great correlation between the plants' life forms and topography of their habitats (Kassas and Girgis, 1964; Zohary, 1973; Shaltout et al., 2010).

In study site, the dominant plant chorotype is the Saharo Arabian. The species of Saharo Arabian chorotype are distributed only along the central strip of Saudi Arabia and are more abundant in habitats providing protection and/or habitats characterized by more favorable micro-climate conditions (Zohary, 1973; Hegazy et al., 1998; El-Ghanim et al., 2010; Ghazanfar and Fisher, 2013). The central region of Saudi Arabia covers a wide range of bioclimatic zones and characterized by the existence of different habitats that supports several other chorotypes which were found in the study area beside the Saharo Arabian species e.g. the Mediterranean, Irano Turanian and Somali Masai. Furthermore, the Central region of Saudi Arabia covers the transition zone between these regions (Zohary, 1973; Mandaville, 1990; White and Léonard, 1990; Hegazy et al., 1998; Alfarhan, 1999; Ghazanfar and Osborne, 2010).

The three associations (VG) I: *Haloxylon persicum-Plantago boissieri*, VG II: *H. persicum-Stipagrostis plumosa*, VG III: *H. persicum* are comparable to the previous studies and represented the open sandy desert shrubland in center Saudi. This open shrubland is the most widespread community in An Nafud and corresponds to Vesey-Fitzgerald's (1957) 'central Arabian red sand vegetation' and the 'abal-'adhir sand shrubland described by Mandaville (1990). It is found near the mid-upper parts of dunes and also on undulating sheets of deep sand. Annual and perennial herbs are commonly associated with these communities of *H. persicum* Nabkhas such as *Plantago boissieri*, *Stipagrostis plumosa*, *Moltkiopsis ciliata, Monsonia heliotropoides*, *Stipa capensis, Centropodia fragilis* and *Cyperus conglomeratus* (Chaudhary, 1983). The distribution of plants and diversity are correlated with some edaphic factors, such as Mn, Fe EC, Na, clay and Ca content. Many authors stated that the climate, topography and habitat heterogeneity (John et al., 2007), seed and fruits dispersal (Svenning et al., 2008) and biotic interactions (Richards et al., 1997; Araújo and Guisan, 2006). However, determinants of species distributions vary on spatial and temporal scales. For instance, climate appears to be important at the landscape level and above (Davis and Shaw, 2001; Walther et al., 2002). Soil or topography dominates at landscape and local scales, hydrology at local scales, and dispersal functions at all scales (Angert and Schemske, 2005). Moreover, our finding indicated that the species diversity is positively correlated with soil content of soil Fe, Mn and sand content; and has a negative correlation with soil silt clay and Na content. Other studies reported the same pattern of correlation in desert habitats of Saudi Arabia (El-Demerdash et al., 1994; Abbadi and El-Sheikh, 2002; El-Sheikh et al., 2010, 2013, 2018).

The results obtained via the analysis of size structure and frequency of *H. persicum* plants in the studied area showed an inversed-J shape approving that there is a significant growth of these plants all over the protected area as the young individuals constitute the highest percentage. Similarly, the northern part of the studies area showed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27812794

the inversed-J pattern of size structure percentages showing that juvenile and medium individuals of *H. persicum* plants represent the highest percentages among all the other age categories. On the other hand, frequency calculation of size structure of *H. persicum* plants growing in the southern part of the studied area showed a bi-modal pattern of growth indicating that there is a significant abundance of young individuals and old individuals as well in the similar area (El-Sheikh, 2013). This could be considered as an indicator of dangers threatens the *H. persicum* community in the studied area. The obtained result showed significant evidence that *H. persicum* plants in managed area of Unaizah goes under a great negative human impact threating their abundance in the studied area (El-Sheikh, 2005, 2013). Therefore, these plants should be protected via all available means. Over-grazing and wood cutting are considered among the main factors affecting the abundance of *H. persicum* plants. The removal of *H.* and *Calligonium* for fuel is widespread as it is long and clean burning.

(Received 23rd Sep 2019; accepted 30th Jan 2020)

Abstract. This research was carried out to determine the quality values of Hungarian vetch silage mixed with wheat and barley grown in winter under the ecological conditions of Eastern Anatolia region, Turkey in the 2017-2018 growing season. To determine the quality values and chemical composition of the silage mixtures obtained from the different of Hungarian vetch, wheat and barley it was prepared as three replications and filled in 2-L jars and then firmly suppressed and tightly closed so that they do not breathe. The mixture rates of Hungarian vetch (HV), wheat (W) and barley (B), their pure sowed were 80%, 60%, 40%, 20% of B + 20%, 40%, 60%, 80% of HV + 80%, 60%, 40%, 20% of W. Silage jars were opened after 60 days and pH value, acid detergent fiber (ADF), neutral detergent fiber (NDF), crude protein content and organic acid values and some macro element contents were measured. The values for ADF, NDF, digestible dry matter (DDM), dry matter intake (DMI), relative feed value (RFV), dry matter (DM), crude protein (CP) of silages were 28.57-41.65%, 29.69-59.05%, 56.45- 66.63%, 2.62-4.05%, 89.78-201.62%, 22.22-33.00%, 8.15-17.27%, respectively. At the same time, values of lactic acid (LA), acetic acid (AA), butyric acid (BA) and propionic acid (PA), calcium (Ca), phosphor (P) and potassium (K) were 1.50-1.94%, 0.33-0.71%, 0.27-0.76%, 0.02-0.08%; was 0.30-1.68%, 0.33-0.62%, 1.93-4.48%, respectively. According to these results, it can be proposed that silages achieved from the HV + B mixture have some superior properties for CP, ADF, NDF, RFV, Ca, P, and K compared with HV + W mixtures.
Keywords: *barley, chemical composition, Hungarian vetch, mixture rates, silage quality, wheat*

Introduction

Turkey's Eastern Anatolia region which it is cold and snowy in winter and hot and dry in summer has a significant potential for animal breeding. As similar to other regions, Turkey, the pasture areas at Eastern Anatolia Region have noticeably declined as a result of excessive and uncontrolled grazing and the quality of pasture have decreased to the lowest levels. Because of this degradation of the pastures, a major decrease has occurred in the production of quality roughage and a quality. For this reason, to fodder forage crop cultivation, diversity the forage crops, produce alternative fodder crops and obtain silage from different fodder plants are quite important to overcome these problems.

In recent years, a considerable increase in silage production has become in Turkey. More than 80% of the total silage produced is corn silage (Alcicek and Karaayvaz, 2003). Corn, a hot climatic plant, can be effective in good maintenance and sufficient water conditions. The planting of silage corn at eastern Anatolia region or similar ecological places can appositely be affected from short period of vegetation and even sometimes spring and autumn frost damages. Therefore, Hungarian vetch is more

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27952806

resistant to cold and drought in comparison with vetch species, which it is grown and harvested without watering.

It can be said that silages of Hungarian vetch + barley mixtures have higher nutrition properties, because these crops contain both protein and carbohydrate. Thus, Miller (1984) reported that silages mixtures were more productive and quality when compared with pure ones. Lithourgidis et al. (2011) reported that environmental sources in mixed cultivation can more effectively be used and that it obtained the higher yields compared with pure sowing ones. Similarly, Tuna and Orak (2007) stated that the protein/carbohydrate ratio is better for silages obtained from these mixtures. In another study (Tas, 2002) it was reported that there was a lodging rate rising with an increase development of Hungarian vetch and for this reason it can be suggested that Hungarian vetch sowed mixing by wheat or triticale in winter sowings is better. In a study which investigated the effect of grass pea (*Lathyrus sativus* L.) and barley (*Hordeum vulgare* L.) on silage properties in Diyarbakır conditions (Seydosoglu and Gelir, 2019) was detected that pH and DM of silages at 100% of Grass pea and 100% barley were 3.99-4.09 and 28.28-32.98%, respectively. Likewise, Saruhan et al. (2011) reported that DM, CP ratio and pH for mixtures of different levels of barley and birdsfoot trefol (20, 30, 40, 50, 60, 70% birdsfoot trefol + 80, 70, 60, 50, 40, 30% barley) in same conditions of Diyarbakir were, respectively, 28.08-32.60%, 10.08-12.20% and 4.76-5.11.

Also, Koc et al. (1997) conducted to determine effect of microbial additive use in silages achieved form mixtures vetch *(Vicia sativa* L.) with cereal in laboratory conditions. In the study, the DM, pH, CP, NH3-N, LA, AA, BA of the this silages were 32.00-35.00%; 3.70-3.65;11.15-10.01%; 3.03-2.75 g/kg DM; 2.48-2.83%; 0.40-0.40%; 0.10-0.05%, respectively, whereas these values showed an difference in field conditions (it were, respectively, 48.00-44.00%; 3.86-4.59; 11:37 to 11:49%; 1.57-1.73 g/kg DM; 3:36 to 3:16%; 0.63-0.42%; 0.00-0.05%). After the 56 days of silage harvested during flowering of vetch and at milk stage of barley, Polat et al. (1998) observed that pH, CP, LA and AA and ADF of the silages with control and Lactobacillus plantarum + Enterecoccus faecium groups were 4.40-4.37; 10.84-10.77%; 2.25-2.38%; 0.67-0.59%; 65.20-65.20%; 41.80-42.62%.

Aykan and Saruhan (2018) conducted to determine the ensiled ability of silages achieved mixing by in different rates of barley and pea intercrops forage plants. In that study, pH value, DM, ADF, NDF, CP of these silages were 3.90-4.12, 19.23-30.98%, 35.33-40.50%, 55.02-69.76%, 13.00-18.29%, respectively. The dry matter, CP, pH of silages obtained from different levels mixtures of white clover and barley were 27.53-31.38%, 10.17-13.63% and 5.05-5.34, respectively (Demirel et al., 2010). Bergen et al. (1991) reported that DM, pH, NDF ADF, LA and AA in the silages of wheat harvested at milk stage and dough stage after ensiling of 64 days were, respectively, 34.50-43.50%,4.00-4.10, 50.00-51.80%, 34.50-35.60%, 5.96-6.12%, 1.17-0.82%. In some studies on silage it was indicated that propionic acid content of silage varied to type of silage or mixture (Homan, 2016; Seydosoglu, 2018).

In this study, it was aimed to determine the contents of organic acid, composition of some nutrient matter and values with quality of silages obtained from mixture Hungarian vetch with barley and wheat at different levels of mixture and thus to detect the best mixture ones.

Materials and methods

This research was carried out at Mus city located at the Eastern Anatolia region, Turkey in 2017-2018 growing season (*Fig. 1*). As barley and wheat, the sowing of Hungarian vetch was made in winter season (3 November 2017). As material of plant, we used the Hungarian vetch which it is the most cultivated plant in Mus, Syrena (wheat), and Tokak 157/37 (barley) varieties. These varieties used are resistant to cold and drought and are recommended to Southern Marmara, Northern Inner and Aegean, Thrace, Black Sea, Southeast and Eastern Anatolia, Central Anatolia as well as Mediterranean Regions.

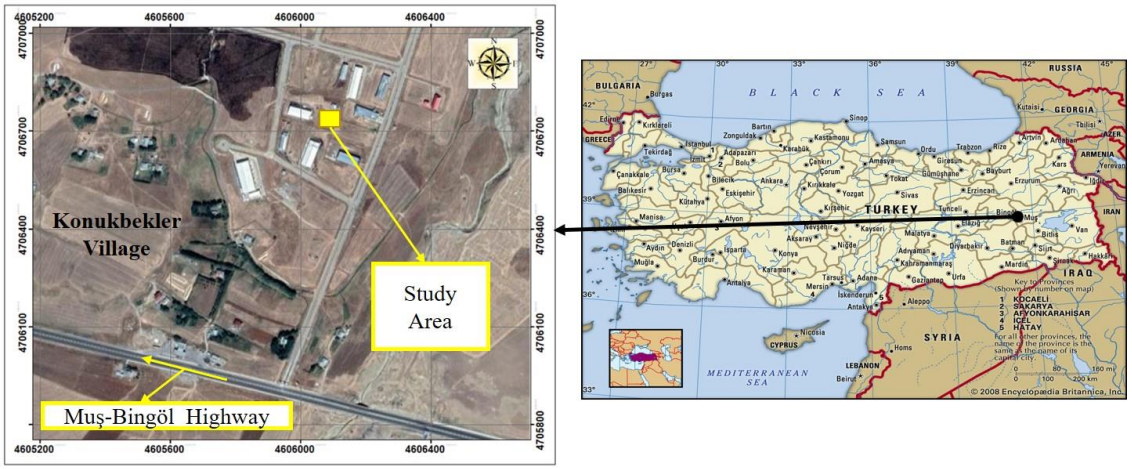

Figure 1. *Location map of the study area*

Each of these varieties was separately planted in 0.004 ha. 200 kg ha^{-1} of barley and wheat, and 100 kg ha^{-1} of Hungarian vetch were sowed. At the same time, 150 kg ha^{-1} of DAP fertilizer (27 kg ha^{-1} N, 69 ha^{-1} P) were applied to barley and wheat during sowing; whereas it was 100 kg ha^{-1} DAP (18 kg ha^{-1} N, ha^{-1} P) for Hungarian vetch.

Harvests were made in at full bloom for Hungarian vetch, at milking stage for barley and at heading stage for wheat (3 June 2018). The plots were separately simultaneously harvested with hand sickle. After the harvesting, material of silage was faded in the shade for 3-4 h and then cut into 0.5-1 cm dimensions with a silage harvester working with the tail shaft. After the chopping process, the materials were weighed on the sensitive scale according to the standardized rates.

The materials weighed were filled homogeneously and filled in 2-L plastic jars with 3 replications. The jars filled with silage materials are hand-tightened thoroughly. After the lid of the jars is closed tightly, they are wrapped with duct tape so that they do not breathe. It was then allowed to ferment into the dark environment for 60 days. At the end of this period, the maturing silages were opened and after the 4-5 cm part of the mouth of the jars were removed; the pH values were measured (Polan et al., 1998). After weighing 500 g of silage from each jar, it was dried to a constant weight for 48 h (AOAC, 1990) at 60 °C. After the dry weight of the silages was obtained, the samples were ground and prepared for analysis.

The content of crude protein (CP), calcium (Ca), magnesium (Mg), phosphor (P), potassium (K) content of silage, acid detergent fiber (ADF) and neutral detergent fiber (NDF) was determined with Near Infrared Reflectance Spectroscopy (NIRS), Near

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27952806

Infrared Analysis (NIR) by spectroscopic technique (Hoy et al., 2002), while organic acid ratios such as LA, AA, PA and BA were detected with HPLS (Canale et al., 1984).

The data obtained were analyzed to variance analysis by using JUMP program based on 5% and 1% of significance levels (SAS, 1998). The differences between the mean values were compared according to the LSD, multiple comparison tests (Gulumser et al., 2006). Digestible dry matter [DDM = 88.9 - (0.779 x ADF%)] and dry matter consumption (DMI = 120/NDF%) and relative feed value from DDM and DMI ratios [RFV = (DDM x DMI)] were calculated from formulation described by Van Dyke and Anderson (2000).

Climate characteristics of research area

The average rainfall for many years in Mus province was 745.02 mm, the relative humidity was 61.99%, and the temperature was 8.10 °C. In planting period which relative humidity in January was highest, the temperature was low and rainfall was high (*Table 1*).

Table 1. *Temperature, precipitation and relative humidity values of their search area*[*]

*Meteorological Service of Mus. **LYA: Long years' average (2009-2018)

The temperature was above the average temperature during the growing season for a long time. However, relative humidity and rainfall was lower than the average of long years. The experiment area was harvested without required irrigation.

Soil characteristics of research area

Soil analysis of the experiment area was made in the soil analysis laboratory of private Mus. According to results of soil analyses of the experiment area, it was neutral, calcareous, salt-free and organic matter was low and also, the amount of phosphor is poor and potassium is sufficient (*Table 2*).

Results and discussion

Content of ADF, NDF, DDM, DMI, RFV and DM

In the present study we found that there were significant differences in silage mixtures achieved Hungarian vetch, barley and wheat for ADF, NDF, DDM, DMI, RFV and DM ($P < 0.01$) (*Table 3*).

Table 3. *The mean values of silages for ADF, NDF, DDM, DMI, RFV and DM and groups*

ADF and NDF ratio

The rate of ADF of silages obtained from pure wheat and Hungarian vetch with wheat were higher than those of other mixture silages. Average ADF of these silages was 37.09%, though the ADF values ranged in 28.57-41.65%. According to the quality standards of legume, wheat and legume mixtures (Rohweder et al., 1978), ADF ratio of mixture silages obtained from wheat and Hungarian vetch (except 80% HV + 20% W) was in the 3 grade quality class (41-42%), whereas the silage obtained from barley and Hungarian vetch is in the 2 grade quality class (36-40%) for ADF. In the current study, while The ADF content of the pure barley silage is in the top-quality class, Hungarian vetch silage is in the 1st quality class. NDF ratios of mixture silages pure wheat silages with Hungarian vetch + wheat were higher than pure barley with Hungarian vetch + barley mixture silages. Average NDF of pure and mixture silages 39.17%, though the ADF values ranged in 29.69-59.05%. According to the quality standards of legume, wheat and legume mixtures (Rohweder et al., 1978), NDF of mixture silages obtained wheat with Hungarian vetch was in the 1st quality class (40-46%). Similarly, NDF of mixture silages achieved barley and Hungarian vetch was in the top-quality class (*Tables 3* and *4*).

There are many of studies on ADF and NDF rates of silage and findings of these studies Bergen et al. (1991) 34.50-35.60%; Aykan and Saruhan (2018) 35.33-40.50%;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27952806

Polat et al. (1998) 41.80-42.62% have changed at regular intervals. At the same time, rates of NDF were indicated by Bergen et al. (1991) 50.00-51.80%; Aykan and Saruhan (2018) 55.02 - 69.76% and Polat et al. (1998) 65.20-65.20%.

Our findings for ADF and NDF in this study were different in some of the literature mentioned above. It is suggested that these differences between the findings can be resulted from the differences of plant species, periods, rations of mixture and ecological conditions.

Table 4. *Quality standards for legume, wheat and legume mixtures (Rohweder et al., 1978)*

Standard of quality	CP	ADF	NDF	DDM %	DMI % of BW	RFV
	% of DM					
Prime	> 19	<< 31	<< 40	> 65	> 3.0	> 151

5	<< 8	> 45	> 65	<< 53	<< 1.8	<< 75

DDM (digestibility dry matter) ratio

The mean DDM of the pure and mixture silages in this study was 60%. DDM was the highest in pure barley silage with 66.63%, whereas it was the lowest in mixture silages of 40% HV + 60% W (56.44%) and 20% HV + 80% W (56.45%) in the same group. The digestible dry matter (DDM) of pure barley silage was in the top-quality class, pure Hungarian vetch was in the first quality class and DDM of other pure and mixture silages were in the second quality class (58-61%) based on the quality class described by Rohweder et al. (1978) (*Tables 3* and *4*).

DMI (dry matter intake) ratio

The mean DMI for all silages studied were 3.19% and the highest DMI were observed from mixture silages of 100% HV (4.05%) and 80% HV + 20% B (3.88%), indicating that it is in the top-quality class based on the quality class described by Rohweder et al. (1978). The lowest DMI was observed in the pure wheat silage and it was in the 3nd quality class, whereas mixture silages of Hungarian vetch and wheat at different mixing levels 60% HV + 40% W, 40% HV + 60% W, 20% HV + 80% W were in the second quality class based on the quality class described by Rohweder et al. (1978) (*Tables 3* and *4*).

RFV (relative feed value)

In the present study the mean RFV of pure and mixture silages was 149.57. The highest RFV was founded at 100% HV (201.62) and 100% B (188.66) of silage in the same group and its quality class was the highest, while silage of pure wheat for RFV was in the 3rd quality class according to quality criteria's Rohweder et al. (1978). Additionally, we observed that RFV of silage obtained from Hungarian vetch + barley mixture was higher than Hungarian vetch + wheat silage ones and it was better quality based on classification on quality (*Tables 3* and *4*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27952806

DM (dry matter) ratio

In the present study, the mean DM of silages was 26.25%. The highest DM was achieved from pure wheat silages (33%), whereas it was the lowest pure and the mixtures containing high Hungarian vetch with barley [80% HV + 20% B (22.22%); 60% HV + 40% B (21.78%)]. Besides we detected that DM contains of mixture silages increase with increasing wheat.

The results of this study were different in findings reported in a several studies (Saruhan et al., 2011; Basaran et al., 2018; Aykan and Saruhan, 2018). These differences among studies mentioned above for DM of silage can be resulted from diverse harvesting periods or plant material of silage.

Mineral matters and crude protein content

In this present study, there were significant differences in calcium (Ca), potassium (K), phosphor (P) and crude protein (CP) contents of silages obtained from different mixture ratios of Hungarian vetch with barley and wheat ($P < 0.01$) except for magnesium (Mg) (*Table 5*).

Table 5. *The means of Ca, P, Mg, K and CP of mixture silages*

Mixtures	Ca (%)	P (%)	Mg (%)	K (%)	CP (%)
100% H	1.68 ^{a}	0.57 ^{ab}	0.26	3.63 ^{b}	17.27 ^{a}
100% B	0.88 ^{e}	0.62 ^{a}	0.12	4.48 ^{a}	9.83 ^{e}
100% W	0.30 ^{f}	0.33 ^{e}	0.23	4.47 ^{a}	8.15 ^{f}
80% HV + 20% B	1.44 ^{b}	0.54 ^{bc}	0.21	3.25 ^{bc}	16.39 ^{ab}
60% HV + 40% B	1.40 ^{b}	0.50 ^{c}	0.22	2.98 ^{bd}	16.56 ^{ab}
40% HV + 60% B	1.13 ^{cd}	0.50 ^{c}	0.21	2.96 ^{bd}	15.82 ^{ac}
20% HV + 80% B	0.98 ^{de}	0.58 ^{ab}	0.19	3.05 ^{bd}	15.96 ^{ab}
80% HV + 20% W	1.23 ^{bc}	0.49 ^{c}	0.22	2.90 ^{ce}	14.35 ^{c}
60% HV + 40% W	1.14 ^{cd}	0.41 ^{d}	0.21	2.39 ^{df}	12.68 ^{d}
40% HV + 60% W	0.96 ^{de}	0.38 ^{de}	0.19	2.22 ^{ef}	10.35 ^{e}
20% HV + 80% W	0.94 ^{de}	0.35 ^{de}	0.23	1.93 ^{f}	15.41 ^{bc}
Average	1.10	0.48	0.21	3.12	13.89
CV (%)	12.34	8.51	16.72	12.88	6.54
LSD	0.48**	0.15**	NS	1.41**	3.20**

Values indicated by the same letters are not significantly different at the 1% level of significance, **$P < 0.01$ significant, NS: No significant, Ca: Calcium, P: Phosphor, Mg: Magnesium, K: Potassium, CP: Crude protein

Average Ca, P, K contents of silages was 1.10%, 0.48%, and 3.12%, respectively. The highest Ca was in the Hungarian vetch silage (1.68%), but it was lowest in wheat silage (0.30%). While silages of pure barley and Hungarian vetch and 20% HV + 80% B had the most P content, it was the lowest in pure wheat silage. The highest K content was found in pure barley and wheat silage in the same group. However, it was the lowest in 20% HV + 80% W mixture silage (*Table 5*). These elements are quite important in animal nutrition and animal rates should be contained at levels of 0.21% P, 0.65% K, 0.31% Ca and 0.1% Mg (Kidambi et al., 1989).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27952806

According to these findings, when the mineral content of silages is evaluated; the mean Ca (1.10%), P (0.48%), K (3.12%) contents are above the amounts required to be in the feed rates of cattle and therefore there is no feeding problem in terms of the mentioned nutrients. In order to determine the yield and the quality of the mixture silages of Grass pea and Oat and Barley, Basaran et al. (2018) conducted a study. In that study, the highest of K (2.89%), Ca (0.87%), P (0.30%) were founded in the mixture ratio of 80% HV + 20% B. We however, observed that our findings for these elements were higher than values reported by that study.

The CP values of silages analyzed were presented in *Table 5*. The average crude protein ranging from between 17.27% and 8.15% in silages studied was 0.89%. It was observed that the CP content of the pure Hungarian vetch and Hungarian vetch + barley silages was higher than the CP content of the Hungarian vetch + wheat mixture silages.

Although the CP of pure wheat and barley silage was low (8.15-9.83%, respectively), mixing of Hungarian vetch with wheat and barley improved the ratio of CP. The highest CP was obtained from pure Hungarian vetch (17.27%) or silages of different mixing rates such as 80% HV + 20% B (16.39%); 60% HV + 40% B (16.56%); 40% HV + 60% B (15.82%); 20% HV + 80% B (15.96%) (*Table 5*). We found that there are differences for silage CP between the results reported by various researchers such as Polat et al. (1998) (10.84-10.77%), Saruhan et al. (2011) (10.08-12.20%), Seydosoglu (2019) (12.10-18.75%), Aykan and Saruhan (2018) (13.00-18.29%), Demirel et al. (2010) (10.17-13.63%) and Polat et al. (1998) (10.84-10.77%). Generally, our findings for pure or mixture silage CP were in accordance with literature for CP. Differences observed can be resulted from harvest periods and different plant species.

pH and organic acid contents of silages

In the present study we observed that there were significant differences in the pH values and ratios of organic acids of the silages obtained from the mixture silages achieved Hungarian vetch and barley and wheat in different ratios ($P < 0.01$).

In this study, the pH values of the silages ranged from 3.76 to 4.08, with an average pH of 3.90. Indicating differences in rates of mixture with barley, pH values of mixture Hungarian vetch with wheat was higher than mixture Hungarian vetch with barley ones. The highest pH was obtained from Hungarian vetch and barley mixtures in the same group. These groups were 80% HV + 20% B (3.99%), 60% HV + 40% B (4.08%), 40% HV + 60% B (4.01%) and 20% HV + 80% B (3.99%).

Nonetheless, the pH of pure wheat silage was the lowest and also it was low in the other some groups such as 80% HV + 20% W (3.82%), 60% HV + 40% W (3.83%), 40% HV + 60% W (3.81%) and 20% HV + 80% W (3.81%). The authors reported that the most adequate of silage pH ranged from between 3.5 and 4.2. Our finding (3.76-4.08) for silage pH was in accordance with values of silage pH reported by these studies, showing that it was appropriate for nutrition quality (Kilic, 2006; Acikgoz et al., 2002; Aykan and Saruhan, 2018).

However, there were contrast with values of pH reported by Saruhan et al. (2011), Polat et al. (1998), Basaran et al. (2018), Demirel et al. (2010), Seydosoglu and Gelir (2019) and Bergen et al. (1991) and it was lower than in comparison with the results of these researches. The lactic acid (LA) values of the silages obtained mixed by at difference levels ranged from 1.50% to 1.94%, with an average pH of 1.69%. The highest LA was in the mixture group of 80% HV + 20% W (1.94%) and pure wheat

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27952806

(1.80%), whereas it was the lowest. In mixture silages of 60% HV + 40% B (1.50%) and 20% HV + 80% W (1.50%) in the same group.

The acetic acid (AA) values of the silages ranged from 0.31% to 0.71%, with an average pH of 0.49%. The highest AA of pure Hungarian vetch, pure wheat and mixture of 20% HV + 80% B were 0.71%, 0.65% and 0.66%, respectively. It was the lowest for mixture of 60% HV + 40% B (0.31%). The butyric acid (BA) values of the silages ranged from 0.27% to 0.76%, with an average pH of 0.47%. It was highest in the pure Hungarian vetch (0.73%) and mixture of 80% HV + 20% W (0.76%). The propionic acid (PA) values of the silages ranged from 0.02% to 0.08%, with an average pH of 0.06%. The highest of propionic acid (PA) was obtained from mixtures of 80% HV + 20% W and 60% HV + 40% W of silages (*Table 6*).

Table 6. *The means of pH, LA, AA, BA and PA of mixture silages*

Values indicated by the same letters are not significantly different at the 1% level of significance, $^{**}P < 0.01$ significant, LA: lactic acid, AA: acetic acid, BA: butyric acid, PA: propionic acid.

According to some authors the butyric acid is not adequate for quality of silage and in general it has 0.1-0.6% of butyric acid (Woolford, 1984). By contrast, some researchers showed that there is a significant relationship between LA, AA and BA ratios with high quality of silage. According to these authors, LA ratio in these forages was above 2%, whereas AA ratio must be between 0.3-0.7% percent in type of these silages (McDonald et al., 1991; Alcicek and Ozkan, 1996). In this present study, it is observed that the LA ratio is lower than when compared with studies mentioned above, but ration of AA was normal. However, the amount of butyric acid was found to be higher than normal values in pure Hungarian vetch silage (0.73%) and in mixtures of 80% of Hungarian vetch + wheat silages (0.76%). However other groups of silages were normal for butyric acid (*Table 6*).

The insufficiency of homo-fermentative lactic acid bacteria (LAB) of the plant material used for silage leads to a delay in the decrease in pH. Because of the insufficiency of LAB, an increase in the loss of nutrients and a decrease in the consumption of silages occur (Woolford, 1984). Therefore, in order to increase the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_27952806

lactic acid content in silages consisting of Hungarian vetch + wheat or Hungarian vetch + barley mixture, it is recommended to use various additives like *Lactobacillus plantarum*, which are homo fermantative. On the contrary, Kung et al. (2003) reported that the main ingredient used for legume silage in the USA is bacterial inoculants.

In current study, the findings with organic acids were lower than the results reported by Seydosoglu (2018) (2.01-2.16%), Polat et al. (1998) (2.25-2.38%) and Bergen et al. (1991) (5.96-6.12%). However, our findings with AA, BA and PA showed differences in results reported by some authors (Bergen et al., 1991; Polat et al., 1998; Homan, 2016; Seydosoglu, 2018; Basaran et al., 2018).

Conclusion

In this present study it was conducted to determine the quality and chemical composition of the silage obtained by mixing Hungarian vetch with barley and wheat in different proportions, which they have same vegetation periods. At the same time, it was conducted to determine the quality and chemical composition of the silage obtained by mixing Hungarian vetch with barley and wheat in different proportions, which they have same vegetation periods. As a result, we observed that CP, Ca, P, K and RFV of Hungarian vetch + wheat silages were higher than compared other groups of silages. Similarly, when the proportion of Hungarian vetch in mixing was increased, it also leads to an increase of Ca, P, K and RFV, DM and LA ratios of these silages. However, ADF and NDF ratios were lower in Hungarian vetch + barley silages.

Abstract. A two-year study was conducted to find how mineral and organic fertilisation and *Trichoderma* sp. strains influenced the total count of molds, including *Fusarium*, *Alternaria* and *Trichoderma* genera, the biological index of fertility (BIF) and the yield of spinach (*Spinacia oleracea* L.). Eleven variants were used in a field experiment conducted on lessivè soil: a control sample, mineral fertilisation, organic fertilisation with manure and eight variants with tomato or onion waste composts. Some of them were inoculated with *Trichoderma atroviride* (T1) and/or *T. harzianum* (T2 and T3) isolates. The addition of manure resulted in the greatest increase in the total count of moulds in the soil. The highest BIF value was noted in the soil enriched with tomato compost and inoculated with both T1 and T2 strains. The count of *Fusarium* sp. was reduced the most in the soil fertilised with onion compost with the addition of T1 and T3 isolates. The greatest decrease in the count of *Alternaria* sp. was observed in the soil fertilised with compost inoculated with the T1 strain. The onion compost inoculated with *Trichoderma* T1 and T3 resulted in the highest yield of spinach, which was comparable to the one obtained after mineral fertilisation.
Keywords: *pathogens, molds, soil, biofertiliser, plant*

Introduction

Currently one of the main focuses in waste management and energy generation from biomass is to reduce the amount of plant waste produced and to reuse it properly, in accordance with the Regulation of the Minister of the Environment on Recycling R10 (Journal of Laws of 2015, item 132).

According to the data of the Central Statistical Office (Statistics Poland, 2018), the amount of waste generated in Poland increases every year and most of it is disposed of in landfills. In 2017 23 kg of biodegradable waste was generated per capita, whereas in 2010 it was 4.7 kg. According to Minelgaitė and Genovaitė (2019), Germany, Italy and the United Kingdom are leaders in the production of this waste, whereas Poland ranks eighth.

Directive 2008/98/EC of the European Parliament and of the Council of 19 November 2008 is the main act specifying general requirements concerning waste management. This

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28072821

directive establishes a legal framework for handling waste within the community to protect the environment and human health by from the negative effects of waste generation and management. The current waste policy in the EU is a challenge for Poland because according to the Regulation of the Minister of the Environment of 25 May 2012 (Journal of Laws of 2012, item 676), by 2020 Poland will have to limit the amount of landfilled biodegradable waste to 35%.

Adequate handling of organic waste, by composting, for example enables disposal of troublesome material and acquisition of a high-quality fertiliser product, which can be reintroduced to the environment (Journal of Laws of 2015, item 132).

During the composting process the thermophilic phase, when the temperature reaches 60-70°C, guarantees effective hygienisation of the composted material, which is to be used as a carrier for moulds of the *Trichoderma* sp. genus entered into the soil, which are regarded as a biocontrol agent (López-Mondéjar et al., 2011; López-Bucio et al., 2015).

The Regulation of the Minister of Agriculture and Rural Development of 18 April 2013 (Journal of Laws of 2013, item 505) and Directive 2009/128/EC imposed the obligation to search for alternative methods of plant production so as to limit or completely eliminate chemical crop protection products and mineral fertilisers. Organic fertilisers inoculated with *Trichoderma* moulds, which are antagonistic to plant pathogens, seem to be an excellent solution (Smolińska et al., 2014; Wolna-Maruwka et al., 2017).

Mycoparasitism against plant pathogens is the most powerful biocontrol mechanism caused by filamentous fungi of the *Trichoderma* genus. According to John et al. (2010), Hermosa et al. (2011 and 2012), this phenomenon provides plants with biological protection against plant pathogens such as *Fusarium* sp., *Pythium* sp., *Alternaria* sp., *Verticillium* sp., *Colletotrichum* sp., *Rhizoctonia solani*, and *Botrytis cinerea*.

Trichoderma sp. also protect plants by producing substances which act as antibiotics. These are: gliotoxin, viridine, and peptide antibiotics (peptaibols): trichotoxins A and B, trichodecenins, trichocellins, trichorovins, alamentacins, trichorzianines A and B, trichorzins HA and MA, tricholongins BI and BII, longibrachins, trichocongins, atroviridins A-C, neoatroviridins A-D, sesquiterpenoids, isonitriles, polyketides, purine alkyls, as well as metabolites containing the isocyanide group (Wojtkowiak-Gębarowska, 2006).

According to Smolińska et al. (2014), Colla et al. (2015) and Druzhinina et al. (2011), the antagonism exhibited by *Trichoderma* moulds also involves competing with plant pathogens for the place of colonisation and nutrients, as well as modification of environmental conditions through acidification and production of siderophores.

Apart from that, research has proved that fungi of the *Trichoderma* genus are capable of inducing systemic immunity of plants. Secondary metabolites released by *Trichoderma* hyphae, e.g. enzymatic proteins, as well as components of the cell wall of plants and of these filamentous fungi are the substances inducing systemic immunity (Mathys et al., 2012).

The aim of the study was to assess the influence of composts inoculated with three *Trichoderma* strains on the sanitary condition of soil, measured with the count of potentially pathogenic moulds of the *Alternaria* and *Fusarium* genera. Apart from that, the soil activity and yield of spinach were measured.

The research assumption was that *Trichoderma* strains in combination with organic fertilisation had positive effect on the sanitary condition of soil and significantly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28072821

influenced the soil enzymatic activity, thus increasing the yield of crops. This treatment strictly follows the policy of integrated crop protection.

Currently the Polish market does not offer any organic fertilisers containing native Polish strains of *Trichoderma* sp. The development of an innovative fertiliser based on composted plant waste and isolates of *Trichoderma* fungi will promote the growth and development of plants. In consequence, it will result in development of the domestic and global biofertiliser management.

Material and methods

Experimental design

A two-year experiment (2013 and 2014) was located on a private farm in Lubosz, Commune of Kwilcz, Greater Poland Voivodeship, Poland.

The experiment was conducted on the following three *Trichoderma* isolates: *T. atroviride* (T1) and *T. harzianum* (T2 and T3), which were supplied by the Institute of Horticulture in Skierniewice, Poland. They were used for the inoculation of onion and tomato waste composts and then they were applied to the soil under spinach (*Spinacia oleracea* L.), Renegade F1.

The experimental composts were produced on a technical scale (in prisms with about 20 tonnes of input). Both the tomato waste compost and onion waste compost (mostly clusters, leaves, etc.) were mixed with wheat straw (about 10% added) and a small amount of pig manure (5%).

When the thermophilic phase finished (the prism temperature was about 25°C), the composts were inoculated with *Trichoderma* strains.

The output concentration of individual spores in the resulting suspension was measured by means of a haemocytometer under a light microscope (Zeiss). The following results were noted: strain T1 – $3.9 \cdot 10^8$, T2 – $2.3 \cdot 10^8$, T3 – $3.1 \cdot 10^8$ spores per 1 ml. The composts were inoculated with a suspension of conidial spores concentrated at 10^4 per g wet mass of compost. Therefore, after calculation each prism of the composted material was respectively inoculated with 512.01 ml of T1 strain spore suspension, 869.21 ml of T2 isolate, 645.16 ml of T3 strain, 690.60 ml of a T1+T2 mixture and 578.58 ml of a T1+T3 strain suspension. These conidial spore suspensions were mixed in 5 l of dechlorinated tap water and applied with a hand sprayer.

One month after the inoculation of the composts they were entered into the soil. The following amounts were applied: onion waste compost – 43 t ha^{-1} and tomato waste compost – 38 t ha^{-1}. Apart from the aforementioned composts, pig manure fertilisation (37 t ha^{-1}) and mineral fertilisation with nitrogen as urea (90 kg N ha^{-1}), with phosphorus as triple superphosphate (40 kg P ha^{-1}) and with potassium as potassium salt (182 kg Kha^{-1}) were also applied in the experiment. All organic fertilisers entered into the soil were equivalent to 170 kg N ha^{-1}.

The field research was conducted after harvest of winter burley, on typical haplic luvisols formed from light loamy sands, deposited in a shallow layer on light loam. The granulometric composition of the soil ranged from light clayey to strong sands deposited on light clays. Selected soil characteristics are shown in *Table 1*.

Experiment was designed as randomised complete block, with four replications and plot size 9.3 m^2 (6 x 1.55 m). Spinach, v. Renegade F1, were planted by means of a manual, precision seed drill Terradonis JP-1, with 25 seeds m^{-2}, at 40 cm row spacing. Planting was carried out of August 16, both years.

DOI: http://dx.doi.org/10.15666/aeer/1802_28072821

Table 1. *Chemical characteristics of the soil*

Pure components	Value (mg kg^{-1})
N	94.0
P	36.01
K	69.77
Mg	60.02
pH_{KCl}	5.8

Eleven fertiliser combinations were used in the experiment: 1 – control sample, no fertiliser, 2 – mineral fertiliser, 3 – manure, 4 – onion waste compost, 5 – onion waste compost inoculated with strain T1, 6 – onion waste compost inoculated with strain T3, 7 – onion waste compost inoculated with strains T1 and T3, 8 – tomato waste compost, 9 – tomato waste compost inoculated with strain T1, 10 – tomato waste compost inoculated with strain T2, 11 – tomato waste compost inoculated with strains T1 and T2.

Both in 2013 and 2014 soil samples for microbiological and biochemical analyses were collected at three periods (ten replications), according to the Polish standard PN - ISO 10381 – 2: 2007. Depending on the research year, the sample collection dates coincided with the pre-sowing phase (15, 16 July) – term I, crop emergence phase (8, 9 August) – term II and harvesting phase (3, 6 October) – term III.

At each term of analyses 20 representative soil samples weighing about 0.5 kg were collected with an Egner-Riehm soil stick from each experimental site at a depth of 0-20 cm. A collective sample was prepared in accordance with the recommendations of the Polish Standard: PN-ISO 10381-2: 2007. On collection the soil and plant samples were transported to the laboratory of the Department of General and Environmental Microbiology and the Department of Agronomy, Poznań University of Life Sciences for microbiological and enzymatic analyses and to estimate the spinach yield value.

Soil microorganisms

The total count of moulds as well as the counts of *Trichoderma* sp., *Alternaria* sp. and *Fusarium* sp. were measured in the experiments (in five replicates). The microorganisms were cultured with the plate method on solid substrates. Appropriate soil solutions were used and expressed as cfu g^{-1} DM of soil. The count of molds in the medium was measured according to the procedure developed by Martin (1950), with 3.5ml·l^{-1} rose bengal and 0.1g·l^{-1} aureomycin added. The plates were incubated for 6 days at a temperature of 25°C. The count of *Trichoderma* sp. was measured with the plate method, on a modified Martin's medium with 0.05g·l^{-1} chloramphenicol, 0.05g·l^{-1} streptomycin, 0.29g·l^{-1} metalaxyl and 0.01g·l^{-1} PCNB (pentachloronitrobenzene) added. The plates were exposed to visible light and incubated for 7 days at a temperature of 24°C. In order to confirm that *Trichoderma* sp. belonged taxonomically to the *Trichoderma harzianum* or *Trichoderma atroviride* species the fungal colonies were inoculated to a PDA substrate (Sigma Aldrich). They were initially identified with a microscope. Next, the identification was confirmed by means of fluorescent in situ hybridisation (FISH) (Amann et al., 1990) with 4% PFA (paraformaldehyde), 0.5% Triton solution, alcohol series (70%, 80%, 96%), 70% formamide solution and two probes, whose ends were marked with Cy3 marker (ACT CCC AAA CCC AAT GTG AA and ATA CCA AAC TGT TGC CTCGG) (Siddiquee et al., 2010).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28072821

In the experimental variants where the aforementioned *Trichoderma* sp. isolates were not applied, but native *Trichoderma* sp. strains were identified in the soil (e.g. in the control sample), only the counts of *Trichoderma harzianum* and *Trichoderma atroviride* were measured.

The count of *Fusarium* sp. was measured with the plate method, on a Komada medium (Komada, 1975) with 0.5g·l^{-1} ox bile, 0.05g·l^{-1} chloramphenicol, 0.3g·l^{-1} streptomycin, 1.0 g·l^{-1} borax and 1.0 g·l^{-1} PCNB (pentachloronitrobenzene) added. The plates were incubated for 14 days at a temperature of 24°C. The count of *Alternaria* sp. was measured on a medium developed by Hong and Pryor (2004). It was composed of 20% lactic acid, 0.005 g·l^{-1} botram (active ingredient: dichloran), 0.2 g·l^{-1} bayleton (active ingredient: triadimefon) and 0.3 g·l^{-1} streptomycin. The plates were incubated at a temperature of 24°C for 7 days. The fungal colonies were inoculated to a PDA substrate (Sigma Aldrich). Next, they were identified taxonomically on the basis of mycological keys (Gerlach and Nirenberg, 1982; Chełkowski, 1989; Chełkowski and Visconti, 1992; Domsch et al., 1993).

Soil enzymes

Spectrophotometry was used for biochemical analyses. The dehydrogenase activity (DHA) was measured according to the procedure developed by Thalmann (1968), with some minor modifications. The soil (1 g) with 2, 3, 5-triphenyltetrazolium chloride (TTC) was incubated for 24 h at 30°C, pH 7.4. Triphenylformazan (TPF) was produced, extracted with 96% ethanol and measured spectrophotometrically at 485 nm. The dehydrogenase activity was expressed as μmol TPF g^{-1} DM of soil 24 h^{-1}.

The catalyse activity (CAT) in the soil was measured by means of titration (Johnson and Temple, 1964). The soil with 0.3% H_2O_2 solution was incubated for 20 minutes. Next, 1.5 M H_2SO_4 was added. The resulting solution was titrated with 0.02 M $KMnO_4$. The catalyse activity was expressed as μmol H_2O_2 g^{-1} D.M. of soil min^{-1}.

The dehydrogenases and catalyse activity were measured to determine the soil BIF (Biological Index of Fertility) (*Eq.1*) (Stefanic et al., 1984):

$$BIF = (1.5\,DHA + 100\,k\,CAT) / 2 \qquad \text{(Eq.1)}$$

where k – the proportionality coefficient = 0.01.

Crops

The whole plant, aboveground biomass of spinach was harvested manually from two central rows in the plot for the yield measurement.

Statistical analysis

Statistica 12.0 software (StatSoft Inc., 2012) was used for statistical analyses. Two-way analysis of variance was used to determine the significance of variation in the count of groups of microorganisms and the soil enzymatic activity, depending on the soil combination and term of analysis. Homogeneous subsets of means were identified by means of Tukey´s test at a significance level of $p < 0.05$.

The second step of the diagnostic procedure involved stepwise regression to determine the optimal set of variables for a given characteristic of the microorganisms. The best

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28072821

regression model was chosen on the basis of the highest F-value for the model and the significance of all the independent variables.

The relation between the count of microorganisms, soil enzymatic activity and the yield was illustrated by means of Principal Component Analysis (PCA).

Results and discussion

The analysis of the soil samples at the first term, i.e. before the application of the *Trichoderma* sp. strains, showed that these microorganisms were part of the natural, autochthonous soil microbiome (*Table 2*).

Table 2. *The count of Trichoderma sp. in the soil with the fertilisers at the three terms of analysis*

Explanation: The means followed by the same letters do not differ significantly at *p=0.05*; Combination: Control – no fertiliser, MIN – mineral fertiliser, MAN – manure, O – onion waste compost, O1 – onion waste compost inoculated with strain T1, O3 – onion waste compost inoculated with strain T3, O1+3 – onion waste compost inoculated with strains T1 and T3, T – tomato waste compost, T1 – tomato waste compost inoculated with strain T1, T2 – tomato waste compost inoculated with strain T2, T1+2 – tomato waste compost inoculated with strains T1 and T2; Terms: Ist – pre-sowing phase, IInd – crop emergence phase, IIIrd – harvesting phase

According to Smolińska et al. (2014), these microorganisms are commonly found in all soil types around the world. They usually occur on the surface of roots. Only few species can penetrate deeper. Apart from that, *Trichoderma* sp. can quickly colonise the substrate by competing with other microorganisms for the place of colonisation and nutrients. This situation was observed at the second term of analyses. It is most likely that the intensive growth of *Trichoderma* sp. in that period was caused by a change in the qualitative and quantitative composition of spinach root secretions, which acted as attractants (Vallance et al., 2011).

On harvesting the plants (the third term) the count of *Trichoderma* sp. decreased sharply or was totally reduced, especially in the control variant (without fertilisation). *Trichoderma* sp. were found only in the variant where the mineral fertiliser had been applied, in the one with onion compost inoculated with two strains and in three variants enriched with tomato compost. The highest, but statistically insignificant count of these microorganisms was noted in the soil with the onion compost inoculated with both the T1

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28072821

and T3 strains (O1+3). The rapid, but in most cases statistically insignificant decrease or total reduction in the count of *Trichoderma* sp. in the experimental variants may have been caused by more intense proliferation of the total count of molds (*Fig. 1*). This may have resulted in the occurrence of species inhibiting the growth and development of *Trichoderma* sp.

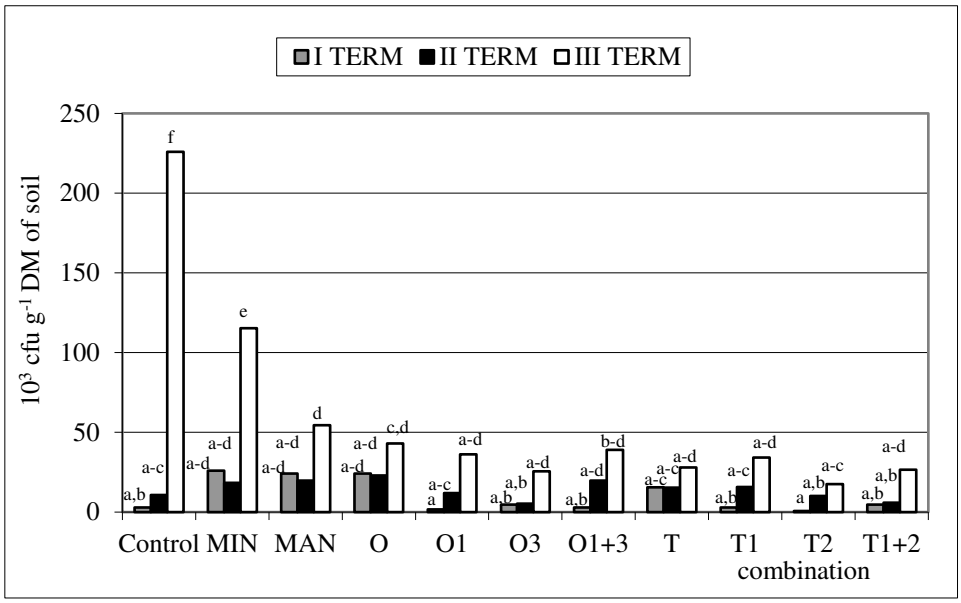

Figure 1. *Changes in the total count of molds in the soil. Explanation: The means followed by the same letters do not differ significantly at p=0.05; Combination: Control – no fertiliser, MIN – mineral fertiliser, MAN – manure, O – onion waste compost, O1 – onion waste compost inoculated with strain T1, O3 – onion waste compost inoculated with strain T3, O1+3 – onion waste compost inoculated with strains T1 and T3, T – tomato waste compost, T1 – tomato waste compost inoculated with strain T1, T2 – tomato waste compost inoculated with strain T2, T1+2 – tomato waste compost inoculated with strains T1 and T2; Terms: I^{st} – pre-sowing phase, II^{nd} – crop emergence phase, III^{rd} – harvesting phase*

According to Piegza et al. (2009), the fact that fungi of the *Trichoderma* genus exhibit poorer adaptation properties in vitro may be caused by their poorer ability to compete for nutrients and place of colonisation as well as their less abundant sporulation than some other species of fungi. Wawrzyniak and Waśkiewicz (2014) proved that some *Penicillium* species were capable of producing antibiotics and mycotoxins, e.g. ochratoxin A and citrinin, which inhibit the growth and development of other microorganisms, including *Trichoderma*.

The analysis of changes in the total count of molds during the experiment showed that the most intense colonisation of the soil with these microorganisms occurred particularly at the third term and at the second term of analyses and that it depended on the experimental variant (*Fig. 1*). There were statistically significant differences ($p = 0.05$) between the experimental variants in the count of moulds mainly at the plant harvesting phase. In comparison with the previous two terms the count of microorganisms increased significantly in the control and MIN treatments.

During the experiment the highest average count of these microorganisms was found in the control variant, while the lowest count was observed in the soil sample with the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28072821

tomato compost enriched with the T2 strain (T2 treatment). Wolna-Maruwka et al. (2016) conducted research on the influence of analogous experimental variants on the microbiological parameters of soil under a radish plantation. During the experiment the highest count of molds was found in the soil fertilised with manure, whereas the lowest count was observed in the variant where a mineral fertiliser had been applied. These observations clearly indicate that the count of these microorganisms in soil depends on various factors, i.e. the type of fertiliser, species of a plant and its phase of development (Baetz and Martinoia, 2014; Guo, 2019).

The sanitary analysis of the soil showed that, like in the case of *Trichoderma* sp., in most of the experimental variants the highest statistically significant counts of fungi of the *Alternaria* and *Fusarium* genera were noted at the phase of the plants' emergence (the second term) (*Figs. 2 and 3*), especially in the variants where the onion waste compost had been added. During the period under analysis the lowest, statistically insignificant increase in the count of these microorganisms in relation to the control variant was noted in the experimental variants enriched with the tomato compost.

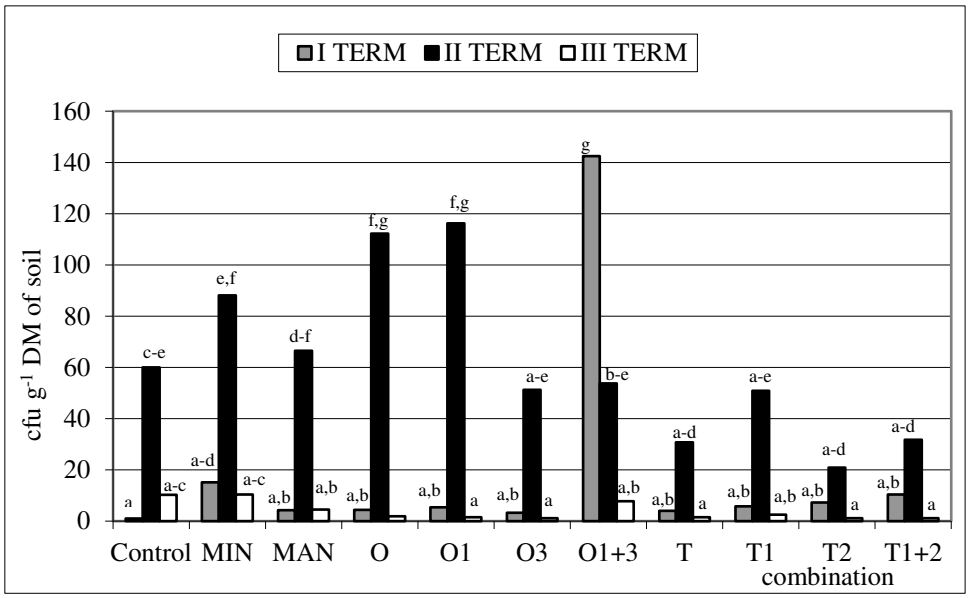

Figure 2. *Changes in the count of Fusarium sp. in the soil. Explanation: The means followed by the same letters do not differ significantly at p=0.05; Combination: Control – no fertiliser, MIN – mineral fertiliser, MAN – manure, O – onion waste compost, O1 – onion waste compost inoculated with strain T1, O3 – onion waste compost inoculated with strain T3, O1+3 – onion waste compost inoculated with strains T1 and T3, T – tomato waste compost, T1 – tomato waste compost inoculated with strain T1, T2 – tomato waste compost inoculated with strain T2, T1+2 – tomato waste compost inoculated with strains T1 and T2; Terms: Ist – pre-sowing phase, IInd – crop emergence phase, IIIrd – harvesting phase*

According to Utama et al. (2002), during the decomposition of plant residue contained in composts many different substances with strong biological properties (such as phenols, aldehydes, alcohols, essential oils, terpenes and acids) may be released and they may inhibit the development of soil microorganisms. As results from the study by Steinka and Kukułowicz (2008), caffeic acid, which can be found in tomato tissues, has strong antimicrobial properties.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28072821

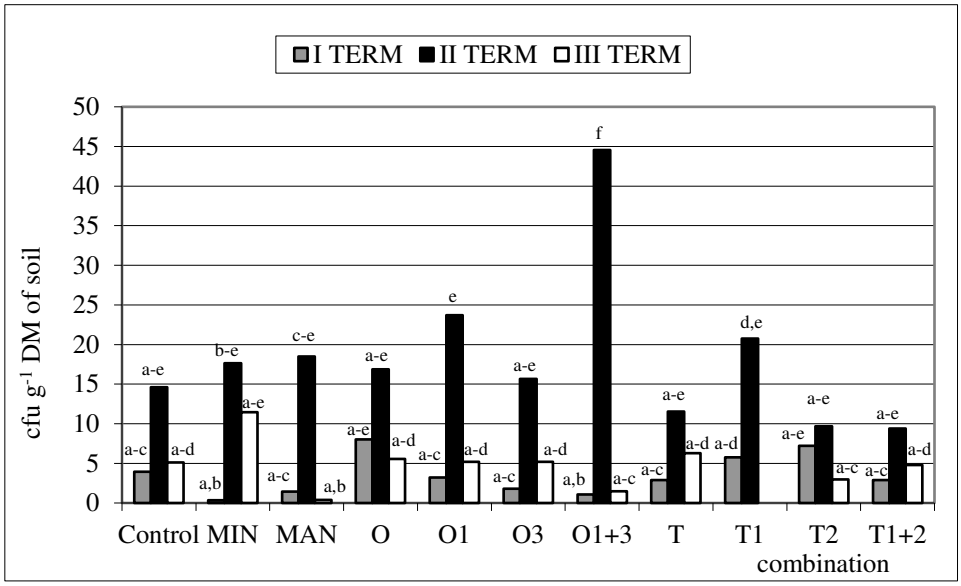

Figure 3. *Changes in the count of Alternaria sp. in the soil. Explanation: The means followed by the same letters do not differ significantly at p=0.05; Combination: Control – no fertiliser, MIN – mineral fertiliser, MAN – manure, O – onion waste compost, O1 – onion waste compost inoculated with strain T1, O3 – onion waste compost inoculated with strain T3, O1+3 – onion waste compost inoculated with strains T1 and T3, T – tomato waste compost, T1 – tomato waste compost inoculated with strain T1, T2 – tomato waste compost inoculated with strain T2, T1+2 – tomato waste compost inoculated with strains T1 and T2; Terms: Ist – pre-sowing phase, IInd – crop emergence phase, IIIrd – harvesting phase*

Poorer proliferation of *Alternaria* sp. and *Fusarium* sp. in the variants with the tomato waste compost was additionally intensified by the effect of the *Trichoderma* sp. strains (especially applied separately in the case of *Alternaria*). The phenomenon was illustrated by the regression curves (*Figs. 4 and 5*).

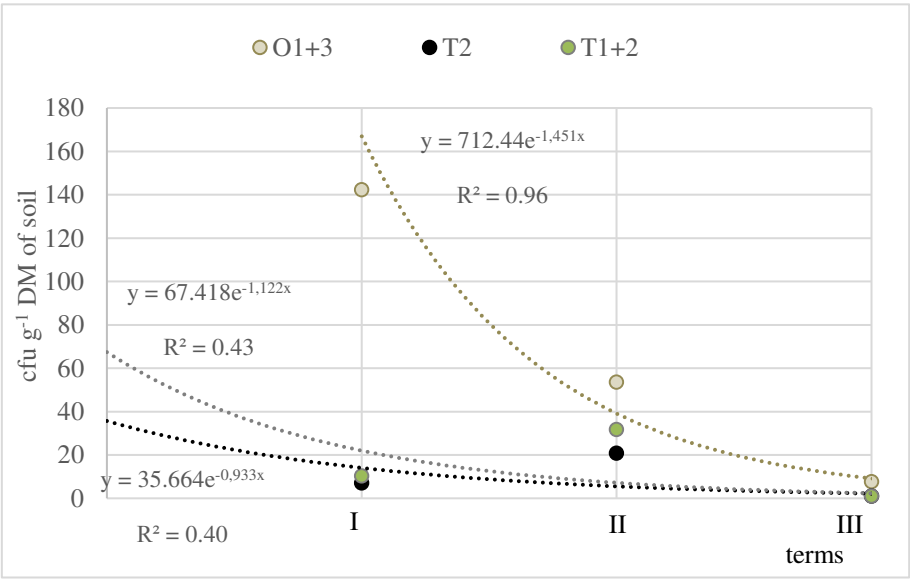

Figure 4. *The dynamics of changes in the count of Fusarium sp. during the experiment*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28072821

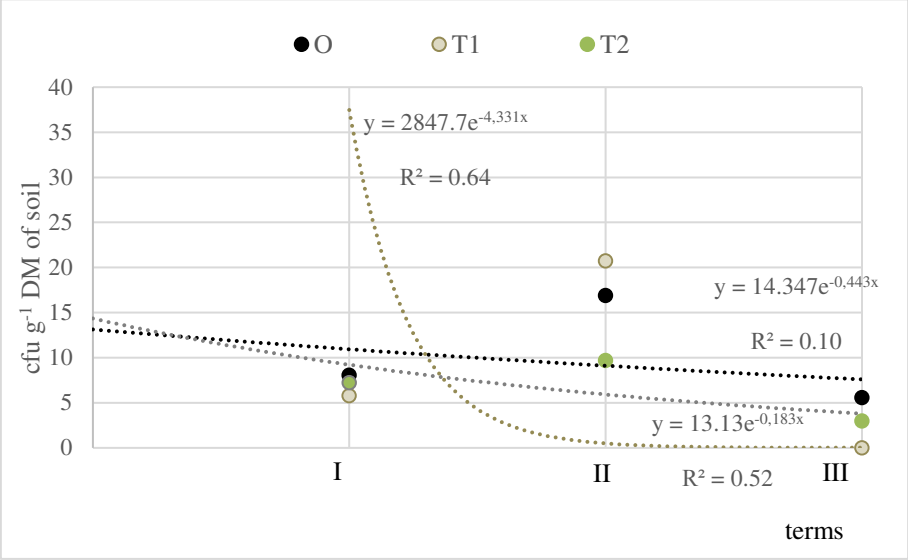

Figure 5. *The dynamics of changes in the count of Alternaria sp. during the experiment*

The comparison of the sanitary condition of the soil variants at the first term of analyses with the harvest phase (the third term) showed that the greatest statistically significant limitation of the development of *Fusarium* sp. took place in the variant enriched with the onion compost, additionally inoculated with two *Trichoderma* sp. strains – T1 and T3, and in the soil fertilised with the tomato compost, also with the addition of two isolates – T1 and T2 (statistically insignificant limitation at *p=0.05*). There was a statistically significant decrease in the count of *Alternaria* sp. in the soil where the tomato compost and T1 strain had been added and in the variant with the tomato compost and T2 strain (statistically insignificant limitation at *p=0.05*).

The analysis of changes in the activity of soil enzymes (BIF) during the study showed that the highest enzymatic activity occurred at the phase of spinach emergence (*Fig. 6*).

In most of the experimental variants (except the control and MIN treatments) these were statistically significant differences in comparison with the other two terms of analyses.

As results from the research conducted by Sasse et al. (2018) and Vallence et al. (2011), the composition of plant root secretions depends not only on the type of plant but also on the phase of its development. This finding explains the differences in the activity of soil enzymes. According to these authors, root secretions, which are rich in sugars, amino acids and vitamins, modify both the count of soil microorganisms and their activity. This fact was confirmed by the principal component analysis (*Fig. 7*), which showed a positive dependency between the enzyme activity and the counts of *Trichoderma* sp., *Fusarium* sp. and *Alternaria* sp.

In our experiment, at the second term of analyses the BIF reached the highest statistically significant values (in most cases they were statistically significant at *p=0.05*) in the soil samples enriched with manure (MAN) or various compost variants, especially in the ones based on tomato waste (T and T1+2). The BIF values were greater than at the other terms of analyses. This observation was in agreement with the findings of the study by Wolna-Maruwka et al. (2017). The soil sample with the mineral fertiliser (MIN) exhibited the lowest statistically insignificant enzymatic activity. According to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28072821

Acosta-Martinez and Tabatabai (2000), this phenomenon can be explained by the fact that although mineral fertilisation positively affects the physicochemical properties of soil, it may reduce its enzymatic activity due to the presence of easily absorbable forms of mineral compounds.

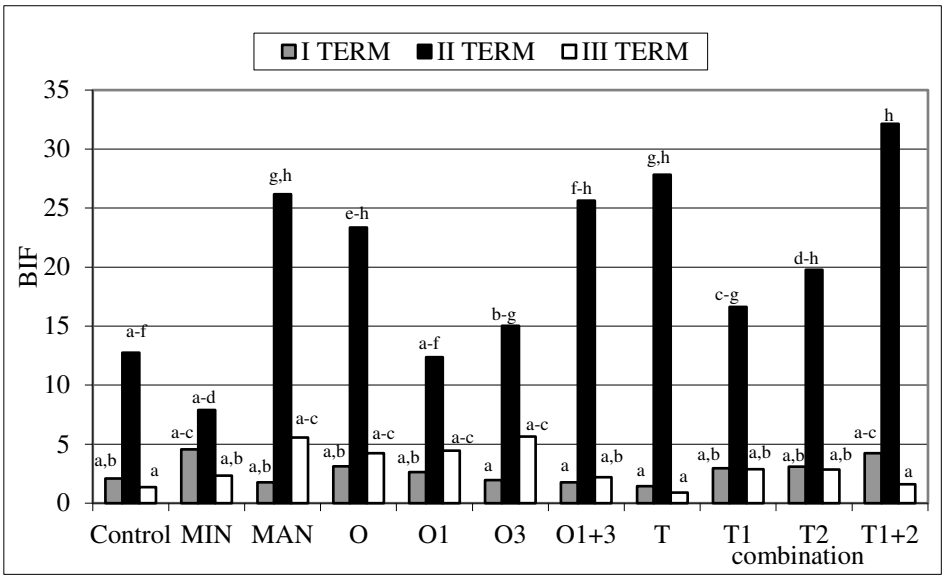

Figure 6. *Changes in the Biological Index of Fertility (BIF) in the soil. Explanation: The means followed by the same letters do not differ significantly at p=0.05; Combination: Control – no fertiliser, MIN – mineral fertiliser, MAN – manure, O – onion waste compost, O1 – onion waste compost inoculated with strain T1, O3 – onion waste compost inoculated with strain T3, O1+3 – onion waste compost inoculated with strains T1 and T3, T – tomato waste compost, T1 – tomato waste compost inoculated with strain T1, T2 – tomato waste compost inoculated with strain T2, T1+2 – tomato waste compost inoculated with strains T1 and T2; Terms: Ist – pre-sowing phase, IInd – crop emergence phase, IIIrd – harvesting phase*

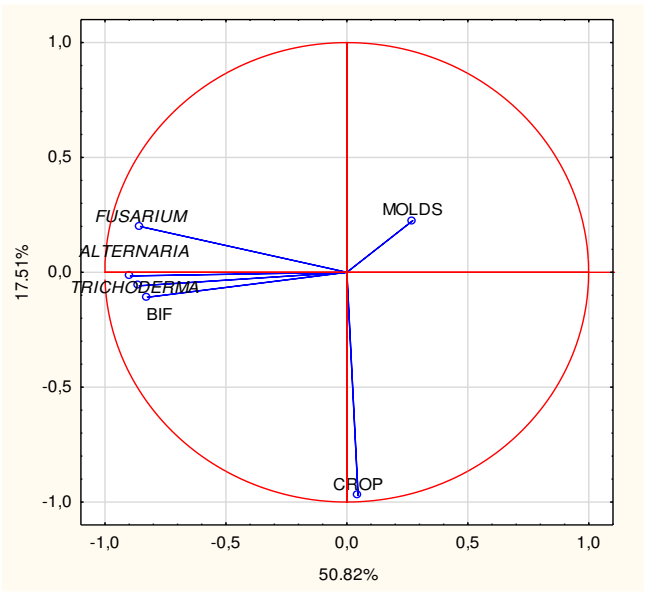

Figure 7. *Dependences between the number of groups of microorganisms and the enzymatic activity in the experimental soil combinations at the consecutive terms of analyses (PCA)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28072821

At the harvest phase (the third term) the BIF dropped rapidly in all the experimental variants, especially in the ones enriched with the tomato compost. This decrease in the soil enzymatic activity was statistically significant at *p=0.05.*

The mineral fertilisation (MIN) resulted in the highest yield (8.89 $t \cdot ha^{-1}$) of the fresh mass of spinach (*Fig. 8*). However, the total yield of the fresh mass of spinach in the unfertilised control (7.09 $t \cdot ha^{-1}$), variant with manure (8.50 $t \cdot ha^{-1}$), the ones with the tomato waste compost, (T1, T2, T1+2 treatments), and the combination O1+3 did not differ significantly from the yield in the MIN variant application. The other types of onion waste composts (O, O1, O3) resulted in a statistically significant decrease in the yield in comparison with the MIN, O1+3, T1, T1+3 treatments, but did not differ from MAN, T, T2 and control variant.

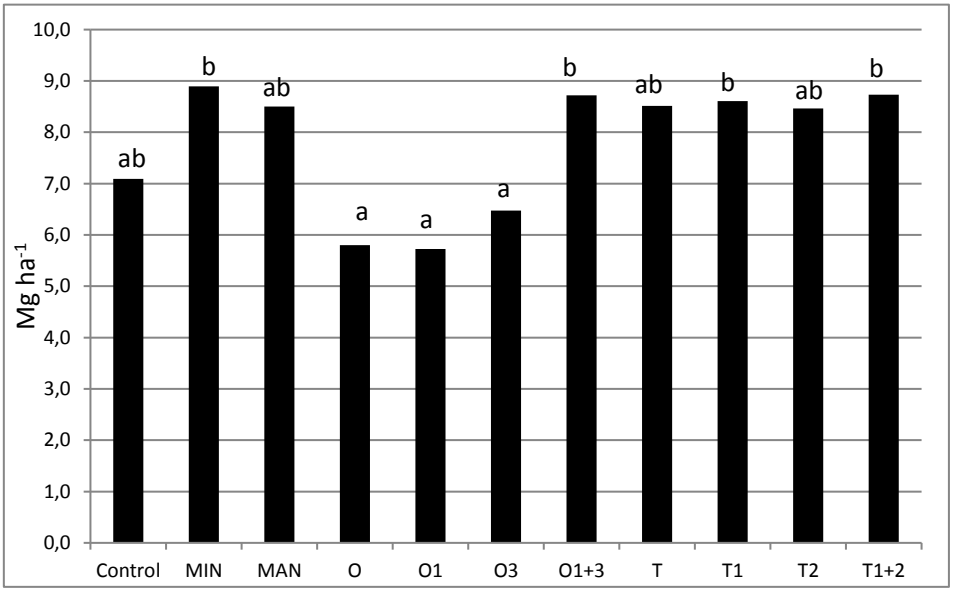

Figure 8. *The average yield of spinach leaves as affected by fertilisation between 2013 and 2014 (Mg ha^{-1}). Explanation: The means followed by the same letters do not differ significantly at p=0.05; Combination: Control – no fertiliser, MIN – mineral fertiliser, MAN – manure, O – onion waste compost, O1 – onion waste compost inoculated with strain T1, O3 – onion waste compost inoculated with strain T3, O1+3 – onion waste compost inoculated with strains T1 and T3, T – tomato waste compost, T1 – tomato waste compost inoculated with strain T1, T2 – tomato waste compost inoculated with strain T2, T1+2 – tomato waste compost inoculated with strains T1 and T2*

Organic fertilisers are a valuable source of nutrients because they contain all macro- and micronutrients that are necessary for plants and thus they minimise the risk of deficiency of any of them. Nitrogen is the component that usually determines the yield level. Its bioavailability in organic fertilisers is usually lower than in mineral fertilisers (Chambers et al., 2000).

The direct yield effect of solid organic fertilisers, including composts, is usually smaller than that of mineral fertilisers due to the wide C/N ratio and the slow release of nitrogen in mineral forms. In our experiment the same dose of nitrogen was used in all the composts and manure, but there were extreme differences in the effects. The yield in the variants with manure and tomato waste compost was equal to the yield after mineral fertilisation. However, in the sample fertilised with the onion waste compost the yield

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28072821

decreased even below the level in the control variant. The situation improved significantly when a mixture of *Trichoderma* strains was applied into this compost. This fact lets us suppose that the composts matured at different rates, depending on their composition. The tomato waste became composted faster and gave a more mature compost, from which nutrients were released. The onion waste compost was still immature and the nutrients were not accessible to plants. Only when the two *Trichoderma* strains were added, maturation was accelerated and the availability of nutrients increased.

Apart from the direct yield effect, organic fertilisers significantly affect the content of humus. Humus deficiency is common in agricultural soils. It results in defective physical properties of soil, which can be improved only by applying large doses of organic matter (Piechota, 2005).

Conclusions

1. The phase of plants' development and the type of fertilisation significantly modified the microbiological and enzymatic condition of soil.
2. The application of manure resulted in the most intense proliferation of molds.
3. The most intense proliferation of *Trichoderma* sp. was observed in the soil enriched with the onion waste compost inoculated with the T1 and T3 strains.
4. The simultaneous application of the *Trichoderma* T1 and T3 strains into the onion waste compost provided the best protection of spinach against fungal pathogens of the *Fusarium* genus. The T1 isolate applied together with the tomato compost resulted in the most effective limitation of the development of *Alternaria* sp.
5. The onion compost inoculated simultaneously with the T1 and T3 strains gave the highest yield of spinach, which was comparable to the one obtained after mineral fertilisation.
6. The study proved that vegetable waste could be used as a carrier when applying *Trichoderma* sp. isolates into soil. It may increase the yield of crops and limit the development of some pathogens, but it is important to select the right strain of *Trichoderma* sp.
7. The research is strictly related with integrated crop and environment protection and provides huge prospects for organic waste management. Organic matter can be recovered as a valuable organic fertiliser and used as a carrier for selected *Trichoderma* sp. strains that exhibit antagonism to pathogens and promote the growth and development of plants.

(Received 15th Oct 2019; accepted 8th Jan 2020)

Abstract. Antibiotics modulate gut microbiomes and enhance broiler chicken productivity. Nevertheless, their use in chicken nutrition has been linked to the spread of resistant strains of bacteria. Studies have shown that probiotic-yeast improves the productivity of broiler chickens. However, agreement has not been reached among investigators as to whether yeast improves the production indices of broiler chickens. The objective of this meta-analysis therefore was to determine the effect of yeast supplementation on feed consumption (FC), feed conversion ratio (FCR) and body weight gain (BWG) in broiler chicken using meta-analysis. The study focused on published primary studies comparing broiler chickens fed diet supplemented with yeast versus without yeast. Sixteen published primary studies were included in the meta-analysis. Results of pooled effects estimate revealed that yeast supplementation improved FCR ($p < 0.001$), BWG ($p < 0.001$) and reduced FC ($p < 0.001$) in broiler chickens. The results of sub-analysis indicated that broiler chickens that received yeast at < 10 g/kg diet had better performance than those that received yeast at 10 g/kg feed and > 10 g/kg feed. The chosen moderators were predictors of study effect observed in the meta-analysis. It is concluded that yeast can be used as a performance enhancer in broiler chickens instead of antibiotics.

Introduction

Broiler chicken farming plays a vital part in supporting the livelihoods of most households in many parts of the world, because of its role as a source of animal protein. Incidentally, several households in developing nations, still regard poultry products as luxury (Adene and Oguntade, 2006). This has been attributed to the high cost of poultry products driven mainly by the elevated feed price, which led poultry nutritionist to search for feed additives with the potential to increase feed digestion and nutrient uptakes (Gadde et al., 2017). Antibiotics, one of such feed additives has been reported to modulate gut microbiomes, enhance feed efficiency, boost growth rate as well as deter the emergence of diseases in chickens (Costa et al., 2017). Regardless of the established positive actions of in feed antibiotics in boosting growth performance in chickens, their use has been tied to the proliferation of resilient strains of bacteria and meat with remnants of antibiotics (Kabir et al., 2004; Chen et al., 2017; Gadde et al., 2017) which is a threat to public health (Kabir et al., 2004; Piątkowska et al., 2012). Although, views are mixed on whether the use of antibiotics in poultry feed can transfer resistance genes from animals to humans (Gadde et al., 2017), consumers of poultry meat were increasingly concerned about the risk of continued use of antibiotics in animal feeds (Kabir et al., 2004; Piątkowska et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28232843

2012). This ugly development called for an investigation into the use of probiotics as an alternative to antibiotics in broiler nutrition (Ahmed et al., 2015; Gao et al., 2017; Ogbuewu et al., 2019).

Probiotics are living organisms that elicit positive health effects in animal and humans when included in the diet at the right proportions (FAO, 2016). The beneficial health property of probiotics can be ascribed to either its ability to modulate gut microbiomes or their direct nutritional effect (Saulnier, 2007; Shareef and Al-Dabbagh, 2009). Yeast (*Saccharomyces cerevisiae*), one of the commonly used probiotics in both human and animal food is a single-celled organism that measures about 3 to 4 microns in size. Yeast is rich in protein and amino acids (Gomes et al., 2014; Ogbuewu et al., 2019) as well as vitamin B complex and minerals (USDA, 2018). Chand et al. (2014) reported that yeast contains 93.00% dry matter, 1.00% ether extract, 44.40% crude protein, 2.70% crude fibre, 0.12% calcium and 1.40% phosphorus. Indisputably, the results of the production parameters of broiler chickens fed yeast supplemented diets in literature as reported by several authors were disaggregated and conflicting, hence calling for evidence synthesis. Evidently, there are several studies on the actions of yeast on broiler performance (Paryard and Mahmoudi, 2008; Ezema, 2013; Ahmed et al., 2015; Chen et al., 2017), and many have undoubtably shown that yeast enhance broiler chicken productivity (Ezema and Ugwu, 2014; Ogbuewu et al., 2019). Earlier reviews conducted to ascertain the beneficial effect of yeast on broiler chicken performance, however, were narrative, which is bias-friendly due to non-repeatability of the results and lacked the ability to manage large datasets. For example, Ezema and Ugwu (2014) did a narrative review of published studies of the effect of probiotic-yeast on broiler productivity and discovered that yeast improve growth rate and nutrient digestibility in chickens. Incongruity, a recent narrative review by Ogbuewu et al. (2019) found disparity on production data of broiler chickens fed yeast supplemented diets. The current study aims to use meta-analytical technique to identify and quantify several variables that affect the outcomes of the effect of probiotic yeast on the growth performance indices of broiler chickens.

Materials and methods

Selection guidelines and ethical approval

The main criteria for selecting the primary studies included in this meta-analysis were: randomized and controlled tests (RCTs) in diseased-free broiler chickens fed yeast supplemented diets. Studies were included if peer-reviewed and published in English. Study reported at least one of these growth performance indices (FC, FCR and BWG) and a dispersion metric such standard error (SE), standard deviation (SD) or 95% confidence interval (CI) for each effect size. This study was conducted at the University of South Africa during the months of June to September 2019. Literature search and data analysis were conducted in line with the guidelines of the University of South Africa Ethics Committee.

Data sources, extraction and data integrity

The investigators independently searched for articles in PubMed, Scopus and Google scholar databases from 1999 to 2017. Studies were panel-selected to guarantee the reliability of outcome of the meta-analysis, which relies on the validity of papers that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28232843

make up the database. Yeast* and broiler chickens* were included in the search conditions. Articles were evaluated, and those that met the selection guidelines were selected. Information on the surname of the first author, the year the study was published, broiler breed, yeast supplementation level, duration of yeast supplementation, outcomes of interest (FC, FCR, BWG) and measures of variance (SE, SD or p-value) from the papers included in the meta-analysis are presented in the supplementary file. Most of the articles assessed did not report the yeast type used and the failure of the authors to obtain extra information from the corresponding author led to the removal of yeast type from the a priori selection criteria that an article must meet in order to be included in the meta-analysis. Furthermore, where the SD was not supplied, but can be estimated from SE, where it is reported using the method (Higgins and Deeks (2011).

Statistical analysis

Data analysis was performed in Open Meta-analyst for Ecology and Evolution (OpenMEE) software and forest plots were produced (Wallace et al., 2016). Continuous variable results (FC, BWG and FCR) were evaluated as the difference between the groups in yeast treatment and control with 95% CI. Q-statistic (DerSimonian and Laird, 1986) and I^2 – statistic; (Higgins et al., 2003) were used to calculate heterogeneity. Pooled effects estimate of the responses of broiler chickens to yeast supplementation were calculated using the DerSimonian and Laird (1986) random-effects model (REM). The REM selection is based on the premise that information used in the current study were not the same, therefore, the variance must be split into variance within and variance between studies plus sampling error (Borenstein et al., 2009).

For robustness of our results, we used sensitivity analysis which according to Lean et al. (2009) is used to assess the impacts of studies judged to be deviant or to have an undue influence on the analysis. This was accomplished by leaving one study each time the analysis was conducted. The influence graph shows the global impact without each study. The magnitude of the effect of yeast supplementation on broiler chicken productivity may be affected by several explanatory variables (moderators). The moderators considered in this study matched the factors we assumed to predict the association between yeast supplementation and broiler performance. In the subgroup analysis, the data were stratified using the following modifiers (study continent, study country, supplementation level, duration of supplementation and broiler breed used) thought to influence the physiological traits of broiler chickens fed probiotic yeast. Subgroup analysis was not performed when there are comparatively few studies (< 3 comparisons) in an individual stratum. The same variables used in the subgroup analysis were included as the modifier variables in the meta-regression (Dohoo et al., 2003). Meta-regression was used to examine whether the selected predictors (study continent, study country, yeast supplementation level, duration of yeast supplementation and breed of broiler used) explained any of the sources of heterogeneity.

Rosenberg's fail-safe number (Nfs) and funnel plots were used in this study to assess the existence of publication bias. Studies are said to have no publication bias when the funnel is inverted and symmetrical. Evidently, Jennions et al. (2013) have shown the robustness of meta-analysis results in the presence of publication bias regarded Nfs is greater than "5 (n = number of effect sizes) + 10". Forest plots (DerSimonian and Laird, 1986; IntHout et al., 2014) displayed the outcome of yeast intervention on broiler chicken productivity. Points to the left of the no effect line show a decline in the results

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28232843

of our parameters of interest, and the opposite demonstrates the reverse. The effect size is represented by individual square in the forest plot, while the upper and lower 95% CI for the effect size are the line that joined the square. According to Leah et al. (2009), the inverse of the effect size variance is shown by the weight of each study, whereas the square box size is equivalent to the inverse variance of the estimates with larger square boxes suggesting greater weight. The pooled effects estimate depicts the dotted line with the diamond at the bottom making up 95% CI. The pooled estimate was not significant when the diamond at the bottom is in contact with the no effect line (Koricheva et al., 2013). Effect sizes of approximately 0.2 and 0.5 are designated low and medium respectively, and large when they are more than 0.8.

Results

Overview of the articles included in the meta-analysis

The literature search in PubMed, Scopus and Google scholar produced 64 articles evaluating the productive indices of broiler chickens fed yeast supplemented diets (*Fig. 1*). A total of 25 articles were excluded from the analysis because they were reported in animal species other than broiler chickens. Six papers were removed from the study because they were narrative reviews, while five papers were excluded because they reported only the abstract. Five articles were excluded from the meta-analysis because of they were not randomized, and the control group was missing. Seven articles were not considered suitable for the analysis because they did not report any of the outcomes of interest. For the analysis of FC, 16 studies (with 4874 birds and 62 comparisons) representing 10 study countries drawn from three study continents met the eligibility criteria (*Table 1*). The publications used in the meta-analysis to assess the effect of yeast supplementation on FC in broiler chickens span 18 years with first study published in 1999 and the most current published in 2017 (*Table 1*). The FCR analysis included 15 studies containing 59 comparisons and 4874 birds conducted in 10 study countries drawn from 3 study continents (*Table 1*), while 13 studies comprising 49 comparisons and 3930 birds were included for the assessment of the effect of yeast on BWG in broiler chickens (*Table 1*). Of the all articles used in the meta-analysis to evaluate the effect of yeast on production indices of broiler chickens, the oldest study was published in 1999 and the most recent published in 2017. Most of the studies used Ross followed with Arbor acres. Yeast was added via the feed in the present meta-analysis.

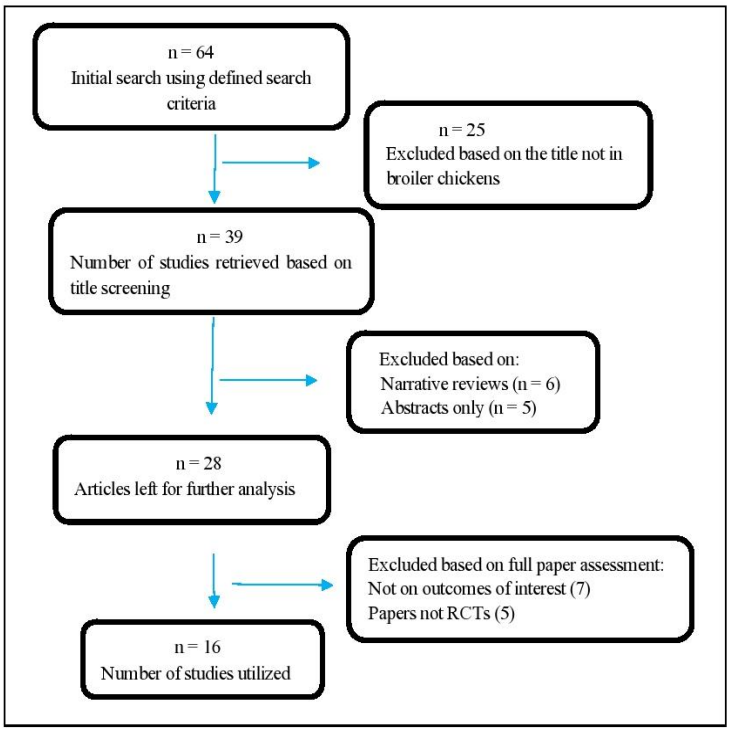

Figure 1. *Flow chart of articles used for the meta-analysis*

Feed consumption (FC)

The results of the overall effects estimate of yeast supplementation revealed that the incorporation of yeast in broiler diets reduced FC relative to broilers on control diet (d = -0.429, 95% CI: -0.606 to -0.253, I^2 = 89.59%, p < 0.001; *Fig. 2*). The temporal trends of the outcome of yeast supplementation on FC of broiler chickens are presented in *Figure 3*. The results of stratified subgroup analysis of the relationship between modifier variables and FC in broiler chickens are presented in *Table 2*. When the analysis was disaggregated, the results of the grand mean indicated that FC was significantly influenced by the explanatory variables (study continent, study country, duration of supplementation, supplementation level, broiler breed used; p < 0.001) following the removal of subgroup with one or two effect sizes. Disaggregation based on study continent, revealed that FC was not significantly reduced for studies performed in Africa, whereas studies conducted in Asia (p < 0.001) and Europe (p < 0.001) had significantly reduced FC. Results of the disaggregated studies of the effect of yeast on FC in broiler chickens based on study country showed that studies conducted in Pakistan, Egypt, India and Turkey were significantly different from zero (p < 0.001). Broiler chickens fed diet supplemented with yeast at < 10 g/kg feed had significantly reduced FC (p < 0.001). However, there was no association between FC and supplementation level (> 10 g/kg feed, p = 0.054;10 g/kg feed, p = 0.113, respectively). Stratified subgroup analysis results showed that FC was significantly reduced in broiler chickens fed yeast supplemented diet for 21 days (p = 0.001), 35 days (p = 0.038) and 42 days (p < 0.001), while FC in studies where broiler chickens were placed on yeast supplemented diets for 28 days (p = 0.340) and 56 days (p = 0.665) were not significant. Ross (p < 0.001), Arbor acres (p < 0.001) and Cobb (p < 0.001) had significantly decreased FC, whilst other breeds were not significant (p > 0.05).

DOI: http://dx.doi.org/10.15666/aeer/1802_28232843

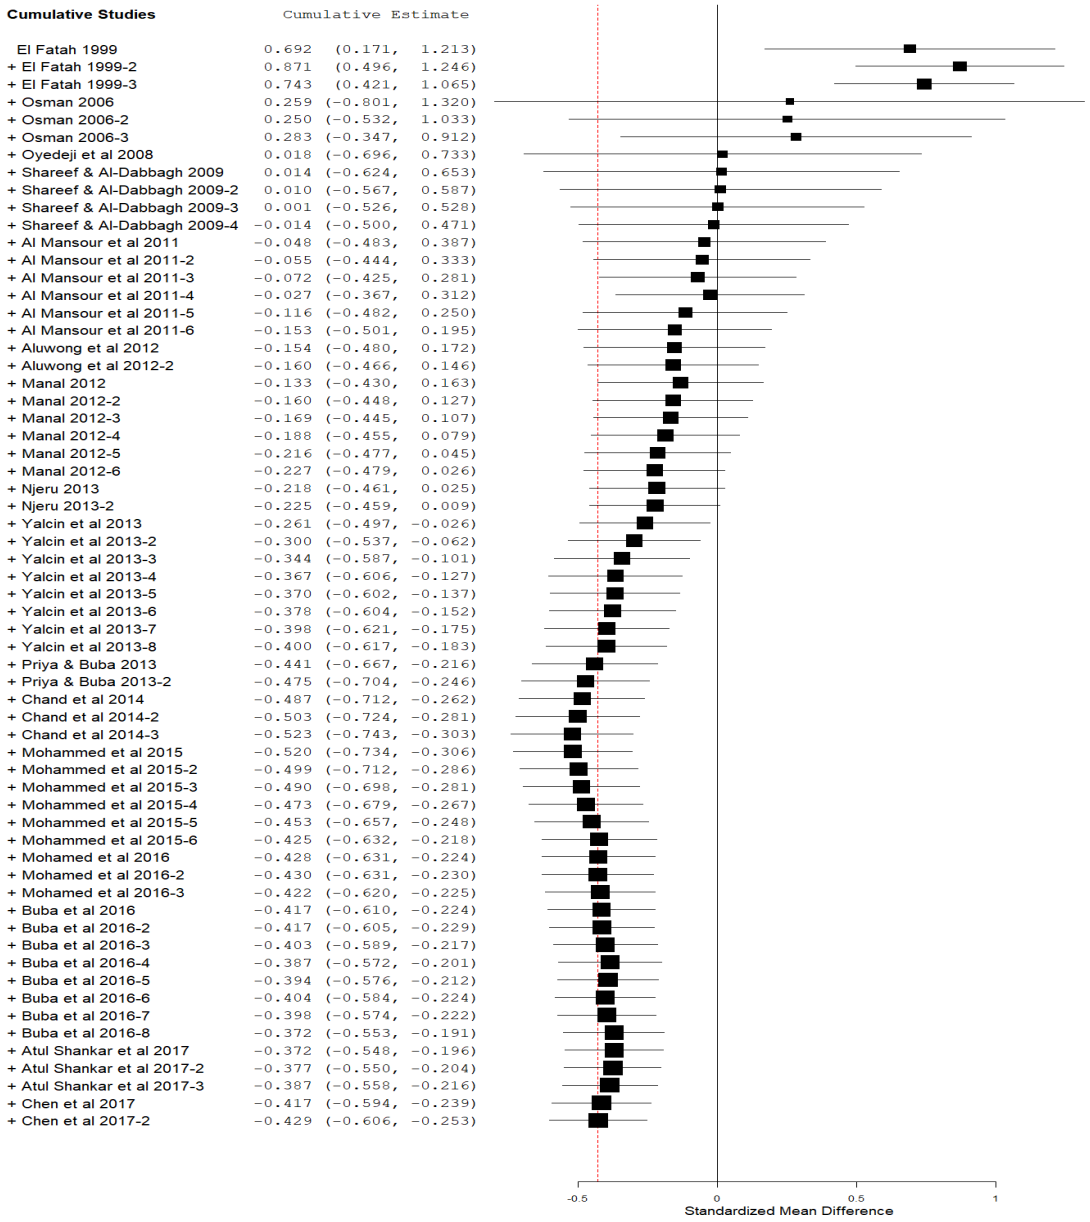

Figure 3. *Trends of FC in broilers fed yeast supplemented diets*

Feed conversion ratio (FCR)

The results of pooled effects estimation found a positive association between yeast supplementation and FCR in broiler chickens (d = -0.354, 95% CI: -0.517 to -0.190, I^2 = 87.27%, p < 0.001; *Fig. 4*). The temporal trends on the effect patterns of yeast supplementation on FCR in broiler chickens are shown in *Figure 5*. The results of the stratified analysis found an association between modifier variables and FCR in broiler chickens on yeast diet as presented in *Table 3*. Results of the stratified subgroup analysis revealed that FCR was positively influenced by the explanatory variables (study continent, p < 0.001; study country, p < 0.0001; duration of supplementation, p < 0.001; supplementation level, p < 0.001; broiler breed used, p < 0.001) when subgroup with one or two effect size(s) were removed from the analysis. Birds from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28232843

studies undertaken in Europe ($p < 0.001$) and Asia ($p < 0.001$) had superior FCR compared to chickens from studies performed in Africa ($p = 0.296$). Stratified analysis results indicate that the FCR for studies performed in Pakistan, Egypt, Indian and Turkey differed significantly ($p < 0.001$). There was a correlation between FCR and duration of supplementation (21 days, $p = 0.002$; 35 days, $p < 0.001$; 42 days, $p = 0.038$), whereas no correlation exists between the FCR and the duration of supplementation (28 days, $p = 0.340$; 56 days, $p = 0.665$). Broiler chickens fed yeast supplemented diet at a level of > 10 g/kg feed ($p = 0.111$) and 10 g/kg feed ($p = 0.113$) had poor FCR, whilst those that received yeast supplemented diet at a level of < 10 g/kg feed ($p < 0.001$) had improved FCR. Ross ($p = 0.001$), Arbor acres ($p = 0.003$) and Cobb ($p < 0.001$) had significantly improved FCR relative to Hubbard ($p = 0.354$), Lohman ($p = 0.742$), Faobrow CD ($p = 0.648$) and White Rose ($p = 0.718$).

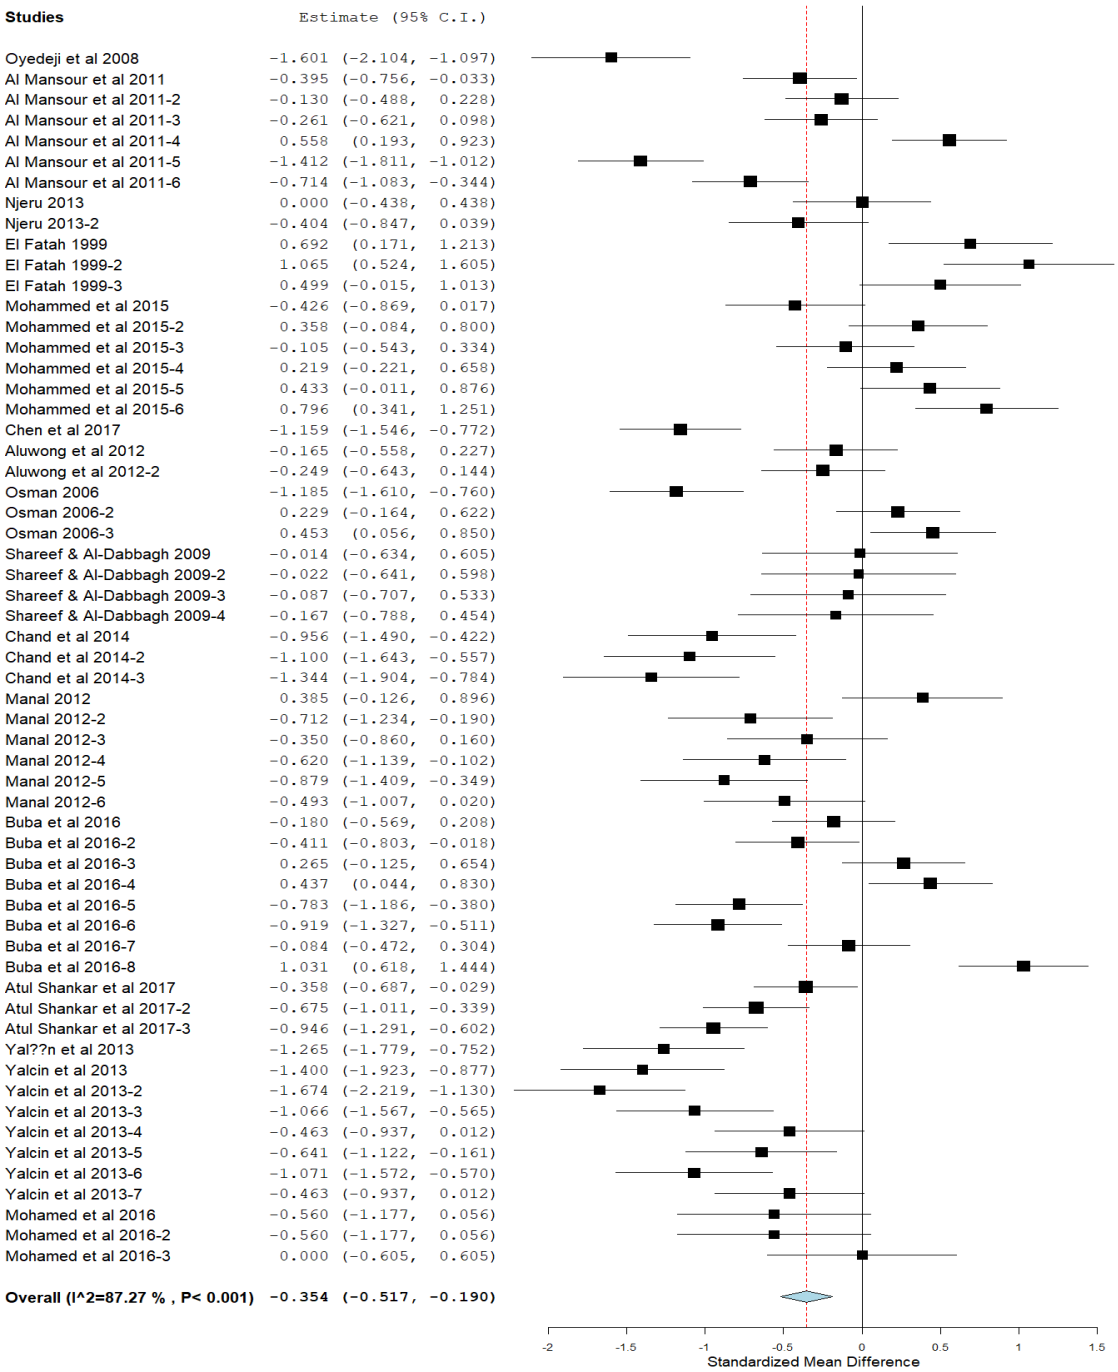

Figure 4. *Effect of probiotic-yeast supplementation on FCR of broiler chickens*

Body weight gain (BWG)

BWG was statistically increased from zero ($d = 0.310$, 95% CI: 0.130 to 0.491, $I^2 = 87.13\%$, $p < 0.001$; *Fig. 6*). The impact of yeast on BWG in broiler chickens in chronological order are shown in *Figure 7*. The results of the stratified subgroup analysis of the association between the explanatory variables and the BWG in broiler chickens are presented in *Table 4*. The mean effects estimate for the meta-analysis were 0.310, 0.325, 0.329, 0.310 and 0.310 for study continent ($p < 0.001$), study

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28232843

country (p = 0.001), duration of supplementation (p < 0.001), supplementation level (p < 0.001) and broiler breed used (p < 0.001), respectively, when the analysis was stratified. When the BWG analysis was disaggregated by study continent, studies conducted in Asia (p < 0.001) and Europe (p < 0.001) had improved BWG compared to those conducted in Africa. The results of BWG disaggregated by study country revealed that studies conducted in Iraq (p = 0.015), India (p = 0.019) and Turkey (p < 0.001) had statistically increased BWG following the removal of studies conducted in Saudi Arabia, Kenya and Taiwan that had less than 3 effect sizes. Studies conducted in Egypt, Sudan and Nigeria had similar values (Egypt: p = 0.556, Sudan: p = 0.728, Nigeria: p = 0.172). Broiler chickens from experiments that received yeast supplemented diets for 21 days (p < 0.001) had increased BWG, while those that received yeast supplemented diets for 42 days (p = 0.125) and 56 days (p = 0.983) were not significant. Studies that fed yeast for 35 days were removed from the analysis because they had less than 3 effect sizes. There was a significant positive association between BWG, and yeast supplementation level (< 10 g/kg feed, p < 0.001), whereas there was no significant association between BWG, and supplementation level (10 g/kg feed, p = 0.135; > 10 g/kg feed, p = 0.349). When BWG was disaggregated by breed of broiler used, Ross (p = 0.001), Faobrow CD (p = 0.015) and Cobb (p < 0.019) had significantly improved BWG.

Analysis of heterogeneity and moderators

Data in *Table 5* presents the mixed effects meta-regression of the impact of yeast supplementation in broiler chicken performance. Forest plots of the 16 studies comprising 62 comparisons that evaluated the effect of yeast on FC in broilers provided evidence of significant heterogeneity (I^2-statistic = 89.59%, 95% CI: -0.606 to -0.253, $p < 0.001$, *Fig. 2*) and sensitivity analysis was not able to resolve the problem heterogeneity. Subgroup analysis did not remove the challenges of large heterogeneity among the studies included in the meta-analysis. Thus, the substantial heterogeneity continues, suggesting that these analyses cannot fix the problem of heterogeneity. Meta-regression, revealed that study continent ($Q_B = 19.9$, degree of freedom, $df = 2$, $p < 0.001$), study country ($Q_B = 44.87$, $df = 9$, $p < 0.001$), duration of supplementation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28232843

(Q_B = 15.5, df = 5, p = 0.0084) and supplementation level (Q_B = 23.8, df = 2, p < 0.001) accounted for most the heterogeneity. Heterogeneity existed amongst the articles utilized in the analysis (FCR; I^2 = 87.27%, 95% CI: -0.517 to -0.190, p < 0.001, *Fig. 4* and BWG; I^2 = 87.13%, 95% CI: 0.130 to 0.491, p < 0.001, *Fig. 6*). Mixed effect meta-regression analysis revealed that study continent and yeast supplementation level were predictors of the study effect observed on FCR, whereas study continent, study country, supplementation level and broiler breed were predictors of study effects noticed on BWG results.

Analysis of publication bias

The results of the funnel plot of the impact of yeast supplementation on the productivity of broiler chickens as shown in *Figure 8A-C* revealed that the plots were asymmetrical. However, the Rosenberg fail-safe number of 3138 (FC), 1913 (FCR) and 964 (BWG) which is more than 9, 6 and 4-folds, respectively above the threshold of 320

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28232843

(5 × 62 + 10), 305 (5 × 59 + 10) and 255 (5 × 49 + 10) is required to declare the mean effect size robust. Consequently, the existence of publication bias was not a problem in this study as comparatively large number of unpublished studies would be needed to alter the statistically significant effects.

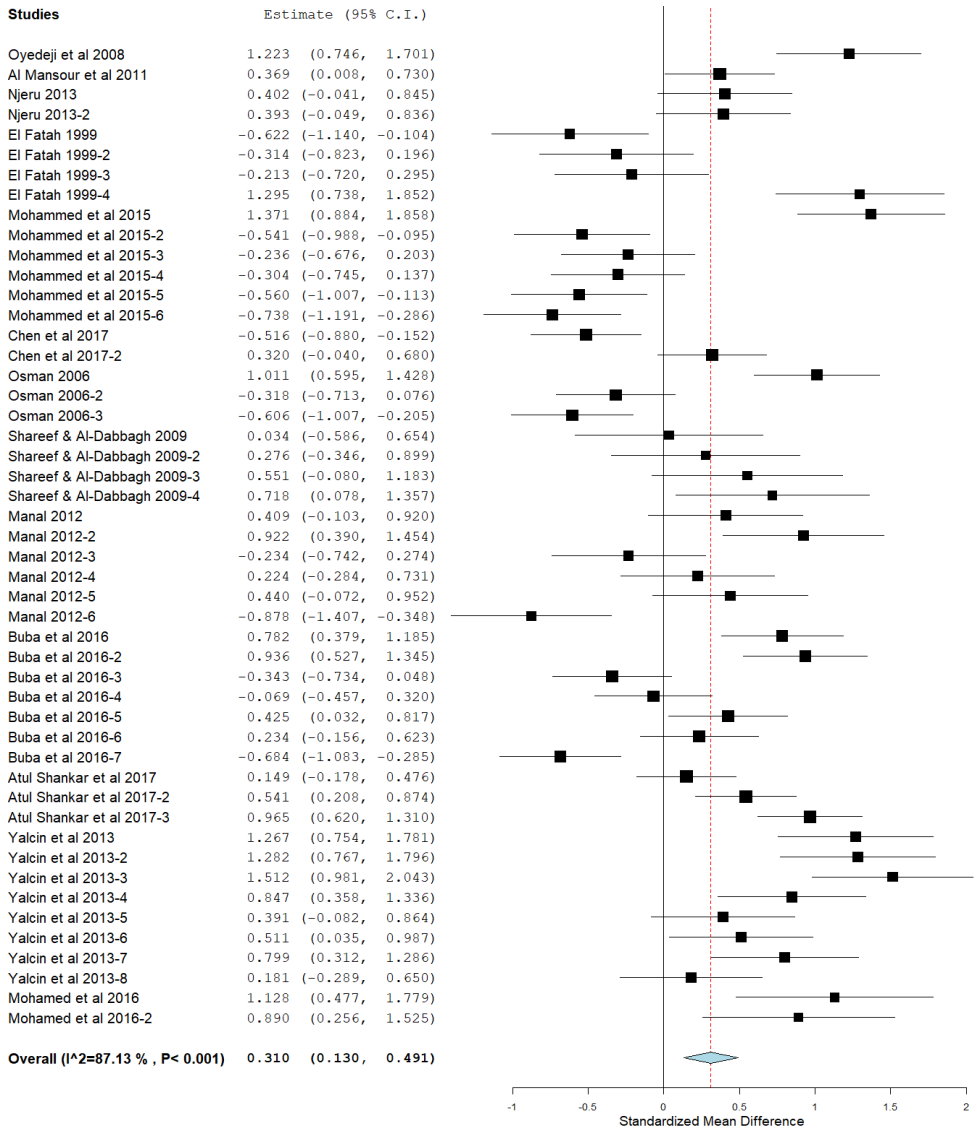

Figure 6. *Forest plot of the effects probiotic (yeast) supplementation on BWG of broiler chickens*

Discussion

Probiotic effect

In the last couple of years, the incorporation of small amounts of yeast in animal feed as a growth enhancing agent instead of antibiotics has received considerable attention (Ahmed et al., 2015; Gao et al., 2017; Ogbuewu et al., 2019). Basically, yeast is rich in essential nutrients and contains mannan oligosaccharides (MOS) that helps in the multiplication of beneficial microbes in the guts of broilers (Spring et al., 2000). The findings from the present meta-analysis of 16 RCTs representing 10 study countries

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28232843

drawn from three study continents indicated that broilers fed yeast supplemented diets had improved productive indices. This finding is consistent with the previous results of Hooge (2004) and Frizzo et al. (2011) who reported that probiotic (lactic acid bacteria) and actigen® (second-generation, yeast (*Saccharomyces cerevisiae* var. *boulardii*) cell wall product) supplementation improved BWG and FCR in broilers and calves, respectively. The enhanced FC, FCR and BWG recorded in the current meta-analysis could be partly ascribed to the direct nutritional effect of yeast that has been documented to increase productivity in broiler chickens (Hooge, 2004; Yalcin et al., 2013; Mohamed et al., 2016) and in calves (Frizzo et al., 2011). In addition, yeast has been recorded to improve the multiplication of helpful microbes in the intestines of chickens (Schneitz, 2005; Awad et al., 2006; Apata, 2008; Musa et al., 2009). It has also been documented that yeast activates the innate immune response of broilers (Haghighi et al., 2006; Apata, 2008; Musa et al., 2009); stimulates digestive enzyme production and activity (Yoon et al., 2004); and competes with pathogens for adhesion sites in the gut, thus preventing their multiplication in the intestine (Choudhari et al., 2008). The enhanced feed efficiency and the resultant increase in body weight gain is the ultimate result of probiotic intervention as reported by Bozkurt et al. (2009) in male broiler chickens fed MOS.

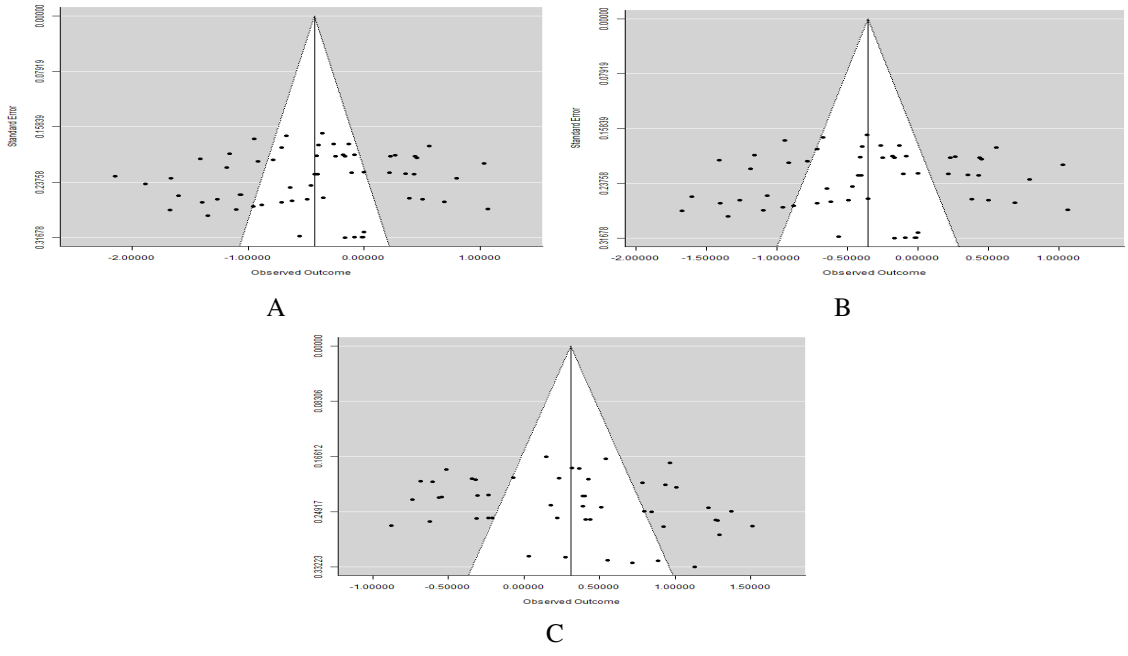

Figure 8. *Funnel plots of the effect of yeast on FC (A), FCR (B) and BWG (C) in broiler chickens*

Analysis of moderators

The current meta-analysis disclosed an important association between yeast supplementation in broilers and some elements of our selected explanatory variables. This revealed that the moderators chosen were responsible for the inconsistency of results reported in broiler chickens fed probiotic yeast supplemented diets. There is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28232843

significant relationship between probiotic (yeast) supplementation and FC, FCR and BWG in broiler chickens for studies performed in Asian and Europe. However, studies undertaken in Europe found a bigger relationship (FC, $d = 0.993$; FCR, $d = 0.993$; BWG, $d = 0.838$) than those conducted in Asia. The effect of yeast on FC, FCR and BWG in broilers for studies conducted in Africa had no significant association. The observed disparity between the production indices of broiler chickens from studies undertaken in Africa and those performed in Europe and Asia can be partially attributed to differences in the environmental conditions of the three study continents. The environmental conditions hampering chicken performance and health include temperature, relative humidity, light and housing system (Elijah and Adedapo, 2006). Environmental temperatures have a negative impact on the survival and success of the broiler production. Broiler chickens are susceptible to environmental change because there is a narrow range of thermal conditions under which they can maintain a stable body temperature. However, no data was reported on the weather conditions of the study countries and continents as at the time the investigated was conducted. The failure of the authors of the study included in the meta-analysis to report the weather condition of the study region as at the time the study was carried out was the reason we could not identify the specific variables that might have been accountable for the differences in the productivity of broilers raised in Africa compared to those raised on the other two continents. The current meta-analysis also found that there was significant association effect of yeast on FC and FCR in broilers raised in Egypt, India, Pakistan, Iraq and turkey, whereas for BWG it was evident on studies undertaken in India, Iraq and Turkey. Yeast effect on FC and FCR was found in studies which lasted for 21, 35 and 42 days. However, there was no beneficial effect of yeast on studies that lasted 28 and 56 days. Enhancement in FC and FCR for studies that lasted for 21 days translates to an increase in body weight gain in broiler chickens. This indicate that study continent, study country, duration of supplementation are the limiting factors in several of the studies included in the meta-analysis. The level of yeast supplementation is a determinant in many studies and has led to differences in the outcomes reported by the various authors (Frizzo et al., 2011; Ezema and Ugwu, 2014). In this study, the beneficial activities of yeast on FC, FCR and BWG were shown in studies that fed diet supplemented with yeast at the rate of < 10 g/kg feed. The Ross and Cobb broiler type had enhanced FCR and BWG with less feed intake, whereas Arbor acre had enhanced FCR, which did not translate to increased body weight gain in the current meta-analysis.

Source of heterogeneity and publication bias

This meta-analysis included research conducted in several parts of the world. In this context, the generalization and validity of the conclusions reached are strong. Potential biases, however, such as publication bias and heterogeneity were evident in the present meta-analysis and this was anticipated as most of the studies were undertaken in 10 study countries drawn from 3 continents. Substantial heterogeneity was recorded, sensitivity and stratified analysis fail to fix the issue. Results of meta-regression analysis showed that explanatory variables (study continent, study country, duration of yeast supplementation, yeast supplementation level and breed of broiler used) accounted for most of the variations among the studies included in the meta-analysis. For FC, FCR and BWG, the Rosenberg Nfs is 3138, 964 and 1913 respectively, which is 9, 4 and 6 times higher the threshold of 320 ($5 \times 62 + 10$), 255 ($5 \times 49 + 10$) and 305 ($5 \times 59 + 10$) required to consider the mean effect size robust. Thus, publication bias was not an issue

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28232843

in the current meta-analysis since a relatively large number of unpublished studies would be required to alter significant impacts of yeast supplementation on broiler chicken productivity.

Conclusion

This meta-analysis provided baseline information on guidelines to standardize the experimental designs of future trials on the effect of probiotic-yeast supplementation on broiler chicken productivity. Results found that adding yeast to the broiler chicken diet at a level less than 10 g/kg feed improved the productivity of broiler chickens. There was also a significant association effect between probiotic-yeast and explanatory variables. These results will encourage feed producers, poultry nutritionists, and farmers to make informed choices about the use of yeast in broiler chicken diets as an alternative feed additive instead of antibiotics. More research is, however, needed to ascertain the effect of yeast supplementation on quality characteristics of broiler chicken meat using meta-analytical approach.

Abstract. Nano-biochar with unique characteristics compared to common biochar has been confirmed to promote soil physical properties. Highly weathered soils in arid and semi-arid areas are characterized by low soil nutrients and high erosion potential. This study evaluated the influences of nano-biochar made from oak tree branches on the soil, water, and nutrient conservation on a sloping land of the Chinese Loess Plateau. Five nano-biochar rates (0.0%, 0.1%, 0.5%, 0.7%, and 1.0% by mass, equal to 0 t/ha, 0.0263 t/ha, 0.131 t/ha, 0.184 t/ha, 0.268 t/ha) were applied in three bands with simulated rainfall plots (1.0 m in length, 1.0 m in width) with five different vegetation covers (bare, alfalfa, bean, *Caragana microphylla*, and corn). A simulated typical rainfall event of 90 mm h^{-1} was performed for all the treatments. Experimental results indicated that the initial runoff time was delayed with the increasing nano-biochar contents. Compared to the treatments with no biochar application, soil, water, and nutrient losses in runoff significantly decreased. The conservation effect of nano-biochar was the most significant in the alfalfa plot. Soil containing 0.7% nano-biochar (0.131 t/ha) with alfalfa planting mollusc. This study provides an effective method for soil water and nutrient conservation.
Keywords: *nano-biochar, soil and water loss control, nutrient loss and conservation, conservation value, vegetation cover*

Introduction

Semi-arid loess region of northwestern China has been suffering from severe soil erosion (up to 1000–15,000 t/km^2 per year) and nutrient loss (Shi et al., 2000; Chen et al., 2008), which is the primary cause of soil degradation and water pollution (Guo et al., 2013). In order to control the serious soil water erosion and nutrient loss, huge researches have been conducted since the end of 1950s (Huang et al., 2015). Over the years, China government has taken various conservation measures to solve this serious soil and water erosion, as well as nutrient loss problems, such as minimum tillage and no-tillage, Hedgerows, and straw mulch (Lin et al., 2009; Wang et al., 2017; Rahma et al., 2017). However, in practical terms, the effects were quite limited because of different perceived problems. Minimum tillage and no-tillage resulted in more weeds and lower yield than conventional tillage (Wozniak and Kwiatkowski, 2013; Beibei Zhou, et al., 2016). Hedgerows would also consume water, nutrient and sunlight which will reduce crop yields, besides the existence of hedgerows will also make tillage inconvenient (Sun et al., 2001). Straw mulch could be an adoptable method which could help with reducing soil and water runoff, as well as evaporation, but the straw will be washed away when the storm came (Peng et al., 2016; Li et al., 2017). Thus, to find an

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28452861

appropriate and effective method in controlling soil, water erosion and nutrient loss on the Loess Plateau remains an urgent task.

Moreover, soils in semi-arid loess region of northwestern China have high silt content, low organic matter content, and poor soil structure, which is difficult to overcome. The poor soil condition, combined with inappropriate land use, makes soil and nutrient loss very vulnerable to rainfall. Since the 1990s, kinds of soil amendments have been widely studied in order to control soil erosion and nutrient loss, such as polyacrylamides (PAM) and biochar (or black carbon) (Busscher et al., 2011; Wang et al., 2013). The PAM has been proved to control soil and water erosion for a long time, but PAM could also restrict infiltration which in turn accelerates runoff (Lu and Wang, 2016). The increased runoff will facilitate erosion in the downslope with villages that may turn out to be a big disaster. Besides, PAM belongs to water-soluble polyacrylamide and its limited capability in improving soil structures and quantity makes the PAM less feasible for soil and water conservation. Because of the high porosity and large inner surface area, biochar has been widely used to improve soil physical properties, especially soil water holding capacity since the 2000s (Hina et al., 2010; Herath et al., 2013; Li, 2017). Moreover, lots of studies have shown that biochar is promising to ameliorate soil physicochemical properties, improve nutrient utilization and crop yield (Laird et al., 2010; Mukherjee and Zimmerman, 2013). However, high biochar rate such as 40 to 50 tons per hectare is usually suggested (Cheng et al., 2015; Nguyen et al., 2010; Li et al., 2017). The high biochar rate together with its high mobility with storm runoff largely limits the biochar application.

Compared with common biochar, nano-biochar made of tree branches is also a carbon-rich product, which has similar properties as common biochar. Furthermore, due to the small size, nano-biochar could also achieve similar properties to nano material which have strong absorption. But little research has been done. The objective of this study was to examine the impact of nano-biochar applied into a sloping land on soil erosion, water runoff, as well as nutrient loss under five vegetation species on Loess Plateau of China using simulated rainfalls.

Materials and methods

Experimental site

The experiment was done at Liudaogou watershed (35°20’ − 40°100’N, 110°21’ − 110°23’E), which is located in the northern part of the Chinese Loess Plateau. The catchment is 6.89 km^2 and the elevations is between 1,081 and 1,274 m which belong to semi-arid area. The annual average temperature of the experiment site is 8.4 °C with the lowest temperature -9.7 °C in January and the highest temperature 23.7 °C in July. The annual mean rainfall is about 437 mm with the minimum rainfall of 109 mm and maximum rainfall of 891 mm. The underground water level is more than 20 m.

Experimental plots

In this study, five nano-biochar application rates (0.0%, 0.1%, 0.5%, 0.7%, and 1.0%, equal to 0 t/Ha, 0.0263 t/ha, 0.131 t/ha, 0.184 t/ha, 0.268 t/ha) and five vegetation types (i.e., bare, alfalfa, bean, *Caragana microphylla* and corn) were considered, so the total number of the treatments were 25, together with one plot in bared soil without

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28452861

nano-biochar which was used as the control. Each treatment was conducted in one plot with 1 m in length and 1 m in width.

To study how the nano-biochar affect the soil and nutrient loss, the nano-biochar was mixed well with soils and then applied in bands (5 cm wide, 200 cm long, and 5 cm thick) 5–10 cm under the surface. The bands were located at top, middle, and bottom of the plot shown in *Figure 1,* respectively. Before nano-biochar was applied into the plots, soils of top 10 cm in the band were removed. The nano-biochar was then mixed uniformly with half of the removed soils at a mass rate of 0.0% (control), 0.1, 0.5, 0.7, and 1.0% of nano-biochar, respectively, to make a 5 cm-thick soil nano-biochar mixture layer in the original position. Finally, the other half of the removed top soil was piled onto the soil nano-biochar mixture layer with its original bulk density. To minimize the possible influences by human disturbance, the mixtures-buried plots were sitting for four months before rainfall simulation experiments.

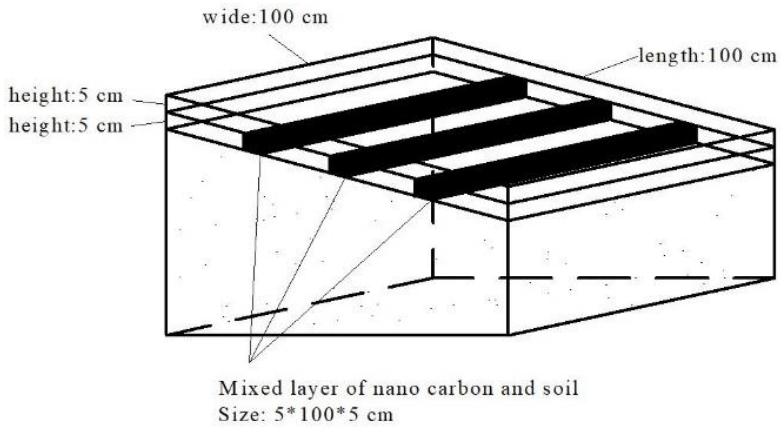

Figure 1. *The position of nano-biochar bands applied in the plot (1 m × 1 m)*

The plants were seeded 3 months before experiments. Before the rainfall experiment was conducted, vegetation was trimmed to similar vegetation coverage (*Table 1*). To reduce the disturbance due to agriculture, the vegetation specified above was planted in the plots and left undisturbed for a period of 4 m before simulated rainfall after NB was applied to the soil. *Caragana microphylla* and alfalfa were drill sown, with rows spaced 25 cm apart; corn and bean were bunch planted, with rows spaced 25 cm apart and individual plants were spaced 35 cm apart in each row. Planting and field management of vegetation were carried out according to local farming practices. Status of vegetation growth was taken before the simulated rainfall. Vegetative coverage of *Caragana microphylla* and corn was 45.93% and 42.39% on slope of plot area, respectively, which could represent the local general situation. The vegetation coverage was calculated with Matlab software. Each plot has an average slope of 152°.

Table 1. *Vegetation growth status in the experimental area*

Vegetation species	Height (cm)	Leaf area of a single plant (cm^2)	Vegetation coverage
Corn	84.3−93.9	163.2−201.5	41.4%
Bean	36.7−45.8	25.1−34.7	42.3%
Alfalfa	41.3−49.6	1.2−2.7	43.3%
Caragana microphylla	54.1−71.3	0.9−1.5	43.9%

DOI: http://dx.doi.org/10.15666/aeer/1802_28452861

The physical and chemical characteristics of the experimental soil are shown in *Table 2*. The experimental soil was sandy textured which belonged to the Aeolian sandy soil (Hillel, 1982).

Table 2. *Physical and chemical properties of the experimental soil*

Clay (%)	Silt (%)	Sand (%)	Soil texture	Organic content (g kg^{-1})	pH
5.5	30.5	64.0	Sandy	3.5	6.2

Physical and chemical properties of nano-biochar

The nano-biochar applied in this experiment was provided by the Hainuo Nano Company (Shanghai, China) and produced by oak tree branches over 5-6 h at 500 ℃. The diameter of nano-biochar was less than 40 nm. Its physics-chemical properties are shown in *Table 3*.

Table 3. *Basic properties of the nano-biochar used in this study*

pH	Water content (kg kg^{-1})	Ash content (kg kg^{-1})	Bulk density (g cm^{-3})	Iodine sorption value (mg g^{-1})	BET* (m^2 g^{-1})
9.6	5%	60.0%	0.38	1,300	1,300

*BET refers to Brunauer, Emmett and Teller, which is a classical method to measure the specific area of particles

Rainfall simulation

The simulated rainfall experiments were conducted in the plots shown in *Figure 1* using a pinhole rainfall device invented by Zhou and Hu (2015) (*Fig. 2*) from June to September of 2016. The raindrops of 2.5 mm could be produced from the tubes of the simulated rainfall device 2.0 m above the plant canopy in experimental plots. The simulated rainfall intensity of this study was 90 mm h^{-1} (Chen and Zhou, et al., 2019), which is the average rainfall intensity in summer of the local. The simulated rainfall experiment will last for 40 min after the runoff occurred.

Before the simulated rainfall experiment, a mixed solution with 1.0 mol L^{-1} potassium bromide (KBr), 1.0 mol L^{-1} potassium nitrate (KNO_3), and 1.0 mol L^{-1} monopotassium phosphate (KH_2PQ_4) was sprayed on the soil surface. The application rate for each individual solution was 40 $g \cdot m^{-2}$. The water runoff and soil sediment will be collected at the low end of each plot. Once the water runoff started, the runoff samples (volume depending on time and the plot) will be collected with a plastic bottle every 3 min. All the samples were then transported in an ice box to the laboratory where samples will be analyzed immediately. The concentrations of NO_3^--N, K^+, PO_4^{-3}, together with the total solids (T_s, representing sediment) in runoff and soil sediment samples were measured by the ultraviolet spectrophotometric method, atomic absorption spectrophotometer HG-9602A, and standard methods, respectively (Bao, 2005).

After the first simulated rainfall experiment was finished, the plot was left for a period of time (depending the weather, mostly, it will usually be one month) until the soil water content measured by oven dry method dropped back to the status right before

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28452861

the first rainfall simulation. Then another replication of rainfall simulation was conducted in the same way.

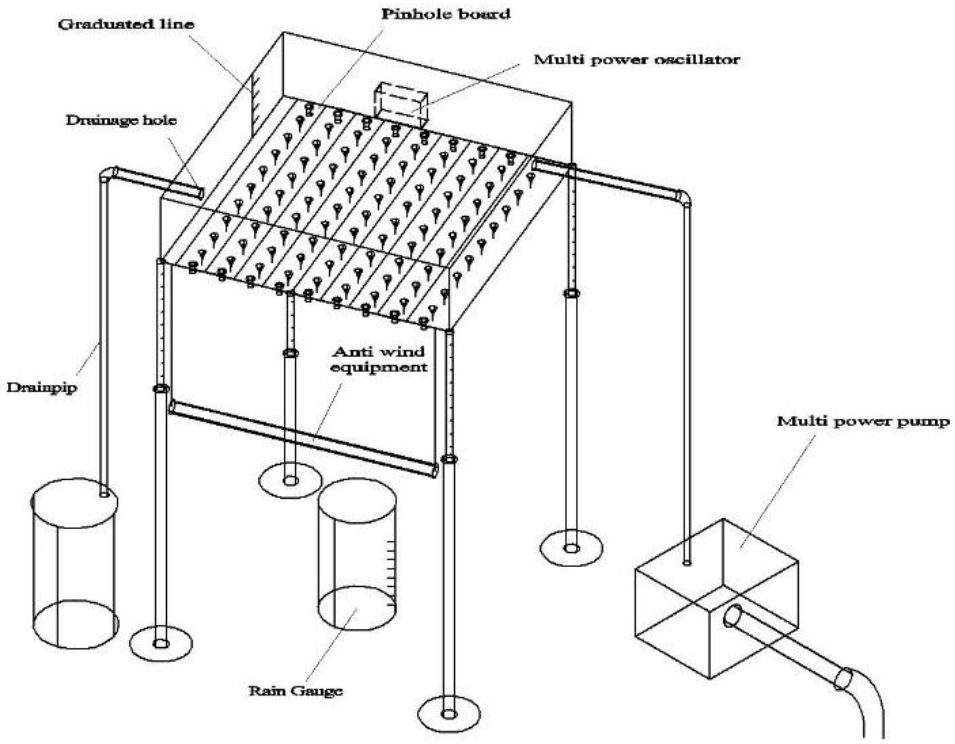

Figure 2. *Pinhole type simulated rainfall device for experiments on effect of rainfall on erosion on the Loess Plateau, China*

Conservation value (C_v) of soil, water, and nutrients for each treatment was calculated with the equation as follows (Kumar et al., 1992):

$$C_v = \left(1 - \frac{S_p}{S_0}\right) \times 100\% \quad \text{(Eq.1)}$$

where S_p, S_0 are the total amount of soil, water, or nutrient loss from the experimental plots and control plots, respectively.

Statistical analysis

Analysis of variance (ANOVA) method was used to determine the effect of nano-biochar contents and vegetation species on water runoff, soil erosion, as well as nutrient loss.

Results and discussion

Nano-biochar contents affect water runoff and soil erosion

Effect of nano-biochar contents on initial runoff time

In order to know the effect of nano-biochar on initial runoff time is one of the important parameters for characterizing runoff. The initial runoff time increased with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28452861

an increase in nano-biochar contents (*Table 4*), indicating that the nano-biochar delayed the runoff generation. Infiltration excess overland flow is the main reason of runoff on the slope in the semi-arid loess region of China. Based on the laboratory experiment of Lv et al. (2016), the result indicated the nano-biochar applied 5 cm under the soil surface can increase the infiltration rate obviously. So in this study, the increased infiltration rate delayed the initial runoff time comparing to that in control plot. Moreover, the effect of nano-biochar on the initial runoff time was more pronounced when the nano-biochar content was larger than 0.5%. However, when nano-biochar content approached to 1.0%, the effect became weak (*Table 4*). Similar results were obtained by Sadeghi et al. (2016), of which it showed an effective impact of biochar application on delaying runoff time by 55% comparing to that in control experiment.

Table 4. *Effect of nano-biochar content on initial runoff time in minute*

Vegetation type	Nano-biochar content (%)				
	0 (control)	**0.1**	**0.5**	**0.7**	**1.0**
Bare (control)	5.2	5.5	8.0	7.5	8.4
Alfalfa	15.2	20.0	29.5	29.6	/
Bean	11.8	12.2	13.2	14.3	14.3
Caragana microphylla	13.1	13.3	13.9	14.1	14.5
Corn	12.0	12.8	13.2	13.4	13.4

"/" represents no runoff. The values in this table were average values

The initial runoff time in the plots with vegetation cover lagged behind as compared with the control plot (*Table 4*), indicating that vegetation also delayed the runoff time. The main reason is that the presence of the vegetation root could effectively prevents runoff, together with plant interception impact. As a result, vegetal cover provided sufficient time for infiltration and slowed down the runoff commence (Marques et al., 2007). Alfalfa followed by *Caragana microphylla* was the most efficient species to delay runoff, which was in agreement with a previous study (Wu et al., 2011). The dense vegetal cover and well-developed root of alfalfa and *Caragana microphylla* may contribute to the slower movement of simulated rainfall. Therefore, planting alfalfa and *Caragana microphylla* with band application of nano-biochar (≥0.5% or 0.488 t/ha) would be a good method to slow down the runoff on the sloping land in the study area.

Effect of nano-biochar content on water runoff and soil loss

Table 5 shows the amount of runoff and soil loss and associated C_v values of various vegetation species and nano-biochar contents averaged for two simulated rainfall events. The maximum amount of runoff and soil loss was obtained in the bare plot with no nano-biochar. With the increase of nano-biochar content, the runoff was reduced from 3,911 to 2,538 cm^3 and the soil loss (sediments) was reduced from 565 g to 239 g. No water runoff and soil loss were obtained in alfalfa plot with 1% of nano-biochar. The runoff amount was significantly reduced when nano-biochar amendments were used, and almost kept unchanged when the nano-biochar content was 0.7 – 1.0% (*Table 5*). The decreasing amount of soil loss also clearly confirmed the benefit of nano-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28452861

biochar in improving field water holding capacity and conserving soil particles. Water runoff and soil erosion in vegetal plots with nano-biochar were generally reduced compared with the control plot which showed the maximum runoff. This was because vegetal cover slowed down water movement and rendered more time for infiltration thereby less runoff. Among plots with no nano-biochar, the alfalfa plot showed the minimum runoff (1,008 mL) and soil loss (58 g), with C_v values of 74.2% and 81.9%, respectively. This again indicated that alfalfa was the most efficient species in soil and water conservation especially when nano-biochar content was 1%, runoff was eliminated. *Caragana microphylla* was the second most efficient species showing C_v values of 48.7% and 54.1%, respectively, for runoff and soil loss.

Table 5. *Effect of nano-biochar content on runoff, soil loss, and associated conservation values (C_v)**

"/" refers to no runoff. *All the data shown in *Table 5* are averaged values of two simulated rainfall events

The observed behavior has a much more good results comparing to the previous studies reported by Smetanová et al. (2013) who indicated that 10% biochar in mass

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28452861

could reduce runoff events by more than 40%. In this study, nano-biochar could reduce 0.57–43.5% runoff in bare land, 74.2%-100% runoff in alfalfa land, 40.3–87.0% runoff in bean land, 48.7–97.4% runoff in *Caragana microphylla* land, and 34.7–78.7% runoff in corn land. The significant effect of nano-biochar on reducing runoff production could be attributed to the strong water capacity of nano-biochar and increasing infiltration rate (Lv et al., 2016; Li et al., 2017).

Water drops triggered soil erosion and soil deposition at the outlet of bared plots (Srivastava and Singh, 2012). Artificial rain drops also broke soil clumps into finer particles, which made the soil easily be carried over by runoff. For all the plots with nano-biochar, however, the runoff was reduced due to the increased infiltration and absorption. The effect of reducing runoff was larger at a higher rate of nano-biochar application. For the vegetated plots, the vegetation intercepted water drops and formed local hindrance to free and fast movement of water. Besides, runoff always moved down the slope more strongly forming narrowing channels in the bared plots, whereas the vegetated plots reduced the free flow of runoff and therefore reduced soil loss. The vegetation roots and nano-biochar also bound soil firmly and prohibited soil moving along the slope. Corn did not have abundant roots. This may explain why corn was the least efficient species in reducing soil loss.

The ANOVA analysis indicated that both nano-biochar content and vegetation cover had significant ($p < 0.001$) effects on soil and water conservation (*Tables 6* and *7*). Based on the discussion above, planting alfalfa with application of nano-biochar at a rate of 0.5% would be an efficient and economic method to reduce water and soil loss on Loess Plateau of China.

Effect of nano-biochar content on nutrient loss

Effect of nano-biochar on nutrient loss in runoff

Loss of nutrients (i.e., NO_3^--N, K^+, PO_4^{-3}) in the runoff presented the same temporal trend for different treatments except for the control plot in the first 10 min (*Figs. 3–5*). Concentration of all three ions increased over time approximately in the first 10 min followed by a constant or slowly decreased nutrient concentration. The solute

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28452861

concentration in the runoff at the early stage was mainly caused by the raindrops and solute concentration in subsurface of the plot. Few minutes after the water runoff production, more solute will be found in the runoff which was transferred from the surface. In the control plot, however, the nutrient on the surface was washed downward directly as there were no nano-biochar or vegetation to prevent runoff. As such, concentration of nutrients in the runoff reached a relatively high values in a short time, and dropped quickly due to the fast attenuation of nutrients in the surface layer. The solute concentration in the runoff was controlled by diffusion from the soil at the later stage. This resulted in a stabilized concentration of solute in the runoff. The higher solute concentration in the soil usually led to more solute loss with runoff. But the runoff was reduced remarkably with application of nano-biochar, especially at rates greater than 0.5%. The nano-biochar was, therefore, confirmed to reduce the nutrient loss due of the reduction of runoff and strong absorption capacity.

NB is short for nano-biochar

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28452861

The loss quantity of three ions varied greatly because of different chemical properties. As nitrate nitrogen is always lost through runoff and leaching, the amount of runoff would directly affect the quantity of nitrate nitrogen loss in runoff. From *Figures 3–5,* it could be found that in the initial 10 min, the nitrate nitrogen loss in runoff increased continuously in the soil surface after the simulated rainfall started. Subsequently, the nitrate nitrogen loss reduced gradually. As a result, the total nitrates loss at the initial time was about 4 times of that at the end of the experiment. The main reason is that at the beginning of runoff, the soil has a much higher clay particle which could absorb more nitrate nitrogen and more nitrate nitrogen was kept in soil water. So high nitrate contents could be obtained at the initial stage in runoff. With the reduce of nitrate nitrogen and the increase of mixed layer depth, nitrate was reduced gradually. Besides, the nitrate nitrogen loss was reduced obviously in the plots with nano-biochar, especially when the nano-biochar contents were 0.7% and 1.0%. The cumulative loss of nitrate nitrogen in the control treatment was much higher than that of others, which further indicating that the application of nano-biochar in soil could effectively reduce the loss of nitrate in the soil. Furthermore, the cumulative loss of nitrate in runoff was negatively correlated with increased nano-biochar contents. In bare, the runoff of each treatment with different nano-biochar reduced nitrite loss by 29.9–42.7%. With more nano-biochar was applied, more nitrate was kept in soil profile which could attribute to the excellent properties of nano-biochar, such as an enormous specific surface area, rich pore structure, and strong adsorption capacity (Deborah et al., 2011). As a result, can reduce the loss of nutrients by absorbing nutrient ions, preventing deep leaching from the surface soil.

Similar to nitrate nitrogen, at the initial time of the rainfall, more phosphorus was kept in soil water or be absorbed in soil particle, so the loss of phosphorus in runoff also first increased sharply in the initial 10 min (Vadas and Busch et al., 2015). The soil on Loess Plateau, has a poor structure, which prevent phosphorus from deep leaching but make phosphorus easily involved in runoff (Yan et al., 1999). As a result, the phosphorus loss tended to be stable. While with the increase of nano-biochar, the loss of phosphorus in runoff was also reduced.

Potassium was easily dissolved in soil water and runoff, so the potassium loss in runoff was much greater than that of other two nutrients for all the treatments (Poss et al., 2010). But the potassium loss also increased in the early 10 min and then became constant. Moreover, the effect became more significant at a higher rate of nano-biochar content.

In order to further analyze how nano-biochar affect nutrient loss, the nutrient loss and nutrient conservation values in runoff were calculated (*Table 8*). Nano-biochar effectively reduced the nutrient loss. With the increase of nano-biochar content, the nutrient loss was reduced and nutrient conservation value increased, especially when the nano-biochar content was 0.7% and 1.0%. Furthermore, nutrient conservation values of phosphorus, which is the main element to contribute to eutrophication, were much greater than those of nitrate nitrogen and potassium. The main reason was that the chemical interactions between phosphorus and clay minerals (Dutta, 2007; Tomer et al., 2007) largely reduced the mobility of phosphorus in soils except very sandy or organic soils. Most of the phosphorus was lost with the eroded soil particles. Vegetation species also affected the amount of nutrient loss in runoff (*Figs. 3–5; Table 8*). The bared plots showed the highest amount of nutrient loss in the surface runoff. Plots with alfalfa followed by *Caragana microphylla* showed the lowest amount of nutrient loss and highest nutrient conservation values. This indicated that nano-biochar application with planting alfalfa and *Caragana microphylla* had a positive influence in conserving nutrient.

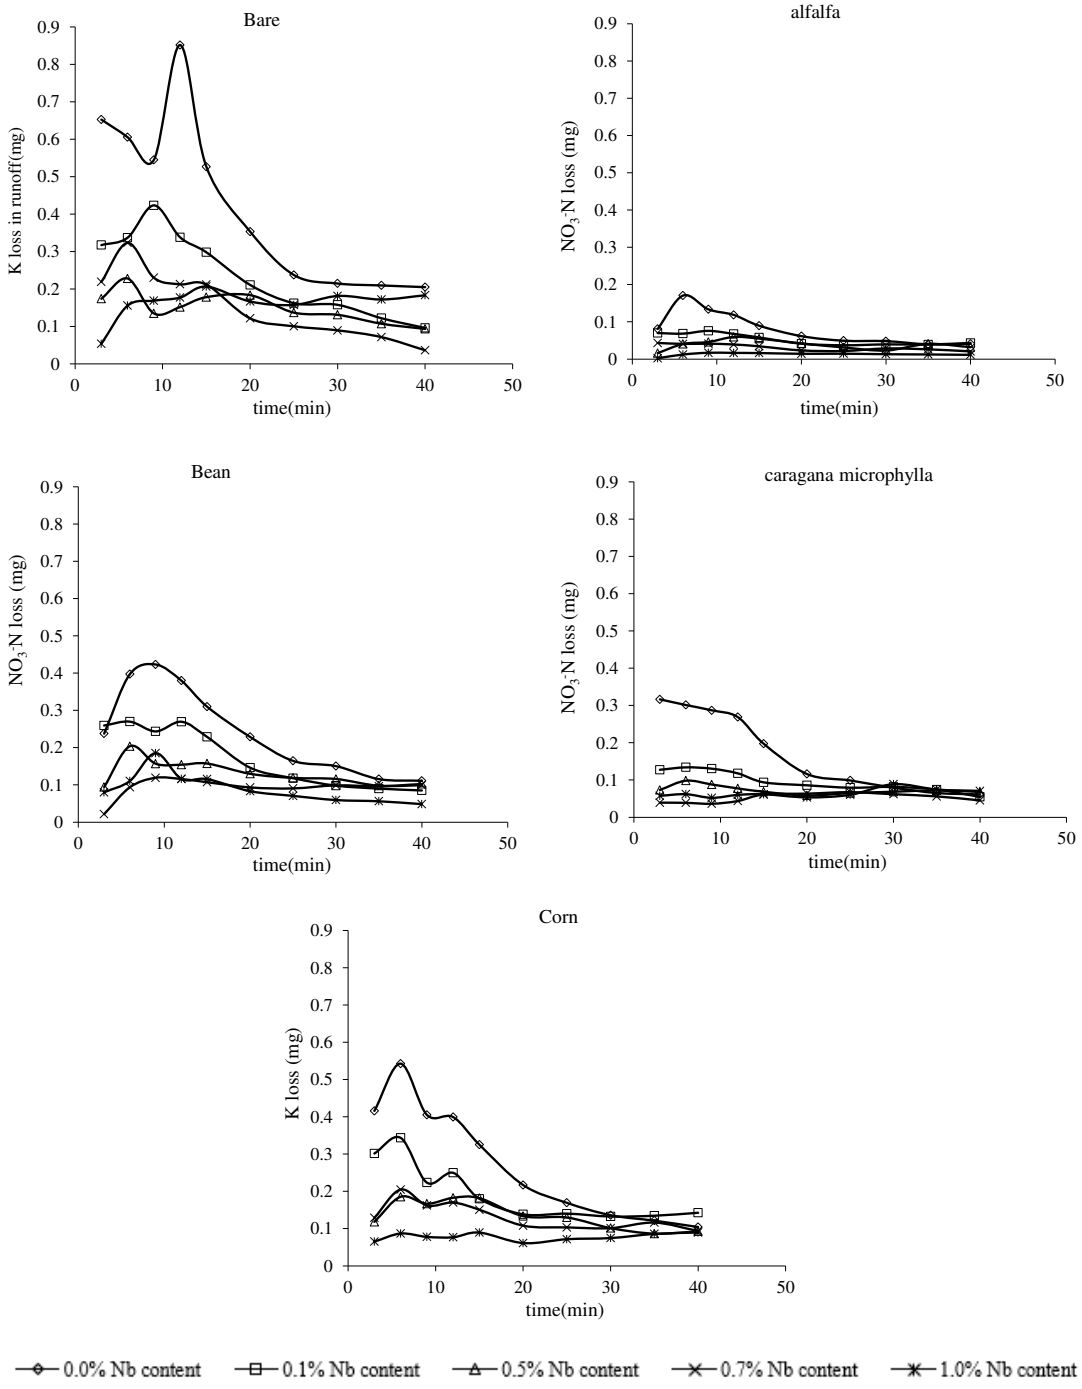

Figure 3. *Effect of nano-biochar on nutrient losses in runoff, showing the averaged nitrogen (N) mass loss as a function of time in two simulated rainfall events*

Effect of nano-biochar on nutrient loss in sediments

Nutrient loss not only occurred in runoff but also in sediments. The amounts of nutrient loss and nutrient conservation values in sediments are shown in *Tables 7* and *8*. Similar to the nutrient loss in runoff, nutrient loss in sediments was the greatest in the bared plots. The nutrient loss in sediments was reduced effectively with the increase of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28452861

nano-biochar contents. The lowest nutrient loss was found in plots with nano-biochar contents of 0.7% and 1.0%. Nano-biochar delayed the initial runoff time and reduced the quantity of runoff hence soil loss by erosion. This resulted in less nutrient loss with sediment. Moreover, at the initial time, absorptive and dissolved nutrient was much higher, so nutrient loss in sediment was much higher. With further process of the simulated rainfall, more nutrient was washed away with soil particles. When the energy of soil adsorption and desorption was in a dynamic equilibrium, the nutrient contents in sediment tended to be stable. Besides, nutrient loss in sediments was less than that in runoff. The main reason was that nitrate nitrogen and potassium were hardly bound by soil particles and hence easily dissolved in the runoff. Moreover, phosphorus transport along slope was mainly controlled by water flow rather than by sediment movement (Osborne and Kovacic, 1993).

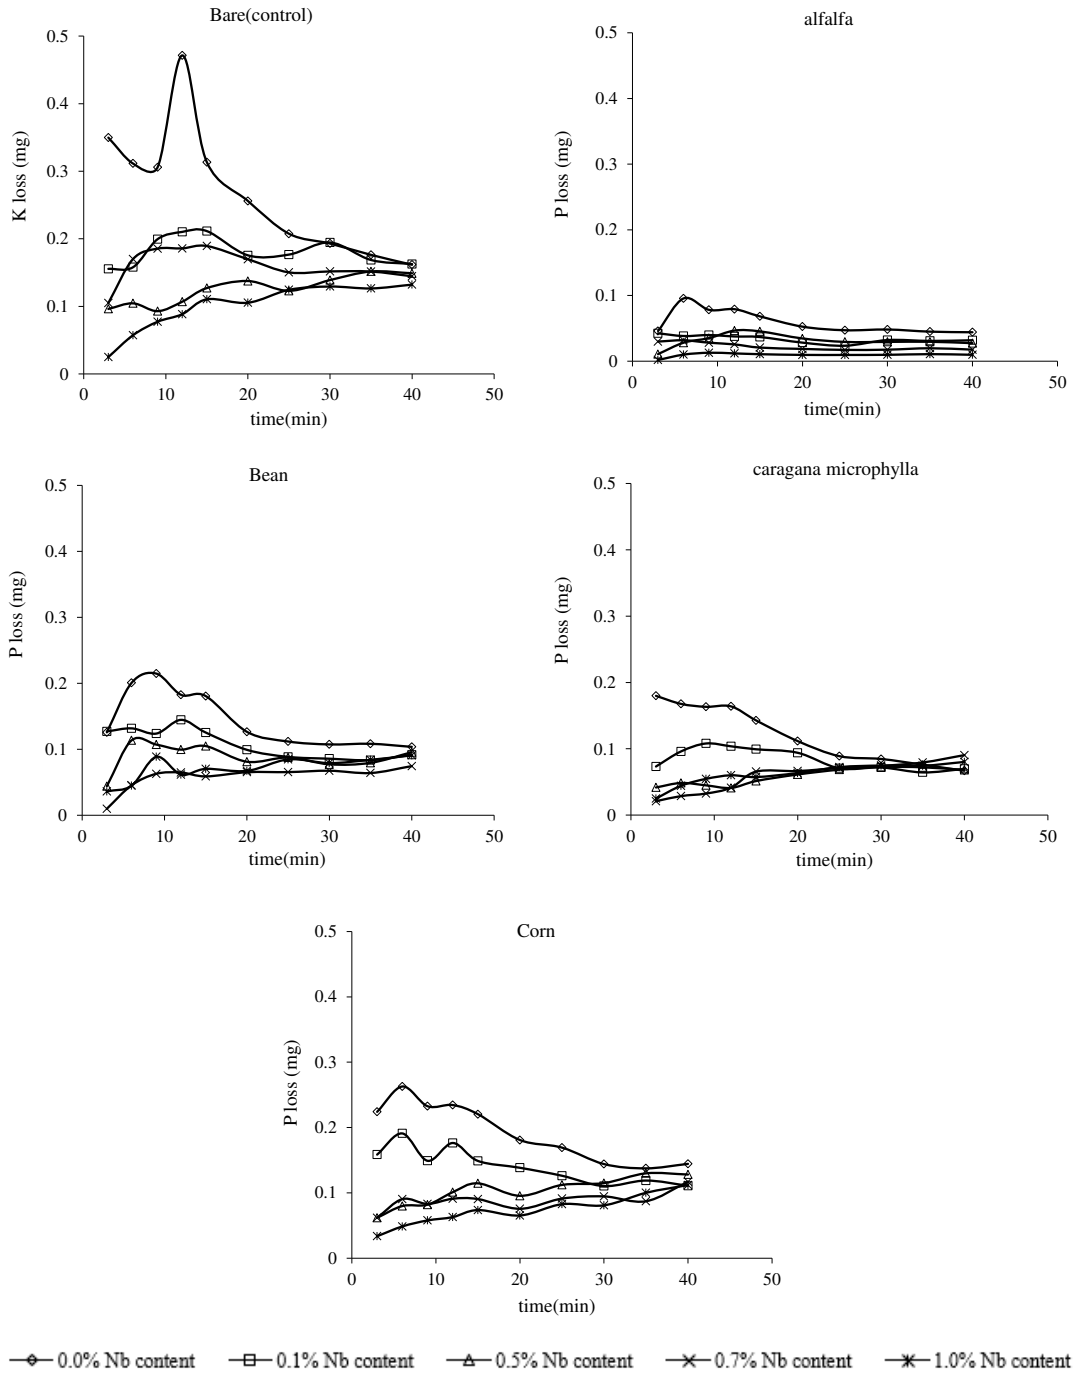

Figure 4. *Effect of nano-biochar on nutrient losses in runoff, showing the averaged phosphorus (P) mass loss as a function of time in two simulated rainfall events*

The nutrient loss in plots with vegetation was much smaller comparing to that in bare. The main reason for that is vegetal cover could reduce the energy of rain drops falling on the soil surface. This in turn reduced the amount of eroded soils that move down the slope. Besides these, plots with vegetation would accumulate more decayed leaves. Due to decomposition of humus, mollusk will always exist (such as earthworms) (Lipiec et al., 2015) which could loosen the soil and make it for air and water to reach

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28452861

the roots of plants. As a result, loose soil and good structure improved soil infiltration rate. Meanwhile, for bare land, due to the impact and erosion of rain drops, the soil structure was damaged, resulting in the reduction or blockage of soil surface pores, which will lead to a significant decrease in soil infiltration rate. Thus, the nutrient will be easily lost. Among all the vegetation species considered in this study, alfalfa was the most efficient species to reduce the nutrient loss in sediments.

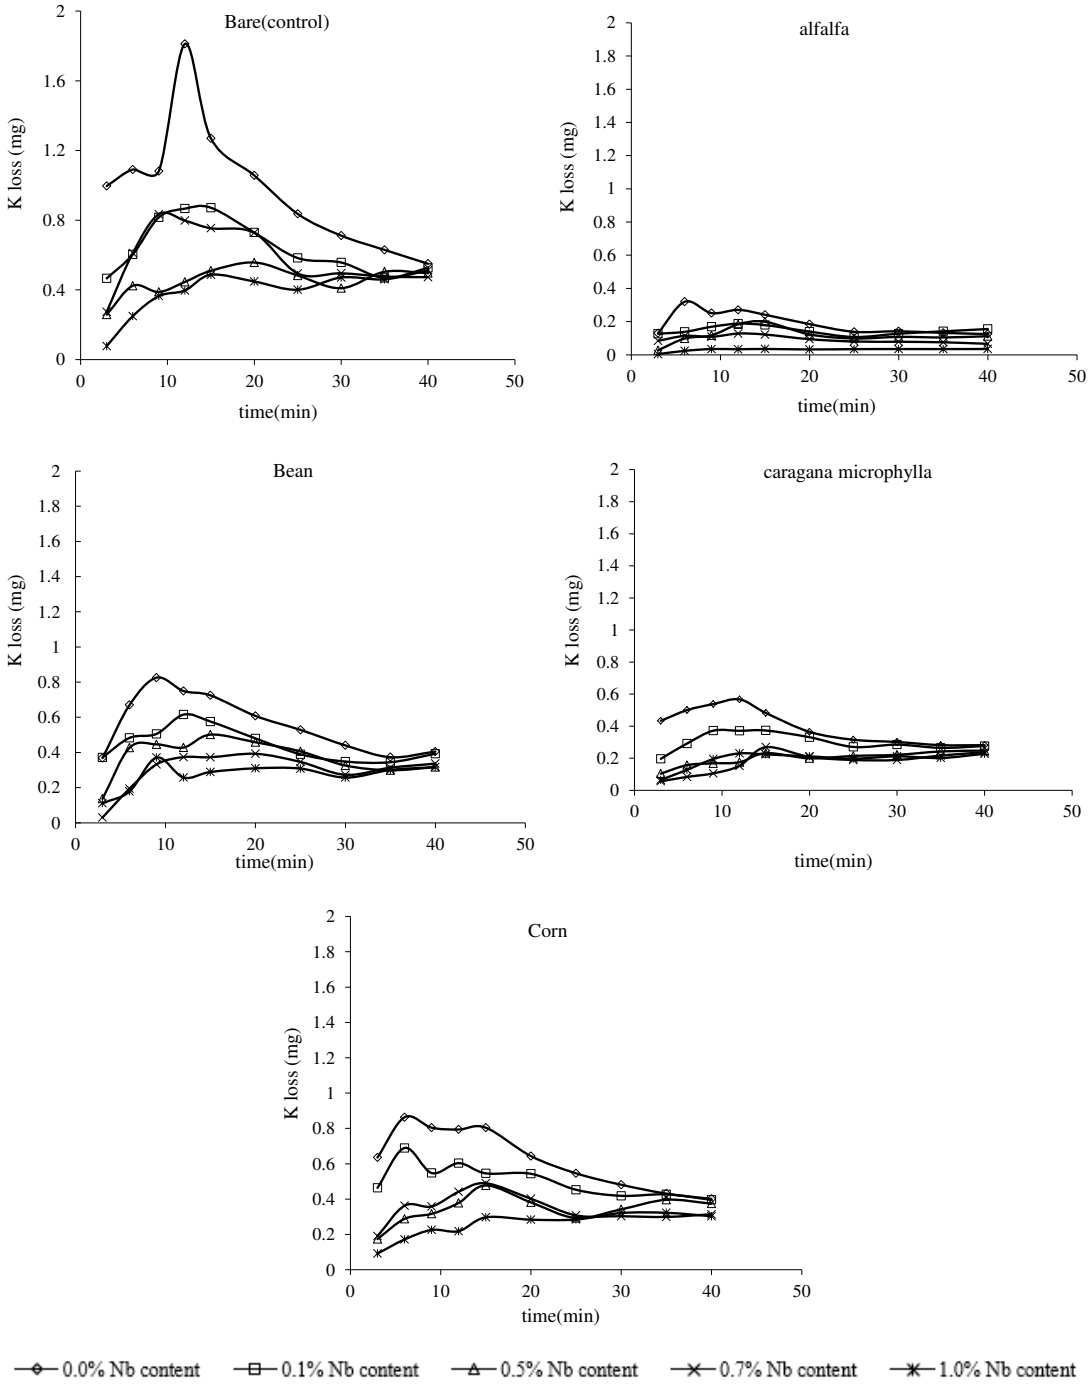

Figure 5. *Effect of nano-biochar on nutrient losses in runoff, showing the averaged potassium (K) mass lost as a function of time in two simulated rainfall events*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28452861

In general, the nano-biochar and even biochar is still at its initial research stage, most of the experiment related to soil and water conservation are conducted in pot experiment with short period. So long-term experiments are still needed to know the effects of nano-biochar application to control soil and water control better, as well as nutrient loss. Additionally, Sadeghi et al. (2016) and Li et al. (2107) also found biochar particles in the runoff, which indicated that biochar will be runoff easily with rainfall. So, in order to use biochar effectively, straw covering, manure or polyacrylamide, et al., could be used to help with coherence of biochar-soil particles and to avoid floating away by runoff. But in our study, no nano-biochar was found in runoff and soil sediment which showed a superior property to biochar. Moreover, high biochar rate such as 40 to 50 tons per hectare is always needed, together with its high mobility with storm runoff largely limits the its application. However, further comprehensive studies are still needed to examine the stability of nano-biochar in a long time before large-scale application of nano-biochar was used as a new soil amendment.

Conclusion

This study showed a positive effect of nano-biochar on the conservation of soil, water, and nutrients. We found that nano-biochar addition of more than 0.5% (0.131 t/ha on a mass basis) could delay the initial generation of runoff as well as reduce the amount of water runoff, soil erosion, and nutrient loss in a sandy soil of semi-arid loess region of China. Nutrient loss in runoff and sediment significantly decreased with the increase of nano-biochar content in all the treatments. Alfalfa was the most efficient species to conserve soil, water, and nutrient. The two-way ANOVA indicated that nano-biochar content and vegetation species had significant influences on soil water and nutrient conservation. Therefore, planting alfalfa with 0.131 t/ha nano-biochar in a sloping land have positive effects on soil and water conservation in the loess area. In the Loess Plateau of China, the wide application of vegetation cover has great influence on the treatment of soil erosion, and the combined application of nano-biochar will promote the effect of which more positive.

