For MDA measurement, 0.25 g leaf sample was homogenized in 5 ml 0.1% TCA. The homogenate was centrifuged at 10,000 ×g for 10 min. to 1 ml aliquot of the supernatant, 4 ml of 20% TCA containing 0.5% TBA was added. The mixture was heated at 95 °C for 30 min and then quickly cooled in the ice bath. After centrifugation at 10,000 ×g for 10 min, the absorbance of the supernatant at 532 nm was read and the value of the nonspecific absorption at 600 nm was subtract. The MDA content was calculated by using an extinction coefficient of 155 mM^{-1} cm^{-1}. For the measurement of H2O2, we weighted 0.5 g leaf tissues were homogenized in an ice bath with 5 ml 0.1% (W/V) trichloroacetic acid (TCA). The homogenate was centrifuged at 12000 × g for 15 min and 0.5 ml of the supernatant was added to 0.05 ml 10 mM potassium phosphate buffer (pH 7.0) and 1 ml 1 M KI. The absorbency of supernatant was assessed at 390 nm.

Abstract. Salinity is one of the most serious environmental stresses at the irrigated areas that causes problems for the plants and soil. *Kochia scoparia* is an annual plant of the Chenopodiaceae family, which can be a valuable source of forage growth using saline water. Salinity changes many traits and processes, including the amount of chlorophyll a and b, activity of antioxidant enzymes, protein content, and concentration of sodium and potassium in the plant. An experiment was performed with two salinity levels of 100 and 300 mM on *Kochia scoparia*. Among the measured traits, the levels of chlorophyll a, b, peroxidase and catalase specific enzyme activity, and protein content were not affected by salinity. In contrast, this plant limited sodium Influx and the amount entered accumulated in the stem. Also, the study results showed that potassium concentration in this plant significantly increased in the stem. The results of other studies indicate that potassium plays an important role in tolerance to salinity. Therefore, potassium has a function in tolerance to salinity in this plant.
Keywords: *catalase, K/Na ratio, peroxidase, potassium, sodium*

Introduction

In worldwide, the salinity is one of the main factors that cause losses of crop. The human activity including: extractions of oil, industrial waste production, salt usage for road way maintenance and intensive farming activity, are sources of soil salinization. The salinity of soil and freshwater exist in many places. The publication for this issue increased fivefold from 2004 to 2018 (Litalien and Zeeb, 2020).

Soil salinity is the most serious environmental constraint affecting the production of crops, which is estimated to affect 45 million hectares of irrigated lands and is expected to increase due to global climate changes and frequent irrigation operations (Rengasamy, 2010; Munns and Tester, 2008 quoted by Roy et al., 2014).

Kochia scoparia L. Schrad (Common name: burning bush) is an annual plant of the Chenopodiaceae family, tolerant to salinity and drought, which can be a valuable source of forage growth by saline water (Danesh Mesgaran and Stern, 2005; Riasi et al., 2008 quoted by Kafi et al., 2010).

Kochia scoparia exists in wide range of temperatures and climatic regions in the world, but this plant has adapted specifically to arid and semi-arid regions (Friesen et al., 2009 quoted by Casey, 2009). *Kochia* has shown that it is capable of rapid germination, which makes it possible to use the limited moisture content soil in the spring in arid and semi-arid regions (Eberlein and Fore, 1984 quoted by Casey, 2009). The seed germination occurs several times during the growing season, which enables the plant to use the advantage of moisture when available. The seeds of this plant are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33733385

capable to germinate under severe stress conditions, such as lack of moisture, high salt, and high pH (Friesen et al., 2009 quoted by Casey, 2009).

An experiment was done on *Kochia scoparia* at five levels of 100:00, 75:25, 50:50, 25:75, and 00:100 tap water:seawater ratio, respectively. The total dry matter (g $plant^{-1}$) of *kochia* reduces in response to this condition. A trend of decline in linear phase was observed form the highest total dry matter in control plants (100:00) to 75:25, 50:50, 25:75, and 00:100 (the lowest) respectively. Additively, the relative growth rate (RGR, g g^{-1} d^{-1}) and Specific leaf area (SLA, cm^2 g^{-1}) were measured in this study. The RGR between 100:00, 75:25, 50:50 were not significant and between 25:75 and 00:100 it was significant. The SLA trait between 100:00, 25:75, and 00:100 were significant and between of 75:25, 50:50 it was not significant (Lopez-Aguilar et al., 2013).

The salinity effect was investigated on Indian and Sabzevar genotype of *kochia* at salinity of 5, 15, and 20 dS m^{-1}. Results show that salinity reduce yield of seed Sabzevar, although at high salinity levels the yield of seeds was 890 kg ha^{-1} that approximately 80% of yield at 5 dS m^{-1}. The seed production genotype of Indian great decreased with salinity raise (Kafi et al., 2010).

Salinity stress causes many physiological changes in plants, including the followings. According to the study of Agastian et al. (2000), chlorophyll and total carotenoid is significantly reduced by salinity. In tomato leaves, total chlorophyll (Chl-a + b) chlorophyll a and beta-carotene reduced with sodium chloride stress (Khavarinejad and Mostofi, 1998 quoted by Parida and Das, 2005).

With increasing salinity, the leaf protein content of *Bruguiera parviflora* reduced, which indicates that the protein synthesis process may be disturbed, or more probably, proteolytic activity increase (Parida et al., 2002). The soluble protein content in the berries increased under low salinity and reduced in high salinity (Agastian et al., 2000).

Salinity stress causes water deficiency as a result of osmotic effects on a wide range of metabolic activities of plants, and this water deficiency has resulted in oxidative stress due to the formation of reactive oxygen species (ROS) such as superoxides, proxy and hydroxy radicals. The (ROS) are by-products of hyper osmotic and ionic stress that interfere with cell membrane and cell death (Bohnert and Jensen, 1996 quoted by Parida and Das, 2005). With the increase of the formation of (ROS), enzyme activities of detoxification increase in these species (Apel and Hirt, 2004; Foyer and Noctor, 2005; Logan, 2005 quoted by Munns and Tester, 2008). In halophyte *Sesuvium portulacastrum*, antioxidant enzymes such as catalase, peroxidase and polyphenol oxidase increased to 600 mM and reduced slightly at higher levels (Rajaravindran and Natarajan, 2012). Agarwal and Pandey (2004) have been shown that salt treatment increased sodium and chloride ions in *Cassia angustifolia* seedlings and increased the activity of superoxide dismutase, catalase, peroxidase and polyphenol oxidase.

Sodium concentration in rice that was treated with NaCl was significantly higher. Also, potassium concentration was higher in older stems and leaves (Morales et al., 2012). For plants ability to distinguish between sodium and potassium, the K+/Na+ ratio index usage. There are many references for this index that can be determined for plants and their organs (Flowers, 2004). The K+/Na+ ratio in leaves of rice cultivars sensitive to salinity is significantly lower than that of salinity tolerant cultivars (Moradi and Ismail, 2007 quoted by Morales et al., 2012).

Regarding tolerance of *Kochia* to salinity, this study was done to investigate physiological cases mentioned above and to find some aspects of salinity response in this plant.

Materials and methods

Sowing, sampling and experiment design

First, *Kochia* seed was sowed in sand and manure with a ratio of 3:1. Plant growth was carried out under greenhouse conditions (*Fig. 1*). About 3 to 4 weeks after planting, salt treatment at a concentration of 100 mM was performed. Two days after the treatment, samples from the roots, stems and leaves of treated and control plants were harvested in three replicates, and samples were transferred to a freezer at -70 °C. Then, the treatment was performed at a concentration of 300 mM and two days after treatment in three replications of leaves, stems and roots treatment and control plants, sampling was done with the same method as mentioned above. The experiment design which data can be analysis with two samples T-test.The controls for each treatment at 100 and 300 mM were selected separately and sampling was done. The controls for each treatment were selected separately, because environmental condition changed over time.

Figure 1. *Plants sowing in green house condition for salinity stress*

Extraction and measurement of chlorophyll

Wellburn (1994) method with partial modification was done to measure chlorophyll content. For this purpose, 50 mg of the leaf tissue well grinded with methanol in a mortar with pestle, and homogenized tissue was transferred to the microcentrifuge tubes. At the next stage, centrifugation was carried out at 5,000 rpm, the supernatant was transferred to a new tube and diluted with methanol. Using spectrophotometer (Smart Spec™ Plus, Bio-Rad), the absorbance of the resulting solution at wavelengths of 653 and 666 nm was read and chlorophyll a and b values were calculated using the following formulas:

$$Ca = 15.65\ A666 - 7.34\ A653$$

$$Cb = 27.05\ A653 - 11.21\ A666$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33733385

Sodium and potassium measurements

Munns et al. (2010) method with partial modification was used to measure sodium and potassium. The root, stem and leaf samples were dried in an oven at 70 °C for 48 h. The dried samples were then weighed, about 20 mg, and extracted using 1 Normal hydrochloric acid. The solution was thoroughly mixed with up and down movements and placed in a water bath for 45 min at 60 °C. During this period, the falcone is moved up and down to be mixed well with acid. Then, centrifuge was performed for 15 and 5 min at 5,000 rpm. The supernatant was transferred to the 50 ml falcon and the samples were diluted at a ratio of 1:10. Flame photometer model PFP7 (jenway) was used to measure sodium and potassium content.

Extraction of crude extract to measure enzyme activity and protein content

For this purpose, 50 mg of leaf was weighed and using sodium phosphate buffer (at a concentration of 0.1 M and pH = 6.8) based on Kar and Mishra (1976) method a homogenous solution was obtained. At the next stage, centrifugation at 10,000 (g) was carried out for 15 min at 2 °C. The supernatant was transferred to a new tube and kept at -20 °C until usage. At the extraction stage, the samples were kept on ice.

Measuring enzyme activity of peroxidase

The peroxidase enzyme activity was measured according to Mac Adam et al. (1992) method with partial modification. First 2810 µl of sodium phosphate buffer 0.1 M, 40 µl of 30 mM of hydrogen peroxide (H2O2) and 50 µl of Guaiacol solution of 200 mM were added to the 15 ml falcon. Then 100 µl of enzyme extract was added (total volume of the resulting solution was 3 ml). After moving the falcons up and down, the resulting solution was placed at room temperature for 10 min until the formation of tetraguaiacol from guaiacol (color of the solution was orange), and then absorption was read at 470 nm by spectrophotometer.

Measuring enzyme activity of catalase

Catalase activity was done according to Verma and Dubey (2003) procedure with partial modification. For this purpose, first 2840 µL of 0.1 M sodium phosphate buffer, 60 µl of hydrogen peroxide (H2O2) 1 M was added before starting the reaction and 100 µl of enzyme extract was also added. The falcon tube was moved up and down a few times to mix the reaction components and then placed at room temperature for 10 min to decompose hydrogen peroxide and the absorbance was read at 240 nm using spectrophotometer.

Measuring protein content

Protein content was measured according Bradford method (1976) with partial modification. First, a Stock 1 (mg/ml) of bovine serum albumin (BSA) was used to provide standards of protein. Then, using this we prepared series of dilutions of 10, 20, 30, 40, 50, 60, 70, 80, 90 and 100 (µg/ml) in a volume of 500 µl. At the next stage, 100 µl of each of these was mixed with 900 µl of Bradford solution (total volume of 1 ml), and absorption was read at 595 nm after 2 min. The final concentration of standards was 1, 2, 3, 4, 5, 6, 7, 8, 9 and 10 (µg/ml) in 1 ml of total volume.

In order to measure the protein content in extracted samples similar to the standard method. first 100 µl of the extracted solution was mixed with 900 µl of Bradford solution and absorption was read.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33733385

Calculation of specific enzyme activity

In order to calculate the enzyme activity, volume activity was calculated according to *Equation 1* (Bisswanger, 2011, 2014):

$$\text{Volume activity}_{(\mu mol/min/ml)} = \frac{\text{absorption/min} \cdot \text{assay volume} \cdot \text{dilution factor}}{\text{absorption coefficient} \cdot \text{path length} \cdot \text{enzyme volume}} \quad \text{(Eq.1)}$$

Absorption coefficient of tetraguaiacol and H2O2 was 0.036 and 26.6 (mM^{-1}. cm^{-1}), respectively.

Then, the obtained value was used according to *Equation 2* in order to calculate the specific enzyme activity:

$$\text{Specific enzyme activity}_{(\mu mol/min/mg)} = \frac{\text{Volume activity}}{\text{protein concentration}} \quad \text{(Eq.2)}$$

Data analysis

The data obtained from the above were evaluated using software R version 3.2.3 for the normalization of the data. Comparison between control and treatment at 100 mM was done with two samples T-test. Also Comparison between control and treatment at 300 mM was done with two samples T-test. Two samples T-test were analyzed using software SAS 9.1. The correlation coefficients between traits were calculated by Pearson method with the R software. The figures were drawing by R software.

Results

Chlorophyll content

As shown in *Figure 2,* the levels of chlorophyll a and b at 100 mM level were higher in treatment than in control, and their level reduced to less than control with an increase at 300 mM. Of course, their difference was not significant.

Sodium and potassium content

The content of potassium and sodium in the stem, root and leaf is shown in *Figure 3,* which is described in the followings.

The concentration of potassium in the stem at level of 100 and 300 mM in treatment samples is higher than in control samples. These differences are significant at a concentration of 100 mM at $\alpha = 0.05$ and at a concentration of 300 mM at $\alpha = 0.01$.

The content of potassium in the root at treatment level of 100 and 300 mM in treatment samples was higher than in control samples. But these differences were not significant.

The content of potassium in the leaf samples at 100 mM in control was higher than in treatment samples. But at 300 mM, the content of potassium in the leaves in treatment was more than in control. The two concentrations of 100 and 300 mM were significant at $\alpha = 0.05$.

Sodium concentration in stem at both levels of 100 and 300 mM in treatment was higher than in control. As shown in *Figure 3,* this difference is only significant at $\alpha = 0.01$ at 100 mM.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33733385

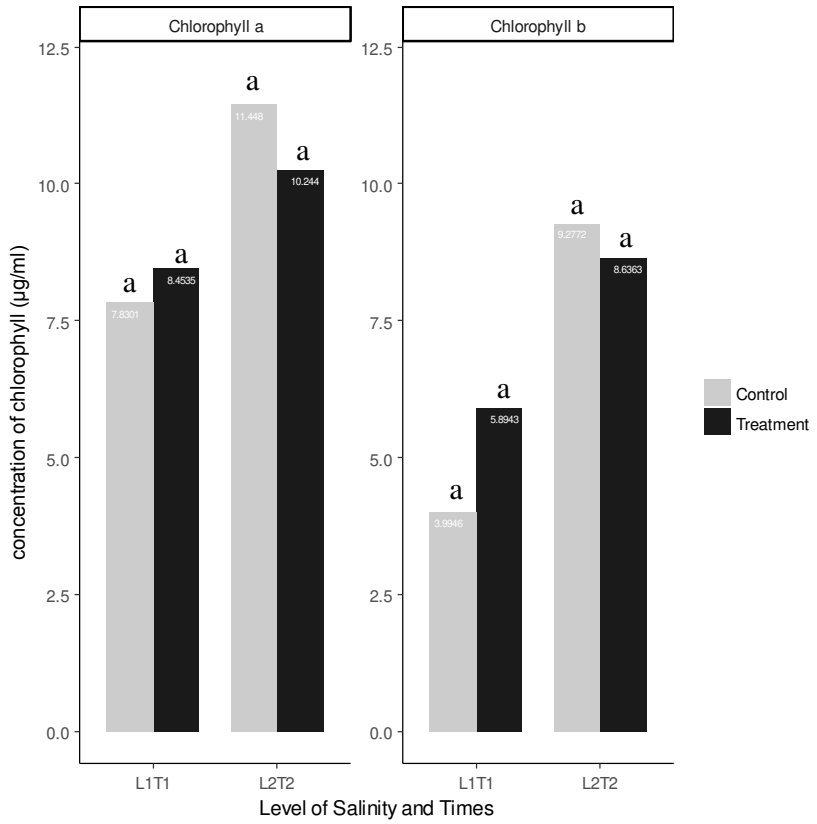

Figure 2. *Chlorophyll a and b content [L1T1: L1 = 100 mM level, T1 = two days after treatment] [L2T2: L2 = 300 mM level, T2 = two days after treatment]. Columns with a-a above are not significant*

Sodium content in the root at concentration of 100 mM is approximately not different in control and treatment samples, but in control samples it is more than in treatment samples at 300 mM. At both levels, the difference is not statistically significant.

Sodium concentration at leaf samples at 100 mM in control samples was more than in treatment samples. It is equal at 300 mM. Only at 100 mM level, a statistically significant difference was found at $\alpha = 0.05$.

K/Na ratio in stems, roots and leaves

As shown in *Figure 4,* the K/Na ratio in stem at 100 mM level in control sample was higher than in treatment samples, but at 300 mM at treatment it was higher than control. Neither of the two levels of this ratio was significant.

The K/Na ratio in root at both levels of 100 and 300 mM in treatment was higher than control and neither was statistically significant.

The K/Na ratio in leaf in treatment was higher than in control at both level and neither was statistically significant.

Protein content

As shown in *Figure 5,* protein content at the salinity level of 100 mM in control samples is higher than in treatment samples although it is reversed by increasing salinity to 300 mM. but neither was statistically significant.

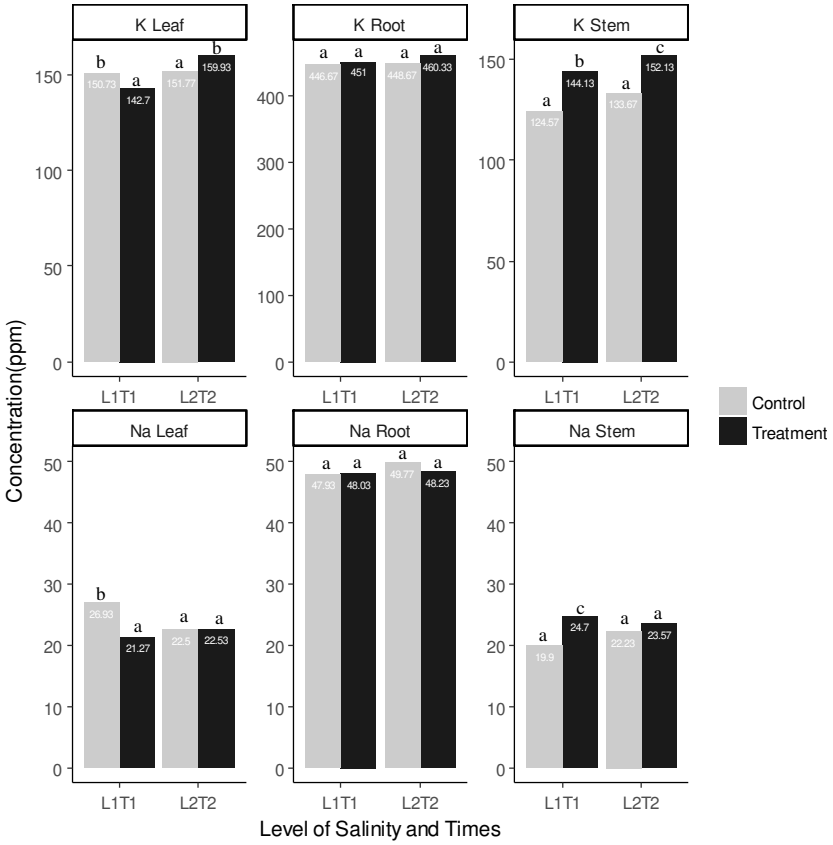

Figure 3. *Potassium and sodium content in stems, roots and leaves. columns with a-a above are not significant. Columns with a-b and a-c above are significant at α = 0.05 and α = 0.01 respectively. Legend same as Figure 2*

Peroxidase

According to *Figure 6,* the activity of this enzyme at 100 mM concentration and two days after the treatment was more than control, and it was equal at a concentration of 300 mM. Of course, there is no statistically significant difference between them.

Catalase

As showed in *Figure 6,* the specific enzyme activity of catalase at 100 mM concentration in control was higher than in treatment, but vice versa at 300 mM concentration. Although these differences were not significant.

Study of correlation coefficients

The values of correlation coefficients are given in *Figure 7*. Among all correlation coefficients, 14 cases were significant at $\alpha = 0.05$. Among correlation coefficients, chlorophyll a and protein, chlorophyll b and leaf K/Na ratio, stem Na and stem K, stem Na and leaf K/Na ratio, leaf K and protein, leaf K and stem K/Na ratio, stem K and root K, stem K and leaf K/Na ratio showed significant and positive correlation. However, between chlorophyll a and peroxidase, protein and peroxidase, leaf Na and stem Na, leaf Na and stem K, leaf Na and leaf K/Na ratio, root Na and root K/Na ratio a significant and negative correlation was found.

Discussion

Chlorophyll a and b and total carotenoid in *Morus alba* L were affected differently by salinity, but their total amount reduced with salinity (Agastian et al., 2000).

The leaf chlorophyll content of *Bruguiera parviflora* increased by 6% in plants treated with 100 mM of NaCl compared to the control plants, and then reduced at 200 and 400 mM (Parida et al., 2004).

Leaf total chlorophyll and carotenoid reduced under salt stress (Parida and Das, 2005). But Wang and Nil (2000) quoted by Parida and Das (2005) reported that chlorophyll content increased under salinity conditions in Amaranthus.

But results of this study showed that Chlorophyll a and b at 100 mM level in treatment was higher than in control, while at 300 mM level this relationship was reversed, however, neither was significant. The study results showed that salinity had no significant effect on the amount of chlorophyll a and b.

The most important trait among salinity specific traits is the plant's ability to limit the high accumulation of sodium entering into xylems. This trait is described by the term "Na^+ exclusion". Within a species or even within a genus, sodium concentration in leaves can be considered as a sign of relative ability to "exclude Na^+", especially if well-defined tissues are sampled (Colmer et al., 2006). According to *Figure 3,* it seems that the plant allows low sodium entering the root, but the low amount entered accumulated in the stem. In leaves at L1T1, sodium is higher in control sample than in treatment sample with unknown reason, but in L2T2 it is reduced and equal in both samples.

The high salt uptake competes with other nutrient ions uptake, especially potassium, that cause deficiency of this element. An increase in sodium chloride treatment induces an increase in sodium and chloride and leads to a reduction in calcium, potassium and magnesium in a number of plants (Khan et al., 1999, 2000; Khan and Aziz, 2001 quoted by Parida and Das, 2005). As shown in *Figure 3,* in stems, roots and leaves at two levels and times, which for each element is six cases in total, in three cases potassium is higher in the treatment compared to the control, and in one case control is more than the treatment and is statistically significant. But sodium is significant in two cases, that one is more in control and one more in treatment. According to these results, it seems that in the competition between potassium and sodium, more potassium enters the plant, which is contrary to the above-mentioned works. With low sodium uptake, this substance accumulates less in the plant and prevents the toxicity it can cause.

The plant cells require high levels of potassium to maintain normal metabolic reactions. Potassium also plays an important role in maintaining turgor pressure (Sairam and Tyagi, 2004). It is possible that the plant at the early stages that is exposed to water deficiency stress also absorbs more potassium to maintain turgor pressure. It is also necessary to maintain the uptake of potassium and transfer to growing tissues for salinity tolerance (Greenway and Munns, 1980 quoted by Colmer et al., 2006). These reasons can be explanations to the increased K uptake of this plant.

Analysis of ions had shown that tolerant genotypes had lower sodium concentration in the shoot, and more potassium in the shoot that sensitive genotypes. Salt-tolerant crops are characterized by absorbing more potassium than sodium (Teakle and Tyerman, 2010; Kausar et al., 2014 quoted by Oyiga et al., 2016). The ratio of K/Na was significantly higher in the shoot compared to sensitive ones, which is due to high concentration of potassium in the shoot and low concentration of sodium in the shoot. The optimum ratio of K/Na plays an important role in maintaining the optimum osmotic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33733385

potential and membrane potential for regulating cell volume in the plant under salinity stress and participate in increasing the tolerance of salinity in wheat (El-Hendawy et al., 2009 quoted by Oyiga et al., 2016). According to *Figure 4,* in most cases, K/Na ratio is higher in the treatment plants, which indicates the *kochia* tolerance to salinity and as mentioned above has a role in salinity tolerance of this plant.

As mentioned in Introduction, with the increase of hyperosmotic stresses, the activity of antioxidant enzymes increases. According to *Figure 6,* the activity of peroxidase in L1T1 in stressed plants is more than in the control, but catalase at this level and time in the control samples is more than in the treatment. In L2T2, the activity of catalase in treatment is more than in control, and peroxidase at this level and time is almost equal in the control and in the treatment. It can be said that the function of both enzymes is the opposite of each other except of L2T2 peroxidase that was different. Although these differences are not significant, they are remarkable. Probably a factor or process makes these two enzymes at any time and level one is higher for lower energy consumption.

As shown in *Figure 7,* a significant and negative correlation (r = -93) was found between the leaf Na and leaf K/Na ratio. Also, a significant and negative correlation was found between root Na and root K/Na ratio (r = -89). This result is consistent with the study results of Karimi et al. (2014) in safflower, which concluded that a negative and significant correlation was found between the leaf Na and leaf K/Na ratio, and the root Na and root K/Na ratio.

Furthermore, a significant and negative correlation was observed between chlorophyll a and peroxidase activity (r = -65). Moreover, a significant and positive correlation was found between chlorophyll a and protein content (r = 75). Anaya et al. (2017) reported a significant and positive correlation between chlorophyll a and peroxidase activity. They also observed a significant and negative correlation between chlorophyll a and protein. As mentioned, the study results were inconsistent with the study results of Anaya et al. (2017).

The results showed that salinity had no significant effect on chlorophyll a, b, peroxidase, catalase, and protein content. But this plant was limited sodium entering to the plant, and prevented its toxic effects. It also has been shown that potassium plays an important role in tolerance to salinity.

Abstract. The rapid pearl farming industry causes environmental pollution to aquatic ecosystems. However, fish-mussel systems with highly productive, profitable and environment-friendly characteristics are appropriate aquaculture practices under the current polluted state of the environment in China. Phytoplankton are excellent indicators and play indispensable roles in maintaining the stability of a freshwater ecosystem. Therefore, samples were seasonally collected determine the seasonal phytoplankton community dynamics and potential driving factors in three subtropical reservoirs with integrated fish-mussel aquaculture. All water physicochemical parameters varied seasonally, and water quality had a trend of eutrophication. A total of 189 species were identified, among which Chlorophyta (83 species) dominated in species richness. Cyanophyta, in particular remained to be highly abundant (57.53% of the total seasonal biomass). The NMDS analysis indicated that summer was an independent branch. The CCA analysis and Spearman rank correlation analysis suggested that water temperature might be the main abiotic factor. Furthermore, pH, conductivity, DO, chlorophyll, TC and TN also significantly affected the community. The aquaculture enhanced the similarity in community structure which have happened due to predation pressure. The present study also identified the potential influences caused by the integrated fish-mussel aquaculture on phytoplankton seasonal succession, bringing some guidance to protect the reservoir ecosystem.
Keywords: *phytoplankton community structure, seasonal variation, reservoir ecosystem, predation pressure*

Introduction

Large scale freshwater pearl production began in the 1960s in China, and accounted for 95% of the freshwater pearl production of the world (Li, 2007), making China the most crucial contributor to the world's freshwater pearl production. However, rapid development of freshwater pearl farming causes environmental pollution. The traditional industry is facing urgent transformation and upgrading. Therefore, we have formed a fish-mussel system aiming at aquaculture water, "One Water, Two Treatments; One Mussel, Two Functions": the breeding of mussels and fish bring about the effective governance of aquaculture water, and mussels produce clean water and generate pearls (http://www.pyhfish.com/article-821-1.html). *Hyriopsis schlegelii* (*H. schlegelii*) was the very important producer of freshwater pearl in China due to its better quality of pearls, pretty breeding technology, and simple artificial pearl producing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33873408

operation (Peng et al., 2012; He et al., 2013). Several aspects fundamentally accounted for the success of the freshwater pearl industry. Species with superduper performance of pearl production and continuously optimized culture models have contributed to the increasing annual freshwater pearl production, from approximately 3.5 tons during the period of 1958-1971 to approximately 4,448.34 tons during the period of 2002-2007 (Bai et al., 2014).

It is well known that freshwater pearl mussel, bighead carp and silver carp are aquaculture animals with high economic value, mainly grazing plankton. Among these culture models, integrated fish-mussel aquaculture, which cultures some filter fish, such as silver carp and bighead carp, into the water body with mussels, was practical, and improved water quality deterioration (Neori et al., 2004). Meanwhile, the concentrations of nitrogen, phosphorus and organics decreased in a planktivorous fish-mussel system, with an increase in the yield and growth of *H. cumingii* (Wang et al., 2009). Polyculture could improve the utilization efficiency of nutrients and water quality and increase yield, which has been widely applied for aquaculture (Milstein, 1992; Troell et al., 2003; Schneider et al., 2005). Water-quality deterioration and eutrophication might occur as a result of the significantly increased concentrations of nitrogen and phosphorus, which lead to cyanobacterial blooms, and bring negative impacts on photosynthesis in submerged plants on the account of blocking light (Hauxwell et al., 2001). This would further lessen the dissolved oxygen and might destroy aquatic ecosystems (Guo et al., 2009). However, various studies have focused on the optimization of the aquaculture production models, which were mainly on the integrated combination and management regimes. Researches with regard to production efficiency under the combination of various species were conducted by Tang et al. (2015) and Yan et al. (2009). Zheng et al. (2018) conducted a preliminary study on optimizing water quality and bacterial community in fish-mussel systems by regulating the C/N ratio. However, little attention was attached to the impact on the water ecosystem (including phytoplankton distribution, composition, etc.) caused by integrated fish-mussel aquaculture, even though phytoplankton was the most basic and nuclear primary producer, and contributed high effects on the dynamic equilibrium and relative stabilization. Furthermore, diatoms even affected the atmospheric CO_2 levels, considering that phytoplankton occupies a crucial position in the water ecosystem (Meyer et al., 2017; Leblanc et al., 2018; Milligan and Morel, 2012).

In particular, the diversity and richness of species generally exist in subtropical reservoirs, and Connell (1978) indicated determining factors that maintain the diversity in an ecosystem is crucial. Phytoplankton, as a kind of excellent bait for aquatic animals, and helps to better manage and maintain the sustainable utilization of water resources. Degefu et al. (2011) evaluated the potential impact of Nile Tilapia cage culture on water quality, and the zooplankton and phytoplankton community. It was indicated that cage culture enhanced the ammonium nitrogen levels and Cyanobacteria as a dominator, contributing 84% of the total phytoplankton abundance. In addition, And (1999) discovered that water quality deteriorated, and that the diversity and abundance of phytoplankton changed in shrimp ponds. Furthermore, Nile tilapia and *Macrobrachium rosenbergii* poluculture reduced the phytoplankton biovolume, and afternoon pH level was lower, when compared to prawn monoculture (Danaher et al., 2007). Rainbow trout cage cultures decreased the dissolved oxygen, and made *Daphnia sp.* dominant species (90% of the zooplankton), according to a study (Cornel and Whoriskey, 1993). Nevertheless, studies on the cumulative effect of natural- and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33873408

human-induced processes on environment factors and phytoplankton in *H. schlegelii*-bighead carp and silver carp systems remains scarce. It is expected that the seasonal pattern of phytoplankton could be influenced by fish-mussel polyculture. In order to investigate the hypothesis, the seasonal investigation of phytoplankton was conducted from August 2017 to March 2018 in three sub-tropic reservoirs with integrated fish-mussel aquaculture. The specific aims were as follows: (1) to determine the seasonal variation and succession rules in the phytoplankton community, and the potential driving factors; (2) to clarify whether the fish-mussel polyculture might induce the similarity of phytoplankton community between seasons.

Materials and methods

Experimental design

Duchang county is the most important freshwater pearl production region in China. Experiments were carried out in Dagang (DG, with fish feed), Zhouxi (ZX, with bio-feeding) and Hetang (HT, with organic fertilizer) in reservoirs located in Duchang county. The three reservoirs are about 8 acers and 10 m deep. And these reservoirs were cleaned and sterilized by lime prior to experiments. The conditions and the placing of plots were similar for these three experimental plots, with alike water supply and husbandry management. Bighead carps and silver carps were left to swim freely, and H. schlegelii were hung in the water column at approximately 50 cm below the water surface (8 mussels in each water column, 600 columns in each acer). The whole aquatic organisms were purchased from local commercial farms.

Sampling design

Phytoplankton were seasonally sampled (spring = March, summer = August, autumn = October, and winter = December) at three points in three reservoirs from August 2017 to March 2018. The sampling points were set according to the occupation area of each reservoir, and sampling was performed for three times for each point (*Fig. 1*). At approximately 100 cm below the water surface, 10 L of mixed water were collected using a 10-L modified Schindler–Patalas sampler. A plankton net with a mesh size width of 64 μm was used to filter the water, and phytoplankton were collected from the end of the net and placed into a 10-ml plastic tubing with 1% Lugol's solution. Counting and identifying were conducted under a microscope (Olympus SZ61, Japan; Olympus CX23, Korea). The biomass of the phytoplankton (wet weight) was calculated, according to the study conducted by Zhang and Huang (1991). For the physico-chemical parameters, WT, pH, conductivity (Cond), dissolved oxygen (DO), turbidity (Turb) and Chl-a were measured for three times in situ using a Multifunction Water Quality Monitor (YSI 6600 V2, USA). Then, 25 ml of water was collected from each sampling point with two replications. The samples were storing at -20 ℃ in a laboratory, and the total nitrogen (TN) and total carbon (TC) were determined using a carbon-nitrogen analyzer.

The 1 L of collected water was filtered through a Whatman GF/F fiberglass filter membrane (burned at 450 ℃ for 2 h before removing the organic matter), which had a diameter of 25 mm. Then, the membrane was dried under 60 ℃ for 48 h, and allowed to cool after weighing in the dryer. The dried GF/F fiberglass filter membrane was burned at 450 ℃ for 2 h and weighted (ash weight after burning) again after cooling. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33873408

content of the particulate organic matter in the water sample was calculated according to the weight of the blank filter membrane, the dried sample filter membrane, and lost weight after burning, and the volume of the water sample.