Abstract. Soil erosion and nutrient loss on the Loess Plateau cause severe desertification and land degradation, which results the loss of soil fertility and grain production. To improve soil quality and grain yield, nano-biochar was banded (5 cm in width, 5 cm in depth) into a plot (3 m × 3 m) in Shenmu County, in northern Shaanxi Province on Loess Plateau. The effects of different nano-biochar contents (0, 0.1%, 0.5%, 0.7%, 1% in mass) on soil moisture, nutrients, maize growth and yields, were analyzed. The result showed that with increased nano-biochar rates, soil bulk density also increased, and soil aggregates with particle size > 2mm increased from 0.69 to 37.12%. At the seedling and shooting stages, soil moisture content in the plots with nano-biochar were significantly higher than those in control. Nano-biochar slowed transport rate of nitrogen from the surface to deeper soil profile. At 0–10 cm soil depth, the amount of available potassium with nano-biochar applied was higher than those in control plot. The plots with higher nano-biochar content (0.7% and 1%) significantly increased the 1000-grain weight and yield of maize.
Keywords: *nano-biochar, growth parameters, 1000-grain weight, maize yields*

Introduction

Northern Shaanxi, China, is large and rich in natural resources. Changes in land use patterns and increasing population have resulted a decrease in the number of grain fields in this area. The remaining farmland is mainly located on slopes, but the plains are suitable for spring maize growth. Rainfall is the main source of water in this region. During the growing period, high rates of evaporation from soil occur due to high solar radiation intensity and high temperature. This results in insufficient water supply for spring maize growth. Previous studies have assessed how changes to management can improve the soil environment, and nutrient and water use efficiency, however, poor soil structure often impedes these efforts (Liu et al., 2012b; Manivasakan et al., 2013; Reese et al., 2014; Zhou et al., 2017, 2018). More research is needed to develop innovative strategies to improve fertilizer use by crops to increase crop yields, enhance plant use of nutrient, and minimize environmental damage.

As a soil amendment, biochar can be used to improve the utilization efficiency of chemical fertilizers and increasing grain yield. High rates (tons per hectare) are often applied, and because soil biochar may be lost via runoff, successfully using biochar to optimize fertilizer strategies may be unpractical. However, researchers have reported that after special treatment, biochar can become nano-biochar, which exists widely in soil-vegetation-atmosphere cycling. Due to the large specific surface and small particle size, nano-carbon is easily coupled with nutrient elements and soil microelements to become a

DOI: http://dx.doi.org/10.15666/aeer/1802_28632877

high-efficiency fertilizer (Roy et al., 2000; Vacher et al., 2003; Mesarič et al., 2013; Guo et al., 2013). Zhou et al. (2018) proposed that nano-biochar could reduce nutrient loss from rainfall-induced erosion on loess slopes under different vegetation cover and concluded that nano-biochar significantly affected soil moisture movement in the Loess Plateau. Wang et al. (2016) found that fertilizer with nano-biochar can increase crop yield by 10% to 20%, while reducing the amount of fertilizer required by 30% to 50%.

The objectives of this experiment were to test how banding different nano-biochar concentrations (0, 0.1%, 0.5%, 0.7%, 1%) affected soil physical and chemical properties, growth characteristics and soil water, and fertilizer utilization efficiency of spring maize crop.

Materials and methods

Site description

The experiment was conducted in Liudaogou Village, Xigou Township, Shenmu County, Northern Shaanxi, China (longitude 110°21'–110°23'E, latitude 38°46'–38°51'N). The experimental site was 6.89 km^2 in area and situated in an ecologically fragile zone prone of water and wind erosion. The annual mean temperature is 8.4℃ with the lowest temperature in January and the highest in July. The annual average precipitation is 437.4 mm and varies from 108.6 to 819.1 mm. (Fu et al., 2015; Jia et al., 2013). The soil types in the basin include aeolian sandy soil and sandic entisols. Poor soil structure is causing serious soil erosion (Wang et al., 2015; Tan et al., 2016). The soil in the test plot is aeolian sandy soil, and the soil physical and chemical properties are shown in *Table 1*.

Experimental materials and crops

A local spring maize (the type of maize grown in the region was spring sowing, harvested in autumn, and the region grows only one season of maize so that it is spring maize) was selected in this study. The species of tested maize was Dafeng 30, which came from Shanxi Dafeng Seed Industry Co., Ltd. The tested nano-biochar was a black powder produced by Shanghai Hainuo Carbon Industry Co., Ltd. The nano-biochar diameter was 40 nm, and was carbon powder made of coconut shells, carbonized at high temperature, activated by water vapor and refined by ultrafine grinding at nanometer level. It had rich micropore structure, strong specific surface area and strong absorbability, which can load soil microbes and nutrients. The biochar had a pH of 9.6, a water content of ≤ 5 and volume density of 0.38 g/cm^3.

Experimental design

The experiment was performed from March 2016 to July 2018, which have three consecutive growing seasons. The plot size of 3 m × 3 m was allocated for each treatment. Different concentrations of nano-biochar (0, 0.1%, 0.5%, 0.7%, 1%) were banded at 5-10 cm under the soil surface.

The nano-biochar was added to the soil by removing the top 5 cm of soil, mixing the nano-biochar with soil at 5-10 cm depth, then replacing the previously removed top 5 cm of soil. To monitor the water content at different soil depths, five one-meter TRIME pipes were installed at the tested plot. A 3 m × 3 m protective net was arranged on the periphery of each test plot to prevent farm livestock and wild animals from interfering with the

DOI: http://dx.doi.org/10.15666/aeer/1802_28632877

plots. The row width and the plant-to-plant distance were 50 cm and 25 cm. In replicates of two for each treatment, total of 10 experimental plots were established.

Table 1. *The soil physical and chemical properties of experimental field*

Soil	Particle content (%)			pH	$CaCO_3$ (%)	Organic matter ($g \cdot kg^{-1}$)	Total nitrogen ($g \cdot kg^{-1}$)	Total phosphorus ($g \cdot kg^{-1}$)
	Clay (<0.001 mm)	Silt (0.05-0.001 mm)	Sand (>0.05 mm)					
Aeolian sandy soil	15.70	37.47	46.83	8.0	4.31	5.32	0.82	0.61

The maize seeds were washed with 10% H_2O_2 for 30 min before sowing. After rinsing with water, the spring maize seeds were soaked in saturated calcium sulfate ($CaSO_4$) solution for 4 h, and were transferred to gauze soaked with saturated $CaSO_4$, covered with black plastic film at 25 ℃ to accelerate germination. The seeds were sowed after the radicals appeared. Before sowing, nitrogen fertilizer (N) 1.458 kg, phosphate fertilizer (P_2O_5) 0.874 kg, potassium fertilizer (K_2O) 0.874 kg were evenly applied in each plot. The field was irrigated before sowing but not after. The sowing depth was 3-5 cm.

Date collection and calculations

Initial and post-sowing soil nutrients throughout the experiment were measured. The soil moisture characteristic curve was determined by using the H–1400 pF soil moisture characteristic curve measurement system produced by Kokusan in Japan. The soil water stable aggregates were determined by a wet sieving apparatus (wet screening device) produced by Eijkelkamp in Netherlands. At different growth stages of maize (seedling stage; shooting stage; tasselling stage; filling stage; and maturation stage), the soil moisture content at different soil depths was measured. Five maize samples (roots, stems and leaves intact) were randomly selected to measure plant nutrients. Soil moisture evapotranspiration in the soil profile was measured by micro-lysimeter. At the same time, five points were randomly selected in each plot to collect soil samples. The plant N content was determined by the salicylic acid-zinc powder reduction method. The plant phosphorus content was measured by the molybdenum antimony colorimetric method. The plant potassium content was measured by flame photometer. The stem diameter and plant height of the crops was measured by caliper and ruler. After the crop was mature, its production was recorded according to the degranulation of the plot.

The result use Microsoft Excel, IBM Spss10.1 software and Origin function drawing software for statistical analysis, and charting of relevant parameters, single factor variance analysis for significance test (95% confidence interval).

Results and discussion

Effects of nano-biochar on the physical and chemical properties

Effects of nano-biochar on the soil water characteristic curves

The soil water characteristic curves of eolian sandy soil with different nano-biochar content are shown in *Figure 1*. *Figure 1* shows that under the same soil moisture content, the water suction increased with increasing nano-biochar contents. The soil moisture

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28632877

content in soil with higher nano-biochar contents was higher than in lower nano-biochar contents, and the control, at equivalent soil water suction. Similar results regarding nano-biochar effects on soil water capacity have been reported (Fan et al., 2014 and Han et al., 2010). This is because the addition of nano-biochar decreases the number of large pores and increases the number of small pores in the soil. When the suction is applied, the water in the small pores is less affected by the external suction compared with the large pores. The nano-biochar also has a large specific surface area, high surface energy, and a high water retention force. Therefore, nano-biochar has potential to promote root water absorption and improve the water retention of sandy soil.

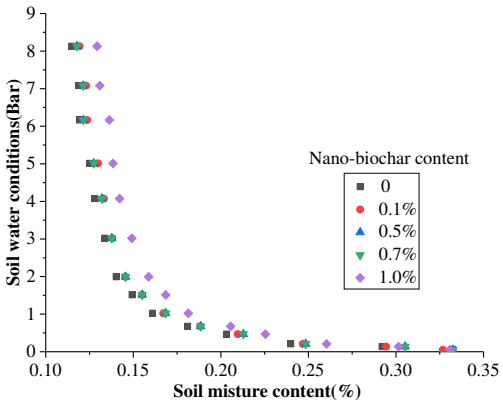

Figure 1. *The effect of different nano-biochar content on the soil water characteristics curve*

Effect of nano-biochar on soil water stable aggregates

The influence of nano-biochar application on soil water stable aggregates was determined and the results are presented in *Table 2*. From *Table 2* it was shown that with increases of nano-biochar content in soil, soil aggregates with particle sizes < 0.25 mm were reduced from 38.21 to 24.33%, while soil aggregates with particle size > 2 mm increased from 0.69 to 37.12%. The content of soil aggregates with particle size > 2 mm had the greatest increases with nano-biochar application, showing the ability of nano-biochar to improve soil aggregation. Nano-biochar mass contents of 0.7% and 1% had the greatest effects on improving soil water-stable aggregates. Different materials (e.g., minerals, organic matter) with various molecular sizes and chemical characteristics attach to nano-biochar surfaces, and this reduces the nano-biochar's surface area at a molecular scale, thus serving as the binding agents for the formation and stability of soil aggregates (Liang et al., 2006; Bossuyt et al., 2001). The nano-biochar enhanced the formation and stabilization of the soil macroaggregates, especially in sandy loam soil (Six et al., 2004; Liu et al., 2015).

Table 2. *The influence of nano-biochar content on the soil water stable aggregate*

Soil particle size analysis (mm)	**Nano-biochar content**				
	0	**0.10%**	**0.50%**	**0.70%**	**1%**
< 0.25	38.21%	33.38%	30.48%	26.47%	24.33%
0.25 ≤ d < 0.5	44.85%	40.52%	36.14%	31.53%	28.74%
0.5 ≤ d < 2	16.25%	12.96%	13.66%	11.16%	9.81%
> 2	0.69%	13.14%	19.72%	30.84%	37.12%

Effects of nano-biochar on water and fertilizer utilization rates of maize

Effects of nano-biochar on soil moisture content in the soil profile

The effects of different nano-biochar concentrations on the soil moisture content is shown in *Figure 2*. From *Figure 2* it is shown that the soil moisture content amended with nano-biochar was significantly higher than in the control, especially in the maize seedling and shooting stages. Within 10 cm of the soil surface, the soil moisture content changed slightly, and it gradually increased with increasing soil depth. At soil depths of 10–30 cm, the soil moisture content increased rapidly. At soil depths of 30–35 cm, soil moisture content gradually stabilized. The surface soils had the lowest soil moisture content because they were affected by high rates of evapotranspiration. With increasing soil depth, the soil moisture content gradually increased. Ouyang et al. (2013) concluded that amending soil with biochar affected the shape of soil water retention curves. Itabari et al. (1993) and Shukla et al. (2012) found that below field capacity, higher soil moisture content in the 0–20 cm soil layer resulted in faster emergence of maize. Biochar added to soil reduces the number of macro-pores, increases the number of small pores and increases the water-holding capacity of the soil. Ahmed et al. (2018) indicated that biochar amended to soil at rates of 1% and 3% increased soil moisture content at field capacity. The results suggest that the application of nano-biochar to soil has potential to greatly improve the water-holding capacity of farmland which may increase the emergence rates of maize.

Effects of nano-biochar on soil nitrate

Optimal amounts of nitrogen fertilizer to maize crops can promote absorption and use of nitrogen, thereby increasing maize biomass and yield. At the seedling stage of spring maize, the horizontal and vertical distribution of roots is small, root hairs are fine, and root density is sparse. These root characteristics limit the uptake capacity of nitrogen from soil by maize. We observed that the difference between initial and after sowing measurements of soil nitrate were small, and the nitrate content was high (*Fig. 3*). During the shooting and tasselling stages, the growth and development rate of spring maize increased as the root system increased in size and density. Some of the nitrogen in the soil was absorbed by maize roots and some was transported to the deeper soil layers. These factors resulted in a decrease in soil nitrogen content and greater differences in nitrate between the initial and after sowing measurements. At the grain filling and maturation stages, the growth and development of maize was complete and the rate of nitrogen absorption decreased. The differences in nitrogen between filling and maturation stages were smaller than between the jointing and heading stages. Further analysis of *Figure 3* shows that the soil nitrate differences in the plots amended with nano-biochar at rates of 0.7% and 1% were smaller than the control group. At the advanced stages of spring maize growth, the differences in nitrate in the soil profile decreased as the nano-biochar contents increased. This indicated that under a consistent crop, the presence of nano-biochar decreases the rate of nitrogen transported to the deep soil (Albiter et al., 2010). Excessive nitrogen application causes the accumulation of nitrate in the soil and increases the risk of nitrate leaching (Zhang et al., 2010). Dempster et al. (2016) found that biochar application increased nitrate adsorption. Therefore, banding nano-biochar at 5–10 cm below the surface can inhibit nitrate leaching and increase nitrogen use efficiency in fertilized soils.

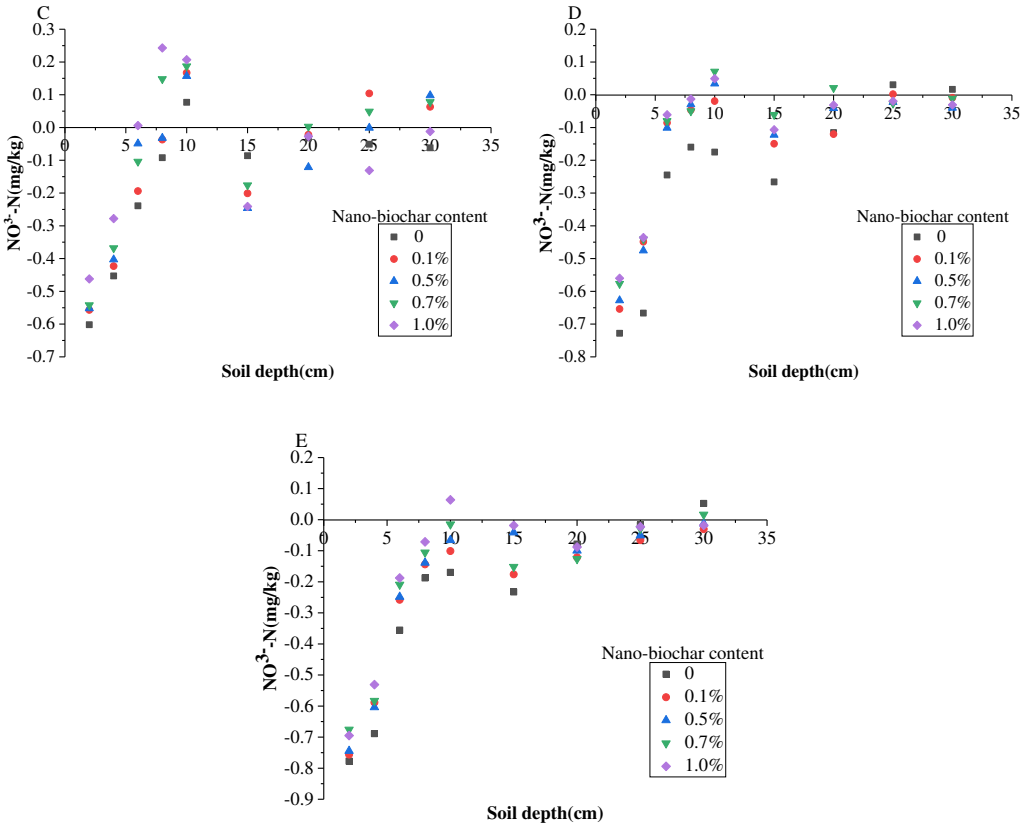

Figure 3. *The effect of different nano-biochar content of soil nitrate content: (A) seedling stage; (B) shooting stage; (C) tasselling stage; (D) filling stage; (E) maturation stage*

Nano-biochar effects on soil available potassium

The differences in potassium content in the soil profile at different growth stages of spring maize are shown in *Figure 4*. At 0–10 cm soil depth, the amount of available soil potassium in nano-biochar amended soil was higher than in the control. In the 5–10 cm soil layer, the average available potassium content in soil amended with nano-biochar at rates of 0.7% and 1% increased by 11.1% and 22.6% compared to the control, respectively, during the tasselling stage. During the early stages of spring maize growth, low amounts of potassium were absorbed by the plants. With the growth and development of spring maize, the uptake of potassium by plant roots gradually increased. At the filling and maturation stages, the growth of spring maize ended and the rate of potassium absorption decreased. Liu et al. (2012a) concluded that when nano-biochar was added to compost, plant-available Ca, K, P, and Na contents increased by a factor of 2.2, 2.5, 1.2, and 2.8, respectively. By increasing the availability of micro-nutrients like potassium in soil, nano-biochar can promote soil fertility (Dong, et al., 2016). When adsorption is poor, available potassium is highly mobile in the soil (Rens et al., 2018). The agglomeration of nano-biochars on soil particles increased the number of small soil pores thus inhibiting the longitudinal migration of potassium ions. This increases the residence time of the available potassium ions in the nano-biochar layer, and ensures high concentrations of potassium ions in the root layer. By doing so, this improves potassium use by spring maize.

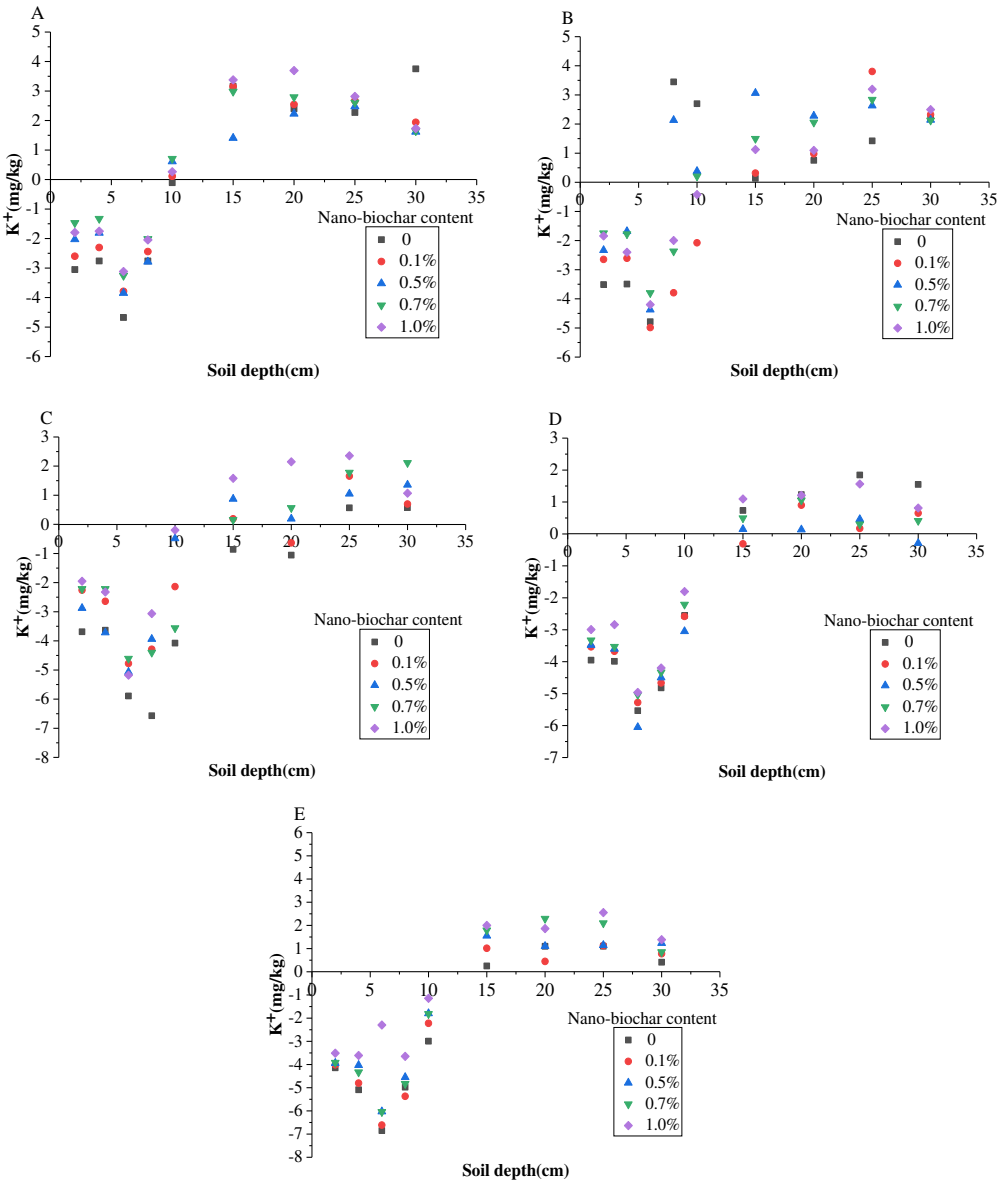

Figure 4. *The influence of nano-biochar content on soil potassium content: (A) seedling stage; (B) shooting stage; (C) tasselling stage; (D) filling stage;(E) maturation stage*

Nano-biochar effects on soil available phosphorus

The effects of nano-biochar content on soil available phosphorus in spring maize at different growth periods are shown in *Figure 5*. Available soil phosphorus concentrations of each treatment were lower in the measurements made after sowing than the initial measurements. There were few differences in soil phosphorus concentrations between each growth period. In the 0–5 cm soil depth, the differences in soil available phosphorus between the initial and after sowing measurements in nano-biochar amended soil were smaller than in the control group. The variation of the differences between the initial and after sowing soil concentrations decreased with increased nano-biochar concentrations. At 10–35 cm soil depth, available soil phosphorus variation was low, but the differences in available soil phosphorus initial

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28632877

and after sowing measurements in each treatment fluctuated greatly. This suggests that the ability of soil to maintain available phosphorus in the upper layers was greater when soil was banded with nano-biochar, and the ability to regulate available phosphorus in the soil below the carbon layer was limited. In soil, available phosphorus is easily adsorbed by soil particles; phosphorus has strong stability and weak mobility (Sharma et al., 2015; Petr et al., 2011). The soil available phosphorus contents increased with increasing amounts of applied biochar (Arif et al., 2017). Biochar amendments to degraded soils have been shown to improve crop yield and soil quality (Novak et al., 2009). Nano-biochar can significantly improve the inherent soil physical and chemical properties, increasing the proportion of large particles and reducing the soil porosity. A large amount of phosphorus was stabilized in the root zone where nano-biochar was banded because the phosphorus was absorbed to soil particles. This increased the content of phosphorus available for spring maize in the root zone.

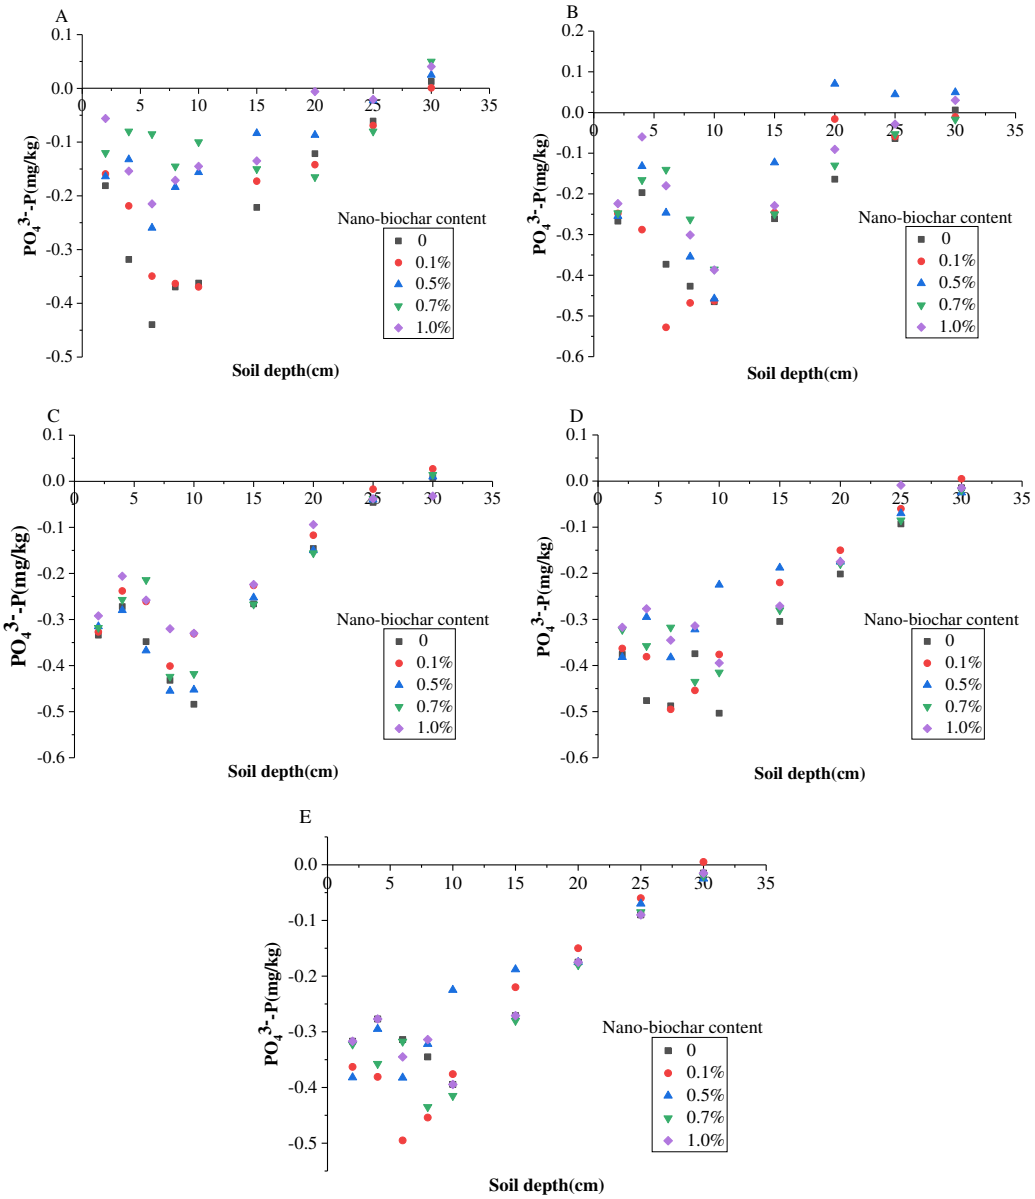

Figure 5. *The influence of nano-biochar on soil phosphorus content: (A) seedling stage; (B) shooting stage; (C) tasselling stage; (D) filling stage; (E) maturation stage*

DOI: http://dx.doi.org/10.15666/aeer/1802_28632877

The effects of nano-biochar on growth traits of spring maize

The effects of nano-biochar on plant nutrients

The effects of nano-biochar content on spring maize root, stem, leaves and nutrients in each growth period are summarized in *Table 3*. As shown in *Table 3,* there is a significant correlation between each factor of different nano-biochar contents; the P-value < 0.01, indicating that each factor has a very significant effect on the test results. Visible, the application of nano-carbon in the soil has an important effect on maize growth. The roots, stems, leaves and other organs had the highest nutrient demand during the shooting stage. Nutrient uptake and accumulation rates in the shooting stage were higher than the tasselling, filling and maturation stages. After the shooting stage, the accumulation of nitrogen, phosphorus and potassium in spring maize plants gradually decreased. Adding nano-biochar to the soil resulted in strong adsorption of nano-biochar to soil nutrients which inhibited the vertical migration of nitrogen. This increased the plant nitrogen concentrations because it promoted nitrogen absorption from the soil by the spring maize, and then nitrogen was transported from the roots to other parts of the plant. Therefore, the spring maize in the nano-biochar amended plots had high concentrations of nitrogen.

Table 3. *The influence of nano-biochar content on spring maize nutrient content*

N = available nitrogen; P = available phosphorus; K = available potassium

The amount of phosphorus absorbed by spring maize plants was lower than that of nitrogen and potassium. Applying phosphate fertilizer to soil can result in the accumulation of high concentrations of phosphorus in surface soils which cannot be

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28632877

effectively converted into plant-available forms of phosphorus (Turtola et al., 1999). At different growth stages in nano-biochar amended soil, the phosphorus content of spring maize plants was higher than the control group, indicating nano-biochar can promote phosphorus leaching and the absorption of phosphorus by spring maize roots.

With strong mobility and water solubility of potassium ions in soil, its content is higher than nitrogen and phosphorus. This is why we observed that the accumulation of available potassium was larger than nitrogen and phosphorus in the plant during the growth period of spring maize. However, soil adsorption of potassium ions is poor, so water-soluble potassium ions tend to migrate downward into the soil. Following banding, the nano-biochar adsorbed potassium and the longitudinal migration rate of potassium in the soil decreased, which extended the retention time of potassium in the root soil layer of spring maize.

Spring maize biomass accumulation and yields are closely related to the accumulation of plant nutrients. After the jointing stage, the growth and development of spring maize organs accelerates, and the absorption and accumulation rate of nutrients also greatly increases (Qin et al., 2012). We noted the accumulation of plant nutrients increased continuously throughout the whole growth period. The soil nitrogen and potassium contents were highest at the filling stage, and the soil phosphorus content were highest at the maturation stage. Nutrient accumulation in the spring maize plants was the product of soil nutrient availability and plant biomass requirements. During the spring maize growth period, the nutrient content of crops tended to decline while the nutrient accumulation tended to increase.

Figure 6 summarizes the accumulation of nitrogen, phosphorus and potassium in spring maize plants for each nano-biochar treatment during each spring maize growth period. As shown in *Figure 6,* plant accumulation of nutrients increased rapidly after the shooting stage, the accumulation of nitrogen and potassium were highest at the filling stage, and the accumulation of phosphorus was highest at the maturation stage. In each growth stage, nano-biochar had a significant effect on the absorption of nutrients in spring maize, with the greatest accumulation of nutrients associated with 0.7% and 1% nano-biochar treatments.

The effects of nano-biochar on spring maize growth and yield

Table 4 shows the effects of nano-biochar contents on growth indicators of spring maize in every growth stage. As shown in *Table 4,* in the plots with higher nano-biochar content, the plant height, stem diameter and leaf area of spring maize (0.7% and 1%) were significantly higher than those in the control group in the same growth stage. Over the spring maize life-cycle, the plant height and leaf area increased, but the basal stem diameter first increased and then decreased. This was attributed to the vigorous growth of spring maize at the shooting stage when a large amount of water was absorbed by the roots and transported upward. During this time, spring maize was more inclined to radial development, which weakened the horizontal growth.

Table 5 shows the effects of nano-biochar content on maize yields. Based on *Table 5,* there was a significant correlation between the 1000-grain weight, yield and different nano-biochar contents; the P-value was less than 0.01, indicating that the application of nano-carbon in the soil has an important effect on maize yield. The plots with higher nano-biochar content (0.7% and 1%) had significantly greater 1000-grain weight and yield than the control. Compared with the control group, the yield of 0.7% and 1% nano-biochar treatment plots were 4.4% and 5.7% greater, respectively.

Conclusion

The study tested different rates of nano-biochar application and analyzed the subsequent effects on physical and chemical properties of soil, soil water characteristics, fertilizer use and growth characteristics of spring maize in the field. The results indicated that banding nano-biochar in the root zone slightly increased soil bulk density. Amending soil with nano-biochar increased soil aggregates with the soil particle size > 2 mm from 0.69 to 37.12%, and nano-biochar application rates of 0.7% and 1% had the greatest effects on improving soil water-stable aggregates. The band of nano-biochar in the soil inhibited the movement of soil moisture to the deep soil and decreased evapotranspiration. It also improved nutrient retention and delayed the leaching of nitrogen, phosphorus and potassium in soil. Nano-biochar also prompted spring maize uptake of soil nutrients. Maize grown in soil amended with nano-biochar had significantly greater plant height, stem diameter and leaf area than those grown in soils without nano-biochar. The plot with the highest nano-biochar contents (0.7% and 1%) has the greatest 1000-grain weights and yields. Compared with the control group, the yields of 0.7% and 1% nano-biochar were increased by 4.4% and 5.7%, respectively. Nano-biochar has an obvious effect on soil improvement and crop growth, but its application is slightly complicated. In order to promote the large-scale popularization of this method on Loess Plateau, how to simplify the method is still the key problem we should consider.

Abstract. In this paper, the effect of nitrogen application on nitrate reductase activity of the Sidan 19 maize (*Zea mays* L.) cultivar was studied. The Sidan 19 maize is a medium maturity maize single variety, which is a hybrid of 44/4 (Huangzao4 improved line) as the female parent and Mo17 as the male parent. It has high average hectare yield, good early-onset, easy to catch seedlings and other excellent properties, so it was selected as a model plant. In order to study the effect of nitrogen application on the activity of nitrate reductase in maize, the method of this paper is to prepare nitrate reductase, extract corn leaves, add trichloroacetic acid solution to stop the enzyme reaction, and use standard curve method to determine the content of maize nitrate reductase. The experimental results show that: (1) N application rate of nitrate reductase activity (NRA) was N300 > N200 > N100 > N0. (2) NRA activity of maize leaves was the lowest at the seedling stage, the highest at heading stage, and then decreased. Under 15% pec-6000 drought stress, 72 mmol/L salt stress and 72 mmol/L Saline-alkali stress, nitrate reductase activity of maize leaves and roots was the highest. (3) Under the same amount of nitrogen application, the nitrate reductase activity of maize roots increased, and the nitrate reductase (NR) activity of leaves was higher than that of roots under the same stress effect. (4) Under the same amount of nitrogen application, the nitrate reductase activity of maize leaves was the highest. At nitrogen levels of N_0, $N_{0.1}$ and $N_{0.5}$, the activity of nitrate reductase enzymes in roots of each treatment from highest to lowest were sodium nitrate > urea > ammonium chloride. It showed that the activity of nitrate reductase increased with the increase of nitrogen application. The nitrate reductase activity of maize root was the highest at heading stage, and under low nitrogen condition.
Keywords: *single variety, model plant, trichloroacetic acid solution, standard curve method, heading stage*

Introduction

As the world's largest crop, maize is not only an important food crop, but also a feed and industrial raw material. It occupies an important position in the national economy (Zheng et al., 2018). Scientists have been working to increase their production and productivity in order to solve the food problem and the shortage of feed and industrial raw materials in China (Helmers et al., 2017). At present, with the increase of population, the expansion of animal husbandry and the shortage of energy, the total demand for crop production in the market are increasing day by day, and the demand for grain in China is increasing rigidly. At present, the number of cultivated lands in China is decreasing year by year, so improving the unit yield is one of the key measures to solve the food shortage (Russo et al., 2017). The increasing dependence of high-yielding varieties on chemical fertilizers, especially nitrogen fertilizers, has resulted in the increasing use of nitrogen fertilizers in China (Li et al., 2017). Excessive application of nitrogen fertilizer resulted in low efficiency of nitrogen fertilizer use in maize production in China, resulting in a large amount of nutrient loss to the environment and serious environmental problems (İlhan et al., 2018). How to improve the utilization rate of nitrogen fertilizer, reduce the loss of nitrogen fertilizer and the environmental

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28792894

pollution caused by the application of nitrogen fertilizer in maize under the current difficult conditions is a difficult problem to be solved urgently in the maize planting industry (Juárezhernández et al., 2017). Breeding and screening nitrogen-efficient maize varieties is one of the main ways to solve the problems of food shortage, shortage of arable land and environmental pollution (Zhang et al., 2017). It is the premise and basis for breeding maize varieties with high nitrogen efficiency to study the nitrogen uptake regularity and identify and excavate candidate genes for high nitrogen efficiency (Iqbal et al., 2017). Nitrate reductase, as an important inducible enzyme in nitrogen metabolism of maize, is the first rate-limiting enzyme in the process of nitrogen uptake and utilization. Nitrate reductase plays a key biological role in the process of efficient nitrogen utilization in maize (Kang et al., 2017).

In the process of plant growth and development, many biological metabolic reactions, such as N metabolism, are involved. N is one of the essential elements in plants. N is an important factor in plant metabolic system related to yield. Nitrate, ammonia and amino acid are the three main forms of nitrogen uptake by plants, and nitrate is the most important form of nitrogen uptake. When external nitrogen enters plants, ammonia, amino acids and amides are formed in turn, and then they participate in the biosynthesis of other living substances for plant growth, development and metabolism (Li, 2017). Nitrate reductase plays an important role in plant nitrogen uptake and development. As a key enzyme, nitrate reductase plays an important role in plant nitrogen uptake and assimilation. Its activity can directly reflect the status of plant nitrogen uptake and utilization (Liu et al., 2018). The results showed that nitrate reductase activity was affected by environmental factors such as water, nitrate concentration, light, carbon dioxide, molybdenum and temperature, and exogenous hormone analogues such as cytokinin, abscisic acid, indole-3-acetic acid, gibberellin and ethephon could affect nitrate reductase activity (Sui et al., 2017). Nitrate reductase was found in all tissues of maize, but its activity was the highest in maize leaves. Nitrate reductase activity has an important impact on the utilization of nitrate nitrogen, is an important basis for crop selection of nitrogen fertilizer, and is also one of the breeding indicators for crop nitrogen efficient utilization (Castillogodina et al., 2018). The main content of this paper is to study the effect of nitrogen application rate on nitrate reductase activity of maize, so as to improve crop yield, avoid nitrogen loss, promote the development of agricultural technology and promote the progress of agricultural economy. Therefore, it is necessary to study the effect of nitrogen application rate on nitrate reductase activity of maize.

Materials and methods

This study was carried out in the experimental site of Sichuan Agricultural University in 2019. The GPS coordinates are N29° 58′ 54.23″ north latitude and E102° 59′ 57.54″ east longitude. The experimental variety is Sidan 19, and the sowing time is July. The method of sowing or strip sowing is adopted, the temperature is 20 °C, the water is sufficient, and the time is 5-7 days. The nutrient content of the soil is shown in *Table 1*.

Effects of different amounts of pure ammonia fertilizer on nitrate reductase activity in maize

Fixed the amount of phosphorus and potassium, four nitrogen fertilizer treatments were set up in the experiment:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28792894

(1) N0: no nitrogen fertilizer
(2) N100: 100 kg of pure nitrogen per hectare
(3) N200: 200 kg of pure nitrogen per hectare
(4) N300: 300 kg of pure nitrogen per hectare

The experiment was designed by random block design and repeated three times. The length of residential area is 5 m and the distance of 6 rows is 70 cm.

Table 1. *Nutrient content of soil*

Organic matter content	2.56%
Total nitrogen	0.134
Total phosphorus	0.064
Slowly available potassium	98
Hydrolyzable nitrogen	146.2
Available phosphorus	44.78
Available potassium	143.2
pH value	6.62

Effects of different proportion of nitrogen fertilizer applied by stages on nitrate reductase activity in maize

The total amount of chemical fertilizer application is fixed, which is pure N 370 mg/hm^2, pure P_2O_5 150 kg/hm^2 and pure K_2O 150 kg/hm^2. Nitrogen fertilizer is applied in stages according to different proportions, as detailed in *Table 2*.

Table 2. *Distribution ratio of nitrogen fertilizer in different growth periods*

Handle	Base fertilizer	Topdressing at jointing stage	Topdressing at silking stage
N1	370	0	0

N4	222	148	0
N5	222	111	37
N6	222	74	74

Nitrate reductase activity in leaves and roots was measured at seedling stage, jointing stage, trumpet mouth stage, booting stage, silking stage, filling stage and maturity stage (Ma et al., 2017). The top fully unfolded leaves were selected before silking, and the ear leaves were selected after silking (Han et al., 2018), and the roots were selected to be measured at a distance of more than 1 cm from the root tip.

Effects of nitrogen fertilizer application rate on nitrate reductase activity in maize under different stress environment

Formulas of simulated solutions for different stress treatments are shown in *Table 3*. After 48 h of stress treatment, physiological indexes were measured (Wang et al., 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28792894

Table 3. *Formulas of solutions for different stress treatments*

Stress treatment	Ratio of nitrogen fertilizer	Solution formulation	Solution J_c (MPa)	Solution pH
Drought stress	Application of pure nitrogen per hectare 100 kg	Hoaglangsolution + 15% PEC-6000 (Actual site conditions)	-0.363	6.8
		Hoaglangsolution + 15% PEC-6000 (Water culture experiment)		
Salt stress	Application of pure nitrogen per hectare 100 kg	Hoaglang solution + 72 mmol/L NaCl (Actual site conditions)	-0.363	6.7

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28792894

Method of determination

(1) Nitrate reductase production (Hwang et al., 2018) could be induced by adding 50 mmol/L KNO_3 or $NaNo_3$ to the water of maize seedlings one day before sampling.

(2) 0.5 g of maize leaves were weighed (three parts were cut into about 1 cm segments) and put into three triangular bottles, one of which was used as control, and the other two were used for enzyme activity determination (Song et al., 2017).

(3) Reaction: First add 1 mL 30% trichloroacetic acid solution to the control triangle bottle, then add 9 ml 0.1 moL/L KNO_3 solution to each triangle bottle. After mixing, put it into the dryer immediately, and exhaust for 30 min (during several times, air is injected, then vacuum is pumped to make the blade sink completely into the bottom of the bottle, and then react in 25-degree darkness for half an hour, respectively (Ahamed et al., 2017). 1 m 130% trichloroacetic acid was added to the determination bottle (except the control bottle) to terminate the enzyme reaction.

(4) Colorimetric determination: Shake each bottle for 2 min, take 2 mL reaction solution, add 1 mL sulfonamide, shake well, add 1 mL vinylamine, and then color in 35 water baths for 15 min, and then colorimetric 540 nm.

(5) Blank solution: 2 mL distilled water + 1 mL sulfonamide, the same as the sample solution for 15 min.

Nitrate reductase activity in maize was determined by standard curve method (Johansson et al., 2017). The content of NO_2^- ($\mu g/\mathrm{mL}$) was detected from the standard curve, and the activity of nitrate reductase in maize was expressed by the amount of NO_2^- produced per gram fresh weight per hour. The calculation method was as follows:

$$\text{Enzymatic activity} \quad \left[\mu g/(g\cdot h)\right]=\frac{(C_1-C_0)\times V_t}{FW\times t\times V_s} \qquad \text{(Eq.1)}$$

In the formula, C_0 and C_1 are the amount of NO_2^- obtained from the standard curve ball at the beginning of the test and in the course of the test respectively; V_t is the total volume of the reaction liquid; V_s is the sampling volume at the time of determination; FW is the fresh weight; t is the reaction time.

Results

In order to further verify the effect of nitrogen application rate on nitrate reductase activity of corn, relevant test experiments need to be carried out. The research content of this experiment is as follows: effect of pure nitrogen fertilizer application rate on nitrate reductase activity in maize at different growth stages, effects of different proportion of nitrogen fertilizer applied by stages on nitrate reductase activity in maize, effects of nitrogen fertilizer application rate on nitrate reductase activity in maize under different stress environment and effects of nitrogen fertilizer varieties and nitrogen fertilizer dosage on nitrate reductase activity in maize. The experimental environment is shown in *Figure 1.*

Effect of pure nitrogen fertilizer application rate on nitrate reductase activity in maize at different growth stages

After analyzing the effect of nitrogen fertilizer application rate on nitrate reductase activity in maize at different growth stages, the results are shown in *Figure 2*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28792894

Figure 1. *Experimental environment diagram*

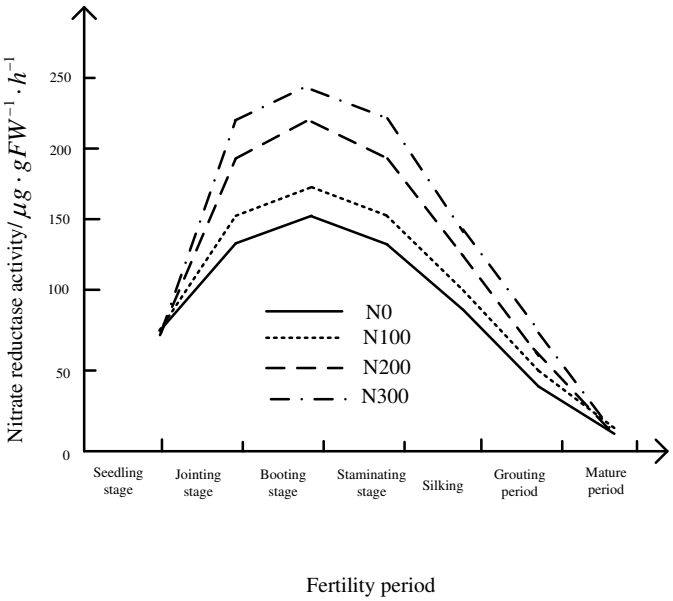

Figure 2. *Effects of nitrogen fertilizer application rate on nitrate reductase activity in maize at different growth stages*

The activity of nitrate reductase changed with the amount of nitrogen. The activity of nitrate reductase showed a single peak curve during the whole growth period. With the advancement of fertility process, it gradually increases and then decreases after reaching the peak. Nitrate reductase activity increased with the increase of nitrogen application (Yang et al., 2017). Nitrate reductase activity increased rapidly after jointing stage, reached its peak at booting stage, decreased gradually from booting stage to maturity stage, and decreased after heading stage.

After analyzing the effect of nitrogen application rate on nitrate reductase activity in ear leaves of maize during grain filling, the results are as shown in *Table 5*.

Table 5 shows that nitrate reductase activity in ear leaves of maize decreases gradually with the advance of grain filling, and increase with the increase of nitrogen nutrition level. From 7 to 49 days after silking, the activity of nitrate reductase was N300 > N200 > N100 > N0. With the increase of nitrogen fertilizer application rate, the nitrogen metabolism of maize maintained a high level at the later growth stage.

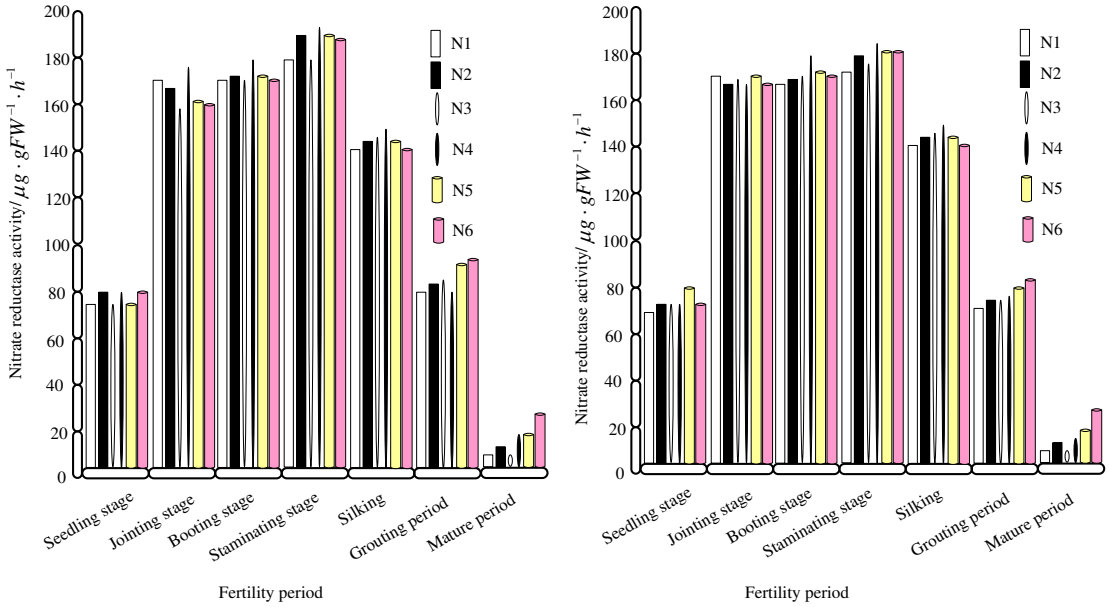
Effects of different proportion of nitrogen fertilizer applied by stages on nitrate reductase activity in maize

(1) Effect of different proportion of nitrogen fertilizer on nitrate reductase activity in maize leaves

The effects of different proportion of nitrogen fertilizer on nitrate reductase activity in maize leaves were analyzed. The results are shown in *Figure 3*.



(a) 85 thousand/plant hm^2 (b) 95 thousand/plant hm^2

Figure 3. *Effects of different proportion of nitrogen fertilizer applied in stages on nitrate reductase activity in maize leaves*

Figure 3 shows that nitrate reductase activity is lower at seedling stage and reaches the maximum at male-drawing stage, then it shows a downward trend, and changes in a single peak curve during the whole growth period. Because the male-drawing stage is the key period for the morphological formation of maize reproductive organs, carbon and nitrogen metabolism is the most vigorous, and nitrate reductase activity is the highest in the male-drawing stage, so a large number of nitrates can be assimilated into leaves to meet the needs of crop growth and development.

Nitrate reductase activity changed with the application ratio of nitrogen fertilizer at different growth stages. Nitrate reductase activity of maize leaves treated with N6

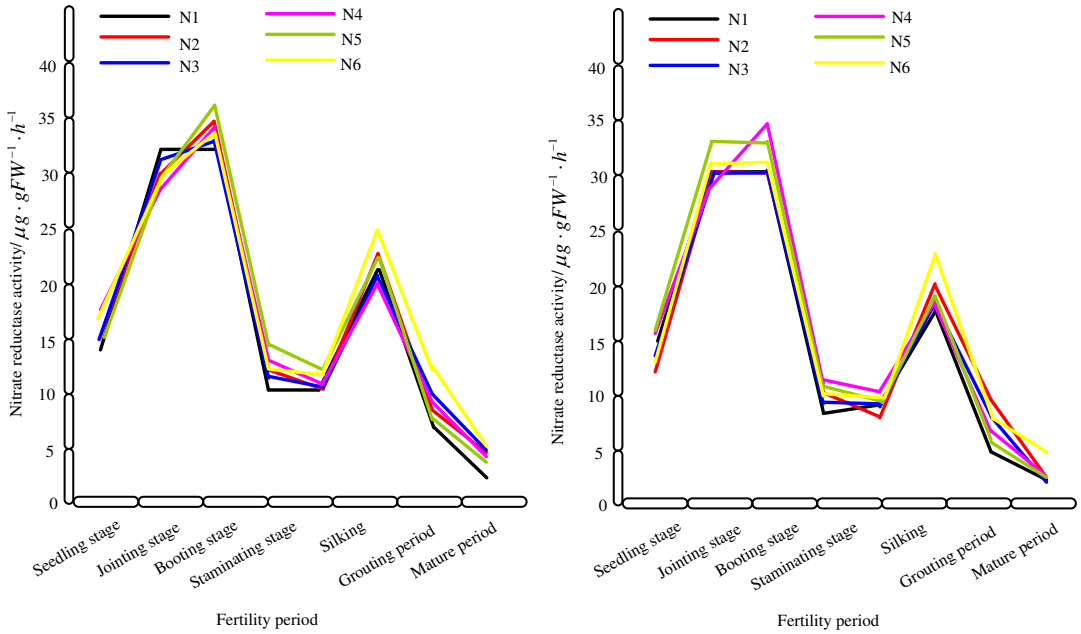
http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28792894

maintained higher activity of nitrate reductase than that of other treatments in the process of decreasing from silking stage (Chelladurai, 2017). Nitrogen metabolism in maize is an integral part of photosynthesis, which determines the accumulation of dry matter and has an important impact on yield.

By comparing the changes of nitrate reductase activity in maize leaves under two planting densities, it can be seen that the nitrate reductase activity of maize leaves under 85,000 thousand/plant hm^2 density and 95,000 thousand/plant hm^2 density had little difference at seedling and jointing stages, and the nitrate reductase activity under 85,000 thousand/plant hm^2 density began to be higher than 95,000 thousand/plant hm^2 from booting stage, indicating that the activity of nitrate reductase in the leaves of high-density planted maize was lower.

(2) The effect of different proportion of nitrogen fertilizer applied by stages on nitrate reductase activity in maize roots

After analyzing the effect of different proportion of nitrogen fertilizer on nitrate reductase activity in maize roots by stages, the results are shown in *Figure 4.*



(a) 85 thousand /plant hm^2 (b) 95 thousand/plant hm^2

Figure 4. *Effects of different proportion of nitrogen fertilizer on nitrate reductase activity in maize roots*

From *Figure 4,* it can be seen that the nitrate reductase activity in roots changes in a bimodal curve with the development of the growth process. It is highest at booting stage, then decreases sharply, and begins to rise after silking stage, and then decreases after the second peak at grain filling stage.

Nitrate reductase activity in roots varied with the proportion of nitrogen fertilizer applied in different growth stages. Nitrate reductase activity was the highest in N4 treatment at booting stage.

Before booting stage, the nitrate reductase activity in maize roots had little difference between the two densities (Sarkar et al., 2017). From booting stage, the nitrate reductase

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28792894

activity of 85,000 thousand/plant hm^2 densities were higher than 95,000 thousand plant/hm^2.

Effects of nitrogen fertilizer application rate on nitrate reductase activity in maize under different stress environment

Nitrate Reductase (NR) is an important regulator and rate-limiting enzyme in plant nitrogen metabolism. NR plays an important role in plant growth and development, yield formation and protein content. NR activity is induced by substrates and is influenced by many other environmental factors. The effects of nitrogen application rate on nitrate reductase activity in maize under different stress environments, as shown in *Table 6*.

Table 6. *Effects of nitrogen fertilizer application rate on nitrate reductase activity in maize under different stress environments*

Stress treatment	NR activity/ $\mu g \cdot gFW^{-1} \cdot h^{-1}$		Activity ratio
	Root system	Blade	
Contrast	36.52 ± 3.10	106.22 ± 6.77	65.6
15% PEC-6000	37.70 ± 2.00	34.00 ± 4.99**	-9.8
72 mmol/L NaCl	61.96 ± 5.24**	38.93 ± 2.24**	-59.2
72 mmol/L	142.58 ± 8.40*	43.2 ± 3.00**	-230.0

* Activity ratio (%) = (leaf NR activity - root NR activity), leaf NR activity 100; ** t test reached a very significant level

Table 6 shows that the nitrate reductase activity of maize roots increases under different stress environments with a certain amount of nitrogen fertilizer. In 72 mmol/L saline-alkali stress environment, the increase of NR activity was 69.7% compared with the control, and the t test also reached a very significant level (Ramezani et al., 2017). In 15% PEC-6000 drought stress environment, the increase of NR activity was the smallest, which was 3.2% higher than the control, and t test was not significant. For comparison, we also measured the NR activity of maize seedling leaves under the same stress conditions as the root. As shown in *Table 6,* NR activity in leaves was higher than that in roots, reaching 106.22 $\mu g \cdot gFW^{-1} \cdot h^{-1}$, which was 2.9 times higher than that in roots. However, NR activity in leaves decreased significantly under different stress environments, and reached a significant level by t-test analysis compared with the control values. The NR activity ratios of roots treated with the same treatment were - 9.8% under drought stress, - 59.2% under salt stress and - 230.0% under salt stress, respectively. The results showed that leaf NR activity stress was greater than root NR activity stress under the same stress.

Effects of nitrogen fertilizer varieties and nitrogen fertilizer dosage on nitrate reductase activity in maize

(1) The effect of different nitrogen fertilizer varieties and dosage on nitrate reductase activity in maize leaves

Figure 5 is a comparative study of nitrate reductase activity in maize leaves under different nitrogen fertilizer varieties and nitrogen levels. The results showed that the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28792894

variety and amount of nitrogen fertilizer had significant effects on the activity of nitrate reductase in maize leaves.

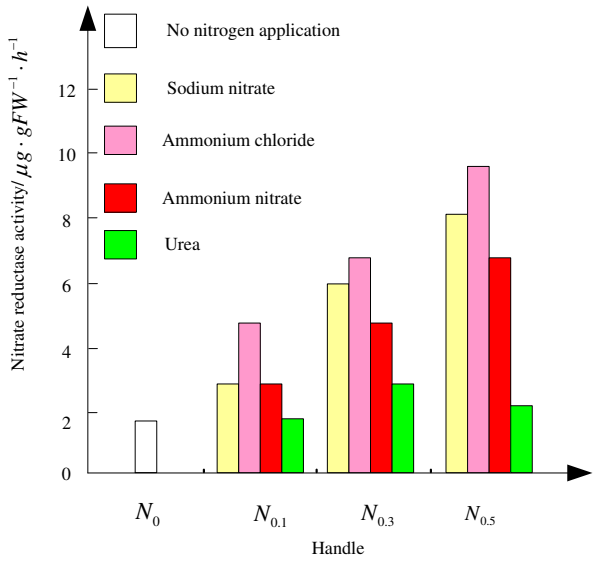


Figure 5. *Effects of different nitrogen fertilizer varieties and amounts on nitrate reductase activity in maize leaves*

Nitrogen fertilizer application could significantly increase the activity of nitrate reductase in maize leaves. The results showed that the nitrate reductase activity of maize leaves treated with sodium nitrate, ammonium chloride, ammonium nitrate and urea was higher than that of maize leaves without nitrogen application. The nitrate reductase activity of maize Treated with sodium nitrate increased significantly from $N_{0.1}$ to $N_{0.5}$, and increased 59.5%, 200.5% and 299.5% under three levels of nitrogen application compared with N_0, respectively. When the nitrogen supply level increased from N_0 to $N_{0.5}$, the nitric acid in leaves of maize Treated with ammonium chloride increased. The activity of nitrate reductase increased significantly with the increase of nitrogen application level. There was no significant difference in the activity of nitrate reductase between the treatments with ammonium nitrate application amount of N_0, $N_{0.1}$ and $N_{0.5}$, but the activity of nitrate reductase in leaves increased significantly with the further increase of nitrogen application amount of $N_{0.5}$. The activity of nitrate reductase in urea treatment was significantly higher than that in $N_{0.3}$ treatment. Compared with other nitrogen supply levels, the activity of nitrate reductase was 107.1%, 87.1% and 30.8% higher than that of N_0, $N_{0.1}$ and $N_{0.5}$, respectively. There was no significant difference in the activity of nitrate reductase between $N_{0.5}$ and $N_{0.1}$ levels.

Nitrogen fertilizer varieties also had a great influence on nitrate reductase activity. According to *Figure 5,* the difference of nitrate reductase activity in maize leaves treated with low-nitrogen $N_{0.1}$ was as follows: ammonium chloride > sodium nitrate > sodium nitrate > urea due to different varieties of nitrogen fertilizer. That is to say, when ammonium chloride was used as nitrogen source, the nitrate reductase activity of maize leaves was the highest, reaching 4.72 $\mu g \cdot gFW^{-1} \cdot h^{-1}$, and the value was 2.4 times of the control at this time. When urea was used as nitrogen source, the nitrate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28792894

reductase activity of maize leaves was the lowest, only 1.86 $\mu g \cdot gFW^{-1} \cdot h^{-1}$, which was 1.1 times of the control. The nitrate reductase activity of maize leaves treated with medium nitrogen $N_{0.3}$ and high nitrogen $N_{0.5}$ were the highest with ammonium chloride and sodium nitrate as nitrogen sources. There was no significant difference in nitrate reductase activity between the two nitrogen fertilizer varieties, and the nitrate reductase activity of maize leaves treated with four nitrogen fertilizer varieties was the same under the same nitrogen application level.

It can be seen that the nitrate reductase activity of leaves treated with nitrogen fertilizer increased to varying degrees, regardless of which nitrogen fertilizer variety was used as nitrogen source.

(2) Effects of different nitrogen fertilizer varieties and amounts on nitrate reductase activity in maize roots.

The effects of different nitrogen fertilizer varieties and amounts on nitrate reductase activity in maize roots are shown in *Figure 6*.

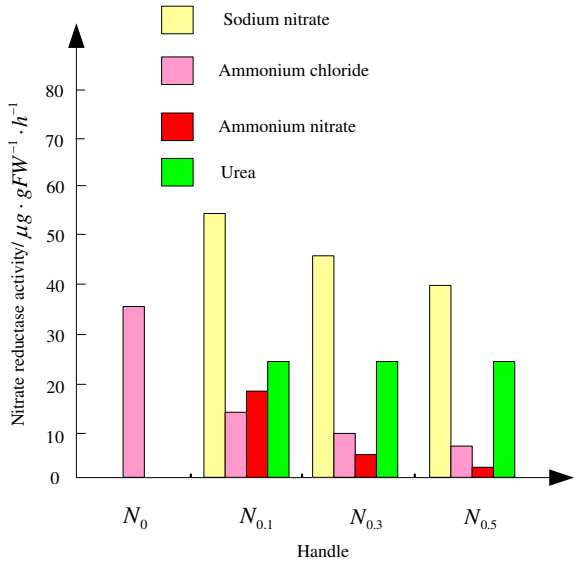

Figure 6. *Effects of different nitrogen fertilizer varieties and amounts on nitrate reductase activity in maize roots*

The results of *Figure 6* showed that the activity of nitrate reductase decreased with the increase of nitrogen fertilizer application. The nitrate reductase activity of roots treated with sodium nitrate increased in varying degrees compared with the control, while the nitrate reductase activity of roots treated with other three fertilizers was lower than that of the control. (1) Nitrate reductase activity was most affected by nitrogen application, which was significantly decreased under three levels of fertilization: $N_{0.1}$, $N_{0.3}$ and $N_{0.5}$; (2) Nitrate reductase activity in urea treatment was least sensitive to the amount of nitrogen application, and there was no significant difference among the four nitrogen treatments.

(3) The nitrate reductase activity of ammonium chloride and ammonium nitrate treatments was not significantly different under three levels of nitrogen application. The nitrate reductase activity of ammonium nitrate treatments of $N_{0.3}$ and $N_{0.5}$. were significantly lower than that of $N_{0.1}$.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28792894

The difference of nitrate reductase activity in roots caused by different nitrogen fertilizers was as follows: at the same level of nitrogen application, the nitrate reductase activity in roots of different treatments was sodium nitrate > urea > ammonium chloride, ammonium nitrate, ammonium chloride and ammonium nitrate, but there was no significant difference between the nitrate and urea, and between the other two nitrogen fertilizer varieties.

According to the results of nitrate reductase activity in maize Leaves under different nitrogen fertilizer varieties and different amounts of nitrogen fertilizer, the nitrate reductase activity in leaves and roots of maize treated with urea as nitrogen source did not change much compared with the other three nitrogen sources, while the nitrate reductase activity in leaves treated with other three nitrogen sources were all in the same condition. The nitrate reductase activity of roots was the highest under high nitrogen and low nitrogen. Nitrate reductase activity in leaves and roots showed opposite trends in four fertilizers when nitrogen application increased.

Discussion

Combining with the research contents in this paper, the technical principles of improving the utilization rate of nitrogen fertilizer are discussed. The utilization rate of nitrogen fertilizer in China's agricultural production is low and its loss is great, and the effect of increasing production is far from being fully exerted. The potential of reducing the loss of nitrogen fertilizer, improving its utilization rate and increasing production effect is also great. According to the experimental analysis, under the condition of increasing application of pure nitrogen fertilizer, the nitrate reductase activity of maize increased gradually at the start-up stage and before, and decreased gradually at the beginning of endurance stage; different application proportion of nitrogen in each period will have an impact on the nitrate reductase activity of maize; under different stress environment, a certain amount of nitrogen is applied Under the same stress, the NR activity of leaves was higher than that of roots; the effect of nitrogen fertilizer on NR activity of leaves was the greatest. Following is a brief description of the relevant technical principles:

(1) Avoiding excessive accumulation of mineral nitrogen in soil as far as possible

Exchangeable ammonium and nitrate nitrogen in soil are not only available nitrogen that crops can absorb directly, but also the common source of various nitrogen loss processes. It is undoubtedly necessary to have a proper amount of available nitrogen in soil, but excessive nitrogen will increase the loss of nitrogen. Therefore, it is one of the important principles for effective application of nitrogen fertilizer to avoid its excessive presence in soil.

(2) The countermeasures for the main loss ways of nitrogen fertilizer

Due to the different environmental conditions of different soils and crops, the loss of nitrogen through different mechanisms and pathways and their proportion in total loss of nitrogen fertilizer are quite different, so the technology to reduce the loss of nitrogen fertilizer should also be different. However, there are some internal links between different ways of loss. Therefore, when taking one of the loss mechanisms and ways as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28792894

the control object to formulate technical countermeasures, we should take into account its possible impact on other loss mechanisms and ways.

A. Reducing ammonia volatilization

Ammonia volatilization rate is a function of partial pressure of ammonia in surface water and wind speed above surface water. The former is also a function of $\left[NH_3+NH_4^+\right]-N$, pH and temperature of surface water. Therefore, reducing $\left[NH_3+NH_4^+\right]-N$ and pH in surface water after fertilization is the key technology to reduce ammonia volatilization. In addition, ammonia volatilization can be reduced by inhibiting the loss of ammonia from surface water of maize fields to the atmosphere.

For dry farming, these principles are basically applicable, but because there is no water layer in dry farming soil, the key to reducing ammonia volatilization loss is to try to apply ammonia fertilizer in a certain depth of soil layer to reduce the partial pressure of ammonia on the soil surface.

B. Inhibition of nitrification

Nitrification of ammonium not only produces a small amount of N_2O, but also forms nitrate nitrogen which is easy to pass through denitrification (also produces part of N_2O) and leaching loss. Therefore, for ammonium nitrogen fertilizer and ammonia fertilizer that can be formed, delaying or maintaining nitrification is one of the important ways to reduce losses, improve utilization rate and reduce environmental impact.

(3) Improving the ability of crops to absorb mineral nitrogen

There is a competition between the uptake of mineral nitrogen and the loss of nitrogen in crops. Therefore, eliminating all kinds of limiting factors affecting crop growth, such as lack of phosphorus and potassium, drought and flood, to improve the ability of crops to absorb mineral nitrogen, will help to improve the utilization rate of nitrogen fertilizer and reduce losses. In addition, in the period of vigorous crop growth, nitrogen fertilizer applied will be absorbed rapidly because of the strong absorption ability of root system, which is beneficial to reduce its loss; moreover, because of the high vegetation coverage on the ground, it is also helpful to reduce the wind speed across the soil (dry farming) or water surface, thus reducing ammonia volatilization.

In the process of this experiment, the experimental environment is in line with the actual measurement conditions, and the experimental data is accurate and reliable. Therefore, we can draw relevant conclusions through the experimental results, which has scientific guidance and statistical significance. The results showed that the nitrate reductase activity could be significantly increased by increasing nitrogen content. The amount of nitrogen should be controlled at the early stage of crop growth, and the top dressing should be focused at the vigorous stage of crop growth.

Conclusions

In order to deeply analyze the effect of nitrogen fertilizer application rate on nitrate reductase activity of maize, the effects of different application rates of pure ammonia fertilizer on nitrate reductase activity of maize, the effects of different proportions of nitrogen fertilizer applied in stages on nitrate reductase activity of maize, the effects of

DOI: http://dx.doi.org/10.15666/aeer/1802_28792894

nitrogen fertilizer application rate on nitrate reductase activity of maize in different stress environments, and nitrogen fertilizer products were studied. The effects of seed and nitrogen fertilizer on nitrate reductase activity in maize were analyzed in four aspects. The results showed that:

Conclusion 1: Nitrate reductase activity tends to increase with the increase of nitrogen application. Nitrate reductase activity increases rapidly after jointing stage, peaks at booting stage, decreases gradually from booting stage to maturity stage, and decreases after heading stage.

Conclusion 2: Because the male-drawing stage is the key period for the morphological formation of maize reproductive organs, carbon and nitrogen metabolism is the most vigorous, and nitrate reductase activity is the highest in the male-drawing stage; nitrate reductase activity in roots varies with the proportion of nitrogen fertilizer applied in different growth stages. Nitrate reductase activity was the highest in N4 treatment at booting stage.

Conclusion 3: Nitrate reductase activity in maize roots increased under different stress environments and with a certain amount of nitrogen fertilizer.

Conclusion 4: Nitrate reductase activity of maize leaves was higher than that of maize leaves without nitrogen application. When ammonium chloride was used as nitrogen source, the nitrate reductase activity of maize leaves was the highest. When nitrogen source was urea, the nitrate activity of leaves and roots increased with the increase of nitrogen application. Compared with the other three nitrogen sources, the activity of nitrate reductase in maize leaves was the highest under high nitrogen conditions, and the activity of nitrate reductase in roots was the highest under low nitrogen conditions.

To study the effect of nitrogen application on nitrate reductase activity of maize is helpful to improve the quality and yield of maize, promote the economic development of our country, and improve the international status of our country. In order to further understand the effect of nitrogen application rate on nitrate reductase activity of maize, we can study the environmental temperature, soil moisture and other factors, so as to better realize the research of this part.

(Received 28th Oct 2019; accepted 12th Feb 2020)

Abstract. Through no tillage, deep ploughing, shallow ploughing + straw mulching and deep ploughing + straw mulching, sorghum planting experiments were carried out in hilly areas to study the effects of different tillage methods on soil enzyme activity. The acidity of Sorghum at jointing, flowering and harvesting stages was determined. The results showed that deep tillage and straw mulching could improve soil enzyme activities of sorghum. RS tillage improved soil invertase, acid phosphatase, polyphenol oxidase, catalase, soil urease, soil invertase and alkaline phosphatase activities in the whole growth period of sorghum, and the effects were relatively significant. There were differences between growth periods. At the jointing and flowering stages of sorghum, the protease activity of R and TS treatments was significant, and the activity of soil beta-glucosidase in T treatment was higher than that in RS treatment. Tillage can change the activity of sorghum soil enzymes and improve soil fertility in Hilly environments. Therefore, the method of Sorghum planting in hilly environment can be reasonably selected according to the growth demand of sorghum soil enzymes.
Keywords: *deep ploughing, straw mulch, growth period, protease, soil fertility*

Introduction

Sorghum (*Sorghum bicolor* (L.) Moench) is an annual herb of Gramineae. Its stalks are thicker and erect, basally with root sheaths glabrous or slightly white; leaf ligules dura mater, apex rounded. The ciliated panicles are loose at the edges, the main axis is bare, and the total stem is erect or slightly curved. Caryopsis convex on both sides, light red to reddish brown, 2.5-3 mm wide at ripening, apex slightly exposed. Spikelets with stalks are about 2.5 mm long, and linear to lanceolate, flowering and fruiting occurred in June-September. Soil enzymes activity refers to the ability of soil enzyme to catalyze material transformation (Jun et al., 2017). It is usually expressed by the amount of catalytic reaction products per unit of soil or the amount of residual substrates per unit of time. Domestic scholars have done a lot of research on Sorghum planting and growth: Bo (2016) showed that with the increase of planting density, the leaf area per plant of sorghum decreased, the ventilation and light transmission conditions deteriorated, and the ear, ear grain number and 1000-grain weight decreased, which was harmful to the development of sorghum. With the increase of planting density, the number of sorghum leaves did not change significantly. Zhang et al. (2016) studied the sweet sorghum 8 agronomic traits such as the simple correlation, plant height and spike length, section number, stem diameter, sugar content, significantly associated heading stage, plant height and yield of straw, stem length, node number were positively correlated, and straw yields were positively correlated, stem diameter and the grain yield was significantly positively related, and plant height and fresh weight, leaf area per plant were positively correlated,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28952908

were very significant positive correlation, and ear length were very significant negative correlation with thick stems.

Sorghum is the main raw material for liquor brewing. The traditional habit of planting sorghum in southeastern Sichuan is the dominant production area of waxy sorghum in China. The waxy sorghum planted under unique ecological conditions is the preferred raw material for famous liquor manufacturers in Sichuan, Guizhou and Chongqing provinces (Supriya et al., 2017). However, due to the wide range of hills, fewer flat dams, more slopes, small plots and small scale of concentrated production of Sorghum in southeastern Sichuan, some of them adopt the way of planting sorghum in hills. Sorghum planting in hilly environment is more common, the degree of mechanization is very low, the phenomenon of "old, chaotic and miscellaneous" varieties is serious, the cultivation techniques are relatively backward, the control of diseases and insect pests is not in place in time, the docking of production and demand is not keeping pace with other factors, resulting in higher relative cost and poor efficiency of Sorghum planting (Kosmambetova et al., 2017). Under the condition of market economy, sorghum producers should aim at pursuing the highest economic benefits.

Soil enzymes are the general term of enzymes existing in soil, and they are one of the components of soil (Feng et al., 2018). Soil enzyme activity includes not only the enzymes accumulated in the soil, but also the enzymes released from the proliferating microorganisms to the soil. It mainly comes from the cell secretions of animals, plant roots and microorganisms in the soil and the decomposition of residues. Soil enzymes are involved in the synthesis and decomposition of humus, hydrolysis and transformation of organic compounds, plant and animal residues and various redox reactions of organic and inorganic compounds in soil (Xu et al., 2017). These processes are closely related to the release and storage of various nutrient elements in soil, the formation and development of humus in soil, the structure and physical condition of soil. They participate in the whole process of the occurrence and development of soil and the formation and evolution of soil fertility. Therefore, soil enzyme activity directly affects soil fertility and indirectly affects Sorghum yield (Cao et al., 2016). It is a feasible way to optimize the yield of Sorghum in hilly environment from the perspective of improving soil enzyme activity. In this paper, a sorghum cultivation area in hilly environment was selected as the research area, and sorghum was cultivated by different tillage methods to study the effect of Tillage Methods on soil enzyme activity. In order to increase the yield of sorghum, we should improve the activity of soil enzymes and optimize the formation and evolution of soil fertility.

Materials and Methods

Experimental Design

The experimental area is located in the hilly area of 29°51', 106°27' and 244 m above sea level, with a subtropical monsoon humid climate. This is because there is a small difference in soil enzyme activity between flat land use patterns, while there is a large difference in soil microbial quantity in the hilly area with obvious characteristics. The average slope of the experimental area is between 10^{-6}~10^{-2} mol/L. The annual total solar radiation is 87,108 kJ·cm^{-2}, the annual total sunshine time is 1,276.7 hours, the annual average temperature is 18°C (≥ 10°C), the accumulated temperature is 5,979.5°C, the highest temperature in summer is about 40°C and the average rainfall is 1,133.7 mm. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28952908

soil of the test plot is purple soil of dry land, with gentle slope and relatively uniform soil fertility. The cultivated soil in hilly environment is irrigated and silted soil with early cultivation and high maturity. Its thickness can reach 30-60 cm. The cultivation layer is light in texture and poor in water retention capacity. The volumetric heat capacity is generally 1-2.5 coke/$cm^3 \cdot ℃$. Moreover, due to the limiting factor of soil fertility level, the fertility level is quite different.

The experiment was started in April 2018. Four tillage treatments (no-tillage, deep tillage, shallow tillage + straw mulching, deep tillage + straw mulching) were set up. Each treatment set was repeated three times. The area of each treatment plot ranged from 12 to 24.75 hm^2 and was arranged in random blocks. In order to facilitate experimental recording and improve detection efficiency, the following four methods are set as follows: (1) No-tillage (T): no tillage of the land, plastic film was replaced until the experimental Jiedong; and (2) Deep tillage (TS): tillage 30 cm of cultivated land with subsoiling shovel after autumn harvest, and rotary tillage, mulching and sowing in spring. (3) Shallow tillage + straw mulching (R): Stalk-straw cutting and shallow harrow suppression-ploughing-shallow tillage-fertilization preparation-open-field drilling-weeding, pest control, treatment area 2.4 hm^{-2}, straw returning amount of 104 hm^{-2}. (4) Deep tillage + straw mulching (RS): Stalk-straw cutting and shallow harrowing to suppress, deep tillage-fertilization preparation-open field drilling-weeding, pest control during sorghum harvesting in the previous crop. The treatment area is 2.67 hm^{-2}, and the amount of straw returned to the field is about 114 kg hm^{-2}.

Sorghum was planted uniformly, sowing time was April 20, plant spacing was 20 cm, row spacing was 30 cm, and 7.2×10^4 plants/hm^2were planted. Unified fertilization measures were adopted. The fertilizers used were urea, diamine phosphate, calcium and potassium chloride. The amount of chemical fertilizer used in each treatment was uniformly N 180 kg/hm^2 and $P_2O_5$95-98 kg/hm^2 per year. Diamine iodate, calcium and potassium chloride were applied on the whole, urea 20%, jointing to heading 20%, heading to flowering 10%, and filling 50%. Irrigation for the whole growth period ranged from 34.1 to 36.3 m^3/hm^2. The fertilization, irrigation and management of sorghum cultivated land are the same in four different tillage modes of No-tillage, shallow tillage + straw mulching, deep tillage, deep tillage + straw mulching, which are different only in farming methods. Sorghum cultivation in the experimental area is shown in *Figure 1*.

Sample Collection and Indicator Determination

Sampling of soil samples

In 2018, root soil was collected during the jointing, flowering and harvesting periods of sorghum. During the collection, 2 cm of topsoil was taken, and 0-20 cm of root soil was taken for each plot according to the s-shaped sampling method. Soil enzyme activity is different in different areas. In order to ensure the accuracy of experimental data, it is necessary to control the consistent amount of experimental enzymes. Therefore, different plot sizes are needed, and the sampling points of each plot are 90, 80 and 70, respectively. After collecting at multiple points on each plot, the soil is evenly mixed. Some are packaged in sterile, self-sealing bags. They were immediately placed in an ice box and taken back to the lab. 4℃ refrigerator preservation, soil microbial diversity measurement. The other part of the soil was removed, dried and stored in a 2mm screen for the determination of soil enzyme activity and soil nutrient content.

(a) Sorghum planting coverage

(b) Mature sorghum

Figure 1. *Sorghum planting in hilly environment*

Method for determination of enzyme activity

Soil invertase activity (in terms of glucose quality, $mg \cdot g^{-1}$, 24h, 37°C) was determined by 3,5-Dinitrosalicylic acid colorimetry, soil acid phosphatase (in terms of phenol quality, $\mu mol \cdot g^{-1}$, 24h, 37°C) and soil polyphenol oxidase (in terms of purple gall quality, $mg \cdot g^{-1}$, 24h, 37°C) were extracted by Suzhou Keming Biotechnology Co., Ltd. Soil acid phosphatase (S-ACP) kit and soil polyphenol oxidase (PPO) kit (Pan et al., 2018); catalase activity was determined by potassium permanganate titration, expressed in milliliters of potassium permanganate consumed by 1 g of dry soil after 20 minutes; urease activity was determined by Indigo phenol colorimetry, and transformed into biogenic soil after 6 hours and 1 g of dry soil. The NH3-N milligram number was expressed; the activity of sucrase was determined by nitrosalicylic acid colorimetric method, expressed by the milligram number of glucose in 1 g of dry soil after 24 hours (Wen et al., 2017); the activity of alkaline phosphatase was determined by sodium phosphate colorimetric method; the activity of protease was determined by Indigo colorimetric method; and the activity of β-D-glucosidase was determined by B-D-glucosidase colorimetric method.

Microbial bacteria determination

The number of bacteria, actinomycetes and fungi were counted by dilution plate method.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28952908

Soil respiration measurement

Soil respiration flux was measured by Li-8100 soil carbon flux automatic measurement system. Seasonal variation was determined according to the main growth stages of summer sorghum. Fertilizer application and irrigation should be avoided, and the optimum period was about 15 days. Soil respiration was measured at different growth stages, from 8:00 to 20:00 (every 2 hours). It was required that the plastic film should be uncovered on the bare area of the respiratory chamber edge one day before each measurement to remove the accumulated CO_2 in the film. On the premise of not disturbing the soil and the PVC ring, the above-ground green plants were cut off from the roots and litter was removed from the circle one day before each determination (Zheng et al., 2017; Faust et al., 2018). In order to reduce the error of temperature to the test in the diurnal variation of respiration, we adopt the sequential measurement method to carry out the cyclic measurement. The flux value can also be automatically calculated by synchronous measurement of CO_2 volume fraction in the respiratory chamber, soil temperature, near-surface air temperature and air relative humidity (Wang et al., 2017).

Soil nutrient determination

Soil organic carbon: using chromic acid redox titration dilution method; total nitrogen: using semi-micro Kjeldahl method; quick-acting potassium: using Extraction Flame photometry; pH value using potentiometric method.

Data Processing

The experimental data were unified by Excel 2003, and then analyzed by SPSS 22.0 statistical analysis software for variance, correlation ($p < 0.05$), and significant difference ($p < 0.05$).

Results

Effects of Different Tillage Ways on Soil Enzyme Activities in Soil of Sorghum

Effects of different tillage methods on soil invertase activity in Sorghum

Soil invertase can hydrolyze sucrose into corresponding monosaccharides and be absorbed by the organism. Enzymatic products are closely related to the content of organic matter, nitrogen and phosphorus in soil, the number of microorganisms and the intensity of soil respiration (Moon et al., 2019). They are important indicators for evaluating soil fertility. *Table 1* shows that the invertase activity changes in different treatments are basically the same, that is, with the development of sorghum growth period, the invertase activity in rhizosphere soil of each treatment increased rapidly from jointing stage to flowering stage, and decreased rapidly at maturity stage. The activity of invertase in Sorghum soil was increased by different treatments at different growth stages, but the increment was different among different treatments. At jointing stage, there was significant difference between treatments and T treatment ($P < 0.05$), but there was no significant difference between them. At flowering stage, there was significant difference between RS treatment and T treatment ($P < 0.05$), and the activity of TS and TS treatment was significantly higher than that of T treatment ($P < 0.05$); at harvesting stage, the activity of RS and R was significantly higher than that of T and TS treatment ($P < 0.05$), and other treatments ($P < 0.05$). There was no significant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28952908

difference between them. The results showed that RS, R and TS treatments could improve the activity of transformation enzymes in Sorghum rhizosphere soil during the whole growth period, and RS treatment had the most significant effect.

Table 1. *Changes of invertase activity in Sorghum soil ($mg \cdot g^{-1}$)*

Different lowercase letters in the same column indicate significant difference in $P < 0.05$ level. The same below

Effects of different tillage methods on acid phosphatase activity in Sorghum soil

Soil acid phosphatase is a kind of enzymes that catalyze the mineralization of soil organic compounds. Its activity directly affects the decomposition and transformation of soil organic compounds and their bioavailability. It is an index to evaluate the direction and intensity of soil phosphorus biotransformation. *Table 2* shows that the activity of acid phosphatase in the rhizosphere of sorghum is higher at flowering and ripening stages. The activity of acid phosphatase in the rhizosphere of sorghum treated by RS, R and TS is higher than that of T during the whole growth period of sorghum (Xu et al., 2017). The activity of acid phosphatase in rhizosphere soil under RS treatment at flowering stage was significantly higher than that of other treatments ($P < 0.05$), but there was no significant difference between other treatments and control. The results showed that RS could significantly increase phosphatase activity in Sorghum rhizosphere soil at flowering stage, and R and TS could also increase phosphatase activity in Sorghum soil, but the effect was not significant compared with RS.

Table 2. *Changes of soil phosphatase activity in Sorghum ($\mu mol \cdot g^{-1}$)*

RS	103.25±14.00a	113.10±2.07a	112.81±23.66a

Effects of different tillage methods on polyphenol oxidase activity in Sorghum soil

Soil polyphenol oxidase mainly comes from the decomposition and release of soil biological, plant root exudates and animal and plant residues, catalyzing the oxidation of aromatic compounds into quinones, quinones react with soil proteins, amino acids, sugars, minerals and other substances to form organic matter and pigments, completing soil aromatic compounds recycling for soil environmental remediation. During sorghum growth period, the change trend of polyphenol oxidase activity in rhizosphere of different treatments was similar (Basak et al., 2018). The polyphenol oxidase activity increased rapidly from jointing stage to flowering stage, and then decreased rapidly at harvest stage (*Table 3*). At jointing stage and harvest stage, the activities of polyphenol oxidase in Sorghum soil treated with RS and R were significantly higher than those

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28952908

treated with T ($P < 0.05$). At flowering stage, the activity of enzyme under RS and R treatment was higher than TS and T, but only the difference between RS and R reached significant level ($P < 0.05$). The results showed that RS and R could significantly increase the activity of polyphenol oxidase in Sorghum soil, while TS could improve the activity of polyphenol oxidase in Sorghum rhizosphere to a certain extent, but the effect was not significant.

Table 3. *Changes of polyphenol oxidase activity in Sorghum soils ($mg \cdot g^{-1}$)*

RS	9.28±0.22a	11.47±0.26ab	9.12±0.86a

Effects of different tillage methods on catalase activity in Sorghum soil

Table 4 shows that the catalase activity of all treatments has the same trend during the growth period of sorghum. The catalase activity of all treatments is the highest at jointing stage, then decreases at flowering stage, while the catalase activity of treatments T, R and RS rises slightly at harvest stage. Different tillage treatments could increase the activity of soil catalase in different stages of sorghum. At jointing stage of sorghum, the activity of soil hydrogen peroxide changed from 1.54 to 1.66 mL/g (Kylili et al., 2018). Among them, the activity of hydrogen peroxide in RS treatment was higher than that in other treatments, reaching 1.66 mL/g, and there was no significant difference with other treatments. During the flowering stage of sorghum, the change of catalase activity in soil was 1.30-1.46 mL/g, and there was no significant difference among different tillage treatments. During sorghum harvest period, the change of soil catalase activity was 1.36-1.58 mL/g, and the order of soil catalase activity was RS > R > T > TS.

Table 4. *Changes of catalase activity in Sorghum soil ($mL \cdot g^{-1}$)*

Effects of different tillage methods on soil urease activity in Sorghum

From *Table 5*, it can be seen that the trend of urease activity in different growth stages of sorghum is basically the same, and the peak value of urease activity is reached at flowering stage. Soil urease activity changed from 2.34 mg/g to 2.46 mg/g at jointing stage of sorghum, and there was no significant difference among different fertilization treatments. At the flowering stage of sorghum, the soil urease activity changed from 2.51 mg/g to 2.86 mg/g, and the activity of urease in RS treatment was the highest (Ye et al., 2017). The urease activity in each tillage treatment was RS > R > TS > T, and the difference between treatments was small. Soil urease activity changed from 2.05 mg/g to 2.32 mg/g during harvest period. The order of size and flowering time of all tillage treatments were the same. RS treatment was significantly higher than T treatment, with an increase of 13.1%.

Effects of different tillage methods on invertase activity in Sorghum soil

Table 6 shows that all tillage treatments can improve soil invertase activity at different stages of sorghum. The changes of soil invertase activity at jointing stage and harvest stage of sorghum are 15.03-25.55 mg/g and 15.60-34.42 mg/g, respectively. The activities of RS and TS in treatment are significantly higher than those in treatment T and R. At the flowering stage of sorghum, the change of soil sucrose activity was 21.14-34.3.7 mg/g, the order of size was RS > TS > R > T. Compared with T treatment, the increase of RS, TS and R were 62.58%, 38.55%, 21.71%, respectively. The soil enzyme activity of RS treatment was significantly higher than that of T treatment.

Table 6. *Changes of invertase activity in Sorghum soils ($mg \cdot g^{-1}$)*

Effects of different tillage methods on alkaline phosphatase activity in Sorghum soil

Table 7 shows that the change trend of alkaline phosphatase activity is basically the same in all growth stages of sorghum. The alkaline phosphatase activity is higher at jointing stage, slightly decreased at flowering stage, increased at harvest stage and reached the peak value. Soil alkaline phosphatase activity was increased by different tillage treatments. Soil alkaline phosphoric acid activity changed from 0.926 g/g to 1.205 mg/g in jointing stage of sorghum. The order of size was RS > TS > R > T. The activity of RS and TS in treatment was significantly higher than that in treatment T, and there was no significant difference between treatment R and treatment R. At the flowering stage of sorghum, soil alkaline phosphatase activity changed from 0.933 mg/g to 1.037 mg/g. The soil alkaline phosphatase activity of RS treatment was 1.037 mg/g significantly higher than that of T treatment, and there was no significant difference with other treatments. Soil alkaline phosphatase activity changed from 1.107 mg/g to 1.40 mg/g during sorghum harvest, and the order of size was RS > R > TS > T. Among them, RS treatment was significantly higher than T and TS treatment, and there was no significant difference between R treatment and RS treatment.

Effects of different tillage methods on soil protease andβ-glucosidase activities in Sorghum

Table 8 shows that there are significant differences in protease activity between different treatments at jointing and flowering stages. The effects of R and TS treatments are significant in the two growth stages, but not in the harvest stage. *Table 9* shows that the activity of soil beta-glucosidase is better in R treatment at different stages of sorghum growth and development, jointing stage and flowering stage, T > RS, harvest stage, T < RS.

Correlation Analysis

Analysis of correlation between soil microbial biomass and soil enzymes (invertase, phosphatase, polyphenol oxidase) activity

Soil enzymes are involved in various soil metabolic processes and energy transformation, and have a good correlation with the number of soil microorganisms. Pearson correlation analysis of soil microbial quantity and soil enzyme activity showed that there was a certain correlation between them (*Table 10*). Among them, bacteria were positively correlated with acid phosphatase, transformation and polyphenol oxidase; fungi were positively correlated with acid phosphatase and invertase, but not with polyphenol oxidation; actinomycetes were positively correlated with acid phosphatase, invertase and polyphenol oxidase.

Table 10. *Number of soil microorganisms and correlation coefficients of soil enzymes under different tillage patterns*

Content	Bacteria	Actinomyces	Fungus
Acid phosphatase	0.568**	0.908**	0.586**
Polyphenol oxidase	0.468**	0.699**	0.323
Invertase	0.603**	0.550**	0.757**

** indicates a significant correlation at P < 0.01 level and * a significant correlation at P < 0.05 level

Correlation between soil respiration rate and activities of soil enzymes (catalase, urease, invertase, alkaline phosphatase, protease, beta glucosidase) and soil nutrients

Soil respiration in this area varies significantly with different growth stages (*Figure 2*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28952908

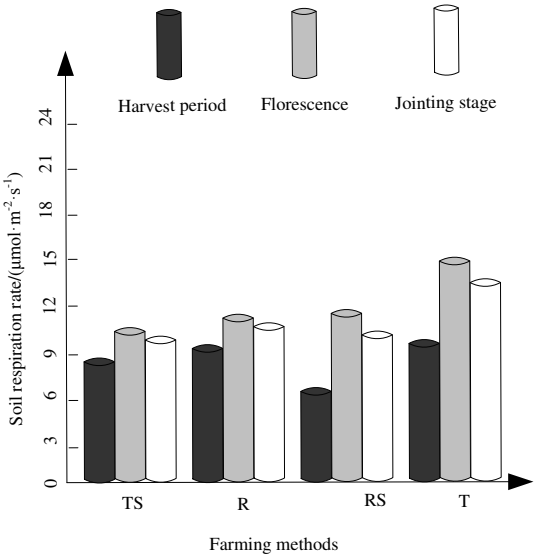

Figure 2. *Changes of soil respiration rate during Sorghum growth period under different tillage patterns*

In the figure above, T represents no-tillage, TS represents deep tillage, R represents shallow tillage + straw mulch, and RS represents deep tillage + straw mulch. It can be seen from figure 2 that soil respiration rates vary at different growing stages. The soil respiration rate at harvest stage was the lowest when RS method was adopted, with a value of 6.5 $mol \cdot m^{-2} \cdot s^{-1}$, and the soil respiration rate at elongation stage was also the lowest with a value of 9.8 $mol \cdot m^{-2} \cdot s^{-1}$. The soil respiration rate at flowering stage was the lowest when TS mode was adopted, and the value was 10.5 $mol \cdot m^{-2} \cdot s^{-1}$.

Soil nutrient content of Sorghum in hilly environment includes organic carbon, total nitrogen, available potassium and pH value. The change of soil organic carbon content during sorghum growth period is only listed in this paper as shown in *Figure 3*.

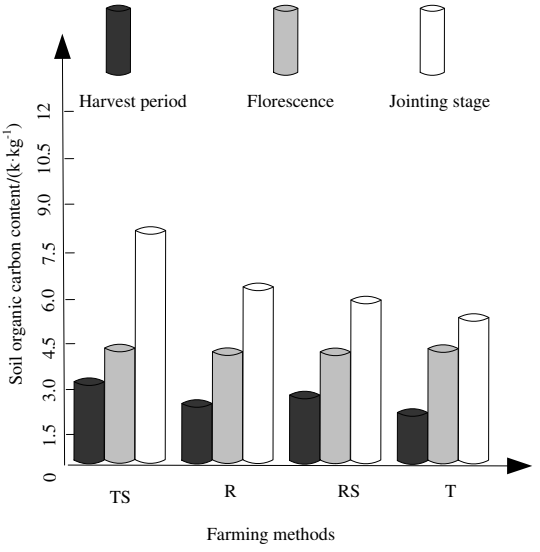

Figure 3. *Changes of soil organic carbon content in Sorghum growing period under different tillage patterns*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28952908

In the figure above, Trepresents no-tillage, TS represents deep tillage, R represents shallow tillage + straw mulch, and RS represents deep tillage + straw mulch. It can be seen from *Figure 3* that soil organic carbon content varies at different growing stages. The soil organic carbon content in the harvest period was the lowest when R method was adopted, and the value was $3.3k \cdot kg^{-1}$. The soil organic carbon content in jointing stage was the lowest when T method was adopted, and the value was $5.8k \cdot kg^{-1}$. The soil organic carbon content at flowering stage was the same in all four ways, and the value was $4.5k \cdot kg^{-1}$.

The results of correlation analysis between soil respiration and soil fertility factors showed that *(Table 11*) the correlation degree between soil nutrients was high, and the correlation among various indicators reached significant or extremely significant levels, which could be used to evaluate the soil fertility. The correlation analysis of soil enzyme activities showed that urease and other enzymes except protease reached a significant level, among which catalase, alkaline phosphatase andβ-glucosidase reached a very significant level ($p < 0.01$). There was a good correlation between soil respiration rate and other soil fertility indicators except alkaline acid enzyme, total nitrogen, available potassium and pH value, among which catalase, urease and invertase reached a very significant level ($p < 0.01$).

Table 11. *Relationships between soil respiration rate and soil enzyme activity and soil nutrients*

Content	Respiratory rate	Protease	Catalase	Alkaline phosphatase	Urease	Invertase	Beta-glucosidase	Organic carbon	Total nitrogen	Available potassium	PH value

Discussions

The total activity of soil enzymes can reflect the soil fertility to a certain extent. Material cycle and energy conversion in soil ecosystem are closely related to soil enzyme activity (Nannipieri et al., 2017). The results showed that different crop tillage, fertilization system and planting methods could cause changes in soil enzyme activity. In this study, we found that the activities of polyphenol oxidase, invertase and acid phosphatase in Sorghum rhizosphere soil were higher at flowering stage (Chen et al., 2016). The main reason is that the enzyme activity is affected by temperature and soil properties. When the soil temperature is low, the activity is weak, and when the soil

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28952908

temperature is suitable, the enzyme activity increases. At harvest time, the microbial activity decreases, and the enzyme activity decreases at a certain level. At the same time, the results showed that deep tillage and straw mulching could improve soil enzyme activity in varying degrees, and the effect was most significant under both deep tillage and straw mulching (Sun et al., 2017). This is because straw mulching not only regulates soil temperature, but also has a greater impact on soil organic matter and available nutrients, and can increase the number of soil microorganisms, increase the substrate for microbial transformation, so soil enzyme activity will increase.

The results showed that the effects of different tillage methods on soil enzymes in Sorghum growth period were different. On the whole, straw mulching and deep tillage could significantly improve the activities of soil hydrogen peroxide and urease in Sorghum at different stages. However, there was no significant difference in soil catalase and urease activities among different tillage treatments, except TS, T and T treatments at jointing stage of catalase, which indicated that the activities of hydrogen peroxide and urease in sorghum were less affected by straw mulching and deep tillage. Deep tillage and straw mulching can improve soil acid and alcohol activity. The results showed that alkaline acidase activity of soil treated by deep tillage or straw mulching was higher than that treated by chemical fertilizer. Straw mulching played a key role. Straw mulching improved soil productivity, increased the activity of plants, animals and microorganisms in soil, promoted the secretion of extracellular enzymes and enhanced soil enzyme activity (Wang et al., 2018). Deep tillage or straw returning can improve soil invertase activity, which is similar to the conclusions reported in many literatures. The straw returned to the field also provided the substrate for soil enzymes, provided enough energy for microorganisms, and caused changes in soil enzyme activities (Gopalsamy et al., 2017).

The correlation between urease, alkaline phosphatase, sucrose alcohol, protein alcohol, catalase and beta-glucosidase and soil respiration rate were studied in this experiment to provide basis for improving soil enzyme activity. The results showed that there was a good correlation between soil respiration and soil enzyme activity (except alkaline phosphatase) (Chen, 2017). In addition, the effect of growth period on soil respiration rate should not be neglected. This study found that the respiration rate of Sorghum at jointing stage and before jointing stage was higher than that at flowering and harvesting stage. This may lead to a large loss of soil organic carbon and an increase in CO release from soils caused by early tillage and sowing, on the other hand, it may be caused by early irrigation. The increase of water content promoted root respiration and the activity of biological community, which enhanced soil respiration.

Conclusions

This study analyzed the soil enzyme activity of sorghum under different tillage methods at different growth stages. The activities of sucrase, acid phosphatase, polyphenol oxidase, catalase, soil urease, soil invertase and alkaline phosphatase in deep tillage and straw mulching were detected by colorimetry. Under tillage, shallow tillage + straw mulch and deep tillage, enzyme activity was significant. Protease activity was significantly different between treatments at jointing and flowering stages. In the two stages of growth, R treatment and TS treatment were effective. The activity of soil -glucosidase was better during the growth, jointing, flowering, ripening, harvesting and ripening of sorghum. Using li-8100 soil carbon flux automatic measurement system, it

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_28952908

was proved that soil microbial quantity was positively correlated with soil enzymes, bacteria and actinomycetes were positively correlated with acidity, invertase and polyoxygenase, and fungi were positively correlated with acid phosphatase and invertase. Choose deep tillage and straw mulching cultivation, therefore, to improve the soil microorganism quantity and activity, to the growth of sorghum in the hilly environment to build a good ecological environment, to keep the hilly ecosystem sustainable production capacity at the same time is important, then can be tested with different temperature experiment indexes such as, in order to promote the further development of this part.

Abstract. Date palm trees are liable to be attacked by many insect pests which cause serious damage to the different parts of tree. The most serious insect pest is the red palm weevil, *Rhynchophorus ferrugineus* (Oliver) (RPWs). To evaluate the impact of four botanical oils of *Melissa officinalis*, *Borago officinalis*, *Laurus nobilis* and *Carapichea ipecacuanha* on *R. ferrugineus*. 4 botanical oils were tested against newly emerged adults of *R. ferrugineus* for the purpose of investigating their insecticidal activity and effects on some biological aspects. Males of *R. ferrugineus* were more susceptible to the four botanical oils than females, followed by the immature larvae. The larvae showed different degrees of susceptibility to the four botanical oils. They showed the highest susceptibility to *C. ipecacuanha* and the lowest to *B. officinalis* oil at LC_{50} levels. Adult males and females were more susceptible to *C. ipecacuanha* and the least to *L. nobilis* oil at LC_{50} levels. The four tested oils disrupted some biological aspects of the insects. These oils remarkably reduced male and female longevity, female fecundity and hatchability of the laid eggs.
Keywords: *effects, botanical oils, Rhynchophorus ferrugineus, control*

Introduction

Date palm trees are liable to be attacked by a lot of insect pests. The most serious insect pest was the red palm weevil, *Rhynchophorus ferrugineus* (Oliver) (Saleh, 1992). Essential oils have high volatility and toxicity towards stored-grain pests and weevils (Regnault-Roger and Hamraoui, 1995; Regnault-Roger, 1997; Shaaya et al., 1997). Various chemical organic compounds have been isolated from plants; they include fixed oils, volatile oils and other plant constituents which expressed potential action against insect species. Extraction, isolation and identification of the fixed oils have been studied by Abdallah et al. (1986), Moustafa et al. (1986), Baraka and El-Hady (1993), Hussein and Shoukry (1997) and Shoukry-Karima (2003). El-Sayed et al. (1989) mentioned that maize oil and coconut oil used on *Callosobruchus maculatus* reduced their progeny.

Abdel-Kawy and Gharib (1991) stated that oils of cotton seeds, sesame and peanut showed efficiency in treatment of yellow meal corn against the rice weevil, *Sitophilus oryzae* (L.). Jood et al. (1993) used neem oil (*Azadirachta indica*), powders of neem leaf and neem kernel, *Citrus limon* leaf, *Allium sativum*, *Mentha spichata* leaf in wheat grains at levels of 1% and 2% (w/w) against larvae of *Trogoderma granarium* Everts and they found that neem products completely prevented damage by an introduced larval population. *C. macculatus*, adult emergence of was completely inhibited by castor oil, black seed oil and olive oil at concentration 1% for 30 days (Swidan, 1996; Ismail et al., 2014, 2016; Salem et al., 2016). Also, the essential oils were tested against many insect species (Bouda et al., 2001; Isikber et al., 2006). The volatile oils of *Boxus chinensis* against 10 days-old larvae of the *R. ferrugineus* showed toxicological and pathological effects (Abdullah, 2009; Ahmed et al., 2015). Huseyin et al. (2006) noticed that ethanolic extracts of some aerial parts of lamiaceae species showed high larvicidal activity after 24 hours and *M. officinalis* (Linn.) oil was the highest toxic against larvae of *Culex pipiens* Linn. Karahroodi-Zahra et al. (2011) using of six essential oils from *M. officinalis* (L.), *M. piperata* (L.), *P. sativum* (Hoffman), *L. angustifolia* (Mill.), *Z. clinopodioides* (Lam.), and *A. dracunculus* (L.), on eggs and first instar larvae of *P. interpunctella*, they found that *M. officinalis* recorded moderate ovicidal activity. Ben Jemâa et al. (2011) studied the chemical composition and the repellent activity of *Laurus nobilis* essential oil against 7-10 days old-adults of the cigarette beetle, *Lasioderma serricorne*. The repellent action was highly dependent upon oil concentration and exposure time and *L. nobilis* essential oil may have potential as a control agent against this beetle. The essential oil of *B. officinalis* (L.) showed good larvicidal potential after 48 hours of exposure period against *A. gambiae* (Kweka et al., 2012). Essential oil of *L. nobilis* showed strong fumigant toxicity against *T. granarium* larvae (Tayoub et al., 2012). The ability of the aggregation pheromone to capture more females than males RPWs in the traps which makes trapping a potential tool for managing *R. ferrugineus* (Lee et al., 2001; Khalaf et al., 2009; El-Bokl et al., 2015). Powder of four plants, *B. officinalis*; *M. piperta*; *Officinalis anisum*; *Eucalyptus glubulus* was tested by Farman-Khansaa (2009) on the red flour beetle, *Tribolium castaneum* and found that *M. piperta* had most repellent efficiency plant, followed by *O. anisum*, *E. glubulus*, while the lowest was *B. officinalis*. The plant oils, (fixed and volatile) seriously disrupted some biological aspects of *R. ferrugineus* (Oliver) (Ahmed et al., 2015). Essential oils from various plants have shown promise as sources for insecticides. Earlier attempts to explore the toxicity of plant derivatives against *R. ferrugineus* have been made by essential oils. Two natural insecticides, *Boxus chinensis* oil and precocene II topically against larvae, prepupae and adult of red palm weevil, *R. ferrugineus* and the larvae of the palm beetle, pseudophilus testsceous. They found that larvae of *R. ferrugineus* were less tolerant to *B. chinensis* oil and more tolerant to precocene II than palm beetle larvae (Nassar and Abdullah, 2005). Nemazal and ethanolic neem extracts have a considerable significant remedial efficacy altogether with an effective, repellency against *R. ferrugineus* infestations (Merghem and Mohamed, 2017). An artificial diet incorporated with Picrotoxin was proven to inhibit the growth activities and to reprogram the detoxification defense mechanism of red palm weevils. Picrotoxin, a natural plant neurotoxin, is an important addition in the list of red palm weevil controlling products. Future research should focus on various aspects including formulation, safety, and application in order to optimize the e_cacy of Picrotoxin for managing red palm weevil infestations (Hussain et al., 2019). In this

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29092919

study, four botanical oils of *Melissa officinalis*, *Borago officinalis*, *Laurus nobilis* and *Carapichea ipecacuanha* were tested against newly emerged adult males and females of the red palm weevil, *R. ferrugineus* (Oliver) for investigating their insecticidal activity and effects on some biological aspects.

Materials and Methods

This study was carried out in Pests & Plant Protection Department, National Research Centre, Giza, Egypt and Biology Department, College of Science, King Khalid University, Abha, Saudi Arabia.

Mass rearing of R. ferrugineus

Adults of *Rhynchophorus ferrugineus* were obtained from coccons collected from infested date palm trees, incubated in plastic boxes (120 × 60 × 30 cm). These coccons were kept in wet toweling till adult emergence. The newly emerged adults were sexually differentiated and fed on small pieces of red palm core.

Used plants

The plants under investigation were originally obtained from international markets, identified, divided into two groups fixed and volatile oils, these plants are listed in *Table 1*.

Table 1. *Tested plants*

Group	Plants		Family name	Used parts
	Common name	Scientific name		
A Fixed oils	Lemon balm	*Melissa officinalis*	Lamiaceae	Leaf
	Borage	*Borago officinalis*	Boraginaceae	Leaf
B Volatile oils	Bay Laurel	*Laurus nobilis*	Lauraceae	Leaf & fruit
	Rio ipecac	*Carapichea ipecacuanha*	Rubiaceae	Root &leaf

Oils extraction

Extraction of fixed oils was performed from crushed and previously steam distilled plant parts of group A, where the dry powdered plants were macerated in petroleum ether (40/60) according to Harbourne (1984) and El-Sayed et al. (1989). The petroleum-ether extracts were filtered through anhydrous sodium sulphate. The solvent was removed by using rotary evaporator. The volatile oils were extracted from plants in group B, by using steam distillation technique according to the method of Anderson et al. (1980). Then oils were saturated with sodium chloride and extracted again with diethyl ether. The extracts were dried over anhydrous sodium sulphate and evaporated under reduced pressure by using rotary evaporator apparatus.

Methods of bioassay

The concentrations of the two groups of oils were prepared and added 0.1% tween to the fixed oil as an emulsifier. Pieces of date palm hearts were rinsed in each concentration for 20 seconds, and left to dry at room temperature. Treated pieces were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29092919

put separately in all replicates of pairs of newly emerged adults or 8 days-old larvae of the second generation. 100 (larvae, and adults) were used for each treatment, divided into 4 groups, each of 25 (larvae, and adults) were placed in Petri dishes, one individual/dish. For each concentration individuals of larvae were counted after 7 days and after 10 days for adults after treatments under laboratory conditions (30°C, 75 ± 5% R.H., and 12D : 12 L hrs.) to determine the % mortality.

Analysis of results

Toxicity lines were established and LC_{50} values were determined. The Toxicity lines were analyzed according to the method described by Finney (1952). The slope function and the relative potency of the tested oils were determined according to Sun (1950).

Results

Table 2 showed that the *C. ipecacuanha* was the highest toxic to the larvae (LC_{50}=1260.09 ppm), followed by *L. nobilis* oil (LC_{50}=2412.30) and then *B. officinals* (LC_{50}=2500.71 ppm). The relative potencies based on *C. ipecacuanha* were 1.20, 1.87 and 1.90 for *M. officinalis*, *B. officinalis* and *L. nobilis*, respectively. The relatively low values of slope functions revealed the homogenous response of the tested stages to the different concentrations of the tested oils.

Table 2. *Toxicity and the relative potency of the fixed oils and volatile oils on R. ferrugineus*

Botanical oil	**Tested plant**	**LC_{50} (ppm) (Confidence limits)**	**Slope function**	**Relative potency**
8 days-old larvae:				
Fixed oils	*Melissa officinalis*	1600.635 (1260.820-2010.140)	2.300	1.200
	Borago officinalis	2500.712 (2368.900-2652.556)	4.333	1.871
Volatile oils	*Laurus nobilis*	2412.300 (2288.700-2522.806)	5.233	1.900
	Carapichea ipecacuanha	1260.093 (1030.866-1510.820)	2.533	1
Adult females:				
Fixed oils	*Melissa officinalis*	1280.556 (1140.284-1460.300)	2.000	1.200
	Borago officinalis	1350.210 (1230.500-1500.239)	2.500	1.270
Volatile oils	*Laurus nobilis*	1880.763 (1778.800-2000.500)	4.400	1.755
	Carapichea ipecacuanha	1060.500 (960.800-1170.130)	2.457	1
Adult males:				
Fixed oils	*Melissa officinalis*	1130.75 (1023.744-1252.700)	2.320	1.290
	Borago officinalis	1248.155 (970.053-1515.300)	3.120	1.400
Volatile oils	*Laurus nobilis*	1750.645 (1440.210-2020.120)	4.400	2.000
	Carapichea ipecacuanha	870.721 (780.840-970.900)	2.111	1

Table 3 showed a highly significant decrease in both male and female longevity of *R. ferrugineus* when treated with the plant oils of *M. officinalis* and *B. officinalis* as fixed oils; *L. nobilis* and *C. ipecacuanha* as volatile oils. Also, the treatment with the tested plant oils of *M. officinalis*, *B. officinalis*, *C. ipecacuanha* and *L. nobilis* showed a high significant reduction on the fecundity. Hatching percentage of eggs laid by adult females treated with the all tested oils decreased significantly. The hatching percentages were 55.3±0.22% and 64.2±0.24% in case of treatment with *C. ipecacuanha*, and *L. nobilis* volatile oils, respectively. While the hatching percentages in case of treatment with the two fixed oils reached 58.8±0.3% in *M. officinalis* and 59.09±0.21% in *B. officinalis* oil.

Table 3. *Effect of (LC_{50}s) of plant oils on biological aspects of newly emerged adults of R. ferrugineus*

Treatment		LC_{50} (ppm)		Adult longevity (days) Mean ± S.E.		Fecundity (eggs/♀) Mean ± S.E.	(Eggs /♀/ day) Mean ± S.E.	Fertility (eggs/♀) Mean ± S.E.	Hatching percentage (%) Mean ± S.E.
		♂	♀	♂	♀				
Control		----------		140 ±3.10	130.23 ±3.08	148 ±2.20	2.40 ±0.02	135.13 ±0.42	89.70 ±1.3
Fixed oils	Lemon balm *(Melissa officinalis)*	1138	1288	75.2 ±4.33**	82.45 ±2.2**	95.20 ±2.80**	1.13 ±0.52**	56.0 ±1.83**	58.8 ±0.3**
	Borage (*Borago officinalis)*	1357	1368	92.0 ±4.52**	103.65 ±8.10**	120.0 ±1.79**	1.10 ±0.15**	72.30 ±1.66**	59.02 ±0.21**

Without * Non significant (P>0.05). * Significant (P<0.05). ** highly significant (P<0.001)

Table 4 showed that, there was significant increase in larval duration in case of treatment with the volatile oils while statistical analysis of the decrease in the larval duration in case of treatment with the two fixed oils of *M. officinalis* and *B. officinalis* was not significant. Significant increase in prepupal and pupal durations occurred by the treatment with *C. ipecacuanha* as it reached 7.0±0.34 and 11.3±1. 2 days, respectively. While treatment with fixed oils of *M. officinalis* and *B. officinalis* decreased non significantly in the prepupal and pupal durations. High significant reduction in the pupation percentage of treated larvae reached 40.2±0.2% by *C. ipecacuanha*, 54.2±2.0% by *M. officinalis*, 60.2±1.2% by *B. officinalis*, and 60.2±2.2% by *L. nobilis*, while that, of control was 90.0±0.0%. The 8 days treatment of old-larvae with (LC_{50}) of plant oils (fixed oils and volatile oils) resulted in high significant reduction of adult emergence (%). Both male and female longevity also decreased significantly when treated by the two fixed oils and volatile oils and showed high significant decrease in their duration when treated with *C. ipecacuanha*. The tested plant oils had variable effects on fecundity of females emerged from treated larvae. The mean number of eggs deposited by a female decreased high significantly in case of treatment with *C. ipecacuanha* oil and was non-significant in case of treatment with *M. officinalis*,

DOI: http://dx.doi.org/10.15666/aeer/1802_29092919

B. officinalis and *L. nobilis*. Also, *Table 4* showed non-significant decrease in hatching (%) of eggs laid by females emerged from treated larvae except that, of *C. ipecacuanha*, which showed a significant decrease. It was clear that, the plant oils (both the fixed and volatile) seriously disrupted some biological aspects of *R. ferrugineus* (Oliver).

Table 4. *Effect of (LC_{50}s) of plant oils on different biological aspects of 8 days old larvae of R. ferrugineus*

Discussion

Essential oils from many plants have become promising sources of insecticides. Several attempts to explore the toxicity of plant derivatives against *R. ferrugineus* have been made by by the use of essential oils. Nassar and Abdullah (2005) tested two natural insecticides, *Boxus chinensisoil* and precocene II topically against larvae, prepupae and adult of red palm weevil, *R. ferrugineus* and the larvae of the palm beetle, *pseudophilus testsceous*. They found that larvae of *R. ferrugineus* were less tolerant to *B. chinensis* oil and more tolerant to precocene II than palm beetle larvae. Huseyin et al. (2006) studied the larvicidal activity of ethanolic extracts of some arial parts of Lamiaceae species against *Culex pipiens* (Linn.). They found that all plant extracts had strong larvicidal activity after 24 hours exposure tests. *Melissa officinalis* (Linn.) oil showed the highest toxic activity. Abdullah (2009) tested the volatile oil of *Boxus chinensis* against 10-day old larvae of the red palm weevil, *R. ferrugineus*. He found that it had toxicological and pathological effects on *R. ferrugineus* larvae. The results of the current study, concerning the toxicity of the four botanical oils to the 8-day old larvae and adults of *R. ferrugineus*, showed that the (*C. ipecacuanha*) oil was superior to the other three oils of lemon palm (*M. officinalis*), Bay leaf (*L. nobilis*) and the borage (*B. officinalis*) oils, while Borage was the least toxic oil. The variation in the toxicological effects of the tested oils might be due to differences in their chemical composition as well as the variation in sensitivity and response to the various cells and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29092919

tissues. This might also depend on the amount of poison that reaches the site of action. Mostafa et al. (1995) mentioned that the volatile oils of some plants increased the activity of Malic Dehydrogenase Enzyme (MDE) and decreased the activity of (Malic Enzyme) (ME) in *Pectinophora gossypiella* and *Erias insulana* larvae. From the above mentioned data we concluded that the two fixed and the two volatile oils caused a similar significant decrease in both male and female longevities. This result is in line with findings of Andronikashvili and Reichmuth's study (2003) who concluded that the volatile oil of *L. nobilis* had high repellency effect towards adult of red flour beetle, *Tribolium castaneum* explaining its moderate insecticidal activity and reducing periods of male and female longevity. Similar results were obtained by Isikber et al. (2006). Farman-Khansaa (2009) investigated the repellent effect of powder of four plants; *B. officinalis*, *M. piperta*, *O. anisum* and *Eucaluptus glubulus* against the red flour beetles *Tribolium castanium*, reflecting the first essential reason of weevil longevities decrease, which is due to their high repellency. The same high repellency was recorded by Ben Jemâa et al. (2011) against adults of the cigarette beetle *Lasioderma serricorne*, and also led to decrease in adult longevity. Also Mohamad et al. (2011) studied the causes of attraction and repellency effect of some plants extracts from leaves and roots of Borago and Tages plant against the Southern cowpea weevil, *C. maculates* (Fab.). The results showed significant differences in attraction and repellency effect according to the kind of extracted plant and concentration. When repellency occurs, it refers to the major reason of dramatical weevil longevity decrease. The same result was achieved by the volatile oil and this is similar to the results obtained by Karahroodi-Zahra et al. (2009) who came to the concusion that the volatile oils of *M. officinalis* had a moderate repellency against adults of *P. interpunctella* reflecting the first essential reason of weevil longevities decrease. Furthermore, the present study revealed that both fixed and volatile oils caused a significant decrease in both male and female longevities. This result was confirmed by Andronikashvili and Reichmuth (2003) who illustrated that the volatile oil of *L. nobilis* had high repellency effect towards adult of red flour beetle, *T. Castaneum*. Similar results were obtained by Isikber et al. (2006). The present study revealed that, fixed oils remarkably decreased the average number of eggs deposited by treated females. This was confirmed by the findings of Schoonhoven (1978) and Shankaranarayana et al. (1979). Singh et al. (1978) mentioned that, groundnut oil prevented the emergence of progeny rather than affecting the oviposition of *C. maculates*. Abdel-Kawy and Gharib (1991) indicated that cotton seed oil, sesame, peanut and paraffin oils reduced the number of progeny in *Sitophilus oryzae*. Taheya and Al-Moagel (1993) indicated that tumeric extract reduced the khapra beetle F1 progeny, and interfered with its development. Regnault-Roger and Hamraoui (1995) showed that the volatile oils of *L. nobilis* could protect kidney beans by direct or delayed insecticidal effect through increased adult mortality and inhibition of beetle reproduction of *Acanthoscelides obtectus* (Say). Also, the authors of this study concluded that the treatments by fixed and volatile oils had a significant effect on the reproductive potential of *R. ferrugineus* (Oliver). The average number of eggs laid per female as well as hatching (%) was reduced significantly. Similar results related to the fecundity of other treated insects with volatile oils were obtained by several authors (Frik and Nazirov, 1981; Dongre and Rahalkar, 1982). Nassar (1995) stated that complete sterility of *Muscina stabulans* adult was achieved by larval treatment with some plant extracts and Hussein (1995) reported that treatment of the second larval instar of *Parasarcophaga aegyptiaca* with some volatile plant oils induced a remarkable

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29092919

reduction in reproductive potential of developing adults. Shoukry-Karima (2003) stated that the tested plant volatile oils of Pipe rcubebae and Sativa officinalis had a high significant decrease effect on pupation percentage, adult emergence percentage, fecundity, fertility and hatchability of females emerged from treated larvae of *P. interpunctella*. In contrast, Singh et al. (1989) found that volatile oils extracted from *Callicarpa macrophylla* and *Zanthoxylum alatum* plant increased the fecundity of *S. oryzae* and *Sitophilus granarius*. Karahroodi-Zahra et al. (2011) referred to the great toxicity of the volatile essential oils of *M. officinalis* against the first instar larvae and eggs of *P. interpunctella* leading to significant decrease in the number of hatched eggs. Karahroodi-Zahra et al. (2008) investigated fumigant toxicity of the essential oil from *M. officinalis* L. against first instar larvae and eggs, of *P. interpunctella* (Hübner) showing moderate ovicidal and egg deterrence effect against this pest. Nassar and Abdullah (2001, 2005) recorded some pupal morphogenetic abnormalities of the red palm weevil resulting in incomplete adult eclusion due to the treatment with azadirachtin and *Boxus chinensis*. The same result was also reported by Bream et al. (2001). As most of the puparia failed to reach adults (aborted puparia).

Conclusion

The four tested oils disrupted some biological aspects of the tested insects. These oils remarkably reduced male and female longevity, female fecundity and hatchability of the laid eggs. In the future the authors will use it as Nano Particles against the insects to get more effects on the insects.

(Received 7th Nov 2019; accepted 12th Feb 2020)

Abstract. In fragmented landscapes, the accessibility of resources not only influences the spatial distribution of the predators themselves, but may similarly affect the abundance of their prey. We studied the influence of habitat dynamics and predator density on the spatial abundance of Cape hare (*Lepus capensis*) in the Karakorum Range in a 5700 km^2 area in Shigar valley during 2015–16 and 2017. We found that, seasonally the population density of Cape hare at deciduous forest plantation (site 3), was the highest and the lowest density of Cape hare was found in the closed to open herbaceous vegetation (site 1). Seasonally the detection probability and encounter rate were found the highest in the closed to open herbaceous vegetation (site 1), and detection probability was the lowest in the grassland and bare lands (site 2). In summer, we found a positive correlation between Cape hare and Red fox density in the deciduous forest plantation (site 3). In winter, a positive relationship between Cape hare and Red fox density were observed in the grassland and bare lands (site 2). Seasonally, the density of Cape hare were the highest recorded in the deciduous forest plantation (site 3) where the relative density of Red fox and encounter rate of active burrows were the lowest. In this economically poor study area, humans often retaliate against damages caused by local wildlife using guns. The conclusions are discussed in the perspective of predator –prey interaction and the implications for management and mitigation of human – wildlife conflicts are also considered.
Keywords: *distance samplings, habitat factors, human – wildlife conflict, predator – prey, seasonal estimation*

Introduction

Prey population density can fluctuate in responses to both lethal and non-lethal effects caused by predators (Preisser et al., 2005). In such habitats with the presence of predators, the prey is likely to be more alert, to lower the risk of being killed (Brown et al., 1999). For prey species, the decision of when and how to escape from a potential threat is a complex process that is subject to relations between numerous biotic and abiotic factors (Stankowich and Blumstein, 2005). Typically, herbivore behavior is divided into three main activity types: grazing, resting and moving (Arnold and Dudzinski, 1978). These activities have significant impacts within the landscape (both spatial and temporal distribution, and habitat and vegetation preference) (Lima, 1998). It has been shown that both natural predation and anthropogenic threats cause similar behaviors such as increased alertness in herbivores (Lima and Dill, 1990). These risk effects are negatively influence foraging efficiency (Møller, 2008).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29212934

Predation risk effects are dependent on the body–size of prey like small (e.g. rodent) and medium–sized prey (e.g. lagomorph). Medium–sized prey in open habitat is able to run fast, and in dense habitats, prey are expected to persist due to the availability of refuge (Waggett and Buskey, 2007). Cape hare is a medium–sized herbivore and active at night time or day time as well as hares have adopted a very strong active anti–predator tactic; such as they can leap and immobile (Weterings et al., 2016). The predation risk on hare is increased as they cannot depend on a burrow system (Creel, 2011). The obtainability and quality of resources influences the size of animal home range (Macdonald, 1983), such that, in canids for example, a home range in a resource–rich area may be smaller than in a resource–poor area (e.g., 0.4 km^2 and > 40 km^2, respectively, Macdonald, 2004). Furthermore, den selection is influenced by prey availability in the corsac red fox (*Vulpes corsac*) (Murdoch et al., 2009), the Eurasian badger (*Meles meles*) and the red fox (Márton et al., 2016).

However, Red foxes prey on hares (Goszczyński and Wasilewski, 1992a), and utilize dens for birthing and rearing offspring ('breeding dens') and as resting sites outside the breeding periods ('non–breeding dens) (Meia and Weber, 1992). Predator and preys interaction in a landscape were demonstrated by Hearn et al. (1987), that decreasing in the survival rate of juvenile arctic hares (*Lepus arcticus*) in Newfoundland was predation by the red fox (*Vulpes vulpes*). Santilli et al. (2007) defined that high Red fox predation was related to the mortality of European hares (*Lepus europaeus*) in Italy. Furthermore, in Sweden, Artic hare (*Lepus timidus*) densities enhanced when Red foxes were controlled from two islands (Marcström et al., 1989). Additionally, when sarcoptic mange killed many Red foxes in Sweden during the late 1970s and 1980s, mountain hare populations increased and their cyclicity vanished, but decreased again when Red foxes recovered from the disease (Kauhala et al., 1999; Newman et al., 2002). The hunting bags manage for Red fox in the Norway during 1976–19, 86 decreased the population, in contrasts, the hare population has ultimately increased (Selås and Vik, 2006). Goszczyński and Wasilewski (1992b) reported positive correlation between Red fox and hare density in central Poland.

In northern Pakistan, Karakoram range is occupied by globally important wildlife species such as snow leopard (*Panthera uncia*) and Tibetan wolf (*Canis lepus*) of which prey on or competitively displace red foxes (Roberts, 2005; Raza et al., 2015; Zaman et al., 2019b). Locally, Red fox are also a main predator of small mammals (e.g, Indian Pika (*Ochotona roylei*)) (Schneider, 2001). Major factors affecting declining Red fox population involve retaliatory killing for wheat crop damage and local poultry damages, local perception of the Red fox as a pest species (Maheshwari, 2018). Major threats affecting the decrease of hare population has been explained (Smith et al., 2005) as agricultural practices and human activities (Reichlin et al., 2006).

Assessments of the proportions of wildlife populations are essential to various phases of conservation and wildlife monitoring (Thomas et al., 2006), and hare abundance ecologically performing a vital role to regulate and maintain predator density, such as Red fox (Schneider, 2001). Similarly, predators density affect on the abundance, daily activities and spaitial distribution of their prey (Gilg et al., 2003). If predators vanished from a landscape, prey species become 'naive' to the predator (Berger et al., 2001). However, population density of hare from the interaction with predator density in study sites yet is unstudied and such experiments under the human disturbance are lacking (Weston et al., 2012). Besides the clear gap in the knowledge, the aims of the study were: 1), to determine a relationship between hare density and Red fox density, with the underlying hypothesis that hare density would be expected to be lower in areas of higher Red fox density, i.e., a positive correlation. 2), to determine an association between hare habitat association in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29212934

areas of high Red fox densities, with the underlying hypothesis that hares would be expected to have a heightened density were Red fox burrows would be low. In this study, we focused on the population density of Cape hare (*Lepus capensis*) and their predator, i.e., Red fox (*Vulpes vulpes montana*), since the surmised predator can change in habitat assortment of medium–sized prey by predation risks (Frid and Dill, 2002).

Materials and Methods

Study area

We conducted our study in 2015–2017 at Shigar Valley (8500 km^2; 35° 26′ N, 75° 44′ E) within the Karakorum range. The valley stretches approximately 80 km from the gateway of Shigar to Askole, Gilgit Baltistan Pakistan. The total survey area was approximately (5700 km^2) involved the current range of hare and observed predator. The valleys are dry with the annual precipitation around 200 mm with a maximum of almost 600 mm at elevations of 3962 m and snow depth maximum of 0.304 meter and a minimum of 0.127 meter. Shigar 1, is located in Karakorum range part, at the elevation of 2527 m above sea level (asl) the North–East. The major plant species are *Rosa webbiana*, *Hippophae rhamnoides*, and *Berberis lyceum*. The habitat and vegetation composition described by Zaman et al. (2019a).

Data collection

Cape hare and predator population density survey

The field surveys of Cape hare population abundance were made in three consecutive years. Our study was conducted in summer (3 June to 5 September 2015) and in winter (25 October to 27 December) in 2016, and in the summer of 2017 (27 May to 29 August) in Shigar Valley. Hare population density was estimated based on line transects (Langbein et al., 1999). The basic assumptions of distance sampling were for estimation of flushing-out distances (1) perfect detection of hare at line centers; (2) distance quantity are the initial positions, before reactive movement; (3) correct count of grouped Cape hare (4); measurement of detection distances without fault, and; (5) representative sampling of the study area (Marques et al., 2001; Buckland et al., 2008). Perpendicular distances (x) were measured from the line to each detected Single/ cluster of Cape hare. n hare was detected at perpendicular distances. Animals at the truncation distance from the transect line (w) and lengths of the transect (L) were recorded. The surveyed area was (a = 2wL) within which n animals were detected. Ṗa is the probability that a randomly chosen animal within the surveyed area was detected, and individual hare density (Ď$_s$) was estimated by

$$Ď_s = n/2WLṖa \quad \text{(Eq.1)}$$

To gain the estimated density of cluster, we multiplied by mean group size in the population, therefore:

$$E(s): Ď = (f(0)E(s))/2LṖa$$
$$Ṗa = 1/f(0) \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29212934

Probability is estimated of perpendicular distance at zero. E(s) estimated is expected cluster sized and Ď is the estimated density of cluster, respectively (objects/km). We designed 8 sample plots with 9 km lengths and each sample plots were divided into 4×4 km grid size and 5 to 10 parellel array 50 meter transects were laid out in each samples plots, the distance between one sample plot to another was 5 and 10 km. Each of the four study areas represented a huge variation in different habitat types, these were spaced between 3 km and 14 km apart in different selected sites (*Fig. 1*).

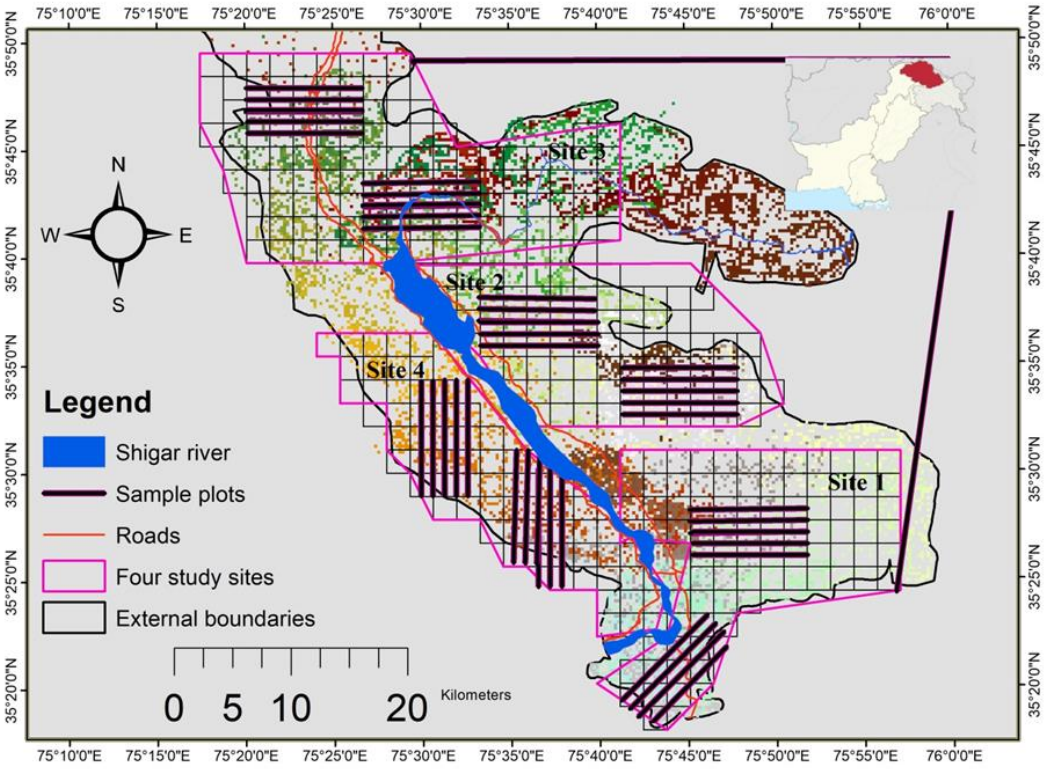

Figure 1. *Three consecutive years sampling sites and four selected area, in Shigar Valley Karakorum range in both winter (25 Oct to 27, Dec – 2015) and summer (3 June to 5 Sept – 2016 and 27 May to 29 August –2017. Hence, Shigar valley ~ 80 km from gateway of Shigar to Askole, Gilgit Baltistan Pakistan*

The study site 1, union council (UC) Marapi, extends from gateway of Sarfaranga (35°21'47.81"N, 75°44'24.82"E) to Ghazapa (35°25'5.05"N, 75°45'11.65"E), and Kanikernullah, Gangdrong nullah. Site 2, sampling areas were selected from UC Markunja nullah, Sarafa ranga thang, upper site of Chipping near historical Shigar fort (35°25'27.43"N, 75°44'34.83"E), to Taherping (35°26'17.90"N, 75°44'8.84"E), Chorkah ranga and extended from eastern part of valley to southern part. The 3rd study site containing sixteen different villages, UC Markuja extended from Bounpi ranga (35°26'3.02"N, 75°43'15.27"E) to UC Chorkah ranga (35°27'49.17"N, 75°41'15.65"E), Sildi, Hyderabad, Tiser. The study site 4, UC Gulapure and Barqzo contained Gulapur nullah (35°22'56.84"N,75°42'11.43"E) and, Nialinullah, Alochorinullah, Markunja nullah, Marapi nullah, Chorkah nullah, Azamkhan to second gateway of Shigar valley linked to Bonpa Gulapur (35°27'55.75"N, 35°27'55.75"N) near the catchment of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29212934

river. We only recorded distance for our targeted hare and each sample plots were sufficiently apart which was sufficient to avoid multiple recording of the same individuals across transects of different study areas (Smith et al., 2004). The abundance of hare pellet counts was used to estimate the hare abundance for broad–scale studies (Fa et al., 1999), counting fresh and old hare pellets within 10 plots of 10 m x 10 m at 30 m intervals, eluding counts on or proximate latrines. The abundances of pellets were counted in 30 plots along each transect to derive pellet abundance indices (the number of presences divided by the number of plots multiplied by transects length as pellet abundance indices/km). We used Pellet uncleared plots methodology (Perry and Robertson, 2012) to check habitat association of Cape hare. It is assumed that the hare defecation rates were incredibly high (300 to 700 pellets/day (Welch, 1982). The direct estimation of relative population density of Red fox is given by this formula, $D = n/A$, where n represents a number of sample efforts with a particular survey time and A stands for sampling area in each site. Whenever a Red fox was encountered, time, date and number of individuals were noted (Raza et al., 2015). We estimated Red fox number of individuals/4 km as described by Walton et al. (2017). We estimated Red fox abundance based on counts of active burrow entrances with a strip width of 30 m, considering the number of active burrow entrances/4 km as an index of Red fox abundance (Panek, 2009).

Habitat covariates sampling

We surveyed hare according to four different habitat features (Zaman et al., 2019a,b), and relative abundance, relative frequency, density and importance value index (IVI) of plant species were recorded as described by Mahmood et al. (2010). In a random stratified sample, 10 plots, each of the same size, were evaluated in all kinds of habitat types in each transect. The hare habitat types were extracted by polygons and we measured proximity factors: i.e., distance to rivers, roads, and agricultural lands and streams by ArcGIS (10.2) (Zaman et al., 2019a).

Data analyses

We calculated the seasonal density of hare population by the use of Distance 6.0 software (Thomas et al., 2010). The best model with the lowest delta akaike information criterion (Δ AICc = 0) values with the akaike information criterion (AICc) of the best–fitting model subtracted was selected for estimating population density (Thomas et al., 2010). We used Kolmogorov–Smirnov tests and quantile-quantile (Q–Q) plots to test the normality of data and data were normally distributed in selected sites (Thomas et al., 2010). We used Students samples t–test to compare the means of red Red fox population density. We used Pearson's correlation to analyze the relationships between pellets and burrow entrance abundance indices in two seasons. To measure the direct relationship between the hare and Red fox, we used the average means of population density in summer and winter. Multiple regression analysis was used to check seasonal habitat associations of hare pellet abundance index to the habitat variables in different sites (Broome, 2001). We used pellets abundance indices as dependent variables and independent categorical variables (habitat type) and ordinal variables (importance value index) for each habitat 10 plots of herbs, shrubs, trees, and grasses were used for analysis. The parameter estimates of variables were considered significant at $P < 0.05$. All data analyses were done in SPSS Statistics 21.0 (IBM SPSS, Chicago, IL, USA).

Results

Spatial distribution of Cape hare and their predator population density

In summer, the population density of Cape hare in the selected site 3 was the highest and the lowest density of hare was found in selected site 1 (*Table 1a*). The average detection probability, Encounter rate and cluster size of Cape hare was the highest in selected site 1 (*Table 1b, Fig. 2b*). When using hazard rate key function with series expansion the observed and expected distances were significant (*Table 1b*). The lowest detection probability for hare was recorded in selected site 2, (*Table 1b, Fig. 2c*). The selected model key half–normal for Kolmogorov–Smirnov test was insignificant (*Table 1b*). In the selected site 4 (*Fig. 2d*) detection probability was low. Uniform normal key with extension key showed to be significant in Kolmogorov–Smirnov test. The detection probability, encounter rate and cluster size of hare in the study site 3, was low (*Table 1b, Fig. 2a*). Half–normal key function with series expansion revealed no significant differences between observed and expected distances (Kolmogorov–Smirnov test, *Table 1b*).

The relative density of Red fox was the lowest in the study site 3 and the highest in the selected site 1 (*Table 2a*).

In winter, the population density of Cape hare in the study site 3 was the highest and the lowest density of hare was found in selected site 2 (*Table 1a*). The average detection probability of Cape hare was the highest in the site 1 and average encounter rate was recorded and Hazard Rate key with extension key showed significant Kolmogorov–Smirnov test (*Table 1b, Fig. 2e*) and the lowest detection probability and encounter rate was observed in site 2. Half–normal key with extension key for Kolmogorov–Smirnov test was not significant (*Table 1b, Fig. 2f*). Detection rate and encounter rate was moderate in the site 4 (*Table 1b, Fig. 2h*) and observed and expected distance was significant (*Table 1b*) and, detection probability and encountered rate were accompanied by an expected cluster size; Uniform key with extension revealed significant differences for expected distance and observed distance (*Table 1b*). The relative density of Red fox was the lowest in site 4 and the highest in site 2 (*Table 2a*).

Discussion

Spatial relationships of predators and Cape hare population density relating to habitat factors

We found that the detection probability of Cape hare in the summer (site 1 and site 4) and in the winter, site 1and site 3 showed a higher broad shoulder in the histogram as compared to other selected sites. This situation led to a comparatively higher detection rate resulting in lower density estimates may influenced by biased or small sample size (Herrmann et al., 2010). It was an assumption that we were attentive to, that transects within dense vegetation show lower visibility despite the higher density, this is typical across the heterogeneous survey region (Buckland et al., 2001; Herrmann et al., 2010). While maximum detections of hares were single, we were attentive in counting hares in clusters, and regardless of vegetation structure (Rivera-Milán et al., 2015).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29212934

Although there were a great number of Cape hares at 0 m distance from the 1 km length transect line. The 0 m distance assumption is critical (Buckland et al., 2001). Herrmann et al. (2010) studied spring Cape hare, and steenbok (*Raphicerus campestris)* densities in South Africa by distance sampling in different seasons in forestland with associated open land hare density, which was higher in summer. The European hare has been measured in numerous countries and its abundance has been found to be between 21 and 330/ ha, varying according to the landscape type (Smith et al., 2004). The abundance of lagomorph was counted in many countries using transects but was much higher than those found in our study area where e.g., Australia (25 rabbits/km, (Moreno et al., 2008)) and New Zealand (125 rabbits/km (Olsen et al., 2014)). European abundances of brown hares can extent densities in excess of 100 hares km^2 (Smith et al., 2005). Seasonally Pellets abundance also differed among the habitat, but high counted in site 1. The defecation rates of mountain hares *(Lepus timidus*) vary with season (Hewson, 1989). Pellet abundance index was greater in the site 1. We used the uncleared way to calculation pellets abundance due to some transect not accessible for winter and Cape hare defecation rates were also high, similar results were found in previous results described by (Welch, 1982). The abundance of pellets was higher in site 1, for examples, the accessibility of food resources and escape covers also influenced on latrines site selection of hare (Krebs et al., 1995).

In this study, we found that the seasonal and spatial distribution of Red fox density was altered among the habitat, although we have not previously reported of Red fox density in the study area so it was difficult to compare spatial Red fox abundance. In summer we encountered the highest density of Red fox 0.028/4 km in site 1 (*Table 2*), and less than 0.009/4 km in site 4, the highest den sites were encountered in site 1 3.01/4 km; site 1, in winter Red fox density (0.010/4 km) was the highest for site 1. Our density estimates were lesser because of revenge to damage, poisons, and inadequate baseline data reports available for Red fox in the current study area, than estimates found in areas of maximum density of Red fox in Europe (3.30 Red foxes/km^2, (Sarmento et al., 2009)). However, some English rural areas Red fox were recorded (0.64 Red foxes/km^2, (Heydon et al., 2000)) and in Portugal as well (0.63 Red foxes/km^2 (Sarmento et al., 2009)).

In the summer Red fox density was significantly positively related to hare density in the closed to open broadleaved or needle–leaved forest, for example Snow shoe hare (*Lepus americanus*) abundance is closely associated with habitat characteristics, and the primary reason for mortality for snow shoes hare is predation (Goszczyński and Wasilewski, 1992b). Seasonal Red fox burrow entrance were negatively correlated with hare pellets abundance in site 1, as others also report, according to those of the hares studies described by (Angelstam and Lindström, 1984). In this work, we investigated the distribution of Red fox per 4 km as considering that the variation in Red fox home range sizes (0.95 km^2 to 358 km^2; (Walton et al., 2017). It was not possible to census Red foxes using torch light counts in site 3, because of the large amount of dense vegetation (Heydon et al., 2000). We found that seasonally the Red fox utilizes dens for birthing and rearing offspring (‘breeding dens’) in the grassland and barren land, where higher accessibility afford less natural boulder, rock cervices dens as well as abundance of prey (Meia and Weber, 1992) in site 3 due to abundance of prey and shelters. We also expected that fuel wood collection and illegal hunting by local people reduced concealment throughout the landscape and increased the compensation of detection for example, den selection is influenced by prey availability in the cases of the Corsac Red

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29212934

fox (*Vulpes corsac*) (Murdoch et al., 2009), the Eurasian badger (*Meles meles*) and the Red fox (Márton et al., 2016). We assumed that high density of Red fox in site 1 and low density of Red fox in other habitats significantly depend on the abundance of prey species and avoid human conflicts.

Our study results explained that hare abundance is positively associated with vegetation such as shrubs, herbs, such a similar results also found in case of snowshoe hare (*Lepus americanus*) (Hodges et al., 2009). Roads are negatively linked with hare abundance (Roedenbeck and Voser, 2008). Hare abundance was also negatively associated with agricultural land at site 2 due to conflicts by farmers, such results were also described by (Santilli et al., 2015).

Agricultural land and roads were positively linked with hare abundance(Reichlin et al., 2006). The hare seasonal pellets abundance index was positively linked with herbs and trees , e.g. snow hare (Hodges et al., 2009). Similarly, Hodson et al. (2011) reported that shrubs and saplings provide lateral protective cover for hare. Furthermore, in Pakistan, the Cape hare prefers alpine meadows in the summer season while in winter it moved down to steppe meadows (Roberts, 2005).

Conclusions

Our finding also showed that Cape hare density plays a key role in the natal den site selection and spatial distribution of Red fox. Furthermore, we expected that prey density distribution, habitat association and behavioral response may result from the lethal (predation) or non–lethal (landscape fear) effect of a predator, or human. Human-wildlife interactions can result in conflict where perceived damage to livelihoods occurs in socio-economically poor areas. In the Shigar Valley, Karakorum Range, Pakistan, subsistence mixed farming is the predominant land use and Red foxes as well as preys are extensively persecuted. Understanding on the effects of human activity and habitat features of Red fox and Cape hare feeding behaviors in the region are lacking. The findings recommended that Red fox and Cape hare do not avoid human settlements area. In the future, further Red fox genetics studies are needed to be conducted with a focus on ecosystem functions via seed dispersal, carrion removal and regulation of prey populations. It is envisioned that this work can be offered to local authorities as the first piece of scientific literature for the area, serving as a valuable resource for local public education, and also for tourists and NGO community visitors of the Karakorum national park.

Acknowledgments. We would like to thank Dr. M. Anwar, M. Rais, T. Mahood, I. Hussain and Mr. J. Hussain for their moral support. We would also like to thank Mr. N. J. Roberts et al in Feline Research Center of National Forestry Administration, for their useful comments for revising the manuscript. This work was supported by the Fundamental Research Funds for the Central Universities (2572017PZ14) and NSFC (31872241; 31572285).

Abstract. Fertility degradation of Mollisols affects world food security. Understanding the degradation mechanisms of Mollisols is essential in order to restore the soils' productivity. A long-term field experiment was conducted to assess soil phosphorus (P) concentrations and fractions in a Mollisol at its early development stage under different cropping systems in Northeast China. Parent material (PM) and mature Mollisol (OM) were used for comparison. Organic P (Po) concentrations under natural fallow (Pnat), alfalfa (*Medicago sativa L.*) (Palf) and soybean-maize (S-M) rotation without fertilizer application (PCS-F) increased by 68-74% after 10 years. S-M rotation with mineral fertilizer (PCS + F), organic matter amendment (PCS + F + OM), or crop straw return (PCS + F + BM) increased Po concentrations by 74.1-108 mg kg^{-1}, which is equivalent to 33% of total Po in the OM; and increased Ca_2-P, Ca_8-P, Al-P and Fe-P concentrations by 0.9-1.3, 7.1-8.8, 2.1-2.7 and 1.6-1.7 times, respectively. 67% of the applied fertilizer P was transformed to Pi for the treatments with chemical fertilizer. The results indicate that return of crop residue combined with chemical fertilizers enhances the accumulation of P in soils at their early development stage, which has important implications for the fertility restoration of a Mollisol in Northeast China and elsewhere in the world.
Keywords: *soil development, natural fallow, long-term restoration experiment, organic phosphorus, inorganic phosphorus*

Introduction

Phosphorus (P) is one of the essential elements for crop growth and development. Over 80% of P absorbed by crops comes from a soil reserve (Fageria et al., 2008) and applied fertilizer P reverts to less available forms in the soil (Han et al., 2005a, b). Therefore, the fractions and availability of soil P, and the transformation and availability of applied fertilizer P have received much attention in agronomic research (Milic et al., 2019; Sun et al., 2019). Soil P fractions include inorganic P (Ca_2-P, Ca_8-P, Al-P, Fe-P, O-P, Ca_{10}-P) and organic P (labile organic P, moderately labile organic P, moderately stable organic P and highly stable organic P). Generally, organic P (Po) accounts for 30-65% of the total P in soils (Pätzold et al., 2013; Jin et al., 2013), while organic P in Mollisol accounts for 42-69% of total P (Song et al., 2007), which can be attributed to the relatively high organic matter contents (Hou et al., 2014). Crops directly utilize inorganic P (Pi) in soil solution (generally orthophosphates), which is in dynamic equilibrium with phosphate minerals and surface adsorbed P in soil (Xiang et al., 2004). With the advancement of soil development, Po fractions become dominant and P availability is more closely related to the activity of soil microorganisms (van der

DOI: http://dx.doi.org/10.15666/aeer/1802_29352948

Bom et al., 2019; Richardson et al., 2011). Generally, plant available P comes from the pools of Fe-P, Al-P, moderately labile organic P (MLOP) and labile organic P (LOP) in acid soil; while from the pools of Ca_2-P, Ca_8-P, LOP and MLOP in alkaline soil (Li et al., 2005). Therefore, Po fractions play an important role in P supply, especially in soils with relatively high organic matter content (Vanden Nest et al., 2016; Nobile et al., 2020).

The development and utilization of a Mollisol in Northeast China underwent both natural virgin stages through the stages of cultivation without fertilizer application, cultivation with organic matter application, and cultivation with the combination of organic matter and inorganic fertilizers. The impacts of different cropping systems and agricultural practices on the content and fractions of P in Mollisol have been reported (Song et al., 2007). Mollisol was fertile in nature and could sustain P supply under both natural and agricultural production systems. Excessive applications of chemical P fertilizers increased both available and unavailable P fractions (Song et al., 2007). However, the soils in Northeast China suffered from severe erosion as a result of intensive agricultural practices, which has caused 60% loss of soil organic matter content (Miao et al., 2019). In some extreme cases, soil erosion has removed the surface layer, with exposed parent material (C horizon). It is important to understand P transformations in soil during the period from parent material to current stage.

The restoration of degraded soil has been undertaken at a large-scale and proven to be successful in terms of above-ground ecosystem properties. However, it still lacks understanding regarding soil development in relation to vegetation changes (Griffiths et al., 2008; Harris, 2009), which could be attributed to the fact that it takes a long time to build a high level of soil fertility under natural conditions (Harrison et al., 2008). Anthropogenic activities can accelerate the pedogenic process as indicated by a significant increase in soil organic matter content with all the treatments including no fertilizer, chemical fertilizer and chemical fertilizer plus organic residue amendments during the first eight years of soil development from parent material (You et al., 2017). The inputs of crop residue and manure changed the distribution of carbon (C) density fraction and humic substances. High organic matter input first caused an increase in labile C pool, followed by stable C fractions (You et al., 2014). Soil microbial activity increased with tillage and organic amendment at the early pedogenic stage of parent material, as evidenced by an increase in soil microbial biomass-C and total PLFAs, as compared to the parent material (Li et al., 2014). The soil food web was quickly developed with fertility restoration practices (Li et al., 2016). However, information was limited about P transformations at the initial stage of soil development from the parent material.

Prior studies have focused on the impact of different vegetation types and agricultural practices on P fractionation in mature Mollisol, with much less attention being paid to young soils. Lu et al. (2015) reported that fertilizer P applied in Mollisol was transformed to Al-P and Fe-P, with less than 20% being accumulated as Po. Few reports are available about the effects of cropping systems (or vegetation types) and related agricultural practices on the changes of P fractions in the initial stages of soil development. Accordingly, a field experiment was established in 2004 to examine soil development from parent material (C horizon) of a Mollisol. To simulate the effects of cropping systems and agricultural practices on P fractions at the early development stage of soil, it was hypothesized that application of exogenous P including chemical fertilizer P and P in organic amendment can enhance the accumulation of P in parent

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29352948

material, which can reach relatively high levels within a short term. The objectives of this study were to: (1) identify P fractions in parent material and; (2) determine the effect of cropping systems and agricultural practices on P fraction in the initial stage of soil development.

Materials and methods

Site description and soil sampling

The long-term restoration experiment was located in the center of the Mollisol' area in Northeast China at the State Key Experimental Station of Agroecology, Chinese Academy of Sciences, Hailun, Heilongjiang province (47°26′N, 126°38′S). The Mollisol was derived from the sedimentary material of loamy loess parent material (Xiong et al., 1987). Typical soil profiles consist of A-AB-BC-C horizons (A, 0-60 cm; AB, 60-115 cm; BC, 115-150 cm; C, > 170 cm depth). The depth to bedrock is > 20 m. Soil classification is Pachic Haploborolls (fine-silty, mixed, superactive, mesic Pachic Ultic Haploxeroll) according to the USDA Soil Taxonomy (Soil Survey Staff, 2014). The climate in the region is typical temperate continental monsoon, characterized by cold winters and hot summer; with the mean annual temperature of 2.2 ℃. The average total annual precipitation is 550 mm, with approximately 358 mm occurring from June to August.

The long-term restoration experiment started in June 2004 with 24 enclosed plots (each plot measured 1.4 m long, 1.0 m wide and 0.8 m deep). The enclosures consisted of cement strips (0.2 m wide and 0.8 m deep) that protruded 0.1 m above the ground. These enclosures were refilled with parent material taken from the 2 m depth (C horizon) below surface near the experimental station. The parent material had a semi-blocky structure. Nylon mesh with 75 μm openings was placed on the parent material at 0.8 m depth to prevent root penetration, but it allowed water and nutrient exchange. The parent material contained 4.79 g C and 0.41 g N kg^{-1} soil, had a pH of 6.88 (soil: DI water 1:2.5), bulk density of 1.35 g cm^{-3}, 420 g kg^{-1} clay (< 0.002 mm) and 356 g kg^{-1} silt (0.02-0.002 mm). The dominant clay minerals were vermiculite, chlorite and illite (*Fig. 1*).

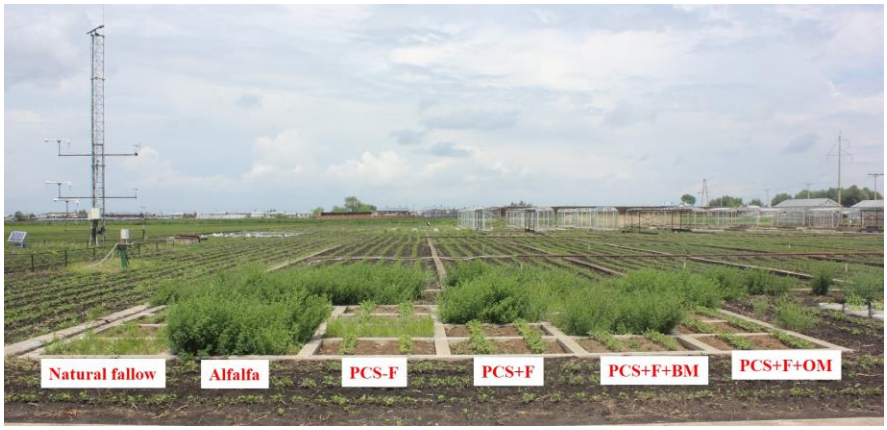

Figure 1. *The experimental plots in the field*

The following six treatments were assigned to the 24 plots with the parent materials as a randomized block design with four replications: natural fallow without weed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29352948

control (*vegetation consisted mainly of Leymus chinensi, Poa annua L. and Equisetum tataricus*) (Pnat), N-fixing alfalfa (*Medicago sativa L.*) (Palf) and four Soybean (S)-Maize (M) rotation: (i) S-M without mineral fertilizer and biomass removed (PCS-F), (ii) S-M with mineral fertilizer and biomass removed (PCS + F), (ii) S-M with mineral fertilizer and partial return of residue as a soybean powder-maize straw mixture (PCS + F + OM) and (iv) S-M with mineral fertilizer and all biomass incorporated (PCS + F + BM) (*Table 1 and 2*). The biomass in each plot of Pnat and Palf treatments was left in the fields as mulch. In P + F-OM, 2250 kg ha^{-1} ground soybean seeds that had been baked at 200 ℃ and 4500 kg ha^{-1} chopped (20-50 mm long pieces) maize straw were incorporated into the soil at the same time as the other residue return treatments. The C content in the soybean powder and maize straw was equivalent to the C content of a typical organic manure application and return of maize straw C in this region (Qiao et al., 2014). In the PCS + F + BM treatment, the biomass of each year's crop was incorporated into the field, but the maize grain and soybeans were pulverized as above. The fertilizer sources were diammonium phosphate and potassium sulphate, applied at 54, 60, and 54 kg N, P and K ha^{-1} $year^{-1}$, respectively, for soybean and maize. An additional 140 kg N ha^{-1} $year^{-1}$ was applied as urea at the V8 stage of maize growth. The parent material was tilled to 20 cm depth with a spade to incorporate the chopped crop residue, and ridges (70 cm wide and 25 cm high) were made after applying the organic amendments. The first crop of rotation was soybean. The crop densities were 70000 and 270000 plants ha^{-1} for maize and soybean, respectively. The varieties of soybean and maize were Dongsheng 7 and Haiyu 6, respectively. The crops were sown in rows in May and harvested in October. At harvest, the above-ground biomass in each plot was cut and weighed, and subsamples were oven-dried at 60 ℃ to determine the dry weight of grain and non-grain biomass.

Table 1. *The list of abbreviations for field treatments*

Field treatments	Natural fallow	Alfalfa	Parent material	Mineral fertilizer	Biomass	The mixture of soybean powder-maize straw
Abbreviations	Pnat	Palf	PCS	F	BM	OM

Table 2. *Experimental treatments (i.e. crop rotations, inputs of plant material and mineral fertilizer, tillage) in the 10 years field experiments*

Field treatments	**Cropping systems[a]**	**Organic incorporation[b]**	**Mineral fertilizer input[c]**	**Tillage[d]**
Pnat	Natural fallow	Litter and roots	None	No
Palf	Alfalfa	Litter and roots	None	No
PCS-F	Crop rotation	Roots	None	Yes
PCS + F	Crop rotation	Roots	NPK	Yes
PCS + F + BM	Crop rotation	All crop straw, seeds and roots	NPK	Yes
PCS + F + OM	Crop rotation	Roots, and amended soybean seeds and maize straw	NPK	Yes

[a]Crop rotation is the rotation of soybean and maize in different years since 2004
[b]The amendment rates in PCS + F + OM were 2250 kg hm^{-1} of baked soybean powder and 4500 kg hm^{-1} of maize straw mixed homogeneously. The C:N ratios were 7.4:1 in soybean seeds, 33.5 in maize, 63.3:1 in maize straw and 59.1 in soybean straw
[c]Diammonium phosphate was source of N and P and applied at a rate of 300 kg hm^{-1} yr^{-1}; Potassium sulfate (K) was applied at a rate of 120 kg hm^{-1} yr^{-}
[d]Tillage was performed manually down to 20 cm with ridges made in October after harvest

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29352948

Soil samples at the surface layer (0-20 cm) were collected from the six treatments in all four replications after harvest in October 2013. Composite soil samples, consisting of four random subsamples, were removed with a spade from the ridge and furrow locations and mixed thoroughly. The soil surface layer (0-20 cm) of each treatment was air-dried after removing all visible roots and plant fragments and sieved through a 2 mm or 0.25 mm sieve. The samples of parent material (PM) were taken below 2 m depth in 2004. Mature Mollisol (OM) was sampled from the A horizon (0-20 cm) from an adjacent experimental field, which had been cropped to a maize and soybean rotation since 1993 and received only mineral N (120 g kg^{-1}, urea) and P (51.8 g kg^{-1}, diammonium phosphate) fertilizers for maize and N (20.3 g kg^{-1}, urea) and P (51.8 g kg^{-1} diammonium phosphate) fertilizers for soybean. All aboveground biomass had been removed from field of the mature Mollisol and soil tillage had been manually conducted to the 20 cm depth using a spade.

Soil sample analysis

The soil samples were air-dried and sieved through a 2-mm sieve for the laboratory experiment. Total P (T-P) in soil samples was determined by digesting soil in a tri-acid mixture (HNO_3, $HClO_4$, and H_2SO_4 at a 3:1:1 ratio) and P concentration in the digested samples determined calorimetrically using the vanado-molybdate-yellow color method (Jackson, 1973). Soil total organic P was determined after the soil was combusted at 550 °C and extracted with 4 M H_2SO_4 (Anderson, 1960). Available P was analyzed with the colorimetric molybdenum method following extraction with 0.5 M $NaHCO_3$ (Olsen et al., 1957).