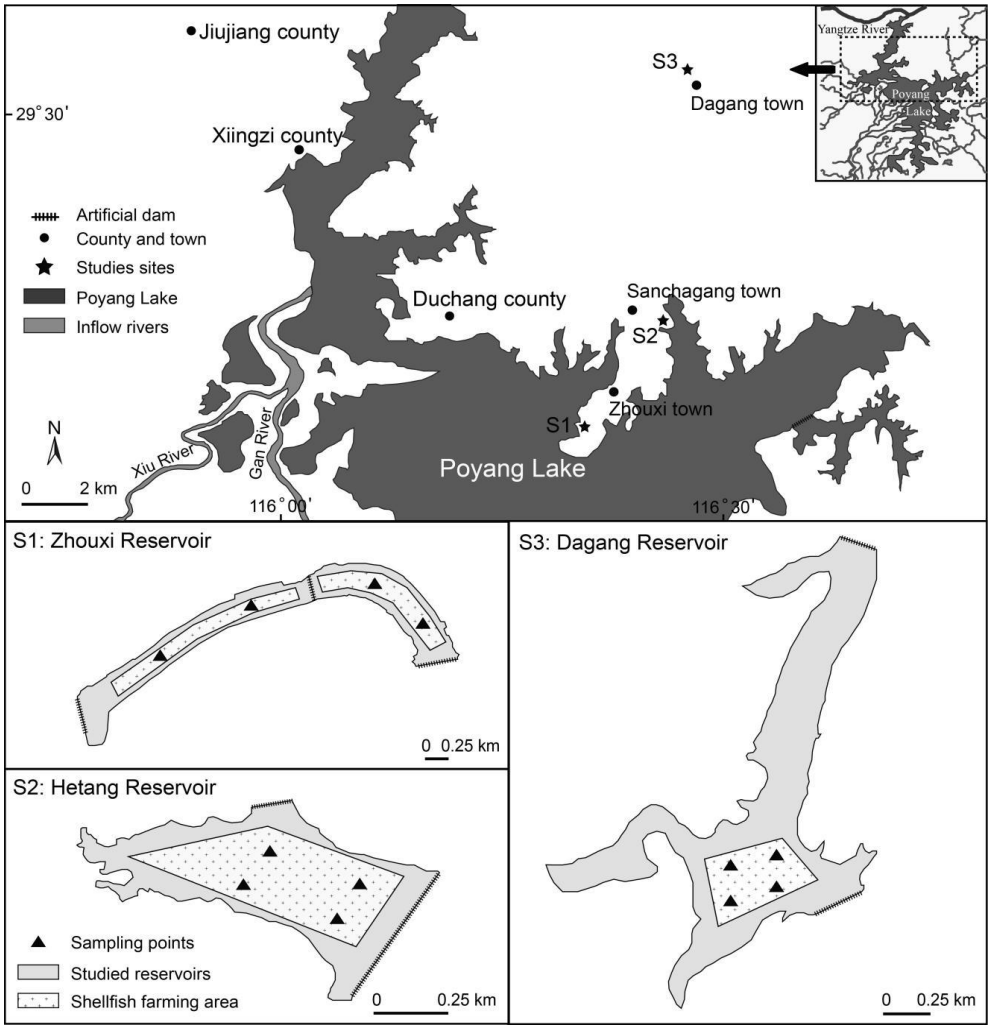

Figure 1. *Location of the studied sites and sampling points in the DG, HT and ZX reservoirs*

Statistical analysis

The Shannon–Weiner diversity index (H'), Margalef richness index (D) and Pielou evenness index (J') were calculated, as follows:

$$H' = -\sum Pi \ln (Pi)$$
$$D = (S-1) / \ln N \quad \text{(Eq.1)}$$
$$J' = H' / \ln S$$

where Pi is the proportion of i species densities in the total phytoplankton density, and S is species number.

The dominance index was as follows:

$$Y = n\,i \times f\,i / N \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33873408

where ni represents the number, fi represents the occurrence frequency of i species, and N represents the whole numbers. The species was deemed as dominant species when $Y \geq 0.02$.

The seasonal variations in water physico-chemical parameters (i.e. WT, pH, Cond, DO, Turb and Chl-a), TN, TC and phytoplankton parameters (i.e. biomass, H', D and J') were examined by one-way ANOVA, and the differences were further tested with LSD multiple comparison under various treatments. Spearman rank correlation analysis was performed to identify the correlation among physico-chemical parameters, TC, TN and the biomass of phytoplankton. $P < 0.05$ was the significant level. The seasonal variation in phytoplankton community structure was determined by NMDS analysis with the biomass data of dominant species using a ranked similarity matrix based on Bray–Curtis similarity measures.

A detrended correspondence analysis on species data was performed prior to the analysis of species-environmental correlation, and revealed the longest gradient length of 4.9, indicating that the Canonical correspondence analysis was applicable. Therefore, the correlation between water physico-chemical parameters and phytoplankton dominant species was examined with CCA, and the significance was determined by the Monte Carlo test using the Canoco for Windows 4.5 software (Microcomputer Power, Ithaca, USA). Then, one-way ANOVA, LSD multiple comparison and Spearman rank correlation analysis were performed with SPSS (version 22.0; IBM Corp., Armonk, USA). NMDS ordination analysis was performed with the PRIMER 5 computer package (Clarke and Warwick, 1994).

Results

Physico-chemical parameters

The one-way ANOVA indicated that all water physico-chemical parameters differed seasonally. The fluctuation rule for water temperature was that it increased from spring, reaching a maximum (±SE) of 30.93 ± 0.22 ℃ in summer, and continuously dropped from autumn to winter, reaching a minimum of 4.77 ± 0.31 ℃ (*Table 1*). A similar fluctuation rule was also observed in pH, conductivity and turbidity. In general, the water was characterized by alkalinity, ranging from 7.86 ± 0.04 to 8.80 ± 0.05. The DO concentrations ranged from 8.98 ± 0.11 mg/L in winter to 10.45 ± 0.17 mg/L in spring, indicating that a higher oxygen capacity occurred in spring. Conductivity and turbidity ranged from 101.61 ± 30.20 to 1,342.28 ± 85.87 μS/cm, and from 5.26 ± 0.69 to 14.48 ± 2.65 NTU, respectively. Furthermore, chlorophyll-a values and total carbon, which included total organic carbon and total inorganic carbon, peaked in autumn (24.64 ± 2.12 μg/L and 9.75 ± 0.62 mg/L, respectively), followed by a gradual decrease, reaching a minimum value in winter (2.39 ± 0.11 μg/L and 6.16 ± 0.35 mg/L, respectively). On the contrary, TN had a minimum of 0.63 ± 0.03 mg/L in autumn, but peaked to 1.10 ± 0.1 mg/L in summer.

Species composition

A total of 189 species were identified and belonged to seven groups: Cyanophyta, Chlorophyta, Bacillariophyta, Xanthophyta, Pyrrophyta, Euglenophyta and Chrysophyta. Chlorophyta was deemed as the most abundant group, which had 83 species (approximately 43.92% of the total species number), followed by Cyanophyta

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33873408

(59 species) and Bacillariophyta (25 species). The others, such as Xanthophyta, Pyrrophyta, Euglenophyta and Chrysophyta, were sporadically recorded (*Table A1* in the *Appendix*).

Table 1. *Mean values (±standard error) of the physicochemical factors*

	Spring	Summer	Autumn	Winter	F	P
WT (℃)	14.68±0.09^{b}	30.93±0.22^{d}	21.93±0.09^{c}	4.77±0.31^{a}	3002.41	<0.001

TN （mg/L）	1.05±0.14^{b}	1.10±0.15^{b}	0.63±0.03^{a}	0.87±0.07^{ab}	3.684	0.016

The phytoplankton composition changed with the seasons and sites, which indicate a trend, in which taxa numbers gradually increased from spring to autumn, reached a peak period, and decreased (*Fig. 2*). A total of 112 species were recorded in spring, with a minimum (29) in DG, and these were similar in HT (42) and ZX (41). A total of 153 and 120 species were observed in summer and winter, respectively. In general, the taxa numbers exhibited a slight fluctuation of approximately 50 (in summer) and 40 (in winter) in three reservoirs. A total of 180 species were captured in autumn, with the minimum (50), and the number of taxa in HT (67) were slightly higher than those in ZX (63). In addition, 4, 6 and 5 species remained as co-existing species from spring to winter in DG, HT and ZX, respectively, and these mainly comprised of Bacillariophyta, in addition to Chlorophyta and Cyanophyta.

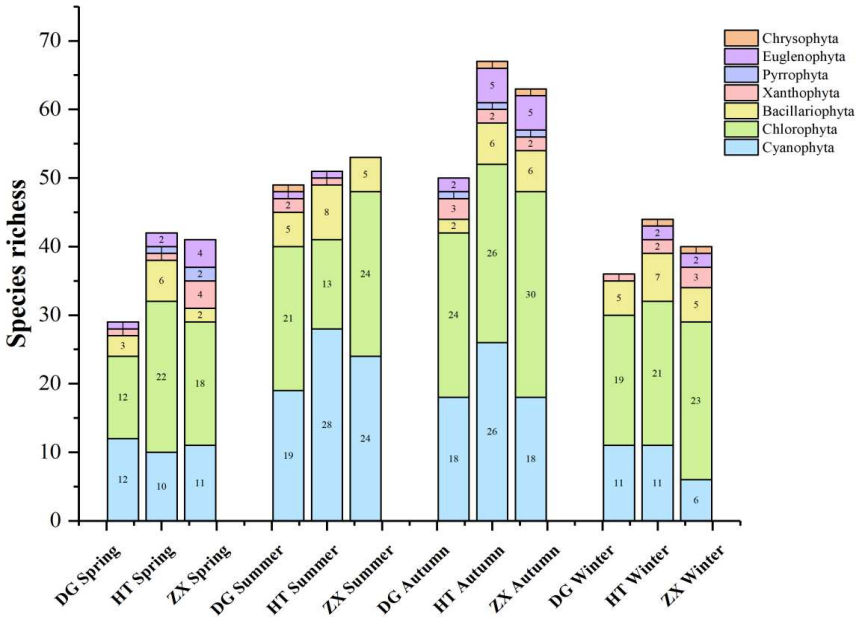

Figure 2. *Seasonal species richness of each phytoplankton group in the DG, HT and ZX reservoirs from August 2017 to March 2018*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33873408

Dominant species

The number of dominant species were 9, 9 and 12 for DG, HT and ZX throughout the sampling period. Furthermore, 9, 3, 6 and 7 dominant species occurred from spring to winter. These dominant species changed with the seasons. *Microcystis pallida* dominated in spring and summer. S*ynechocystis aquatilis* and *Ulothrix tenerrima* were the dominant species in summer and winter, and in spring and winter, respectively. *Microspora stagnorum* dominated the four seasons, except for summer, and merely *Chlorella pyrenoidosa* was the dominant species from spring to winter.

The highest dominance was marked by Jaaginema angustissimum in spring, Synechocystis aquatilis in summer, Microcystis minutissima in autumn, and Oscillatoria tenuis in winter, with a dominance index of 0.57, 0.93, 0.25 and 0.20, respectively.

Biomass of phytoplankton

A similar trend was found in the seasonal dynamics of phytoplankton biomass. There was a relatively low biomass in spring, which peaked in summer on account of the outbreak of Cyanophyta, and progressively decreased to the minimum in winter. The fluctuation rule was consistent with the seasonal dynamics of Cyanophyta. Cyanophyta contributed to the seasonal total biomass, which ranged from 17.80% (winter in ZX) to 98.86% (summer in HT). The mean proportions were 52.74%, 90.68%, 53.72% and 32.72% for spring to winter, respectively. Therefore, a lot of Cyanophyta characterized the phytoplankton assemblages in these three reservoirs. This was followed by the main contributors to the total biomass of the phytoplankton community, which included Chlorophyta, Xanthophyta and Bacillariophyta (*Fig. 3*). From spring to winter, the mean value was 1,409.44 ± 228.51, 7,436.94 ± 1481.36, 1,187.5 ± 194.29 and 674.72 ± 138.55 ind/L. Summer significantly differed with the other seasons ($P < 0.01$). In addition, the phytoplankton biomass in ZX was higher than that in the rest of reservoirs, except for summer, and the maximum was 13,690 ± 2,682.11 ind/L in HT.

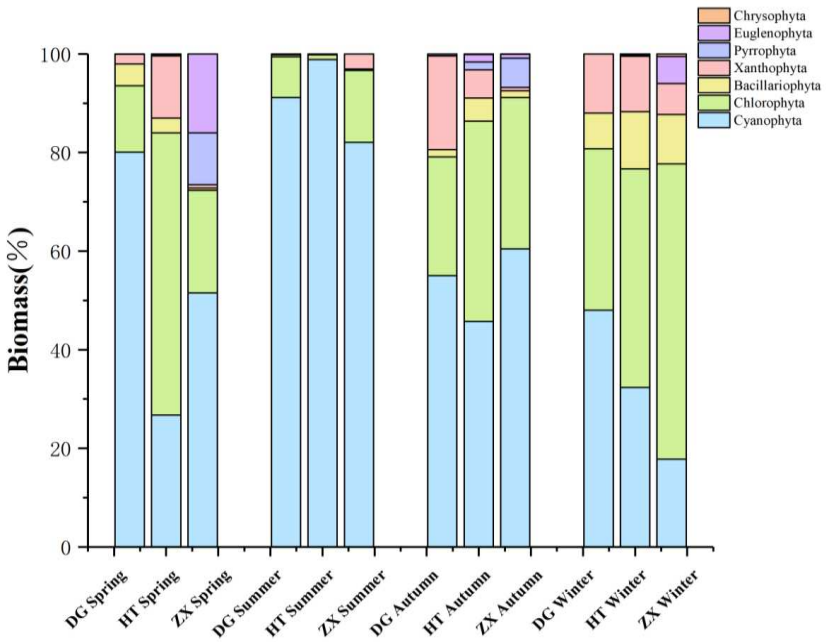

Figure 3. *Seasonal biomass that comprise of the proportion of each phytoplankton group in the DG, HT and ZX reservoirs from August 2017 to March 2018*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33873408

Species of the diversity index

It was essential to study the Shannon–Weiner diversity index (*H'*), Margalef richness index (*D*) and Pielou evenness index (*J'*) to clarify the structure of the phytoplankton community. The overall pattern of the three diversity indexes represented a peak in autumn, and a minimum that was often shown in summer (*Fig. 4*). H', D and J' all indicated significant differences among the four seasons. The Shannon–Weiner index ranged from 0.58 (summer in DG) to 2.13 (autumn in HT), with an average of 1.50. The Margalef index ranged from 1.41 (spring in DG) to 3.46 (autumn in HT), with an average of 2.36. As for the Pielou's evenness index, this ranged from 0.16 (summer in HT) to 0.78 (winter in ZX), with an average of 0.58.

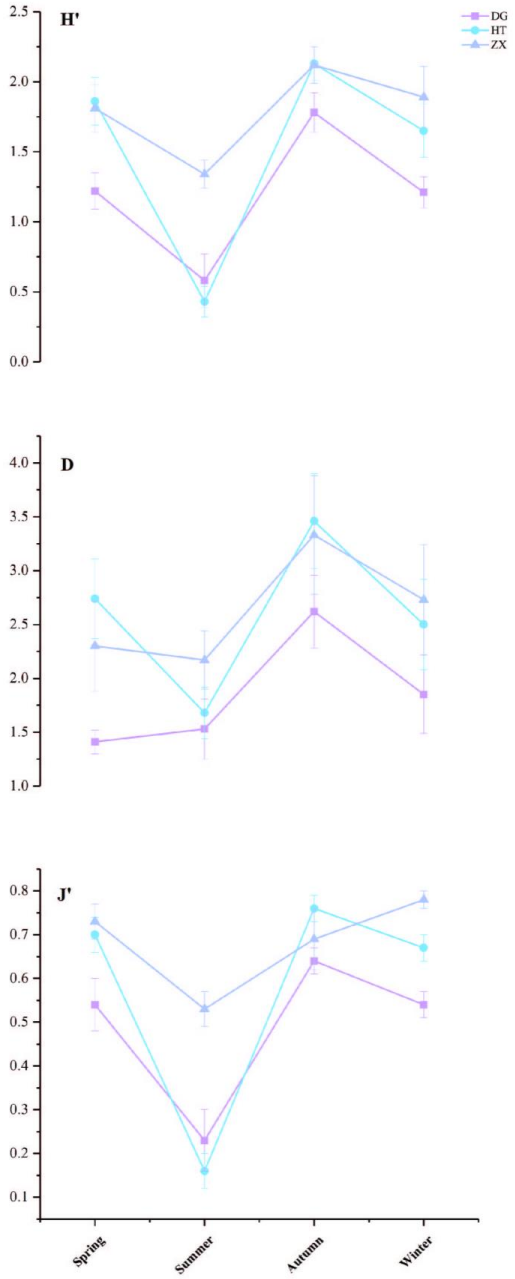

Figure 4. *Seasonal H' (Shannon–Weiner index), D (Margalef index) and J' (Pielou'sindex) in the DG, HT and ZX reservoirs from August 2017 to March 2018*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33873408

Phytoplankton community structure

Temporal pattern

The result of the NMDS analysis based on the seasonal variance in dominant species biomass was presented in *Figure 5*. In the significant difference result for the component and biomass of dominant species between summer and others, summer was separated as an independent branch. Meanwhile, it was noteworthy that the other seasons did not gather together closely into a branch. In particular, a partial separation was observed in spring and winter, which meant that some variance in composition and abundance existed.

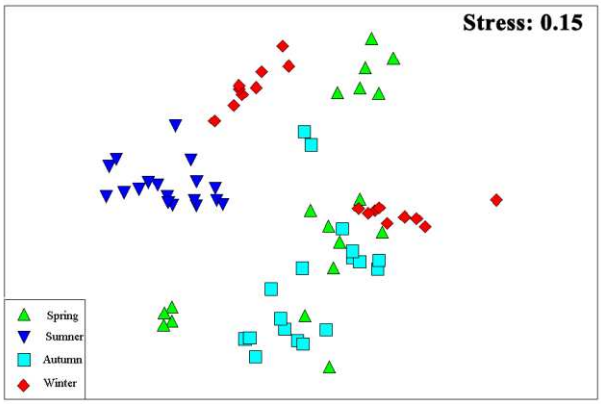

Figure 5. *Temporal pattern of the phytoplankton community structure of the DG, HT and ZX reservoirs by non-metric multidimensional scaling ordination (NMDS) analysis from August 2017 to March 2018*

Spatial pattern

NMDS was also conducted to determine whether the phytoplankton community structure expressed spatial differences. Different degrees of variance in phytoplankton structure among the three experimental plots was revealed from spring to winter (*Fig. 6*). Corresponding to the result of the temporal variance analysis, this strongly varied among the three plots in summer. In spring, DG exhibited a considerable difference with ZX and HT. However, no distinct rules were demonstrated in autumn and winter.

The relationship of the phytoplankton community with environmental parameters

The results of the CCA analysis indicated that 33.00% and 59.93% of the variance in the species-environmental relationship were carried out on the first and second axes, suggesting that there was some correlation between the environmental parameters and phytoplankton structure (*Fig. 7*). The Monte Carlo permutation test revealed that WT ($P = 0.002$), pH ($P = 0.002$), conductivity ($P = 0.002$), dissolved oxygen ($P = 0.002$), chlorophyll-a ($P = 0.002$), TC ($P = 0.022$) and TN ($P = 0.002$) were the crucial factors that had significant impacts on phytoplankton communities, and WT explains the largest variation, which was 10.4%. Along with the Spearman rank correlation analysis, pH, WT and conductivity had a strong positively correlation with total biomass, the biomass of *Cyanophyta*, and the main component, *Synechocystis aquatilis* (R value: pH > WT > conductivity; *Table 2*) However, pH, conductivity and TC were negatively correlated with *Bacillariophyta*. In addition, the

Discussion

Effects of environmental factors on the phytoplankton community

The objectives of the present study were to investigate the seasonal variations in phytoplankton communities, and attempt to determine the potential factors that affected the community structure. In addition, the diversity, richness and components of the structure of the phytoplankton community were predicted, and all differed from natural reservoirs without aquaculture. The findings of the present study suggest that environmental factors and anthropogenic pressure affected the phytoplankton community structure in several aspects. However, to some extent, the results in some water physico-chemical parameters and species richness were within a reasonable range of fluctuations. However, these still exhibited different succession patterns between seasons, when compared to some natural subtropical reservoirs. That is, the hypothesis was partially supported.

On one hand, the physico-chemical parameters of water had a significant impact on the structure of phytoplankton and zooplankton, such as species richness, the value of the biomass, dominant species distribution, and the composition of the community (Li et al., 2019; Horváth et al., 2017; Zhao et al., 2013). The seasonal characteristics of these ecosystems could be explained by the variability of the environment, which was due to the temporal change. The present study also revealed all water physico-chemical factors, D, H' and J', were significantly different among the four seasons. In addition, the phytoplankton community structure could display a change when the temporal changed (Fabiana Schneck et al., 2011). Furthermore, the present study demonstrated that the composition of the phytoplankton community in these three reservoirs changed between seasons. In particular, Cyanophyta dominated the phytoplankton community mostly during the experimental periods. Water temperature, N levels, P levels and dissolved oxygen could contribute to the variation of the phytoplankton community (Xu et al., 2017). The present study indicated that water temperature, pH, conductivity, dissolved oxygen, chlorophyll-a, TC and TN were the primary factors that influenced the phytoplankton community, and that water temperature contributed the most variation. Simultaneously, the Spearman rank correlation analysis also indicated that water temperature occupied the crucial factors. These results agreed with the results reported by Wu et al. (2012). In addition, WT, pH, conductivity and turbidity revealed similar fluctuation patterns. Furthermore, abundant data have indicated the effect of water temperature on phytoplankton growth, photosynthesis, respiration and community succession in the water ecosystem (Williamson et al., 2010; Moore, 2010; Edwards and Richardson, 2004). The optimum temperature for microalgae belonging to various groups differed, in general, and high temperature always promoted the growth of phytoplankton (Wu et al., 2013). It is not surprising that the biomass of phytoplankton generally reached a peak in summer, and decreased in spring and winter. These findings indicate that the biomass in summer considerably increased, and was far greater than that in the other seasons. The NMDS results also suggested that the phytoplankton community in summer was separated as an independent branch. Diatoms were adapted to grow in cool water, with an optimum temperature of approximately 20 ℃, which tended to dominate in spring. As for others, such as A. tamarense, which are not eurythermal, these reached the greatest abundance at temperatures near 18 ℃ (Wang et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33873408

al., 2009). However, Cyanobacterias thrived at relatively high temperatures (approximately 28-32 ℃), according to Ribeiro et al. (2018).

The phytoplankton community was characterized a lot of Cyanobacterias, which are indicators of an ecosystem with an excess of trophic state (Kangro et al., 2005). Cyanobacteria would show significant advantages, when compared to other groups, when facing an elevation in temperature. However, even in spring and winter, Cyanobacteria continued to play an important role in the phytoplankton community, and *Microcystis pallida* and *Microcystis pallida, Synechocystis aquatilis* and *Oscillatoria tenuis* were the dominant species in spring and winter, respectively. Therefore, temperature was not the only affecting factors that resulted in the abundance of Cyanobacteria in these three reservoirs. In addition, other factors also accounted for the phytoplankton temporal dynamics. The CCA analysis also indicated TN and pH had a significant impact on the structure of the phytoplankton community. Nevertheless, Cyanobacteria occupied over 90% of the biomass in summer. The Spearman rank correlation analysis revealed that pH, water temperature and conductivity had a strong positively correlation with Cyanobacteria. These results agree with other study conducted in a reservoir with cage farming (Degefu et al., 2011). Therefore, significant high biomass in summer could also be attributed to the blue-green algae outbreak. Based on previous studies on phytoplankton community structure, the rough features of Cyanobacteria could be demonstrated (Mwaura et al., 2002; Xiao et al., 2018; Smith, 1986; Sarma et al., 2005; Li et al., 2019). The Cyanobacteria exhibited better performance under high temperature, with relatively high pH and nutrition levels. These could shift to a position required for a suitable environment in the water column, and with a special allelopathy to dwindle other species that co-exist in the ecosystem with a possible competitive relationship. It was obvious, to some extent, that this might be attributable to the abundance of Cyanobacteria, which is advantageous of the better tolerance of grazing, homeostatic mechanism, and relatively suitable living environment for Cyanobacteria provided by these reservoirs. Meanwhile, the composition and succession rules were contrary to natural subtropical reservoirs (Yang et al., 2014). Among the four seasons, chlorophyta and cyanophyta were always the main dominant species, and the major contributors to the total biomass. However, no significant and clear phytoplankton community succession was observed. The diversity index could instruct the water trophic states, according to the study conducted by Kuang et al. (2005). These reservoirs were all in a moderately eutrophic state with the use of the method described as Kuang. That is, fish and mussels introduction might have brought some impact on the water quality, and further impacted the phytoplankton community.

Effects of aquaculture on the phytoplankton community

In addition to abiotic factors, biotic factors would affect the phytoplankton community structure, and may further bring a great impact on the water ecosystem (Reissig et al., 2006; Sarà, 2007). Integrated fish-mussel aquaculture might contribute to the variance in the composition and succession in several ways. On one hand, as far as aquatic organisms are concerned, a new predation pressure would be created, and the origin food web in the water ecosystem might be forced to change. Furthermore, the responses of the phytoplankton biomass in some groups of could be accurately predicted, based on food chain theory responses (Hansson et al., 2004). The predation pressure could be a direct or indirect major factor that affects the structure of phytoplankton, and the zooplankton community would also respond to the dynamics

DOI: http://dx.doi.org/10.15666/aeer/1802_33873408

through the food web (Huston, 1979; He et al., 2017). He et al. discovered that the contribution and biomass of diatoms in the water column significantly increased due to the increasing competitiveness of microalgae with big cells caused by Crucian carp foraging activities. However, although a filter-feeder without capturing devices feeds majorly on phytoplankton and organics by forming a water flow to filter food, relying on the gill and cilium of the labial surface, cyanobacteria were a kind of inedible microalgae for these (Yan et al., 2009). Therefore, the specific selection of food by mussels has a significant impact on the food web composition, leading to a high quantity of cyanobacteria, when compared with other algae. This influenced the succession of phytoplankton communities, and possibly enhanced the similarity of species composition between seasons. Reissig et al. (2006) considered that the cyanobacteria dominated in lakes with introduced fishes. However, this phenomenon was absent in lakes without fishes. The proportion of cyanobacteria biomass in total biomass sharply plummeted, and was approximately equal to that of green algae, or even lower than that of green algae, in addition to environmental factors, and this may be correlated to the decrease in mussel population in autumn and winter. When the biomass of some microalgae occupied an absolute dominant position, this might lead to a relatively single species composition, thereby affecting the stability of the community structure and the balance of the ecosystem, while reducing the ecosystem to withstand this (Lawton, 1994). Mussels and fish polyculture had a limited effect on controlling blue-green algae blooms, but induced a decrease of some groups, which agrees to the study conducted by Soto and Mena (1999). Meanwhile, the increase in nitrogen, phosphorus concentrations and other water physico-chemical or trophic levels could be detected due to the feces, and maintenance respiration and activities. The bio-deposit degradation from aquatic organisms also may have toxic effects. On the other hand, husbandry management, such as feeding and fertilizing, were essential for some aquaculture types. Therefore, maintaining the balance and stabilization in water quality and tropical states meet greater challenges, and have an obvious impact on the microalgae community. Sarà et al. (2011) indicated that the N and P levels were continuously enhanced after the introduction of aquaculture, and approximately 34.2.5% of the relative N and P total input was caused by tuna fish-farming activities per year. In addition, relatively low dissolved oxygen, high total chlorophyll-a, and high phytoplankton abundances, but low species richness, were recorded by Er et al. (2018). However, different aquatic organisms affected the water column differentially, the dissolved inorganic nitrogen and total phosphorus concentrations in fish farms were significantly higher than that in bivalve cultures, and the bivalve cultures exerted lighter pressure than fish cultures (Sarà, 2007; Zhang et al., 2013). These reservoirs exhibited some obvious variations in oxygen capacity and community structure, including species composition and richness, which might be due to the various management schemes, based on the NMDS analysis. The physico-chemical parameters were mostly in the favorable range for aquaculture. For example, the dissolved oxygen was suitable for the fish-mussel system, and was not in a low level, which might be a relatively low abundant biomass. For silver carp, bighead carp and mussels, the filter feeder displayed crucial roles in the reservoir ecosystem, and this might have contributed to the low abundant biomass that further decreased the oxygen expended by the respiration of micro-algae. Calcium oxide was frequently applied to increase the calcium ion concentration and regulate water quality, and these might be reasonable to understand that the water was deemed alkaline in these three reservoirs. Seasonal phytoplankton

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_33873408

community dynamics would be affected from a lot of aspects, but other factors were absent from the present study, such as phosphorus levels, bacteria, zooplankton and the interaction among fish, mussel and phytoplankton.

It remains challenging to clarify the mechanism of variation in water quality and the phytoplankton community caused by the hydrological regime and man-made disturbances based on the simple investigation environment factors and community component. Hence, monitoring is fundamental to clarify the internal correlation between affecting factors and the responses, and explain the complex ecological succession from a comprehensive point. Nevertheless, the present study demonstrated the seasonal dynamic characteristics of phytoplankton and its potential risks to water ecosystems attributed to integrated fish-mussel aquaculture.

Conclusion

The total water quality parameters revealed seasonal variations and an appropriate range for aquaculture, as well as a trend of eutrophication. The phytoplankton community was characterized by high species richness and abundance, and was dominated by cyanobacteria in the three reservoirs. The biomass in summer had a significant difference, when compared to other seasons. The community structure of phytoplankton had unclear patterns due to the fish-mussel polyculture, which possibly enhanced the similarity in species composition and dominance species. In a word, environment factors, aquaculture and human disturbances have an impact on its seasonal succession and structure, in direct and indirect means.

The planning of water areas and tidal flats for aquaculture has become a fundamental strategy in ecological civilization construction at present. Fish-mussel polyculture is the main culture model, and this has been continuously generalized for pearl production, which is an important industry in aquaculture. The present study was helpful in identifying the seasonal characteristics of phytoplankton and the potential risks of fish-mussel polyculture, which might bring some instructions to the better management and utilization of reservoir resources.

Abstract. This investigation was conducted during the winter seasons of 2017-2018 the Experimental Farm of the College of Agricultural Sciences, University of Sulaimani at Bakrajo, using split plot design to study the effect of three levels of phosphorus fertilizer on the growth, yield and yield components of safflower varieties. Three varieties namely Zaafarani, Aidn and; Al-shamia, were applied to the main plots, three phosphorus fertilizer levels (0, 50 and 100 kg P2O5/ha from Tsp. 48% source, were implemented in the subplots. Comparisons between means were carried out by the least significant difference (L.S.D) at 1% and 5% level of significance. The results showed that the Al-shaima varieties produced the best values at 15398.22 Kg/h and 1914.06 Kg/h followed by Aidn with values of 14508.77 Kg/h and 1655.72 for biological yield and seed yield respectively, finally the lowest values of 13662.88 Kg/h for biological yield and 1914.06 Kg/h for seed yield produced by Zaafarani. While the highest oil percentage was obtained from Zaafarani with values of 32.28% followed by Aiden with value of 29.62%, finally the lowest value of 28.10% was obtained from variety Al-shamia. The application of 100 Kg P/ha was found to be the best level for producing the highest seed yield with the highest percentage of oil. The trait of 100 seed weight showed a highly significant and positive correlation with seed yield, whereas the number of seeds/plant exerted the highest direct effect on seed yield Kg/ha, both traits were observed to be the most important trait for seed yield improvement in safflower.
Keywords: *safflower production, fertilization, growth parameters, protein percentage, oil components, correlation and path coefficient analysis*

Introduction

Safflower (*Carthamus tinctorius* L.) is an important annual industrial crop which is classified as a composite. It has more than 150 species that are scattered from Spain to North Africa, West Asia and India (Rastgou, 2013). These in turn are considered as the parental species of the cultivated species (*C. tinctorius* L.) in fact (*C. persicus,* and *flavenscens*) are the common subsidiary members of the Oak Forest association in Kurdistan (Guest, 1966). The stem, leaves, seeds and flowers are used as vegetable and industrial oil, bird feed, forage plant, medicinal purpose and for its colorful petals used as food coloring and flavoring agent (Dordas, and Sioulas, 2008). The oil content of seeds in Safflower is approximately 35 to 50 percent. Safflower oil preferred for its higher poly unsaturated fatty acid (78% linoleic acid) which reduces blood cholesterol level (Belgin and et al., 2007) also contains tocopherols, known to have antioxidant effect and high vitamin E content. For this reason, safflower oil is used in the diets of patients with cardiovascular disease, and bears great importance for its anti-cholesterol effect (Arsalan and Tuntruk, 2003). Safflower has different varieties from local to wild ones which are adapted to distinct climates in Iraq. This plant is considered as an almost tolerable plant to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34093418

different conditions, because it is adapted to different weather conditions (Omidi-Tabrizi et al., 2000). In Safflower, some physiological treats like growth, seed quality and oil content are controlled by variety, different for instance plant density, and chemical fertilizer application (Weiss, 2000). But, the productivity of safflower is very low as the crop is cultivated under nutrient stress environment conditions. This necessitates rational application of these elements as they have become limiting factor for obtaining higher yields in safflower. Phosphorus (P) is vital to plant growth and is found in every living plant cell. It is involved in several key plant functions, including energy transfer, photosynthesis, transformation of sugars and starches, nutrient movement within the plant and transfer of genetic characteristics from one generation to the next (Sultenfuss and Doyle, 1999). Phosphorus (P) is the most limiting nutrient for crop growth and yield in many regions of the world (Rodriguez and Goudriaan, 1999), and application of P fertilizer represents an important measure to correct nutrient deficiencies and to replace nutrients having been removed in the products harvested (Dambroth and El-Bassam, 1990). However, recovery of fertilizer P in the first year is often below 15% and hardly reaches 50% after 30 years (Roy et al., 2000).

Therefore, the aim of this study was to evaluate the impact of phosphorous apply on growth, yield and oil percentage of safflower and to determine the best variety of safflower for yield and oil percentage.

Materials and methods

This study investigated in Sulaimani region, at Experimental Farm of the College of Agriculture Science Engineering, University of Sulaimani at Bakrajo located in the southwest of Sulaimani city (Latitude: 35° 33' N; Longitude 45° 27' Est altitude of approximately 830 m) during the winter season of 2017-2018. The meteorological data of Bakrajo location is shown in *Table 1*. The experimental area plots were ploughed twice, harrowed and well leveled. A brief account of some physical and chemical properties of the experimental soil is given in *Table 2*.

Three safflower varieties were selected for cultivation, which has been provided by The Sulaimani Agricultural Research Center, namely; Zaafarani, Aidn and; Al-shamia. The experiment was arranged as split- plot layout. The varieties were implemented in the main plots and conducted with Randomized Complete Block Design (RCBD), different levels of Phosphorus fertilizer (0, 50 and 100 Kg P_2O_5/ha) from TSP 46% were implemented in the subplots. Each main plot was consisted of three subplots with four rows (0.40 m between rows and 0.20 m between plants); thus, the plant population was 142,857plant/ha. Planting date was on 12th December of 2017. The cultural operations and weed control were accomplished according to normal field practices. Half of recommended dose of fertilization were added to the whole experiment which were 50 Kg Nitrogen/ha as urea and divided into two equal doses and were applied at the seeding time and after 20 days from germination.

The LSD test was done to find the significant differences between treatment means at 5% and 1% probability levels. Mature plants were harvested on 5th July, of 2018 for estimating seed yield, yield components and growth rate.

The studied characters were:

- 50% flowering.
- Dry matter/plant (g/plant): the mean weight of five plant sample were dried in oven for 48 h in 65 °C then weighted and recorded.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34093418

- Plant height (cm): the mean height of the plant from ground level to the tip of five plants was recorded.
- No. of leaves/plant: the mean number of leaves per plant of the five plants was recorded.
- No. of seeds/plant: the mean number of seeds per plant of five plants was counted and recorded.
- 100 seed weight (g): 100 seeds were weighted and recorded and repeated three times.
- Oil %: 2 gm of the harvested seed of each treatment was powdered by electric blender. Digital soxhlet instrument used for oil distillation, with n-hexane solvent (Ferreira-Dias et al., 2000), the oil content calculated as follows:

$$\text{Oil percent} = \{(W2 - W1) \times 100\} / S \quad \text{(Eq.1)}$$

W1 = weight of empty flask (g), W2 = weight of flask and extracted oil (g), S = weight of sample.