Organic P fractions

Soil organic P (Po) was separated into four fractions using a modified sequential extraction procedure developed by Bowman et al. (1978) and modified by Fan et al. (1990). A flow diagram for the Po fraction procedure is given in *Figure 2*. Highly stable organic P (HSOP) was determined by subtracting the moderately stable organic P (MSOP) from the stable organic P.

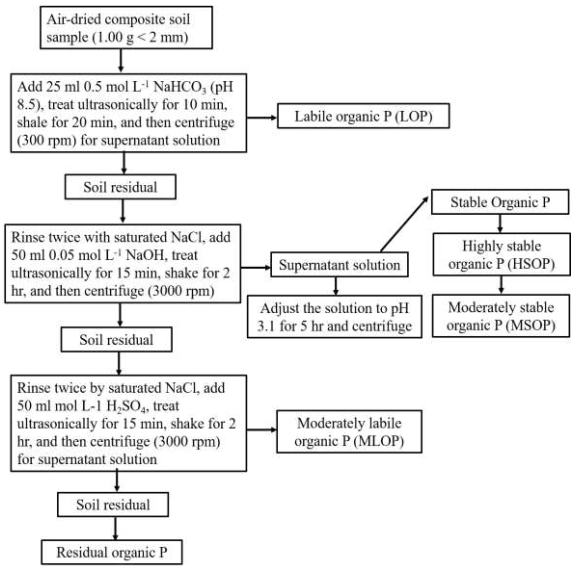

Figure 2. *Scheme of sequential extraction of organic P in a Mollisol (Yang et al., 2006)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29352948

Inorganic P fractions

Inorganic P fractions were measured according to the fractionation scheme of Jiang et al. (1989) modified from the method described by Chang et al. (1957) and Hedley et al. (1982). Briefly, the fractionation involved a sequential extraction with (1) 0.25 M $NaHCO_3$ (pH 7.5) to extract Ca_2-P, (2) 0.5 M CH_3COONH_4 (pH 4.2) to extract Ca_8-P, (3) 0.5 M NH_4F (pH 8.2) to remove Al-P, (4) 0.1 M NaOH-0.1 M Na_2CO_3 to obtain Fe-P, (5) 0.3 M sodium citrate-$Na_2S_2O_4$-0.5 M NaOH to obtain the occluded P and (6) 0.5 M H_2SO_4 to extract Ca_{10}-P. These fractions were designated as $NaHCO_3$-soluble P (Ca_2-P), NH_4Ac-soluble P (Ca_8-P), NH_4F-soluble P (Al-P), NaOH-$NaCO_3$-soluble P (Fe-P), occluded P (O-P), and H_2SO4-soluble P (Ca_{10}-P).

Statistical analysis

The analysis of variance (ANOVA) was performed using the SPSS (version 16, IBM SPSS Statistics, Somer, NY) to determine the significant difference between the treatments. Standard errors were calculated for mean values of determinations. The multiple comparison test was performed using Fisher's (protected) Least Significant Difference (LSD) at the 0.05 significant level. A principal component analysis (PCA) of the soil phosphorus fractions for all the field treatments, mature Mollisol and parent material was generated using CANOCO 5.0 software (written by Cajo J. F. ter Braak and Peter Smilauer, http://www.canoco5.com).

Results

Total P and Olsen P

Compared to parent material (PM), total P in unfertilized soils (Pnat, Palf and PCF-F) did not significantly increase ($P > 0.05$), but Olsen P did ($P < 0.05$) (*Fig. 3*). For the treatments with mineral fertilizers and organic matter amendment (PCS + F, PCS + F + OM and PCS + F + BM), total P concentrations increased by 282.1-330.6 mg kg^{-1} (*Fig. 3*), which was equivalent to the total P concentration in the OM. Olsen P concentrations increased by 93.3-114.9 mg kg^{-1}(*Fig. 3*), which was higher than that in the OM, indicating that application of chemical fertilizers and organic amendment enhanced P accumulation in soil after the initial10 years of treatments from parent material.

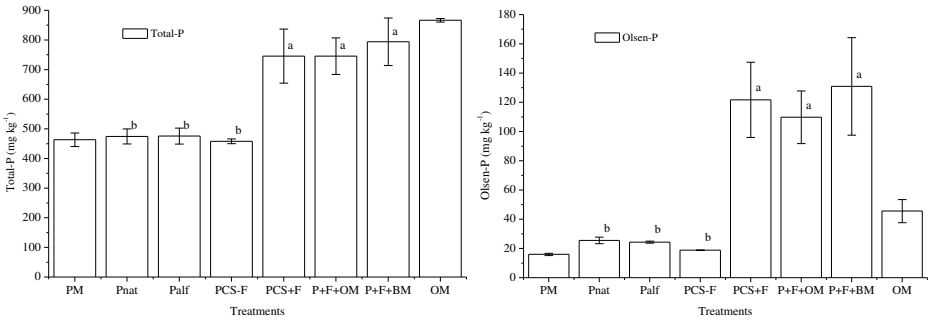

Figure 3. *The contents of total P and Olsen P in parent material of soil formation, parent material and mature Mollisol. (Pnat, natural fallow (grasses); Palf, alfalfa; PCS-F, unfertilized soybean-maize (S-M) control; PCS + F, chemical fertilizer S-M; PCS + F + OM, organic amendment plus chemical fertilizer S-M; PCS + F + BM, chemical fertilizer and all crop biomass returned S-M. Values followed by different letters differ significantly at* $P < 0.05$*)*

DOI: http://dx.doi.org/10.15666/aeer/1802_29352948

Organic and inorganic P

Total organic and inorganic P

Compared to PM, the treatments without chemical fertilizers (Pnat, Palf and PCS-F) increased organic P (Po) but decreased inorganic P (Pi) (*Fig. 4*). However, the treatments with chemical fertilizers and organic amendment (PCS + F, PCS + F + OM and PCS + F + BM) significantly increased Pi concentrations with the highest value of 586.8 mg kg^{-1} occurred to the PCS + F treatment, which was higher than that in OM (348.7 mg kg^{-1}) (*Fig. 4*). The Po concentrations in all the field treatments increased by 68.2-138%, as compared to PM, and the highest value (186.2 mg kg^{-1}) was observed in the PCS + BM treatment, which was 39.4% of Po in the OM. OM had a similar Pi concentration as the PM, but had more Po (*Fig. 4*). The percentages of Po in the total P were lower in PM than OM, which were 57.4%, 18.2% and 20.6 - 31.9%, respectively for OM, PM and all the tested soil. The percentage of Po in total P within Pnat, Palf and PCS-F treatments was higher than those in the PCS + F, PCS + F + OM and PCS + F + BM treatments (*Fig. 4*).

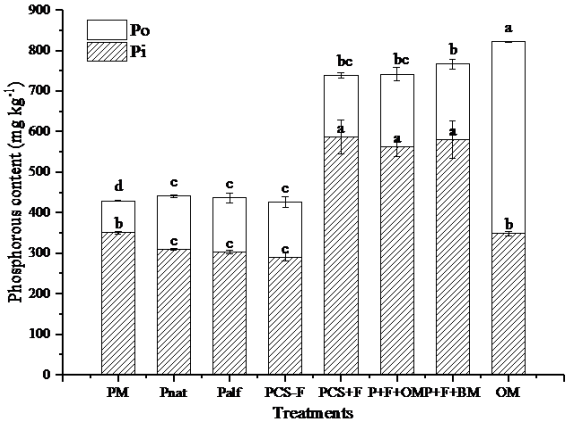

Figure 4. *The concentrations of organic p and inorganic P in parent material of soil formation, parent material and mature Mollisol. (Pnat, natural fallow (grasses); Palf, alfalfa; PCS-F, unfertilized soybean-maize (S-M) control; PCS + F, chemical fertilizer S-M; PCS + F + OM, organic amendment plus chemical fertilizer S-M; PCS + F + BM, chemical fertilizer and all crop biomass returned S-M; Po, organic P; Pi, inorganic P; PM, parent material; OM, mature Mollisol. Values followed by different letters differ significantly at* $P < 0.05$*)*

320 mg P kg^{-1} was applied to the soil as diammonium phosphate every year during the 10 years of the experiment in the treatments with chemical fertilizers (PCS + F, PCS + F + OM and PCS + F + BM) (*Table 2*). Compared to PM, total P concentrations in the treatments with chemical fertilizers increased by 282.1-330.6 mg kg^{-1}, which was comparable to the amount of P applied in fertilizers (*Fig. 4*). The different total P concentrations among treatments could be attributed to the removal of P in aboveground biomass, which possibly caused P loss in the PCS + F treatment. Total P concentrations in the PCS + BM treatment reached the highest value of 330.6 mg kg^{-1} (*Fig. 3*), which is higher than the total P input via fertilization. This can be attributed to biomass decomposition including aboveground and root biomass (*Fig. 3*). This indicates that most of the applied P accumulated in the top 0-20 cm of soil depth. This increased in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29352948

total P was made up of the increase of 211.1-235.9 mg kg^{-1} of Pi and 74.1-108.0 mg kg^{-1} of Po over the 10-year period of the experiment (*Fig. 4*). Compared to PM, available P in the PCS + F, PCS + F + OM and PCS + F + BM treatments increased by 93.8-114.9 mg kg^{-1}, indicating that approximately 33% of the applied fertilizer P accumulated in the Olsen P pool (*Fig. 4*).

Phosphorus fractions

The total P concentrations in soil increased after the initial 10 years of experiment regardless of treatments, whilst vegetation types and agricultural practices showed different effects on Pi fractions (*Table 3*). There was an increase mainly in the concentrations of LOP and MLOP. Compared with the LOP of PM without P fertilizers, the highest concentration of LOP was found in the PCS + F + OM treatment, which accounted for approximately 25% of the amount in OM (*Table 3*). MLOP concentrations in all the tested soils increased by 2.9-5.3 times, with the highest value in the PCS + BM treatment, which was similar to that in OM (*Table 3*). Treatments with P fertilization increased MSOP by 15.3-62.2%, and this accounted for approximately 33% of the MSOP in the OM (*Table 3*). The PCS-F and PCS + F treatments decreased the contents of HSOP, but the rest of treatments did not affect HSOP concentrations. The HSOP concentrations in all the tested soil were much lower than that in OM (*Table 3*).

Pnat, natural fallow (grasses); Palf, alfalfa; PCS-F, unfertilized soybean-maize (S-M) control; PCS + F, chemical fertilizer S-M; PCS + F + OM, organic amendment plus chemical fertilizer S-M; PCS + F + BM, chemical fertilizer and all crop biomass returned S-M; PM, parent material; OM, mature Mollisol; LOP, labile organic P; MLOP, moderate labile P; MSOP, moderate stable organic P; SOP, stable organic P; Ca_2-P, $NaHCO_3$-soluble P; Ca_8-P, NH_4Ac-soluble P, Al-P NH_4F-soluble P; Fe-P, NaOH-$NaCO_3$-soluble P; O-P, occluded P; Ca_{10}-P, H_2SO_4-soluble P. Values followed by different letters at same column differ significantly at $P < 0.05$

In contrast with PM, the treatments without fertilization (Pnat, Palf and PCS-F) decreased the concentrations of Ca_2-P, Al-P and Ca_{10}-P and increased the concentrations of Ca_8-P and Fe-P, whereas the treatments with fertilization (PCS + F, PCS + F + OM and PCS + F + BM) significantly increased the Pi fractions except for Ca_{10}-P and O-P (*Table 3*). The concentrations of Ca_2-P, Ca_8-P, Al-P, and Fe-P increased by 0.9-1.3, 7.1-8.8, 2.1-2.7 and 1.6-1.7 times (*Table 3*). The concentrations of Ca_2-P,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29352948

Ca_8-P, Al-P, and Fe-P in OM were much higher than those in PM, but the concentrations of O-P and Ca_{10}-P in OM was lower than those in PM (*Table 3*).

Pedogenic process of parent material under Mollisol

Principal component analysis demonstrated that a large difference was found between OM and PM (*Fig. 4*), parent material with the field treatments had developed into mature Mollisol over the 10-year period of the experiment. Compared with the treatments without fertilizers (Pnat, Palf and PCS-F), the soils receiving fertilized treatments were closer to mature Moillisol (*Fig. 5*). Inorganic P concentrations in the soils treated with chemical fertilizers (PCS + F + BM, PCS + F + OM and PCS + F) were similar to the Pi in the OM, but a large difference in Po concentration exists between PM and OM (*Fig. 5*).

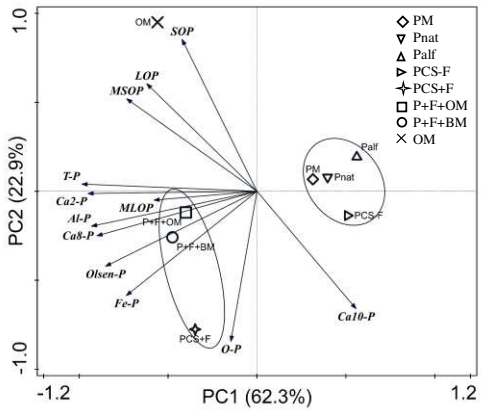

Figure 5. *The first two principal components (PC1 and PC2) of soil phosphorus fractions for all the field treatments, mature Mollisol and parent material. (Pnat, natural fallow (grasses); Palf, alfalfa; PCS-F, unfertilized soybean-maize (S-M) control; PCS + F, chemical fertilizer S-M; PCS + F + OM, organic amendment plus chemical fertilizer S-M; PCS + F + BM, chemical fertilizer and all crop biomass returned S-M)*

Discussion

Changes in different P fractions

Most P was present as calcium phosphates at the early pedogenic stage of rock, and vegetation occurrence converted Pi to Po in soil (Lu, 1980). In the parent material of Mollosil, the Pi concentration was 78.2 mg kg^{-1}, which accounted for 16.55% of that in mature Mollisol (*Fig. 4*). The unfertilized treatments (Pnat, Palf and PCS-F) did not increase total P, but increased Po to 131.5-136.1 mg kg^{-1}, accounting for 27.8-28.8% of Po in OM (*Fig. 4*), which is consistent with the organic carbon change measured by You et al. (2017), who reported that organic carbon increased by 7-60% in the same site. Soil organic carbon gradually increased in the parent material after vegetation occurrence, which resulted in an increase in Po, but a decrease in Pi concentration of a similar amount, indicating the transformation of Pi to Po during soil development from parent material. Specifically, Ca_2-P, Al-P, O-P and Ca_{10}-P were transformed to LOP and MLOP (*Table 3*), indicating that plants absorbed Pi and returned Po in residues to soil.

The Pnat and Palf treatments demonstrated a similar effect on the transformation of P fractions, which differed from the PCS-F treatment (*Table 3*) where SOC was only

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29352948

derived from root and litter. This resulted in a relatively low Po concentration with a decrease in HSOP in the PCS-F treatment. Perroni et al. (2014) has documented that Alfalfa growth resulted in an increase in Po in a desert scrub soil in Mexico. Parent material used in the present study had a low SOC (4.8 g kg^{-1}) in this study, and the field treatments rapidly increased SOC (You et al., 2017) and subsequently Po in the soil. However, Alfalfa did not show any advantage in the accumulation of Po fractions in the parent material.

A mature Mollisol had been cultivated for hundreds of years, underwent no fertilization stage, farmyard manure stage and chemical fertilization stage. The accumulation of Po increased during soil development and utilization. However, the accumulation of Po concentration became steady at a certain level without the application of inorganic P fertilizers (Song et al., 2011). The transformation of Pi to Po occurred at a lower rate in the treatments without fertilizers where Po accumulation per year accounted for 1% of that in the mature Mollisol (*Table 3*). Apparently, external P inputs could accelerate the accumulation of Po in soil under field conditions.

Effects of fertilizer application on P fractions

In this study we attempted to accelerate P formation in the parent material by adding P fertilizers to contrast with the natural soil development process. P fertilizer applied to soil was mainly presented as Pi in the plant-available fractions in parent material under the imposed cropping systems and agricultural practices (*Table. 3*). The rate of Po accumulation in the treated parent material was relatively slow, but approximately 33% of the fertilizer P was transformed to Po. Total P concentration in the treated parent material was close to that in the mature Mollisol, which may be attributed to the application of P fertilizers over the 10-year of the experiment (*Fig. 4*). Soil development in the Mollisol parent material was accelerated by P fertilization based on the result of PCA (*Fig. 5*), whilst soil development in the vegetation restoration contexts may take hundreds of years to accomplish this level of fertility (Harrison et al., 2008). Po accumulation was as high as 40% in the mature Mollisol, which is an evidence of the acceleration of soil development in the parent material used in this study.

Reddy et al. (2000) found that soil P fractionation was affected by soil type and fertilization practices, and the application of cattle manure increased the concentration of Po, activated fixed Pi in soil, and thus enhanced uptake of P by crops. Application of chemical fertilizers, straw and animal manure increased Pi concentration in the soils of Northwest China (Wei et al., 2011). Chemical fertilizers and organic manure also affected P sorption capacity in a Mollisol (Song et al., 2007). The long-term experiment with a Mollisol showed that chemical fertilizers (N and P), and the combination of chemical fertilizers with pig manure increased both total P and Olsen P, dominantly in the forms of Ca_2-P, Ca_8-P and Al-P, but no significant increase in Po was noted (Song et al., 2011). Similar results were obtained in present study. P fertilization enhanced Pi accumulation in the treated parent material, which resulted in a significant increase in Pi with the treatments of PCS + F, PCS + F + OM and PCS + F + BM.

The concentrations of Pi showed a decreasing order of PCS + F + AM, PCS + F + OM > PCS + F > Pnat, Palf, PCS-F. The highest value reached 186.2 mg kg^{-1}, accounting for 39.4% of that in the mature Mollisol (*Fig. 4*). Accumulated Po in the parent material was mainly derived from crop residues, and a higher rate of organic amendment resulted in more accumulation of Po in soil.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29352948

Long-term field experiments have documented that organic amendment significantly increased the concentration of Olsen P and reduced soil adsorption capacity for P (Motavalli et al., 2002; Allen et al., 2006). Low molecular weight organic substances in organic amendment reduced the adsorption capacity of variable charge minerals for P by competition for adsorbing sites (Guppy et al., 2005). There was no significant difference in the total P and Olsen P concentrations between chemical fertilizers alone and the combination of chemical fertilizers and organic amendment. Applied fertilizer P was mainly presented in the Olsen P pools in the treated parent material. Compared with chemical fertilizer treatment alone (PCS + F), the treatments of chemical fertilizers with organic amendment (PCS + F + OM and PCS + F + BM) had no significant difference in Pi and Po concentrations or the Po : total P ratio.

Conclusions

The long-term field experiment was established in 2004 to determine the impact of cropping systems and agricultural practices on soil P concentration and fractionation during the first 10 years of soil development from parent material of a Mollisol. Po and Pi concentrations were 78.9 and 350.9 mg kg^{-1} in parent material, and 472.6 and 348.7 mg kg^{-1} in mature Mollisol. The treatments without chemical fertilizers (Pnat, Palf and PCS-F) enhanced P transformation from Ca_2-P, Al-P, O-P, Ca_{10}-P to Po in PM. The treatments with chemical fertilizers (PCS + F, PCS + F + OM and PCS + F + BM) increased total P concentration in PM to a level similar to that in OM, Po by 74.1-108 mg kg^{-1}, accounting for 20.6-31.9% of in the total P, lower than that in the Mollisol. The results from the present study indicate that agricultural practices with fertilizer application can enhance the accumulation of P during soil development from parent materials of a Mollisol in semi-arid and semi-humid climatic regions in a relatively short period. This information has important implications in the restoration of degraded Mollisols. The further studies are warranted to detect the mechanisms of P transformation during the process of fertility restoration.

Abstract. Due to the constantly increasing interest in growing spelt, research on the effects of different agronomic factors on grain quantity and quality is still valid and necessary. Nevertheless, the available literature lacks comprehensive studies on optimization of spelt mineral fertilization, especially concerning grain chemical composition. The aim of this study was to evaluate some grain quality characteristics and macro- and micronutrient content in grain of winter spelt cultivars ('Oberkulmer Rotkorn', 'Badengold', 'Frankenkorn') depending on foliar fertilizers applied (Santaura Pro+ or Prohorti Micro Amin Mg). Fertilizers were applied three times during the spelt growing season. The chemical composition of spelt grain was mostly dependent on cultivar and weather conditions during the crop growing season. The highest N, Ca, Mn, Fe, and Zn contents were determined in grain of the cultivar 'Oberkulmer Rotkorn'. Moreover, this cultivar contained most protein and gluten and was characterized by the highest sedimentation index. Grain of cv. 'Badengold', in turn, was poorest in terms of protein and gluten and, at the same time, exhibited the lowest N, P, Mg, Ca, Mn, Fe, and Zn content. Application of foliar fertilizers increased N, P, K, Cu and Mn content in spelt grain compared to plants grown without foliar fertilization.
Keywords: *macro- and micronutrients, protein, gluten, sedimentation index, biofortification*

Introduction

To reduce the dominant position of common wheat as a basic food material, a growing interest has been observed in the cultivation of ancient wheat forms in recent years. One of them is spelt wheat (*Triticum aestivum* ssp. *spelta* L.), belonging to the biological species *T. aestivum* L. Spelt played an important role in nutrition in old Europe, becoming the main bread cereal. With time, however, it lost its importance and its crop area gradually declined (Arzani and Ashraf, 2017). For some period of time, spelt was a forgotten cereal, but during the last 20 years its popularity has been growing. Spelt is valued due to its favorable chemical composition and high nutrient uptake (Ziegler et al., 2016). Its grain is particularly rich in some minerals and vitamins as well as in active biological substances with antioxidant properties (Suchowilska et al., 2012; Świeca et al., 2014; Andruszczak, 2017; Zrcková et al., 2019). According to some authors, it is characterized by a more favorable chemical composition compared to common wheat cultivars because it contains more protein, gluten, amino acids, dietary fiber, fat-soluble vitamins (A, D, and E), and unsaturated fatty acids (Ruibal-Mendieta et al., 2005; Gomez-Becerra et al., 2010; Escarnot et al., 2012; Jablonskyte-Rašče et al., 2013; Stępień et al., 2016). It has been proven that consumption of spelt wheat promotes a reduction in blood

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29492958

cholesterol, supports digestive system activity, and reduces the risk of diseases related to the formation of gallstones in the body (Abdel-Aal and Rabalski, 2008).

The cultivar factor plays a major role in determining the chemical composition of cereal grains. Habitat conditions are also of essential importance, whereas agronomic practices, fertilization in particular, have a smaller impact (Cazzato et al., 2013). In modern agriculture, a proper cereal fertilization strategy should include not only soil fertilization, but also foliar feeding of plants. Such treatment enables quick supply of macro- and micronutrients both in the case of their deficiency in soil and inhibited nutrient uptake by root system (Mikos-Szymańska et al., 2018). Foliar fertilizer application is particularly advisable during the period of critical nutrient requirement of cereals, i.e. at stem elongation stage. In the case of micronutrients, foliar fertilization can essentially meet plants' requirement for these nutrients (Bharti et al., 2013). An insufficient amount of micronutrients in a plant leads to its reduced resistance to adverse habitat conditions and, as a consequence, to a decrease in yield and deteriorated grain quality (Potarzycki and Grzebisz, 2009).

The present study hypothesized that foliar application of the compound fertilizers Santaura Pro+ and Prohorti Micro Amin Mg would improve macro- and micronutrient supply to plants and beneficially affect the processing quality of spelt wheat grain. The aim of this study was to determine mineral content and also protein, gluten, and starch content as well as sedimentation index in spelt wheat grain depending on cultivar and foliar plant feeding.

Materials and methods

Field experiment and cultivation management

A field experiment was conducted over the period 2015–2017 at the Bezek Experimental Farm located near the city of Chełm (51°19′ N, 23°25′ E), Poland. The experiment was set up on *Rendzic Phaeozem* [WRB, 2006] derived from Cretaceous bedrock and with a texture of loam. It was characterized by alkaline pH, and the content of minerals was as follows: N_{total} – 3.05 g kg^{-1}, K – 194.7 mg kg^{-1}, P – 406.4 mg kg^{-1}, Mg – 17.9 mg kg^{-1}, S-SO_4 – 4.1 mg kg^{-1}, Zn – 22.33 mg kg^{-1}, Mn – 195.83 mg kg^{-1}, Cu – 2.55 mg kg^{-1}, Fe – 176.76 mg kg^{-1}. The content of C_{org} was 31.3 g kg^{-1}.

A two-factor field experiment was established in a split-plot design in triplicate with a plot area up to 12 m². The experimental design included three winter spelt wheat cultivars, i.e. 'Oberkulmer Rotkorn', 'Badengold', and 'Frankenkorn'. The second research factor was application of foliar fertilizers Santaura Pro+ (SDP – Société de Distribution et de Prestation, France) or Pro Horti Micro Amin Mg (Adob, Poland). The fertilizers were applied three times during the spelt growing season, i.e. at tillering (BBCH 23-25), stem elongation (BBCH 33-35), and heading (BBCH 53-55), at rates of 1 l ha^{-1} and 4 kg ha^{-1}, respectively. The fertilizers were dissolved in 300 l of water per hectare. The control treatment comprised plots without foliar fertilization. Santaura Pro+ is an organic fertilizer obtained from sea algae, which contains nitrogen in the organic form (8%), potassium (K_2O 3%), and micronutrients (iron, manganese, boron, zinc, copper), while its organic matter content is 20%. Pro Horti Micro Amin Mg fertilizer includes the following components: total nitrogen (2.0%), ammonium nitrogen (2%), magnesium oxide (20.0%), sulfur trioxide (39.3%), boron (0.05%), water soluble molybdenum (0.01%), amino acids (5.0%), IDHA (D,L-Aspartic acid, (N-1,2 dicarboxyethyl)-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29492958

tetrasodium salt) chelated zinc (0.1%), IDHA chelated copper (0.05%), IDHA chelated iron (0.15%) and IDHA chelated manganese (0.2%).

The previous crop of spelt was oats. Spelt spikelets were sown at the beginning of October at an amount of 350 kg per hectare. The thousand kernel weight of spelt was 41 g. Mineral fertilization was as follows (in kg of pure ingredient per hectare): N 60 (20+40); P 26.2; K 83. Phosphate and potassium fertilizers as well as 20 kg N ha^{-1} were applied before sowing spelt. In spring, 40 kg N ha^{-1} was applied at stem elongation stage (BBCH 32-34).

Chemical analysis of spelt grain

Grain for chemical analysis was harvested every year at fully ripe stage of spelt (BBCH 89) following the methodology used in experiments on cereals (Ostrowska et al., 1991). Spikelet samples were collected in triplicate in three randomly selected places on each plot, delineated by a 1 m x 0.5 m rectangular frame. After harvest, the collected spelt spikelets were threshed in a Wintersteiger LD 180 thresher. The following elements was determined: N (Kjeldahl method), P (spectrophotometrically), K and Ca (flame photometry), Mg, Cu, Zn, Mn, Fe (atomic absorption spectrometry (AAS)), and B (spectrophotometric curcumin method). The chemical analysis was carried out in an accredited laboratory (accreditation certificate No. AB 1375 issued by the Polish Centre for Accreditation), which meets the requirements of the PN-EN ISO/IEC 17025:2005 standard.

Grain total protein, gluten, and starch content as well as Zeleny sedimentation index were determined using an OmegAnalyzer G computer transmission analyzer of whole grain (Bruins Instruments, Germany).

Statistical analysis

The obtained results were statistically analyzed by analysis of variance. The means were compared using least significant differences based on Tukey's test ($P \leq 0.05$). Calculations were made using ARSTAT statistical software, developed at the Faculty of Applied Mathematics and Information Technology of the University of Life Sciences in Lublin.

Weather conditions

During the field experiment, the average air temperature was generally higher than the long-term average from 1.0°C in the 2016–2017 growing season to 2.2°C in the 2015-2016 season (*Fig. 1*). In the 2014–2015 season, the total rainfall was lower than the long-term average for the relevant period by 23%, while the highest rainfall deficit was found during the period from September to November and also from July to August. The second year of the experiment was much wetter and in that year the total rainfall was higher than the long-term average by 31%. The total rainfall during the 2016–2017 season was close to the long-term average, but the rainfall distribution during the crop growing season varied. The most moisture was recorded in October – in that month the total rainfall exceeded three times the long-term average. In June and August, in turn, a significant rainfall deficit was observed; compared to the long-term average, the amount of rainfall was lower by 65% and 44%, respectively.

Results and discussion

This study shows that the genetic factor had a significantly differential effect on the contents of all macronutrients evaluated in spelt grain (*Table 1*). Among the cultivars studied, most N and Ca were found in grain of cv. 'Oberkulmer Rotkorn'. Cv. 'Frankenkorn' contained most P and Mg, while cv. 'Badengold', in turn, was characterized by the highest K content. At the same time, grain of cv. 'Badengold' was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29492958

found to have a significantly lower N, P, and Ca content in comparison to the other cultivars, whereas relative to cv. 'Frankenkorn' – a significantly lower Mg content. The obtained results corroborate the studies of other authors which indicate high variation in the mineral composition of spelt grain due to the genotype (Gomez-Becerra et al., 2010; Andruszczak, 2018; Kraska et al., 2019).

Foliar feeding of plants did not have a significant effect on magnesium and calcium content in spelt grain. On the other hand, it resulted in a significant increase in nitrogen and phosphorus content compared to the control treatment. At the same time, this study demonstrated that spelt wheat fertilized with the fertilizer Prohorti Micro Amin Mg contained significantly less phosphorus and potassium in grain compared to plants fertilized with Santaura Pro+. Existing research shows different directions in changes in the chemical composition of cereal grains as influenced by foliar fertilization. Seadh et al. (2009) revealed a beneficial impact of foliar application of micronutrients on N, P, and K content in wheat grain. In turn, in a study by Majcherczak et al. (2006) foliar application of micronutrient fertilizer and copper caused a significant decrease in K content in spring barley grain, whereas zinc and manganese application reduced P concentration.

In the opinion of Kraska et al. (2013) and Gomez-Becerra et al. (2010), mineral content in spelt grain is significantly affected by habitat conditions, in particular weather conditions. This is confirmed by the present study which showed spelt wheat to exhibit high sensitivity to variable weather conditions during the study period. Spelt grain harvested in 2015 was characterized by a significantly higher Mg and Ca content compared to the other years. In the second year of the experiment, the highest grain N and P content and at the same time the lowest K content were obtained, whereas the pattern of weather conditions in 2017 was least favorable for macronutrient content. The then recorded rainfall deficit during spelt flowering and grain ripening, coupled with high air temperature, caused a significant decrease in N, P, Mg, and Ca content in grain, whereas the amount of K increased.

Micronutrient content is an important characteristic from the point of view of the consumer and the nutritional value of a food material. Even though micronutrients are taken up by plants in small amounts, they perform important physiological functions, participating in many metabolic reactions occurring in plants (Potarzycki and Grzebisz,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29492958

2009). The present study reveals that the cultivar factor caused significant differences in Mn, Zn, and Fe content in spelt grain, while Cu and B content showed small variations (*Table 2*). Most micronutrients were found in grain of cv. 'Oberkulmer Rotkorn', whereas cv. 'Badengold' grain was poorest in Mn, Fe, and Zn. The obtained Mn and Fe contents in spelt grain did not substantially differ from the values found for the same cultivars by Kraska et al. (2013). However, these authors demonstrated a much higher Cu and Zn content in grain.

* different letters indicate significant differences at P≤0.05)

Application of the compound foliar fertilizers Santaura Pro+ and Prohorti Micro Amin Mg, compared to the control treatment resulted in significant increase in Mn and Cu concentration in spelt grain, respectively. On the other hand, foliar fertilization did not affect Fe, Zn, and B content. In a study by Knapowski et al. (2017), foliar application of manganese and copper in the form of Adob Mn and Adob Cu fertilizers significantly increased the content of these elements in spelt grain, at the same time reducing Zn content. In turn, Wojtkowiak and Stępień (2015), who applied foliar fertilization of spelt wheat with copper, zinc, and manganese, found grain Fe, Zn, and Mn content to increase.

Micronutrient content (except for B) in spelt grain was significantly affected by weather conditions, which was also confirmed by Gomez-Becerra et al. (2010) as well as by Wojtkowiak and Stępień (2015) in their studies. In the first year of the experiment, spelt grain was characterized by the highest Mn and Fe content, whereas significantly more Cu and Zn were found in grain harvested in 2017 compared to the other years.

Baking quality, which characterizes the suitability of flour for making bread products with appropriate quality characteristics, can be indirectly determined using processing quality parameters such as total protein and gluten content. The present study demonstrates that the spelt cultivars compared differed in terms of grain protein content, which ranged from 13.2% to 15.9%. Cv. 'Oberkulmer Rotkorn' exhibited the significantly highest protein and gluten content, while cv. 'Badengold', in turn, was poorest in these components (*Figures 2* and *3*). Jablonskytė-Raščė et al. (2013) showed similar contents of this component in their research, while Wojtkowiak and Stępień (2015) determined protein content to range between 12.4% and 13.5%.

In a study on the winter spelt cultivar 'Rokosz', Knapowski et al. (2016) proved that foliar application of micronutrients has a beneficial effect on grain quality traits. This study did not confirm such a relationship. The protein and gluten content in spelt grain under application of the fertilizers Santaura Pro+ and Prohorti Micro Amin Mg and in the control treatment was similar. Significant differences were however found between years. Grain harvested in 2016 contained most protein and gluten, whereas the lowest contents of these components were shown in the last year of the study (*Figures 2* and *3*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29492958

Starch content in spelt grain was significantly dependent on cultivar and weather conditions during the growing season, but foliar fertilizer application did not result in significant differences in this trait (*Figure 4*).

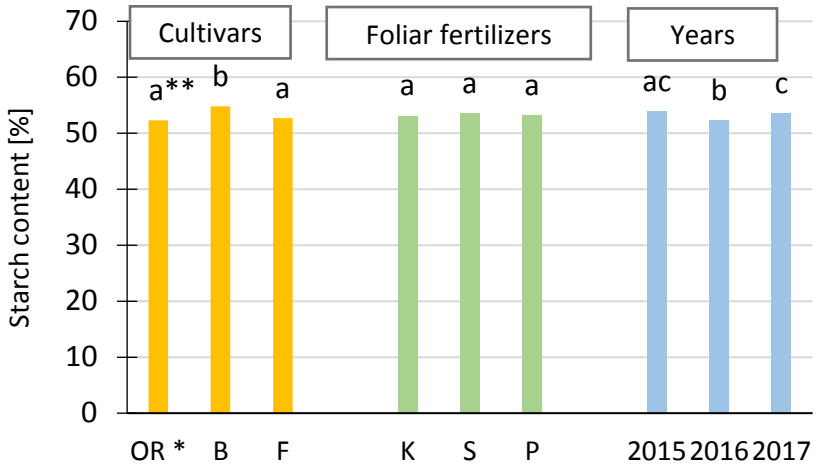

Figure 4. *The starch content in spelt wheat grain depending on experimental factors (* OR – Oberkulmer Rotkorn, B – Badengold, F – Frankenkorn, K – control object without foliar fertilization, S – Santaura Pro+, P – Prohorti Micro Amin Mg; ** different letters indicate significant differences at P≤0.05)*

Among the spelt cultivars in question, the highest sedimentation index was found in the case of cv. 'Oberkulmer Rotkorn', its value was significantly lower for cv. 'Frankenkorn', whereas the lowest value of this index was obtained for cv. 'Badengold' (*Figure 5*). The experiment did not prove that application of the fertilizers Santaura Pro+ and Prohorti Micro Amin Mg had a significant effect on Zeleny sedimentation index, but this study found significant differences in the values of this index between years – the highest sedimentation value was obtained for grain harvested in 2016.

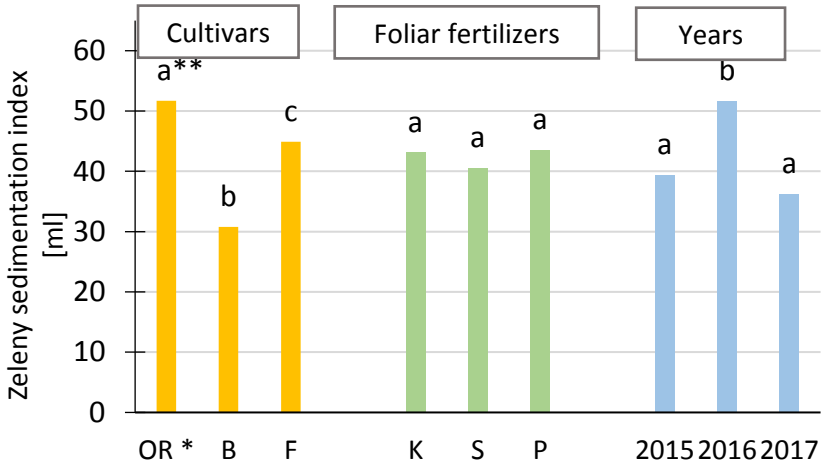

Figure 5. *The Zeleny sedimentation index of spelt wheat grain depending on experimental factors (* OR – Oberkulmer Rotkorn, B – Badengold, F – Frankenkorn, K – control object without foliar fertilization, S – Santaura Pro+, P – Prohorti Micro Amin Mg; ** different letters indicate significant differences at P≤0.05)*

Conclusions

To sum up, it should be stated that the chemical composition of spelt grain was determined by the individual characteristics of a specific cultivar, weather conditions during the crop growing season, as well as foliar application of the fertilizers Santaura Pro+ and Prohorti Micro Amin Mg.

Most N, Ca, Mn, Fe, and Zn were found in grain of the cultivar 'Oberkulmer Rotkorn'. This cultivar was also distinguished by the highest protein and gluten content as well as the highest sedimentation index. In turn, grain of cv. 'Badengold' was characterized by the least favorable chemical composition since it contained the least N, P, Mg, Ca, Mn, Fe, and Zn, and was also poorest in protein and gluten.

Application of foliar fertilizers significantly increased N and P content in spelt grain. In addition, Santaura Pro+ had a positive effect on the K and Mn content, while Prohorti Micro Amin Mg caused the increase in Cu content compared to spelt grown without foliar fertilization.

Due to the constantly growing interest in spelt cultivation, research on the effect of biofortification on grain quality is still valid and necessary. An interesting aspect, however, seems to be testing other foliar fertilizers to improve grain nutritional value. At the same time, it is worth considering more varieties of spelt in the study to draw more general conclusions.

(Received 14th Nov 2019; accepted 12th Feb 2020)

Abstract. In order to understand the evolution of zooplankton communities in the Dongting Lake tourist area, Hunan, China, a one-year experiment was started in January 2018. Investigation of the water quality conditions and the evolution of zooplankton communities at 24 sampling points including the "three mouths" and "four waters" in the Dongting Lake area, including the incoming water section, the lake area and the exit section. The Wanshen AlgaeC type zooplankton and algae intelligent identification counter was used to obtain the relevant data of phytoplankton in the experimental water. By analyzing zooplankton diversity, water eutrophication results, zooplankton density, and the correlation between zooplankton abundance and environmental factors, conclusions are drawn. The results show that 4 phyla and 20 genera of zooplankton are detected. The density of zooplankton ranges from 5.0 to $3.4\times103\cdot L^{-1}$. The dominant genera of "three-port river structure" was Difflugia. The dominant genera of "four-port river structure" is the Difflugia and Tintinnopsis. The dominant genera of lake region are the Difflugia and Polyarthra. The eutrophication degree of Dongting Lake is evaluated by comprehensive trophic state index and plankton Shannon diversity index. The results of CCA show that salinity and water temperature are the main environmental factors influencing the distribution of zooplankton community in Dongting Lake tourist area. Different zooplankton have different tolerance to temperature and salinity changes, and their species composition and quantity distribution will vary with temperature and salinity changes. Temperature directly affects the body temperature of biological organisms. The temperature of the body determines the strength of zooplankton's metabolic process and affects the growth, development and reproduction of zooplankton.
Keywords: *eutrophication, plankton, diversity index, nutrition status index, ecotourism, environmental monitoring*

Introduction

Since the 1990s, tourism has rapidly developed globally. The growth of ecotourism market is the most significant (Xia et al., 2017). Relevant data shows that the growth rate of global ecotourism has increased from 10% to 30% (Hu and Li, 2017). Because the development of ecotourism is based on the natural environment and natural resource, it can't exist independently without the use of resource, the development of ecotourism must premised on the natural and cultural environment (Wang et al., 2017). The ecotourism uses the natural environment to create wealth continuously, but it will bring unexpected threats to the environment, culture and economic sustainable development. In order to promote the healthy development of ecotourism in China, it is necessary to research the sustainable mechanism to develop the regional ecotourism resource.

Dongting Lake (110°40'E—113°10'E, 28°30'N—30°20'N) is located in the north of Hunan Province and the South Bank of Yangtze River. Dongting Lake stretches across Hunan and Hubei, including eighteen counties and fifteen state-owned farms in the north of Hunan Province, with a land area of 3.2×104 km^2, in which the area of cultivated land is 8.93×104 hm^2, and the population is about 1/5 of Hunan, so Dongting Lake is a famous base of commodity grain and freshwater fishery (Wang et al., 2017). It is also an ecotourism area in China (Van Dorssen et al., 2017). Dongting Lake is the second largest fresh water lake in China (Duan and Liu, 2019). It receives the water from Songzikou, Taipingkou and Ouchikou of the Yangtze River (referred to as "san kou"), the inflow of Xiangjiang, Zijiang, Yuanjiang and Lishui (referred to as "si shui") in the local drainage area of Dongting Lake, and the inflow of Xinqiang River and Miluo River around the lake. After storing water in a reservoir or lake and regulating the volume of flow in the lower reaches, it flows into the Yangtze River from the Chenglingji in the north. The relationship between rivers and lakes is very complex. Due to the long-term joint action of special geographical environment, natural conditions and human activities, the unique wetland ecotourism resource landscape is formed. In recent years, with the rapid development of social economy in Dongting Lake basin, the water body is seriously over the standard of nutrients, and the water body pollution of Dongting Lake is prominent, leading to significant changes in biological community structure and function.

Zooplankton is small aquatic organisms suspended in the water (Xie et al., 2017). They feed on phytoplankton, bacteria and organic debris in the water. Meanwhile, they are an important part of the water ecosystem. On the one hand, the feeding relationship between zooplankton and phytoplankton can regulate the density and biomass change of phytoplankton community appropriately (Ye et al., 2017). On the other hand, zooplankton can provide important food for fish, shrimp, crab and other animals in the sea, so they play an important role in the food web of marine ecosystem. To some extent, the quantity, species and distribution of plankton can be used as indexes to reflect the ecological environment of the lake. Therefore, the research on the community structure and distribution characteristics of zooplankton is very important to the lake monitoring and management of the ecological environment.

In the early 21st century, Zhang and Ye (2017) found that the zooplankton community structure of Dongting Lake is relatively complete and the diversity level is high. Ou, L. found that the increase of nutrients and eutrophication level was the direct reason of the increase of zooplankton in the water of South Dongting Lake (Ou, 2018). In recent years, there are many researches on the community structure and diversity of zooplankton, but most of them are concentrated in Tai Lake and Chao Lake. There are few studies on zooplankton community in Dongting Lake (Shelley et al., 2017). As the only inland lake that is directly connected with the Yangtze River in the middle reaches, Dongting Lake has a variety of ecological service functions and it plays an important role in the regional ecotourism environment function. Therefore, it is urgent and important to investigate the zooplankton community of Dongting Lake under the influence of human activities in recent years, so as to understand its eutrophication status. On this basis, this article researches the correlation of evolution law of zooplankton community in Dongting Lake tourism area, and thus to provide scientific basis for the monitoring of ecotourism environment and technical support for controlling eutrophication.

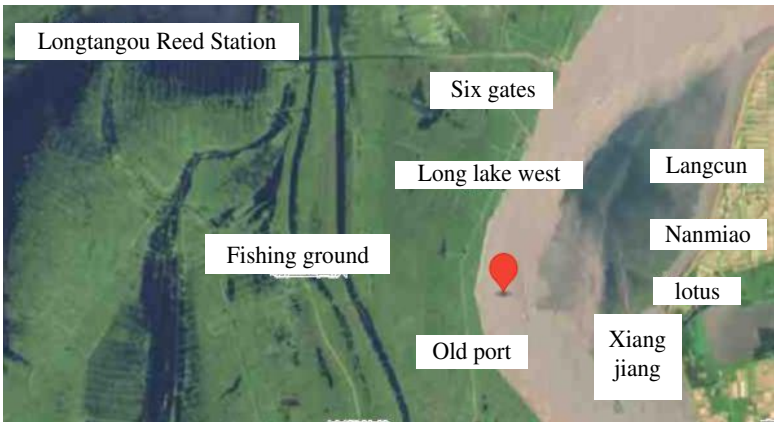

Figure 1. *Actual geographic location*

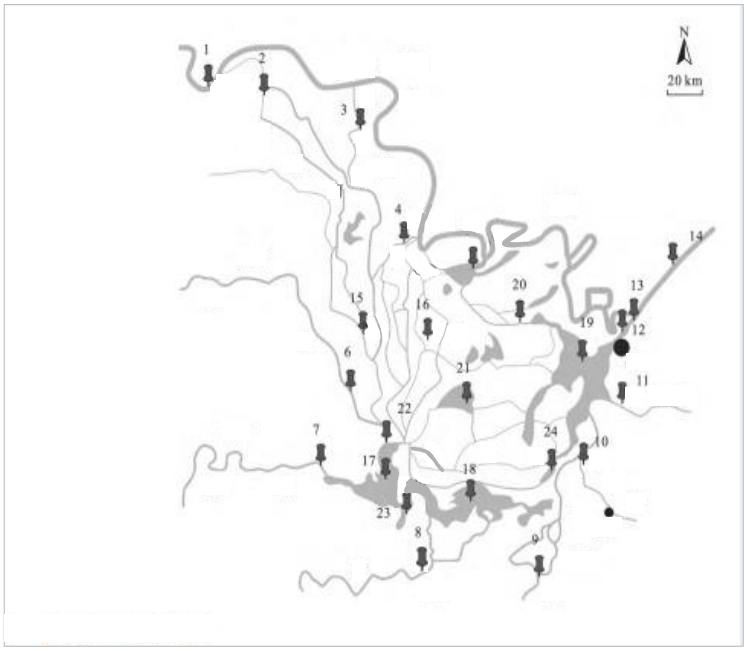

Figure 2. *Layout of sampling points in Dongting Lake Tourist Area*

In order to conduct a more comprehensive study on the evolution of zooplankton communities in the Dongting Lake Scenic Area, they were divided into zones. There is only one Yangtze River main stream background section (1#). There are four “three-port river structure” sections flowing into the lake (He et al., 2019) (2#~5#). There are four "four-port water system" sections flowing into the lake (Hu et al., 2018) (6#~9#). There are two inflow sections such as Miluo River, Xinxiang river (10#~11#). There are ten sections in Dongting Lake region (15#~24#). In addition, the number of exit and its background section are three (12#~14#). The experiment started on January 1, 2018, including the four seasons of spring, summer, autumn and winter, and the experiment cycle was one year. Among them, the sampling interval is 8 hours, and the samples are taken 3 times a day, respectively at 8am, 16pm, and 12 midnight. Record 11 environmental parameters including water temperature (WT), salinity (Sal),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29592974

transparency (T), dissolved oxygen (DO), chemical oxygen consumption (COD_{Mn}), and active phosphate (PO^{3-}_4) at these three time points Each sample is sampled 30 times and the average value is taken as the experimental sample data.

Sampling and sample processing

Zooplankton sampling: type I shallow plankton net (length is 145 cm, net internal diameter is 50 cm, net area 0.2 m^2) trawls from the sea bottom to the sea surface vertically. The samples were put into sample bottles, and then they are fixed and preserved with 5% formalin solution (Dai et al., 2017). After that, they are brought back to the laboratory for identification and analysis. Eleven environmental parameters such as water temperature (WT), salinity (SAL), transparency (T), dissolved oxygen (DO), chemical oxygen demand (COD_{Mn}), orthophosphate (PO^{3-}_4) were investigated simultaneously at each monitoring station. All operations were in accordance with the marine monitoring specification (GB17378-2007). Using the Wanshen AlgaeC type zooplankton and algae intelligent identification counter for plankton identification.

Sample analysis

The transparency of water samples collected from Dongting Lake in Hunan was measured by the method of Secchi disc (Hou et al., 2017). The chemical oxygen demand, chlorophyll a, total nitrogen and total phosphorus were determined in laboratory. The determination method refers to the monitoring and analysis method of water and wastewater (State Environmental Protection Administration, 2002). The plankton samples were identified and counted by microscope. Olympus BX53 microscope was adopted. Based on "China freshwater algae: system, classification and ecology" and "Research methods of freshwater plankton", the samples were identified.

The protozoa and rotifers were counted by 10×20 times microscope. The branch angle and copepoda were counted in full by 10×10 times microscope (Li and Jin, 2017). Genus was identified by qualitative analysis. The amount of zooplankton per litre of water should be calculated by following formulas:

$$N=\frac{nv}{VC} \quad \text{(Eq.1)}$$

In *formula (1)*, n is the number of calculating samples, v is the constant volume (mL) of concentrated sample, V is the sampling volume (L), C is the volume of counting sample (mL).

Data analysis

Eutrophication calculation

The eutrophication parameters of water quality are evaluated and calculated. The calculation method refers to “environmental quality evaluation method for surface water (Trial)” issued by Ministry of Environmental Protection. The eutrophication condition of Dongting Lake is evaluated by the comprehensive trophic state index TLI (∑) (Tang et al., 2019). Evaluation grade: TLI (∑) < 30, oligotrophy; 30 ≤ TLI (∑) < 50, mesotrophy; 50 < TLI (∑) < 60, light eutrophication; 60 < TLI (∑) < 70, moderate eutrophication; TLI (∑) > 70, severe eutrophication.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29592974

Calculation of zooplankton diversity

The diversity of zooplankton is denoted by Shannon-Weaver diversity index (*H'*) (Xiang et al., 2017). The evenness of community is denoted by Pielou evenness index (*J*) (Zhu and Yang, 2018). The richness of community is denoted by richness index of species (*D*) (Huang, 2017). The dominant species of community is denoted by dominance index (*Y*) (He et al., 2019). The formulas of indexes are as follows:

$$H' = -\sum P_i \ln P_i \quad \text{(Eq.2)}$$

$$J = \frac{H'}{\ln S} \quad \text{(Eq.3)}$$

$$D = \frac{(S-1)}{\ln N} \quad \text{(Eq.4)}$$

$$Y = \frac{n_i}{Nf_i} \quad \text{(Eq.5)}$$

In *formulas (2)-(5)*, P_i is the quantity proportion of species; *S* is the species quantity of zooplankton. *N* is the total number of zooplankton; *f* is the occurrence frequency of species. If the dominance index (*Y*) of species≥ 0.02, it will be selected as superior species (Yang et al., 2017). SPSS17.0 software is used to analyze the correlation between abundance, biomass and environmental factors. The Shannon-Weaver index and evenness index are calculated by Primer6 (Zhang et al., 2018). CANOCO for Windows5 is applied to CCA analysis, so that the relationship between zooplankton and environmental factors can be obtained. Google earth and MapInfo are used to draw the station distribution.

Results

Water quality and eutrophication assessment of Dongting Lake tourist Area

Analysis of water quality

The transparency, permanganate index, chlorophyll a, total nitrogen and total phosphorus of twenty-four in Dongting Lake tourist area were measured. The results are shown in *Table 2*.

Based on the results in *Table 2*, each single factor is evaluated by the environmental quality standard for surface water (GB3838-2002), so as to understand the water quality of Dongting Lake. From the physical and chemical monitoring results, we can see that the water quality of Dongting Lake tourist area is not optimistic, and the nutrient content is high. The fluctuation range of total nitrogen in Dongting Lake tourist area is 0.81-2.00 $mg \cdot L^{-1}$, with an average value of 1.49 $mg \cdot L^{-1}$. The results of monitoring points of "three-port water systems" and "four water systems" all exceed the class IV water standard, so the total nitrogen pollution of Dongting Lake is relatively serious. The fluctuation range of total phosphorus in Dongting Lake is 0.06-0.21 $mg \cdot L^{-1}$, and the average value is 0.09 $mg \cdot L^{-1}$. The average value of total phosphorus in lake area is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29592974

0.08 mg·L^{-1}, which meets the class IV water standard. The maximum value measured by No. 7 monitoring point (Zhouwenmiao) is 0.21 mg·L^{-1}. Zhouwenmiao is the entrance of Yuanjiang River to Dongting Lake. The reason for high total phosphorus is due to the aquaculture, agricultural production, soil erosion, feces and other pollution. As an index of organic pollution, when the concentration of COD_{Mn} exceeds 4 mg·L^{-1}, the water body has been polluted. The result of COD_{Mn} determination in Dongting Lake is 1.9-3.9 mg·L^{-1}, and the average value is 2.6 mg·L^{-1}. Therefore, some areas of Dongting Lake are close to the stage of pollution. We should pay enough attention to these areas.

Table 2. *Basic physical and chemical properties of Dongting Lake Tourist Area*

Monitoring point No.	COD_{Mn}/mg·L^{-1}	TN/mg·L^{-1}	SD/mg·L^{-1}	TP/mg·L^{-1}	Chlorophyll a/μg·L^{-1}

Eutrophication assessment

The eutrophication of Dongting Lake tourist area was evaluated according to the surface water environment quality evaluation method (Trial implementation), and the eutrophication is shown in *Figure 3*.

The transparency in the water body exceeds the average value by more than 500 px, the biochemical oxygen demand is greater than 10 mg/L, the concentration of chlorophyll a that marks the growth of algae is greater than 10 μg/L, the nitrogen content is greater than 0.2~0.3 mg/L, and the phosphorus content is greater than 0.01 mg/L, indicating that the water body is in a state of eutrophication. Through the calculation of trophic state index (TLI) of transparency, chemical oxygen demand, chlorophyll a, total nitrogen and total phosphorus, we can see that all monitoring points are in the state of eutrophication. Among all the monitoring points, TLI value in No. 20 monitoring point is the highest, 63.66, belonging to the moderate eutrophication state. This is consistent with the water bloom phenomenon found in the field sampling.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29592974

During field sampling, cyanobacteria bloom was found in No. 20 monitoring point (Liumen floodgate), and the water body of the monitoring point was green with odour. The causes of water bloom in Liumen sluice are analyzed. Firstly, the concentration of nutrients such as nitrogen and phosphorus is high. When the total nitrogen and total phosphorus are more than 0.5 and 0.02 $mg \cdot L^{-1}$ respectively, cyanobacterial blooms may occur. During the lake eutrophication, as the limiting factor of algal growth, the increase of phosphorus will lead to a large number of algal growths. Liumen sluice is in the state of moderate eutrophication. Respectively, the total nitrogen and total phosphorus of this monitoring point are 1.27 $mg \cdot L^{-1}$ and 0.08 $mg \cdot L^{-1}$. The high nitrogen and phosphorus content and eutrophic water create conditions for cyanobacteria bloom. The second is the impact of hydrological conditions. Generally, the cyanobacteria are difficult to gather effectively to form water bloom if the water retention time is too short. The longer the water retention time is, the greater the possibility of water bloom is. When the flow velocity is low, the flow velocity is the key regulating factor of nutrient concentration and transparency. When the flow velocity is low, the nutrient concentration increases and the transparency decreases. The average velocity at Liumen sluice is only 0.02 $m \cdot s^{-1}$. If the water retention time is too long, the high concentration of nutrients will provide sufficient nutrition for the mass propagation of algae, leading to water bloom. Therefore, the interaction of environmental factors and hydrological conditions led to the outbreak of cyanobacteria bloom.

Evolution law of zooplankton community in Dongting Lake tourist area

Composition of zooplankton

In this article, four phyla and twenty genera of zooplankton are found in Dongting Lake tourist area, in which six species are protozoa, and they account for 30.00% of the total number of zooplankton. Seven species are rotifers, accounting for 35.00%. Four species are Cladoceran, accounting for 20.00%. Three species are Copepoda, accounting for 15.00%. Nauplius is detected form all monitoring points, Cyclopoidea and Difflugia are more than 70% detection rate. Keratella and Bosmina are more than 50% detection rate. The composition of zooplankton is shown in *Figure 4*.

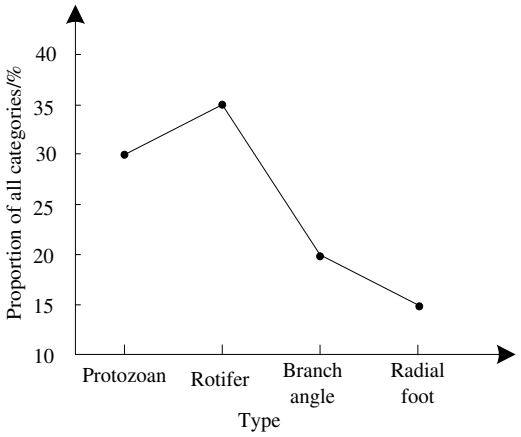

Figure 4. *Species composition of zooplankton*

The spatial distribution of zooplankton species is shown in *Figure 5*.

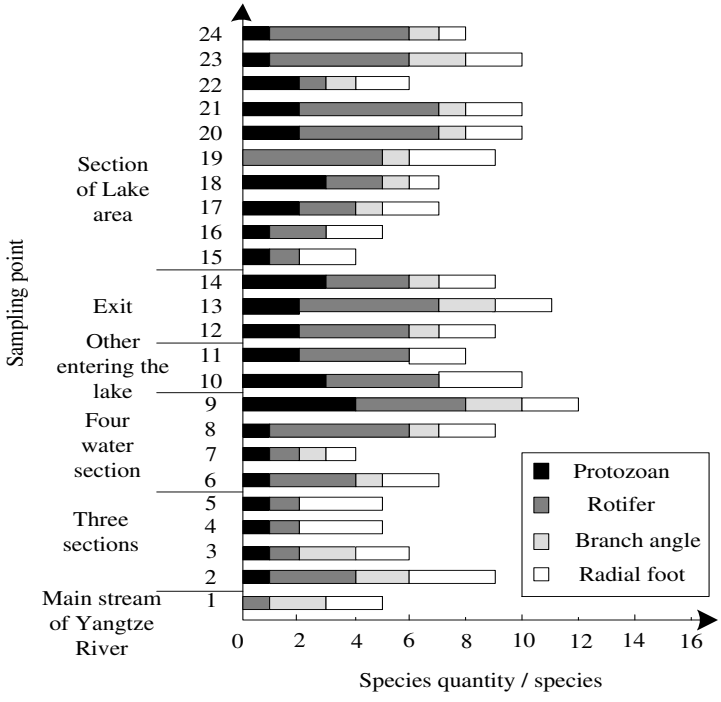

Figure 5. *Spatial distribution of zooplankton species composition*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29592974

Figure 5 shows that the number of zooplankton species in No.9 monitoring point is the most abundant, with a total of twelve species. No. 7 monitoring points and No.9 monitoring points have the least species. Only four species of zooplankton can be detected. There are ten species of zooplankton in the "three diversions river system" and there are fourteen species in the "four diversions river system". There are seventeen species in the lake area.

Zooplankton density

The spatial distribution of zooplankton is shown in *Figure 6*.

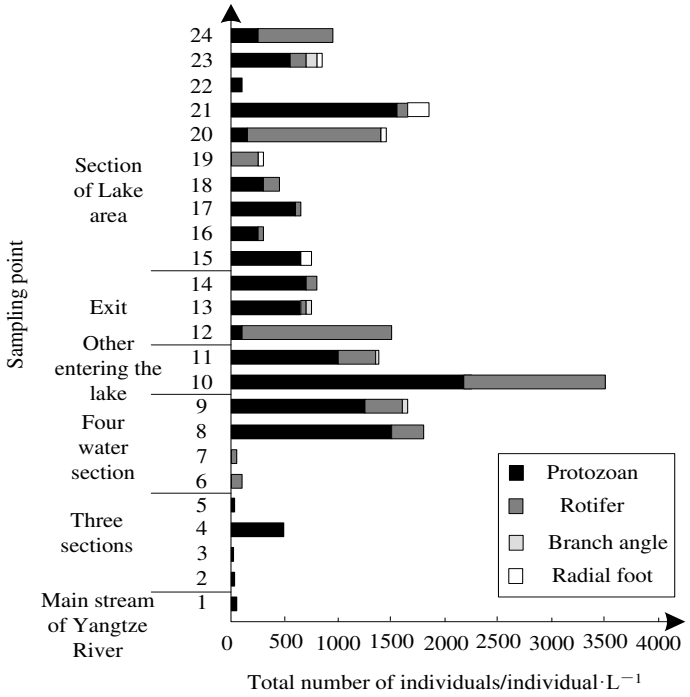

Figure 6. *Spatial distribution of zooplankton density*

The monitoring points in this paper are all equidistant, and the selection positions are random. *Figure 6* shows that the density of zooplankton changes from $5.0\sim3.4\times10^3\cdot L^{-1}$, and the average density is $802\cdot L^{-1}$. The density of No. 3 monitoring point is only $3.2*10^2\cdot L^{-1}$, almost no zooplankton can be detected. The distribution rule of density of zooplankton in Dongting Lake: three-port water system < lake area < four-water system. The average cell density of "three-port water system" is 140 L^{-1}. The average cell density of "four-water system" is 853 L^{-1}. The cell density of "four-water system" flowing the lake is 6.1 times of that of "three-port water system". The average cell density of Dongting Lake area is 791 L^{-1}. The distribution rule of density of zooplankton in lake area: East Dongting Lake < South Dongting Lake < West Dongting Lake. The dominant genera identified by zooplankton in Dongting Lake are as follows: the dominant genera of "three-port water system" are Difflugia; the dominant genera of "four-water systems" are Difflugia and Tininnidium; the dominant genera in lake area are Difflugia and Polyarthra. In addition, Difflugia are dominant in the whole Dongting Lake. *Figure 5* shows that Dongting Lake is dominated by protozoa and rotifers. Small

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29592974

zooplanktons are dominant in species number and individual number, while Cladocera and copepod are less, and the trend of miniaturization is obvious. Some researches show that the community structure of zooplankton changes from large to small with the improvement of water nutrition level, and the eutrophication degree of water body in Dongting Lake is more serious, which is not conducive to the feeding of large zooplankton such as Cladocera. That is the main reason why the small zooplanktons in Dongting Lake become dominant. Meanwhile, some researches show that the filter-feeding way of silver carp and variegated carp will lead to the reduction of macro zooplankton. It will show a miniaturization trend. Due to the high culture rate of silver carp and variegated carp, the filter-feeding way of silver carp and variegated carp leads to the miniaturization of zooplankton. In addition, the cyanobacteria in Dongting Lake are the dominant species, which are not conducive to the feeding of Cladocera and other macro zooplankton. The rotifers can use Cyanobacteria for growth and reproduction, leading to the dominance of micro zooplankton in water.

Assessment of zooplankton diversity and eutrophication

The Shannon diversity indexes of zooplankton were calculated at 24 monitoring points in Dongting Lake. The spatial distribution of H-value measurement results is shown in *Figure 7*.

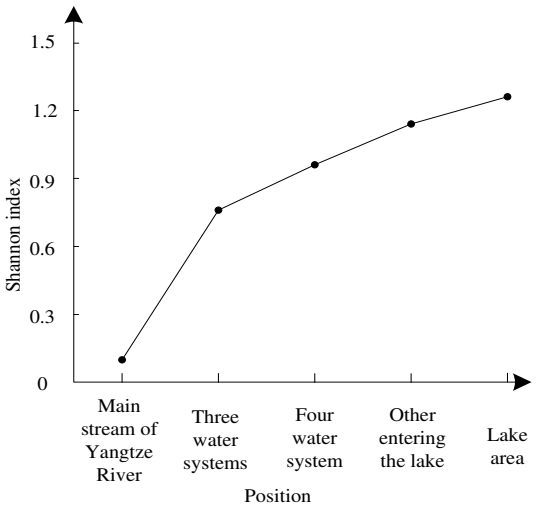

Figure 7. *Spatial distribution of Shannon diversity index and Margelef index*

When the Shannon diversity index in a water body exceeds 0.95, the water body is in a state of eutrophication. The range of H value in Dongting Lake is 0.02-1.59. The average value is 0.99. The average value of H in three diversions river systems is 0.75. The average value of H in four diversions river systems is 0.88. The average value of H in the lake region is 1.08. The distribution rule of zooplankton biodiversity is three diversions river system < four diversions river system < Lake region. The distribution law in lake region is West Dongting < South Dongting < East Dongting. The state of eutrophication in Dongting Lake was evaluated by Shannon index. All the results show that Dongting Lake is in the state of eutrophication.

DOI: http://dx.doi.org/10.15666/aeer/1802_29592974

Correlation between zooplankton abundance and environmental factors

The correlation of eleven physical and chemical factors such as zooplankton abundance, water temperature, salinity, nutrient salt and transparency is shown in *Table 3*.

Table 3. *Correlation coefficient between zooplankton abundance and environmental factors*

Correlation coefficient	2018		
	May	July	November
NO_2^-	0.134	-0.363	-0.099
NH_4^+	-0.318	-0.324	0.195
NO_3^-	-0.102	-0.248	0.347
PO_4^{3-}	0.017	-0.427	-3.433
T	-0.741**	0.080	-2.210
WT	0.611*	-0.082	-0.734**
Sal	0.611*	-0.452	0.589*
DO	-0.525	-0.079	0.481
pH	0.030	0.437	-0.472
COD	0.132	-0.118	-0.531
H	0.23	0.534	0.223

From *Table 3*, the zooplankton abundance has a significant negative correlation with water transparency in spring ($P < 0.01$) and a significant positive correlation with water temperature and salinity ($P < 0.05$). In summer, the zooplankton abundance does not have significant correlation with the monitored chemical parameters ($P > 0.05$). In autumn, the zooplankton abundance has a significant negative correlation with water temperature ($P < 0.01$) and a significant positive correlation with salinity ($P < 0.05$). There was no significant correlation between zooplankton abundance and other chemical parameters ($P > 0.05$). Therefore, the water temperature and salinity are important environmental factors influencing the community structure of zooplankton.

Discussion

Since the 1980s, a trend of thought has gradually emerged, which calls for strengthening the management of tourism resources in the process of tourism activities. Meanwhile, it calls for formulating a draft plan that can be generally agreed and abided by the relevant parties. This trend of thought developed in the late 1980s, and then the concepts of "Science to tourism", "Natural to tourism" and "E-tourism" appeared. The ecotourism has become the trend of tourism development in the world, but there is no clear definition of ecotourism. Mesfin et al. (2017) studied emerging zooplankton conservation methods in shallow tropical lakes supported by large aquatic plants. From January 2016 to August 2016, monthly monitoring of a large large-scale gushing plant, including monitoring of physical, chemical and biological parameters. Sampling points were selected to represent areas of large plant vegetation and open waters of the lake. Sites with large plants were found to be homes of more dense and diverse zooplankton communities. Based on this, the related methods are optimized, the experimental period is extended, and the research area is enlarged. The evolution of zooplankton community during this period is studied, and the following conclusions are drawn:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29592974

In this article, the evolution law of zooplankton community in Dongting Lake tourist area of Hunan Province is researched. Four phyla and twenty genera of zooplankton are found in Dongting Lake tourist area, in which six species are protozoa, and they account for 30.00% of the total number of zooplankton. Seven species are rotifers, accounting for 35.00%. Four species are Cladoceran, accounting for 20.00%. Three species are Copepoda, accounting for 15.00%. There are ten species of zooplankton in the "three diversions river system" and there are fourteen species in the "four diversions river system". There are seventeen species in the lake area. The average H value of zooplankton biodiversity is 0.99. The average D value of species richness is 1.02. The distribution rule of Shannon index of zooplankton is: three diversions river system < four diversions river system < lake region. The result of water quality evaluation by plankton Shannon diversity index shows that the water body is already in the state of eutrophication.

The composition and distribution characteristics of zooplankton are related to the ecological factors such as water temperature, salinity, dissolved oxygen, chlorophyll a, pH and nutrient content, in which temperature and salinity are the most important factors affecting zooplankton distribution. Different zooplanktons have different tolerance to the change of temperature and salinity, and their species composition and distribution will be different with the change of temperature and salinity. The temperature directly affects the body temperature of organisms, and the body temperature determines the intensity of the metabolism process of zooplankton and affects the growth, development and reproduction of zooplankton. When Jiang Huichao et al studied the community structure of zooplankton in Jincheng sea area of Laizhou Bay, they found that the species of zooplankton was positively correlated with the water temperature in the range of 2.2~27.4℃ ($P < 0.01$). The salinity is another important factor affecting the community structure of zooplankton, which is negatively related to the distribution of species. The cumulative contribution rate of selected environmental factors to explain species variables of zooplankton is as high as 90%, so the temperature and salinity are the main environmental factors affecting the distribution of zooplankton.

According to the resource characteristics of "particularity, diversity and fragility" of Dongting Lake tourist area and the current situation of utilization, the development of Dongting Lake tourist area should be positioned as a kind of protective resource development, which should develop towards the direction of ecotourism. The ecotourism can be used to improve and restore the quality of natural environment in lake area, so as to promote the virtuous cycle of ecosystem and sustainable development.

(1) return farmland to lake and ensure the area of natural ecosystem

The ecosystem of Dongting Lake belongs to the inland wetland ecosystem, including natural ecosystem and artificial ecosystem. According to its landscape, the natural ecosystem can be divided into river ecosystem, fresh water lake ecosystem, freshwater swamp ecosystem, wetland ecosystem dominated by trees, marsh wetland ecosystem dominated by reed. The artificial ecosystem mainly contains fish and shrimp pond, irrigation ditch, paddy field, irrigation land, seasonal flood farmland and other agricultural ecosystems. Zooplankton is one of the main biological groups in the natural ecosystem, and it is also the basic material element of forming the ecotourism landscape. Meanwhile, it is an important component of the ecological function of Dongting Lake.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29592974

To maintain natural ecosystem is the premise of developing Dongting Lake ecotourism and the fundamental guarantee of virtuous cycle of ecosystem. In the past, there were more people and less land in the lake area. In order to solve the problem of grain, the area of constructed wetland was expanded and the area of natural ecotourism resource was reduced. That is a problem of economic benefit between the whole and the part, the near term and the long term. The lake is reclaimed, leading to the sharp reduction of the flood storage capacity of the lake. Therefore, it is necessary to adjust the agricultural structure and promote “the avoiding calamity agriculture ", and develop "sightseeing agriculture". For example, reclaiming wetlands on low floodplain not only destroys the original eco-tourism resource, but also loses the proper benefits. It is necessary to return farmland to lakes and marshes, restore the original natural eco-tourism landscape, and make it play a variety of ecological functions. In conditional areas, it is necessary to build a pilot demonstration area of sightseeing agriculture and develop a sustainable sightseeing agriculture that adapts to the alternation of drought and flood. Aiming at shallow water, surrounding lakes, low lake waterlogged land and specific areas with more than one year of flooding, it is necessary to establish a variety of suitable composite and efficient tourism agricultural ecological engineering modes, so as to make overall arrangements for planting and breeding industries.

(2) restoration, reconstruction, standardization and expansion of nature reserves

According to the principle of ecology, the restoration and reconstruction of ecosystem is to change and eliminate the disadvantageous factors restricting the development of ecosystem, so as to restore the degraded ecosystem as soon as possible. Finally, it develops healthily. For a degraded ecosystem, it is necessary to establish a series of ecological sustainability indicators and conduct long-term monitoring before and after restoration to restore its ecological rationality and achieve its sustainability ultimately.

The primary task for the restoration and reconstruction of Dongting Lake ecosystem is to standardize and expand the nature reserve. The practice proves that the establishment of nature reserves is the most effective way to protect ecotourism resource. Dongting Lake Nature Reserve, established in Yueyang City since 1982, which has been listed in the list of international important wetlands, with an area of about 19×104 hm^2. The protected objects mainly include rare birds, wetlands and lakes. In 2000, World Wide Fund For Nature decided to take Qingshan Lake as the first implementation project of returning farmland to Lake, wetland restoration demonstration and "river of joint protection of life" in Qingshan Lake of Hanshou, West Dongting Lake. It is listed as a world wetland restoration demonstration area, with a total area of about 1100 hm^2. In the demonstration area, there are six functional areas. In South Dongting Lake, Dongting Lake environmental protection monitoring station of Hunan Province is established. In the past, some works had been done and great achievements have been made in the construction of wetland nature reserves, but it is far from the actual requirements. The number of protected areas (demonstration areas) is too small. The existing nature reserves still can’t effectively protect the ecotourism resources. It is necessary to strengthen the management and play a role in the established nature reserves. Meanwhile, we should increase the number of ecotourism resource reserves and increase the investment. Combined with scientific research institutes, the ecosystem research network is built. Based on "3S" technology, we should strengthen the monitoring of ecotourism resources, especially the monitoring of dynamic system and biodiversity change after the use of ecotourism resources, and then

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29592974

prepare the ecotourism resource information management system, so as to promote the continuous improvement of reserve system. These provide scientific basis for scientific management and rational use of ecotourism resources. Moreover, it is necessary to establish a comprehensive planning and management organization of eco-tourism resources in lake area, study and formulate relevant laws and regulations, strengthen the management for the utilization of ecotourism resources, unify the planning, implement the environmental impact assessment system, and enforce the approval procedures for the development and utilization of ecotourism resources. In addition, the blind development and destruction of ecotourism resources are strictly prohibited, so that the tendency of paying attention to production function but neglecting its ecological function is completely changed. The comprehensive economic and ecological benefits are fully exerted and thus to achieve the sustainable utilization of ecotourism resource.

Conclusions

Dongting Lake in Hunan is one of the three major wetland resource areas in the middle and lower reaches of the Yangtze river. Under the long-term action of special geographical environment, natural conditions and human activities, the unique ecotourism resource landscape, obvious saucer-shaped basin landform, typical subtropical monsoon climate, rich animal and plant resources and other ecotourism resources. Zooplankton plays a bioindication role in the distribution of many important ocean currents and water masses and the climate change. Zooplankton is very sensitive to the changes of various hydrological factors due to their special life style. They often swim with the stream. The distribution and quantity change of species is corresponding to the hydrological conditions, water masses, ocean current and climate. To master the change dynamics of zooplankton community structure is an important content to understand the structure and function of the reservoir ecosystem. This article researches the evolution law of zooplankton community in Dongting Lake and analyzes the characteristics of zooplankton community structure, so as to provide basic data and theoretical basis for the rational construction and sustainable development of Dongting Lake.

In the future, this paper will use the results of this research to rationally plan the protection of the ecosystem and obtain a better ecological environment.

(Received 14th Nov 2019; accepted 12th Feb 2020)

Abstract. Desertification, as one of the most severe socio-economic, environmental and ecological problems, has attracted widespread attention. In this study, the severity of desertification in the southeastern edge of the Mu Us sandy land of China was classified into five stages using the space-for-time method. A field experiment was conducted in July 2015 to investigate the dynamics of soil organic carbon (SOC) and total nitrogen (TN) concentrations and stocks. The results show that SOC and TN concentrations and stocks decreased significantly with the severity of desertification, reducing SOC and TN concentrations by 55.5% and 55.1% in 0-30 cm depth, SOC and TN stocks decreasing by 54.4% and 54.0%, respectively. The losses of SOC and TN stocks indicate that the impacts of desertification were more evident in upper soil, because the losses in them were higher than those in other layers, and early stages are vital to the restoration of desertification for more losses of SOC and TN stocks. SOC (4.25×10^8 kg) and TN (0.71×10^8 kg) accumulated from 2003 to 2015 indicate that desertification was reversed. Overall, key stages of combating desertification were identified, and the feasibility of integrating field experiment data and temporal-spatial data to evaluate the dynamics of desertification was verified.

Keywords: *soil property, desertification assessment, integrated method, desertification reverse, ecological restoration*

Introduction

During the past decades, carbon (C) and nitrogen (N) stocks in terrestrial ecosystems have attracted significant attention worldwide because of the enormous effect of C and N levels on the environment and human life (Agren et al., 1987; Deng et al., 2016; Jenkinson et al., 1977; Kelly et al., 1996). Soil, as the largest organic carbon pool in terrestrial ecosystems, plays a significant role in the soil carbon sequestration and global C cycle, and has intimate connections with atmospheric CO_2, for it could act as its source or sink (Dessie et al., 2017; Detwiler, 1986; Post et al., 1982). According to statistics proposed by Batjes and Emanuel, soil stores about 1500 Pg organic carbon in the top one meter, which is about 2.1 times the amount of organic carbon stored in the atmosphere and 2.7 times that in terrestrial plant biomass (Batjes, 1996; Emanuel et al., 1984). Soil also significantly affects N recycling, with values of 92–117 Pg to a depth of one meter, as a comparison the vegetation biomass held 10 Pg of N and microbial biomass holds about 2 Pg N (Batjes, 1996; Mehari et al., 2016; Wang et al., 2006). As key indicators for assessing soil quality and ecosystem productivity, the roles of soil organic carbon (SOC) and total nitrogen (TN) were recognized more than a century ago (Spycher et al., 1983; Twongyirwe et al., 2013). SOC and TN stocks in the soil vary as a result of climate change, land use changes, and even vegetation disturbances or

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29752988

succession (Alireza et al., 2017; Bouwman, 1990; Van Minnen et al., 2009). Therefore, understanding changes in SOC and TN stocks also plays a role of significance in determining regional, national, and even international carbon and nitrogen budgets.

Desertification is one of the most severe socio-economic, environmental, and ecological threats to the world, especially in arid, semi-arid, and dry subhumid areas (Carr et al., 1996; UNCCD, 1994). Desertification is estimated to affect 20% of the world's population and 25% of the world's land surface (Binns, 2000; UNCCD, 1994). As an extreme case of soil degradation, variation in the amounts of SOC and N stocks concerning desertification caused much concern in recent years (Hu et al., 2017; Tang et al., 2015; Zhao et al., 2009). Published studies have confirmed that desertification leads to a noticeable decline in SOC and N (Aweke et al., 2015; Huang et al., 2007; Zhou et al., 2008), which not only cause depletion of natural resource and losses of ecosystem services, but also enhance emissions of CO_2, NO_x, and other greenhouse gases to the atmosphere (Kirschbaum, 2000; Russell et al., 2005). Zhao et al. (2009) estimated SOC and N contents in the desertification process in Inner Mongolia (Zhao et al., 2009). Tang et al. (2015) analyzed changes in C and N concentrations and stocks in the desert steppe ecosystem in Ningxia (Qiu et al., 2012). However, there have been only few studies on changes in SOC and TN stocks in the Agro-pastoral transitional zone. The Mu Us sandy land is one of the four largest sandy lands in China. The southeast edge of the Mu Us sandy land in Shaanxi province of Chian is of particular concern as it is a typical Agro-pastoral ecotone and semi-arid grassland area of China (Li et al., 2017).

In the past two decades, numerous studies focus on the temporal and spatial monitoring and evaluating of the desertification process with the wide application of GIS and RS (Lamchin et al., 2016; Zhang et al., 2018). These researches could directly display desertification changes based on the dynamic area data of different desertification stages (Liu et al., 2018; Qi et al., 2012). However, these studies only show spatial changes (Duan et al., 2019; Gao et al., 2006), and could not precisely measure the desertification status (aggravation or reversion) along with a time series. Previous studies indicated that desertification processes directly resulted in the depletion of SOC and TN stocks, which declined sharply with the deterioration of desertification (Allington et al., 2010). Accordingly, we supposed that SOC and TN stocks can be used as indicators of desertification. In this study, an integrated method of experimental field data and temporal-spatial changing data was adopted to quantify the desertification process, and this is a new approach for desertification assessment.

This study aims to evaluate the effects of desertification on SOC and TN concentrations and stocks and assess changes of desertification status along with a time series. We selected the southeast edge of the Mu Us sandy land as the study area, used the space-for-time method to classify the desertification degradation gradient into five stages, analyzed variations in SOC and TN concentrations and stocks along the desertification gradient, and quantified total changes of SOC and TN stocks in study area since the Conversion of Cropland to Forest Project has implemented.

Materials and methods

Study area

In this investigation, the study area is located on the southeast edge of the Mu Us sandy land, in Yulin City, northern Shaanxi Province, China (*Fig. 1*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29752988

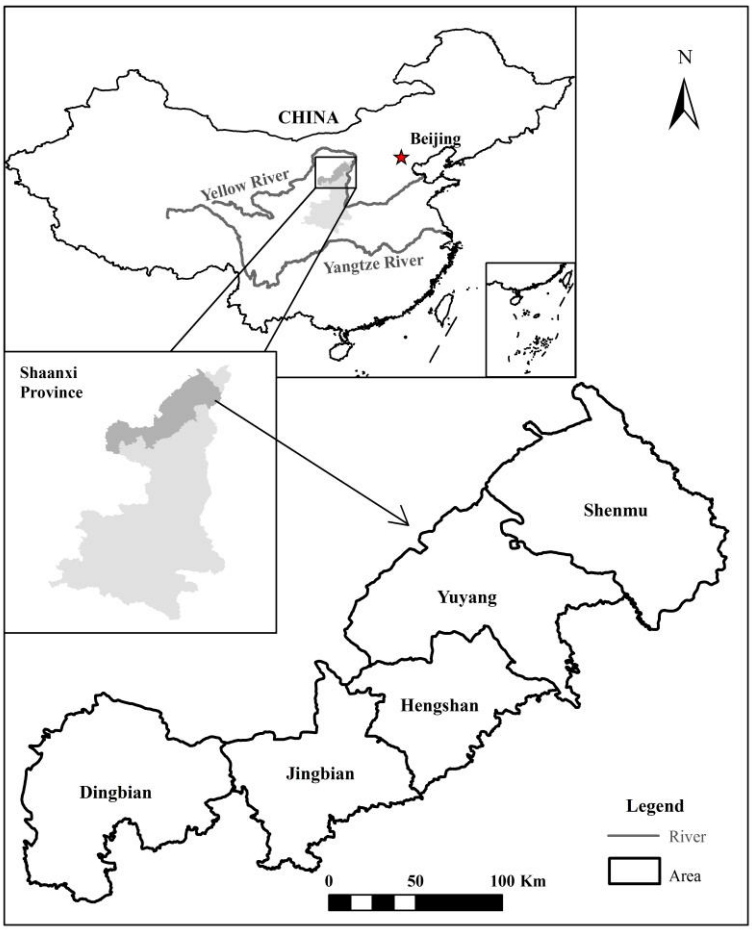

Figure 1. *The location of the study area*

Geographically, it is located from 36°49' to 39°27' E longitude and 107°15' to 110°54' N latitude, and the elevation is 2170 to 3054 m above sea level, with the relative altitude of 10 to 50 m. It is a temperate continental semi-arid monsoon climate. The mean annual precipitation ranges between 250 and 440 mm, with 60 to 75% of total yearly precipitation occurring from June to September. The mean annual temperature of this area is about 8 ℃. The main soil types are light chestnut soil and chestnut soil in the study area (according to the Chinese Soil Classification System), and according to FAO Soil Classification System, the main soil type is Kastanozem. About 80% of the study area is sandy land, among which each of fixed sand dunes, semi-fixed sand dunes, and moving sand dunes occupy one third. The dominant vegetation in the moving sand dunes is *Chenopodiun album*, which is an annual plant. The semi-fixed sand dunes are dominated by shrubs such as *Lespedeza davurica* and *Artemisia ordosica*. The fixed sand dunes are dominated by grasses such as *Stipa bungeana* and *Cleistogenes squarrosa*.

Sampling and laboratory analysis

Experimental design and sampling

In this study, we used the space-for-time method to classify desertification. According to the field survey and the classification of desertification degrees and types

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29752988

by Zhu and Wang (Wang et al., 2002), five different desertification stages were selected to represent desertification succession stages. The five stages were the non-desertification stage (ND), potential desertification stage (PD), light desertification stage (LD), moderate desertification stage (MD), and severe desertification stage (SD). *Table 1* shows the main characteristics (location, coverage, and dominant species) of each stage. *Figure 2* shows some photos of the sampling sites in the study area.

Table 1. *The classification of desertification and the main characteristics*

Desertification stages	Coverage	Main community	Constructive species	Coordinates

In this research, the fieldwork was conducted at the end of July 2015. We selected five study sites (10 m × 10 m) for each desertification stage. At each study site, five quadrats were selected to collect samples (*Fig. 2*). Four quadrants are located in the middle of the line connecting the center point to the center of each side, and one is at the center of all study sites. A total of 125 quadrats were dug for collecting soil samples. Soil samples were taken from six soil depth categories of 0–5 cm, 5–10 cm, 10–15 cm, 15–20 cm, 20–25 cm, and 25–30 cm. Then the soil samples were put into a sealed plastic bag. Soil bulk density at each site was calculated with a cylinder of 5 cm diameter and 5 cm height for each depth interval.

Laboratory analysis

When the soil samples were brought to the laboratory, they were passed through a 2 mm sieve to remove roots and litters and air-dried for chemical analysis. SOC was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29752988

measured using the Walkley-Black method, and TN was determined using the Kjeldahl's method (Bao, 2008). Bulk density for each soil layer was calculated using the core method (Bao, 2008).

Figure 2. *Photos of the sampling sites*

Due to the lack of coarse fragments > 2 mm in the study area, SOC stocks in each soil sample were calculated by *Equation 1:*

$$SOC = \sum_{i=1}^{k} B_i \times C_i \times D_i \times 10 \quad \text{(Eq.1)}$$

where SOC is soil organic carbon stocks ($g \cdot m^{-2}$); k is the number of depth categories ($k = 6$); B_i denotes the soil bulk density ($g \cdot m^{-3}$); C_i is the soil organic carbon content ($g \cdot kg^{-1}$), and D_i presents soil thickness (cm).

TN stocks in each soil sample were calculated by *Equation 2:*

$$TN = \sum_{i=1}^{k} B_i \times N_i \times D_i \times 10 \quad \text{(Eq.2)}$$

where TN is total nitrogen stocks ($g \cdot m^{-2}$), and N_i is the soil nitrogen concentration ($g \cdot kg^{-1}$).

DOI: http://dx.doi.org/10.15666/aeer/1802_29752988

Data analysis approach

Statistical analyses were performed using IBM SPSS Statistics software. One-way analysis-of-variance (ANOVA) and multiple comparisons were used to examine the differences of the concentrations and stocks of SOC and TN among different desertification stages and different depths (McHugh, 2011).

Results

Changes in soil bulk density

Table 2 shows that bulk density varied across soil depths and among different desertification stages. The bulk density in the top layer (0–5 cm) changed from 1.571 $g \cdot cm^{-3}$ in the ND stage to 1.694 $g \cdot cm^{-3}$ in the SD stage, but there was no significant difference among five desertification stages ($P > 0.05$). The minimum value of mean bulk density (0–30 cm) was 1.655 $g \cdot cm^{-3}$ in the ND stage, and the maximum value of mean bulk density (0–30 cm) was 1.671 $g \cdot cm^{-3}$ in the SD stage. There was no significant difference among the five desertification stages ($P > 0.05$). Bulk density fluctuated among different soil depths, and the largest values of bulk density were different in every profile. There were no significant differences among the profiles in every desertification stage ($P > 0.05$).

Table 2. *Changes of bulk density in the five stages of desertification*

Bulk density ($g \cdot cm^{-3}$)	0-5 cm	5-10 cm	10-15cm	15-20 cm	20-25 cm	25-30 cm
ND	1.571 ± 0.073	1.627 ± 0.069	1.667 ± 0.061	1.696 ± 0.146	1.674 ± 0.015	1.694 ± 0.038
PD	1.586 ± 0.139	1.612 ± 0.035	1.601 ± 0.128	1.656 ± 0.051	1.669 ± 0.077	1.652 ± 0.062

SD	1.658 ± 0.104	1.681 ± 0.077	1.663 ± 0.110	1.688 ± 0.046	1.668 ± 0.065	1.670 ± 0.023

Values are means ± SD. The values of bulk density were measured in five desertification stages: ND-non-desertification, PD-potential desertification, LD-light desertification, MD-moderate desertification, SD-severe desertification

Changes in SOC and TN concentration

Figure 3 shows that the SOC and TN concentrations decreased significantly across the desertification stages ($P < 0.05$). With the process of desertification, SOC concentrations (0–30 cm) ranged from 2.409 $g \cdot kg^{-1}$ in the ND stage to 1.072 $g \cdot kg^{-1}$ in the SD stage, whereas TN concentrations (0–30 cm) ranged from 0.251 $g \cdot kg^{-1}$ in the ND stage to 0.113 $g \cdot kg^{-1}$ in the SD stage, showing decreases of 55.5% and 55.1%, respectively. Both SOC and TN concentrations (0-30 cm) decreased significantly with the severity of desertification ($P < 0.05$). Compared with the ND stage, SOC concentration in the SD stage decreased by 63.45%, 56.74%, 51.22%, 48.56%, 53.84%, and 54.99% at soil depths of 0–5, 5–10, 10–15, 15–20, 20–25, and 25–30 cm, while the TN concentration decreased by 67.48%, 67.40%, 46.00%, 49.79%, 42.61%, and 37.48%, respectively. There also existed significant differences at different layers among different desertification stages ($P < 0.05$). The largest decreasing ranges of SOC

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29752988

and TN concentrations were all observed in the upper layer (0–5 cm), which showed that desertification had a greater impact on the upper layers than on the deeper layers.

Figure 3 also shows the comparing differences of SOC and TN concentrations between different desertification stages in different soil layers. For SOC concentration, there existed significant differences between PD and SD stage at most soil layers (except 10-15 cm) ($P < 0.05$). For TN concentration, significant differences existed between ND and PD stage (except 0–5 cm and 10–15 cm) ($P < 0.05$), and in the upper layer (0–5 cm), a significant difference existed between PD and SD stage ($P < 0.05$). The decreasing results also indicate that the decline ranges of SOC and TN concentrations differed among two desertification stages. The highest decreasing ranges of SOC concentration was existed in the PD to SD stage, with decreases of 24.9% throughout 0–30 cm layer and 37.42% in the top layer (0–5 cm). Influenced by the top layer, the greatest decreasing ranges of TN concentration also existed in the PD to SD stage, which were 18.8% in 0-30 cm layer and 43.13% in 0-5 cm layer. These results show that SOC and TN concentrations in different desertification stages were significantly affected by desertification, especially in the early stages.

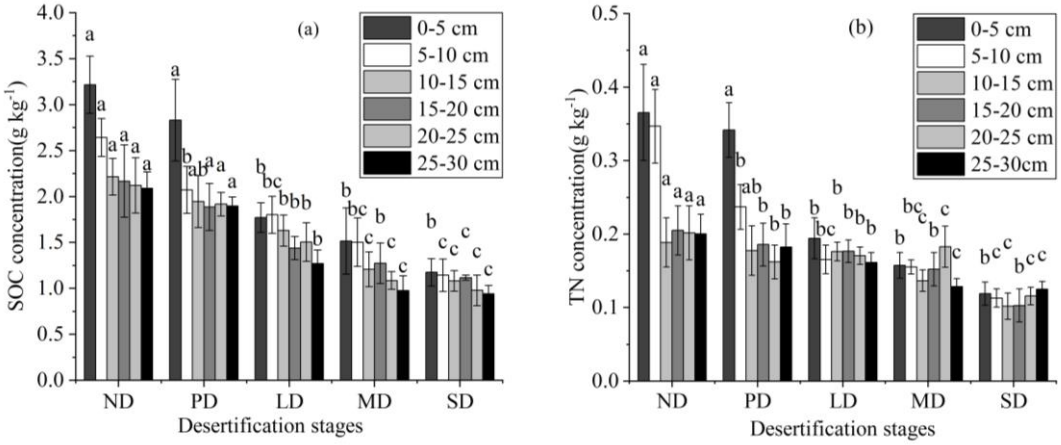

Figure 3. *Changes in the SOC and TN concentrations in five desertification stages. (a) SOC concentration; (b) TN concentration. SOC and TN concentrations were measured in five desertification stages: ND-non-desertification, PD-potential desertification, LD-light desertification, MD-moderate desertification, SD-severe desertification. Error bars indicate the standard deviation. Variations significant at the 0.05 level is indicated by different lowercase letters ($P < 0.05$)*

Changes in SOC and TN stocks

According to *Figure 4*, with the desertification development, SOC and TN stocks decreased significantly ($P < 0.05$). SOC stocks in the top soil layer (0–5 cm) ranged from 252.73 $g \cdot m^{-2}$ in the ND stage to 97.84 $g \cdot m^{-2}$ in the SD stage, and TN stocks in this layer declined from 28.86 $g \cdot m^{-2}$ in the ND stage to 9.90 $g \cdot m^{-2}$ in the SD stage, decreasing by 61.3% and 65.7%, respectively ($P < 0.05$). The SOC and TN stocks also decreased from the top soil layer to the deeper layer, but the decreasing magnitudes were different in different desertification stages. From 10–15 cm to deeper soil layers, there was no significant difference ($P > 0.05$) in both SOC and TN stocks.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29752988

Figure 4 also shows the comparing differences of SOC and TN stocks between different desertification stages in different soil layers and at different soil depths. *Figure 4a* shows that, for SOC stocks, there existed significant differences between PD stage and the LD stage ($P < 0.05$) in most of the soil layers. *Figure 4b* shows that, for TN stocks, significant differences were observed mainly between PD stage and LD stage ($P < 0.05$) in 0–5 cm and 5–10 cm depths ($P < 0.05$). *Figure 4c* and *d* show that SOC and TN stocks decreased significantly at different soil depths ($P < 0.05$), and there existed significant differences between every two desertification stages ($P < 0.05$). These results show that desertification strongly influenced SOC and TN stocks in the study area.

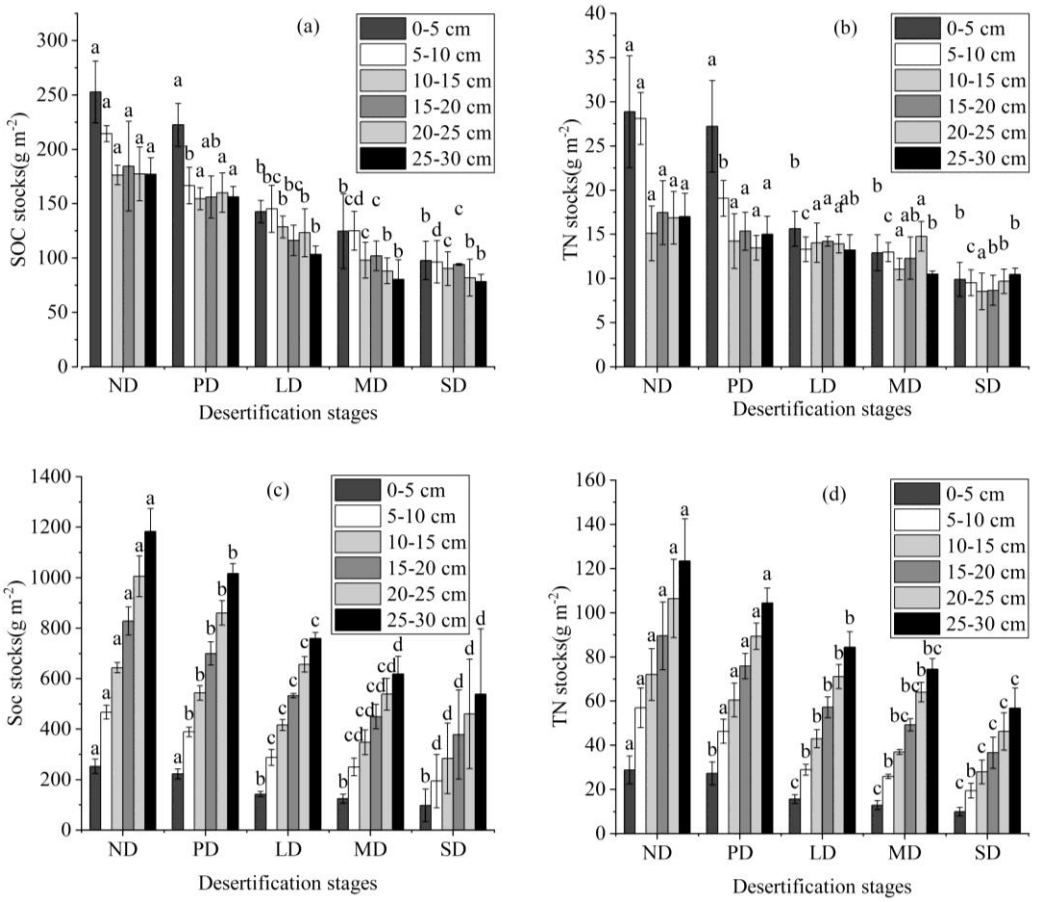

Figure 4. *Changes in the SOC and TN stocks in five desertification stages. (a) SOC stocks in different soil layers; (b) TN stocks in different soil layers; (c) SOC stocks at different soil depths; (d) TN stocks at different soil depths. SOC and TN stocks were measured in five desertification stages: ND-non-desertification, PD-potential desertification, LD-light desertification, MD-moderate desertification, SD-severe desertification. Error bars indicate the standard deviation. Variations significant at the 0.05 level are indicated by different lowercase letters ($P < 0.05$)*

Figure 5 shows that, with the process of desertification, SOC, and TN stocks in 0–30 cm depth reduced significantly ($P < 0.05$). SOC stocks (0–30 cm) decreased from 1182.73 $g \cdot m^{-2}$ in the ND stage to 539.21 $g \cdot m^{-2}$ in the SD stage, and TN stocks (0–30 cm) decreased from 123.42 $g \cdot m^{-2}$ in the ND stage to 56.75 $g \cdot m^{-2}$ in the SD stage, accounting for decreases of 54.4% and 54.0%, respectively ($P < 0.05$). The total losses of SOC and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29752988

TN stocks in the SD stage compared to the ND stage were 653.52 $g \cdot m^{-2}$ and 66.67 $g \cdot m^{-2}$, respectively. The data also showed that the losses of SOD and TN stocks from the PD to LD stages were the most comparable to the losses between other contiguous stages.

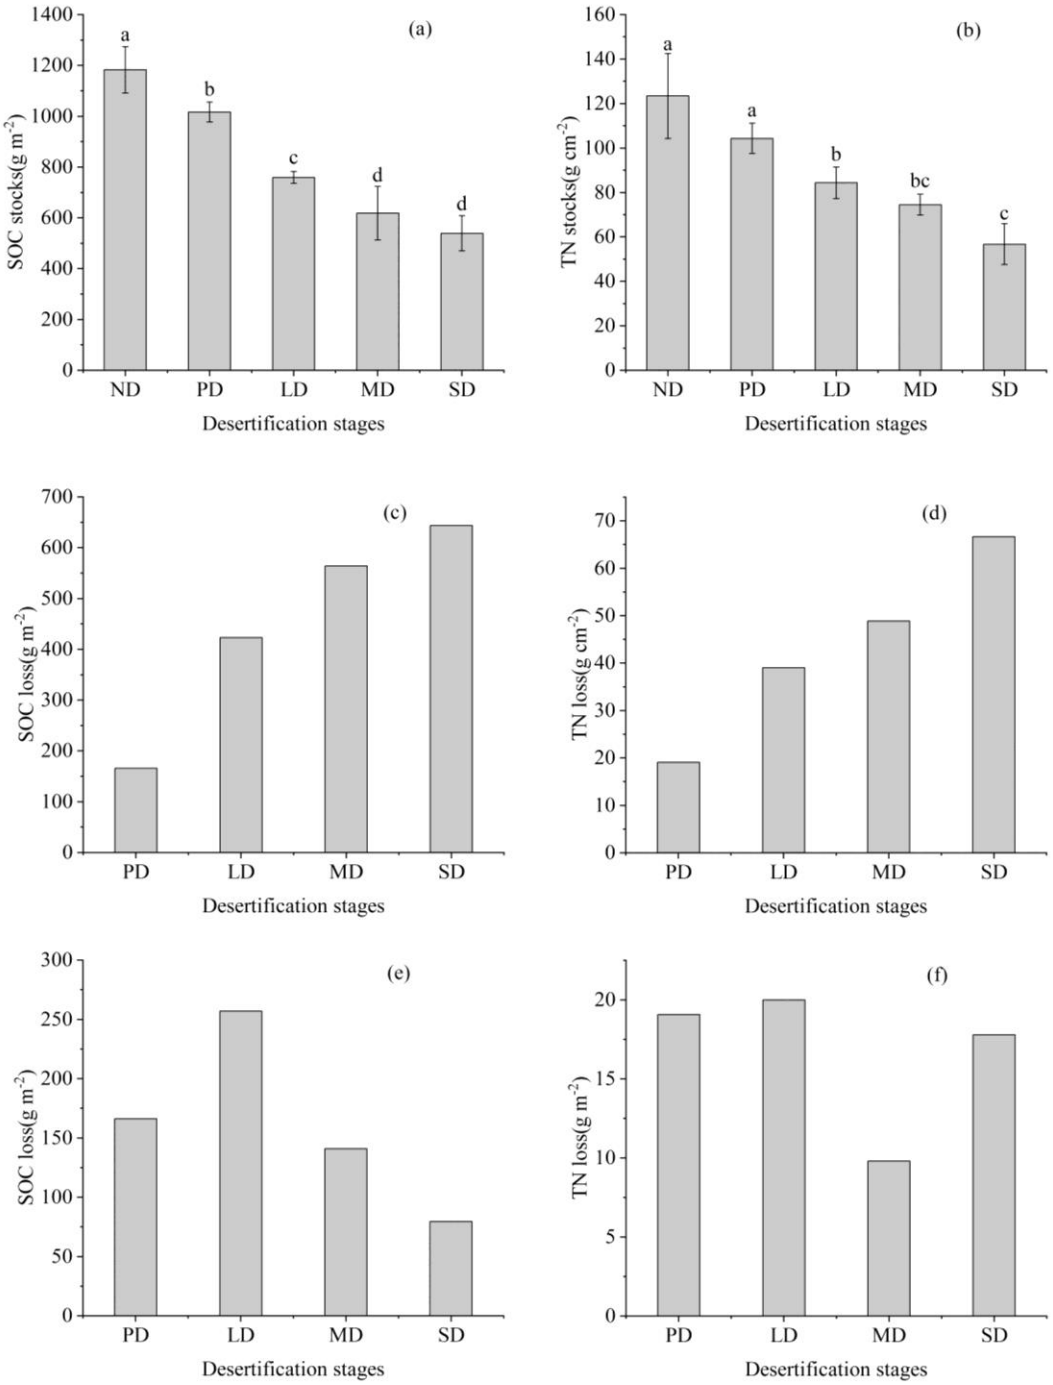

Figure 5. *Changes in the SOC and TN stocks in 0-30 depth in five desertification stages. (a) SOC stocks in 0-30 depth; (b) TN stocks in 0-30 depth; (c) SOC loss compared to ND; (d) TN loss compared to ND; (e) SOC loss compared to contiguous stages; (f) TN loss compared to contiguous stages. SOC and TN stocks and losses were measured in five desertification stages: ND-Non-desertification, PD-potential desertification, LD-light desertification, MD-moderate desertification, SD-severe desertification. Error bars indicate the standard deviation. Variations significant at the 0.05 level are indicated by different lowercase letters ($P < 0.05$)*

Total changes in SOC and TN stocks from 2003 to 2015

According to *Table 3*, we monitored the area changes of different desertification stages from 2003 to 2015. The area changes between different desertification stages could be observed, but the reversal or aggravation of desertification could not be precisely assessed. Calculation of the total changes of SOC and TN stocks from 2003 to 2015 show that the SOC and TN stocks increased by 4.25×10^8 kg and 0.71×10^8 kg, respectively. Thus, the authors conclude that the same amounts of SOC and TN were accumulated during this period. Therefore, we could conclude that the desertification was a reversal from 2003 to 2015.

Table 3. *The total changes of SOC and TN stocks (0–30 cm) in the study area from 2003 to 2015*

ND-non-desertification, PD-potential desertification, LD-light desertification, MD-moderate desertification, SD-severe desertification

Discussion

Desertification is a global disaster and has strongly affected many places and large populations around the world. Many studies have demonstrated that desertification would induce dramatic changes in the physical properties and nutrients of soil (Hu et al., 2017; Qiu et al., 2012). The results of our study demonstrate that the soil bulk density changed little in the upper layer (0–5 cm) with desertification, there was no significant difference among different desertification stages ($P > 0.05$).

Our results demonstrate that desertification had a remarkable effect on SOC and TN concentrations in the southeast edge of the Mu Us sandy land. The effects were observed not only in different desertification stages but also at different soil depths. SOC and TN concentrations decreased significantly with the process of desertification, which is similar to the outcome of Zhou et al. (2008). This could be mainly due to the decrease in vegetation cover and wind erosion (Albaladejo et al., 1998). Vegetation is the primary source of soil nutrients, and aeolian erosion is considered the trigger of desertification because it could remove fine soil particles rich in nutrients, and then leads to the reduction of SOC and TN concentrations. The results also indicate that the declining rates of SOC and TN concentrations were different between two contiguous stages. From the PD stage to the LD stage, the decreasing ranges of both SOC concentration and TN concentration were larger than those in other contiguous stages.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29752988

This situation supports the results of Zhao et al. (2009) and Tang et al. (2015), which also demonstrated that SOC and TN decreased more sharply in early desertification stages.

In contrast, in a study on the impacts of desertification on alpine-cold grassland, Hu et al. (2017) reported that, with the progression of desertification, the rate of SOC loss accelerated, which is not consistent with our results (Hu et al., 2017). This may be because of the different climate between alpine-cold and semiarid areas. The results of our study also show that SOC and TN concentrations decreased with deeper soil layers, but they declined faster in the upper layer, which indicated that desertification has more significant effects on the top soil. Our results are consistent with the findings of Zhu et al. (1994), in which desertification was found to firstly affect the top soil.

This study shows that, with the aggravation of desertification, both SOC and TN stocks decreased significantly, with the highest SOC and TN stocks in the ND stage and lowest of them in the SD stage. Compared with the ND stage, the losses of SOC and TN stocks were the largest in the SD stage. The losses of SOC and TN stocks would result in the deterioration of land productivity, which will further lead to land degradation and increased desertification; it increases the release of CO_2, NO_x, and other greenhouse gases to the atmosphere, which could accelerate climate change. Besides, *Figure 5* shows that desertification effects on SOC and TN stocks were most severe in the LD stage, which confirmed the results of SOC and TN concentrations. This is also consistent with the viewpoint of Wang et al. (2002) and Zhou et al. (2008), their studies reported that the impact of desertification on C and N stocks were significantly different in five desertification stages. In the further control of desertification, the stages with the most severe changes should be given more attention because they are vital to the restoration of desertification.

Human factors, such as over-cultivation and overgrazing, are believed to be critical factors promoting desertification (Li et al., 2017). The Mu Us Sandy Land, which is located in the agropastoral ecotone of China, is extremely sensitive and fragile and has poor self-restoration ability to external disturbance (Liu et al., 2012). In the 20th century, this area suffered from extensive grazing and cultivating, and experienced the threat of sandy desertification (Li et al., 2017). Fortunately, since 1999; the Conversion of Cropland to Forest Project was implemented, and inappropriate land-use activities were forbidden (Li et al., 2017). Recently, many studies based on statistic data or RS and GIS reported that the Conversion of Cropland to Forest Project had practical impacts on combating land desertification and promoting vegetation restoration in this area (Liang et al., 2016; Wang, 2018; Zhang et al., 2008). These studies show that desertification reversion is associated with the restoration of soil nutrient levels. However, previous research only analyzed area changes of different land use or different desertification stages. Accordingly, this study calculated the total changes of SOC and TN stocks to evaluate the changes in soil nutrient levels for further assessing whether the desertification has reversed or not since the implementation of the Conversion of Cropland to Forest Project. Our results showed that 4.25×10^8 kg SOC and 0.71×10^8 kg TN were accumulated since 2003, which confirmed the findings of previous studies and indicates the active influence of the Conversion of Cropland to Forest Project on the restoration of the ecosystem. Indeed, this study not only presents a new method for the quantitative assessment of desertification but also has meaning for the calculation of the potential of soil carbon and nitrogen fixation in the reversal of desertification. At the same time, the results support the view that returning cultivated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29752988

land to grassland and long-term livestock removal were effective in restoring desertification in this site and also provide encouragement for managers to re-establish the ecosystem of damaged grasslands.

Conclusions

In this investigation, results show that desertification affected SOC and TN concentrations significantly, especially in the top soil, and deeper soil depths. Desertification also resulted in remarkable losses of SOC and TN stocks (0–30 cm), with losses of 643.52 $g \cdot m^{-2}$ and 66.67 $g \cdot m^{-2}$, respectively. Besides, the losses of SOC and TN stocks from PD stages to LD stages were the largest between two contiguous stages, which means that the early stages of desertification are crucial periods for the restoration of desertification. More attention should be given to these stages of combating desertification. An integrated analysis of field experiment data and temporal-spatial changing data was used to calculate the total changes of SOC and TN stocks, the results show that, from 2003 to 2015, total SOC and TN stocks increased by 4.25×10^8 kg and 0.71×10^8 kg, respectively. The results not only indicate that the desertification reversed during this period, but also indicate that this method could provide a new quantitative method to assess the desertification process. The results of this study also support the effectiveness of the Conversion of Cropland to Forest Project in grassland ecosystems. For the future study, a more accurate method needs to be furtherly explored so that the fieldwork and experiment data can be in better accordance with the temporal-spatial analysis data.

Abstract. The study evaluates the impact of climatic factors on the success of hunting in the Doupov Hills in the Czech Republic. The aim was to assess the impact of climatic factors on the success of individual and group hunting of various game species and their sex and age between 2005–2012. Overall, 27 thousand animals of the following game species were analyzed: red deer (*Cervus elaphus* L.), sika deer (*Cervus nippon* Temminck), fallow deer (*Dama dama* L.), mouflon (*Ovis musimon* L.), roe deer (*Capreolus capreolus* L.), wild boar (*Sus scrofa* L.), European badger (*Meles meles* L.) and red fox (*Vulpes vulpes* L.). The results show that mostly temperature co-determines the success of both hunting methods. Atmospheric pressure represents another important factor of influence, especially in group hunting. Snow cover supports variability of the probability of game hunting success. The success of hunting increased with decreasing temperature, increasing snow cover and increasing atmospheric pressure. Conversely, precipitation and wind speed had low effect on the success of hunting. Individual hunting was associated with significantly better climatic conditions in comparison to group hunting. Moreover, male game species were hunted in more favourable climatic conditions compared to female. Findings on the influence of climatic factors on the success of hunting can support planning the suitable time and method of hunting, thus increasing the success of hunting in montane and submontane regions of Central Europe.
Keywords: *hunting method, ungulate, temperature, precipitation, Czech Republic*

Introduction

Over the past decades and even centuries, European landscape has undergone significant changes due to the intensification of agriculture and land use (Ramankutty and Foley, 1999; Cukor et al., 2019a). As the landscape was being transformed and the demand for food was growing, agricultural production was increasing, field blocks widening, and structure of the crops changing (Levers et al., 2016; Wrzesień and Denisow, 2016). The new situation proved favourable for the ungulates that adapted well, and their populations increased in most European countries (Bleier et al., 2012; Hagen et al., 2014; Heurich et al., 2015; Thulin et al., 2015; Baltzinger et al., 2016).

The increase in numbers of large mammals does not derive only from the changes in landscape and intensification of agriculture – game populations are further influenced, for example, by climatic conditions (Hone and Clutton-Brock, 2007; Borowik et al., 2013; Koons et al., 2015). The 20th century witnessed gradual changes of climate; in most cases, studies have used summary factors such as mean temperature or total rainfall (Thomas et al., 2004, 2006). The changes influenced population dynamics (Balmford et al., 2003; Forsman and Mönkkönen, 2003; Sauerbrei et al., 2014), ecosystem functioning (Peñuelas et al., 2002; Hays et al., 2005) and also natural systems

DOI: http://dx.doi.org/10.15666/aeer/1802_29893014

(Böhning-Gaese and Lemoine, 2004; Hays et al., 2005; Parmesan, 2006). Recently, there has been a substantial increase in the amount of literature on climate change affecting populations of vertebrates. For large herbivorous mammals, most attention has been paid to distribution responses to climate variation. Much less information is available about how climate affects animal behaviour, i.e. the climate mechanisms (Rivrud et al., 2010, 2014). The dynamics of animal populations are influenced by climatic conditions, on both the local and regional scale (Newton, 1998; Hallett et al., 2004).

Climatic conditions during the year have a significant impact on the populations of ungulates and their dynamics, either directly through changes in mortality or indirectly through the quantity and quality of food (Post and Stenseth, 1999; Hone and Clutton-Brock, 2007; Borowik et al., 2013). Harsh winter conditions, for instance, have influenced the survival rate of domestic sheep (*Ovis aries* L.) (Milner et al., 1999; Coulson et al., 2001), red deer (*Cervus elaphus* L.) (Forchhammer et al., 1998) and roe deer (*Capreolus capreolus* L.) (Gaillard et al., 1993) and increased the numbers of mountain-dwelling woodland caribou (*Rangifer tarandus caribou* Gmelin) (Hegel et al., 2010). Autumn weather negatively influenced the reproduction rate of white-tailed deer (*Odocoileus virginianus* Zimmermann), while spring weather conditions supported successful reproduction (Simard et al., 2010). For red deer, the weight at birth was affected by rainfall in winter and spring temperatures (Sims et al., 2007).

Pettorelli et al. (2007), for example, report that forest mammals are very sensitive to the climate change of primary productivity and the phenological timing of green plants as their principal source of food. The annual fluctuation in weather affected the time and rate of the growth of plants that influenced juvenile growth of bighorn sheep (*Ovis canadensis* Shaw) and mountain goats (*Oreamnos americanus* Blainville), survival of bighorn sheep and Alpine ibex (*Capra ibex* L.) (Pettorelli et al., 2007) and the age of first reproduction of red deer (Langvatn et al., 1996).

Another major reason for the changes in populations of ungulates is the absence of natural predators, i.e. beasts of prey that play a key role in regulating the abundance of the ungulate populations (Buckland et al., 1996; Nilsen et al., 2009; Heurich et al., 2012). Gradually, hunting management became a tool to control game populations and regulate their distribution (Hothorn and Müller, 2010; Bischof et al., 2012; Heurich et al., 2015). In recent years, the importance of hunting management has been mentioned especially in the context of ever-increasing game-induced damage to field crops (Herrero et al., 2006; Bleier et al., 2012) and orchards (Mower et al., 1997; Marada et al., 2019). Moreover, increasing game populations significantly negatively affect forests by browsing of natural regeneration (Vacek et al., 2014, 2015; Ambrož et al., 2015; Slanař et al., 2017) and by bark stripping of young stands (Gerhardt et al., 2013; Månsson and Jarnemo, 2013; Cukor et al., 2019b, 2019c). The damage is caused not only by the native species of cloven-hoofed game but also by species introduced to the European continent in the past (Putman and Moore, 1998; Pitra and Lutz, 2005; Ward, 2005; Pérez-Espona et al., 2009). Due to the aforementioned, it is important to thoroughly monitor game populations using modern technology to determine appropriate wildlife management (Linchant et al., 2015; Cukor et al., 2019d).

Hunting management is a complex process driven by interactions between the dynamics of the natural system and stakeholders' decision-making and behaviour (Keuling et al., 2013; Quirós-Fernández et al., 2017). The effects of hunting pressure on spatial behaviour depend on several factors, including the hunting method (Root et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29893014

al., 1988; Millspaugh et al., 2000; Vieira et al., 2003), level of hunting pressure (Johnson et al., 2004), local laws and hunting philosophy (Williams et al., 2013). The social structure is also important for animals living in a group: the loss of an individual may have different consequences depending on the hierarchical role it played within the group (Tuytten and McDonald, 2000). Findings on game behaviour that could improve hunting success were investigated e.g. in sika deer (*Cervus nippon* Temminck), whose pasture practice was observed during autumn and winter, using a Global Positioning System (GPS) tracking collar. During the hunting season, the collared deer stayed in a hiding place and avoided the pasture the entire day, while after the hunting season, the collared deer preferred sunny and calm pastures during the day as there was no human disturbance (Kamei et al., 2010).

A successful hunt is also co-determined by the habitat characteristics of the hunting district (Vercauteren and Hyngstrom, 1998; Millspaugh et al., 2000; Conner et al., 2001) and current climatic conditions. An open site such as a field is exposed to harsh weather more intensively in comparison to forest stands (Solberg et al., 2010). Weather can also affect the behaviour of the hunter (Rivrud et al., 2010) but, as far as we know, no study on the extent to which the hunter's behaviour is influenced by specific weather conditions has been published. In accordance with a general notion, hunting at moonlit nights seems to be more successful than when the sky is overcast (Theuerkauf et al., 2003). Hunting is always more intensive over the weekend compared to working days regardless of weather (Ciuti et al., 2012). Ciuti et al. (2012) also state that hunting success depends on the behaviour of animals, which is different in an open site and in the forest. Animals of different age and sex behave differently depending on the type of environment. Younger individuals are less alert than the older and more experienced individuals (Ciuti et al., 2012), therefore they can be hunted more successfully than older individuals.

It is well known that some habitat features, including biotope characteristics and climate change, generally affect the predator-prey dynamics (Kunkel and Pletscher, 2000; Lebel et al., 2012; Kuijper et al., 2013). On hunting grounds, the hunters are sometimes considered to be predators and hunted animals the prey (Nugent and Choquenot, 2004). Ecological differences on the site affect the hunters as well. For example, extreme cold or heavy rainfall is less attractive for hunting than hot and rain-free weather (Rivrud et al., 2014).

The success of game observation and hunting depends on numerous factors, some of which can be taken advantage of by the hunters, improving their hunting success (Merkel, 2010). These include, for example, familiarity with the environment, biology of game and its resting haunts, and appropriate timing of the hunt (Bunnefeld et al., 2009). There are factors unsusceptible to our will, especially weather conditions at a given time and place (Rivrud et al., 2014).

Knowledge of the influence of detailed climatic characteristics on the success of hunting of various game species is still inadequate. The aim of this work is therefore to assess the influence of detailed climatic factors (maximum and minimum wind speed in m s^{-1}, mean, minimum and maximum daytime temperature in ^{o}C, 30-minute-interval temperature progress during the course of the day in ^{o}C, daily precipitation in mm, total daily snow cover in cm, atmospheric pressure reduced to sea level in Pa) on the method and success of hunting of various game species (red deer, sika deer, fallow deer */Dama dama* L./, mouflon */Ovis musimon* L./, roe deer, wild boar /*Sus scrofa* L./, European badger */Meles meles* L./, red fox /*Vulpes vulpes* L./) and their sex (male, female) and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29893014

age (adults, young animals) in 2005–2012 in the hunting grounds of the Karlovy Vary division of Military Forests and Estates, state enterprise (VLS) in Doupov Hills. In terms of game and hunting management it is important to know detailed information about the history of the study territory (Pohja-Mykrä et al., 2005; Rivrud et al., 2013). The settlement of the Doupov Hills, especially of their marginal parts and the Ohře River valley, dates back to the Neolithic (5500–4000 years BC). After the Thirty Years' War, the area was almost completely depopulated, and people were returning very slowly. After 1880, the area witnessed another depopulation as the inhabitants were leaving to seek work in nearby industrial cities. After the Second World War, prevailing German population was expelled. By Government resolution of March 4, 1953, Hradiště military training ground was set up on 290.4 km^2, gradually expanding to 331.6 km^2 (Culek et al., 2013), which helped to preserve natural landscape of the Doupov Hills and protect it from processes typical of the 20th century landscape (large-scale agricultural and forestry management, fertilization, application of chemical methods and amelioration) to the present day (Tscharntke et al., 2005; Lundmark et al., 2013; Cukor et al., 2017; Vacek et al., 2019).

The hypotheses of this research were that:

1) Favourable climatic characteristics (temperature, atmospheric pressure and precipitation) increase the success of particular game species hunting.
2) The hunting method is selected not only by climatic characteristics but also by particular hunting ground conditions, forest stand characteristics, and sex and age of particular game species.

Materials and Methods

Study area

The Doupov Hills are a geomorphological complex in the south of the Ore Mountains system in the north-west of the Czech Republic (*Fig. 1*). The area of the Doupov Hills is 607 km^2. Most of the range is situated on the right bank of the Ohře River, while a minor part is located also on its left bank. The Doupov Hills are composed of tertiary volcanic materials: lava (tephrites, leucitites) and tuff. The range is shaped as flat circular highlands, with the highest peaks reaching from 700 to 934 m a.s.l. (Vacek et al., 2003). According to Köppen world climate classification (Köppen, 1936), the study area predominantly belongs to humid continental climate characterized by a moderately warm to hot climate summers and cold winters (classification Dfb), while the highest parts belong to a boreal climate area characterized by long, usually very cold winters, and short, cool to mild summers (classification Dfc). Windward southwest and northwest slopes are wetter than the eastern, rain-shadowed slopes. The sunny exposures where the foothills verge into the basins are warmer than the inversion narrow steep-walled valleys and terrain depressions affected by water. The average annual air temperature ranges from 5.0 to 6.9°C and the precipitation ranges from 550 to 960 mm (*Fig. 1*). The average relative air humidity is in a range of 67-84%. The number of days with snow cover is around 80 (mean occurrence between October 27th and April 30th) and the average maximum snow depth is between 25-45 cm. The length of sunshine ranges from 30 hours in December to 225 hours in June (annually 1,554 hours). The length of the vegetation season varies from 110 to 150 days. Destructive winds come mainly from the west (Plíva and Žlábek, 1986; Tolasz, 2007).

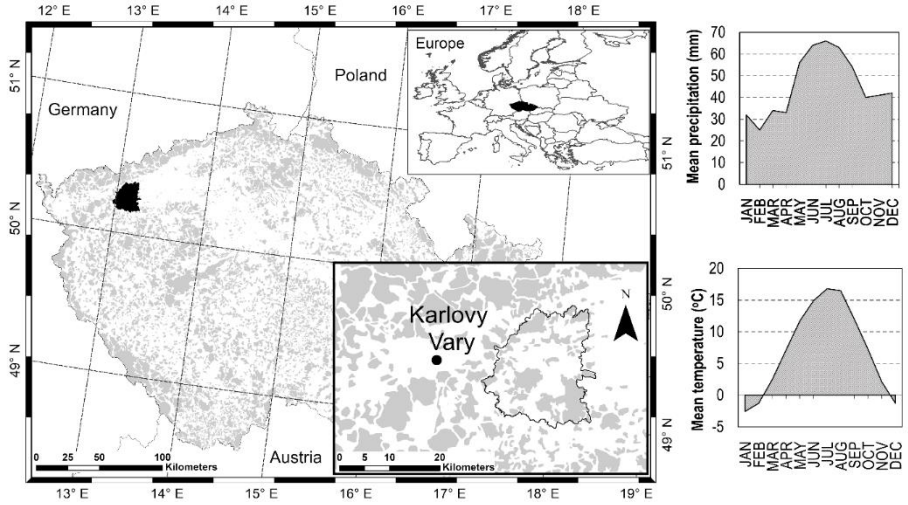

Figure 1. *The area of interest the Doupov Hills in the Czech Republic; the grey colour indicates the forest cover; mean monthly climate values (air temperature and precipitation) in 1939-2017 (right)*

Regarding soils, cambisols prevail in the lower and middle parts of the range, followed by cryptopodzols and podzols in the higher parts. Pseudogleys, gleys and organozems are common in terrain depressions (Demek et al., 2006). Plants of the area have typical features of Hercynian flora of montane and submontane zones. There are acidophilous oak forests on sunny exposures, verging into herb-rich beech forests and dominant woodrush beech forests on more nutrient soils. As the elevation rises, there are acidophilic montane beech forests, and in damp localities we observe water-drenched spruce forests and transitional peat bogs. Along the streams there are meadows and alder woods, and talus forests on the steep slopes. Sparse hornbeam oak, acidophilic and relic pine forest (Průša, 2001) should also be mentioned.

The landscape, essentially uninhabited and used only for training the troops, has acquired unusual features. The most striking – for a mountain range – are vast shrubby areas, pools in missile craters, rocket ranges battered by frequent fires, or exposed surface of tank roads, i.e. phenomena non-existent in civilian countryside. We also observe well-preserved genuine biotopes at sustaining stages of succession, such as herb-rich beech forests, ash-alder alluvial forests, oak-hornbeam, oak and talus forests. The most interesting vegetation is traditionally found on rocky steppes, dry grasslands and wetlands. We can also see managed species-rich meadows and extensively managed ponds rich in macrophyte vegetation (Matějů et al., 2016).

Hunting management

Hunting management reflects the specific regime of a military district. The Hradiště hunting grounds has a total area of 36,029 ha, of which 41.2% is forest land, 5.8% farm land, 0.2% water bodies and 52.8% other areas, largely covered by shrubs. The specific use of the landscape with its vast shrubby areas makes hunting considerably more complicated. Hunting from hides and stalking is used for individual hunting, while in the case of group hunting the hunters opt for battues and dog driving. Female animals, deer fawns and wild boar piglets are hunted in fee-charged battues and individually by gamekeeping staff; male animal hunting is usually subject to a charge. In the period

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29893014

2005-2012, a total of 27,729 animals of the following species were hunted in this area: red deer (6,835 ind.), sika deer (8,294 ind.), fallow deer (103 ind.), mouflon (167 ind.), roe deer (4,292 ind.), wild boar (7,297 ind.), European badger (68 ind.) and red fox (673 ind.) (*Table 1*). Of these, animals shot for sanitary reasons were subtracted from the statistical evaluation, i.e. approximately 150 animals in the Hradiště hunting grounds every year. Northern raccoon (*Procyon lotor* L.) and pine marten (*Martes martes* L.) were also subtracted because of the low number of hunted animals (< 20 ind.). Moreover, in accordance with Act No. 449/2001 Coll., the Northern raccoon can be hunted only by professional gamekeepers or hunting guard.

Table 1. *The numbers of the hunted animals in Hradiště hunting grounds by the particular game species in 2005-2012*

Game species	Year								Total
	2005	2006	2007	2008	2009	2010	2011	2012

Data collection

The analysis of the impact of climatic data on the success of game hunting was based on climatic data provided by the Karlovy Vary meteorological station, Olšová vrata (603 m above sea level), which conveniently represents the climatic conditions in the Doupov Hills. Climatic data (maximum and minimum wind speed in m s^{-1}, mean, minimum and maximum daytime air temperature in °C, 30-minute-interval temperature progress in the course of the day in °C, daily precipitation in mm, total daily snow cover in cm, atmospheric pressure reduced to sea level in hPa and daily atmospheric pressure change) cover the period of 2005–2012. Data on hunting various game species (red deer, sika deer, fallow deer, mouflon, roe deer, wild boar, European badger, red fox), their sex (male, female) and age (adults, young animals), method and date of hunting in 2005-2012 were obtained from the VLS. In the VLS hunting grounds of the Doupov Hills, all hunted animals are recorded. Hunting seasons are strictly observed, as in the rest of the Czech Republic (*Table 2*). For generalized comparing, game species (including their age and sex) were divided in relation to hunting season to five groups.

Table 2. *The dates of hunting season for different species of game in the Czech Republic in 2005-2012*

The date of hunting	Game species	Group
01 Aug – 15 Jan	red deer, male and female	1
01 Aug – 31 Mar	red deer fawn	2
01 Aug – 15 Jan	sika deer, male and female	1
01 Aug – 31 Mar	sika deer fawn	2
16 Aug – 31 Dec	fallow deer, male and female	1
16 Aug – 31 Mar	fallow deer fawn	2
16 May – 30 Sep	roe deer	4
01 Sep – 31 Dec	roe deer fawn and female	1
01 Aug – 31 Dec	mouflon, male and female	1
01 Aug – 31 Mar	mouflon fawn	2
01 Jan – 31 Dec	wild boar	3
01 Jan – 31 Dec	red fox	3
01 Sep – 30 Nov	European badger	5

Statistical data processing

Testing for differences in values of selected climatic parameters was performed via Kruskal-Wallis tests with subsequent multiple comparisons. Game species were analysed in relation to their mean deviations from average climatic characteristic on the day of individual hunting and group hunting. Principal component analysis (PCA) was used to describe overall characteristics of analysed multivariate data. Climatic data (air temperature, precipitation, snow cover, wind speed, atmospheric pressure, atmospheric pressure change) were standardized according to hunting season of each species prior to statistical analyses. Furthermore, the success of hunting was focused on the period (November and December) with the highest occurrence of hunted animals (over 54% of the annual number), where the number of daily hunted animals was compared with climatic data by linear regression. All statistical tests were performed on significance level α=0.05. Statistically significant differences among game species in relation to climatic characteristic were marked by different indices (homogenous groups). Error bars indicate standard error of mean (SE). Computations were performed in R software (R Core Team, 2018).

Results

Climatic characteristics of the date of hunting for game species

The climatic characteristics for each game species at the time of hunting are shown in *Figs. 2-4*. *Fig. 2* shows average air temperatures in ºC on the hunting day by particular game species, varying considerably in relation to hunting time for each species. Average temperatures in the hunting time range from 0.5°C for wild boar piglets to 15.3°C for roe deer males. The greatest standard error of the mean (SE) of average temperature were found in fallow deer fawn (SE 1.22), mouflon male (SE 1.15) and fallow deer female (SE 1.00).

Comparing game species with the similar hunting season (same group in *Table 2*), red deer male showed the highest average air temperature in group 1, followed by fallow deer male, while the lowest temperature was observed in roe deer female and mouflon female. In hunting group 1, higher average air temperature (2.4ºC) was observed in all cases in male game species compared to female. In group 2, the highest temperature on hunting

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29893014

day was in fallow deer fawn and the lowest in mouflon fawn. In wild boar, the highest temperature was found in the case of fawn and vice versa in piglet.

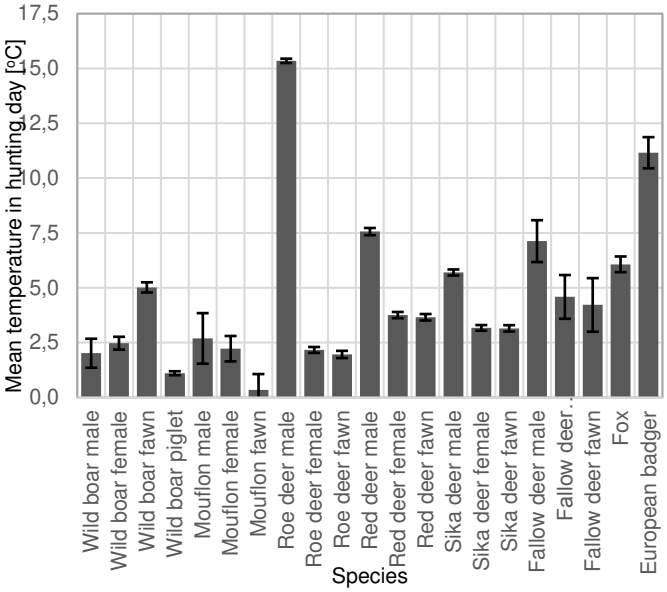

Figure 2. *Average air temperatures in ºC on the hunting day by particular game species in 2005-2012; error bars indicate standard error of the mean*

Fig. 3 shows average rainfall in mm on the day of hunting by particular game species, varying only insignificantly in each species (0.9–1.4 mm), being slightly higher only for European badger and roe deer male (1.8–2.1 mm). The greatest SE of average rainfall were found in European badger (SE 0.45), fallow deer fawn (SE 0.47) and fallow deer male (SE 0.54).

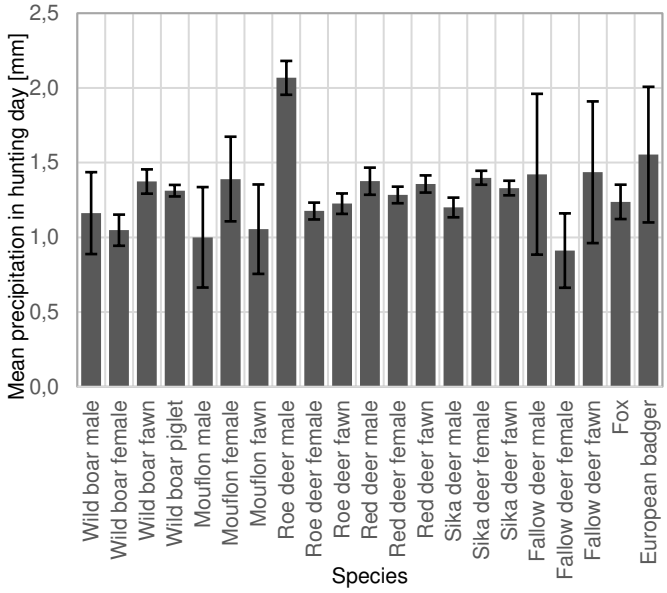

Figure 3. *Average precipitation in mm on the hunting day by particular game species in 2005-2012; error bars indicate standard error of the mean*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29893014

Regarding hunting group 1, fallow deer male showed the highest average precipitation, followed by mouflon female, while the lowest precipitation was observed in fallow deer female and mouflon male. Similarly, in group 2, the highest precipitation on hunting day was in fallow deer fawn, while the lowest was found in mouflon fawn. In wild boar, the highest temperature was found in the case of fawn and vice versa in female.

Fig. 4 shows the average snow cover in cm on the day of hunting by game species, varying from 0 to 8 cm for particular species. It was the highest in mouflon male (7.9 cm) and mouflon fawn (6.7 cm); it was also fairly high in wild boar piglet (6.0 cm), sika deer fawn (5.4 cm), sika deer female (5.3 cm), roe deer fawn (5.0 cm), while it was zero in roe deer male (0.0 cm) and only 0.1 cm in European badger. The greatest SE of average snow cover was found in fallow deer male (SE 1.88), mouflon male (SE 1.44), mouflon fawn (SE 1.21) and fallow deer female (SE 1.14).

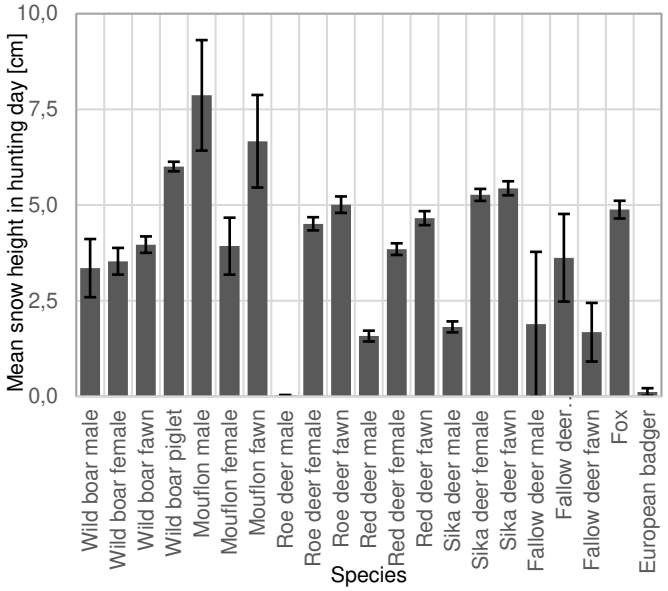

Figure 4. *Average snow cover in cm on the hunting day by particular game species in 2005-2012; error bars indicate standard error of the mean*

Comparing game species with the similar hunting season, fallow deer male showed the highest average snow cover in group 1, followed by fallow sika deer female, while the lowest snow height was observed in red deer male and sika deer male. In hunting group 1, higher average snow cover (0.9 cm) was observed in female game species compared to male (except mouflon). In group 2, the highest snow cover on hunting day was for mouflon deer fawn and the lowest for fallow fawn. In the wild boar group, the highest snow height was in the case of piglet and vice versa in male.

Fig. 5 shows the average atmospheric pressure in hPa on the hunting day by particular game species, varying inconsiderably and ranging from 1016.0 hPa (in fallow deer fawn) to 1020.7 hPa (in mouflon fawn). The greatest SE of average atmospheric pressure was found in fallow deer male, mouflon male, mouflon fawn and fallow deer fawn (SE 1.48-1.85).

Regarding hunting group 1, sika deer male showed the highest average atmospheric pressure, followed by fallow deer male, while the lowest atmospheric pressure was observed in roe deer female and sika deer female. In hunting group 1, higher average

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29893014

atmospheric pressure (1.3 hPa) was observed in male game species compared to female. In group 2, the highest precipitation on hunting day was in mouflon fawn, while the lowest was found in fallow deer fawn. In group 3, the highest atmospheric pressure was in the case of wild board male, while it was lowest in female.

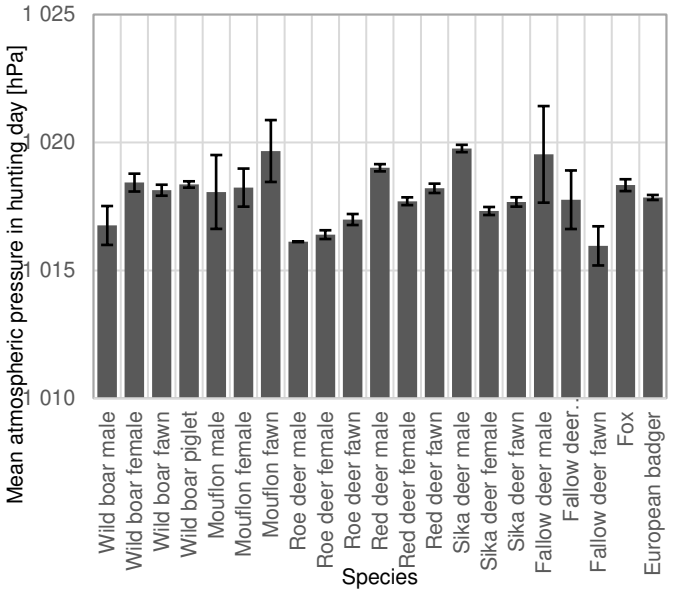

Figure 5. *Average atmospheric pressure in hPa on the hunting day by particular game species in 2005-2012; error bars indicate standard error of the mean*

Comparison of climatic characteristics of the hunting days by game species

Temperature impact

Standardized climatic characteristics for each game species at the time of hunting are shown in *Figs. 6-9*. *Fig. 6* shows average deviations from the average temperature in ºC on the hunting day for particular game species (for individual hunting and group hunting). Y-axis shows the mean temperature deviation on the hunting day from the average temperature over the whole investigated period. Game species reaching values above 0 are hunted when temperature is higher than mean value during the hunt and vice versa; the particular value then shows "how much temperature is higher or lower" it is than at usual hunting time.

Most game species were individually hunted at lower-than-average temperatures for the given time of hunting, except for yearling boar (0.1ºC), roe deer male (0.4ºC), fallow deer female (1.1ºC), red deer male (1.8ºC), fallow deer male (1.8ºC), fallow deer fawn (2.8ºC) and European badger (3.6ºC), which were hunted at higher-than-average temperatures. Markedly lower-than-average temperatures are suitable especially for individual hunting of wild boar piglets (-6.0ºC), mouflon females (-4.3ºC), wild boar males (-3.5ºC), mouflon fawns (-3.1ºC), mouflon males (-3.0ºC), sika deer females (-2.6ºC) and wild boar females (-2.0ºC). The standard errors of the mean are rather high in fallow deer fawns (SE 1.6), fallow deer females (SE 1.5), wild boar males (SE 1.3) and mouflon males (SE 1.3).

In terms of group-hunting, markedly lower-than-average temperatures are suitable especially for hunting of mouflon males (-10.5ºC), wild boar yearlings (-6.8ºC), wild boar

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29893014

piglets (-6.8ºC), red deer males (-6.5ºC), red foxes (-6.4ºC), sika deer males (-6.3ºC), wild boar males (-6.2ºC), wild boar females (-6.0ºC), sika deer females (-5.9ºC), red deer females (-5.8ºC), roe deer fawns (-5.7ºC), mouflon females (-5.4ºC), roe deer females (-5.2ºC), fallow deer males (-4.8ºC), fallow deer females (-4.8ºC), mouflon fawns (-4.5ºC), sika deer fawns (-4.1ºC) and red deer fawns (-3.3ºC). The standard errors of the mean are rather large in fallow deer males (SE 3.5), mouflon males (SE 1.6), mouflon fawns (SE 1.2) and fallow deer fawns (SE 1.0).

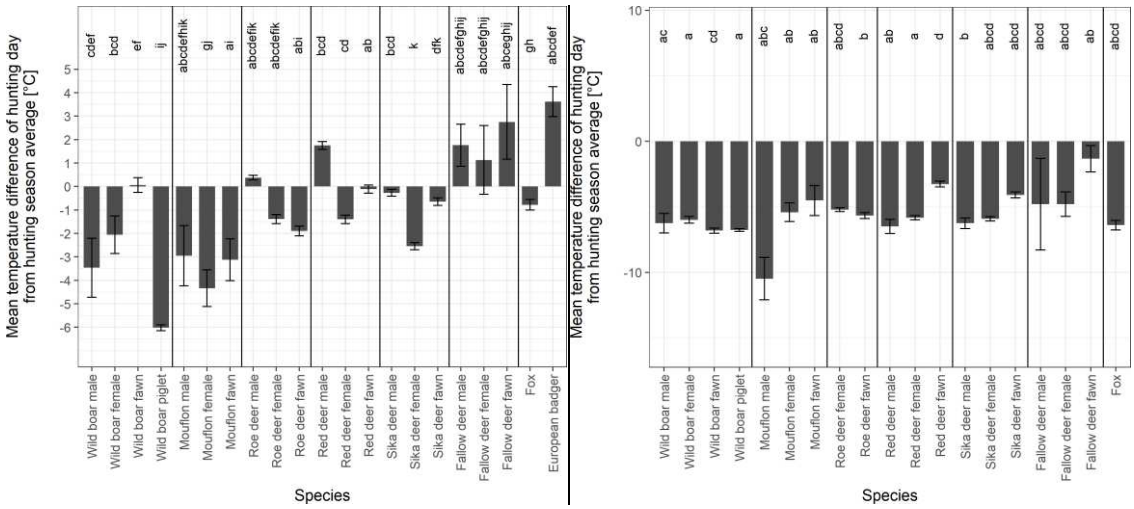

Figure 6. *Mean deviations from the average temperature in ºC on the day of individual hunting (left) and group hunting (right) by particular game species between 2005-2012; statistically significant differences among species are marked by different indices; error bars indicate standard error of the mean*

In the case of individual hunting, statistically significant differences were observed in the deviations from the average temperature between values for wild boar piglet, whose respective values were significantly different from the values of all species, except mouflon female, mouflon male, mouflon fawn and wild boar male. Mouflon and wild boar are generally hunted at temperatures lower than usual in their hunting season. In contrast, European badger, fallow deer fawn, red deer male and fallow deer male are generally hunted in weather with higher temperature than usual. The values for red deer male proved to be different from red deer female, sika deer female and sika deer male, while in the case of red deer and sika deer, we observed significant differences in values for females and fawns.

Significant differences between temperature deviations from the average for the particular hunting time can be identified in the case of group hunting of wild boar yearling and piglet in comparison with red deer female, sika deer male and roe deer fawn. Also, we find a difference in the value for red deer fawn and sika deer fawn, whose values differ significantly from those found for adults.

Precipitation impact

Fig. 7 shows average deviations from precipitation in mm on the day of hunting for particular species. Most game species were hunted individually at lower-than-average precipitation sums except for European badger (0.1 mm) that is hunted at higher

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29893014

precipitation sums. Red deer fawns and sika deer fawns were hunted at boundary values of average precipitation. Significantly lower-than-average precipitation was suitable for hunting fallow deer females (-0.7 mm), mouflon males, fallow deer fawns, mouflon fawns (-0.4 mm), wild boar males, sika deer males, foxes (-0.3 mm), wild boar yearlings, mouflon females and wild boar females (-0.2 mm). The standard error of the mean was larger in fallow deer males, wild boar males (SE 0.6), mouflon males, mouflon females and European badgers (SE 0.4), mouflon fawns and fallow deer fawns (SE 0.3).

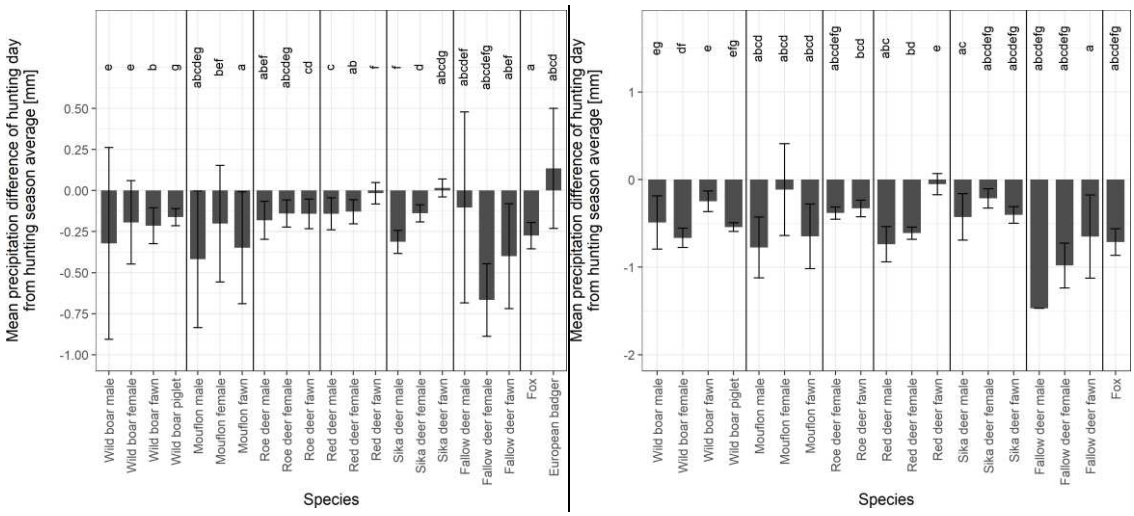

Figure 7. *Mean deviations from the precipitation in mm on the hunting day of individual hunting (left) and group hunting (right) by particular game species in 2005-2012; statistically significant differences among species are marked by different indices; error bars indicate standard error of the mean*

All game species were group-hunted at lower-than-average-precipitation. Markedly lower-than-average precipitation was suitable for hunting fallow deer males (-1.5 mm), fallow deer females (-1.0 mm), mouflon males (-0.8 mm), red deer males, foxes, wild boar females, fallow deer fawns, mouflon fawns (-0.7 mm), red deer females (-0.6 mm), wild boar piglets and wild boar males (-0.5 mm). The standard error of the mean was slightly higher in fallow deer fawns, mouflon females (SE 0.5), mouflon males, mouflon fawns (SE 0.4) and wild boar males (SE 0.3).

In the case of individual hunting, significant differences were not found between deviations from the average precipitation for red deer fawns and sika deer fawns, similarly to wild boar males and wild boar yearlings, and mouflon males, mouflon females and mouflon fawns, but in the case of wild boar yearlings and piglets there was a statistically significant difference, similar to that of roe deer males and roe deer fawns, whoes values did not differ from the value for the roe deer females. The values for red deer fawn and sika deer fawn differed from the values for the adult animals, but the values for red deer males and females showed no significant differences.

Group hunting also brought statistically significant results in wild boar yearlings and piglets, or red deer males and fawns in the case of red deer and sika deer. The average precipitation values were comparable, as in the previous case of fawns of both deer species.

DOI: http://dx.doi.org/10.15666/aeer/1802_29893014

Snow cover impact

Fig. 8 shows average deviations from the snow cover in cm on the hunting day by particular game species. Half of the game species are hunted individually at the lower-than-average snow cover, the other half at the higher-than-average snow cover, as compared with the average. The higher-than-average snow cover suits hunting wild boar piglets (3.3 cm), mouflon males (2.8 cm), sika deer females (2.5 cm), mouflon females (2.2 cm), foxes (1.7 cm), fallow deer females (1.5 cm) and roe deer fawns (1.2 cm). The lower-than-average snow cover suits hunting fallow deer fawns (-5.1 cm), fallow deer males (-2.2 cm), wild boar males (-1.5 cm) and red deer males (-1.3 cm). Snow cover of around the average is suitable for hunting red deer fawns and roe deer males. The standard error of the mean is rather large in fallow deer females (SE 1.8), mouflon males (SE 1.6), mouflon fawns (SE 1.5), wild boar males, mouflon females (SE 0.9).

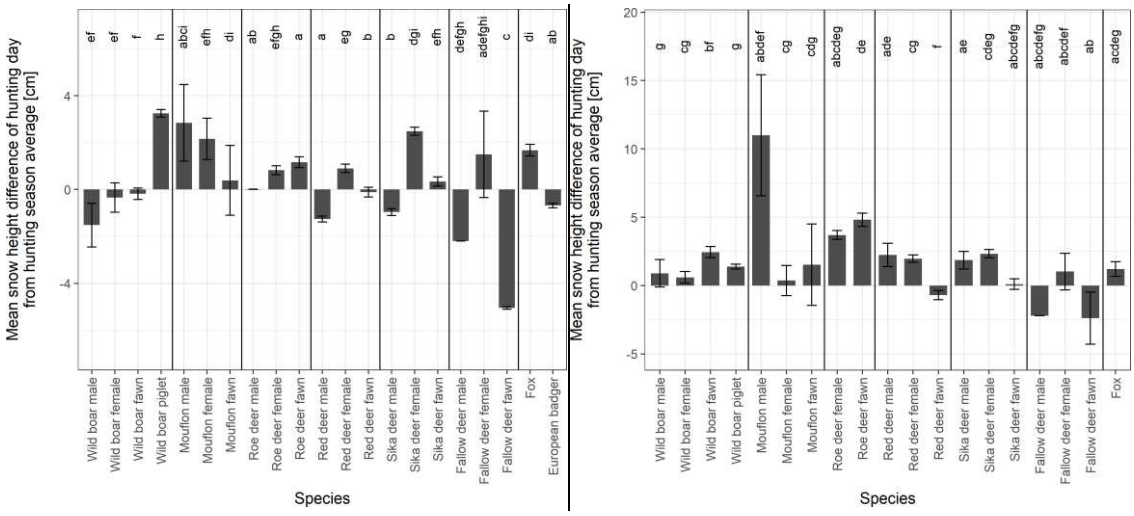

Figure 8. *Mean deviations from the snow cover in cm on the hunting day of individual hunting (left) and group hunting (right) by particular game species in 2005-2012; statistically significant differences among species are marked by different indices; error bars indicate standard error of the mean*

A vast majority of game species were group-hunted at higher-than-average snow cover. The highest levels of snow cover suited the group hunt of the mouflon male (11.0 cm), roe deer fawn (4.8 cm), roe deer female (3.7 cm), wild boar yearling (2.5 cm), sika deer female (2.3 cm), red deer male (2.2 cm) and sika deer male (1.9 cm). Lower-than-average snow cover suited group hunting of fallow deer fawn (-2.4 cm) and fallow deer males (-2.2 cm). Sika deer fawn was hunted at the average snow cover margin. The standard error of the mean was rather large in mouflon males (SE 4.4), mouflon fawns (SE 3.0), fallow deer females (SE 1.3), mouflon females (SE 1.1), wild boar males (SE 1.0) and red deer males (SE 0.9).

A statistically significant difference in height of the snow cover was recorded in the case of individual hunting of fallow deer fawn and fallow deer male, similarly to the case of wild boar yearling and piglet. Different values were observed in red deer male, red deer fawn and red deer female. Values for red deer males and sika deer males are similar to those found in previous cases, as well as for fawns of both species. In the case of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29893014

mouflon male and mouflon female, the values were also comparable, though significantly different from the mouflon fawn values.

In the case of group hunting, differences between red and sika deer adults and fawns were identified. There was no statistically significant difference between adult and young mouflons, similarly to the roe deer and fallow deer, or between the wild boar female, male and yearling, whose values, however, are statistically significantly different from piglet.

Atmospheric pressure impact

Fig. 9 shows average deviations from the atmospheric pressure in hPa on the hunting day by particular game species. Slightly over half of the game species (12) were hunted individually at higher-than-average atmospheric pressure, while the rest (10) at lower-than-average pressure. Average atmospheric pressure was suitable for hunting mouflon females (1018 hPa, SE 1.44). Lower-than-average pressure was suitable especially for hunting fallow deer fawns (-1.8 hPa), fallow deer females (-1.3 hPa), roe deer females, sika deer females and wild boar males (-0.8 hPa). The highest atmospheric pressure suited mouflon fawns (3.4 hPa), fallow deer males (2.5 hPa), sika deer males (1.6 hPa), wild boar piglets (1.0 hPa), red deer males (0.9 hPa) and foxes (0.7 hPa). A rather large SE was found in wild boar male (SE 2.3), mouflon fawn (SE 2.0), fallow deer fawn (SE 1.8), mouflon male (SE 1.7), fallow deer female, mouflon female (SE 1.4), wild boar female (SE 1.0) and European badger (SE 1.0).

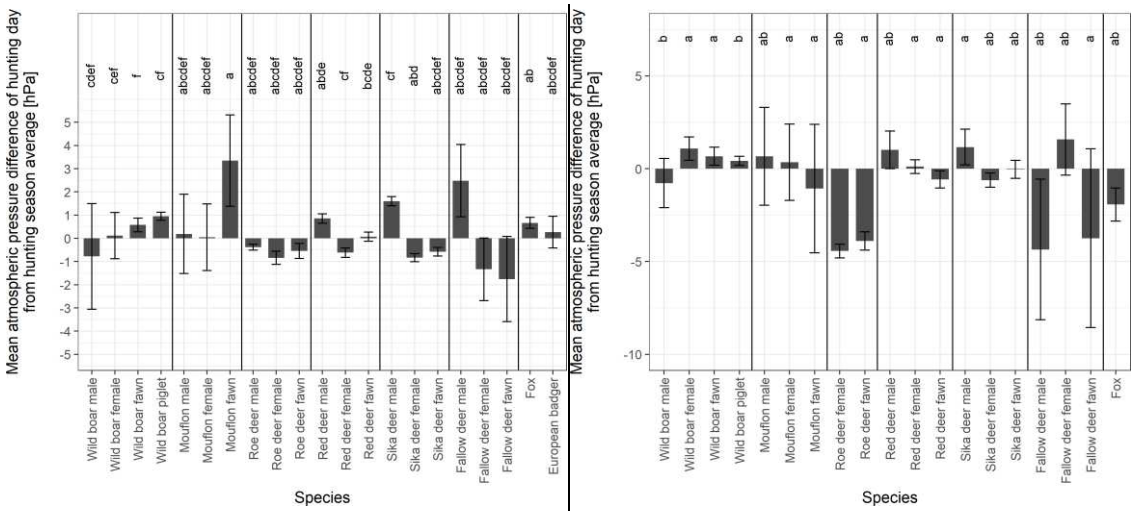

Figure 9. *Mean deviations from the atmospheric pressure in hPa on the hunting day of individual hunting (left) and group hunting (right) by particular game species in 2005-2012; statistically significant differences among species are marked by different indices; error bars indicate standard error of the mean*

Slightly over half of the game species (10) were group-hunted at lower-than-average atmospheric pressure, 2 species at average atmospheric pressure, and 8 species at higher-than-average atmospheric pressure. Average atmospheric pressure is suitable for hunting sika deer fawn and female (1018 hPa, SE 0.5 and 0.4). Lower-than-average pressure is suitable for hunting roe deer female, fallow deer male (-4.4 hPa), roe deer fawn (-3.9 hPa), fallow deer fawn (-3.7 hPa). Higher-than-average atmospheric pressure suits group-hunting of fallow deer female (1.6 hPa), sika deer male (1.2 hPa), wild boar female

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29893014

(1.1 hPa) and red deer male (1.0 hPa). Very large SE was found in fallow deer fawn (SE 4.8), fallow deer male (SE 3.8), mouflon fawn (SE 3.5), mouflon female (SE 2.1), fallow deer female (SE 1.9); it was rather high in wild boar male (SE 1.3), red deer male and sika deer male (SE 1.0).

In the case of individual hunting, no statistically significant differences were identified in deviations from the average atmospheric pressure at the time of hunting between adult and juvenile fallow deer, roe deer or wild boar. Statistically significant differences were not detected even in the comparison of the females and fawns of both red and sika deer but significantly differed from the values of adult male deer. In the case of group hunting, there were no substantial differences between any of the game species mentioned.

Interaction of climate and success of hunting

The main part of data variability appeared to be caused by standardized values of temperature, which is an important parameter for both methods of hunting (*Figs. 10 and 11*). Standardized values of atmospheric pressure could be important as well, especially in the case of group hunting. Snow cover height is naturally negatively correlated with temperatures, similarly, negative correlation is observed between atmospheric pressure and precipitation. Increased variability in game hunting probability is observed when snow cover is present. In the case of individual method, roe deer male showed the lowest variability in relation to climatic factors in hunting days compared to high variability in mouflon fawn and wild board, where increasing atmospheric pressure, respectively snow cover had positive effect on success of hunting. Higher difference among game species was observed in the case of group hunting. For example, temperature had a positive effect on the success of hunting of European badger, respectively snow height on hunting of mouflon male.