- Protein (%): quantification of total protein by Bradford assay method (He, 2011).
- Ash content (%): seed ash content was estimated by muffle furnace on the 550 °C according to the following equation:

$$\text{Ash\%} = \text{Total ash / weight of the sample} \times 100 \quad \text{(Eq.2)}$$

- Biological yield (Kg/ha): the mean of weight of the five plant samples without the roots was recorded in each plot (g/plant) and converted to Kg/ha.
- Seed yield (Kg/ha): the mean of seeds weight of the five plant samples was recorded in each plot (g/plant) and converted to Kg/ha.

Correlation analysis

The correlation coefficient was conducted to determine the degree of association of characters with seed yield and also among all the criteria studied. Phenotypic correlations were computed between the characters in the growing season using the formula given by Singh and Chaudhary (1985).

Path coefficient analysis

The path coefficient analysis was carried out as suggested by Dewey and Lu (1959). Seedyield was kept as resultant variable and other characters as causal through (Analysis of Moment Structures) AMOS Ver. 18 Software.

Results and discussion

Data in *Table 3* confirm that the differences among varieties were highly significant for the studied criteria plant height, number of leaves per plant, dry matter weight oil % and seed yield, while it was significant for the characters100-seed weight, Protein % and biological yield. More leave number, and oil percentage was obtained by Zaafarani, as compared to Aidn and; Al-shamia with values of 616.22 and 32.58 respectively, followed by Aidn which was recorded value of 133.88 cm plant high, values of

DOI: http://dx.doi.org/10.15666/aeer/1802_34093418

102.25 g total plant dry mater accumulate (leave, stem, and flower dry weight) and values of 3.76 g 100-seed weight. While, Al-shamia was significant in producing biological yield with value of 15398.22 Kg/ha and with value of 1914.06 Kg/ha for seed yield. This variation between the studied varieties was related to genetic variation and variation in their responses to the use of different levels of phosphorus fertilizer, as previously reported by Banna (2011) and Ryan et al. (2009).

Table 1. *Average air temperature and rainfall during the growing seasons of 2017-2018 at Bakrajo location*

Months	Average air temperature (°C)		Rainfall (mm)

The effect of phosphorus fertilizer application was found to be highly significant for all characters except of plant height and Ashe% (*Table 4*). The best values of 658.22, 561.78, 101.971 g, 3.897 g, 31.59%, 12.99, 16728.77 Kg/ha and 1972.433/ha for the number of leaves per plant, number of seeds per plant, dry matter weight, 100 seed weight, oil percentage, protein percentage, biological yield and seed yield respectively, were obtained by plants grown under 100 Kg P/ha except protein percentage was obtained by plants grown under 0 Kg P/ha. While the lowest values of 473.333, 422.67, 81.906 g, 3.177 g, 28.69%, 7.94%, 11118.88 Kg/ha and 1470.06 Kg/ha for the number of leaves per plant, number of seeds per plant, dry matter weight, 100 seed weight, oil percentage, protein percentage, biological yield and seed yield respectively, were obtained by plants grown under control, except protein percentage was obtained by the plants grown under 100 Kg P/ha. Because Phosphorus plays a major role in several physiological processes like photo-synthesis, respiration, energy storage and transfer, cell division, cell enlargement and development of meristematic tissues (Mengal and Kirkby, 2000). In addition, P is also an integral structural component of many biochemical, i.e. nucleic acids, which is the basic component of gene and chromosomes and asses to heredity (Blevins, 1999; Halvin et al., 1999). The P availability may affect yield formation by differential influence on individual yield components. However, little is known on this response in safflower as compared to sunflower (Kumar, 2000).

Data in *Table 5* confirm that the interaction between varieties and phosphorus application levels was significant only for the character Biological Yield Regarding the characters of Biological yield the interaction between Aidnand 100 Kg/ha of phosphorus fertilizer recorded maximum Biological yield reached 18113.00 Kg/h, while the minimum Biological yield was 9341.66 Kg/h recorded by the variety Aidnand the control treatment.

Data in *Table 6* explain the correlation coefficients among the characters. Highly significant and positive correlation represented between seed yield and 100 seed weight similar finding was showed by Singh (2004), while significantly and positively correlated with no. of seeds/plant and biological yield this agree with Pavithra (2016). The character no. of leaves/plant showed highly significant and negative correlation with protein percent, while correlated highly significantly and positively with no. of seed/plant and correlated positively with the character oil percent. Highly significant and positive correlation observed between the characters no. of seed/plant and biological yield, whereas the characters no. of seed/plant was highly significantly and negatively correlated with protein percent. Data in the same table confirm the presence of significant and positive correlation between the character dry matter weight and biological yield. The estimation of correlation coefficient between the character 100 seed weight and biological yield were significant and positive. The character biological yield showed significant and negative correlation with protein percent.

Data in *Table 7* represented the estimation of path coefficient analysis between characters. The character no. of Seeds/plant had maximum positive direct effect on seed yield/plant with 1.803 similar findings was also reported by Semahegn (2016), whereas the character oil% showed maximum negative direct effect on seed yield/plant with -0.690 this result is correspondence with Jadhav (2016). All characters except the plant height and protein% were exhibited maximum positive indirect effect via the character no. of seeds/plant on the seed yield/plant with 1.639, 1.494, 1.054, 0.852 and 0.781, while maximum negative indirect effect was showed by the character protein% via no. of seeds/plant on the seed yield/plant with -1.678.

Conclusions and recommendation

From the results obtained in this study, it can be concluded that the variety of Zaafarani with non-phosphorus fertilizer application to cultivate for produce oil yield. However, the variety of Al-shamia with the level of 100 Kg P_2O_5/ha for produce economic seed yield under the rain fed condition of Sulaimani province and both traits observed to be the most important trait for seed yield improvement in safflower, so we recommended cultivation of these varieties in our region under the application of 100 Kg P_2O_5/ha to reach maximum yield.

Abstract. Parasitism has been ignored in most of the food web research. However, it has been found to play an important role in maintaining food web structure. In order to present further evidences and findings on the functionality of parasitism in food webs, this study used the methodology of network science and meta-analysis to analyze and compare topological properties of seven high-resolution marine and estuarine food webs that include free-living species only and all species with parasites respectively. The results showed that parasites significantly changed the species structure in the food webs. The number and proportion of top species declined and that of intermediate species increased once parasites were included in the food webs. The number of links and cycles, the connectance and link density of food webs significantly increased, among which most links are related to parasites and the complexity of food webs was thus enhanced. Parasitism increased food web spacing and overall clustering coefficient and food webs were made more closely connected. Parasitism was proved to have significant influence on the relative importance of species, and even to make some species crucial species in terms of food webs.
Keywords: *link density, connectance, clustering coefficient, network biology, meta-analysis*

Introduction

A food web is the network to describe between-species trophic relationships and energy / matter flows (Pimm et al., 1991; Kuang and Zhang, 2011; Jiang and Zhang, 2015), in which species are nodes and interacting species are connected by links. In a representative food web, plant species are at the trophic level of the first or primary producers, herbivores are at the second or primary consumer trophic level, and carnivorous animals are at the third or secondary consumer trophic level. In addition, if there are more advanced carnivores that feed on other carnivores, they will produce an even higher trophic level. Food webs are the focus of research on stability, diversity and complexity of ecosystems (Montoya and Pimm, 2006; Pascual and Dunne, 2006; Dunne et al., 2013). As self-organizing systems, they can be used to describe the nutritional relationship between species in the nature (Pimm et al., 1991; Williams and Martinez, 2000; de Araújo et al., 2017; de Araújo, 2018; Zhang, 2015, 2018). Studying food webs helps us understand the patterns of ecosystem organization and their relationship with ecological stability (Pimm, 1991; Pimm et al., 1991; Warren, 1994; McCann, 2000; Ferrarini, 2017; Wahab et al., 2017). A further objective of food web studies is to understand how they affect the functioning of ecosystems, thus further predict the environmental problems such as climate changes and species invasion (Ings et al., 2009).

The early studies of food webs began with MacArthur (1955). Major works during his period included: (1) food webs were in text and graphically expressed; (2) spatial uniformity and relationship linearity of between-species trophic relationships were assumed to analyze the stability and equilibrium of food webs. The studies during 1990s

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34193437

to 2000s have focused on general principles of link distribution. How to find general and stable patterns in food webs was one of the focuses of those studies (May, 1973; Cohen et al., 1993; Navia et al., 2010). Studies have shown that food webs, including terrestrial, freshwater and marine food webs shared some common patterns and features as (Pimm et al., 1991; Jiang and Zhang, 2015): (1) cycles were rarely found in the food web; (2) the mean of the proportion top species (T) / intermediate species (I) / basal species (B), was an invariant value (Cohen and Newman, 1985); (3) the proportion, intermediate to top species links / basal to intermediate species links / basal to top species links, was averagely an invariant; (4) link density was nearly an invariant in the food webs with fewer species, and link density would increase with the increase of species; (6) omnivores were rarely found in certain food webs; (7) compartments were rarely found; (8) for top predators, their food chain length was generally 2 or 3, other chain lengths were rarely found.

As a biological network, the food web has various topological properties, including the number of species (S) and links (L), connectance (C; L/S^2), link density (L/S), cycles, chain length, etc (Kuang and Zhang, 2011; Dunne et al., 2013; Nuwagaba and Hui, 2015). Among these, the number of species and links represent species richness. Connectance and link density can be used to quantify the complexity of food webs and are thus important indicators of food web stability (Pimm and Lawton, 1980; Dunne et al., 2002; Montoya and Solé, 2003; Dunne, 2006; Montoya et al., 2006; Allesina et al., 2008; Allesina and Pascual, 2008; Zhang, 2012a,b). In addition, other topological properties such as Degree Centrality (DC) and Between Centrality (BC) help us measure the importance of a species in the food web (Zhang, 2018).

Unfortunately, most of the above findings have been achieved by analyzing the interactions between free-living species. Recent studies have found that parasites can profoundly affect food web properties. Parasites were found to have almost the same richness and productivity as their free-living hosts with the similar sizes and trophic levels. Studies have demonstrated that in terms of the trophic relationship, parasites had the body size ratio to their hosts that opposites the most free-living consumer-resource body size ratio, which helps them adjust the abundance of their host species. Parasites often have complex life cycles, and sometimes need to live in different host species with various body sizes. They may have the trophic specialization modes different from the free-living predators. They may be associated with their hosts in different topological positions. Their interactions with hosts can reorganize ecological communities and change the functioning of ecosystems. All these factors may lead to their difference with free-living organisms in adapting food webs and affecting food web structures. More and more evidence have been demonstrating that parasites may uniquely alter the food chain length, connectance and robustness of food webs, and thus change the topology of food webs or even the stability, interaction strength and energy flow of food webs (Anderson and May, 1978; McCallum and Dobson, 1995; Dobson et al., 2006; Wood, 2007; Allesina et al., 2008; Allesina and Pascual, 2008a,b; Kuris et al., 2008; Hechinger et al., 2011; Nedorezov, 2012; Sato et al., 2012; Dunne et al., 2013; Jiang et al., 2015; Shakil et al., 2015).

Although most of the food web studies have shown that the vulnerability at the highest trophic level is the smallest, if the parasites parasitize the species at the intermediate trophic level rather than at the lowest trophic level, those species may have the highest vulnerability to natural enemies' attack. These findings indicated that the food web without considering parasites is incomplete. Parasitic links are so important to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34193437

ecosystem stability because they can increase the link density and nestedness (Lafferty et al., 2006a,b). Parasites are always ignored mainly due to their small sizes, and lack of cross-disciplinary collaboration, identification and quantification of parasites in food webs, and parasitology skills (Lafferty et al., 2008).

Given the importance of parasites in food webs, how to include parasites in food web studies is becoming a very important topic in recent years and findings have been achieving (Huxham et al., 1995, 1996; Marcogliese and Cone, 1997; Memmott et al, 2000; Marcogliese, 2003; Lafferty et al., 2006a,b; Hernandez and Sukhdeo, 2008; Lafferty and Kuris, 2009; Amundsen et al., 2009, 2012; Warren et al., 2010; Kuang and Zhang, 2011; Dunne et al., 2013; Jiang et al., 2015; Jiang and Zhang, 2015). However, the further confirmation of above findings and deep exploration of the impact of parasites on topological structure of different food webs is still a problem to be addressed. For example, Kuang and Zhang (2011) studied the Carpinteria Salt Marsh (CSM) food web and have reached certain conclusions, such as the changes in species structure, and the increase in the number of cycles and links, and the increase of chain length and omnivorousness if parasites have been included, etc. Nevertheless, these results have been obtained from the topological analysis on a single food web with relatively low accuracy. In addition, although ecologists acknowledge the important role that parasites play in ecological communities, but few literatures have examined whether the addition of parasites changes the crucial species in the food web. In general, the specific mechanism of influence of parasites on the topology of food webs is still unclear and needed to be further exploited.

In recent years, with the advance of food web studies, we have been obtaining more and more full and fine quantitative data (Ings et al., 2009). These data make the findings of food webs more rigorous and credible. However, many of these results appeared to be non-natural laws because the data used was incomplete and the error has thus produced (Cohen et al., 1993; Winemiller and Polis, 1996). Aiming to present further evidences on the functionality of parasitism in food webs, the present study used the methodology of network biology and meta-analysis to analyze and compare the topological properties of seven high-resolution marine and estuarine food webs that include free-living species only and all species with parasites respectively.

Materials and Methods

Materials

Data sources

The food web data used in present study were achieved from seven sources: (1) Carpinteria Salt Marsh (CSM) (Hechinger et al., 2011); (2) Estero de Punta Banda (EPB) (Hechinger et al., 2011); (3) Bahía Falsa in Bahía San Quintín (BSQ) (Hechinger et al., 2011); (4) Flensburg Fjord on the Baltic Sea (FFB) (Zander et al., 2011); (5) Otago Harbour (OHR) (Mouritsen et al., 2011); (6) Sylt tidal basin in Germany and Denmark (STB) (Thieltges et al., 2011), and (7) the Athan estuary, Aberdeenshire (YEA) (Huxham et al., 1996). For the seven high-resolution coastal estuary food webs above, two versions of each network were analyzed: one containing predators and preys only (-FREE), and the other containing all species and links including parasitoid relationships (ALL).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34193437

These food webs are composed of basic species, free-living species and parasites. Among them, the BSQ ALL network contains 171 species, of which 52 species are parasitic. The CSM ALL network contains 165 species, of which 58 species are parasitic. There are 214 species in the EPB ALL network, of which 76 species are parasitic. FFB ALL includes 123 species, of which 46 are parasitic species. OHR ALL has 142 species, of which 19 species are parasitic. STB ALL network contains 161 species, of which 35 species are parasitic. YEA ALL contains 134 species, of which 42 species are parasitic. The raw data for each network consists of two columns, the first column is the consumer species, and the second column contains the species with the same category as the first column, but exists as predators or hosts.

Data transformation

Before making analysis, the format of the data obtained above should be transformed. First, we constructed the $n \times n$ food web matrix of n species based on the predation relationship between species, in which the elements were composed of 0 or 1. If there is the predation relationship between the two species and the column species is predator, the element is represented by 1. Otherwise, 0 means that there is no predation between the two species. Second, after constructing the food web matrix, UCINET and Netdraw software were used to transform the ".xlsx" file in Excel to the ".net" file in Pajek. And in UCINET, the command series was used: data→data editors→matrix editor, and then ".##h" format data was saved. In Netdraw, the command series was conducted: file→open→ucinet dataset→network, and the previously saved ".##h" file was opened by the command series: →file→save data as→pajek→net file, and finally, we saved the data as ".net" format file for forthcoming analyses (Jiang and Zhang, 2015; Zhang, 2012a, 2018).

Methods

Pajek

Pajek is the computational platform for analyzing and visualizing complex networks that contain up to millions of nodes. A variety of methods/algorithms for network analysis are embedded in Pajek. It is mainly used to conduct global analysis on complex networks (Batagelj and Mrvar, 2004; Kuang and Zhang, 2011; Jiang and Zhang, 2015; Zhang, 2018).

Network analysis

(1) Category of species

In the network analysis, the number of species (nodes) is generally denoted by S. The species in the food web can be divided into top species (T; i.e., the species that cannot be fed by other species), intermediate species (I; i.e., the species acting as both predators and preys), and basal species (B; i.e., the species unable to feed on other species) (Pimm et al., 1991; Dunne et al., 2013).

(2) Degree analysis

The degree of a node refers to the number of nodes connected to the node (Zhang, 2012c, 2018). Degree is the most basic topological property for complex networks. In general, the greater the degree of a node is, the higher the importance of the node in the network will be. In a directed network, the degree of a node is the sum of incoming degree and outgoing degree. Food webs are directed networks. In the Pajek software, we

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34193437

can execute the command series, Net→Partions→Degree→In/Out/All under Net/Partitions/Degree menu, to achieve the incoming degree, outgoing degree and total degree.

(3) Food chain and food cycle analysis

A cycle (i.e., circuit) is a closed chain in the food web. In the food web, there are sometimes phenomena such as *A* feeds on *B*, *B* feeds on *C*, and *C* feeds on *A*. In such a situation, a closed loop is generated among the species *A*, *B* and *C*. Cannibalism is one of the food cycles. In the Pajek, the food cycles can be obtained by running the command series, Net→Count→4-rings→Directed→Cyclic.

(4) Link and connectance analysis

Two species (i.e., nodes) produce a link through predation relationship. The number of links in the network is represented by *L*. The link relationships are generally classified into basal species –intermediate species link (*B-I*), intermediate species - intermediate species link (*I-I*), basal species - top species link (*B-T*), and intermediate species - top species link (*I-T*).

Connectance (*C*) refers to the percentage of links *L* observed in the food web as a percentage of all possible connections that may be present in the web. That is, $C=L/S^2$ (Dunne et al., 2013). Link density refers to the ratio of the number of links in the food web to the number of total species (*L*/*S*) (Zhang, 2012a,b, 2018). If link density remains the same, the more species in the food web has, the greater the connectance will be (Pimm et al., 1991).

(5) Crucial species and node centrality analysis

Every species in the food web are different in maintaining ecosystem function. It is often necessary to identify crucial species that are extremely important or have a large impact on the food web, which is also due to the consideration of species protection (Jordán, 2009). Network topology analysis plays a powerful role in quantifying the importance of species (Livi et al., 2011). Node centrality measures can be used to quantify the importance of species in food webs. In present study, degree centrality (*DC*) and closeness centrality (*CC*) were used (Jiang and Zhang, 2015; Zhang, 2012a, 2018) to identify crucial species. In the Pajek, degree centrality can be obtained by implementing the command series: Net→Partions→DC→All. Closeness centrality is the average shortest path between a node and other nodes (Wasserman and Faust, 1994):

$$CC_i = \frac{N-1}{\sum_{j=1}^{N} d_{ij}} \quad \text{(Eq.1)}$$

where d_{ij} is the distance of the shortest path between node *i* and node *j*. Generally, the larger the *CC* value is, the smaller the average distance between the node *i* and all other nodes will be, and the greater the importance of the node *i* is.

(6) Triadic structure analysis

Three nodes (i.e., vertices, species) may maximally generate 16 possible structures (triadic structures) in a directed network. For example, all possible structures generated by three nodes A, B, and C are 003=A, B, C; 012=A→B, C; 102=A↔B, C; 021D=A←B→C; 021U=A→B←C; 021C= A→B→C; 111D=A↔B←C; 111U=A↔B→C; 030T=A→B←C, A→C; 030C=A←B←C, A→C; 201=A↔B↔C; 120D=A←B→C, A↔C; 120U=A→B←C, A↔C; 120C=A→B→C, A↔C; 210=A→B↔C, A↔C; 300=A↔B↔C, A↔C (Wasserman, 1977). However, four

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34193437

possible structures exist in the undirected network, i.e., 003, 102, 201, and 300, in which the structure 300 is a complete network called triadic structure. The number of triadic structures can be used to reflect the spacing degree of a food web. The effect of parasites on the food web spacing can be understood by comparing the numbers of triadic structures that contain free-living species and all species respectively. Since the food web is a directed network, in Pajek we can analyze triadic structures by implementating the command series, Net→Transform→Arcs-Edges→All,Info→ Network→Triadic Census, or Nets→Fragment (First in Second)→Find.

(7) Clustering coefficient and similarity analysis

The clustering coefficient refers to the proportion of closed dual chains occupying the network (Dunne et al., 2013), which reflects the closeness of node connections in the network. The clustering coefficient of a node can be represented by the ratio of the observed number of links existing between adjacent nodes of the node and the total number of possible existing links. The clustering coefficient of the entire network can be achieved implementing the command series in Pajek: Net→Vector→Clustering coefficients→CC1. In addition, if two nodes share more adjacent nodes, the two nodes can be considered to have the higher similarity. In present study, we used the command series in Pajek to conduct hierarchical clustering analysis and, to compare the similarity between food webs with or without parasites, and to further understand whether parasites have any influence on the similarity of species in food webs: Cluster→Create Full Cluster→Operations→ Dissimilarity→Network based→Dl→All.

Results

Tropic structure of food webs

According to statistic survey, the number and proportion of top, basal and intermediate species for seven food webs, including the complete food webs with parasites (BSQ-ALL, EPB-ALL, etc.), and the food webs containing free-living species only (BSQ-FREE, EPB-FREE, etc.) are shown in *Table 1*.

From *Table 1*, we can find that the inclusion of parasites in each food web does not change the number of basal species. For instance, there are always four basal species in YEA-ALL and YEA-FREE, however, the number and proportion of intermediate and top species change greatly in all food webs. In general, the inclusion of parasites has greatly reduced the proportion of top species. For example, the number of top species in YEA reduced from 31 and 13, and the proportion reduced from 33.70% and 9.70%; the number of top species in STB decreased from 27 and 11, and the proportion decreased from 21.43% and 6.83%. These changes may have been due to the increase in the complexity of food web after the inclusion of parasites. In this process, some of the original top species were parasitized, and their role in the food web changed from the top species to the intermediate species. At the same time, the parasites that were temporarily the top species had the possibility of being preyed by other species, and transformed to intermediate species from the top species. As a consequence, the number of intermediate species increased and the number of top species declined drastically. Nevertheless, there were some exceptions. For instance, in the CSM food web, we can find that the number of species did not change although the species composition has changed, and the proportion increased correspondingly. This result is different from the previous research. It may be due to that other species joined the food web through migration or invasion during the later period (e.g., the number of species of free-living

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34193437

species increased from 83 and 107), which changed the original trophic relationship in the food web, and further changed the proportion of top species. Taking the EPB food web as an example (*Figures 1 and 2*), it is obvious that the inclusion of parasites significantly led to the reduction of top species (from 9 and 3 species), which in turn changed the proportional relationship in the food web.

Link analysis

There are in total of 1192 links (i.e., connections) in the predator-prey food web of BSQ-FREE. The connectance and link density of the predator-prey food web of BSQ-FREE are 0.08 and 10.02, respectively (*Figure 3*). For the BSQ-ALL, the total number of links, connectance and link density are 3889, 0.13, and 22.74, respectively. In addition, the total number of species in BSQ-FREE accounts for 0.696 (69.6%) of BSQ-ALL species, while the total number of links of the former is 0.307 only. Further details of link and connectance statistics are indicated in *Table 2*, and *Figures 3 and 4*.

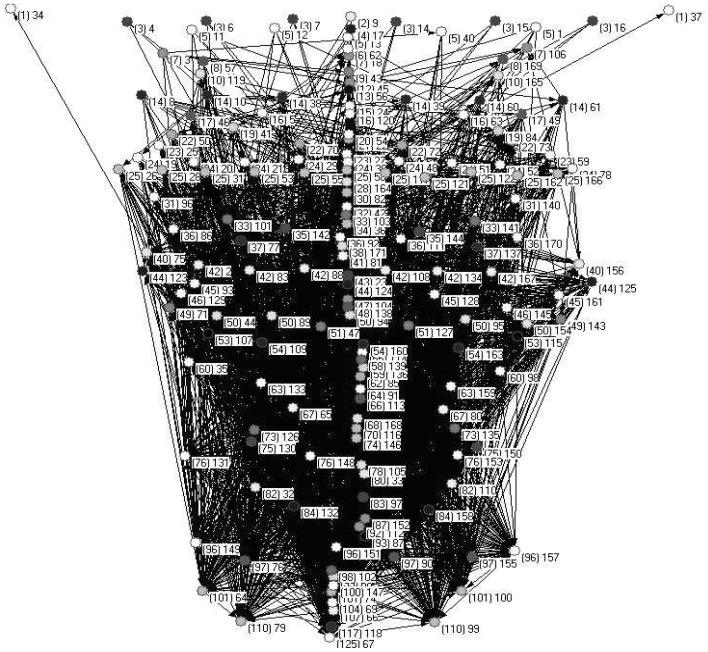

Figure 3. *The BSQ-ALL food web. The number outside the brackets is species ID and the number inside the brackets is total links of the species. From top layer to bottom layer, the species are arranged in the order from the smallest to the greatest number of links. There is the same number of links for the species at the same layer*

Table 2 indicates that in exception of FFB, the total number of links, connectance and link density of other free-living food webs increased significantly after parasites have been included, because the number of species in the predator-prey food webs accounts for nearly two-thirds of the complete web but the proportion of total links is rarely greater than one-third. Taking YEA as an example, the total number of YEA-FREE species accounts for 68.66% of YEA-ALL, while the proportion of total links is 33.34% only. Therefore, the inclusion of parasites has greatly enriched the trophic relationships in the food web and led the links in the food web, which increased the complexity of the food web.

Food cycles

Pimm et al. (1991) demonstrated that food cycles seldom occurred in most of the food webs. Conversely, our results indicated that food cycles frequently occurred in the food webs above, including the food webs without parasites. The inclusion of parasites may greatly increase cycles in the food web (*Table 3*).

Crucial species and species centrality

From *Figures 5 and 6*, we can find that BSQ-ALL has more connections than BSQ-FREE, and the closeness centrality of species in BSQ slightly increases if parasites are included (BSQ-ALL). Parasitic species ID 147 shows some more importance in BSQ-ALL.

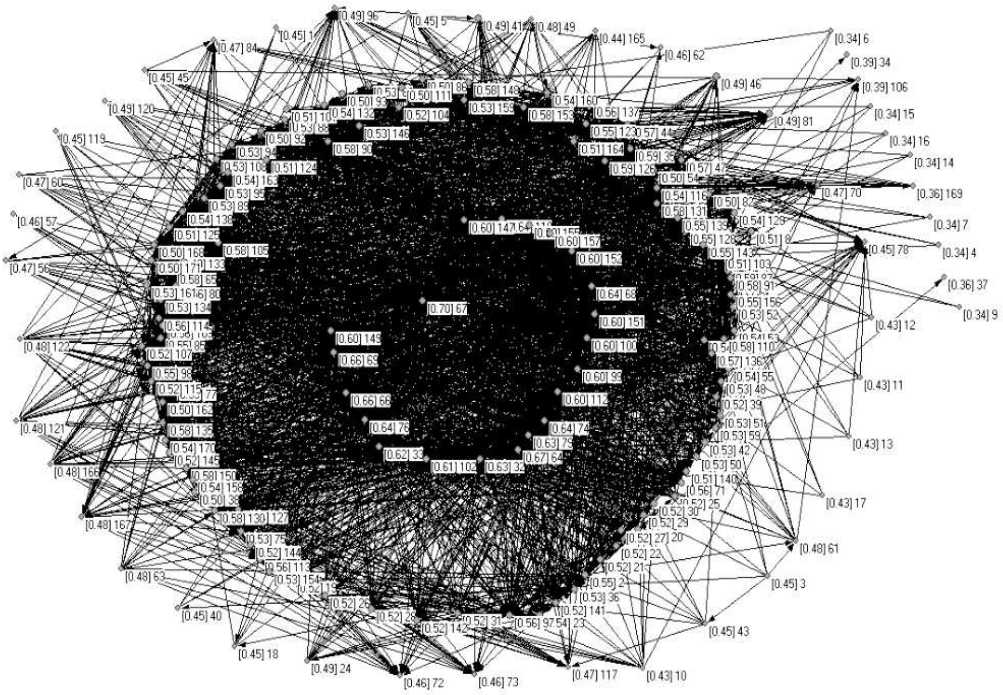

Figure 5. *Closeness centrality of species in BSQ-ALL food web. The number outside the brackets is species ID and the value inside the brackets is closeness centrality of species*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34193437

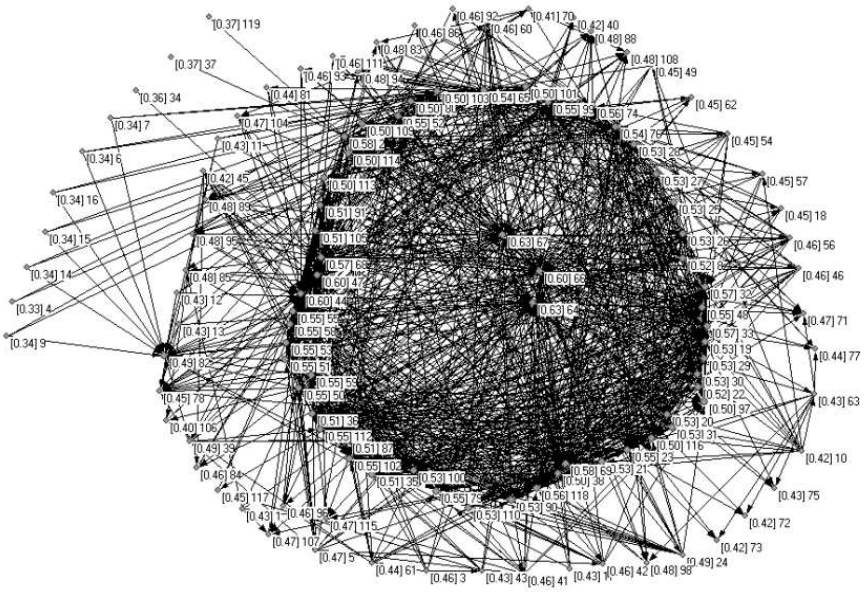

Figure 6. *Closeness centrality of species in BSQ-FREE food web. The number outside the brackets is species ID and the value inside the brackets is closeness centrality of species*

The species with the greater degree centrality (*DC*) and closeness centrality (*CC*) in the BSQ-ALL and BSQ-FREE food webs are shown in *Table 4*.

Table 4. *The species with greater degree centrality (DC) and closeness centrality (CC; Eq. (1)) in BSQ food web*[*]

BSQ-ALL		**BSQ-FREE**	
DC	***CC***	***DC***	***CC***
67	67	67	64
118	64	64	67
79	69	66	44
99	66	74	47
66	118	44	66
69	76	47	69
64	68	76	2
74	74	69	32
100	32	2	33
147	79	65	68

[*]Food web BSQ was sourced from Hechinger et al. (2011)

Since the *DC* value of a node can generally reflect the influence of other nodes on this node, and the *CC* value focuses on the local topology (Okamoto et al., 2008), *DC*s and *CC*s in *Table 4* can be combined to measure and rank nodes' importance, as indicated in *Table 5*. The results show that crucial species in the BSQ-ALL food web are the species IDs 67, 118, 64, 66 and 69, while the species with greater importance in the BSQ-FREE food web are the species IDs 64, 67, 44, 66 and 47.

According to *Table 5*, the rank of species importance changes if the parasites are included the food web. In some food webs, parasites have the greater importance and become crucial species. For instance, there are seven parasite species in the top ten species list of STB-ALL. Parasites may have lowered the relative importance of some free-living species (e.g., the species ID 1 in FFB), or enhanced the importance of other species (e.g., the species ID 5 in YEA).

Triadic structures

Details of the triadic structures of the seven food webs are listed in *Table 6*.

According to *Table 6*, for example, FFB-ALL food web contains 3888 triadic structures while FFB-FREE food web contains 673 triadic structures only. It is obvious that the inclusion of parasites greatly increased the number of triadic structures in food webs.

Clustering coefficients

A greater clustering coefficient means the greater closeness of connections and species are thus more likely parasitized. As shown in *Table 7*, the clustering coefficients of each food web increase if the parasites are included.

Table 7. *Clustering coefficients of the seven food webs*[*]

Conclusions

In present study, seven high-resolution riparian food webs were used to analyze topological properties of the complete food webs (-ALL) and the food webs containing only free-living species (-FREE). The conclusions on the importance of parasites were drawn or further confirmed in the following aspects:

(1) Parasitism changes trophic structure of species in the food web, i.e., the number and proportion of top species decline and the number and proportion of intermediate species increase. Although the number of top species in the CSM-ALL and CSM-FREE food webs was the same (Kuang and Zhang, 2011), the number and proportion of intermediate species increased significantly after parasites were included, which was basically consistent with the present conclusion.

(2) The presence of parasites increases the complexity of the food web. The number of links in food webs was proved to increase significantly as the inclusion of parasites, and most of the links were related to parasites, which means that parasites play an important role in the food web and the complexity of the food web is enhanced.

(3) Parasites significantly increase the number of cycles in the food web. Pimm (1991) found that there were few cycles in the predator-predator food webs. In present study, the results of FFB, STB, and YEA food webs coincided with his conclusion. In addition, the number of cycles in the food webs increased sharply after including parasites. On the one hand, the original connection relationship became more complex and thus the possibility of cycle occurrence increased due to the existence of parasites. On the other hand, considering the complicated life cycles of parasites, a series of cycles may also be produced among parasites.

DOI: http://dx.doi.org/10.15666/aeer/1802_34193437

(4) The presence of parasites alters the importance of species in the original food web. Network analysis demonstrated that parasites have produced a great impact on the relative importance of species in the food web, even as a crucial species in the complete food webs due to their great importance.

(5) Parasites increase the food web spacing. The number of triadic structures increased as the inclusion of parasites in the food web, thus making food web spacing significantly increased.

(6) Parasites increase the overall clustering coefficient of the food web, making the food web more closely connected. Parasitism is further enhanced with positive feedback mechanism as the increase of the clustering coefficient of the food web. The interaction between parasitism and the clustering coefficient is mutually reinforced.

Discussion

The food web is a major theme of fundamental ecology, which concerns with the stability, diversity and complexity of ecosystems (Pascual and Dunne, 2006). Traditional food web research mostly focuses on free-living species, while parasitism that are widespread in nature and are often difficult to detect has been ignoring (Price, 1980). As researchers become more aware of the importance of parasites and their possible effects on the structure, dynamics, and function of food webs, many have begun to focus on this potential area and a series of research have been conducting (Pascual and Dunne, 2006; Dunne et al., 2013; Michalska-Smith et al., 2018). More and more complete food webs containing parasites have been built and some research results were obtained. Studies have confirmed that parasites may change the structure and function of food webs (Sato et al., 2012). Nevertheless, the impact of parasites on the topological properties of the food web needs to be further exploited. The number of links, connectance and link density in the above food webs can reflect the potentiality of energy circulation paths, and thus may indicate the complexity of the food webs. MacArthur (1955) argued that the complexity of food webs can be considered as a key indicator of web stability. The research on the topological properties of networks also helps us measure the stability of food webs. In addition, studies have shown that parasites as pathogens of infectious diseases or as crucial species play an important role in maintaining the stability of ecological communities and ecosystems (McCallum and Dobson, 1995). Our conclusions further proved that parasites change the importance of the original species and may even become crucial species. They will increase the clustering coefficient of the food web and expand the epidemics of infectious diseases. It may be beneficial to the construction of relevant models in epidemiological studies (Shams and Khansari, 2019).