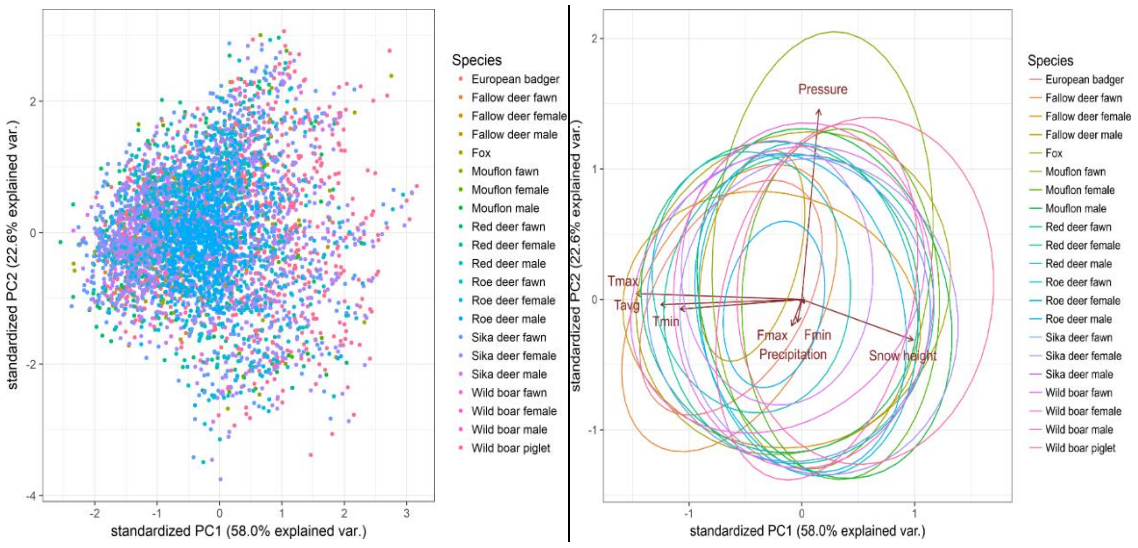

Figure 10. *Analysis of the main components for standardized climatic data (F – minimum and maximum wind speed, T – mean, minimum and maximum day time temperature, daily precipitation, daily snow cover, atmospheric pressure) for individual game species and respective individual hunting times – points (left) and ellipses of 50% probability of occurrence (right) are displayed*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29893014

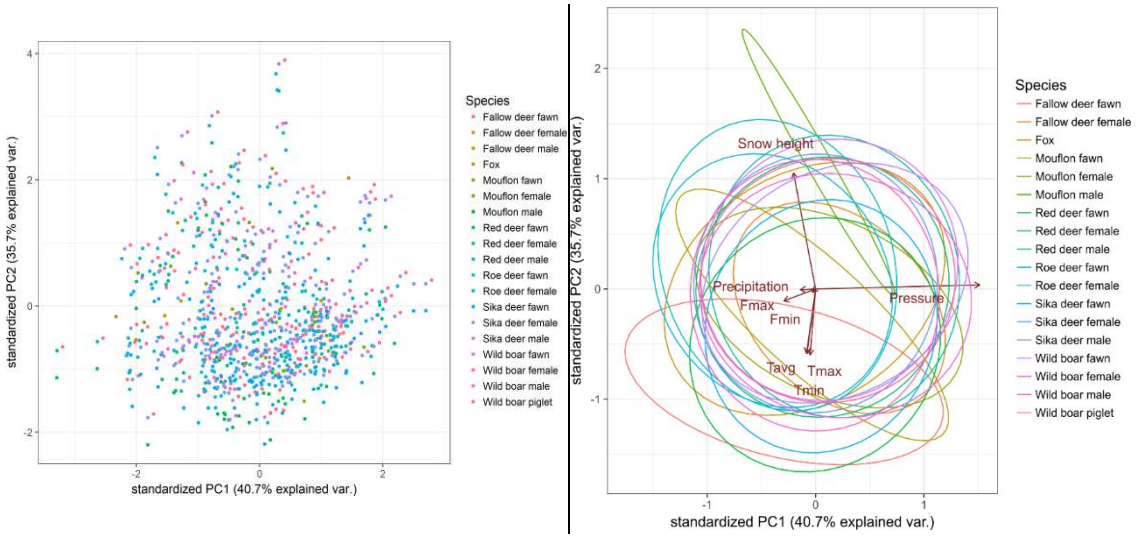

Figure 11. *Analysis of the main components for standardized climatic data (F – minimum and maximum wind speed, T – mean, minimum and maximum day time temperature, daily precipitation, daily snow cover, atmospheric pressure) for individual game species and respective group hunting times – points (left) and ellipses of 50% probability of occurrence (right) are displayed*

Focusing on November and December (period with the highest number of hunted game), the success of hunting (both methods together) of all game species was increasing with increasing snow cover, increasing atmospheric pressure change and decreasing temperature, while there was no effect of precipitation. In individual hunting, the factors which had the highest effect on the success of hunting were: decreasing temperature, increasing snow cover and increasing atmospheric pressure change. The lowest effect was observed also in term of precipitation. In more detail in relation to deer species, the highest effect on the success of hunting was connected with decreasing temperature, while in wild boar it was increasing atmospheric pressure. In group hunting method, the highest positive effect on success of hunting was connected with decreasing temperature and increasing snow cover. Generally, lower effect of climate was observed in group hunting compared to individual hunting method.

Discussion

Numerous studies generally admit that climatic factors have a significant impact on forest game species populations and their dynamics. Borowik et al. (2013), for example, report that the climatic conditions (temperature, precipitation and snow cover) greatly influence the dynamics of ungulate populations by affecting the productivity of plants and, consequently, the energy requirements of ungulates (Saether, 1997; Martinez-Jauregui et al., 2009). Loison and Langvatn (1998) analysed the stock density of the red deer population in Norway and found that deep snow and high wind velocities correlated with low density of red deer. In the case of Polish red deer populations, the average January temperature negatively affected its population dynamics due to mortality in winter months (Okarma et al., 1995). Borowik et al. (2013) further confirmed the positive influence of increasing average temperature in January on the number of red deer in Poland.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29893014

In our case, the assessment of temperature on the day of hunting of particular game species showed significant temperature fluctuations against an average value of the total hunting season for the given game species. In general, it is possible to observe – on the basis of the results found – that most game species are hunted at lower temperatures compared to the average at the time of hunting, especially in group hunting. However, this fact can be explained to some extent by the season of battues, which, most frequently, take place at the turn of the year, i.e. from November to January.

The influence of ambient temperature on ungulate populations has been verified and evaluated in relation to various habitat types used by the ungulates to relieve temperature stress (Merill, 1991; Mysterud and Østbye, 1995, 1999). The studies showed that high temperatures caused temperature stress, especially in the summer months, when the game seeks cover and is less active. Thus, the ungulates prefer habitats rich in cover and food, and significant reduction in their activity was observed (Godvik et al., 2009; Rivrud et al., 2014). Larger deer species are more susceptible to overheating (Mysterud and Østbye, 1999). An increase in the average temperature in January positively influenced the occurrence of roe deer in Poland (Borowik et al., 2013). Under unfavourable low temperature winter conditions, Holand et al. (1998) reported heavy leg strain, small body size and low chest height as factors hampering deer's survival. Okarma et al. (1995) in Poland and Kiili (1991) in Estonia found a relation between heavy frost, snow cover and the number of deer deaths from exhaustion, hunger and increased predatory pressure. In our research, analyses of numbers of hunted individuals confirmed that the assumption of a higher success rate was in lower-than-average temperature periods for particular game species. It was also confirmed inyear 2006, when winter temperature was extremely high (+ 3.2^{o}C above average) with almost no snow and the smallest number of animals was hunted in this period.

Body heat losses due to precipitation were measured in white-tailed deer – with the resulting observation that heavier body heat losses were observed than in the case of low-temperature-induced stress (Parker, 1988). Game seeks cover options to hide from fur-dampening, and thus reduces energy expenditure (Parker et al., 1984; Mysterud and Østbye, 1999). For these reasons, physical activity is minimized, and the game remains in the forest cover. It prefers mature forest habitats that provide more cover than young forest areas (König, 1987). A trend to hunt various game species in periods of less rainfall was also confirmed by our analyses. Fallow deer was hunted – both individually and in groups – on days of the lowest precipitation, both on group and on individual hunts. The original natural range of fallow deer is in Asia Minor and the Mediterranean (IUCN, 2018), i.e. in areas with lower precipitation totals compared to the Czech Republic. Another game species hunted in low-rainfall periods, is mouflon, which comes from the islands of Corsica and Sardinia and also from places of lower annual precipitation total (Schröder et al., 2016).

However, the native deer species are also hunted in periods of lower precipitation, which clearly confirms the theory of lower game activity on rainy days (Parker et al., 1984; König, 1987; Mysterud and Østbye, 1999). Low game activity reduces the chance for hunters to see it and successfully hunt it (Curtis, 1971). On the other hand, we can expect increased physical activity on days of lower-than-average rainfall from our results, which can be explained by the availability of good forage (Golodets et al., 2013; Lombardini et al., 2017). At the same time, the point of view of hunters also needs to be considered, as their effort to hunt and anticipation of worthwhile hunting experience on rainy days is reduced as well (Rivrud et al., 2014). However, to some extent, this fact can

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_29893014

be ruled out in the case of the studied Hradiště hunting grounds in hunting female and young game as hunting is performed by forest and hunting management staff who are required to fulfil the hunting quota. The influence of increased snow cover on the number of deer is very well documented from other studies, for example, for the sika deer. In the second half of the 19th century, Japanese islands witnessed a dramatic decline in sika deer numbers due to high snow cover, resulting in the banning of regulatory and commercial hunting (Kaji et al., 2000, 2010). On the other hand, the prediction for the development of sika deer numbers, which anticipates climate change and thus the reduction of snow cover, expects a significant increase in the population in the next decades (Ohashi et al., 2016).

Our direct assessment of the effect of the snow cover height on individual hunting success showed very varied values for particular game species. A dense canopy closure of forest stands reduces the height of snow cover; therefore, the game needs to emit less energy moving around the forest and finds fodder more easily (Mysterud and Østbye, 1999). However, in wild boar populations, Melis et al. (2006) indicate that deep snow and frozen soil significantly restrict their physical activity and ability to get food. Long and unfavourable winter conditions (low temperature at the beginning of spring) directly affected the survival rate of newborn wild boars in Switzerland (Geisser and Reyer, 2005). Okarma et al. (1995) in Poland and Kiili (1991) in Estonia found a correlation between high snow cover and the number of deer deaths caused by exhaustion.

Therefore, it appears that the success rate of hunting in the case of snow cover depends on the behaviour and nutritional requirements of the particular game species. In wild boar, for example, hunting from hides is considered the most effective as it takes only 18 man-hours to hunt an animal (Keuling et al., 2008). Efficiency of hunting from hides can be increased by sharpshooting at bait (Doerr et al., 2001). This method is popular in the Czech Republic especially for wild boar hunting in seasons of natural food deficiency. That explains, for example, a higher success rate of hunting piglets on days with higher-than-average snow cover in our study. Higher success rate of battues can probably be explained by the term they are organized, i.e. especially in winter months. Generally, most of the game is hunted in the winter months, while in our study we focused in particular on November and December (such as in other studies – Cupples and Jackson, 2014), when on average over 54% of the total number of animals was hunted during the year in the Doupov Hills. Our results showed that success of hunting of game species was increasing with increasing snow cover, increasing atmospheric pressure change and decreasing temperature.

The fluctuation of atmospheric pressure explains a large part of annual variability of temperatures and precipitation in Northern Europe (Hurrell, 1995). High pressure combined with high temperature and sufficient precipitation at nesting time had a beneficial effect on the reproduction of snow goose (*Chen caerulescens atlantica* Kennard) (Dickey et al., 2008). Atmospheric pressure, together with temperature and precipitation, are the most important variables in relation to weather conditions and also in relation to living organisms (Hawkins and Klimstra, 1970; Knape and de Valpine, 2010). Rapid changes in atmospheric pressure influence the animal-activity patterns (Ables, 1969; Bender and Hartman, 2015) and it can significantly affect the success of the hunting. Hynes (2014) documented that the best hunting time of white-tailed deer is when the pressure is changing, especially when the pressure immediately increases. Our study confirmed the effect of positive atmospheric pressure effect on the success of hunting, especially in individual hunting method and in wild boar. Slightly over a half of

DOI: http://dx.doi.org/10.15666/aeer/1802_29893014

game species are hunted at a lower-than-average atmospheric pressure in the the Doupov Hills. Also, in our case, a negative correlation between atmospheric pressure and precipitation was found. A comparison of the atmospheric pressure on the day of hunting showed no statistically significant differences between females and fawns of the two deer species, but they did differ significantly from the values for adult males.

Long-term influence of weather during the vegetation season is also indisputable, as it affects the quality and quantity of natural food (Albon and Langvatn, 1992; Solberg et al., 1999). It can be documented, for example, in the wild boar. The number of wild boar piglets was positively influenced by higher temperatures and higher precipitation in summer, as well as by the higher yield of acorns (Frauendofr et al., 2016) which is, together with beech nuts, the most important source of natural food (Jędrzejewska et al., 1994, 1997) and its yield is also very closely related to climatic influences. The success of the hunt is therefore indirectly influenced by the climate-supported higher numbers of game. The hunter is then more likely to see the game and successfully hunt it.

Borowik et al. (2013) report that, as part of the ongoing changes that are directly related to global warming, ever-milder winter conditions improve the lives of ungulates in Central Europe, leading to their increased numbers. In addition, rising temperatures cause changes in the utilization of the ungulates' habitats. In recent decades, a shift in phenology and tree composition has been observed, with coniferous stands being gradually replaced by mixed and deciduous forests (Sykes et al., 1996; Root et al., 2003; Hanewinkel et al., 2013), increasing the carrying capacity of hunting grounds (Gallo and Pejchar, 2016).

Conclusion

The success of game hunting depends on many factors that can be influenced to a certain extent, improving hunting success significantly. Hunters are supposed, for example, to be familiar with the hunting grounds, with biology of the game and its habitats, and should be able to choose suitable hunting and method (individual or group). There are more factors beyond the hunters' will. Among the most notable unavoidable factors influencing hunting activities are undoubtedly the weather patterns at a given time and place, e.g. air temperature, atmospheric pressure, precipitation, wind speed and snow cover height on the hunting day. In the Doupov Hills, it was the air temperature on the hunting day that had the greatest impact on hunting success. In the case of the snow cover, an increased variability in the values of the studied climatic parameters was observed on the day of hunting. Atmospheric pressure, together with temperature, was one of the most important variables in relation to weather conditions and to living organisms, substantially influencing their physiological processes and well-being and hence the success of hunting. Results showed that the success of hunting was increasing with decreasing air temperature, increasing snow cover and increasing atmospheric pressure change, especially in the case of individual hunting method. On the other hand, precipitation and wind speed had relatively low effect on the success of hunting. Individual hunting was associated with significantly better climatic conditions in comparison to group hunting, such as in the case of hunting of male game species compared to female. However, in relation to the success of the hunting, it is also necessary to focus on other factors not analysed in this study, for example habitat conditions, time of hunting, food source, air humidity, sunshine (clouds), wind direction, fog etc. The findings of this study can contribute to future research and planning of suitable times and methods of hunting and thus supporting successful hunting in montane and submontane regions of Central Europe.

(Received 16th Nov 2019; accepted 12th Feb 2020)

Abstract. The effects of seeding rate and tillage on water use and nitrogen use efficiencies were studied based on a field experiment carried out from 2012 to 2016. The results showed that subsoiling significantly increased the soil water storage before sowing in all years. The water consumption (ET) during the four years was, on average, 461 and 301 mm for subsoiling (SS) and CK, respectively. The average yield of SS was 4821 kg/ha, which was 944 kg/ha higher than that of CK. The average yield was highest at the mid-seeding rate for both SS and CK, with values of 5115 and 4394 kg/ha, respectively. Since the nitrogen fertilizer application rate was the same, a higher yield indicates a higher nitrogen use efficiency (NUE). Contribution analysis showed that the higher seeding rate led to a lower contribution of nitrogen uptake efficiency (UPE) and a higher contribution of NHIp to NUEp. In summary, subsoiling during summer fallow period increased the soil water retention and improved the wheat yield and WUE. It also increased nitrogen uptake and NUEp. The mid-seeding rate (approximately 90 kg/ha) under subsoiling is optimal for improving water use efficiency (WUE) and NUE in the Loess Plateau.
Keywords: *dryland farming, contribution analysis, water use efficiency, soil tillage, nitrogen fertilizer*

Introduction

In dryland farming areas, water is a limiting factor for crop production. In most regions of the Loess Plateau, the groundwater is deep, and no irrigation water can be obtained; hence, the crops are rain-fed (Kang et al., 2002). Winter wheat (*Triticum aestivum* L.) is one of the main crops in this area. With a continental monsoon climate, the rainfall in the Loess Plateau is low and mainly falls in July, August, and September (Wang et al., 2011). However, this period occurs during the fallow period of winter wheat, which grows from early October to the following June. The rainfall during the wheat growth season is insufficient for optimal crop growth; approximately 30-40% of the required water comes from the soil water stored before sowing (Zhang et al., 2013).

A higher temperature in the fallow period makes it easier for the soil water to be lost by evaporation (Han et al., 2015). To conserve more water in the soil for wheat growth, the precipitation storage efficiency (PSE) should be increased during that period. In agronomy, there are two main types of practices to increase the PSE: reduce soil evaporation and increase soil infiltration (Nielsen and Vigil, 2010). To reduce evaporation, soil surface mulching techniques can be applied, among which plastic mulching and straw mulching are widely used (Zhang et al., 2013). Research shows that plastic film increases soil moisture in topsoil by 12.9% (Ma et al., 2018). Soil infiltration is related to soil physical properties. Tillage modifies the soil physical properties, such as the soil bulk density, which will further influence soil infiltration (Gómez et al., 1999). Subsoiling is a tillage practice that decreases the soil bulk density

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30153026

and increases the amount of water infiltration. Previous studies have shown that subsoiling increases the water storage in drylands (Bhatt and Khera, 2006). In the Loess Plateau, soil water storage was increased by 76 mm in the 0-200 cm layer under subsoiling during the summer fallow period (Liao et al., 2002).

Nutrients represent another limiting factor in dryland farming. The nitrogen fertilizer use efficiency (NUE) is low in dryland farming areas (Zhu and Chen, 2002). Low soil moisture decreases nutrient availability sand impacts the uptake of nutrients by crops; thus, the NUE in the dryland farming area is low (Guntiñas et al., 2012). The improved soil water conditions under subsoiling may improve the nutrient conditions in the field by making nutrients such as nitrogen more available for crops (Zhu et al., 2018), which providing crops with a better growth environment and increases productivity (Basso et al., 2010).

The seeding rate influences the wheat population, which further influences the use of soil water and nutrients and finally influences wheat growth and yield formation (Kühling et al., 2017). Wheat yield increases with the increase in seeding rate under the low sowing rate and peaks at a certain threshold value, after which it might not increase and may even cause a decrease in grain yield (Bhatta et al., 2017). Whether the optimum seeding rate changes due to the application of subsoiling still need to be addressed.

The process of nitrogen use by winter wheat can be simplified into two stages (Sadras and Lawson, 2013). In the first stage, plants uptake N from the soil and store it in leaves and stems. In this process, the N availability impacts its uptake. In winter, wheat N uptake represents 75 to 90% of the total N in the plant at harvest (Delogu et al., 1998). In the second stage, N is translocated to grains during grain filling. Many previous studies have focused on the uptake and translocation of nitrogen. However, few studies have focused on how nitrogen absorption and transportation respond to subsoiling and seeding rates. To clarify this issue, a field experiment on subsoiling in the fallow period and different wheat seeding rates was carried out from 2012 to 2016 in the Loess Plateau of China.

Materials and methods

Site description

The study was conducted at the experimental station of Shanxi Agricultural University in Wenxi County, Shanxi Province, China (35°20'N, 111°17'E, and elevation 639 m), from 2012 to 2016. The experimental site is a dryland area, with an average precipitation of 484 mm, 60-70% of which is concentrated during the fallow period of winter wheat. To improve the water use, all the experiment was carried out based on plastic film mulch. The basic nutrient properties of the soil in the experimental field in 2012 are shown in *Table 1*.

Crop management

After harvesting the previous wheat, wheat stubble with a height of 20-30 cm was left in the field until mid-July. Subsoiling was performed during the fallow period by a subsoiler (IS-200, Xiuyuan Agricultural Machinery Co.) to a depth of 30-40 cm in mid-July, followed by rotary tillage to crumble large soil lumps and to level the field around 20 August. The winter wheat variety used in this study was 'Yunhan20410', which was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30153026

the recommended variety by the local agricultural extension department due to its drought stress resistance ability. The suggested sowing rate of Yunhan20410 is 90 kg/ha, if the sowing date is delayed due to climate condition, the sowing rate may be increased to 105 kg/ha. During the four experimental years, wheat was sown in late September or early October and harvested around 20 June. Before sowing, chemical fertilizer was applied at a rate of 150 kg ha^{-1} nitrogen, 150 kg ha^{-1} P_2O_5 and 150 kg ha^{-1} K_2O. Since no irrigation was applied during the experiment, no fertilizer was applied during the entire growth period. Weeds and pests were controlled by herbicides as needed.

Table 1. *Main soil chemical properties before sowing in 2012*

Soil nutrients	Content
Organic matter (g kg^{-1})	11.88
Total nitrogen (g kg^{-1})	0.61
Alkali-hydrolysis nitrogen (mg kg^{-1})	38.62
Available phosphorous (mg kg^{-1})	14.61
Available potassium (mg kg^{-1})	238.16
pH	8.08

Experimental design

The experiment was conducted with a two-factor split plot design, taking the tillage practice as a main factor and the planting density as a sub-plot factor. The two tillage practices were the subsoiling (SS) and the no tillage (NT) condition, which was the control. Under each tillage method, three planting densities, low (L, 60-75 kg seed ha^{-1}, < 190 × 10^6 plants ha^{-1}), mid (M, 90-105 kg seed ha^{-1}, 190-260 × 10^6 plants ha^{-1}), and high (H, 112.5-120 kg seed ha^{-1}, > 320 × 10^6 plants ha^{-1}) were used in the experiment. Seeds were sown at rates of 67.5, 90 and 112.5 kg ha^{-1}, after which a 3-leaf stage planting density of 190, 260 and 320 plants m^{-2} was attained by thinning. Each treatment was repeated three times with a total of 18 plots. Each sub-plot (150 m^2) was 50 m long and 3 m wide with a line spacing of 30 cm.

Measurements

Soil water storage

The soil was sampled every 20 cm to a depth of 300 cm and soil water content was determined gravimetrically before planting and after harvest. The precipitation data were obtained from the meteorological station at the experimental site (*Table 2*).

Table 2. *Precipitation and mean temperature in fallow period and in growth stage during the experiment (mm)*

	Stage	2012-2013	2013-2014	2014-2015	2015-2016
Precipitation (mm)	Fallow period	188	288	284	95
	Growth stage	167	202	190	292
Temperature (℃)	Fallow period	24.9	26.7	24.8	24.7
	Growth stage	10.4	10.7	10.5	10.0

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30153026

As the plots were on a flat experimental field with ridges around them, the plots were not influenced by surface runoff. Moreover, the influence of groundwater can be ignored because the groundwater level is low in this region. The evapotranspiration (ET) and water use efficiency (WUE) were obtained through *Equations 1* and *2* (Li et al., 2013):

$$ET = P + \Delta W \quad \text{(Eq.1)}$$

$$WUE = \frac{Y}{ET} \quad \text{(Eq.2)}$$

where ΔW is the soil water depletion during the wheat growing stage, and Y is the grain yield.

Nitrogen content

Plant nitrogen content was determined using the semi-micro Kjeldahl method, and wheat protein content was obtained by multiplying the N content (%) by 5.7 (Halvorson et al., 2004).

Grain yield

At maturity, plants from three 1 m^2 size sample plots were harvested from each plot to determine the grain yield (kg ha^{-1}).

Contribution analysis

In this research, because soil available nitrogen was not measured, we focused on the use efficiency of nitrogen from fertilizer and then the NUE, which is defined as the ratio of the grain yield (Y) and nitrogen fertilizer application rate (Nf) (Moll et al., 1982). The nitrogen fertilizer use efficiency for protein (NUEp) is defined as the ratio of the grain nitrogen (Ng) and nitrogen fertilizer application rate. The NUE can be partitioned into the components of UTE (the ability of the plant to convert the absorbed N into harvested grain yield, Y/Nt) and UPE (nitrogen uptake efficiency, Nt/Nf). NUEp can be separated into the components of UPE and NHI (nitrogen harvest index, Ng/Nt) (Van Sanford and Mackown, 1986). *Equations 3* and *4* express the relationship between these indexes.

$$NUE = UPE \times UTE \quad \text{(Eq.3)}$$

$$NUEp = UTE \times NHI \quad \text{(Eq.4)}$$

To analyse the contribution of the components to NUE, we calculated the natural log of the three components using *Equation 5:*

$$ln\ NUE = ln\ UPE + ln\ UTE \quad \text{(Eq.5)}$$

Then, both individual components of NUE can be regressed with respect to NUE: ln UPE = a1 + b1 ln NUE; ln UTE = a2 + b2 ln NUE; (b1 + b2) must be = 1 and thus

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30153026

explains the complementary contribution of each component to NUE (Giuliani et al., 2011). Similarly, the contribution of each component to NUEp can be calculated by this means.

Statistical analysis

An analysis of variance was conducted on the experimental data using SAS 9.3 (SAS Institute Inc., Cary, NC, USA) to study the main effects of mulching methods and their interactions. The least significant difference (LSD) test was performed to calculate the significance of differences between means at $P < 0.05$.

Results

Yield and water use

Based on the boundary function concept proposed by French and Scultz (1984) and the improved boundary function establishment method developed by Lin and Liu (2016), we obtained the winter wheat boundary function of yield-ET in the Loess Plateau (*Fig. 1*). The upper boundary of the yield-ET relationship can be fitted using the function Yield = 14.8 (ET-42.3), which means that under plastic film mulch in this area, the maximum transpiration efficiency is 14.8 kg ha^{-1} mm^{-1}.

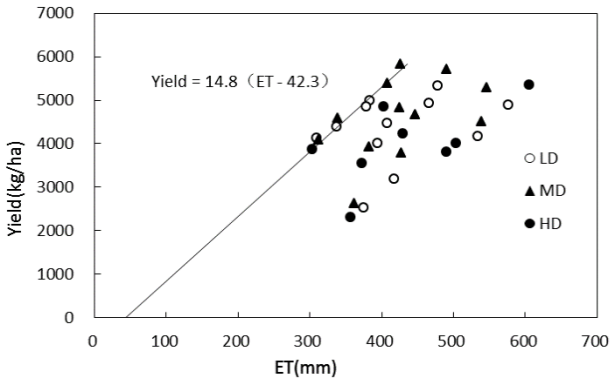

Figure 1. *Yield and ET relationship under different seeding rates. The boundary line was generated according to (Lin and Liu, 2016) and shows the maximum yield under different ET*

The results show that compared with CK, SS increased the soil water storage by an average of 58 mm during the 4 years ($p < 0.001$). The average yield under SS was 4821 kg/ha, which was 950 kg higher than the 3877 kg/ha of CK ($p < 0.001$). Higher soil water storage provided more water for crop use during the growth period; hence, the ET for SS was significantly higher than that of CK. The WUEs for SS and CK were 10.6 and 10.2 kg ha mm, respectively, without a significant difference. The WUEp for SS was significantly higher than that of CK (*Table 3*).

To evaluate the seeding rate impact on the yield and water use of winter wheat, we calculated the data based on the seeding rate (*Table 4*). The results showed that the wheat yields were 4324, 4787 and 3998 kg/ha for the low-, mid- and high-seeding rate treatments, respectively ($p < 0.05$). No significant difference was observed for ET among different seeding rates. The difference in WUE and WUEp under different

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30153026

seeding rates was much the same as that of yield, i.e., highest at the mid-seeding rate, second in the low-seeding rate and lowest in the high-seeding rate.

Table 3. *Yield, water consumption and WUE under different tillage measures*

Tillage	Yield (kg/ha)	Soil water storage before sowing (mm)	ET (mm)	WUE (kg ha^{-1} mm^{-1})	WUE$_P$ (kg ha^{-1} mm^{-1})
SS	4821	526	461	10.6	11.3
CK	3877	468	391	10.2	9.1
Prob	0.041**	0.045**	0.045**	0.064	0.041**

**Significant difference between SS and CK based on t test at the $p < 0.05$ significance level; ns: no significant difference was observed

Table 4. *Yield, water consumption and WUE under different seeding rates. L, M, and H represent low-, mid- and high-seeding rates, respectively. Values followed by different letters within the same row are significantly different ($P < 0.05$)*

Seeding rate	Yield (kg/ha)	ET (mm)	WUE (kg ha^{-1} mm^{-1})	WUE$_P$ (kg ha^{-1} mm^{-1})
L	4324 b	421 a	10.5 b	10.1 b
M	4787 a	431 a	11.3 a	11.1 a
H	3998 c	433 a	9.4 c	9.4 c
$LSD_{0.05}$	301	12.5	0.7	0.7

Nitrogen uptake and translocation

Under subsoiling, the NUE was 31.31, 34.10 and 30.43 kg/ha for the low-, mid- and high-seeding rates (*Table 5*). Under CK, the NUE decreased to 25.32, 26.51 and 21.91 kg/kg, respectively. The UTE for SS was significantly higher than that of CK under all seeding rates. However, the situation among different seeding rates was not the same for the NUE. The NUEs were highest under the mid-seeding rate. The UTE was highest at a low-seeding rate under SS and highest at a high-seeding rate under CK. The UPE is a component of both NUE and NUEp, and it was highest at the mid-seeding rate, with values of 1.06 and 1.01 in SS and CK, respectively (*Table 5*). However, for CK, there was no significant difference among seeding rates. The NUEp tended to be lower under CK than under SS. Under the same tillage method, the mid-seeding rate showed the highest NUEp. The average NHI was approximately 0.82, and no significant difference was observed between treatments.

Contributions of NUE and NUEp

Figure 2 shows the calculation process for NUEp under SS and CK. The slope of the regression function is the contribution of each component to NUEp. The contribution of NHI to NUEp was 20.84%, and under CK, it decreased to 12.92%. The contribution of UPE to NUEp was 79.16%, and under CK, it increased to 87.08%. Hence, SS led to a higher contribution of UPE and a lower contribution to NHI.

The contribution of UPE to NUEp was 84.96%, 81.12% and 76.59% for the high-, mid- and low-seeding rates, respectively (*Table 6*). The contribution of UPE to NUE was 67.05%, 48.95% and 36.06% for the high-, mid- and low-seeding rates,

DOI: http://dx.doi.org/10.15666/aeer/1802_30153026

respectively (*Table 7*). The contribution of NHI to NUEp was 15.04%, 17.87% and 23.41% for the high-, mid- and low-seeding rates, respectively. The contribution of UTE to NUE increased as the seeding rate increased, ranking 32.95%, 51.05%, 63.94% for the high-, mid- and low-seeding rates, respectively.

Discussion

Seeding rate and wheat water yield potential

The boundary analysis results show that most of the dots close to the boundary line were the mid-seeding rate treatment and low-seeding rate treatment (*Fig. 1*). This result means that a high seeding rate is not appropriate for making full use of water resources in this region. The intercept of the boundary line represents the minimum soil evaporation in this area (Sadras and Angus, 2006). In this research, the intercept is 42.3 mm, which was lower than the value of 60 mm reported by Zhang (2013). The main reason is that plastic film was used in this research, and plastic is effective in reducing soil evaporation (Li et al., 2005).

Subsoiling influence on wheat yield and WUE

In SS, the ET and yield increased significantly, but no significant difference was observed in the WUE (*Table 3*). However, this does not mean that SS had no impact on water resource use in dryland wheat. SS increased precipitation infiltration into the soil in the summer period; hence, more water was stored in the soil before sowing (Williams et al., 2006), which means that more water was available for crop growth and soil evaporation. Hence, the ET was increased (Lin et al., 2016). Because ET and yield were increased in a similar ratio under SS in this research, the WUE remained the same. However, in dryland farming, a high WUE should be considered, but it makes no sense if the high WUE is based on a low yield and low ET. The effective use of water should be the goal to improve the crop yield in dryland areas (Blum, 2009). In the Loess Plateau, without irrigation and groundwater supplementation, soil water is supplied by precipitation; hence, precipitation is the only source of water for crop growth (Lin et al., 2019). However, more water was used under SS because more water was within reach for the crop. We further calculated the WUE of precipitation (WUEp) in a hydrological year (fallow period + growth period) and found that the WUEp under SS increased significantly (*Table 3*). SS significantly used the limited precipitation available in the dryland farming area.

Fang (2010) found that ET increased as the seeding rate increased. In this study, although ET showed an increasing trend as the seeding rate increased, no significant difference was found in the ET values among the different seeding rate treatments. This difference may be due to differences in the environment at the experimental sites. Compared with Fang's research, precipitation was lower in this research. Under a high-seeding rate, the large population calls for more water for transpiration use, but the shading effect of higher shoot coverage may reduce the soil evaporation; under a low-seeding rate, less water is used by transpiration, but more soil is exposed to the air

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30153026

directly, and hence more water is evaporated (Li et al., 2013). Iqbal et al. (2012) found that the mid-seeding rate helped obtain a high yield. In this research, we found a similar result. The wheat yield was highest in the mid-seeding rate treatment and lowest in the high-seeding rate treatment. Thus, a suitable seeding rate is important for achieving a high yield. This may be the reason why similar ET values were found among the different seeding rates in this study.

N uptake and utilization

SS increased the soil water content and improved the soil air condition, which increased the availability of nutrients and eased the uptake of nutrients by roots (Zhu et al., 2018); hence, UPE was higher in SS than in CK (*Table 1*). The higher UPE further led to a higher NUEp for SS, although there was no significant difference in the NHI among treatments. Contribution analysis showed that the contribution to NUEp was CK < SS for UPE and CK > SS for NHI. Giuliani et al. (2011) found that the contribution of UPE to NUEp was lower in dry years than in wet years. In this research, SS improved the soil water condition before sowing, which resembled a wetter condition compared with that in CK. A higher contribution of UPE means that the increased NUEp under SS was mainly due to the increased UPE.

NUE and NUEp were highest for the mid-seeding rate treatment. This result means that a moderate planting density helps make full use of nitrogen (Arduini et al., 2006). In agreement with several previous studies (Van Sanford and Mackown, 1986; Giuliani et al., 2011), the contribution of UPE to NUEp was higher than that of NHI under all seeding rates (*Table 6*). The contribution of UPE to NUEp decreased as the seeding rate increased, and the contribution of NHI increased as the seeding rate increased. For NUE, the contribution of UPE was higher than that of UTE at low-seeding rates, similar at mid-seeding rates and lower at high-seeding rates.

In this study, because the available soil N before seeding was not measured, nitrogen from fertilizer (Nf) was used instead of the nitrogen supply (Ns, expressed as Nf plus available soil nitrogen). This represents a limitation of this study. However, fertilizer N is an important N source for wheat growth; hence, the results still make sense for wheat production in dryland areas.

Conclusions

In order to make full use of the limited water resources and improve nitrogen fertilizer use efficiency (NUE) in the dryland farming area, the effects of seeding rate and tillage on water use and nitrogen use were analyzed. We found that under plastic film mulch, soil evaporation is effectively reduced for the winter wheat in the Loess Plateau. Subsoiling during the summer fallow period increased soil water retention and improved wheat yield and WUEp. It also increased nitrogen uptake and NUEp. The mid-seeding rate (approximately 90 kg/ha) increased the wheat yield and WUE and increased the contribution of NHI to NUEp but decreased the contribution of UPE to NUEp, which led to the highest NUEp. The results of this study focused on the overall use of N fertilizer absorption and utilization, to make a full understanding about how seeding rate and subsoiling influence N utilization process, N concentration in plant and enzymatic activity related to N enzymatic activity should be measured in future study.

Abstract. The application of sewage sludge (SS) in agriculture is a wastewater recycling method for soil fertilization. The aim of this study was to assess the influences of SS amendment rates (0, 10, 20, 30, 40 and 50 g kg^{-1}) on the green-salad leafy plant *Eruca sativa*. The SS amendment increased soil salinity and organic matter and decreased soil pH. The heavy metal (HM) contents were below the permissible limits as recommended by the Council of the European Communities. An increase in *E. sativa* morphometric parameters was detected. The leaf, root and total biomasses of *E. sativa* increased at amendment rates 10, 20 and 30 g kg^{-1}. The applications of 40 and 50 g kg^{-1} negatively affected the biomass. The highest concentration of the measured HMs in the plant was detected at the 50 g kg^{-1} amendment rate. The bioaccumulation factors of Cd, Co, Cr, Fe, Mn, Ni, Pb and Zn were < 1.0, whereas those of Cu and Mo were > 1. The translocation factors for all HMs were < 1.0 except for Cd and Pb. Even though, SS increased the biomass of *E. sativa*, SS is not recommended as a fertilizer for *E. sativa*, since translocation factors of Cd and Pb were >1.
Keywords: *soil pollution, rocket plant, health hazards, environmental risks, metal bioaccumulation*

Introduction

Sewage sludge (SS) is a by-product of domestic wastewater treatment processes (Eid and Shaltout, 2016). SS has a variety of elements that are considered nutrients for plants in addition to organic components that increase agricultural soil fertility (Singh and Agrawal, 2008). However, the physical, chemical and microbial properties of SS have to be analyzed before use as agricultural soil fertilizers to avoid any harmful effects on plants, animals and humans (Carbonell et al., 2009). The effect of heavy metals (HMs) on crops differs according to the metal and/or plant (Hara and Sonoda,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30273040

1979). Some HMs are required by plants for physiological processes, including Mn, Fe, Cu, Zn, and Mo, while other HMs are phytotoxic, such as Cd and Pb (Raskin et al., 1994).

The concerns in using SS as soil fertilizer relate to the possible transfer and accumulation of significant HMs in the food chain and, subsequently, their effect on human health (Shrivastava and Banerjee, 2004). Several factors influence the toxic HM accumulation in soil and plants, such as the origin and properties of the SS and agricultural soil, amendment level, metal availability, and plant species (Kabata-Pendias, 2011; Dede and Ozdemir, 2016). Even though use of SS in agriculture is an effective and economically beneficial method of disposal, the potential environmental and health issues should be considered.

Rocket (*Eruca sativa* Mill.) is a vegetable leafy crop belonging to the *Brassicaceae* family. Its fresh leaves are used as a green salad food because it is a fast-growing species, and is available nearly all year (Nail et al., 2017). The nutritional and medicinal benefits of *E. sativa* are documented as an anticarcinogenic, antimicrobial and antioxidant agent (Hassan et al., 2017). The biochemical constituents of *E. sativa* and their bio positive effects on health were explained in several studies (Garg and Sharma, 2014; Jilani et al., 2015). In the current study, SS was used as an amendment to agricultural soil for growing *E. sativa*. The objectives were to (1) evaluate the effect of SS on the growth and biomass of *E. sativa* and (2) assess the HM accumulation in *E. sativa* parts and in the agricultural soil.

Materials and Methods

Plant materials, sewage sludge treatments and experimental design

Eruca sativa seeds were obtained from a local market in Abha. The agricultural soil used in the experiment was collected at a depth of 0-20 cm from neighbouring cultivated fields. The SS was obtained from the Abha municipal sewage treatment plant, Aseer region, Saudi Arabia. The agricultural soil and SS were air-dried for 2 weeks and sieved through a sieve with 2-mm pore diameter. The experiment was performed in the greenhouse of the Biology Department, King Khalid University, Abha, Saudi Arabia.

The SS was mixed with agricultural soil at rates of 0 (the control soil), 10, 20, 30, 40 and 50 g kg^{-1}. Each treatment consisted of six replicates of a plastic pot (6-L volume), and each plastic pot was filled with 4 kg of the respective treatment. Twenty *E. sativa* seeds were planted in each pot. The experimental units were arranged in a complete randomized design. The plants were grown for 40 days, starting from the planting day of January 2nd, 2018 and were harvested on February 10th, 2018, in the greenhouse with a natural day/night regime and irrigated as needed. *Figure 1* shows the experiment setup and postharvest analyses.

Plant morphometric parameters and biomass

From the 120 plants in each treatment, 30 plants (5 plants/6 replicates) were used for morphological and biomass measurements. *E. sativa* plants were washed using running water. Shoot height and root length were measured, and the number of leaves were counted. Leaf area was measured using a leaf area metre (Dynamax AM 300, Dynamax Inc, USA). The absolute growth rate (AGR) was calculated according to the formula by Radford (1967) (*Eq. 1*):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30273040

$$\text{AGR (g DM individual}^{-1}\text{ day}^{-1}) = (W_2 - W_1)/(t_2 - t_1) \quad \text{(Eq.1)}$$

where W_1 and W_2 are the total biomasses (g DM individual^{-1}) at times (days) t_1 and t_2, respectively. The value of t_1 is zero and t_2 is 40 which is the growing period of the plants.

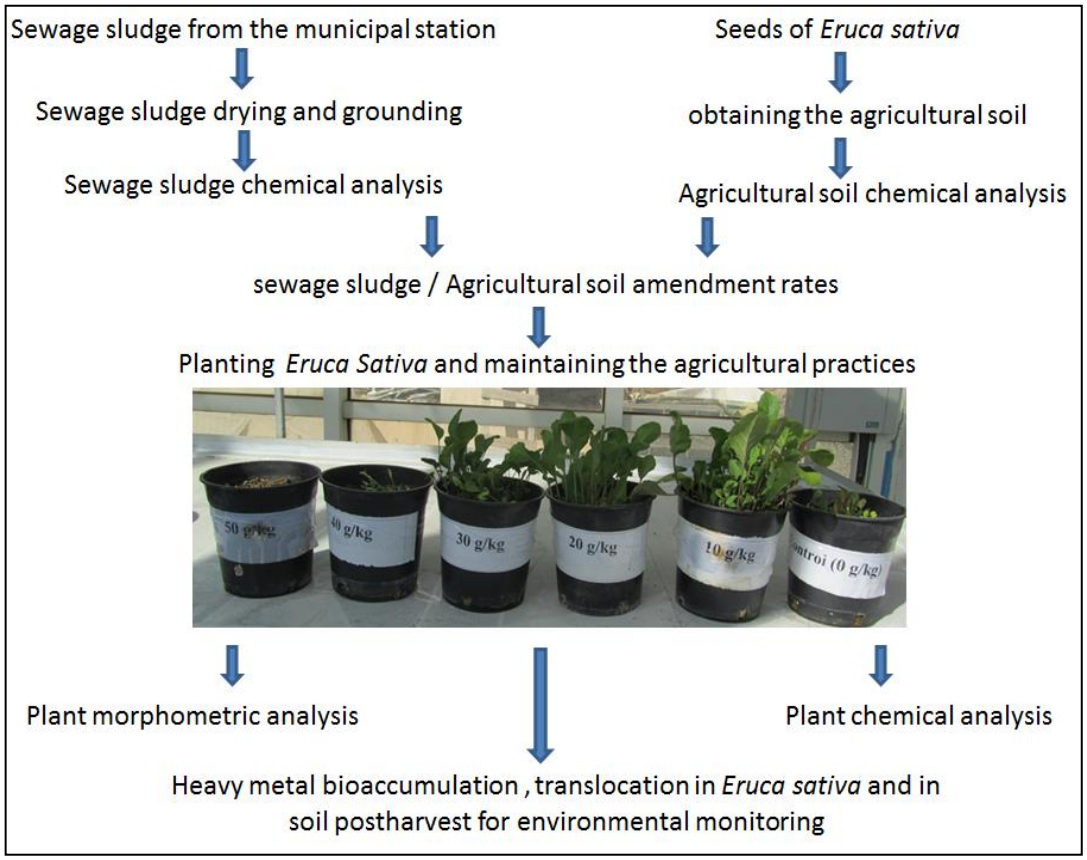

Figure 1. *A graphical demonstration of the experiment steps with pots represents the treatments of sewage sludge-soil amendment rates*

The plant leaves and roots were oven-dried at 60°C for one week and ground using a plastic mill. The biomass of the leaves and roots were determined. The total biomass refers to the summation of the leaf and root biomass.

Sample analyses

Pre-experiment analyses of the SS and agricultural soil were conducted. At the end of the experiment, the amended soil samples representing all treatments were air dried and sieved through a 2-mm sieve. The pre-used agricultural soil, SS and post-harvest amended soil samples (including the control) were analyzed for organic matter content using a loss-on-ignition method at 550ºC for two hours (Wilke, 2005). Soil-water extracts at a ratio of 1:5 were prepared for salinity and pH determination, using conductivity (Myron L Model DA-1, Myron L Company, USA) and pH metres (ICM Model 41150, ICM, USA), respectively. HMs in the pre-experiment agricultural soil, SS, post-harvest amended soil and plant parts samples were detected according to Allen

DOI: http://dx.doi.org/10.15666/aeer/1802_30273040

(1989). HMs were extracted from approximately 0.5 g of each sample using a mixed-acid digestion method (HNO_3 and $HClO_4$; 3:1, v/v). Digestion was performed using a microwave sample preparation system (PerkinElmer Titan MPS, PerkinElmer Inc., USA). Blank samples were used to verify the accuracy. Analytical-grade chemicals were used for sample digestion. Cd, Co, Cr, Cu, Fe, Mn, Mo, Ni, Pb and Zn were determined using an inductively coupled plasma optical emission spectrometry (ICP-OES) (Thermo Scientific iCAP 7000 Plus Series; Thermo Fisher Scientific, USA). The instrument setting and operational conditions followed the manufacturer's specifications. Standard solutions with known concentrations of different HMs were prepared for the standardization of the system.

Estimation of bioaccumulation and translocation factors

Bioaccumulation and translocation factors were calculated as described by Ghosh and Singh (2005). The bioaccumulation factor (BF) was calculated to determine the effectiveness of the plants in accumulating a HM from the soil according the following formula (*Eq. 2*):

$$BF = \text{conc. of a metal in the roots/conc. of the same metal in the soil} \quad \text{(Eq.2)}$$

The translocation factor (TF) was calculated to determine the ability of the plants to translocate a metal from the roots to the shoot according the following formula (*Eq. 3*):

$$TF = \text{conc. of a metal in the shoot/conc. of the same metal in the roots} \quad \text{(Eq.3)}$$

Statistical analysis

The data were tested for normality of distribution and homogeneity of variance, and when necessary, the data were log-transformed. The data were assessed using one-way ANOVA. The significant differences between the means of the six amendment rates were identified using the Tukey HSD test at $P < 0.05$. A quadratic regression analysis (Eid et al., 2020) was performed to evaluate the response of the biomass and plant morphometric parameters of *E. sativa* grown in soils amended with different rates of SS. To evaluate the statistical relationships among the content of HM in plant parts and the amendment rate of SS, linear regression procedures were applied according to the following formula (*Eq. 4*):

$$y = a + bx \quad \text{(Eq.4)}$$

where y is the heavy metal concentration (mg kg^{-1}) in *E. sativa* tissue harvested after 40 days, x is the sewage sludge amendment rate (g kg^{-1}) and the regression coefficients used are a and b. Statistical analyses were conducted using Statistica 7.1 (Statsoft, 2007).

Results and discussion

The application of SS as an amendment to agricultural soils has been reported to play a role in soil fertilization (Jitariu et al., 2011; Eid et al., 2019). Analyses of SS and soil showed that SS had high organic matter content and acidity and was more saline compared

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30273040

to the cultivated soil. The analysis of the ten HMs' content in the SS showed the following order: Fe > Pb > Zn > Mn > Cr > Cu > Ni > Co > Cd > Mo. However, the order of these metals in the agricultural soil was as follows: Fe > Mn > Zn > Cr > Co > Ni > Cu > Cd > Pb > Mo (*Table 1*). The properties of soils amended with sludge depend on the initial constituents of both the soil and SS (Baghina et al., 2014). The HM contents in SS were under the allowed limits for soil application of SS recommended by the Council of the European Communities (1986). The HM contents in the SS were low because of the effective pre-treatment and monitoring of wastewater treatment processes in Saudi Arabia.

Table 1. *Selected chemical properties of sewage sludge and cultivated field soil used in the pot experiment (means ± standard error, n = 3)*

Properties	Sewage sludge	Cultivated fields soil
Salinity (mS cm^{-1})	1.39 ± 0.10	0.07 ± 0.00
pH	6.98 ± 0.02	8.68 ± 0.02
Organic matter (%)	65.0 ± 0.9	0.9 ± 0.2
Cd (mg kg^{-1})	1.17 ± 0.08	2.91 ± 0.05
Co (mg kg^{-1})	25.86 ± 1.31	35.49 ± 1.13
Cr (mg kg^{-1})	168.09 ± 4.45	44.11 ± 0.35
Cu (mg kg^{-1})	162.56 ± 2.32	15.01 ± 0.57
Fe (mg kg^{-1})	24410.0 ± 450.0	17120.0 ± 160.0
Mn (mg kg^{-1})	560.70 ± 9.81	340.43 ± 7.04
Mo (mg kg^{-1})	0.91 ± 0.04	0.40 ± 0.02
Ni (mg kg^{-1})	138.73 ± 3.71	23.20 ± 0.65
Pb (mg kg^{-1})	671.11 ± 6.22	1.51 ± 0.59
Zn (mg kg^{-1})	667.62 ± 13.44	70.59 ± 1.07

The chemical properties of the soil were monitored post-harvest at all the SS amendment rates (*Table 2*). Organic matter and salinity significantly increased, however, salinity gradually increased; the significant increasing was detected only at a SS amendment rate 50 g kg^{-1}. The soil pH significantly decreased at all SS application rates, reaching 7.33 at the highest amendment rate. These results agree with those of our previous study on the leafy plant spinach (Eid et al., 2017) and other studies (Indoria et al., 2013; Kumar et al., 2016). The decreasing soil pH post-addition of SS could be a result of organic acid production resulting from SS decomposition and/or nitrification and mineralization of sulphur-rich compounds (Singh and Agrawal, 2008). All HMs content a significant gradually increased in the soil at all SS amendment rates except Mo (*Table 2*). A significant increase in Cd, Co, Cu and Zn concentrations was detected at an amendment rate of 30 g kg^{-1}. However, Pb and Ni significantly increased at amendment rates of 40 and 50 g kg^{-1}, respectively. Although, the chemical composition of the applied SS and soil were analysed (*Table 1*) before planting *E. sativa*, the concentrations of HM in the soil 40 days after growing *E. sativa* were different according to the SS amendment rate.

The plant *E. sativa* was selected because it is grown in most cases on small farms around and within urban areas and is directly consumed as a fresh green plant. Effects of SS amendments on the morphological parameters of *E. sativa* are shown in *Figure 2*. A significant gradual increase in shoot length, leaf number, whole plant leaf area, single leaf area and AGR was observed in the SS application until an amendment rate of 30 g kg^{-1},

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30273040

with the highest growth improvement at 20 g kg^{-1}, followed by a decreasing trend at a SS application rate of 40 and 50 g kg^{-1}. However, the root length decreased at all SS amendment rates compared to that of the control plants. A similar trend was observed in terms of the *E. sativa* biomass, and a significant increase in leaf, root and total biomass was detected at amendment rates of 10, 20 and 30 g kg^{-1}. The *E. sativa* leaf/root ratio significantly increased at SS amendment rates of 10 and 20 g kg^{-1}. The application rates of 40 and 50 g kg^{-1} caused significant negative effects on the biomass measurements of *E. sativa* compared to those of the control (*Figure 3*). These findings agree with those of Indoria et al. (2013), who reported enhancement of *E. sativa* growth parameters when grown in sludge-amended soil, as well as our previous studies on the effect of SS applications on spinach growth (Eid et al., 2017). Plant growth improvement was a result of increased organic matter, macro- and micro-nutrients contents and availability, soil porosity and bulk density (Antolín et al., 2005). The reduction of the growth at high amendments rates may refer the high HM concentrations in soil which inhibit absorption of beneficial macronutrients such as K and Ca (Burzynski, 1987).

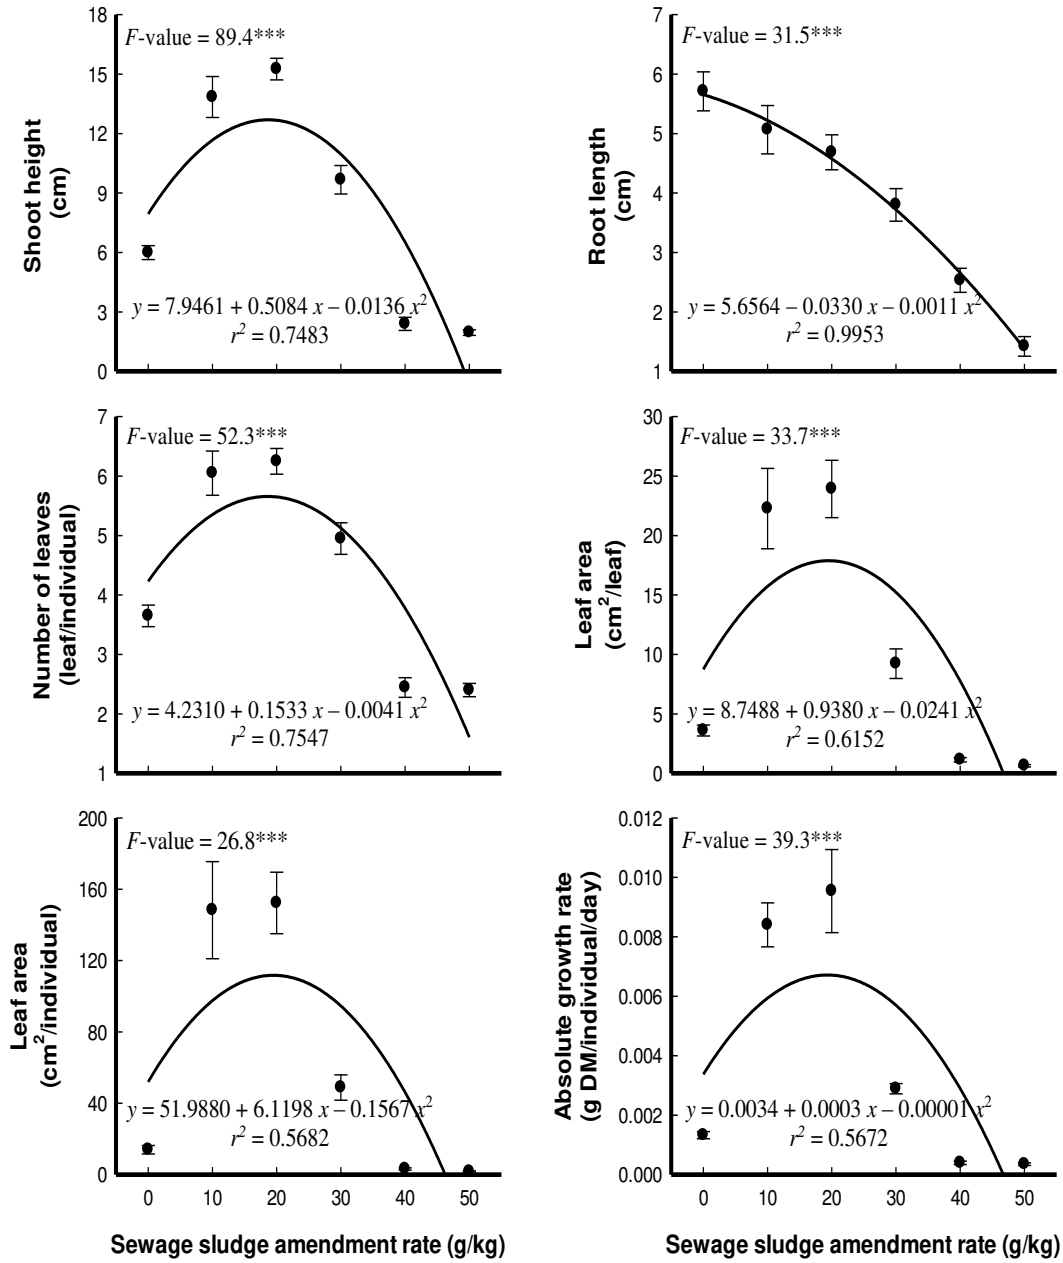

Figure 2. *Effects of different sewage sludge amendment rates on the morphometric parameters of Eruca sativa harvested after 40 days (means ± standard error, n = 30). The F-values represent one-way ANOVA and a degree of freedom (df) = 5. *** = P < 0.001*

The HMs uptake is a complicated method that is affected by numerous factors, comprising soil characteristics and type, environmental conditions, plant species, physiology and phenology, rhizosphere biochemistry and chelating effects of other HMs (Basta et al., 2005). In the current study, SS resulted in increasing shoot and root mass of the measured HMs at all the amendments rates (*Table 3*). The highest concentration of HMs was detected at a 50 g kg^{-1} as the shoot contents of Cd, Co, Cr, Cu, Fe, Mn, Mo, Ni, Pb and Zn increased to 304, 207, 210, 491, 380, 156, 246, 239, 363 and 323%, respectively, compared to the control plants. The high concentration of HMs in plants

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30273040

negatively affects several physiological processes (Kabata-Pendias, 2011). Substitution of Mg in chlorophyll by HMs results in the plants being incapable of photosynthesis (Kupper et al., 1996). HM toxicity in plants reduces the transpiration and photochemical light reactions (Singh and Agrawal, 2010).

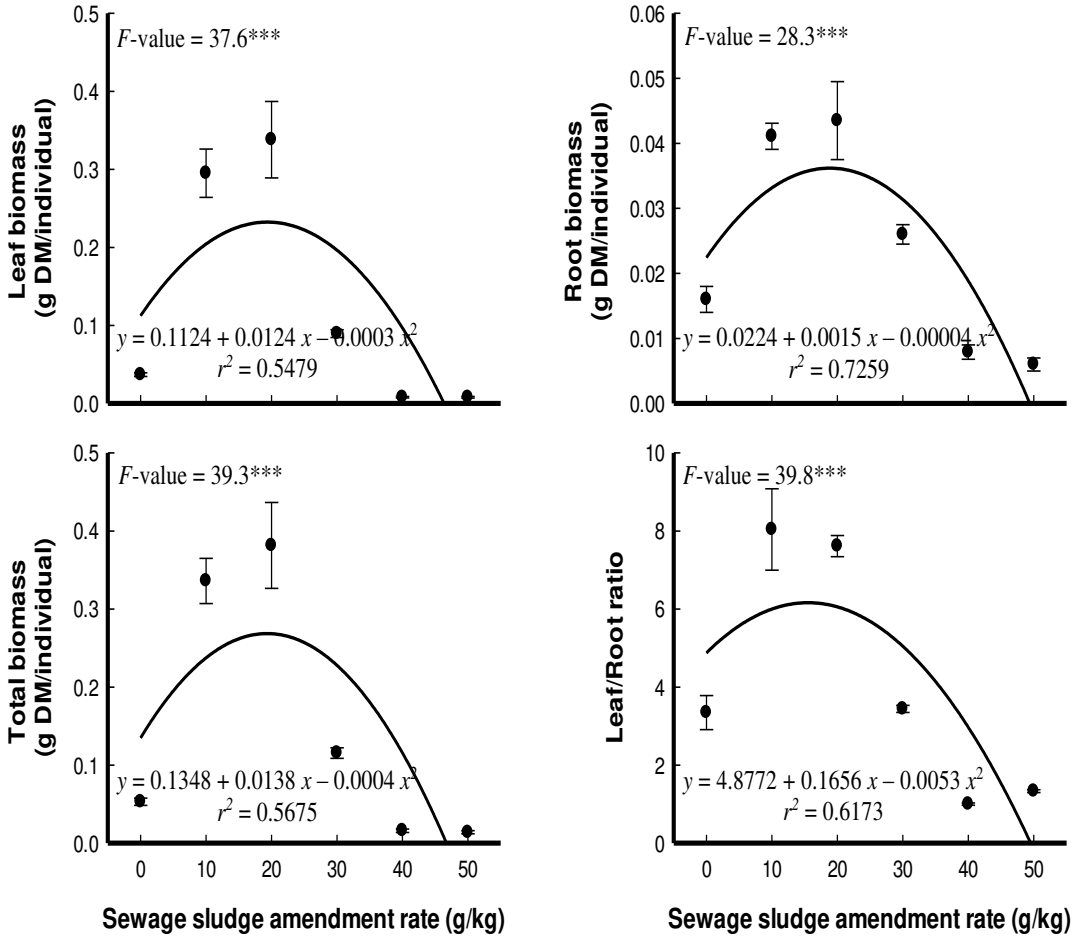

Figure 3. *Effects of different sewage sludge amendment rates on the biomass of Eruca sativa harvested after 40 days (means ± standard error, n = 30). F-values represent a one-way ANOVA and degrees of freedom (df) = 5. *** = P < 0.001*

The regression analysis showed that the increase in the HM contents was correlated with an increase in the SS amendment rates (*Table 4*). The highest R^2 values in the *E. sativa* roots and shoots were 0.942 and 0.936 for the HMs Cr and Zn, respectively. However, the lowest R^2 in the roots and shoots were 0.400 and 0.481 for Zn and Co, respectively (*Table 4*). This variation in R^2 could be related to the physiological role of each element in the plants. Decreasing soil pH increases HM bioavailability (Eid and Shaltout, 2016) as observed in the current study; thus, a follow-up study of the HM concentrations in edible parts of plants grown in sludge-amended soil is a necessity to avoid HM risks. Prediction models of HM concentrations in *Eruca sativa* grown in sewage sludge-amended soil have been developed by our research group and published recently (Eid et al., 2020).

SE: standard error, $n = 36$

HM accumulation in plants depends on the soil properties, SS origin and composition, amendment rate, plant species, plant physiology, climatic factors and metal chemical form (Mahdy et al., 2007). The bioaccumulation factors (BFs) and translocation factors (TFs) of all ten detected HMs in *E. sativa* were calculated (*Table 5*). The BFs of Cd, Co, Cr, Fe, Mn, Ni, Pb and Zn were < 1.0, whereas the BFs of Cu and Mo were > 1. The highest BF was detected for Cu at a SS amendment rate of 10 g kg^{-1}; however, there were no significant differences in the BFs of Cu and Mo between the control and all the SS amendment rates. The lowest BFs were found in the cases of Cd and Pb in roots of *E. sativa* grown in the control soil. The translocation factor (TF) varied among the HMs and soil treatments (*Table 5*). The TFs for all HMs were < 1.0 except for the HMs Cd and Pb. The accumulation of the majority of HMs was detected in roots rather than in the shoots (*Tables 3 and 5*). HMs, and particularly Cd, are inducible factors of phytochelatin which are low-molecular-weight proteins that form various complexes with Cd and as a result, prevent it from circulating as free Cd^{+2} inside the cytosol, subsequently aiding in the complexation and HM accumulation in roots (Clemens, 2006).

Conclusions

The results of the current investigation indicate that a SS amendment to agricultural soils up to rate of 30 g kg^{-1} could be beneficial as a fertilizer for *E. sativa*. SS amendment rates of 40 and 50 g kg^{-1} caused negative effects on the growth, biomasses of *E. sativa.* The translocation factors for all the detected HMs were < 1.0 except for Cd and Pb. However, SS sludge used in the current study increased the biomass productivity of *E. sativa*, it is not recommended to be used as biofertilizer as the *E. sativa* is a green-salad freshly consumed plant. Also, the repeated application of SS at the same site may pose more environmental and health risks of consuming *E. sativa* plants. Thus, regular assessment and monitoring of HMs in agricultural products originating from plants grown in sludge-amended soils is recommended to avoid HM accumulation in the food chain. The future research should consider studying alteration of the crop rotation in cultivated areas that apply SS to introduce crops with low accumulation ability of HMs. Also, investigations of suitable methods for SS treatments are needed before the application in the agricultural system to avoid the health and environmental hazards.

Abstract. Mekong River-Tonle Sap Lake is a typical river-lake interaction system in a monsoon area. The Tonle Sap Lake (TSL) is the largest freshwater lake in Southeast Asia, and is an important component in lower Mekong River (MR) Basin. Water resource managers are highly concerned about the potential impact of climate change on the MR-TSL hydrological system in the future. Thus, it is necessary to develop a numerical model which can simulate MR-TSL interaction system for the assessment of potential impact of natural climatic variations on hydrological cycle in this area. The main objective of this study was to model a river-lake interaction system for water resource assessment in TSL area. The distinctive feature of this study is to develop an integrated River Lake Water Exchange (RLWE) model and couple it to a grid-based distributed hydrological model (YHyM) for MR-TSL system. Using the coupled model, discharge contribution to TSL from tributaries, lake water volume, water exchange between the MR and TSL, and consumptive water use in TSL area were simulated. The potential impact of climate change on TSL hydrological system was also assessed through the application of the coupled model. Several future scenarios were analyzed, and predictions of water budgets within the interaction system under different scenarios were made.
Keywords: *water resource, hydrological model, GCM, water exchange system, potential impact*

Introduction

River-lake interaction systems are significant in large river basins (Sutherland et al., 2018). The Mekong River (MR)-Tonle Sap Lake (TSL) is a typical example of such interaction in a monsoon area. The TSL plays a significant role, not only in the ecology of the lower Mekong River system, but also in the socio-economic life of Cambodia. Most of Cambodian population lives in the lower catchment of the MR basin, with more than 1 million people dependent on fishing for their livelihood (Keskinen, 2006; Kummu and Nikula, 2006; Campbell, 2016; Trisurat, 2018). Normal and reverse discharge occur in the Tonle Sap River. This unique hydrological phenomenon is a complicated river-lake interaction system. Due to rapid development in the upstream zone of TSL, hydrological changes in the TSL catchment have increased in the past decades. Climate changes and increased human activities in Mekong River Basin put the MR-TSL interaction system under a lot of stress, concerning water resources (Sverdrup, 2002; TERRA, 2007; Kummu et al., 2008; Ogston et al., 2017). However,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30413055

not much is known about the interaction of hydrological processes, especially in the Tonle Sap Lake area, where insufficient historical gauge data is available (*Fig. 1*).

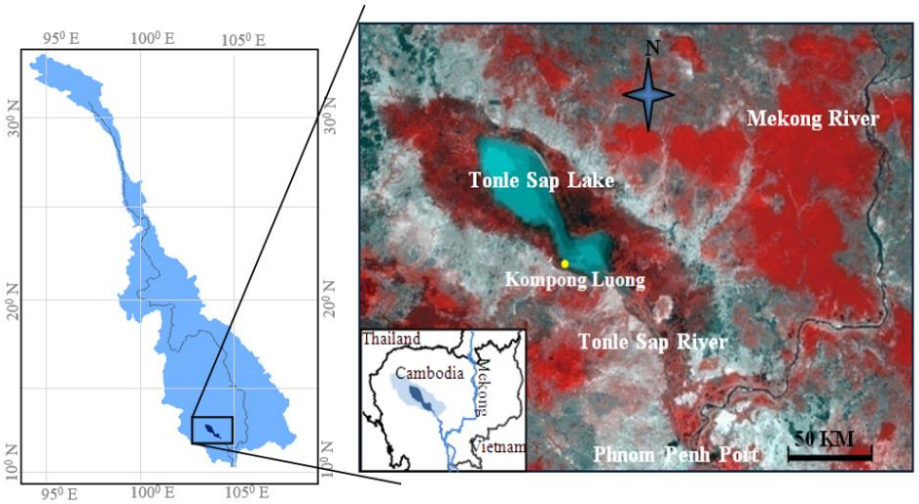

Figure 1. *Map of location of Tonle Sap Lake area*

It is important to investigate how future climate variations may affect the MR-TSL interaction system, and the consequences of these changes in the Mekong River Basin. This issue is highly important for the water resource managers. A comprehensive approach is needed to describe the complex interaction system and provide precise predictions under different future climate scenarios. The objective of this study is to understand the response of the hydrological system of TSL under future climate change, and to provide theoretical basis for water resource management.

Study area

The Mekong River Basin includes parts of China, Myanmar and Vietnam, and comprises nearly one third of Thailand and most of Cambodia and Lao PDR, with a total land area of 795000 km^2. Tonle Sap Lake is an integral part of the Mekong River, located in the northwest part of Cambodia. The lake area has abundant resource such as forests, fisheries, wetlands and agricultural land. It is an important region for socio-economic development of Cambodia. The TSL and its floodplains are located in the central part of Cambodia with the largest natural wetland habitats and the largest permanent freshwater body in Southeast Asia. This lake area is also a crucial source of food and livelihood in Cambodia. More than one million people who live in the area surrounding the Tonle Sap Lake and wetlands are highly dependent on agriculture and fishing (Sverdrup, 2002; Kummu et al., 2008; Chan et al., 2003).

The Tonle Sap Lake area has a tropical monsoon climate, with two distinct seasons i.e. rainy and dry seasons. The rainy season is from May to October. Normal and reverse discharge occur in the Tonle Sap River; this unique hydrological phenomenon constitutes a complicated river-lake interaction system. Mekong River-Tonle Sap Lake system includes Tonle Sap Lake, flood plain, Mekong River and Tonle Sap River. The Tonle Sap River connects the MR and TSL, with the confluence at Phnom Penh Port, as shown in *Figure 1*. Seasonal variations in Tonle Sap Lake floodplain are the determinants of the local ecosystem, fish production, livelihoods and inhabitants. In the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30413055

rainy season, the increased rainfall rapidly accentuates the water level and discharge in Mekong River. In the Tonle Sap River, water flows from Mekong River into Tonle Sap Lake. At early May or late April, the water level in Tonle Sap Lake is about 1 m, and the in-site lake area is only about 2.5×10^9 m^2. As the incoming discharge from Tonle Sap River and tributaries is increased, the water level and inundation area of TSL rise gradually. In October, the water level of TSL peaks at over 10 m, and the inundation area reaches up to about 1.5×10^{10} m^2. After October, the rainfall in the MR basin decreases, thereby reducing the water level and discharge in the Mekong River. Meanwhile, the water level of TSL also drops, but at a slower rate than that in MR because of the storage nature of the lake. The delay in reduction of water level in lake makes the TSL water level higher than that of MR. This water level difference changes the direction of discharge in Tonle Sap River from Tonle Sap Lake to Mekong River (hereafter, the flow from the lake to river is referred to as "reverse flow"). This discharge continues throughout the dry season up to late April or early May. Due to the normal and reverse discharges existing in the Tonle Sap River, huge water exchange occurs between the Mekong River and Tonle Sap Lake every year, and influence the seasonal variation and duration of flood inundation of the plain.

Materials and methods

Yamanashi-distributed hydrological model

The Yamanashi Distributed Hydrological Model (YHyM) is a grid-based distributed hydrological model developed by the University of Yamanashi, Japan (Takeuchi et al., 1999; Ishidaira et al., 2000; Ao et al., 2003a, b; Zhou et al., 2006a). It is a comprehensive system integrated with different modules such as meso-scale precipitation module, potential evaporation module, sediment transport module, run-off generation module, snow accumulation/melt module, water quality module, and water use/control (dam operations) module.

In this study, the core module BTOPMODEL was applied to generate hydrological boundary conditions for the TSL balanced system. The core module of YHyM, run-off generation module is based on extended TOPMODEL concepts (Ao et al., 1999, 2000, 2001, 2006; Takeuchi et al., 1999; Kiem et al., 2004a, b, 2005; Zhou et al., 2005, 2006a, b). The BTOPMODEL was used to divide the whole basin into a number of blocks/sub-basins; each block/sub-basin may consist of several hillslopes, with water shared between hillslopes in each block, and no water exchange between blocks. The topographic index γ was re-defined in *Equations 1* and *2,* for effectiveness in the grid-based applications, especially for large basin analysis:

$$q_{bi} = [a_i f(a_i) r_k]/a_{0i} \quad \text{(Eq.1)}$$

$$\gamma_i = ln \frac{a_i f(a_i)/a_{0i}}{tan\beta_i} \quad \text{(Eq.2)}$$

where $f(a_i)$ ($0 \leq f(a_i) \leq 1$) is the effective contributing area ratio, i.e. the contribution rate of upstream net catchment area to discharge; q_{bi} (m day^{-1}) is the base flow of unit i, r_k (m day^{-1}) is the spatially homogeneous recharge rate over the block k, a_{0i} (m^2) is the area of the grid cell I, and D_i (m day^{-1}) is the ground water discharge ability:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30413055

$$q_{bi} = D_i tan\beta_i exp\ (-\frac{SD_i}{m}) \quad \text{(Eq.3)}$$

where q_{bi} is the outlet discharge in *Equation 3,* the subscript *i* refers to the grid cell *i,* and a block-average value is used for *m*, the discharge decay factor.

The runoff routing used the Muskingum-Cunge method. The vertical column included vegetation zone, root zone, unsaturation zone and saturation zone. The runoff generation in each grid cell is shown in *Figure 2*.

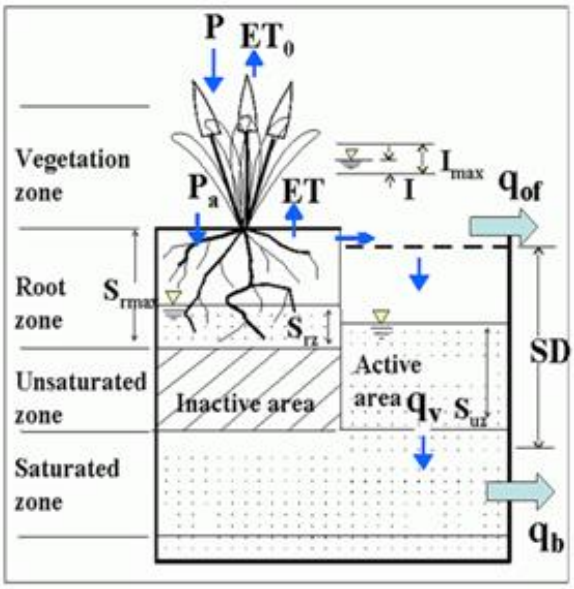

Figure 2. *BTOPMC runoff generation structure*

Three store layers are considered in this model: surface interception and depression store (S_1), near surface infiltration store (S_2) and saturated zone store (S_3). The variable contributing area be outlined and the rainfall on this area will immediately become overland flow. Once the interception store is filled, the infiltration to S_2 can happen. Evaporation is allowed from this store at the estimated potential rate until it is empty. A constant leakage rate i_0 be applied for the infiltration to the S_3. The rate into S_2 is at the rainfall rate *i* in *Equation 4*. However, if the rainfall rate is higher than the maximum infiltration rate i_{max}:

$$i > i_{max} = i_0 + {}^{b}/_{S_2} \quad \text{(Eq.4)}$$

The excess rainfall (i-i_{max}) becomes the infiltration excess overland flow. When the S_2 reach its maximum storage, the saturation excess overland flow will happen. Evaporation are allowed from the infiltration store at a decreasing rate depending on the level of the store S_2 in *Equation 5:*

$$e_a = e_r S_2 / S_c \quad \text{(Eq.5)}$$

where e_r is the potential evapotranspiration remaining once the interception store S_1 is depleted, and e_a is the actual loss from the infiltration store.

RLWE model

The river-lake interactive system in this research consisted of Tonle Sap Lake, its floodplain, Tonle Sap River, and Kampong Cham section to Phnom Penh Port section in main Mekong River. River Lake Water Exchange (RLWE) model was developed to simulate the hydrological process of the interaction system and to have an accurate understanding of the water balance system components.

The model was established based on water balance equation (Szesztay, 1974):

$$V_{in} - V_{out} = \Delta V \quad \text{(Eq.6)}$$

where V_{in} is the water volume going into Tonle Sap Lake, V_{out} is the water volume going out from Tonle Sap Lake, and ΔV is the change in lake storage.

The water balance module was developed to simulate the hydrological cycle of TSL. Due to the huge seasonal area variation, the boundary of the TSL balance system was fixed in this research by the National Highway (NH) 5 and 6 as shown in *Figure 3*. Lake surface area fluctuates inside the NH boundary. The evapotranspiration in the balance system includes potential evaporation from water surface and actual evapotranspiration from flood plain not being inundated inside NH boundary.

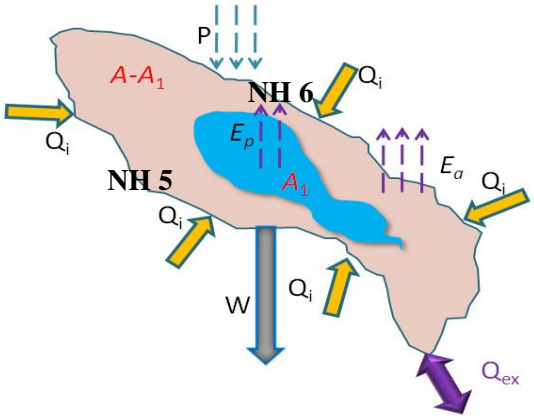

Figure 3. *Balanced system of RLWE model*

Thus, the water balance system for Tonle Sap Lake (*Fig. 4*) can be described in the following equation:

$$(P_j - E_{pj}) \times A_{1j} + (P_j - E_{aj}) \times (A - A_{1j}) + Q_{ij} \pm Q_{exj} - W_j = {}^{(V_{j+1} - V_j)}/_{\Delta t} \quad \text{(Eq.7)}$$

where j is the time step (day) of computation, P_j is the precipitation, E_{pj} is the potential evaporation, E_{aj} is the actual evaporation, A is the area of the National Highway (NH) 5 and 6 boundary which works as the boundary of TSL water balance system, A_{1j} is the area of lake water surface, $Q_{ij}$is the sum of the discharge from tributaries, Q_{exj} is the water exchange between the MR and TSL, W_j is the amount of water consumption, V_j is the lake water volume, and Δt is the time interval of computation.

River Lake Water Exchange model consists of five sub-modules (Wu, et al., 2010): water level-water volume relationship sub-module, water level and discharge convert sub-module, water consumption sub-module, lake-river water exchange sub-module,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30413055

and water balanced system. In this research, lake water storage income components included precipitation, water flow from tributaries, water flow from Tonle Sap River and part of the flood directly flowing into lake through floodplain. Outcome items consisted of potential evaporation from lake water surface, actually evaporation from floodplain, water flow from lake to Mekong River through Tonle Sap River, recharge to ground water, and domestic and irrigation water consumption.

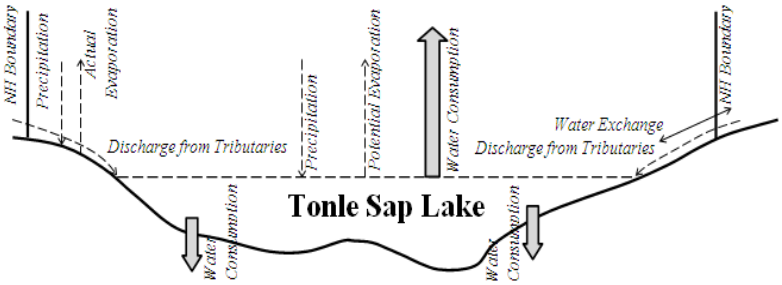

Figure 4. *Water budgets in Tonle Sap Lake water balance system*

Coupled model by YHyM and RLWE

Introduction

The hydrological system of TSL was simulated by coupling RLWE with YHyM. The structure of the coupling model system consisted of three layers (*Fig. 5*). The first layer (YHyM, a grid-based distributed hydrological model was applied to generate the boundary conditions including precipitation, evaporation, discharge from tributaries and discharge in certain cross sections in the main stream of the MR. These boundary conditions were regarded as the inputs for the second and third layers. The second layer was the RLWE model. Daily water consumption and water exchange between TSL and MR, and water level of TSL were calculated in this layer. The third layer was the water balance system of RLWE model. All the items in this system were derived from the first and the second layers. The daily water volume of TSL was calculated from the balance system, and used as the input in the next step.

DOI: http://dx.doi.org/10.15666/aeer/1802_30413055

Data set

Observed daily water level data of Kompong Luong station from 1980 to 2002 were used to analyze the flood frequency of Mekong River. Daily observed water level data sets of Prek Kdam, Kompong Cham and Chroui Changvar stations from 1996 to 2004 (*Fig. 6*) are used for the calculation.

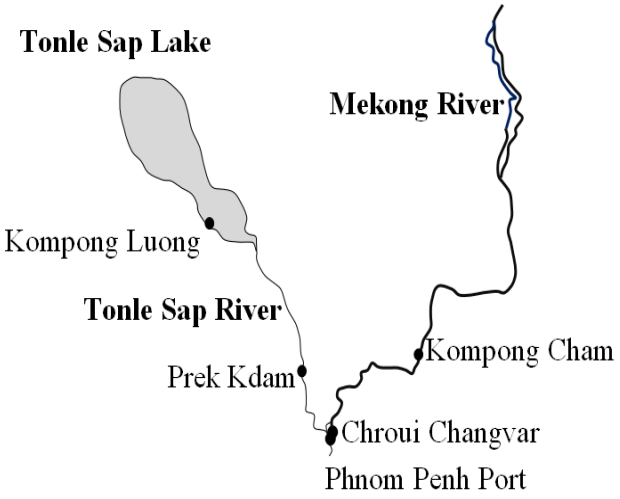

Figure 6. *Locations of the sections in river–lake interaction system*

In this study, BTOP Model was applied to generate the hydrological boundary conditions of TSL area. The implementation of the model in Mekong River basin needed topographic, land cover, soil type, NDVI and meteorological data sets.

The USGS-GTOPO30 was used in this paper to extract topographic information such as channel network, sub-basin division, basin boundary, flow accumulation and direction, and channel slope and length. Land cover data used the International Geosphere Biosphere Program (IGBP) Version 2 with 30 min resolution and 17 types of land cover. The data was converted into 8-km resolution by assigning the biggest potion of the type in each 8 × 8 cell. The soil map of the Food and Agriculture Organization (FAO) was used to describe the soil type. A total 23 soil textural classes in the MR basin and different percentage contents of three types of soil were considered: sand, silt and clay. With respect to NDVI data, average 10-day and monthly NDVI data from NOAA-AVHRR NDVI data set were used in this study. Spatial variation in precipitation was considered based on the Thiessen polygon method, and data from 65 gauging stations were used. Observed precipitation gauging data were obtained from the Mekong River Commission. Other meteorological input data sets including monthly mean temperature, diurnal temperature range, cloud cover and actual vapor pressure, mean monthly wind speed were provided by the Climate Research Unit (CRU), University of East Anglia in UK.

YHyM application in Tonle Sap

The river network system in Tonle Sap Lake catchment was generated from DEM data as shown in *Figure 7*. Ten points at which river network intersected the balance system boundary were acquired. Then, all the hydrological information in each block of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30413055

the intersections were output using YHyM, which included runoff, precipitation (P), potential evaporation (E_p) and actual evaporation (E_a). These output data were used as input for the simulation of water balance.

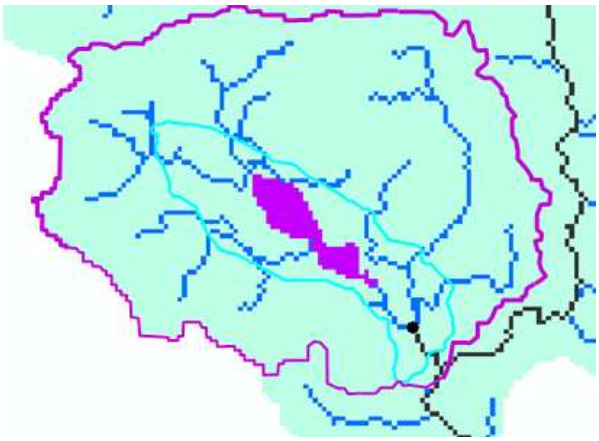

Figure 7. *River net in TSL catchment*

The sum of the runoff generated in these ten blocks was considered as the water flows into TSL contributed from tributaries, which varied from less than 100 m^3/s to more than 15,000 m^3/s in the period of 1987-2000, with an average discharge of 570 m^3/s. The average values of precipitation, potential evaporation and actual evaporation considered in the ten intersection grids provided by YHyM were used in the balance system of RLWE.

Daily observed water level data sets in Kompong Luong in 1980-2002 are used to analyze flood frequency in this region. Based on derived flood frequency curve of Kompong Luong, year 2000 and 1998 were selected as typical 1-20 wet year and typical 1-20 dry respectively.

Model calibration and validation

Based on the previous validation performance of YHyM and RLWE models, all the items in the balance system of RLWE were considered to be accurate, except the water consumption. Trial-and-error method was used to optimize parameter α by minimizing the difference between water volume of TSL calculated using the balanced equation and estimate, by converting observed water elevation Hkl (gauged stage at Kompong Luong) into water volume, based on the relationship between water level and lake water volume illustrated in the previous chapter.

The value of α obtained from optimization based on the data of 1987-1995 was 0.0051. For validation of the coupled model, the calibrated value of α was applied to estimate the daily water volume of TSL for the period of 1996-2000. The average daily absolute error in the period of 1996-2000 was 4×10^{10} m^3 (average V_{obs}: 21×10^{10} m^3), and comparison between observation and simulation is shown in *Figure 8*. The temporal variation of water volume was well reproduced by the simulation. According to the figure, the calculated V was underestimated, especially at the peak time. It probably results from the fact that the constant α cannot reflect the temporal variation of water consumption. Moreover, the assumption that water consumption was totally dominated by water volume at the specific day was another limitation.

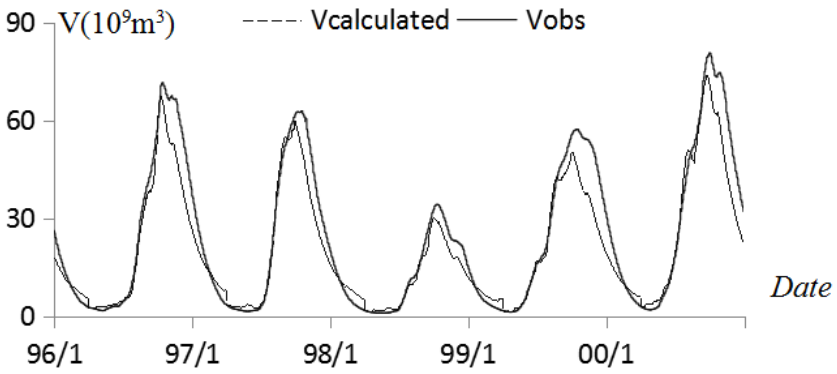

Figure 8. *Validation of daily water consumption*

GCMs

Methodology

Generally, future changes in climate are informed by the global climate models (GCM). In this study, 23 GCMs from IPCC were used for assessment of MR basin. Rainfall output of 23 GCMs and 65 gauge data from 1987 to 2000 were compared to check the performance of each GCM in upper, middle and lower MR basin. The details are shown in *Figure 9*.

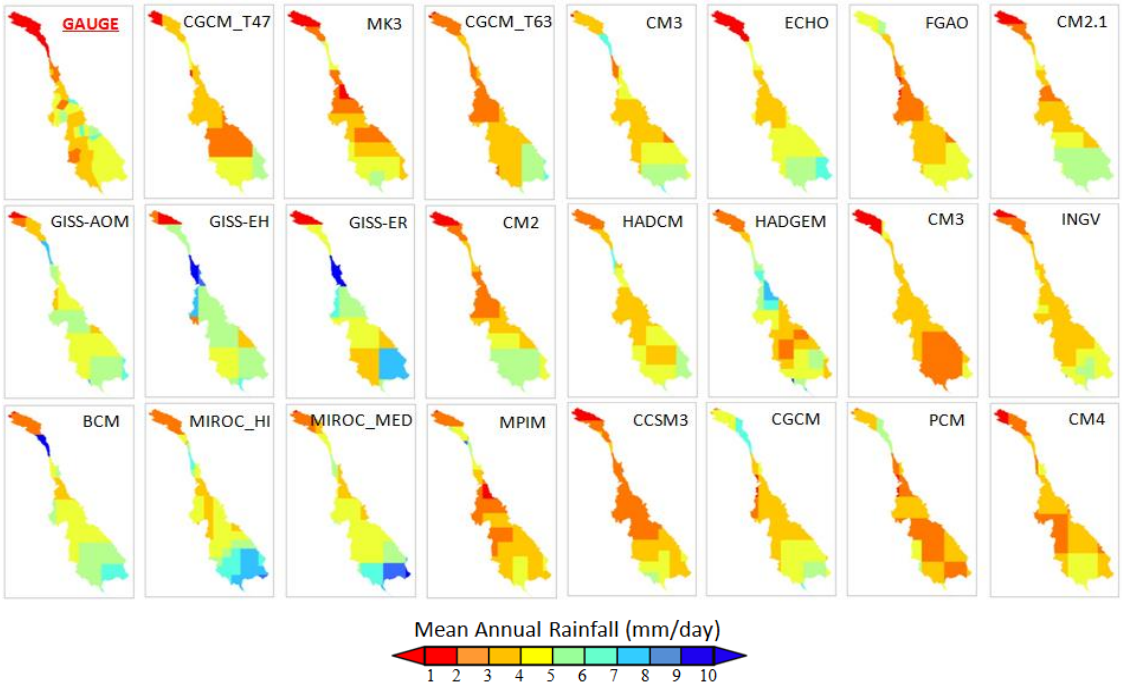

Figure 9. *Rainfall output of 23 GCMs and gauge data from 1987 to 2000*

Four indices were applied to describe the performance of each GCM:

1. Nash-Sutcliffe efficiency (NSE):

This is normalized statistic that determines the relative magnitude of the residual variance, compared to the observed data variance (Moriasi et al., 2006) in *Equation 8:*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30413055

$$NSE = 1 - \left[\frac{\sum_{i=1}^{n}(Y_i^{obs} - Y_i^{sim})^2}{\sum_{i=1}^{n}(Y_i^{obs} - Y_i^{mean})^2}\right] \quad \text{(Eq.8)}$$

2. Correlation coefficient:
This describes the degree of collinearity between simulated and observed data.
3. Coefficient of variation (CV):
This is a normalized measure of dispersion of a probability distribution.
4. Skill scores/M-statistic:
These represent the goodness of fit at simulating rainfall (Perkins et al., 2007).

$$S_{score} = \sum_{1}^{n} minimum\ (Z_M, Z_O) \quad \text{(Eq.9)}$$

where *n* is the number of bins in *Equation 9, Zm* is the frequency of values in a given bin from GCM, and *Zo* is the frequency of values in a given bin from the observed data.

First, outputs of the 23 GCMS from IPCC (AR4, 1987-2000) were used to calculate the area average rainfall for upper, middle and lower parts of MR basin. Then, values of the 4 indices were calculated for each model in each part of the MR basin, relative to the gauge data in the same time period. Then, ranking was made, based on the values of each index in every part: R_i^n, where *i* is the index, *n* is the part of the MR basin. All ranks of each model were summed up in *Equations 10:*

$$S_m = \sum_{\substack{i=1-4 \\ n=1-3}} R_i^n \quad \text{(Eq.10)}$$

where *Sm* is the score of each GCM. Based on the scores in upper, middle and lower part in MR basin, the top five models were applied to derive an ensemble data. The information for these five GCMs are list in *Table 1*.

Table 1. *Information of the top five GCMs*

Model	Center	Horizontal resolution
NIES: MIROC3_2-HI	NIES, *Japan*	1.12 × 1.12
CNRM: CM3	INM, *Russia*	5.0 × 4.0
CONS: ECHO-G	MIUB, *Germany* METRI, *Korea* M&D, *Germany*	3.8 × 3.8
CSIRO: MK3	CSIRO, *Australia*	1.9 × 1.9
UKMO: HADGEM1	UKMO, *UK*	1.9 × 1.25

The potential impact of climate change on MR-TSL interaction system was analyzed using the coupled model. For the scenario analysis, future projected precipitation data were prepared using GCM output. In general, due to the difficulties in quantitative assessment of precipitation with GCM, "bias correction" was applied when GCM output was used for basin scale hydrological analysis.

As has been pointed out by Shibuo and Kanae (2010), proper bias correction method should be selected depending on the purpose of analysis. In this study, constant monthly scaling was used for bias correction. The modeled monthly changes (change ratio for each month) were applied to historical daily precipitation time series for producing future projected precipitation. This is one of the most widely used methods for assessing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30413055

the impact of climate change on water resource, and is appropriate for long-term water balance analysis.

In this study, outputs from the 5 GCMs were obtained from IPCC AR4 for the 20th Century experiment (20c3m), and SRES SRA1B experiment was used for current and future precipitation. The A1 storyline and scenario family describe a future world of very rapid economic growth, global population that peaks in mid-century and the declines thereafter, and rapid introduction of new and more efficient technologies. For the A1B, balance was defined as not relying too heavily on one particular energy source, on the assumption that similar rates of improvement applied to all energy supplies and end-use technologies. In addition, modeled monthly changes were calculated using the data for 1981-2000 (for 20c3m) and 2046-2065, 2080-2099 (for SRA1B). The results of monthly ratios for upper, middle and lower parts in MR basin are shown in *Figure 10*.

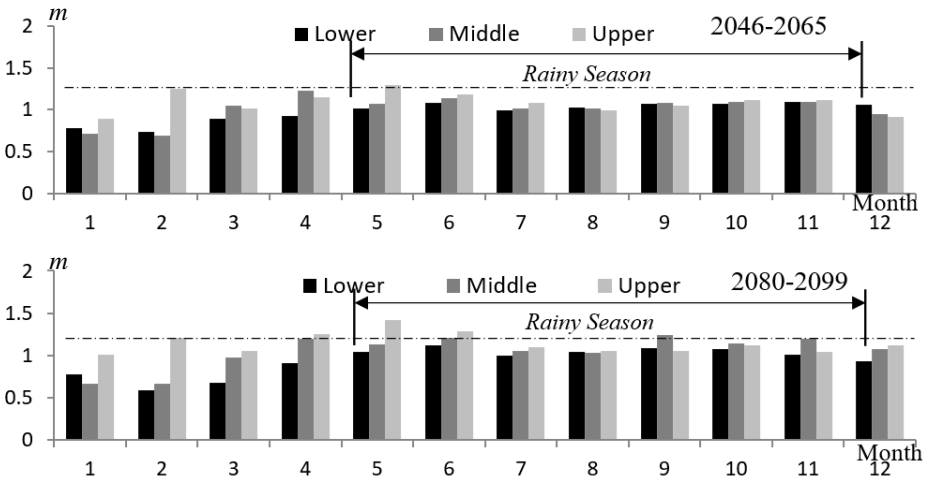

Figure 10. *Monthly ratios in MR basin*

Results and discussion

Typical wet year (20-year return period) and typical dry year (20-year return period) were chosen, based on the derived flood frequency curve of main MR. Through input, the future scenario precipitation in the YHyM and RLWE models, and daily water volume of TSL in a typical wet year and dry year were calculated. The results are shown in *Figure 11*.

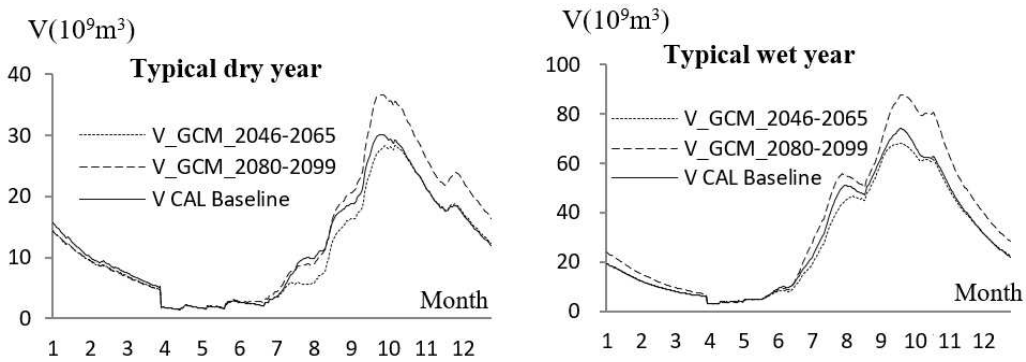

Figure 11. *Daily water volume of TSL in typical years under future scenario*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30413055

In the later part of the rainy season (August–November), the total amount of precipitation changed more clearly than in other seasons, and runoff of main stream, tributary inflow, and water exchange between TSL and MR were also changed accordingly. These result in remarkable changes in water volume of TSL during this season. Values of the components in the water balance system in different typical years for the current period and future scenarios are listed in *Table 2* Vtri (10^{10} m^3) is the total water volume from tributaries within one year, Vex_{in} (10^{10} m^3) is the water volume from MR flow into TSL within one year, Vex_{out} (10^{10} m^3) is the water volume from TSL flow into MR within one year, W (10^{10} m^3) is the total water consumption within one year, P-E (10^{10} m^3) is the total volume of precipitation minus evaporation within balanced system boundary in one year, and max V (10^{10} m^3) is the maximum lake water volume calculated by coupling RLWE with YHyM.

Table 2. *Water budgets in balanced system of TSL*

Year	Vtri	Vex_{in}	Vex_{out}	W	P-E	max V
Wet (current)	2.8	6.6	4.5	5.3	0.9	7.4
Wet (46-65)	2.8	5.8	3.8	5.0	0.8	6.8
Wet (80-99)	3.2	8.2	5.2	6.3	0.5	8.7
Dry (current)	1.1	2.5	1.9	2.2	0.5	3.0
Dry (46-65)	1.1	2.2	1.7	2.0	0.4	2.8
Dry (80-99)	1.3	3.1	2.0	2.5	0.5	3.6

Based on comparisons, the maximum water volume of TSL will decrease in future in the period 2046-2065, and increase in the period 2080-2099. Water flow from the MR made the largest contribution to changes in maximum water volume of the TSL.

The predicted changes in the water income components (2046-2065) in TSL balanced system were as follows: max V will decrease by 0.6×10^{10} m^3 and 0.2×10^{10} m^3 in typical wet and dry years, respectively; P-E will decrease by 0.1×10^{10} m^3 in typical wet and dry year; Vtri will not change too much; Vexin decrease by 0.8×10^{10} m^3 and 0.3×10^{10} m^3 in wet and dry years, respectively. The predicted changes in water income components (2080-2099) in TSL balanced system were as follows: max V will increase by 1.3×10^{10} m^3 and 0.6×10^{10} m^3 in typical wet and dry years, respectively, P-E will decrease by 0.4×10^{10} m^3 in typical wet year, but there will be no obvious change in typical dry year; Vtriwill increase by 0.4×10^{10} m^3 and 0.2×10^{10} m^3 in typical wet and dry year, respectively, while Vex_{in} will increase by 1.6×10^{10} m^3 and 0.6×10^{10} m^3 in wet and dry years, respectively.

Conclusion

This study has successfully modeled the MR-TSL interaction system for water resource assessment and river basin management. The major contribution of this study is the development of an integrated River Lake Water Exchange (RLWE) model coupled with YHyM (a grid-based distributed hydrological model) in Tonle Sap Lake area. Using the coupled model, discharge contributions to TSL from tributaries, daily lake water volume, water exchange between the MR and TSL, and daily consumptive water use in TSL area were analyzed and discussed. In addition, the potential impact of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30413055

climate change on TSL hydrological system were determined through the application of the coupled model.

The potential impact of climate change on MR-TSL interaction system was analyzed using the coupled model. The modeled monthly changes were applied to historical daily precipitation time series for producing future projected precipitation, and constant monthly scaling was used for bias correction. GCM output was obtained from IPCC AR4. The current and future scenarios in this study represent the periods 1981-2000 and 2046-2065, 2080-2099, respectively. Under future scenario, peak water volume will decrease in 2046-2065 and increase in 2080-2099 in typical dry and wet years. Water flow from the MR river the largest contribution to the reduction of maximum water volume of TSL.

The results from different future scenarios showed the potential impact on MR-TSL interaction system. The maximum water volume of TSL will decrease, while minimum water volume will increase under future climate change situations (2046-2065). Moreover, the maximum water volume of TSL will increase under future climate change situations (2080-2099). The range of variation in lake area will decrease as a result of these changes. These scenarios indicate that dams on lake tributaries will not have much effect on TSL, which implies that exchange water is the dominant item within the interaction system.

This study analyzed the hydrological response to future climate change, but does not consider water quality issue. Due to the economic development, water quality management will become a key point of water resource management in the near future. The water quality response study under global climate change can be a future research.

Acknowledgments. This work was financially supported by the Innovation capacity building project of Jiangsu provincial Department of science and technology (BM2018028), MEXT and G-COE Program of University of Yamanashi, Japan. Hydrological data for Tonle Sap Lake was provided by International Centre for Water Hazard and Risk Management (ICHARM) under the project of Research Revolution 2002 (RR2002). We also acknowledge the modeling groups, the Program for Climate Model Diagnosis and Inter-comparison (PCMDI) and the WCRP's Working Group on Coupled Modeling (WGCM) for their roles in making available the WCRP CMIP3 multi-model dataset.

Abstract. Based on the theory of Cobb-Douglas production function, this paper introduces the Socio-Environmental Indicator, industrial blue water footprint and industrial grey water footprint to improve the traditional input-output indicator system, used the Epsilon-Based Measure (EBM) models, to measure green efficiency of industrial water resource (GEIWR) based on provincial panel data from 2004 to 2016 in China, and then applied Tobit model to explore the mechanism. First, the results show that distinct differences in the efficiency from different provinces in China. The efficiency from the eastern regions is higher than that in other regions. Then, some western provinces have a high efficiency with a shortage of water but effective waste water regulation, which indicates that the effective efficiency only symbolizes the region's optimal input-output allocation. In particular, the industrial water-saving potential showed a declining trend but there is still much room for improvement of provinces in central China, such as Hubei, Sichuan and Hunan. Lastly, the environmental regulation, technological progress, regional characteristics, industrial structure, foreign capital utilization and water resource consumption have certain impacts on the efficiency. This paper could be helpful in providing a reference for the evaluation of green efficiency of industrial water resource.
Keywords: *green efficiency of industrial water resource (GEIWR), undesirable output, industrial water footprint, industrial water-saving potential, epsilon-based measure (EBM), Tobit regression model*

Introduction

Water resource is one of the indispensable strategic resource for human survival and economic development. World Commission on Environment and Development (WECD) points out, "Water resource is an important factor that restricts socio-economic development". China is a country lacking in water resource. In addition, the uneven spatial distribution of water resource and water pollution from the extensive economic development have made the water resource to become the bottleneck of the sustainable development of our society and economy. In China's industrial structure, industry plays a leading role in the development of national economy, and industrial water consumption accounts for a large proportion in the total water consumption. Accompanied with the fast development of industrialization in China, the imbalance between water supply and demand and water environmental pollution have constantly challenged the growth quality of China's industrial economy. According to the 2016 Annual Statistic Report on Environment in China, industry is the main industry that consumes water resource and causes the continuous deterioration of water environment. China's industry urgently needs green transformation and takes the road of sustainable development. In particular, the spatial distribution of water resource is extremely uneven in China. Therefore, how to alleviate the contradiction between socio-economic development and resource to improve the efficiency of industrial water resource has become a hot topic among scholars. Water resource is an economic resource that can only generate economic benefits with the help

DOI: http://dx.doi.org/10.15666/aeer/1802_30573072

of other production factors. Therefore, many scholars establish input-output indicator system to measure water resource efficiency. In 2006, Hu et al. (2006) established Data Envelopment Analysis (DEA) model to measure water resource efficiency. Based on this model, many scholars have improved the DEA model and the measurement indicator system. Chen et al. (2018) introduced water resource input into production function from the perspective of input. On this basis, taking the social benefits brought by water resource utilization into the measurement system, Sun et al. (2017) further proposed the concept of green efficiency of water resource, which can fully reflect the coordinated development of society, economy and environment. At the same time, scholars such as You Shaqiu and Ma Hailiang introduced undesirable output indicator into the measurement of green efficiency of water resource, considering the impact of environmental pollution output on water resource efficiency (You, 2017; Ma et al., 2012; Zhang and Liu, 2018). In the selection of DEA model, most scholars choose the traditional radial DEA model, such as Liu et al. (2007), Qian and He (2011) and Chemark et al. (2009). Some scholars choose non-radial SBM (Slack-Based Measure) model (Li and Ma, 2014; Sun et al., 2018; Ding et al., 2018), but both of them have their limitations. In order to comprehensively and objectively apply DEA model, we consider the EBM (Epsilon-Based Measure) model, with both radial and non-radial advantages, which was proposed by Tone and Tsutsui (2010). Once proposed, this model has been widely recognized and applied by scholars, but few studies have applied it to the measurement of green efficiency of industrial water resource (GEIWR).

In summary, scholars have conducted research into the efficiency of industrial water resource, laying the foundation for follow-up development in this field. On the whole, there are still some shortcomings in the current research. (1) The indicators of the efficiency measuring factors must be improved. Currently, there have been many researches on the evaluation and analysis of water resource efficiency from the perspective of economic output, but studies on the environmental and social benefits caused by water resource utilization in the process of economic development are insufficient. Scholars have mainly considered factors such as GDP, labor, capital and water input when studying the efficiency of industrial water resource without considering other factors that reflect socio-economic development (Chen et al., 2018; Li and Ma, 2014; Mai et al., 2014; Zhang et al., 2018; Wang, 2015). The lack of socio-economic development factors fails to reflect the fundamental requirements of the green development concept, will result in an efficiency overestimating or underestimating and deviations from the actual situation. This is not conducive to accurate measure of actual efficiency of industrial water resource and coordinated development of all the country's regions. (2) Most studies only calculated the efficiency and did not further evaluate the water potential regionally. At the same time, some researchers used statistical methods to evaluate the water potential but did not further explore the reasons for the efficiency results. (3) Taking all regions of China as the overall sample will neglect the influence of regional differences caused by various factors of water resource, geographic position and capital input, and lead to errors in the measurement of GEIWR.

Based on thee above understanding, this paper aims to further expand from the following two aspects: (1) Based on the provincial panel data from 2004 to 2016, this paper takes the GEIWR as the research core, chooses China's 30 provinces, cities and autonomous regions as the research object (excluding Tibet, Hong Kong, Macao and Taiwan), uses the EBM model as the main method, introduces SEI (Socio-Environmental Indicator), industrial blue water footprint and industrial gray water footprint to improve

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30573072

indicator system, analyzes the change and trend of the GEIWR in each provincial administrative region of China from the perspective of time and space. (2) In order to provide theoretical guidance for promoting the green transformation of China's industry and realizing the construction of water-saving society in the "13th Five-year plan", this paper estimates the water-saving potential of Chinese provinces, establishes Tobit panel model to explore possible ways to improve the GEIWR. Compared with existing research, the main innovative points of this paper are as follows: (1) It uses EBM to evaluate the GEIWR in China. DEA is a commonly used and effective method for multi-objective decision-making analysis. This paper innovatively applies the EBM method to the study of the GEIWR. At the same time, to eliminate the influence of subjectivity, this paper uses Principal Component Analysis (PCA) to determine the indicator weight of SEI. This method allows it to more objectively reflect the information, rendering the evaluation results more practical. (2) It enriches the indicator system of the efficiency of industrial water resource. In light of the shortcomings of most past studies that do not consider the social benefits of water utilization, this paper adds SEI as desirable output indicators, which can reflect socio-economic development and actual sewage-control situation. Besides, this paper also replaces industrial water utilization by industrial blue water footprint, adds industrial grey water footprint as undesirable output indicators to improve the indicator system. The concept and the indicator system of the GEIWR put forward in this paper better reflect current social development and the water control situation in all provinces, resulting in research results with more practical significance. (3) In the context of this research, we measure industrial water-saving potential by using the measured efficiency. At the same time, this paper also uses panel Tobit model to analyze influencing factors, exploring the underlying causes of the changes in the efficiency.

The structure of this paper as follows: the first section is 'Introduction', the second one, 'Methodology' describes the theoretical mechanism and the research methods, the next sections 'Empirical analysis' and 'Analysis on the influencing factors of GEIWR' demonstrate the results, and the last section provides the conclusion. The second part is the index system and model, the third part is the calculation of efficiency and water-saving potential, the fourth part is the analysis on the influencing mechanism, the fifth part is the conclusions, suggestions and discussions.

Methodology

The indicator system

The DEA approach does not require functional form assumptions between inputs and outputs and can avoid man-made subjectivity in parameter weighting Based on the Cobb-Douglas production function, from the perspective of input and output, this paper established an indicator system for the GEIWR. The indicator system is shown in *Table 1,* and the specific indicators are as follows:

(1) Labor input. The annual average number of employees was used to measure the actual labor input.

(2) Capital input. Referring to the method proposed by Shan Haojie to calculate the capital stock (Shan, 2018), the capital stock of each province is estimated as a measure of the capital input.[1] The perpetual inventory method is used to estimate the capital stock.

[1]Due to the lack of original data of Chongqing and Sichuan, we estimate the respective capital stock based on the population ratio of the two provinces.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30573072

(3) Water resource input. Existing researches showed that the industrial blue water footprint can better reflect the water resource consumption in the process of industrial production, so we used the industrial blue water footprint to measure the input of water resource (Huang et al., 2013).

(4) Desirable output. We took the industrial added value and SEI as the desirable output.

To comprehensively, objectively and scientifically reflect the socio-economic development and the present situation of the pollution control in China, we selected 7 indicators from three aspects of industrial structure, social regulation and technology development.

1) Industrial structure

$$\text{Industrial Structure Proportion}(X1) = \frac{\text{Industrial Added Value}}{\text{Gross Regional Product}};$$

$$\text{Foreign Trade Dependence}(X2) = \frac{\text{Total Value of Imports and Exports}}{\text{Gross Regional Product}}.$$

2) Social regulation

$$\text{Water Resource Restriction}(X3) = \ln(\text{Per Capita Water Resource});$$

$$\text{Population Density}(X4) = \frac{\text{Population}}{\text{Area}};$$

$$\text{Government Waste Water Control}(X5) = \frac{\text{Investment in the Treatment of Industrial Waste Water}}{\text{Industrial Added Value}}.$$

3) Technology development

$$\text{Technical Progress}(X6) = \frac{\text{R\&D Expenditure}}{\text{Industrial Added Value}};$$

$$\text{Technical Market Development}(X7) = \frac{\text{Transaction Value in Technical Market}}{\text{Gross Regional Product}}.$$

Then, to solve the subjective question of the weight assignment, PCA was conducted to obtain the SEI. The weights determined by PCA depends on the characteristics of the data itself, which have strong objectivity and can simplify the statistical data on the premise of preserving the information contained in the original data as much as possible. The results showed that the standardized data passed the KMO-Bartlett test and was suitable for the process of dimension reduction. Through the obtained common factor score and the total variance of each common factor, we can get the factor composite score FAC, and finally the SEI is calculated by using *Equation 1*.

$$\text{SEI}_t = 0.1 + 0.9 * \frac{FAC_t - Min(FAC_t)}{(Max(FAC_t) - Min(FAC_t)} \quad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30573072

FAC_t is the factor composite score of the t th province; $Max(FAC_t)$ and $Min(FAC_t)$ are the maximum and minimum value of the corresponding factor composite score respectively.

(5) Undesirable output. The industrial grey water footprint can reflect the pollution degree of the water environment. It refers to the volume of fresh water needed to dilute certain industrial waste water pollutants based on the existing environmental water quality standards. As industrial waste water is directly discharged into water, the discharge amount of main pollutants, Industrial COD (Chemical Oxygen Demand) Emission and Industrial Ammonia Nitrogen, can usually be directly measured as the industrial grey water footprint (Zhang et al., 2017; Hoekstra et al., 2011). In order to consider the constraint effect of industrial water pollution, we take the industrial grey water footprint as the undesirable output part of the output indicator.

Table 1. *Indicator system*

Project	Inputs/outputs	Indicator selection		Measurement and explanations
Input	Labor input	Annual average number of employees		∑[Average number in (January, February, ..., December)] / 12. This input is used to measure the actual labor input
	Capital input	Capital stock		The actual capital stock at the end of year t = the nominal investment in year t / the fixed capital investment price index + (1-the replacement rate) × the actual capital stock at the end of the previous year
	Water resource input	Industrial blue water footprint		Industrial water consumption - industrial sewage discharge. This input can better reflect the water resource consumption in the process of industrial production
Output	Desirable output	Economic output: Industrial added value		This output is the most ideal variable to reflect industrial economic output, and its specific value can be obtained directly in the statistical yearbook of China
		Social output: SEI	Industrial structure proportion	The two rates describe the degree of government emphasis on industry and foreign trade
			Foreign trade dependence	
			Water resource restriction	The three rates describe the level of social regulation from the prospect of water resource, population and sewage treatment
			Population density	
			Government waste water control	
			Technical progress	The two rates indicate the technical level in China
			Technical market development	
	Undesirable output	Environmental output: Industrial grey water footprint		This output reflects the pollution degree of the water environment

Data source

The data are mainly from the "China Environmental Yearbook", "China Statistical Yearbook", "China Water resource Bulletin", "China Industrial Economic Statistical Yearbook" and statistical yearbook of each province from 2004 to 2016. The study object is China's 30 provinces, because the data are from the yearbook statistics, are single-handed information, the reliability and validity of the data have been tested. Moreover, it needs to be noted that the sample includes panel data from 30 provinces in China, in which data in Tibet are missing and removed. In addition, the research range of this paper was selected from 2004 to 2016, mainly for the following reasons: 1) The availability of data. Some of the key variables used in the study do not have complete annual data until 2004, and the data for 2017 has not yet been released completely. 2) It is related to the research topic. Many scholars' similar researches are mainly published during this time. In conclusion, considering the availability of variables' data and the research theme, this paper selects data from 30 provinces in China from 2004 to 2016.

Methods

EBM models

The traditional DEA model can broadly fit into two types. The first classical DEA model is the CCR model, which is established on the basis of constant returns to scale. On the basis of CCR model, BCC model considering variable return on scale assumption can be proposed. But the two basic DEA models, CCR model and BCC model cannot cover slack variables. Other model extensions include slacks-based measure, SBM model. SBM allows all inputs, intermediate variables and outputs to vary in proportion. However, their work cannot guarantee the stage efficiency and efficiency decomposition of the process. In order to solve this problem, EBM, combining radial and non-radial measurement characteristics, was introduced in this paper to measure the GEIWR from 2004 to 2016 in China in order to get closer to the actual efficiency.

For n decision-making units with s input factors (x) and t output factors (y), EBM model can be expressed as follows.

$$
\begin{gathered}
\mathrm{X}=\sum_{j=1}^{n} x_{ij} \\
\mathrm{Y}=\sum_{j=1}^{n} \lambda_j y_{rj} \\
\sum_{i=1}^{m} w_i^- = 1 \\
\gamma^* = \min_{\theta,\lambda,t^-} \theta - \varepsilon_x \sum_{i=1}^{s} \frac{w_i^- t_i^-}{x_{i0}} \\
\text{s.t.}\, \theta x_{i0} - \sum_{j=1}^{n} \lambda_j x_{ij} = 0\,, i = 1, \cdots, s \\
\sum_{j=1}^{n} \lambda_j y_{rj} \geq y_{r0}\,, r = 1, \cdots, t \\
\lambda_i \geq 0 \\
t_i^- \geq 0
\end{gathered}
\qquad \text{(Eq.2)}
$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30573072

In the formula, γ^* represents the optimal efficiency value of EBM model considering undesirable output; X is the input value, Y is the output value, X, Y > 0; θ represents the radial efficiency value; t_i^- represents the slack vector of non-radial input elements; λ represents the relative weight value; w_i^- represents the weight value of the i th input variable; ε_x represents key parameters of radial θ and non-radial relaxation t_i^- contained in EBM model (Tone and Tsutsui, 2010).

Tobit model

After calculating the green efficiency of industrial water resources in all provinces and cities of China, this paper will further take the efficiency of industrial green water resources in all provinces and cities as the explanatory variable, and construct econometric model to investigate the influence mechanism of industrial green water resource efficiency in China. Since the range of industrial green water resource efficiency is 0-1, it is a limited dependent variable. If the ordinary least square method is still used, the parameter estimation will be biased and inconsistent. Therefore, Tobit regression model is used in this paper, which is an econometric model for dependent variables of partial continuous distribution and partial discrete distribution. Its specific form is as *Equation 3*.

$$Y_i = \begin{cases} X_i\beta + \mu_i & (\text{When } X_i\beta + \mu_i > 0) \\ 0 & (\text{Others}) \end{cases} \quad \text{(Eq.3)}$$

In *Equation 3,* Y_i is the limited dependent variable, X_i is the independent variable vector, β is the parameter vector to be estimated, and the random interference term $\mu_i \sim N(0, \sigma^2), i = 1,2, \ldots$ is the number of observation values. It can be proved that when the Tobit model is estimated by the maximum likelihood method, it can be concluded that $\hat{\beta}$ and $\hat{\sigma}^2$ are consistent estimators.

Empirical analysis

Measurement of GEIWR

Based on the panel data of 30 provinces in China from 2004 to 2016, the green efficiency of China's industrial water resource is calculated by using EBM model in MaxDEA6.0Pro.

The effective GEIWR indicates that its input-output allocation is optimal. As can be seen from *Table 2,* the GEIWR in different provinces showed different development trends from 2004 to 2016. Beijing, Guangdong, Tianjin, Shanghai, Shandong are characterized by having effective DEA value, which indicates that these regions have strong industrial economic strength, optimal allocation of various inputs and outputs in the development process, high level of scientific and technological development and strong ability of comprehensive social development. The GEIWR of these regions is at the optimal level nationwide. The result is consistent with the current situation of China's industrial water resource and social and economic development. In addition, Zhejiang, Chongqing and Fujian have obvious late-mover advantage advantages, and the efficiency value increases gradually from the low initial stage. For example, Zhejiang's efficiency value was only 0.5419 in 2004, but it increased to 0.9240 in 2016.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30573072

On the contrary, Shanxi and Heilongjiang's efficiency values gradually get below 1.0000, which indicates that in the development process of these regions, the allocation of input and output may be unbalanced. In the western region of Inner Mongolia, Qinghai have high GEIWR. By consulting the input-output data of 2004-2016 and related literature, we found despite each of these areas is lack of water resource and has a low economic development level, but the per capita water resource possession ratio is high, the sewage control has been effective. The result proves that the GEIWR in a region is not necessarily related to the region's economic level.

*Efficiency value of 1.0000 means DEA value is effective

From the average efficiency of all provinces in China, we cannot get obvious data characteristics. Therefore, combined with the common regional classification in China, this paper divides 30 provinces into four regions: the east, the central, the west and the northeast, and analyzes the development trend of their average efficiency. The result clarifies that the change of the GEIWR in different regions of China shows certain regularity. The curves of average efficiency in East, middle, West and Northeast China are shown in *Figure 1*. It can be seen from *Figure 1* that the green efficiency of China's

industrial water resource generally presents the law of fluctuation. From 2004 to 2016, except for the eastern region, the changes in the western, central and northeast regions are similar, with the overall efficiency value dropping first till 2006, and then rising, then falling to the lowest level in 2009, and finally rebounding slowly. Combined with China's national conditions in recent years, we find that all these changes show that the three regions especially the central region are greatly affected by different resource and governance policies in different periods. Moreover, the eastern region is always at the leading level of GEIWR in China. Whereas, the GEIWR in the central region is always at the backward level in China, which needs to be improved. This region should be the key area for optimal allocation of water resource.

Figure 1. *The GEIWR values of four regions in China over time*

Assessment of industrial water-saving potential

To sum up, we have analyzed and evaluated China's GEIWR through EBM model. In accordance with the above empirical results, till 2016, the GEIWR in most provinces in China is still less than 1, it proves that the utilization of industrial water resource has not reached the optimal level, and GEIWR can be further improved. We can tap the industrial water-saving potential.[2]

[2]The connotation of water-saving potential is defined in The Outline of National Water Resource Planning, which refers to the difference between the current water consumption and the water consumption at the optimal level. The industrial water-saving potential studied in this paper is the amount of water-saving stock, which refers to the amount of water-saving that can be achieved by water users under the current situation through water-saving measures to achieve effective utilization of Industrial water resource.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30573072

Combined with the meaning of water resource efficiency, the industrial blue water footprint at the optimal industrial water level can be expressed as *Equation 4*.

$$\widehat{BW_{it}} = BW_{it} \times E_{it} \quad \text{(Eq.4)}$$

In the formula, $\widehat{BW_{it}}$ represents the industrial blue water footprint in the optimal input-output configuration; BW_{it} represents the current industrial blue water footprint; E_{it} represents the GEIWR; i represents the provincial region and t represents the year.

Then, the industrial water-saving potential ΔBW_{it} can be measured as *Equation 5* (Li, 2017).

$$\Delta BW_{it} = BW_{it} - \widehat{BW_{it}} = (1 - E_{it}) \times BW_{it} \quad \text{(Eq.5)}$$

We substituted the GEIWR (E_{it}) calculated by EBM into *Equations 4* and *5,* and the estimated results of China's industrial water-saving potential from 2004 to 2016 are shown in *Table 3*.

As can be seen from *Table 3* and *Figure 2,* China's industrial water-saving potential showed an overall downward trend from 2004 to 2016, which indicates that with the accumulation of pollution treatment experience and the improvement of industrial water-saving technology over the years, China's industrial water resource green efficiency has been continuously improved. But industrial water-saving potential rebound in 2016, it showed that the gap of GEIWR among provinces has a declining trend. Provinces at the forefront of the GEIWR saw a smaller decline and maintained their leading level. However, provinces with low efficiency are restricted by many factors, such as water resource and management, and the decline rate is large, which caused the gap between them and frontier cities further widened. These provinces have a large space to improve industrial water saving in the future. Most of the provinces in central China, such as Hubei, Sichuan and Hunan, have a large space to tap the industrial water-saving potential. The governments of these regions should strengthen their drainage monitoring capacity, increase the intensity of industrial waste water treatment, and actively promote renewable water conservancy to improve the GEIWR.

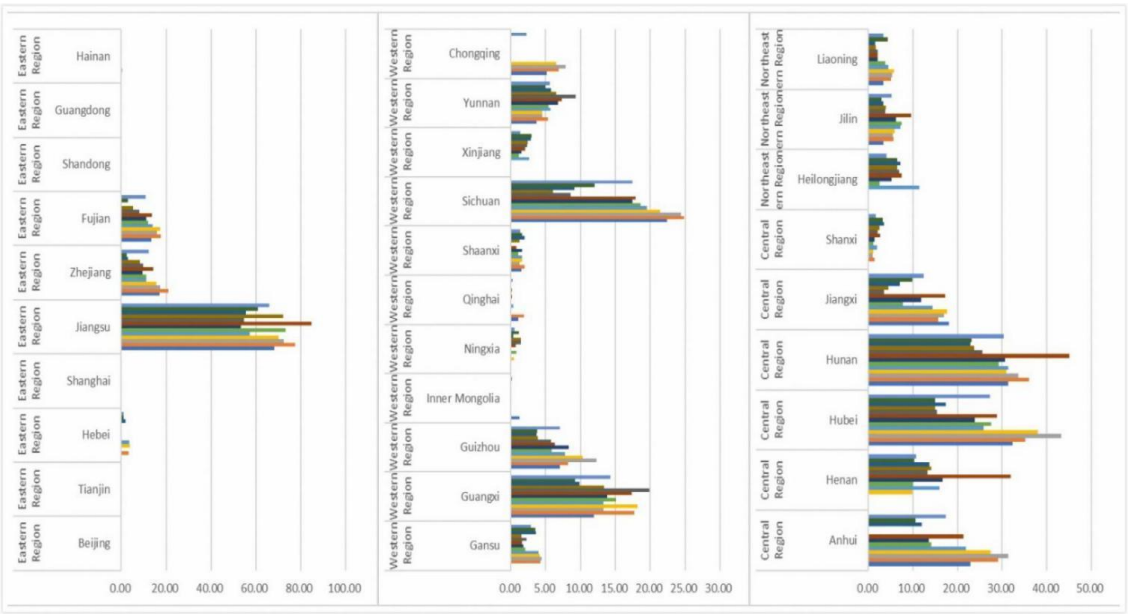

Figure 2. *Industrial water-saving potential of each region in China from 2004 to 2016*

Analysis on the influencing factors of GEIWR

We took the GEIWR in various provinces across the country from 2004 to 2016 as the explained variable; selected six indicators including Environmental Regulation (Government Waste Water Control), Technological Progress, Regional Characteristics[3], Industrial Structure (Industrial Structure Proportion), Foreign Capital Utilization (Foreign Trade Dependence) and Water Resource Consumption (Industrial Blue Water Footprint) as explanatory variables.

[3]Seen by the analysis results, there are obvious regional differences in China's green efficiency of industrial water resource. So we introduces dummy variable (0 represents the eastern region and 1 represents the central, western and the northeast regions) to reflect the influence of region on the green efficiency of industrial water resource.

DOI: http://dx.doi.org/10.15666/aeer/1802_30573072

Because the explanatory variable value of regression equation is between 0 and 1, which is a limited dependent variable, this paper uses the panel Tobit model to test the efficiency effect mechanism. With the help of Stata software, the estimation results of Tobit regression model are obtained by using the maximum likelihood estimation (MLE) method, and are shown in *Tables 4* and 5.

Table 4. *Descriptive statistics*

Variable	Sample size	Mean	Standard deviation	Minimum	Maximum
Green efficiency of industrial water resources	390	0.840,4	0.159,1	0.3100	1.0000

***, **, * means that the variables are significant at the level of 1%, 5% and 10%, respectively

According to the regression results in *Table 5,* the influence mechanism of each factor is analyzed as follows:

(1) Although Environmental Regulation passed the significance test of 1% level, the regression coefficient was negative, which did not promote the improvement of the GEIWR. Generally speaking, increasing environmental regulation is conducive to the improvement of water resource efficiency. However, the regression results do not support this point. The main reason may be that the current government waste water control system is not perfect and the implementation effect is not satisfactory. The government should consider improving the waste water control system to better play the role of policy guidance.

(2) Technological Progress plays a role in promoting the GEIWR to some extent, but do not passed the significance test of 1% level. The positive impact is general.

(3) Regional Characteristic is significant at the 1% level, which shows that regional differences have a very significant impact on the GEIWR (Chen et al., 2016). However,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30573072

the coefficient is negative, probably because the Inner Mongolia, Qinghai in the western region and other regions, despite the lack of water resource and the low level of economic development, have a higher proportion of water resource per capita, a more reasonable industrial structure and a better utilization and allocation of industrial water resource. Meanwhile, some provinces in the central region are constantly developing heavy industry, and problems such as high investment in water resource and high pollution arise. The GEIWR of these provinces is often low.

(4) The increase of the industrial structure proportion has a significant positive effect on promoting the GEIWR. The coefficient of the regression model is positive and significant at the level of 1%. The greater the industrial structure proportion, the greater the investment in the treatment of industrial water pollution, and the higher the GEIWR.

(5) The improvement of Foreign Capital Utilization has a positive impact on the GEIWR, and has passed the significance test at the 1% level.

(6) Although the Industrial Water resource Consumption passes the significance test of 1% level, its regression coefficient is negative, indicating that the increase of industrial water consumption does not promote the GEIWR. This is consistent with the fact that in the actual industrial development, the greater the industrial water consumption, the greater the cost of water resource paid by the industrial development. Therefore, effectively reducing industrial water resource consumption is an important way to improve the GEIWR.

Conclusions, suggestions and discussion

Conclusions and suggestions

In this paper, EBM model was used to objectively analyze and explore the development trend of the GEIWR in 30 provinces from 2004 to 2016, and it was found that the efficiency was differentiated in both time and space. From the perspective of time, the GEIWR in different regions showed different development trends during the period. Thereinto, the GEIWR in Beijing, Tianjin, Shanghai, Guangdong and other regions has maintained a stable and effective state, while efficiency in Yunnan, Sichuan and other regions has been low year by year, so there is a certain space to tap their water-saving potential. From the perspective of space, China's GEIWR has the problem of "central collapse", and the eastern region's efficiency is generally higher than the other regions'. This proves that the developed social services and industrialization level in the eastern region provide certain support for its higher efficiency. The overall low GEIWR in the central region is due to the continuous development of heavy industry in the central region since the implementation of the "rise of the central region" strategy in 2003. Along with the rapid economic growth, problems such as high investment in water resource and high pollution have also emerged. The green development of industrial water resource in the central region is worthy of attention. From the impact mechanism analysis results, increasing the proportion of industrial industry and expanding the utilization of foreign capital are acting the important role in promoting the GEIWR. However, the government's efforts in waste water control and the increase of industrial water consumption have significantly inhibited the improvement of efficiency. Technological progress, although there is a positive effect, the promoting impact is not obvious. Based on the above conclusions, on the premise of ensuring the gradual improvement of the GEIWR and realizing the coordination of economy, society and environment, we put forward the following two suggestions.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30573072

(1) In view of the regional differences in China's GEIWR, each province should not cut at one stroke in dealing with problems, give full play to their regional characteristics, launch industrial water use strategy and water pollution prevention and control countermeasures in line with their own needs, so as to effectively improve the GEIWR. On the premise of ensuring the maximization of economic output and the minimization of environmental pollution, for provinces where the green efficiency of water resource has reached DEA efficiency, such as Beijing and Shanghai, the existing achievements should be consolidated, the steady economic and social development should be promoted, and the frontier level of GEIWR should be maintained. For provinces where the green efficiency of water resource is in the middle level, such as Jilin, Fujian and other regions should further improve the quality of economic growth, strengthen the guidance for the development of high-tech industries, limit the development of pollution-intensive industries, effectively reduce the intensity of industrial water, and improve the comprehensive service capacity of society on the basis of the achieved level. Provinces with low efficiency, such as Guangxi, Sichuan and other places should vigorously develop the economy, improve water management consciousness and ability, prefect the system of local government environmental regulation, develop water-saving potential on the basis of economic prosperity and development, emphasizes the synchronous development of the society to promote its positive role in GEIWR.

(2) In order to shorten the gap in the GEIWR among China's provinces, each province should break the regional blockade, avoid protectionism, increase the communication and cooperation in the field of industrial water-saving and water pollution prevention and control, optimize the industrial economic development pattern, and promote the coordinated development of all provinces.

Discussion

The study on the GEIWR is a complex and valuable subject with broad prospects. Indeed, regions with effective GEIWR are not completely devoid of water-saving space, and their water-saving potential still needs to be further explored. Moreover, there are many potential con-founders that could cause one region to be more efficient than another, including social factors, population health factors, environmental factors, and other economic factors. These factors may impact the GEIWR, and this issue warrants further investigation. Therefore, in terms of research methods, further research on EBM model and measurement ideas of water-saving potential can be carried out in the future to innovate research methods. In terms of research content, we can further enrich the content of the indicator system, such as exploring the impact on the GEIWR from the aspects of water resource price and tax.

Abstract. *Alternanthera philoxeroides* (Mart.) Griseb *i*s a plant species which has become one of the most damaging weeds in ecosystems. We examined potential effects of the invasive plant *A. philoxeroides* on soil animal community by considering four levels of plant invasion (including non-invaded, slightly invaded, moderately invaded and heavily invaded ecosystems) in Nanfeihe, Hefei, China. The following conclusions: A total of 2406 individuals of soil animals, belonging to 25 families, 13 orders and 7 classes, and Acarina and Collembola accounted for 64.52% of the total amount of soil animals captured, thus comprising the dominant species; Individual number of soil animals varied with different rate of invasion; the diversity and evenness indices of the soil fauna showed a pattern of non-invaded < heavily invaded < moderately invaded < slightly invaded, however, there were no significant differences between the moderately and slightly invaded plots. The vertical distribution of the species number and individual number of soil fauna had obvious surface segregation with the increased soil depth; The degree of invasion affects the soil physicochemical properties, and the total potassium content is significantly correlated with the number of soil fauna groups.
Keywords: *biological invasion, exotic plant invasion, Alternanthera philoxeroides, soil meso- and macrofaunal, community diversity, Nanfeihe*

Introduction

Biological invasion is a worldwide ecological phenomenon. Invasive species breed, reproduce, spread and form a stable population. Among them, exotic plant invasion, as an important group of invasive organisms, has seriously affected the biodiversity of the invaded land and the quality of the ecological environment, threatening the global ecological environment and economic development and have aroused worldwide concern, becoming one of the hot spots in global change research (Hui et al.2017).

In recent years, with the continuous increase in our understanding of soil ecosystem processes, research has focused on the impact of invasive plants on soil physicochemical properties, soil biodiversity and ecosystem processes, while soil fauna under the effect of invasive mechanisms has not been researched to such an extent (Yu et al., 2012; Pablo et al., 2014; Fernández et al., 2015; Nicola et al., 2015). Most studies have shown that the invasion of plants will increase the species and number of soil animals. Belnap et al. (2001) compared the numbers of invertebrates in early Brome intrusions and native Bromegrass in Utah, and found that species diversity and abundance were significantly reduced. Soil fauna, an important component of the soil ecosystem, can influence the soil environment through physical and chemical activities. Physical activities include plant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30733085

debris crushing and decomposition, loosening and mixing of soil; The chemical activities include changing soil texture, crumb structure, aeration, water permeability and other physical properties, and influencing the soil pH, organic matter, carbon and nitrogen content and other chemical elements (Yin, 2000). Soil fauna play an important role in plant community succession and soil nutrient cycling (Shao et al., 2015) and some soil animals can also be used to monitor environmental pollution as indicator organisms (Xiang et al., 2007). The spatial distribution and community diversity of soil fauna are of great significance in assessing ecological health, and are important targets in the study of soil ecosystems (Ding et al., 2017)

The exotic plant invasion of *Alternanthera philoxeroides* (Mart.) Griseb, originated from South America, is now widely distributed in the United States, Australia, New Zealand, China and many other countries by virtue of its adaptability, rapid spread and vegetative reproduction (Van et al., 2002). *A. philoxeroides* in China was first introduced as horse feed in the 1930s and is now widely distributed in most parts of China (Zhou et al., 2017). Through investigating the effect of different rates of invasion by *A. philoxeroides* on soil faunal and soil physicochemical properties, this study aimed to improved our knowledge the impact of this invasive plant on the belowground compartment of terrestrial ecosystem. This would provide a theoretical basis to defend against this highly invasive plant.

Materials and methods

Study site

The sampling site was located on the north shore of the Nanfei River in Hefei city, Anhui Province (31.88°N, 117.26°E). The site belongs to a subtropical humid monsoon climate with annual average temperature of 15.8 °C and annual average rainfall of 995.3 mm with average annual sunshine of 1902.0 h (Yao et al., 2014). Along the plain of the river banks, the sampling sites are mainly located near the farmland (*Fig. 1*). According to vegetative ground cover rate (Niu et al., 2007; Chen et al., 2017). we established four rates of invasion by *A. philoxeroides*, that is, non-invaded (O, *A. philoxeroides* number is 0), slightly invaded (S, *A. philoxeroides* accounted for 30% of individuals in each plot), moderately invaded (M, *A. philoxeroides* accounted for 60% of individuals in each plot) and heavily invaded (L, *A. philoxeroides* accounted for > 90% of individuals in each plot).

Sample collection and processing

From July to October 2016, soil samples were collected four times. For each rate of invasion 5 quadrats of 50 cm × 50 cm were randomly selected; each sampling interval was more than 10 m, and the natural environment was basically similar. The aboveground vegetation and litter was removed and soil was collected from 4 depths for each quadrat (0–5, 5–10, 10–15 and 15–20 cm) by soil drilling (with a diameter of 7 cm). Soil samples were placed into labelled ziplock bags before being taken back to the laboratory for analysis. At the same time, soil from the top 0–20 cm in each quadrat was collected and mixed well for analysis of soil physical and chemical properties. Identification of soil animals according to relevant literature (Yin, 1998).

Using the Tullgren method (Yin, 2002), soil animals were extracted in the laboratory using a funnel suspended above a 60 W light with continuous irradiation for at least

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30733085

24 h; the photopathic instinct of the soil animals makes them move away from the light into beakers containing 75% alcohol that are placed underneath the funnel. The soil animals were collected and classified under the optical microscope, and the number of individuals was recorded.

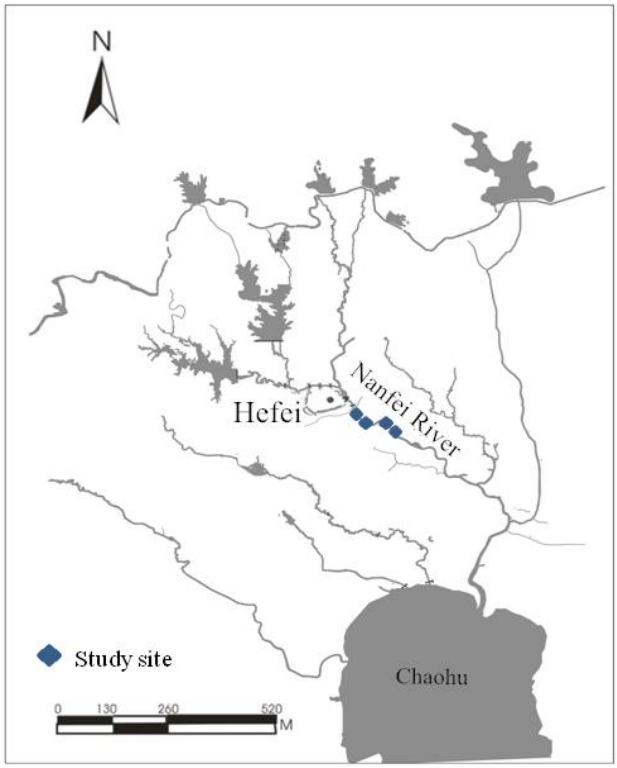

Figure 1. *The sampling site is at Nanfeihe, Hefei, Anhui, China*

Soil samples at depths of 0-5 cm, 5-10 cm, 10-15 cm and 15-20 cm were collected, and roots and stones were removed. Sufficient soil samples were taken by quartering method and air-dried in the room, and then ground through 40-mesh and 100-mesh soil sieves to make soil samples for the analysis of soil physical and chemical properties. Soil organic matter was assessed by potassium dichromate-sulfuric acid oxidation; soil total nitrogen was assessed by the Kjeldahl nitrogen method; soil total phosphorus and available phosphorus was determined by the Mo-Sb colorimetric method; total and available potassium content of soil were determined by flame photometry and soil moisture content measured by conventional drying and weighing method (Bao, 2000).

Data analyses

Diversity indices are usually used to determine the stability of a community or ecosystem; common indices include the Shannon-Wiener diversity index, Pielou's evenness index, Simpson's dominance diversity index and Margalef's richness index. The Shannon-Wiener index is an integrated indicator to measure richness and evenness. The community diversity of soil animals was analysed using the following indices:

$$H' = -\sum_{i=1}^{s} P_i \ln P_i \qquad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30733085

$$E = H' / \ln S \quad \text{(Eq.2)}$$

$$C = \sum (P_i)^2 \quad \text{(Eq.3)}$$

$$D = (S - 1) / \ln N \quad \text{(Eq.4)}$$

where *H'* is the Shannon-Wiener diversity index (*Eq. 1*); *E* is Pielou's evenness index (*Eq. 2*); *C* is the Simpson dominance index (*Eq. 3*); *D* is the Margalef richness index (*Eq. 4*); *S* is the number of species, *N* is the total individual number of soil animals; and *Pi* is the proportion of individuals belonging to species *i* in a sample.

All data were analysed using SPSS for Windows (SPSS, 20.0). Before the analysis, we conducted a diagnostic test of normal distribution and homoscedasticity, and the result is very satisfactory. Statistical analysis was performed by analysis of variance (one-way ANOVA and multiple comparison), and the means were subjected to the Duncan's multiple range test ($p < 0.05$) to obtain the main community differences between the treatments. In addition, to estimate the interaction of soil depth invasion degree among different degree of animal diversity was analyzed by two- way ANOVA analysis. SPSS's correlation analysis was used between soil animals species numbers and soil factors.

Results

Impact of plant invasion on soil physicochemical properties

The contents of soil organic carbon, total nitrogen, available potassium and available phosphorus in the heavily invaded areas were significantly higher than those in other plots (*Table 1*), The contents of available potassium and available phosphorus in the non-invaded area and the moderately invaded area were significantly lower than other treatments ($P < 0.05$), There was no significant difference in total phosphorus content between the four rates of invasion. The total potassium content was higher in the heavily and moderately invaded areas than in the other areas ($P < 0.05$), and there was no significant difference in total potassium content between the slightly invaded and non-invaded areas.

Soil animal composition

From four surveys, 2406 soil micro and meso-fauna were isolated, belonging to 7 classes, 13 orders and 25 families (*Table 2*). Among them, the dominant population (number of individuals accounting for more than 10% of the total number of individuals) consisted of acarina and collembola, accounting for 64.52% of the total amount of soil animals captured; common components of the population (individuals accounting for 1% to 10% of the total individuals) could be classified into nine categories: *Diptera*, *Isopoda, Hymenoptera, Diplura, Psocoptera, nematodes, Haplotaxida, Geophilella* and *Pauropus*, accounting for 32.51% of the total amount of soil animals captured. The rest of the individuals captured were rare populations (individuals accounting for 1% of the total number of individuals), accounting for 2.97% of the total amount of soil animals captured. From slight intrusion area to heavily intrusion area, total individual number of soil animals showed the trend of first increased and then decreased, number of species tends to be stable.

Community diversity of soil fauna under different rates of A. philoxeroides invasion

In the different degree of invasion of *Alternanthera philoxeroides*, there are some differences in community structure in soil animal (*Fig. 2*). The Margalef richness index was not significantly different ($p < 0.05$) among the four rates of invasion, but the Simpson dominance index ($p < 0.05$) in the non-invaded area was significantly different from those in the other three areas, and Shannon-Wiener diversity index space significant difference $p < 0.05$) In the non-invaded communities, soil animals are less and the number of species are relatively concentrated; In the *A. philoxeroides* invaded communities, There was no significant difference between the slight intrusion to heavily invasion areas, but the Simpson's dominance diversity index increased with the increase of the invasion degree, indicating *A. philoxeroides* invasion may affect to some extent of soil animal community, and in moderate intrusion conditions most suitable soil animal survival.

Community diversity of soil fauna at different soil depth

In the vertical direction, the number of species and individual density of soil animals showed a tendency of obvious aggregation, decreasing with the increase of soil depth. For all treatments, the number of individuals and species of soil animals was highest in the 0–5 cm soil layer and lowest in the 15–20 cm soil layer, although there was no obvious trend in the 5–15 cm soil layer (*Fig. 3*).

The Shannon-Wiener diversity index and Pielou's evenness index showed no significant difference with depth (*Fig. 4*), although they increased with increasing soil depth. The Simpson index was significantly different in the 15–20 cm soil layer when compared with the other soil layers ($P < 0.05$), but the Shannon-Wiener and Margalef indices were the lowest at this depth, indicating that as the soil depth increased, species

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30733085

diversity decreased, but there were some dominant species that adapted to the deep soil environment and were uniformly distributed.

The relationship between soil physicochemical properties and soil animals in A. philoxeroides invaded areas

The correlation of soil animals species and soil physical and chemical properties under different rates of invasion is shown in *Table 4*. Except for the non-invasive area (O area), the number of soil animal species in the invaded area (S, M, L) was significantly negatively correlated with total potassium indicating that the distribution

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30733085

of soil animals was greatly influenced by total potassium content. The number of species in the slightly invaded area (S) was significantly correlated with total phosphorus ($P < 0.01$), but this relationship was not observed in other treatments (*Table 4*). The total potassium content increased significantly from the non-invaded area to the severely invaded area ($P < 0.05$). When comparing the numbers of individuals and species of soil animals in different invaded areas (*Fig. 3*), it was found that for both moderately and severely invaded areas, the numbers of soil fauna individuals and species were closely aligned with the total potassium distribution, further indicating that the distribution of soil animals might be affected by the total potassium content.

Discussion

Effect of A. philoxeroides on the soil faunal community

The present study showed that with the increasing rate of invasion, the total number of individuals and groups of soil meso-and microfauna increased first and then decreased, and the number of individuals and species in some soil animals increased (*Table 2*). These results are consistent with those of several other studies: Gremmen (1998) found that communities dominated by exotic plants the grass *Agrostis stolonifera* have more soil invertebrates and mites at sub-Antarctic Marion Island; Kourtev (2002) found that the number of earthworms in invaded areas was significantly increased when compared with native plant communities; Quan et al. (2011) found that *Mikania micrantha* invasion significantly increased the number of soil nematodes and Acarina individuals, community density and the number of groups in the Huolushan Forest Park of Guangzhou, China; Xie et al. (2011) through found that ragweed invasion significantly increased the density of the community–group numbers of soil fauna, Simpson index and Margalef index by the field plot test method in the suburb of Lishi Town, Shaoguan City, Guangdong Province. These results showed the same results about that invasion by exotic plants can increase the biomass or diversity of soil animals.

A. philoxeroides is an amphibious herbaceous plant with strong adaptive and reproductive ability. Chang et al. (2013) research showed that it can quickly form a carpet cover distribution in the invaded area and change the local microclimate environment and soil physical and chemical properties. With the increasing rate of invasion, the soil water content increased and the environmental conditions were more conducive to hygrocoles such as *Nematodes, Mites* and *Collembola*. Soil animals feed on plant humus, radicle and caulicle, Alkemade et al. (2015) showed that after *Spartina anglica* invasion of the European coastal wetland, because of its high net primary productivity, the decomposition of a large number of aging stems provided additional resources into the detritus food web, leading to an increase in the number of soil invertebrates. The development of *A. philoxeroides* roots and stems can provide an

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30733085

abundant food source for soil animals (Pan et al., 2007). In our study, with the increasing rate of invasion by *A. philoxeroides*, the number of hygrophilous *Acarina* and *Collembola* drastically increased, and the biomass of the moderately invaded area was the highest, with slightly less biomass in the severely invaded area (*Table 2*). It could be due to the high vegetation coverage, environmental conditions are changed, such as increased humidity and poor ventilation, thus resulting in the disappearance of *Thysanoptera, Plecopterodae, Hymenoptera, Hemiptera* and other stomatal breathing soil animals, and a significant increase in the number of hygrophilous animals like *Earthworms*. Siersma et al. (2007) also suggested that invasive plant covers may lead to the changes of soil animals' number, but more research is also necessary to support the major claims of this study.

Effect of A. philoxeroides invasion on soil fauna diversity indices

It can be found in the study: with increasing rate of invasion, the Shannon-Wiener, Pielou and Margalef indices decreased, while the Simpson index increased, indicating that although invasion increased the biomass of small and medium-sized soil animals, the diversity, in terms of the number of groups, decreased, indicating that the increase in abundance of soil fauna was concentrated within a small number of groups, such as *Parasiforme, Acariformes* and *Collembola* (*Table 2*).

Many studies have shown that the density of soil animals decreases with depth, with the majority of soil fauna distributing in the top 0–5 cm and significant reductions in number and diversity in deeper soil (*Fig. 3*), for example, Chen and Aoki (1998) surveyed the distribution of soil mites in different soil layers in Changchun and found that the amount and type of mites in the soil layer vertical structure was sharply reduced with increasing soil depth, plummeted with the result what Aoki survey mites distribution in the soil layers (0–5) cm highest plummeted down) coincide. Yin et al. (2003a) studied the diversity of soil fauna in the Lesser Khingan forest and found that diversity in vertical direction of soil animals decreased with soil depth and that the surface aggregation of soil meso-and micro arthropods was more obvious than that of large soil animals. Similar results were found in our study, where the vertical distribution of soil fauna in both invaded and non-invaded areas was highest in the 0–5 cm soil layer and decreased with increasing soil depth (*Fig. 3*).

Effects of soil physicochemical properties on the distribution of soil fauna

There is a close relationship between soil animals and soil environmental factors. Some studies have shown that the soil environmental factors have little effect on the animal groups, just concerning with the number of individual soil animals (Kourtev et al., 1999; Yin et al., 2003b). But in our studies found that *A. philoxeroides* invasion influencing the soil physico-chemical properties, with increasing rate of invasion, soil organic carbon, total nitrogen, available phosphorus, available potassium and total potassium contents increased, there was a significant negative correlation between soil total potassium and the number of soil animal groups ($P < 0.05$), with the increase of total potassium in soil, the soil fauna decreased, it indicated that the regulation of soil potassium content may change the diversity of soil animal communities. Similar results have been found in invasive plants such as *Ambrosia artemisiifolia, Solidago canadensis* and *Ageratina adenophora* (Cruz-Ortega et al., 1998; Tan et al., 2002; Zhang, et al., 2009).

Conclusion

In summary, changes in the soil faunal diversity indices with different rates of invasion and soil depth showed that *A. philoxeroides* invasion affects the species and quantity distribution of small and medium-sized soil animals. Among the communities invaded by *A. philoxeroides*, the *Acarina* and the *Collembola* were dominant members of the population. Soil animals communities were mainly distributed in the topsoil with high vegetation coverage rate and rich humus and litter, presenting a decreasing trend in abundance in the vertical direction under the common constraints of multiple environmental factors and climate conditions. In the future, comprehensive research on soil animals in *A. philoxeroides* should be strengthened to improve the invasion mechanism. Provide a theoretical basis for better prevention and control of invasive species.

Abstract. Invasive plants commonly change soil microbial communities in their introduced range, promoting their own growth while inhibiting the growth of native species. This effect can persist even after invasive plants are removed, thereby hindering restoration of disturbed ecosystems. Our aim was to explore how modifying the altered soil microbe community affected the restoration of an area degraded by *Ageratina adenophora* (Crofton weed), one of the most notorious invasive plants in China. A three-year experiment was performed in the wild. After the removal of *A. adenophora*, the three antimicrobial drugs Chlorothalonil (BJQ), Carbendazim (DJL), and Streptomycin (LMS) were applied to inhibit the activity of soil microbes. The reestablishment of *A. adenophora* and recovery of other plant species were investigated, and soil characteristics were evaluated. All three drugs significantly decreased the total biomass of reestablished *A. adenophora*: relative to the control, BJQ decreased *A. adenophora* biomass by 46.73%, DJL by 70.69%, and LMS by 96.95%. Further, DJL and LMS significantly increased plant community diversity, as well as the biomass of other plant species. Drug treatment also significantly changed soil fertility and decreased soil enzyme activity. Our data indicated that inhibiting the activity of soil microbes is beneficial for both eradication and replacement of *A. adenophora*.
Keywords: *plant community, antimicrobial drugs, interruption, environmental degradation, recovering, exotic species*

Introduction

Invasive plants commonly change soil microbial communities in the introduced range to promote their own growth and inhibit the growth of native species (Klironomos, 2002; Callaway et al., 2004). To stimulate their own growth, invasive plants alter soil microbes such as mycorrhiza and nitrogen-fixing bacterial symbionts (positive feedbacks) (Richardson et al., 2000). However, invasive plants also inhibit the growth of native species (negative feedbacks) either indirectly by outgrowing and excluding native species in soils that lack soil pathogens in the novel range (i.e. enemy release) (Reinhart et al., 2005; Blumenthal et al., 2009), or directly by inhibiting beneficial microbe species that form mutualistic relationships with native plants (Vogelsang and Bever, 2009; Lankau, 2011). Moreover, some invasive plants can promote microbial species that are pathogenic to native plants in the rhizosphere of the soil (Mangla et al., 2008), referred to as the accumulating local pathogen (ALP) hypothesis (Eppinga et al., 2006).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30873100

Restoring an ecosystem degraded by non-native plants is challenging and often unsuccessful, due in part to negative alterations to soil microbial communities that place native plants at a disadvantage (Hamman et al., 2013). This inability of ecosystems to recover from changes to the soil microbial community, referred to as the 'priority effect' (Grman and Suding, 2010) can persist even after non-native plants are removed (Marchante et al., 2009; Elgersma, 2011). Understanding priority effects is therefore essential for restoring degraded ecosystems because many native plants have been found to be especially vulnerable to such modifications (Kardol and Wardle, 2010). Further, eradication of a well-established invasive plant may result in the unexpected release of another, previously suppressed non-native species (Simberloff et al., 2013). For instance, Adler et al. (1998) demonstrated that the eradication of the invasive nitrogen-fixing species *Myrica faya* facilitated the invasion of other fast-growing non-native grasses. Thus, insight into the role of a well-established invasive plant species in an ecosystem is important before eradication is attempted, as risk of invasion by other non-native species can remain high after the removal or reduction in the prevalence of an invader (Simberloff et al., 2013).

Ageratina adenophora (Crofton weed) is one of the most notorious invasive plants in China (Feng and Zhu, 2010; Wang et al., 2011). In the 1940s, Crofton weed began to colonize the Yunnan Province in southwestern China and from there it dispersed north and east at an average rate of 20 km per year (Sang et al., 2010). Although the spread of *A. adenophora* stopped in Yunnan after 1990, it is still rapidly expanding its distribution in neighboring provinces (Wang and Wang, 2006). *Ageratina adenophora* is known to cause acute asthma, diarrhea, depilation, and even death in livestock, as well as cause a decline in crop yields (Wang et al., 2017). The economic losses to animal husbandry and grassland ecosystem services caused by the weed has been estimated at RMB 0.99 billion and 2.63 billion per year, respectively (Wang et al., 2017). Of the multiple mechanisms hypothesized to promote the invasion of *A. adenophora* (Feng et al., 2007, 2009; Wang et al., 2011), changes to soil microbial communities in introduced areas may play an important role in aiding the spread of *A. adenophora* (Yu, 2005). For example, Niu et al. (2007) demonstrated that *A. adenophora* invasion strongly increased both the abundance of soil vesicular-arbuscular mycorrhizal (VAM) fungi and the ratio of fungi to bacteria in soil, and that soil biota in a heavily invaded site had a greater inhibitory effect on native plant species than on *A. adenophora*. *A. adenophora* invasion has also been shown to significantly increase the amount and diversity of nitrogen-fixing bacterial (NFB) in soils (Xu et al., 2012; Zhao et al., 2019). Chen et al. (2019) indicated that this weed can selectively enrich the soil rare bacteria as endophytes in roots.

Currently, mechanical or manual eradication techniques are used to prevent invasion of *A. adenophora*. One study reported that *A. adenophora* was a susceptible plant to herbicide tenuazonic acid (TeA) (Chen et al., 2015), suggesting TeA is a potential chemical control for *A. adenophora* invasion. In some cases, native species are planted following eradication of *A. adenophora* to restore the degraded area (Wang et al., 2008). However, these methods have not been very effective, as *A. adenophora* frequently becomes reestablished after several years of eradication (unpublished data). Such poor restoration efforts may reflect a failure to integrate current ecological knowledge from belowground microbiotas and aboveground vegetation. Although Elliott et al. (2015) reported that microbial community structure is linked to restoration activity, it is unclear if the alteration of the soil microbe community by an invasive plant can affect the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30873100

vegetation restoration in the management and control practices. Therefore, our objective was to determine if modifying the soil microbial community with antimicrobial drugs was sufficient to initiate successful reestablishment of native species after *A. adenophora* removal. In addition, we investigated if other soil characteristics, including soil chemistry and soil enzymes, play a role in the recovery of plant communities.

Materials and methods

Site description

The experimental field site, located on Xishan mountain in Kunming, Yunnan, China (24°58′24″N, 102°37′17″E; altitude 2,214 m), has been heavily invaded (>90% cover) by *A. adenophora* for at least 10 years. Climate data in this site were obtained from the WorldClim database using ArcGIS v10.3 (Yahdjian et al., 2011), with an annual mean temperature of 15.4 ℃ and an annual precipitation of 1024 mm. This site has experienced great changes in soil chemistry and in its soil microbial community since *A. adenophora* invasion (Xu et al., 2012), making it an ideal location for exploring soil priority effects on restoration.

Modifications to soil microbe community

Two plots, each 3 m × 3 m, were selected for manual removal of all *A. adenophora* individuals and other plant species. Each plot was subdivided into four 1 m × 1 m blocks, each separated by 20 cm. In June 2009, before the beginning of the rainy season, each block was randomly treated with one of three antimicrobial pesticides (Chlorothalonil (commercial name Baijunqing, BJQ), Carbendazim (commercial name Duojunling, DJL) or Streptomycin (commercial name Lianmeisu, LMS)) to inhibit soil microbes. BJQ is a broad-spectrum pesticide and inhibits both fungal and bacterial communities. DJL is also abroad-spectrum pesticide, but mainly inhibits the fungal community (Shao et al., 2011). LMS is used to treat soil-born bacterial pathogens. DJL, BJQ, and LMS were applied to the blocks at dosages of 31.96 g/m^2, 21.76 g/m^2, and 28 g/m^2, respectively, inhibiting soil microbes at a depth of 20 cm (Shao et al., 2011). Because pesticide activity continuously diminishes in the soil after initial application, an additional three supplemental treatments were applied to the blocks in July, August, and September 2009. Blocks treated with sterilized water were used as control.

Plant harvest and soil collection

At the end of October 2009, 2010, and 2011, all plants ≥ 10 cm in height were identified and counted in 0.2 m × 1 m subplots in each block (*Fig. 1*). Subsequently, each plant was cut down, placed into a paper bag, dried at 60 ℃ for 48 h, and weighed. About one kilogram of soil was collected from the top 10 cm of soil in each subplot and analyzed for chemical composition and enzyme activity.

Soil chemistry and enzyme analysis

At the end of October 2009 and 2010, soil chemistry and enzyme were analyzed. In 2011, we only harvested plant materials for measurement but did not collect soils, therefore missing of the soil properties for the third year. Soil pH, organic matter, and total and available N, P, and K in all soil samples were measured commercially (see

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30873100

Standard methods for observation and analysis in Chinese ecosystem research network, 1996). Briefly, soil pH was measured by the glass electrode method, after 2.5-fold water extraction. Organic matter was determined using the oil bath-K_2CrO_7 titration method. Total N was assessed by the Kjeldahl method, and available N was determined by the Conway microdiffusion method. Total and available P were measured by Mo–Sb colorimetric analysis. Total and available K were assessed with flame photometry.