Some aspects should be further strengthened in the future studies: (1) network robustness of the food webs with parasites (Zhang, 2016), which is different from stability; (2) food web models specific to the food webs with parasites (Cohen and Newman, 1985; Cohen et al., 1990; Williams and Martinez, 2000), and (3) mechanisms of parasitism in maintaining food web structure.

Abstract. The current study was undertaken to assess the environmental adaptability and water capability of *Hyriopsis cumingii* in a recirculating aquaculture system in the Chongqing region, Southwestern China. A total of 175 species of planktonic algae belonging to 8 phylum and 75 genera were found at all sampling sites. 66.3% - 80.0% of them belong to the Chlorophyta and Bacillariophyta phyla, the main food sources of bivalve shellfish. The annual investigation results show that the range of water physical and chemical indexes fully meets the requirements of *H. cumingii* growth, with its average wet weight increasing from 359.4 g to 525.6 g. Concerning water purification, even though *H. cumingii* had no obvious effect on the composition of planktonic algae, it could reduce the phytoplankton biomass in all five sampling sites in the summer by 23.7% on average. Moreover, the transparency of the ecological purification area can be increased by 15.3% on average. Besides, the decrease of electro conductivity (4.9%), ammonia nitrogen (6.7%) and phosphate (7.2%) in *H. cumingii* purification area was determined in this study. Overall, *H. cumingii* showed excellent ecological purification function, and its mixed farming model based on the recirculating aquaculture system is worthy of further study.
Keywords: *Hyriopsis cumingii, recirculating aquaculture system, phytoplankton, ecological purification, freshwater*

Introduction

Human beings have complex social and ecological dependency on the freshwater ecosystem (Kingsford et al., 2011; Horton et al., 2015). In recent years, the environmental function of freshwater shellfish has gradually attracted the attention of the industry due to the policy guidance in China. Some mixed breeding modes, such as "fish and mussel mixed breeding" and "shellfish and shrimp mixed breeding", have been mentioned and developed again in freshwater aquaculture (Modesto et al., 2018; Wang et al., 2018). However, freshwater shellfish industry has been neglected for a long time in China due to its small scale and long economic cycle. The production of 0.20 million tons only accounts for 0.66% of the total freshwater aquaculture in 2018 (Zhang et al., 2019). Moreover, the freshwater shellfish industry is still in the infancy in southwest China, and its adaptability to the local environment and related water purification mechanisms need to be studied urgently. This project mainly focuses on the growth adaptation and water

purification function of *Hyriopsis cumingii* in the recirculating aquaculture system in the Chongqing region.

Recirculating aquaculture system (RAS) is a water circulation pond with an air stripping device to realize high-density intensive aquaculture in a rectangular mixed-cell rearing unit (Watten et al., 2000; Ebeling et al., 2005). It has transparent functional partitions including the aquaculture area, tail water discharge area and purification area. This mode has been applied and extended in the Chongqing region in recent years. Our group predicts that N, P and phytoplankton are abundant in the tail water discharge area, and potential water purification could be achieved by cultivating shellfish. On one hand, shellfishes may provide an ecosystem service through nutrient assimilation in soft tissues and adamant shells, and facilitate the permanent removal of carbon, nitrogen, phosphorus, bacteriological quality and so on (Cha et al., 2011; Kellogg et al., 2013; Bianchi et al., 2014). Meanwhile, the purification function and physiological responses of shellfish may be expected to vary with environmental conditions (Bianchi et al., 2014; Hoellein et al., 2015). On the other hand, phytoplanktons are primary producers in pond aquaculture, and their species, quantity, community structure and species diversity have significant influence on the growth of aquatic animals (Daines et al., 2014). Previous studies have suggested that freshwater shellfish can effectively control the content of chlorophyll and organic matter in ponds (Hawkins et al., 2013). Besides, bivalves show specific feeding selectivity in the process of filter feeding. For example, the digestibility of greenshell mussel *Perna canaliculus* to dinoflagellates is higher than that of diatoms, showing a carnivorous tendency (Ren et al., 2006). However, the studies remain unknown on phytoplankton growth and reproduction, diversity index and stability of the pond ecosystem.

China's commercial freshwater pearl industry has been developing for more than 50 years and has accounted for more than 90% of the world's total cultured pearl production in recent two decades (Dan and Ruobo, 2002). Among them, as a unique Unionidae family resource in China, bivalve mollusk triangle sail mussel *H. cumingii* is the best selection for producing high quality freshwater pearls and is widely distributed in the Yangtze River basin and Huaihe River basin (Jin et al., 2012; Qu et al., 2018). At present, despite the great development in the research of artificial propagation and seedling raising (Li and Li, 2009), genetic breeding (Bai et al., 2016), growth traits and pearl cultivation (Jin et al., 2019; Zhang et al., 2019), the applied research on the ecological function still lags in *H. cumingii*. Recently, the use of *H. cumingii* has been proposed as an alternative measure to control algal bloom in eutrophic water bodies (Liu et al., 2014). However, there is no comprehensive data on the dynamic response mechanism of phytoplankton and its correlation with water quality factors. Besides, the water environment in southwest China meets the requirements of *H. cumingii* farming in theory. The optimal conditions for *H. cumingii* growth mainly include water temperature (23-32℃), dissolved oxygen (DO, >4 mg/L), pH (>7.5) and salinity (<0.2‰), total alkalinity (24-219 mg/L), total hardness (40-218 mg/L), total nitrogen (TN, 0.52-1.91 mg/L) and total phosphorus (TP, 0.06-0.30 mg/L), etc. (Lin et al., 2004). Also, the growth of bivalve shellfish could be effected by the species of shellfish, the nutrition of the bait, the season changes and mixed culture mode (Naddafi et al., 2007). The aim of the present study was to comprehensively investigate the purification function of *H. cumingii* in a recirculating aquaculture system, including the influence on algal facies and water quality factors.

Methods

Sampling site and H. cumingii layout

In 2018, we first set up five recirculating aquaculture system testing bases in the Chongqing region, southwest China (*Figure 1A*), including Tongliang qinggang breeding bases (29°8449′N, 105°8609′E), Bishan xinyue aquaculture co., LTD (29°6844′N, 106°2537′E), Bishan zhubi breeding base (29°6853′N, 106°2559′E), Changshou dahonghu aquatic co., LTD (30°0406′N, 106°9742′E) and Liang ping hongyun fishery co., LTD (30°6791′N, 107°6472′E). Each flume is about 7 m in length and 2.5 m in width. Healthy *H. cumingii* (Wet weight: 368.9 ± 106.1 g, Shell length: 15.7 ± 1.4 cm; Shell width: 4.2 ± 0.3 cm; Shell height: 12.5 ± 1.2 cm) aged about 3 years were located about 30 cm underwater in the outlet area of the aquaculture pond (*Figure 1B*). Furthermore, the average amount of *H. cumingii* in the purification area is 400-600 per aquaculture pond. The water quality and algal facies of the shellfish purification area, tail water discharge area and ecological purification area were monitored for four quarters on March 21, June 20, September 3 and December 25. Sampling sites Bishan zubi were not fully sampled because the *H. cumingii* were not stocking in spring and the florfenicol induced shellfish death in winter.

Phytoplankton quantitative collection

The collection of water samples from different sampling points and functional areas was accomplished according to the established methods in hydrobiology. Mixed water samples of about 0.5 m depth were collected with plexiglass water sampler, then fixed with 1.5% Lugol's iodine, placed in sedimentator for 24 h and concentrated into 50 mL centrifuge tube. Treated samples were qualitatively and quantitatively analysed by microscope counting. The phytoplankton composition of samples was determined by referring to "The common phytoplankton atlas of Chongqing region of the three gorges reservoir area" and "The common freshwater phytoplankton algae atlas of China" (Zhou and Zheng, 2005; Weng and Xu, 2010). The quantitative formula of phytoplankton is as follow:

$$C = N \times \frac{S_c}{S_f \times n} \times \frac{V_1}{V_2 \times V} \quad \text{(Eq.1)}$$

where, C is the phytoplankton density; N is the count result of phytoplankton in the observation field; S_c is the area of the counting box; S_f is the area per view; n is the number of views per slice; V_1 is the volume after concentration; V_2 is the volume of the counting box; V is the volume before concentration.

The calculation formula of preponderance degree is as follow:

$$Y = \frac{n_i}{N} \times f_i \quad \text{(Eq.2)}$$

where, Y is the preponderance degree; f_i is the frequency of algae i in the sample; n_i is the density of algae i; N is the total algal density. Among them, the dominant species is algae with Y value greater than 0.02, and the absolute dominant species is algae with Y value greater than 0.1.

Investigation in the physical and chemical index of water bodies

Electro conductivity, dissolved oxygen (DO) and pH values were detected by the portable dissolved oxygen meter (HQ30D, HACH Company, USA). Water temperature and transparency were detected by the water thermometer and transparency disc, respectively. Moreover, water samples were collected and brought back to the laboratory for water quality analysis according to relevant national standards (Wei et al., 2002). The collection, fixation and preservation of water samples were conducted following "the code for water environment monitoring (SL219-98, in Chinese)". Ammonia nitrogen was measured by the Nessler reagent colorimetry (NH_4^+-N, GB 7479-87). The phosphomolybdic acid methodologies measured phosphate (PO_4^{3-}-P, GB 9727-2007).

Statistical processing

Electro conductivity, water temperature, dissolved oxygen and pH values were measured twice with a calibrated portable dissolved oxygen meter. Each phytoplankton parameter and waterquality index was determined twice independently. All data expressed as mean.

Results

Phytoplankton composition and structure in sampling sites

A total of 175 species of planktonic algae belonging to 8 phyla and 75 genera were found in all five sampling sites (*Figure 2A*). Among them, Chlorophyta had the highest number of 33 genera and 67 species, accounting for 44.0% and 39.4% of the total. The second to the eighth are Bacillariophyta (16 genera, 45 species), Cyanophyta (13 genera, 24 species), Euglenophyta (5 genera, 21 species), Pyrrophyta (2 genera, 5 species), Cryptophyta (2 genera, 4 species), Xanthophyta (2 genera, 2 species) and Chrysophyta (2 genera, 2 species) phyla, respectively. Moreover, although the number of algae is different in each sampling site, the composition of algae facies is roughly consistent with the overall structure (*Figure 2B*). Moreover, the total number of species of Chlorophyta, Bacillariophyta, Cyanophyta and Euglenophyta phyla at all sampling sites were accounted for more than 90%. Among them, Chlorophyta and Bacillariophyta phyla are important bait categories of shellfish, accounting for 68.5%, 80.0%, 70.8%, 67.1% and 66.3% of the sampling sites respectively (*Figure 2B*). Also, there was a great difference in species classification among the sampling points. Fifty-five of the 175 species, or 32.4 percent, were observed at only one sampling site. And about half of the algae species were detected at only one or two sampling sites. Only 23.5% of the species were detected at all five sampling sites (*Figure 2C*).

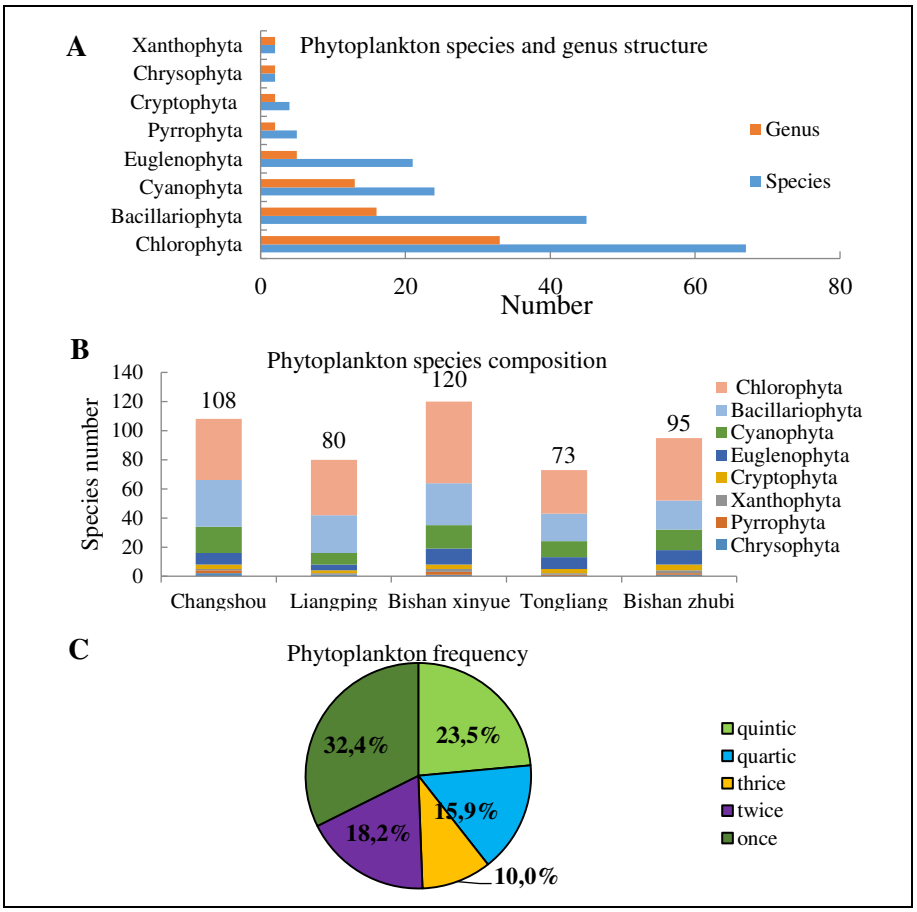

Figure 2. *Distribution of phytoplankton. (A) shows the species and genus structure in all sampling sites. (B) shows the phytoplankton species composition in each sampling sites. (C) shows the distribution characteristics of phytoplankton between sampling sites*

Filtering effect of H. cumingii on phytoplankton

H. cumingii filtering effects on phytoplankton were reflected in *Figure 3*. The results indicated that the phytoplankton biomass in summer and autumn were higher than those of spring and winter in Changshou, Liangping and Bishan xinyue. Sampling sites Bishan zubi were not fully sampled because the *H. cumingii* were not stocking in spring and the florfenicol induced shellfish death in winter. The results also revealed that *H. cumingii* could effectively reduce the biomass of phytoplankton. The phytoplankton biomass of the shellfish purification area and biological purification area were generally lower than that of the tail water discharge area. Results showed a 23.7% biomass reduction on average in all five samplings sites in the summer. Among them, the Liangping biomass of shellfish purification area and ecological purification has fallen by more than 85% in comparison with tail water discharge area in the summer. Besides, in some parts of the sampling sites phytoplankton biomass showed no noticeable change, such as Bishan zubi in winter, Changshou, Liangping and Tongliang in autumn (*Figure 3A-D*).

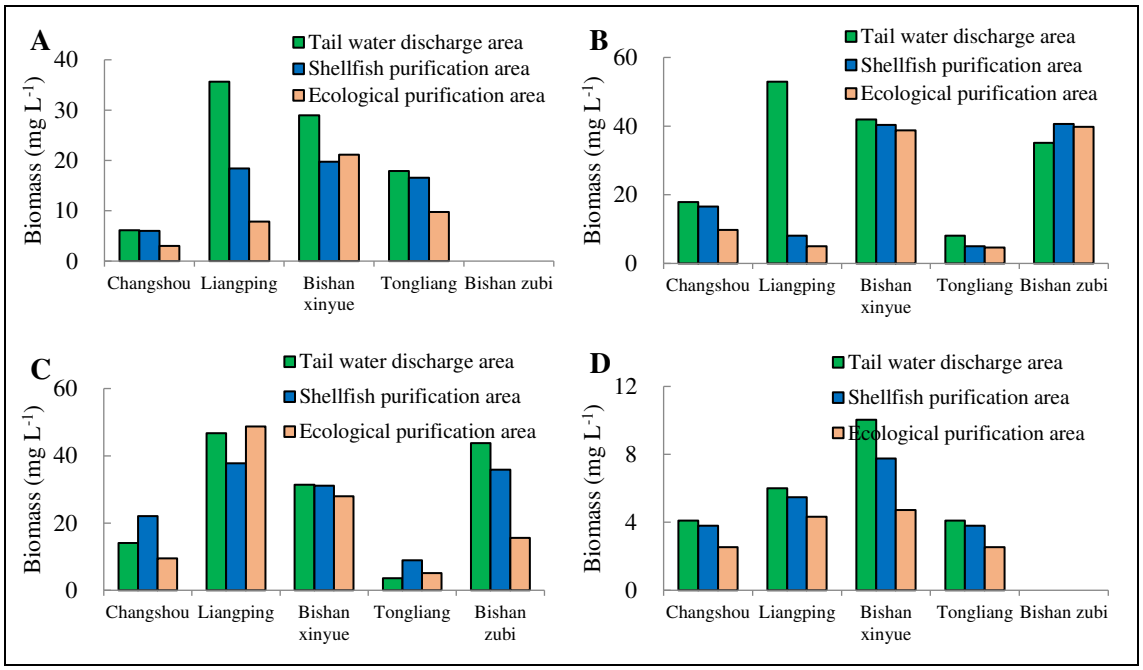

Figure 3. *Filtering effect of H. cumingii on phytoplankton biomass in four seasons (A, Spring; B, Summer; C, Autumn; D, winter)*

Although *H. cumingii* can significantly reduce the phytoplankton biomass, the total number of dominant algae has no obvious change. The preponderance degree and dominant species analysis results of higher biomass in summer and autumn are shown in *Tables 1 and 2*, respectively. Phytoplankton's dominant species mainly belong to the Cyanophyta, Chlorophyte and Bacillariophyta phyla in each sampling site. And a few numbers of dominant species mainly belong to the Xanthophyta, Euglenophyta and Cryptophyta phyla. However, the summer preponderance degree of all the Chlorophyte and Bacillariophyta in Bishan zubi, Tongliang and Bishan xinyue are less than 0.02, except *Chlorella vulgaris* Beij and *Coelastrum microporum* Nägeli (*Table 1*). The autumn preponderance degree of all the Chlorophyte and Bacillariophyta phyla in Changshou are less than 0.02, except *Pandorina morum* Bory and *Synedra acusvar* (*Table 2*).

T represents tail water discharge area, H represents H. cumingii purification area, E represents ecological purification area

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34393454

Furtherly, phytoplankton dominant species in all sampling sites changed constitutively with the turn of seasons. For example, the dominant algae in Liangping mainly belong to Bacillariophyta and Chlorophyte phyla in the summer, and change into Cyanophyta phyla in autumn. Overall, *H. cumingii* showed an excellent filter-feeding feature to *Chlorella vulgaris* Beij, *Sceaedesmus dimorphus* Kütz, *Merismopedia punctata* Meyen, *Cymatopleura stelligera* Grun and *Navicula viridula* Kütz, as the preponderance degree of the shellfish purification area and ecological purification area are lower than that of the tail water discharge area (*Tables 1 and 2*).

Effects of H. cumingii on water environmental characteristics

The basic physical and chemical characteristics of the aquaculture water in the testing base are shown in *Figure 4*. The change of water temperature is basically consistent among five testing bases. Among them, Changshou base autumn water temperature can reach 35.6℃, and the temperature at the Liangping base is as low as 9.2℃ in winter. The results showed that *H. cumingii* adapted to the changes in water temperature in the Chongqing region (*Figure 4A*). The dissolved oxygen at different sampling sites and seasons varied greatly, but all the concentration was within the range of 4-12 mg L^{-1} (*Figure 4B*). Moreover, the water quality of the pond was weakly alkaline at all sampling sites, except Changshou in autumn and winter and Bishan in autumn (*Figure 4C*). Overall, the water environment in the Chongqing region fully meets the requirements of *H. cumingii* farming.

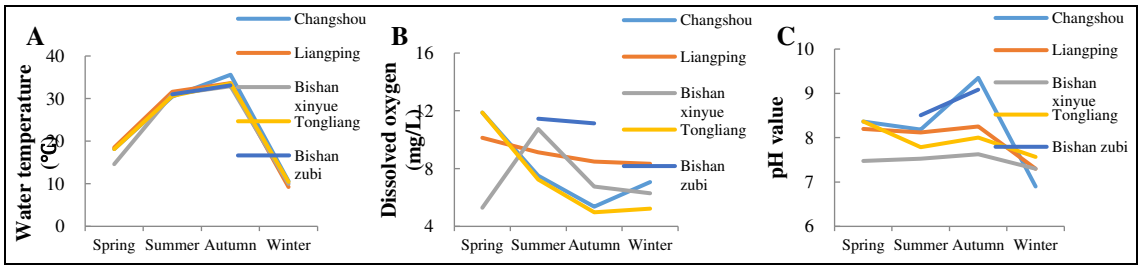

Figure 4. *Basic environmental factor of the aquaculture water in samplings sites. (A, water temperature; B, dissolve oxygen; C, pH value)*

The water purification effects of *H. cumingii* were reflected in *Figure 5*. The water transparency, electric conductivity, ammonia nitrogen and phosphate at different sampling sites and seasons are significantly different (*Figure 5A-D*). And the electro conductivity (4.9%), ammonia nitrogen (6.7%) and phosphate (7.2%) in purification area also decreased in this study. Besides, the results showed that the water transparency of spring and winter were higher than those of summer and autumn in each sampling sites. Generally, *H. cumingii* exhibited certain improvement effect on water transparency (*Figure 5A*). Conversely, the electro conductivity in spring and winter were lower than those in summer and autumn. However, the electro conductivity of the shellfish purification area and ecological purification area generally are equal to or lower than that of the tail water discharge area in sampling sites, except Tongliang and Bishan zubi in the summer (*Figure 5B*). The decrease of ammonia nitrogen and phosphate in the *H. cumingii* purification area has appeared only in part of sampling sites, such as Changshou, Liangping and Bishan xinyue (*Figure 5C-D*). To some extent, *H. cumingii* has improved water quality in inner circulation ponds.

Discussion

Southeast Asia has proved to be a global hotspot for freshwater mussel diversity due to the existence of 228 native and 3 non-native Bivalvia: Unionida (98% Unionidae, 2% Margaritiferidae). In this region, species richness was the highest in China (particularly Yangtze River basin) in absolute numbers and Cambodia when correcting for the country area, and decreased gradually towards the surrounding area (Zieritz et al., 2018). However, freshwater shellfish industry is still in its infancy in upper-middle reaches of the Yangtze River, especially in Chongqing, Sichuan, Guizhou and Yunnan provinces in southwest China, where the production of bivalve shellfish accounts for less than 0.04% of the total freshwater aquaculture in 2018 (Zhang et al., 2019). The newly established Chongqing Comprehensive Experimental Station, as the only freshwater comprehensive experimental station in the non-main producing areas, is mainly responsible for studying the ecological service function and fishery economic value of shellfish, and promoting the healthy development of freshwater shellfish industry in southwest China and even in wider regions. The present annual investigation results confirm that the water quality fully meets the requirements of *H. cumingii* growth in the Chongqing region (Lin et al., 2004; Liu et al., 2020). The average wet weight increased from 359.4 g to 525.6 g within 2018 in the five sampling sites. This investigation can be used as the basis for further development of shellfish industry in southwest China.

Automated closed recirculating aquaculture system, namely partitioned aquaculture system, was early designed in the United States (Brune et al., 2001). In recent years, this mode has been widely used in Zhejiang, Jiangsu and Chongqing regions in China. The renewed interest in recirculating aquaculture systems is also due to their perceived advantages, including significantly reduced water requirements, a high degree of environmental control, improved waste management, promoted nutrient recycling and so

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34393454

on (Martins et al., 2010). Moreover, this water circulation system can realize high-density intensive aquaculture in rectangular mixed-cell rearing unit (Ebeling et al., 2005) and has clear functional partitions including aquaculture area, tail water discharge area and purification area. Our group predicted that N, P and phytoplankton are abundant in the tail water discharge area, and potential water purification could be achieved by cultivating *H. cumingii* in this area. Meanwhile, this "fish and mussel mixed breeding mode" can realize the regional division of *H. cumingii* and fish, and promote the more standardized production management in recirculating aquaculture system (Masser et al., 1999).

H. cumingii is mainly distributed in large lakes and rivers in east China and plays an important role in the fishery economy and aquatic ecosystem as a result of its value of ecological purification, edibility and pearl cultivation. However, despite the great development in the research of artificial propagation (Li and Li, 2009), genetic breeding (Bai et al., 2016), growth traits and pearl cultivation (Jin et al., 2012), the applied research on *H. cumingii* ecological function and environmental suitability still needs to be improved. Therefore, the main purpose of the investigation is to evaluate the adaptability to the local climate and the purification function of *H. cumingii* before popularized in the recirculating aquaculture system in the Chongqing region, southwestern China. Our results showed that *H. cumingii* adapted to the seasonal changes of water temperature, dissolved oxygen, pH and other water-chemistry factor in all the sampling sites. In addition to the influence of water environment factors (Lin et al., 2004), the growth and fertility of bivalve shellfish were also affected by the ratio of male to female (Zhao et al., 2013), different sized mussel (Davenport et al., 2011), phytoplankton composition (Vanderploeg et al., 1996), season variation (Naddafi et al., 2007) and fish-shellfish mixed breeding mode (Wang et al., 2018), such as the integrating culture of the mussel with herbivorous or omnivorous fish species in commercial farming (Wang et al., 2009).

At present, there are few studies on the ecological functions of *H. cumingii*, such as the influence on phytoplankton composition. Studies have shown that filter-feeding *H. cumingii* may potentially support submerged macrophyte growth by reducing cyanobacterial density, but bivalve communities in many lakes and rivers are in decline as a result of overharvesting (He et al., 2014). The present results also revealed that *H. cumingii* could effectively reduce the phytoplankton biomass. The measured value in the shellfish purification area and ecological purification area are generally lower than that of the tail water discharge area in recirculating aquaculture systems. However, the phytoplankton community structure and the total number of dominant algae have no visible change under lower *H. cumingii* stocking density. And more than 65% of them belong to the Chlorophyta, Cyanophyta and Bacillariophyta phyla, the primary food sources of bivalve shellfish (Marroni et al., 2014). Although there was no discernible effect on phytoplankton community structure and dominant algae in the present *H. cumingii* stocking density, the phytoplankton biomass could be significantly reduced. Therefore, the use of *H. cumingii* has been proposed as an alternative mean to control algal bloom in eutrophic water bodies in recent years (Liu et al., 2014).

This investigation revealed the potential role of *H. cumingii* in water purification, including increasing water transparency, decreasing electro conductivity, ammonia nitrogen and phosphate. Other results of different biological units show that *H. cumingii* can effectively enhance the contaminant removal rates from the ecological floating bed containing aquatic plant (*Ipomoea aquatica*), aquatic animal (*H. cumingii*), artificial medium (Wang et al., 2015). Furthermore, this purification of *H. cumingii* unit on nitrogen, phosphorus and COD was much lower than that of the aquatic plants unit and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34393454

microorganisms unit. These results suggest that the filter feeding of *H. cumingii* promotes the solubilization and mineralization of particulate organic matters, and improves the purification efficiency of the floating bed by microorganism purification (Wang et al., 2015). Therefore, the environmental response mechanism and interaction between *H. cumingii* and other aquatic organisms are worthy for further study.

Conclusion

Overall, the results of the annual investigation show that there is plenty of phytoplankton bait in the water environment in southwest China, and the seasonal variation range of physical and chemical indices completely meets the growth demand for *H. cumingii*. Meanwhile, the results also indicate that *H. cumingii* is an excellent way for algal bloom controlling and water quality regulating in the recirculating aquaculture system and the mixed farming model based on the recirculating aquaculture system is worthy for further study.

Abstract. *Olea europaea* subsp. *laperrinei* (Batt. & Trabut) Cif., is an endemic species of Ahaggar (Hoggar) and Tassili N'ajjer in southern Algeria, with powerful adaptation against harsh conditions. Several genetic and phylogenetic studies have been done on this taxon, offering awareness on its reproductive methods and its use as a genetic resource of the cultivated olive, but no attention was given to the ontogenesis and zygotic embryogenesis for this centenary desert plant. This work is focuses particularly on the morphology of the flower followed by the analysis of the cytological and histological changes during early zygotic embryogenesis, with the aim to identify and characterize gametophytes playing a role in this process. The results of this investigation showed different types of flowers as well as imperfections in the female gametophyte that is often absent or without nuclei in this species. These particular observations could be considered as adaptation behaviour of this plant relic against arid conditions.
Keywords: *Olea europaea subsp. laperrinei, cyto-histological study, genetic resource, male gametophyte, female gametophyte, embryos development*

Introduction

The Laperrine's olive tree, (*Olea europaea* subsp. *Laperrinei* (Batt. & Trabut) Cif.), is a relic taxon spread out across the central Saharan mountains (1400-2800 m altitude), considered as an endemic species from the Oleaceae family representing an important genetic resource due to its adaptation to arid conditions.

Note, that *Olea europaea* is a species composed of six subspecies with wild populations extended in large zones of south of Asia, Africa and southern Europe (Green, 2002).

Quézel (1965) has recognized a few individuals of (*Olea europaea* subsp. *laperrinei*) in Algerian Saharan areas. In contrast, the first inventories conducted by Baali-Cherif et al. (2007) indicated the presence of thousands of individuals in Hoggar and Tassili. In addition, it is found in granite massifs of Ahaggar Mountains (Tefedest) but rare at Tassili n'Ajjer and in Mouydir.

Besnard et al. (2007) and Anthelme et al. (2008) showed that this subspecies is distributed across fragmented habitats and locally exposed to extinction by the absence of the populations' regenerative capacities. These studies have reported that multi-centennial individuals which mainly reproduce vegetatively can restore sexuality under

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34553469

favourable conditions. Recently, crosses between the Laperrine's olive and other olive diploid subspecies (subspp. *cuspidata* and *europaea*) have been reported.

Although, this plant species offers a plant matter for animals and prevent other plants disappearance, no natural regeneration was reported since several years (Maire, 1933; Quézel, 1978) causing its genetic diversity limit by the absence of fruits (self-incompatibility), due to the high separation of trees by high mountains reducing the pollen transportation and thus gene flow (Besnard et al., 2007).

Biological reproduction for this relic species is now becoming a priority, and hence its germplasm preservation is needed, among the ex situ methods available, the seed germination is considered the most efficient method (Benarar and Bouguedoura, 2003). Seeds are important starting materials for tree breeding and genetic improvement. Their use enables capturing the natural genetic variation (due to random mating or pollination). Indeed, several populations of this plant species identified by Baali-Cherif and Besnard (2005). These authors envisaged that through sexual hybridization, new and superior genotypes could be developed; they explained the possible sexual reproduction system role in genetic variation loss such as small populations could "turn-over" of the others causing strong genetic erosion and taxon's disappearance.

Therefore, this study reports for the first time a number of information about the reproductive biology by morphological and histological aspects of floral biology. The well knowledge of major steps could be helpful to understand how to prevent the production of abnormal flowers and seeds and enhance the genetic diversity of this important taxon considered as a green belt and rootstock of local varieties.

Material and methods

The present investigation was undertaken with the trees at 1400-2300 m of altitude of Ahaggar in Southern Algeria (*Fig. 1*), characterized by seasonal temperature and rain full regime variations (cold winter 15.40°C and 1.24 mm; hot summer 26.6°C and 8.60 mm).

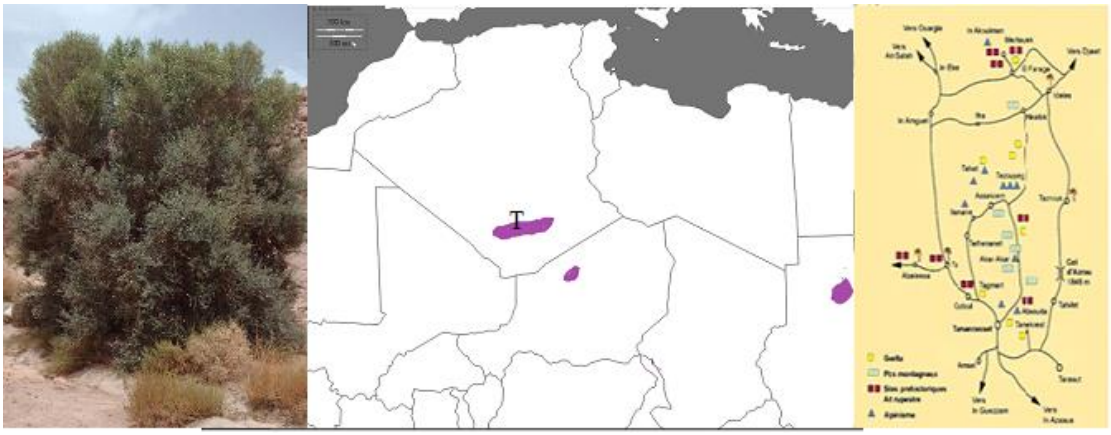

Figure 1. *Natural distribution of Olea europaea ssp laperrinei in southern Algeria (T: Tamanrasset) with some sampling areas (Akar-akar and Tezouyeg) according to website (Algerian agency. Tazrouk stays.com)*

Fresh plant parts (vegetative and floral buds, mature flowers) were collected from adult trees in flowering period for 3years (2013-2015) between March and June according to

DOI: http://dx.doi.org/10.15666/aeer/1802_34553469

areas location (*Table 1*). The vegetative and reproductive organs were examined and compared.

Table 1. *Location of sampling areas according to the altitude (m)*

Local name of Sampling areas	Altitude (m)	Latitude	Individuals number
Aguellala	from 1400 to 1500	22°38 127N 05°36 724E	11
Ainergiouene	1803	22°11 167N 06°02 874E	2
Akar-akar	from 1866 to 1885	23°03 306N 05°42 616E	7
Tagherra	1693	23°09 692N 06°01 529E	5
Tezouyeg	from 2150 to 2331	23°12 593N 05°42 413E	6

Morphological and anatomical studies

The morphological assessment was carried out by external aspects observation and measurement of fresh specimens. The organs were observed and photographs were taken by using Canon Power Shot A640 camera through the stereomicroscope StemiDV4 (Zeiss, Germany).

For the cyto-histological studies, the fresh samples were fixed in FAA fixator (Formaldehyde 37% (1 volume)-glacial acetic acid (1 volume)-Alcohol 70% (8 volume) or in Glutaraldehyde-Paraformaldhehyde-Caffeine fixator (Glutaraldehyde (25%) 4 ml-phosphate buffer pH 7.2-50 ml – paraformaldehyde (10%) 20 ml and caffeine 1% 1 g) (Schwendiman et al., 1990). The specimens were dehydrated and embedded in paraffin or in resin (Reichert-Jung Historesin). Thin sections of 2.5-5 µm were cut with microtome (Leica, Germany) and stained by Periodic Acid Schiff (PAS)-Naphthol Blue Black (NBB) (Feder and O'Brien, 1968; Fisher, 1968). Microphotographs were obtained using Canon camera, Power Shot A640 and Q-imaging Retiga 2000R camera combined with DM4500 microscope (Leica, Germany).

For transmission electron microscopy, floral parts were prefixed in 4% glutaraldehyde (1 volume)-cacodylate buffer pH 7.4 at 0.4 M (1 volume) and were fixed in 2% osmium tetroxide (1 volume)-cacodylate buffer pH 7.4 at 0.4 M (1 volume) - (Pottu-Boumendil, 1989) and then, embedded in Epoxy resin (Fluka). Ultra-thin sections of 0.01 µm were carried out with EM UC7 microtome (Leica, Germany) stained with positive contrast (2% uranyl acetate then lead citrate) (Pottu-Boumendil, 1989). Observations and microphotographs were made using the 1200EXII microscope (Jeol, Japan).

Results

Through sexual reproduction, Laperrine's olive tree individuals form four different types of flowers varying between trees, areas and sampling year (*Table 2*).

The flower (*Fig. 2A*) with fully developed parts: 4 sepals, 4 petals, 2 stamen (type 1) is the most frequent, following by flowers with less prominent and necrotic stigmas (type 2), male flowers with rudimentary and very insignificant pistils (type 3) and flowers with 3 stamen instead 2 (type 4) (*Fig. 3A and B*).

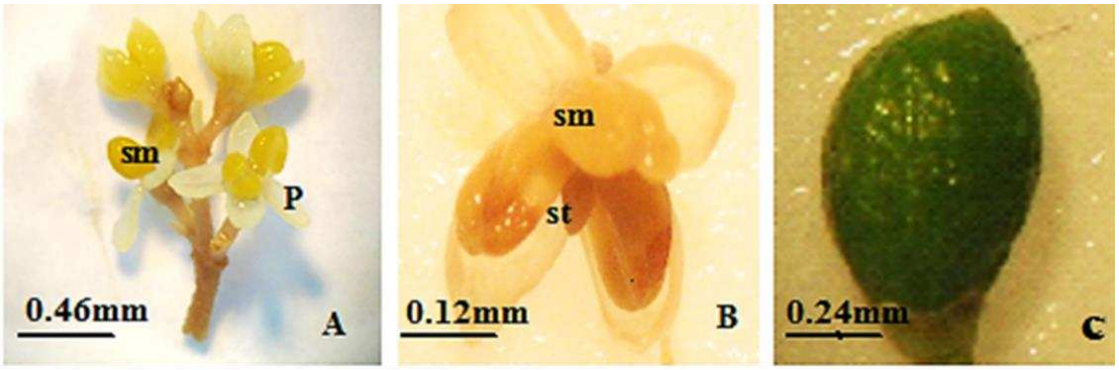

Figure 2. *Inflorescence (A), flower (B) and fruit (C) of Olea europaea ssp. laperrinei. p: petal, sm: staminate, st: stigma*

Mature flower structure

The flower of the Laperrine's olive tree is hermaphrodite or male flowers of 4.5 mm height, each with 4 greenish gamosepals, 4 whitish petals, 2 yellowish stamens with a longitudinal introrsely dehiscence and pistil formed of an ovary of two fused carpels bi-ovuled each, a style and of a two-lobbed dome shaped stigma. The pistil and the stamens have the same length (about 2.5 mm), stigma (1 mm), the style (0.5 mm) and ovary diameter (1-1.2 mm).

Flower ontogenesis: morphology and histology

The vegetative bud's foliar initiation is decussate corresponding to Laperrine's olive tree's phyllotaxis. The observation of axillary vegetative buds showed that previous year's twigs initiate floral buds in comparison to those of actual year which do not flowering.

The morphological analysis of buds before flowering showed that the growth of vegetative twigs starts between March and April depending on the zone's altitude and temperature. The vegetative apical meristem (dome) is wide showing three heterogeneous zones; apical zone formed by tunica of one or two layers; lateral zone on the flanks enabling foliar initiation and the medullary zone located under the apical zone with lined up cells (*Fig. 3A and B*).

According to the histological study, it appears that the future flower bud's apical dome is more prominent (650 µm) than that of the vegetative bud (292,6 µm) covered by external bracts, formed by homogeneous structure of strongly meristematic cells called floral primordium (*Fig. 3C*), which develops into a flower bud (*Fig. 3D*).

Three types of flower buds were observed with variations in pistil; first type with two-lobed prominent stigma (*Fig. 3D*); the second type with less prominent and necrotic stigma (*Fig. 4A*) and the third type with a rudimentary pistil (*Fig. 4B*).

Androecium and male gametophyte

Anthers are composed of four pollen locules of different shape and size. Those with only two or three locules observed are due to their incomplete development.

From outside to inside, each anther contains an epidermis with wide cells, a mechanical layer, a layer of transitional cells, a medullar layer and a tapetum of two to three layers of protein-rich cells with a central big nucleus remembering meristematic cells (*Fig. 5A*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34553469

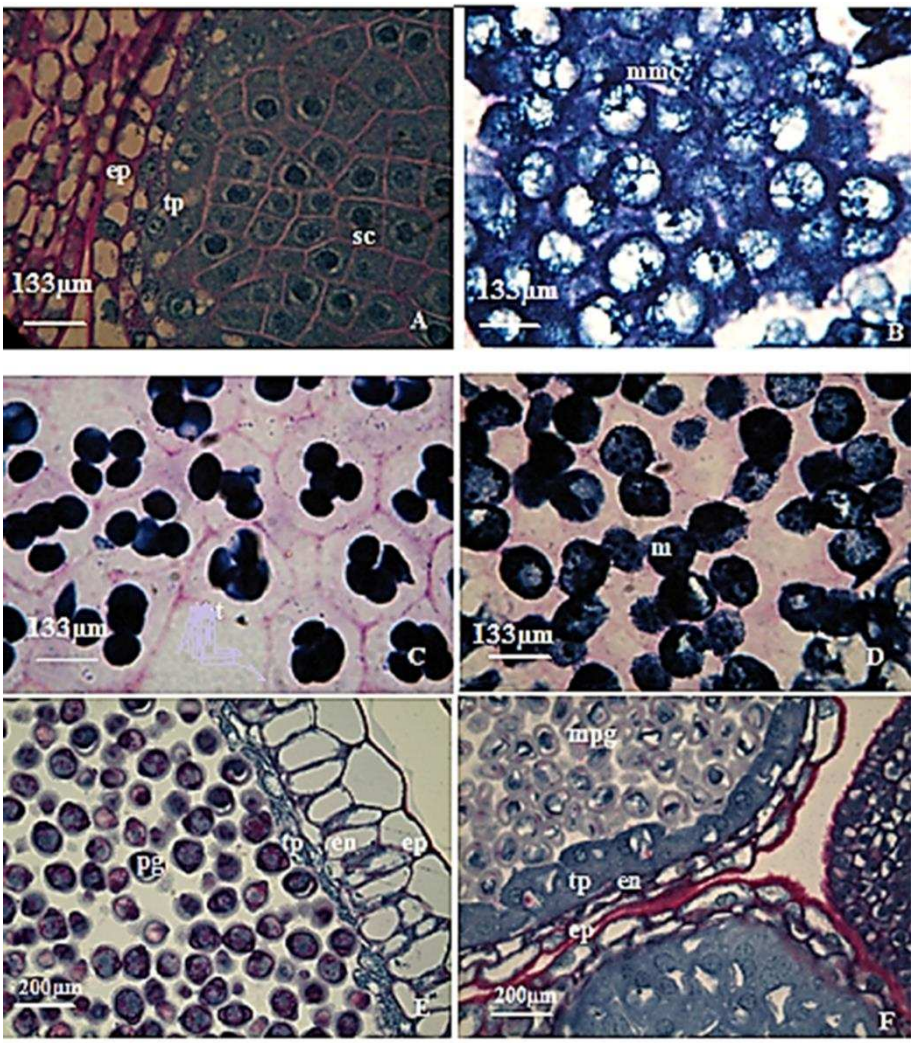

Figure 5. *Stages of male gametophyte development: A. Stamen and sporogen tissues.B. Mother cells. C. Tetrads. D. Microspores. E. Different stamen layers with fertile pollen. F. Different stamen layers with malformed pollen. en: endothecium,ep: epidermis,m: microspore, mmc: mother cell of microspore, mpg: malformed pollen grains, pg: pollen grain, sc: sporogenous tissue, t: tetrad, ta: tapetum*

The medullar layer begins to degenerate in the early stages of meiosis of microsporocytes. Indeed, the tapetum degeneration follows the first uninucleate microspores formation and continues until maturation. The sporogenous tissue is initially formed by polygonal-shaped cells (*Fig. 5B*), which differentiate into mother cells of spores forming tetrads surrounded by callose as tetrahedral type or rarely rhomboidal after meiosis (*Fig. 5C*).

The Electronic microscopy observation shows that mature pollen grains are bicellular and rich in starch at dehiscence time (*Fig. 5E*), the reproductive cell, previously found against the vegetative cell's wall, are in the middle of cells (*Fig. 6A and B*).

Triporate pollen grains presenting TEM images of apertures in equidistant positions composed of ecto aperture covered by a cross-linked tectum and of the endo aperture, these pollen grains can be observed onto the stigma surface and the ovary is fertilised

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34553469

before the dehiscence of this flower's stamens. This situation induces the stigma's responsiveness before the stamens maturation and confirms the allogamy of the species.

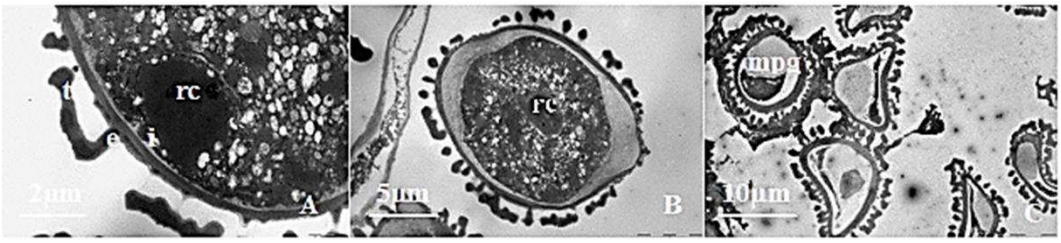

Figure 6. *Transmission electron micrographs of cross-sections through pollen grain during developmental stages. A. Non detached reproductive cell. B. Bicellular pollengrain, C. Malformed pollen grains, e: exina, i: intina, mgp: malformed pollenrc: reproductive cell, t: tectum*

The pollen locule can contain pollen grains showing a degeneration structure by deformation, cells are mostly empty formed of a tectum, exine, intine and a cytoplasm (*Figs. 5F and 6C*). This degeneration is only noted at pollen grain stage in 30% of flower buds observed.

Ovary and female gametophyte

The superior ovary is most commonly composed of two unilocular carpels, each one contains two anatropous ovules (*Fig. 4C*), and its epidermis contains elongate cells covered by a large polysaccharide layer.

Underneath the epidermis exists a layer of cells of different sizes with large active nuclei rich in proteins.

The two carpels reach maturity at the same time containing four ovules that will have a different development: three ovules decline and only one ovule will continue its structuration. Ovaries with three carpels or carpels with three ovules seldom seen are considered as anomalies (*Fig. 4 D, E and F*).

The narrower style covered by a polysaccharide layer (mucilage) is composed by an external epidermis and an intermediate tissue, organised into several cell layers with large vacuoles and of a vascular tissue as well as a transmission tissue that passes over its entire length.

The style widens into a bifid stigma sometimes mono or trifid whose surface is comprised of papilla cells with large vacuoles and covered by a layer of extracellular exudates of carbohydrate nature. The stigmas internal cells are non-papillary and surrounded by an accumulating substance in the intercellular area.

Unitegumented ovules with a very short funiculus, whose micropyle is narrow, develop at the same time but cases exist in which one or two of the four ovules are smaller (*Fig. 4C, D, E and F*).

For hermaphrodite flowers, cyto-histological study by photonic and electron microscopy has most often shown the absence of embryo sacs on a number of sliced ovules (*Table 3*). In some ovules, the embryo sac is involute; and in some rare cases, we could observe a typical embryo sac. This mature sac is of bisporic Allium type, which characterises the *Olea* type, therefore eight nuclei (Altamura et al., 1982). The nuclei located in the different levels of the sac are non-observable at the same time. The mature

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34553469

embryo sac's cavity, narrow and fusiform, contains two synergids and one egg cell on the micropyle's side, two polar nuclei and three antipodal cells on the side of the chalaza (*Fig. 7 A, B, C and D*).

Table 3. *Frequencies of different embryo sacs types in hermaphrodite flowers*

DOI: http://dx.doi.org/10.15666/aeer/1802_34553469

For flowers with a necrotic stigma, the embryo sac is deformed, empty or lacking, thus, the pistil's development is interrupted before the formation of the embryo sac. For male flowers, no embryo sac can be observed and the ovary kept rudimentary (*Fig. 4 A, B*).

Fertilisation and fruit formation

At fertilisation, only one ovule of four is fertilised. The ovules of the sterile carpel degenerate while those of the fertile carpel experience two different evolutions: one ovule is fertilised to become the seed and the other degenerate after long period comparing to sterile carpel's ovules. Note that, in the fruit development, it is possible to observe the remains of the locule surrounding the fertile carpel's non-fertilised ovule.

The ovule's fertilisation leads to the formation of the large spherical shaped zygote at the same time of beginnings of nuclear endosperm by central cells (*Fig. 7 E*).

An embryo is observed after this fertilisation while synergids and antipodal cells degenerate (*Fig. 7 F*).

Discussion

Floral anatomy

The study of Laperrine's olive tree showed that at flowering time, four types of flowers are formed on each tree; the normal hermaphrodite flower, the necrotic pistil flower, the male flower and three stamens flower. The first and the second types were observed by Reale et al. (2009), the third by Breton and Bervillé (2013) on the cultivated olive tree.

After the period of vegetative rest (autumn and winter), the buds have the same morphological structure and sprout from March to give new twigs and flowers for the next year. This seems to correspond to the bud burst and flowering period of the cultivated olive tree. Indeed, Aiachi-Mezghani et al. (2008) confirmed that for the cultivated olive tree, vegetative growth is more or less continuous from spring up to autumn. The typical structure of the vegetative apex is in line with angiosperms (Camort and Boué, 1997; Vallade, 1999) by zonation of the meristematic territory.

Floral differentiation begins at the end of March in some stations and can be delay until June in the others. Indeed, this differentiation depends on the altitude and temperature. In tropical zones, the flowering of Laperrine's olive trees takes place in spring like most olive cultivars in California (Fabbri and Benelli, 2000) due to the endogenous hormones variation (Badr Sayed et al., 1970). On the other hand, in Portugal, the Galega and Verdea cultivars flower as soon as February (Hartmann, 1951).

According to Malik and Pérez (2011), the low temperatures of winter are development of *Olea europaea* subsp. *lapperenei* follows the same steps of development as *Olea europaea* subsp. *europaea* (Yurukova-Grancharova et al., 2011), *Syringa vulgaris* (Jedrzejuk and Wladyslaw, 2005) and *Fraxinux angustifolia* (Rodriguez-Rajo et al., 2010).

After maturation, tetrads give bicellular pollen grains, rich in starch with dehiscence time similar on the cultivated olive tree (Serrano et al., 2010). Anthers' tissue layers develop the same as on cultivated olive trees (Yurukova-Grancharova et al., 2011). However, the difference observed concerns the tapetum cells that at tetrad stage are either mononuclear or binuclear like for *Colobanthus quitensis* (Kunth) Bartl (Gielwanowska et al., 2007).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34553469

Yurukova-Grancharova et al. (2011) observed that cell nuclei of the tapetum are divided and become binuclear, rarely tetra nuclear in 'Regalis', 'Chalkidis' and 'Pomiformis' cultivars of the cultivated olive tree compared to Pomiformis cultivar with 4 to 6 nuclei in tapetal cells.

Note that, Fernandez and Rodriguez-Garcia (1989, 1995) reported that Laperrine's olive pollen grains structure is similar to that of complex *Olea*.

Our results showed well-formed pollen grains and others with incomplete development or malformed (coloured in blue) indicating the absence of carbohydrates. Cuevas and Polito (2004) and Reale et al. (2006) have observed malformed pollen grains in *Olea europaea* subsp. *europaea.* According to Gielwanowscka et al. (2007), the pollen malformation can be a response to thermal or osmotic stress.

The allogamy and self-incompatibility in *Olea europaea* subsp. *laperrinei* confirmed by Besnard et al. (2007) could explain the low fruit production because the long distance separation between populations of *Olea europaea* subsp. *laperrinei*. Serrano et al. (2008) reported a high level of self-incompatibility in cultivated olive tree.

For the female gametophyte, the histological study often showed the absence of an embryo sac in ovules or existed but less developed (no nuclei), these cases are pointed out by Rapoport and Rallo (1991) for the cultivated olive tree, for the 'Manzanillo' cultivar and by Martin et al. (2006) for the 'Morisa' cultivar.

The mature embryo sac was observed only in hermaphrodite flowers belonging to Allium type of the *Olea* gender (Altamura et al., 1982; Yurukova-Grancharova et al., 2011) with eight-nucleate embryo sac.

For the flowers with necrotic stigmas, the embryo sac either was absent or is limited to its wall. These types of flowers and embryo sacs also exist in the cultivated olive tree (Cuevas and Polito, 2004; Martin et al., 2006; Reale et al., 2009). The proportion of each type depends of the tree genetics and climate conditions (Loussert and Brousse, 1978; Lavee et al., 1996). Indeed, according to these authors, the nutritional deficiency increases the pistil abscission leading to the formation of male flowers. For the Laperrine's olive tree, starch reserves are observed in different tissues of hermaphrodite flowers whereas no reserve is noted in the gynoecium of the necrotic pistil flowers.

Reale et al. (2006) made the same observations on the cultivated olive tree. It appears that, the carbohydrates are needed compounds from the flower initiation (Altamura et al., 1982) up to the complete differentiation of all floral organs (Rodrigo et al., 2000).

Abortion cases

Concerning the different abortion cases observed in different flowers studied, our results remind those obtained by Extremera (1985). This author specifies that the formation of ovules with malformed embryo sacs characterize Swan Hill cultivar not producing fruits; these structures can cause abscission of hermaphrodite flowers because the malformed embryo sac cannot be fertilised. This hypothesis can explain the substantial flowers drop for the Laperrine's olive tree by the higher rate of malformed embryo sacs within hermaphrodite flowers.

The production of male flowers following abortion of the olive tree's pistil is subject to genetic regulation and takes place one month before flowering (Reale et al., 2009). The lack of nutrients gives priority to pollen, thus to the production of male flowers (Cuevas and Polito, 2004).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34553469

In different non-grazing areas, the Laperrine's olive trees show abundant flowering with a high percentage of hermaphrodite flowers while the flower drop was significant and the olive production is low.

According to Breton and Bervillé (2013), the cultivated olive tree's fruit production is low when there is no synchronisation between responsiveness of pistils and pollination regardless of the number of hermaphrodite flowers. Indeed, the percentage of hermaphrodite flowers varies from 95% for the Lucques cultivar to 5% for the Salonenque cultivar (Ouksili, 1983) whereas for the oleaste, this percentage reaches 100% or 0% (Hannachi and Marzouk, 2012). For *Olea europaea* subsp *cuspidata,* the vegetative twigs from one year before could have different proportions of male and hermaphrodite flowers (Mukonyi et al., 2012).

In the previous studies of Cuevas and Polito (2004) and Yurukova-Grancharova (2011), the overproduction of flowers with a high level of imperfect flowers and the suppression of fruit constitute a reproduction strategy for olive trees. Indeed, induced abortion of the grains before sclerification of the nuclear (endocarp), about 7 or 8 weeks after complete flower formation, improves or increases the following flowering (Stephenson, 1981).

Abortion is an important phenomenon that allows the tree to control its fruit production according to the availability of nutrient inputs like those that it showed with vines (Lebon et al., 2004).

According to Argenson et al. (1999), there are critical periods for the olive tree during flowering that can have an impact on the potential of fruit-production. Thus, a water or nutrient stress, arising between outbreak and six weeks before the anthesis, reduces the number of flowers per inflorescence and increased ovule abortion.

The overproduction of flowers allows the control of quantity and quality of fruits that depend on environmental conditions and availability of nutrients like it is shown with citrus where only 2% of flowers make fruits (Troncoso et al., 1978). The most anomalies and abortion of *Olea lapperenei* reproductive organs (flowers and fruits) summarised in this investigation could be explained by the advanced age of the trees or by the arid climate conditions (Loussert and Brousse, 1978; Besnard et al., 2012).

Conclusion

This study clearly showed many morphological and reproductive characters of the Laperrine's olive tree summarizing different types of flowers on the same tree with several abortion cases in both male and female gametophytes. All of these features indicate that this woody tree developed reproductive traits to drought tolerance and high longevity.

The absence of regeneration of centenarian's olive tree would be due to the random flowering and fruit drop before ripening. This can be explained by the not fully developed pollen grain production but self-incompatible for sexual reproduction or by malformed sterile pollen grains.

Even if, the female gametophyte, mature and typical, is also capable to conduct the sexual reproduction, the arid conditions cause earlier abortion of flowers and fruits. The results suggest that the well knowledge of flower development and reproduction will be helpful to the conservation of this tree in its natural ecosystem. The involvement of both user cuttings and seed germination trials are suggested. Also, the use of biotechnology-based techniques is needed.

Abstract. Mud ivory whelk (*Babylonia lutosa*) is one of the most economically important seawater mollusks in China. However, currently, there is no report on the molecular markers related to the growth of *Babylonia lutosa*, which hinders the its genetic breeding with dominant growth traits. The present study was the first to sequence the transcriptomes of *B. lutosa*, and then searched for EST-SSR in the growth-related genes. Wild *B. lutosa* samples were collected from the Lianjiang River, Fujian Province of China. The RNA of gastropods and hepatopancreas tissues from three *B. lutosa* were measured and mixed, and sequenced by Illumina HiSeq sequencer. A total of 24,829,460 reads containing 5,015,236,064 bp were obtained through sequencing. Eight growth-related genes (TBC-1-A, TBC-1-2B, FGFR-1, GFRBP2, GFR-15, FGFR-1-A, SMAD6, and TGFβR-1) containing EST-SSR sequences were detected in the *B. lutosa* transcriptomes. Our results would provide theoretical basis for *B. lutosa* breeding based on growth-related EST-SSRs.
Keywords: *aquaculture, Gastropoda, growth-related gene, insulin-like growth factors, microsatellites*

Introduction

Growth-related genes of aquatic animals have always been the focus of researchers. For instance, insulin-like growth factors (IGFs) of aquatic animals are a class of proteins with insulin-like metabolism and mitotic function. IGFs participate in the embryonic development and reproduction of vertebrates and are the main determinants of embryonic and postnatal growth (Reinecke et al., 1997; Upton et al., 1998; Zhang et al., 2011). In addition, IGFs mediate growth-promoting effects of growth hormones (Moriyama et al., 2000). Aquatic animal IGF system includes IGF-I, IGF-IR, IGF-II, IGF-IIR, and IGFBPs (Li et al., 2011), which play important roles in inducing myopoietin (MyoG) gene expression (Florini et al., 1991; Yano et al., 1999), promoting myocyte differentiation (Hembree et al., 1991; Le Roith et al., 2001; Buckingham et al., 2003), regulating skeletal muscle growth (Doumit et al., 1993; Lamberson et al., 1995; Davis et al., 2002), and other aspects. Growth-related genes have genetic polymorphism, and different genotypes correspond to different growth traits.

DOI: http://dx.doi.org/10.15666/aeer/1802_34713482

Single nucleotide polymorphism (SNP) loci and microsatellites are important molecular markers commonly used in population genetic diversity research. Ruan et al. (2011) identified three SNPs by comparing the sequences of exon 1, exon 3, intron 2, and intron 4 of the IGF-1 gene in Giraffe tilapia (*Oreochromis niloticus*). Then they detected intron genotypes of 121 *G. tilapia* from five genetic families by PCR-RFLP, and screened two SNPs that correlated with weight gain. Therefore, the two SNPs could be used as molecular assisted markers for breeding. Microsatellites have been widely used in population genetic diversity analysis, because of their wide distribution in genome, good polymorphism, genetic stability, and easy detection (Nie, 2014). For instance, the population genetic diversities of blacklip abalone (*Haliotis rubra*) (Huang et al., 2000), scallop (*Pectinidae* sp.) (Feng et al., 2014), marine shrimp (*Fenneropenaeus chinensis*) (Zhang et al., 2005), whiteleg shrimp (*Litopenaeus vannamei*) (Tong et al., 2009), and Japanese pufferfish (*Fugu rubripes*) (Lu et al., 2013) have been studied using microsatellite markers. High-throughput sequencing technology provides a convenient way to transcriptome sequence and large-scale screen SNPs and microsatellite markers. Hou et al. (2011) sequenced transcriptomes of the larvae of scallop (*Patinopecten yessoensis*) at different development stages by high-throughput sequencing technology, and screened a large number of expressed sequence tag - sample sequence repeats (EST-SSRs) and SNPs that were correlated to growth, reproduction, and immune recognition.

Mud ivory whelk (*Babylonia lutosa*) is one of the most economically important seawater mollusks in China (Xiong et al., 2015). In 2018, the output of *B. lutosa* is approximately 4,000 tons in China. Although aquaculture output of marine snails has decreased by 6.17% compared with 2017 in China, the cultivation of *B. lutosa* increases (Fishery and Fishery Administration of the Ministry of Agriculture and Rural Areas of China et al., 2019). It is widely distributed in southeast coast of China, southeast Asia and Japan (Xiong et al., 2015). *B. lutosa* inhabits in the sediment bottom of several meters to tens of meters deep in the subtidal zone, mainly feeds on oyster eggs, organic debris, and protozoa in the juvenile stage, and small fish, shrimp, crab, and shellfish in the adult stage (Yin et al., 2007). Currently, studies on *B. lutosa* are mainly focused on morphological comparison (Wang et al., 2007; Pan et al., 2010; Huang et al., 2010; Qi et al., 2011), metamorphosis (Yang et al., 2008), environmental adaptation (Lin, 2012), genetic characteristics (Chen et al., 2011; Qin et al., 2014), and culture technologies (Yin et al., 2007). Molecular breeding is very important for the cultivation of snails with high growth characteristics. However, there is no report on the molecular markers related to the growth of *B. lutosa*, which hinders the genetic breeding of *B. lutosa* with dominant growth traits. The present study was the first time that sequenced the transcriptomes of *B. lutosa*, and then searched for EST-SSR in the growth-related genes. Our results would provide theoretical basis for *B. lutosa* breeding based on growth-related EST-SSRs.

Materials and Methods

Sample collection, RNA extraction, cDNA library construction and sequencing analysis

Wild *B. lutosa* samples were collected from the estuary of Lianjiang River, Fujian Province of China (26°20′ N, 119°42′ E) in 2015 (*Fig. 1*). Three living *B. lutosa* were dissected and their gastropods and hepatopancreas were quickly cut out and used to extract total RNA by a TRIzol reagent kit (TAKARA, China) (Xiong et al., 2015, 2019).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34713482

The RNA concentration and purity were detected by an Ultrospec™ 2100UV/Visible spectrophotometer, and the RNA integrity was detected by 1% agarose gel electrophoresis. The RNA of gastropods and hepatopancreas tissues from the three *B. lutosa* were measured and mixed. After enrichment, purification, interruption and cDNA synthesis, the constructed cDNA library was sequenced by Illumina HiSeq sequencer at Beijing Biomarker Technologies Co., China.

Figure 1. *Map shows the sampling location*

Sequence assembly, annotation, and growth-related EST-SSR screening

The original reads were assembled to transcripts using Trinity software. Several sliceable transcripts were clustered into one gene, and finally obtained the unigene library. SSRs in the cDNA sequence of unigenes were searched using MISA software (http://pgrc.ipk-gatersleben.de/misa/) (Kanehisa et al., 2008). The searching parameters were set as a single base with a minimum repetition of more than 10 times, two bases with a minimum repetition of more than 6 times, and 3 - 6 bases with a minimum repetition of more than 5 times. The distance between two repetitions should not be greater than 100 bp. The ORFs were predicted using Getorf software based on the unigene sequences (Mortazavi et al., 2008). The software parameters were set to predict the forward and reverse directions of three bases at both ends of unigenes, and the longest sequence was as the ORF of unigenes. The reads obtained by the sequencing were aligned to unigenes library, and calculated the expression abundance (RPKM) of each unigene (Mortazavi et al., 2008). The unigenes were annotated using BlastX program referenced to the protein sequence databases of Swiss-Prot (Apweiler et al., 2004), TrEMBL (Apweiler et al., 2004), GenBank Nr (Deng et al., 2006), Gene Ontology (GO) (Ashburner et al., 2000), COG (Tatusov et al., 2000), and KEGG (Kanehisa et al., 2004). The parameter E value was set to $< 1e^{-6}$, and the maximum similar sequence was selected as the annotated gene. According to GO annotation information, functions of the unigenes were classified to molecular function, cellular component, and biological process (Ashburner et al., 2000). KEGG analysis was implemented by KEGG Automatic Annotation Service (KAAS) (Masoudi-Nejad et al., 2007). Growth-related genes were screened from the assembled annotated genes, and EST-SSR markers were excavated for the selected growth-related genes by SSR analysis.

The EST-SSRs were submitted to NCBI GenBank database with accession number from KM972681 to KM972698, and from KT763437 to KT784812.

Results

Transcriptome characteristics and EST-SSR analysis of B. lutosa

A total of 24,829,460 reads containing 5,015,236,064 bp were obtained by sequencing. The GC content of the DNA sequences was 50.54%. CycleQ20 was 100%. A total of 119,113 unigenes that contained 16,877 unigenes with more than 1 kb were obtained through *de novo* assembling. N50 was 835 bp, and the average length of unigenes was 627.3 bp (*Table S1*).

A total of 13,962 EST-SSRs were found from 8,177 unigenes, which total length was 262,687 bp. We also found a large number of mixed repetitive nucleotide sequences. These mixed repetitive nucleotide sequences were distributed in 2,272 unigenes (*Table 1*). The frequency of EST-SSRs in the transcriptome of *B. lutosa* was 11.72% (ratio of the number of EST-SSRs detected to the total number of unigenes); and the frequency of EST-SSR occurrence was 6.86% (ratio of the number of unigenes with EST-SSR to the total number of unigenes). In the transcriptome of *B. lutosa*, an SSR occurred on average every 350.78 kb.

Table 1. *Occurrence of different types of EST-SSR in the B. lutosa transcriptome*

Repeat type	Number	Proportion	Frequency (%)	Average distance (kb)	Total length (bp)	Average length (bp)
Mononucleotide	5,536	39.65	4.65	884.70	75,641	13.7
Dinucleotide	3,906	27.98	3.28	1253.89	68,946	17.7
Trinucleotide	2,141	15.33	1.80	2,287.57	40,314	87.6
Tetranucleotide	100	0.72	0.08	48,976.91	2,536	25.4
Pentanucleotide	7	0.05	0.006	699,670.14	175	25
Compound SSR	2,272	16.27	1.907	2,155.67	75,075	75.5
Total	13,962	100	11.72	350.79	262,687	18.4

EST-SSR was abundant in the transcriptome of *B. lutosa*, and it could be found from mononucleotide repeat to pentanucleotide repeat types, but no hexanucleotide repeat type was found. The frequencies of occurrence of various EST-SSR types were quite different. It mainly focused on mononucleotide, dinucleotide, and trinucleotide repeats, which accounted for 39.65%, 27.98%, and 15.33% of the total EST-SSRs, respectively. The tetranucleotide and pentanucleodite repeats accounted for 0.72% and 0.05%, respectively. Among them, the largest number of SSR types was: A repeat primitives were 3,534 (25.31%), and T repeat primitives were 2,984 (21.37). The number of EST-SSR loci with different repeats was also quite different (*Fig. 2A*). The major EST-SSRs with more than 10 repeat elements were mononucleotides. The dinucleotide repeats with more than 10 repeat elements were very rare. TG repeats were 1,136 (8.14%), CA repeats were 866 (6.35%), AC repeats were 717 (5.14%), and AC/GT repeats were 3,409 (24.42%). In the trinucleotide repeats, GGA repeat was 151, GAG repeat was 114, GGT repeat was 108, GTG repeat was 104, TTG repeat was 100, AGG/CCT repeat was 560 (0.040%), and ACC/GGT repeat was 508 (0.036%; *Fig. 2B*). According to the overall distribution, polynucleotide repeats predominated in the frequency of six repeat.

Through analyzing the length of 13,962 EST-SSRs, the lengths of microsatellite sequences contained in the EST sequences of *B. lutosa* ranged from 9 to 265 bases with a total length of 262,687 bp. The average length of the microsatellite sequences was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34713482

18.4 bp. The length of EST-SSRs was mainly in the range of 12 to 25 bp, of which 8928 (63.95%) were in the range of 12 to 20 bp. Number of SSRs with the length between 21 to 25 bp were 1,276 (9.14%), and the number of SSRs with the length of more than 25 bp were 225 (1.60%; *Fig. 2C*).