Figure 1. *Experimental field (left) and plant harvest for measurement (right)*

Soil enzyme activity was assayed in triplicate. For invertase activity, 5 g of air-dried soil was incubated for 24 h at 37 °C with 15 mL 8% sucrose, 5 mL phosphate buffer at pH 5.5, and 0.1 mL toluene. The glucose released by invertase reacted with 3-5-dinitrosalicylic acid and 3-aminonitrosalicylic acid, which was then measured (as mg glucose released g^{-1} dry soil 24 h^{-1}) at 508 nm (UV 330, Unicam UV-vis). For Casein-hydrolyzing protease activity, 5 g of air-dried soil was incubated for 48 h at 30 °C with 25 mL 1% casein and 1 mL toluene, followed by addition of 25 mL of 10% Trichloroacetic acid to halt the enzyme reaction. The amount of amino acids released was determined by the Folin colorimetric method at 680 nm, measured as mg Tyrosine g^{-1} dry soil 48 h^{-1}. For catalase activity, 2 g air-dried soil was mixed with 40mL distilled water and 5 mL 0.3% H_2O_2, shaken for 20 min at 120 r/min, and the filtrate was titrated with 0.005 mol/L $KMnO_4$. Catalase activity was expressed as mL 0.005 mol L^{-1} $KMnO_4$ g^{-1} dry soil 20 min^{-1}. Soil polyphenol oxidase activity was measured by colorimetric method at 430 nm, determined by purpurogallin formation in soil samples using the substrate pyrogallic acid after 3 h incubation at 30 °C. Soil polyphenol oxidase activity was expressed as mg purpurogallin 100 g^{-1} dry soil 3 h^{-1} (Ma et al., 2003). Urease activity was determined by the modified colorimetric method (McGarity and Myers, 1967). Two milliliters of toluene was added to 20 g of soil and incubated for about 15 min to allow toluene to penetrate into the soil. Twenty milliliters of potassium citrate-citric acid buffer (pH 6.7) and 10 mL of 10% urea were then added and incubated for 3 h at 37 °C. The amount of NH_3-N released (expressed as mg NH_3-N 100 g^{-1} dry soil 3 h^{-1}) was measured using Indophenol Blue Method at 578 nm.

DOI: http://dx.doi.org/10.15666/aeer/1802_30873100

Data analysis

The Shannon-Wiener index (H') was used to assess species diversity of the plant community (Spellerberg and Fedor, 2003). To account for the absence of *A. adenophora* in some subplots (recorded as zero), a value of one was added to all *A. adenophora* seedling records. Data were then transformed using a square root transformation for statistical analysis. The effects of each treatment on the plant community, soil chemistry, and soil enzymes were analyzed with a two-factor (year and drug) repeated-measures analysis of variance (ANOVA) to determine (1) whether these parameters changed over time and (2) whether drug treatments differed. Post hoc comparisons were made using least square differences (LSD). We reported F-tests adjusted for non-sphericity of the variance-covariance matrices using the Greenhouse-Geisser epsilon; hence some degrees of freedom were non-integer (Muller and Barton, 1989). All analyses were conducted in the SPSS software package (SPSS, Chicago, IL).

Results

Effects of soil microbes on the restoration of native plant community

The average biomass of individual *A. adenophora*, plant community diversity (H'), total biomass including *A. adenophora*, and the biomass of other plant species significantly changed cross years (*Table 1*). Moreover, these traits linearly increased over the period of three years of experiment (The biomass of *A. adenophora*, $F = 19.478$, $p = 0.022$; plant community diversity, $F = 34.896$, $p = 0.010$; total biomass including *A. adenophora*, $F = 80.511$, $p = 0.003$; the biomass of other plant species, $F = 32.254$, $p = 0.011$) (*Fig. 2*). But there was no significant change of population density and total biomass of *A. adenophora* over time (*Table 1*).

Table 1. *Repeated measures analysis of variance for plant community*

Source	Year			Drug			Year × drug		
	df	F	P	df	F	P	df	F	P
Population density	1.216	2.115	0.233	3	2.727	0.216	3.648	0.058	0.998
Total biomass of *A. adenophora*	1.096	3.251	0.162	3	15.909	0.024	3.287	0.696	0.620
Average biomass of individual *A. adenophora*	1.186	8.724	0.047	3	5.367	0.101	3.559	1.206	0.435
Diversity (H')	1.012	25.636	0.014	3	8.178	0.059	3.037	3.185	0.182
Total biomass	1.366	69.509	0.001	3	2.472	0.238	4.099	1.013	0.495
Biomass of other plant species	1.126	23.376	0.012	3	6.800	0.075	3.377	0.420	0.767

Drug treatment had a negative, though not significant, effect on the population density of *A. adenophora*, and significantly decreased the total biomass of *A. adenophora* (*Fig. 2A, D*). Relative to the control, BJQ, DJL, and LMS decreased *A. adenophora* biomass by 46.73%, 70.69%, and 96.95%, respectively. Although drug treatment also decreased individual biomass of *A. adenophora*, only streptomycin (LMS) was statistically significant ($p = 0.029$) (*Fig. 2B*). Interestingly, application of DJL ($p = 0.018$) and LMS ($p = 0.038$) significantly increased the biomass of other plant species by 68.5% and 43.87%, respectively (*Fig. 2E*), as well as plant community diversity (*Fig. 2C*).

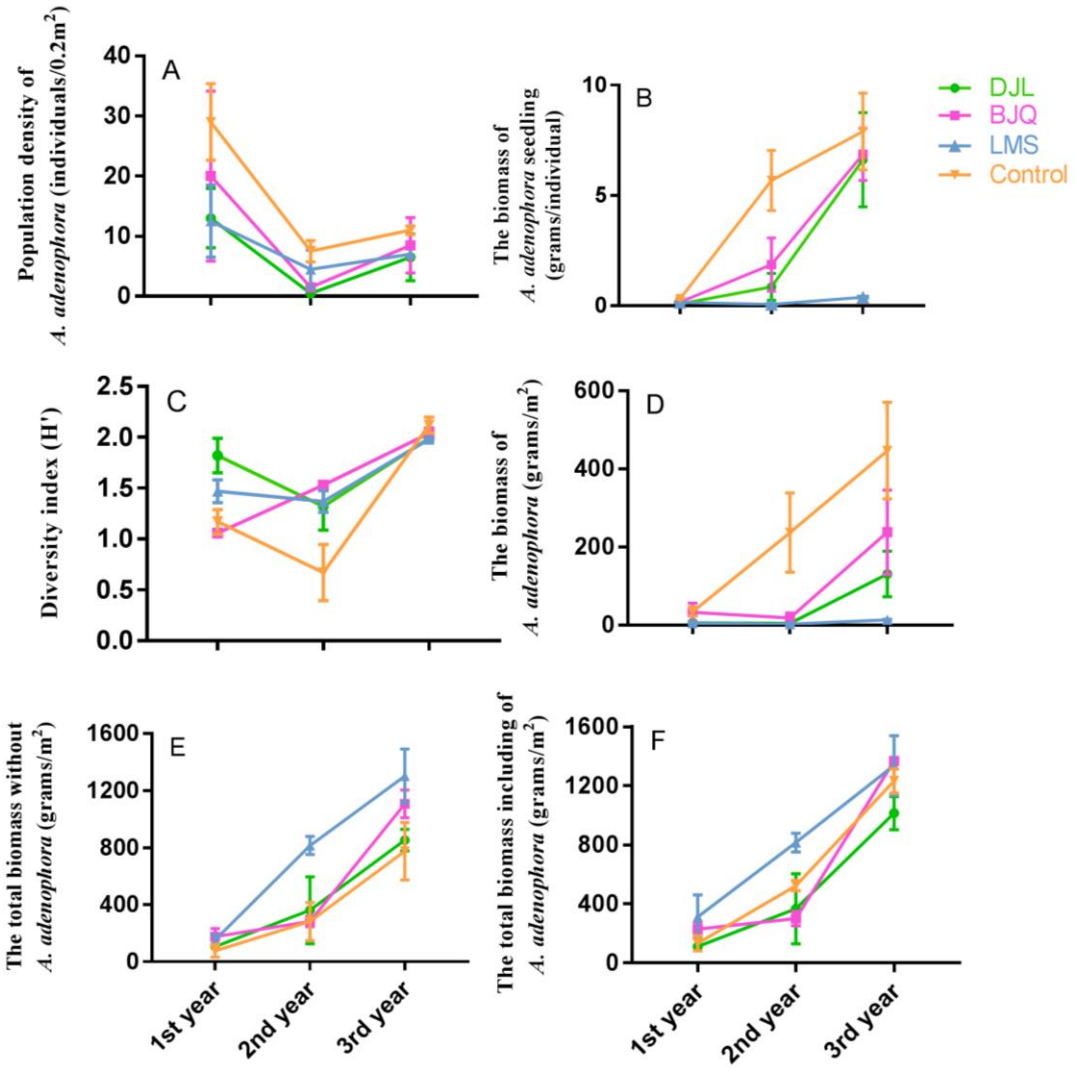

Figure 2. *Effects of modifying soil microbe activity with antimicrobial treatments on plant community. DJL (Carbendazim) is a broad-spectrum pesticide, mainly affecting the fungal community; BJQ (Chlorothalonil) is a broad-spectrum pesticide and is able to inhibit both fungal and bacterial communities; LMS (Streptomycin) is used to treat soil-born bacterial pathogens. Control is represented with water treatment. Error bar represents one standard error*

Soil chemistry enzyme

Only soil samples from 2009 and 2010 were analyzed. All chemistry characteristics significantly changed over years, except for total P ($F = 2.778$, $p = 0.194$) (*Table 2*; *Fig. 3*). Among of them, all pH values decreased from 2009 to 2010, while total K increased. Relative to the control, drug treatment changed most chemistry characteristics of soil, however, significant interactions were observed between treatment and year (*Table 2*). For example, three drugs significantly increased pH values at 2009 but decreased them at 2010; all drug treatments increased organic matter and total N at 2009 but decreased them at 2010 (*Fig. 3*). BJQ increased total P; LMS decreased available K at 2009 but increased it at 2010. DJL and BJQ increased available N and P at 2009 but decreased them at 2010.

Error bar represents one standard deviation*

From 2009 to 2010, soil protease activity significant increased, while the activity of catalase and polyphenol oxidase decreased over years, but urease and invertase had no changed (*Table 2*). Drug treatments significantly affected the activity of protease ($F = 30.182$, $p = 0.032$), catalase ($F = 55.364$, $p = 0.018$) and urease ($F = 28.358$, $p = 0.034$). However, relative to the control, BJQ significantly decreased protease activity; BJQ and LMS significantly decreased catalase activity; and DJL significantly increased urease activity.

Discussion

Ecosystems disturbed by non-native plants are often unable to be restored. Such a situation often results from the impact of non-native plants on soil biogeochemical characteristics and microbial communities, with negative effects persisting even after the removal of non-native plants (Hamman et al., 2013). There are three mechanisms commonly proposed for explaining how non-native plants influence the restoration of native communities by altering soil properties: changes in resource availability, buildup of allelochemicals, and alterations of soil microbial communities (Grman and Suding, 2010).

In general, resource availability increases in soil after invasion of non-native plants (Blumenthal, 2006; Littschwager et al., 2010; Sharma et al.,2010). Because most invasive plant species are adapted to high resource availability, native plants tend to be at a disadvantage when they co-occur with non-native plants (Blumenthal, 2006). In contrast, a low supply of nutrients likely reduces the potential of invasive species to grow (Kueffer, 2010). Previous research suggested *A. adenophora* invasion tends to increase soil fertility (Liu et al., 2007; Niu et al., 2007; Sun et al., 2013). Here, drug treatment decreased the growth of *A. adenophora* (*Fig. 2*) and increased soil fertility at 2009 (*Fig. 2*), indicating that increased resource availability is not the major reason for the soil priority effects of *A. adenophora*.

Although *A. adenophora* generally consumes soil nutrients at a high rate, its invasion tends to increase soil fertility (Liu et al., 2007; Sun et al., 2013). Such a conflict fact was considered resulting from the changed soil microbial community (Niu et al., 2007), for example, increased soil nitrogen-fixing bacterial number after *A. adenophora* invasion may facilitate *A. adenophora* to obtain more nutrients from surrounding soil (Xu et al., 2012). The fact that drug treatment decreased most soil nutrients in 2010 thus suggested that soil microbes play an important role in maintaining the high requirements of the growth of *A. adenophora*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30873100

Interestingly, urease, protease, polyphenol oxidase, and peroxidase activity in plant communities that included *A. adenophora* were greater than that in any native grass community (Liu et al., 2007; Sun et al., 2013). In this case, BJQ significantly decreased protease activity, while BJQ and LMS significantly decreased peroxidase activity (*Fig. 4*). Consequently, modifying the soil microbe community with antimicrobial drug treatments will likely helpful to restore soil enzyme activity to normal levels.

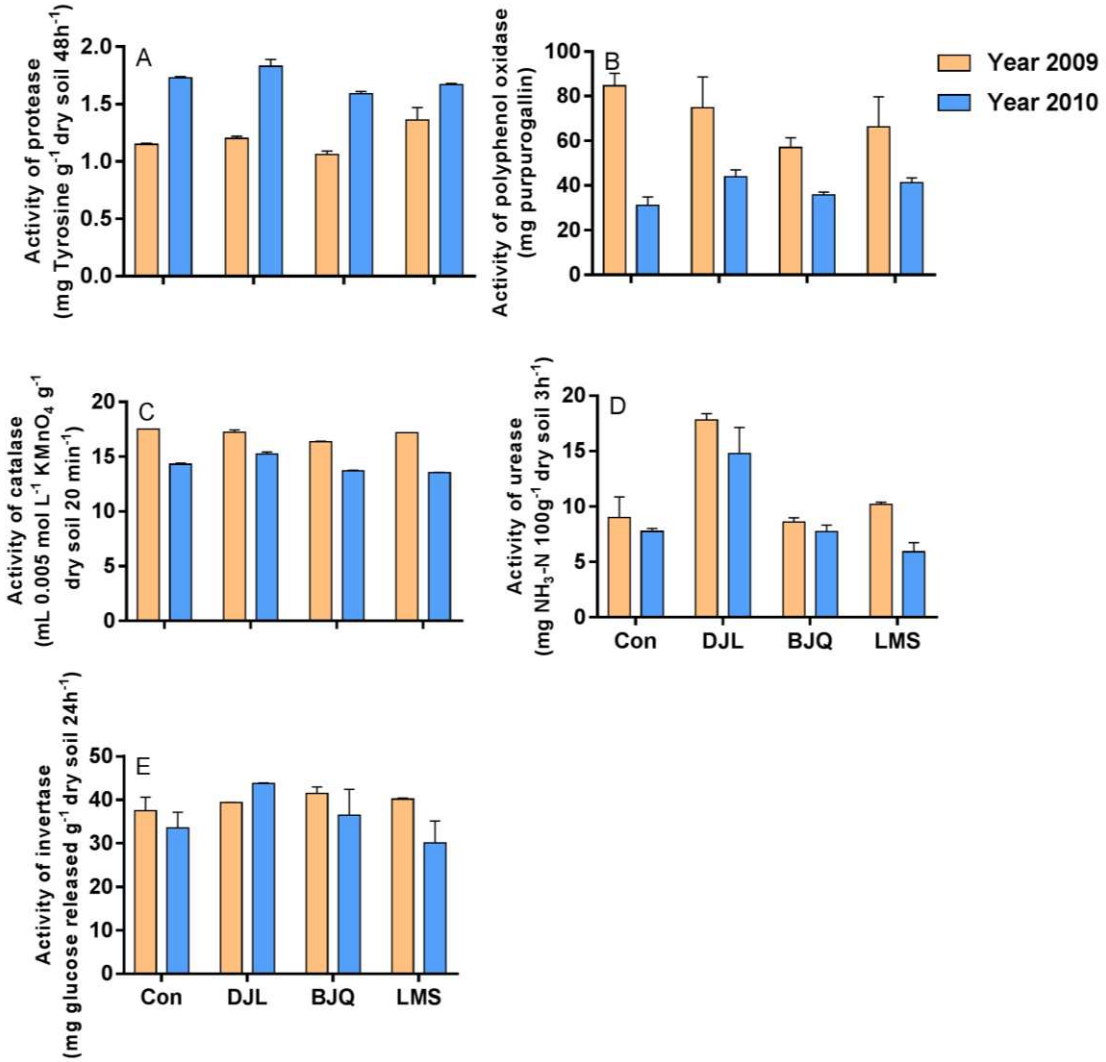

Figure 4. *Effects of pesticide treatment on the activity of soil enzymes. Con, control; DJL (Carbendazim) is a broad-spectrum pesticide, mainly affecting the fungal community; BJQ (Chlorothalonil) is a broad-spectrum pesticide and is able to inhibit both fungal and bacterial communities; LMS (Streptomycin) is used to treat soil-born bacterial pathogens. Error bar represents one standard deviation*

Allelochemical buildup in soil has been demonstrated to be important for the invasion of several plant species, including *Alliaria petiolata* (Bauer et al., 2010; Lankau, 2012) and *Centaurea maculosa* (Perry, 2005). However, the utilization of allelochemicals is also unlikely to be a key factor for the priority effects of *A. adenophora*. Although water extracts of *A. adenophora* leaves adversely affected the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30873100

growth of some plant species (Zhong and Duan, 2006), allelochemicals were not found to persist in the soil after defoliation. Further, a greenhouse experiment also demonstrated that allelochemicals in soils of *A. adenophora* have little effect on native plants (Yu et al., 2005). More recently, *A. adenophora* has been verified to accumulate bacteria which can degrade the allelochemicals and thus decrease the allelopathic effects in soils (Li et al., 2017).

The invasion of *A. adenophora* strongly changes the soil microbial community, including both fungi and bacteria (Niu et al., 2007; Sun et al., 2013). For instance, Xu et al. (2012) found that *A. adenophora* accumulated a greater number and diversity of nitrogen-fixing bacteria than native plant species. In light of these studies, our results indicate that microbes may be the key factor inhibiting the growth of native plants after removal of *A. adenophora*. Moreover, LMS, which mainly inhibits soil bacterial growth, decreased *A. adenophora* biomass to the greatest degree, while DJL, which mainly inhibits soil fungal growth, increased the biomass of other plants the most (*Fig. 2*). This suggests that, if *A. adenophora* accumulates microbes beneficial for its own growth (*Fig. 2,* also see Yu et al., 2005; Niu et al., 2007), these microbes are likely to be bacteria, particularly nitrogen-fixing species (Xu et al., 2012; Zhao et al., 2019) or other selectively accumulated bacteria in roots (Chen et al., 2019). Therefore, the microbes inhibiting native plant growth are most likely pathogenic fungi. However, deciphering which group (or species) of fungi contributes to this inhibition depends on the comparison of the established microbial community by *A. adenophora* invasion with the changed one after the application of antimicrobial drugs, with the integration of the culture-dependent and culture-independent methods. It is too complex and beyond this study aim.

Although initial removal of non-native plants may be successful, reinvasion of non-native plants from remnant seed banks can be challenging to control and hinders restoration of the ecosystem (Adams and Galatowitsch, 2006; Simberloff, 2013). Like most invasive plants, *A. adenophora* produces a vast amount of seeds, and its seed bank persists in the soil for several years (Shen and Liu, 2004). Therefore, modifying the community of soil microbes becomes important for the restoration of the degraded area by *A. adenophora* after eradication. Aside from microbes, soil fauna may affect aboveground vegetation (Sackett et al., 2010); however, we were unaware if there were any side effects on soil fauna from the pesticides used in our experiment. In addition, the impact of an invasive plant on an ecosystem can change over time. For example, native species richness and productivity were initially reduced by the invasive plant *Heracleum mantegazzianum* but tended to recover about 30 years after invasion (Dostál et al., 2013). Therefore, future studies may want to focus on whether the negative effects of soil microbes on ecosystem restoration decrease over the invasion history of *A. adenophora*.

Conclusions

In this study we indicated the effects of soil microbes on the restoration of native plant. Drug treatment had significantly decreased the total biomass of *A. adenophora*. Relative to the control, BJQ, DJL, and LMS decreased *A. adenophora* biomass by 46.73%, 70.69%, and 96.95%, respectively. Meanwhile, application of DJL and LMS significantly increased the biomass of other native plant species, as well as plant community diversity.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_30873100

Chemistry characteristics, including pH, N and K, significantly changed over years, but total P had no changed. Relative to the control, drug treatment changed most chemistry characteristics of soil.

Soil protease activity significant increased, while the activity of catalase and polyphenol oxidase decreased over years, but urease and invertase had no changed. Drug treatments significantly affected the activity of protease, catalase and urease. Our data indicated that *A. adenophora* hinders the successful reestablishment of native species by changing the soil microbial community, and thus inhibiting the activity of soil microbes that promote non-native plant establishment and growth is beneficial for both eradication and replacement of *A. adenophora*.

Finally, although three chemical antimicrobial drugs we used in this study have been commonly applied in agricultural system for disease protection of crops (see materials and methods), the potential risk in natural ecosystems, e.g., carcinogenic and mutagenic effects, needs to be evaluated carefully in the case these drugs are utilized in the restoring vegetation degraded by invasive plants.

(Received 23rd Aug 2019; accepted 8th Feb 2020)

Abstract. The successful use of anaerobic technologies, especially up-flow sludge blanket (UASB) reactors for the treatment of raw domestic sewage and industrial wastewaters in tropical and subtropical countries opened the opportunity to substitute the aerobic processes with anaerobic reactors in removal of organic matter. Proper management of domestic and industrial wastewaters in developing nations is negligible. Even cost effective integrated green technologies like anaerobic reactor with constructed wetland technologies are not applied. Hence the objective of the present review was to assess the pollutant removal efficiency of the up flow anaerobic sludge blanket (UASB) reactor coupled with a constructed wetland (CW) in treating these wastewaters and their capability to produce quality water for sustainable reuse. To achieve the objectives, the review was organized using reputable journals, articles, and review papers. The interpretation of the result of each document was done using tables, bar graphs, Pie chart and lines. The results were reorganized again by calculating average flow rate, hydraulic loading rate, and percentage removal efficiencies. Most research results revealed that use of UASB-CW integrated treatment system is a promising technology in wastewater treatment and able to complying the effluent discharge standards. Globally, the following abatement efficiencies ranged from 79.2-93.9%, 89.2-92.9%, 87.2-96.3%, 22.6-96.9%, 33-85.9%, and 97.9-99.99% were achieved for Chemical oxygen demand (COD), Biological oxygen demand (BOD), Total suspended solid (TSS), Total Kjeldhal Nitrogen (TKN), Total phosphorus (TP) and fecal Coliforms (FC), respectively using UASB-CW treatment systems. UASB-CW technologies are effectively integrated treatment systems and can be used for resource scarce developing countries. Since, both treatment technologies are cost-effective, easy operation and maintenance and capable of meeting effluent standards. Hence, the indiscriminate disposal of wastewaters and their environmental impacts in Ethiopia can be resolved using these low-cost combined treatment technologies.

Keywords: *domestic sewage, industrial wastewaters, UASB reactor technology, constructed wetland, UASB-CW integrated treatment systems, effluent sustainable reuse*

Introduction

Ocean and river quality deterioration is primarily caused by the discharge of inefficiently treated industrial and municipal wastewater. To combat this increasing problem on aquatic environment, strict regulation on pollution discharge is being implemented by various governmental bodies, with the focus primarily of waste reduction (Chan et al., 2009). Nowadays, there are a wide range of wastewater treatment

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

technologies in the world. However, the strategies of treating domestic, municipal and industrial wastewaters by common and aerobic processes were shifted to the anaerobic processes. Anaerobic treatment technologies were known to treat medium to high strength wastewaters. Many advanced anaerobic treatment reactors have been investigated in the past. Among the reactors, Up-flow Anaerobic Sludge Blanket (UASB) reactor is widely used as a sustainable technology to tackle the challenges faced in efficient treatment of various kinds of wastewater. The success of this reactor is due to its strong ability to remove in removal of chemical oxygen demand even at light loading rates and low temperature (Atashi et al., 2010). Besides this, anaerobic treatment of wastewater has recently gained worldwide attention due to its simplicity, low construction costs, small land requirements, plain operation and maintenance, low sludge production and low energy requirements and energy production capacity in the form of biogas compared to aerobic treatment (Bhatti et al., 2014; Kasaudhan et al., 2013; Khan et al., 2011; Airuk et al., 2010; Gomec, 2010; Tandukar et al., 2007). Earlier much attention was not given to the treatment of wastewaters and they were simply dumped into the natural sources of water. This led severe health problems by deteriorating natural water resources.

An organic waste from industries, domestics, municipalities and agricultural sector decomposes in the environment and resulting large scale contamination of land, water and air. In order to protect the environment and prevent health hazards it is necessary to provide adequate treatment for the wastewater to reduce its pollution potential (Lomte and Bobade, 2015). Similarly in Ethiopia, accelerated water quality change due to rapid growth of urbanization and industrialization becomes one of the major environmental concerns in the country. Release of large quantities of industrial wastes to the environment contributes large quantities of nutrients and toxic substances into the water bodies. The pollution of water bodies and human habitat in the major cities, rivers and lakes are one evident for enormous release of wastes (Kenatu, 2011). This rise of environmental protection issue, leads to put strict environmental regulations on the industrial pollutions in order to reduce the levels of discharge standards. To full fill the regulations, some industries begin to use anaerobic reactor technologies to handle ever-increasing complex generated wastes from their processing units (Kebena, 2014). Different investigations were carried out at pilot and full-scale levels to study the effectiveness of UASB reactor for the treatment of various industrial wastewaters like distillery, petroleum, canning industry, paper and pulp, pharmaceuticals, tannery, textile and food industries such as brewery, diary, slaughterhouse, and sugar factories (Atashi et al., 2010). However, the UASB reactor has become the most frequently used method in treating domestic and industrial wastewater and can produce two main valuable resources (i.e., methane and the effluent). The methane gas is produced during the COD removal which with a potential recovery rate of 28% to 75% and can be transformed into energy (Mutombo, 2004).

The successful use of anaerobic reactor technologies for the treatment of wastewaters was restricted in tropical and sub-tropical regions. In these regions, anaerobic reactors have been responsible for the removal of large fractions of organic matters (Foresti et al., 2006). However, despite this success, UASB reactors are usually unable to attain most of the existing effluent discharge standards due to presence of high residual COD and BOD, nutrients and pathogens (Foresti et al., 2006; Yasar and Tabinda, 2010). All these features make the UASB treatment of wastewater is a very important field of research, where improvements and new developments are needed to overcome the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

problem. Thus, additional post treatment strategy is mandatory for the anaerobic bioreactor treated effluents sustainable reuse for developing countries but also for advanced countries (Yasar and Tabinda, 2010). There are different types of post treatment configurations on combination with UASB reactor, such as UASB-Aerobic suspended growth, UASB-Aerobic attached growth, UASB-Final Polishing Units (FPU) or UASB-Polishing Ponds (PP) are some of them used at several sewage treatment plants in India, Colombia and Brazil (Von Sperling and Mascarenhas, 2005; Khan et al., 2011).

Recently, application of constructed wetlands (CW) for the treatment of wastewater has received much attention, due to their cost effectiveness and environmentally friendly approach. In this situation, application of integrated anaerobic pretreatment-constructed wetland for the removal of pollutants is promising (Jamshidi et al., 2014). Constructed wetland technologies can be effectively integrated with anaerobic processes because they require a low energy input, easy operation and maintenance, modest installation and maintenance costs, minor sludge production, and the creation of visually pleasing landscapes. However, they need a large land area. The UASB removes mainly organic matter in wastewater with low and high organic loads; while the Horizontal subsurface flow constructed wetland (HSSFCW) is capable of removing organic matter and nutrients and is commonly used to obtain secondary or tertiary effluent concentration levels. In other words, combining an anaerobic reactor with a constructed wetland brings important benefits to the constructed wetland system such as the reducing of the required planted area, reducing the hydraulic retention time and increasing their life cycle (Lopez-Lopez et al., 2015). In addition to this, for resource scarce developing countries to adopt wastewater treatment, the treatment technologies must be cost-effective and easy to adopt, requires less energy input, and maintenance costs and be capable of meeting effluent discharge standards (Kyambadde et al., 2005).

The objective of this review paper was to assess the potential use of UASB reactor followed by constructed wetland in treating domestic and industrial wastewaters to the discharge standard limit, to compare and contrast UASB-CW wastewater treatment system with other kinds of post-treatment technologies and to assess the limitation of UASB reactor technology for wastewater treatment.

Method of writing the review paper

This review paper was written using journals articles, review papers, master's and doctoral thesis downloaded from Springer Link, Science Direct, Library Genesis, Jester, and www.nap.orgsearching web pages. The interpretation of the result of each document was done using tables, bar graphs, Pie chart and lines in a Microsoft excel. Results were reorganized again by calculating average flow rate, hydraulic loading rate, and percentage removal efficiencies of the scholars for comparison. The pollutant removal rates (%) were calculated for the uncalculated wastewater parameters using the following equation:

$$R\ (\%) = \left[1 - \frac{Cf}{Ci}\right] x\ 100$$

where R is the removal rate, C_i and C_f are the influent and effluent.

DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

Overview of anaerobic reactors

The main anaerobic reactors types used for the treatment of wastewater can be classified as low rate or high rate treatment systems as shown in *Figure 1*. High-rate systems are characterized by retention of sludge (sludge retention time (SRT) > hydraulic retention time (HRT)) whereas most low-rate anaerobic systems have no sludge retention time (SRT = HRT) (Zhang, 2016).

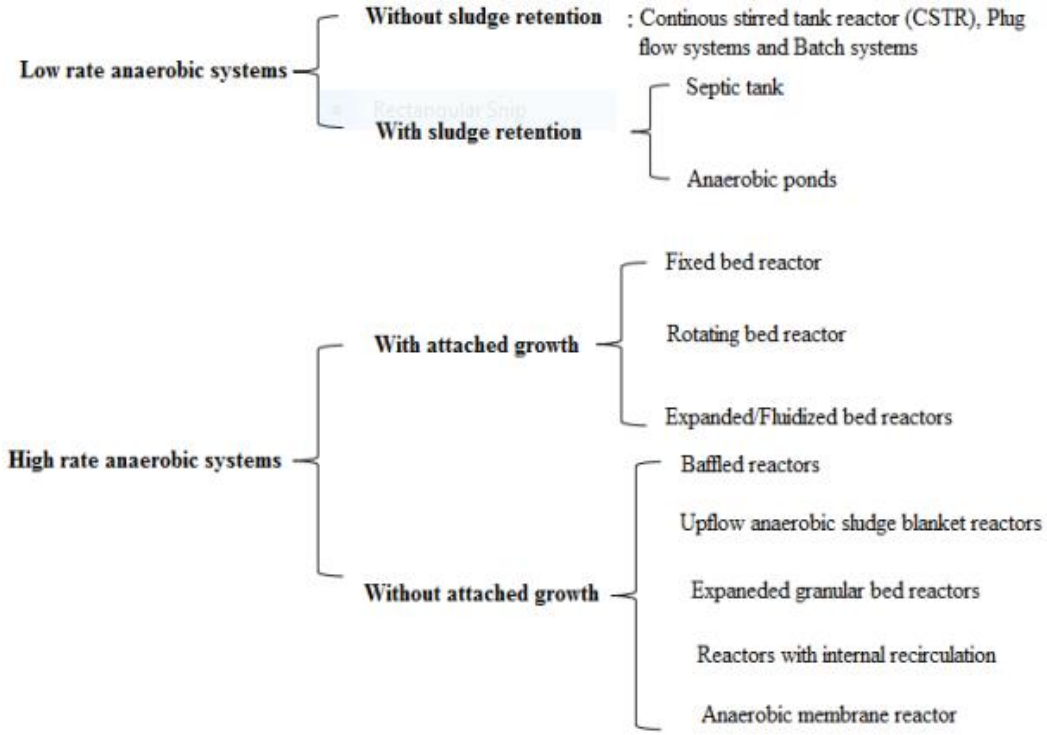

Figure 1. *Spectrums of anaerobic reactors used for wastewater treatment*

Among the spectrums, UASB reactor is one of the most distinguished anaerobic treatment technologies developed in Netherlands. Successful construction of a UASB process is capable of affording self-granulation of anaerobic microbes. The distinguished characteristic of this reactor is the presence of active biomass at the bottom of the reactor operating on suspended growth system. In this type of bioreactor, wastewater flows upwards direction through sludge bed and sludge blanket and is degraded by anaerobic microorganisms. Small sludge granules begin to form whose surface area is covered in aggregations of bacteria. Gas produced is then separated by a gas–liquid separator and the clarified liquid is discharged over a weir, while the granular sludge naturally settles at the bottom *Figure 2* (Saleh and Mahmood, 2003). Full-scale UASB reactors are now operational in Europe, US, Japan (Bani, 2011) and Ethiopia (Kebena, 2014).

Industries discharge wastes that contain high levels of organic materials which could adversely affect the environment. To meet the discharge limits, industries prefer economical and practical treatment methods. Anaerobic treatment has gained more attentions in developing countries due to their eco-friendly, low energy input, low biomass outputs, simple and inexpensive technologies to operate (Bukhari et al., 2015).

DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

Several anaerobic reactor technologies have been designed and constructed for the treatment of high strength wastewater. UASB reactors have received much attention due to their ability to treat high strength wastewater at higher organic loading rate (OLR) and a lower HRT. The treatment of high strength wastewater such as brewery wastewater using anaerobic digestion has been employed throughout the world. However, anaerobic digestion has some disadvantages like bad odor, and effluent that sometimes needing post-treatment to meet the discharging standards for nutrients levels, organic matter and pathogens content.

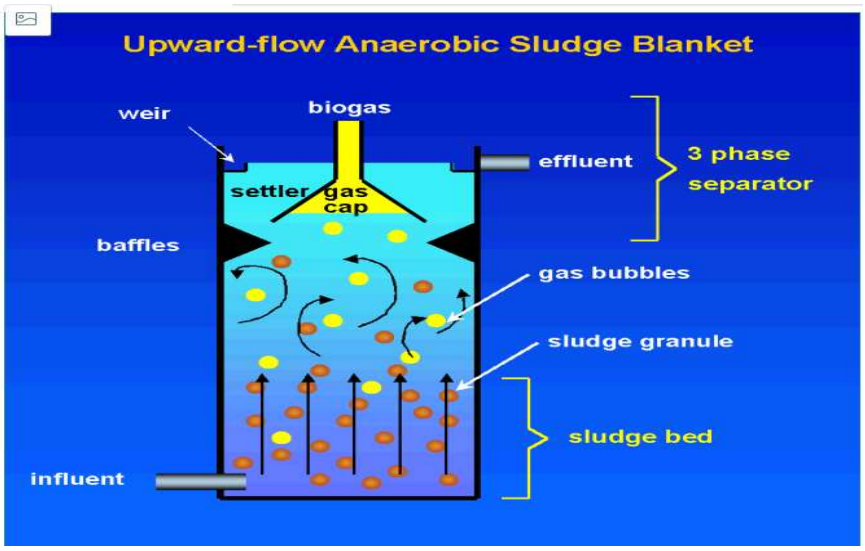

Figure 2. *Up-flow anaerobic sludge blanket reactor (UASB)*

Over the past times, different types of reactors have been developed and their installations have been commercialized. Among those, UASB reactor configuration is the most widely used high-rate anaerobic reactor for the treatment of high strength wastewater. An overview of the different anaerobic treatment systems used for different industrial wastewater pre-treatment and their proportions and types of anaerobic digestion systems that have been installed and commercialized for the treatment of industrial wastewater is presented in *Figure 3a* and *b* (Enitan, 2015).

Anaerobic reactor technologies have been widely applicable in the past decade for the treatment of various types of industrial wastewaters such as food processing, textile industry, paper and pulp industry (Pantea and Romocea, 2008). Anaerobic reactors have been used mainly for industrial wastewater treatment. This technology is also rarely applied for the treatment of municipal sewage, because municipal sewages are too weak (low BOD or COD) to maintain high biomass (i.e., in the form of granules-suspended solids or fixed film) content in the reactor. However, anaerobic wastewater treatment plants for municipal wastewater have been successfully operated in tropical countries such as Mexico, Colombia, India and China, the process until now has not been applied in countries with moderate and low temperatures.

According to Khan (2012) report indicates that there are 200 UASB reactors are used for municipal and industrial wastewater treatment application in India. The UASB reactor treating wastewater can produce main valuable resources (i.e., methane and the effluent) which can be recovered and utilized. Worldwide, more than 2000 anaerobic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

systems are also in operation for the treatment of industrial wastewater and landfill leachates (IEA, 2001). At lower temperature, the removal of COD by anaerobic reactor is limited and long HRT is needed for one step system to provide sufficient hydrolysis of particulate organics (Gašpariková et al., 2005) because low temperature causes deleterious effect on anaerobic digestion through relatively longer generation time of anaerobic bacterial populations and lower biochemical activity, resulting in the decrease of biogas yield and digester failure (Singh et al., 1999).

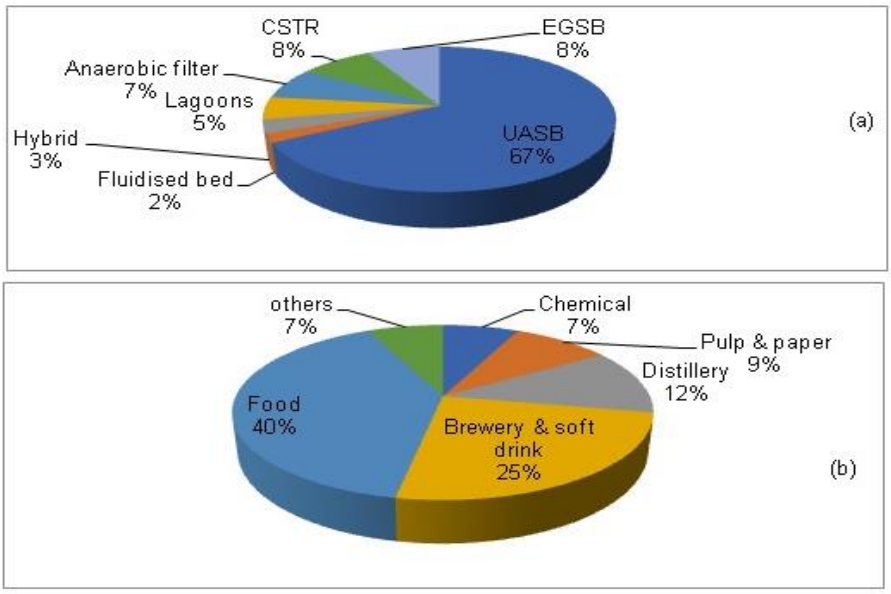

Figure 3. *(a) Proportions and types of anaerobic reactors that have been installed and commercialized for the treatment of industrial wastewater and (b) percentage of industries used anaerobic reactor technologies for wastewater treatment*

Anaerobic digestion process

Anaerobic reactors have a unique diverse group of bacteria that catalyzes the conversion of complex organic compounds to methane and carbon dioxide under a properly controlled and coordinated fashion. Degradation of organic matter in anaerobic process undergoes a complex microbial process consisting of several interdependent consecutive and parallel reactions. In this anaerobic digestion process, several groups of bacteria playing a vital role (Foresti et al., 2006) (*Fig. 4*).

Anaerobic effluents/UASB effluent characteristics

The output of anaerobic reactor indicates that the effluent contains residual organics in terms of BOD, COD, TSS and rich nutrients (N and P), microbial pathogens and reduced species such as sulfides, nitrate, ammonia, etc.

Organics and suspended solids

The concentration of BOD, COD, and TSS of anaerobic treatment system like UASB reactors in treating sewage without any post treatment system has been reported to vary from 60 to 150; 100 to 200; and 50 to 100 mg/l respectively (Foresti et al., 2006). The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

process efficiency depends on different factors like wastewater strength and composition, temperature, pH, and others. The dissolved mineralized compounds such as ammonia, phosphate and sulfides in the effluents also varied with these factors. The performance of these treatment systems highly depends on temperature and decrease with a decrease in temperature (Elmitwalli et al., 2001; Lew et al., 2003).

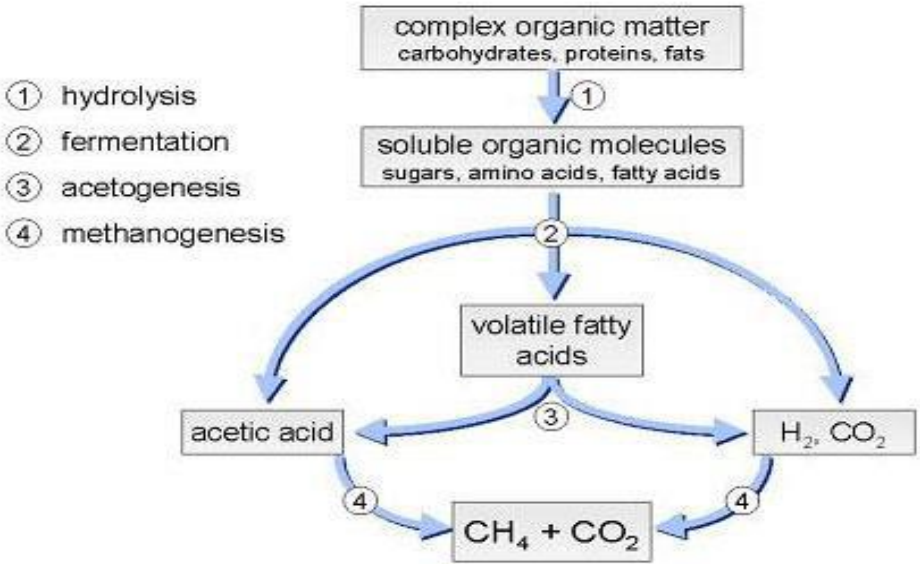

Figure 4. *The chemical reactions that occur during anaerobic digestion (Metcalf and Eddy, 2003)*

Nutrients

Insignificant or negligible removal of nutrients may be expected from anaerobic treatment systems (Foresti et al., 2006; Moawad et al., 2009). The poor removal of nutrients in anaerobic process is due to organic nitrogen and phosphorus hydrolysis into ammonia and phosphate respectively, which are not removed by this process and in consequence, their concentration increases in the liquid phase. Other highly mineralized sulfur compounds exist as sulfides in anaerobic systems effluent treating sewage. The effluent total sulfides concentration depends on the concentration of sulfates in the influents and sulfate reducing bacterial activity present in the reactor (Khan, 2012).

Indicators of microbial pathogens

The reduction of fecal coliforms is around one order of magnitude, i.e., from 108 to 107 in UASB treatment system which indicates that it is not designed for pathogenic removal, while helminth eggs removal efficiency has been reported to be 60-90% (Chernicharo et al., 2001; Von Sperling and Mascarenhas, 2005). In general, the UASB reactor effluent has a significant count of FC which is greater than the permissible limits specified by WHO (1989) for unrestricted irrigation. This indicates that the removal efficiency of UASB reactor is insufficient towards residual organics, nutrients and pathogens.

This may be due to the excessive hydraulic loading which consequently resulting higher up-flow velocities that may cause bypass of these pollutants with the final effluent without any microbial degradation. The temperature effect may be also one

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

factor, because low temperature leads to insufficient mixing and more organic matter usually remains un-degraded as a result of slow hydrolysis of volatile solids at a given HRT. Considering the intrinsic limitations associated with the anaerobic systems and the stringent discharge standards, it is imperative to include a post-treatment stage for the effluents from anaerobic reactors. Therefore, the polishing stage has the purpose to improve the microbiological quality of the effluents, in view of the public health risks and limitations imposed on the use of treated effluents in agriculture. In an environmental approach, the post-treatment needs to guarantee the effluent quality in terms of organic matter and nutrients, in view of the environmental damages caused by the discharge of these remaining pollutants into the receiving surface water (Noykova et al., 2002).

Post-treatment of anaerobic reactor effluents

The insufficient removal of nutrients in anaerobic process is organic nitrogen and phosphorous hydrolyzed to ammonia and phosphate, respectively, which are not removed by anaerobic processes. Therefore, to minimize these problems, low rate natural settling systems (polishing ponds, constructed wetlands and duckweed pond), high rate aerobic methods (chemically enhanced primary treatment, Zeolite column, sequential batch reactor) and micro-aerobic methods (down-flow hanging sponge) are used for removal of the stabilized suspended matters, nutrients and fecal coliforms (FC) present in the UASB reactor (Khan et al., 2013).

Polishing ponds (PP)

Von Sperling and Mascarenhas (2005) found that the feasibility of PP (Polishing ponds) for the post treatment of effluent of UASB reactor in Brazil. The performance of the four series shallow depth PPs (i.e., 0.4 m) for the treatment of UASB effluent at a total of 7.4 day or 1.4 to 2.5 days results the final effluent concentration of BOD and COD, 44 and 170 mg/l, respectively. The mean overall FC removal efficiency was remarkably high (i.e., 99.99996%). The high FC removal efficiency together with total nitrogen concentration of 10 mg/l in the effluent were found compatible with the discharge standards for urban wastewater from European community, 15 mg/l or 70% removal. The ammonia nitrogen concentration in effluents from combined system was 7.3 mg/l or 67% removal. However, phosphorus removal was low (i.e., 28%). Other research study done on integrated anaerobic-aerobic systems carried out in Brazil also showed that shallow ponds in series even at short HRT, are able to produce effluents complying with the WHO guidelines for unrestricted irrigation in respect to FC concentration which is lower than 1000 MPN/100 ml. In general, all polishing pond systems were able to produce a quality effluent, which is a compliance with the WHO guidelines for unrestricted and restricted irrigation (Cavalcanti et al., 2001).

Constructed wetland (CW)

Constructed wetland system is technically and economically feasible alternative for wastewater treatment for small communities (Okurut, 1999). The systems consist of a solid medium (sand, soil or gravel) used to develop a natural process under suitable environmental conditions and wetland plant species provides a substrate (roots, stems and leaves) which microorganisms can grow as they break down organic matters. These plants species have a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

great role in utilization of the nutrients and other constituents, oxygen transfer to the solid medium and support medium for bio-films on the roots and rhizomes (De Sousa et al., 2001). According to Sousa et al. (2001) investigation, the pilot scale wetland system for the treatment of effluent of UASB reactor for the removal of residual organic matter, suspended solids, nutrients (N and P) and fecal coliforms. The 1500 L holding capacity of the UASB reactor was operated at HRT of 3 h and 6 h while the effluent of the UASB reactor was treated in four units of CW, each 10 m long and 1.0 m wide, filled with coarse sand substrate media and planted with Juncus sp. Macrophyte were planted in three CWs, whereas the other serves as a control unit without plants.

The final result revealed that the effluent COD from the four CW units had substantially constant concentration values, indicating that there was no influence of varied hydraulic load applied and presence of plant in CWs on its removal efficiency. The phosphorus removal was very efficient during the whole study periods; this removal was mainly due to the utilization by plants and microorganisms as well as adsorption and precipitation. In unplanted CW, the removal was due to precipitation and adsorption as well as assimilation by the bio-film developed on sand grains. The total nitrogen removal efficiency varied from 59 to 87% in wetlands containing macrophytes. This may be due to assimilation by plants and microorganisms present in wetlands, probably nitrification due to transport of oxygen from atmosphere by plants. The output indicated that the presence of macrophytes enhance the nitrogen removal efficiency significantly. The highest removal efficiency occurred in the unit with lowest hydraulic load corresponding to HRT of 10 day. The removal efficiency of the fecal coliforms was observed to be very high in wetlands with macrophytes. The increase in hydraulic load reduced the removal efficiency.

Duckweed pond (DP)

The aquatic macrophytes based treatment systems such as DP (Duckweed Pond) can be used to recover the nutrient and transformed them into easily harvested protein rich by products. The UASB effluents are highly rich in nutrients which should not be removed but, recovered. DP is covered by floating mat of macrophytes, which prevents light penetration into the pond resulting in shading. The high growth rates of the macrophytes permits regular harvesting of the biomass and hence nutrients are removed from the system. The produced biomass has economic value, since it can be applied as fodder for poultry and fish. El-Shafai et al. (2007) evaluated the performance of a combined UASB-DP system (3 pounds in series). The UASB reactor had a holding capacity of 40 L and run at 6 h HRT while each pond had 1 m^2 surface areas and 0.48 m depth and operated at HRT of 5 day in each pond. The duckweed ponds were inoculated with Lemna gibba, obtained from a local drain, at 600 grams fresh duckweed per m2. At the end, the system removed 93% COD, 96% BOD and 91% TSS during warm season. While residual values of ammonia, total nitrogen and total phosphorus were 98%, 85%, and 78%, respectively. The system also achieved 99.998% FC removals during the warm season. The removal efficiency of the system at the winter season was the same for BOD, COD, and TSS, but not for nutrients and fecal coliforms.

Chemically enhanced primary treatment (CEPT) and zeolite column

This treatment system was proposed by Aiyuk et al. (2004), which works in an integrated approach (i.e., coagulation and flocculation - UASB - Zeolite). In this integrate treatment system; domestic wastewater is initially treated with CEPT using

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

$FeCl_3$ as a coagulant and polymer to remove suspended material and phosphorus followed by UASB to remove soluble organics. The UASB effluent was then subjected by re-generable zeolites to remove total ammonia nitrogen. The CEPT pre-treatment on average removed 73% COD, 85% TSS and 80% phosphate (PO_4^{3-}). The coagulation/flocculation step of this integrated system produced a concentrated sludge (8.4% solids), which can be stabilized in conventional anaerobic sludge digester used as fertilizer for agricultural purposes.

After, this step, UASB reactor consequently received pre-treated wastewater with COD loading of 140 mg/l and it was operated with hydraulic loading rate of 0.4 g COD/L/day. For these conditions, the system removed about 55% COD. The zeolite removed almost 100% NH_4^+. The integrated coagulation/flocculation - UASB - Zeolite system effectively decreased the TSS and COD up to 88% and more than 90% respectively. The nitrogen and phosphorus were decreased 99% and 94%, respectively. The column of zeolite proved most beneficial due to very high removal efficiency of ammonia and the oxidation of residual organic matter. Pathogenic indicators (FC) removal is 99%. The final effluent from the system can be used for crop irrigation or discharged into surface waters.

Down-flow hanging sponge (DHS)

This treatment system is a high rate micro-aeration treatment method. Micro-aeration implies that aeration of the treated effluent for about 30 min. The role of micro-aeration is to strip off and to oxidize the reduced species such as sulfides, ferrous ions etc., which exert immediate oxygen demand and remaining easily biodegradable organic pollutants and to remove the dissolved methane gas. In this DHS reactor designed, sponge cubes diagonally linked through nylon string have been used to provide a large surface area to accommodate microbial growth under non-submerged conditions. Then the wastewater trickled through the sponge cubes supplies nutrients to resident microorganisms. Oxygen is supplied through natural draught of air in the downstream without equipment. The system provides dissolved methane gas to be recovered. The performance efficiency of combined UASB-DHS cube process, with post-denitrification and an external carbon source, 84% in average nitrogen (NO3- + NO2-) was removed with HRT of less than 1 h. The DHS reactor was capable of stabilizing TN through nitrification, which ranged from 73 to 78% (Khan et al., 2013).

Sequential batch reactor (SBR)

SBR is a fill and draw type modified activated sludge process, where four steps of fill, aeration, settle and decant takes place sequentially in a single batch reactor. The operation of SBR can be adjusted to obtain aerobic, anoxic and anaerobic phases inside the standard cycles. The performance of the system was evaluated through a bench scale set-up comprising of a 4 L volume UASB reactor followed by two SBRs of 3.6 L each. The UASB reactor was fed with partially mixed synthetic substrate in sewage while SBR received effluent of UASB reactor. The HRT of 4 h in UASB was maintained constant throughout the study while the 4 h cycles in the following sequence of fill (0.1 h), reaction (1.9 h), sedimentation (1.6 h), discharge (0.25 h), idle (0.15 h) were maintained in SBR. The combined system removed 85% TN through nitrification. The COD removal in UASB reactor was around 86% while in SBR around 65% of the remaining, thus combined systems removed 95%. The combined system was also

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

removed 96% of TSS and 98% of BOD (Khan et al., 2013). Mouawad et al. (2009) also studied the performance of the combined UASB-SBR system under different operating conditions for the treatment of domestic wastewater.

The reaction time was run for 3 h and the aeration time in the SBR cycle varied from 2 to 5 h, and then to 9 h. The observed average percentage removal for the three runs for COD, BOD and TSS was 94%, 97% and 98% respectively. Complete nitrification of ammonia was achieved after 5 h aeration in the SBR. The average percentage removal of phosphorus reached up to 65%. Increasing the HRT in the SBR from 2 to 9 h caused a significant improvement in FC removal. The overall removal efficiencies of the different post-treatment systems were mentioned in *Table 1*.

Table 1. *Treatment performance efficiency of UASB reactor integrated with different post-treatment systems in treating sewage (Khan et al., 2011)*

Treatment systems	Removal efficiencies of pollutants						
	BOD	**COD**	**TSS**	**NH_4 - N**	**TN**	**TP**	**FC (MPN/100 ml)**
CEPT + UASB + Zeolite	85%	91%	88%	99%	94%	94%	99%
UASB + PP	92%	79%	96%	50%	55%	-	99.999%
UASB + CWs	-	82%	79%	70%	70%	89%	99.998%

UASB + DHS	96%	91%	93%	28%	40%	-	99.95%
UASB + SBR	97%	94%	98%	100%	77%	65%	-

Irrigation suitability of post-treated effluents

The UASB reactor process has been recognized as one of the environment friendly methods for treatment of urban wastewater in tropical countries due to its low capital investment, less land and energy requirements, less sludge generation, low maintenance cost and its potential to generate biogas. Effluent from this reactor, however, does not meet the disposal standards specifically in relation to organic content, suspended solids, nutrients and pathogen content. This makes the post-treatment of UASB reactor effluent necessary before its discharge into water bodies or its reuse in irrigation (Nair and Ahammed, 2013).

Domestic sewage treatment using UASB reactor is an interesting approach, provided the recovery of carbon in the form of energy-rich methane gas and nutrients. However, the effluent reusing for agriculture has some constraint because of the presence of pathogenic organisms and over nutrient dosage in the non-growing season. The UASB effluent still contain excess nutrients, salts and pathogens and is to be post-treated to remove pathogens after which the effluent can be used for irrigation and fertilization purposes. Unrestricted irrigation requires a high degree of pathogen removal and will increase the overall treatment costs. At presently, constructed wetland brings interesting results in removal of pathogens more effectively in a cost-effective way. The big advantage of this post-treatment system is its simplicity in operation, and the low investment costs when land prizes are low (van Lier et al., 2002) (*Fig. 5*).

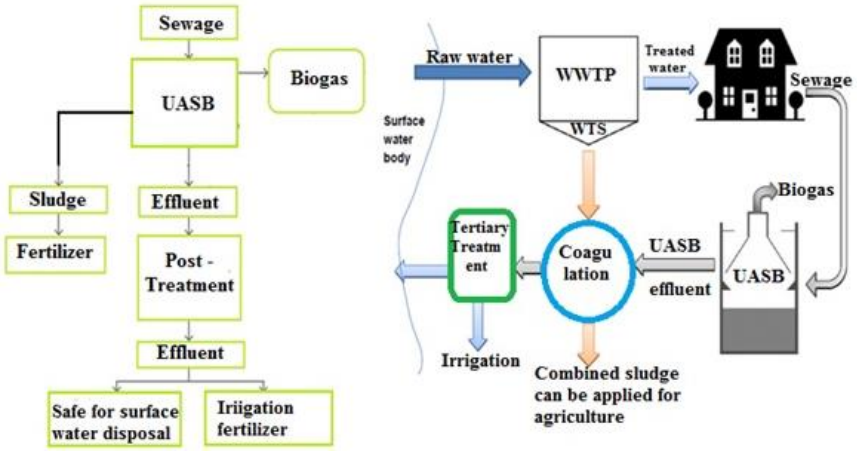

Figure 5. *(a) Post-treatment of UASB reactor domestic sewage effluents by onsite treatment options like CW for pathogen reduction and subsequent agricultural reuse (modified from van Lier et al., 1999) and (b) conceptual framework of reuse of treatment plant biosolids for UASB effluent post-treatment (Nair and Ahammed, 2013)*

Factors influencing the UASB reactors performance

The anaerobic process is a vital option for the treatment of industrial and domestic wastewater. The UASB reactor technology proved economically more attractive for treating sewage in both tropical and subtropical countries. However, a wide range of factors influence its performance efficiency. The most important factors are designing of UASB following parameters such as operational conditions (temperature, pH, organic loading rate, hydraulic retention time, and up-flow velocity), wastewater characteristics (influent concentration, influent particle size and influent particle charge), and sludge bed characteristics (particle size distribution, extra cellular polymeric substances and charge) and toxic substances should be considered as the most important factors affecting performance efficiency of UASB reactor (Sushma and Pal, 2013).

pH (potential hydrogen)

Due to the formation of different intermediates, anaerobic reactions are highly dependent on pH value particularly for methane producing bacterial ranging in 6.8-7.2. While, acid forming bacteria can survive in a more acidic condition. So, the pH of anaerobic system should be maintained between the methanogenic limits to avoid the predominance of the acid forming bacteria which may cause volatile acid accumulation. Therefore, microbial groups involved in each phase require different pH conditions for optimum growth. To achieve this, it is essential to provide buffering agents like sodium bicarbonate to neutralize any eventual VFAs accumulation. Addition of NaHCO3 is useful for supplementing the alkalinity, which shifts the equilibrium to the desired condition without disturbing the microbial population (Saleh and Mahmood, 2004).

Temperature

An aerobic occurs under a variety of temperatures depending on the species of microorganisms employed. In general, controlled anaerobic digestion is subdivided into

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

three temperature ranges, psychrophilic (10-20 ℃), mesophilic (20-40 ℃), and thermophilic (50-60 ℃). The structures of the active microbial communities at each temperature optima are quite different. For example, bacterial growth and conversion of organic materials is slower under psychrophilic conditions.

The rate of methane production increases as temperature increases until maximum mesophilic temperature ranges, 35-37 ℃, because in this temperature ranges mesophilic microorganisms are actively involved. In general, biogas production yield depends on the choice of optimal temperature conditions for microorganism activity. most conventional anaerobic digestion processes occur under mesophilic temperatures. Because, this operation conditions are more stable and requires less energy input compared to operations under thermophilic conditions, and results in a higher degree of digestion (De Mes et al., 2003). The maximum (i.e., thermophilic) and minimum (psychrophilic) temperatures explains the limits of the temperature ranges for microbial optimal growth rate. The optimum temperature ranges are suitable conditions for maximum microbial growth rate. While the microbial growth become typically low below the optimal temperature levels and in some extent, it increases its growth exponentially at higher temperatures but some while microbial growth become restricted. The temperature effects on the removal efficiency of the anaerobic reactors depend on the type of the reactor as well. For example, a decline of the removal efficiency of the UASB reactor at lower temperature is due to the decreases in biological activity (Chernicharo, 2007).

C/N ratio

Unbalanced C/N ratio is one of a limiting factors of anaerobic digestion. Substrates with high C/N ratios, such as paper and most crop residues will be deficient in nitrogen, which is an essential nutrient for microbial cell growth. Thus, anaerobic digestion of very high C/N ratios may be limited by nitrogen availability. In the case of substrates with low C/N ratios, such as some animal manure, toxic ammonia build-up may become a problem. To overcome deficiencies in either carbon or nitrogen, co-digestion of low C/N materials with high C/N materials has been proven an effective solution (Martin-Ryals, 2012).

Organic loading rate (OLRs)

Organic loading rate is defined as the number of volatile solids or chemical oxygen demand fed to the system per unit volume per time. Higher OLRs can allow for smaller reactor volumes thereby reducing the associated capital cost. However, at high OLRs there is a danger in overloading of the reactor, especially during reactor start-up. At higher OLRs, retention times must be long enough such that the microorganisms have enough time to sufficiently degrade the material. Thus, there is a balance between OLR and HRT that must be determined in order to optimize digestion efficiency and reactor volume (Martin-Ryals, 2012). Hydraulic retention time (HRT) can be defined as the amount of time that waste remains in the digester and in contact with the biomass. For easily biodegradable compounds such as sugar, the HRT is low whereas more complex compounds need longer HRTs. HRT values influences the rate and extent of methane generation and is one of the most significant factors affecting the transformation of volatile substrates into gaseous products (De Kock, 2015).

DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

Nutrients

Nutrient at optimal levels are important for microorganisms for cellular building blocks and ensures that the cells are able to synthesize enzymes and co-factors responsible for driving metabolic activities. These include macronutrients such as nitrogen, phosphorous and Sulphur, vitamins and trace elements (iron, nickel, magnesium, selenium, copper, and cobalt). Even though, nutrients are required in very low amounts, lack of them causes significant effect on growth of microbes (De Kock, 2015).

UASB reactor removal efficiency

The efficiency and reliability the treatment system of a domestic sewage containing of an anaerobic reactor were assessed. Considering the slight balance of the micro-biota arose following the sludge extractions and these promoted reactor imbalances. This additional took about a reduction in reactor performance and hence of the over-all sustainability of the reactor development when treating domestic sewage directly. On the other hand, the system could not eliminate the nutrients such as nitrogen and phosphorus (Aiyuk et al., 2010). For example, performance assessment of complete scale UASB reactor in India by Sharda et al. (2013) indicates that, the high BOD and COD removal efficiencies. These high elimination efficiencies of the UASB reactor might be due to the proper functioning of the reactor.

While, the TSS removal efficiency was reduced, this may be attributed due to the high volatile suspended solids resulting in the creation of granular sludge bed in the UASB reactor. Similarly, performance assessment of full-scale UASB reactor in Ethiopia shows that higher removal efficiency in terms of COD while it was limited in removal of BOD, TSS and nutrients (Kebena, 2014). *Figure 6* demonstrates that the performance competence of full-scale anaerobic reactor treating domestic and industrial wastewaters.

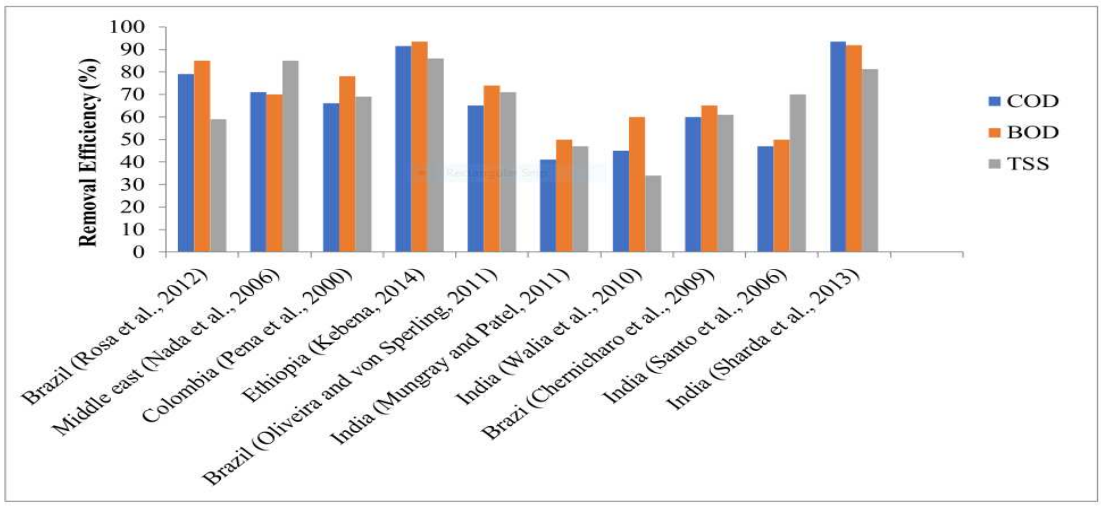

Figure 6. *Performance efficiency of full-scale anaerobic reactor treating sewage and brewery wastewater (Sharda et al., 2013; Kebena, 2014) treatment plants in different parts of the world*

The process efficiency of UASB reactor efficiency depends on diverse issues like strength and composition of wastewater, temperature and diurnal fluctuations. The

DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

dissolved mineralized compounds such as sulfides ortho-phosphate and ammonia, in the effluent also varied with factors. The performance of these treatment systems highly depends on temperature and decreases with a decrease in temperature (Khan et al., 2011) The performance efficiency of pilot and complete scale UASB reactor in treating sewage and industrial wastewater at different temperature and hydraulic retention time is summarized in *Table 2*.

India is a foremost country in terms of sewage wastewater treatment by UASB development where 37 UASB grounded sewage treatment plants (STPs) is already operating. It has been requested that 80% of total UASB reactors installed worldwide for sewage treatment are in India. The straightforward approach towards the selection of this technology for sewage treatment is due to its low capital cost, low energy requirements, small operation and maintenance costs and sustainability aspect. The performance of three STPs at Agra, Surat and Ludhiana (i.e., 78, 100, and 48 MLD) was greatest and the removal of COD, BOD and TSS was 45-48%, 29-43% and 40-51% respectively. The reason for poor performance was improper operation and maintenance and lack of screening control, grit removal and sludge wasting. The performance of 27 and 152 MLD at Noida and Ludhiana reactors was observed relatively good with the BOD, COD and TSS removal efficiencies of 53-59; 41-55 and 49-59%, respectively (Khan et al., 2014) (*Fig. 7*).

These results indicated that UASB reactor requires post treatment in order to obey with the removal standards. The monitoring of 10 STPs of diverse cities of India was agreed out in order to investigate their performance. The primary objective of research was to evaluate the treatment performance of full-scale UASB reactors and diverse post treatment systems. The general performance of these STPs was extended from 66 to 95% for BOD, COD and TSS removal (*Fig. 8*). However, three UASB reactors at 78, 100 and 48 MLD STPs at Agra, Surat and Ludhiana revealed minor treatment efficiency due to poor operation and maintenance (Khan et al., 2014).

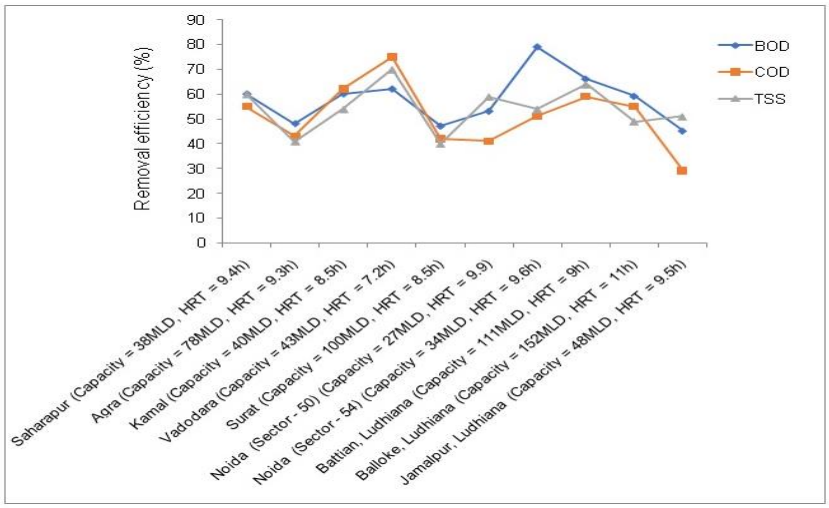

Figure 7. *Performance efficiency of full scale UASB reactor in treating sewage at different cities of Indian towns*

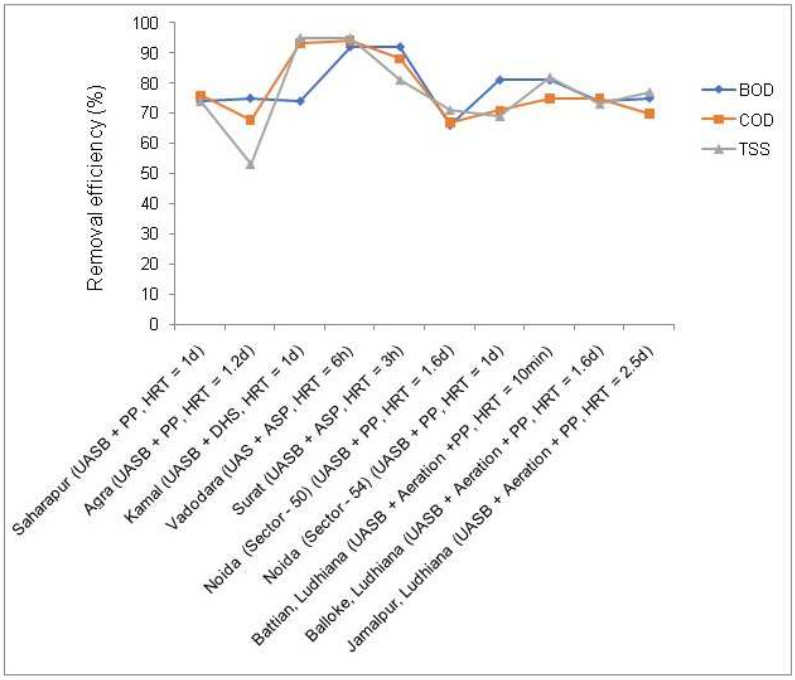

Figure 8. *Removal efficiency of the full-scale UASB reactor integrated with different post-treatment systems in different cities of India*

According to Mahmood et al. (2013) investigation, the laboratory scale UASB reactor performance for the treatment of original wastewater of COD concentration of 474 mg/l was reduced to 297 mg/l with 37.3% removal efficiency. Similarly, the TSS, BOD, NO_3 - N, and NH_4 - N were reduced from 1400 mg/l, 84.8 mg/l, 16 mg/l and 82 mg/l to 115 mg/l, 18.5 mg/l, 16 mg/l and 10 mg/l with removal efficiency of 91.7%, 78%, 88.9% and 87.8% respectively. Similarly, Khan et al. (2011) pilot scale of UASB reactor in treating sewage indicated that the performance efficiency of BOD, COD, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

TSS was 66.3%, 60.1% and 62%, respectively. The indicators of pathogens that is FC in UASB reactor was reduced to 10%. The removal of reduced species like NH_4 - N, NO_3 - N and PO_4 - P were insignificant in both pilot and full scale UASB reactors. The performance efficiency of pilot scale and full scale UASB reactors operated at OLR of 60 L and HRT of 8 h in removal organics, nutrients and pathogens were shown in *Figure 9a* and *b*.

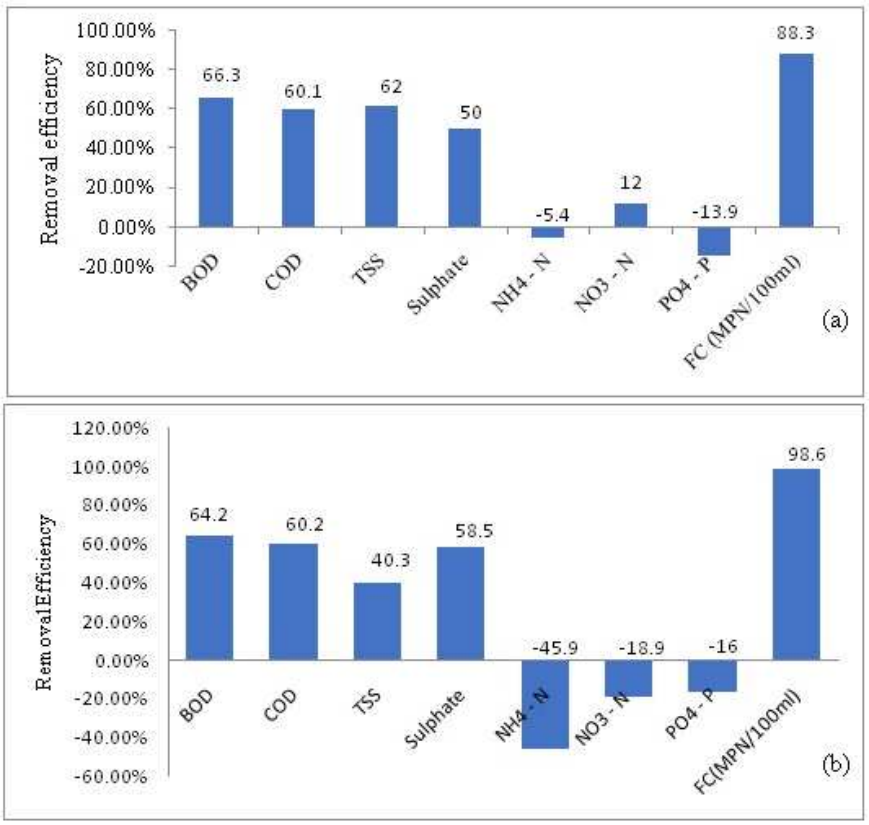

Figure 9. *Performance efficiency of UASB reactor at (a) pilot scale and (b) full scale levels in treating sewage wastewater*

The performance of the 111 ML/day full scale UASB reactor was also evaluated by Khan et al. (2011). The performance of full- and pilot-scale UASB reactors at ambient temperature (from 9 to 39 °C) was comparable. The percentage COD, TSS and BOD removal efficiency in the full-scale UASB reactor varied between 55 and 65%, whereas the removal in pilot scale ranged from 60 to 70%. The indicator of pathogens, which is FC in UASB reactors, was decreased to 10%. The removal of NH_4 - N, NO_3 - N and PO_4 - P were insignificant in both UASB reactors; the effluent pH remained within the optimal working range for anaerobic digestion (6.9-7.9). The research results were consistent with other UASB reactors investigated by El-Khateeb and El-Bahrawy (2003), i.e., the concentrations of COD, BOD, and TSS were decreased by 67.7%, 71.4% and 65.5%, respectively.

On the other hand, the TKN and TP were also reduced by removal efficiency of 11.3% and 23% respectively including fecal coliform removal efficiency of 96.7%. This high removal efficiency of COD, BOD and TSS is mainly attributed due to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

relatively high sludge residence time (HRT = 38.1 days), which improves the hydrolysis and biodegradation of organic matter of wastewater content. Whereas the UASB reactor removed only the particulate nutrients by sedimentation and filtration and therefore, it had relatively low nutrient removal efficiency (El-Khateeb and El-Bahrawy, 2013).

Removal efficiency of UASB-CWs

Up-flow anaerobic sludge blanket (UASB) proved to be a cost-effective pretreatment system for wastewater. In addition, constructed wetlands provides a low-cost alternative for wastewater treatment in developing countries mainly in the arid and semi-arid regions. According to El-Khateeb et al. (2009) investigation, UASB reactor was used as a mainly treatment step followed by a horizontal subsurface constructed wetland for the treatment of grey municipal wastewater. The HRT and organic loading rate of the UASB reactor was 6 h and 1.88 Kg COD/m^3/day respectively. Within these operating conditions, the COD removal efficiency of the UASB reactor was 60%. Further enhancement of the quality of the treated wastewater was attained after the application of HSSFCW. The overall removal efficiency of the complete systems for COD, BOD and TSS were 87.7%, 89.5% and 94%, respectively (*Fig. 10*).

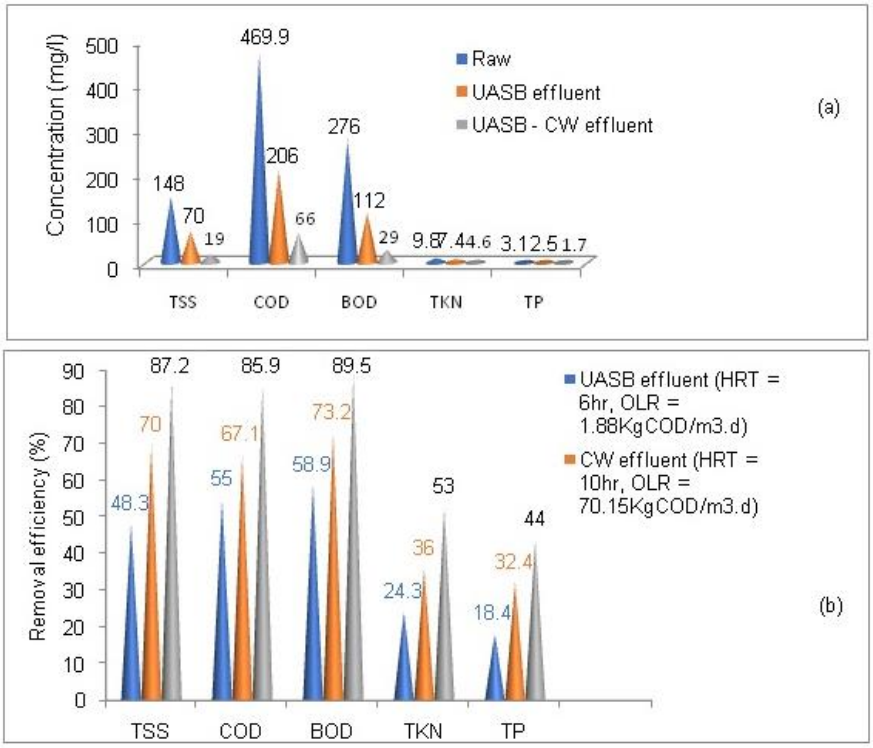

Figure 10. *(a) Concentration of raw grey wastewater and (b) removal efficiency of UASB-CWs in treating grey wastewater*

El-Khateeb and El-Bahrawy (2003) also found that the UASB reactor was operated at wastewater temperature varying from 15 °C during winter time to 30 °C during summer time. The UASB reactor efficiency at 8 h HRT was quite satisfactory. Average removal of COD and TSS were 63.2% and 66.5% respectively. The removal of FC in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

the reactor was 86%. After post-treatment with SSF CW COD reduction of 78%, BOD reduction of 78%, TSS and TP reduction of 78% and 79% were obtained respectively. The comparison of the removal competence of UASB reactor and its SSF CW integrated system in removal of COD, BOD, TSS, NH_4 - N, TKN, TP and FC are indicated in *Figure 11*.

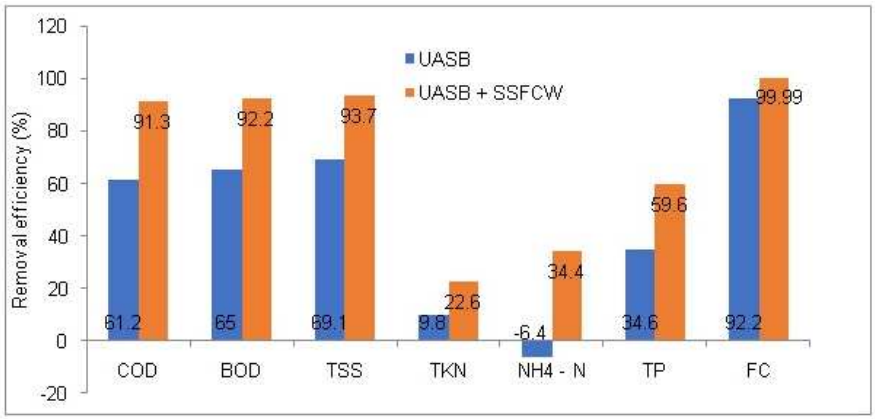

Figure 11. *Comparison between UASB reactor and UASB-SSFCW in removal of pollutants from sewage wastewater*

The likelihood of using treatment schemes consists of a UASB reactor tracked by subsurface flow constructed wetland for the treatment of sewage water is an effective system. The UASB reactor was designed at operating conditions of HRT (6 h), HLR (4 m^3//day), and OLR (2.45 Kg/m^3/day). The performance of this reactor for the treatment of raw sewage indicates that the concentration of COD, BOD, TSS, TN and TP were reduced by 67.7%, 71.4%, 65.5%, 11.3% and 23% respectively. The bacterial count was reduced to 96.7%. *Figure 12* shows that the performance of SSF wetland unit integrated with UASB reactor. The concentration of ammonia also greatly decreased in the final effluent of SSF unit. This may be due to aerobic conditions adjacent the root section of the plant in the CW unit (El-Khateeb and El-Bahrawy, 2013).

Research studies indicated that nitrogen and phosphorus elimination by plant uptake is not a significant mechanism for the removal of these elements in wetlands receipt moderately treated municipal wastewater because nitrogen and phosphorus are taken-up and free in the cycle of plant growth and death. In El-Khateeb and El-Bahrawy (2003) finding, the removal of TP was initiate to be high at the beginning of the experiment. As the plant reaches the maturation state the removal was decreased and there is some release of phosphorus from the dead parts of the plant. The removal efficiency the SSF CW was increased and noted that the final effluent was complying the WHO guidelines for treated effluent reuse.

According to Cheng et al. (2010) investigation, the removal percentage of pollutants in the influent and effluent following the UASB - CW1 - CW2 treatment systems achieved a greater reduction of pollutants (i.e., COD removal of 93.9%). The result indicates that the UASB reactor is capable of removing 60-80% of total COD, 75-85% of BOD, and 70-80% of total SS from the raw sewage, while the removal efficiency of nutrients such as TN and TP are only 10-25% and 10-20%, respectively. This removal limitation of UASB reactor can be improved by utilization of some aerobic processes such as activated sludge and constructed wetlands. *Figure 15* shows changes of NH_4 -

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

N, NO_3 - N and PO_4 - P concentrations in the influent and effluent of the treatment units. From the data presented, the UASB reactor only removed 75% of NH_4 - N, 3.9% of NO_3 - N and 42.9% of PO_4 - P. However, the CWs removed almost over 85% of NH_4- N and PO_4 - P except NO_3 - N. The removal of NH_4 - N may be due to its oxidation into nitrite and nitrate–nitrogen compounds by microbial processes. Less removal of NO_3 - N may be due to the leaves of floating lettuces covered almost all the water surface in CW2 and protected direct sunlight from penetrating into the water body could suppress the growth of algae cells. As a result, the nitrogen removal capacity of the CW could be reduced. Whereas, the removal of TP levels in the UASB reactor was 42.9%, this may be achieved by metabolism of anaerobes and adsorption into the sludge. This less removal of TP can be improved by integrating with CW, in which the CW removes TP by microbial metabolism and plant uptake (*Fig. 13*).

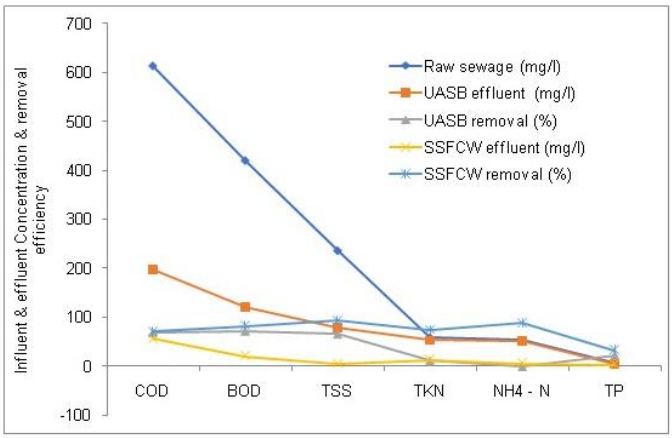

Figure 12. *Performance of the UASB reactor alone and post treated with SSFCW of raw sewage*

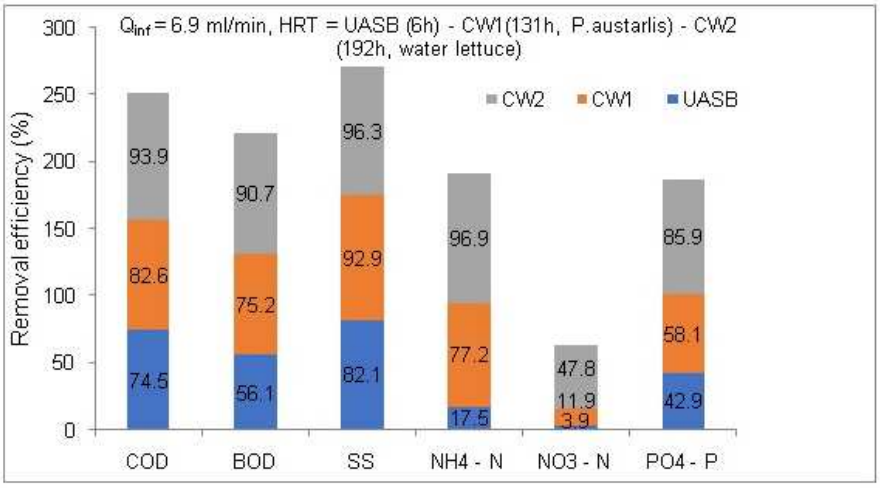

Figure 13. *Removal efficiency of UASB-CW1-CW2 in treating mixture of raw sewage and partially treated swine wastewater*

Similar study on the use of UASB reactor followed by a HSSFCW treatment system showed an important health advantage. In specific, there were no substantial odor

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

emissions, and there was no indication of the proliferation of insects and other disease vectors. According to Raboni et al. (2015) investigations, the quality of raw sewage indicates that a high strength characteristic. Treatment of this sewage with UASB reactor results in the achievement of average removal efficiencies in the UASB reactor as high as 74% for BOD5, 71.15 for COD, and 65% for TSS. With regard to fecal indicators, the removal efficiency of UASB reactor appears low (i.e., 67.4% for fecal coliforms and 65.2% for fecal enterococci). Further treatment of UASB reactor effluents with SSFCW achieves removal efficiency of 92.9% for BOD5, 79.2% for COD, and 94% for TSS.

In addition to this, the SSFCW step concludes the removal of pathogens with an overall removal efficiency of 98.8% for fecal coliforms and 97.9% for fecal enterococci. The overall removal efficiency of the UASB reactor joint with subsurface flow constructed wetland on the removal of pollutants from raw sewage wastewater were indicated in *Figure 14*.

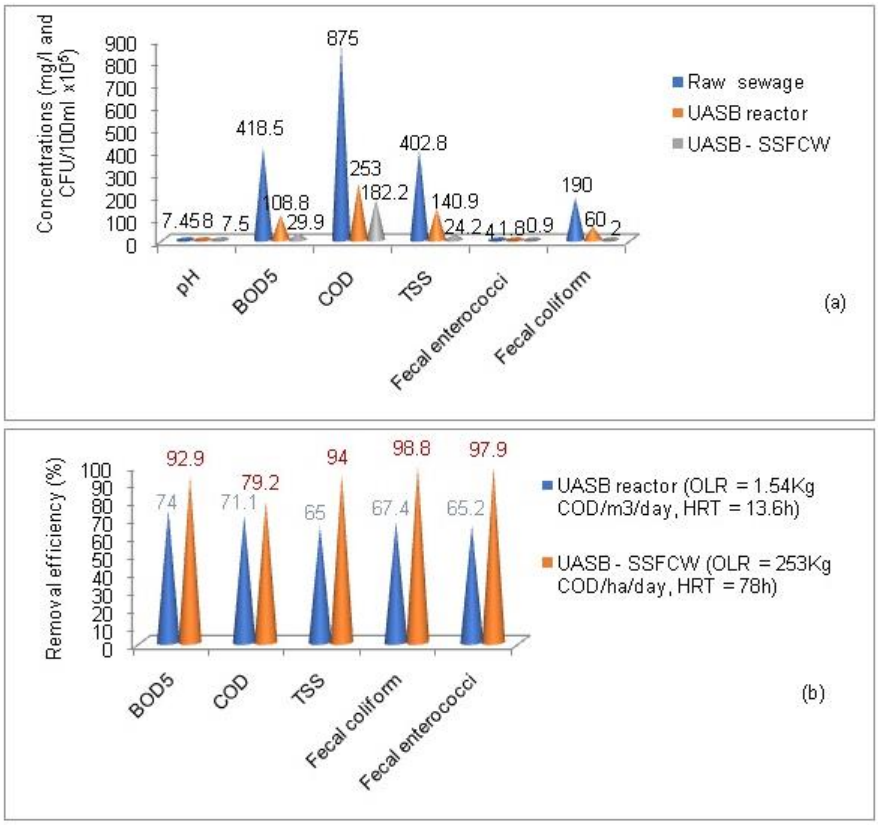

Figure 14. *(a) Concentration of pollutants in raw sewage, UASB and SSFCW and (b) removal efficiency of combined UASB-SSFCW treatment system*

It was observed that the effluent from the UASB reactor still contains significant count of fecal coliforms. These counts are larger than the permissible limit set by WHO (1989) for unrestricted irrigation. The feasibility of widespread post treatment using a horizontal subsurface flow constructed wetland for the treatment of sewage water has been studied by El-Khateeb and El-Bahrawy (2003). The result showed that the UASB-HSSFCW integrated treatment system was found to be efficient for removal of COD, BOD and TSS including nutrients and fecal coliforms. These may attribute due to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

aerobic conditions near the root zone of the plants in the wetland units. Similarly, the water quality parameters at different sampling themes of hybrid system of UASB-CW were reduced due to through three systems. The overall removal competence of the UASB - SFCW - SSFCW was 91% for COD, 91.2% for BOD and 97.9% for TSS at applied organic loading rate in the range of 1200-6500 g BOD/m^2/day in UASB and 5-21 g BOD/m^2/day (10 g BOD/m^2/day on average for the two CW units) (de la Varga et al., 2013) (*Fig. 15*).

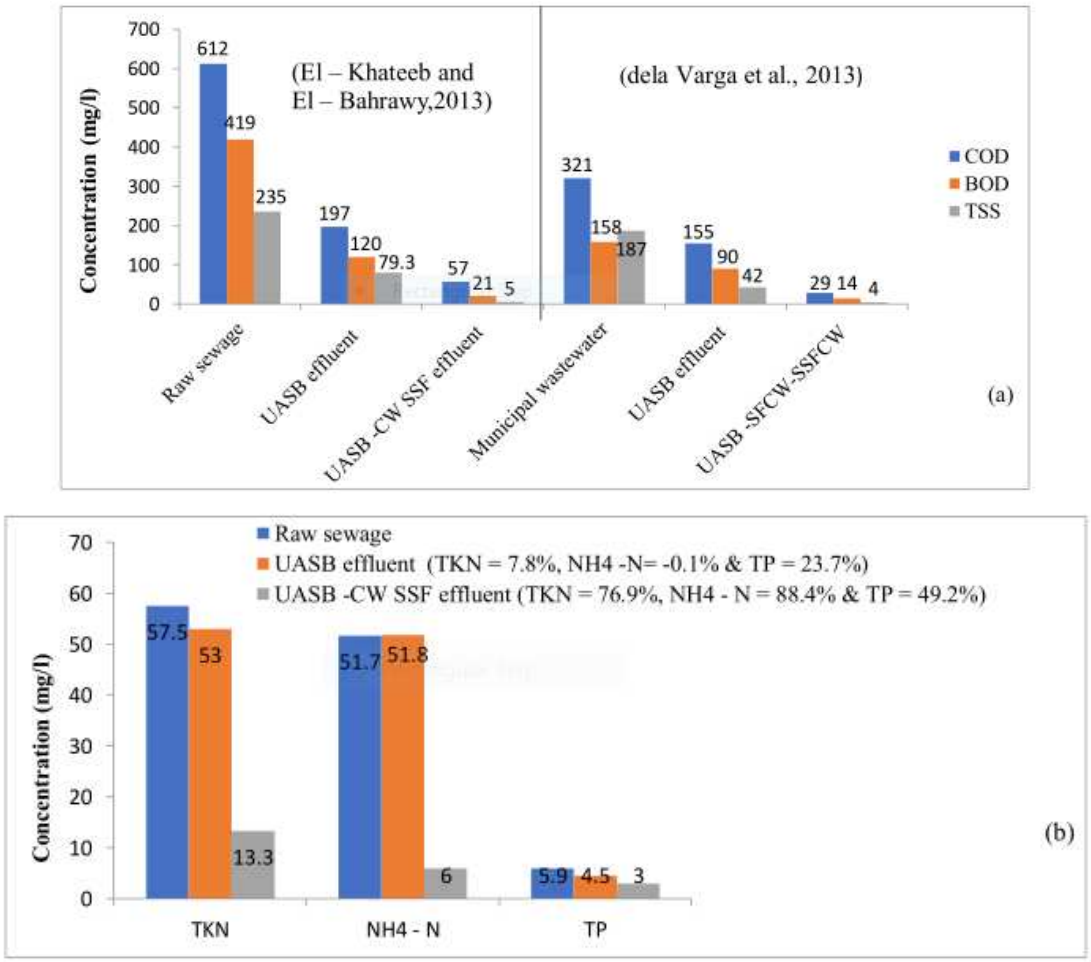

Figure 15. *Concentration of pollutants in raw sewage, UASB and SSFCW effluents and removal efficiency of combined UASB/SSFCW system (a and b)*

The anaerobic bioreactor indicates that removal of the residual concentration of organic (BOD and COD) less infective which usually exceeds the extreme permissible level prescribed by the effluent discharge standards of most developing countries. From this stand point; post treatment of anaerobic effluent is necessary to reduce the release of these contaminants to the required level. Due to this, the UASB effluent was further treated by CW at HRT of 3 days. The original wastewater fed into the UASB reactor and then post-treated by laboratory scale CW showed removal efficiencies of COD, BOD, TSS, nitrates and Ammonia were 82.4%, 78-82%, 91.7%, 88-92% and 100%, respectively (Mahmood et al., 2013). The overall results on the elimination efficiencies of the UASB-CW is summarized in *Table 3*.

The performance efficiency of constructed wetland integrated with UASB reactor is comparable with other post treatment techniques. According to Sharda et al. (2013) investigation, the assessment of the performance efficiency of a full scale brewery wastewater treatment plant, UASB reactor plus aeration (holding capacity of 380 m^3 at HRT of 23 h) followed by sand and activated carbon filter (holding capacity of 15 m^3 at HRT of 1 h) for a period of thirteen weeks showed an overall percentage reduction of COD, TSS and BOD values ranges from 96-98%, 88-98%, and 99% respectively. Similarly, Gasparikova et al. (2005) investigates, characterization of real wastewater treatment plant working on the principle of anaerobic-aerobic system, there was a problem with the high organic pollution on the effluent of anaerobic-aerobic treatment system. The high COD and BOD effluent concentration as well as TSS concentration are due to the incorrect operation of the wastewater treatment plant.

Among these operation problems, the primary settling tank was full of greases which lead to failure of the process. Another problem may rise from location of the air blower that used for oxygen delivery, which is inside the plastic tank of the wastewater treatment plant. The air circulates only there and no fresh air gets inside which means that there is not adequate oxygen for the aerobic post-treatment. This operation causes the presence of filamentous bacteria in the aerated part. Another study by Sharda et al. (2013), on the general performance of the brewery wastewater treatment plant indicates a reduction in TSS, COD and BOD. During the three-month study periods of the brewery's wastewater treatment plant, the overall removal efficiencies of TSS, COD and BOD were ranges from 96-98%,88-98% and 99% respectively which may be due to the proper functioning of the remaining treatment units such as aeration tank, sand filter and activated carbon filter. The comparison of overall performance of UASB reactor followed by different post treatment techniques are indicated in *Figure 16*.

According to Bhatti et al. (2014), UASB effluent was treated with 40% H_2 O_2 in a further step. A 2 ml/l dose of H_2O_2 was originate to be very effective and shows a removal of 73% for TSS, 99.9% for COD, 84% for TN and 19.8% for PO4 3 - Post-treatment of UASB effluents using H_2 O_2 was very attractive in removal of COD and TN. Similarly, the combined UASB-DHS system was operated continuously and the result showed that UASB-DHS system performs satisfactorily even at high organic loading rate. The total removal efficiency of the COD, BOD, and TSS were 93%, 93%,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

and 98%, respectively, during the first phase and decreased by 1% and 2% during the second and third phases, respectively (Doma et al., 2016) (*Fig. 17*).

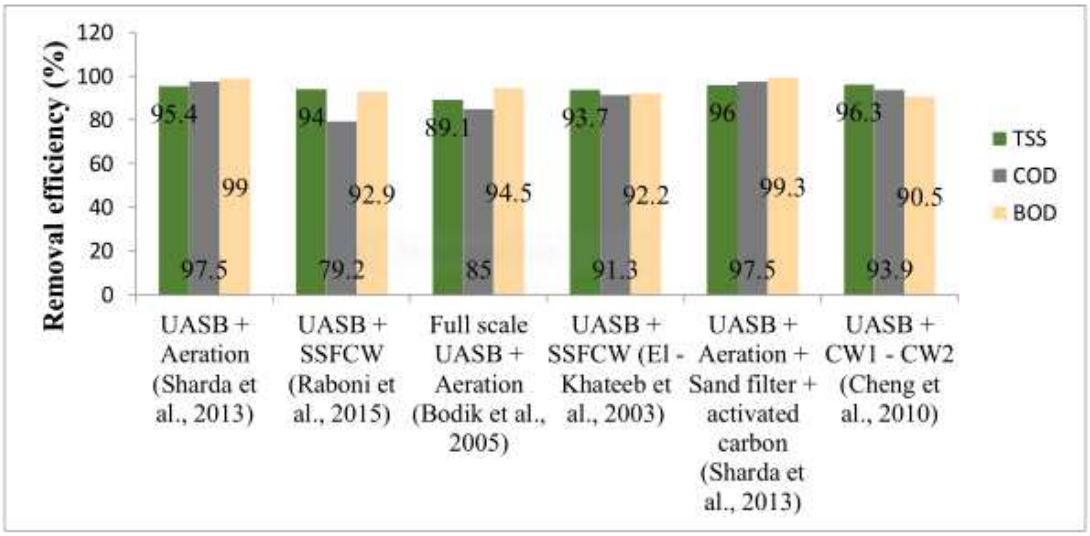

Figure 16. *TSS, COD and BOD removal efficiencies of UASB reactor integrated with different post-treatment system*

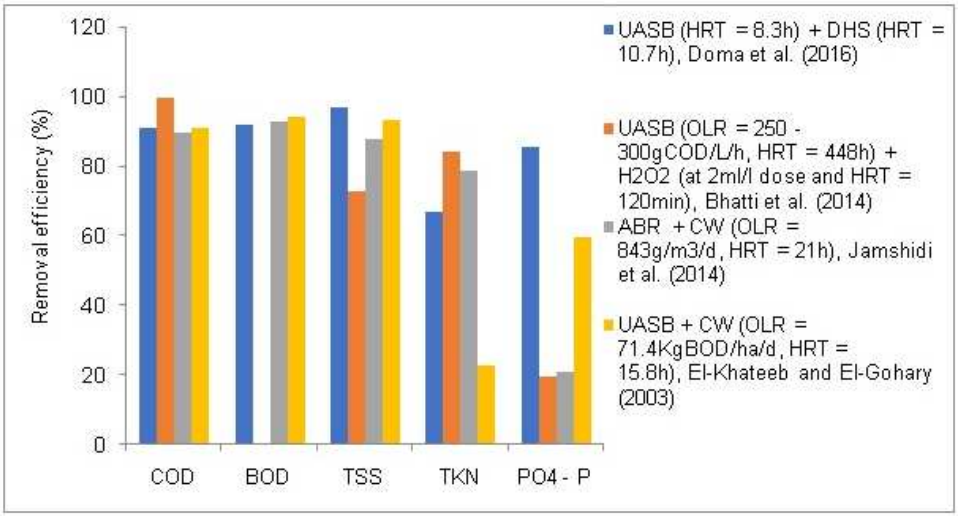

Figure 17. *Nutrient removal efficiencies of UASB reactor integrated with different post-treatment techniques*

Conclusion and recommendations

Conclusion

Now days, the strategies of treating domestic, municipal and industrial wastewaters by common and aerobic processes were shifted to the anaerobic processes. Globally, the following abatement efficiencies were achieved by UASB reactor: COD ranges from 29-92.9%, BOD ranges from 45-93.4%, TSS ranges from 40-82.6%, TKN and TP from negative values up to 74.8% and 23% and FC up to 98.6% respectively for both lab and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31013129

full scales. Despite its success, UASB reactors are regularly unable to attain most of the present effluent discharge standards due to presence of high residual COD and BOD, nutrients and pathogens.

All these features make the UASB treatment of wastewater is a very significant field of research, where enhancements and new progresses are needed to overcome the problem. Thus, additional post treatment approach is compulsory for the anaerobic bioreactor treated effluents for sustainable reuse. At present, integrated constructed wetlands are recognized as a reliable wastewater technology because, they are low cost, simply functioned and sustained and have a strong potential for application in developing countries.

Most research investigation results revealed that use of a UASB reactor followed by a subsurface horizontal flow phytoremediation treatment system is a hopeful natural technology in the treatment of municipal or industrial wastewater. Because, the combined treatment system was found to complying with WHO (1989) standards for treated effluent reuse. Globally, the subsequent abatement efficiencies were achieved using UASB-CW treatment systems: COD ranges from 79.2-93.9%, BOD ranges from 89.2-92.9%, TSS ranges from 87.2-96.3%, TKN ranges from 22.6-96.9%, TP ranges from 33 to 85.9%, and FC ranges from 97.9 to 99.99%, respectively.

Recommendations

Enhanced water quality change due to industrial pollution is one of the great environmental concerns in the world. Most of the wastewaters in developing countries are still discharged directly to rivers, streams and open lands without adequate and comprehensive management. To reduce the indiscriminate disposal of these industrial and municipal wastewaters it is essential to provide a low-cost strategy which can bring comprehensive resource management. Literature review indicates that UASB-CW technologies are effectively integrated treatment particularly for resource scarce developing countries to adopt wastewater treatment, the treatment technologies must be cost-effective and easy to adopt, requires less energy input, easy operation and maintenance costs. Therefore, it is inevitable to adopt this technology in our country for in order to encounter effluent discharge standards with low costs.

(Received 30th Aug 2019; accepted 12th Feb 2020)

Abstract. Reasonable allocation of water resources in dryland pastures plays a decisive role in local ecological protection and economic development. Changes in the local climate and vegetation have a direct impact on the local runoff. With Darhan Muminggan Joint Banner (DM Banner) as the study area in China, we made use of the Soil and Water Assessment Tool (SWAT) hydrological model, calibrated and fitted the parameters into the model according to the local meteorological statistics and data on land utilization, soil texture and runoff. After fitting and calibration, we built a SWAT model for arid desert grasslands to simulate and forecast re-distribution of water resources in the study area under changes in the climate and vegetation. This study is expected to provide technical support for reasonable development and utilization of water resources in dryland pastures as well as ecological recovery in Inner Mongolia of China.
Keywords: *water resources, SWAT model, hydrological response unit, scenario simulation, efficient utilization*

Introduction

The hydrological process of surface runoff is a very complicated natural mechanism subject to impacts of multiple factors including the climate, geomorphological conditions and vegetation. This process follows varied working mechanisms under different dimensions of time and space, and the accompanying water dynamics and water circulation in the process is subject to changes by time, space and the conditions of the underlying surface. The hydrological process can be divided into three interconnected parts: the physical process, the chemical process and the ecological effect. The runoff yield and confluence are closely correlated with the hydrological process in dryland pastures (Wang et al., 2003, 2008; Zhang et al., 2003, 2005; Huang and Zhang, 2010).

To identify the mechanism of the hydrological cycle in the arid pastoral area under climate changes and intensive human activities in this region of China, this study used the SWAT model to simulate the runoff of the arid pastoral area in DM Banner in Inner Mongolia, China, and analyzed the changes in the runoff with changes in land utilization to provide a scientific basis for optimized management of land resources and water resources in this region.

Review of Literature

The SWAT model is a distributed hydrological model developed by USDA Agricultural Research Center (USDA-ARS), which is a distributed hydrological model developed on the basis of CREAMS, EPIC, GLEAMS and other models. SWAT model can simulate the effects of land management activities on water volume and quality, sediment migration, pesticide and nutrient leaching in large and complex rivers (Hoang et al., 2017). Manoj and Friedrich (2016) applied SWAT model to conduct comparative evaluation on the simulation results of runoff and nutrient loads in Onkaparingacatchment basin of south Australia through single-station and multi-station calibration. Bannwarth et al. (2014) applied SWAT model to simulate the pesticide transport in Mae Sa basin in northern Chiang mai, Thailand. El-Khoury et al. (2015) used SWAT model to simulate the effects of future climate and land use changes on nitrogen and phosphorus content in Canadian river basins. On the basis of research achievements by international researchers, researchers in China have improved research methods and used new technologies in recent years, and they have made substantial progress in analysis, simulation and forecast of runoff generation and confluence. Many Chinese researchers have done research on changes of runoff in different regions via the SWAT model, such as studies on water basins in Loess Plateau, studies on the Black River basin by Lai et al. (2013), studies on the Wei River basin by Zhao et al. (2015), studies on the Jing River basin along the northern slope of Mount Tianshan in Xinjiang by Meng et al. (2014), and studies on the Kuye River basin by Cheng et al. (2009). Besides, Duan et al. (2014) and Guo et al. (2014) analyzed whether the SWAT model was applicable to research on the Huang-Huai-Hai region. Li et al. (2013) and Yuan et al. (2015) have studied the influence of land utilization and climate changes on the runoff of the Taihu basin and the Liuxi River basin, respectively, in 2013 and 2015. Li et al. (2014) analyzed the characteristics of changes in the land surface albedo on Loess Plateau. Chen et al. (2014) made forecasts on the runoff of the purple-soil slope land in basins and hills in southeast China. Wei et al. (2014) made sensitivity analysis of the SWAT model to landscape changes with the Old Guan River basin in Danjiangkou as the study case in 2014. Yu et al. (2013) improved the computing of the snowmelt module in SWAT with Yingluo Gorge in Shaanxi as the study case.

Studies mentioned above focused on regions including the Loess Plateau, mountainous areas in southwest China and hills in Sichuan and Shanxi; however, there are few studies made on arid grasslands in Inner Mongolia that are subject to semi-arid and arid continental climates in the temperate climate zone. Currently, few studies have been made on correlations between the hydrological process of surface runoff in in China's arid pastoral area and the local climate and ecology, so it is difficult to summarize the hydrological mechanism of this special region according to existing studies.

Materials and Methods

Study Area

Located in the north of Baotou City, Inner Mongolia Autonomous Region, China, Darhan Muminggan Joint Banner adjoins Mongolia on the north, the Wulate Middle Banner of Bayannur City on the west, Wuchuan County of Hohhot and Guyang County of Baotou on the south, and the Siziwang Banner of Ulanqab on the east. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31313145

geographic coordinates are between 41º16´N and 42º45´N, between 109º15´E and 111º25´E. Under the administration of this banner are Bayinhua Town, Mandula Town, Wuke Town, Shibao Town, Bailingmiao Town, Xilamuren Town, Mingan Town and Darhan Sumu, covering an area of 18177 km^2. Subject to the temperate continental climate, the DM Banner has cold winters, dry springs with strong sandstorms and hot summers. The average annual temperature in this region is 4.34℃, the highest annual temperature reaches 38℃ and the lowest reaches -39.4℃. The maximum precipitation is 425.2 mm, the minimum precipitation is 165.3 mm, and the average annual precipitation is 253.45 mm. The average amount of surface water evaporation is 2480.57 mm and the frost-free season lasts 90 to 120 days long. The Banner is located on the north of Mountain Daqing and the central area of the Inner Mongolian Plateau. With the southern region higher than the northern region, the study area has low mountains in the south, mild hills in the north and a flat and open plateau in the center, with an average altitude of 1376 m. With the highest altitude of 1846 m at Habtegegisu Ovoo, mountains in the study area is about 1300 m high, with a relative elevation of 30 m to 100 m. The Tengenor Lake marks the lowest point of the study area, with an altitude of 1058 m. Due to horizontal and vertical soil zones, the soil structure of the DM Banner has salient zonal features; meanwhile, because of differences in the landform and water resources, part of the soil in the study area shows intrazonal features.

The natural vegetation in DM Banner varies as the landform, soil, and hydrothermal conditions differ, forming three vegetation zones – typical arid grassland vegetation zone, desert grassland zone and steppe desert zone, from south to north, with vegetation of steppe deserts as the major type of vegetation. The typical arid grassland is mainly in the southern part of the Banner, accounting for 33% of the total area of grasslands there, the rate of grass coverage reaches 28%. The desert grassland is in the central area of the Banner, covering 27% of the area of the grassland in the Banner, the rate of grassland coverage is between 22% to 23%. The steppe desert is located in the north of the Banner, covering 35% of the area of the grasslands in the Banner, the vegetation is sparse and the rate of grassland coverage is between 15% and 22%.

Database Building and Data Analysis

Through the SWAT2009 model the paper builts a model for the basin of the arid pastoral area in DM Banner. The data required to build the SWAT model are shown in *Table 1*. Of all the parameters used by the model, rainfall uses the series daily precipitation provided by Bailingmiao Hydrological Station and Meteorological Station (not a site) from 1975 to 2015. And meteorological data includes mean daily maximum temperature for 12 months, mean daily minimum temperature for 12 months, daily deviation of monthly maximum temperature, daily deviation of monthly minimum temperature, monthly mean precipitation, monthly precipitation deviation, monthly day precipitation skewness coefficient, two precipitation probabilities of wet and dry transition, monthly mean precipitation days, most half hour precipitation, monthly mean net solar radiation, monthly average dew point temperature and monthly mean wind speed. All the parameters of the Bailingmiao Meteorological and Hydrological stations for 12 months are calculated by programming according to the daily data and written into the meteorological database according to the input format of the model.

DEM-based Hydrological Data Extraction

The basin map is produced based on the surface runoff model and according to the flow routes identified by the concept of hydrological overland flow. This method determines the direction of water flow according to the largest slope between a given grid cell in the DEM (*Figure 1*) and its eight adjacent cells, calculates the area of upstream catchment area of each cell, demarcates a drainage basin according to the threshold of a catchment area and extracts the hydrological features of the study area, as shown in *Figure 2*.

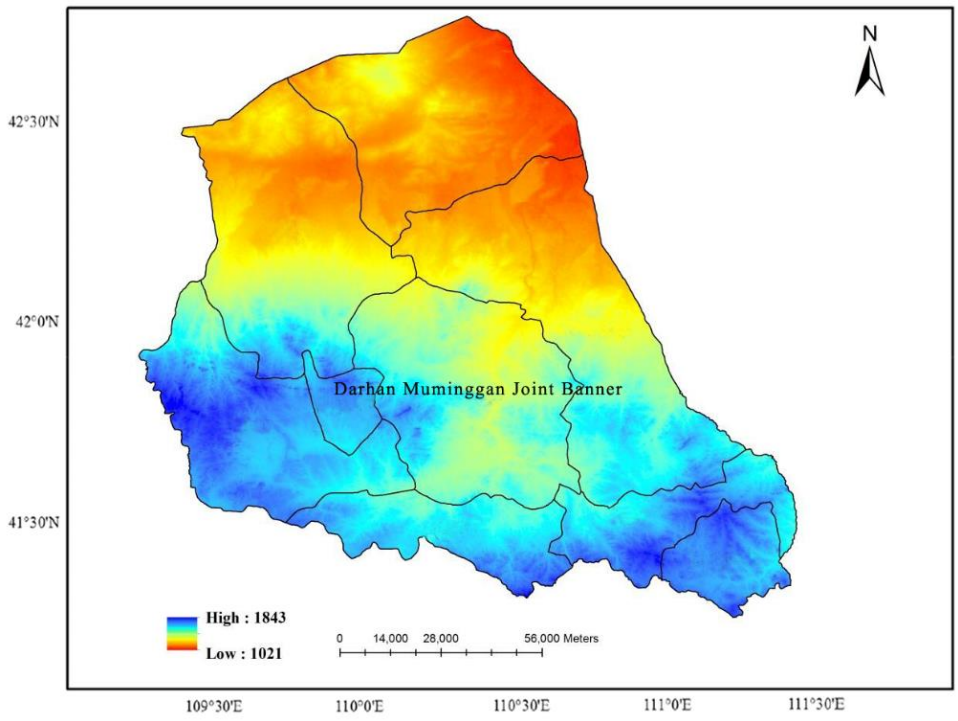

Figure 1. *Digital Elevation Model of DM Banner*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31313145

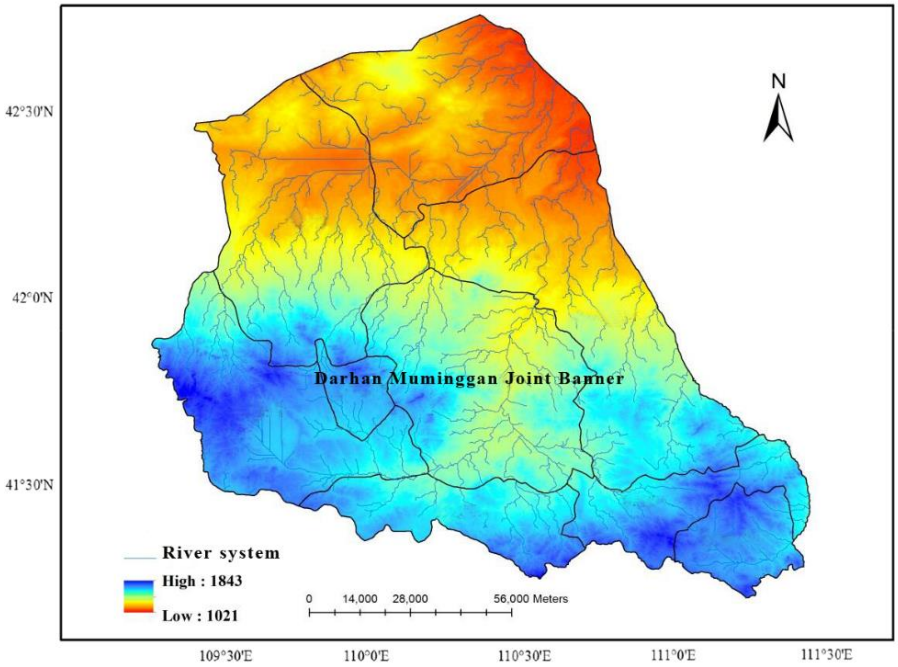

Figure 2. *Natural Drainage System of DM Banner*

Soil Database

The soil database uses the traditional "soil genetic classification" system and the basic charting unit is the subgroup level. There are 12 types of soil in the study area, including Calcic Gleysols (GLk), Cambic Arenosols (ARb), Calcaric Arenosols (ARc), Luvic Calcisols (CLl), Calcaric Fluvisols (FLc), Salic Fluvisols (FLs), Haplic Kastanozems (KSh), Calcic Kastanozems (KSk), Calcaric Phaeozems (PHc), Gleyic Phaeozems (PHg), Calcic Planosols (PLk) and Water Regime (WR), as shown in *Figure 3*.

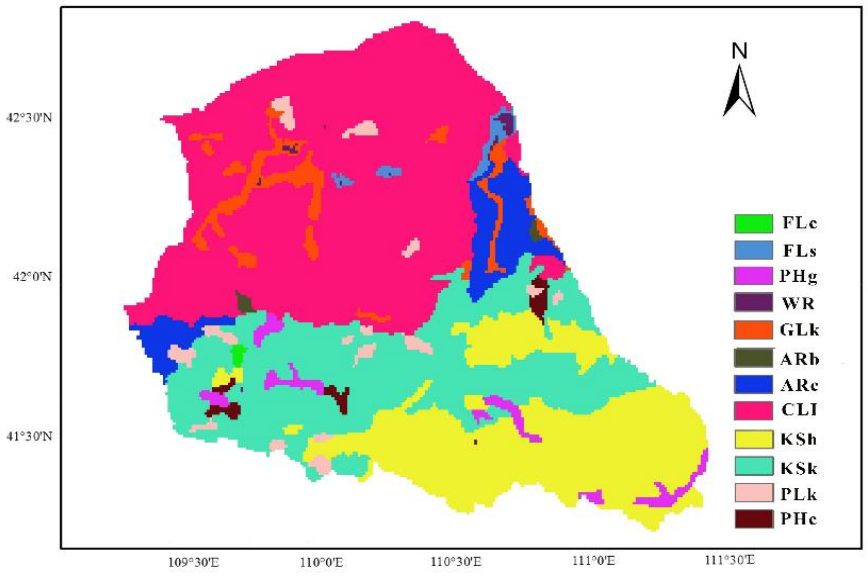

Figure 3. *Types of Soil in DM Banner*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31313145

The soil database needs to input physical and chemical parameters of various types of soil, mainly including soil name, soil stratification number, soil hydrology grouping, total soil thickness, porosity and physical and chemical parameters of each layer of soil. These parameters are given by DM Banner Soil and the physical and chemical parameters' investigation results of typical soil profile.

Vegetation Database

The vegetation map reflects the types of vegetation, the formation and sub-formation of vegetation, the conditions of horizontal zonal features and vertical zonal features. This study classified the vegetation in the study area according to the national land utilization classification system and built a vegetation database, as shown in *Figure 4*. The vegetation map and the attribute data in the vegetation database were connected through the lookup table (luc.txt) of the land utilization data. The physiological parameters of the vegetation are mostly determined through actual surveying, and given the actual conditions, the measured types of vegetation were compared and matched with the configured types of vegetation in the database of the model so that the types of vegetation in the study area were converted to the configured types in the model. The respective physiological parameters were revised according to actual conditions.

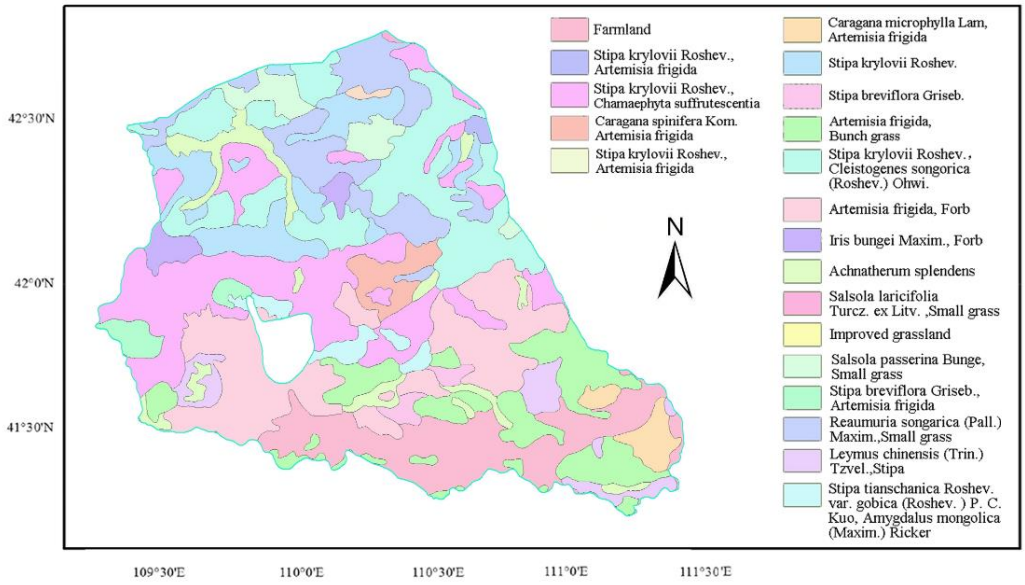

Figure 4. *Vegetation Map of DM Banner*

Hydrological Data

There was only one monitoring section in the study area, so a control node was set at the Bailinmiao Hydrologic Station to be used as runoff control and check section. The time scale was from 1975 to 1996. There are seven artificial reservoirs in the research area, as shown in *Figure 5*. Among them, the total reservoir capacity of Huanghua Beach reservoir, which is of medium and large size, accounts for 45.3% of the total reservoir capacity. And the total reservoir capacity of Yangyoufang reservoir accounts for 25.7% of the total reservoir capacity. The total storage capacity of the above two

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31313145

reservoirs accounts for 71% of the total storage capacity of the region. So the paper selects the above two reservoirs as a representative. In model, all of above two reservoirs' operation parameters, such as normal water level and its corresponding storage capacity, flood discharge level and corresponding storage capacity, hydraulic permeability coefficient of reservoir bottom, the year when the reservoir began to operate, the water storage way and drainage way, are input database. The water consumption data in the study area were obtained from statistical data and visits and surveys of relevant industry departments. According to the above data, the average annual total water consumption of each department in the region was 50,797,000 m³, which was mainly obtained from surface water and groundwater, and the total displacement is 6,688,800 m³, including 721,100 m³ for irrigation regression recharge of groundwater, 4,879,800 m³ for industry, 568,000 m³ for tertiary production, 520,000 m³ for urban residents living.

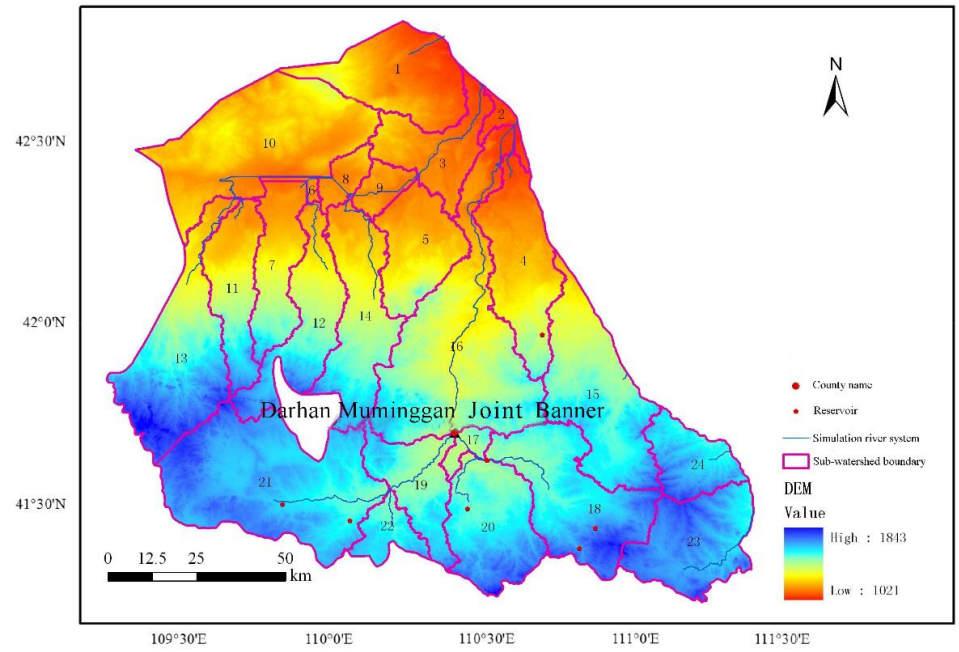

Figure 5. *Drainage System and Sub-Catchments*

The multi-year average water resources utilization and excretion data were modeled. Identifiable file by the model, which is composed of the position of intake and discharge ports, monthly water discharge and monthly water displacement, is input into the model.

Modelling and Result Analysis

Sub-Catchment and Division of Hydrological Response Unit (HRU)

On the distributed hydrological ArcSWAT model platform and according to the pre-set threshold of accumulated flow of 100 km^2, the study area was distributed into 24 sub-catchments, as shown in *Figure 5*. The hydrological response unit consisted of three layers of data including the types of vegetation, the types of soil and the types of slopes. The types of vegetation were defined according to the vegetation map and the vegetation classification link; the types of soil was defined according to the soil map

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31313145

and the soil link; as there are no large gradients of slopes in the study area, there types of slopes were defined: slopes with a gradient between 0 and 15°, slopes with a gradient between 15° and 30°, and slopes with a gradient of 30°. The hydrological response units were divided according to the percentage of data on each layer. We assume that when the rate of vegetation coverage in a region exceeds 15%, the area of a type of soil exceeds 15% and the area of a type of slope exceeds 15%, it forms a hydrological response unit. Each sub-catchment has multiple HRUs and there are 70 HRUs in the study area.

Model Calibration and Validation

Given that the underlying surface conditions including vegetation coverage and soil in the 1980s and the 1990s are distinct from those in the 1950s and 1960s due to rapid development, and one hydrological cycle was included during the calibration period, the years from 1975 to 1985 are selected as the period for calibration of model parameters, and the years from 1987 to 1996 are selected as the period for model validation. The SWAT model uses the Nash–Sutcliffe model efficiency coefficient (NSE), the relative coefficient (R^2) and the relative error (RE) to analyze the modelling accuracy to identify the modelling accuracy during the calibration period and the validation period at Bailingmiao Town Hydrological Station. On the yearly scale, the NSE during the model calibration period was 0.88, the relative coefficient was 0.91 and the average error over years was 5%; during the model validation period, the NSE was 0.41, the relative coefficient was 0.42 and the average error over years was -7%, as shown in *Table 2*. The results of modelling accuracy during the model calibration period and the model validation period on the yearly scale are shown in *Figure 6* and *Figure 7*.

Table 2. *Simulation Effect of Yearly Scale Runoff by SWAT Model*

Period of time	Year	Runoff (m^3/s)	Simulated runoff (m^3/s)	NSE	RE	R^2
Calibration period	1975	0.19	0.18	0.88	5%	0.91
	1976	0.50	0.49			
	1977	0.42	0.31			
	1978	0.10	0.09			
	1979	0.70	0.68			
	1980	0.25	0.21			
	1981	0.99	1.14			
	1982	0.12	0.12			
	1983	0.21	0.36			
	1984	0.37	0.22			
	1985	0.24	0.31			
Validation period	1987	0.089	0.22	0.41	-7%	0.42
	1988	0.55	0.27			
	1989	0.25	0.22			
	1990	0.34	0.35			
	1991	0.084	0.13			
	1992	0.25	0.41			
	1993	0.12	0.2			
	1994	0.4	0.42			
	1995	0.42	0.4			
	1996	0.13	0.21

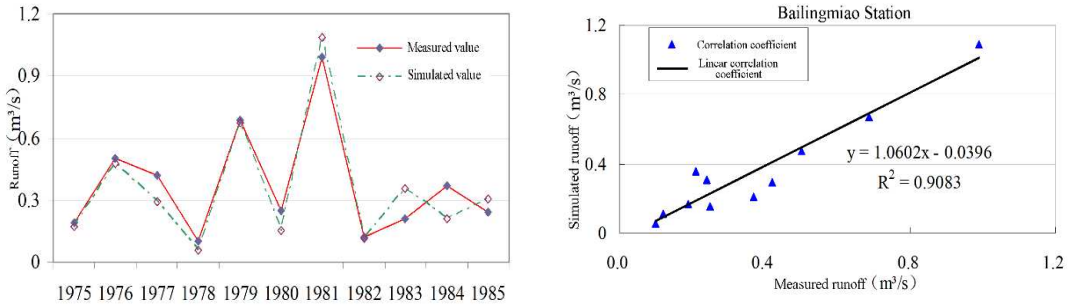

Figure 6. *Accuracy during Calibration Period on yearly scale*

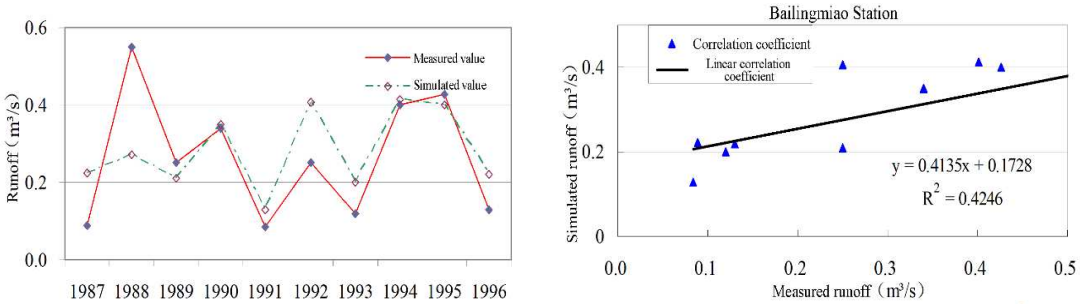

Figure 7. *Accuracy during Validation Period on yearly scale*

On the monthly scale, the NSE of Bailingmiao Town Hydrological Station during the calibration period was 0.70, the relative coefficient was 0.70 and the average relative error over years was 7%; during the validation period, the NSE was 0.47, the relative coefficient was 0.57 and the average relative error over years was 26%. Due to the large number of monthly scale data series, it is not detailed here, and the coefficients are shown in *Table 3*. On the monthly scale, the accuracy during the calibration period was shown in *Figure 8* and *Figure 9*, and that during the validation period was shown in *Figure 10* and *Figure 11*.

Table 3. *Simulation Effect of Monthly Scale Runoff by SWAT Model*

Period of time	Year	NSE	RE	R2
Calibration period	1975-1985	0.70	7%	0.70
Validation period	1987-1996	0.47	26%	0.57

The total water yield of the basin (WYLD) equals the sum of surface runoff (SURQ), lateral runoff (LATQ) and underground runoff (GWQ) subtracting the runoff losses (TLOSS) and the amount of water left in reservoirs and lakes(pond). The equation is as shown below:

$$WYLD = SURQ + LATQ + GWQ - TLOSS - pond \quad \text{(Eq.1)}$$

where, TLOSS can be neglected.

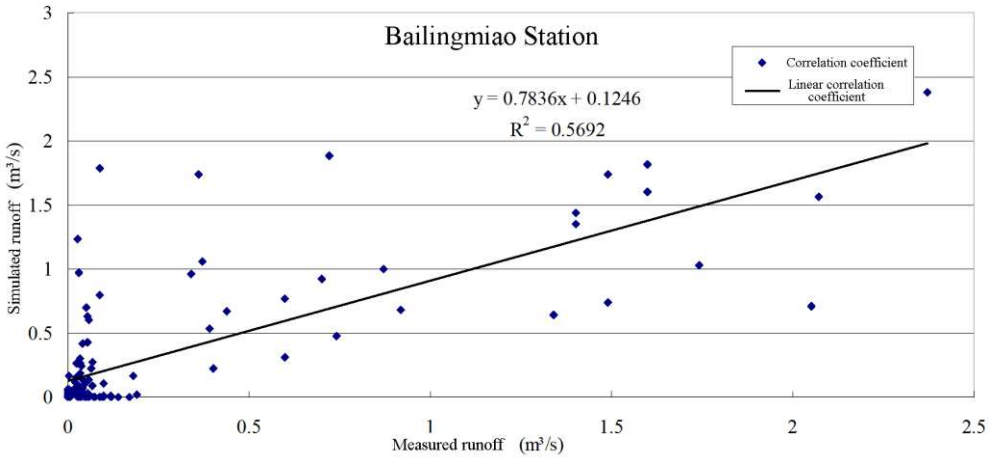

Figure 11. *Correlation between Measured Runoff and Simulated Runoff during Validation Period on Monthly Scale*

After verification with the data rate model parameters from 1975 to 1985 and the data from 1987 to 1996, the Nash coefficient and correlation coefficient were reasonable and the model parameters were reliable, the model could be used to predict the runoff changes under the changes of temperature and precipitation in the future.

Future Scenario Prediction

As the impact of the global and regional climate on forecast of climate changes in a small region is uncertain, this study defines the basic land use scenarios based on analysis of the trend of changes in meteorological factors and vegetation in the study area, and conducted quantitative modelling with calibrated model parameters to explore the impact of environmental changes on the water resources in the study area.

Climate Change

Since the end of 1980s, especially after 1995, the annual average temperature in the study area has been in the peak region, and the trend of temperature rising is very obvious, as shown in *Figure 12*.

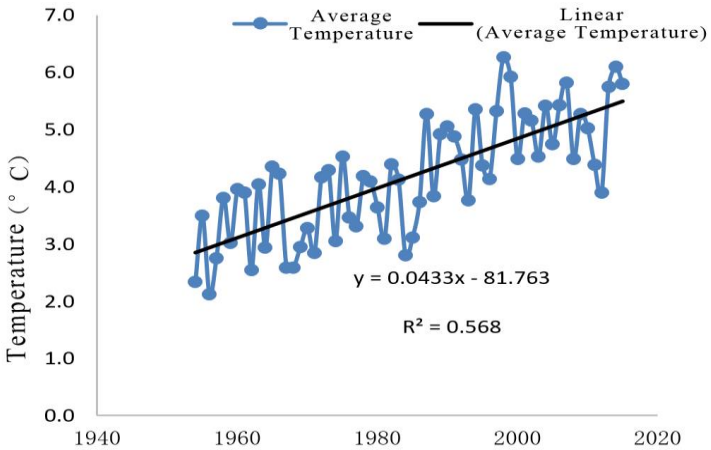

Figure 12. *Trend of Annual Average Temperature*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31313145

The annual distribution of precipitation in the study area was extremely uneven, and the precipitation presented a wet - dry - wet - dry periodic change, as shown in *Figure 13*.

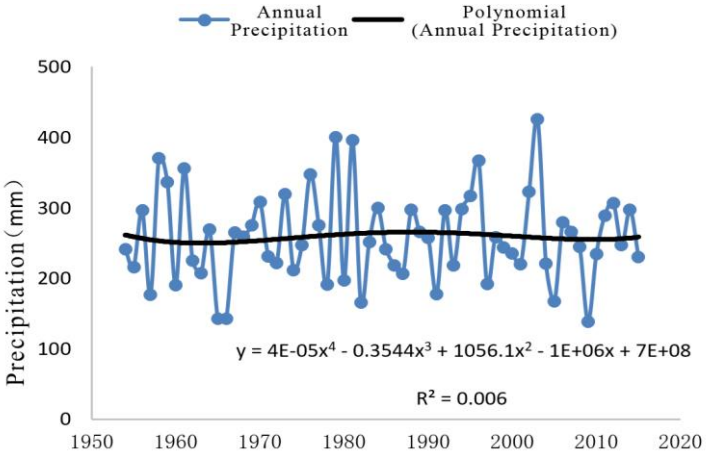

Figure 13. *Trend of Annual Precipitation*

Vegetation Changes

From 2000 to 2010, NDVI in DM Banner showed an overall trend of decrease. For many years, the maximum mean value of NDVI was 0.32, which appeared in 2004 and the minimum mean value of NDVI was 0.19, which appeared in 2009. From the above, difference degree of fluctuation was strong and there was no obvious linear relationship. It indicated that the anti-interference ability of desert steppe was poor, and the grassland showed a trend of degradation. The analysis of the relationship between the vegetation and the interannual variation of climate factors showed that temperature had positive and negative effects on the growth and development of herbage. The positive effects were mainly manifested in high temperature and good thermal conditions, which were conducive to the growth of herbage, but also the negative effects were caused by the increase of evapotranspiration consumption. And it could be showed that there was a significant positive correlation between precipitation and NDVI, with a correlation coefficient of 0.89 and increased precipitation is conducive to the growth of grass. The annual fluctuation of vegetation in DM Banner desert steppe was mainly controlled by the water condition, but the temperature was also an important factor, especially the minimum temperature (Hao et al., 2014).

Future Scenario Setting

As the result of analysis shows, the temperature in the study area increased, the precipitation showed cyclic changes, the area of surface vegetation was positively correlated to precipitation but showed no clear correlation to the temperature. Therefore, the following four future scenarios were set.

- Scenario 1: when the temperature rises 1℃ and the precipitation reduces by 10%, the rate of surface vegetation coverage drops by 10%.
- Scenario 2: when the temperature rises 1℃ and the precipitation increases by 10%, the rate of surface vegetation coverage increases by 10%.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31313145

- Scenario 3: when the temperature rises 2℃ and the precipitation reduces by 10%, the rate of surface vegetation coverage drops by 10%.
- Scenario 4: when the temperature rises 2℃ and the precipitation increases by 10%, the rate of surface vegetation coverage increases by 10%.

Results

Table 4 shows the simulation result of changes in temporal and spatial distribution of water resources in four future scenarios, and the water yield in the study area in different scenarios was achieved. In Scenario 1, the water yield is 3.53 mm, equivalent to 64.16 million m^3 of water; In Scenario 2, the water yield is 5.68 mm, equivalent to 103.25 million m^3 of water; In Scenario 3, the water yield is 3.64 mm, equivalent to 66.16 million m^3; In Scenario 4, the water yield is 5.77 mm, equivalent to 104.88 million m^3. As the model requires input of lots of data, only the basic parameters available were input into the model in this study. In particular, the pastures in China are large and rivers abound in grasslands, but there are few hydrological stations which can produce only short-series data. Insufficient data may to some extent influence the accuracy of parameter model calibration and validation.

Table 4. *Forecast of Water Resources in Different Scenarios*

Scenario	Precipi-tation	Surface runoff	Underground runoff	Soil water content	Evapo-ration	Potential evaporation	Water yield	Measured Water yield

Discussion

Because of the lack of water resources and the fragile ecological environment in arid pastoral area of China, grassland ecological animal husbandry and regional economic and social development are mainly restricted by water resources. Reasonable and efficient use of limited water resources is the importance premise for the implementation of the corresponding industry development policy. And the ultimate goal is to achieve economic and social development of pastoral areas and grassland ecological protection win-win. So prediction of water resources in arid pastoral areas under future environmental changes is the basis of efficient utilization of local water resources.

In this paper, SWAT model was established in the study area to simulate and predict the change of local future runoff, so as to provide a scientific basis for the optimal allocation and management of region water resources in the future. Although the model input data required more, by the limit of the natural conditions of China's vast pastoral areas and numerous grasslands river, the study only collected the most basic input parameters for model. Now the number of corresponding hydrological stations is very small, and the data series is relatively short. Inadequate data input as mentioned above

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31313145

for parameter calibration and simulation accuracy may cause a certain influence. We have set up another long-term meteorological observatory in the Xilamuren Town of DM Banner. It's just that the monitoring time is short and it's not fully working. But we will continue to collect new meteorological and hydrological data in the future, in order to improve the model that we established and improve the accuracy of the model. This is a better support for sustainable use of water resources to support sustainable economic and social development in arid pastoral areas.

Abstract. The physiochemical parameters and antioxidant properties of plum cultivars, grown in subtropical regions of China are little known. However, in this comparative study, these properties of 6 landraces and 7 introduced cultivars showed evaluated. The major nonvolatile constituents were a significant difference among cultivars. Color parameter values were strongly influenced by cyanidin 3-*O*-glucoside and cyanidin 3-*O*-rutinoside. Remarkably high antioxidant activity, high total phenolic, and ascorbic acid contents were found in black or purple flesh genotypes. Catechinic acid, the most important phenolic acid in Japanese plum, together with vanillic acid, caffeic acid and syringic acid, accounted for > 96% of the total phenolic content. The total phenolics and ascorbic acid concentration revealed significant contributions to antioxidant capacity detected by α, α-diphenyl-β-picrylhydrazyl (DPPH), (r = 0.78**, 0.73**) and ferric reducing antioxidant power (FRAP) (r = 0.74**, 0.57*). Moreover, there was a clear correlation between the total phenolic compounds and the ascorbic acid content (r = 0.76**). Comparison of physicochemical characteristics and antioxidant profiles revealed that both introduced cultivars and landraces had good adaptability in the subtropical region.

Introduction

People consume fruits not only for their taste, but also their vital nutritional content (Liu, 2013), strong antioxidants and health promotion capabilities (Dai and Mumper, 2010; Goodarzi et al., 2018). Bioactive compounds including phenolics, anthocyanins and phytochemicals as well as vitamins E and C are considered to be beneficial properties of fruits (Mirmiran et al., 2009; Wang et al., 2018). Hence, a great deal of research has been carried out, in order to improve the quantity and quality of bioactive compounds in commonly consumed fruits.

Plum (*Prunus salicina* Lindl) commonly known as Japanese plum, is an important stone fruit crop commercially grown in China, Spain and USA. China ranks first in plum production (Li et al., 2015; Vlaic et al., 2018). Likewise, other fruits, various kinds of polyphenolic compounds such as phenolic acids, flavonols, anthocyanins (Turturică et al., 2018) and antioxidant activities have been identified in plum (Gil et al., 2002). Plum are good source of antioxidant that protects from biomolecular damage including aging caused by free radicals (Cefali et al., 2018). However, European plums (*Prunus domestica* L.) and Japanese plums (*Prunus salicina* Lindl.) have several different concentrations of phytochemicals, nutritional properties and antioxidant activities (Arion et al., 2014; Fanning et al., 2014; Jaiswal et al., 2013). Different cultivars have a greater variation of phenolic composition and concentration under various environmental conditions (Bochi et al., 2015; Wang et al., 2018). Several reports have been found on Japanese plum cultivars focusing on large size and homogeneous color (red, purple or yellow) (Lozano et al., 2009). Recently, more attentions have been focused on the functional properties of plum, their reasonable source of dietary-fiber, ascorbic acid, phenolic compounds, anthocyanins and other compounds with antioxidant properties (Fanning et al., 2014; Jaiswal et al., 2013; Kim et al., 2003).

In the past 20 years, many plum cultivars such as Blackamber, Wickson, Fiar, and Methely have been introduced, in order to enhance the plum production scale. Most of the plums are adapted to subtropical regions of Southeastern China. However, little information is available about the phytochemical properties of Chinese genotypes growing in subtropical regions of China (Byrne et al., 2000; Liu et al., 2007). Assuming that physicochemical characteristic, phenolic compounds and antioxidant properties of different Japanese Plums cultivars are influenced in subtropical regions. The main objectives of this study were to analyze the physicochemical characteristics, phenolic compounds and antioxidant properties of 13 Japanese plum cultivars grown in southeastern China.

Materials and methods

Plant materials

Fruit samples of 13 plum cultivars were harvested at commercial maturity stage during early June to end of August from Fujian Agriculture and Forestry Experiment Station Orchard at the hillock reservoir of Gutian county, Fujian, located in Southeastern China (N26°38’56.67”, E118°49’1.02”, Elevation: 323 m). The daily effective accumulated temperature is > 10 ℃, and the annual average rainfall is about 5000 mm. Among 13 cultivars, 7 were introduced (Friar, Gariota, Blackamber, Santa Rosa, Elodrao, Methely, and Akihime) and 6 were landraces (Furongli, Hongnai, Yanzhili, and Xiguali as local cultivars of Fujian, Crown and Cuipingwannai were from the college of Horticulture, Fujian Agriculture and Forestry University. The dates of taking the samples are displayed in *Table A1* in the *Appendix*. After harvesting, fruits were immediately transported to the laboratory and sorted in a refrigerator up to 4 °C, according to the uniformity of their firmness. Plums without stones were cut into several pieces and then stored at -80 °C until extraction. To ensure the uniformity of frozen material before further experiments, the fruits were ground to a fine powder by using liquid nitrogen.

Chemical standards

Standards for sucrose, glucose, fructose and sorbitol, as well as malic, citric, shikimic and fumaric acids were obtained from Fluka Chemical (New York, USA). Catechinic, vanillic, gallic, caffeic, syringic, ferulic and chlorogenic acids, quercetin, cyanidin 3-O-glucoside and cyanidin 3-O-glucoside were purchased from Sigma-Aldrich (Oslo, Norway).

Gas chromatography-mass spectrometer (GC-MS) determination of sugar compounds and organic acids

Organic acids and sugars were extracted according to the protocol described by Liu et al. (2007) and Glew et al. (2003) The extraction of derivatives was carried out by using the method of Jiao et al. (2010). 1 μl of the derivative sample was injected into GC-MS using the split mode 50:1 and injector temperature was 230 °C. Ultra-pure helium served as carrier gas at the constant flow of 1.0 $mL \cdot min^{-1}$. The oven was programmed at the following profile: initial temperature of the column was 70 °C (5 min hold), followed by an increasing the rate of 5 $°C \cdot min^{-1}$ to 310 °C and then hold for 1 min. The mass operating parameters were: interface temperature was 250 °C, ion trap temperature was 200 °C, ion source was EI mode, electron energy was 70 eV, the solvent delay was 8 min. All data were obtained from the full-scan mass spectra within the range of 50 - 600 amu. The organic acids and sugars were identified by comparing the retention times and mass spectral data with the corresponding standards. Concentrations were determined according to the calibration of external standard solution.

High performance liquid chromatography (HPLC) analysis of phenolic compounds and anthocyanins

Plum extraction was carried out by the method of Gil et al. (2002). Samples were filtered through a 0.45 μm filter and then used for the analysis of phenolic compounds by HPLC (Kelebek et al., 2015). Anthocyanins were analyzed at 530 nm by HPLC (Usenik et al., 2008).

Antioxidant activity evaluation

2 g sample was extracted with 15 ml solution of 80% methanol (v/v) at 30 °C, then by an ultrasonic extraction with the power of 300 W for 40 min. Furthermore, it was centrifuged at the acceleration of 10000×g for 10 min (4 °C). For the analysis of the antioxidant activities of the plum fruits, combined supernatants of two replications were filtered by using a 0.45 μm filter. Three methods, i.e., the DPPH(α, α-diphenyl-β-picrylhydrazyl, DDPH) (Arion et al., 2014), ABTS(2, 2'-azino-bis(3-ethylbenzothiazoline-6-sulfonic acid), ABTS) (Maria do Socorro et al., 2010) and FRAP (ferric reducing antioxidant power) (Benzie and Strain, 1996) were used in order to test the antioxidant activity of the plum fruits.

Statistical analysis

Three replications were used for each treatment (n = 3) and statistical analysis were conducted by using SPSS software (version 21.0). Results were expressed as mean values ± standard deviation (SD). To determine whether the bioactive compounds would contribute to the antioxidant capacity, Pearson's correlation coefficients were calculated at $p < 0.05$ and $p < 0.01$ confident levels for all variables. An analysis of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31473159

variance was performed followed by Student's t-test (two-tailed distribution, unequal variance). Relationships between the physicochemical variables and either cultivar of P. salsida or antioxidants capacities of the known DPPH, FRAP and ABTS were analyzed using CCA (Canoco 4.5).

Results

Phenolic compounds and anthocyanins

Eight phenolic compound markers were identified in plums fruit at 280 nm. The acidic phenolics like caffeic acid, chlorogenic acid, ferulic acid and quercetin had more intense absorptance at 320 nm (*Fig. 1*). The concentration of the phenolic compounds of the 13 Prunus cultivars was shown in *Table 1*. The catechinic acid was the most abundant, especially in purple- or red-fresh cultivars Furongli, Xiguali and Yanzhili, which was two times higher than that 10 other cultivars. Additionally, abundant polyphenolic compounds were vanillic acid. Interestingly, the cultivars Xiguali, Gariota, Hongnai and Santa Rosa had outstanding high values of vanillic acid (*Fig. 2*). The hydroxycinnamic acid derivatives, caffeic acid, ferulic acid and chlorogenic in plums showed significant variation in 13 cultivars tested, in which caffeic acid predominated with the mean value of 7.68 $\mu g \cdot g^{-1}$ fresh weight (FW). The acidic phenolics such as chlorogenic acid, ferulic acid and quercetin had low levels, and the neutral phenolic gallic acid tended to have low values as well. It should be noted that catechinic and syringic acids made 84.8% and 11.9% of the phenolic materials, respectively in Furongli.

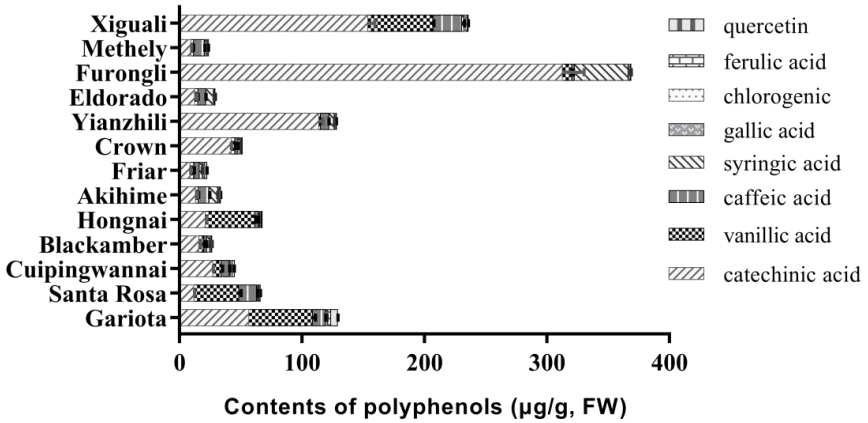

Figure 2. *Contents of polyphenols in 13 plum cultivars (μg/g FW). The bars represent the mean ± standard deviation*

Concerning the anthocyanins content, we observed that cyanidin 3-O-glucoside quantities were two times higher than that of cyanidin 3-O-rutinoside in plums (*Figs. 3* and *4*). Cyanidin 3-O-glucoside was the predominant compound among anthocyanins and detected in Xiguali, Methely and Blackamber, which corresponds to a mean content of 335.0 mg·100 g^{-1} FW among the 10 cultivars tested. The cyanidin 3-O-rutinoside was also detected in abundance and its mean value was 161.5 mg·100 g^{-1} FW in 10 cultivars. In all cases, the levels of cyanidin 3-O-glucoside, cyanidin 3-O-rutinoside and total anthocyanins correlated negatively or positively ($P < 0.01$) with each of the color parameters L*, a*, b*, C and H, respectively (*Table 1*). It seems that the highest values of a* and H corresponded positively to the samples with the highest anthocyanins content. The lowest values of b*, L* and C were negatively correlated with the anthocyanin levels. The darker the fruits, the more negative was the correlation of the color parameters of L*, b* and C to the amount of total anthocyanins, cyanidin 3-O-glucoside and cyanidin 3-O-rutinoside in plums. These results showed that chromatic parameters have a significantly correlate with the evolution of fruit color and anthocyanins levels and indicated that color parameters could be used to monitor pigment evolution and anthocyanins content of plum cultivars.

Total phenolics, ascorbic acid and antioxidant capacity

Thirteen cultivars were analyzed with respect to their content of total phenolics, ascorbic acid and antioxidant capacities (*Table 2*). Total phenolic contents were classified into three categories: low (150-200 mg of gallic acid equivalent (GAE) per 100 g FW), medium (200-250 mg of GAE per 100 gFW) and high (> 250 mg of GAE per 100 g FW). The highest contents of total phenolics were observed among the red- or purple-fresh fruits of Xiguali, Furongli and Yanzhili. The yellow-fresh fruits of Crown and Cuipingwannai had the lowest total phenolics except for Blackamber.

In this study, 13 different cultivars were investigated for their total antioxidant capacity, using the DPPH, FRAP and ABTS methods as shown in *Table 2*. In general, the antioxidant activities of the black or red landraces Furongli and Xiguali were higher than those of the other cultivars. The results showed statistically significant correlation in antioxidant capacity on DPPH within 13 cultivars. The highest DPPH radical scavenging activities for the 13 cultivars fruit extracts was measured in Xiguali, followed by Furongli and Yanzhili, while the lowest values were observed in Friar. The reduction power towards ABTS radical cation was more than 95% in almost all plum cultivars except for Blackamber and Friar. The values obtained by FRAP were less than 10 $\mu mol \cdot g^{-1}$ FW for yellow-flesh cultivars like Crown, Cuipingwannai, Blackamber, Eldorada, and Friar. The FRAP values of red-flesh or red-skin cultivars were higher than those of yellow-flesh cultivars, except Akihime. In general, the measurement from the three methods (DPPH, ABTS and FRAP) demonstrated that Furongli and Xiguali had the highest levels of antioxidants but the lowest was in the Friar cultivar.

Relationships between organic acids and sugars

Correlation analysis of the typical biological characteristics on the components of sugar and organic acid in 13 plums cultivars (*Table 3*), found that, in terms of biological characteristics, succinic played a leading role, showed a extremely significantly positive correlation with Citric (r = 0.98**) and sorbitol (r = 0.54*). In addition, Shikimic showed a significantly positive correlated with Cis-aconitic (r = 0.59*) and a significantly negatively correlated with Ascorbic (r = -0.57*). In the relationship in soluble sugars, sucrose, fructose and glucose were the main three sugars in plums, and there was a significant correlation among them. In addition, sorbitol and glucose were also significantly correlated (r = 0.67**). It can be seen that the interdependent among soluble sugars is significantly stronger than that among organic acids, which may be due to a circulation of the metabolic pathways of these three sugars while not exist in organic acids. It is worth noting, the total phenolics and ascorbic indicated a significant positive correlation (r = 0.76**).

Table 3. *Correlation matrix between organic acids and sugars in 13 plum cultivars*

	Malic	**Citric**	**Shikimic**	**Succinic**	**Fumaric**	**Cis-aconitic**	**Sucrose**	**Glucose**	**Fructose**	**Sorbitol**	**Ascorbic**

* and ** indicate correlated significantly at the level of $P < 0.05$ and $P < 0.01$ respectively

Relationships between bioactive phytochemicals and antioxidant capacity

The amount of total phenolics, ascorbic acid, individual phenolic compounds and anthocyanins showed a good linear relationship with each other (*Table 4*). The total phenolics and ascorbic acid concentration of the 13 plum cultivars correlated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31473159

significantly with the antioxidant capacity detected by DPPH (r = 0.78**, 0.73**) or FRAP (r = 0.74**, 0.57*), but not so significantly by ABTS (r = 0.41, 0.41). Moreover, there was a significant correlation between the total phenolic compounds and the ascorbic acid (r = 0.76**). We found that catechinic acid had a stronger contribution to the antioxidant constituents than DPPH (r = 0.63*), FRAP (r = 0.55*) and the total phenolics (r = 0.77**). The high significant correlations between caffeic acid and DPPH (r = 0.64*), ascorbic acid (r = 0.64*) and vanillic acid (r = 0.63*) indicated that catechinic- and caffeic acids contributed more than ascorbic acid to the total phenolics and antioxidant activity. Cyanidin 3-O-glucoside also shows a significantly correlated (r = 0.94**) with cyanidin 3-O-rutinoside in the flesh of plum cultivars (*Fig. 5; Table 5*). In addition, a positive significant correlation between the ascorbic acid, cyanidin 3-O-glucoside (r = 0.63*), and cyanidin 3-O-rutinoside (r = 0.60*) was identified. Anthocyanins were important bioactive compounds contributing to ascorbic acid. The clear trend between the antioxidant capacity and the Prunus genotypes was analyzed by Canonical correspondence analysis (CCA) (*Fig. 5*). The antioxidant capacity of the purple- or red-flesh cultivars Furongli, Xiguali and Yanzhili showed a bigger variation than that of the other cultivars and correlated with the contents of total phenolics (*Fig. 5*). In general, black and red Prunus cultivars had a higher antioxidant capacity compared with yellow-flesh genotypes such as Methely, Santa Rosa, Akihime, Crown, Hongnai, and Cuipingwannai (*Table 4*).

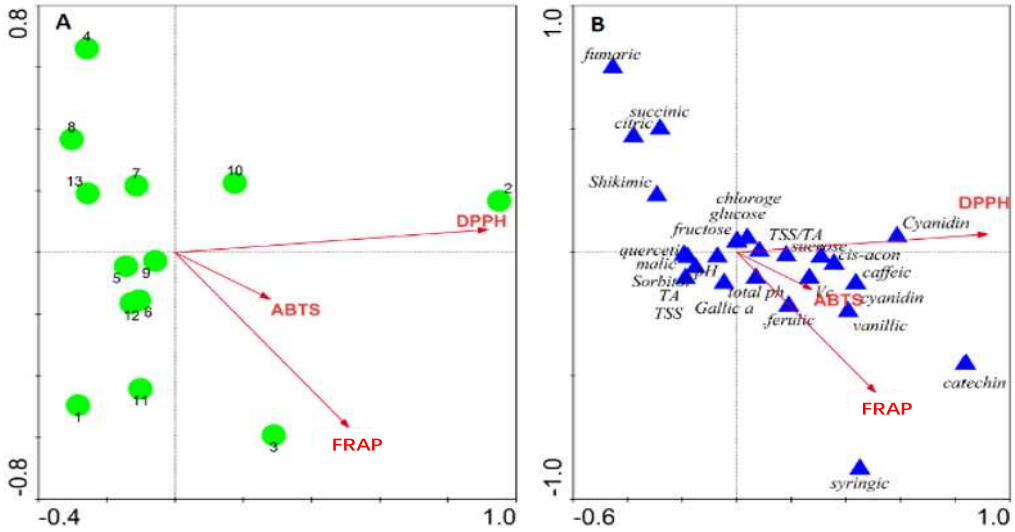

Figure 5. *CCA ordination of the 13 plum cultivars (green circles) for the 29 phytochemical profiles (blue triangles), with respect to antioxidant capacities (red arrows) using DPPH, FRAP and ABTS methods*

Discussion

The presence of polyphenolics correlated with previous investigations in which they showed that plums were rich in phenolic compounds and there are great differences among the phenolic contents in Prunus. Salicina and P. domestica (Arion et al., 2014; Mubarak et al., 2012; Slimestad et al., 2009). The occurrence of catechinic acid, vanillic acid and syringic acid has already been reported in plums (Jaiswal et al., 2013). However, some reports also showed smaller amounts of chlorogenic, caffeic acid and quercetin (Kim et al., 2003; Mubarak et al., 2012).

DOI: http://dx.doi.org/10.15666/aeer/1802_31473159

The plums contain mainly cyanidin 3-O-glucoside and cyaniding 3-O-rutinoside (Kim et al., 2003). Slimestad et al. (2009) reported that cyanidin 3-O-rutinoside represents more than 60% of the total anthocyanin content. It should be noted that cyanidin 3-Oglucoside and 3-O-rutinoside in fruit extracts of the yellow-flesh cultivars Crown, Akihime and Cuipingwannai were not detected due to their low contents, which is consistent to previous findings (Kim et al., 2003; Lozano et al., 2009).

The ascorbic acid content showed significant differences ($p < 0.05$) in the 13 selected cultivars. The ascorbic acid detected in our experiments was higher rather than previous reports. Most of the fruits contained considerable amounts of ascorbic acid (Asami et al., 2003; Fang et al., 2017) which were higher than 10 $mg \cdot 100\ g^{-1}$, and apparently higher than that in Spain (Gil et al., 2002). These results demonstrated that plum cultivars grown in subtropic areas have higher level of ascorbic acid than those grown in other regions.

Many assays were used for the determination of antioxidant activity in fruits and vegetables (Bustos et al., 2018; Moo-Huchin et al., 2015; Nayak et al., 2015).

These observations indicated that purple- or red-flesh Prunus cultivars had higher contents of the total phenolics (except cultivar Gariota) compared with other cultivars. However, Other researchers have also reported that plum is rich in total phenolic contents (Gil et al., 2002; Granato et al., 2018). Unfortunately, the range of total phenolics in plum differs among different reports due to their cultivar differences, agricultural practices, growth conditions and seasons (Arion et al., 2014; Kim et al., 2003).