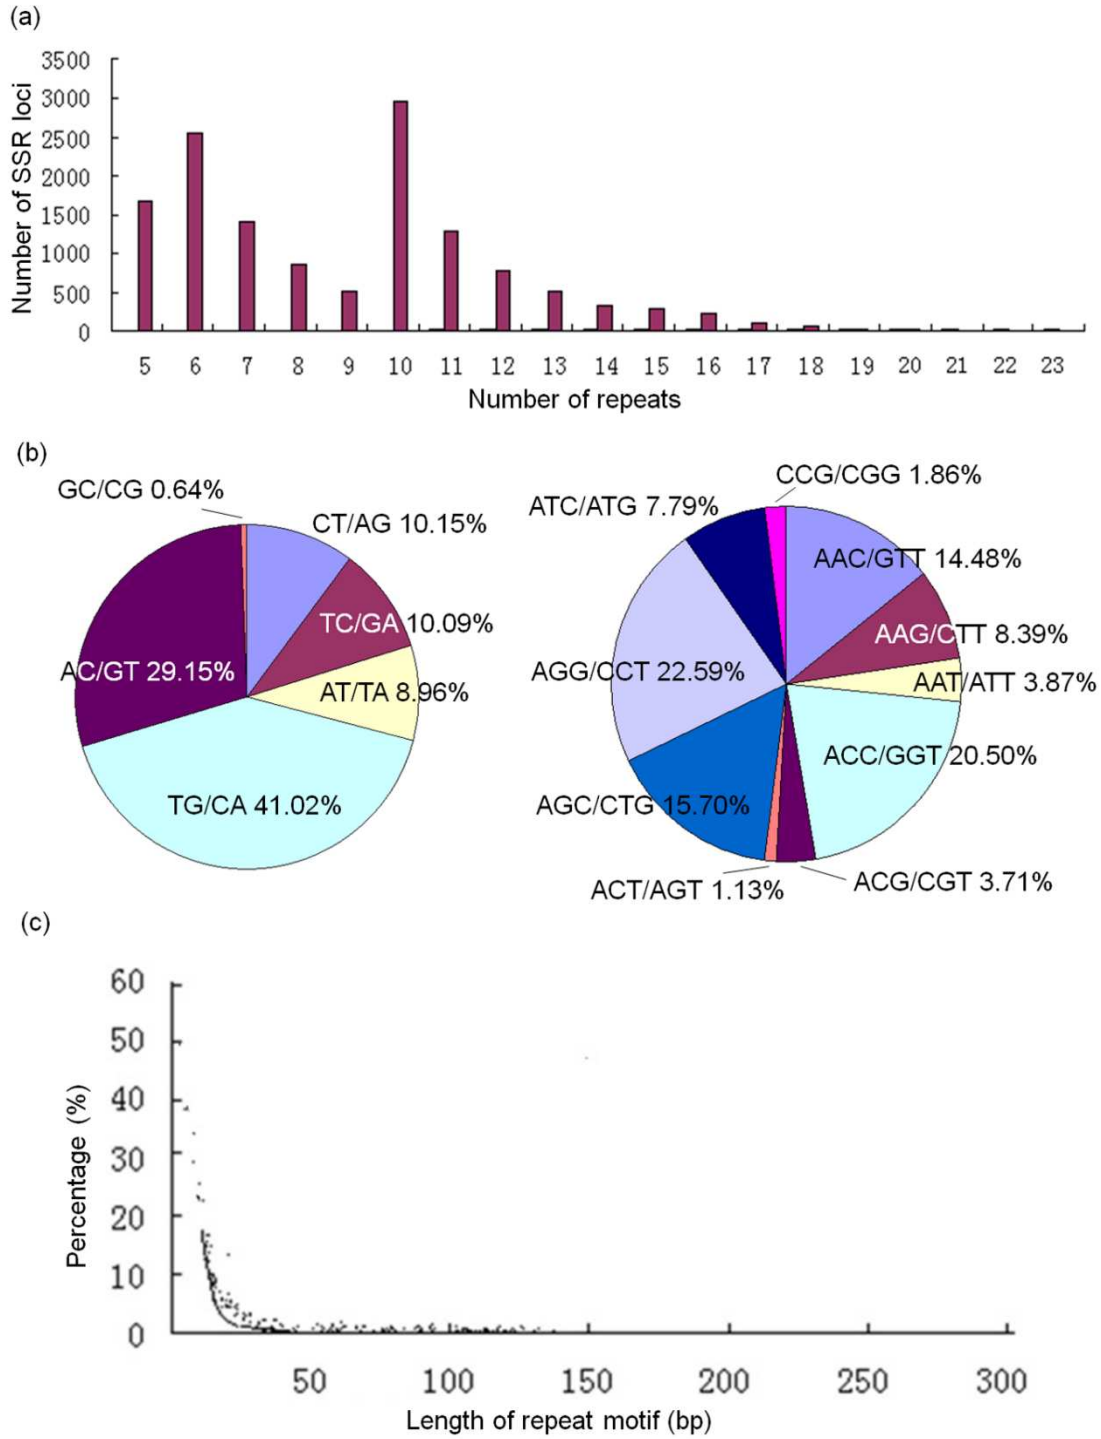

Figure 2. *Distribution of the number of repeats of EST-SSR (A), percentage of different motifs of dinucleotide and trinucleotide SSRs (B), and distribution of the repeat motif length of SSRs in B. lutosa transcriptome (C)*

Functional annotation and Growth-related Genes Containing EST-SSR Sequences

Total of 118,608 unigenes were protein encoding unigenes, of which 78.84% were unigenes within 300 bp, and 6.18% were unigenes above 900 bp (*Appendix 1*). A total of 24,829,460 reads were belonged to the protein encoding unigenes, which showed the high reliability of the obtained transcriptome data (*Appendix 1*).

Total of 35,931 unigenes were annotated, which were in corresponding the sequences from sea-slug (*Aplysia californica*), oyster (*Crassostrea gigas*), polychaete worm (*Capitella teleta*), amphioxus (*Branchiostoma floridae*), sea urchin (*Strongylocentrotus purpuratus*), acorn worm (*Saccoglossus kowalevskii*), filarial nematode worm (*Brugia malayi*), eye worm (*Loa loa*), and sea anemone (*Nematostella vectensis*) (*Appendix 2*), and some sequences did not have similar homologous sequences in the databases, which was probably caused by the lack of mollusk EST sequences in these databases. A total of 35,931 annotated functions were obtained from the *B. lutosa* transcriptome annotation analysis (*Appendix 3*).

Total of 109,359 unigenes obtained GO information, of which 60,143 (55.0%) unigenes were belonged to biological process, 31,931 (29.2%) genes were belonged to cellular component, and 17,285 (15.8%) were belonged to molecular function. In the GO classification system, the biological process, cellular component, and molecular function were classified into more detailed 56 sub-categories (*Fig. 3*). In the biological process, there were 3,289 unigenes participated in the reproduction, 7,751 unigenes participated in the metabolic process, 353 unigenes participated in the immune system process, 387 unigenes participated in the cell proliferation, 8,826 unigenes participated in the cellular process, 2,876 unigenes participated in the reproductive process, and 5,562 unigenes participated in the biological regulation.

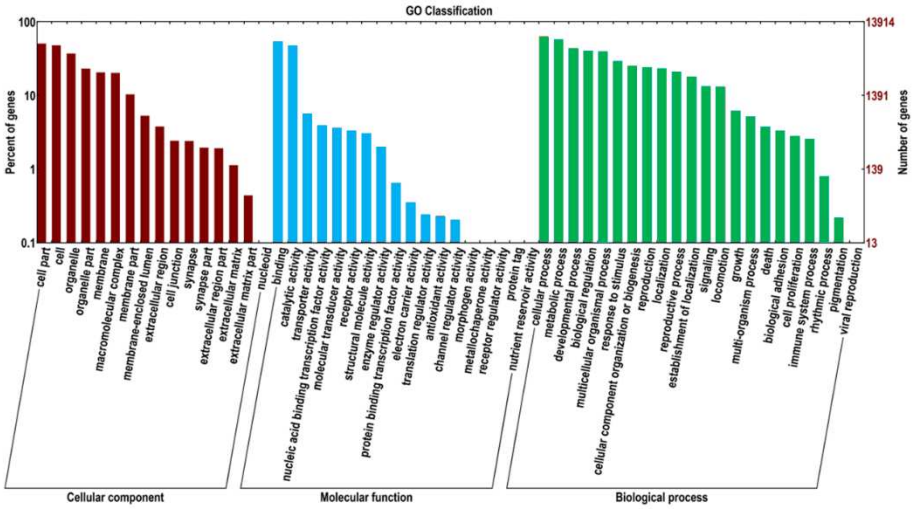

Figure 3. *GO function annotation results of B. lutosa transcriptome library*

Growth-related gene containing EST-SSR sequences were growth hormone-regulated TBC protein 1-A (TBC-1-A), growth hormone-regulated TBC 1 domain family member 2B (TBC-1-2B), fibroblast growth factor receptor 1 (FGFR-1), growth factor receptor-bound protein 2 (GFRBP2), growth factor receptor substrate 15 (GFR-15), fibroblast growth factor receptor 1-A (FGFR-1-A), SMAD family member 6 (SMAD6), and TGF-beta receptor type-1 (TGFβR-1, *Table 2*).

Discussion

A total of 13,962 EST-SSRs was obtained from the *B. lutosa* transcriptome, which total length was 262,687 bp. The number and frequency of EST-SSRs in the *B. lutosa* transcriptome were more abundant than those in *P. yessoensis* (2,700 EST-SSRs; Hou et al., 2011). Besides the improvement of NGS technology provided more quantity and higher quality sequencing data of *B. lutosa* transcriptome, the reason caused the more SET-SSRs were detected from the *B. lutosa* transcriptome was we used a mixture of *B. lutosa* hepatopancreas and gastropodal muscle samples, which contain abundant transcriptional sequences. These EST-SSR molecular markers had laid an important foundation for large-scale development of *B. lutosa* molecular markers, evaluation of artificial multiplication effect, and population genetic diversity and molecular assisted breeding.

If EST-SSR markers can be directly identified on growth-related genes, it would effectively improve the breeding efficiency of *B. lutosa* with fast-growth traits. In the present study, we found eight growth-related genes that contain EST-SSR sequences in the *B. lutosa* transcriptome. These EST-SSR sequences were likely to participate in the expression and regulation of their representative genes, and affect the growth-related traits of *B. lutosa.*

TCB-1 gene was found in the growth-related genes containing EST-SST sequences. TBC-1 is a kind or nucleic acid protein. Richardson and Zon (1995) first discovered this nucleic acid protein in the mouse labrocyte cDNA library. A total of 29 proteins were found in the TBC-1 family, in which TBC-1-D4 and TBC-l-D1 have been extensive studied. Koumanov and Holman (2007) speculate that TBC-1-D4 and TBC-l-D1 play key roles in cell membrane transport and connection signal transduction. Bryant (2002) report that TBC-1D1 stimulates glucose transporter protein (GLUT4) from a cellular location to the cell surface in muscle and adipocytes, thereby completing signal transduction and substance transport. Hargett et al. (2015) confirm that TBC-1D1 regulates the expression of GLUT4 in skeletal muscle cells through knockout TBC-1D1 gene in mice.

Fibroblast growth factor (FGFR) belongs to tyrosinkinase (TK) receptor family (Kornbluth et al., 1988). Four kinds of FGFRs, i.e. FGFR-1, FGFR-2, FGFR-3, and FGFR-4, have been found. Deng et al. (1994) find that mouse embryos with defective FGFR-1 gene are severely blacked and died during development. Li (2008) shows that the FGFR1 regulates phosphorus metabolism and calcium metabolism in blood and bone through ALK3, and FGFR1 regulates osteoblasts proliferation and apotosis through inhibiting PI3K and promoting MAPK signaling pathway, and inhibits osteoblasts mineralization and proliferation physiologically. Gudernova et al. (2015) find that mutant FGFR3 causes human dwarfism-achondroplasia (ACH) symptoms.

Conclusion

In conclusion, we firstly sequenced the transcriptomes of *B. lutosa*, and detected eight growth-related genes (TBC-1-A, TBC-1-2B, FGFR-1, GFRBP2, GFR-15, FGFR-1-A, SMAD6, and TGFβR-1) that contain EST-SSR sequences in the *B. lutosa* transcriptome. However, which EST-SSR sequences should be used as biomarkers for breeding need to further study.

EFFECT OF VARIOUS SYSTEMS OF TILLAGE ON WINTER BARLEY YIELD, WEED INFESTATION AND SOIL PROPERTIES

WOŹNIAK, A.

Department of Herbology and Plant Cultivation Techniques, University of Life Sciences in Lublin, Akademicka 13, Poland
(e-mail: andrzej.wozniak@up.lublin.pl)

(Received 21st Nov 2019; accepted 12th Mar 2020)

Abstract. A field experiment was performed to evaluate the yield of winter barley, weed infestation, and soil properties in various systems of tillage and crop rotation The following experimental factors were examined: tillage systems (TS): 1) CT – conventional tillage, 2) RT – reduced tillage, 3) NT – no-tillage; and crop rotation (CR): 1) winter wheat – winter barley, 2) pea – winter barley. Shallow ploughing and pre-sowing ploughing were performed in CT, cultivation in RT and glyphosate only was used in NT. The study found the highest barley grain yield in CT after pea, whereas the lowest one – in NT after wheat. A higher number and mass of weeds per m^2 was determined in RT than in CT and NT systems. Also the number and mass of weeds were found to be more affected by TS than by CR. The soil sampled from NT plots contained more organic C than that collected from RT and CT plots, and more total N than soil samples collected from CT plots. Higher contents of organic C and total N were also found in the soil from plots wherein barley was sown after pea compared to the soil from plot wherein barley was grown after wheat.
Keywords: *crop rotation, organic carbon, soil tillage, species composition of weeds, total nitrogen*

Introduction

The goal of soil tillage is to provide the best conditions for plant growth, development, and yield. Tillage systems determine soil properties (West and Marland, 2002; Tabaglio et al., 2008; Celik et al., 2011; Aziz et al., 2013), crop weed infestation (Hernández Plaza et al., 2015; Gawęda et al., 2018), water-air balance, and consequently crop yield and its quality (Ruisi et al., 2014; Montemurro and Maiorana, 2015; Rachoń et al., 2015; Woźniak and Stępniowska, 2017). Opinions on the effect of tillage systems on grain yield and weed infestation of crops are inexplicit and result mainly from various soil and weather conditions occurring during cultivation (Derpsch et al., 2010; Gruber et al., 2012; Zikeli et al., 2013). Soil tillage in the no-plough system (no-tillage, reduced tillage, strip-till) is practiced increasingly more often by farmers as it significantly reduces production costs compared to the conventional system (Haliniarz et al., 2018). Nevertheless, as reported by De Vita et al. (2007), there are strong correlations between wheat grain yield, tillage system, and total precipitation in the growing season. The no-tillage (NT) system has a positive effect on wheat grain yield when the total precipitation is low, whereas conventional tillage (CT) – when it is high. The better production effect in NT is due to the smaller evaporation of water the soil which results in its greater availability to plants (De Vita et al., 2007). Also in the study conducted by Ruisi et al. (2014), the no-tillage system ensured a higher grain yield of durum wheat after shortage of precipitation, whereas the conventional tillage system increased grain yield when water availability was sufficient. In turn, the experiment conducted by Woźniak and Kwiatkowski (2013) demonstrated a higher barley grain yield in the conventional tillage system than in reduced tillage and herbicide systems. In addition, it showed various responses of barley cultivars to the tillage system applied. In turn, López-Bellido et al. (2001) demonstrated a significant effect of tillage system on wheat grain quality. In their

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34833496

study, the conventional tillage had a more favorable effect on grain quality attributes than no-tillage, which was due to better availability of nitrogen for plants. Also in the experiment performed by Ruisi et al. (2014) the conventional tillage increased protein content of durum wheat grain, compared to the no-tillage system. In contrast, Woźniak and Stępniowska (2017) concluded that contents of protein and wet gluten in the grain as well as specific weight of the grain, and grain uniformity were affected by study years to a greater extent than by tillage systems. Tillage system was also found to differentiate the chemical composition of the grain. Conventional tillage facilitated accumulation of phytic-P and iron, reduced tillage – accumulation of calcium and manganese, whereas no-tillage – accumulation of phosphorus, potassium, magnesium, and copper. In addition, heavy rainfalls promoted the accumulation of phytic-P and copper in the grain, whereas precipitation shortages increased contents of potassium and magnesium in the grain.

Tillage system affects also the extent and structure of crop infestation with weeds. In a moderate climate, the no-plough and no-tillage systems increase the number and weight of weeds compared to the conventional system. Tillage systems influence also the species composition of weeds and their distribution in cereal stands. This, in turn, affects the competitiveness between weeds and crops, with the weeds of the upper level being more competitive to cereals than these off the ground and lower levels (Hernández Plaza et al., 2015; Woźniak, 2018). In the experiment performed by Gruber et al. (2012), a few to several times more weeds were found on plots cultivated in the no-tillage system than on these cultivated in the conventional tillage system. As reported by Hernández Plaza et al. (2015), tillage systems affect also the vertical distribution of weed seeds in the soil. The NT system promotes species with fine seeds and of high fertility, capable of germinating from soil surface. In turn CT plots are predominated by weed species having large seeds and capable of germinating from deeper soil layers. In the study conducted by Woźniak (2018), a high number of weed species belonging to the upper and middle layers of wheat crop was detected in the herbicide system (HT) than in conventional (CT) and reduced (RT) tillage systems. In the no-tillage system, weeds of the upper layer – *Apera spica-venti*, *Papaver rhoeas* and *Sonchus oleraceus* – spread mainly anemochorically by increasing the seedbank on soil surface. According to Koning et al. (2019), in this system weeds are eradicated with glyphosate which may form biotypes resistant to this herbicide. As claimed by Farooq et al. (2011), resistance of weeds to herbicides in the herbicide tillage system poses a problem across the world, while solution to this problem may be offered by conservation agriculture.

This study aimed to evaluate the effect of tillage systems and crop rotation on winter barley grain yield and its structure as well as on weed infestation and soil properties.

Material and Methods

Experiment location and description

A field experiment with tillage systems was established in 2007 at the Experimental Station Uhrusk belonging to the University of Life Sciences in Lublin, south-east Poland. The results presented in this manuscript were collected in the year 2018 from the 11-year CT, RT and NT systems. The experiment was established with the method of complete sub-blocks (6 m x 25 m in size), in three replications. The following experimental factors were tested: (I) tillage systems: 1) conventional tillage (CT), 2) reduced tillage (RT) and 3) no-tillage (NT); (II) crop rotation (CR): 1) winter wheat – winter barley and 2) pea –

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34833496

winter barley. The tillage plan is presented in *Table 1*. Winter barley cultivar 'Titus' was sown between 20 and 30 of September, at sowing density of 400 seeds per m^2.

Table 1. *Scheme of soil tillage*

Crops	Tillage system (TS)		
	conventional tillage (CT)	**reduced tillage (RT)**	**no-tillage (NT)**
After-harvest	shallow ploughing, depth of 10 cm	cultivator (twice)	Glyphosate (360 g L^{-1}, 4 L ha^{-1})
Pre-sowing cultivation	pre-sow ploughing (20 cm)	tillage unit for pre-sowing tillage (cultivator and roller)	

Soil and weather conditions

The experiment was established on *Rendzic Phaeozem* (WRB, 2014), which contains 24.5% of silty fraction and 13.7% of dust fraction. The soil has slightly alkaline pH (pH_{KCL} = 7.4), high contents of available phosphorus (120 mg kg^{-1} P dm) and potassium (194 mg kg^{-1} K), and a moderate content of magnesium (73 mg kg^{-1} Mg).

In the multi-year period of 2007-2017, the total atmospheric precipitation at the study area was 640 mm, including 230 cm since November till April (cold half-year) and 410 mm since May to October (warm half-year). In 2018, the total annual precipitation reached 440 mm, including 160 mm in the cold half-year and 280 mm in the warm half-year (*Fig. 1*). In the multi-year period, the average air temperature reached 1.8°C in the cold half-year and 15.6°C in the warm half-year. In 2018, the air temperature was slightly higher and reached 2.0°C and 17.1°C, respectively. The coldest months turned out to be January (average temperature: −2.7°C) and February (−2.1°C), whereas the warmest ones – July (20.2°C) and August (19.3°C). The growing season at the study area spans for 210–215 days; it begins from 20 to 31 of March and ends at the beginning of November.

Fertilization and plant protection

Phosphorus-based (30 kg ha^{-1} P) and potassium-based (75 kg ha^{-1} K) fertilizers were used in the autumn before winter barley sowing. Nitrogen-based fertilizers were administered in three terms: in the autumn before barley sowing – 20 kg ha^{-1} N, in the spring at the tillering stage (23–24 BBCH) – 50 kg ha^{-1} N, and at the heading stage (52-53 BBCH) – 20 kg N ha^{-1} (BBCH Working Group, 2001). Fertilization doses were computed based on the chemical analysis of soil. Chemical protection of barley plants included administration of fungicides containing flusilazole + carbendazim at the shooting stage (31–32 BBCH) and propiconazole + fenpropidin at the heading stage (43-44 BBCH). Weeds were eradicated with a herbicide containing MCPA + mecoprop + dicamba at the tillering stage (23–24 BBCH), and herbicide treatment was performed after the first term of assessment of weed number and species composition.

Yield components and statistical analysis

The following yield components were analysed in the experiment: 1) plant number per m^2 at the tillering stage (23–24 BBCH); 2) spike number per m^2; 3) grain weight per spike; 4) 1000 grain weight; 5) number and species composition of weeds per m^2 at the tillering stage (23–24 BBCH); and 6) number, species composition, and air-dry weight of weeds in g m^{-2} at the milk maturity stage (73–74 BBCH). Additional determinations were conducted for contents of organic carbon (C) and total nitrogen (N) in the soil.

Grain was harvested using a plot harvester at 14% moisture content of the grain. Grain weight per spike was evaluated based on 40 plants randomly collected from each plot, whereas 1000 grain weight was determined by measuring out 2 × 500 grains. Weed infestation was evaluated with the botanical-gravimetric method which consists in determination of the number and species composition of weeds and of their air-dry weight from the surface area of one m^2 of each plot. This surface was determined at random (twice) using a frame (0.5 × 1.0 m). Determination of the air-dry weight of weeds consisted in their manual picking from frame surface, removing their root system, and placing them in a ventilated room until their constant weight has been achieved (Woźniak, 2018). Soil samples collected from all plots were determined for organic C content with the Tiurin method and total N content with the Kjeldahl method.

Results obtained were subjected to the analysis of variance (ANOVA), whereas significance of differences between mean values for tillage systems (TS), crop rotation (CR) and TS × CR interaction was evaluated using Tukey's HSD test, $p < 0.05$.

Results

Grain yield and its components

A higher barley grain yield was determined in CT system compared to RT system (by 24.8%) and NT (by 54.2%) systems (*Table 2*). A higher barley grain yield was also noted on plots where barley was sown after pea than after winter wheat. Tillage systems (TS) and crop rotation (CR) affected plant number per m^2 (*Table 3*). At the 23–24 BBCH stage, the number of barley plants per m^2 was higher in CT than in RT and NT. A higher plant number was also observed on plots where barley was sown after pea than after wheat. Likewise, the number of spikes per m^2 was higher in CT than in RT and NT, and on plots with barley sown after pea than after wheat. Tillage systems and crop rotation were also found to affect grain weight per spike and 1000 grain weight. Their values were more

ns – not significant

Variance component analysis indicates that barley grain yield, plant number per m^2, spike number per m^2, and grain weight per spike were affected to a greater extent by TS than by CR, whereas 1000 grain weight – to a greater extent by CR than by TS (*Table 4*).

Indices of crop infestation by weeds

At the tillering stage of winter barley (23-24 BBCH), more weeds per m^2 occurred in RT than in CT and NT systems (*Table 5*).

Table 5. *Number of weeds per m^2 in winter barley crop*

Crop rotation (CR)	Tillage system (TS)			Mean
	conventional tillage (CT)	reduced tillage (RT)	no-tillage (NT)	
23–24 BBCH

ns – not significant

The higher number of weeds was also observed on the plot where barley was sown after winter wheat than after pea. Also at the milk maturity stage of barley (73–74 BBCH) more weeds were found in RT than in CT and NT systems, and on plots where barley was sown after wheat than after pea. Similar observations were made for the air-dry weight of weeds (*Table 6*). The greatest biomass was developed by weeds in RT, smaller one in NT, and the smallest one in CT system. Variance component analysis indicates that, in both terms of evaluation, the number of weeds per m^2 and air-dry weight of weeds were more influenced by TS than by CR (*Table 7*).

Tillage systems (TS) and crop rotation (CR) affected also the number and composition of weed species in barley stands (*Table 8*). At the tillering stage (23–24 BBCH), a higher number of weed species was observed on RT than on CT and NT plots, as well as on plots where barley was sown after pea than after wheat. Also at the milk maturity stage of barley (73–74 BBCH) was the number of weed species higher in RT than in CT and NT systems, and in plots where barley was sown after wheat than after pea.

Soil properties

The soil sampled from NT plots contained more organic C than that from RT and CT plots (*Table 9*). Also more organic C was determined in the soil from plots where barley was sown after pea than after wheat. In turn, total N content was similar in soil samples from NT and RT plots, and significantly higher in the soil from CT plots. Also a higher N total content was determined in the soil sampled from plots where barley was sown after pea than after wheat.

Table 9. *Effect of crop rotation and tillage system on chemical properties of soil (0–30 cm)*

Crop rotation (CR)	Tillage system (TS)			Mean
	conventional tillage (CT)	reduced tillage (RT)	no-tillage (NT)	
Organic C (g kg^{-1} dm)				
Winter wheat – winter barley	8.33	11.03	12.43	10.60
Pea – winter barley	10.70	11.70	13.03	11.81
Mean	9.52	11.37	12.73	-
$HSD_{0.05}$ for TS = 1.08, CR = 0.72, TS × CR = ns				
Total N (g kg^{-1} dm)				
Winter wheat – winter barley	0.86	0.94	0.96	0.92
Pea – winter barley	0.91	1.06	1.08	1.01
Mean	0.88	1.00	1.02	-
$HSD_{0.05}$ for TS = 0.10, CR = 0.07, TS × CR = ns				

ns – not significant

Variance component analysis demonstrates that organic C content in the soil was influenced to a greater extent by TS than by CR, whereas total N content was similarly affected by CR and TS (*Table 10*).

Discussion

Soil tillage aims to provide the best conditions for plant growth and yielding, and also to keep weed infestation at the level posing no threat to crop stands (Nichols et al., 2015; Santín-Montanyá et al., 2016). A study conducted by Gruber et al. (2012) indicates that, in moderate climate, the conventional tillage system is more effective in reducing weed infestation than the no-tillage system. Also Woźniak and Kwiatkowski (2013) demonstrated significantly lesser weed infestation in the conventional tillage than in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34833496

reduced and herbicide systems. In contrast, in the arid Mediterranean regions, better production results and smaller weed infestation are observed in the no-tillage system compared to the conventional tillage (López-Bellido et al., 2001; De Vita et al., 2007). According to Ruisi et al. (2014), caution should be exercised to the appropriate crop rotation in the no-tillage system (NT), with cereals cultivation after themselves found as the inappropriate sequence. Also in our study, the highest barley yield was determined in CT after pea (5.57 t ha^{-1}), whereas the lowest one – in NT after pea (1.89 t ha^{-1}). It is due to a lower number of plants per m^2 in NT than in CT, a lower spike number per m^2, a lower grain weight per spike, and also a lower 1000 grain weight. The outcomes of barley cultivation after wheat included also: a lower plant number and spike number per m^2, a lower grain weight per spike, and a lower 1000 grain weight than after its cultivation after pea. In the present study, values of these traits depended to a greater extent on tillage systems (TS) than on crop rotation (CR). Similar dependencies were observed by Jug et al. (2011).

The no-till systems and cereal monoculture are characterized by increased number and weight of weeds as well as by predominance and compensation of a few weed species, compared to the conventional tillage and crop rotation (Koning et al., 2019; Woźniak, 2019). As reported by Hernández Plaza et al. (2015), the NT system promotes species with fine grains and high fertility whose seeds accumulate mainly on soil surface from where they sprout under convenient conditions. According to Farooq et al. (2011), these weeds are effectively eradicated by herbicides, but the inappropriate use of these preparations may develop plant resistance to them. In turn, greater species diversity of weeds having seeds of various sizes and exhibiting various fertility is observed in the CT system (Hernández Plaza et al., 2011). During cultivation, these seeds are transferred into deeper soil layers from where only some of them are capable to sprout (Santín-Montanyá et al., 2016). Generally, it may be concluded that the conventional tillage system (ploughing) and the use of glyphosate in the no-tillage system reduce the number and weight of weeds and also affect their species composition. This has also been confirmed in the present study where a lower number of weed species and lower weed density were observed in CT and NT systems than in the RT system. Weed distribution in the crop is also of high importance. It may, generally, be concluded that weeds of the upper and the middle levels spread with wind (anemochorically) or during harvest of cereals, whereas weeds of the lower and the ground levels ripe and spread on the stubble field. In the study conducted by Woźniak (2018), 45% of weeds identified in the herbicide tillage system were represented by species with small grains belonging to the upper and middle levels. Also in the present study, most of the weed species formed the middle and the upper layer of the crop, from where they could easily spread before the harvest of cereals.

Tillage system and crop rotation affect also soil properties (Woźniak, 2019). Soil from the cereal monoculture contains less organic matter and organic carbon (Maillard et al., 2016) than the soil from crop rotation; in addition, its biological activity decreases (Kretzschmar and Monestiez, 1992). Also in the present study, the soil sampled after pea cultivation contained more organic C and total N than the soil after wheat cultivation. More organic C and total N was also determined in the soil samples from NT and RT systems than from CT system, which is in agreement with findings reported earlier by Tabaglio et al. (2008), Zikeli et al. (2013), Santín-Montanyá et al. (2016) and Woźniak (2019).

Conclusion

Tillage systems and crop rotation caused significant differences in grain yield of winter barley, weed infestation, and soil properties. The highest grain yield was determined for barley grown in the conventional system after pea, whereas the lowest one for barley grown in no-till system after winter wheat. Grain yield, numbers of plants and spikes per m^2, and grain weight per spike depended to a larger extent on tillage systems than on crop rotation. A higher number and weight of weeds per m^2 was determined in the reduced tillage system compared to the conventional and no-till systems. Also, a higher number of weeds was found on the plot where barley was sown after winter wheat than after pea. The number and weight of weeds per m^2 were affected to a greater extent by tillage system than by crop rotation. Tillage systems differentiated also species number and composition of weeds. A higher number of weed species was found in the reduced tillage system than in the conventional and no-till systems. The soil sampled from plots cultivated in the no-till system contained more organic C than the soil collected from reduced and conventional systems as well as more total N than from the conventional system. Likewise, more organic C and total N was found in the soil sampled from the plot where barley was sown after pea than after wheat.

Abstract. In order to study the effect of mutagenesis on growth, physiology and cell structure in alfalfa (*Medicago sativa* L), the seeds of *Longmu806* were treated with two kinds of mutagenesis methods including ^{60}Co-γ irradiation (50, 150, 300, 450, 600 Gy) and EMS (ethyl methane sulfonate 0.1%, 0.2%, 0.4% (v/v)). The results showed that the seed germination rate, seedling growth, fresh grass yield and plant height were significantly ($P < 0.05$) higher than their corresponding controls under 50-150 Gy, and then decreased with the increasing of radiation dose. However, these indicators decreased with the increasing of EMS concentration. Two mutagenic treatments increased alfalfa branch number. The chlorophyll content was promoted by a dose of 50-150 Gy and 0.4% EMS concentration. It was also found that mutagenic treatments could promote the activity of three anti-oxidant enzymes including superoxide dismutase (SOD), peroxidase (POD) and hydrogen peroxidase (CAT), and the highest antioxidant enzyme activity was 150 Gy ^{60}Co-γ irradiation and 0.4% EMS treatment. The leaf thicknesses increased, the vein protuberant degrees decreased and the compactness of cell structure was enhanced. Being more conducive for screening mutants, ^{60}Co-γ irradiation with 150 Gy and EMS with 0.4% were the ideal mutagenic treatments.
Keywords: *^{60}Co-γ irradiation, ethyl methane sulfonate, seedling growth, antioxidant enzyme activity, chlorophyll content*

Introduction

Alfalfa (*Medicago sativa* L.) is very important legume forage crop, which has been planted all over the world. However, in alpine areas such as northeast China, short frost-free period, narrow genetic basis, low harvest index and widespread biotic and abiotic stresses constrains alfalfa production, and feed supplies are often insufficient in some years, which seriously restricts the production productivity of livestock (Shen et al., 2016; Nan et al., 2011). Modern biotechnological approaches, including mutagenic technology, are gaining interest to augment the efforts of alfalfa genetic improvement (Jain, 2011).

The mutagen is very efficient for creating genetic variability in the natural gene pool of crops (Kumari et al., 2016; Kumar et al., 2010). It provides raw materials for the genetic improvement of any crop (Adamu et al., 2004). Artificial mutagenesis can be used to induce mutations in crop plants and subsequent improvement be done through

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34973510

selection. They made a significant contribution to agricultural development. Some scholars have screened a number of new varieties through mutagenic research on alfalfa. For example, Zhang et al. (2007) have selected a new alfalfa variety *Nongjing 1* from *Longmu 803* mutant through magnetic field free space; and selected alfalfa varieties *Nongjing 8 and Nongjing 10* from *Zhaodong* alfalfa *and Longmu 803* mutant by satellite.

Some reports provide evidence of a stimulating effect on growth and physiological characteristics when seeds or seedlings are treated at different mutation (Zhang et al., 2017). The growth and physiological responses of alfalfa to mutagens were elucidated (Dhawi and Al-Khayri, 2011). Mutagenesis inflicted modifications in seedling growth (Li et al., 2013); chlorophyll (Dhawi and Al-Khayri, 2008); SOD, POD, CAT and MDA (Dhawi and Al-Khayri, 2008); and water content as well as growth expressed in fresh weight (Dhawi and Khayri, 2009). Wu et al. (2015) discovered that the EMS mutagenesis treatment can inhibit the germination and growth of alfalfa seeds. In higher plants, the structure of the cell changes under different degrees of environmental and mutagenic stresses and is closely related to the degree of stresses implied and the inherent stress resistance capacity of the plant. Zhang et al. (2010) reported that after the space mutagenesis, the leaf thicknesses of alfalfa increased and the palisade tissues were significantly thickened. The mutants provide materials to be selected for breeding. The above studies have shown that mutagenesis can change the physiological and growth characteristics of alfalfa, and has practical production significance for alfalfa breeding research.

In this study, we selected ^{60}Co-γ radiation and EMS two types of mutagenesis treatments, because they had higher mutagenic efficiency, their mutant materials were more abundant, and can lead to be helpful to improve cold resistance of alfalfa. The two mutagenesis methods operations were simple and low in cost. The study aim to comprehensive understand the effects of physical mutagenesis and chemical mutagenesis on alfalfa growth, physiological characteristics and cell structure, and provide a theoretical basis for the selection of resistant mutant in the alpine region and the selection of new forage varieties.

Materials and methods

Climatic condition

An experimental field was established in the Jiamusi City, which was located in the east part of the Heilongjiang Province, P. R. of China, 2017. The longitude is 129°30′ – 135°5′E, and its latitude 45°56′ – 48°27′N. This region has a climate type of cold humid monsoon with annual average temperature of 3 ℃, annual average precipitation of 489.8 mm, annual sunshine of 2052.3 h, annual active accumulative temperature of 2500 ℃, and the annual average frost-free period is 128.9 d.

Growth condition

The row to row and plant to plant spacing were kept at 30 cm and 12 cm, respectively. The organic matter was 2.49% in the tested meadow black soil with available nitrogen 86.3 mg·kg^{-1}, available phosphorus 64.6 mg·kg^{-1}, available potassium 79.9 mg·kg^{-1}. Its total nitrogen, phosphorus, potassium was 0.14%, 0.15%, and 3.12%, respectively. Its soil pH was 6.5. The previous crop for this site was corn.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34973510

Plant materials

The tested alfalfa (*Medicago sativa* L.) was local and widely cultivated variety *Longmu806* (Shen et al., 2015). It was supplied by the Jiamusi branch of the Heilongjiang Academy of Agricultural Sciences.

Experimental design

^{60}Co-ray irradiation

For ^{60}Co-γ irradiation treatment, the seeds taken from the aforementioned alfalfa were treated with 6 ^{60}Coγ-ray irradiation doses viz., 50 Gy, 150 Gy, 300 Gy, 450 Gy, 600 Gy (300 seeds per dose) from 60 cobalt source at the Institute of Atomic Energy Utilization of Chinese Academy of Agricultural Sciences. The dose of 0 was set as control. Each treatment lasted for 7 days.

Ethyl methyl sulfonate (EMS)

900 seeds taken from the aforementioned alfalfa were soaked with concentrated sulfuric acid for 5 min, and then rinsed with distilled water several times. The treated seeds were completely water-swelled by soaking in the phosphate buffer (100 mmol L^{-1}, pH 7.0) at 4 °C for 12 h. The seeds thus treated with phosphate buffer, were subjected to 0.1, 0.2 and 0.4% (v/v) EMS and incubated in the dark at room temperature for 15 h. During the procedure, the seeds were gently shaken. Finally, the seeds were rinsed with distilled water repeatedly for removing the residual EMS from the seed surface (Feng et al., 2018).

Germination percentage and seedling growth

After mutagenic treatments, the seeds along with its control seeds were germinated on moist filter paper at 28 ℃. After 2 weeks, the germinated seeds were counted and seedling growth was measured.

Germination percentage = Number of germinating seeds / Total number of seeds × 100

Sampling time

During alfalfa florescence (June 15th - June 25th), ten plantings were selected at random to record observations on planting height, the branches of each plant, the average yield of single plant and the stem-leaf ratio (Shen et al., 2018). The alfalfa functional leaves were taken and mixed from each treatment to measure physiological indexes.