These results indicated that the total phenolic compounds and ascorbic acid have a strong contribution to the antioxidant activity as also described in previous reports (Kim et al., 2003; Lozano et al., 2009; Mubarak et al., 2012). In some other reports, no correlation between antioxidant capacity and vitamin C was found (Hassimotto et al., 2005), even a negative influence of vitamin C was detected (Kalt et al., 1999). These similar results showed that cyanidin 3-O-rutinoside and cyanidin 3-O-glucoside were responsible for the pigmentation of the fruits (Kim et al., 2003; Raynal et al., 1989; Tomás-Barberán et al., 2001). These results were supported by previous reports which have shown that the main phytochemicals responsible for the antioxidant capacity in plums were total phenolics, ascorbic acid, and phenolic compounds (Gil et al., 2002; Vlaic et al., 2018), although other compounds may also be involved (Kim et al., 2003).

Conclusion

Overall, the results of this study demonstrated that many plum cultivars exhibited significant difference in levels of phenolic compounds, anthocyanins, total phenolics, ascorbic acid, and antioxidant capacities (DPPH, FRAP and ABTS). The highest levels of phenolic compounds, anthocyanins, and antioxidant capacities were observed in the black- or purple-flesh genotypes. Catechinic acid was the predominant polyphenolis in all tested plum cultivars and if combined with caffeic acid would make more important contributors to antioxidant capacities and total solute phenolic compounds, ascorbic acid in Japanese plums. The content of antioxidant capacities, polyphenols and anthocyanins has a certain correlation with the color of the peel and pulp, but it is not absolute, there were not found anthocyanins in yellow-skin or yellow-flesh cultivars. We conclude that phenolics, anthocyanin, and the antioxidant capacity could reflect the fruit quality and other important parameters for human health. It is not always a simple

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31473159

task to choose the most appropriate method to evaluate high-quality cultivars. Comparison of physicochemical characteristics and antioxidant profiles revealed that both introduced cultivars and landraces had good adaptability in the subtropical region. Thus, in order to achieve the maximum health-beneficial effects of plum consumption and their optimal organoleptic and nutritive properties, it would be advisable to get the cultivars with a high content of ascorbic acid, catechinic acid, caffeic acid, and syringic acid. The next work, we will conduct an depthly study on the main polyphenols and antioxidant activities in plums, and explore the best hybrid breeding model of plums to improve the functional components and nutrient content of fruits.

Abstract. In this study, the soil moisture migration pattern was studied under the sprinkler irrigation method with different modes of a stepped slope with 3 steps and its affecting factors. The results showed that at the early stage of the vegetation reconstruction, natural precipitation was enough to ensure the normal growth. This was found valid as long as the soil moisture content (SMC) was higher than 2.45% of the wilting coefficient at the non-irrigation stage. At the non-irrigation stage and at the stage of irrigation once every two days, the SMC increased with depth in the three slope surfaces. However, at the stage of irrigation once daily, the SMC decreased with depth. As the irrigation frequency decreased, the SMC dropped and the coefficient of variation (CV) of SMC rose. The order of CV of SMC within depths in 0-50 cm soil layer was the depths of 40-50 cm > 0-2 cm and 0-20 cm > 20-40 cm. The average soil moisture content (ASMC) increased from the top to the bottom of the stepped slope under different frequencies of sprinkler irrigation. The slope position and hardness and vegetation cover correlated negatively with the SMC ($P < 0.01$). Whereas, the slope gradient correlated positively with the SMC ($P < 0.05$).
Keywords: *Lanzhou New Area, Loess Plateau, ecological restoration, vegetation reconstruction, spatial differentiation, environmental factor*

Introduction

Excavation and filling of large mountains in Lanzhou New Area, located in the Loess Plateau of the Peoples Republic of China have produced a very high number of exposed stepped slopes during infrastructure construction. This has greatly changed the original ecological environment and led to water and soil loss (Cohen-Fernández and Naeth, 2013; Sharma et al., 2017). The total area suffering this loss was about 40 hm^2. Each exposed stepped slope usually consists of three steps and every two adjacent steps are isolated by a terrace. For these steep slope surfaces, vegetation slope protection is an effective pathway towards ecological restoration (Stokes et al., 2008). For this, the primary technical measures are available for sustainable development of the Loess Plateau (Wu and Yang, 1998). Soil moisture is a key factor affecting vegetation growth in the Loess Plateau (Engelbrecht et al., 2007; Wu and Yang, 1998). Small-scale topographical changes control secondary distribution of light, heat, precipitation and surface runoff (Crave and Gascuel-Odoux, 2015). All these, further affect the variability of soil moisture content (SMC) across the space. The spatial variation of SMC thus resulted, has a decisive impact on the surface vegetation type, density and structure (Vivoni et al., 2010). Steep slopes are usually associated with severe soil moisture shortage due to low permeability and high surface

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31613175

runoff (Miyazaki et al., 1993). The phenomenon is distinct especially for the slopes with greater hardness (Morgan, 1980). Hardness occurs because the slopes are formed via engineering construction. The process causes a compaction of particles which decreases the porosity and increases the bulk weight (Soane et al., 1980). The resultant condition hinders the circulation of moisture and nutrients, which is not conducive to the root growth of vegetation (Ishaq et al., 2001). Previous studies mostly dealt with the spatial variation of SMC in the gentle natural slopes of the Loess Plateau (Jia et al., 2013; Yang et al., 2015) and in typical roadbed side slopes (Yang et al., 2016). However, we know little about the spatial variation of SMC in stepped slopes. In this study, vegetation reconstruction was carried out for the steep slopes in Lanzhou New Area by sprinkler irrigation and mechanized grass growing. Then, a correlation analysis was conducted between the spatial variations of features of SMC in the 0-50 cm soil layer. In the correlation studies, different irrigation frequencies and four environmental factors namely, soil hardness, slope position and gradient and vegetation cover were considered. The soil moisture response to slope gradient and soil hardness in vegetation reconstruction of stepped slope was discussed. The present study provides a theoretical basis for developing irrigation regime and engineering measures for vegetation restoration in similar stepped slopes.

Study sites

Lanzhou New Area (103°29′22″-103°49′56″ E, 36°17′15″-36°43′29″ N), is located in Qinwangchuan Basin of the Peopole's Republic of China. The study area is about 60 km away from the city of Lanzhou (*Fig. 1*). The area is located in the intersect of Qinghai-Tibet-, Mongolian- and Loess Plateau. In that the eastward extending ranges of the Qilian Mountain run into the interlaced region of Longxi Basin. The primary landform of Lanzhou New Area is the Loess Plateau. The area enjoys typical temperate, continental and semiarid climate with an annual average temperature of 6.9 °C and annual precipitation of 300-350 mm. Because of the slope factor, the vegetation of the Loess Plateau near Lanzhou New Area shows two different categories i.e., shady and sunny slopes. The shady slope is predominantly grown with *Stipa breviflora* Desf. accompanied by undershrubs and perennial herbs such as *Caragana tibetica* (Maxim. *ex* C.K. Schneid.) Kom., *C. opulens* Kom., *Kraschenninnikovia ceratoides* (L.) Gueldenst., *Ajania achilleoides* (Turcz.) Poljakov *ex* Grubov, *Torularia humilis* (C.E. Mey) O.E. Schulz, *Peganum harmala* L., *Limonium aureum* (L.) Hill and *Reaumurta soongorica* (Pall.) Maxim. Whereas, the sunny slope is mainly grown with desert shrub *R. soongorica* accompanied by annual plants such as *Salsola collina* Pall., *Suaeda glauca* (Bunge) Bunge and *Setaria viridis* (L.) P. Beauv. The above undisturbed soil vegetation is an important indicator for vegetation reconstruction of steep slopes in Lanzhou New Area.

Methods

Time and location of the experiments

Experiments for the present study were performed from June 2nd to October 23rd, 2018. The experimental slopes (103°44′11″ E, 36°27′41″ N) was located on the west side of Nanraocheng Highway (from Shuiqin Road Overpass to Jingshiqi Road) (*Fig. 1*). The slopes were faced eastward and followed three successive steps having an elevation of 1930 m MSL. The slope surface was smooth, the soil characteristic had been analysed and the results showed that the soil was barren (*Table 1*) and without undisturbed soil vegetation. The wilting coefficient of the slope was 6.20 ± 0.60%.

Table 1. *Soil nutrient characteristics in the study area*

Organic matters (g/kg)	Total nitrogen (g/kg)	Total carbon (g/kg)	Total phosphorus (g/kg)	Alkali-hydrolyzable nitrogen (mg/kg)	Rapidly available phosphorus (mg/kg)	Rapidly available potassium (mg/kg)
1.742	0.268	15.405	1.28	10.50	11.46	120.00

Experimental layout

Slope engineering and grass growing

One study in 2017 indicated that a definite strip soil preparation (average length × width × depth = 45 × 8 × 5 cm) brought about the best water-retaining and vegetation restoration effects (Liu et al., 2019). Thus in 2018, after manually removing the rubbles and garbage from the slope, the experimental slope was prepared. To produce strip-like trenches with a depth of about 7 cm, a three-teethed harrow was used. The trenches were parallel with each other and spaced about 15 cm apart. From June 2nd to 6th, 2018 mechanized grass growing was carried out using sand-fixing mixture. Spray seeding was performed for the test slopes. The seeds of *Caragana korshinskii* Kom. (6 g/m^2), *Agropyron cristatum* (L.) Gaertn. (12 g/m^2) and *Medicago sativa* L. (2 g/m^2) were sown. After spray seeding, the test slope was covered with non-woven fabrics, which were fixed with disposable chopsticks. The date of first germination was June 11th, 2018 and the non-woven fabrics were removed after germination.

Sample plot layout

The bottom slope surface in the stepped slope (*Fig. 2a*) was considered the first (1st) one. It had a length of 12 m in the upper and lower direction and the slope gradient was 60°. The middle slope surface was considered the second (2nd) one which had a length of 14 m. In this case, the slope gradient was 40°. Between the first and second slope surfaces, there was a 3 m-wide terrace. The top slope surface was considered the third (3rd), with a length of 12 m. Here the slope gradient was 25°. There was a 12 m wide terrace between the second and third slope surfaces.

A 1×1 m sample plot was arranged at the upper (P), middle (M) and lower (D) positions of the first, second and third slope surfaces, respectively and each with three replicates. Thick iron wires and hemp ropes were used for immobilization (*Fig. 2b*). Nine plots were arranged for each slope surface. So, the entire test slope had 27 plots. The plot in the upper position of each slope surface was 1 m away from the top of this slope

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31613175

surface. The lower position was 1 m away from the bottom of the slope surface. The transverse spacing between adjacent plots was 10 m and the vertical spacing was 3-4 m.

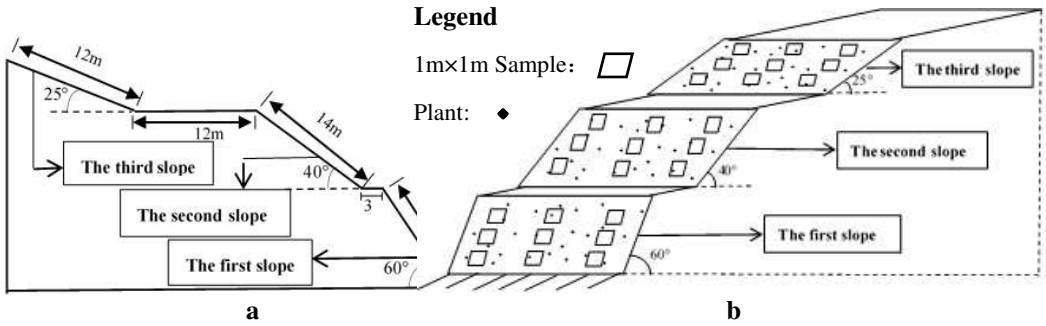

Figure 2. *The schematic diagram of profile and sample layout for the test slope.* ***a*** *Schematic for the s profile of the test slope.* ***b*** *Schematic for the sample plot layout of the test slope*

Sprinkler irrigation method and its application frequency

Sprinkler irrigation was performed for the experimental slopes. That is, all the three slope surfaces were irrigated by a sprinkling truck at 7-8 a.m. every day. The sprinkler irrigation amount was the same for different slope surfaces and the total sprinkler irrigation amount of the three slope surfaces was 12 MT/day. The frequency of irrigation followed three-time intervals. These are: (i) from June 2nd to July 10th sprinkler irrigation once daily; (ii) from July 11th to August 15th sprinkler irrigation once at every two days interval and (iii) from August 15th to November 23rd no irrigation, but natural precipitation was the only source of water. Sprinkler irrigation was avoided on the day of precipitation for all the experimental plots.

Sample collection, data collection and processing

Method of sample collection for SMC determination

At the irrigation stage, each plot was sampled once every 2 h since 9 a.m. on the morning of sprinkler irrigation. However, at the non-irrigation stage (natural precipitation), each plot was sampled at 9 a.m. once every 10 d.

A soil auger was used to collect samples for SMC determination. The sampling was carried out at randomly chosen positions for the soil depth of 0-50 cm under different irrigation frequencies. The soil was divided into 6 layers, namely, topsoil at 0-2 cm, 2-10 cm, 10-20 cm, 20-30 cm, 30-40 cm and 40-50 cm. The collected soil samples were put into specialized high-density ziplock bags prior to determination. The sampled soil pits were backfilled.

Determination of SMC

SF - 60 Moisture Tester (Shenzhen Houwang Electronic Technology Co., Ltd.) was used to determine the SMC. The measuring range was 0.01-100% and the measuring precision was 0.01%. During the first determination, the tester was calibrated by using the oven drying method (error 0.5-1%). For subsequent determinations, the SMCs were all detected using the electronic soil moisture tester. Each detection was repeated for three times and the average was taken.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31613175

Determination of soil hardness

Soil hardness tester (Takemura Electric Works, Ltd) was placed perpendicular to the soil surface. The top length of the tester was 4.5 mm, and its bottom was inserted deep into the soil. The soil hardness tester was removed perpendicular out of the soil and the readings were taken. The measuring range of the soil hardness tester was 0-500 $kg \cdot cm^{-2}$ and the measuring precision was 0.1 $kg \cdot cm^{-2}$. A quincunx pattern was chosen for random selection of 5 points in each plot for each determination and average was taken after repeated determinations.

Determination of vegetation cover

Densities of different plants were calculated for each plot using the quadrat method. Three individuals were randomly selected for each plant species. After collection the crown breadth was measured and the average was taken. The vegetation cover was calculated for each plot based on the projected area of the stems and leaves on the ground.

Division of soil layers based on CV of SMC

According to the principle of soil layer division based on SMC variability (Yang and Shao, 2000), coefficient of variation (CV) was used to measure the degree of variation of SMC in the vertical direction. CV was calculated by

$$CV = \frac{SD}{S} \quad \text{(Eq.1)}$$

CV of *Equation 1* is the coefficient of variation, SD is the standard deviation and S is the average. The smaller the CV, the more stable the SMC was. On the other hand, the larger the CV, the stronger the changes of SMC. Soil layers with $CV > 30\%$, $20\% < CV \leq 30\%$, $10\% < CV \leq 20\%$ and $CV \leq 10\%$ were considered as rapid changing, active, less active and the relative stable layers, respectively.

Sources of precipitation data in Lanzhou New Area

Precipitation data of Lanzhou New Area during the test period (*Fig. 3*) came from the Meteorological Service Center of Gansu Province.

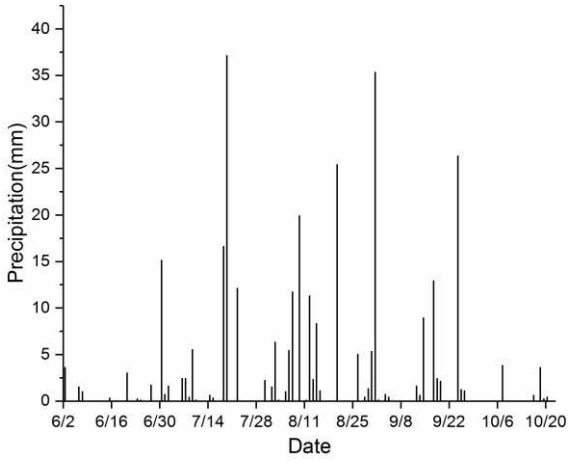

Figure 3. *Precipitation in Lanzhou New Area from June 2nd to October 23rd, 2019*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31613175

Data analysis

Statistics was conducted using Microsoft Excel (2013), plots were drawn using Origin (2017) and data analysis was carried out using SPSS (20.0).

Results

Vertical spatial variation of SMC in the three slope surfaces of stepped slope

The SMC of each soil layer in different positions of the three slope surfaces have been presented in *Fig. 4*. At 34 d under the condition of irrigation once daily, the average soil moisture content (ASMC) ranged between 8.65 and 16.01% (*Fig. 4a*). In the 0-50 cm soil layer, the SMC decreased with increasing depth. At 50 d, under the condition of irrigation once every two days ASMC ranged between 9.81 and 16.28%. The variation trend of SMC in the 0-50 cm soil layer first increased and then decreased with increasing depth. The SMC, however, reached the highest in the 10-20 cm soil layer. At 60 d under the condition of irrigation once every two days, the ASMC ranged between 6.11 and 14.30%. In the 0-50 cm soil layer, the variation trend in the SMC increased with increasing depth. At 76-144th d and after grass growing, natural precipitation is the only source of recharge to soil moisture in the slope. The ASMC of each soil layer in different positions of the three slope surfaces ranged between 7.47 and 13.39%. Except for the lower position of the third slope surface, the ASMC of the 0-50 cm soil layer increased with depth. However, ASMC of the 0-50 cm soil layer in the lower position of the third slope surface remained basically constant with increasing depth. The magnitude of increase or decrease of SMC in each soil layer was below 1%.

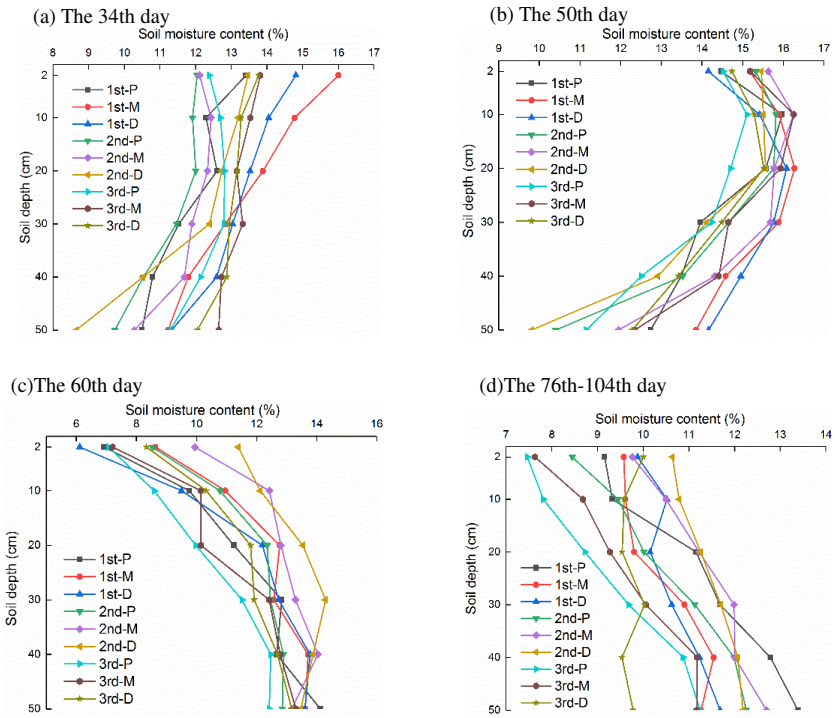

Figure 4. *The SMC of three slope positions on the first, second and third slopes in the stepped steep slope under different sprinkling irrigation frequency. (The first, second and third slope surfaces are represented by 1st, 2nd, 3rd and the upper, middle and lower slope positions are represented by P, M and D)*

ASMC under different frequencies of sprinkler irrigation

Two factor analysis of variance was used to analyze the influence of different frequencies of sprinkler irrigation and slope positions on the variation of ASMC and based on the outcomes of this statistic data could be further processed with least significant difference method (LSD) test. The results showed that there was no significant difference in soil moisture between different slope positions ($P > 0.05$), different frequencies of sprinkler irrigation has a significant effect on ASMC ($P < 0.05$). ASMC after strong precipitation was significantly higher than that in other periods ($P < 0.05$) (*Table 2*), in addition, ASMC at the non-irrigation stage was significantly higher than that at the stage of sprinkler irrigation once every two days ($P < 0.05$).

Table 2. *LSD test of ASMC under different sprinkler irrigation*

Frequencies of sprinkler irrigation	The 34th day	The50th day	The 60th day	The 76th-104th day
The 34th day	1	-1.977*	-0.500	0.814
The 50th day		1	1.477*	2.792*
The 60th day			1	1.314*
The 76th-104th day				1

Figure 5 shows the variation of ASMC along 0-50 cm soil layer, error bars were expressed by standard deviation of ASMC. In addition, dotted lines with integer values close to range of the actual ASMC are added to the figure to make the change trend of ASMC clearer. In the second slope surface, the value was the highest in the lower position, followed by the middle and upper positions successively. However, no consistent variation pattern was found in different positions of the other two slope surfaces. Of the three slope surfaces, at 34 d (*Fig. 5a*) the value was the highest in the third slope surface. This was followed by the first and second slope surfaces successively. ASMC of the middle and lower positions of the first slope surface were significantly higher than that of the second slope surface ($P < 0.05$). However, the differences were not statistically significant as compared with the third slope surface. ASMC of the upper position in the second slope surface was significantly lower than that of the third slope surface ($P < 0.05$), but the difference was not significant as compared with the first slope surface. Of the three slope surfaces, ASMC at 50 d (*Fig. 5b*) was the highest in the first slope surface, followed by the third and second slope surfaces successively. But the value in the middle position of the first slope surface was significantly higher than that of the second slope surface ($P < 0.05$). However, the differences were not of statistically significant as compared with the third slope surface. ASMC in the upper and lower positions of the other slope surfaces were not significantly different. Of the three slope surfaces, at 60 d (*Fig. 5c*) ASMC was the highest in the second slope surface, followed by the first and third slope surfaces successively. In the lower position of the second slope surface, the value was significantly higher than that of the first and third slope surfaces ($P < 0.05$). However, the differences were not of statistically significant as compared with the upper and middle positions of each slope surface. At 76-104 d (*Fig. 5d*), the value was the highest in the first slope surface, followed by the second and third slope surfaces successively. In the upper position of the first slope surface it was higher than that of the second and

DOI: http://dx.doi.org/10.15666/aeer/1802_31613175

third slope surfaces ($P < 0.05$). However, the differences were not statistically significant as compared with the middle and lower positions of each slope surface.

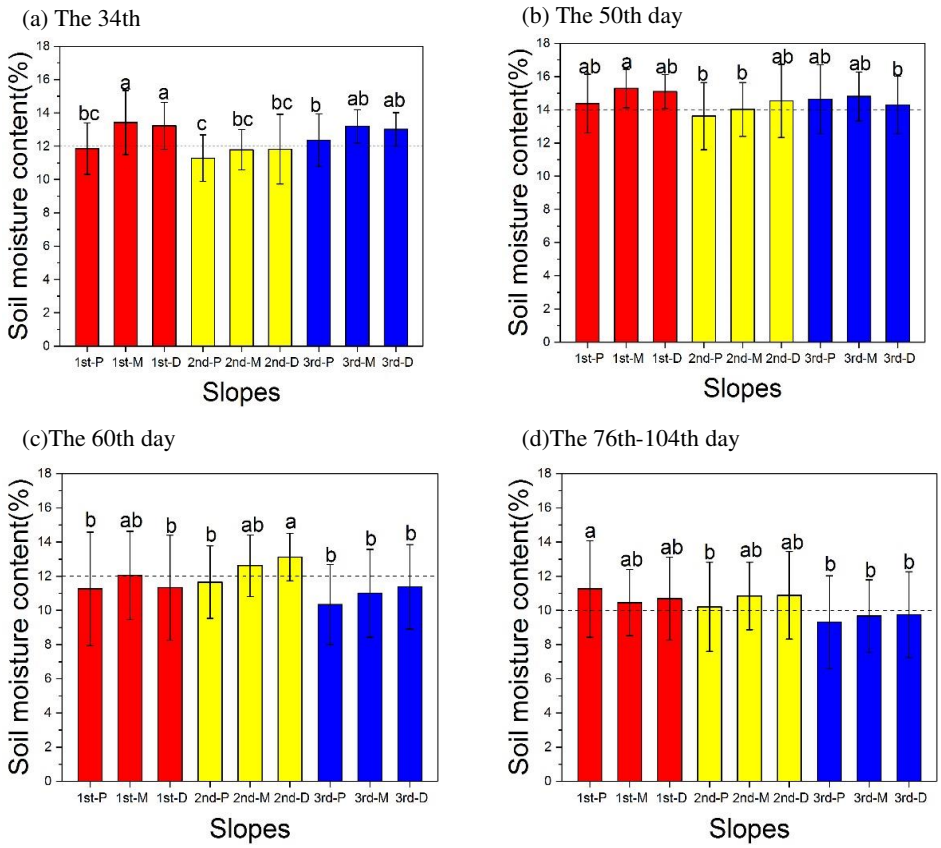

Figure 5. *Mean soil moisture content (ASMC) with error bars for different slope positions under different sprinkler irrigation. Different lower-case letters indicate levels of significance ($p < 0.05$) in mean soil water content at different slope positions in the same sprinkler irrigation. (Different lowercase letters are used to indicate significant difference in the ASMC at different slope positions under the same sprinkler irrigation condition ($P < 0.05$); first, second and third slope surfaces (1^{st}, 2^{nd} and 3^{rd}), upper, middle and lower slope surfaces (P, M and D))*

Stability of SMC of three slope surfaces in the stepped slope

Soil layers were divided vertically according to the SMC of each slope surface under different irrigation conditions (*Table 3*). At 34 d, the SMC was basically stable in the three slope surfaces, and CV based on *Equation 1* of ASMC was 8.9%. CV was larger in the 0-2 cm and 40-50 cm soil layers. These layers were thus considered as the less active layers. CV of other soil layers was all below 10%, indicating stable SMC. At 50 d, the SMC was generally stable in the three slope surfaces. The CV of ASMC was 6.7%. CV of each soil layer was below 10%, indicating stable SMC. At 60 d, the three slope surfaces were generally in a less active state and CV of the ASMC was 14.1%. CV of ASMC was larger in the 0-10 cm and 40-50 cm soil layers, corresponding to less active and active state, respectively. The CV was below 10% in the 10-40 cm soil layer, indicating stable SMC. At 76-104 d, the three slope surfaces were generally in an active state. In this finding the CV of ASMC was 21.9%. Recording of larger CV in the 0-

DOI: http://dx.doi.org/10.15666/aeer/1802_31613175

20 cm and 40-50 cm soil layers, indicated an active state. The CV of the 20-40 cm soil layer showed a value below 20%, so the layer was in a less active state.

Correlation between slope gradient, soil hardness and SMC of the three slope surfaces in the stepped slope

Of the three slope surfaces (*Table 4*), the slope gradient was the highest in the first slope surface (60°), followed by the second (40°) and third (25°) slope, successively. As to the average soil hardness, it was the highest in the third slope surface (5.3 ± 3.68 kg·cm^{-2}), followed by the second (4.1 ± 2.78 kg·cm^{-2}) and first (2.6 ± 1.24 kg cm^{-2}), successively. The ASMC in the 0-50 cm soil layer during the test period was the highest in the first slope surface (12.48 ± 1.80%), followed by the second (12.20 ± 1.44%) and the third slope (11.98 ± 2.19%), successively.

Table 4. *Slope gradient, soil hardness and the average soil moisture content in the 0-50 cm soil layer during the test period of the three slope surfaces in the stepped slope*

Slope position	Slope gradient	Soil hardness (kg·cm^{-2})	Soil moisture content (%)
The 1st slope	60°	2.6 ± 1.24	12.48 ± 1.80
The 2nd slope	40°	4.1 ± 2.78	12.20 ± 1.44
The 3rd slope	25°	5.3 ± 3.68	11.98 ± 2.19

Correlation analysis was conducted between SMC of each soil layer within the depth of 0-50 cm and four environmental factors, namely, slope position and gradient, soil hardness and vegetation cover (*Table 5*), Pearson correlation coefficient was used to express the magnitude of correlation between soil moisture content and environmental

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31613175

factors. The sample size was 90 for SMC determination in each soil layer. The SMC correlated negatively and significantly with the soil hardness ($P < 0.01$). In the 0-50 cm soil layer, the average correlation coefficient was -0.695. The correlation coefficient decreased between the SMC and soil hardness with increasing depth. The SMC correlated negatively with the soil hardness. The average correlation coefficient was -0.205 in the 0-50 cm soil layer. The correlation coefficient between SMC and slope position increased with increasing depth. The SMC in the 40-50 cm soil layer correlated negatively and significantly with the slope position ($P < 0.05$). The SMC correlated positively to slope gradient. The average correlation coefficient was 0.179 in the 0-50 cm soil layer and it increased with increasing depth. The SMC in the 40-50 cm soil layer correlated positively and significantly to slope gradient ($P < 0.05$). The SMC correlated negatively to vegetation cover. The average coefficient of correlation in the 0-50 cm soil layer was -0.155. It first increased and then decreased with increasing depth.

Discussion

Vertical migration features of SMC in the stepped slope

At the stage of sprinkler irrigation once every two days and at the non-irrigation stage, the SMC in the 0-50 cm soil layer of the stepped slope increased with increasing depth (*Fig. 4*). The results are in agreement with the findings by Gwak and Kim (2017), Qiang et al. (2013) and Yang et al. (2015). At the stage of sprinkler irrigation once daily, the soil moisture content decreased with increasing depth in the 0-50 cm soil layer. This finding is just contrary to the variation pattern as described above. Strong precipitation under irrigation once every two days could alter the variation pattern as mentioned above. As a result, the SMC in the 10-20 cm soil layer was the highest. This is because irrigation once daily was a considerable source of recharge for the slope with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31613175

shorter interval between the irrigations. Strong precipitation usually resulted significant rainwater infiltration and small evaporation and thus provided an efficient recharge to soil moisture in the 0-50 cm soil layer.

As the frequency of sprinkler irrigation decreased, the soil layer with strong changes in SMC extended from the depth of 0-2 to 0-10 cm and finally to 0-20 cm (*Table 5*). The SMC in the middle soil layer, i.e., at the depth of 20-40 cm, remained stable. The SMC was stronger at the greater depth of 40-50 cm, which was consistent with the findings by Choi and Jacobs (2007) and Yao et al. (2012). This is because in the semi-arid regions, the surface soil moisture is more vulnerable to the influence of precipitation, vegetation transpiration and soil evaporation (Seneviratne et al., 2011). Dense sprinkler irrigation (e.g., once daily) can timely recharge the surface soil moisture. As the frequency of irrigation decreased to once every two days, the surface soil moisture cannot be timely recharged after retention, evaporation and infiltration, leading to significant changes in SMC. In an absence of stable recharge from irrigation at the non-irrigation stage, precipitation served as the only recharge to soil moisture. At this stage, randomness of precipitation made the changes of SMC strongest. The local wilting coefficient was $6.20 \pm 0.60\%$. At the early stage of vegetation construction, natural precipitation was enough to ensure the normal growth of vegetation as long as the soil moisture content was higher than 2.45% of the wilting coefficient and that the vegetation entered the non-irrigation stage.

Spatial variation features of SMC in different slope positions

Of the three slope surfaces, the ASMC at the non-irrigation stage was the highest in the first slope surface, followed by the second and third slope surfaces, successively. On the whole, the SMC increased from the top to the bottom of the slope surface (Feng et al., 2013; Legates et al., 2011). The SMC of the three slope surfaces at the irrigation stage were different from the above. The reason was probably that the variability of environmental factors in the three slope surfaces of the stepped slope led to spatial differentiation features of soil moisture content. A correlation analysis was performed between the SMC and environmental factors (*Table 5*). The results showed that soil hardness and terrain factor had a larger impact on soil moisture in the stepped slope. As to the soil hardness, it was highest in the upper position of the second slope surface (3.14 $kg \cdot cm^{-2}$), followed by the middle (4.46 $kg \cdot cm^{-2}$) and lower (4.61 $kg \cdot cm^{-2}$) positions successively. However, the variation pattern was different for the other two slope surfaces. The average overall soil hardness was the highest in the third slope surface (5.3 $kg \cdot cm^{-2}$), followed by the second (4.1 $kg \cdot cm^{-2}$) and first (2.6 $kg \cdot cm^{-2}$) slope surfaces successively. The lower the soil hardness, the smaller the negative effect on the SMC was. As to the influence of terrain factor, the infiltration-excess surface runoff flowed from the third, then to the second and finally to the first slope surface. In relevant to the slope gradient, it was the highest in the first slope surface, followed by the second and third slope surfaces, successively. The larger the slope gradient, the more likely the runoff formation will be, thus leading to soil moisture loss. Therefore, under the joint influence of soil hardness and terrain factor, SMC of the stepped slope showed the above features of spatial variation.

Most studies would believe that soil hardness, slope position and slope gradient correlated negatively with SMC, while vegetation cover correlated positively with SMC (Ali et al., 2010; Cantón et al., 2004; Ishaq et al., 2001; Yang et al., 2015). In this study, we found that both the soil hardness and slope positive correlated negatively with soil

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31613175

moisture content, which agreed with the previous researches (Ali et al., 2010; Cantón et al., 2004; Ishaq et al., 2001; Yang et al., 2015). However, the findings that the SMC correlated positively with slope gradient and negatively with vegetation cover were consistent with the previous researches (Ali et al., 2010; Cantón et al., 2004; Ishaq et al., 2001; Yang et al., 2015). This was because soil hardness and slope position had a greater impact on SMC. Moreover, the test was conducted at the initial stage of vegetation reconstruction, where the root system of the vegetation was not fully developed. For this reason, the slope gradient and vegetation cover had little impact on SMC.

Influence of environmental factors on the stability of SMC in the stepped slope

Many studies have indicated that the main factors affecting spatial variation of SMC in slopes are soil properties (Fitzjohn et al., 1998; Zhang and Berndtsson, 1988), terrain (Crave and Gascuel-Odoux, 2015; Gómez-Plaza et al., 2001) and vegetation (Bromley et al., 1997; Rodriguez-Iturbe et al., 1999). But given the interaction between these factors and multiplicity of the effect of these factors on SMC, we can hardly determine their relative importance (Grayson et al., 1999). It is widely recognized that soil properties are important affecting factors of spatial distribution of soil moisture. For example, Martinez et al. (2010) opined that the effect of soil properties on spatial differentiation of SMC was greater than that of the terrain factor. However, the effect of terrain factor on spatial distribution of soil moisture was indescribable. Schneider et al. (2011) proposed that soil properties had greater impact on soil moisture, while the influence of vegetation on soil moisture was smaller. Famiglietti et al. (1998) suggested that under humid conditions, soil moisture content variability received the greatest impact from soil properties. While under dry condition, SMC variability was controlled jointly by terrain and soil properties. There are also contending opinions. For example, Tromp-van Meerveld and Mcdonnell (2006) showed that vegetation exerted a greater impact on the spatial distribution of soil moisture content than local terrain. Gwak and Kim (2017) and Kim (2012) opined that terrain was an important affecting factor of spatial distribution of SMC. The soil hardness had significant impact on the spatial variation of SMC. This explained why the SMC was still the smallest even when the gradient of the third slope surface was 25°. This agreed with the findings by Martinez et al. (2010) and Schneider et al. (2011), but disagreed with Gwak and Kim (2017), Kim (2012), Tromp-van Meerveld and Mcdonnell (2006). Ishaq et al. (2001) and Feng et al. (2013) showed that the correlation between soil hardness and SMC weakened with increasing depth, while the correlation of slope gradient and aspect to SMC was strengthened. Our results were in agreement with those. A correlation analysis was performed between the SMC and environmental factors (*Table 5*). The results showed that soil hardness and terrain factor had a larger impact on soil moisture in the stepped slope.

Conclusion

Our results indicated that the soil moisture migration of the three slope surfaces (bottom, middle and top) exhibited a similar pattern under different methods and significant of sprinkler irrigation. That is, at the non-irrigation stage and the stage of irrigation once every two days, the SMC increased with increasing depth. Whereas, at the stage of irrigation once daily, the SMC decreased with increasing depth. The SMC

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31613175

decreased and the CV of SMC increased with the decreasing frequency of sprinkler irrigation. However, the ASMC content increased from the top to the bottom of the stepped slope under different frequencies of sprinkler irrigation. The correlation analysis among the four environmental factors, namely, slope position and gradient, soil hardness and vegetation cover showed positive and negative relationships. The slope position, slope hardness and vegetation cover correlated negatively with the SMC ($P < 0.01$). On the other hand, the slope gradient correlated positively with the SMC ($P < 0.05$). In order to ensure better vegetation growth in the stepped slope under the water conservation context, the frequency and amount of sprinkler irrigation should be adjusted according to the growth status of vegetation. Moreover, reasonable tillage measures such as ploughing should be adopted to reduce soil hardness, increase SMC and promote fast vegetation restoration of the slopes.

The duration of the study is short, so it is difficult to assess and eliminate the impact of soil disturbance caused by infrastructure construction, and the spatial variation of SMC in different slope direction, number of steps and slope gradient needs further study.

(Received 27th Sep 2019; accepted 4th Feb 2020)

Abstract. Hydrological exchange between the trunk stream and the floodplains is the key factor maintaining ecological functioning. The water discharge diverting from the Yangtze River to the Dongting Lake has recently decreased considerably in China. However, their variation characteristics and major driving factors remained unclear. In this study, Mann Kendall trend and Pettitt abrupt tests were employed to determine the changes of time series. Double mass curve analysis and regression analysis were used for the qualitative analysis of the impacts of climate change and human activity. Results revealed that precipitation change trends significantly decreased in autumn. The water discharge at the trunk Yangtze River had a decreasing trend in autumn and an increasing trend in winter. The annual and seasonal water discharge diverting from the Yangtze River to the Dongting Lake, except at Xinjiangkou in summer, exhibited significant downward trends. No consistent trends in precipitation and water discharge were identified, thereby indicating that the seasonal relationships between them had been disturbed by human activities. Human activities had a dominant effect on the water discharge exchange between them during 1967–2018. Along with the intensification of human activities, the hydrological connectivity between the Yangtze River and the Dongting Lake would probably be further changed in the near future.
Keywords: *hydrological connectivity, river–floodplain systems, the Jingjiang Three Outlets, the Three Gorges Dam, Mann–Kendall test, Pettitt test*

Introduction

Floodplains have the highest levels of production and biodiversity worldwide (Tockner and Stanford, 2002) and not only provide habitat and refuge for species (Whited et al., 2007; Hung et al., 2012) but also supply important services for humankind (Kummu et al., 2014). The hydrological exchange between the trunk river and its floodplains is the most important factor for maintaining ecological function and biodiversity and for flood attenuation (Thomaz et al., 2007; Zurbrügg et al., 2012). In recent decades, river floodplain systems have been heavily disturbed by human activities (Heiler et al., 1995; Clilverd et al., 2013). Moreover, the hydrological cycle in major rivers worldwide has undergone dramatic spatiotemporal changes along with global climate changes (Palmer et al., 2008). Hydrological connectivity between the trunk river and its floodplains are changed by human activities and climate change significantly in many large rivers (Heiler et al., 1995; Knowlton and Jones, 1997;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31773193

Amoros and Bornette, 2002; Tockner et al., 2010) and caused the biodiversity and bioproduction degradation in many river–floodplain systems, including the Danube in Europe (Besemer et al., 2005), the Missouri in the USA (Knowlton and Jones, 1997), and the Mackenzie in Canada (Lesack and Marsh, 2010). Numerous previous studies have concentrated on the benefits of river floodplain connections (Bullock and Acreman, 2003; Acreman et al., 2003; Zurbrügg et al., 2012). However, the effects of human activities and climate change on hydrological connectivity have not received significant attention. Therefore, quantitative assessments of the influences of human activities and climate change on the hydrological connectivity of these systems are extremely essential to make effective management and conservation plans for river–floodplain ecosystems.

The Yangtze River floodplain is characterized by a number of lakes of various sizes in China (Nie et al., 1999; Yang et al., 2008). The Yangtze River freely connected with many lakes in the history (Ru and Liu, 2013). Along with the intensive human activities such as the construction of dam, deforestation, water diversion, and sand extraction, the hydrological connectivity has been remarkably changed. At present, only three lakes (Dongting Lake, Poyang Lake, and Shijiu Lake) retain direct connections with the Yangtze River. The obstruction of hydrological connectivity changes the patterns of the lake wetland vegetation (Hu et al., 2015), damages the diversity of fish species (Xie et al., 2003), and increases flood risk (Nakayama and Shankman, 2013) in the Yangtze River floodplain. Thus, the obstruction of hydrological connectivity is one of the top threats to the Yangtze River floodplain (Liu and Wang, 2010; Pan et al., 2011).

The hydrological connectivity between the Yangtze River and the Dongting Lake is the most typical and complex in the floodplain of Yangtze River in China (Lai et al., 2014a). The Dongting Lake receives water from the Yangtze River through the tie channels of the Jingjiang Three Outlets (JTO). During 1956–1966, the JTO could recharge averaged 29.3% of the main river water discharge into the Dongting Lake; however, after 2003, it can divert only 11.8% (Zhu et al., 2015). The hydrological connectivity at the JTO has considerably decreased (Ou et al., 2014). Thus, significant attention is paid to investigate the reasons for the decreased hydrological connectivity at the JTO, especially after the Three Gorges Dam (TGD) in 2003. Chang et al. (2010) and Zhu et al. (2015) analyzed the variations in the water exchange at the JTO to determine the TGD influences on the water exchange capability, and they had different opinions on the effect factors of the water exchange changes at the JTO. Zhang et al. (2015a) found that the TGD impoundment was responsible for 31.1% of the decrease in the water exchange at the JTO. Li et al. (2016) found that river channel changes were responsible for 23.6% of the decrease in the water exchange at the JTO after the TGD. However, it still disagrees on how human activities influent the water exchange at the JTO (Chang et al., 2010; Zhu et al., 2015; Zhang et al., 2015a; Li et al., 2016). Furthermore, previous studies mainly focused on the influences of human activities, but the effects of climate change were neglected. The properties of changing water exchange and their influence factors at the JTO were not extensively analyzed. Therefore, this study objectives are as follows: (1) to detect the annual and seasonal variations in the water exchange at the JTO on the basis of the daily hydrologic data during 1960–2018; (2) to quantify the effects of precipitation changes on water exchange; and (3) to assess the contributions of human activities and climate change to water exchange reduction. This study hopes to provide an important scientific basis for

DOI: http://dx.doi.org/10.15666/aeer/1802_31773193

the optimization control of the river–lake relationship and the protection of river–floodplain ecosystems.

Study area and data

Study sites

Human activities in the Yangtze River have remarkably intensified during the past half century, especially after the economic reform and opening-up policy was implemented in 1978 in China (Chen et al., 2014). The storage capacity of large reservoirs and dams has significantly increased, especially after 1981 and 2003 (*Fig. 1*). Water–soil conservation (i.e., terracing, planting trees, and protecting vegetation) was implemented in 1988. In 1992, the cumulative area of water–soil conservation displays an upward trend from 156.56×10^3 km^2 to 320.58×10^3 km^2.

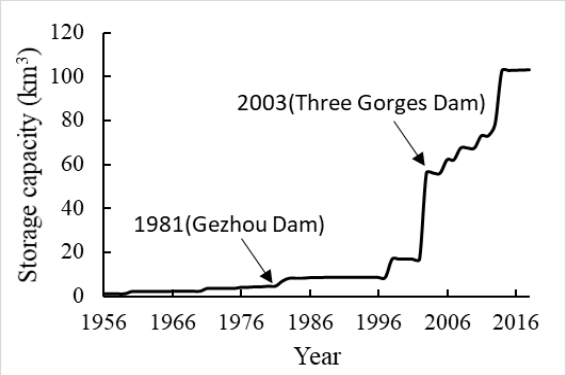

Figure 1. *Storage capacity of large reservoirs in the upper Yangtze River*

Local river channel cut-off events. As shown in *Table 1*, three instances of artificial and natural channel cut-offs occurred in the lower Jingjiang River from 1967 to 1972. Artificial channel cut-off projects at Zhongzhouzi in 1967 and Shangchewan in 1969 were carried out, which respectively shortened the channel lengths of the lower Jingjiang River (the lower Jingjiang River from the Ouchikou to the Chenglingji) to approximately 32.4 and 29.2 km. Natural channel cut-off at Shatanzi occurred in 1972, which resulted in a channel length decrease of 18.95 km.

Table 1. *River channel cut-off events in the lower Jingjiang River. (Data originated from Qin et al., 2013)*

Cut-off name	Cut-off year	Cut-off reason	Channel length before the cut-off (km)	Channel length after the cut-off	Channel length change
Zhongzhouzi	1967	Artificial	36.7	4.3	32.4
Shangchewan	1969	Artificial	32.7	3.5	29.2
Shatanzi	1972	Natural	20.3	1.35	18.95

The Songzi, Taiping, and Ouchi outlets comprise the JTO. The Zhicheng Hydrological Station situated 18 km upstream of the JTO was used to reflect the influence of the mainstream. Zhicheng is approximately 60.8 km distant from Yichang

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31773193

Hydrological Station that is the hydrological control station of the upper Yangtze River. They have very similar streamflows. Xinjiangkou and Shadaoguan are the hydrological stations at the Songzi outlet. Mituosi Hydrological Station controls the Taiping outlet. Ouchi (kang) and Ouchi (guan) are the hydrological stations at the Ouchi outlet (*Fig. 2*).

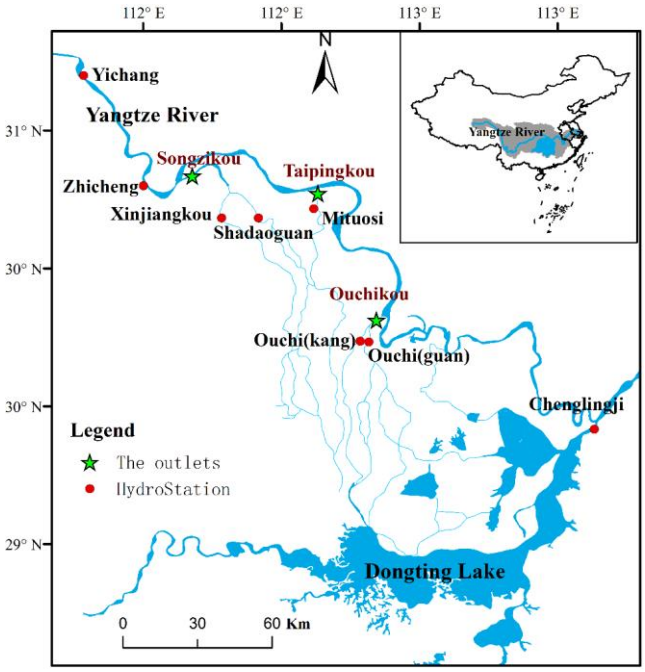

Figure 2. *Geophysical location of the JTO in the Yangtze River Basin*

Data

The daily water level and discharge data during 1960–2018 were obtained from the Bureau of Hydrology, Changjiang Water Resources Commission in China. The data of daily precipitation from 180 meteorological stations situated in the Yangtze River Basin were obtained from the China Meteorological Data Network (http://data.cma.cn/). A total of 70 meteorological stations with continuous precipitation record stations during 1960–2018 are located in the upstream of Zhicheng (*Fig. 3*). Based on the climate features in the Yangtze River Basin, there are four seasons divided: spring between March and May, summer between June and August, autumn between September and November, winter between December and February.

Methods

Mann–Kendall trend test

The trend analyses which are the hydrological-meteorological time series used the non-parametric Mann–Kendall (MK) test (Mann, 1945; Kendall, 1975). The test statistic for a time series $(x_1, x_2, x_3, \dots, x_n)$ is given as follows:

$$S = \sum_{i=1}^{n-1} \sum_{j=i+1}^{n} sgn(x_j - x_i) \quad \text{(Eq.1)}$$

$$\operatorname{sgn}(x_j - x_i) = \begin{cases} +1 & \text{if } (x_j - x_i) > 0 \\ 0 & \text{if } (x_j - x_i) = 0 \\ -1 & \text{if } (x_j - x_i) < 0 \end{cases} \quad \text{(Eq.2)}$$

where x_i and x_j respectively represent the data values at times i and j. n is the time series length.

$$\operatorname{Var}(S) = \frac{[n(n-1)(2n+5) - \sum_{i=1}^{m} t_i\,(t_i-1)(2t_i+5)]b}{18} \quad \text{(Eq.3)}$$

where m and t_i respectively represent the number of tied groups and data in the tied group. The standard normal variable Z is given by *Equation 4:*

$$Z = \begin{cases} \frac{S-1}{\sqrt{Var\,(S)}}, & \text{if } S > 0 \\ 0, & \text{if } S = 0 \\ \frac{S-1}{\sqrt{Var\,(S)}}, & \text{if } S < 0 \end{cases} \quad \text{(Eq.4)}$$

The positive Z value is an increasing trend, and the negative Z value is a decreasing trend. If $|Z|$ is greater than 1.96 at the 0.05 significance level, the null hypothesis of the absent trend is rejected.

Pettitt abrupt change test

The abrupt change of the hydrological-meteorological time series used the Pettitt test (Pettitt, 1979). The method uses a version of the Mann–Whitney statistic $U_{t,n}$, including two parts ($x_1, x_2, x_3, \dots, x_t$ and $x_{t+1}, x_{t+2}, x_{t+3}, \dots, x_T$) from the same time series. The test statistic $U_{t,n}$ is computed as follows:

$$U_{t,T} = \sum_{i=1}^{t} \sum_{j=1}^{T} sgn\,(x_t - x_j) \quad \text{for } t = 2, \dots, n \quad \text{(Eq.5)}$$

The largest $|U_{t,T}|$ value is the abrupt change point

$$K_T = max|U_{t,T}| \quad \text{(Eq.6)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31773193

The significance testing are as follows:

$$p \cong 2\exp\left\{-\frac{6(K_T)^2}{T^3+T^2}\right\} \quad \text{(Eq.7)}$$

Once the p value is less than the 5% significance level, a significant abrupt change point exists.

Double mass curve analysis

Double mass curve (DMC) is a common method to test the consistency and variation of the relationship between two parameters. A DMC is a line drawn between the continuous cumulative values of one variable and the continuous cumulative values of another variable for the same period. Generally, the Double mass curve analysis kept a straight line if water discharge was not affected by human activities. Therefore, evident abrupt change points in the DMCs suggest the variations influenced by human activities (Zhao et al., 2017).

Regression analysis for quantifying the influences of human activities and climate change

Reconstruction of the natural water discharge at the JTO is necessary to better understand and quantify the influences of human activities and climate change on hydrological connectivity between Dongting Lake and Yangtze River. The amount of water exchange at the JTO is impacted by various factors, such as the position between the JTO entrance and the trunk stream, the channel scouring and silting changes, and river regime variations in the mainstream (Lu et al., 2012). The changes of relative position and river channel gradually and slowly occur under natural conditions (Zhang et al., 2015b). Thus, the amount of water exchange at the JTO is directly related to the changes of water discharge at the mainstream of Zhicheng. To quantify the impact of precipitation changes and human activities on water exchange at the JTO, the regression analysis method was applied in the current study.

Previous studies indicated that the precipitation and streamflow in the Yangtze River Basin were minimally affected by human activities before the 1970s (Yang et al., 2015; Zhao et al., 2015). Thus, the period 1960–1966 was used as the reference period to achieve the requirement of this study. Although streamflow is related to many factors, such as precipitation, temperature, dam construction, and GDP in the Yangtze River Basin, numerous studies found that precipitation is the most correlated with streamflow at the mainstream which can explain 80% of the variance during the past 50 years (Chen et al., 2014; Zhao et al., 2015). Therefore, regression equations are established between annual precipitation and water discharge at Zhicheng based on data collected in the period 1960–1966 to estimate the natural water discharge at Zhicheng. Afterward, regression equations are established between the water discharge at Zhicheng and the water exchange at the JTO in the period 1960–1966. Thus, water exchange changes at the JTO in response to precipitation change in subsequent years can be quantified by estimating the natural water exchange at Zhicheng. The hydrological response to human activities can be provided by the difference between the estimated and the observed water discharge.

Results and discussion

Annual and seasonal precipitation trends in the basin

The trends of the basin-averaged seasonal and annual precipitation in the upstream of Zhicheng from 1960 to 2018 on the basis of MK test are shown in *Figure 4*. The mean annual precipitation during 1960–2018 was 996.09 mm (from 756.50 mm to 1027.80 mm). Annual precipitation shows an inconspicuous tendency. On a seasonal basis, precipitation trends in spring, summer, and winter present no statistical significance. However, precipitation trends show a remarkable decreasing trend with a 99% confidence level in autumn.

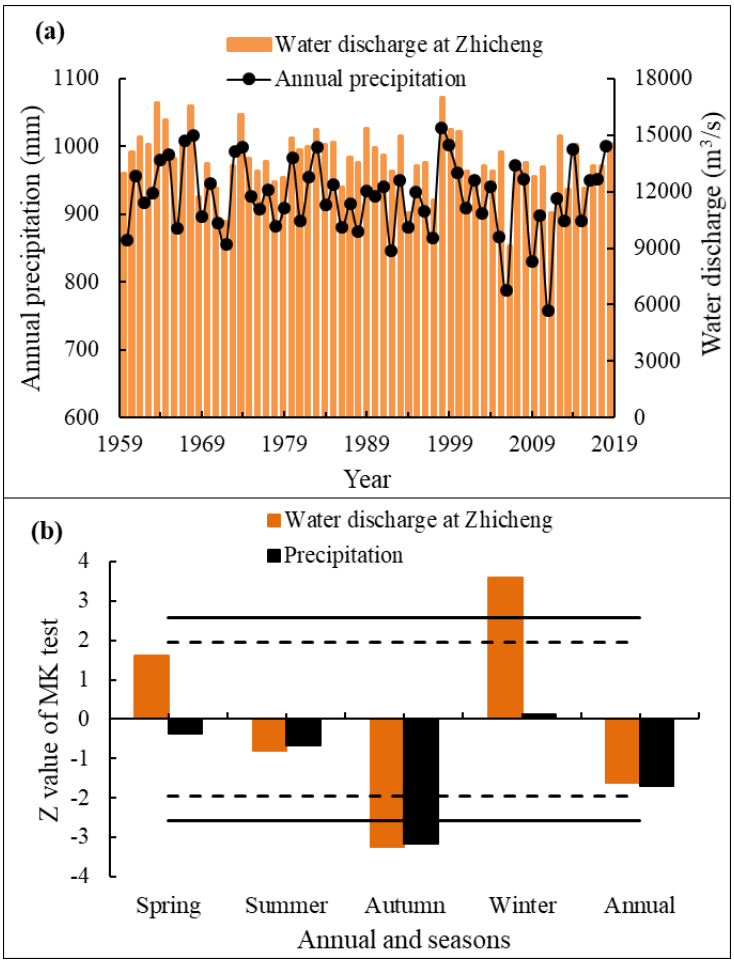

Figure 4. *Temporal trend changes in the annual-seasonal precipitation and water discharge at Zhicheng. (a) Annual precipitation and water discharge, (b) trends of the annual and seasonal precipitation and water discharge with the MK test. Horizontal dashed lines and solid lines in (b) denote confidence levels of 95% and 99% respectively*

Annual and seasonal water discharge trends at Zhicheng

Variations of the annual and seasonal water discharge at Zhicheng in the mainstream of Yangtze River are detected based on the observed data from 1960 to 2018 (*Fig. 4*). The annual average water discharge during 1960–2018 was 13,698.12 m^3/s, with a range from 12,995.85 m^3/s to 17,005.78 m^3/s (*Fig. 4a*). The annual average water discharge shows no significant decreasing trend and decreases by an average of 28.01

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31773193

m^3/s every year (*Fig. 4*). The seasonal water discharge time series exhibited different change trends (*Fig. 4b*). Water discharge shows an upward trend in spring and a downward trend in summer, with no statistically significant levels. However, a decreasing trend in autumn and an increasing trend in winter were detected with a 99% confidence level.

Annual and seasonal water discharge trends at the JTO

The changes of annual and seasonal water discharge at the JTO are shown in *Figure 5*. The annual and seasonal water discharge at different stations fluctuated and decreased from 1960 to 2018. The annual average water discharge at Xinjiangkou, Shadaoguan, Mituosi, Ouchi (kang), and Ouchi (guan) decreased by an average of 7.15, 6.42, 8.29, 1.91, and 27.91 m^3/s every year, respectively. Before the 1970s, the average water discharge at Ouchi (guan) was significantly larger than at the other outlets, whereas it was smaller than that at Xinjiangkou after the 1970s (*Fig. 5a*). The seasonal water discharge dramatically fluctuated throughout the year at all stations. More than 90% of water discharge at all stations occurred in summer and autumn. In winter, water discharge at the JTO, except at Xinjiangkou, almost presented a zero-water discharge state after the 1970s (*Figs. 5b–f*).

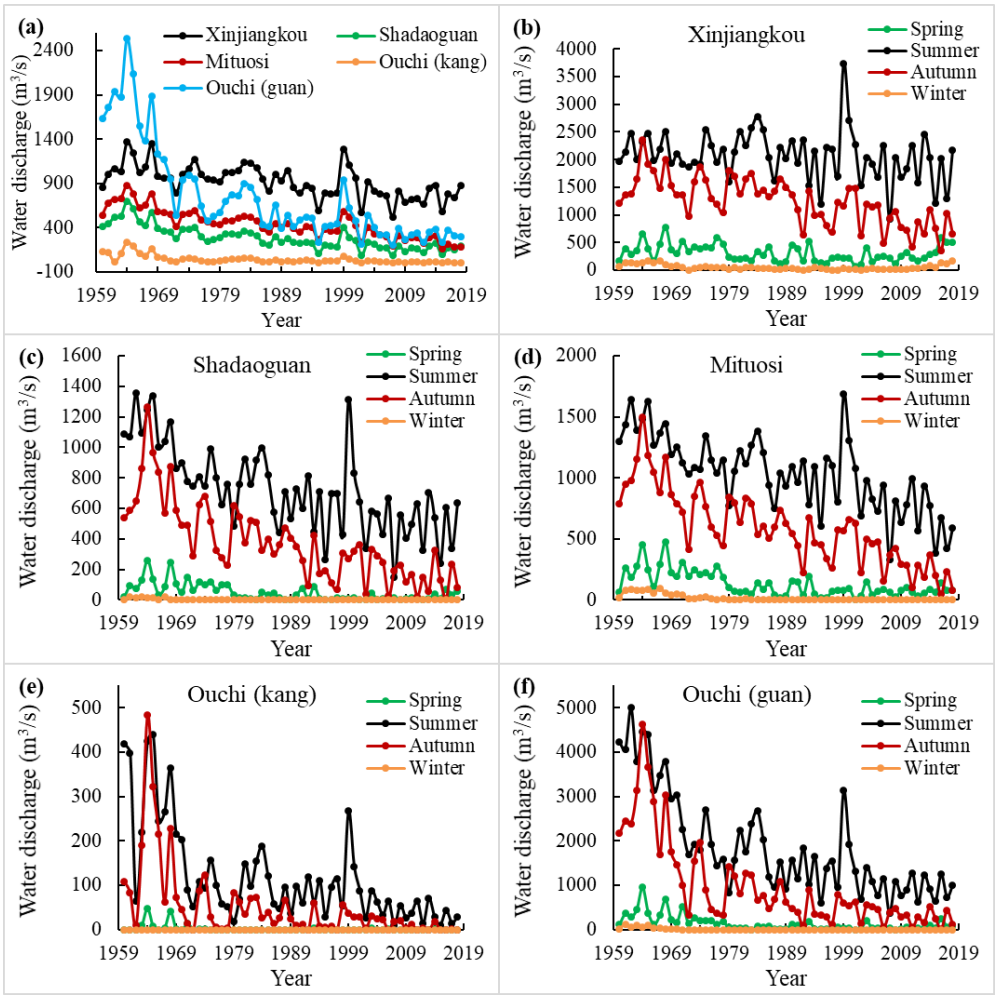

Figure 5. *Changes in the annual and seasonal water discharge at the JTO during 1960–2018. (a) Annual water discharge, (b–f) seasonal water discharge at different stations*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31773193

The annual and seasonal water discharge except at Xinjiangkou, in summer exhibited significant downward trends with a 99% confidence level (*Fig. 6*). The consistent trend results of annual and seasonal water discharge indicated that they might experience similar driving factors.

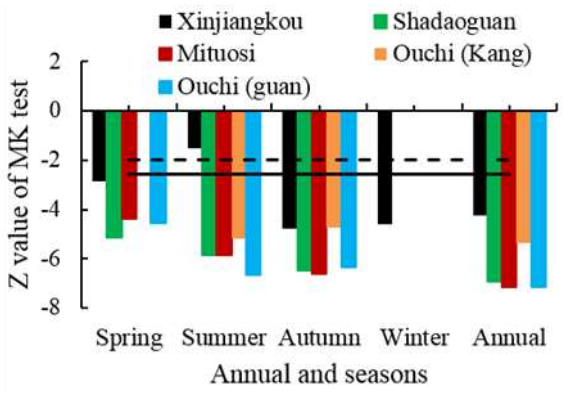

Figure 6. *Temporal trend changes in the annual and seasonal water discharge at the JTO with the MK test during 1960–2018. Horizontal dashed lines and solid lines denote confidence levels of 95% and 99% respectively*

Abrupt change point in annual-seasonal precipitation and water discharge

The Pettitt test was employed to detect abrupt change points in precipitation and water discharge for the control hydrological stations at the trunk stream of the Yangtze River and at the JTO during 1960–2018. The results are shown in *Table 2*. Only precipitation in autumn exhibited a downward abrupt change occurring in 1989. For the mainstream of Zhicheng, the water discharge in autumn and winter displayed significant abrupt changes in 1990 and 1999 with confidence levels of 99% and 95% respectively. On the other hand, every spring and summer, no significant abrupt changes occurred during 1960–2018. For the five control hydrological stations at the JTO, except water discharge in summer at Xinjiangkou and in spring at Ouchi (kang), significant abrupt changes were found in the annual and seasonal water discharge time series. All the stations at the JTO showed consistent outcomes with the test in spring (1977), summer (1982), and autumn (1989), whereas the abrupt stating times in annual and in winter were displayed differently. In general, abrupt stating times occurred mainly around 1980 and 1990. In particular, the abrupt stating times of the Ouchi (kang) and Ouchi (guan) at the Ouchi outlet were earlier than those of other outlets. Under the same conditions of the upstream, the change heterogeneity and inconsistency of annual and seasonal water discharge at the JTO indicated that local human activities affected the amount of water discharge in a complex way.

Impact of human activities and climate change on water exchange

The water exchange changes at the JTO have complex dynamic processes, which are not only closely associated with alterations in the hydrological regimes and channel morphology of the mainstream near the JTO, but also related to the scouring and silting changes in the diversion channels (Lu et al., 2012).

Precipitation and human activities in the upstream of Zhicheng caused the downstream water discharge changes, while water discharge changes at Zhicheng affected the amount

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31773193

of water exchange at the JTO. The decreasing trend of the average annual water discharge at the mainstream of Zhicheng was consistent with the annual precipitation change. This result is in agreement with previous findings. Chen et al. (2017) and Gao et al. (2012) used different methods to demonstrate that the annual streamflow at Yichang had a decreasing trend and confirmed that the decrease in annual precipitation was the primary driver. However, the seasonal change trends between the precipitation and the water discharge at Zhicheng displayed a complicated condition (*Fig. 4*).

Table 2. *Results of the Pettitt test for abrupt change points in the annual-seasonal precipitation and water discharge*

To further address the reasons for the seasonal water discharge changes at Zhicheng, the DMCs were plotted to show the relationship between the precipitation and the water discharge (*Fig. 7*). Abrupt changes in the DMCs are inapparent, especially in summer (*Fig. 7*). In spring and winter, similar with precipitation, water discharge after the transition years was larger than the before in the DMCs. In autumn, water discharge after the transition years was smaller than the before. These results on the seasonal trends and the DMC analysis indicated that the seasonal relationship between water discharge and precipitation had been disturbed by human activities. The operations of reservoirs and dams changed the distribution of inner-annual water discharge downstream. For example, the Three Gorges Reservoir increased low flow in the winter and decreased flood flow in summer since 2003 (Gao et al., 2012). The implementation of water–soil conservation caused a decrease in streamflow from the upper Yangtze River Basin (Yang et al., 2015).

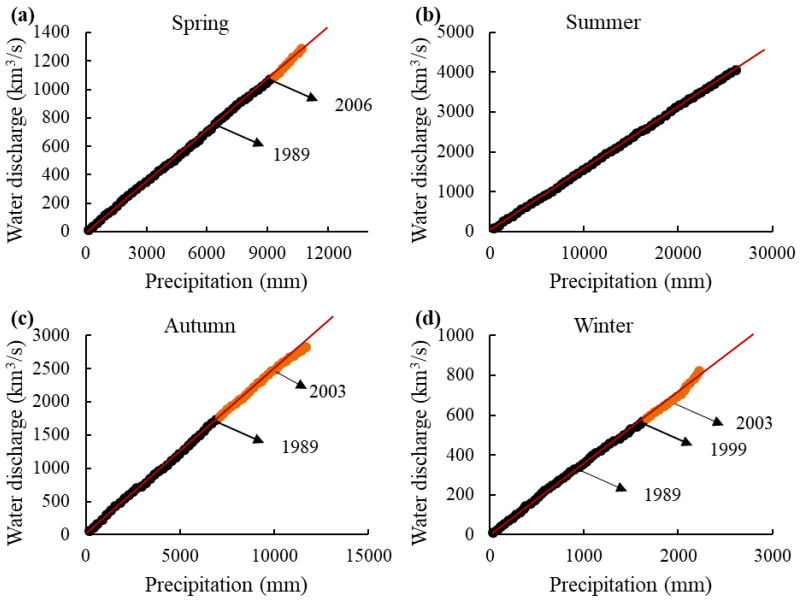

Figure 7. *DMC analysis between precipitation and water discharge at Zhicheng in different seasons*

The annual and seasonal trends of water discharge at the JTO were incompletely homologous to the hydrological variations at the mainstream of Zhicheng (*Figs. 4b* and *6*) because of alterations in the channel morphology (Lai et al., 2014b). The operations of reservoirs and dams trapped a large amount of sediment yield, especially after the operation of Gezhou Dam in 1981 (Zhang et al., 2006; Yang et al., 2014; Gao et al., 2015a, b). The implementation of water–soil conservation also caused a distinct in sediment yield from the upper Yangtze River Basin (Wang et al., 2011). Sediment yield decrease caused the channel erosion in the mainstream channel (Yua et al., 2018). The channel erosion resulted in the lowering water level with the same water discharge (*Figs. 8a*) which decreased the water level differences between the mainstream and the JTO, and resulted in the decline of water diversion ability. Meanwhile, the water level with the same water discharge at the JTO generally shifted up (*Figs. 8b–f*) because of the deposition at the diversion channel at the JTO. The alterations of the channel

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31773193

morphology counteracted the increase in water discharge of the mainstream and resulted in increased zero-discharge days at the JTO (Chang et al., 2010). Under the same precipitation and human activity conditions in the upper stream, the reduced magnitudes of water discharge at the different outlets during 1960–2018 were also different due to the different magnitudes of the scouring and silting changes in the diversion channels (*Figs. 8b–f*). River channel cut-offs caused strong channel erosions in the lower Jingjiang River and relative deposition in the diversion channels (Qin et al., 2013).

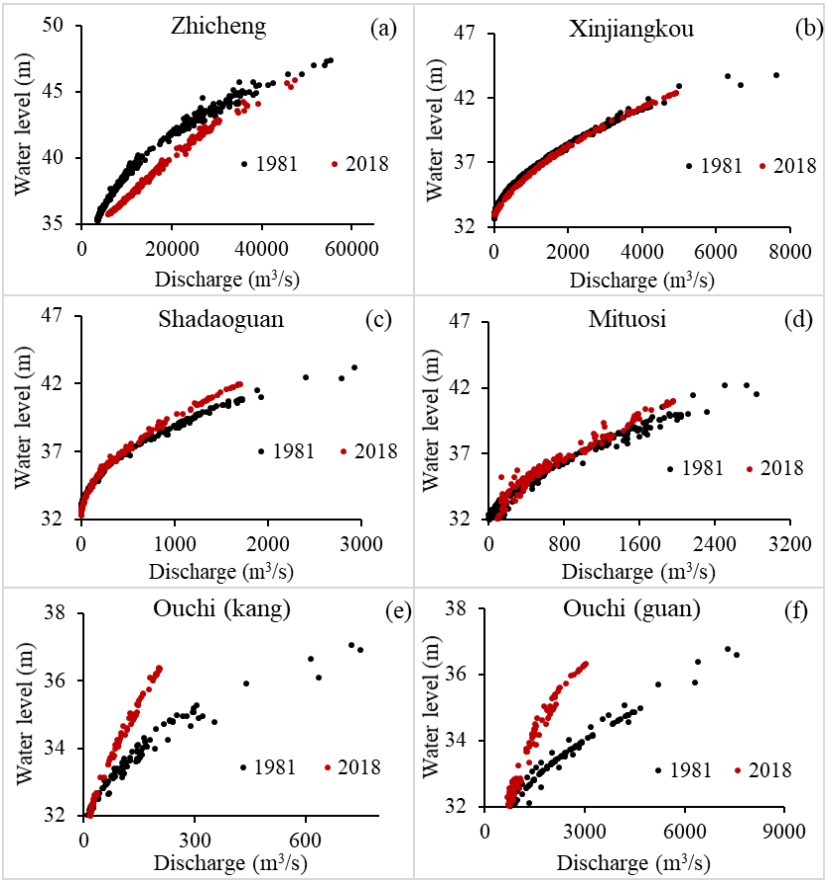

Figure 8. *Rating curves between water level and discharge at Zhicheng and the JTO after the 1981*

Regression analysis for quantifying the influences of precipitation and human activities on the water exchanges at the JTO

Regression analysis was used to quantify the relative contributions of precipitation and human activities to water exchanges at the JTO. The correlation equations are established as shown in *Equations 8–13* based on data observed in the reference period 1960–1966. Their significance levels are as follows:

$$Q_Z = 4.775P + 68.303, \quad R^2 = 0.7837, P = 0.002 \qquad \text{(Eq.8)}$$

$$Q_X = 0.124P - 232.06, \quad R^2 = 0.984, P < 0.001 \qquad \text{(Eq.9)}$$

$$Q_S = 0.0727Q_Z - 171.11, \quad R^2 = 0.964, P < 0.001 \qquad \text{(Eq.10)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31773193

$$Q_M = 0.08Q_Z - 146.98, \quad R^2 = 0.919, P < 0.001 \quad \text{(Eq.11)}$$

$$Q_{OK} = 0.0308Q_Z - 96.609, \quad R^2 = 0.763, P = 0.01 \quad \text{(Eq.12)}$$

$$Q_{OG} = 0.2395Q_Z - 507.04, \quad R^2 = 0.886, P = 0.002 \quad \text{(Eq.13)}$$

where Q_Z is the streamflow at Zhicheng; P is the basin-averaged annual precipitation above Zhicheng; and Q_X, Q_S, Q_M, Q_{Ok}, and Q_{OG} are the amounts of water discharge at Xingjiangkou, Shadaoguan, Mituosi, Ouchi (kang), and Ouchi (guan), respectively.

The modeling results are validated by comparing the observed and estimated water discharges in the reference period 1960–1966, as shown in *Table 3*. The calculated water discharges are consistent with the measured values. The comparison between the observed and the estimated is shown in *Figure 9*. The precipitation changes played a main role in the decreasing of streamflow in the the Yangtze River (*Table 4*), an effect that is consistent with previous studies (Chen et al., 2014; Yang et al., 2015; Zhao et al., 2015). However, the impact of human activities was gradually intensified and had a dominant status on the water discharge at the JTO. The impact degrees of human activities on water discharge were different at each outlet (*Fig. 9*). *Table 4* shows the contributions of human activities and climate change to impacts in water discharge from 1967 to 2018. At Xinjiangkou, human activities were responsible for 57.20% of the changes. In the other JTO stations, the impact of human activities on streamflow were 84.01% at Shadaoguan, 83.69% at Mituosi, 84.02% at Ouchi (kang), and 89.21% at Ouchi (guan). These results indicated that human activities played a more important influence than climate change in the decrease of water discharge at the JTO.

Table 3. *Results of regression analysis for the water discharge at the JTO in the reference period 1960–1966*

Station name	Duration	Water discharge (10^8 m^3/yr)		R^2
		Observed	Estimated	
Zhicheng	1960–1966	4,098.371	4,149.261	0.784
Xinjiangkou	1960–1966	342.510	337.368	0.853
Shadaoguan	1960–1966	165.892	163.524	0.778
Mituosi	1960–1966	223.622	220.741	0.912
Ouchi (kang)	1960–1966	46.104	46.022	0.715
Ouchi (guan)	1960–1966	602.649	593.825	0.850

Table 4. *Impact of climate change and human activities on water discharge at the JTO*

Station name	Period	Water discharge (10^8 m^3/yr)			Impact of climate change (%)	Impact of human activities (%)
		Observed	Estimated	Total change		
Zhicheng	1967–2018	4,689.641	4,636.272	390.427	62.63	37.37
Xinjiangkou	1967–2018	287.322	318.890	55.188	42.80	57.20
Shadaoguan	1967–2018	82.630	152.579	83.261	15.99	84.01
Mituosi	1967–2018	132.873	208.820	90.749	16.31	83.69

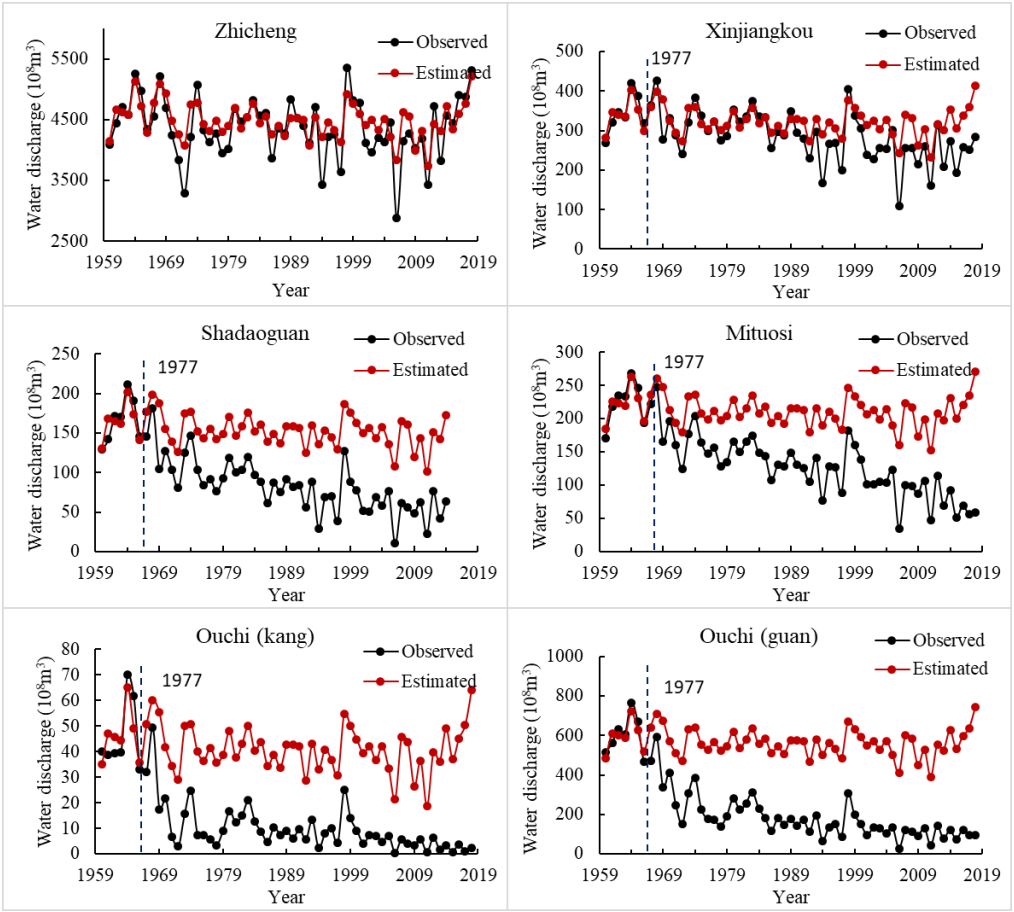

Figure 9. *Comparison between the observed mean annual streamflow and the estimated mean annual streamflow at the JTO with the regression analysis. The period 1960–1966 was the baseline period, and the period 1967–2018 was the prediction period*

Conclusions

This study utilized the MK Pettitt tests to analyze the spatial–temporal variations of precipitation and water discharge at the mainstream and at the JTO from 1960 to 2014. In addition, the impacts which human activities and climate change on water exchange between Yangtze River and Dongting Lake were assessed using the DMC method and regression analysis. Conclusions were summarized as follows:

(1) Precipitation change trends presented no statistical significance, except in autumn with a significant decrease at the 99% confidence level. Water discharge at Zhicheng showed a decreasing trend in autumn and an increasing trend in winter with a 99% confidence level. However, other periods displayed no significant trend changes. Annual and seasonal water discharge at the JTO, except at Xinjiangkou in summer, all exhibited significant downward trends with a 99% confidence level. The lack of consistent trends in the seasonal precipitation and water discharge at Zhicheng and at the JTO indicated that the seasonal relationships between them had been disturbed by human activities.

(2) Abrupt stating years of all the stations at the JTO were mainly around 1980 and 1990, and the Ouchi (kang) and Ouchi (guan) at the Ouchi outlet were earlier than the other stations. Under the same conditions of climate changes and human activities in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31773193

upstream of the Yangtze River, the change heterogeneity and inconsistency of annual and seasonal water discharge at the JTO indicate that local channel cut-off projects affect the amount of water discharge in a complex manner.

(3) Human activities had a dominant effect on the water discharge at the JTO, and the impact degrees of human activities on water discharge were different at each station. During 1967–2018, the impact of human activities on water discharge at Xinjiangkou were 57.20%. The impact of human activities on water discharge were 84.01% at Shadaoguan, 83.69% at Mituosi, 84.02% at Ouchi (kang), and 89.21% at Ouchi (guan).

(4) This research is an important step toward understanding the impact of climate changes and human activities on streamflow reduction at the JTO and provides an important scientific basis for the optimization control of the Yangtze River–Dongting Lake relationship.

Abstract. Huang-huai-hai River basin is an important grain production area and economic zone of China. Under the impact of global warming, energy resources are changing all around the world. Studying the ≥ 10 °C accumulated temperature (*AT*10) is of great importance for the food security and economy of Huang-huai-hai River basin. The slope of *AT*10 and Mann-Kendall statistical test were applied to quantify the trend magnitude and detect the significant trend respectively. And the distribution pattern and movement characteristics had been analysed with GIS technology. The results shown that *AT* 10 of Huang-huai-hai River basin has an increasing trend during since 1960s; *AT* 10 has a moving tendency towards the northwest and decreased from the southeast region towards the northwest region. The ratio between active area and stable area in different classes has fluctuated during the study period.
Keywords: *Huang-huai-hai River basin, accumulated temperature, spatiotemporal characteristic analysis, global warming*

Introduction

In the long-term interaction process between the climate system and land surface, climatic regionalization and agricultural distribution came into being, which are relatively stable. It has been proven that global mean surface temperature has increased by 0.85 °C during 1880-2012. Mean temperature of 2003-2012 has increased by 0.78 °C compared to that of 1850-1900 (IPCC, 2013) and the temperature in China also has shown a similar increasing trend (Wang et al., 2013). As a result, climatic zones and plant phenology have responded to these changes. Temperature determines crops' emergence, flowering and maturity dates (Skaugen and Tveito, 2004; Iannucci et al., 2008; Hou et al., 2014), while each plant species has a base temperature above which biological processes are able to function (Major et al., 1983; Stevens et al., 1986; McMaster and Smika, 1988; Hodges et al., 1994; Bonhomme et al., 1994; Olivier and Annandale, 1998; Kadioglu and Saylan, 2001; Berti and Johnson, 2008; Sacks and Kucharik, 2011). Most crops have a base temperature of 10 °C known as the active temperature. Previous researches have proven that the change of activity accumulated temperature will affect the growth rate of winter wheat and soybean (Li et al., 2015;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31953209

Liang et al., 2015). Lv et al. (2019) has found that when the cumulative temperature was below 3300 °C·d, the maize yield increased with the cumulative temperature, while when the cumulative temperature was below 3800 °C·d, the soybean and rice yields increased with the cumulative temperature ≥ 10 °C accumulated temperature (hereinafter referred to as AT10) is the sum of mean daily temperature during the period in which mean daily temperature is above 10 °C for every day (Yan et al., 2011). Accumulated temperature plays a fundamental role in a plant's growth and spatial distribution (Xu et al., 2009). International research on AT10 is limited. Concerning researches on this subject has mainly been focused on the northeast of the China, while very little research has been carried out for Huang-huai-hai river basin (hereinafter referred to as HHHRB).

Using the meteorological data from Mikhelson station, Chirkov and Kononova (1984) analysed the spatial and temporal changes of ≥ 10 °C AAT in Moscow from 1890 to 1981. Dong et al. (2009) studied the spatiotemporal changes of accumulated temperatures ≥ 10 °C of China from the late 1980s to 2000 and found out that since the late 1980s it has increased on a national scale. Yan et al. (2011) studied the spatial-temporal changes of various decadal AT10 and the climatic means of ≥ 10 °C accumulated temperature in the north-eastern China. Significant increase of decadal AT10 since the 1980s was discovered and the change became larger and more obvious in the 1990s and 2000s. Wang et al. (2011) explored the tempo-spatial characteristics of AT10 and the results showed that the AT10 had a decreasing trend from southwest to northeast and also had 2.5-4a oscillations in Northeast China. Wu (2011) studied the changing trend of ≥ 10 °C accumulated temperature in Shenyang, Liaoning Province of China and found a significant increasing trend. Song et al. (2011) found a significant increase of accumulated temperature and length of growing season of North China Plain from 1961 to 2009. The start of growing season moved up and the end of growing season was delayed.

This paper analysed the spatial and temporal changes of *AT*10 in HHHRB, China. The tendency, distribution pattern and movement characteristics had been selected for the analysis, which can provide data for the basis of decision making for food security in HHHRB as well as give agriculture production technological support to respond to global warming.

Materials and methods

Study area

Huang-huai-hai River basin (HHHRB) encompasses the Yellow River basin, Huaihe River basin and Haihe River basin. HHHRB is located in the east of China and lies between 32°-42°N, 110°-120°E. The entire or partial part of the following provinces form HHHRB: Qinghai Province, Sichuan Province, Gansu Province, Ningxia Hui Autonomous Region, Inner Mongolia Autonomous Region, Shaanxi Province, Shanxi Province, Henan Province, Hebei Province, Shandong Province, Anhui Province, Jiangsu Province, Beijing and Tianjin (*Fig. 1*). The Yellow River basin has an area of 75.2×10^4 km^2. Temperature difference is large and stark regional differences can be seen. The catchment area of Huaihe River basin is 27.5×10^4 km^2 and its temperature increases from the north to the south with the temperature span from 11 to 16 °C. For Haihe River basin, it has an area of 31.8×10^4 km^2 and its mean annual temperature ranges from 1.5 to 14 °C.

DOI: http://dx.doi.org/10.15666/aeer/1802_31953209

One third of China's population, grain yield and gross domestic product comes from HHHRB (Shen et al., 2002; Liu et al., 2010; Yu et al., 2012). As an important grain producing area and economic zone, HHHRB plays a fundamental role in guaranteeing China's economic and social development. Thus, studying AT10 in HHHRB is of great importance for safeguarding China's food security. In the meantime, data base will be provided for agriculture to response to global warming in the context of climate change.

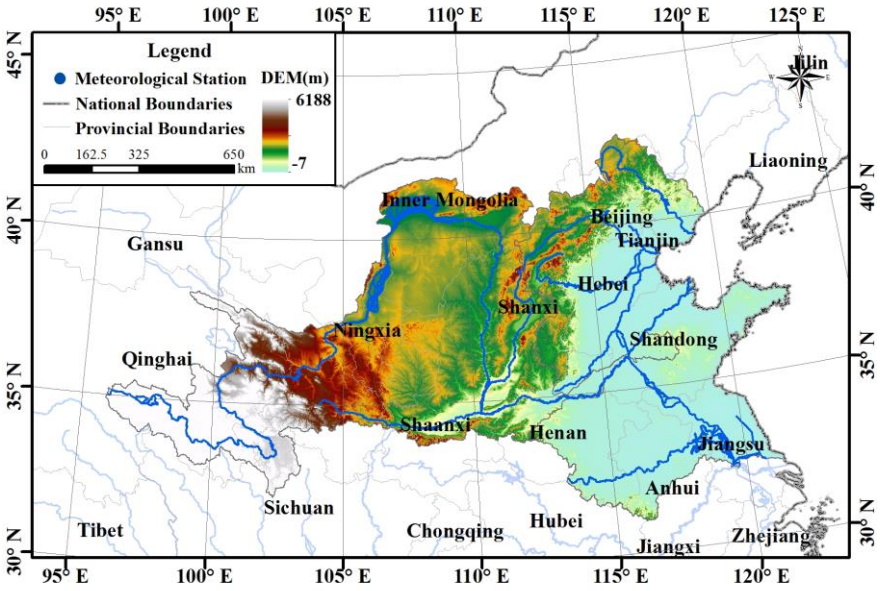

Figure 1. *The location of Huang-Huai-Hai River basin*

Dataset

The basic data for this study was the time series of daily air temperature, which were obtain from 982 meteorological stations within and surrounding HHHRB (*Fig. 2*). The daily air temperature was download from National Meteorological Information Centre (http://data.cma.cn/). Inverse Distance Weighted (IDW) spatial interpolation was used to create daily grid data (5 km × 5 km) of temperature. Data processing process was based on ArcInfo Workstation 10.0 platform using the ARC Macro Language (AML) to conduct the relevant calculations.

Methodology

Calculation of ≥ 10 °C accumulated temperature

The *AT*10 in each grid were calculated with 5-day simple moving average temperature in this study, which is defined as *Equation 1.*

$$AT10_n = \sum_{i=1}^{D} T_i \qquad \text{(Eq.1)}$$

$$T_i = \begin{cases} Ta_i & Ta_i \geq 10 \\ 0 & Ta_i < 0 \end{cases} \qquad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31953209

where $AT10_n$ is ≥ 10 °C accumulated temperature for the nth year. Ta_i is the 5-day simple moving average air temperature for ith day. D is days for the nth year.

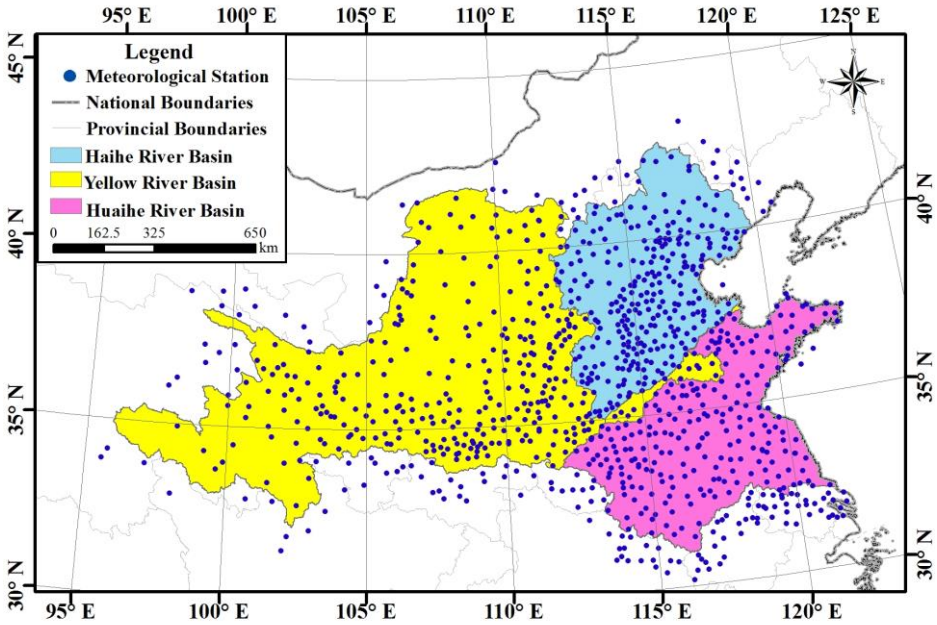

Figure 2. *The location of meteorological stations within and surrounding Huang-Huai-Hai River basin*

Mann-Kendall trend test

A non-parametric approach, Mann-Kendall statistical test (M-K) (Mann, 1945), is widely used in hydrology and climatology analysis because of less sensitive to outliers than parametric approaches (Hamed, 2009; Tian et al., 2012; Wang et al., 2008). In this study, the M-K method was used to was utilized to test the tendency of $AT10$ in the HHHRB. The test statistic U was established as *Equations 3–5*.

$$U = \frac{\tau}{\sqrt{V_{ar}(\tau)}} \quad \text{(Eq.3)}$$

$$\tau = \frac{4p}{n(n-1)} - 1 \quad \text{(Eq.4)}$$

$$V_{ar(\tau)} = \frac{2(2n+5)}{9n(n-1)} \quad \text{(Eq.5)}$$

where n is the length of the data sequence and p is the allelomorph of the random sequence. If U is positive the sequence has an increasing trend, if U is negative the sequence has a decreasing trend, and if $|U| > U\alpha = 1.96$ while the significance level is $\alpha = 0.05$, then the sequence has passed the significance test with a significant changing trend.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31953209

Linear regression analysis and the slope

Linear regression method was utilized to calculate the slope of annual mean AT10 of HHHRB. Its tendency was analyzed and a test for significance was done (Zhang et al., 2011).

$$Slope = \frac{n \times \sum_{i=1}^{n}(i \times K_i) - \sum_{i=1}^{n} i \sum_{i=1}^{n} K_i}{n \times \sum_{i=1}^{n} i^2 - (\sum_{i=1}^{n} i)^2} \quad \text{(Eq.6)}$$

where slope is the tendency rate, n is the number of whole study years, and Ki is the AT10 in the ith year. If slope＞0 in a certain area, it means that the AT10 in this area has an increasing trend from 1956-2011.

Geographic center for ≥ 10 °C accumulated temperature

On the platform of ARCGIS10.0, the ARC Macro Language (AML) was used to conduct the analysis. For each different class of AT10 of HHHRB, CENTROIDLABLES was utilized to calculate the longitude and latitude of each continuous partition's centroid (*xi*,*yi*). After that, area was used as the weight to compute the centroid of each class of AT10 of HHHRB:

$$X_a = \frac{\sum_{i=1}^{n} x_i s_i}{\sum_{i=1}^{n} s_i} \quad \text{(Eq.6)}$$

$$Y_a = \frac{\sum_{i=1}^{n} y_i s_i}{\sum_{i=1}^{n} s_i} \quad \text{(Eq.7)}$$

where, x_a is the longitude of the centroid for a certain class of AT10 of HHHRB, x is the longitude of the centroid of each partition, s is the area of each partition, and n is the number of partitions in a certain class of AT10 of HHHRB. The calculation method for latitude is the same as that for longitude.

Results and analyses

Temporal changes of ≥ 10 °C accumulated temperature in HHHRB

The maximum value, minimum value, range (difference between maximum value and minimum value) and standard deviation of *AT*10 temperature of HHHRB were calculated (*Fig. 3*). The test statistic values for maximum value, minimum value, range and standard deviation of *AT*10 were 5.203, 3.223, 4.976 and 4.947, respectively. It could be concluded that all the characteristic values had a significant increasing trend at the 95% confidence level.

Annual accumulated temperature is an important factor which will affect the crop yield. The grain yield per hectare has a positive correlation with accumulated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31953209

temperature (Wang et al., 2011). The range of AT10 of HHHRB increased while the maximum value and minimum value both increased as well which is consistent with the trend of global warming. What was also revealed was that since 1956, energy resources in the study area has increased, which will help to produce more food（Anwar et al., 2013). However, the risk of drought will be increased at the same time.

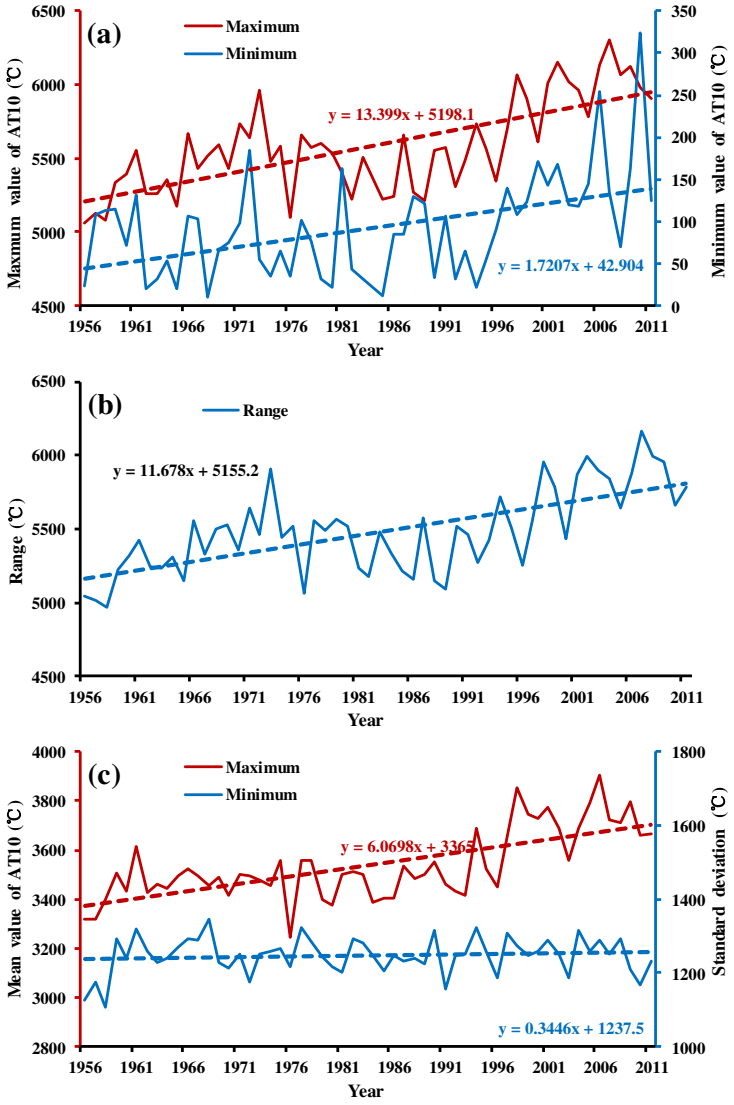

Figure 3. *Maximum/minimum value (a), range (b) and standard deviation (c) of AT10 of HHHRB*

Another factor which has great impact on crop growth is the length of thermal growing season. In this study the duration of development period, time started and ending time of *AT*10 were calculated for the HHHRB (*Fig. 4*). Since 1956, duration of thermal growing season of *AT*10 of HHHRB has an increasing trend. $U_{\text{duration}} = 4.142$ which has passed the significance test at the 95% level. The starting time of thermal growing season has moved forward with $U_{\text{time started-min}} = -1.145$, but it has not passed the significance test at the 95% level. The ending time has been postponed with $U_{\text{ended time-max}} = 0.297$, but it still has not passed the significance test at the 95% level.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31953209

This result shows that the length of the thermal growing season of HHHRB from 1956-2011 has extended and may be a potential outcome of global warming in the river basin. The start of the growing season has moved forward while the end of growing season has lagged. To examine the effect of temporal changes in *AT*10 the whole study period (1956-2011) is be divided into 7 phases for each decade: A for 1956-1959, B for 1960-1969, C for 1970-1979, D for 1980-1989, E for 1990-1999, F for 2000-2009 and G for 2010-2011. Duration of thermal growing season of ≥ 10 °C accumulated temperature of HHHRB in each phase was calculated, which are 209.5 days, 214.3 days, 210.4 days, 212.0 days 218.1 days, 222.6 days and 225.2 days. Compared with that of phase A, the duration of F and G have increased significantly by 13.1 days and 15.7 days, respectively. The thermal conditions of HHHRB have improved for crop growth during 1956-2011, thus crop production may benefit from this increasing trend.

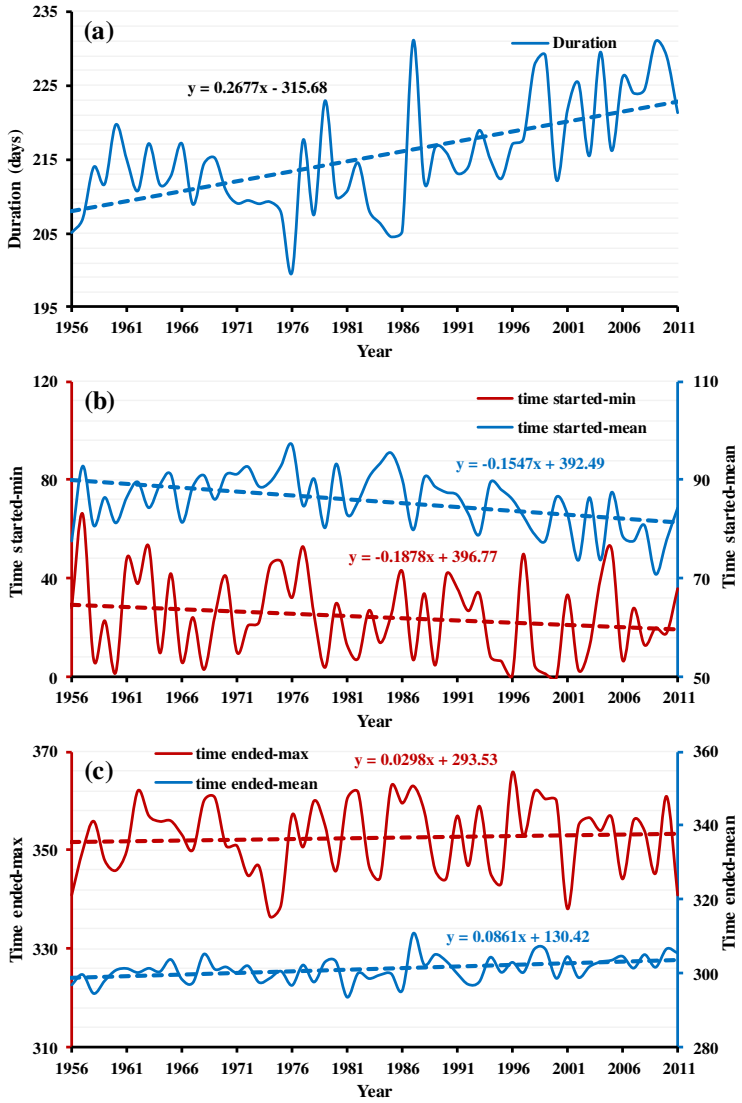

Figure 4. *Duration (a), time started (b) and ended time (c) of thermal growing season of AT10 of HHHRB. (Time started-min is the minimum value of the start time of all the grids in the study area, time started-mean is the mean value of the start time of all the grids in the study area, ending time-max is the maximum value of the ending time of all the grids in the study area, and ending time-mean is the mean value of the ending time of all the grids in the study area)*

Spatial changes of ≥ 10 °C accumulated temperature of HHHRB

Distribution pattern of ≥ 10 °C accumulated temperature of HHHRB

Temperature belts are defined into 5 classes for *AT*10 to study its spatial distribution as follows: (1) Cold temperature zone where the *AT*10 is less than 1600 °C. The planting system is one crop a year and its main crops are early-matured spring wheat, barley, potato, etc. (2) Mid temperate zone where the *AT*10 is less than 3400 °C while more than 1600 °C. The planting system is one crop a year and its main crops are spring wheat, soybean, maize, millet, sorghum, etc. (3) Warm temperate zone where the *AT*10 is less than 4500 °C while more than 3400 °C. The planting system is three crops every two years or two crops a year consisting mainly of multiple cropping buckwheat after winter wheat or multiple cropping maize, millet and sweet potato after winter wheat, etc. (4) Subtropical zone where the *AT*10 is less than 8000 °C while more than 4500 °C. The planting system is two or three crops a year. The rotation system is wheat-rice rotation or double-rice rotation, etc. (5) Where the *AT*10 is more than 8000 °C, the planting system is three crops a year and its main crops are rice, sugarcane, etc.

According to the classification standard mentioned above, decadal spatial distribution patterns of *AT*10 of HHHRB from 1956-2011 were analysed. Since the AT10 of the whole study area is less than 8000 °C, only (1), (2), (3) and (4) were analysed. Generally speaking, AT10 of HHHRB decreased from southeast to northwest (*Fig. 5*). Distribution area of AT10 of different classes were calculated as well as the tendency of the distribution area: $U_{(1)} = -5.527$, $U_{(2)} = -4.919$, $U_{(3)} = 2.375$, $U_{(4)} = 4.227$. Distribution area of class (1) and (2) have a downward trend while that of class (3) and (4) have an upward trend. All of them have passed the significance test at 95% level (*Fig. 6*).

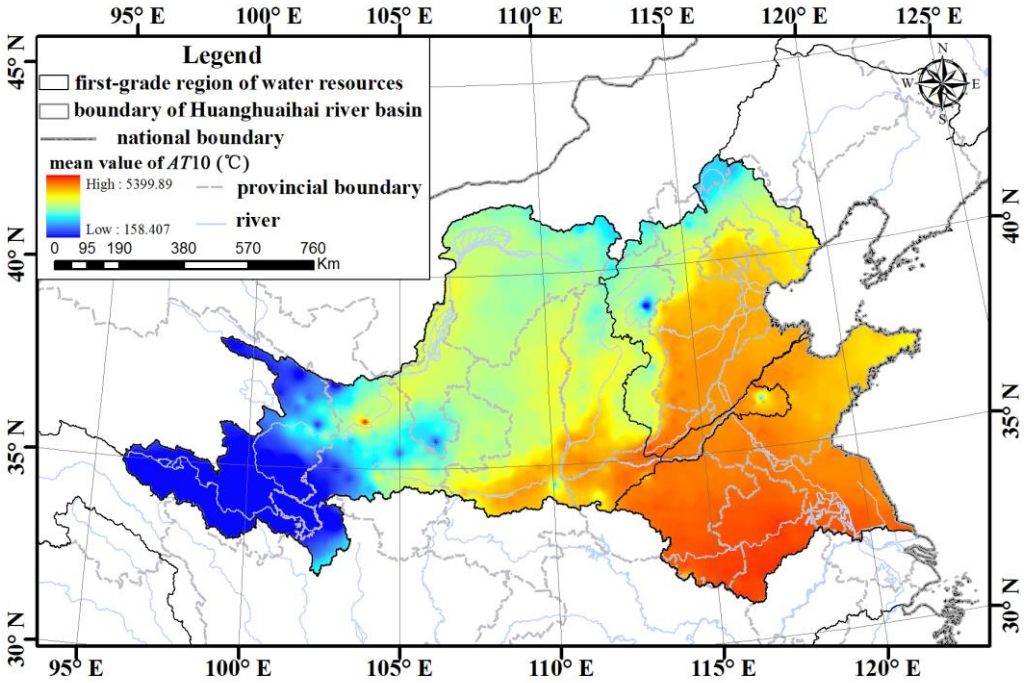

Figure 5. *Spatial distribution of AT10 of HHHRB*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31953209

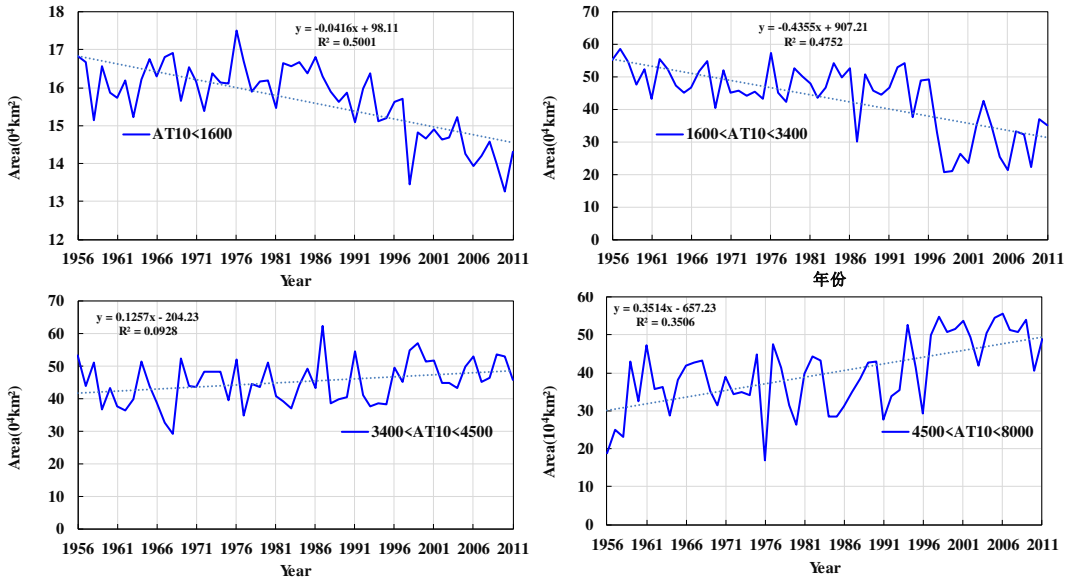

Figure 6. *Area of different classes of AT10 of HHHRB*

For each grid of a certain class of *AT*10 of HHHRB, the accumulated temperature either fits in the class or does not. By dividing the number of years when the accumulated temperature fits in a given class by the total number of years of the study period, the frequency of the occurrence of *AT*10 in a certain class in each grid can be obtained. The spatial distribution of the frequency of AT10 in HHHRB for each class are displayed in (*Fig. 7*).

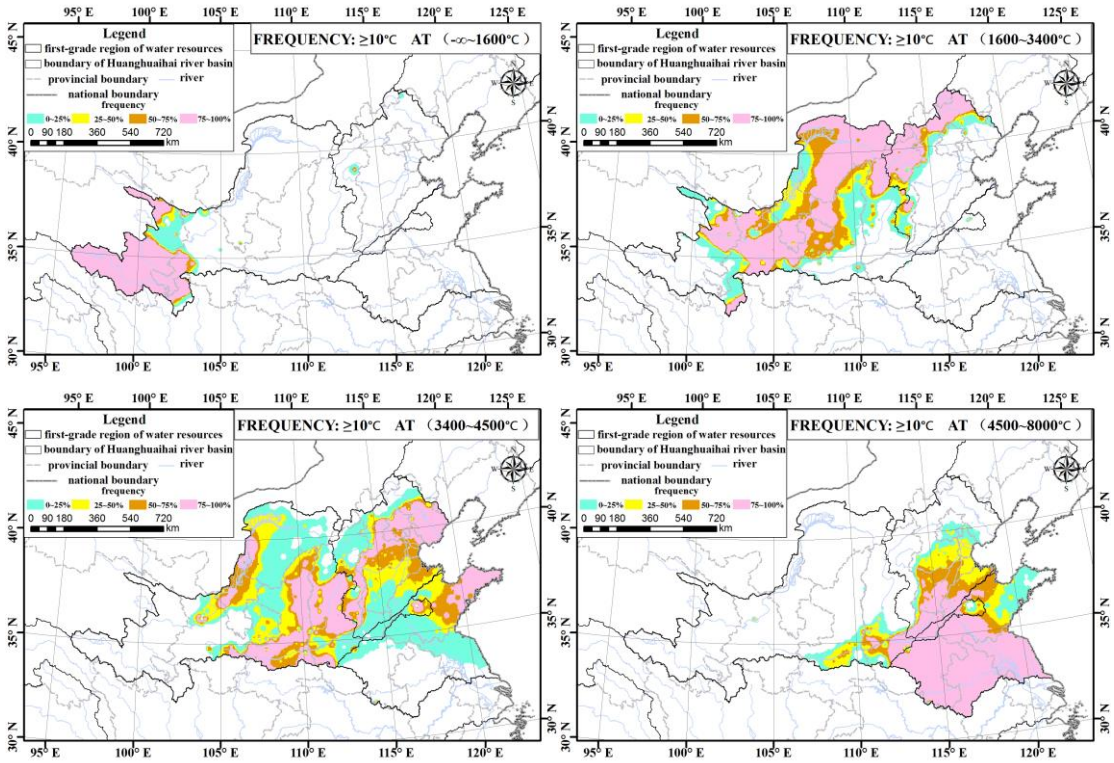

Figure 7. *Spatial distribution of the frequency of AT10 of HHHRB in different classes*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31953209

Most of the regions in class (1) consist of high frequencies except in the northeast region. For class (2), the region of highest frequency lies mainly in the central region, while the periphery is the low frequency region. In addition, the area of high frequency region is significantly larger than the area of low frequency region. For class (3), the high frequency region lies in the middle and the low frequency region lies on its two sides. The area of high and low frequency regions is approximately the same. For class (4), most of its area is high frequency region, while the northwest rim is in the low frequency region.

From *Figures 8* and *9* we could see that except the most westerly part and some scattered areas, AT10 of HHHRB has an increasing trend. Additionally, the trend in most areas has passed the significance test at the level of 95%.

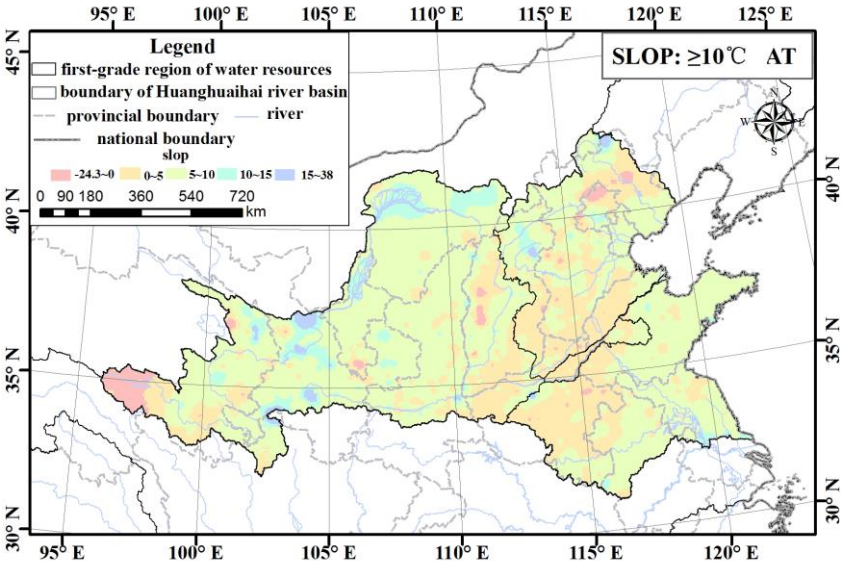

Figure 8. *Slope of AT10 of HHHRB*

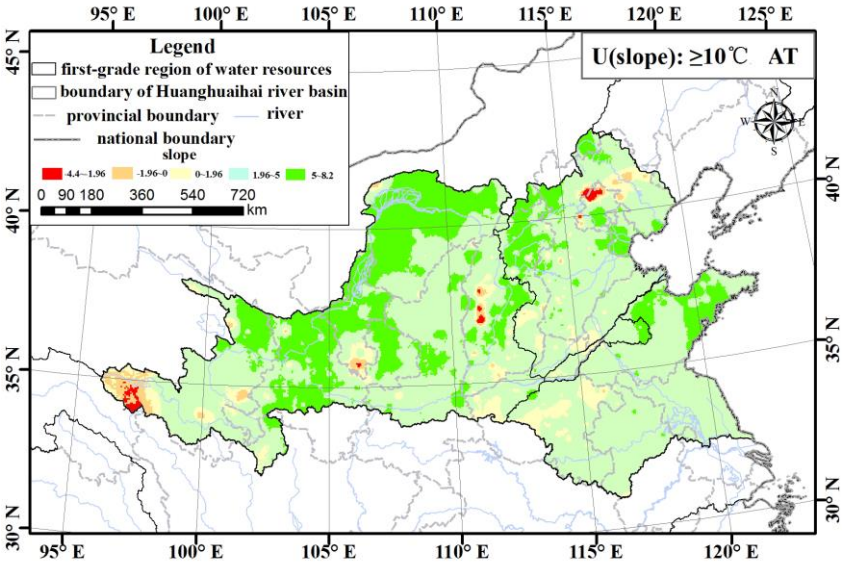

Figure 9. *U value of the slope of AT10 of HHHRB*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31953209

Movement characteristics of ≥ 10 °C accumulated temperature of HHHRB

From *Figure 10* we can see that class (1) of AT10 of HHHRB has a moving tendency towards southwest. $U_{(1)\text{longitude}}$ = -5.710 and $U_{(1)\text{latitude}}$ = -6.742. They both have passed the significance test at 95% level. For class (2), $U_{(2)\text{longitude}}$ = -2.572 so the westward trend of class (2) is significant. $U_{(2)\text{latitude}}$ = -1.697, therefore class (2) has a southward trend but is not significant. For class (3), $U_{(3)\text{longitude}}$ = -5.612 and $U_{(3)\text{latitude}}$ = 3.703, thus class (3) has a significant trend moving towards northwest. For class (4), $U_{(4)\text{longitude}}$ = -1.682 and $U_{(4)\text{latitude}}$ = 4.311. So the northward trend is significant while the westward trend is not significant.

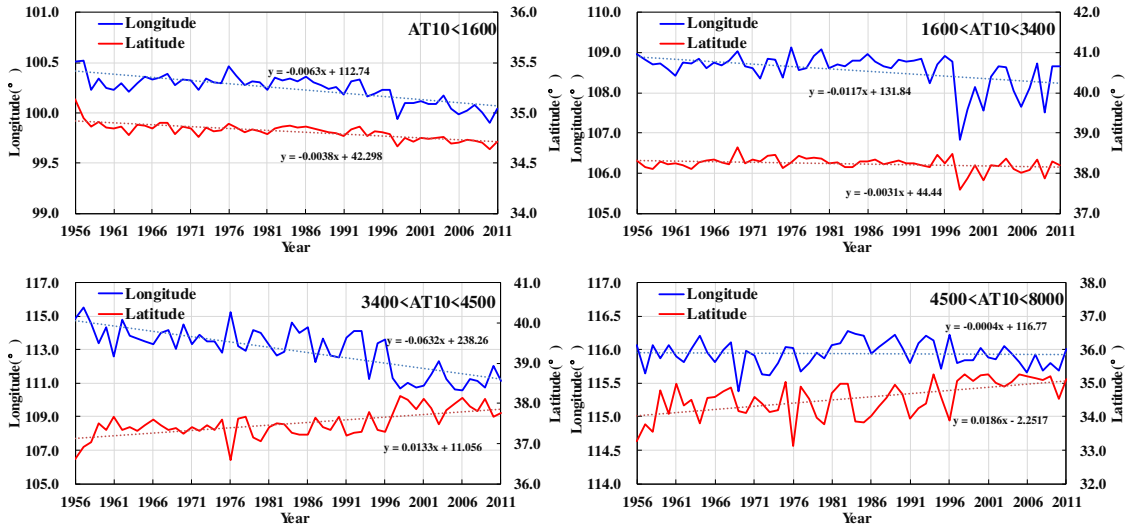

Figure 10. *Movement characteristics of AT10 of HHHRB*

The study period 1956-2011 was divided into 7 phases: A-G. Since phase A only includes four years, which are 1956, 1957, 1958 and 1959, and phase G only includes 2010 and 2011, phase A and G were deleted in the following analysis. For the remaining phases, spatial distribution of active area and stable area of the study area of AT10 were analysed (*Fig. 11; Table 1*). In a given phase, active area is the area where a certain class of AT10 appeared one or more times. Stable area is the area where the occurrence number of a certain class of AT10 is equal to the number of study years in a given phase.

For class (1), decadal change of active area and stable area are not obvious. For class (2), both stable area and active area are moving towards northwest and their areas are decreasing. For class (3), stable area and active area also have a moving trend towards northwest, which is particularly obvious in 2000-2010. For class (4), active area did not change much, while stable area moved northward notably during 2000-2010.

For class (1), the ratio between active and stable areas has been around 1:9. For class (2), the ratio between active and stable areas has changed from 4:6 to 6:4, thus the ratio of active area has increased. For class (3), the ratio between active and stable areas has changed from 7:3 to 6:4, thus the ratio of active has decreased. For class (4), the ratio between active and stable areas has changed from 4:6 to 5:5, and then back to 3:7, thus the ratio between these two areas have reversed.

Conclusion and discussion

In general, *AT* 10 of HHHRB has an increasing trend during the study period, which is in accordance with the paradigm of global warming. Since 1956, energy resources in the HHHRB have increased. On one hand, this will contribute to the food production in the study area but on the other, the risk of drought could be increased. The maximum value, minimum value, range and standard deviation of *AT*10 of HHHRB all had a significant increasing trend, which verified significant warming and increasing energy resources in the study area. Duration of thermal growing season of *AT* 10 of HHHRB has an increasing trend. The starting time of thermal growing season has moved up and the ending time has been postponed. Compared with the duration of phase A, the duration of F and G have increased significantly by 13.1 days and 15.7 days respectively.

Generally speaking, *AT*10 of HHHRB has a moving tendency towards the northwest. *AT*10 of HHHRB decreased from the southeast region towards the northwest region. Except the west most part and some scattered area, *AT*10 of HHHRB has a significant increasing trend. Area of class (1) and (2) have a downward trend while that of class (3) and (4) have an upward trend. Class (1), (2), (3) and (4) of *AT*10 of HHHRB have a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_31953209

moving tendency towards southeast, west, northwest and north respectively. For class (2) and (3), stable area and active area are moving towards the northwest. The active area and stable area of class (1) have not experienced a notable change. For class (4), stable area moved northward but the active area remained changeless. What is more, the ratio between active area and stable area in different classes has fluctuated during the study period.

Table 1. *Decade ratio of active area and stable area of different classes of AT10 of HHHRB (100%)*

Class	**(1)**				
	1960s	1970s	1980s	1990	2000s
Active area	11.9	13.7	9.9	18.1	9.2
Stable area	88.1	86.3	90.1	81.9	90.8
Class	**(2)**				
	1960s	1970s	1980s	1990	2000s
Active area	40.2	39.5	50.5	69.9	58.3
Stable area	59.8	60.5	49.5	30.1	41.7
Class	**(3)**				
	1960s	1970s	1980s	1990	2000s
Active area	67.3	74.1	65.1	80.3	56.9
Stable area	32.7	25.9	34.9	19.7	43.1
Class	**(4)**				
	1960s	1970s	1980s	1990	2000s
Active area	43.4	66.0	45.2	54.5	27.2
Stable area	56.6	34.0	54.8	45.5	72.8

Ratio of active area in a certain phase and a certain class = (area of active area) / (area of active area + area of stable area); ratio of stable area in a certain phase and a certain class = (area of stable area) / (area of active area + area of stable area)

In the previous studies, Zhao et al. (2016) have found that the accumulated temperature had a strong positive effect on the components of maize yield in East Gansu. Wang et al. (2006) have detected that winter wheat yield increased with the increase of AT10, but decreased with the increase of AT20. The climate change would affect the crop productivity and food supply, which decrease the stability of the global food system. However, the potential impact on a regional scale is unclear (Wheeler et al., 2013). Global Climate change and regional climate change are not completely consistent due to the large regional differences in natural environment and human behavior. It is necessary to analyze the characteristics of regional accumulated temperature and its impact on local crop yield in the context of global climate change.

(Received 27th Sep 2019; accepted 4th Feb 2020)

Abstract. With an increasing trend in global warming, extreme weather and a variety of related climate events frequently occur in the Southwestern China. In this research, we analyzed daily maximum and minimum temperatures, and daily precipitation data of 39 meteorological stations in the Sichuan Province between the years of 1968 and 2017. Nineteen different indices representing extreme climate change were selected, and linear regression analysis, Mann-Kendall mutation test, sliding T test, wavelet analysis and R/S analysis were applied. According to the results, we concluded that: (1) most extreme cold indices showed a decreasing trend, while the extreme warm indices displayed an increasing trend. There was no significant interannual variation for extreme precipitation indices. (2) Most extreme temperature indices presented no significant mutation years, and the significant periods were mainly 2-6 years long. The mutation years of heavy and very heavy precipitation events mainly appeared in the 1980 and the early 21st century, and the significant periods of most extreme precipitation indices were 2-7 years long. (3) As shown by the Hurst exponent analysis and interannual variation trends, it is very likely that the extreme temperature and extreme precipitation events in the Sichuan Province will increase in the future.
Keywords: *extreme temperature indices, extreme precipitation indices, M-K test, sliding T test, wavelet analysis, R/S analysis*

Introduction

According to the IPCC (Intergovernmental Panel on Climate Change, IPCC) Fifth Assessment Report, from 1880 to 2012 the global mainland and sea surface temperature increased by 0.85 °C. The change in temperature for the 2003-2012 period was 0.78 °C higher than for the period 1850 to 1990 (Stocker, et al., 2013). In the second half of the 20th century, the number of cold nights on land in over 70% of the areas worldwide began to show a significant decrease, while the number of warm nights increased (Alexander, et al., 2006). Extreme temperatures mainly manifest as more frequent incidences of extreme high and low temperature events and a prolongation of their duration. Extreme precipitation events mainly manifest with an increasing frequency and intensity of droughts, rainstorms, and extraordinary flood disasters (Ding, et al., 2018). As indicated by historical observations, in the past century global warming led to an increase in the intensity and frequency of extreme events (droughts, floods, and cold waves), as well as an expansion of the area of influence (Zhao, et al., 2016; Liu, et al., 2019).

At present, under the general context of global warming, extreme climate changes at different scales have attracted the attention of researchers all over the world. Alexander et al. (2006) have stated that, on a global scale, global warming has caused a significant reduction in the number of cold nights and a significant increase in the number of warm nights in many regions worldwide. The extreme precipitation indices including the number of continuous rainless days and number of continuous rainy days have also

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32113242

substantially increased (Easterling, et al., 2000). Song et al. (2013) analyzed the extreme temperature events all over the world from 1981 to 2010. They determined that the frequency of occurrence of heat and cold waves increased 2.7 and 6.4 times, respectively. On a regional scale, scholars have determined that the number of cold days and nights has been continuously decreasing, while the number of warm days and nights has been increasing. Similar variation trends have been observed for extreme temperature and precipitation events on a global scale. For example, in the United States, the increasing trends were identified for temperature, and the frost and ice days dwindled as growing season length, tropical nights and summer days increased (Sohrabi, et al., 2013). In Europe, significant increasing trends in annual precipitation extremes have been detected in different regions (Vogel, et al., 2018; Arnone, et al., 2018). The extreme temperature indices of Nile river basin decreased in cold, but increased in warm night/days, and most precipitation extreme indices increased (Tariku and Gan, 2018). For the Caribbean small islands, most extreme temperature indices at Piarco Point (Trinidad) showed significant warming trends on annual and seasonal scales as well as for most months. For Crown Point (Tobago), trends indicated an increase in annual precipitation totals and extremely wet days were observed (Dookie, et al., 2018). In some Asian country, with a large proportion of stations having statistically significant trends for all temperature indices, temperature extremes showed a warming trend over Iran (Soltani, et al., 2016). Sajjad and Ghaffar (2018) observed and projected extreme climate indices over Pakistan in changing climate, the results showed there were a significantly increasing trend in the mean maximum temperature and summer days, and frequency of heavy precipitation also significantly increased. In addition, studies on extreme temperatures and precipitation occurrences have shown that in most Chinese regions, the cold night index and warm night index displayed a similar intensity and yet an opposite trend of variation, which indicated a good symmetry (Yang, et al., 2010). Both, the frequency and intensity of extreme precipitation events have been increasing, though with apparent inter-regional differences (Jiang, et al., 2017; Yin and Sun, 2019). Some researchers have suggested that the extreme precipitation events have been increasing in the Yangtze River Basin and part of Southeastern China and Northwestern China. However, a decreasing trend was observed for some parts of Northern, Northeastern, and Southwestern China (Gao and Xie, 2014).

Two abnormal drought events occurring in 2005-2006 and 2009-2010 in Southwestern China have drawn widespread attention regarding extreme climate incidents in this region. Yuan and Zheng (2015) studied extreme temperature indices observed in Southwestern China during the period 1962 to 2012. In general, extreme high and low temperature events showed an increasing and decreasing tendency, respectively. An opposite variation trend was observed in some regions, which was a unique climate change feature of Southwestern China. In addition, when considering extreme precipitation events for the same period and region, results indicated that there was a large variability. The extreme precipitation events showed an overall increasing trend during the past 50 years; however, it was not significant. This may be related to abnormal changes in sea surface temperature and complex geographical environments (Yuan, et al., 2014). Luo et al. (2016) determined the trend for extreme temperatures in Southwestern China for the years of 1970 to 2010. Their results showed that there was a good local symmetry between the number of warm days and the number of cold days in this region, as well as a good symmetry between the number of warm nights and number of cold nights for the past 41 years. The warm indices increased in value, while

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32113242

the cold indices decreased. Ding (2014) studied the spatio-temporal changes of extreme precipitation in Southwestern China, and the results indicated that the frequency of extreme precipitations in this area have increased since the 1960s. There were significant inter-regional differences in inter-decadal variations. The frequency of extreme precipitations in the monsoon period significantly increased, while that in the non-monsoon period decreased.

The Sichuan Province is located in Southwestern China and marks the transition belt between the Tibetan Plateau of China and the eastern plain. With a complex landform and diverse climate types, it is a sensitive, vulnerable and strategic area affected by climate change. The inter-regional difference in temperature in this province can reach more than 20 °C, and the regional precipitation distribution varies significantly. In recent years, the occurrence of extreme climate events has led to frequent natural disasters in the Sichuan Province. For example, in 2006, this area suffered an extraordinary drought that was estimated to occur only once-in-a-hundred-year period. From the winter of 2009 to the spring of 2010, a persistent severe drought affected 71 cities, districts and counties of 13 Sichuanese municipalities. It was estimated that this drought affected a population of 8.282 million, a crop area of 511 000 hm^2, with a resulting direct economic loss of 1.38 billion RMB. In this same area, in 2011, the numbers were as follows: crop area affected by the drought reached the 346 000 hm^2, and the direct economic loss was of 1.2 billion RMB (Wang, et al., 2017). In 2012 and 2017, another historical extreme temperature hit the summer season in this same province. In July of 2007, the Sichuan Basin was struck by a once-in-a-hundred-year extraordinary heavy rain. On July 19th in the year of 2010, a heavy severe flood hit Guang'an City in Sichuan. In July of 2016, a persistent rainstorm occurred in Jiuzhaigou, which triggered a severe debris flow disaster and resulted in the shutdown of the Jiuzhaigou Scenic Area. In July of 2018, Mianyan area in Sichuan was hit by the most severe flood ever seen since the founding of New China. These extreme climate events have resulted in enormous economic losses to the Sichuan province, threatening people's life and property safety. A variety of studies related to the extreme temperatures and precipitation events in Sichuan have been conducted. For example, Liu (2013) defined extreme temperature events based on percentile thresholds at three representative stations in the Sichuan Basin (Chengdu, Nanchong, and Shapingba). His study showed that from the mid-1970s to the 1980s, the frequency and intensity of extreme high temperature events in the Sichuan Basin decreased. However, after the late-1990s, the frequency and intensity of extreme high temperature events increased, while the variation trend of extreme low temperature events was just the opposite. Sun et al. (2017) studied the extreme precipitation events of Sichuan that occurred between 1971 and 2014. They found out that in the past 44 years, the overall precipitation in this region slightly decreased. In addition, there was a general warming and drying trend in most parts of Sichuan, except for an increasing humidity pattern observed in the Western Sichuan Plateau. However, the investigations dealing with the distinctive topography and climate conditions in this area are far from being enough.

In view of the above, the objective of this study was to investigate the spatio-temporal and abrupt changes, as well as periodic trends in extreme temperature and precipitation in the Sichuan Province for the period 1968 to 2017 by using 10 extreme temperature indices and 9 extreme precipitation indices, which are recommended by the WMO (World Meteorological Organization, WMO). Furthermore, to explore the relationship between extreme climate indices and geographical factors and to project

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32113242

future change trends by using Hurst exponent. Through deep and comprehensive analysis, our research findings provide valuable information that may help in coping with climate change and for disaster prevention and relief in the Sichuan Province.

Materials and methods

Study area

The Sichuan Province is located in Southwestern China (97°21′~108°33′ longitude and 26°03′~34°19′ latitude). The entire region covers an area of 485 000 km^2, it is 1 075 km from east to west and 921 km from south to north (Zhan and Wen, 2006). The terrain is higher to the west and lower to the east. To the northwest, the area is mainly covered by plateaus and high mountains, while the southwest is a mountainous region, and the eastside is both, basin and mountains. Due to the varied landforms and the alternating influence of different monsoon winds, a unique climatic type has been formed. Taking into account temperature, precipitation, and sunshine conditions, the Sichuan Province can be divided into three major climatic zones: (1) A cold climatic zone in the high mountains and plateaus in the Northwestern area. Herein, there is an annual average temperature between 4~12 °C; the winter is cold and the summer is cool, and the total annual precipitation is only 500-900 mm. Also, the annual sunshine hours are as many as 1 600~2 600; (2) The subtropical semi-humid climatic zone in the mountainous areas in Southwestern Sichuan, where the annual average temperature oscillates between 12~20 °C, and the total annual precipitation is 900~1 200 mm; however, 90% of the precipitation occurs from May to October, and the annual sunshine hours are between 2 000~2 600; (3) The middle subtropical humid climatic zone in the Sichuan Basin with an intermediate annual average temperature of 16~18 °C; the winter is warm and the summer is hot; the annual precipitation is abundant (1 000~1 200 mm) and the annual sunshine hours are short (only 1 000-1 400) (Zhou, et al., 2011). The inter-regional climatic differences are significant in the Sichuan Province. Large climatic variations are related to altitude. Rapid climatic changes have led to a great number of meteorological disasters, such as droughts, rainstorms, floods and low temperature freezing events. These disasters have frequently occurred and they have affected extensive regions (Ma, 2016). *Figure 1* shows the geographical location of the Sichuan Province and a zoning map of this area based on terrain and climate.

Data sources

The main data source used in this study was collected from the MDSCC (Meteorological Data Service Center of China, MDSCC) (http://www.nmic.cn), and the principles of continuity and longest duration were considered. The data on daily maximum temperature, daily minimum temperature, 24h precipitation and annual precipitation at 39 meteorological stations from 1968 to 2017 were collected. Three quality control methods were used in handling these data, namely, internal consistency check, climate limit value check and station extreme check. Linear regression was applied in order to calculate missing data by interpolation using the available information on adjacent stations. In this endeavor, care was taken in order to ensure that the corrected meteorological data displayed high scientificity, accuracy, and continuity. *Figure 2* and *Table 1* show the spatial distribution, detailed information, and zone division for each station.

Extreme climate indices

In this study, from all extreme climate indices recommended by the WMO, we selected 10 extreme temperature indices and 9 extreme precipitation indices (*Table 2*). These data were extracted by running the program.

Table 2. *List of the 19 selected extreme climate indices*

Categories	No.	Indices	Descriptive names/units	Definitions
Extreme temperature indices	1	FD	Frost days/d	Annual count when Tn (daily minimum) < 0 °C
	2	Tnn	Min Tmin/°C	Annual minimum value of daily minimum temperature
	3	Tnx	Max Tmin/°C	Annual maximum value of daily minimum temperature
	4	Tn10	Cool nights/d	Number of days when Tn < 10th percentile
	5	Tx10	Cool days/d	Number of days when Tx (daily maximum) < 10th percentile
	6	SU	Summer days/d	Annual count when Tx > 25 °C
	7	Txn	Min Tmax/°C	Annual minimum value of daily maximum temperature
	8	Txx	Max Tmax/°C	Annual maximum value of daily maximum temperature
	9	Tn90	Warm nights/d	Number of days when Tn > 90th percentile
	10	Tx90	Warm days/d	Number of days when Tx > 90th percentile
Extreme precipitation indices	11	CDD	Consecutive dry days/d	Maximum number of consecutive days with RR > 1 mm
	12	CWD	Consecutive wet days/d	Maximum number of consecutive days with RR ≥ 1 mm
	13	R10	Number of heavy precipitation days/d	Annual count of days when PRCP ≥ 10 mm
	14	R20	Number of very heavy precipitation days/d	Annual count of days when PRCP ≥ 20 mm
	15	R50	Number of rainstorm days/d	Annual count of days when PRCP ≥ 50 mm
	16	R95p	Very wet days/mm	Annual total PRCP when RR > 95th percentile
	17	R99p	Extremely wet days/mm	Annual total PRCP when RR > 99th percentile
	18	SDII	Simple daily intensity index/(mm/d)	Annual total precipitation divided by the number of wet days
	19	PRCPTOT	Annual total wet-day precipitation/mm	Annual total PRCP in wet days (RR ≥ 1 mm)

RR: daily precipitation; PRCP: precipitation

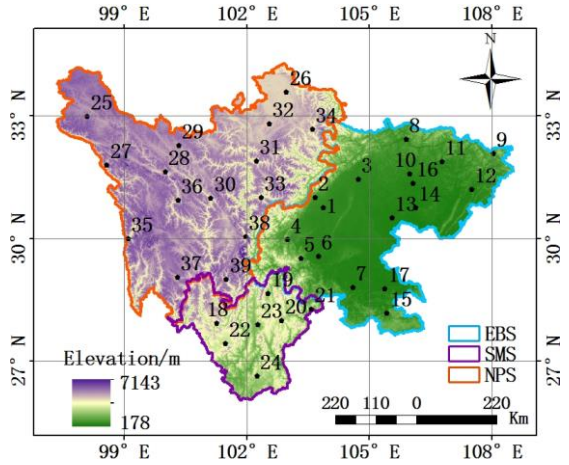

Figure 2. *The spatial distribution of 39 meteorological stations in Sichuan Province*

Main research methods

The following analyses or tests were performed: linear regression, Mann-Kendall trend test, sliding T test, wavelet, correlation, and R/S analyses. The main methods involved in the present study were as follows:

(1) Mann-Kendall trend test: it is also known as the M-K or nonparametric test. This method is recommended by the WMO, and is a valuable tool for effectively differentiating natural fluctuations from definite variation trends. It is a nonparametric statistical test to analyze the variation trends of climate and hydrological series over time. It is also used for the detection of precipitation trends as well as drought frequency under the influence of climate change (Liu, et al., 2011a). Samples used for M-K test may or may not conform to anormal distribution. In addition, analysis is not affected when samples display a few outliers. For these reasons, M-K test surpasses other tools when dealing with abrupt climate changes (Ma, et al., 2018). The main steps of M-K test are listed below (Wei, 2007):

For time series X comprising n samples, a rank sequence is constructed as:

$$S_k = \sum_{i=1}^{k} r_i = \begin{cases} 1, x_i > x_j \\ 0, x_i \le x_j \end{cases}, \quad j = 1, 2, \ldots, i \qquad \text{(Eq.1)}$$

where k is: the sample size; r_i is used to determine whether the value at time i is larger than that at time j; the rank sequence S_k represents the cumulative number when values are larger at time j than those at time i.

Statistics is defined as:

$$UF_k = \frac{S_k - E(S_k)}{\sqrt{Var(S_k)}}, k = 1, 2, \ldots, n \qquad \text{(Eq.2)}$$

where:

$$E(S_k) = \frac{n(n+1)}{4} \qquad \text{(Eq.3)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32113242

$$Var(S_k) = \frac{n(n-1)(2n+5)}{72} \quad \text{(Eq.4)}$$

where $UF_1 = 0$, $E(S_k)$, $Var(S_k)$ is the mean and variance of the rank sequence S_k. UF_i obeys a normal distribution. Through *Equation 2,* a positive UF trend was obtained. The same method was applied to the inverted series to obtain the corresponding UB curve, i.e., $UB_k = -UF_k$. When plotting the curves, if the UF test statistics result is above 0, the variable has an increasing trend. On the contrary, if the UF test statistics result is below 0, the variable has a decreasing trend. In addition, an intersection point between the UF and UB statistics result lying between the critical lines determines the starting time of climate alteration, i.e, the year of climate change.

(2) Sliding T test: This test is helpful in detecting climate mutations by determining if there is a significant difference in the means of two different groups. The basic principle is that the significant difference between the means of two subseries in one given climate series is tested by treating such difference as if it is the result of comparing two separate series. Should the difference in the means of the two subseries exceed a certain significance level, the means are considered to have undergone qualitative change, i.e., the mutation occurred.

For a time series $\{X_i, i=1, 2, \ldots, n\}$ composed of n samples, a given time is selected as the reference point. Before and after this point, n_1 and n_2 represent the number of elements in the samples for their corresponding two sub-sequences X_1 and X_2 (generally $n_1=n_2$). The means of the two sub-sequences are $\overline{X_1}$ and $\overline{X_2}$, and the variances s_1^2 and s_2^2, respectively. Statistics is defined as (Liu, et al., 2011b):

$$t = \frac{\overline{x}_1 - \overline{x}_2}{s\sqrt{\frac{1}{n_1} + \frac{1}{n_2}}} \quad \text{(Eq.5)}$$

where:

$$s = \sqrt{\frac{n_1 s_1^2 + n_2 s_2^2}{n_1 + n_2 - 2}} \quad \text{(Eq.6)}$$

Then, t obeys a t distribution with a degree of freedom n_1+n_2-2.

(3) Wavelet analysis: This is a method for the analysis of signal frequency and has a multi-resolution capacity. Wavelet analysis accurately provides information on local signal features in both, the time and frequency domains, and can be used for multi-scale detailed signal analysis. Since this method is more robust than Fourier transform, it has been widely used in multi-scale climate analysis in recent years (Xu, et al., 2004).

The wavelet function is defined as follows: Let the function φ(t) be a square-integrable function, i.e., $\varphi(t) \in L^2$ (R), where R is any real number. If the Fourier transform ψ(ω) satisfies the admissibility condition (Wei, 2007):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32113242

$$\int_R \frac{|\psi(\omega)|^2}{\omega} d\omega < \infty \quad \text{(Eq.7)}$$

then φ(t) is called a basic wavelet or wavelet generating function. By expansion and translation of the wavelet function φ(t), the continuous wavelet is obtained as:

$$\varphi_{a,t}(t) = \frac{1}{\sqrt{a}} \varphi\left(\frac{t-\tau}{a}\right),\ a, \tau \in R, a > 0 \quad \text{(Eq.8)}$$

For any function $f(t) \in L^2(R)$, the continuous wavelet changes into

$$W_f(a, \tau) = \left\langle f(t), \varphi_{a,\tau}(t) \right\rangle = \frac{1}{\sqrt{a}} \int_R f(t) \varphi\left(\frac{t-\tau}{a}\right) dt \quad \text{(Eq.9)}$$

where a is the scale factor; τ is the translation factor; and $W_f(a,\tau)$ is the wavelet coefficient.

Herein, the Morlet wavelet was used for continuous wavelet transform of the extreme climate indices. The wavelet function is:

$$\psi(t) = e^{i\omega t} e^{-t^2/2} \quad \text{(Eq.10)}$$

(4) R/S analysis: This is also known as rescaled range analysis, which is an important analytical method under the chaos theory. It can be applied to analyze the fractal features and long-term memory process of a variety of time series. The calculation method is illustrated below:

A time series $\{X_t\}$ is divided into A subintervals with equal length N. For each subinterval, let

$$X_{t,n} = \sum_{u=1}^{t} \left(X_u - M_n\right) \quad \text{(Eq.11)}$$

Where M_n is the mean of the n^{-th} internal X_u; $X_{t,n}$ is the cumulative dispersion of the n^{-th} interval; u is the time series. Also,

$$R = \max\left(X_{t,n}\right) - \min\left(X_{t,n}\right) \quad \text{(Eq.12)}$$

where $\max(X_{t,n})$ and $\min(X_{t,n})$ are the maximum and minimum values, respectively. Let S be the standard deviation of the X_u series, then the rescaled range R/S can be defined. Through long-term practice, the following relationship can be established in terms of the Hurst exponent:

$$R / S = K(n)^H \quad \text{(Eq.13)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32113242

where H is the Hurst exponent and K(n) is a constant. Logarithm is taken on both sides to calculate the Hurst exponent, which can be used to measure the trend intensity and noise level variation over time. It is a measure of statistical correlation of time series (Zhao, et al., 2000).

Based on the above methods, first, a linear regression analysis was performed for the 19 extreme climate indices, and the spatio-temporal variation trend for each extreme climate index from 1968 to 2017 was obtained. In order to identify the major stages in the variation, a Mann-Kendall trend test and sliding T test were respectively implemented. By comparing and verifying the results of the two tests already mentioned, the year of abrupt change was determined. Next, a wavelet analysis with high resolution for the waveform characteristics was used to derive the periodic features of the climatic index changes. Given the relevant influence of terrain on climate, a correlation analysis between climate indices and geographical factors was performed. With this, it was possible to measure such degree of influence. Finally, R/S analysis was done with the purpose of predicting future climate trends in the Sichuan Province.

Results

Spatio-temporal variation characteristics of extreme temperature indices

Interannual temporal variations

Extreme weather events refer to a kind of rare events occurring at a specific area and time. The occurrence of extreme weather events can be estimated using extreme climate indices. *Figure 3* displays the interannual variation trend for extreme temperature indices observed in the Sichuan Province from 1968 to 2017. Specifically, *Figure 3a-e* shows the five extreme cold indices FD, Tnn, Tnx, Tn10, and Tx10, among the ten extreme temperature indices, where linear tendency rates indicated either a decreasing or a warming trend. The inter-decadal variation tendency rates for those indices were -133.73d/10a, 0.64 °C/10a, 0.23 °C/10a, -296.75d/10a, and -132.97d/10a, respectively. In *Figure 3f-j,* the five extreme warm indices include SU, Txn, Txx, Tn90, and Tx90, where their linear tendency rates indicated either an increasing or a warming trend. In this case, the inter-decadal variation tendency rates were 32.30d/10a, 0.28 °C/10a, 0.39 °C/10a, 272.1d/10a, and 273.7d/10a, respectively. For all these results, the tendency rates complied with the 0.05 significance level test. In addition, it was observed that the FD, Tnn, and Tx90 variation amplitudes were significantly higher than those corresponding to SU, Txn and Tx10 values. These results represented an asymmetry in temporal variation features of the extreme cold and warm indices. Generally speaking, warming was predominant in the Sichuan Province, which is a region with positive response to global warming.

Figure 4 shows the spatial distribution for the regression coefficients of extreme temperature indices observed in 39 meteorological stations of the Sichuan province for the past 50 years. Results indicated that among the five extreme cold indices, FD, Tn10, and Tx10 showed a decreasing trend in space, while Tnn and Tnx were the opposite. In general, the 5 extreme warm indices showed a warming or increasing trend, which was consistent with the interannual variation. For all these results, the regression coefficients complied with the 0.05 significance level test. The overall FD reduction was of -10~0d/10a, and the Muli Station displayed the largest reduction data

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32113242

with an inter-decadal variation of-19.5d/10a; Yuexi was the only station with a positive increase, showing an inter-decadal variation of 0.3d/10a. These two stations are both located in the MSW. More significant changes were observed in the mountainous regions, where the highest average variation rate was of -5.73d/10a. These types of changes were mostly insignificant in the basin regions, where the lowest average variation rate was obtained as -1.51d/10a. The overall Tnn increasing range was 0~0.5 °C/10a, and the fastest increase was found at the Muli Station (1.1 °C/10a). Tnn decreased only at the Yuexi Station (-0.21 °C/10a). These two stations are located in the mountainous region. The average variation trend of Tnn was 0.46 °C/10a in the MSW vs. 0.55 °C/10a in the PNW (a total of 9 stations had a variation rate larger than 0.5 °C/10a). The ESB displayed the smallest variation (0.27 °C/10a). Regarding Tnx, the Muli Station showed the highest increasing trend (0.64 °C/10a). In addition, only the Shaojue Station contained a negative change, which was -0.05 °C/10a. Among different terrain types, the largest average increasing trend was obtained in the PNW (0.29 °C/10a).

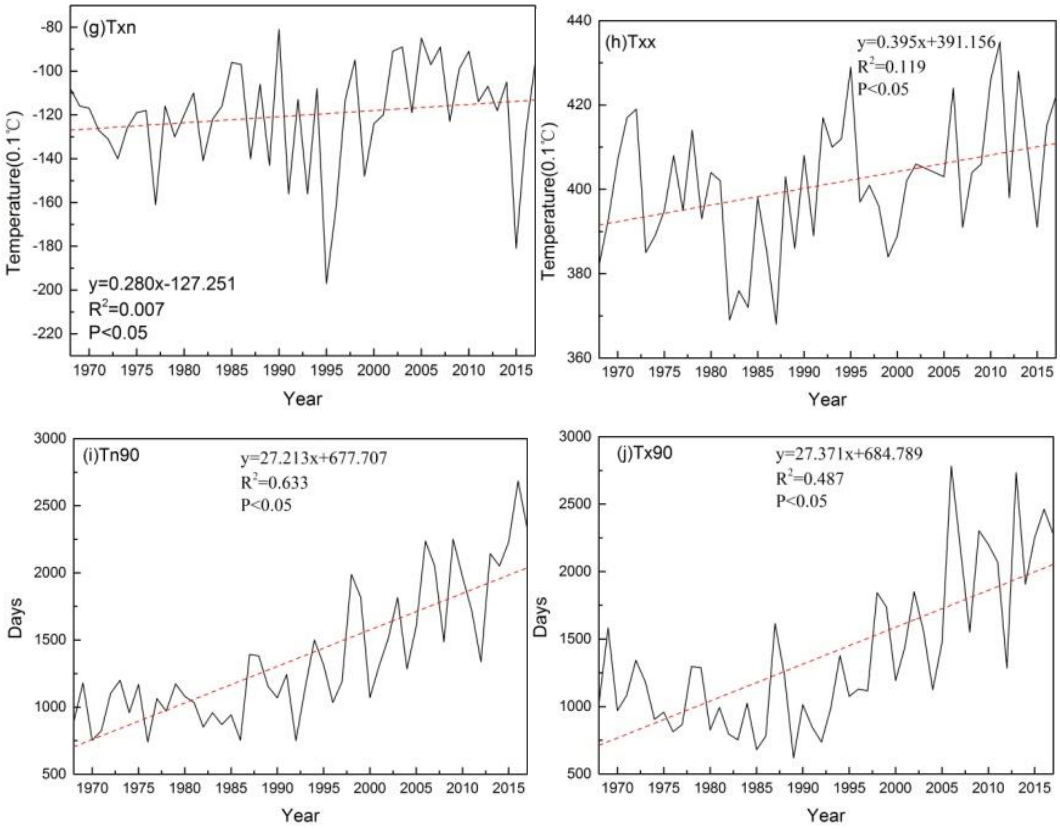

Figure 3. *Interannual temporal change trends of 10 extreme temperature indices from 1968 to 2017. (a) Frost days (FD), (b) Min Tmin (Tnn), (c) Max Tmin (Tnx), (d) Cool nights (Tn10), (e) Cool days (Tx10), (f) Summer days (SU), (g) Min Tmax (Txn), (h) Max Tmax (Txx), (i) Warm nights (Tn90),(j) Warm days (Tx90)*

Spatial change trends

It was also observed that Tn10 values gradually decreased from west to east. That is, the variation in the PNW (-9.0d/10a) was higher than that observed in the MSW (-8.5d/10a) as well as than that in the ESB (-6.0d/10a). In addition, the largest reduction was found at the Muli Station, which value was of -21.0d/10a. The Tx10 reduction range in the MSW (-4.7d/10a) was greater than those in both, the PNW (-3.7d/10a) and the ESB (-2.6d/10a). The largest reduction was determined at the Leibo Station, which was -11.9d/10a. Comparing the values for different terrain types, the average SU increase was larger in the ESB (1.7d/10a) than those in the PNW (0.05d/10a) and MSW (0.2d/10a). 13 stations in the plateau and 4 stations in the mountainous region showed a value of 0d/10a. In the case of Txn and Txx results, most of the stations showed an increasing trend, with an amplitude of 0~0.5 °C/10a. Also, the increasing rate value in the MSW (0.41 °C/10a, 0.4 °C/10a) was larger than those obtained for the PNW (0.31 °C/10a, 0.32 °C/10a) and the ESB (0.23 °C/10a, 0.39 °C/10a). The station with the highest increase (1.09 °C/10a, 0.78 °C/10a) was the Leibo Station, which is located in the mountainous area. Growth trends of Tn90 and Tx90 gradually decreased from west to east, and the increase was the fastest in the mountainous region (8.0d/10a, and 10.3d/10a, respectively). The largest increase was also found at the Muli Station in the mountainous area (19.2d/10a, 17.7d/10a).

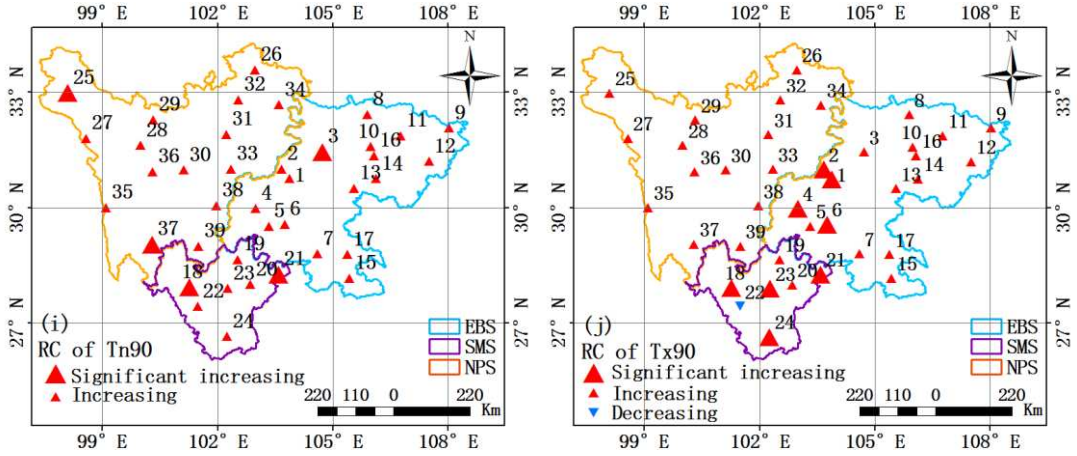

Figure 4. *Spatial change trends of 10 extreme temperature indices from 1968 to 2017, (a)Frost days (FD),(b) Min Tmin (Tnn),(c) Max Tmin (Tnx),(d) Cool nights (Tn10),(e) Cool days (Tx10), (f) Summer days (SU), (g) Min Tmax (Txn), (h) Max Tmax (Txx), (i) Warm nights (Tn90), (j) Warm days (Tx90)*

As these results showed, the extreme temperature in Sichuan exhibited an increasing trend during the past 50 years. The cold extreme events showed a warming or decreasing trend, while the warm extreme events showed a warming or increasing tendency. The variation trend in the west was more significant than that in the east, that is, the warming amplitude was higher in the PNW and MSW than in ESB. Particularly, the mountain to basin transition regions (Muli and Yuexi Station), as well as high-altitude areas were the most affected by global warming.

Mutation characteristics

Climate modifications are identified as abrupt changes in statistical spatio-temporal features, and can be represented by mutation points (Fu and Wang, 1992). To ensure the scientificity and accuracy of this research, the M-K and sliding T tests (subseries length 5) were simultaneously used for cross-validation. The purpose is to exclude false mutation points, which are identified by one of the two above-mentioned methods. This way, the reliability of the mutation analysis results is enhanced. *Table 3* shows the results for the M-K and the sliding T tests, as well as wavelet analysis for extreme temperature indices during the period of 1968 to 2017. Due to space constraints, only selected resulting diagrams are shown herein. Tnn diagrams for cold indices as well as SU diagrams for the warm indices are presented in *Figure 5*. It is important to state that other analysis yield similar results.

As shown in *Figure 5a,* the UF curve for Tnn showed overall increasing values over time. However, considering time stages, a decreasing trend was observed before the 1980s. Later, between the early 1980s and the mid-1990s, an increasing tendency occurred, followed by a slight decline. Finally, after the year of 2000, a growing trend was observed. The change was significant after 2010 ($P < 0.05$). The two UF and UB statistics intersected in the year of 2002, which indicated the starting mutation time and increasing. As data show in *Figure 5c,* the Tnn curve was both, concave and convex in shape; however, no mutation point appeared. Combining the results of the two tests, it was judged that there was no mutation year for Tnn, however this index steadily increased after the year of 2000. In *Figure 5b,* the UF curve for SU showed an

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32113242

increasing trend before the 1980s, while between the 1980s and the 21st century the tendency decreased. It was also observed that, before and after 1990, such decline was significant. In addition, after the 21st century SU increased, especially after 2012 when the change was significant ($P < 0.05$). The UF and UB statistics corresponding to SU intersected in 2009. This point indicated starting time of increasing change and mutation. As shown in *Figure 5d*, the t statistic exceeded the 0.05 significance level test in 1979. Since the t statistic is greater than zero, it indicated that SU experienced a significant mutation from lower to higher values in 1979. However, as two test cross-validation results indicated, no year for SU mutation occurred.

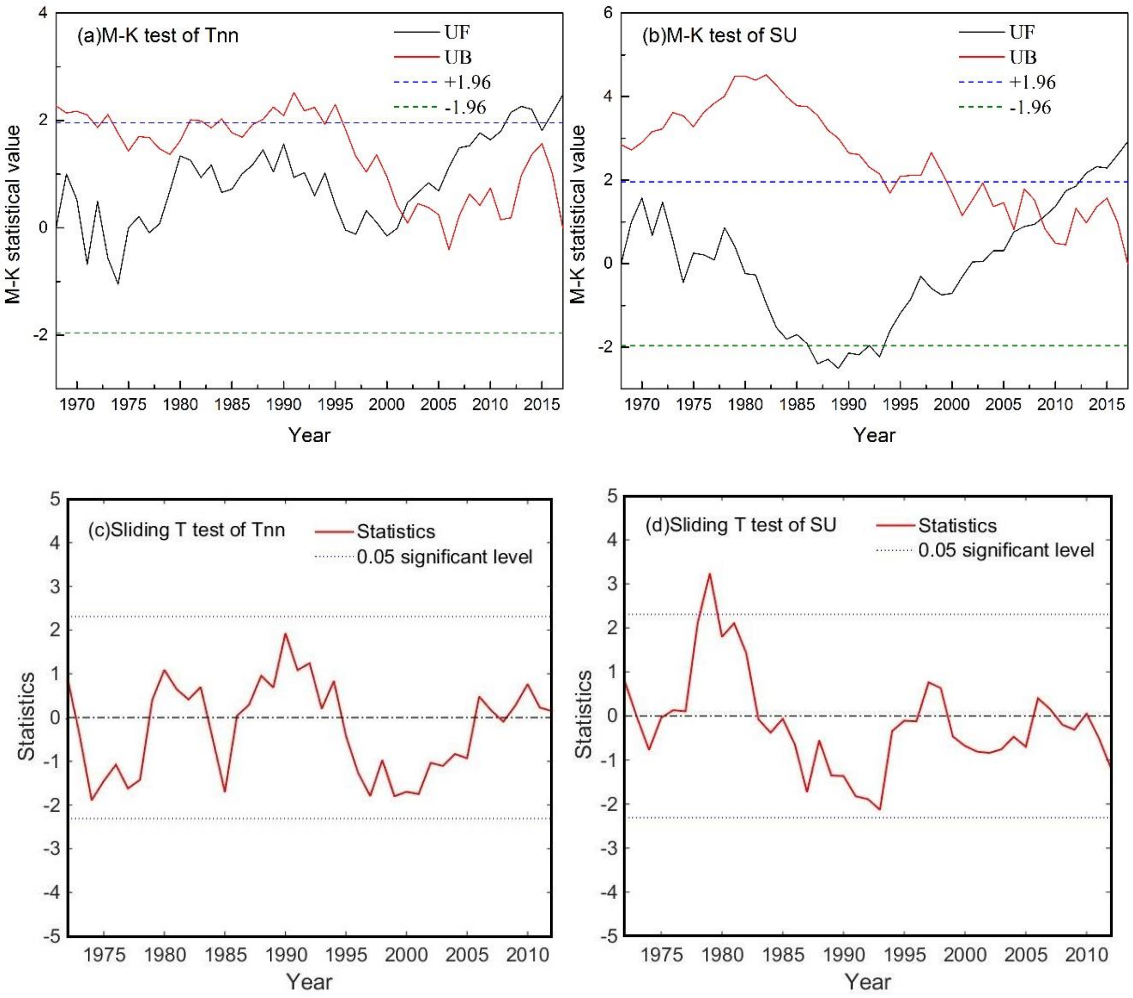

Figure 5. *M-K and sliding T test of Tnn and SU, (a) M-K test of Tnn, (b) M-K test of SU, (c) Sliding T test of Tnn, (d) Sliding T test of SU*

Table 3 displays the results of mutation points identified for all extreme temperature indices by the M-K and sliding T test. Taken together, except for the mutation year of Tnx in 1995, there were no significant mutation years in the other extreme temperature indices during the past 50 years. It was also determined that there was no significant mutation in extreme temperatures. However, increasing temperature trends were noticeable in the 1980s and the early 21stcentury.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32113242

Periodic characteristics

Considering Tnn and SU as references, a detailed analysis in terms of wavelet periodic characteristics were performed (*Fig. 6*). *Figure 6a, d* shows the corresponding normalized time series. The threshold for the Tnn time series varied within ± 2.5 and changes were not significant. The threshold for the SU time series was about ± 2, with only a significant increase in the normalized value for the year of 2006. *Figure 6b, e* shows the wavelet power spectrum, which represents the fluctuation magnitude of the time series on the given wavelet scale and within a given time domain. The larger the wavelet power, the greener the color. The inverted cone-shaped lines in the figure correspond to the influence lines. The portion of the wavelet power spectrum below these influence lines indicates the marginal influence effect. Also, periodic features exhibit a greater uncertainty. Closed curves in the spectrum are related to regions with high power values. Tnn and SU closed regions corresponded to periods of significant interannual variation, which were all 2-6 years in length. Intense periodic change effects on this scale occurred in 1968~1980 and 1982~2017 for Tnn, while for SU happened from 1968 to1982 and from 1991 to 2017. Since time series variances of many physical quantities increase with time (red noise features), these red noises can be used as background when performing wavelet spectrum analysis. *Figure 6c, f* represents the full wavelet spectrum obtained when significance test is applied to the wavelet spectrum. When the solid lines (wavelet power spectrum curve) are smaller than the dotted line (this line represents the 0.05 significance level), it means that the periodic feature corresponding to this region passed the 0.05 significance level test. Thus, according to the data obtained, every Tnn and SU period that passed the significance test previously mentioned was all 2-6 years. In addition, when the period was 6 years long, the energy and oscillation were the strongest. As shown in the wavelet analysis results, between all the extreme temperature indices included in *Table 3,* the Txn period that passed the significance test was also the one which was 2-6 years. However, FD and Tn10 did not show significant wavelet periods. The periods for Tnx and Txx that passed the significance test were all 2-4 years, and for Tx10, Tn90 and Tx90 were all 3-4 years.