Experimental method

Chlorophyll analysis

The plants leaves washed with distilled water, then weighed it about 0.2 g. Chlorophyll content in the leaves of treated and control plants were extracted in 80% acetone and 95% ethanol 20 ml, after 24 h dark extracted in 50 ℃ water bath, then determined the absorbance of the solution at 645 and 663 nm. Chlorophyll content was expressed by following equations (Ahmadreza et al., 2009):

$$Ca = (12.71A_{663} - 2.59A_{645}) \times (V / M) \times 1000 \quad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34973510

$$Cb = (22.88A_{645} - 4.67A_{663}) \times (V / M) \times 1000 \quad \text{(Eq.2)}$$

$$Ct = (8.04\ A_{663} + 20.29A_{645}) \times (V / M) \times 1000 \quad \text{(Eq.3)}$$

Ca, Cb, Ct were chlorophyll-a, chlorophyll-b, and total chlorophyll, V were solvent amount, M were leaf weight, A_{645}, A_{663} were the absorbance value at 645 nm and 663 nm.

Enzyme activities analysis

The SOD was determined with the nitroblue tetrazolium (NBT) method (Dai et al., 2011), while the POD determined with the guaiacol method (Shen et al., 2018); and the CAT determined with the ultraviolet absorption method. The content of malondialdehyde (MDA) was measured with the glucosinolate and pentobarbital acid colorimetric method (Nahla et al., 2015). The instrument used in the test was a 721 UV-visible spectrophotometer (model: U-T6, Made in China).

Microstructure

The functional leaves of the M0 generation plants were selected and cut along the middle veins in an inverted trapezoidal shape having a size of 5 × 5 mm. The samples were fixed with FAA (formalin-acetic acid-alcohol) solution and underwent conventional paraffin sections with a thickness of 5 μm and then stained with Safranin'O/Fast Green. The slides were observed under a Nikon-DIAPHOT (Model: Diaphot TMD, Made in Japan) microscope. The mean of the 4 values of leaf thickness, vein thickness, palisade thickness and spongy thickness of the tested alfalfa was determined by Motic Image 2000 1.3. Cell tense ratio, Spongy ratio, Vein protuberant degree were calculated as follows:

$$\text{Cell tense ratio (CTR \%)} = \text{Palisade tissue thickness / Leaf thickness} \times 100 \quad \text{(Eq.4)}$$

$$\text{Spongy ratio (SR \%)} = \text{Spongy tissue thickness / Leaf thickness} \times 100 \quad \text{(Eq.5)}$$

$$\text{Vein protuberant degree (VPD)} = \text{Vein thickness / Leaf thickness} \times 100 \quad \text{(Eq.6)}$$

Statistical analysis

The data were analyzed by using the Statistical Analysis System (SAS Inc. CARY, NC) and EXCEL software were used for the statistical analysis of data.

Results

Alfalfa seed germination after mutagenesis

The alfalfa seed germination rate is shown in *Figure 1a, b*. The results showed that the germination ability of the treated seeds was significantly increased by ^{60}Co-γ radiation from 50 Gy (85%) to 150 Gy (91.08%) as compared to the control (82.33%), and then the seed germination percentage decreased gradually from 73.67% (300 Gy) to 50.43% (600 Gy). However, for the chemical mutagen treatment, the significant reduction in seed germination percentage (72.67%) began at 0.1% of EMS and continued to decline to up to 44.57% at 0.4% (*Fig. 1b*). The results suggested that ^{60}Co-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34973510

γ radiation could stimulate the alfalfa seed germination percentage at lower dose (50-50 Gy), but higher doses (300-600Gy), inhibit the germination rate. However, EMS mutagenesis could always inhibit seed germination. It can be seen that the inhibition rate of seed germination by EMS treatment was significantly ($P < 0.05$) higher than low-dose (50-150 Gy) ^{60}Co-γ radiation treatment (*Fig. 1*).

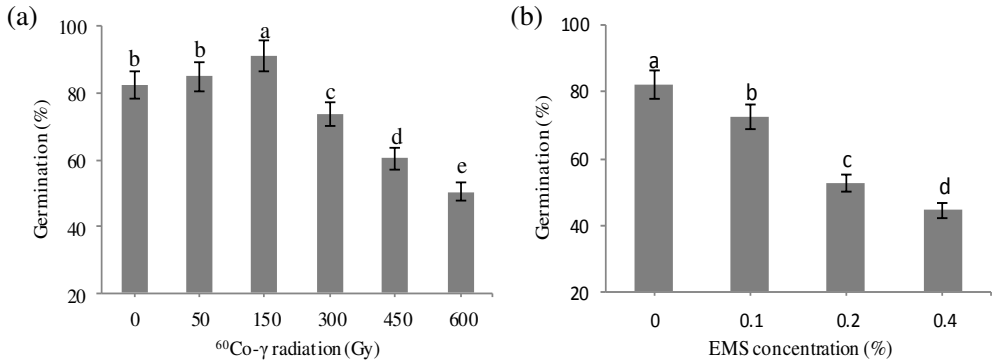

Figure 1. *Effects of different mutagenic treatments on germination rate of alfalfa seeds (a, b). Different small letters are significantly different ($p < 0.05$) in statistics. Each column represents the average of triplicate treatments, error bars represent the standard deviations of three replicates. (a) ^{60}Co-γ irradiation treatment and (b) ethyl methyl sulfonate treatment (EMS)*

Alfalfa seedling growth after mutagenesis

The measured root length of alfalfa is shown in *Table 1*. The root growth increased significantly from 50 Gy to 150 Gy of ^{60}Co-γ irradiation. The maximum root length was 4.50 cm at 150 Gy, after that the root length decreased gradually with increase in doses of the mutagen. The minimum root length was 1.88 cm at 600 Gy, which was significantly lower than their corresponding controls ($P < 0.05$). EMS mutagenesis inhibited root growth. The root length was significantly inhibited with increasing concentration ($P < 0.05$). Maximum root length was observed in 0.1% concentration (2.56 cm), and minimum root length was 1.38 cm in 0.4% concentration.

Table 1. *Effect of different mutagenic treatment on root length of alfalfa*

Treatments	Dose	Root length (cm)	Shoot length (cm)
CK	0 Gy	3.78 ± 0.3bc	3.19 ± 0.41b
^{60}Co-γ	50 Gy	3.86 ± 0.47bc	3.29 ± 0.29ab
	150 Gy	4.50 ± 0.38a	3.79 ± 0.11a
	300 Gy	3.21 ± 0.48c	3.00 ± 0.45b
	450 Gy	2.38 ± 0.46d	2.52 ± 0.42c
	600 Gy	1.88 ± 0.24e	2.06 ± 0.34d
EMS	0.10%	2.56 ± 0.26d	2.82 ± 0.36bc
	0.20%	2.01 ± 0.44d	2.51 ± 0.22c
	0.40%	1.38 ± 0.63e	2.06 ± 0.15d

Data in the table is the mean ± SE. Average is the value of different agronomic traits in the different treatments. Different small letters in same column are statistically different at $p < 0.05$ and same small letters in same column are not statistically different at $p < 0.05$. ^{60}CO-γ: ^{60}Co-γ irradiation treatment and EMS: ethyl methyl sulfonate treatment

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34973510

The variation trend of shoot length was consistent with that of root length. Maximum shoot length was observed in 150 Gy dose (3.79 cm) of ^{60}Co-γ radiation and 0.1% EMS concentration (2.82 cm) while the higher doses/concentrations retarded shoot length. In addition, it was found that the growth inhibition effect of EMS mutagenesis on seedlings was significantly ($P < 0.05$) greater than that of low-dose (50-300 Gy) ^{60}Co-γ radiation. The increase in mutagenic doses/concentration lead to decrease in seedling vigor because of increase in physiological damage induced in the seeds and seedlings and variations in stimulation due to cell division rates as well as an activation of growth hormones such as auxin.

Alfalfa agronomic traits after mutagenesis

Variable degree of agronomic traits response was observed in different dose/concentrations (*Table 2*). The variation range of agronomic characters increased with the increase of mutagenic dose/concentrations. The fresh grass yield increased from 5.24 to 13.85% when the ^{60}Co-γ treatment dose increased from 50 Gy to 150 Gy, and then it decreased with increasing dose. The fresh grass yield reduction ranged from 4.51% in 300 Gy to 21.23% in 600 Gy dose compare to control. While for EMS treatment, its reduction ranged from 3.24% in 0.1% EMS to 32.69% in 0.4% EMS. The change trend of plant height was consistent with that of fresh grass yield. The highest plant height was 139.70 cm in 150 Gy, and the lowest plant height was 59.30 cm in 0.4% EMS. In summary, compared with the control, the effects of ^{60}Co-γ radiation treatment on grass yield and plant height increased first and then decreased, while EMS treatment showed a significant inhibitory effect ($P < 0.05$).

Table 2. *Effect of mutagenic treatments on agronomic traits*

Treatments	Dose	Yield/plant (g)		Height (cm)		Branch/per plant		Stem-leaf ratio (%)

Data in the table is the mean ± SE. Average is the value of different physiological indexes in the different treatments. Different small letters in same column are statistically different at $p < 0.05$ and same small letters in same rows are not statistically different at $p < 0.05$. CK: control treatment ^{60}Co-γ: ^{60}Co-γ irradiation treatment and EMS: ethyl methyl sulfonate treatment

Both mutagenesis treatments promoted alfalfa branching. The branch number of alfalfa enhanced with the increase in dose/concentration both in physical and chemical mutagens. It reaches the maximum value at 600 Gy, nearly 43.76% more than the control. Similarly, the branch number was improved from 24.95% in 0.1% EMS to 54.61% in 0.4% EMS. Overall, EMS treatments are more conducive to increasing the number of alfalfa branches, but it is not significantly different from ^{60}Co-γ radiation treatment. The stem-leaf ratio was also different with the different mutagenesis. The difference of stem-leaf ratio were not significantly affected between low dose (50 Gy-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34973510

150 Gy) and low concentration (0.1%-0.2%), but there were significant reduction ($P < 0.05$) with the increase of dose and concentration. The decrease of the stem-leaf ratio indicates that alfalfa leaf increased and the nutrient content of alfalfa was improved.

Influence of mutagen on the chlorophyll content

The chlorophyll content and the ratio of chlorophyll a/b can reflect the adaptability of plant varieties, and also an important indicator for the utilization of environmental factors. The chlorophyll content obtained according to *Equations 1-3* is shown in *Table 3*. The chlorophyll a content of alfalfa leaves under the treatments with 150 Gy ^{60}Co-γ radiation and 0.4% EMS treatment were significantly higher than their corresponding controls ($p < 0.05$). The changes trend of chlorophyll b content was consistent with chlorophyll a content under different mutagenesis treatments. The change of total chlorophyll of alfalfa was increasing at first and then decreasing under the ^{60}Co-γ radiation, and it increased with the increase of EMS treatment concentration. Under low dose (50-150 Gy) ^{60}Co-γ radiation treatment and 0.4% EMS treatment, the total chlorophyll content was significantly ($p < 0.05$) higher than other treatments. The maximum was observed in 150Gy (4.36 mg•g^{-1}) and 0.4% EMS concentration (4.27 mg•g^{-1}). Except for 0.4% EMS treatment, the proportion of chlorophyll a/b in alfalfa leaves was basically lower than the control.

Table 3. *Effect of mutagenic treatments on chlorophyll content*

Treatments	Dose	Chl. content (mg•g^{-1})			
		Chl.a	Chl.b	Total Chl.	Chl. a/b
CK	0	2.94 ± 0.10b	0.94 ± 0.03a	3.88 ± 0.09b	3.13 ± 0.08a

Influence of mutagen on the enzyme activity

The activity of SOD, POD, CAT and MDA content of alfalfa after treatments are shown in *Table 4*. The ^{60}Co-γ radiation treatment promoted the accumulation of SOD in alfalfa. The SOD activity was significantly increased ($P < 0.05$) in low dose, and after that it was decreased with the increase of dosage. However, the SOD activity increased with increasing of EMS treatment concentration, but was lower than that of control. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34973510

changes of POD activity and CAT activity were consistent in the two mutagenesis treatments and higher than their corresponding controls ($p < 0.05$). The POD and CAT activity increased when treated by 50-150 Gy, and decreased when treated by 300-600 Gy. The activity of the two enzymes decreased with the increase of EMS concentration. Furthermore, from the change of enzyme activity analysis it was shown that the promoted strength of activity was as follows: POD > CAT > SOD. The activity of three antioxidant enzymes in low-dose (50-150 Gy) ^{60}Co-γ radiation treatment were higher than in low-dose (0.1-0.2%) EMS treatment, and the enzyme activity at 150 Gy dose was significantly higher than all other treatments ($p < 0.05$). The activity of the three enzymes showed the tendency of increasing firstly and then decreasing, this is possibly because of that the higher dose of mutagen shifted from stimulation to inhibition or disturbances for the enzyme activity.

Compared with the control, the MDA content increased first and then decreased under the two mutagenesis treatments. In all the treatments, the MDA content under 0.1% EMS treatment was significantly higher than other treatments ($p < 0.05$).

Table 4. *Effect of different doses mutagenic treatments on physiological indexes*

Treatments	Dose	SOD (U•g^{-1})	POD (U•gFW•min^{-1})	CAT (U•gFW•min^{-1})	MDA (μmol•g^{-1})
CK	0 Gy	230.29±33.85b	2443.78±305.23d	250.00±75.85f	35.64±3.20c
^{60}CO-γ	50 Gy	242.63±22.47b	4218.44±746.86b	474.40±139.46b	37.89±1.52b

EMS	0.10%	209.52±19.46c	4004.67±28.09c	436.27±24.37bc	39.77±8.33a
	0.20%	214.70±16.53c	4130.22±23.59bc	331.20±39.83de	34.57±12.52d
	0.40%	221.46±14.50bc	6416.32±19.33a	441.73±43.03bc	36.95±0.46bc

Data in the table is the mean ± SE. Average is the value of different physiological indexes in the different treatments. Different small letters in same column are statistically different at $p < 0.05$ and same small letters in same rows are not statistically different at $p < 0.05$. CK: control treatment, ^{60}Co-γ: ^{60}Co-γ irradiation treatment, EMS: ethyl methyl sulfonate treatment. SOD: the abbreviation of superoxide dismutase, POD: the abbreviation of peroxidase, CAT: the abbreviation of hydrogen peroxidase, MDA: the abbreviation of malondialdehyde

Microstructure of leaves

In the experiment, different mutagenic treatments showed different effects on the microstructure of the alfalfa leaves from the M0 generation. The mutagenic direction and degrees varied with the mutagenic methods and doses (Loutou et al., 2016; Zhu et al., 2015). In this study (*Table 5*), the leaf thickness of Longmu806 alfalfa was significantly higher than its corresponding controls ($p < 0.05$). The leaf thickness under 0.1% EMS treatment was significantly ($p < 0.05$) higher than the control and ^{60}Co-γ radiation treatment. The vein protuberant degree (VPD) was calculated according to *Equation 6,* and the VPD of all the treatments were significantly less than their corresponding controls ($p < 0.05$) (*Table 5; Fig. 2*).

The leaf thickness of plants primarily depends upon the thickness of the palisade tissue and the spongy tissue. In this experiment, the thicknesses of the palisade tissues

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34973510

and the spongy tissues for all the treatments were higher than their corresponding controls. This proves that a thicker palisade tissue and spongy tissue could be the result of mutation treatment. In this study, the changes occurred in the compactness and looseness of cell structure of the alfalfa was different. The cell tense ratio (CTR) was calculated according to *Equation 4,* and the compactness of cell structure for the lower dose/concentration treatments was lower than control, but it was significantly ($p < 0.05$) higher than control under 600 Gy ^{60}Co-γ and 0.4% EMS treatment. However, the spongy ratio (SR) was calculated according to *Equation5,* the looseness of cell structure increased compared to control in all treatments.

Table 5. *Comparison of main structural features (mean ± SE) of alfalfa under different mutagenic treatments (μm)*

Discussion

Mutation induction through the use of different kinds of mutagens has proved vital in inducing variability that could be exploited in the improvements of alfalfa growth and types. It is therefore the origin of genetic variability as suggested by Tamarin (1999). The changed mean germination percent due to various EMS concentrations and ^{60}Co-γ radiation doses revealed the effects of the mutagen in the germination process. In this study, the germination of seeds decreased with increase in dose/concentration both in physical and chemical mutagens except 50 -150 Gy. This result is consistent with the findings of Dhakshanamoorthy et al. (2010) who reported the germination of Barbados nut decreased with the increase dose of irradiation mutagen. This reduction/stimulation in seed germination might have been due to the effect of mutagens on meristematic tissues of the seed, or may be either due to the inhibition or promotion in physiological and biological process necessary for seed germination (Wu et al., 2013).

The reduction in lengths of root and shoot due to mutagenic treatments has been observed in alfalfa (Shen et al., 2018). In the present study, the root and shoot length decreased with increased doses of radiation except 50 Gy, which is in agreement with the findings of Ge et al. (2011) who reported the seedling germination rate and seedling growth of *Chrysanthemu morifolium* Ramat. decreased obviously when treated with high dose of ^{60}Co-γ radiation. Li et al. (2013) demonstrated that the seedling emergence rate and seedling height of watermelon (*Citrullus lanatus* (Thunb.) Matsum. et Nakai) decreased significantly as the radiation dose increased. However, in this experiment, both root length and stem length of alfalfa seedlings were inhibited by EMS. Huo et al.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34973510

(2014) using EMS treated the seeds of *Vicia sativa L.*, the result showed that the seedling growth were inhibited, and the inhibition enhanced with longer processing time. The increase in mutagenic doses lead to decrease in seedling vigor because of increase in physiological damage induced in the seeds and seedlings (Anbarasan et al., 2013) and variations in stimulation due to cell division rates as well as an activation of growth hormones such as auxin (Zaka et al., 2004). The reduced seedling growth in mutagenically treated seeds might be due to injury caused at cellular level because of gene controlled biochemical processes or acute chromosomal aberrations or both (Satpute et al., 2012).

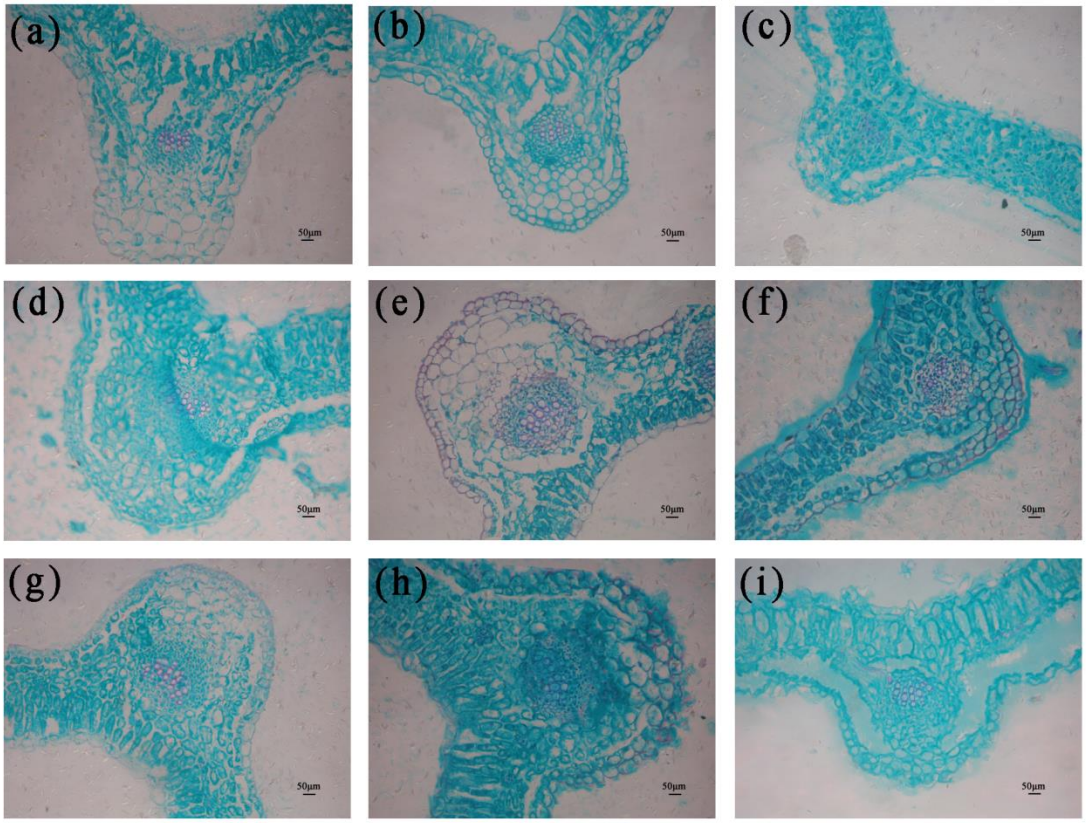

Figure 2. *Microstructure changes of leaf veins. a: control treatment, b: 0.1% ethyl methyl sulfonate treatment, c: 0.2% ethyl methyl sulfonate treatment, d: 0.4% ethyl methyl sulfonate treatment, e: 50 Gy ^{60}Co-γ irradiation treatment, f: 150 Gy ^{60}Co-γ irradiation treatment, g: 300 Gy ^{60}Co-γ irradiation treatment, h: 450 Gy ^{60}Co-γ irradiation treatment, i: 600 Gy ^{60}Co-γ irradiation treatment*

In this study, the change of fresh yield had the same trend with the plant height, which was firstly ascending and then descending following the dose increasing (*Table 2*). This might be due to the alteration of its genome integrated by environmental signals as reported by Wang et al. (2010). For the reason of the number of branch increased after mutagenesis, it might be caused by increasing the rates of cellular division and expansion at their meristematic regions. This is also in agreement with the findings of Yang et al. (2012) who reported that the increase of branch number of alfalfa was due to radiation mutagenesis. But it was in contrast with the findings of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34973510

Maluszynski et al. (2001) who independently reported that the decrease of branch number was due to induced mutation in rice and other cereals. For the reason of that the stem-leaf ratio increased in lower dose (50 Gy) (*Table 2*), the explanation might be due to a greater increase in the yield of fresh forage. Following the dose increasing and the different concentrations of EMS, the stem-leaf ratio decreased, this means that the leaf area or leaf number was increasing, as leaf is a major nutrition tank and hence it would be helpful to improve the quality of alfalfa. This result was consistent with the reports of Yang et al. (2015) who reported that mutagen could decrease the stem-leaf ratio, and improve leaf number and increase leaf area.

In the present study, 150 Gy dose of ^{60}Co-γ radiation and 0.4% EMS all increased the content of chlorophyll in alfalfa. This is also in agreement with the findings of Yang et al. (2017) who reported increased in chlorophyll content of tomato and pepper due to radiation mutagenesis. Since the content of chlorophyll has a direct impact on the strength of photosynthesis, this also shows that mutagenesis could promote the photosynthesis of crops.

The active oxygen radical in plant cells is in a state of dynamic equilibrium under normal conditions. When plants are stimulated by mutagen, plants are equipped with antioxidant systems composed of low-molecular weight antioxidants and enzymes that protect the cell from the damaging effects (Ma et al., 2011). In the present study, the SOD activity increased in the range of 50-300 Gy, and then decreased as the dose gradually increased (*Table 4*). The later occurred decrease might be related to that the irradiated alfalfa suffered excessive mutagen stress. Both POD and CAT were found significantly increased in the leaf of alfalfa under ^{60}Co-γ radiation and EMS treatments, their activities also showed the trend of decreasing as the doses/concentrations increasing. The change of the antioxidant enzyme activity indicated that plants suffered oxidative stress induced by the over-production of the ROS, which was consistent with the results of Uruc and Demirezen (2012). The MDA is one of the membrane fat peroxidation products, its content can reflect the cell membrane fat peroxidation degree and the cell suffering injury degree (Pan et al., 2002). Under mutagen stress, the accumulation of reactive oxygen free radicals beyond a certain limit in alfalfa body will cause the membrane fat peroxidation, and its product MDA will accumulate (Gao et al., 2003) massively. In this study, the content of MDA was increased compared to their corresponding controls under the different mutagens stress, but the difference was not significant ($p < 0.05$). It indicates that the antioxidant enzyme system has certain protective effect on alfalfa under mutagenesis.

The structural characteristics of cells, including the thicknesses of the palisade tissue and the spongy tissue and the compactness and the looseness of the leaf tissue structures all contribute to the resistance mechanism of plants. According to Pavel et al. (2016) more compact the cell structure, the stronger the cold resistance of the species. Feng et al. (2008) demonstrated that after completing a space flight, leaves of alfalfa sowed increased thickness with high relative water content. In the same experiment, the thickness and compactness of spongy tissue was also increased. Zhang et al. (2015) showed that with respect to the microstructure of the alfalfa leaves, the spongy tissue and the palisade tissue reacted differently to the space mutagenesis, which had a bigger effect on the spongy tissue than on the palisade tissue. In this study, after mutagenesis, the thickness of the leaves increased, and the protrusion degree of the veins decreased. The thicknesses of the palisade tissues and the spongy tissues for all the treatments were significantly higher than their corresponding controls ($p < 0.05$), which was consistent

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_34973510

with the conclusion of Dhakshanamoorthy et al. (2010). Compared to the control, the cell compactness structure of cells and looseness did not change obviously in the low dose/concentration of all mutagenesis treatments, but which were increased with the increase of dose/concentration. There are beneficial in increasing the adversity resistance and cold resistance capacity of alfalfa.

Conclusion

Artificial mutation by using of ^{60}Co-γ radiation and EMS proves vital in the improvement of genetic variability in alfalfa. Both mutagenesis treatments can enhance the physiological activity of alfalfa. Furthermore, ^{60}Co-γ-ray treatment can promote the growth of plant height and increase the yield. EMS treatment can inhibit the plant height and promote the branching of alfalfa. In this study the 150 Gy dose of ^{60}Co-γ radiation and 0.4% EMS are better mutagenic treatment for screening mutants. It shows that in the future research, the mutagenesis treatment method can be selected according to the actual production needs. This study analyzes the growth and physiological changes of alfalfa. In the future, it is necessary to further study the molecular mechanism of its mutation to provide a theoretical basis for the screening and breeding of new mutants.

Abstract. The selection of parents and superior genotypes is a primary task for plant breeders. In line × tester mating design, seven lines and three testers were crossed to create twenty-one hybrids. The hybrids and parents were evaluated together in the field for various yield and yield related traits at maturity under water stress conditions. The variance assessment implies prominent contrasts between the lines, and testers, crosses for various traits. The differences for GCA and SCA were observed significant for the traits. The line WM13RA and OH33-1 showed the highest general combining ability for most of the traits. The cross combination WM13RA C × Agati85 provided the highest positive better parents heterosis. Specific combining ability was also high, ML17 × Agati85 and ML3 × Agati85 produced higher grain yield in term of said production of early maturing hybrids. Concerning molecular component, ten SSR primers were used to check the hybrid purity. One primer showed the polymorphism with parents and hybrids, results showed that seventeen hybrids were confirmed based on the presence of the polymorphic bands. Genetic purity was 80.95%.
Keywords: *combining ability, line × tester, maize, heterosis, SSR markers, water stress*

Introduction

Agriculture is a main pillar of the economy in Pakistan adding 0.85% to GDP. Maize is the third largest cereal crop in Pakistan (Anonymous, 2019). It is grown on an area of 191 million ha and 1104 million metric tons are produced with a yield of 5.77 metric tons/ha (FAO, 2019). Maize is grown on an area of about 1318 thousand ha with grain production of 6.309 million tons in Pakistan. Punjab and Khyber Pakhtunkhwa (KPK) contribute significantly to maize production in Pakistan. The Province Punjab share 56.76% growing area with 80.12% grain production while KPK share 42.52% crop growing area with 19.59% grain production (Anonymous, 2019). In Punjab it is grown in spring and autumn but only in the spring season in KPK because of no space crop pattern (Rana, 2014). Maize is also a "5F" crop, i.e. food, feed, fuel, fiber and fodder crop. Its insoluble fiber used to cure the acidity of stomach. It is backbone of the feed for the poultry. Maize grain as food contains protein, starch, fiber, oil, sugar, ash 11, 71, 5.7, 4.8, 3.0 and 1.7%, respectively (Chaudhary, 1983). Pakistan generated about 52 thousand million liters of ethanol while the world produce 28.9 million liters (Anonymous, 2019). Maize fodder can be fed to animals at any time after sowing without toxicity of chemicals (Dahmardeh et al., 2009). The demand of maize increases as the population increase, due to multiple usage of the maize grains as food for human while maize fodder as feed for animals (Mishra and Cherkauer, 2010) Pakistan has deep rich soil in South Asia and it is one of the densely packed nations of the world. Agricultural production stayed low in 2018-19. The underperformance of the agricultural sector was due to a decrease in the cultivation region, a decrease in the supply

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35113523

of water and a decrease in fertilizer usage (Aaliya et al., 2016; Ali et al., 2015, 2017). Abiotic stresses make large area unfit for agriculture due to adverse effects such as drought. In the Punjab plain and Sindh provinces, there is low precipitation (< 200 mm) and warm spell throughout the year (Ali et al., 2013, 2016). Due to the enormous exploitation of fresh reservoirs, water shortages are severe threat to our agriculture. Drought has a serious impact on the development of maize plant (Wynne et al., 1970). Pakistan is unable to fulfill the requirements of the maize seed. The demand of maize seed is about 28892 metric tons from which the public sector provides 237 metric tons, the private sector companies provide 1222 metric tons, while 12776 metric tons of seeds is imported, in total 14235 metric tons are available. The supply of seed is about 50% of the demand so there is a shortage of seeds (Anonymous, 2019). There are various threats for maize grain and fodder yield throughout the globe, there is a need to develop such maize genotypes and hybrids which can produce higher grain yield. The present study is designed for the selection of the parents to develop local hybrids and synthetic varieties on the basis of combining ability and heterosis and to confirm hybrid nature with molecular analysis.

Materials and methods

The seven screened out tolerant lines (which showed higher root length, shoot length and ratio of root shoot length, were selected as tolerant maize genotypes) were grown during the spring season of 2016 and hybridized with three testers to produce 21 hybrids line × tester mating design. The location and average climate during the research period were the followings; Latitude = 31° 44' N, Longitude = 73° 06' E, Altitude = 184.4 m, the average temperature was 35.7 °C, rain fall was 2.6mm, pan evaporation was 8.4 mm, sun shine was 12.4 h, ETO was 7.9 mm and wind speed was 6.23 km/h. Both (parents and hybrids) were grown in triplicate randomized complete block design in the field during the autumn of 2016 and the performance of the hybrids were evaluated considering drought tolerance on the basis of PH (PH) in cm, Leaf area (LA) in cm^2, Leaf angle (La) in degree, chlorophyll contents (CC), leaf temperature (LT) in °C, Days to silking (DS), Days to tasseling (DT), Anthesis to silking interval (ASI) in days, Cob length (CL) cm, Cob diameter (CD) in cm, Kernels rows per cob (KR),100 grains weight (GRW) in grams, Grain yield per plant (GYPP: grams). The data were recorded for 10 plants from each of the three replications.

Biometrical and statistical analysis

The general combining ability and specific combining ability was calculated according to Kempthorne (1957). Heterosis was calculated as Meredith and Bridge (1972) suggested.

Molecular analysis

The samples of the leaves were taken from the parents and their hybrids after two weeks of germination in the evaluation field. The samples were stored at -80 °C for molecular analysis. The DNA extraction was done by modified CTAB method from each sample as described by Doyle and Doyle (1990). Quantification was done with the Nano Drop 2000 (spectrophotometer). The 1% agarose gel was used to check the quality of DNA containing (EDTA/Tris/borate) buffer. About 3 µL of bromophenol blue was added to parental DNA samples. Ten polymorphic SSR primers were selected from already available database as shown in *Table 1*. Working solutions both (parent and hybrid) contain 30 ng/µl sample. The

DOI: http://dx.doi.org/10.15666/aeer/1802_35113523

reaction mixture for SSR analysis was 10X PCR buffer with $(NH_4)_2SO_4$, $MgCl_2$, concentrations of genomic DNA, SSR primers and polymerase enzyme (taq polymerase), dNTPS (dATP, dCTP, dGTP, dTTP) were optimized. The master mixture for 10 parental and 21 hybrids contained 2.5 µL of 10X PCR buffer, 2.5 µL $MgCl_2$, 1.0 µL dNTPs, 0. 2 µL of taq polymerase, 1.0 µL of forward primer, 1. 0 µL of reverse primer in 14.8 µL of d3 H_2O. 2 µL of diluted DNA was mixed with the master mixture in PCR tube. Initial denaturation was carried out at 94 °C for 5 min, subsequent cycle consisted of denaturation at 94 °C for 1 min, primer annealing at 45-60 °C for 1 min, primer extension at 71 °C for 2 min, final extension at 71 °C for 7 min. When all the samples were uploaded, gel was run at 100 V for 2 h. The gel was examined under gel documentation system GDC and photographed. Polymorphism was determined through visualization of the presence and absence of bands.

Results and discussion

Genetic variability

The analysis variance for the line × tester mating design for each trait was conducted under water deficit condition and their mean of square were given in *Table 2*. The genotypes showed highly significant contrast for PH, LA, La, CC, LT, KR, CL, CD, GRW, GYPP and significant in DS days to tasseling, and ASI. The parent showed prominent differences for most of the attribute except LA, DS, and DT. The crosses showed significant difference for all the traits except DT. The interaction parents vs crosses showed significant difference for PH, CD and KR. The lines revealed significant difference for most of the traits except La, LT, DS, ASI, GYPP. Tester showed significant difference for La, CC, ASI, CD, KR, GYPP. The interaction line × tester showed significant difference for most of the traits PH, LA, La, LT, DS, ASI, CL, CD GYPP. It revealed that variability was present among the genotypes for various traits (*Table 3*).

Combining ability analysis

Identifying the highest performing lines and lines that can be used as parents in future crossings are two objectives in most crop breeding programs. Assessment of GCA and SCA effects is necessary to identify and select the better performing inbred lines and F1 crosses for each trait improvement (Areous et al., 2005; Danish et al. 2020, Ivy and Howlader, 2000; Oakey, 2006). General combining ability GCA can be defined as the performance of genotypes in the series of crosses while the SCA as the production in specific cross (Sprague and Tatum, 1942). The line WM13RA had high GC effect among the lines for La, CL, KR, GRW, GYPP and poor general combiner for LA, DT and DS. The line OH33-1 showed high GC effect for LA, CC, DT and low GC effect for ASI. The lineML17 had high GC effect for the LT while general combiner for La. The line ML3 had high GC effect for PH, DS, ASI and KR. The line A545 showed high GC effect among lines for CD. The line AES204 was noted low GC effect for PH. The line A50-2 proved to be poor combiner among the lines for CC, LT, CL, CD, GRW, GYPP (*Tables 3* and *4*). Specific combining ability WM13RA × EV189 top ranked among the negative SCA effects best for the reduction of PH. A545 × EV189 showed maximum negative SCA and proved to be good specific combiners for the leaf area. The cross ML 17 × Ev189 displayed the highest negative and significant SCA declared as good specific combiner for La. The cross ML3 × EV189 was found the highest positive and significant SCA was declared as good specific combiner for CC. The cross A50-2 × Ev189 *Table 5* was found to have maximum negative and significant SCA for the LT and revealed to be good specific combiners. The Cross combination ML3 × Agati85 displayed the highest negative and significant SCA, parent revealed to be good specific combiners for DS. The cross AES204 × Agati85 displayed the highest negative and significant SCA, and proved to be good specific combiner for DT. The Cross combination ML3 × Agati85 showed the maximum negative and significant SCA effects, and proved to be good specific combiner for ASI. The cross AES204 × Golden top ranked among positive and non -significant SCA, and revealed as good specific combiner for CL. The cross A545 × Ev189 showed the highest positive and significant SCA, and for CD it was a good specific combiner. The cross WM13RA × Golden showed the maximum positive and significant SCA for KR. The crossOH33-1 × Ev189 was found to have the highest positive and non-significant SCA and revealed as best specific combiners for GRW. The crossML17 × Agati85 showed the maximum positive and significant SCA for GYPP (*Table 5*) The results were in line with the results of Asif et al. (2020), Bibi et al. (2018), Kumar et al. (2004, 2016), Muraya et al. (2006), Uddin et al. (2008), Amiruzzaman et al. (2013), Gissa et al. (2013), Aminu et al. (2015), El-Shamarkaet al. (2015).