Table 3. *M-K test, sliding T test and wavelet analysis results of 10 extreme temperature indices*

Indices	M-K test	Sliding T test	Mutation years	Wavelet significant periods

Spatial and temporal variation characteristics of extreme precipitation indices

Interannual temporal variations

Considering the integrity and uniformity of data, 5 stations, namely, Batang (No.35), Huili (No.24), Guangyuan (No.8), Daxian (No.12), and Xuyong (No.15) where the precipitation data were incomplete, were excluded when analyzing extreme precipitation events in Sichuan. Therefore, only 34 stations were included in this type of analysis. As observed from the interannual variation trend of 9 extreme precipitation indices (*Fig. 7*), extreme precipitation occurred in the past 50 years; in addition, in the days of these events larger fluctuations were observed. Overall trend variation was not obvious, though. Also, R10, R95p, R99p and SDII displayed a mild increasing trend, with interannual variation tendency rate of 0.9d/10a, 79.5 mm/10a, 160.6 mm/10a and 0.05(mm/d)/10a, respectively. All remaining indices (CDD, CWD, R20, R50, and PRCPTOT) exhibited decreasing tendencies, with inter-decadal variation rates of -0.8d/10a, -0.4d/10a, -0.1d/10a, -0.5d/10a and -39.5 mm/10a, respectively. Inter-decadal variation tendency rates of every station analyzed in this research passed the 0.05 significance level test. On an overall perspective, the interannual variation of the extreme precipitation indices in Sichuan was not significant for the past 50 years. Nevertheless, some violent fluctuations occurred. Moreover, data also indicated that a regional peak appeared every 5 years.

Spatial change trends

Figure 8 shows the spatial distribution of extreme precipitation indices at 34 stations during the past 50 years. In the PNW area, CDD mostly showed a decreasing trend, with an average variation of -0.81d/10a. In contrast, in the MSW and ESB areas, this same index showed an increasing trend, with an average variation of1.57d/10a and 0.82d/10a, respectively. In every Sichuan region, except for 8 stations, CWD decreased. Among all geographical areas analyzed, the average PNW variation rate was of 0.04 d/10a, and those corresponding to MSW and ESB were -0.25 d/10a and -0.18 d/10a, respectively. R10 and R20 PNW showed an increasing trend (0.55d/10a, and 0.14d/10a, in that order), and the R50 variation rate at 12 stations was of 0d/10a. Thus, R50 for the PNW region basically remained unchanged (0.007d/10a). R10, R20,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32113242

and R50 variation rates for the MSW area were of -0.03d/10a, 0.12d/10a, and 0.10d/10a, respectively. Values decreased in the ESB, where R10, R20 and R50 reduction rates were -0.40d/10a, -0.22d/10a, and -0.11d/10a, in that order. R95p and R99p showed an increasing trend, and PRCPTOT decreased. In general, the average variation rates of these three indices in PNW were 9.97 mm/10a, 6.70 mm/10a, and 12.64 mm/10a, respectively; those in the MSW region were 7.85 mm/10a, 4.68 mm/10a, and 1.37 mm/10a, in that order. However, the variation trend in ESB was slightly different (variation rates were -7.64 mm/10a, 2.06 mm/10a, and -15.56 mm/10a, correspondingly). SDII mostly increased in PNW and MSW (variation rates were 0.008 (mm/d)/10a and 0.003 (mm/d)/10a, respectively). However, a decreasing trend was observed in ESB, where the variation rate was -0.005 (mm/d)/10a. As shown, variation amplitude was rather small. According to the previous analysis, there were noticeable spatial and regional differences in the extreme precipitation events in Sichuan during the past 50 years. Precipitation increased in PNW and MSW, and significantly decreased in ESB. In particular, precipitations registered in the Ya'an, Emeishan, and Leshan Station where the precipitation used to be very abundant, showed a decrease. Among different regions, the precipitation as well as extreme precipitation events in PNW and MSW considerably increased. In detail, the number of heavy rain, rainstorm and very heavy precipitation events in the plateau increased. There was also arise in the number of extreme precipitation events in the mountainous regions. However, the amplitude was not as large as that observed in the plateau. The basin, however, displayed a drying trend with decreased precipitation, and the extreme precipitation was also reduced.

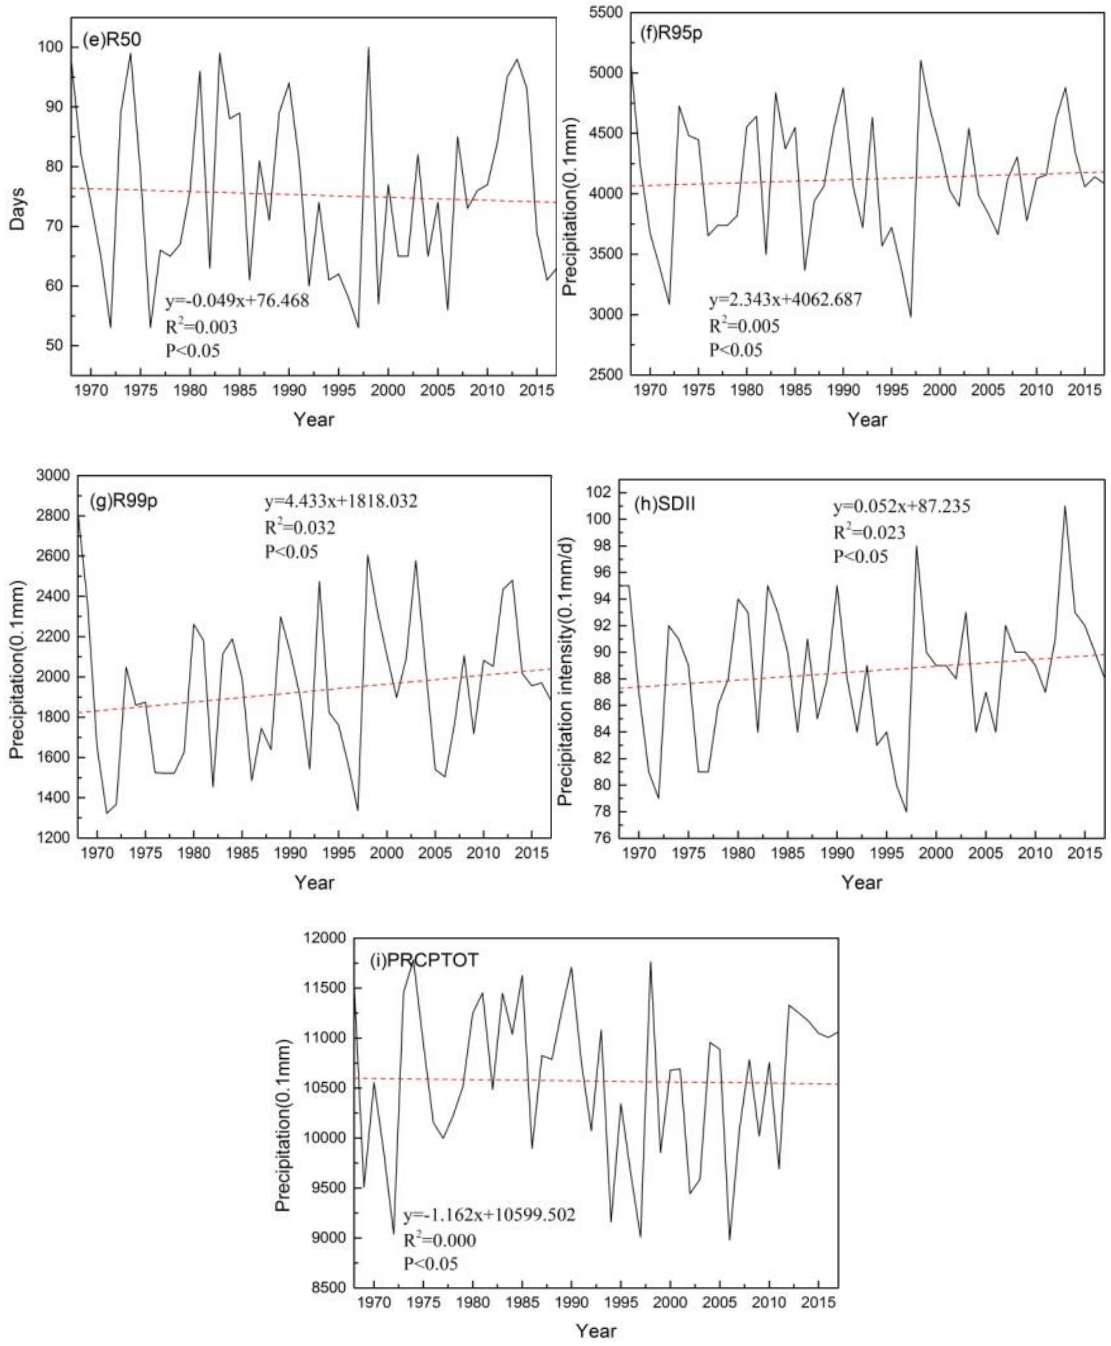

Figure 7. *Interannual temporal change trends of 10 extreme precipitation indices from 1968 to 2017. (a) Consecutive dry days (CDD), (b) Consecutive wet days (CWD), (c) Number of heavy precipitation days (R10), (d) Number of very heavy precipitation days (R20), (e) Number of rainstorm days (R50), (f) Very wet days (R95p), (g) Extremely wet days (R99p), (h) Simple daily intensity index (SDII), (i) Annual total wet-day precipitation (PRCPTOT)*

Mutation characteristics

Table 4 shows the results when extreme precipitation indices from 1968 to 2017 were assayed using the M-K test, sliding T test, and wavelet analysis. The process was similar to that applied to the extreme temperature indices. Only the CWD and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32113242

PRCPTOT test results were analyzed as examples. *Figure 9* shows the M-K test and sliding T test statistical diagrams for these two indices. As our results showed, the CWD UF curve displayed an increasing trend during the period going from the 1980s to the early 21st century; also, in 1996 this curve over passed the 0.05 significance level line (*Fig. 9a*). CWD significantly increased in 1996, and after this point, it started decreasing. Moreover, UF and UB statistics intersected in 2013 and 2015. The CWD t-test statistic showed a wavy fluctuation, where no significant values or mutation points occurred (*Fig. 9c*). Combining the results of the two tests, it was concluded that there was no mutation year. For PRCPTOT (*Fig. 9b*), the intersections between the UF and UB statistics first occurred in 1973, and later in 1991, 2012, and 2014, successively. Combining this with the sliding T test results for the mutation points (*Fig. 9d*), it was verified that these were true in 1991. Due to limited space, other indices do not be analyzed in detail. A summary of the results is shown in *Table 4*. Taken together, CDD, CWD, R10, R20, and SDII extreme precipitation indices did not show significant mutation years in the past 50 years. In addition, mutation years for R50, R95p, R99p, and PRCPTOT occurred in 1980, 2010, 2004, and 1991, respectively. This means that mutation years corresponding to heavy and very heavy precipitation events mainly appeared in the 1980 and the early 21st century.

Table 4. *M-K test, sliding T test and wavelet analysis results of 9 extreme precipitation indices*

Indices	M-K test	Sliding T test	Mutation years	Wavelet significant periods
CDD	1970,1971,1984,1985,1986	1996,2003,2008	No	2~4
CWD	2013,2015	No	No	2~5
R10	1973,1975,1979,1989,1990,1991,2015	1992,2011,2012	No	2~6

Periodic characteristics

As previously mentioned, detailed analysis was performed for CWD and PRCPTOT test results in terms of wavelet cycle features (*Fig. 10*). *Figure 10a, d* shows the normalized time series. The threshold for CWD and PRCPTOT time series was about ± 2, and the normalized CWD value significantly increased in 1969. *Figure 10b, e* shows the wavelet power spectrum. The CWD closed region corresponded to a period of 2-7 years and that of PRCPTOT corresponded to a period of 2-8 years. In other words, intervals of significant interannual variation were of 2-7 and 2-8 years for CWD and PRCPTOT, correspondingly. Strong concentration periodic change effects on this scale appeared in the intervals 1968~1975, 1977~2002, and 2006~2017 for CWD. Also, in the case of PRCPTOT, time domains were 1968~1980 and 1982~2012. Red noises

DOI: http://dx.doi.org/10.15666/aeer/1802_32113242

were used as background for the analysis of the wavelet spectrum. *Figure 10c, f* presents the full wavelet spectrum corresponding to the CWD and PRCPTOT period that passed the significance test. These periods were 2-4 and 2-6 years, respectively. The interval with the strongest wavelet energy was 4 years in length and that of PRCPTOT was 3 years. As indicated in *Table 4* that corresponds to the wavelet analysis of all extreme precipitation indices, periods where R10, R20, and R99p passed the significance test were also from 2-6 years. In the case of R50, R95p and SDII, interval was 2-7 years, and for CDD, it was 2-4 years.

Relationship between extreme climate index and geographical factors

According to the spatial distribution and regional difference analyses for extreme climate indices, it was demonstrated that topographical changes greatly affect extreme climate changes in the Sichuan Province. This region is roughly limited by the Guangyuan-Jiangyou-Dujiangyan-Yingjing-Muli line, and the topography is high to the northwest and low to the southeast. Extreme climate indices changes are highly related to longitude, latitude and altitude. In this research, the influence of these parameters on extreme climate indices was discussed (*Table 5*). Correlation analysis showed that Tnn, Tnx, SU, Txn and Txx were negatively correlated to elevation ($P < 0.01$), and positively to longitude ($P < 0.05$). Tnn, Tnx, Txn and Txx were negatively correlated to latitude; however, only Tnn and Txn passed the test at the 0.05 significance level. This indicated that the higher the altitude, the lower the longitude and the lower the latitude, the closer to the southwestern mountain area of Sichuan, the greater the change of the given extreme index value. Warmer extreme minimum and extreme maximum temperatures mainly occurred in the western alpine plateau area, and the warming range was larger as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32113242

compared to that of the eastern basin. FD and Tn10 were positively correlated to elevation ($P < 0.01$) and latitude ($P < 0.05$), and negatively to longitude ($P < 0.05$). This indicated that the higher the altitude, the higher the latitude and the lower the longitude, the closer the alpine plateau area in northwest Sichuan, the greater the change of extreme index value, the greater the reduction of extreme cold events in the west, and the smaller the reduction in the eastern basin. There was no significant correlation between other extreme climate indices (Tx10, Tn90 and Tx90) and geographical factors. Of the extreme precipitation indices, CDD, CWD and SDII positively correlated to elevation ($P < 0.01$), and negatively to longitude (except SDII, others passed the test at the 0.05 significance level); other indices (R10, R20, R50, R95p, R99p, PRCPTOT) negatively correlated to elevation and latitude, and positively to longitude, and most of them passed the test at the 0.05 significance level. This indicated that the higher the altitude, the lower the longitude and the higher the latitude, the closer the plateau and mountainous area in west Sichuan, the greater the change of extreme index value. These results were consistent with those of the spatial distribution for the extreme climate indices previously mentioned. Terrain characteristics affect spatial variation of extreme climate indices in Sichuan Province.

Change trends of extreme temperature and precipitation in the future

In order to analyze future variation trends of extreme climate indices in Sichuan, Hurst exponents were calculated for every 19 extreme climate indices, and the results are shown in *Table 6*. As data indicated, Tn10, Tx10, SU, and Tn90 Hurst exponents were all obtained with values above 0.5, which indicated the hidden long-term trend in the time series, i.e., strong long-term memory and a positive effect as well as a high probability of continuing the current trend. The Hurst FD, Txx, R10, R20, R50, and PRCPTOT exponents were all smaller than 0.5, indicating that the time series was either not persistent or persistent in the inverse state. According to these results, they might well mark the beginning of weakened memory and inversion. The Hurst Tnn, Tnx, Txn, Tx90, CDD, CWD, R95p, R99p, and SDII exponents were close to 0.5, indicating that the variation approached a random series, and the accuracy of a future trend prediction decreased to a certain extent. Of all extreme climate indices, the Hurst exponent for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32113242

Tn90 was the largest (0.802), and that of the PRCPTOT was the smallest (0.320). This was significantly greater (less) than the critical value of the random walk hypothesis. This means that an apparent positive (negative) continuity and fractal structure resulted in the time series. This is, an increment in the past might represent an increment (decrement) in the future. By combining the Hurst exponent analysis and the interannual variation trends for the 19 extreme climate indices (*Figs. 3* and *7*), it was determined that among all extreme temperature indices in Sichuan, FD, SU, and Tn90 may increase in the future. Conversely, Tn10, Tx10, and Txx may decrease, i.e., as a whole, extreme cold events will decrease and extreme warm events will increase. Of all extreme precipitation indices, R20, R50 and PRCPTOT may increase, while R10 may decrease. That is, it is very likely that the precipitation and the number of heavy precipitation and rainstorm events will increase in the future, and that both, the extreme temperature and extreme precipitation events of the Sichuan Province, will increase in the future.

Table 6. *Hurst exponents of 19 extreme climate indices*

Extreme temperature indices	Hurst exponents	Extreme precipitation indices	Hurst exponents
FD	0.353	CDD	0.440
Tnn	0.428	CWD	0.442
Tnx	0.433	R10	0.338
Tn10	0.556	R20	0.362

SU	0.570	R95p	0.446
Txn	0.440	R99p	0.494
Txx	0.405	SDII	0.493
Tn90	0.802	PRCPTOT	0.320
Tx90	0.473		

Conclusions and discussion

Under the general context of global warming, this study used daily meteorological data at 39 stations from MDSCC for the period 1968 to 2017. The 19 extreme climate indices recommended by the WMO were selected. Linear regression analysis, M-K test, sliding T test, wavelet analysis, correlation analysis and R/S analysis were performed for these indices. The interannual spatio-temporal variations, mutation and period features of extreme temperature and precipitation of Sichuan in the past 50 years were analyzed. On this basis, we further discussed the correlation between the extreme climate indices and geographical factors. Finally, some future trends were predicted based on the Hurst exponents. The main conclusions and discussion will cover the five aspects of this research.

(1) As to interannual temporal variations in the past 50 years (*Fig. 3*), in five extreme cold indices, the linear tendency rates of FD, Tn10 and Tx10 showed a decreasing trend, while those of Tnn and Tnx showed a warming trend. The five extreme warm indices include SU, Txn, Txx, Tn90 and Tx90, where their linear tendency rates indicated either an increasing or a warming trend. That is, most of extreme cold indices of Sichuan showed a decreasing trend, while the extreme warm indices showed a warming trend. Moreover, there was an asymmetry in temporal variation features of the extreme cold

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32113242

and warm indices. Generally speaking, warming was predominant in the Sichuan Province. The results observed are in agreement with other research previously carried out in the Southwestern China (Sun, et al., 2012; Qin, et al., 2015; Yuan and Zheng, 2015; Luo, et al., 2016) and Sichuan Province (Sun, et al., 2017). However, the inter-decadal variation tendency rates of extreme temperature indices are different. For instance, Sun et al. (2017) found that the inter-decadal variation tendency rates for Txx, Txn, Tnx and Tnn were 0.4 °C/10a, 0.3 °C/10a, 0.2 °C/10a, 0.3 °C/10a, respectively. The discrepancies may be caused by the data with different time periods and number of different meteorological stations used in the two studies.

The interannual variation of the extreme precipitation indices in Sichuan was not significant for the past 50 years (*Fig. 4*). Among them, R10, R95p, R99p and SDII displayed a mild increasing trend, and all remaining indices of CDD, CWD, R20, R50 and PRCPTOT exhibited decreasing tendencies. Nevertheless, some violent fluctuations occurred, and a regional peak appeared every 5 years. The temporal trends in our work are similar to previous studies in reporting trends of precipitation extremes over the past few decades in the Southwestern China (Sun, et al., 2012; Yuan, et al., 2014; Luo, 2015; Qin, et al., 2015) and Sichuan Province (Sun, et al., 2017; Li, et al., 2019a). For example, in Li's work (2019a), they found the trends in extreme precipitation indices constituted slight changes in the Sichuan Province and extreme precipitation was a fluctuation process from 1961 to 2017. Results showed that the ENSO (El Niño-Southern Oscillation, ENSO) events have long and strong relations with extreme precipitation. Sun et al. (2017) noted that the overall change trend of precipitation in Sichuan Province was not significant from 1971 to 2012.

(2) As to spatial change trends (*Fig. 7*), among 5 extreme cold indices, FD, Tn10 and Tx10 showed a decreasing trend in space, while Tnn and Tnx were the opposite. The 5 extreme warm indices showed a warming or increasing trend. The extreme temperature in Sichuan exhibited an increasing trend during the past 50 years. The cold extreme events showed a warming or decreasing trend, while the warm extreme events showed a warming or increasing tendency. The variation trend in the west was more significant than that in the east, that is, the warming amplitude was higher in the PNW and MSW than in ESB. Particularly, the mountain to basin transition regions (Muli and Yuexi Station), as well as high-altitude areas were the most affected by global warming. Li et al. (2012) studied the altitude dependency of trends of daily climate extremes in Southwestern China from 1960 to 2008. Characteristics of regional trends indicated the obvious warming with altitude. There is an enhanced sensitivity of climate extremes to elevation in southwestern China in the context of recent warming, and which are consistent with our results.

There were noticeable spatial and regional differences in the extreme precipitation events in Sichuan during the past 50 years (*Fig. 8*). Precipitation increased in PNW and MSW, and significantly decreased in ESB. In particular, precipitations registered in the Ya'an, Emeishan, and Leshan Station where the precipitation used to be very abundant, showed a decrease. Among different regions, the precipitation as well as extreme precipitation events in PNW and MSW considerably increased. In detail, the number of heavy rain, rainstorm and very heavy precipitation events in the plateau increased. There was also arise in the number of extreme precipitation events in the mountainous regions. However, the amplitude was not as large as that observed in the plateau. The basin, however, displayed a drying trend with decreased precipitation, and the extreme precipitation was also reduced. Previous studies have reported that the intensity,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32113242

frequency, and duration of extreme precipitation increased in the Sichuan plateau, while the intensity and frequency of extreme precipitation decreased, but the duration of extreme precipitation did not change in the Sichuan basin (Li, et al., 2019a). Sun et al. (2017) determined that the precipitation distribution was low in the western Sichuan and high in the eastern Sichuan, and most of the extreme precipitation indices had no significant change trend. Although the average change trend and spatial distribution of CDD and CWD indicated that the Sichuan as a whole tended to dry, the humidity in some areas of the plateau increased from 1971 to 2014. Our results are roughly consistent with the previous work above.

(3) As shown by the M-K test, sliding T test and wavelet analysis (*Table 3*), of 10 extreme temperature indices, except for the mutation year of Tnx in 1995, there were no significant mutation years in the other extreme temperature indices. That is, there were no significant mutation in extreme temperature, but the increase and warming trend of temperature were obvious in the 1980s and the early 21st century. Except for FD and Tn10 that had no significant wavelet periods, Tnn, SU and Txn showed significant variation with a period of 2-6 years, and for Tnx and Txx were all 2-4 years, and for Tx10, Tn90 and Tx90 were all 3-4 years. Of 9 extreme precipitation indices (*Table 4*), except for R50, R95p, R99p and PRCPTOT that had mutation years occurred in 1980, 2010, 2004 and 1991, respectively, the other indices had no mutation years. Namely, mutation years corresponding to heavy and very heavy precipitation events mainly appeared in the 1980 and the early 21st century. Except for CDD and CWD that had significant variation with the periods of 2-4 years and 2-5 years, R50, R95p and SDII showed significant variation with a period of 2-7 years, and for R10, R20, P99p and PRCPTOT were all 2-6 years.

The method of M-K trend test is a valuable tool for effectively differentiating natural fluctuations from definite variation trends. It is a nonparametric statistical test to analyze the variation trends of climate and hydrological series over time (Song et al., 2019). But sometimes there are false mutation points in the results of the test. The method of sliding T test is also helpful in detecting climate mutations by determining if there is a significant difference in the means of two different groups. To ensure the scientificity and accuracy of this research, the M-K and sliding T tests (subseries length 5) were simultaneously used for cross-validation. By using M-K trend test, Luo et al. (2016) conducted mutation test of Tx90, Tx10, Tn90 and Tn10 in Southwestern China from 1970 to 2010. The results showed that there was an obvious mutation in the number of warm days in 2004, and there was a significant increase in the number of warm days from 2005 to 2010; the number of cold nights had an obvious mutation in 1994 and decreased significantly from 1995 to 2010; the number of cold days had a mutation in 1997, but it was not obvious; the number of warm nights had no mutation. Liu and Xu (2014) also discussed the mutation years of some extreme temperature indices in Southwestern China. Results indicated there were no mutation years of Tx90 and Tnn from 1951 to 2010; however, increasing temperature trends were noticeable in the early 21st century, which are in agreement with our results. Other discrepancies may be caused by the data with different time periods, extent of different study areas and singularity of mutation method used in the previous studies.

About the abrupt change point of extreme precipitation, Zhang and Ma (2011) indicated there was no mutation in the number of days of annual average extreme precipitation in Sichuan Province from 1961 to 2009. The intensity of extreme precipitation increased before 1990s, and there was a significant mutation point in 1980.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32113242

After 1990s, the trend was decreased and there was a mutation before and after 2002, but it was not significant. Li et al. (2019a) analyzed mutation characteristics of extreme precipitation by using M-K test, and found R20, CWD and SDII were not detected the abrupt change point from 1961 to 2017 in Sichuan Province, moreover, most of the break points were in 1979 and 1991, which are consistent with our work.

Wavelet analysis can accurately provide information on local signal features in both, the time and frequency domains, and can be used for multi-scale detailed signal analysis. Luo et al. (2016) investigated the periodic characteristics of extreme temperature in Southwestern China, the results showed both the number of warm days and the number of warm nights had a short period of 3-4 years and a long period of 14 years, the number of cold days had a short period of 4 years, and two long periods of 7 years and 11 years, and the number of cold nights had a short period of 1-4 years, two long periods of 7 years and 10 years. The results of short period are in accord with our work, but the difference of long-period analysis may be caused by the data with different time periods, extent of different study areas and different specific method of wavelet analysis used in the two studies. In term of periodic characteristics of extreme precipitation, our results are roughly consistent with the previous work of Li et al. (2019a). As pointed by Li et al. (2019a), the ENSO events have the longest and strongest relations with extreme precipitation in the Sichuan Province.

(4) According to the correlation analysis between extreme temperature indices and geographical factors (*Table 5*), the results showed that Tnn, Tnx, SU, Txn and Txx were negatively correlated to elevation, and positively to longitude. Tnn, Tnx, Txn and Txx were negatively correlated to latitude. This indicated that the higher the altitude, the lower the longitude and the lower the latitude, the closer to the southwestern mountain area of Sichuan, the greater the change of the given extreme index value. Warmer extreme minimum and extreme maximum temperatures mainly occurred in the western alpine plateau area, and the warming range was larger as compared to that of the eastern basin. FD and Tn10 were positively correlated to elevation and latitude, and negatively to longitude. This indicated that the higher the altitude, the higher the latitude and the lower the longitude, the closer the alpine plateau area in northwest Sichuan, the greater the change of extreme index value, the greater the reduction of extreme cold events in the west, and the smaller the reduction in the eastern basin. The results of correlation analysis between extreme precipitation indices and geographical factors also indicated that the higher the altitude, the lower the longitude and the higher the latitude, the closer the plateau and mountainous area in west Sichuan, the greater the change of extreme index value.

The terrain of Sichuan is higher in the west and lower in the east, and the variation from west to east is mainly plateau-mountain-basin, and its position change is very related to longitude, latitude and altitude. Changes of extreme climate indices are highly related to longitude, latitude and altitude. Previous studies have reported that warming at high elevation regions appeared much more rapid than at low elevations on the basis of ice cores data from the Tibetan Plateau (Tian et al., 2006; Kang et al., 2007). Li et al. (2012) indicated for precipitation extremes, it was obvious that the larger decreasing in summit station than others, and following was flat stations, but the increase mainly in valley stations, which are also consistent with our studies.

(5) As shown by Hurst exponents and interannual variation trends of the 19 extreme climate indices (*Table 6*), in the future, FD, SU and Tn90 may increase, while Tn10, Tx10 and Txx may decrease, i.e., as a whole, extreme cold events will decrease and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32113242

extreme warm events will increase. Of all extreme precipitation indices, R20, R50 and PRCPTOT may increase, while R10 may decrease. That is, the precipitation and the number of heavy precipitation and rainstorm events will increase, and that both the extreme temperature and extreme precipitation events of the Sichuan Province will increase, but there will be obvious regional differences under different topographic zones in the future. Among them, the results on the overall trend of future change are in agreement with many model projections of extreme climate change. (Liu et al., 2012; Li et al., 2019b; Peng et al., 2019; Zhao et al., 2019).

In this study, some future trends of extreme climate indices are predicted only based on the Hurst exponents. Because climate models are a powerful tool to study climate system and climate change, and its simulation results are an important data base for climate projection and climate change risk assessment. Furthermore, the use of climate models to assess and predict the future climate change features can provide a scientific basis for adjusting human development strategies to adapt to climate change. In the future research, we can use the simulation results of CMIP5 (Coupled Model Intercomparison Project Phase 5, CMIP5) model and high-resolution statistical downscaling data set, combined with RCPs (Representative Concentration Pathways, RCPs) proposed by IPCC, to project the possible future changes of extreme climate events in Southwestern China, even in Sichuan Province. Moreover, the mechanistic understanding of how some climate drivers impact extreme temperature and extreme precipitation in Sichuan Province through forcing large-scale atmospheric circulation changes need to be further investigated, especially, the relationships between ENSO events, SASM (South Asian Summer Monsoon, SASM), EASM (East Asian Summer Monsoon, EASM) and extreme climate indices need to be further discussed, and the analyses of the physical causes of these variability will also become the basis of our future work.

(Received 27th Sep 2019; accepted 4th Feb 2020)

Abstract. Based on the LandsatTM/ETM+/OLI remote sensing data (30 m resolution) of the Shule River basin in the past 20 years, the land use data was obtained by interpretation. By using Erdas9.2 and ArcGIS10.3 software, the land-use types were divided into 6 primary landscape types and 25 secondary landscape types, and the spatial database of watershed land use was established. By using GIS spatial analysis technology, transfer matrix, land use dynamics and many other spatial-temporal statistical analysis methods, the transformation process and temporal and spatial pattern analysis of land-use types in river basin in recent 20 years were carried out, with results showing that: In the past 20 years, different degrees of changes have taken place in land use in the Shule River basin. On the whole, the area of cultivated land, woodland, grassland and urban and rural industrial and mining residents increased, among which grassland increased the most, with an annual increase rate of 0.33%. The area of cultivated land increased, with an annual growth rate of 0.0959%. While water area and unused land decreased, with an annual decline rate of 0.4490%. The decrease of water area was the smallest, with an annual decline rate of 0.0122%. There are obvious differences in the speed and type of change in water area and unused land. The hot spot of land use type transformation in the basin is the middle reaches oasis, mainly Dunhuang, Guazhou and Yumen counties (cities).
Keywords: *land use, spatial change, transition matrix, characteristic study, Shule River basin*

Introduction

Land use is the most direct form of interaction between human activities and natural environment, and it is also a frontier and hot issue in the study of global change (Liu et al., 2003; Naef et al., 2002; Weng, 2002). The spatiotemporal change of land use can intuitively express the interaction between human activities and natural environment, reflect the relationship between the Earth's environmental system on which Human beings depend for their Survival and the growing production system of mankind (agriculture, industrialization/urbanization, etc.), it will also cause a variety of natural phenomena and ecological process changes (Wu et al., 2006; Guan et al., 2011). Under the background of global change, the change of land use pattern in river basin is gradually strengthening the imbalance and instability of hydrological cycle, thus affecting the controllability, reproducibility, total amount, composition and distribution of water resources. Furthermore, it brings great challenges to the safety of water supply, flood control, water ecology and so on (Ku, 2016; Ning et al., 2018). Therefore, in order to explore the interaction between human activities and natural environment in the inland river basin, we took the Shule River basin as the research area and carried out the analysis

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32433250

and study on the transformation process of land-use types and the temporal and spatial pattern in the past 20 years, which provide policy support and technical guarantee for the sustainable and healthy development of the river basin.

Overview of the study area

The Shule River basin is located in the hinterland of the arid area of northwest China, and is located between 93°22' - 98°59' E and 38°1' - 42°47' N. The watershed area is about 1.25×10^5 km^2, which is one of the three inland river basins in Hexi Corridor and one of the seven water rights pilot basins. The watershed location map is shown in *Figure 1*. The altitude of the river basin is between 914 and 5816 m, lower in the north and higher in the south. It belongs to continental desert climate. As a typical inland river basin, water supply is mainly composed of glacier melt water and mountain precipitation. There are 7 soil types, 31 subclasses and 63 soil genera in the watershed soil. By the end of 2018, the total population of the basin was 524200, and the agricultural population was 221400, with a natural population growth rate of 4.54% for many years. At present, the per capita share of water resources is 2933.7 m^3 (Yue et al., 2019).

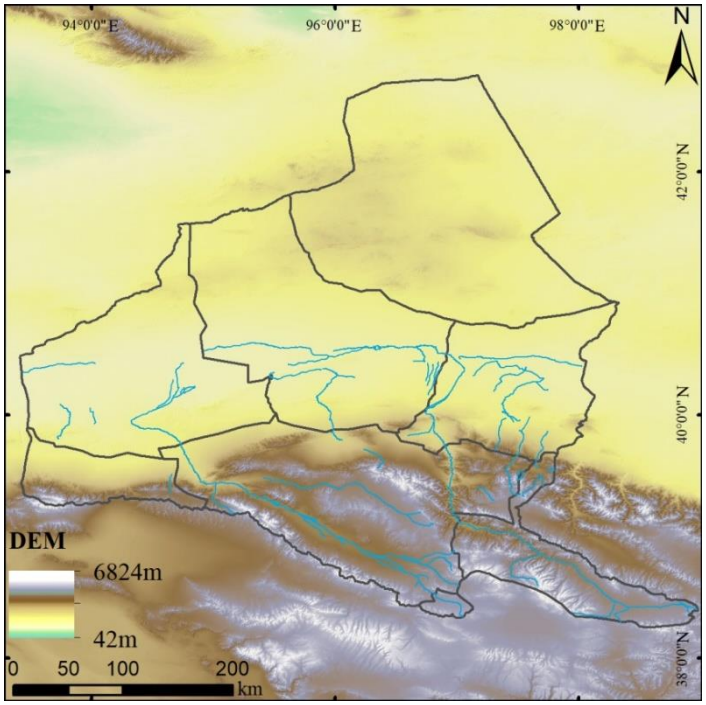

Figure 1. *The location of Shule River basin*

Research methods

According to the distribution of rivers and their tributaries, the boundary of the Shule River basin is delineated by using the digital elevation model of the study area in the SWAT hydrological model. The Landsat TM, ETM remote sensing image with spatial resolution of 30 m in watershed in summer and autumn is selected since in summer and autumn in 1995 and 2015, plants grow best with highest vegetation coverage and it is easy to distinguish from desert, which is conducive to visual interpretation. When extracting for land by information, the 4 (R), 3 (G), 2 (B) band of TM/ETM+ image is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32433250

combined first to generate a standard false color image and unitedly conversed to Albers projection. Combined with the information of GPS measuring points in the field, geometric correction is carried out. The second is to establish the identification of remote sensing interpretation. First, the interpretation logo is initially established indoors. Then field observation and recording are carried out through GPS positioning and to correct and calibrate the interpretation in turn. The land-using information is extracted again. Adopting the visual interpretation method of human-computer interaction, taking the relevant drawings as a reference, with application of correlation analysis and comprehensive image feature, the boundary of various surface features is to be determined and then to generate the current land-using thematic map by using ArcGIS plug-in. On this basis, the thematic map of land-using change in two time periods is generated by applying ArcGIS spatial overlay analysis function. Finally, the type of surface features is determined while verifying the accuracy of the predicted map through comparing the high-resolution data view provided by GoogleEarth and combining with field observation and experience knowledge. By using Erdas9.2 and ArcGIS10.3 software, the land-use types were divided into 6 primary landscape types and 25 secondary landscape types, and a five-stage land use spatial database of river basin was established.

(1) Single land-use dynamic degree: Quantitative description of the speed of change and the type difference of change, its form of expression is as follows (Chen et al., 2012; Guo et al., 2015; Yang, 2018):

$$K = \frac{U_b - U_a}{U_a} \times \frac{1}{T} \quad \text{(Eq.1)}$$

In the formula, K is the dynamic attitude of land use in the study area; U_a and U_b are the number of land-use types before and after the change; T is the length of the study period.

(2) The integrate dynamic degree of land use: It is an index to describe the regional difference in the rate of change of land-use types, and reflects the comprehensive impact of human activities on the change of land-use types. Its mathematical model is (Le et al., 2018; Doelman et al., 2018; Bovet et al., 2018; Jin et al., 2013; Huang et al., 2014):

$$S = \left[\sum_{i=1}^{n} \Delta S_{i-j} / S_i \right] \times \frac{1}{T} \times 100\% \quad \text{(Eq.2)}$$

In the formula, S is the comprehensive dynamic attitude of land use, $\Delta S_{i\text{-}j}$ is the sum of the area of land-use types before and after conversion, S_i is the total area of type i land use, and t is the time of land use change.

Study on the change process and characteristics of land use in Shule River basin

Structural change of land-use types in watershed

As can be seen from *Table 1* and *Figure 2,* between 1995 and 2015: (1) The area of cultivated land, woodland, grassland and urban and rural industrial and mining residents increased, among which grassland increased the most, with an increase of 2069.54 km^2. The proportion of grassland increased from 19.88% in 1995 to 21.54% in 2015, with an

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32433250

annual increase rate of 0.33%. The area of cultivated land increased by 596.73 km^2, and the proportion of cultivated land increased from 0.85% to 1.33%, with an annual growth rate of 0.0959%. (2) The area of water area and unused land decreased, the area of unused land decreased the most, with a decrease of 2794.74 km^2. The proportion of unused land decreased from 78.03% in 1995 to 75.78% in 2015, with an annual decline rate of 0.4490%. The decrease of water area was the smallest, with an area of 76.06 km^2, and the proportion of grassland decreased from 0.66% in 1995 to 0.60% in 2015, with an annual decline rate of 0.0122%.

Table 1. *Land use change in Shule River basin from 1995 to 2015 (km^2)*

Land use type	1995		2015		Area of change	Annual rate of change
	Area	Proportion (%)	Area	Proportion (%)		
Cultivated land	1062.00	0.85	1658.73	1.33	596.73	0.0959
Woodland	583.35	0.47	627.02	0.50	43.67	0.0070
Grassland	24741.53	19.88	26811.07	21.54	2069.54	0.3325
Water	819.54	0.66	743.48	0.60	-76.06	-0.0122
Urban and rural	142.67	0.11	303.54	0.24	160.87	0.0258
Unused land	97127.90	78.03	94333.16	75.78	-2794.74	-0.4490

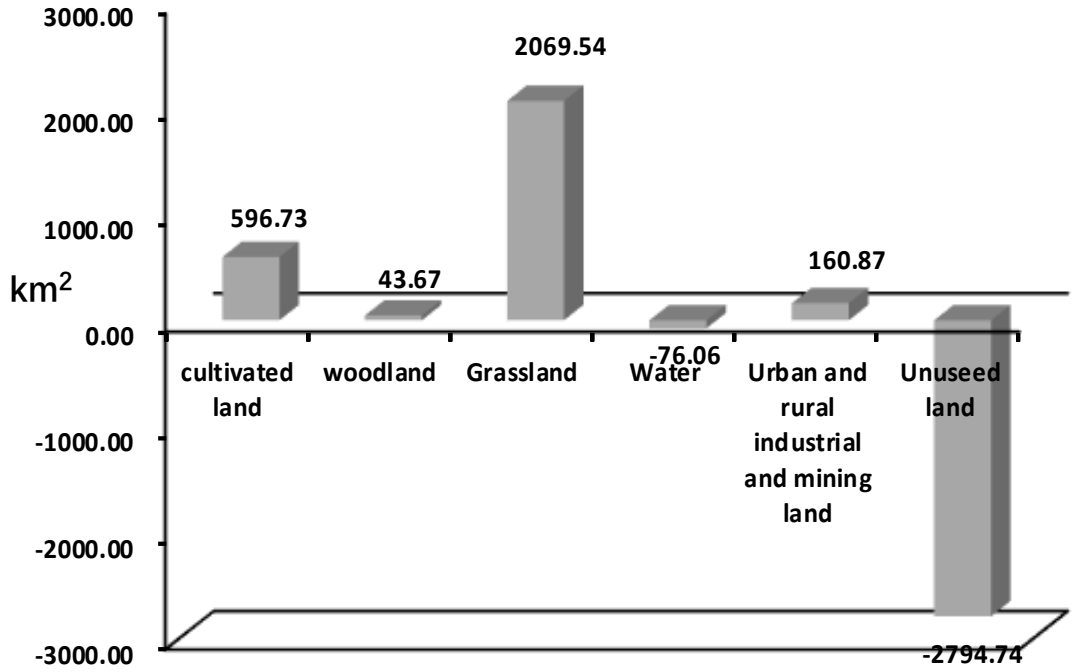

Figure 2. *Map of land use change in Shule River basin from 1995 to 2015*

Use *Equations 1* and *2*. Through the dynamic attitude analysis from 1995 to 2015, the dynamic degree of cultivated land, forest land, urban and rural industrial and mining land, water area, grassland and unused land were 0.03%, 0.0037%, 0.006%, -0.0046%, 0.0042% and -0.0014%, respectively. It can be seen that there are obvious differences in the speed and type of change in water area and unused land. The spatial distribution pattern of land-use types in Shule River from 1995 to 2015 is shown in *Figure 3*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32433250

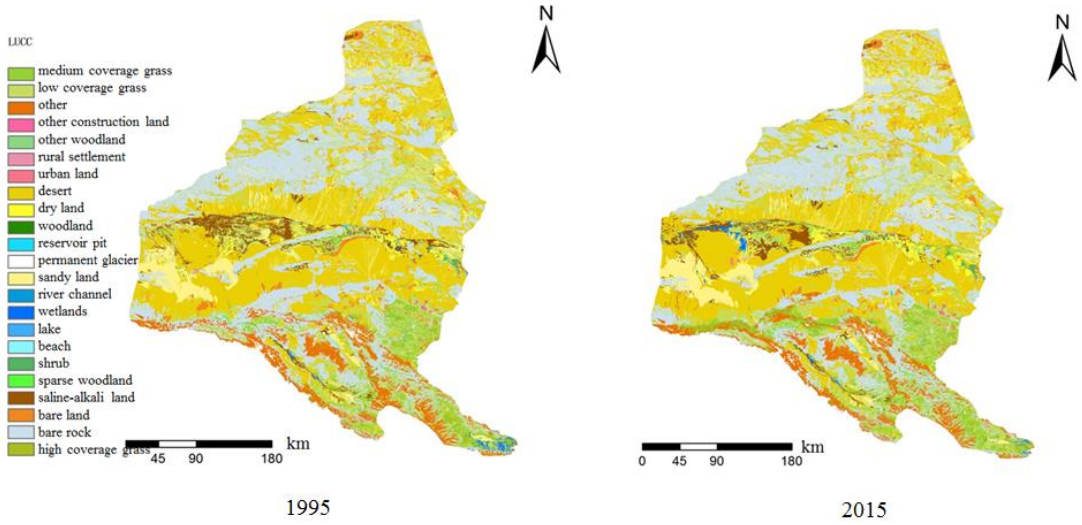

Figure 3. *Changes of land-use types in Shule River from 1995 to 2015*

From *Figure 3,* although the land use of the river basin has changed in the past 20 years, the main pattern has not changed. The north is mainly bare rock texture and Gobi; the middle and lower reaches are mainly dry land, grassland and Gobi; there are a lot of saline-alkali land and some grassland between Dunhuang city and Guazhou city, and there are a lot of sandy land in the south and southwest of Dunhuang city. There is bare land, a large area of grassland and permanent glacier snow fields in the upper reaches of the river basin.

Study on transformation of land-use types in river basin

In order to describe the conversion process of various land-use types from 1995 to 2015, the transfer matrix of land-use types in each period was calculated by using the function of ArcGIS spatial analysis (*Tables 2* and *3*), and the map of land use transfer matrix in each period was generated (Mishra et al., 2018; Andraschko et al., 2014; Dai et al., 2012).

Table 2. *Transfer matrix of land-use types in Shule River basin from 1995 to 2015 (km^2)*

1995 / 2015	Cultivated land	Woodland	Grassland	Water	Urban and rural	Unused land	Total
Cultivated land	859.70	40.44	332.52	2.47	20.69	402.70	1658.51
Woodland	9.68	445.80	76.57	0.92	0.81	93.16	626.94
Grassland	55.20	40.63	22188.93	17.55	1.87	4492.56	26796.75

Unused land	57.00	53.55	2075.50	180.54	3.34	91918.46	94288.39
Total	1061.63	583.14	24731.12	816.94	142.62	97082.03	124422.4

Table 3. *Transfer matrix of different land-use types from 1995 to 2015 (%)*

1995 / 2015	Cultivated land	Woodland	Grassland	Water	Urban and rural	Unused land

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32433250

Cultivated land	51.84	2.44	20.05	0.15	1.25	24.28
Woodland	1.54	71.11	12.21	0.15	0.13	14.86
Grassland	0.21	0.15	82.80	0.07	0.01	16.77
Water	0.95	0.12	4.77	82.79	0.06	11.31
Urban and rural	24.04	0.60	7.30	0.01	38.03	30.01
Unused land	0.06	0.06	2.20	0.19	0.00	97.49

The area of cultivated land showed an increasing trend as a whole. The cultivated land area was 1062 km^2 in 1995 and 1658 km^2 in 2015, which increased 597 km^2. Among them, the conversion amount is 798.81 km^2, accounting for 0.64% of the total land area, mainly converted to grassland and unused land. The amount of transfer is 201.94 km^2, and the main types of transfer are urban and rural areas, industrial and mining areas, residential land and unused land. The woodland area showed an increasing trend as a whole. The woodland area increased by 44 km^2 from 583 km^2 in 1995 to 627 km^2 in 2015, of which the transferred area reached 181.14 km^2, accounting for 0.15% of the total land area, and the main types of transfer were unused land and grassland. The amount of transfer was 137.34 km^2, and the main types of transfer were unused land and grassland. The grassland area is generally increasing. The grassland area increased by 20693 km^2 from 24741 km^2 in 1995 to 26811 km^2 in 2015, of which the transferred area reached 4607.82 km^2, accounting for 3.70% of the total land area, and the main types of transfer are unused land and cultivated land; the amount of transfer was 2542.19 km^2, and the main types of transfer were unused land and cultivated land. The water area showed a slight decreasing trend. The water area decreased 76 km^2 from 820 km^2 in 1995 to 743 km^2 in 2015, in which the transfer area reached 127.97 km^2, accounting for 0.10% of the total land area, the main types of transfer were unused land and grassland. The amount of transfer was 201.53 km^2, and the main types of transfer were unused land and grassland. The land use of urban and rural, industrial and mining, residents showed an increasing trend. The land area increased 161 km^2 from 304 km^2 in 1995 to 304 km^2 in 2015, of which the transfer area reached 188.08 km^2, accounting for 0.15% of the total land area, the main types of transfer were unused land and cultivated land; the amount of transfer was 27.19 km^2, and the main types of transfer were cultivated land and unused land. Unused land showed a decreasing trend, the unused land area decreased 2794 km^2 from 97128 km^2 in 1995 to 94333 km^2 in 2015, the transferred area reached 2369.93 km^2, accounting for 1.90% of the total land area. The amount of transfer was 5163.57 km^2, and the main types of transfer were grassland and cultivated land.

Conclusion and discussion

In order to solve the problem of ecological degradation of Shule River, the State Council approved The Comprehensive Plan for Rational Utilization of Water Resources and Ecological Protection in Dunhuang in June 2011. The plan studies and proposes the overall planning idea of “protecting water source in the south, establish oasis in the middle, resist sandstorm in the west, and dredge the Shule River in the north” and the overall planning layout of “coordination of internal and external adjustment, simultaneous protection in the west and dredge in the north, stability of water and oasis, and maintenance of economic and ecological balance”. The land use is the most direct manifestation pattern of the interaction between human activities and the natural

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32433250

environment. On the other hand, it can also reflect the regional ecological environment problems. In order to further protect the ecological environment of Shule river watershed, and to prevent ecological degradation, the research on the process and characteristics of land use change in Shule River watershed are developed.

The Landsat TM, ETM remote sensing image with spatial resolution of 30 m in watershed in summer and autumn is selected since in summer and autumn in 1995 and 2015. By using GIS spatial analysis technology, transfer matrix, land use dynamics and a variety of spatio-temporal statistical analysis methods, the transformation process and temporal and spatial pattern analysis of land-use types in river basins in recent 20 years were carried out: In the past 20 years, different degrees of changes have taken place in land use in Shule River basin:

(1) The area of cultivated land, woodland, grassland and urban and rural industrial and mining residents increased, among which grassland increased the most, with an annual increase rate of 0.33%. The area of cultivated land increased, with an annual growth rate of 0.0959%. The area of water area and unused land decreased, with an annual decline rate of 0.4490%. The decrease of water area was the smallest, with an annual decline rate of 0.0122%.

(2) Through the dynamic attitude analysis from 1995 to 2015, the dynamic degree of cultivated land, forest land, urban and rural industrial and mining land, water area, grassland and unused land were 0.03%, 0.0037%, 0.006%, -0.0046%, 0.0042% and -0.0014%, respectively. It can be seen that there are obvious differences in the speed and type of change in water area and unused land.

(3) Although the land use of the river basin has changed in the past 20 years, the main pattern has not changed. The north is mainly bare rock texture and Gobi; the middle and lower reaches are mainly dry land, grassland and Gobi; there are a lot of saline-alkali land and some grassland between Dunhuang city and Guazhou city, and there are a lot of sandy land in the south and southwest of Dunhuang city. There are is bare land, a large area of grassland and permanent glacier snow fields in the upper reaches of the river basin.

Abstract. Maize (*Zea mays* L) as an important crop in the world is strongly affected by climatic and teleconnection factors, it is therefore necessary to fully assess their impacts on maize yield. Given the complexity and non-stationarity of the maize yield fluctuations in China, the empirical mode decomposition (EMD) and cross-wavelet methods were adopted to explore the correlations between maize yield including its whole series and various frequency series decomposed by the EMD and climatic and teleconnection factors from both macroscopic and microscopic perspectives. Results indicated that: (1) from the macroscopic perspective, sunspots were the main influencing factor of maize yield; (2) from the microscopic perspective, mainly precipitation, temperature, El Niño-Southern Oscillation (ENSO), Atlantic Oscillation (AO), and Pacific Decadal Oscillation (PDO) impact the high-medium frequency components (i.e., the frequency domain is 1~4 years and 6~10 years) of the detrended maize yield sequence, whilst solar activities (i.e., sunspots) primarily influence its low-medium frequency components (i.e., the frequency domain is 8~14 years); (3) three complete influencing hierarchical frameworks of sunspots-teleconnection factors-climatic factors on the various frequency components of the detrended maize yield were constructed, which help develop a physical significance of maize yield prediction model The study provides new insights into crop yield forecasting, thereby laying a solid scientific basis for crop yield decisions.
Keywords: *EMD, the cross wavelet method, climate change, different perspectives*

Introduction

Climate change has been one of the most studied topics during the last decades due to its socioeconomic, environmental and biological implications (IPCC, 2014; Fang et al., 2019; Guo et al., 2020). In the coming decades, global climate change will affect all sectors of the global economy (Huang et al., 2020; Ren et al., 2020; Li et al., 2020). But most of the impacts will concentrate on the agricultural sector, inducing food insecurity, particularly in developing countries (Ringler, 2008; Nelson et al., 2009). Despite significant advances in technology and in crop yield potential, food production and food security remain highly dependent on weather and climate change, as solar radiation, temperature and precipitation are the main drivers of crop growth (Angstrom, 1924; Hunt et al., 1998; Rosenzweig et al., 2001). Climate is one of the major uncontrollable factors affecting crop yield and causing global yield stagnation among the ones (You et al., 2009; Godfray et al., 2010). Maize is the crop with the largest planting area and production in China. According to FAO, the planted area of maize in 2016 was 36.8 million ha, and production was 219.6 million tons (Planting Industry Management Department, 2018; Tian et al., 2019; He et al., 2019). Therefore, it is necessary to explore the impact of climate change on corn yield to ensure the security of China's grain yield.

DOI: http://dx.doi.org/10.15666/aeer/1802_32513275

Climate change is causing significant change in water supply and further threats to food production in various parts of the world (Hanjra et al., 2010; Knox et al., 2012; Smith et al., 2013; Zhao et al., 2013; Zhao et al., 2020a). As a result, food security problems caused by extreme climate events have sparked research and public interest in the analysis of climate change and agricultural production (Kummu et al., 2012). The increased rainfall recorded in the Pampas region led to yield increases of rainfed crops in the order of 38% for soybean, 18% maize, 13% wheat and 12% in sunflower (Zhang et al., 2008). The fluctuation of temperature has an adverse effect on food production (Magrin et al., 2005; Lobell et al., 2008; Battisti et al., 2009). ENSO condition has been related to agricultural yields in many parts of the world (Garnett et al., 1992; Cane et al., 1994; Hammer et al., 2001; Butler et al., 2013). Low maize yields in Zimbabwe were found to be a result of El Nino (Podestá et al., 2002; Butler et al., 2013). Similar negative effects caused by El Nino were also reported concerning lowland rice yields and total rice production during the wet season in the Philippines and Indonesia (Phillips et al., 1998; Lansigan et al., 2000). There was a significant negative correlation between the Atlantic oscillation (AO) index and maize and rice yield in northeast China (Naylor et al., 2001). Some complex impacts of the Pacific Decadal Oscillation (PDO) on dryland corn and wheat yields in the Missouri River Basin were found (Kim et al., 2005). Besides, solar radiation affects crop yield by affecting the process of crop growth (Angstrom et al., 1924; Hunt et al., 1998; Mehta et al., 2012), the change of crop yield is therefore affected to some extent by the intensity of solar activities (usually expressed by the number of sunspots). As mentioned above, long-term fluctuations in crop yield are closely related with climatic factors such as temperature and precipitation, teleconnection factors (i.e. ENSO, AO, PDO) (for the sake of brevity, climatic and teleconnection factors are collectively referred to as signals of climate variability) (Zhao et al., 2015a; Xu et al., 2018) and solar activities (i.e. sunspots). And, the above-mentioned research indicates that global climate change is slowly affecting the spatial pattern of global and regional food production and their yield levels, which plays an important role in investigating the food production changes and their possible causes under the context of global climate change. Nevertheless, these studies only considered the impact of a single factor on crop yield from a macroscopic perspective, neither comprehensively taking into account the combined effects of these factors on crop yield, nor exploring the differences of effects of the above-mentioned influencing factors on food production at different time scales including the macroscopic and microcosmic scales.

As previous studies mentioned that crop yield is affected by the signals of climate variability and solar activities. However, all of these factors possess different periodic signals. For instance, Plaut et al. (1995) reported the detection of 5.2, 7.7, 14.2 and 25.0 years periods in the 335 years the Central England Temperature by using the SSA technique. Chen et al. (2016) found that four significant cycles with alternation patterns of precipitation were detected mainly at the time scales of 3-5, 10-11, 20-23, and 31.2 years for each of the four subregions of Liaoning province. ENSO, first described in 1923 by Sir Gilbert Walker (Walker, 1923), is a coupled atmospheric-oceanic oscillation in the tropical Pacific with an average period of 2-7 years. Like ENSO, the PDO is dominated by oceanic temperature oscillations with a typical period of 20-30 years (Mantua et al., 1997; Zhang et al., 1997; Nigam et al., 1999; Stoner et al., 2009). The Arctic Oscillation is a mode of the climate variability with decadal-scale variability oscillation (Mokhov et al., 2013). Besides, average period of a sunspot number cycle is 11.2 years, actual periods have ranged from 7 to 14 years (Kane et al., 2008). In other words, the crop field under the influence of multiple signals of climate variability and solar activities must be provided with complex periodic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32513275

signals. Therefore, studying the impact of the signals of climate variability and solar activities on crop yield from a macroscopic scale can only reveal the response characteristics of crop yield change to the changing environment in part.

In order to increase our awareness of the impacts of climate change and develop adaptation projects, it is necessary to separate the effects of climate change from the effects of each climate variable on observed changes in crop yields (Bai et al., 2015). Now that crop yield is the result of a combination of factors. Under the influence of multiple factors, its fluctuations do not move in a fixed cycle, but include changes in various time scales (periods) and local fluctuations, which lead it to change in multiple levels of time scales and localizations in the time domain. Hence, if the signal of which cycle of grain yield is affected specifically by the above factors can be explained clearly (that is, the effects of signals of climate variability and solar activities on different frequencies of maize yield are studied from the microcosmic scale), which will provide a very favorable forecasting approach for crop yield prediction, helping policy makers to accurately control the future trend of crop yield, and contributing to the reasonable development of national food security. The empirical mode decomposition (EMD) method is used to linearize and smooth the nonlinear and non-stationary signals step by step (Huang et al., 1998, 2013; Zhao et al., 2017; Yu et al., 2018; Zhao et al., 2020b). The method can separate the fluctuations of different scales step by step, and produce a series of intrinsic mode functions (IMFs) containing local characteristic information at different time scales of the original signal, and the residue (R), which retains the data itself in the process of decomposition characteristic. Therefore, this study will employ the EMD method for wave decomposition analysis, with a purpose of exploring the multi-scale characteristics of China's maize yield fluctuations and their correlations with major influencing factors (including the signals of climate variability and solar activities), which provide a new insight into the impact of various influencing factors on maize yield fluctuations at multiple scales including the macroscopic and microcosmic scales. This work helps to physically reveal the impact of climate change on grain production variations, thereby being helpful for reliable grain production forecasting. Additionally, since overall trend in increasing food production mainly caused by human activities (e.g. technological advances, fertilization, irrigation, etc.) (Lu et al., 2017), the yield data employed in this study is detrended in order to focus on analyzing climate effect on crop yield.

The main objectives of this study therefore are: (1) to examine the changing periods of detrended maize yield and the IMFs of maize yield in China; (2) to explore the possible causes of detrended maize yield variation from the perspective of climate change including the signals of climate variability (i.e. precipitation, temperature, AO, ENSO, PDO) and solar activities (i.e. sunspots) at the macroscopic scale; (3) to investigate the related implications of the signals of climate variability and sunspots on maize yield decompositions at the microcosmic scale; (4) to construct a complete influencing hierarchical framework of sunspots-teleconnection factors (ENSO, AO, PDO)-climatic factors (precipitation and temperature) on the various frequency components of the detrended maize yield. The remainder of the paper is structured in four sections. Section 2 describes the study database and methods. Results and discussion are provided in Section 3 and Section 4, Section 5 presents the conclusions.

Data sources and methodology

Data sources

This study used annual, country-level yield data for corn during 1961-2016 from Food and Agriculture Organization of the United Nations (http://www.fao.org/fao-stat/en/#home). The meteorological data (included, precipitation, temperature) from the China meteorological data network (http://data.cma.cn/). The ENSO indices were derived from the National Oceanic and Atmospheric Administration (NOAA) Earth System Research Laboratory (www.esrl.noaa.go -v/psd/data/correlation/amon.us.data) and www.esrl.noaa.gov/psd/data/correlation/nina34.data), the AO index was derived from the NOAA National Climatic Data Center (www.ncdc.noaa.gov/tele -connections/ao/), and the PDO index was derived from the Tokyo Climate Center (ds.data.jma.go.jp/tcc/tcc/p-roducts/elnino/decadal/annpdo.txt).

Methods

The Empirical Mode Decomposition

Empirical Mode Decomposition (EMD) is an adaptive method for separating the spectrum of nonlinear and non-stationary signals (Wu et al., 2007). It decomposes a given time series, or signal, in components with different frequencies and amplitudes, known as Intrinsic Mode Functions (IMFs). IMFs have two attributes that differentiate them from other signals:

- The number of extreme and zero crossings must differ at most by one.
- The mean value between the upper and lower envelope is zero.

The original time series $X(t)$ can be written as *Eq.1*.

$$X(t) = \sum_{i=1}^{m} IMF_i(t) + r(t) \quad \text{(Eq.1)}$$

where m is the number of IMFs.

The Stopping Criterion for the extraction of each IMF consists of verifying whether or not the component h can be defined as an IMF, as well as optional criterion such as the component maintaining its characteristics after S additional number of siftings (S-number) and a maximum number of siftings. The sifting process runs iteratively, extracting IMFs from the signal until the residue becomes a monotonic function, a constant value or a function with only one extremum from which no more IMFs can be extracted (Zhao et al., 2017).

The cross wavelet analysis

The cross wavelet analysis developed by Hudgins et al. (1993) is a new technique in exploring the associations between two associated time series. It combines wavelet transform with cross-spectrum analysis to ideally reflect the variation characteristics and coupled oscillations of the two time series in the time and frequency fields. (Hudgins et al., 1993; Torrence et al., 1998).

The cross wavelet transform of two time series x_n and y_n is expressed as $W^{XY}=W^X W^{Y*}$ where * denotes their complex conjugation. The cross wavelet power can be expressed as $|W^{XY}|$. The complex argument arg(W^{XY}) can be regarded as the local relative phase

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32513275

between x_n and y_n in time-frequency field. The theoretical distribution of the cross wavelet power of these two series with their background power spectra P_K^X and P_K^Y is expressed as follows (Hudgins et al., 1993):

$$D\left(\frac{W_n^X(S)W_n^{Y*}}{\sigma_x\sigma_y} < p\right) = \frac{Z_\nu(P)}{\nu}\sqrt{P_K^X P_K^Y} \quad \text{(Eq.2)}$$

where $Z_\nu(P)$ is the confidence level associated with the probability P for a probability distribution function defined by the square root of two χ^2 distributions (Grinsted et al., 2004). The relevant codes can be freely downloaded from the website http://www.pol.ac.uk/home/rese-arch/waveletcoherence/.

Corn production shows fluctuating changes in time. The signals of climate variability can explain this variability to a certain extent (Talaee et al., 2014; Huang et al., 2016; Dai et al., 2020). Besides, photosynthesis must be conducted during the growth and development of maize. Therefore, solar activities are expected to have a certain impact on corn yield. Hence, the linkages between maize yield and the signals of climate variability/solar activities at both of the macroscopic and microcosmic scales were explored to fully reveal the impacts of these factors on corn yield in the China mainland, which has the largest population in the world. This work helps to physically reveal the impact of climate change and solar activities on the change in grain production China, thereby being helpful for its reliable maize yield prediction.

Results

Analysis of the changing periods of detrended maize yield and the IMFs of maize yield in China

Analysis of the changing periods of detrended maize yield in China

Lu et al. (2017) found that the all trends of yield of various crops are increasing, mainly caused by technological advances. The trends should be removed before other basic applications are implemented, such as computing the correlation function (Wu et al., 2007). The definition of the residual component in EMD method is almost identical to the definition of the trend when the data span in the trend covers the whole data length (Wu et al., 2007). Based on that, the study gets detrended maize yield data by eliminating the residual of original maize yield data. The continuous wavelet transform (CWT) is used to identify the period of the detrended maize yield data. The results are shown in *Fig. 1*. Detrended maize yield has a primary period of approximately 18 years, a secondary period of probably 12 years, a third period of roughly 6 years of corn yield and a fourth period of summarily 3 years. It is obviously seen that maize yield fluctuates at different frequencies in time domain (changing from low and medium frequencies to high frequency).

Analysis of the changing periods of the IMFs of maize yield in China

In this paper, the EMD method was used to decompose the detrended maize yield data. The results were shown in *Fig. 2*. It can be seen form *Fig. 2* that, 1961-2016, detrended maize yield time series in China was decomposed into 4 IMFs and 1 trend item R. Among them, 1) IMF1 reflects a fluctuation of 2~6 years, and the oscillations are more uniform

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32513275

throughout the scale period fluctuations. The peaks and valleys of the adjacent years appear one after another, indicating that the short-period maize yield fluctuations are more common, and the maize yield increase and decrease periodicity caused by the scale fluctuations is obvious; 2) IMF2 behaves a fluctuation of 6~11 years. The oscillation frequency is slower and the amplitude is relatively stable and small, as well as the fluctuation is relatively flat, which indicates that the maize yield fluctuation intensity of this scale is lighter; 3) there is a 12~19 years fluctuation displayed in IMF3. The period of the oscillation is relatively long and the amplitude is larger than IMF1 and IMF2, indicating that the fluctuation of maize yield at this scale does not occur often, but the intensity is relatively large; 4) it can be seen that IMF4 has a 27 years fluctuation with the long period, large amplitude and intensity indicating that fluctuations in maize yield at this scale rarely occur; 5) for the residual, Maize yield shows an upward trend at 1961-1990, and a downward trend at 1991-2016.

Analysis of the effects of the signals of climate variability and solar activities on detrended maize yield at the macroscopic scale

As we all know, long-term fluctuations in corn yield are closely related with climatic factors. In this paper, the cross-wavelet analysis was used to analyze the correlations between influencing factors including precipitation, temperature, sunspots, AO, ENSO as well as PDO and detrended maize yield (*Fig. 3*).

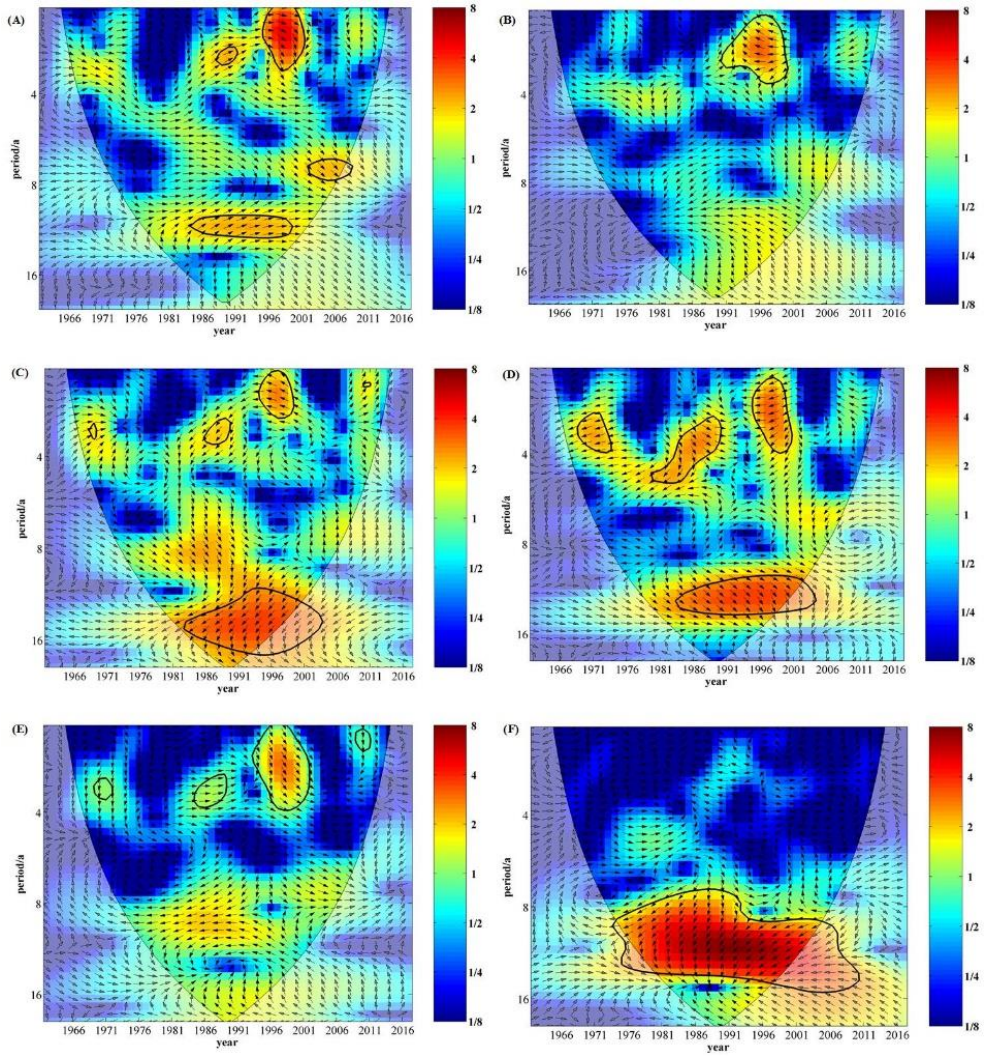

Figure 3. *The cross wavelet transforms of signals of climate variability (included precipitation (A), temperature (B), AO (C), ENSO (D), PDO (E)) and solar activities (sunspots (F)) and detrended maize yield, respectively*

To reveal the relationship between precipitation and detrended maize yield data in the Chinese mainland, the cross-wavelet analysis was performed and the results were shown in *Fig. 3A*. *Fig. 3A* displays that there are statistically positive correlations between precipitation and detrended maize yield with a 1-3 year signal in 1995-2001, a 2.5 year signal in 1987-1992, a 11~13 year signal in 1984~2000 and a 7.5 year signal in 2002~2008 at the 95% confidence level. There are some differences in the *Fig. 3B*. It exhibits the cross wavelet transforms between temperature and detrended maize yield. Temperature has relatively

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32513275

significant negative linkages with detrended maize yield at the 95% confidence level with a 1-3.5 year signal in 1990-2000. These directly demonstrate that precipitation and temperature play an important role in corn yield and have the opposite relationship with corn yield. The results were basically consistent with Zhao et al. (2015b). They found that precipitation and temperature had significant opposite effects on the climate-induced yield of maize from the macroscopic perspective.

AO has comparatively significant positive correlations with detrended maize yield with a 3 year signal in 1967-1970 and a 1.5 year signal in 2009-2011 (*Fig. 3C*). It also shows negative correlations with detrended maize yield with a 3-3.5 year signal in 1985-1990 and a 1-2.5 year signal in 1994-2000. Similarly, ENSO (Nino3.4) has relatively significant negative linkages with detrended maize yield at the 95% confidence level with a 3-4 year signal in 1967-1972 and a 1.5-4 year signal in 1995-2001, and it has significant positive correlations with detrended maize yield with a 3-5 year signal in 1980-1990 and a 11~14 year signal in 1982-2004 (*Fig. 3D*). In addition, *Fig. 3E* exhibits that PDO has a significant positive correlation with detrended maize yield at the 95% confidence level with a 1-4 year signal in 1992-2002. It also has a comparatively positive correlation with detrended data at the 95% confidence level with a 3.5 year signal in 1984-1990. It can be observed from *Fig. 3F* that sunspots show a statistically significant negative correlation with detrended maize yield at the 95% confidence level with a 7.5-15 year signal in 1973-2011. In addition, some relevant papers (Kim et al., 2005; Butler et al., 2013; Zhao et al., 2015b) reported that the linkages between maize yield and the signals of climate variability (AO, PDO and ENSO) and solar activities at macroscopic scale, which further verifies the reliability of our findings in this study.

Based on *Fig. 3A~Fig. 3F*, it was evident that the signals of climate variability (i.e., precipitation, temperature, ENSO (Nino3.4), AO, PDO) and solar activities (sunspots) had statistically correlations with detrended maize yield. These demonstrate that the short and long-medium periods of maize yield in China are subject to the interaction of above-mentioned factors. It is worth noting that sunspots had the most significant effects on corn yield, and their impacts were concentrated on low frequency regions of maize yield at the macroscopic scale. In contrast, the high-frequency fluctuations were mainly caused by the signals of climate variability at the macroscopic scale. According to influence intensity, this paper found that sunspots had the strongest influence on maize yield, followed by ENSO and AO, followed by precipitation, followed by PDO, and temperature had the weakest influence on maize yield found in *Fig. 3*.

Analysis of the effects of the signals of climate variability and solar activities on decomposition of detrended maize yield at the microcosmic scale

Section 3.2 shows that maize yield is the result of a combination of factors. Based on the above analysis, the application of the empirical mode decomposition (EMD) method in this manuscript to decompose maize yield data. Detrended maize yield data was decomposed into 4 intrinsic mode functions (IMF) and a residual component. The cross-wavelet analysis was employed to explore the correlations between the four IMFs and signals of climate variability, which is contributed to a deeper understanding of the impact of the signals of climate variability on maize yield at the microcosmic scale. Similarly, the cross-wavelet analysis was used to analyze the impact of solar activities on the decomposition of detrended maize yield. The results are displayed in *Fig. 4~Fig. 9.*

As seen from *Fig. 4A* that there was a statistically positive correlation between precipitation and the IMF1 of corn yield with a 3 year signal in 1987-1992, a 1-3.5 year signal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32513275

in 1995-2001 and a 8 year signal in 2000-2010 at the 95% confidence level. There were some differences in *Fig. 4B* compared with *Fig. 4A*. In the figure, it shows that the cross wavelet transforms between precipitation and the IMF2. Precipitation had statistically significant positive linkages with the IMF2 at the 95% confidence level with a 4-13 year signal in 1970-2011. In addition, *Fig. 4C* displays that precipitation had a comparatively significant positive correlation with the IMF3 at the 95% confidence level with a 12 year signal in 1977-2002. *Fig. 4D* and *Fig. 4E* indicated that the correlations between precipitation and IMF4/residue were not significant. These results demonstrated that precipitation mainly impacted the medium-high frequency regions of maize yield and had a certain influence on the low frequency regions.

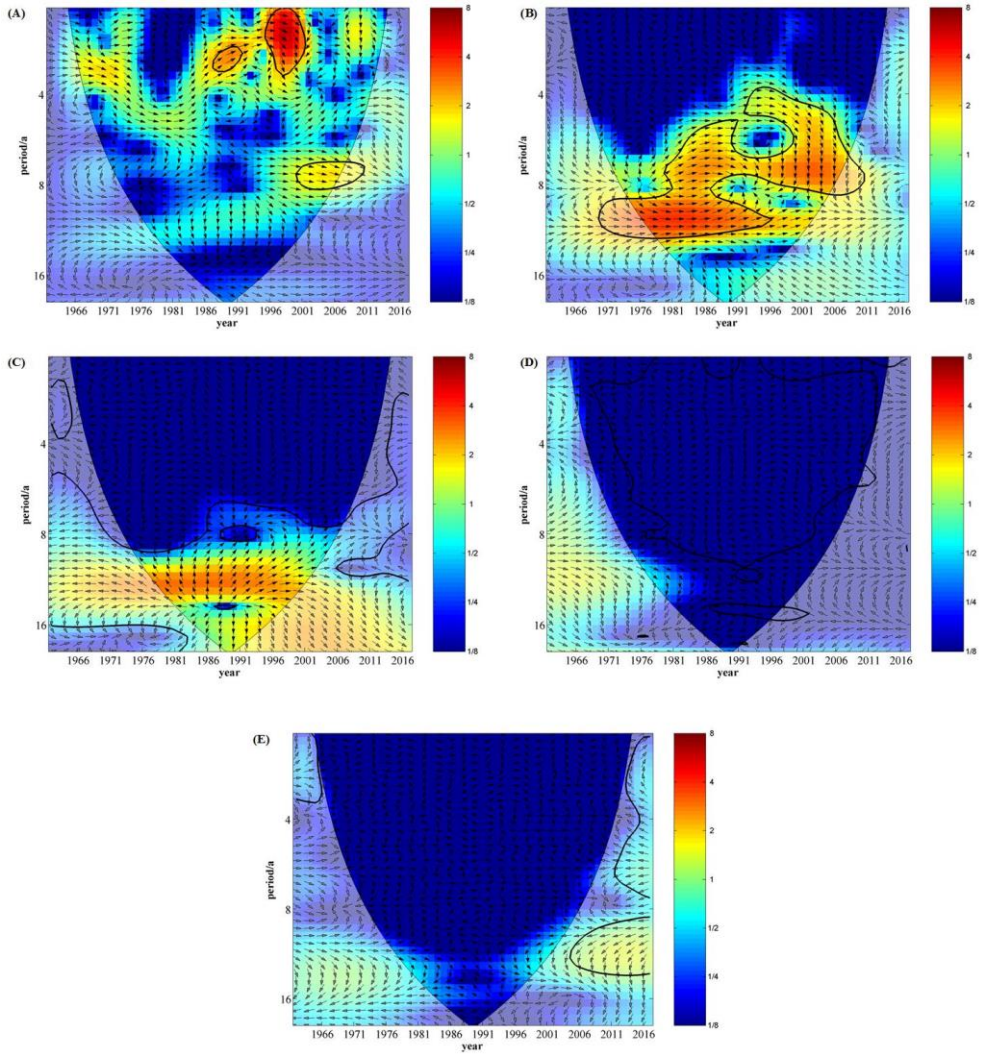

Figure 4. *The cross wavelet transforms of precipitation and IMF1~4 and residue of maize yield (A~E), respectively*

It can be observed from *Fig. 5A* that temperature showed a statistically significant negative correlation with IMF1 at the 95% confidence level with a 1.5-3.5 year signal in 1990–2001. There was a positive correlation between precipitation and the IMF1 of corn yield a 4 year signal in 1975-1982 at the 95% confidence level. There are some differences in *Fig. 5B*. It reveals that temperature has relatively significant positive

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32513275

linkages with the IMF2 at the 95% confidence level with a 4 year signal in 1992-1997 and a 6~7.5 year signal in 2000-2006. In addition, *Fig. 5C* displays that temperature has a comparatively significant positive correlation with the IMF3 at the 95% confidence level with a 13~15 year signal in 1976-2016. *Fig. 5D* and *Fig. 5E* have weaker correlations between temperature and IMF4/residue. In a word, temperature concentrated influence on medium and high frequency of corn yield.

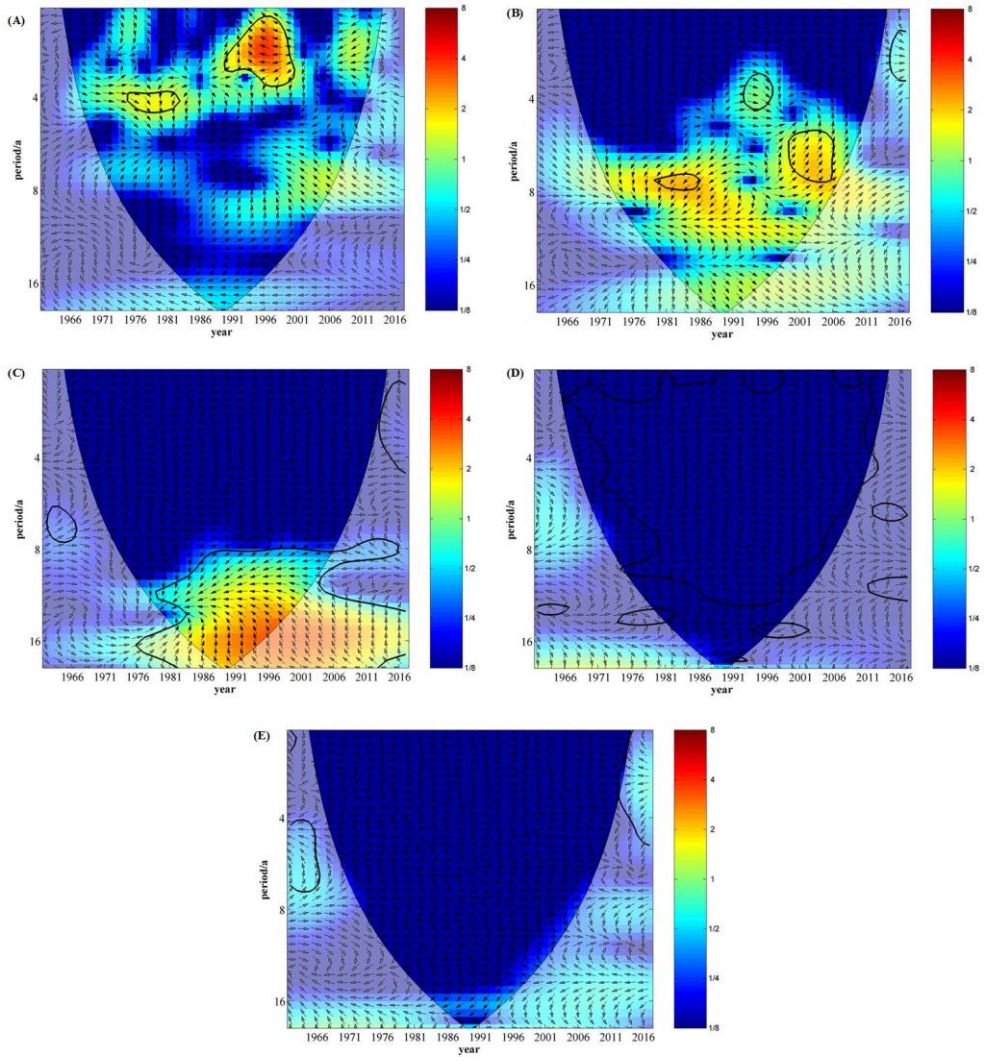

Figure 5. *The cross wavelet transforms of temperature and IMF1~4 and residual of maize yield (A~E), respectively*

Fig. 6A displays that there is a statistically positive correlation between AO and IMF1 of corn yield in the Chinese mainland with a 3-4 year signal in 1967-1972 and it has a significant negative linkages with IMF1with a 3-4 year signal in 1983-1991 and a 2 year signal in 1994-1999 at the 95% confidence level. There are some differences in the *Fig. 6B*. It exhibits the cross wavelet transforms between AO and IMF2 of corn yield. AO has significant positive linkages with IMF2 at the 95% confidence level with a 4-10 year signal in 1972-2000 and a significant negative correlation with IMF2 with a 5 year signal (*Fig. 6B*). It can be observed from *Fig. 6C* that there is a statistically negative correlation between AO and IMF3 of corn yield with a 9-17 year signal in 1961-2016. No significant relationship between AO and IMF4

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32513275

and residual term was found in the *Fig. 6D* and *6E*. We can see that AO primarily affects medium and low frequency of maize yield.

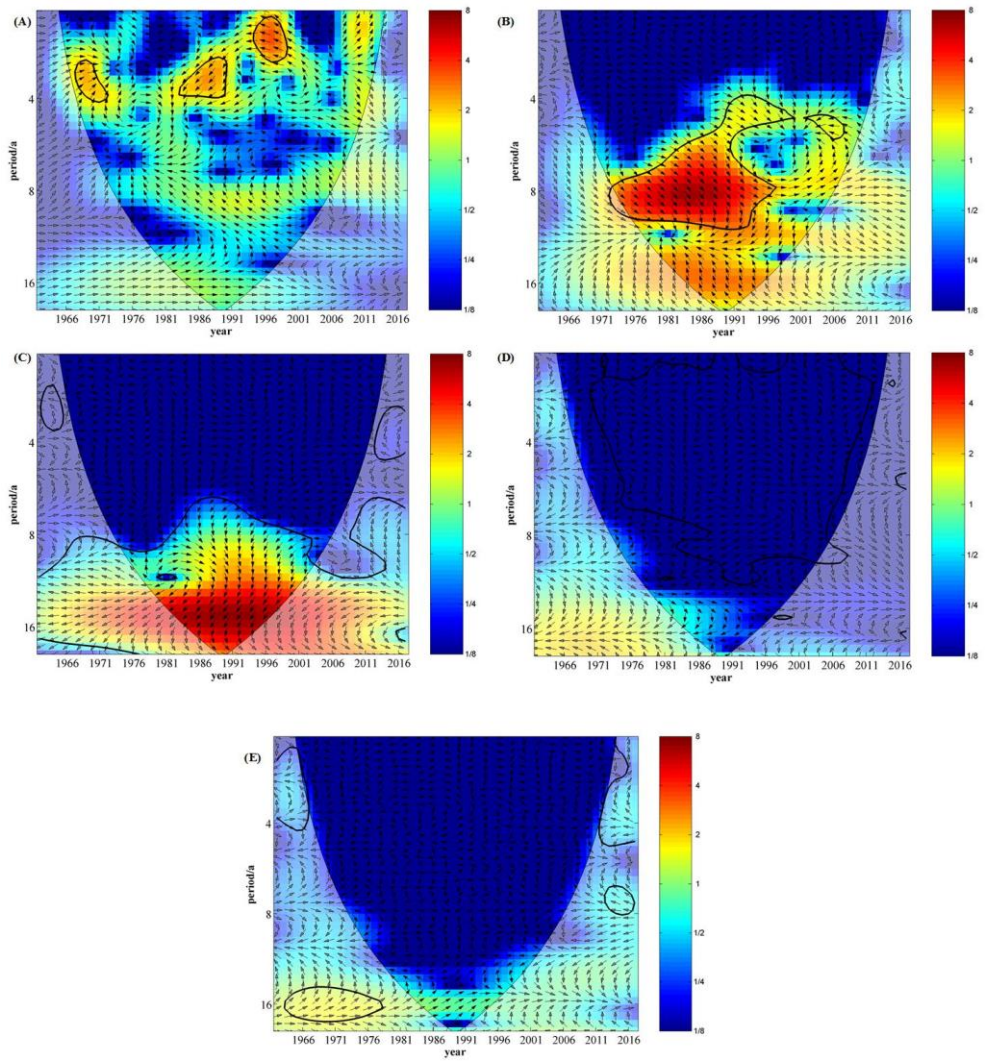

Figure 6. *The cross wavelet transforms of AO and IMF1~4 and residue of maize yield (A~E), respectively*

Similarly, the cross wavelet analysis was applied to reveal the correlations between ENSO (Nino3.4) and the IMFs of maize yield. There are the results shown in *Fig. 7* ENSO has a statistically positive correlation with IMF1 of corn yield with a 3-5 year signal in 1968-1991 and a 1.5-4 year signal in 1994-2001 (*Fig. 7A*). It also shows a significant correlation between ENSO and IMF2 with a 4-7 year in 1982-2007 and a significant positive linkage with IMF2 with a 14 year signal in 1977-2015 (*Fig. 7B*). Besides, *Fig. 7C* exhibits a comparatively significant positive correlation with IMF3 at the 95% confidence level with a 14 year signal in 1976-2016. There are weaker correlations between ENSO and IMF4 and residue seeing from *Fig. 7D* and *7E*. Above all, it is obviously seen that ENSO mainly impact on medium-high frequency of maize yield.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32513275

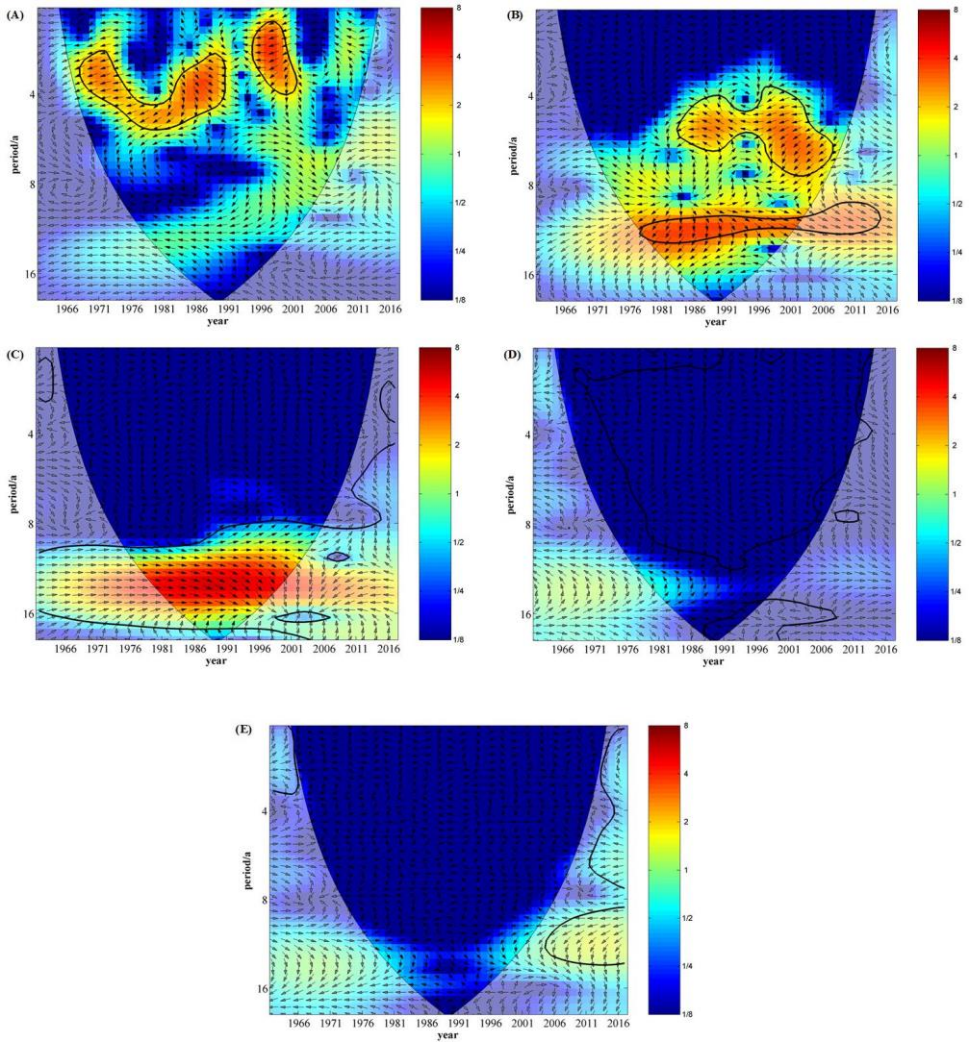

Figure 7. *The cross wavelet transforms of ENSO (Nino3.4) and IMF1~4 and residue of maize yield (A~E), respectively*

In addition, PDO has statistically significant positive linkages with IMF1 of corn yield at the 95% confidence level with a 1-4 year signal in 1992-2002 and a 3-4 year signal in 1982-1990 (*Fig. 8A*). It also shows that a comparatively significant correlation between PDO and IMF1 with a 3-4 year signal in 1967-1972. *Fig. 8B* exhibits PDO has a statistically significant linkage with IMF2 with a 6-9 year signal in 1972-2007. It can be seen from *Fig. 8C* that PDO has a relatively significant linkage with IMF3 with a 8~16 year signal in 1976-2016. Based on *Fig. 8*, we can see that PDO mainly influence medium frequency of maize yield.

In addition to analyzing the correlations between signals of climate variability and maize yield components, the cross-wavelet transform was used to explore the linkage the IMFs and solar activities (sunspots). The results are displayed in *Fig. 9*. It can be seen from *Fig. 9A* that sunspots have a relatively significant positive linkage with IMF1 of corn yield at the 95% confidence level with a 4-5 year signal in 1976-1982 and a statistically significant negative linkage with IMF1 with a 8-14 year signal in 1977-2005. *Fig. 9B* exhibits a statistically significant correlation between sunspots and IMF2 with a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32513275

5-14 year signal in 1966-2016. Sunspots have a comparatively significant linkage with IMF3 with a 8-16 year signal in 1967-2016 (*Fig. 9C*). Interesting, sunspots mainly influence on medium and low frequency of maize yield components.

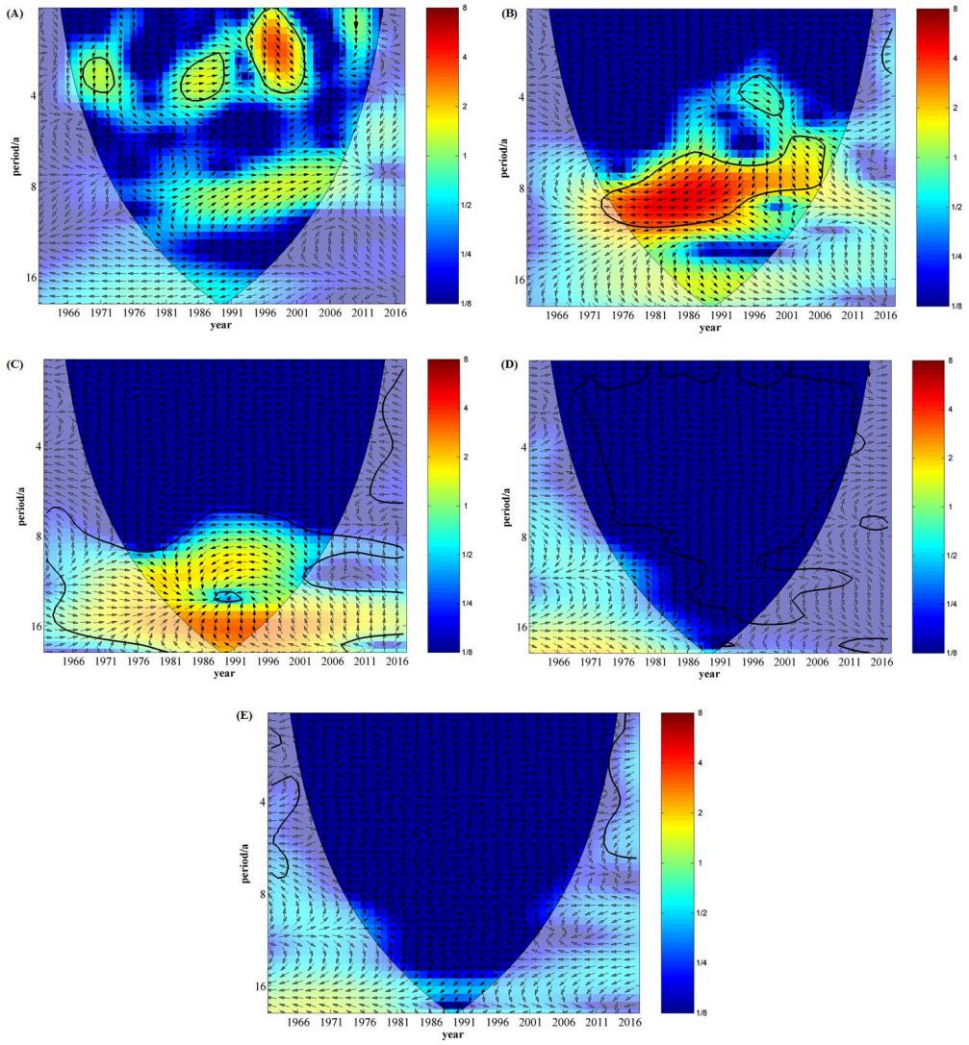

Figure 8. *The cross wavelet transforms of PDO and IMF1~4 and residue of maize yield (A~E), respectively*

Based on *Fig. 4* and *Fig. 9*, it was evident that PDO mainly affect the first and second components of detrended maize yield, and the second and third components of detrended maize yield were mainly impacted by sunspots and AO, whilst the first three components of detrended maize yield were influenced by ENSO and precipitation, moreover, the effect of temperature on detrended maize yield was relatively weak, and mainly affect the first and third component of detrended maize yield. These results indicated that the yield components of corn were not only affected by a single factor, but the result under the combined action of multiple factors, and the influence factors of different components were not the same. As far as was known, there were a number of papers (Plaut et al., 1995; Stonter et al., 2009; Mokhov et al., 2013; Zhao et al., 2015b; Chen et al., 2016) had proved that the signals of climate variability (i.e. precipitation, temperature, ENSO (Nino3.4), AO, PDO) and solar activities

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32513275

(sunspots) dominated by different periodic signals, which further verified the rationality and accuracy of the above findings.

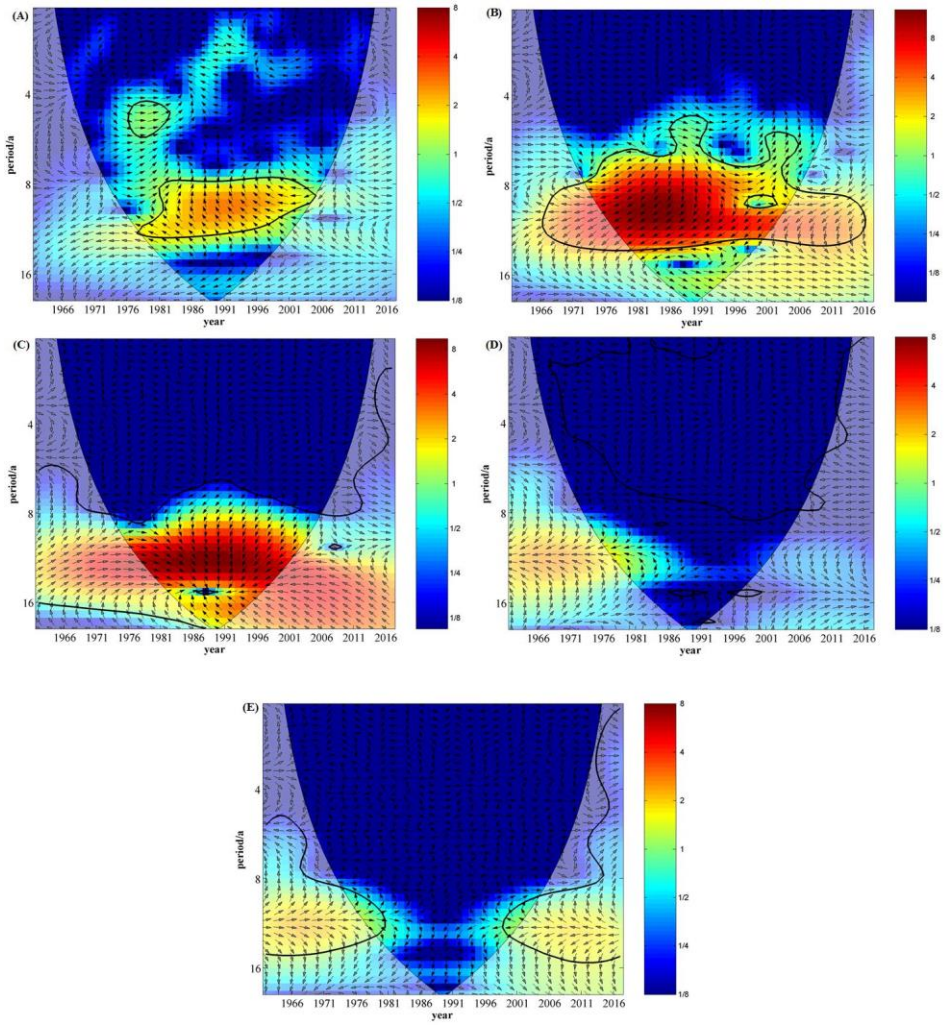

Figure 9. *The cross wavelet transforms of sunspots and IMF1~4 and residue of maize yield (A~E), respectively*

The complete influencing hierarchical framework

More and more studies indicate that teleconnection factors (e.g. ENSO, AO, PDO) and sunspots have major impact on global atmospheric circulation and regional climatic anomalies (Kenyon et al., 2008; Schubert et al., 2008; Alexander et al., 2009; Dikpati et al., 2010; Owens et al., 2011; Meehl et al., 2013). According to the analysis results in section 3.3, different impacting hierarchical frameworks were constructed for IMF1~3.

It can be seen from *Fig. 4A*, *Fig. 5A*, *Fig. 7A* and *Fig. 8A* that there were statistically positive correlations between precipitation, PDO and the IMF1 of detrended maize yield in 1980-2000, and ENSO had a significant positive linkage with IMF1 of detrended maize yield in 1983-1990. In contrast, temperature and ENSO showed statistically significant negative correlations with IMF1 in 1991-2001. These suggested that precipitation, PDO, ENSO and temperature had significant different effects on the growth of maize, and also suggested that the effect of ENSO on maize yield was different in different years. The effects of aforementioned factors on IMF1

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32513275

were extremely complicated and each factor had mutually reinforcing or weakening influence on maize yield. In view of the aforementioned results, the hierarchical framework of ENSO, PDO-climate variability (precipitation, temperature)-the IMF1 of detrended maize yield may be constructed. In other words, there was a chain effect, which was ENSO and PDO definitely showing impact to precipitation/temperature in some degree and in some land areas, and consequently the climate variability in such variables being certainly associated with detrended maize yield.

Compared the correlations in *Fig. 4B*, *Fig. 6B*, *Fig. 7B*, *Fig. 8B* and *Fig. 9B*, it can be found that precipitation and teleconnection factors had effect on IMF2 of detrended maize yield in the time domain of sunspots influencing IMF2. Therefore, the framework of sunspots-teleconnection factors (ENSO, AO and PDO)-precipitation-the IMF2 of detrended maize yield linkage may be constructed. In other words, there was a chain effect, which was sunspots definitely showing impact to teleconnection factors in some degree, and subsequently, the teleconnection factors exhibiting impact to precipitation in some degree and in some land areas, and consequently precipitation in such variables being certainly associated with detrended maize yield.

Combine the information of these figures (including *Fig. 4C*, *Fig. 5C*, *Fig. 6C*, *Fig. 7C* and *Fig. 8C*) to know that the framework of sunspots-teleconnection factors (ENSO, AO)-climatic variability (precipitation, temperature)-the IMF3 of detrended maize yield linkage may be constructed.

Based on that, the cross wavelet method was used to explore the correlation between sunspots and AO, ENSO as well as PDO (*Fig. 10*) in this study. *Fig. 10* showed that sunspots had significant linkages with AO, ENSO and PDO at the 95% confidence level with an 8~14 year signal in 1966-2001. The findings suggested that sunspots had significant effect on three teleconnection factors, and these also confirmed the first step of the chain effect (for IMF2 and IMF3).

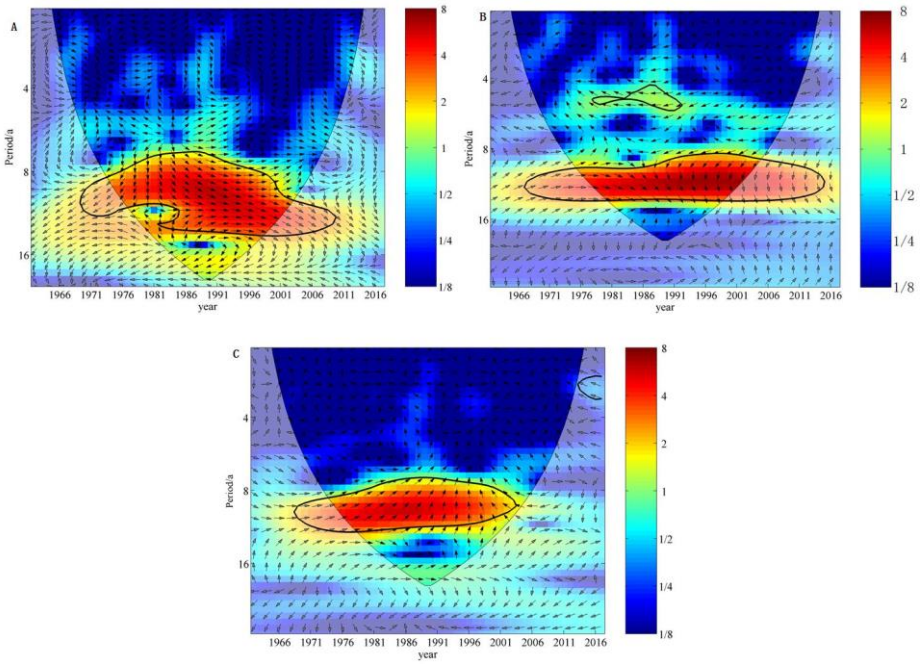

Figure 10. *The cross wavelet transforms of sunspots and AO (A), ENSO (B) and PDO (C), respectively*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32513275

Both precipitation and temperature were decomposed by means of EMD decomposition in this paper, since they are also affected by various factors. Similar to the *Fig. 10*, the cross-wavelet method was utilized in the study, to explore the relationship between AO, ENSO, PDO and the components of precipitation and temperature (as shown in *Fig. 11* and *Fig. 12*). *Fig. 11* displayed that AO and ENSO were significantly correlated with the IMF2 and IMF3 of precipitation, and that there was a significant correlation between PDO and the IMF2 of precipitation. These results indicated that AO, ENSO and PDO had an important influence on precipitation. By contrast, the effects of AO and ENSO on precipitation were significantly stronger than that of PDO on precipitation. *Fig. 12* exhibited that there were significant linkages between AO, ENSO, PDO and the IMF1 and IMF2 of temperature. In comparison, AO and ENSO had a stronger effect on temperature than PDO. In a word, AO, ENSO and PDO had a certain influence on precipitation and temperature. And more, the findings confirmed the first step (for IMF1) and the second step (for IMF2 and IMF3) of the chain effect. As AO, ENSO and PDO had no significant influence on the IMF4 and residual term of precipitation and temperature, the correlations between them are explored in this paper. Three complete influencing hierarchical frameworks were shown in *Fig. 13*.

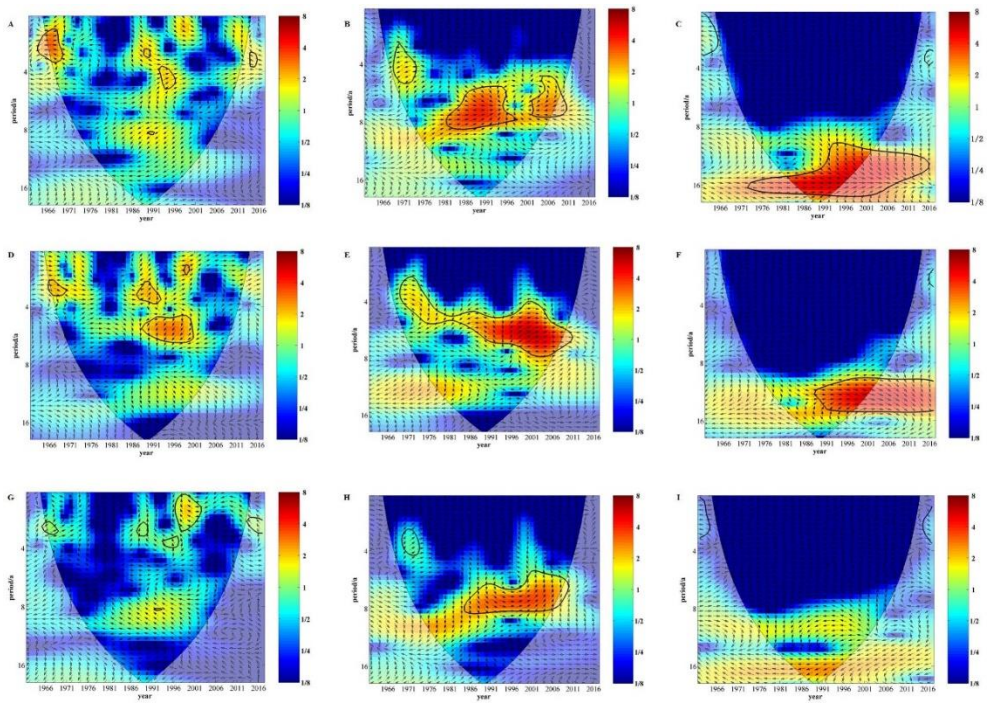

Figure 11. *The cross wavelet transforms of AO and the IMF1 (A), IMF2 (B) and IMF3 (C) of precipitation, ENSO and the IMF1 (D), IMF2 (E) and IMF3 (F) of precipitation as well as PDO and the IMF1 (G), IMF2 (H) and IMF3 (I) of precipitation, respectively*

Besides the above findings, we can also see from the figure that the signals of climate variability and solar activities have no significant influence on the IMF4 and residual terms of corn yield. This is mainly because the maize yield sequence was detrended in this paper, which made the low-frequency signals in the maize yield sequence be removed, so that the climatic factors had no obvious influence on the detrended maize yield sequence after decomposition.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32513275

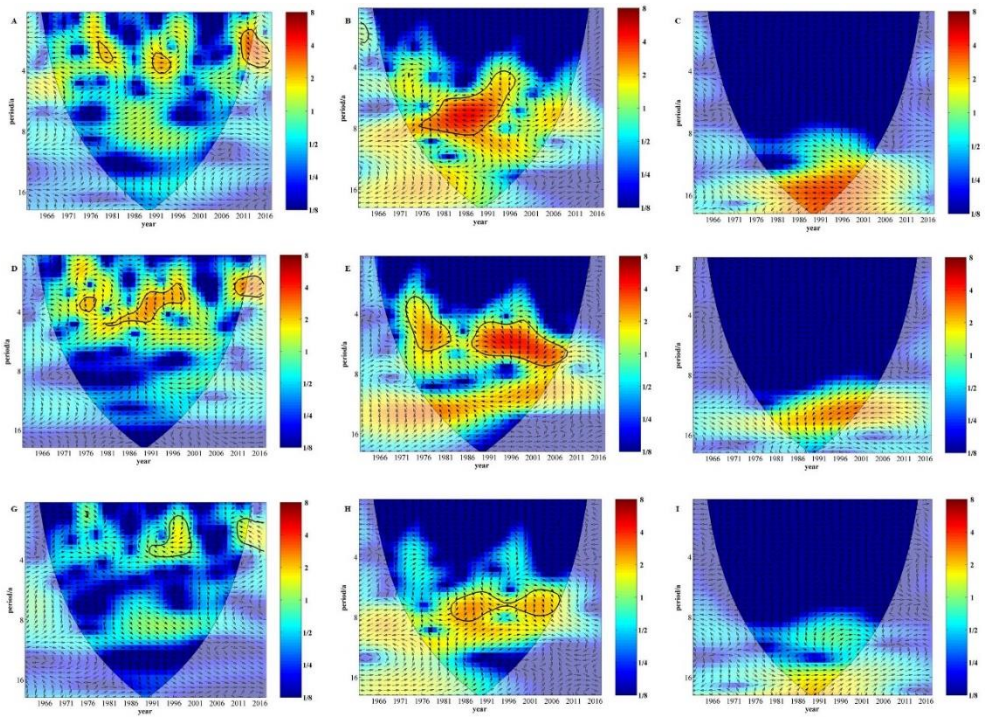

Figure 12. *The cross wavelet transforms of AO and the IMF1 (A), IMF2 (B) and IMF3 (C) of temperature, ENSO and the IMF1 (D), IMF2 (E) and IMF3 (F) of temperature as well as PDO and the IMF1 (G), IMF2 (H) and IMF3 (I) of precipitation, respectively*

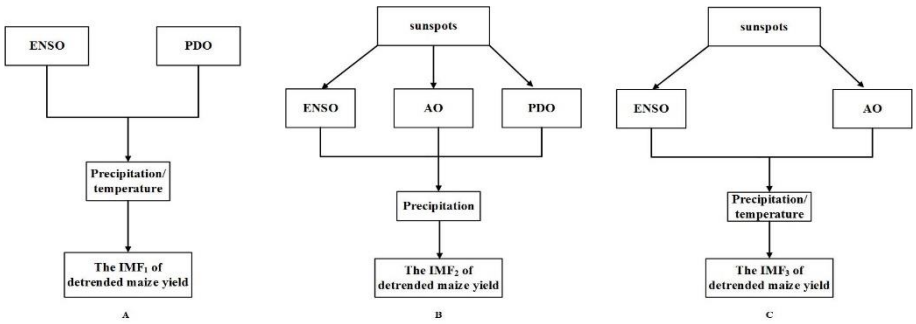

Figure 13. *Three complete influencing hierarchical frameworks for IMF1 (A), IMF2 (B) and IMF3 (C)*

Above all, three frameworks were constructed. These also showed that the effects of signals of climate variability and solar activities on the IMFs of corn yield can not only verify the accuracy of the effects of these factors on maize yield after detrending, but also demonstrate each single component of the IMFs was synthetically affected by the above factors. Based on these findings, this study can provide a new idea for the grain prediction model, that is, the above factors can be used to predict the different components of corn (i.e. ENSO, PDO, precipitation and temperature could be used to predict the IMF1 of maize yield; sunspots, ENSO, AO, PDO and precipitation could be used to predict the IMF2 of maize yield; and sunspots, ENSO, AO, precipitation and temperature could be used to predict the IMF3 of maize yield), and then the predicted results can be combined with relevant means to improve the prediction accuracy of grain yield to a certain extent.

Discussion

The necessity of the signals of climate variability and solar activities affect the changes in detrended maize yield at microcosmic scale

Compared to the effects of precipitation on detrended maize yield and the IMFs of detrended maize yield (*Fig. 3A* and *Fig. 4*), it can be discovered that there were statistically positive correlations between precipitation and detrended maize yield with a 1-3 year signal in 1995-2001, a 2.5 year signal in 1987-1992 and a 7.5 year signal in 2002-2008 at the 95% confidence level (*Fig. 3A*), which was basically consistent with the effect of precipitation on detrended maize yield (*Fig. 4A*). Besides, the interesting findings in *Fig. 4B*, *Fig. 4C* and *Fig. 3A* were that a 11~13 year signal of significance in 1984-2000 (shown in *Fig. 3A*) was included in the time-frequency domains beyond significance of *Fig. 4B* and *Fig. 4C*. These findings suggested that precipitation had a significant positive effect on detrended maize yield and mainly affected the fluctuation of detrended maize field in the short and long-medium terms in macroscopic scale, which was fully verified on the microscopic scale (shown in *Fig. 4A~4C*). Notably, in *Fig. 3A*, the regions with high energy in the low and medium frequency regions but not exceeding the significance test all exceeded the significance test in *Fig. 4B* and *Fig. 4C*. On the one hand, the findings showed that the correlations of precipitation and the IMF1~3 of detrended maize yield were obviously superior to the relationship between precipitation and undecomposed detrended maize yield, suggesting that the microscopic scale to a certain extent, can isolate the influence of other factors; On the other hand, the feature that cannot be expressed on the macroscopic scale was observed on the microscopic scale, which indicated from the side that the yield of maize was subject to the influence of various factors. Similarly, temperature also influenced high frequency of detrended maize yield found from *Fig. 3B* and *Fig. 5A*, which was expressed in the time domain in 1990-2001. In contrast, there was a significant negative correlation between temperature and detrended maize yield (compared to *Fig. 3A* and *Fig. 3B*). In addition, the discoveries of temperature and detrended maize yield on macroscopic and microscopic scales were basically consistent with that of precipitation and detrended maize yield. In other words, the analyses of the correlations between temperature and the IMF1~3 of detrended maize yield in microscopic scale were the verification and supplement of the relationship between temperature and detrended maize yield.

It can be seen from *Fig. 3C~3E* and *Fig. 5~8* that the correlations between AO (ENSO, PDO) and detrended maize yield were roughly similar with the relationship between AO (ENSO, PDO) and the IMF1, which demonstrated that AO (ENSO, PDO) had strong effects on the high frequency of detrended maize yield. It was worth noting that sunspots influenced medium frequency of detrended maize yield (a period of 8~12 years in the frequency domain) exhibited in *Fig. 3F* and *Fig. 9A*, which was different with the effect of the signals of climate variability on detrended maize yield. As we all know, sunspots have an average period of 11 years, which was basically consistent with the frequency domain of sunspots impacting on detrended maize yield. Similar to the comparison of the correlations between precipitation or temperature and detrended maize yield in macroscopic and microscopic scales, the relationship between AO (ENSO, PDO and sunspots) and detrended maize yield had this feature, as well.

Based on the above analyses we all know that the signals of climate variability (including precipitation, temperature, AO, ENSO, PDO) made a difference to high frequency of detrended maize yield. It indicated that the short-term cycle changes of corn

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32513275

yield were mainly caused by meteorological factors (which is consistent with the results of Zhao et al. (2013) and Niu et al. (2018)), whilst mid-cycle changes in corn yield were mainly influenced by solar activities. The correlations between the above factors and the components of detrended maize yield proved the correctness of the above conclusion. For this reason, the above factors can be considered as input variables of corn production prediction model to improve the accuracy of the prediction when predicting the future corn production in China. In addition, this study found that not only the cross wavelet analysis between each influence factor and each component of detrended maize yield sequence can verify the relationship between the factors and detrended maize yield on the macroscopic factors and enhance the analysis accuracy, also found at the macroscopic scale some relevant information cannot be accurately captured on the microscopic scale to get the corresponding added. These findings indicate that correlation analysis from the microscopic scale can help reduce information distortion and ensure the accuracy of correlation analysis.

Potential application of the hierarchical frameworks

Past studies indicated that there were strong relations between solar activities and teleconnection factors (i.e. ENSO, PDO and NAO) (Kapala et al., 1998; Tudhope et al., 2001; Georgieva et al., 2012; Hassan et al., 2016; Maruyama et al., 2017; Liu et al., 2018; Han et al., 2019). Moreover, these teleconnection factors reflect on local weather conditions (precipitation and temperature) (Leathers et al., 1991; Thompson et al., 1998; Higgins et al., 2002; Huang et al., 2017 ; Zhao et al., 2019). In addition, climate variability, especially precipitation and temperature, have been shown to have important effects on crop yields in major crop growing regions in China (Tao, 2012; Wang et al., 2014; Zhang et al., 2015). The research content of the above literature fully shows that the three influencing hierarchical frameworks established in this paper are reasonable. Therefore, it is entirely possible to construct similar influencing hierarchical frameworks for other crops in other areas, such as rice in China, which can provide very reliable basis for food prediction model and reduce the error of food prediction.

Conclusions

In this study, we examined the effects of the signals of climate variability (i.e., precipitation, temperature, AO, ENSO, PDO) and solar activities (i.e., sunspots) on maize yield in China mainland during the period 1961-2016 at both of the macroscopic and microcosmic scales. First, we got rid of the trend of maize yield data sequence, and the periodical features of the detrended sequence was explored by means of CWT analysis. The detrended maize yield had a primary period of approximately 18 years, a secondary period of probably 12 years, a third period of roughly 6 years of corn yield and a fourth period of summarily 3 years. Then the effects of signals of climate variability and solar activities on detrended maize yield and the IMFs of original maize yield were investigated by cross-wavelet transforms. Findings showed that (1) sunspots had the strongest influence on maize yield, followed by ENSO and AO, followed by precipitation, followed by PDO, and temperature had the weakest influence on maize yield at macroscopic scale; (2) the signals of climate variability mainly impact the high-medium frequency (i.e., frequency domain is 1~4 years and 6~10 years) of maize yield and solar activities primarily influence medium frequency (i.e., frequency domain is 8~14 years) for detrended sequence; (3) PDO mainly affect the first and second components of detrended

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32513275

maize yield, and the second and third components of detrended maize yield were mainly impacted by sunspots and AO, whilst the first three components of detrended maize yield were influenced by ENSO and precipitation, moreover, the effect of temperature on detrended maize yield was relatively weak, and mainly affect the first and third component of detrended maize yield; (4) the hierarchical framework of ENSO, PDO-climate variability (precipitation, temperature)-detrended maize yield was constructed for IMF1; the hierarchical framework of sunspots-teleconnection factors (ENSO, AO and PDO)-precipitation-detrended maize yield was constructed for IMF2; the hierarchical framework of sunspots-remote correlation factors (ENSO, AO)-climate variability (precipitation, temperature)-detrended maize yield was constructed for IMF3. The results of the present study could contribute to improve the crop prediction (considering signals of climate variability and solar activities as the potential influence factors both on whole and decomposition of the maize yield sequence) and hence would provide possibilities for ensuring food security. This study explored the impact of climate change on maize yield on multi-temporal scales. Therefore, when predicting maize yield based on climatic conditions, it is possible to consider the prediction of grain component resynthesis from a multi-temporal perspective, which may improve the prediction accuracy of maize yield.

Abstract. The long-term mean air temperature has increased with continued greenhouse-gas emissions in the past decades in the Wei River Basin (WRB) (China), with little understanding of the changes in extreme temperatures. In this study, the change characteristics of both maximum (Tmax) and minimum (Tmin) temperatures at daily, monthly, and annual scales were fully examined, and their relations with the Arctic Oscillation (AO) were also explored. The modified Mann-Kendall trend test method (MMK) and heuristic segmentation method were employed to detect the trends and change points of the Tmax and Tmin at multiple scales, respectively. Subsequently, the cross wavelet transform was adopted to reveal the correlations between Tmax/Tmin and AO. Results indicated: (1) both monthly and annual Tmax and Tmin showed significantly increasing trends, whilst at daily scale they generally exhibited no obvious trends; (2) change points were found in monthly, seasonal, and annual Tmax and Tmin, implying that the stationarity of Tmax and Tmin series in the WRB has been ineffective; (3) AO had strong impacts on Tmax and Tmin changes in the WRB. Our results highlight the asymmetric response of Tmax and Tmin at the monthly, seasonal, and annual scales, which has great implications for ecosystem functions and agricultural production.
Keywords: *temperature extremes, Arctic Oscillation, the heuristic segmentation method, the cross wavelet transform, the Wei River Basin*

Introduction

The Fifth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC, 2007) has stated that global average temperature has risen by nearly 0.85°C (IPCC, 2013) within the 1880-2012 period. Regionally, China has warmed by 0.45±0.05°C during 1860-2005 (CMA, 2006). Accompanying increased surface air temperature are the enhanced evaporation demand (Leng et al., 2015a), accelerated global hydrologic cycle (Menzel et al., 2002; Wang et al., 2013; Huang et al., 2016, 2017; Han et al., 2019; Fang et al., 2019a), and the increase of extreme events (WMO, 2003; Guo et al., 2013, 2019a,b; Leng et al., 2015b,c; Zhao et al., 2019a; Dai et al., 2020; Guo et al., 2020). Compared to the variations of mean conditions, variations of extremes can exert more adverse influences on both the natural environment and human society (Easterling et al., 2000a; Patz et al., 2005; Kapsomenakis et al., 2013; Zhao et al., 2019) and have attracted much attention during the last decades (Beniston et al., 2004; Lehner

DOI: http://dx.doi.org/10.15666/aeer/1802_32773295

et al., 2006; Piao et al., 2010; Sheffield et al., 2012; Fang et al., 2019b; Zhao et al., 2019b; Ren et al., 2020).

Although many researchers have investigated the spatial and temporal changes in temperature extremes (Kunkel et al., 1999; Easterling et al., 2000b; Nasrallah et al., 2004; Fuhrer et al., 2006), the changing characteristics of temperature extremes vary regionally, showing obvious changes in some areas and no striking trends in other areas (Bonsal et al., 2001).

As for a time series, change point is a vital change characteristic. The statistical characteristics of a specific time series before a change point differ significantly from those after the change point. If a change point is found, it indicates the time series is not stationary and is characterized by a noticeable variation. Change point is a time when the temporal pattern of a time series changes significantly. Detection of change points in hydrological series is highly important not only for understanding the location and timing when there is a change in the factors driving the complex system, but also helps us make inference about the issue of non-stationarity (Li et al., 2020; Zhao et al., 2020a, b). Indeed, if the issue of non-stationarity in a hydrological time sequence exists, the conventional hydrological frequency analysis assuming the stationarity of time sequence would be useless in practice (Milly et al., 2008; Vogel et al., 2011; Gilroy et al., 2012). Many previous studies concerning temperature extremes focused on their trend variations, few of them paid attention to their change point detection. In view of the importance of identifying change points for a specific time series, the investigation on identifying change points in maximum (Tmax) and minimum (Tmin) temperatures series was conducted in this study.

Furthermore, majority of previous studies on temperature extremes paid attention to the spatial and temporal variations of Tmax and Tmin series, rare studies explained detected changes. Indeed, understanding of the cause of Tmax and Tmin series changes is extremely important, which helps better understand climate change. Therefore, this study attempts to reveal the possible relations between temperature extremes and the Arctic Oscillation (AO). AO is an important pattern of climate change in the Northern Hemisphere and has been shown to exert strong influences on the climate change in the middle and high latitude areas (Toreti et al., 2010; Wang et al., 2013). The meteorological and hydrological processes may show various characteristics at different spatial scales (Tudesquea et al., 2014). In order to fully reveal the scale effect on the correlations between temperature extremes and AO, the response of temperature extremes to AO at different spatial scales was also explored in this study.

Here, the Wei River Basin (WRB) is chosen as a case study. The WRB is located in a typical climatic zone (monsoon region) (Huang et al., 2014a). Tmax and Tmin series have been reported to exert strong adverse influences on both agricultural production and runoff variations. Investigation of the spatio-temporal changes in temperature extremes in the WRB can help to understand and effectively guide local water resources management in a changing climate. We focus on the temperature extremes at multiple time scales, i.e. daily, monthly, and annual Tmax and Tmin series. The major objectives of this study are: (1) to reveal the spatial and temporal variations of Tmax/Tmin; (2) to detect the change points in Tmax/Tmin series at different timescales in the WRB; (3) to analyze the possible relations between Tmax/Tmin and the AO series at different spatial scales.

Materials and Methods

Introduction of the WRB

The WRB was selected as the study area in this study. It was partitioned into eight sub-basins based on the secondary basin boundary in China, and their zone ID are 26, 28, 29, 31, 33, 36, 40, and 41, respectively (*Figure 1*). Situated in a continental monsoon climate-impacted zone, the region is characterized by rich precipitation and high temperature in summer, and dominated by rare precipitation and low temperature in winter. Its annual precipitation is nearly 559 mm (Zhang et al., 2008; Liu et al., 2018a). The precipitation in the WRB varies obviously at seasonal scale, with flood season (from June to September) precipitation accounting for roughly 60% of the annual average (Huang et al., 2020).

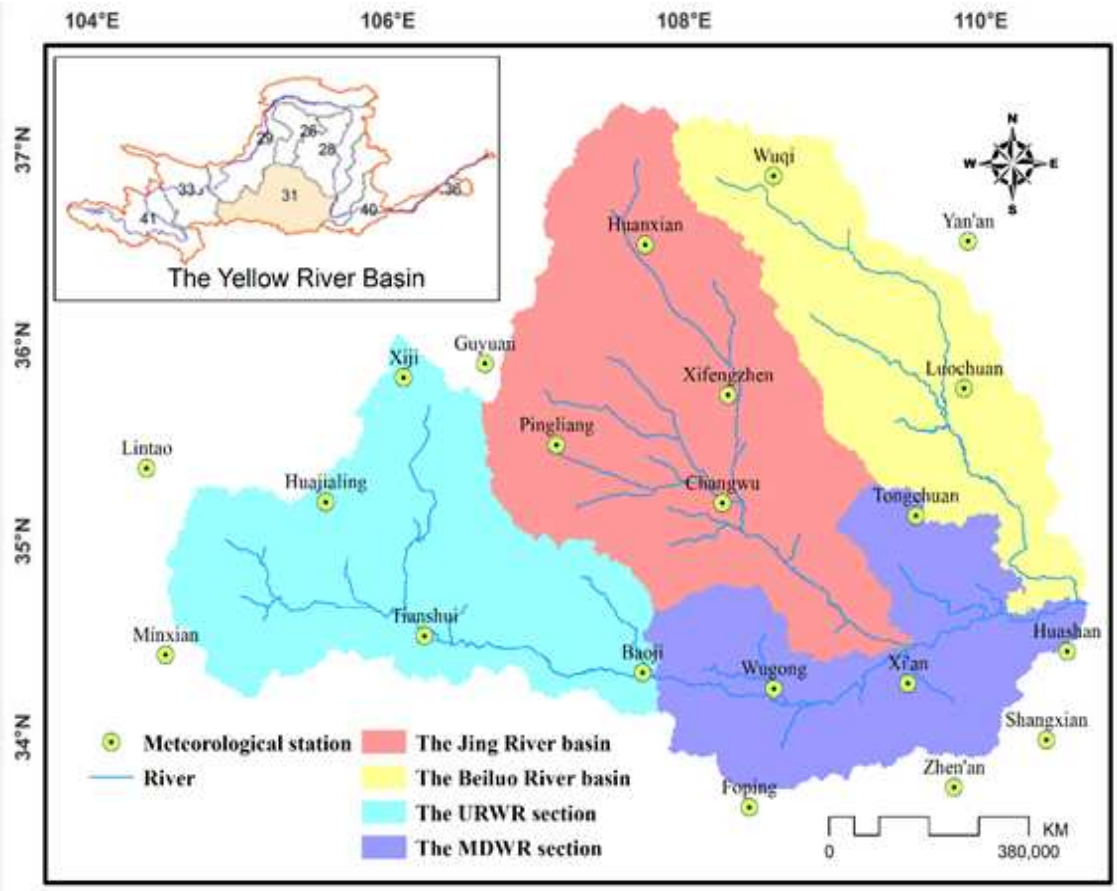

Figure 1. *Location of the WRB and related meteorological stations in the Yellow River Basin, China*

In order to explore the changing characteristics of temperature extremes and their correlation with AO at various spatial scales, the WRB was divided into four sub-basins primarily based on the distribution characteristic of its river system. The four sub-basins are the upper reaches of the Wei River (URWR) section, the middle and downstream of the Wei River (MDWR) section, the Jing River basin, and the Beiluo River basin (*Figure 1*).

Data

Daily minimum and maximum air temperature are collected from 21 meteorological stations located in the WRB (*Figure 1*). The dataset is obtained from the National Climate Center (NCC) of the China Meteorological Administration (CMA), and are homogenized before their release. Note that monthly Tmax/Tmin was determined by the largest/lowest daily data in a month, and annual Tmax/Tmin was determined by the largest/lowest monthly data in a year. The sub-basin Tmax and Tmin are determined from point Tmax and Tmin based via calculating the arithmetic mean value of point Tmax and Tmin. The detailed information of these stations is summarized in *Table 1*. Each station has daily maximum and minimum temperature records spanning January 1st, 1958-December 31st, 2008. These data have been successfully applied in our previous studies (Huang et al., 2014b, c) in investigating drought evolution characteristics in the WRB. Additionally, the monthly AO series within 1958-2008 was obtained from the National Oceanic and Atmospheric Administration (NOAA).

Methodology

The modified Mann-Kendall trend test method

Given initial Mann-Kendall (MK) trend test method is easily influenced by the persistence of hydro-meteorological series, Hamed and Rao (1998) proposed a modified MK (MMK) trend test method to remove the persistence through taking into account the lag-i autocorrelation. Daufresne et al. (2009) found that the MMK is more robust than MK in terms of examining the trends of hydro-meteorological series. Given the weakness of the MK mentioned above, the MMK trend test method was employed to in this study to calculate the change trends of Tmax/Tmin in the WRB. The detailed computation processes can be referred to Huang et al. (2014a, b).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32773295

The heuristic segmentation method

Generally, traditional statistical test methods such as the sliding T test, rank sum test, sliding F test, and Mann-Kendell test are frequently adopted to detect change points, assuming the time series of interest is linear and stationary. Nevertheless, extreme temperature time series is extremely nonlinear owing to the high variability caused by many factors. Hence, it is difficult for them to obtain the real change points accurately. To this end, the heuristic segmentation method which was proposed by Pedro et al. (2001) was adopted to capture the change points in temperature extremes series in this study. The method is based on the sliding T test and further modified, which can be applied to identify the change points in highly nonlinear and nonstationary time series. The detailed calculation processes can be referred to Huang et al. (2017) and Liu et al. (2019).

The cross wavelet transform

The cross wavelet transform proposed by Hudgins et al. (1993) is a new technique in revealing the correlation between two-time series of interest. It is featured with combining the cross spectrum analysis with wavelet transform, and can reveal the changing features and the coupled oscillations of two-time series of interest in both time and frequency domains (Hudgins et al., 1996; Torrence et al., 1998). Hence, it was applied in this study to examine the correlation between Tmax/Tmin in the WRB and AO. The detailed calculation processes can be referred to Huang et al. (2018).

Results

Spatial and temporal changes in Tmax and Tmin

In order to vividly present the spatial change characteristics of Tmax and Tmin in the WRB, the stations adopted in this study were ranked according to the magnitude of their longitudes. Additionally, the MMK statistics of Tmax and Tmin in each month during 1958-2008 in the WRB were calculated, which were plotted in *Figure 2* and *Figure 3*, respectively, with x axis of station number ranked according to the magnitude of their longitudes and y axis of the MMK statistics of Tmax and Tmin in each month. A positive value of MMK statistics represents an increasing trend of Tmax/Tmin series, especially for the value is larger than 1.96, indicating a statistically significant increasing trend at the 95% confidence level. Otherwise, the detection trend is no obvious, and vice versa. Hence, the spatial and temporal changes in Tmax and Tmin at the monthly scale can be displayed in *Figure 2* and *Figure 3*, respectively.

Spatially, in the western and middle basin (*Figure 2*), increase of monthly Tmax is found for almost all months, especially for station 9 where significantly increasing trend is detected in February, April, June, and July. Changes in Tmax in the eastern basin is a little complex with decreasing trends in summer (June, July, and August) and increasing trends in Spring (February, march, April). The change pattern is especially evident for station 17, in which Tmax decreased significantly in June, but increased significantly in January, February, March, October, November, and December. Generally, changes in Tmax at the monthly scale exhibited a noticeable spatial difference. Temporally, the MMK of Tmax series is dominated by positive values in February, April and summer (June, July, and August), indicating a statistically increasing trend. Particularly, February and April show significant increasing trend. In contrast, the Tmax series for January, March, May, November, and December generally have decreasing trends.

DOI: http://dx.doi.org/10.15666/aeer/1802_32773295

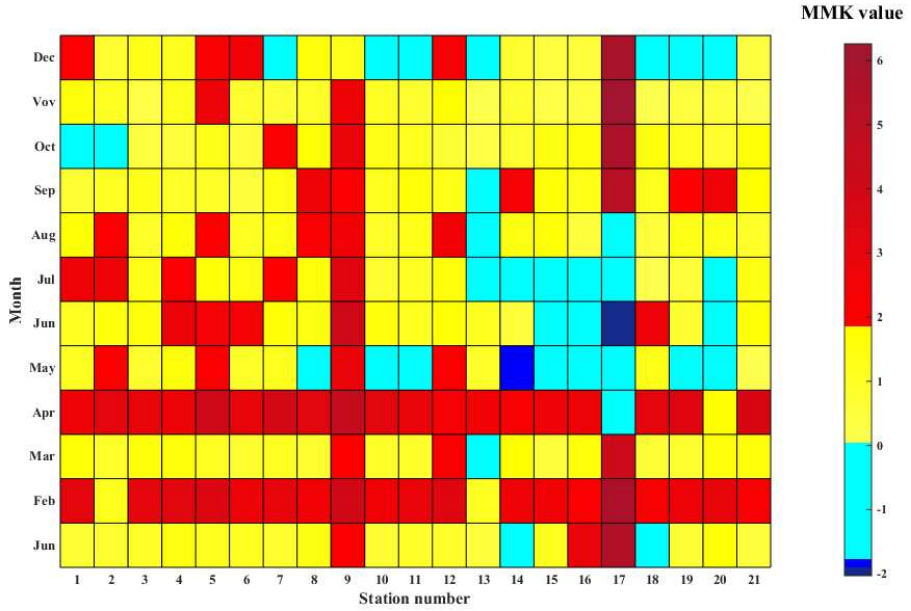

Figure 2. *The change trends of monthly maximum temperature in the WRB (Red, dark blue, yellow and sky blue represent significant increasing, significant decreasing, no obvious increasing and no obvious decreasing trends, respectively)*

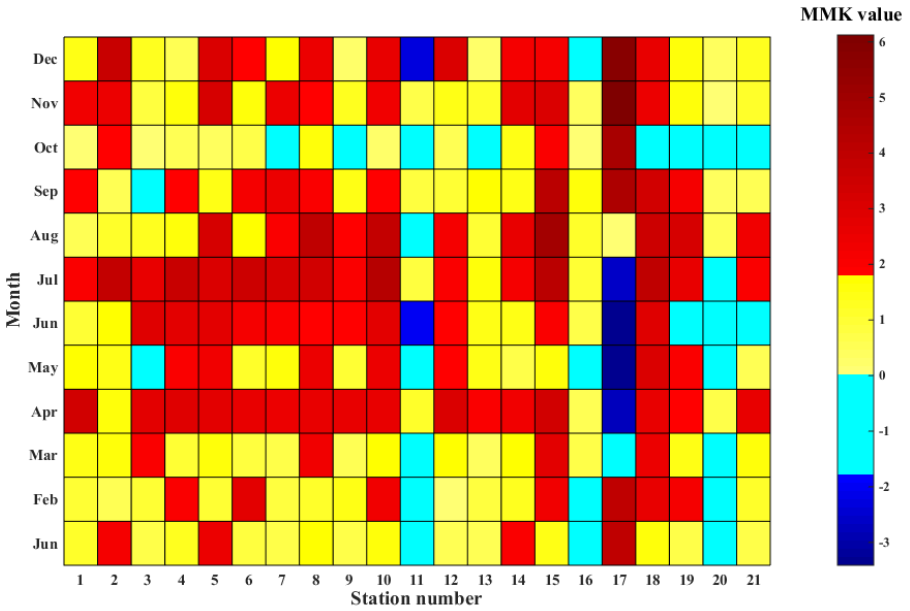

Figure 3. *The change trends of monthly minimum temperature in the WRB*

As for the changes in Tmin (*Figure 3*), spatially, being similar to the changes in Tmax, the western and middle basin is mainly characterized by increasing Tmin in almost all months except for station 11 experiencing decrease in January, February, March, May, June, October and December. In general, the eastern basin is characterized by increasing Tmin except for stations 17 and 20. Note that the Tmax and Tmin at station 17 have a significantly increasing trend at the 99% confidence level in autumn and winter and a significantly decreasing trend

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32773295

at the 99% confidence level in summer. The cause may be related to its location near to the edge of monsoon region compared with other meteorological stations, its temperature extremes therefore are easily impacted by the changing global climate (Huang et al., 2014c). The underlying causes of the strange behavior of station 17 need to be further investigated in the future study. Temporally, a statistical increase is detected in almost all months in most of the basin. In particular, April, June and July are dominated by significant increasing trends. In contrast, only October showed no obvious decreasing trends.

Overall, the spatial and temporal change patterns of Tmin are similar to that of Tmax. The MMK statistic of the diurnal temperature range in the whole basin is 0.16, which exhibits no obvious trend. The normalized annual Tmax and Tmin series during 1958-2008 in the four sub-basins are illustrated in *Figure 4*, which is based on the *Eq.1*. Note that the sub-basin Tmax and Tmin are determined from point Tmax and Tmin via calculating the arithmetic mean value of point Tmax and Tmin. It can be found that all of the sub-basins are characterized by increasing annual Tmax and Tmin. The MMK statistics of annual Tmax in the four sub-basins are 3.88, 4.51, 3.91 and 2.36, respectively, whilst those of annual Tmin are 5.11, 4.54, 3.64 and 3.89, respectively. The increase in annual Tmin is faster than that of annual Tmax in these sub-basins except for the Jing River basin.

$$\frac{x - x_{\min}}{x_{\max} - x_{\min}} \qquad \text{(Eq.1)}$$

The MMK statistics of daily Tmax and Tmin were also calculated in this study, and the spatial and temporal distribution of daily Tmax and Tmin in the WRB is presented in *Figure 5*. It can be found that the MMK statistics of daily Tmax at all the stations are positive, and those at stations 2, 5, 12, and 17 are significant at the 95% confidence level (*Figure 5A*). Similarly, most of the MMK statistics of daily Tmin at all the stations are positive, and those at stations 5,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32773295

10, 15, and 18 are significant at the 95% confidence level (*Figure 5B*). Differently, it also has a significant decreasing trend at stations 11 and 20 (*Figure 5B*).

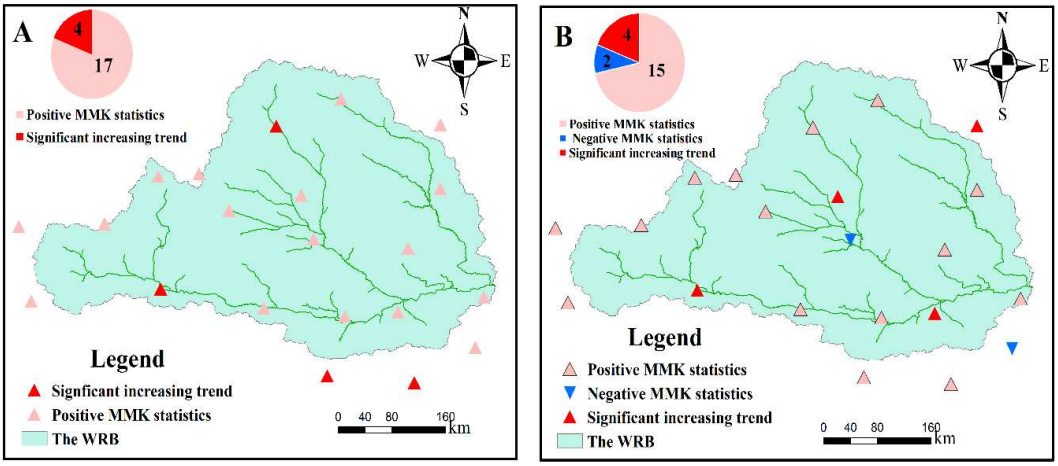

Figure 5. *The spatial and temporal distribution of daily Tmax (A) and Tmin (B) in the WRB*

Identification of change points of Tmax/Tmin and AO index series

The heuristic segmentation method introduced in previous was adopted to identify change points of Tmax and Tmin in the four sub-basins. The threshold P_0 was set to 0.95 and l_0 was set to 25. The segmentations and identified change points of the annual Tmax and Tmin in the four sub-basins are exhibited in *Figure 6* and *Figure 7*, respectively.

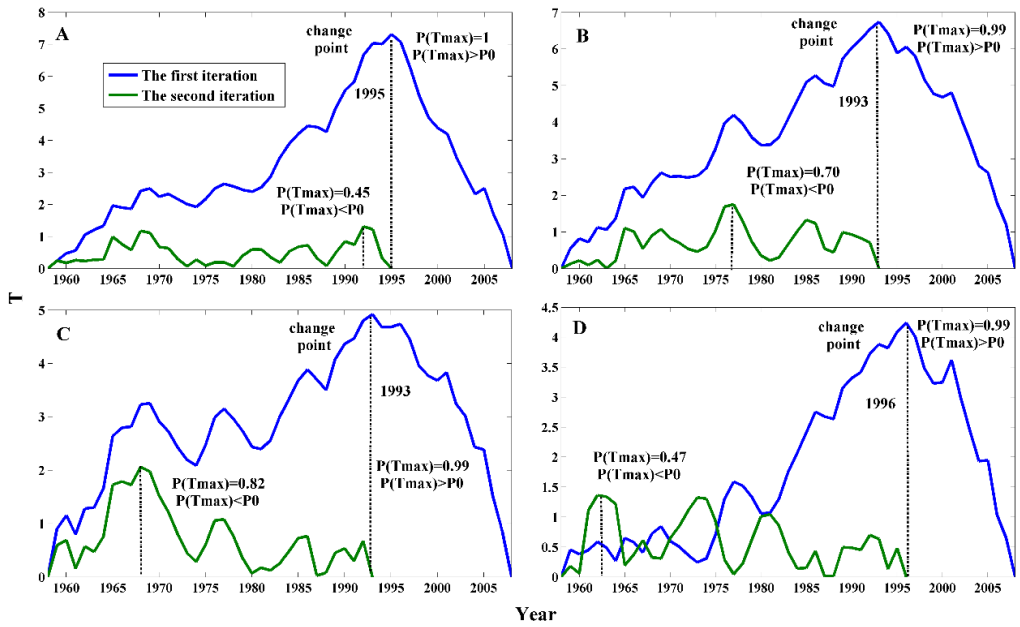

Figure 6. *Segmentations and identified change points of annual maximum temperature in the WRB. A, B, C and D denote the URWB section, the MDWR section, the Jing River basin and the Beiluo River basin, respectively*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32773295

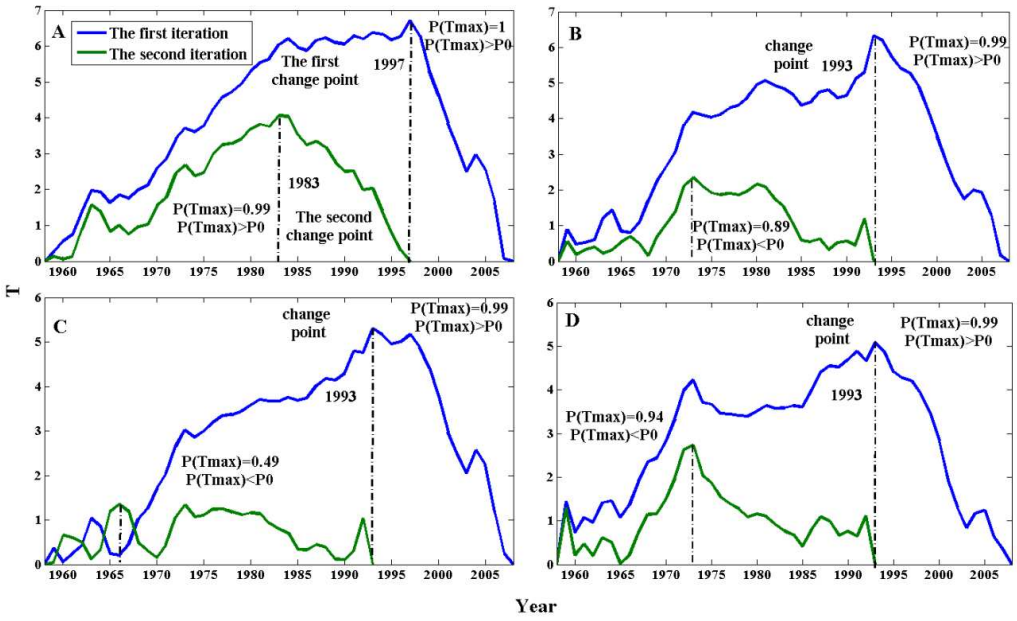

Figure 7. *Segmentations and identified change points of annual minimum temperature in the WRB. A, B, C and D denote the URWB section, the MDWR section, the Jing River basin and the Beiluo River basin, respectively*

In general, both of annual Tmax and Tmin series have change points, implying that the stationarity of temperature extremes in the WRB is invalid. As shown in *Figure 6A*, a change point of 1993 in Tmax was identified in the URWB section in the first iteration due to the condition that $P(t_{max})=1 > P_0$, while no change point was detected in the second iteration due to the condition that $P(t_{max})=0.45 < P_0$. For the MDWR section and the Jing River basin, a common change point (1993) was found in the first iteration due to the condition that $P(t_{max}) > P_0$, while no change point was detected in the second iteration due to the condition that $P(t_{max}) < P_0$. For the Beiluo River basin, a change point of 1996 was detected in the first iteration, whilst no change point was found in the second iteration. From *Figure 7A*, it can be found that a change point of 1997 was detected for the annual Tmin series in the URWB section. For the Tmin in the MDWR section, Jing River basin, and Beiluo River basin, a change point of 1993 was detected.

Moreover, the change points of monthly and seasonal Tmax in the four sub-basins in the WRB were also identified, and their results are displayed in *Table 2* and *Table 3*. It can be found that the change points of monthly Tmax in the four sub-basins vary from 1967 to 2003 with a striking variation (*Table 2*). Note that the monthly Tmax in May in the four sub-basins has no change point. As for the seasonal Tmax in the four sub-basins, their change points are concentrated in 1990s (*Table 2*). In general, the change points of the monthly and seasonal Tmax in the Beiluo River basin are less than those in the other sub-basins. The monthly Tmin in November and December in the four sub-basins has no change point (*Table 3*). Comparatively, the change points of the monthly and seasonal Tmin are less than those of the monthly and seasonal Tmax in the four sub-basins (*Table 3*). Similarly, the change points of the monthly and seasonal Tmin in the Beiluo River basin are less than those in the other sub-basins. Since the change points of monthly, seasonal, and annual Tmax and Tmin were found, the stationarity of temperature extremes in the WRB is ineffective.

In addition, identification of the change points of monthly and seasonal AO index was also conducted based on the heuristic segmentation method. Related results are displayed in *Table 4*. In general, from the monthly perspective, there are change points identified in January, February, May, July, August, September, November, and December. However, from the seasonal perspective, change points are detected in four seasons, indicating that the stationarity of AO status is also ineffective. Through comparison between the change points of Tmax/Tmin and AO, it can be observed that there is no solid linkage between Tmax/Tmin and AO at monthly and seasonal time scales.

Table 4. *Identification of the change points of monthly and seasonal AO index*

M and S denote month and season, respectively

Tmax and Tmin variations are associated with the large-scale atmospheric circulations (Liang et al., 2014), underlying surface conditions (Yu and Li, 2015), as well as human activities such as carbon dioxide emissions (Pereira et al., 2013). To further explain the phenomenon in a quantitatively way is out of the scope of this study, since the major objective of this paper is to investigate the spatial and temporal variations of maximum and minimum temperature at various spatial and temporal scales, along with exploring the correlation between temperature extremes with the AO series. Therefore, the detailed reasons for the occurrence of the change points in annual maximum and minimum temperature series will be investigated in the future study.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32773295

The linkages between temperature extremes and AO

As mentioned above, temperature extremes are associated with the large-scale atmospheric circulations (Liang et al., 2014), underlying land surface conditions (Yu and Li, 2015), as well as human activities such as carbon dioxide emissions (Pereira et al., 2013). To quantitatively separate the changes in Tmax and Tmin from various large-scale and local scale factors is important but not within the scope of this study. Arctic Oscillation (AO) is found to be closely associated with the climate variations in middle and high latitudes regions (Toreti, 2010; Wang, 2013). Hence, we attempt to examine the possible relations between AO and Tmax/Tmin variations. We focus the analysis on summer and winter seasons. The AO values corresponding annual Tmax were summer AO values (the average of those in June, July and August), and the AO values corresponding annual Tmin were the winter AO values (the average of those in December, January and February) (Xue et al., 2012). Based on the Morlet wavelet, the cross wavelet transform between Tmax/Tmin and AO are conducted, and relevant results are shown in *Figure 8* and *Figure 9*, respectively. The 95% significance confidence level against red noise is exhibited as a thick contour, and the relative phase relationship is denoted as arrows (with anti-phase pointing left, in-phase pointing right). It can be found that Tmax has a no obvious positive relationship with AO in the URWB section in the entire period except for the period of 1966-1973 when a statistically significant anti-phase relationship with a 2~3 signal is detected. Similarly, Tmax has a no obvious positive relationship with AO in the MDWR section in 1958-1989, with significant correlations with 4-year signal during 1962-1969. However, a significant negative correlation is detected in 1966-1970. As for the Jing River basin, Tmax has a no obvious positive correlation with AO in the entire period. With regards to the Beiluo River basin, the correlations between Tmax and AO are dominated by significant linkages with a 5-year signal during 1960-1966.

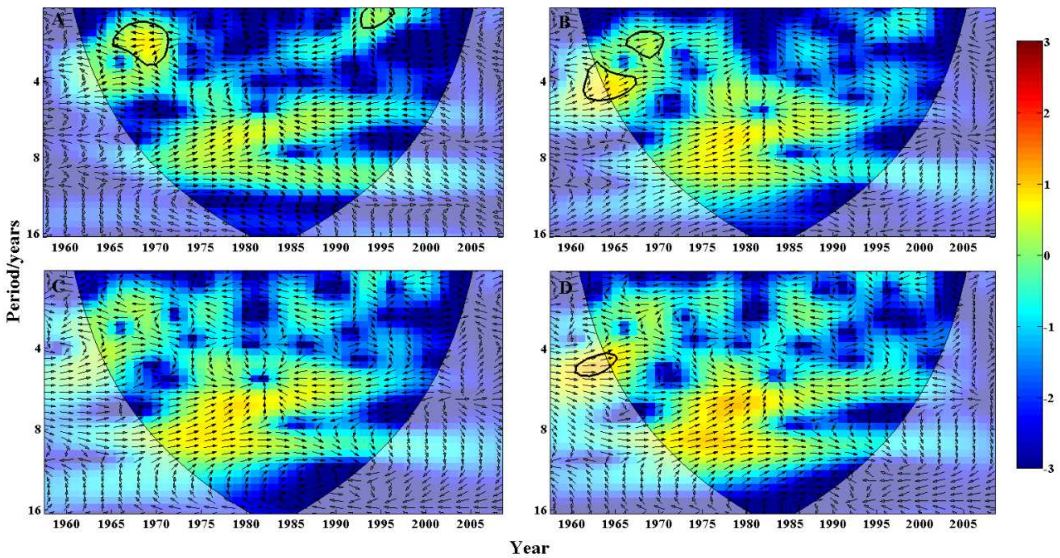

Figure 8. *The cross wavelet transform between maximum temperature and AO. The 95% significance confidence level against red noise is exhibited as a thick contour, and the relative phase relationship is denoted as arrows (with anti-phase pointing left, in-phase pointing right). A, B, C and D denote the URWB section, the MDWR section, the Jing River basin and the Beiluo River basin, respectively*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32773295

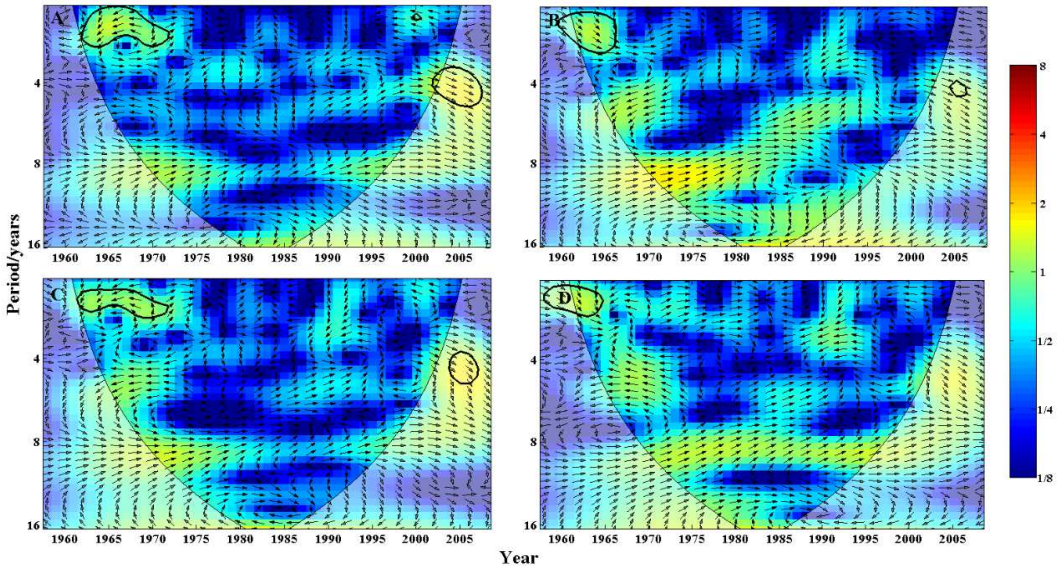

Figure 9. *The cross wavelet transform between minimum temperature and AO. The 95% significance confidence level against red noise is exhibited as a thick contour, and the relative phase relationship is denoted as arrows (with anti-phase pointing left, in-phase pointing right). A, B, C and D denote the URWB section, the MDWR section, the Jing River basin and the Beiluo River basin, respectively*

As for the relations between Tmin and AO in the URWB section, the significantly positive relationship is found with a period of 4 years during 2000-2007, and a significantly negative relationship with AO is detected in 1960-1970 with a 1~2-year signal. Regarding the MDWR section, Tmin has a generally no obvious positive correlation with AO, but the relation become significant in 1960-1969 with a 1~2-year signal. As regards to the Jing River basin, the relationship between Tmin and AO is also dominated by positive correlations, and that in 2003-2006 is significant with a period of 4 years, whilst they have a significantly negative association in 1961-1973 with a 2-year signal. With regards to the Beiluo River basin, the relationship between Tmin and AO is also primarily dominated by positive linkages, and that in 1958-1966 is significant with a 1~2-year signal. Generally, the relations between Tmax/ Tmin and AO in the four sub-basins have both similarity and difference. For example, both *Figures 8B* and *8D* show that the Tmax has a strongly positive correlation with AO with the same 4~5-year signal during 1960~1965 in the MDWR section and the Beiluo River basin. In addition, both *Figures 9A* and *9C* indicate that the Tmin has a strongly negatively relations with AO with the same 1~2-year signal during 1960~1970 and a significantly positive correlation with AO with the same 4~5-year signal in the URWR section and the Jing River basin. Through the comparison between *Figure 8* and *Figure 9*, it can be roughly observed that the area enclosed by the thick contour in *Figure 9* is larger than that in *Figure 8*, indicating that the correlation between Tmin and AO is stronger than that between Tmax and AO. Previous studies have reported that temperature extremes are modulated by the variability of precipitation (Liu et al., 2017), humidity (Krautgasser et al., 2015), wind speed (Jiménez-Hornero et al., 2011), and vegetation type (Migała et al., 2014) in addition to the anomaly of the large-scale atmospheric circulations. The combined effects of these factors may contribute to the different responses of temperature extremes to AO in the four sub-basins in the WRB. For example, Tabari et al. (2014) investigated the links

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32773295

between AO and inter-annual variability of Iranian evapotranspiration in 41 weather stations, and found that different stations had different characteristics in the response of evapotranspiration to AO. That is, the impacts of the large-scale circulation anomaly on local climatic variations may be different, especially for extreme events which is sensitive to climate change (Kapsomenakis et al., 2013; Zhao et al., 2019), depending on different climate types and underlying surface.

Furthermore, we selected the sub-basin 26 in the Yellow River Basin shown in *Figure 1* which is near to the WRB (the sub-basin 31) in the Yellow River Basin (YRB) to conduct a similar analysis. The cross wavelet transform between annual Tmax/Tmin and summer/winter AO in the sub-basin 26 in the YRB are exhibited in *Figure 10*. It can be observed from *Figure 10A* that Tmax temperature shows a strongly positive correlation with AO with a signal of 4~6 year during 1959~1966 in sub-basin 26 in the YRB. The response is similar to that in the Beiluo River Basin in the WRB which is close to the sub-basin 26 in the YRB. Importantly, it can be observed that a significantly positive relation is found between Tmax and AO with a signal of 2~3 year during 1975~1983 in the sub-basin 26, which is different from that in all the four sub-basins. The results further indicate that the relations between AO and Tmax would exhibit different features even in small areas in the WRB. Similar conclusions can be drawn for the relations between AO and Tmin as shown in *Figure 10B*.

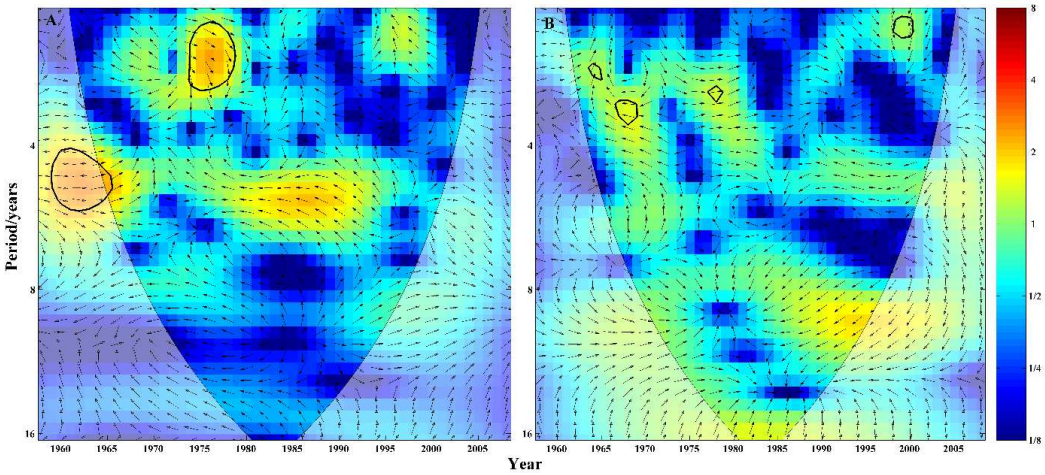

Figure 10. *The cross wavelet transform between maximum (A)/ minimum (B) temperature and summer/winter AO in sub-basin 26 in the Yellow River Basin*

In order to explore the response of temperature extremes to AO at different spatial scales, the correlations between Tmax/Tmin and AO in the whole WRB and YRB were obtained based on the cross wavelet analysis, and their cross wavelet transforms are shown in *Figure 11*. For the whole WRB, Tmax has a significantly negative correlation with AO with a signal of 2~3 year during 1965~1970 (*Figure 11A*), while Tmin exhibits a strongly positive correlation with AO with a signal of 4~5 year during 2002-2006 (*Figure 11B*). Regarding the whole YRB, Tmax has a strongly negative correlation with AO with a signal of 2~3 year during 1966~1980 and a significantly positive relation with AO with a signal of 4~6 year during 1959-1966 (*Figure 11C*), while Tmin exhibits a strongly positive association with AO with a signal of 2~3 year during 1965-1970 (*Figure 11D*). Therefore, the pattern of the correlations between temperature extremes and AO in the whole WRB has both

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32773295

similarity and difference compared with that in the whole YRB, but the difference is more obvious than its similarity. Generally, the URWB section in the WRB, the WRB, and the YRB has negative correlations between Tmax/Tmin and AO in 1965-1970. Differently, the WRB has significantly positive correlations between minimum temperature and AO in 2002-2007, whilst the YRB has significantly positive correlations between maximum temperature and AO in 1960-1965.

Discussion

Extreme climatic events frequently occur in the context of global warming, including extreme temperature and extreme precipitation events. In this study, the spatiotemporal variation characteristics of extreme temperature (Tmax/Tmin) are discussed, and it is found that the maximum and minimum temperature in WRB showed an increasing trend at different degrees. Liu et al. (2018b) found that the frequency of extreme temperature is increasing. In particular, station 17 is dominated by significant increasing trends in autumn and winter, while the summer is reversed. It is near to the monsoon zone than

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32773295

other meteorological stations, thus is impacted by climate change. However, increasing extreme temperatures will lead to a change of the temperature difference, which will have a serious impact on crops. Therefore, extreme temperature events should be given more attention.

It is found that AO is a possible factor influencing the extreme temperature changes in WRB. Similarly, AO also affect temperature changes in other areas (Zhong et al., 2017; Gao et al., 2019; Liu et al., 2019). Therefore, this study can provide a reference for other areas of high concern.

In addition, the present research focuses on the spatiotemporal variation of extreme temperatures, and tries to explain possible causes of the changes at different scales from the perspective of atmospheric circulation. Note that the spatiotemporal variation of extreme temperatures are also related to underlying surface conditions, human activities and carbon dioxide emissions. Therefore, future work should extend current research to reveal the effects of different factors on extreme temperature dynamics.

Conclusion

Changing characteristics of Tmax and Tmin in time and space across the WRB were thoroughly investigated in this study. The modified Mann-Kendall trend test method was applied to identify the change trends, and the heuristic segmentation method was used to identify possible change points of Tmax and Tmin at the monthly, seasonal, and annual scales. Additionally, the cross wavelet transform was utilized to reveal the correlation between annual Tmax and Tmin and AO to explore the possible cause of temperature extremes variations from the perspective of atmospheric circulation anomaly. The primary conclusions are presented as follows:

(1) The WRB is primarily characterized by increasing monthly Tmax especially in the western and middle basin, whilst monthly Tmin is found to decrease in the eastern basin in summer, but increase in winter. Similar pattern of changes in Tmin is found with significant increase in most months. The annual Tmax and Tmin in the WRB have an obviously increasing trend. As for the daily scale, most of stations show no obvious trends. The increasing Tmax and Tmin are expected to accelerate the rate of water circulation, thus resulting in high frequent extreme events such as droughts and floods, which will affect local ecosystem functions and agricultural production.

(2) The change points in monthly, seasonal, and annual Tmax and Tmin series were identified, and all of them have change points found. This suggests that the stationarity of the temperature extremes in the WRB has been invalid in 1958-2008.

(3) The Tmax has a strongly positive correlation with AO with 4~5-year signal during 1960-1965, whilst the Tmin has a strongly negatively relations with AO with the 1~2-year signal during 1960-1970 in the WRB. Overall, Tmax and Tmin have strong correlations with AO, implying that the increasing temperature extremes in the WRB are closely related to the variation of AO.

(Received 27th Sep 2019; accepted 4th Feb 2020)

Abstract. The study aims to analyze the effects of chemical applications on the leaf senescence and yield of maize under different planting densities in Northeast China. Dongnong 253 (hybrid maize), was planted at four densities, i.e. 50,000, 60,000, 70,000, and 80,000 plants ha^{-1}. The leaves were sprayed with the plant growth regulator 'Yuhuangjin' (the main components of which include aminoacyl esters and ethephon) during the jointing stage. The results showed that the highest maize yield, i.e. 13290.95 kg ha^{-1}, was obtained when the plants were treated with 'Yuhuangjin' and 70,000 plants ha^{-1}. As the planting density increased in the water treatment, the height gradually increased, the dry weight of individuals decreased, and the barren stem proportion and lodging risk increased. In contrast, 'Yuhuangjin' reduced plant height, increased the dry weight of individual plants, and reduced both the barren stem proportion and the lodging risk. As planting density increased, the degree of reduction in leaf SPAD increased and the degree of leaf senescence increased in water. However, 'Yuhuangjin' increased leaf greenness and delayed senescence. During leaf senescence process, the activities of antioxidant enzymes (SOD, POD, CAT) decreased, the MDA content increased, and the soluble protein content decreased in the water treatment in response to increasing density. Compared to the water, 'Yuhuangjin' increased the activities of SOD, POD and CAT as well as the soluble protein content but reduced the MDA content. Under high planting densities, 'Yuhuangjin' have important values with respect to increasing maize yields and delaying leaf senescence during the late growth stage. This research provides a theoretical and experimental basis for maize production in Northeast China.
Keywords: *maize, plant growth regulator, density, leaf senescence, yield, antioxidant enzymes*

Introduction

Density is an important factor that determines maize yields (Ogunlela et al., 1988). The planting density of maize (*Zea mays* L.) in Northeast China is generally low, and increasing density is an important cultivation practice that can increase yields. Taking the United States as an example, maize planting density has been increasing since the 1960s, from 60000 plants ha^{-1} in the 1990s to more than 70000 plants ha^{-1} at the end of the 20th century. At present, high-yield fields are generally about 100000 plants ha^{-1} (Lu et al., 2011; Xu et al., 2019). However, a planting density that is too high will reduce individual plant production, and improper control may even reduce yields (Andrade and Calvino, 2002; Shin et al., 2014; Ren et al., 2017; Tokatlidis, 2017). The key to achieving high yields involves the ability to increase the density and sustain reasonable yields of individual maize plants. Plant growth regulators can effectively control maize growth and development. Many studies have recently shown that plant growth regulators play positive roles in improving crop quality, shaping ideal phenotypes and increasing yields (Zhao et al., 2006a; Chen et al., 2013; Cao et al., 2016; Xu et al., 2017). The process of maize leaf senescence reflects the length of its

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32973311

functional period, which is directly related to yield production (Pommel et al., 2006). Therefore, research conducted on maize yield and senescence physiology under different planting densities and in response to the applications of plant growth regulators has important practical significance.

Within a certain range, maize yield increases with increasing density. As maize planting density increases, light transmission within the canopy decreases, senescence increases, the grain number per spike and the 100-grain weight decrease, and the lodging rate increases (Li et al., 2011; Cao et al., 2013). Planting density significantly affects the leaf area index, plant height, ear length, and number of grains per ear, grain weight per ear, 100-grain weight, biological yield and grain yield (Shafi et al., 2012). Population yield increases with increasing density within a certain density range, and rational close planting is an important cultivation practice for achieving high yields (Zhang et al., 2006). The grain yield of an individual maize plant decreases as the plant density increases, and competition for photosynthate may lead to ear and grain abortion during the flowering phase (Andraski et al., 2000; Andrade and Calvino, 2002).

Exogenous substances can accelerate the rate of protein synthesis in plants, increase enzymatic activity and promote other physiological processes. Studies conducted on various plants have shown that exogenous substances can increase antioxidant enzyme (superoxide dismutase (SOD), guaiacol peroxidise (POD), catalase (CAT)) activity during leaf senescence, reduce malondialdehyde (MDA) contents, and increase soluble protein contents and as well as the stay-green ability of plant leaves (Bajguz and Hayat, 2009; Pan et al., 2013). 'Yuhuangjin' is a plant growth regulator that was developed for maize; the regulator consists of an aminoacyl ester combined with ethephon. 'Yuhuangjin' can improve lodging resistance, enhance the stay-green ability of leaves, and increase both the photosynthetic rate and number of aerial root layers. This plant growth regulator has shown clear effects on generating ideal phenotypes and increasing the lodging resistance of maize (Diallo et al., 2015). The planting density of spring maize in the northeastern region of China is relatively low, and the yield potential has not been attained. Research on the application of 'Yuhuangjin' has focused on morphological indexes, investigations of physiological indexes related to yield increases are scarce.

In this experiment, we studied the yield and senescence process of maize during the late growth stage in response to both 'Yuhuangjin' treatment and different planting densities. The results from this study provide a theoretical and experimental basis for further rational application of 'Yuhuangjin' to spring maize in Northeast China.

Materials and methods

Experimental materials and treatments

The field experiments were performed at the Xiangfang Experimental Station of Northeast Agricultural University (126°63′E, 45°44′N), Harbin, Heilongjiang Province, China, in 2014 and 2015. Dongnong 253 (compact growth habit, plant height of 280 cm, ear height of 110 cm) was used as the experimental material. The plant growth regulator 'Yuhuangjin' was provided by Fujian Haoluon Biology Engineering Technology Co. Ltd, China. The soil was previously planted with soybean and is classified as a chernozem (pH 6.85); the soil contained 25.25 g kg^{-1} organic matter, 1.7 g kg^{-1} total nitrogen (N), 179.35 mg kg^{-1} available potassium (K), 65.34 mg kg^{-1} available phosphorus (P), and 118.21 mg kg^{-1} alkaline N. The monthly weather data, i.e.

[a] Precipitation and sunshine are monthly sums, while temperature is a monthly mean of daily means

The experiment was established as a two-factor, randomized block design consisting of three replications. Each plot was 10 m long and consisted of 12 rows with a 0.7-m row spacing. The experiment involved four planting densities, i.e. 50,000, 60,000, 70,000, and 80,000 plants ha^{-1}. Maize kernels were sown by hand on April 25th, 2014, at the same spacing across all replications via a planting density rope. The plant growth regulator 'Yuhuangjin' was applied evenly at the jointing stage (20 mL of liquid 'Yuhuangjin' in 30 kg water was applied per hectare), whereas only water was applied for the control treatment (CK represents the water treatment used for comparisons, and Y indicates the 'Yuhuangjin' treatment. 5CK represents the treatment in which plants at a planting density of 50,000 plants ha^{-1} were subjected to the water treatment, and 5Y represents the treatment in which plants at a planting density of 50,000 plants ha^{-1} were subjected to the 'Yuhuangjin' treatment. 6CK, 6Y, 7CK, 7Y, 8CK, 8Y and so on follow the same convention). The maize plants received 250 kg ha^{-1} diammonium phosphate, 75 kg ha^{-1} urea, and 150 kg ha^{-1} potassium sulphate at the seedling stage, and 300 kg ha^{-1} of urea was topdressed at the jointing stage.

Two 4-m-long sections of consecutive rows were selected in each treatment to calculate the numbers of plants, ears number, barren stalks and barren tip. All the maize plants were harvested, and twenty ears were randomly selected for calculating the number of ears per row, number of kernel per row, 100-grain weight and theoretical yield of each treatment. The average value of the three replications was calculated.

Measurement of SPAD values

The SPAD values were measured using a PAM-2100 chlorophyll meter (Heinz Walz GmbH, Eichenring 6·91090 Effeltrich, Germany). The degree of leaf senescence was considered the relative reduction in the SPAD value: degree of leaf senescence = $(SPAD_{t1}–SPAD_{t2})/ SPAD_{t1}\times100\%$. Beginning at the onset of pollen shedding (July 29th), sampling was conducted at 4 p.m. every 10 d. The ear leaf was placed in an ice box, transported to the laboratory, and maintained in a refrigerator at -80°C. On the following day, each physiological index was measured using the same part of the leaf that was washed and dried with absorbent paper.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32973311

Measurement of antioxidant enzyme activity

To determine the antioxidant enzyme activity, fresh leaves (0.5 g) were homogenized by grinding with a mortar and pestle in 10 mL of ice-cold potassium phosphate buffer (KPB; pH 7.0) in an ice bath. The mixture was then centrifuged at 12000 rpm for 20 min at 4°C. CAT activity in the supernatant was determined in accordance with the methods of Aebi (1984). POD activity was assayed in accordance with previously described methods (Saba et al., 2012), with some modification. The change in absorbance at 410 nm was recorded during a 3-min period. One unit of POD activity was defined as an increase of 0.1/min. SOD activity was assayed as described by Huang method (Huang et al., 2008). The reaction mixture was incubated for 10 min under fluorescent light, after which the absorbance at 560 nm was measured. The ascorbic acid in maize leaves was assayed in accordance with the method reported by Mukherjee and Choudhuri (1983).

Measurement of Soluble protein

Soluble protein contents within fresh leaf extracts (0.1 g) were quantified in (KPB) (50 mM, pH 7.5). These extracts were filtered through four layers of cheese cloth and then centrifuged at 15500 rpm for 15 min at 4°C. The supernatant was collected and subsequently stored at 4°C for protein determination. The leaf soluble protein contents were measured via the protein dye-binding method of Bradford (1976); bovine serum albumin served as the standard.

Measurement of biomass and yield

To determine the biomass and yield, two consecutive four-meter lengths were selected for each process. The rows per ear, number of ear, kernels row, number of row and hundred grain weight were calculated. After harvest, 20 ears were selected to calculate the kernels row, number of row, hundred grain weight, and the theoretical yield. The biomass was determined by the drying method, and the stalks and grains were dried separately. Each process was repeated three times, and the results were averaged.

Statistical analyses

All the data are presented as the mean values of three replications. The data were collated using Microsoft Excel 2003 (Microsoft Corporation, Redmond, Washington, USA). Treatment effects on grain yield; yield components; plant height; dry weight; SOD, POD, and CAT activity; MDA content; and soluble protein contents were analysed in accordance with the principles of analysis of variance; the generalized linear model (GLM) package in SPSS 17.0 software (SPSS Inc. Chicago, Illinois, USA) was used.

Results

Effects of 'Yuhuangjin' and planting density on maize yields

The yield factors of maize include mainly the effective number of ears per unit area, grain number per spike and grain weight, among which ear per unit area is the most easily controlled. Therefore, increasing density is an effective way to obtain high yields.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32973311

The results showed that, as the planting density increased, the grain number per ear and the 100-grain weight decreased, the effective number of ears increased, and the yield increased within a certain range (Abuzar et al., 2011; Li et al., 2015). Therefore, the tight coordination between the effective number of ears per unit area and the grain yield per plant is a key component of attaining high yields. *Table 2* shows that the yield in the water treatment increased initially but then decreased as the planting density increased; the highest yield, i.e. 12346.40 kg ha^{-1}, occurred at a planting density of 70,000 plants ha^{-1}. This value was 34.94% and 12.89% higher than the that in the 5CK and 6CK treatments, respectively, and reached an extremely high level, and this value was significantly higher (9.58% higher) than that in the 8CK treatment. The barren stem ratio in the 7CK and 8CK treatment was 1.857% and 4.037% higher, respectively, than that in the 5CK treatment. These results indicated that increasing density would lead to a decrease in airflow and light transmission within the canopy, affecting the pollination characteristics of plants and resulting in lower production capacity per plant (*Table 2*).

Table 2. *Effects of 'Yuhuangjin' application and plant density on maize yield components*

Treatment	Plant density (plants ha^{-1})	Effective number of ears (ears ha^{-1})	Rows per ear	Kernels per row	100-grain weight (g)	Theoretical yield (kg ha^{-1})
Water	50,000	49428.57	16.05^{a}	33.95^{bc}	33.97^{a}	9150.31^{d}
	60,000	59714.29	15.93^{a}	35.58^{abc}	32.31^{a}	10937.00^{c}
	70,000	67894.29	16.39^{a}	33.89^{bc}	32.74^{a}	12346.40^{b}
	80,000	75857.14	16.00^{a}	31.50^{de}	29.47^{b}	11266.74^{c}
'Yuhuangjin'	50,000	49571.43	15.80^{a}	33.95^{ab}	34.49^{a}	9711.98^{d}
	60,000	59857.14	15.95^{a}	33.50^{cd}	34.36^{a}	10989.10^{c}
	70,000	68085.71	15.45^{a}	36.50^{a}	34.61^{a}	13290.95^{a}
	80,000	76942.86	15.90^{a}	31.28^{e}	31.71^{ab}	11694.96^{bc}

The 100-grain weight and yield were both converted to those at a 14% moisture level. The different letters indicate a significant difference ($P<0.05$) between treatments

Compared with that in the water treatment, the maize yield in the 'Yuhuangjin' treatment increased but did not reach a significant level. The maximum maize yield (13290.95 kg ha^{-1}) occurred at a planting density of 70,000 plants ha^{-1}, which occurred for both the water and 'Yuhuangjin' treatments. Under different planting densities, compared with those in the respective water treatments, the yields in the 5Y, 6Y, 7Y and 8Y treatments increased by 6.14%, 0.48%, 7.65% and 3.81%, respectively. The 'Yuhuangjin' treatment had the best effect on increasing production of planted that were planted at a planting density of 70,000 plants ha^{-1}. Therefore, the proper combination of 'Yuhuangjin' and planting density can increase yields (*Table 2*).

Effects of chemical regulators and planting density on maize plant height and dry matter weight

Table 3 shows that, in the water treatment, plant height increased gradually and the dry matter weight of individual plants decreased gradually as the planting density increased. The height of plants that were planted at a planting density of 80,000 plants ha^{-1} was 23.3 cm higher than that of plants that were planted at a planting density of 50,000 plants ha^{-1}; however, the dry matter weight was 100.01 g lower. This result showed that an increase in the number of plants per unit area increased the plant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32973311

height, reduced the dry matter weight and could greatly increase the risk of lodging. There are limits associated with trying to increase yields by altering the population structure.

Table 3. *Effects of 'Yuhuangjin' application and plant density on maize height and dry weight*

Treatment	Plant density (plants ha^{-1})	Plant height (cm)	Dry weight (g)
Water	50,000	305.00±5.00^{bcd}	354.79±36.27^{ab}
	60,000	318.33±1.53^{ab}	303.95±59.18^{bcd}
	70,000	310.33±4.51^{bc}	273.68±18.63^{de}
	80,000	328.33±8.50^{a}	243.00±10.16^{e}
'Yuhuangjin'	50,000	293.33±10.41^{d}	386.02±10.21^{a}
	60,000	310.00±5.00^{bc}	329.85±21.24^{bc}
	70,000	302.67±2.52^{cd}	295.19±22.13^{cde}
	80,000	314.33±14.36^{bc}	251.77±13.16^{de}

The values are the means ± standard deviations. The different letters indicate a significant difference ($P<0.05$) between treatments

The heights of plants in the 'Yuhuangjin' treatment were 3.83% (50,000 plants ha^{-1}), 2.47% (60,000 plants ha^{-1}), 2.62% (70,000 plants ha^{-1}) and 4.26% (80,000 plants ha^{-1}) lower than those in the water treatment, whereas the corresponding dry matter weights were 8.80% (50,000 plants ha^{-1}), 7.86% (60,000 plants ha^{-1}), 8.51% (70,000 plants ha^{-1}) and 3.61% (80,000 plants ha^{-1}) higher. The 'Yuhuangjin' treatment somewhat reduced plant height, increased the maize dry weight and promoted the transport of more nutrients to the grain, which increased both plant lodging resistance and grain yields. In conclusion, the application 'Yuhuangjin' improved the physiological function of individual leaves of plants at a high planting density, resulting in a reasonable plant phenotype and increased production depending on individual performance (*Table 3*).

Effects of 'Yuhuangjin' and planting density on ear leaf SPAD values after the pollen-shedding period

Chlorophyll is an important substance involved in the absorption and transformation of light energy during photosynthesis in leaves. The chlorophyll content reflects the degree of leaf senescence, and the SPAD value reflects the leaf chlorophyll content. Therefore, in this experiment, changes in SPAD values were used to represent changes in chlorophyll contents. *Table 4* shows that, during the process of leaf senescence, the SPAD values in the water treatment decreased as the planting density increased. Immediately after the pollen- shedding period began (0 d), the SPAD values in the 6CK, 7CK, and 8CK treatments were 11.16%, 17.59% and 20.28% lower, respectively, than those in 5CK treatment. In addition, compared with those at 0 d after pollen shedding, the SPAD values in the 5CK, 6CK, 7CK and 8CK treatments at 40 d after pollen shedding were 20.08%, 30.76%, 33.34% and 34.65% lower, respectively. The extent of the reduction in leaf SPAD values increased as the planting density increased, and the degree of leaf senescence increased.

Table 4 also shows that the SPAD values of the ear leaves treated with 'Yuhuangjin' also decreased after the pollen-shedding period, and compared with those in the water treatment, the SPAD values at different densities and during different periods in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32973311

'Yuhuangjin' treatment was higher. The SPAD values in the 5Y, 6Y, 7Y and 8Y treatments decreased by 18.52%, 16.54%, 12.30% and 16.71%, respectively, from 0 to 40 d after pollen shedding. The SPAD values in the 'Yuhuangjin' treatment were higher than those in the water treatment, i.e. the values increased by 4.83% (50,000 plants ha^{-1}), 19.16% (60,000 plants ha^{-1}), 26.12% (70,000 plants ha^{-1}) and 22.00% (80,000 plants ha^{-1}), at 40 d after pollen shedding (*Table 4*). In conclusion, the SPAD values of the ear leaves decreased as the planting density increased. The 'Yuhuangjin' treatment prolonged the functional period by delaying leaf senescence, allowing more nutrients to be transferred to the grain, resulting in higher yields. Under the experimental conditions, a planting density of 70,000 plants ha^{-1} resulted in optimal results.

Table 4. *Effects of 'Yuhuangjin' application and plant density on ear leaf SPAD values measured at different periods after pollen shedding*

Treatment	Plant density (plants ha^{-1})	Days after pollen shedding				
		0 d	10 d	20 d	30 d	40 d
Water	50,000	77.1±11.4^{b}	76.6±8.3^{a}	71.2±5.5^{a}	66.4±1.2^{ab}	64.2±9.8^{ab}
	60,000	68.5±2.4^{d}	63.4±3.0^{c}	59.1±3.9^{d}	58.3±1.8^{d}	52.4±4.0^{d}

	80,000	61.3±6.2^{e}	59.3±3.6^{d}	53.0±1.3^{e}	53.7±4.2^{e}	45.5±9.0^{e}
'Yuhuangjin'	50,000	82.7±9.5^{a}	78.4±1.3^{a}	71.2±3.3^{a}	68.2±2.3^{a}	67.3±2.1^{a}
	60,000	74.8±4.7^{bc}	66.1±6.8^{b}	63.6±3.1^{bc}	62.6±3.4^{bc}	62.5±1.2^{bc}
	70,000	68.6±6.2^{d}	68.3±4.7^{b}	65.2±1.9^{b}	64.3±3.4^{b}	60.1±5.1^{c}
	80,000	66.6±4.1^{d}	64.7±1.8^{bc}	62.5±1.6^{c}	60.9±1.3^{c}	55.5±3.4^{d}

The values are the means ± standard deviations. The different letters indicate a significant difference ($P<0.05$) between treatments

Effects of 'Yuhuangjin' and planting density on ear leaf SOD activity after pollen shedding

SOD is a protective enzyme in organisms that can catabolise O_2^- into H_2O and O_2 and protect the biomembrane system. *Table 5* shows that the SOD activity of the ear leaf in the water treatment decreased as the planting density increased. After the pollen-shedding period, the SOD activity initially decreased, followed by an increase and then a decreasing trend; the peak value occurred at approximately 20 d after pollen shedding. The peak values in the 5CK, 6CK, 7CK and 8CK treatments were 208.58, 178.89, 169.49 and 147.84 U g^{-1} fresh weight (FW), respectively. The change trend of SOD activity in the 'Yuhuangjin' treatment was similar to that observed in the water treatment. The maximum values of SOD activity measured in the 'Yuhuangjin' treatments were 6.83% (5Y), 6.17% (6Y), 27.87% (7Y) and 23.42% (8Y) higher than those measured in the corresponding water treatments (*Table 5*).

In conclusion, increasing density led to a reduction in SOD activity in the ear leaf, which would reduce the scavenging ability of superoxide ion free radicals, aggravate the destruction of cell structure and accelerate the process of leaf senescence. The SOD activity in the ear leaf was greater in the 'Yuhuangjin' treatment than in the water treatment, which played a positive role in delaying the process of leaf senescence.

Effects of 'Yuhuangjin' and planting density on POD activity in ear leaves after pollen shedding

POD is another important enzyme involved in the plant protective enzyme system. POD can effectively eliminate the accumulation of peroxides in plants and reduce the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32973311

degree of membrane lipid peroxidation, and this enzyme plays a positive role in maintaining leaf greenness. *Table 5* shows that the POD activity in the water treatment decreased as the planting density increased; the activity increased initially but then decreased over time after pollen shedding. The maximum POD activity occurred at approximately 20 d after pollen shedding. The maximum POD activity values in the 5CK, 6CK, 7CK and 8CK treatments were 64.8, 66.47, 56.13 and 53.5 (ΔA470 min^{-1}. g^{-1} FW), respectively. *Table 5* also shows that the POD activity in the 'Yuhuangjin' treatment increased at a later stage, and compared with those in the water treatment, the maximum values in the 'Yuhuangjin' treatment were 21.14% (50,000 plants ha^{-1}), 7.28% (60,000 plants ha^{-1}), 27.38% (70,000 plants ha^{-1}) and 16.72% (80,000 plants ha^{-1}) higher. These results indicate that maximum POD activity occurred at a planting density of 70,000 plants ha^{-1} (*Table 5*).

In summary, an increase in planting density led to a reduction in POD activity, which can cause hydrogen peroxide (H_2O_2) accumulations in the leaves, damage the cell membrane system, and reduce the ability of leaves to remain green. Spraying 'Yuhuangjin' can improve the canopy structure of a high-density population, increase both the POD activity in the ear leaves and the ability of leaves to remain green, and create favourable conditions for yield formation.

Effects of 'Yuhuangjin' and planting density on CAT activity in ear leaves after pollen shedding

CAT can promote the catabolism of H_2O_2 into molecular oxygen and water and can prevent the accumulation of H_2O_2 in cells. Table 5 shows that the CAT activity in the water treatment decreased as the planting density increased, and as the time after pollen shedding increased, an initial decrease followed by an increase and a subsequent decrease was observed; the peak value occurred at approximately 20 d after pollen shedding. The peak CAT activity values in the 6CK, 7CK and 8CK treatments were 10.47%, 16.95% and 35.22% lower, respectively, than the values in the 5CK treatment. The change trend of the 'Yuhuangjin' treatment was similar to that of the water treatment; the peak values were 4.62% (50,000 plants ha^{-1}), 10.34% (60,000 plants ha^{-1}), 11.11% (70,000 plants ha^{-1}) and 7.14% (80,000 plants ha^{-1}) higher than those of the corresponding controls (*Table 5*).

Therefore, increasing planting density reduced the physiological function of the ear leaves, and the CAT activity decreased. However, the 'Yuhuangjin' treatment improved the CAT activity, which positive affected the greening ability of the leaves.

Effects of 'Yuhuangjin' and planting density on the MDA content in the ear leaves after pollen shedding

MDA is one of the end products of membrane lipid peroxidation. The MDA content reflects leaf senescence to a certain extent, and the accumulation of MDA can severely damage the subcellular structure of plants. *Table 5* shows that, on the whole, the change trend of the MDA content in the water treatment was the same as that in the 'Yuhuangjin' treatment, i.e. an increase was observed in response to increasing planting density and time after pollen shedding. However, the 'Yuhuangjin' treatment caused a reduction in MDA contents, which, after 40 d, were 8.71% (50,000 plants ha^{-1}), 7.86% (60,000 plants ha^{-1}), 8.36% (70,000 plants ha^{-1}) and 7.41% (80,000 plants ha^{-1}) lower than those in the water treatment. The results showed that increasing planting density resulted in an increase both in membrane lipid peroxidation products and in leaf

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32973311

senescence. Less MDA accumulated in the 'Yuhuangjin' treatment than in the water treatment; in addition, the degree of membrane lipid peroxidation was lower in the former, and the leaf greenness retention ability was higher (*Table 5*).

Effects of 'Yuhuangjin' and planting density on the soluble protein contents in ear leaves after pollen shedding

Soluble protein enzymes in leaves include PEP carboxylase and RuBP carboxylase; changes in the contents of these enzymes reflect changes in enzyme activity. In addition, soluble protein contents are also associated with leaf metabolism, which is another important index of leaf senescence. *Table 6* shows that, as planting density increased in the water treatment, the soluble protein contents in the ear leaves decreased. As time after pollen shedding increased, the soluble protein content increased initially but then decreased; the peak value occurred at approximately 10 d after pollen shedding. The soluble protein contents in the 6CK, 7CK, and 8CK treatments were 20.72%, 23.37% and 27.11% lower, respectively, than those in the 5CK treatment. The results show that an increase in planting density can reduce light transmission within the canopy, resulting in poor environmental conditions for individual plants. In addition, increased planting density can reduce the soluble protein content, the activity of enzymes involved in N metabolism, and the yield of individual plants (*Table 6*).

Table 6. *Effects of 'Yuhuangjin' application and plant density on the soluble protein content of ear leaves after the pollen-shedding period*

Treatment	Plant density (plants ha^{-1})	Days after pollen shedding				
		0 d	10 d	20 d	30 d	40 d

	70,000	25.84±0.93^{d}	28.00±1.73^{cd}	24.66±0.67^{d}	25.17±0.23^{c}	19.30±1.01^{d}
	80,000	22.64±0.91^{e}	26.63±0.73^{e}	21.13±1.00^{e}	20.17±1.18^{e}	16.54±0.69^{e}
'Yuhuangjin'	50,000	36.51±1.31^{a}	35.69±1.02^{a}	39.67±1.13^{a}	35.43±0.52^{a}	26.48±1.27^{a}
	60,000	32.94±1.49^{b}	30.82±1.08^{b}	33.99±1.49^{b}	27.04±0.93^{b}	25.32±0.82^{a}
	70,000	30.01±0.94^{c}	29.73±0.66^{bc}	32.31±1.12^{b}	26.90±1.29^{b}	22.76±1.55^{b}
	80,000	27.02±0.96^{d}	26.45±0.81^{e}	28.61±1.10^{c}	24.57±2.02^{c}	20.57±0.87^{c}

The values are the means ± standard deviations. The different letters indicate a significant difference ($P<0.05$) between treatments

Table 6 also shows that, compared with the water treatment, the 'Yuhuangjin' treatment led to increases in soluble protein contents at each period; the maximum values occurred at approximately 20 d after pollination and were 8.57% (50,000 plants ha^{-1}), 17.35% (60,000 plants ha^{-1}), 15.42% (70,000 plants ha^{-1}) and 7.43% (80,000 plants ha^{-1}) higher than those in the water treatment. The 'Yuhuangjin' treatment increased the metabolic activity of the maize ear leaf soluble proteins, which prolonged their functional period; increased the leaf greenness retention ability; and provided conditions for high yields.

Discussion

Increased maize yield records have been reported in recent years, indicating that the average level of maize production in China may continue to improve (Zhao et al., 2006b). Increasing the planting density is the main cultivation practice to increase maize production. The results of this study showed that, when the planting density was between 50,000 and 70,000 plants ha^{-1}, the yield increased as the planting density increased, and when the planting density exceeded 70,000 plants ha^{-1}, the yield decreased as the planting density increased. Previous studies have shown that, under relatively high planting densities, an increase in the number of ears per unit area led to an increase in the number of grains per ear, which ultimately resulted in increased yields (Wei et al., 2017). The amount of dry matter is the material basis for the formation of grain yield, and the harvest index is an important factor affecting the yield (Gao et al., 2017). Increasing the planting density can significantly increase the amount of dry matter of groups and thus achieve the goal of increasing yield (Ogunlela et al., 1988). In the present study, the amount of dry matter per plant decreased as the planting density increased. The yield decreased after the planting density exceeded 70,000 plants ha^{-1}. The harvest index can decrease in response to increase of planting density, and the efficiency of dry matter allocation from the stem to the grain can decrease, which results in relatively lower yields when the planting density is too high (Wei et al., 2017). Previous studies have shown that a lack of source material is the main limiting factor for yields at low planting densities; therefore, increasing the planting density can increase production. However, the source and sink materials increased simultaneously, but the proportion of increase was different under the high planting density, causing the relative shortage of sink tissue to be the main limiting factor for production. Currently, measures such as increasing the grain number, grain weight and harvest index represent the main mechanisms for increasing yield (Wang et al., 2013). Previous studies have shown that applications of chemicals could increase the harvest index, increasing the distribution of photosynthetic products to the grain, promoting the development of the ear, increasing both the number of grains per ear and the 100-grain weight, and increasing yields (Zhang et al., 2014; Otie et al., 2016). In this study, the 'Yuhuangjin' treatment significantly increased the amount of dry matter per plant and increased the yield of the population. The yield was highest at a planting density of 70,000 plants ha^{-1} in the 'Yuhuangjin' treatment.

The flowering stage of maize is a critical period for yield formation, but it is also the time during which the physiological function of leaves gradually decreases. The length of the leaf functional phase directly influences the formation of maize yield. During the senescence process, the gradual loss of leaf chlorophyll is the most definitive characteristic of leaf senescence, and leaf chlorophyll content and senescence are significantly negatively correlated (Mohr and Schopfer, 1995; Taiz and Zeiger, 2006). Research has shown that delayed leaf senescence, the retention of green leaves, and high photosynthetic rates can prolong the late growth stage of maize, significantly increasing yields (Huffaker, 1990; Ma and Dwyer, 1998). The results of this study showed that increasing planting density reduced leaf chlorophyll contents after pollen shedding. In addition, leaf senescence increased as the number of days after pollen shedding increased. Previous studies have shown that chemical control was beneficial for delaying the senescence of leaves in the middle and lower parts of the plant and for maintaining a relatively greater effective photosynthetic area during the middle and late stages of grain filling. The results of this study showed that 'Yuhuangjin' could increase

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32973311

leaf chlorophyll contents, delay leaf senescence and increase the accumulation of photosynthetic products, ensuring high yields.

Increasing the planting density is one of the key ways to increase yields. However, as the planting density of maize increases, competition for light, temperature, water and other environmental resources increases, which affects plant growth and development (Wei et al., 2017); this competition reduces stem thickness, increases plant height, reduces stem mechanical strength and increases the risk of lodging (Zhang et al., 2017). Compared with normal-height plants, dwarf plants exhibit better lodging resistance, which lays a good foundation for close planting and high yields (Ren et al., 2016). The results of the present study showed that, as the planting density increased, the height of the maize plants significantly increased, and the plants were prone to lodging. 'Yuhuangjin' applications significantly reduced plant height, increased lodging resistance and ensured maize yields under high planting densities, which is consistent with previous results (Zhang et al., 2017).

Since Harman hypothesized the involvement of free radicals in senescence in 1956, research on the mechanism of the active oxygen defence response in plants has expanded (Shen, 2001). Many studies have shown that, under normal and abnormal metabolic conditions, plants produce reactive oxygen free radicals; however, reactive oxygen species can be controlled, mainly by protective enzymes (e.g. SOD, POD, CAT) and non-protective enzymes, vitamin C, and soluble proteins. When the metabolic balance is disturbed, free radicals accumulate in large amounts, leading to increased peroxidation of membrane lipids and increased MDA contents, which results in the destruction of the entire cell structure and function (Pan et al., 2006; Prochazkova and Wilhelmova, 2007). Previous studies have shown that leaf senescence is accompanied by the accumulation of reactive oxygen species and a decrease in antioxidant enzyme activities in cells (Prochazkova et al., 2001). Soluble protein contents are closely related to leaf function and senescence, which affect plant photosynthate accumulation and grain yields (Wang et al., 2016). The results of this study showed that increased planting density both led to a reduction in the activities of antioxidant enzymes (SOD, POD, CAT) in the ear leaves, an increase in MDA contents, and a decrease in soluble protein contents and accelerated leaf senescence. By regulating the balance of endogenous hormones, chemical controls can regulate plant growth and development, increase both the activity of plant protection enzymes and the soluble protein content, and improve plant adaptability to the environment, ultimately increasing crop yields (Wang et al., 2016). In the present study, 'Yuhuangjin' applications increased the activity of antioxidant enzymes, reduced the MDA content, increased the soluble protein content, increased the stay-green ability of the leaves and prolonged the functional period of the ear leaves, resulting in higher yields.

Conclusion

In a proper density extent, as the planting density increased, the 100-grain weight, rows per ear and number of grains per row decreased, whereas the barren stalk proportion and lodging risk increased. However, the increase in the effective number of ears per unit area compensated for the yield reduction caused by this density-induced stress. Under the premise of ensuring a specific density, 'Yuhuangjin' applications can reduce plant height, increase lodging resistance, shape a reasonable phenotype and delay leaf senescence to extend the functional period of the leaves, improve production

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_32973311

conditions and increase production to a certain extent. Applications of chemical growth regulators and close planting at a reasonable density are therefore important ways for improving spring maize yields in Northeast China.

Abstract. Non-engineering flood control measures have gradually become an important part of flood disaster management in the past decades, and it cannot be separated from regional flood risk analyses. Flood risk analyses can be regarded as a complex of three aspects: flood hazard analyses, vulnerability analyses and comprehensive evaluation of both. In this paper, taking Huaihong South Flood Control Protected Area (simplified as HHS) of the Huaihe River Basin in China as an example, a one-dimensional (1-D) and two-dimensional (2-D) coupled hydrodynamic model of the study area was established to simulate the evolution process of the floods with different return periods and acquire inundation data in the flood hazard analysis. Concerning the vulnerability analysis, based on the composition mechanism of vulnerability and the available data of the study region, the vulnerability evaluation index system was established, then the magnitudes of vulnerability of the townships in the research were analyzed through the catastrophe progression method. Combined with the analysis results above, the flood risk of 15 townships in HHS can be classified into 6 magnitudes by factor analysis and hierarchical clustering analysis. The results show that the flood risk is medium or even higher in most zones of HHS. The integrated method used in this research can also be applied to other regions.
Keywords: *flood risk, vulnerability analysis, 1-D and 2-D coupled hydrodynamic model, catastrophe progression method, factor analysis, hierarchical clustering analysis*

Introduction

In recent decades, with the climatic changes, population growth and urban development in flood-prone areas, the ability of human beings to control floods has become stronger and stronger, but the devastating impacts on people's livelihood, economy and the environment due to floods had an increasing tendency in the past 25 years in China (Yu et al., 2018). A possible way to reduce the loss of flood disasters is the mapping of flood-prone areas to risk awareness and support sustainable land-use planning and urban development (Horritt et al., 2007). Flood risk analysis is a useful source of information in rescue and relief agencies for their operations. In 2007, the European Union has adopted Flood Directive, with the main objective of reducing and managing flood risk (Van Alphen et al., 2009).

Flood risk analyses can be basically divided into three parts: flood hazard analyses, vulnerability analyses and comprehensive evaluation of both. The researches on flood hazard analyses at domestic and abroad generally include two aspects: one is to explore the inner relationship between the different return periods and the actual scales of flood events; the other one is to predict future flow regime characteristics in flood-affected

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33133329

areas, and the flood hazard has usually been expressed by inundation information of flood (inundation range, depth, duration, etc.). The aim of vulnerability analyses is to assess the multi-dimensional vulnerability (Physical, Social, Economic and Environment) of the region. This exercise will be used to develop a vulnerability map as an input towards flood risk analysis.

In scientific literature, for both the hazard and vulnerability analyses, a number of approaches and models of different complexity levels are available (Kourgialas and Karatzas, 2011). Kourgialas and Karatzas (2011) presented a method to estimate the flood-hazard areas considering six factors: flow accumulation, slope, land use, rainfall intensity, geology and elevation. The study area was divided into five regions characterized by different magnitudes of flood risk ranging from very low to extremely high. Apel et al. (2009) tested numerous combinations of models of different complexity both on the hazard and on the vulnerability side in a case study. On the hazard side, the models selected include a mixed 1D/2D hydraulic model. On the vulnerability side, the models used for the estimation of direct damage to residential buildings are in order of increasing complexity, such as a rule-based micro-scale model applied to a detailed building inventory (Apel et al., 2011).

Materials and methods

Study area

The riverine area of the Huaihe River Basin in the Anhui Province (in China) has always been prone to flooding disasters (Wang, 2015). One of the most serious flooding areas in the Anhui Province is HHS which is located between 32°50′N–33°20′N latitude and 117°10′E–117°50′E longitude, covering an area of about 1480 km^2 (*Fig. 1*). It covers 15 townships in three counties, one district. The general trend of HHS is higher in the north and lower in the south.

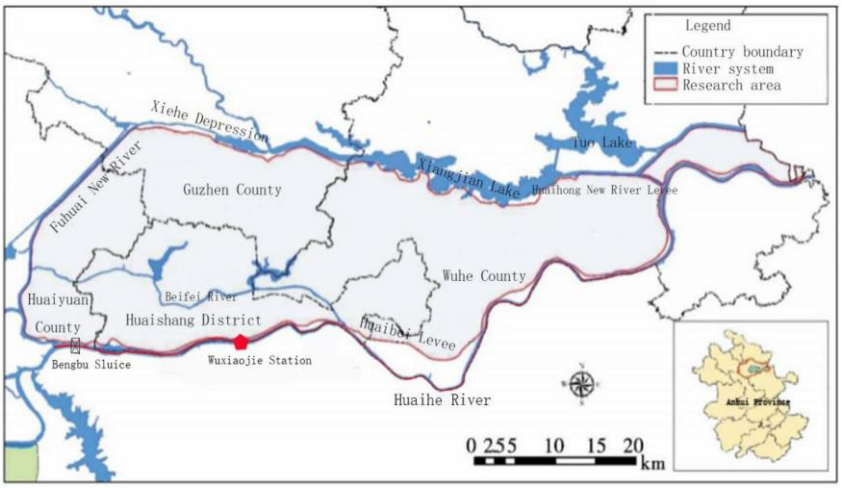

Figure 1. *Location of HHS*

Available data

The topographic data used in this research is based on 1:10000 topographic data and the DEM of the entire study area with a horizontal resolution of 5 m provided by Anhui

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)

Provincial Flood Control Office. Topographic map of the research region is shown in *Figure 2*. The cross-sectional data of the main stream of the Huaihe River are 104 cross-sections with 1-2 km spacing between the cross-sections measured in 1993.

Total length of the river reach in study is 110.0 km. Discharge curves of 50-, 100- and 200-year floods in Wujiadu Station are available (*Fig. 3*). Generalized river network of main stream of the Huaihe River considered in this research is shown in *Figure 4*.

According to the information sheet of key dangerous sections provided by the relevant water conservancy department, the Wuxiaojie Station on the Huaibei levee (indicated in *Fig. 1*) is selected as the possible dyke burst. *Table 1* shows the data of evaluation indicators (refer to Statistical Yearbook of Bengbu City in 2015) used in this research.

Flood hazard analysis

Flood hazard analysis is one of the methods of flood forecasting. In this paper, a 1-D hydrodynamic model was used to simulate the flood course of Huaihe River in the study area, a 2-D hydrodynamic model was used to simulate the flood routing in HHS, and a 1-D and 2-D coupled hydrodynamic model was used to simulate the flood course of a levee breach (Zhang et al., 2019). MIKE software with the advantage of stability, reliability and high accuracy was selected for modelling calculation.

1-D hydrodynamic modelling

For the 1-D hydrodynamic modelling, in terms of topographic data, it required a certain number of cross-sections to represent the river channel and its surrounding

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33133329

topography (Cook and Merwadee, 2009). The 104 cross-sections measured in 1993 were used in the model for describing the geometry of the river reach. Considering Wuxiaojie Station was the breach of Huaibei levee, the discharge curves of 50-, 100- and 200-year floods at the breach were taken as the upstream boundary condition, whereas the stage-discharge relation at Xiaoliuxiang Station was used as the downstream boundary condition (Brandimarte and Di Baldassarre, 2012). The 1-D model was established to simulate floods in the one-dimensional channel from Bengbu Sluice to Xiaoliuxiang Station with MIKE 11 (Ferdous, 2012). The initial discharge of the river is set to 0, and the initial water level is set to the measured water level at the beginning of the simulation.

2-D hydrodynamic modelling

The domain of the 2-D hydrodynamic model is described by a mesh consisting of nodes and triangular elements (Tewodros and Abdusselam, 2019; Jungkyu et al., 2019). The topographic data adopted in this model was the 1:10000 topographic data and DEM of the entire study area with a horizontal resolution of 5 m. In this model, a hybrid grid model was established to reflect the overall terrain variation characteristics of the region. The 2-D model was used to simulate the flood routing in HHS with MIKE 21.

1-D and 2-D coupled hydrodynamic modelling

The 1-D and 2-D coupled hydrodynamic model simulated the 1-D flow in river channels and the 2-D flow in floodplains with MIKE FLOOD to acquire inundation depth, inundation duration and velocity of the floods with different recurrence periods (Parto et al., 2009). During the coupling process, the left embankment of Huaihe River, the right embankment of Huaihong New River and the 20.5 m contour line of Fengshan in Sihong County of Jiangsu Province in China were taken as the external boundary; the dispatching process of dikes, roads, bridges, culverts and other structures were used as the internal boundary conditions. The 1-D model and 2-D model exchanged water level and flow information with each other. The 1-D model used the water level of the 2-D model's grid at the coupling point as the boundary water level, whereas the 2-D model used the outflow of the 1-D model at the coupling point as the inflow.

Vulnerability analysis

Vulnerability index system

In this study, vulnerability of the evaluation object at flood risk is regarded as a state variable. In the absence of a thorough study on the formation mechanism of vulnerability to flood, the index system method which is based on the hierarchy and the correlation between structural indicators of vulnerability is the most common method. It can reflect the overall macro-situation of the magnitudes of flood vulnerability in the region (Fan et al., 2000).

Defined as the inherent attribute of an element at risk, vulnerability was usually composed of three parts: exposure degree (Baldassarre et al., 2009), sensitivity, capacity of disaster prevention and mitigation. According to this, representative indicators (*Table 2*) are selected to construct the vulnerability index system of the evaluation object at flood risk.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33133329

Table 2. *Vulnerability index system of the evaluation object at flood risk*

Target layer	Criterion layer	Index layer
Vulnerability (A)	Exposure degree (B1)	GDP per unit area (C1)
		Density of population (C2)
		Density of residential structures (C3)
		Density of lifeline engineering structures (C4)
	Sensibility (B2)	Average elevation (C5)
		Proportion of agricultural population (C6)
		Land-use sensitive index (C7)
		Proportion of female population (C8)
	Capacity of disaster prevention and mitigation (B3)	GDP per capital (C9)
		Density of shelters (C10)
		Density of medical aid institutions (C11)

Among these indicators, GDP per unit area refers to the gross domestic product of agriculture, industry and tertiary industry; density of lifeline engineering structures refers to the lifeline length per unit area; land use sensitive index is defined in the literature (Chen et al., 2012); density of shelters refers to the number of large and medium-sized sites, such as schools, shopping malls and hotels, that can accommodate the affected people on unit area of the evaluation township; density of medical aid institutions refers to the number of medical aid institutions on unit area of the evaluation township.

Catastrophe progression method

In order to avoid the subjectivity of determining the weight assignment of vulnerability indicators, this study used the catastrophe progression method to evaluate the magnitudes of vulnerability to flood of the townships in the region (Li et al., 2010; Liu et al., 2010).

When calculating the vulnerability indicators of evaluation townships, the original values of indicators in the *Table 1* should be uniformly normalized and transformed into positive indices in the range of [0,1].

For the larger-the-better indices:

$$r_{ij} = \frac{x_{ij} - \min(x_{ij})}{\max(x_{ij}) - \min(x_{ij})} \quad \text{(Eq.1)}$$

For the smaller-the-better indices:

$$r_{ij} = \frac{\max(x_{ij}) - x_{ij}}{\max(x_{ij}) - \min(x_{ij})} \quad \text{(Eq.2)}$$

where x_{ij} – original value of index 'j' of evaluation township 'i'; $\max(x_{ij})$ and $\min(x_{ij})$ – maximum and minimum value of index 'j'; r_{ij} – normalized value of x_{ij}.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33133329

Catastrophe progression method is a multilevel objective decomposition for evaluation objects which combing the catastrophe theory and fuzzy mathematics, the ultimate catastrophe function is obtained through quantitative computing by the normalization formula of different catastrophe models, and thus the comprehensive assessment of alternatives is realized, then a catastrophe progression model is obtained to classify the vulnerability classification of evaluation townships.

In this paper, according to the number of variables, we chose the proper catastrophe progression model and used the corresponding normalization formula layer by layer to calculate until the ultimate catastrophe functional value (value of vulnerability to flood) was obtained. The mean value was taken as the upper index value when calculating the catastrophe progression of each layer for the reason that the evaluation indices considered in this study could make up for their deficiencies. Alternative catastrophic models are shown in *Table 3* (Li et al., 2010).

Table 3. *Alternative catastrophe progression models.*

Catastrophe progression model	Number of variables	Normalization formula
Cusp catastrophe	2	$X_a = a^{1/2}$; $X_b = b^{1/3}$
Swallowtail catastrophe	3	$X_a = a^{1/2}$; $X_b = b^{1/3}$; $X_c = c^{1/4}$
Butterfly catastrophe	4	$X_a = a^{1/2}$; $X_b = b^{1/3}$; $X_c = c^{1/4}$; $X_d = d^{1/5}$

X_a, X_b, X_c, X_d – catastrophe progression of a, b, c, d; a, b, c, d – normalized values of indices

Risk analysis

Flood risk index system

In a flood risk index system, according to the process of flood hazard analysis and vulnerability analysis (Fuchs et al., 2012; Merz et al., 2010; Masood and Takeuchi, 2012), inundation depth, inundation duration and velocity of 200-year flood were selected as indicators of flood hazard, drainage density, proportion of agricultural population, proportion of female population, land-use sensitive index, GDP per unit area, density of population, density of residential structures, density of lifeline engineering structures, GDP per capital and density of shelters were taken as vulnerability indicators.

Factor analysis

In the study of flood risk assessment, it generally involves multiple evaluation indicators and numerous evaluation objects (Li et al., 2003). Attempting to synthesize the characteristics reflected by various indicators and minimize the loss of raw information, we transformed several evaluation indicators into a few comprehensive factors through factor analysis (Helena et al., 2003). The basic idea of factor analysis approach is to divide the original indicator variables into several groups by making the correlation of variables in the same group become higher, while the correlation of variables from different groups become lower. Each group of indicator variables can be represented by an immeasurable comprehensive variable which is also called a common factor (Kuo et al., 2013). In this way, a few representative common factors can be used to summarize the information provided by the original variables (Muangthong and Shrestha, 2015). The part of the original variables which cannot be explained by the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33133329

common factors will be regarded as special factors (Wan et al., 2013). It can be expressed by mathematical formula as follows (Ma et al., 2011; Zhang et al., 2009).

$$\begin{aligned} x_1 &= a_{11}F_1 + a_{12}F_2 + \cdots + a_{1m}F_m + \varepsilon_1 \\ x_2 &= a_{21}F_1 + a_{22}F_2 + \cdots + a_{2m}F_m + \varepsilon_2 \\ &\cdots \\ x_p &= a_{p1}F_1 + a_{p2}F_2 + \cdots + a_{pm}F_m + \varepsilon_p \end{aligned} \quad \text{(Eq.3)}$$

where x_i (i = 1,2,…,p) – original indicator variable; F_j (j = 1,2,…,m) – common factor; a_{ij} (i = 1,2,…,p; j = 1,2,…,m) – load of common factor F_j on variable x_i; $\varepsilon_i (i = 1,2,\ldots, p)$ – special factor.

F_j (j = 1,2,…,m) can be represented as follows:

$$F = BX \Leftrightarrow \begin{aligned} F_1 &= b_{11}x_1 + b_{12}x_2 + \ldots + b_{1p}x_p \\ F_2 &= b_{21}x_1 + b_{22}x_2 + \ldots + b_{2p}x_p \\ &\cdots \\ F_m &= b_{m1}x_1 + b_{m2}x_2 + \ldots + b_{mp}x_p \end{aligned} \quad \text{(Eq.4)}$$

where x_i(i = 1,2,…,p) – standardized variable; B – factor loading matrix.
Calculating the score 'S' of each evaluation unit:

$$S = \sum_{i=1}^{m} \left[(F_i \times (C_i / C) \right] \quad \text{(Eq.5)}$$

where C_i(i = 1,2,…,m) – contribution of variances of each common factor; C – accumulated contribution of variances.

Hierarchical clustering analysis

The evaluation objects are further classified by clustering to reveal the internal relationship among multiple evaluation objects with the method of hierarchical clustering algorithm in this research. Suppose there are 'n' samples to be clustered, for hierarchical clustering, the steps are as follows:
Step1: Initialization (take each sample as a class, and calculate the distance between each two classes, that is, the similarity between samples).
Step2: Find the two nearest classes among these classes, and classify them into one class (so that the total number of classes is one less).
Step3: Recalculate the similarity between the newly generated class and each old class.
Step4: Repeat Step2 and Step3 until all samples are in the same category.

Using MATLAB to perform the steps above can obtain the clustering dendrogram of hierarchical clustering analysis like *Figure 5*.

Based on clustering 15 samples (taking the comprehensive flood risk score 'S' and the vulnerability index value of one township as a sample) by the hierarchical clustering method, the townships falling in HHS were divided into various flood risk zones

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33133329

namely extremely-high-, high-, medium-high-, medium-, low-medium- and low-risk zones, taking township as a stratum.

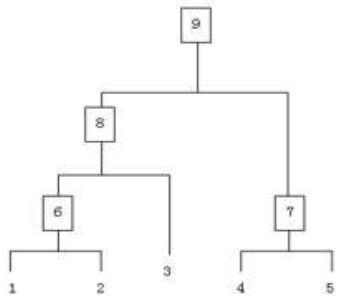

Figure 5. *Generalized dendrogram of Hierarchical clustering analysis*

Results

Flood hazard

A simulation was conducted according to the above-mentioned model (the 1-D and 2-D coupled hydrodynamic model) by MIKE software, the simulation inundation data based on the 50-year, 100-year and 200-year return period floods are presented in *Table 4*.

Table 4. *Simulation inundation data based on the 50-year, 100-year and 200-year return period flood*

Vulnerability

Taking Chengguan town in Huaiyuan county (CG) as an example, the original values of indicators in the *Table 1* could be uniformly normalized and transformed into positive indicators in the range of [0,1], as shown in *Table 5*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33133329

Table 5. *Normalized values of indicators of CG.*

Target layer	Criterion layer	Index layer	Normalized values
Vulnerability of CG (A)	Exposure degree (B1)	GDP per unit area (C1)	0.2374
		Density of population (C2)	0.5181
		Density of residential structures (C3)	1
		Density of lifeline engineering structures (C4)	0
	Sensibility (B2)	Average elevation (C5)	0.1270
		Proportion of agricultural population (C6)	0
		Land-use sensitive index (C7)	0
		Proportion of female population (C8)	0.7234
	Capacity of disaster prevention and mitigation (B3)	GDP per capital (C9)	0.7842
		Density of shelters (C10)	0.3370
		Density of medical aid institutions (C11)	0.6687

C1, C2, C3, C4 in index layer could constitute a cusp catastrophe:

$$X_{c1} = C1^{1/2} = (0.2374)^{1/2} = 0.4872$$
$$X_{c2} = C2^{1/3} = (0.5181)^{1/3} = 0.8032 \quad \Rightarrow B1 = (X_{c1} + X_{c2} + X_{c3} + X_{c4})/4 = 0.5726$$
$$X_{c3} = C3^{1/4} = (1)^{1/4} = 1$$
$$X_{c4} = C4^{1/5} = (0)^{1/5} = 0$$

C5, C6, C7, C8 in index layer could constitute a cusp catastrophe:

$$X_{c5} = C5^{1/2} = (0.1270)^{1/2} = 0.3564$$
$$X_{c6} = C6^{1/3} = (0)^{1/3} = 0 \quad \Rightarrow B2 = (X_{c5} + X_{c6} + X_{c7} + X_{c8})/4 = 0.3234$$
$$X_{c7} = C7^{1/4} = (0)^{1/4} = 0$$
$$X_{c8} = C8^{1/5} = (0.7234)^{1/5} = 0.9373$$

C9, C10, C11 in index layer could constitute a swallowtail catastrophe:

$$X_{c9} = C5^{1/2} = (0.7842)^{1/2} = 0.8856$$
$$X_{c10} = C6^{1/3} = (0.3370)^{1/3} = 0.6959 \quad \Rightarrow B3 = (X_{c9} + X_{c10} + X_{c11})/3 = 0.8286$$
$$X_{c11} = C7^{1/4} = (0.6687)^{1/4} = 0.9043$$

B1, B2, B3 in criterion layer could constitute a swallowtail catastrophe:

$$X_{B1} = B1^{1/2} = 0.7567$$
$$X_{B2} = B2^{1/3} = 0.6864 \quad \Rightarrow A = (X_{B1} + X_{B2} + X_{B3})/3 = 0.7991$$
$$X_{B3} = B3^{1/4} = 0.9541$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33133329

Thus, the value of vulnerability to flood of CG is 0.7991 and the rest of townships could be calculated by analogy. The results are shown in *Table 6*.

Table 6. *The values of vulnerability of each evaluation township*

Vulnerability were classified into five magnitudes (micro vulnerability, light vulnerability, medium vulnerability, high vulnerability and severe vulnerability) by natural breakpoint method in ArcGIS (Wu and Li, 2013). The ranges of values for each level were [0.7991, 0.8277], [0.8394, 0.8598], [0.8848, 0.8971], [0.9081, 0.9141], [0.9196, 0.9287], respectively. The spatial distribution of the magnitudes of vulnerability in the study area is shown in *Figure 6*.

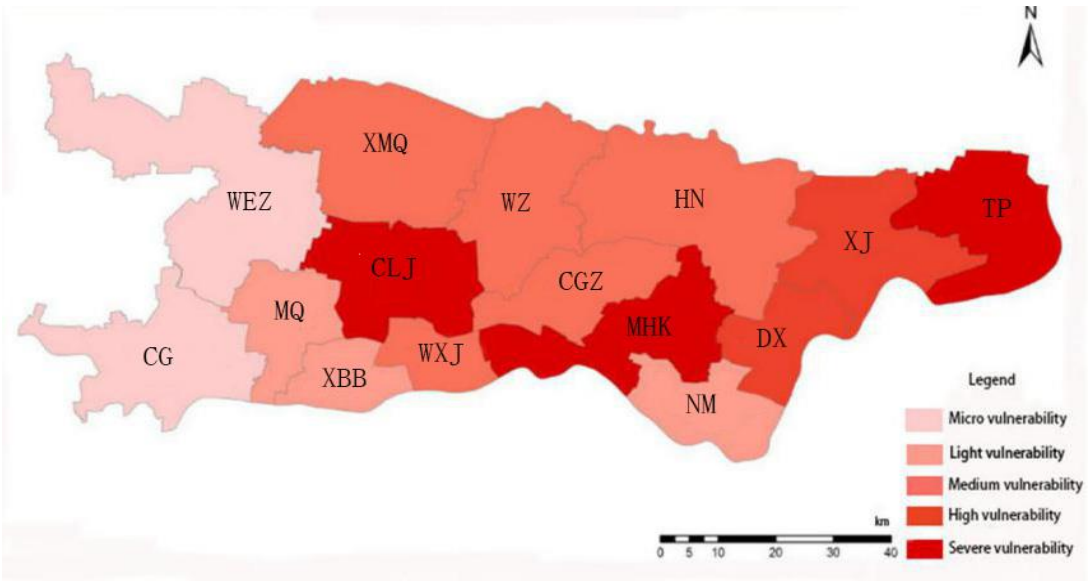

Figure 6. *Spatial distribution of the magnitudes of vulnerability in the study area*

Risk

We standardized the original values of the indicators in flood risk index system (include 13 evaluation indicators and 15 evaluation objects) as the matrix firstly. Through factor analysis, it could be found that the accumulated contribution of variances of the first three factors could reach to 82.78% (close to 85%), so they were extracted as common factors to summarize the information provided by the original indicators. As computed, $C_1/C = 0.6357$; $C_2/C = 0.2057$; $C_3/C = 0.1586$, the comprehensive flood risk score 'S' of each evaluation township is presented in *Table 7*. With the application of hierarchical clustering analysis, the clustering dendrogram of evaluation townships was drawn by MATLAB, as shown in *Figure 7*. Based on *Figure 7*, we classified the flood risk in HHS into 6 magnitudes, as shown in *Table 7*.

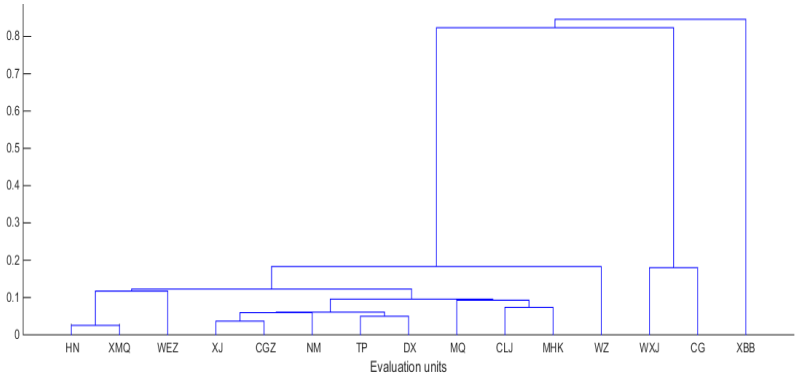

Figure 7. *The clustering dendrogram of evaluation townships*

Table 7. *The comprehensive flood risk score 'S' and the magnitudes of the flood risk of these evaluation townships*

Evaluation township	Comprehensive flood risk score (S)	Vulnerability index value	Magnitude of flood risk
HN	-0.509	0.8951	Low-risk
XJ	-0.326	0.9141	Low-medium-risk
TP	-0.253	0.9270	Low-medium-risk
DX	-0.207	0.9081	Low-medium-risk

Discussion

The results of the research show that the flood risk in most areas of HHS is medium or even higher, which are consistent with the facts (Guo and Zha, 2010; Zhang, 2018; Huang et al., 2011). Huang et al. (2011) demonstrated that the flood disaster prevention and mitigation capacity of areas in the south of the main stream of Huaihe River was relatively low. Most areas of HHS are in medium, high even severe vulnerability which calculated in this article corroborates the study by Huang et al. (2011). The hypothesis used in this study that the flood risk is a combination of the natural hazard and vulnerability which was schematized in an equation: Risk = Hazard × Vulnerability (Wisner et al., 2003; Kubal et al., 2009).

One of the planned extensions to the integrated method is a more comprehensive index system of flood risk assessment, which will inevitably involve more relevant regional indicators inputs associated with, for example, average age of population, type of housing and traffic situation in the region. In theory, the more considerate the indicators are, the more reliable the results become. A further possibility that could be considered for future development of the integrated method is to identify the evaluation units. The present-day results of flood risk are not completely actual because the administrative units (townships) are not the actual space units of flooding influence, thus it is difficult to distinguish the magnitudes of flood risk within a township. To a certain extent, this restricts the applicability of the integrated method in a small region. Besides, in the process of a flood, there is usually more than one breach in the floodplain. Therefore, the flood risk analysis considering multiple breaches is another future research direction to be supplemented and improved.

Conclusions

This paper fully understands the flood risk, considering that when assessing the flood risk for a specific region, we should investigate the flood hazard factors and different vulnerability indicators of the region at risk. In flood hazard analysis, a 1-D and 2-D coupled hydrodynamic model was established through MIKE software and used to simulate the floods with various return periods for obtaining the data of the flood hazard factors, such as inundation depth, inundation duration and flood flow velocity. In vulnerability analysis, according to the vulnerability evaluation index system of the object at flood risk, the catastrophe progression method was used to calculate the index value of vulnerability. Combining the flood hazard factors under the 200-year flood with the vulnerability indicators to flood disasters in HHS, a relatively complete index system of flood risk under the current conditions was established, and the flood risk were classified into 6 magnitudes by the method of factor analysis and hierarchical cluster analysis. The results are as follows:

The values of inundation depth, inundation duration and flood flow velocity of evaluation townships under 50-year, 100-year and 200-year floods in HHS show an increasing trend following the increasing return periods. When faced with the 50-year flood, the maximum inundation depth can reach 3.649 m and the maximum inundation duration can reach about 446 h. When faced with the 100-year flood, the maximum inundation depth can reach 3.879 m and the maximum inundation duration can reach about 456 h. When faced with the 200-year flood, the maximum inundation depth can reach 4.253 m and the maximum inundation duration can reach about 475 h.

DOI: http://dx.doi.org/10.15666/aeer/1802_33133329

According to the spatial distribution map of the magnitudes of vulnerability, vulnerability in most areas of HHS towards flood disasters is high.

Among the 15 townships evaluated, XBB is an extremely high-risk zone, WXJ and CG are the high-risk zones, WZ is the medium-high-risk areas, MQ, CLJ, MHK are the medium-risk zones, while XJ, TP, DX, CGZ, NM are the low-medium-risk zones. HN, XMQ and WEZ are low-risk zones.

(Received 27th Sep 2019; accepted 4th Feb 2020)

Abstract. To analyse the spatial distribution patterns and sources of heavy metals (Cr, Cu, Ni, Zn), 25 road dust samples were collected from a typical industrial area of Wuhan in July 2017. The multivariate statistics, geostatistics, and the field source survey were adopted to study the sources and pollution pattern of studied metals. The results indicated that the concentration distribution of heavy metals was related to dust particle size and pollution source. Cr had high spatial aggregation in QD, could be concentrated easily in 63-150 μm dust, and was discharged by industrial sources. Cu, Zn, and Ni were also enriched in 63-150 μm dust. Cu had high spatial aggregation in less than 45 μm and was derived from building construction sources. Zn and Ni were concentrated in 63-150 μm and originated from traffic sources and building construction sources. Pollution source influenced particle size and the content and distribution pattern of different heavy metals in atmospheric sediments, but the influence had obvious spatial limitations and compound effects.
Keywords: *Moran's I, heavy metal, ArcGIS, PMF, atmospheric sediments*

Introduction

The heavy metal contamination, such as Cr, Ni, Cu, Pb, Zn, and Cd, are high in urban soils and road dust (RD) in developed and industrial cities, and the pollution level of heavy metals in urban RD is usually much higher than that in urban soil (Wei and Yang, 2010; Chen et al., 2011) RD can easily enter the human body through uptake, absorption, and skin absorption, thereby threatening human health. RD also easily affects the urban environment quality through the hydrological cycle and atmospheric circulation. The damage is often hidden, potent, and long-term (Dockery and Pope, 1994; Sadiq et al., 1994; Crosby et al., 2006; Aelion et al., 2008; Wei et al., 2009, 2010; Wei and Yang, 2010; Sun et al., 2014). In China, most of the cities are dusty because a lot of infrastructures and buildings are under construction. Extensive research has been made on the human health risks and environmental ecological risks of heavy metals in urban RD, but the evaluation system of heavy metals in RD remains imperfect compared to soil standards (Soltani et al., 2015; Huang et al., 2016; Jayarathne et al., 2018). Heavy metal contamination in dust has obvious regional characteristics and mutable distribution and is interfered by many complicated pollution sources (Liang et al., 2011; Sun et al., 2014; Li et al., 2015, 2017; Dehghani et al., 2017; Škrbić et al., 2018; Alsubaie et al., 2019). The identification of heavy metal sources of RD is beneficial to risk management and control, and it can provide a theoretical basis for the uniform evaluation of dust pollution.

DOI: http://dx.doi.org/10.15666/aeer/1802_33313347

Sources of heavy metals in RD are always classified into anthropogenic and natural sources. Anthropogenic sources include traffic pollution, industrial activities, and demolition or construction. Natural sources are mainly from secondary blowing dust of adjacent soils in the streets (Amato et al., 2009; Soltani et al., 2015). Heavy metals are greatly affected by different pollution sources (such as Pb, Cu, Zn, As, Mo, Ni, and Ti), industrial sources, and ground dust; Ni is mostly derived from alloy manufacturing; Cd, Hg, Zn, Fe, Ba, Cu, and Pb are mainly from vehicle traffic sources; Zn and Fe always come from multiple tires; Ba, Cu, Fe, Pb, and Zr are mostly derived from brake wear (Christoforidis and Stamatis, 2009; Soltani et al., 2015; Dehghani et al., 2017; Valotto et al., 2018; Urrutia-Goyes et al., 2018). Compared with point source pollution, such as industrial activities and dust removal at demolition or construction sites, traffic pollution has nonpoint source characteristics. Traffic density has a significant impact on RD and heavy metals and has regional characteristics. For instance, the concentration of heavy metals in the dust of Zhengzhou Branch Road is the highest, whereas the secondary trunk road has the lowest concentration. However, no obvious law exists on the concentration of heavy metals in RD of different sizes in Beijing. Among them, Ni, Cu, Zn, Cr, Pb, and Cd are affected by traffic (Shen et al., 2018). The heavy metal content in the dust on both sides of roads decreases exponentially with an increase in distance from highways, and it is affected by traffic flow, vehicle type, terrain and road conditions, green belt configuration, and wind and rainfall conditions (Guo et al., 2008). Pb and Zn often exist in the dust, and the Zn concentration is always high due to traffic pollution (Long et al., 2015). The measurement of traffic pollution always focuses on the division of main and secondary roads. Nevertheless, traffic volume can directly reflect the degree of traffic pollution because of the traffic congestion section and the main roads do not overlap completely in China.

The source identification of RD is complex because of the variation in regional features, the unstable influence of sources, and the unstable characteristics of components. For example, Zn, Cr, and Pb in Shanghai's surface dust are mainly concentrated in particles smaller than 75 μm, followed by 75-150 μm (Wang et al., 2009). Similarly, the heavy metals in the street dust of the old town of Zhenjiang City decrease with particle size, and the heavy metal content shows a highly progressive tendency (Xu et al., 2012). Cu, Pb, Zn, and Cr in the street dust of Xuchang City are remarkably correlated with 50-100 μm coarse silt, whereas Mn and Ni are highly correlated with 10-50 μm fine silt. Nonetheless, their content does not follow grain size. Co has a strong correlation with the component of clay smaller than 10 μm, and its particle size distribution is prominent (Yan et al., 2016).

An interaction occurs between the contamination of heavy metal and the grain size distribution of urban dust. For instance, Cu and Zn in the surface dust of a middle school in the Datong mining area are mainly concentrated in coarse particles, but no significant difference exists in Pd and Cd enrichment at different grain levels (Guo et al., 2013). The heavy metals in the construction site of Guiyang City indicate the largest fine particle enrichment (exceeding 40%) in all areas, whereas the coarse particle enrichment is the lowest (Liu et al., 2017). The particle size distributions of Cd and Cu in Luoyang City are obvious in densely populated areas, and Cd enrichment tends to be fine (75-96 and 75 μm). The mass fraction of Cu in 150-180 μm increases rapidly, and the particle size decreases and peaks at 75 μm. Zn is mainly concentrated in the 150-180 μm particle size in the traffic congestion zone, whereas Pb only has the grain size effect in the industrial zone (Li et al., 2018). However, in the process of rapid urban development in China, many

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33313347

cities have no strict boundary lines in commercial, industrial, residential, and transportation areas. The division of areas is difficult to equate with pollution sources. The effect of particle size of heavy metals in the dust on the study area cannot directly explain the law among pollution sources, particle size, and heavy metal.

From the preceding analysis, this study aims to investigate the sources of RD heavy metals in Qingshan District (QD) in Wuhan City, which is an old industrial area of developed cities. This study analyzes the correlation between heavy metal concentration and particle size of dust by ArcGIS and Moran's index (Moran's I). We discuss the relationship between grain size classification and pollution source and distinguish the main source of heavy metals in dust in the effective particle size range with the positive matrix factorization (PMF)-Environmental Protection Agency (EPA) method. This study reveals the interaction between heavy metal pollution in dust and pollution sources and particle size segments in a typical industrial city area under development and provides important data support and research reference to prevent and control RD heavy metal pollution in industrial cities.

Materials and methods

Study area and sample collection

QD covers an area of nearly 80.47 km^2 and is located in Wuhan City, Hubei Province, China. This old industrial area is built up around the Wuhan Iron and Steel Company, which is the fourth largest enterprise company in the world's steel industry, and has more than 5.4 million inhabitants. QD has a continental climate, with cool winters and hot summers. Winter lasts from mid-December to mid-March with southeast winds, whereas summer lasts from mid-June to mid-September with northwest winds. Twenty-five RD samples were collected by mesh points and expert point method. The sample plot was selected beside the main road, crossroads, and overpass from 25 different locations in QD during the summer (July 2017), as shown in *Fig. 1* and the original data is shown in *Table 1*. The sampling process was completed throughout the day of low wind speed (1.6 m/s-5.5 m/s), within 3 days after several days without any rain. One sample area contained multiple points and a plot area of 1 m width by the distance from the curb to the road centerline was demarcated at each study site to ensure the representative collection of solids distributed across the road surface (Christoforidis and Stamatis, 2009; Urrutia-Goyes et al., 2018; Shen et al., 2018). Plastic brushes were used to sweep RD up into a locked plastic bag. A cotton cloth was used to clean tools after sampling to avoid cross-contamination. Each sample of 500-1000 g of street dust (surface atmospheric sediments on cement road) was separated by a 2000 μm stainless steel sieve using a diagonal line method at a distance of a few centimeters away on the curb. The samples needed sufficient quality (500-1000 g) to classify particle size. Subsequently, the composite samples were thoroughly mixed and air-dried. Approximately 150 g of dust was dispersed in rotary vibration (BZS-200DC) and investigated by the weighing method to characterize the particle size distributions. Samples were sieved into six stages (more than 500, 500-250, 250-150, 150-63, 63-45, and less than 45 μm) as subsamples for the following experiment. These particle size ranges were selected in view of their significance in metal-solid adsorption and health risk characteristics, which can lead to variable contamination levels (Chang et al., 2009; Karmacharya and Shakya, 2012; Shi et al., 2018).

The field source survey

In the data statistics process, we counted the local traffic flow three eight-hour shifts per day, in several sample collecting days. According to the Public Safety Industry Standards of the People's Republic of China, Road Traffic Congestion Degree, and Evaluation Method, we give value to various traffic conditions into 4 levels. In addition, population density (*Appendix Table 1*) is collected by China Statistical Yearbook, industry pollution and construction pollution statistics are from a field visit, both are shown in *Table 1*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33313347

Chemical analysis

Approximately 500 mg of each subsample was weighed with an analytical balance of nominal sensitivity of 0.01 mg and digested by an electric hot plate (5:5:3 nitric acid, hydrofluoric acid, and perchloric acid). All digested samples were then stored in Teflon bottles. The digested and properly diluted samples were analyzed with an atomic absorption spectrophotometer (AAS; ZEEnit-700P). Cu, Cr, Zn, and Ni were analyzed by flame method.

The content of heavy metals used in this study was calculated by *Equation (1)* to eliminate the diversity in dust's content in different particle sizes. In the formula, C_{1i} represents the heavy metal content of one grain-size segment in the dust sample (mg/kg), C_{0i} is the concentration analyzed by the AAS (mg/kg), m_{1i} (g) is the mass of the entire dust sample, m_{2i} (g) is the mass of dust of the grain-size segment, and i represents the sampling points.

$$C_{1i} = C_{0i} \times \frac{m_{2i}}{m_{1i}} \quad \text{(Eq.1)}$$

Receptor models

Moran's I

The global Moran's I method has been widely used to reflect the degree of spatial autocorrelation, spatial agglomeration, and distribution divergence. Moran's I was calculated by the following *Equation (2)*:

$$I = \frac{n\sum_{i=1}^{n}\sum_{j=1}^{n} w_{i,j}(D_i - \bar{D})\,(D_j - \bar{D})}{\sum_{i=1}^{n}\sum_{j=1}^{n} w_{i,j}(D_i - \bar{D})^2} \quad \text{(Eq.2)}$$

where i and j are the ith and jth sampling points, respectively; D represents the concentration of heavy metals; and $W_{i,\,j}$ is a matrix of spatial weights. The global Moran's I value range is [−1, 1]. A positive value indicates the spatial agglomeration distribution, whereas a negative value indicates the spatial divergence distribution. High Moran's I values indicate a strong spatial structure, whereas low Moran's I values indicate weak spatial structure. Zeroes represent random spatial distributions, i.e., no spatial correlation.

PMF

PMF has been applied in the source apportionment of various pollutants in the atmosphere, soil, and dust (Cao et al., 2015; Tian et al., 2018; Lv, 2019). PMF modeling was performed using the US-EPA PMF 5.0 program (Lv, 2019), which is a multivariate factor analysis tool. The initial data matrix X with the order of m × n can be expressed as *Equation (3)*:

$$\mathrm{X} = \mathrm{GF} + \mathrm{E} \quad \text{(Eq.3)}$$

E can be written as *Equation (4)*:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33313347

$$e_{ij} = \sum_{k=1}^{p} g_{ik} f_{kj} - x_{ij} \quad \text{(Eq.4)}$$

where X_{ij} is the concentration of species j measured on sample i, p is the number of factors contributing to samples, g_{ik} is the relative contribution of factor k to sample i, f_{ik} is the concentration of species j in source profile km, and e_{ij} is the error of the PMF model for species j measured on sample i. The values of g_{ik} and f_{kj} are always positive and adjusted until a minimum Q value for a given p is found. The Q value can be expressed as *Equation (5)*:

$$Q = \sum_{i=1}^{n} \sum_{j=1}^{m} \left(\frac{e_{ij}}{u_{ij}} \right)^2 \quad \text{(Eq.5)}$$

where u_{ij} is the uncertainty of the jth species concentration in the ith sample, n is the number of samples, and m is the number of species.

PMF requires the concentration of heavy metals and uncertainty files to run the model. The uncertainty is calculated based on the element-specific method detection limit (MDL), and error percent is measured by standard reference materials. All measured contents are above the MDL; therefore, the equations of uncertainty are adopted as follows:

If the concentration is less than or equal to the MDL used, then the uncertainty (Unc) is calculated using the following *Equation (6)*:

$$U_{nc} = \frac{5}{6} \times MDL \quad \text{(Eq.6)}$$

If the concentration is greater than the MDL used, the uncertainty is calculated by *Equation (7)*:

$$U_{nc} = \sqrt{(ErrorFraction \times concentration)^2 + (0.5 \times MDL)^2} \quad \text{(Eq.7)}$$

Results

Granularity content

The dust of each sampling point is graded and screened. The particle size distribution characteristics of dust are calculated by the gravimetric method, as shown in *Table 2*, which indicates the particle size distribution proportion. MAX/MIN means the weight of the sample in the specific particle size over the total weight in that size, which can characteristics of special points and reduce the error and judgment of the sorting and analysis of individual cases. AVG is the mass of each particle size segment is a percentage of the total dust mass, shown in *Appendix Figure 1.* The particle size distribution is generally not uniform and concentrates in the range of 63-150 (33%), 150-250 (16%), and 250-500 μm (26%). The particle size with range below 45 μm accounts for 1%-14%, particulate matter (PM) = 45-63 μm for 3%-14%, PM = 63-150 μm for 19%-59%,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33313347

PM = 150-250 μm for 10%-27%, PM = 250-500 for 10%-40%, and PM >500 μm for 3%-25% of the total dust at each sampling site. The coefficient of variation increases gradually with the decrease in particle size when it is less than 63 μm. The regularity occurrence suggests that fine particles are vulnerable to local sources; this result is consistent with the study of Xu, who showed that fine particles are enriched in heavy metals (Xu et al., 2012).

Table 2. *Distribution of dust particle size*

Particle size (μm)	AVG (%)	MAX (%)	MIN (%)	SD (%)	CV (%)
>500	11	25 (S11)	0 (S17)	6+-*/*-+	50
250-500	26	41(S17)	13(S14)	7	25
150-250	16	27(S20)	10(S9)	4	27
63-150	33	59(S24)	19(S23)	8	26
45-63	8	14(S24)	2(S23)	3	34
<45	6	14(S8)	0(S19-21)	4	67

Pollution sources

Particle size is a significant parameter which determines the environmental fate and the behavior of dust particles it has been found to be influential on the pollutant concentrations, while overestimation or underestimation would occur with improper strategies (Jayarathne et al., 2018). It is difficult to analysis of pollution sources precisely; the survey records can accurately reflect the current relationship between heavy metals in dust and pollution sources more than just Multivariate statistical analyses.

This study divides the pollution sources in QD into traffic, domestic, industrial, and building pollution sources (still under construction within one week of the sampling time), as shown in *Fig. 2*. The traffic source is considered from the vehicle speed, vehicle quantity, and residence time, and this study selects traffic flow as the index. According to GA115-1995 (Public Safety Industry Standards of the People's Republic of China, Road Traffic Congestion Degree, and Evaluation Method), the traffic pollution source is divided into four levels: speed not less than 30 km/h is defined as smooth level (1#), speed of 20-30 km/h is defined as mild traffic (2#), speed of 10-20 km/h is defined as traffic jam (3#), and speed less than 10 km/h is defined as serious traffic jam (4#). Traffic flow is obtained through collecting, arranging, and analyzing the data of the roads in QD for a long time. The main and secondary roads are highly congested in the northwest. The main roads, road traffic flow, and population density area do not overlap completely.

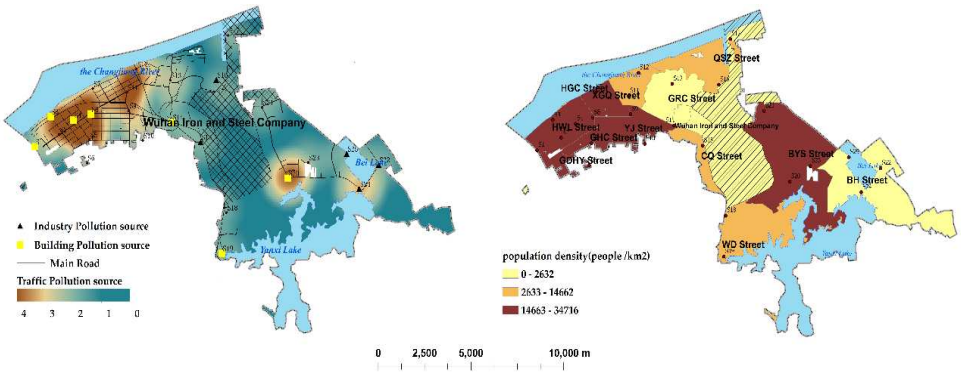

Figure 2. *Distribution of dust pollution sources*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33313347

RD can contribute different PM10 rates in a different city area, the highest contributions were modeled in the commercial/residential district where most of the population live and work (Feng, 2016). The domestic pollution source measured by a population density responds to the frequency of human activities, such as waste disposal and cleaning. In this study, areas with population density between 14663 and 34716 people/km^2 are defined as a high-density zone, those between 2633 and 14662 people/km^2 are considered a medium-density zone (M zone), and those between 0 and 2632 people/km^2 are regarded as a low-density zone (L zone). *Figure 2* shows that most areas of the domestic pollution source overlap onto traffic pollution sources. For example, BH Street is an L zone but a traffic jam area with frequent starts and stops of large engineering vehicles, whereas WD Street is an M zone but a smooth-level area because of remoteness and residents' habit.

The identification of industrial sources mainly includes all existing industrial plants in QD, such as the coking plant and micropower factory. However, the main plant of the Wuhan Iron and Steel Company is excluded because of closed management. Five industrial pollution sources exist around the company. This research identifies the construction sites as building pollution sources at the sampling period. Seven building pollution sources are scattered around Hongwei Street and an important intersection.

Correlation between heavy metal distribution and grain size

The average contents of Cr, Ni, Cu, and Zn are 63.17, 26.49, 38.46, and 517.62 mg/kg, respectively, which are over the corresponding soil background values by 0.73, 0.71, 1.25, and 6.19 times, respectively. According to the background values of soil elements in China, Hubei (China National Environmental Monitoring Centre, 1990), Cr, Ni, Cu, and Zn are 86, 37.3, 30.7, and 83.6 mg/kg, respectively. Zn is the main contaminant. The Cr contaminant ranges are 6.14-191.54, 6.11-45.97, 0.69-37.91, and 0.14-13.89 mg/kg; the Cu contaminant ranges are 4.53-209.02, 6.07-73.49, 0.34-4.19, and 0.13-7.74 mg/kg; the Ni contaminant ranges are 7.4-39.0, 2.18-27.47, 1.15-6.21, and 0.15-9.80 mg/kg; and the Zn contaminant ranges are 131.2-1537, 625.29-744.18, 8.37-133.89, and 1.01-68.35 mg/kg. Cr, Cu, Zn, and Ni are all enriched in 63-150 μm.

The contamination distributions of Cr, Cu, Ni, and Zn in different grain sizes (all sizes, 63-150, 45-63 μm, and <45 μm) are shown in *Fig. 3*, which is drawn by ArcGIS kernel density method. Density calculation is conducted for the heavy metals' concentration data of the sampling points, which form a corresponding raster layer (the obtained data are reduced by 10^5) and present the trend of concentration in the search range. Spatial aggregation is measured by Moran's I model, as shown in *Table 3*. The contamination of Cr, Cu, Ni, and Zn in different grain sizes presents varying distribution trends.

Cr pollution is mainly present in the particle sizes of 63-150 and 45-63 μm (*Fig. 3a*). Various positive correlation distributions are observed in different grain sizes. The distribution in all sizes is close to the cluster tendency gathering in Ganghuacun Street, Hongwei Road Street, and Beihu Street, and the spatial distribution is positive and relevant. The distribution in 63-150 μm is similar to that in the all-size sample but more inclined to the random distribution, and the spatial distribution is positive but irrelevant. The distribution in 45-63 μm also presents cluster tendency but gathers in North Lake, and the spatial distribution is positively correlated and remarkable. The distribution in <45 μm shows cluster gathering in the streets of Hongwei Road, Xingouqiao, and the spatial distribution is positively correlated but unremarkable. Cr is generally concentrated in 45-63 μm, and the spatial aggregation is obvious and greatly affected by the influence of adjacent sources.

Cu in the full-grain segment is distributed in the cluster and is mainly concentrated in Ganghuacun Street, Hongwei Road Street, and Changqian Street, with a P-value of 0.66 (*Fig. 3b*). The distribution is positively correlated but irrelevant. Cluster distribution occurs in <45 μm; Cu is distributed in Ganghuacun Street and Hongwei Road Street, and the spatial distribution is positively correlated and remarkable. The distribution in 45-63 μm is random, and the spatial distribution is positively correlated but not prominent. Cluster distribution is observed in 63-150 μm; it is mainly located in Ganghuacun Street, Hongwei Road Street, and Xingouqiao Street (P = 0.73), and the spatial distribution is correlated positively but not significant. In summary, the spatial distribution of Cu is similar in different particle sizes. Cu accumulates in 63-150 μm, but the spatial distribution is relatively random.

Ni has different correlations in different particle size distributions (*Fig. 3c*). The Ni full-grain size segment is distributed in the cluster and is mainly concentrated in the streets of Hongwei Road and Ganghuacun, with a positively correlated and significant spatial distribution. Ni is clustered in <45 μm and concentrated in Hongwei Road Street with a normal phase but an insignificant spatial distribution. RD of 45-63 μm represents the random distribution, and the spatial distribution is positively correlated but unremarkable. Ni distribution in 63-150 μm is also random, and the spatial distribution is positively correlated and relevant. Ni mainly has accumulated of 63-150 μm, and the degree of aggregation in the particle size segment is high.

The autocorrelation of Zn at different particle sizes is not high, but the difference is obvious (*Fig. 3d*). Zn in all sizes is clustered in Honggangcheng, Xingouqiao, and Hongwei Road streets with an insignificant negative correlation (the area of high concentration is adjacent to the area of low heavy metal concentration). RD distribution in <45 μm is cluster concentrated in Hongwei Road Street, Ganghuacun Street, and Changqian Street, with an insignificant negative correlation as well. The RD distribution in 45-63 μm is random with a significantly positive correlation (the high concentration area is adjacent to the high heavy metal concentration area). The distribution is random in 63-150 μm, and the spatial distribution is positively correlated but insignificant. In general, the heavy metal Zn has a concentration characteristic in 63-150 μm, but the degree of aggregation is high in 45-63 μm.

Zn and Ni generally have a high degree of aggregation in 63-150 μm, but that of Cr is in 45-63 μm, whereas that of Cu is in less than 45 μm. This finding is consistent with several studies; e.g., heavy metals in surface dust are mainly concentrated in particle sizes

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33313347

of 75-150 μm (Shi and Lu, 2018); heavy metals are easily enriched in small particles, especially in the range of 63-75 μm; and Cu, Zn, and Cr are easy to concentrate in coarse silt (63-150 μm) (Chang et al., 2009). The accumulation space is mainly concentrated in the northwest direction of QD (Hongwei Road Street and Gangdu Garden Street), Beihu Street, and Changqian Street. The distribution analysis of pollution sources also shows that the northwest direction is the area where traffic pollution is mainly concentrated, and relatively small industrial factories exist around Beihu Street. Changqian Street is near the Wuhan Iron and Steel Company, which is the largest factory in QD. The particle size of dust and its medium-heavy metal concentration is affected by adjacent sources of pollution. The influence of different heavy metals on varying particle sizes must be clarified. The concentration distribution and concentration level of heavy metals are relatively different, and pollution does not have the pattern of diffusion distribution around the main plant area of the Wuhan Iron and Steel Company. The distribution of heavy metals in urban dust has strong block limitations.

Grain size distribution and pollution sources

The dust at the sampling points of different pollution sources is counted in this study. The distribution of the maximum, minimum, and mean values of different particle fractions are discussed, and the contribution of pollution sources to dust particle size is analyzed. *Figure 4* shows that the average amount of RD greater than 150 μm is above 50%, but heavy metal pollution is mostly concentrated in particles smaller than 150 μm. This condition is referred to as an effective heavy metal-enriched particle size segment. This segment is divided into particle sizes less than 45, 45-63, and 63-150 μm in accordance with the correlation of various metal contamination concentrations and particle sizes in the previous section. Different pollution sources have a spatial overlapping effect. For instance, the high-population-density area always has heavy traffic flow and building sources. By contrast, the industrial area is far away from the above source areas, and the influence of the industrial source on particle size has a high reference value.

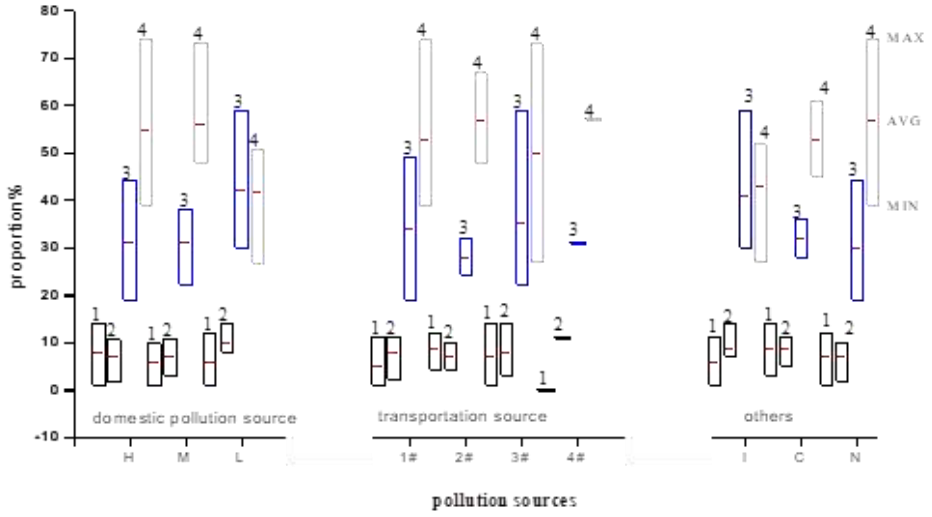

Figure 4. *Map of contribution rate of pollution source to RD particle level (I means the industrial source; C denotes the building source; N indicates no pollution source; and 1, 2, 3, and 4 correspond to particle sizes of <45, 45-63, 63-150, and >150 μm, respectively)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33313347

For particles smaller than 45 and 45-63 μm, the maximum and minimum spans are small and unaffected by various sources. In comparison, high-density populations, low traffic flow, and building sources have a slight advantage in the 45 μm average contribution rate, whereas low-density populations and high traffic flow have a slight advantage in 45-63 μm. The maximum and minimum spans are greatly affected by pollution sources for the 63-150 μm particle size segment. The industrial source mainly contributes to 63-150 μm, and the average value reaches 41%. Particles near other pollution sources are in this particle size segment, and the mean is only 28%-35%.

Heavy metal and pollution source

After PMF analyses of the sources of heavy metals in different particle sizes, the contribution rates of Cr, Cu, Ni, and Zn of domestic pollution, transportation, building, and industrial sources are summarized (*Fig. 5*). Differences in sources of different types of heavy metal pollution in RD in QD are observed. Several studies have found that different heavy metals are greatly affected by different pollution sources; Cu, Cr, As, Mo, Ni, and Ti are affected by industrial sources and ground dust from building operation; whereas Cd, Hg, Zn, Fe, Ba, Cu, and Pb are greatly affected by vehicle traffic sources (Soltani et al., 2015; Dehghani et al., 2017). We analyze the sources at different points.

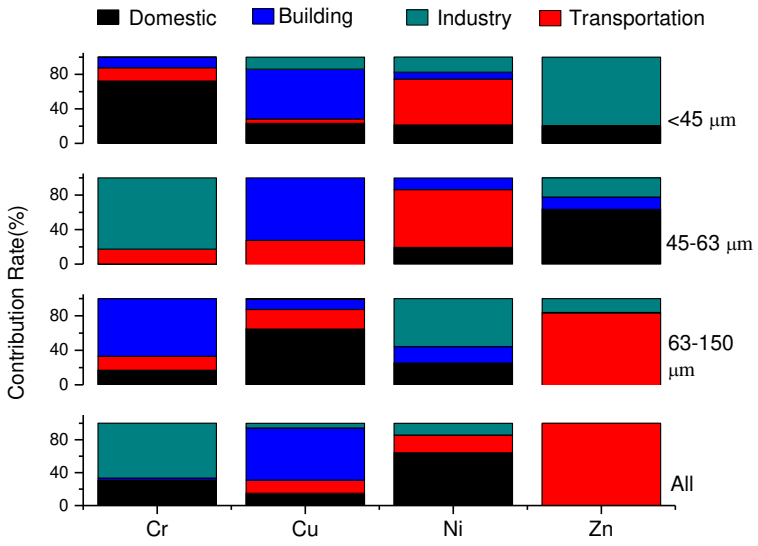

Figure 5. *Correlation diagram of heavy metal concentration and pollution source in characteristic particle size*

Industrial sources are the main sources of Cr and contribute to 45-63 μm dust. Cr is highly attached to 45-63 μm dust, so reducing the formation of 45-63 μm dust is beneficial to the reduction of Cr in urban dust. Traffic sources have the highest contribution to grain-level dust. On-site investigations indicate that large-scale transportation vehicles are frequent in such industrial active areas, with poor road conditions and large dust emission. Control of urban dust Cr pollution can be optimized by regulating pollution sources from car conditions, such as timely sprinklers and control of three waste emissions. Building pollution is the main source of Cu and contributes considerably to dust with a small particle size. The above analysis of construction sources contributes to dust with particle

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33313347

size less than 45 μm. The control of urban Cu pollution can reduce the formation of dust in urban construction. The source of Ni is relatively limited compared with that of Cu, and all four contamination sources have certain contributions. Dust that is less than 63 μm is susceptible to traffic sources, whereas dust larger than 63 μm is susceptible to industrial sources. In contrast to Ni, Zn is highly affected by traffic sources, especially in large particle size segments (greater than 63 μm), and by industrial sources at less than 45 μm. Joint control of industrial and traffic sources can be considered for the formation of Ni and Zn.

Different sources of pollution affect the amount and type of heavy metals, the differences can be observed in the distribution of particle size. The enrichment of heavy metals comes partly from the source discharge process, and other parts are from the process of contact with dust. Therefore, the concentration of heavy metals, pollution sources, and the particle sizes of dust are related. With the source control of different types and sizes of heavy metals in urban RD, dust pollution can be controlled in a targeted manner.

Discussion

Once we determined the sources related to various factors, the source contributions of heavy metals could be easily determined. PMF are widely used for the quantitative analysis of sources of various pollutants in the atmosphere, soil, and dust (Yang et al., 2017; Zhang et al., 2017; Duan et al., 2018; Garaga et al., 2018; Cai et al., 2019; Wang et al., 2019; Zhao et al., 2019). It can be used to calculate the source component spectrum and the contribution rate. Since the uncertainty is added in the calculation, the PMF can be used to solve the weighted factorization to achieve the individual processing of elements and reduce the requirements on the degree of connection between the data, making it suitable for analyzing complex pollution (Dong et al., 2019; Zhang et al., 2019). Khairy et al. found that PMF could afford better source apportionment of pollutants in the atmosphere, soils and sediments than APCS/MLR" (Jain et al., 2018). But The PMF method is unstable when directly used to describe dust sources (Cetin et al., 2018; Hu et al., 2018). The variation mainly stems from the differences in the volume of collected data and in the detection limits of the instruments used (Hu et al., 2018; Men et al., 2019) in this study, the result of the field source survey can match the regularity of PMF.

Conclusion

Our study analyzes the distribution and source of heavy metals in RD from the view of particle size distribution. The contributions of dust in 63-150, 45-63, and <45 μm sections are 33%, 8%, and 6%, respectively. Cr is enriched in 45-63 μm with obvious spatial aggregation; Cu accumulates in 63-150 μm, but the spatial distribution is relatively random; Ni accumulates in 63-150 μm with obvious spatial aggregation, and Zn has a concentration characteristic in 63-150 μm, but the degree of aggregation is higher than that in 45-63 μm. The distribution of these heavy metals has strong limitations and is not only around the main plant area of the Wuhan Iron and Steel Company. It is necessary to add spatiotemporal analysis in the follow-up studies to further discuss this conclusion. The distribution is affected by nearby sources, including traffic, domestic, industrial, and building pollution sources, in this old industrial area. The dominant sources of heavy metals differ in varying particle sizes and heavy metals. The effective size of dust particles

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33313347

must be confirmed for accurate source assessment and effective management of dust pollution. For the PMF model, the number of samples in this paper is relatively small, so it is very necessary to increase the number of analysis samples in subsequent studies.

(Received 7th Oct 2019; accepted 4th Dec 2019)

Abstract. Silicon (Si) application can boost plant growth and physiology under heavy metal toxicity. The article aimed to investigate how the foliar and root application of silicon (Si) affects the uptake, translocation, and concentration of cadmium (Cd) for winter wheat (*Triticum aestivum* L.), and in turn the plant's growth, physiology, and antioxidant enzyme activity, using a complete randomized block design (CRBD)? For this purpose, we used twelve treatments consisting of two levels of Si (0 and 3 mM Na_2SiO_3) against four levels of Cd (0, 50, 100, and 200 µM $CdCl_2$) with three replications. Results showed that all levels of Cd significantly enhanced membrane permeability measured as malonyldialdehyde (MDA) content, osmotic stress measured as hydrogen peroxide (H_2O_2) content, and triggered the enzymatic and non-enzymatic antioxidant system, resulting in a severe reduction in the growth of wheat seedlings. Besides, Si application either as root (SiR3) or foliar spray (SiF3) remarkably encountered Cd toxicity by further improving antioxidative enzymes activities, and by hindering Cd uptake, but more significant results were recorded for SiR3. Therefore, it might be established that Si root supplementation inhibited Cd translocation from root to shoot more effectively than foliar application, thereby lowering the potential health risk of Cd pollution.

Keywords: *enzymatic and non-enzymatic antioxidants, membrane permeability, osmoprotectants, photosynthetic pigments*

Introduction

Wheat (*Triticum aestivum* L.) is the ultimate extensively grown cereal crop which fulfills 20% of the required daily protein for 4.5 billion people in the world (Flister and Galushko, 2016). It is the second most significant food crop in the developing world after rice. The wheat crop has the ability to adapt to various environmental circumstances but, considerable grain yield loss has been reported under heavy metals contamination, predominantly cadmium (Cd) contaminated soils (Rady et al., 2015). Most of the crop production area is under heavy metal stress caused by industrialization, anthropogenic activities, and other agricultural practices, which is currently becoming a worldwide serious threat (Zabin et al., 2015).

Among heavy metals, Cd is a highly lethal element because of its relative mobility, high water solubility, and phytotoxicity (Ali et al., 2011; Wuana and Okieimen, 2011). Due to its dynamic fates, Cd in an ionic form enters into plants through root and being shifted to shoot xylem and phloem through various active transporters and passive transporters (Dong et al., 2019; Takahashi et al., 2012). Higher uptake of Cd reduces photosynthesis by hindering root Fe (III) reductase, affects the activity of the enzyme involved in CO_2 fixation, affects mineral absorption causing a nutritional imbalance (such as N and K^+) and results in stomatal closure (Azevedo et al., 2012). It has been reported that in the intensified oxidative processes occur in cells of Cd-stressed plants which caused the formation of massive amount of reactive oxygen species (ROS) (Balakhnina et al., 2015; Gratão et al., 2005) which caused remarkable reduction of anti-oxidative enzymes activities in plants (Song et al., 2009). Additionally, Cd accumulates in the human body via the food chain, causing kidney, bone, and pulmonary damage (Ali et al., 2014; Fu and Wei, 2013; Li et al., 2014). Thus, developing positive approaches to minimize the potential health risk of heavy metal impurity in food chains is urgent for protecting edible parts of crops being polluted by heavy metals.

To alleviate heavy metals toxicity in plants, various means like soil phytoremediation and soil remediation engineering has been practiced (Rascio and Navari-Izzo, 2011). Although in most cases, these means did not work more effectively, as an alternative and/or accompanied by these means, silicon (Si) as soil or foliar application could be a more effective approach to diminish heavy metals accumulation in plants.

Silicon (Si), as a beneficial element, shows a crucial part in the growth and enlargement of various crops (Keeping, 2017; Zhao et al., 2017). Currently, Si has been conceived by Shi et al. (2014) as a compulsory element for numerous higher plants. However, Si is being proved as useful for plants, and it has the ability to alleviate biotic and abiotic stresses (Dong et al., 2019; Yu et al., 2016; Zhao et al., 2017). Si is the only element that can intake, translocate, and accumulate in considerable quantities in plants without any adverse effects (Ma et al., 2001a). Moreover, Si has been declared as a non-corrosive element (Wang et al., 2016). Consequently, Si, as being high-quality fertilizer may be used for eco-friendly agricultural enhancement.

It has been established in previous findings that Si can improve plant growth by mitigating the adverse influences of heavy metal toxicity (Dong et al., 2019). Numerous scientists have reported that Si treatments detoxify Cd-induced stress in various plants, particularly in graminaceous crops, which are deliberated as Si accumulators (Farooq et al., 2013; Howladar et al., 2018; Keeping, 2017; Zhao et al., 2017). Concerning abiotic stresses, Si counters various stresses, including drought, salinity, and heavy metals toxicity included Cd toxicity in growth medium (Alzahrani et al., 2018). Si, in the form

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33493371

of silicates, converts the exchangeable and the soluble fractions of metals into stable chemicals in soil. Such a decline in metal bioavailability is documented to redox reactions, humification, and precipitation (Vieira da Cunha et al., 2008). Besides, Silicates in soil encourages the polymerization of silicate composts and forms heavy-metals complexes (Sommer et al., 2006). However, evidence suggesting that Si addition improves photosynthetic activity modifies nutrient imbalance, minimizes mineral toxicity, and enhances abiotic tolerance (Ma et al., 2001a). Si maintains photosynthetic activity in Cd-stressed plants, reducing Cd uptake from nutrient solution to plant roots and restricts its translocation from root to shoots, which might be the possible mechanism of Cd detoxification (Kabir et al., 2016a).

Reactive oxygen species (ROS) produced in plants by Cd stress, causing a severe distraction of several metabolic processes in plants (Kim et al., 2017). Different responses have been reported against various environmental stresses within the crop, plant species, and/or cultivars according to their antioxidant defense system (Wael et al., 2015). Optimum ingredients of antioxidants in plants either stimulated and/or constitutive induce more tolerance in plants to oxidative burst (Kusvuran et al., 2016). It has been described by Kim et al. (2017) that Si increased plant tolerance to oxidative damage by regulating a substantial amount of different ROS in heavy metal stressed-plants. These findings can be justified based on Si amounts in plants, which involves improving activities of antioxidative enzymes; particularly those antioxidants which participated in the transformation of H_2O_2 in H_2O, and/or minimizing MDA activity to scavenge negative effects of ROS.

It has been widely studied the protective role of foliar as well as soil application of Si to alleviate the heavy metal toxicity in wheat crops. However, to our best knowledge, this is the first kind of study used Si foliar and root application method in wheat crop to evaluate the most effective Si application method to raise the capability of wheat to tolerate Cd toxicity.

Consequently, the primary aim of the present study was to find the constructive impact of Si in two Si application approaches and to identify the optimum way of Si supplementation for plant physiological traits, chlorophyll contents, anti-oxidative enzymes activities, proline, H_2O_2, and MDA content in Cd-stressed wheat plants grown hydroponically.

Materials and methods

Experimental layout

The experiment was conducted at the experimental site of the Farmland Irrigation Research Institute, Chinese Academy of Agricultural Sciences in Xinxiang City, China. Healthy seeds of winter wheat genotype Xin Mai 23 were immersed overnight in deionized water and sown in pasteurized quartz sand trays with the sand layer of 4 inches in width. The sand dishes were placed in a growing chamber of 16 h light/8 h dark with a light intensity of 375 μmole m^{-2} S^{-1}. The temperature of the growth chamber was set at 28 °C to 30 °C with a relative humidity of 85%. After two weeks of sowing, the five uniform seedlings were enfolded with foam at a root-shoot joint and relocated in each hole (15 in. ×17 in. in size) of plastic sheets fluctuating on 10 L capacity plastic basins. These basins occupied with 8 L modified Hoagland's solution (see *Appendix* heading 1). The pH was adjusted to 6.5 throughout the experiment by using acid (HCl) and base (NaOH). The air pumps were applied to the aerated nutrient solution. During

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33493371

the whole experiment, the nutrient solution was renewed after three days of intervals. After 65 days of transplantation Cd in the form of cadmium chloride ($CdCl_2$) and 3 mM per litter Si in the form of silicates nanoparticles (made by sodium silicate) (see *Appendix* heading 2) were added to nutrient solutions for 15 days to form twelve treatments with three replications as shown in *Table 1*. Si was applied by two different methods; 1) Si root-application (SiR3), 2) Si foliar-application (SiF3). In Si root application, 3 mM Si as silica gel was applied per liter of nutrient solution after every three days during 15 days of treatments. Alternatively, in Si foliar-application, Si with an amount of 3 mmol/L in the form of silica gel was sprayed five times during 15 days of treatment in 100 days experiment.

Two levels of Si (0 & 3 mM) with two methods of Si applications (SiR3 & SiF3) along with four levels of Cd @ 0, 50, 100, and 200 µM

Determination of plant physiological traits

Growth parameters like roots and shoots fresh and dry weights were measured after 100 days of germination. Two plants from each replication were sampled and stored at -80 °C in the freezer (Thermo Fisher Scientific, USA 702) for enzymatic analysis. Remaining plants were detached into root and shoots and were measured for their fresh weights (kept at 70 °C temperatures in the oven till constant dry weight), which were subsequently measured for Si, Cd, K^+, total N, and total protein contents.

Measurements of photosynthetic pigments

Photosynthetic pigments (carotenoids. Chlorophyll a, b, and total chlorophyll) were measured by an ultraviolet-visible spectrophotometer (TU-1810) using the spectrophotometric method of Metzner et al. (1965).

Biochemical analysis

Anti-oxidative enzymes like superoxide dismutase (SOD), catalase (CAT), guaiacol peroxidase (POD), of leaves were analyzed with ultraviolet visible spectrophotometer (TU-1810) by using the kits of Beijing Solarbio Science & Technology Co., Ltd

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33493371

(http://www.solarbio.com). Briefly, 0.5 g weighted fresh samples of leaves were milled with the help of a motor and pestle and standardized in 0.05 M phosphate buffer with pH 7.8 under chilled condition. The standardized mixture was centrifuged at 12,000 rpm for 10 min at 4 °C after sieving through four layers of muslin cloth.

The activity of CAT was measured by the following formula:

$$CAT\left(\frac{\mu}{mgprot}\right)=\left(OD_{Control}-OD_{Test}\right)\times\frac{271}{60}\times\frac{1}{SQ}\times\frac{1}{Protein\,conc.} \quad \text{(Eq.1)}$$

where: SQ = sample quantity, $OD_{control}$ = absorption of light in control, OD_{test} = absorption of light in test samples.

After mixing all reagents in the standardized mixture, the supernatant was again centrifuged at 3500 rpm for 10 min. The light diameter of 1 cm was adjusted to zero by double streaming water. OD was measured at 420 nm wavelength. The activity of POD was measured by the following equation:

$$POD\left(\frac{\mu}{mgprot}\right)=\left(OD_{Test}-OD_{Control}\right)\times\frac{12}{1\text{ cm}}\times\frac{V_t}{SQ\times RT\times Protein\,conc.}\times 1000 \quad \text{(Eq.2)}$$

where: V_t = total volume of the reaction liquid, SQ = sample quantity, RT = reaction time, $OD_{control}$ = absorption of light in control, OD_{test} = absorption of light in test samples.

After mixing all reagents in a standardized mixture, the supernatant was placed at room temperature for 10 min. OD was measured at 550 nm wavelength. The activity of SOD was measured by the following equation:

$$SOD\left(\frac{\mu}{mgprot}\right)=\left(\frac{OD_{control}-OD_{test}}{OD_{Control}}\right)\times\frac{1}{50}\times\frac{V_t}{SQ\times Protein\,conc.} \quad \text{(Eq.3)}$$

where: V_t = total volume of the reaction liquid, SQ = sample quantity, $OD_{control}$ = absorption of light in control, OD_{test} = absorption of light in test samples.

The level of lipid peroxidation in the leaf tissue was assessed by measuring the contents of malondialdehyde (MDA, a by-product of lipid peroxidation. Briefly, 0.2-0.5 g weighted fresh samples of leaves were milled with the help of a motor and added 2 ml 10% TCA and a small amount of quartz sand, ground to homogenate, add 3 ml TCA, further ground. The homogenized sample was centrifuged at 12000 rpm for 10 min. Took 2 ml supernatant, added 0.67% TBA, mixed and boiled for 15 min in 100 °C water bath. Cooled the sample at room temperature and centrifuged again. Absorption values of samples were measured at 532 nm, 600 nm, and 450 nm, respectively. The activity of MDA was measured by the following formula:

$$CMDA=6.45\left(A532-A600\right)-0.56\times A450 \quad \text{(Eq.4)}$$

$$MDA\left(\frac{\mu mol}{g}\right)=CMDA\times\left(\frac{V_t}{SQ\times 1000}\right) \quad \text{(Eq.5)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33493371

where: V_t = total volume of the reaction liquid, SQ = sample quantity.

Proline was also assessed by using the kit of Beijing Solarbio Science & Technology Co., Ltd. Following formula was used to measure the proline contents:

$$Proline\left(\frac{\mu g}{g}\right)=\left(\frac{OD_{sample}-OD_{blank}}{OD_{st}-OD_{blank}}\right)\times C_{st}\frac{5\mu g}{ml}\times\frac{V_{reagent}}{M_{tissue}}\times COD \quad \text{(Eq.6)}$$

where: CoD = the coefficient of dilution in the pre-treatment process, C_{st} = concentration of standard, OD_{st} = absorption of standard sample.

Hydrogen peroxide levels in leaves of wheat plants were assessed by Sergiev et al. (1997) method (see *Appendix* heading 4).

Translocation and bioaccumulation factors

Cd translocation from shoot to root measured and calculated using the following equation:

$$TF=\left(\frac{C_{shoot}}{C_{root}}\right) \quad \text{(Eq.7)}$$

where C_{shoot} and C_{root} are the concentration of Cd in shoot and root, respectively. TF > 1 showed that metals effectively transported from root to shoot (Zhang et al., 2002).

The bioaccumulation factor (BAF) was calculated using the following equation:

$$BAF=\left(\frac{C_{shoot}}{C_{water}}\right) \quad \text{(Eq.8)}$$

where C_{shoot} and C_{water} presented Cd concentration in shoot and water, respectively. BAF was categorizing further as hyperaccumulators samples, which accumulated metals > 1 mg kg^{-1}, accumulator, and excluder samples, which accumulated metals < 1 mg kg^{-1}(Ma et al., 2001b).

Determination of nutrient elements in plant tissues

The N, K^+, Cd, and Si content in the plants were analyzed by inductively coupled plasma mass spectroscopy (ICP-MS, Agilent, and 7700 X, USA) after being oven-dried by following our previous study method (see *Appendix* heading 3) (Fırat et al., 2017).

Statistical analysis

The data were processed and analyzed using the SPSS 21.0 (SPSS, Chicago, IL), and all the graphs were made using the Sigma plot 12.5 software packages. The means of the three replicates were subjected to analysis of variance (two-way ANOVA), and multiple comparisons were performed using Duncan's multiple range test (DMR) at $P < 0.05$.

Results

Cadmium attenuates growth parameters

Cadmium (Cd) caused a significant decrease in plant biomass without Si application (*Fig. 1*). Plant biomass in Cd50, Cd100, and Cd200 was decreased by 42%, 49%, and 68%, respectively, than that of the control plants. However, significantly higher biomass (root and shoot fresh weight) was recorded in Si treatments of combined SiR3 and SiF3 (*Fig. 1*). Plant biomass was increased, 71%, 62%, and 119% respectively, in SiR + Cd50, SiR + Cd100, and SiR + Cd200 than that of the Cd50, Cd100 and Cd200. While, in SiF + Cd50, SiF + Cd100, and SiF + Cd200 was increased, 45%, 40%, and 101%, respectively, than that of Cd50, Cd100, and Cd200. The maximum increase in plant biomass recorded in SiR3 while; minimum plant biomass was recorded in Cd200 than control (*Fig. 1*). Results showed that the overall SiR3 application performed well as compared to SiF3. Results showed that plant biomass in SiR3, SiR + Cd50, SiR + Cd100, and SiR + Cd200 was 10%, 18%, 15%, and 9%, respectively than that of SiF3, SiF + Cd50, SiF + Cd100, and SiF + Cd200. Si concentration was found positively correlated with plant growth parameters (*Fig. 2*).

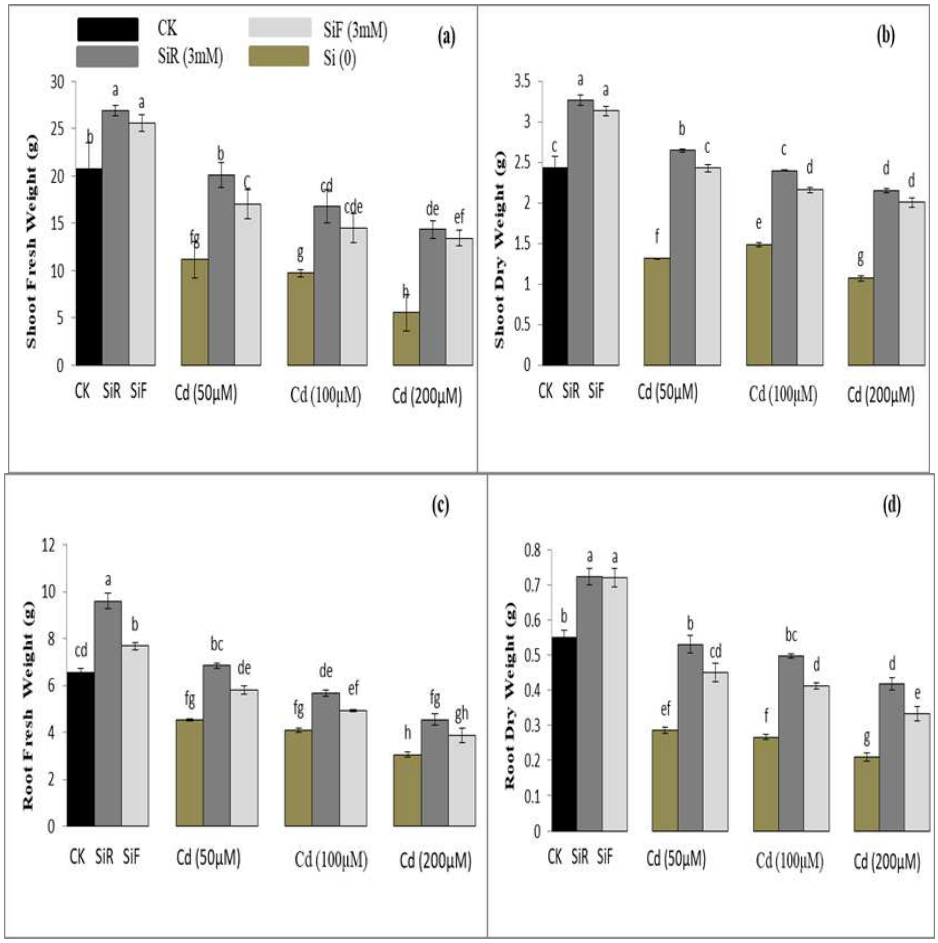

Figure 1. *The effects of silicon application (0, 3 mM) on shoot fresh weight (a), shoot dry weight (b), root fresh weight (c) and root dry weight (d) of the wheat plant grown under 0, 50, 100 and 200 µM Cd containing nutrient solution. Means ± SD (n = 3) with different letters in column indicates significant ($p \leq 0.05$) differences between treatments using Duncan's multiple range test (DMR)*

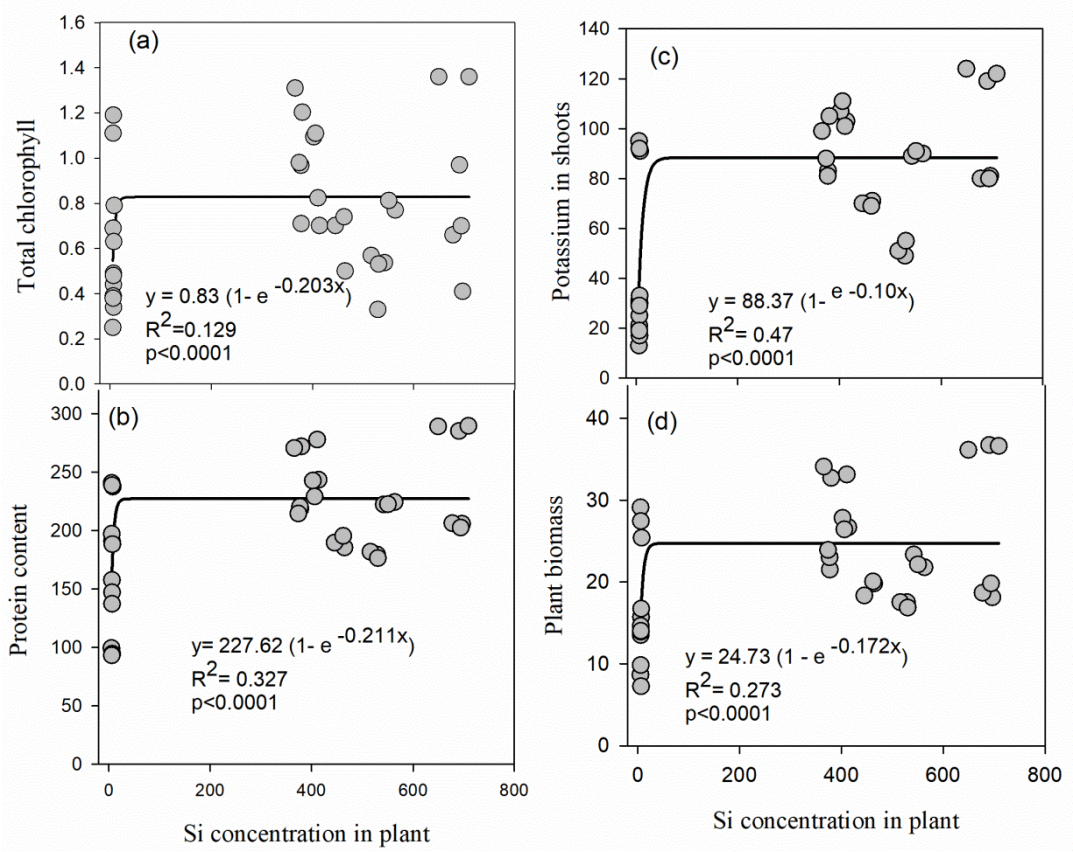

Figure 2. *Relationships among Si concentration in plants with (a) total chlorophyll content (b) protein content (c) potassium in plant and (d) plant biomass*

Cadmium attenuates the photosynthetic pigments

Cadmium (Cd) stress triggered a significant ($p < 0.05$) decline in carotenoids and total chlorophyll contents in wheat plants relative to control (*Table 2*). Total chlorophyll content in Cd50, Cd100, and Cd200 was decreased by 38%, 55%, and 71% respectively, as compared to control. Similarly, carotenoids contents in Cd50 were only 38%, while in Cd100 were 54% and in Cd200 were 71% compared to the control (*Table 2*). In the absence of Cd, Si treatment as SiF3 and SiR3 significantly ($p < 0.05$) elevated carotenoids and total chlorophyll contents. For instance, total chlorophyll contents in SiR + Cd50 were 34% that of Cd50, while, in SiR + Cd100 were 30% that of Cd100 and in SiR + Cd200 were 123% that of the Cd200. Correlation analysis was done between the means of the total concentration of Si in plant and total chlorophyll content, which showed a significantly ($p < 0.05$) positive correlation (*Fig. 2*). Similarly, carotenoids contents in SiR + Cd50 were 67% higher than Cd50, while, in SiR + Cd100 were 69% higher than Cd100 and in SiR + Cd200 were 83% higher than Cd200, respectively. Moreover, total chlorophyll contents in SiF + Cd50 were 43% higher than Cd50, while in SiF + Cd100 were 58% higher than Cd100 and in SiF + Cd200 were 90% higher than Cd200 respectively. Furthermore, the significant increase in total chlorophyll contents observed in SiF3 as compared to SiR3. For instance, total chlorophyll contents in SiF + Cd50 were 6% higher than SiR + Cd50, while in SiF + Cd100 were 18% higher than SiR + Cd100, and in SiF + Cd200 were 17% higher than

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33493371

SiR + Cd200 respectively. Contradictory results recorded in carotenoids content like maximum carotenoids contents observed in SiR3 than SiF3. Carotenoids contents in SiR + Cd50 were 29% higher than SiF + Cd50, while in SiR + Cd100 were 146% higher than SiF + Cd100, and in SiR + Cd200 were 66% higher than SiF + Cd200, respectively (*Table 2*).

Cadmium accumulation in the wheat plant

Results showed that Cd content significantly enhanced when plants received Cd stress relative to control. Silicon (3 mM) addition as SiR3 and SiF3 significantly reduced Cd concentration in all parts of the plant, and the effect was more significant in SiR3 than SiF3. Moreover, results exhibited that Cd concentration in SiR + Cd50 was 25% less than SiF + Cd50, while in SiR + Cd100 was 25% less than SiF + Cd100, and SiR + Cd200 was 32% less than SiF + Cd200 in shoot (*Table 2*). Whereas, Cd concentration in SiR + Cd50 was 27% higher than SiF + Cd50, while SiR + Cd100 was 10% higher than SiF + Cd100, and SiR + Cd200 was 21% higher than SiF + Cd200 in root (*Table 3*). Both Si treatments minimized Cd accumulation significantly, but SiR3 bound more Cd in root cells and restricted its translocation from root to shoot and detoxify its deleterious effects more efficiently than Si foliar-application (*Table 3*).

Silicon attenuates translocation factor and bioaccumulation factor of Cd

Results showed that a significant ($p < 0.05$) positive correlation was recorded between Cd concentration and translocation factor (TF) (*Table 4*), which means Cd translocation factor increased with the rise of Cd levels in the nutrient solution. While Si application as SiR3 and SiF3 both minimized Cd translocation from root to shoot, but more significant results observed in case of SiR3. TF of Cd in SiR + Cd50 was 41% less than SiF + Cd50, while in SiR + Cd100 was 32% less than SiF + Cd100, and in SiR + Cd200 was 33% less than SiF + Cd200, respectively. Moreover, in both SiR3 and SiF3, TF < 1 showed Cd incompetently transport from root to shoot in a wheat plant in the presence of Si. In the case of Cd, bioaccumulation factor recorded data showed significantly ($p < 0.05$) negative correlation between BAF of Cd and Cd existence in the nutrient solution (*Table 5*). Silicon both applications SiR3 or SiF3 showed a significantly negative correlation with both Cd bioaccumulation and translocation factors (*Fig. 4*). Moreover, Si treatments as SiR3 and SiF3 along with Cd (50, 100, and 200 µM) further minimized BAF of Cd, but results were more significant in SiR3 as compared to SiF3. For instance, BAF of Cd in SiR + Cd50 was 26% less than SiF + Cd50, while in SiR + Cd100 was 25% less than SiF + Cd100, and in SiR + Cd200 was 33% less than F3 + Cd200 respectively (*Table 4*).

Table 4. *Effect of different application methods as well as levels of Si on Cd translocation and bioaccumulation factors*

Treatments	Translocation factor (%)	Bioaccumulation factor (%)
Ck	0.007 ± 0.003^{f}	0 ± 0^{g}
SiR 3 mM	0.004 ± 0.012^{f}	0 ± 0^{g}
SiF 3 mM	0.05 ± 0.025^{f}	0 ± 0^{g}
Cd 50 µM	0.65 ± 0.011^{a}	0.121 ± 0.0007^{a}
SiR3 + Cd50	0.27 ± 0.003^{e}	0.025 ± 0.0003^{e}
SiF3 + Cd50	0.47 ± 0.001^{c}	0.034 ± 0.001^{d}

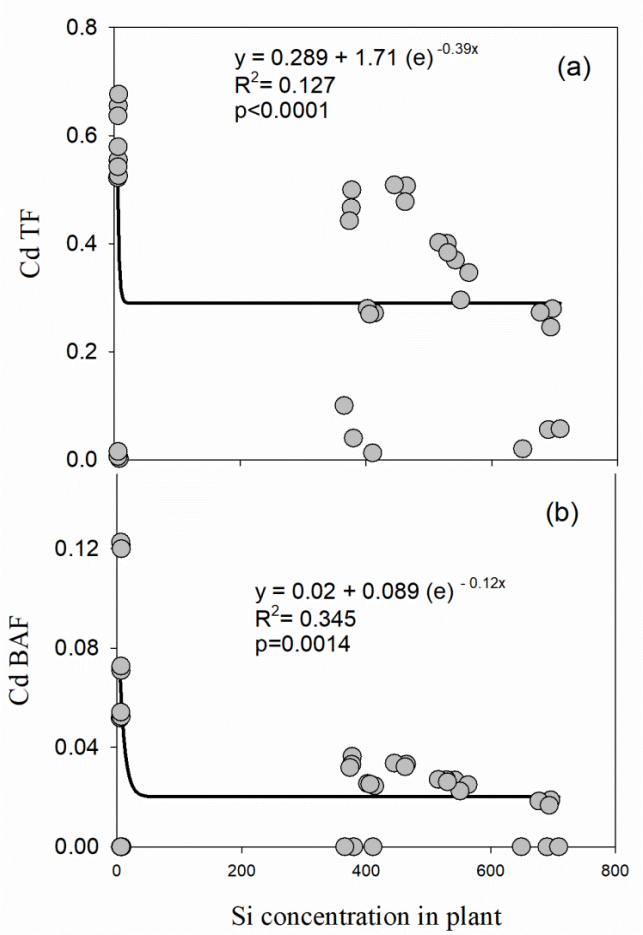

Figure 4. *The relationship among Si concentration in the plant, cadmium translocation factor (Cd TF), and cadmium bioaccumulation factor (Cd BAF)*

Silicon accumulation under cadmium toxicity

Silicon concentration was significantly ($p < 0.05$) increased when plants exposed to Si treatments as SiF3 and SiR3 relative to the control. Si concentration in SiF3 application was higher in shoots as compared to SiR3 application. For instance, Si concentration in SiF + Cd50 was 62% higher than in the SiR + Cd50, while, in SiF + Cd100 was 33% higher than in the SiR + Cd100, and in SiF + Cd200 was 31% higher than in the SiR + Cd200 respectively. While in SiR3 application, Si concentration in SiR3 was higher in root than shoot as compared to SiF3 application. For instance, our results showed that, Si concentration in SiR + Cd50 was 70% higher than in the SiF + Cd50, while, in SiR + Cd100 was 129% higher than in the SiF + Cd100, and in SiR + Cd200 was 189% higher than in the SiF + Cd200 respectively in root. The recorded data showed that Si concentration increased with the increase in Cd levels (*Table 3*). Si accumulation in root was more significant in SiR3 as relatively SiF3 while, Si accumulation in the shoot was more significant in SiF3 as relatively SiR3 (*Table 3*).

Cadmium enhances reactive oxygen species (ROS)

A significantly higher concentration of H_2O_2 and MDA in the shoot was recorded in Cd-treated plants than control (*Fig. 3b*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33493371

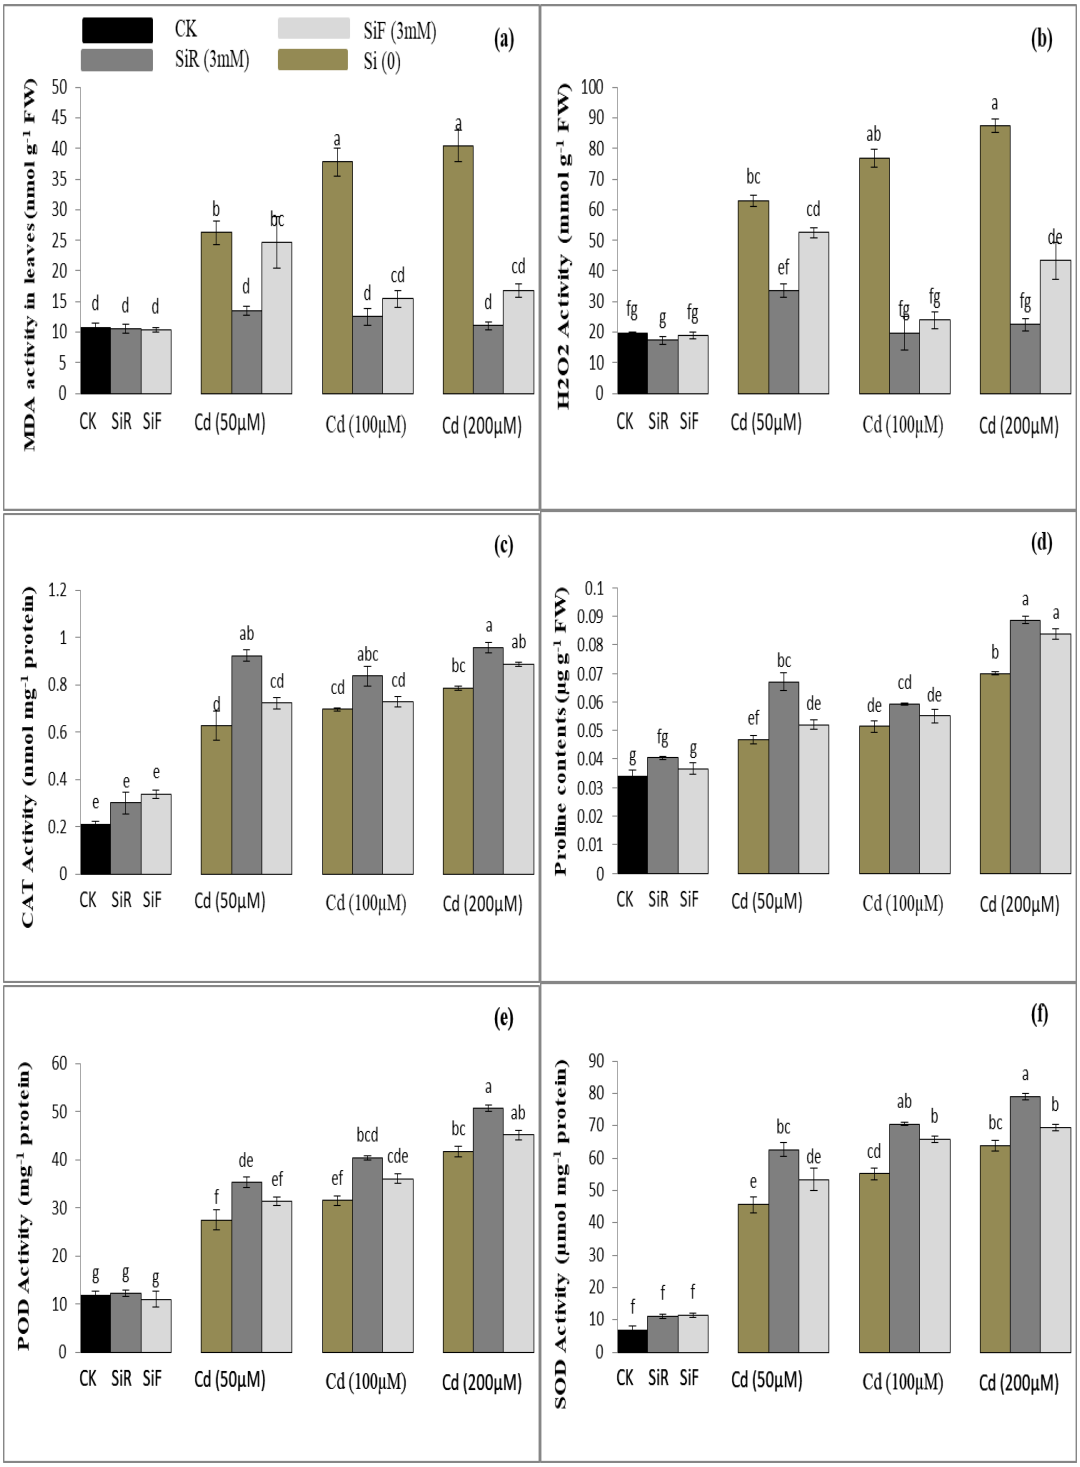

Figure 3. *The effects of silicon application (0, 3 mM) on reactive oxygen species (ROS) activity i.e. MDA (a), H_2O_2 (b), and antioxidative enzymes activity i.e. CAT (c), proline (d), POD (e) and SOD (f) of the wheat plant grown under 0, 50, 100 and 200 µM Cd containing nutrient solution. Bars show S.E. of three replications, the different letter above column within CAT, SOD, POD, MDA, H_2O_2, and proline represents a significant difference at $P < 0.05$ by using Duncan's multiple range test (DMR)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33493371

For instance, H_2O_2 concentration was 219% higher in Cd50, was 290% higher in Cd100, and was 343% higher in Cd200 than in control, respectively. Si application as SiR3 and SiF3 significantly ($P < 0.05$) decreased the concentration of H_2O_2 in shoots (*Fig. 3b*), but SiR3 proved more effective than SiF3. For instance, H_2O_2 concentration in SiR3 + Cd50 was 36% lower than in the SiF3 + Cd50, while in SiR + Cd100 was 17% lower than in SiF + Cd100, and in the SiR + Cd200 was 48% lower than in the SiF + Cd200 respectively (*Fig. 3*b). The same trend recorded in MDA contents. MDA concentration was significantly high in Cd-treated shoots as being compared to control. For instance, MDA concentration was, respectively, 144%, 251%, and 276% in Cd50, Cd100, and Cd200 that of the control (*Fig. 3a*). Added Si as SiR3 and SiF3 significantly lower MDA concentration in shoots of wheat plants at all Cd supply levels (*Fig. 3a*), but the maximum decreased in MDA concentration was noted in SiR3-treated plants along with or without Cd50, Cd100, and Cd200 as compared to all other treatments. For instance, MDA concentration was 45%, 18%, and 34% lower in SiR + Cd50, SiR + Cd100, and SiR + Cd200 that of the SiF + Cd50, SiF + Cd100, and SiF + Cd200 respectively (*Fig. 3a*).

Cadmium meliorates enzymatic and non-enzymatic antioxidants in wheat seedlings

A significant elevation was recorded in enzymatic (superoxide dismutase; SOD, peroxidase; POD and catalase; CAT) and non-enzymatic (proline) antioxidants concentration in Cd-treated plants as being compared to control. For instance, SOD activity was, 568%, 708%, 835% higher respectively, POD activity was 133%, 166%, 253% higher respectively, CAT activity was 198%, 231%, 275% higher respectively, and proline concentration was 37%, 51%, 106% higher in Cd50, Cd100, and Cd200 that of the control (*Fig. 3c, d, e, f*). Added Si as SiF3 and SiR3 further elevated SOD, POD, CAT, and proline activities significantly with or without Cd50, Cd100, and Cd200. Overall, SiR3 alone, as well as with Cd50, Cd100, and Cd200 performed well to boost up SOD, POD, CAT, and proline activities as compared to SiF3, but the difference was not significant. For instance, POD activity in SiR3 along with Cd (50, 100 and 200 µmol/L) was 31%, 36%, 45% respectively, SOD activity was 17%, 7%, and 14% higher, CAT activity was 27%, 15%, and 8% higher, and proline concentration was 28%, 8%, and 6% higher than that of higher than of SiF3 along with same levels of Cd (*Fig. 3*).

Cadmium attenuate essential nutrients in wheat

A significant decreasing trend was recorded in K^+ and N concentration in Cd-stressed plants than that of control (*Table 5*). For instance, K^+ and N concentration was, 66% and 73%, 82% and 19%, 38%, 59% respectively, in Cd50, Cd100, and Cd200 that of the control. Added Si as SiF3 and SiR3 alone, as well as with Cd50, Cd100, and Cd200, significantly increased K^+ and N concentration in the shoot of the wheat plant (*Table 5*). The maximum increase in results recorded in case of SiR3 compared to SiF3. For instance, K^+ and N concentration in shoot was, respectively, 27%, 28%, 55% and 24%, 51%, 113% higher in SiR + Cd50, SiR + Cd100, and SiR + Cd200 that of the SiF + Cd50, SiF + Cd100, and SiF + Cd200. Total Si concentration in plant showed a strong affirmative association with K^+ concentration in shoots of wheat plants (*Fig. 2*). With the increase of Si concentration from 0 to 3 mM significantly increased K^+ concentration from 16 mg g^-1 to 107 mg g^{-1} (*Table 5*).

Discussion

Plants exposed to several biotic and abiotic stressors in different agriculture systems. Abiotic stressors like heavy metals stress, restrict plant biomass, and limit its yield. In present findings, Cd existence in nutrient solution at the concentration of 50 µM, 100 µM, and 200 µM severely decreased wheat plant growth (*Fig. 1*), silicon (Si) contents (*Table 2*), chlorophyll contents (*Table 2*), potassium (K^+) and nitrogen (N) contents (*Table 5*), while it significantly increased Cd content (*Table 3*), Cd translocation and bioaccumulation factors (*Table 4*), lipid peroxidation measured as malondialdehyde (MDA) content (*Fig. 3*), enzymatic and non-enzymatic antioxidative contents (*Fig. 3*). However, Si application either as root or foliar method at a level of 3 mM encountered the negativity of cadmium toxicity in wheat plants by further elevating of enzymatic and non-enzymatic antioxidative contents, reducing Cd, MDA, and H_2O_2 contents, resulting in high plant growth. These findings are consistent with Farooq et al. (2013), Howladar et al. (2018), Silva et al. (2017), Alzahrani et al. (2018), Wang et al. (2016), and Rady et al. (2015). The dominant and diverse thing in the current findings that two separate methods of Si supplementation (e.g., foliar spray, root treatment) were tested and the optimum results were attained with Si root application.

Results of the present study demonstrated that Cd stress interrupted several biological, chemical, and metabolic processes in various plant species (Kim et al., 2014; Shi et al., 2010; Zhang et al., 2014; Zhao et al., 2017). Foyer and Noctor (2005) has been identified Cd as a disruptor of antioxidant defense system by overproducing oxidative burst and reactive oxygen species (ROS), which enhances lipid peroxidation by MDA contents (Howladar et al., 2018). Cd accumulation gradually increased in plant various parts with preference of root, with the rise of Cd levels in growth medium. Our data showed that higher Cd accumulation in root than shoot of wheat plants. Plants take up lower amount of metal solution in upper ground part in any event with highest tolerance (Yang et al., 2004). In this study, Cd stress generated high levels of ROS,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33493371

which indicated by severing reduction of photosynthetic gas exchange parameters in leaf, and significant elevations in MDA and H_2O_2 contents. Therefore, to meet these adverse conditions, plants are grown under Cd-induced oxidative damage to develop complex antioxidant systems (Dixit et al., 2001; Farooq et al., 2013; Howladar et al., 2018).

Silicon as a high-quality non-corrosive fertilizer enhanced plant existence against Cd toxicity by significantly interrupted uptake and/or accumulation of Cd in Cd-toxic plants (Farooq et al., 2013; Song et al., 2009; Wang et al., 2016; Zhao et al., 2017). The constructive effects of Si on plant physio-biochemical traits under various environmental stresses have been well documented (Hashemi et al., 2010). Previous researchers with different findings (Ali et al., 2013; Kabir et al., 2016b; Shi et al., 2005; Song et al., 2009; Zhao et al., 2017) have suggested optimum methods by which Si can enhance plant tolerance against abiotic stresses including Cd that considered the most critical toxic elements, causing limited crop yield in both arid and semiarid regions. The researchers have been conducting various studies to establish Si beneficial effects on the development and yield of wheat cultivars under Cd toxicity. In our present study, Si found effective fertilizer in demolishing Cd toxicity in the wheat plant. The growth traits were significantly elevated in stressed-plants to normal with Si supplementation. Si causes nutritional balance and increases dry matter production of plants while applied in suitable dose (Silva et al., 2017). According to the results of the present study, nutrient medium receiving Si or plants received Si as foliar spray increased growth of stress wheat plants. This upgrading in wheat growth may be recognized to that Si improved photosynthetic rate that is correlated to activity of ribulose biphosphate carboxylase, leaf ultrastructure, and leaf chlorophyll contents (Hamayun et al., 2010).

Oxidative damage generally caused in plants due to ROS, e.g., superoxide radical, H_2O_2, and hydroxyl radical (OH^{-1}) (Shahid et al., 2014; Tamás et al., 2017). Along with the overproduction of ROS, membrane permeability with lipid peroxidation is also the main mechanism in higher plants due to Cd exposure (Farooq et al., 2013). MDA, as a derivative of lipid peroxidation, destabilized cell membrane integrity, and higher the risk of its permeability in various crops (Moussa, 2006; Soylemezoglu et al., 2009). In our findings, Si supplementation significantly lowers the malondialdehyde (MDA) contents in Cd-stressed wheat plants, resulting in sustain cell membranes integrity and reduce their permeability in Cd stress. Plants have various enzymatic (CAT, SOD, and POD) and non-enzymatic (proline) antioxidant defense systems to control different productions of ROS. Among these protective defense systems, the fusion of osmolytes/osmoprotectants is one of the integral protective mechanisms of plants grown in stress conditions (Rios et al., 2017). Proline as osmoprotectants protects plant cells by neutralizing osmotic strength of external environment and the cytosol and vacuole osmotic strengths under salt stress (Gadallah, 1999).

Furthermore, proline, as an impotent osmolyte accumulated in response to osmotic stress, contributes to osmotic adjustments in plant cells (Gadallah, 1999). Proline contents scavenge free radicals of oxidative stress molecules, stabilizes protein and sub-cellular structures under Cd stress (Sharma and Dubey, 2005). As an optimum Si application method, Si root-application improved proline accumulation in wheat plants to increase plant chances to withstand under oxidative stress induced by Cd (*Fig. 3*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33493371

Enzymatic antioxidants included catalase (CAT), superoxide dismutase (SOD), peroxidase (POD), etc. is another defense system in various stresses including Cd (Şen, 2012). In the current study, enzymatic antioxidant activities were higher with Cd-induced oxidative stress and were further improved with Si supplementation with the preference of Si root-application. Cd-induced oxidative stress resulted superoxide radicals that were transformed into H_2O_2 by SOD. H_2O_2 is a powerful oxidant that is accumulated in plant tissues from SOD canalization reaction and is prohibited by the cycle of ascorbate-glutathione. Except H_2O_2, another lethal oxide is the OH^{-1}, which can combine with all macro-molecules. By assimilating their actions, both CAT and SOD can stop OH^{-1} formation in plant tissues (Kusvuran et al., 2016). It has established in previous findings that Si application elevated CAT and SOD (Howladar et al., 2018). Kabir et al. (2016b) found that addition of Si under stress considerably improved CAT and SOD activities in alfalfa plants. Peroxidases (PODs) due to their role in consuming and scavenging H_2O_2 can modify ROS levels in plants. Compared to SOD and CAT, PODs have high attraction to H_2O_2, though PODs can also produce H_2O_2 by the oxidation of NAD(P)H (Ranieri et al., 2005). Several scientists have reported in their findings that Si application elevated POD activity in plants grown under oxidative stress. In general, Si treatment reduced ROS generation and led to raising enzymatic and non-enzymatic anti-oxidants used to scavenge ROS (Rios et al., 2017). Therefore, Si uses ROS scavenging metabolic pathways more effectively, which makes it able to alleviate Cd-induced oxidative stress at cellular level, which may recover the integrity of cell membranes.

Cd accumulation in shoots and roots of wheat plants followed the same trend as shoots, and roots levels reduced with increasing Si dose as a foliar application. The same results found by previous reports (Treder and Cieslinski, 2005), but our results were conflicted with the finding of several studies that examined decreased shoots Cd concentration with increasing Si levels (Rizwan et al., 2012). Interestingly, contradictory results were obtained in case of Si root application as Cd concentration did not follow the same trend as Cd reduced in all three parts of plants than that of Cd alone treatments. But our consequences were conflicted with the finding of several studies which examined decreased Cd shoots concentration with increasing Si levels (Rizwan et al., 2012). Interestingly, contradictory results were obtained in case of Si root application as Cd concentration did not follow the same trend, i.e., Cd shoot concentrations declined while root concentrations elevated with increasing Si dose. Similar results were also found in durum wheat developed in a soil with aged impurity (Rizwan et al., 2012), rice is grown hydroponically (Shi et al., 2005; Zhang et al., 2008), in peanut and cucumber (Shi et al., 2010) and *Brassica Chinensis* (Song et al., 2009), but our results in case of SiR3 disagreed with authors who found Cd increased in both root and shoot with the increase in Si doses (Vaculík et al., 2009), or a decrease in Cd concentration in both roots and leaves with increase in Si levels (Nwugo and Huerta, 2008). In Si root application, increased Cd concentration in roots could be due to the deposition of Cd in roots and formed metal complexes with silicates as reported by numerous studies. i.e., Zhang et al. (2008) established that Cd usually deposited in the section of roots endodermis and epidermis in rice plants, while, Shi et al. (2010) found that Si often stored in the cell walls of the endodermis and formed metal complexes with silicates. However, in SiF3 application Cd concentration in both roots and shoots was decreased with increasing Si levels, it could be due to Si inhibitory behavior, Si deposited in leaves cells and translocated from leaves to shoot and then roots and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33493371

inhibited Cd translocation through xylem and phloem (Treder and Cieslinski, 2005). In both methods of Si, application plant withstand against Cd toxicity may be attributed due to the improvement of plant tolerance and/or due to uptake and transport of Cd which was also reported by Wang et al. (2016). In our study Cd concentration was high in Cd alone treatments as compared to Cd + Si (*Table 2*) that were conflicted with the findings of various authors who found that the Cd concentration in both roots and shoots was higher in Cd + Si treated plants than alone Cd-treated plants (Prabagar et al., 2011; Ye et al., 2012). Our results showed TF < 1 suggesting that Cd could ineffectively be translocated from root to shoots in case of both SiF3 and SiR3, but more significant effects observed in the case of SiR3 (*Table 5*) which is in line of previous findings (Howladar et al., 2018). In our study Si concentration under Cd stress was significantly increased with Si supplementation (Silva et al., 2017), which clarified that in Si both application methods, Si absorbed by roots should have translocation into shoots, where it deposits in the leaf apoplast as a polymer, forming a crucial barrier to protect plants from various environmental stresses counting Cd stress. Furthermore, Si concentration in plant showed a negative correlation with TF, BAF, and BCF of Cd (*Fig. 4*), which suggests that with the increase of Si concentration in plants, Cd translocation and bioaccumulation will decrease simultaneously. Our results showed that BAF of Cd decreased with the rise of Cd concentration in nutrient solution (*Table 5*) which was in line of previous findings (Zhao et al., 2003) but was contrary with some scientists who found increase in BAF with increase of heavy metal accumulation in soil (Rezvani and Zaefarian, 2011).

Micro and macronutrients play an optimum role in the maintenance of biochemical processes, plant growth, and high plant yield if they are up taken in a controlled way, transported to a long distance, and then correctly utilize. Si application against chromium (Cr) and Cd stress improved the utilization of macro (Ca^{++}, Mg^{++}, and K^{+}) and microelements (Fe and Zn) (Tripathi et al., 2012). Our results showed a strong positive correlation between Si and K^{+} concentration, which means with the increase of Si concentration in solution K^{+} would also be increased simultaneously (*Fig. 4*). Previous studies (Jayakannan et al., 2013) showed that Si application increased K^{+} concentration plants under abiotic stresses. According to our hypothesis, Si might improve K^{+} concentration in stressed-plants by mitigating nutrient imbalance created by Cd-stress. Our study showed that Si and K^{+} have positive effects on the production of ROS in plants under stress conditions (*Table 4*).

Conclusion

In conclusion, the addition of Si has been proved high-quality non-corrosive fertilizer under the hostile conditions of Cd-stressed wheat seedlings as a study herein. Our data demonstrated that Si supplementation, with the preference of root application, significantly improved growth traits by successfully encountered toxic belongings of Cd stress. Si root-application enhanced all recorded parameters such as photosynthetic pigments, enzymatic (CAT, SOD, POD), and non-enzymatic (proline) antioxidants and demolished MDA, H_2O_2, and Cd contents. Si showed the antagonistic effect with Cd concentration in plants and showed synergetic effect with essential nutrients like K and N. After analyzing the recorded data, we can be strongly emphasized that Si supplementation with the preference of root-application must be used as an optimum approach to reduce Cd toxicity in wheat plants.

APPENDIX

1. Recipe of Hoagland's solution

The Hoagland's solution had composition (mg L^{-1}): (NH4)2SO4 48.2, MgSO4 65.9, K2SO4 15.9, KNO3 18.5, Ca (NO3)2 59.9, KH2PO4 24.8, Fe citrate 6.8, MnCl2.4H2O 0.9, ZnSO4.7H2O 0.11, CuSO4.5H2O 0.04, H3BO3 2.9, H2MoO4 0.01.

2. Recipe of Si treatment

Silicon (Si) as a silica nanoparticle prepared from sodium silicate. A measured amount of sodium silicate put into the double amount of boiling deionized distilled water in a petri dish for 10 min. For increasing its solubility, we added a small amount of KOH and further heated for 10 min. Continue stirring with a long-handled spoon and at the end added 2 to 3 drops of H_2O_2. The solution removed from heat stove and allowed it to cool at room temperature. Cooled solution transferred into a plastic bottle and sealed it up. From the prepared stock solution, we made subsolution of 3 mM/L and applied as SiF3 and SiR3. Both treatments Si and Cd were applied after 65 days of transplantation. The twelve treatments were arranged factorially in a randomized complete block design with three replications per treatments. A total number of pots were 36, and each pot contained 15 plants.

3. Recipe to determine nutrient elements in plant tissues

Cd and Si were measured in plant root and shoot dry masses by atomic absorption spectrometry method with some necessary modifications (Fırat et al., 2017). After 35 days of treatments, wheat plants were harvested and washed thoroughly with tap water, distilled water, and then with double distilled water. Plant samples were separated into roots and shoots and dried at 70 °C in the oven for 48 h, and ground into powder. Weighed 0.2 g of dried plant sample was placed into a microwave digestion tube. Added 10 ml of nitric acid and covered every sample with a lid. Later, it was put into the microwave digestion instrument and started to dissolve after selection of an appropriate program. After completion of digestion, tubes were removed and put the digestion solution into the PTFE digestion cup with a small number of repeated flushing. Digestion cups were placed on a hot plate at 220 °C temperature until the removal of 2-3 ml liquid. In the end, the digestion fluid was transferred into the 50 ml volumetric flask and made its volume up to 50 ml with double distilled water. Digestion solution used to measure Cd and Si concentrations in root and shoots by using an atomic absorption spectrophotometer (AAS) model AA-6300 SHIMADZU. The total contents of Cd and Si per plant were calculated from Cd and Si concentration (μg g^{-1}) and meant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33493371

the dry weight of below- and above- ground parts. Total nitrogen was measured in plants by the method of (Brookes et al., 1985) with some modifications. Weighted 0.3 g of plant dry sample in digestion tubes with 4 ml of sulphuric acid was put on the curved stem small funnel into the digestion furnace and initiated to dissolve. The temperature was set to 220 °C for 2 h and boiled till brown, yellow endpoint. First, samples were heated at 380 °C and removed these digestion tubes from digestion furnace. Added 20 drops of hydrogen peroxide (H_2O_2) and samples were placed on hot plate and continue to heat again. This cycle was repeated 2-5 times to clear the digestion solution. At every cycle, the amount of H_2O_2 was decreased. The amount of H_2O_2 added to the blank was consistent with the maximum number of samples. After that, a few amounts of multiple flushing methods were transferred to the 100 ml volumetric flask. In the end, total nitrogen was determined in a solution using flow analyzer-3 of brand BRAN + LUEBBE, and potassium was determined in a solution using flame photometer FP6410.

4. Determination of biochemical parameters