Heterosis and better parent heterosis

The cross combination ML3 × Ev189 maximum mid parent negative heterosis and the cross combination ML3 × Ev189 showed the maximum negative heterobeltiosis for PH. The cross combination ML17 × Golden maximal negative mid parent heterosis estimate and the cross ML17 × Golden showed the maximal positive better parent heterotic effects for leaf area. The cross combination WM13RA × Golden showed minimal mid parent negative heterosis and Cross WM13RA × Golden showed minimal better parent heterotic effects for La (Ali et al., 2014; Malook et al., 2016; Mahmood et al., 2019; Paul and Duara, 1991; Yaqoob et al. 2020). The cross combination 5 ML3 × Ev189 maximal positive mid parent heterosis estimate and, the cross WM13RA × Golden showed the maximal positive better parent heterosis for CC. ML17 × Ev189 showed maximum negative mid parent heterosis and the cross combination ML17 × Ev189 showed maximum negative better parent heterosis for LT (Aslam et al., 2012). ML3 × Agati85 showed maximum negative mid parent heterosis and Cross ML3 × Agati85 showed maximum better parent heterosis for DS. In developing early mature, high yield hybrids early silking is considered as basis of breeding. So early flowering can be useful to escape from water scarcity at critical stage of crop development. AES204 × Golden showed maximum negative mid parent heterosis and the cross combination Cross OH33-1 × Golden and AES204 × Golden both showed maximum better parent heterosis for DT. ML3 × Agati85 showed maximum negative mid parent heterosis and Cross ML3 × Agati85 showed the highest better parent heterosis for ASI. The cross combination WM13RA × Agati 85 maximal positive mid parent heterosis estimate and the cross WM13RA × Agati 85 showed maximal positive better parent heterotic effects for CL. The cross combination A545 × Ev189 maximal positive mid parent heterosis estimate and the cross A545 × Ev189 showed maximal positive better parent heterotic effects for CD. The cross combination OH33 -1 × Golden showed maximal positive mid parent heterosis estimate. The cross combination OH33 -1 × Golden showed maximal positive better parent heterotic effects for KR. The cross combination AES204 × Ev189 had maximal positive mid parent heterosis estimate for GRW and GYPP. The cross AES204 × Ev189 showed maximal positive heterobeltiosis for GRW. Cross WM13RA × Agati showed maximal heterobeltiosis for GYPP (*Tables 6* and 7).

Molecular analysis

The primer UMC 2002 was found polymorphic out of the ten SSRs primers used in the study. Hybrids confirmed on the presence and absence of the band in the gel for parents as well as for the hybrid. It was found that the hybrids of lines A50-2 × Golden showed the polymorphism and same fragment was found in the hybrid which confirm the inheritance of same fragment from the parent to offspring. The hybrid A50-2 × Golden was confirmed similarly for all the hybrid confirmed except for four hybrids AES 204 × Golden, OH33-1 × Golden, WM13RA × Ev189 and ML3 × Golden. These hybrids can be confirmed by applying more number of primers and extensive screening of primer 6 is needed to identify the polymorphic fragment in both parents that can be finally detected in the hybrid population *(Figure 1)*. The hybrid genetic purity was found 85.95% (*Table 8*) (Bibi et al., 2015; Hafeez et al., 2015; Farooq et al., 2017; Yaqoob et al. 2020).

Conclusion

It is a need among plant breeders to be able to select and develop tolerant genotypes for water deficit conditions. The research displayed that the line WM13RA and OH33-1 showed the highest and 6 general combining ability for most of the traits. The cross combination WM13RA× Agati85was found to have the highest positive better parents heterosis. Specific combing ability was also high in ML17 × Agati85 for grain yield and ML3 × Agati85 for the production of early maturing hybrids. The genetic purity of the hybrids was found about 80.95% in molecular analysis with SSR markers.

(Received 3rd Dec 2019; accepted 26th Mar 2020)

Abstract. Multiple experiments were performed to evaluate the ecotoxicological effect of mesotrione on soil enzymatic activity, functional diversity, and genetic microbial biodiversity. The results showed that catalase and invertase activity initially increased with higher mesotrione concentration and then declined slightly. However, urease activity experienced a 11.9–23.2% reduction in comparison to control soil. The average well-color development (AWCD) was positively affected by the mesotrione treatment, the amount of carbohydrate, amino acid, and phenolic acid increased by 1.7–2.1, 1.1–1.6, and 1.7–2.5 times, respectively, when compared with the blank treatment. However, the utilization of carboxylic and acid amine was prohibited after applying 50–100 mg kg^{-1} and 20–100 mg kg^{-1} mesotrione. Denaturing gradient gel electrophoresis (DGGE) analysis showed that the shift in the bacterial community structure for different mesotrione treatments can be mainly attributed to an increment in band intensity, while the dissimilarity in the bacterial genetic structure decreased with increasing mesotrione content in the soil. Sequencing and phylogenetic analyses showed that the four bands in the denaturing gradient gel electrophoresis results were closely related to *Bacillus subterraneus*, *Clostridium sp*., and *Bacillus sp*. Obtained results show that abuse of mesotrione may pose a potential risk for soil microbial functioning.
Keywords: *mesotrione, Biolog EcoPlates, denaturing gradient gel electrophoresis, eco-environmental impact*

Introduction

Soil microbes are fundamental components of a soil's ecosystem playing an important role in many metabolic processes, e.g. the biogeochemical cycling of nutrients, decomposition of organic matter, formation of structural and hydrological properties, and various other biological–physical–chemical processes in the soil (Hu et al., 2011; Liu et al., 2015). Microorganisms can also serve as environmental bioindicators of quality due to their rapid and sensitive response to small environmental disturbances (Zhang et al., 2010; Cycoń et al., 2013b; Gryta et al., 2014). Thus, the microbial properties of the soil, and particularly those related to the diversity and activity of the soil's microbial communities, can be a most useful predictor of the fluctuation in soil health (Zhang et al., 2010; Chen et al., 2014; Allegrini et al., 2015). Soil enzyme also plays an important role in the microbial soil ecology by catalyzing various reactions, including those involved in the decomposition of organic residues and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35253541

nutrient cycling in soil–plant systems (Bhattacharyya et al., 2008; Sun et al., 2013a; Giacometti et al., 2014). In general, microbial activity and soil enzyme activity are usually influenced by various soil management practices, e.g. crop rotation, mulching, tillage, and the application of fertilizers and herbicides (Johnsen et al., 2001; Hua et al., 2009; Lupwayi et al., 2010). Therefore, these can all be used as potential indicators of microbial activity, soil fertility, and land quality (Ciarkowska et al., 2014).

Mesotrione [2-(4-methylsulfonyl-2-nitrobenzoyl)-1,3-cyclohexanedione] is a triketone herbicide that has recently been registered for the pre- and post-emergence control of annual broadleaved weeds in maize fields, and constitutes a replacement for atrazine (Sun et al., 2013b; Pose-Juan et al., 2015). Armel et al. (2009) reported that a dose equal to 235 g ai ha^{-1} was required to provide effective (≥80%) control of some common weeds (lamb's quarters, smooth pigweed, and common ragweed). Vyn et al. (2006) documented successful control (≥90%) of another *Amaranthus* species (*Amaranthus tuberculatus* var. rubis) at mesotrione doses of 175 (pre-emergence) and 100 g ai ha^{-1} (post-emergence). However, our previous studies found that the adsorption isotherms of mesotrione fit well into first-order and Freundlich equations. The hysteresis indices in phaeozem and red soil indicated that it had weak–moderate soil retention properties (Sun et al., 2015) and its degradation time (DT_{50}) varies from 6 to 34 d (Crouzet et al., 2010). Therefore, the continuous and extensive use of the herbicides would pose side-effects on the function and fertility of agricultural soils. A few studies have attempted to determine the effects of mesotrione on the nitrogen cycle, enzyme activity, and microbes in soil (Crouzet et al., 2010, 2013; Cycoń et al., 2013a; Pose-Juan et al., 2015). Crouzet et al. (2010) found that mesotrione applied at a dose of 0.45 mg kg^{-1} did not have any effect on the substrate-induced respiration, regardless of the post-treatment exposure time. However, higher doses (45 and 450 mg kg^{-1}) of mesotrione induced significant increases. Similarly, mesotrione had a strong negative impact on soil chlorophyll concentration and cyanobacterial genetic structure and diversity when its content was up to 450 mg kg^{-1} (Crouzet et al., 2013).

Non-targeted effects of herbicides on soil microorganisms can reduce microbial diversity but increase functional diversity. There may even be a tendency towards reversible stimulatory/inhibitory effects on microbial community structure and activity (Zabaloy et al., 2010; Pose-Juan et al., 2015). It has been reported that herbicides are adsorbed by organic matter in the soil to form bound or recalcitrant states, which, in turn, reduces the possibility of microbial attack (Crouzet et al., 2010). This might also account for the insignificant effect (or masking) of the impact of herbicides on the activity of enzymes (Cai et al., 2015). These effects depend on the herbicide's properties and environmental chemical behavior, soil type, environmental conditions, and functioning of the soil's microorganisms (Lupwayi et al., 2010; Pose-Juan et al., 2015). It is therefore essential to assess the ecological and environmental impact of newly marketed xenobiotics such as mesotrione in China. Unfortunately, information on the environmental impact of mesotrione in the soil (on enzyme activity and diversity of the microbial communities) is lacking. Therefore, the experiments reported here are the first aimed at extending our knowledge of these aspects. The objectives of the present study are to determine mesotrione's effects on: (1) soil enzymatic activity (via a microcosm approach), (2) functional diversity (using the Biolog method), and (3) genetic microbial biodiversity (using a method based on denaturing gradient gel electrophoresis, DGGE).

Materials and methods

Test chemicals

The mesotrione ($C_{14}H_{13}NO_7S$) was purchased from Sigma-Aldrich (St. Louis, MO, USA) in the form of dispersible granules (high performance liquid chromatography (HPLC) grade with a purity of 99.9%). The solubility of mesotrione in water increases with pH value (being 2.2, 15, and 22 g L^{-1} at pH 4.8, 6.9, and 9.0, respectively), and the stability stable to hydrolysis is at pH 4–9 (pKa 3.12).

Experimental design and treatment regime

The present research was conducted in Agro-environmental Protection Institute, Ministry of Agriculture and Rural Affairs, China. 10 kg soil samples were collected from 0-20 cm layer of agricultural fields in Changsha City, China (28º03' N and 113º 11' E) and then passed through a 20 mesh sieve for the analysis of physical and chemical fraction. The basic characteristics of this ferralsol soil are that it consists of 44.9% clay, 8.6% silt, and 46.5% sand. The amount of organic matter, total N, pH, available P, and available K equate to 1.03%, 0.84 g kg^{-1}, 4.92, 3.95 mg kg^{-1}, and 40 mg kg^{-1}, respectively.

Weighed amounts (500 g) of dried and sieved soil were placed in plastic pots and preincubated under controlled experimental conditions for two weeks. The effect of mesotrione on soil enzymatic activity and the microbial communities was investigated using 4 different doses of 0, 20, 50 and 100 mg kg^{-1}, respectively. After mixing thoroughly, the treated soils were incubated in a dark experimental chamber at 21 ± 1°C for 30 d, and changed randomly every week. To make moisture conditions comparable to those in the field, the soil's moisture content was adjusted to 40% of the maximum (saturated) value. This was subsequently maintained throughout the experiment by weighing the microcosms on a weekly basis and adding sterile distilled water as needed.

Enzyme assay

Catalase activity was assayed according to the method used by Sun et al. (2015). The measured enzymatic activities were then calculated and expressed using units of mg g^{-1} h^{-1}. Urease activity was measured using the method adopted by Chen et al. (2014) with slight modification. The enzymatic activity was calculated and expressed as NH_4–N mg g^{-1} h^{-1}. Invertase activity was determined using an 8% sucrose solution as substrate and incubation at 37°C for 24 h, after which the glucose produced was measured at 508 nm using a colorimetric method. The enzymatic activity was finally expressed as mg g^{-1} h^{-1} (Kandeler et al., 1999).

Microbiological analyses

Functional diversity determination

The community-level physiological profiles (CLPPs) of the bacteria in the soil samples were evaluated using a Biolog EcoPlate™ system (Biolog Inc., CA, USA). This procedure tests the ability of a microbial community to utilize different carbon substrates contained in microplates. The soil samples (10 g) were mixed with 0.85% NaCl and then shaken for 1 h. After this time, aliquots (150 µL) of the soil suspension were added to the Biolog EcoPlate® microplates containing 31 sole carbon sources and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35253541

a water control. The plates were incubated at 24°C in the dark. Color development in each well was recorded in terms of the optical density (OD) at 590 nm (color development + turbidity) and 750 nm (turbidity). This was carried out after inoculation and at 24 h intervals for 168 h using a microplate reader (Victor TM X5 multilabel plate reader, PerkinElmer) (Osem et al., 2007; Cycoń et al., 2013b). Negative readings, after correction, were adjusted to zero.

Analysis of the microbial structure diversity

The total bacterial DNA in the test soils was extracted and purified according to previously published methods (Qing et al., 2007; Huang et al., 2008). It was then amplified via PCR using forward primer F_{357} (5'-CCT ACG GGA GGC AGC AG-3') and reverse primer R_{518} (5'-ATT ACC GCG GCT GCT GG-3'). As for the forward primer, a 40-base GC clamp (5'-CGC CCG CCG CGC GCG GCG GGC GGG GCG GGG GCA CGG GGG G-3') was added to the 5' end to stabilize the melting behavior of the DNA fragments. The gradient concentrations used in the denaturing gradient gel electrophoresis (DGGE) analysis ranged from 35% to 65% for bacterial DNA. Initial denaturation was carried out at 94°C for 4 min. Amplification was carried out using 35 cycles including denaturation at 94°C for 1 min, annealing at 55°C for 1 min, and DNA extension at 72°C for 1 min, followed by a final extension cycle at 72°C for 10 min.

PCR products from the soils were characterized using a DGGE run on a vertical acrylamide gel in a D-Code System (Bio-Rad Laboratories Ltd., Hertfordshire, UK). The DGGE gels were made from 8% (w/v) acrylamide stock solutions (37.5:1 of acrylamide:bis acrylamide solution) containing 100% denaturant (7 mol L^{-1} urea and 40% (v/v) formamide). The DGGE bands of interest were cut from the gel and soaked overnight at 4°C in 50 μL TAE buffer (10 mmol L^{-1} tris-acetate, pH 7.5, 1 mmol L^{-1} EDTA). The gel was stained for 15 min with ethidium bromide after electrophoresis and visualized using a UV transilluminator table using a gel documentation system (Bio-Rad, Hercules, CA, USA).

The 16S rDNA gene sequences of the excised DGGE bands were compared with existing sequences in the GenBank database using the BLAST 2.0 program (http:/www.ncbi.nlm.nih.gov/BLAST) to determine the nearest matches. The GenBank sequences were added to the data set for CLUSTAL W multiple sequence alignment and the phylogenetic distance tree was constructed using MEGA 4.0.

Statistical analysis

All of the experiments were replicated three times. The means and standard deviations (SDs) of the replicated data were calculated using Microsoft Office Excel 2010. One-way analysis of variance was performed using the SPSS (v10.0) software package. When a significant difference ($P < 0.05$ or $P < 0.01$) was observed between the treatments, multiple comparisons were made by performing an LSD test. Principal component analysis (PCA) was used to identify distinct differences in the soil microbial community functions under different mesotrione treatments.

Average well-color development

The average well-color development (AWCD) can be calculated to reflect the sole-carbon utilization of the soil microorganisms via *Equation 1*:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35253541

$$AWCD = \sum (C_i - R)/31 \quad \text{(Eq.1)}$$

where C_i is OD in each carbon source well and R is OD of the control. When C_i–R < 0, the value is considered to be zero.

Microbial functional diversity indices

Several diversity indices can be calculated using the equations that follow. These are referred to as the Shannon index (H), Simpson index (D), Shannon evenness index (E), McIntosh index (U), and Dice index (C_s), and are given by *Equations 2-6*:

$$H = -\sum P_i \ln\left(P_i\right) \quad \text{(Eq.2)}$$

$$D = 1 - \sum P_i^2 \quad \text{(Eq.3)}$$

$$E = \frac{H}{H_{\max}} = \frac{H}{\ln S_i} \quad \text{(Eq.4)}$$

$$U = \left(\sum N_i^2\right)^{1/2} \quad \text{(Eq.5)}$$

$$C_s = \frac{2j}{a+b} \quad \text{(Eq.6)}$$

In these expressions, N_i is the metabolic activity on each substrate, P_i is the ratio of n_i to the sum of the activities on all substrates, S_i is the natural logarithm of the number of species, j is the number of bands common to samples A and B, and a and b are the number of bands in samples A and B, respectively.

Results and discussion

Soil enzymatic activity

In the present study, the catalase activity initially increased and then declined as the amount of mesotrione increased. Under the application of 20 and 50 mg kg^{-1} mesotrione, the increase was amounted to 11.2% and 12.6%, respectively (*Fig. 1*). However, catalase activity fell by 2.7% when the concentration of mesotrione was increased up to 100 mg kg^{-1}. There was no significant difference in catalase activity across the 20–100 mg kg^{-1} mesotrione treatment range (P > 0.05). Similar results have been obtained by Baćmaga et al. (2014), who found that metazachlor applied at doses of 6.7–106.7 mg kg^{-1} stimulated the activity of catalase in the range of 7.5–92.5%. Moreover, Liu (2000) reported that imidacloprid can also stimulate catalase activity, and that the higher the concentration used, the stronger the observed effect on soil catalase for imidacloprid doses in the range 1–40 mg kg^{-1}. However, there was no obvious effect on catalase activity after application of 0.5 to 50 mg kg^{-1} of acetamiprid for 14 days (Yao et al., 2006).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35253541

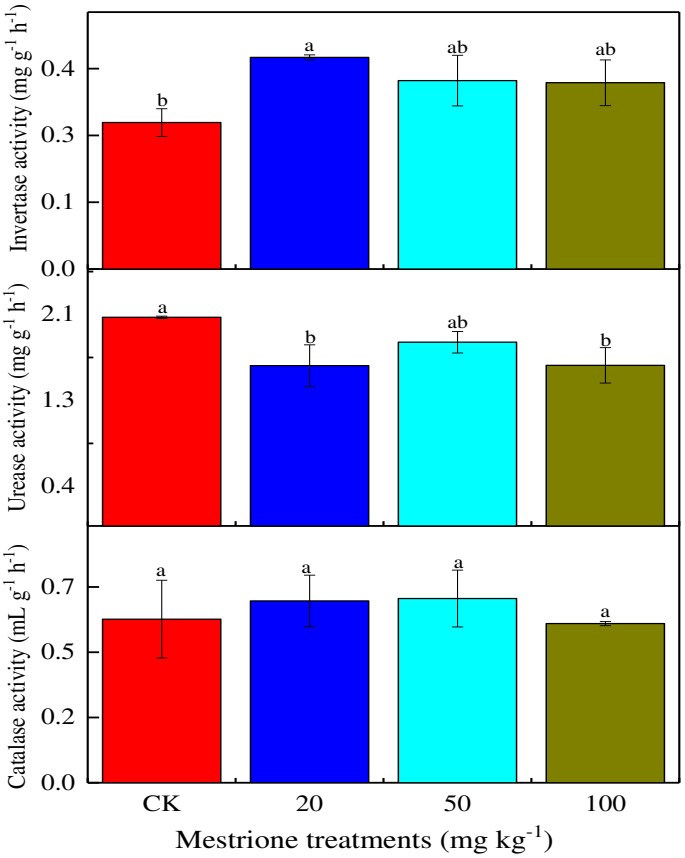

Figure 1. *Effects of mesotrione on soil enzyme activities. Letters above the bar diagram refer to the difference at significance level $P < 0.05$ among different treatments of mesotrione. The same as below*

Urease, which involves in the hydrolysis of urea-type substrates, is an enzyme that quickly responds to changes in the soil environment (Yao et al., 2006). Furthermore, contamination of soil with mesotrione has a destructive influence on the activity of urease. The application of mesotrione caused a 11.9–23.2% reduction in urease activity compared with control soil (*Fig. 1*), and amending the soil with 20 and 100 mg kg^{-1} mesotrione resulted in a significant decrease in urease activity ($P < 0.05$). Results similar to ours concerning the inhibitory effects of herbicides on urease activity have been reported by Baćmaga et al. (2014) who investigated metazachlor and by Sukul (2006) who tested metalaxyl. In turn, Yao et al. (2006), who investigated the eco-toxicology of the herbicide acetamiprid, did not detect any obvious influence on urease activity.

Another enzyme used in assays evaluating the quality of soil is invertase, which is involved in the hydrolysis of sucrose to glucose and fructose. Invertase is more efficient than other enzymes in reflecting soil fertility and biological activity levels (Cang et al., 2009). *Fig. 1* exhibits the promotion effect of mesotrione on invertase activity in the soil, which increased at first and then decreases with increasing concentration. It was, however, always 27.1–44.4% greater than that of the control soil over the 20-100 mg kg^{-1} mesotrione range. In particular, there was a significant increase using 20 mg kg^{-1} of mesotrione ($P < 0.05$). Positive effects of buprofezin and acephate on invertase had already been noted by Raju and Venkateswarlu (2014).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35253541

The results above clearly indicate that soil enzyme activity differs in sensitivity upon application of herbicide. Ye et al. (2003) likewise found that mefenacet strongly prohibited soil dehydrogenase activity in a concentration-dependent manner, but stimulated phosphatase activity. Indeed, both significantly positive and negative, as well as neutral, responses have been recorded compared to untreated soils (Floch et al., 2011; Baćmaga et al., 2014). Herbicides may change enzyme protein or interact directly by binding with protein-active groups which subsequently affects their catalytic activity. Another possible reason is that a herbicide may indirectly affect soil enzyme activity by acting on soil microorganisms (Johnsen et al., 2001; Floch et al., 2011; Baćmaga et al., 2014; Jacobsen and Hjelmsø, 2014). Baćmaga et al. (2014) demonstrated that in soil contaminated with excessive quantities of metazachlor there are significant effects on the biochemical activity of the soil (with correlation coefficients that are negative). In another report, no significant differences ($P > 0.05$) were found in enzyme activity in treated soil compared to a control in the initial 2 weeks, while enzyme activity was stimulated from the third week on (Yao et al., 2006). Moreover, the influence of pesticide on soil was generally a long-term process and closely related to the soil's characteristics (Yao et al., 2006).

Microbial community substrate utilization profile

Color development in the Biolog EcoPlates was analyzed to qualitatively and quantitatively assess the community-level physiological profile of the microbe communities in treated soils (Osem et al., 2007; Gryta et al., 2014). The average well-color development in the Biolog generally followed similar patterns (*Fig. 2a*), i.e. an apparent lag phase was experienced during the first 48 h. After this time, the AWCD values increased rapidly with incubation time for all treatments which is attributable to more rapid bacterial growth taking place. The period selected for metabolic activity analysis was 120 h as this period corresponded to the occurrence of the largest AWCD change. The slope of the AWCD curve at this time can be used to represent the average metabolic activity of a microbial sample (Kong et al., 2013). Thus, the slopes of the AWCD curves after 120 h were selected for use in the metabolic activity analysis. The analysis of the variation in AWCD in the stressed soils over the incubation time (during the period 0–120 h), showed that the AWCD values using 20–100 mg kg^{-1} of mesotrione were all higher than those of the control. Strong oxidation of the supplied carbon sources (high AWCD) usually reflects an increase in bacterial density (Loranger-Merciris et al., 2006). A possible reason for this might be that soil microbes tolerate and adapt to the herbicide after repeated applications, and/or degrade the herbicide as a source of carbon and energy (Yao et al., 2006; Xu et al., 2014). However, after an incubation time of 168 h, the AWCD values decreased with an increase in mesotrione, and a dose–effect relationship could be discerned.

The substrate utilization patterns currently established via the Biolog Ecoplates can be used to determine the changes in the functioning of the soil microbial communities (Floch et al., 2011). As shown in *Fig. 2b*, there were remarkable differences in the substrate utilization profiles of the mesotrione treated soil samples. Carbon source metabolism by the microbial population decreased in the following order: polymer > amino acid > carbohydrate > phenolic acid > acid amine > carboxylic acid. This suggested that the carboxylic acid could be more easily utilized by the microbes subjected to the different mesotrione treatments. Although the variation in the carbon sources appeared to be irregular under the series of mesotrione treatments, the increase

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35253541

in the amount and rate of carbohydrate, amino acid, and phenolic acid utilization observed in the soils subjected to different mesotrione treatments corresponded to increases of 1.7–2.1, 1.1–1.6, and 1.7–2.5 times, respectively (compared to the control). Significant increases ($P < 0.05$) in substrate utilization were observed with a mesotrione concentration of 20 mg kg^{-1} for carbohydrate and amino acid, and 100 mg kg^{-1} for polymer and phenolic acid. However, there appeared a decrease in polymer, carboxylic, and acid amine by 3.0%, 12.5–17.1%, and 13.3–48.1%, respectively, in mesotrione treated soil of 50, 50–100, and 20–500 mg kg^{-1}, respectively, and the amount of acid amine decreased sharply at a mesotrione content of 20 mg kg^{-1} ($P < 0.05$).

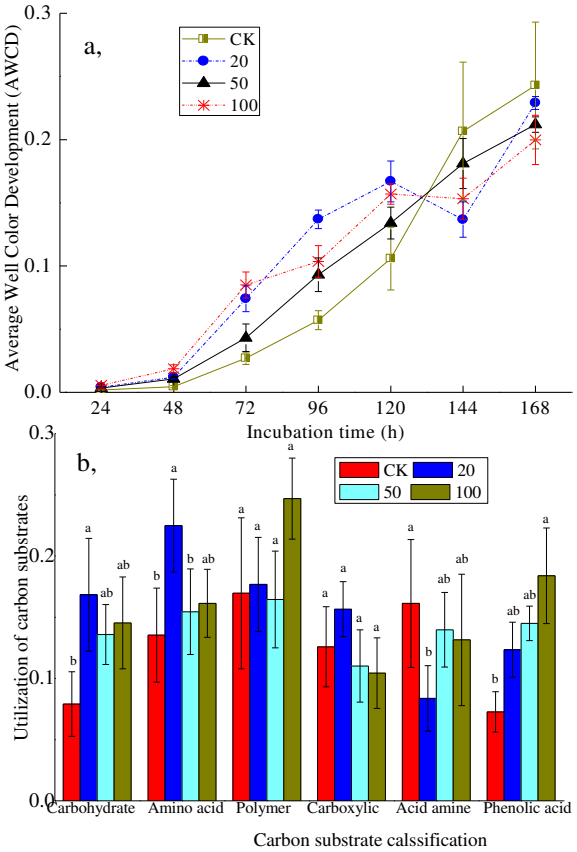

Figure 2. *Microbial community level physiological profiles (CLPP) under different treatments of mesotrione. Note: (a) and (b) refers the variations in AWCD over time and utilization of 6 groups carbon sources, respectively*

Principal component analysis (PCA) was used to assess the microbial communities in the stressed-soil environment (Kong et al., 2013; Shrestha et al., 2015). The PCA results from the Biolog Ecoplates data explained 67.3% of the total variance and components, and the first principal components (PC1) and the second principal components (PC2) accounted for 37.1% and 30.2%, respectively (*Fig. 3a*). Therefore, the first two principal components (PC1 and PC2) were used to describe the effects of the different treatments of mesotrione (0–200 mg kg^{-1}) on the utilization of 31 carbon sources. PC1 and PC2 are plotted against each other in *Fig. 3* for illustration purposes. The PCA plots indicated that bacterial functional diversity changes with the level of mesotrione used.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35253541

Most of the points were clustered in the first and second quadrants of the loading plot, and the plots amended with 20–100 mg kg^{-1} mesotrione were clustered together and are differentiated from the control. *Fig. 3b* also compares the Biolog Ecoplates utilization patterns for each substrate guild (i.e. carbohydrate, amino acid, polymer, carboxylic, acid amine, and phenolic acid) for different mesotrione treatments, using PCA. The first variable (PC1) accounted for 54.8% and the second variable (PC2) accounted for 28.7% of the total variance in the data. Rotation of the matrix revealed that the substrate utilization can be separated into three groups: (a) amino acid and carboxylic (relatively negatively related with PC2), (b) carbohydrate and phenolic acid (positively associated with values of PC1 and PC2), and (c) polymer and acid amine (associated with negative values of PC1 and PC2). The PCA plots indicate that the bacterial communities originally present in the tested soil were shifted after application of mesotrione.

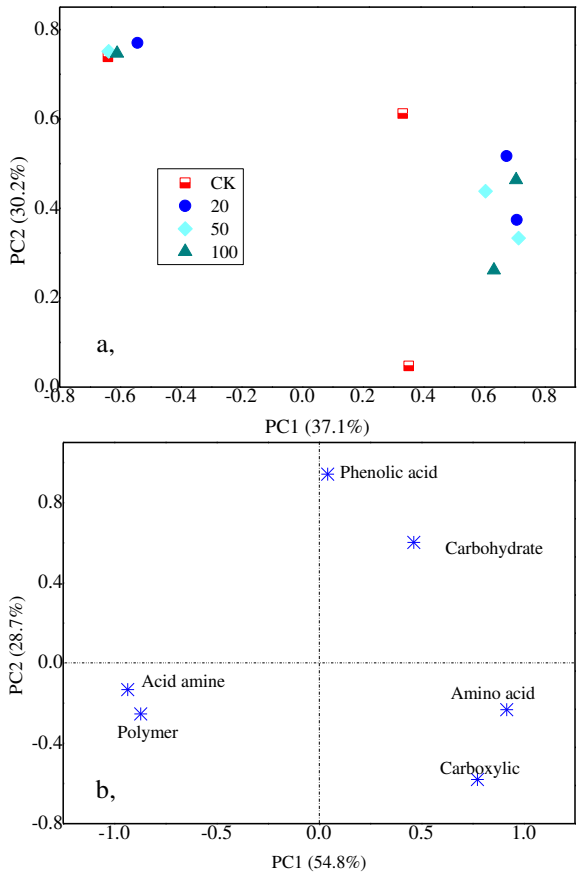

Figure 3. *Scatterplots of principal components scores for soil samples based on (a) different treatments of mesotrione and (b) 6 carbon sources. Numbers in parentheses on axis labels is the percentage of the variation according to principal components analysis (PCA)*

To further investigate the effect of mesotrione on the bacterial properties of the soil, the diversity indices of *H*, *D*, *E*, and *U* are calculated to assess the soil's microbial functional diversity (Gomez et al., 2006), *H* and *E* values indicate the richness and evenness of the soil microorganisms (Zhou et al., 2008), index *D* is often used to emphasize the dominant microbe population, and while *U* (which is based on Euclidean distance) indicated the evenness or homogeneity of the microbial community (Zhou et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35253541

al., 2008). The calculated values of the diversity indices of *H*, *D*, *E*, and *U* are presented in *Table 1*. In general, the *H*, *D*, and *U* values gradually increased with incubation time and then fell. However, the amount of *H*, *D*, and *U* was still 6.6–36.1%, 2.0–12.2%, and 70.1–894.0% greater than those of the control, respectively. Index *E* decreased by 1.6-14.1%, 18.1–32.1%, 7.6–14.6%, and 12.9–27.8%, under mesotrione treatments of 0, 20, 50, and 100 mg kg^{-1}, respectively, when compared with the control. The microbial community analysis was consistent with substantial increases in microbe diversity in the treated soil. The *H*, *E*, *D*, and *U* values were stimulated by the various mesotrione treatments, corresponding to increases of 2.7–3.4%, 1.3–10.2%, 1.4–2.2%, and 6.6-20.0%, respectively (compared to the control). The increase in the microbial activity in the soil may have been higher and the microorganisms more active if the mesotrione was used as an energy source (Crouzet et al., 2010; Zabaloy et al., 2010). The regression coefficients between the richness and Shannon–Weaver indices and organic carbon in the soil suggested that the increase in microbial community functional potential may be explained by the increase in carbon availability resulting from incorporation of the amendment (Gomez et al., 2006). The microorganism communities may have been indirectly stimulated by the dead biomass arising from more sensitive organisms together with a concomitant stimulation of the resistant microbial populations resulting from the loss of protozoan grazers or competitors (Crouzet et al., 2010). The number of live bacteria present was generally higher ($P < 0.01$) in linuron amended soil than in unamended soil (Grenni et al., 2009). However, there were no significant differences observed in the functional diversity parameters *H*, *E*, and *U* among the different mesotrione treatments ($P > 0.05$).

Effect of mesotrione on microbial community structure diversity

The changes in the bacterial structures of the tested soils were elucidated according to PCR–DGGE phylotype. The *H* and *D* indices were calculated to estimate the bacterial diversities in the mesotrione-amended and control soils (*Table 2*). The value of *H* increased after different amounts of mesotrione were applied to the soil, being 0.7-3.6% higher than the *H* value of the control group. However, differences in the *D* index were negligible for the different mesotrione treatments. This indicated the stimulation effect or toxicity of the mesotrione on the soil microbial community was small (Hu et al., 2007).

Table 2. *Diversity indices of DGGE in soils treated with mesotrione*

Treatment of mesotrione (mg kg^{-1})	Shannon index (*H*)	Shannon evenness index (*E*)
0	3.02±0.78	0.93±0.13
20	3.13±1.02	0.96±0.24
50	3.04±0.81	0.95±0.34
100	3.12±0.93	0.95±0.29

The bacterial DGGE profiles generated using universal bacterial primers (F357 and R518) revealed the structural compositions of the communities in the soil samples (*Fig. 4a*). The results showed that there are certain differences in the bacterial community diversities in the soils – some bands disappeared and several new bands appeared – following mesotrione application. The disappearance of bands A and B revealed that the bacterial community structures and genetic diversity were affected by the increase in mesotrione concentration. It appeared that the number of bands is related to the mesotrione content. Nine bands (labeled a–i in *Fig. 4a*) were shared in all profiles. This suggested that the bacterial groups represented by these bands may play an important role in mesotrione ecology (Gu et al., 2010). However, the number of bands in the soil samples initially increased with increasing mesotrione content, and then decreased slightly. Significant increases in microbial biomass were found afterwards (compared to the biomass values in unamended soil) in all cases. The microbial biomass was thus significantly increased. Moreover, the similarity indices decreased with increasing mesotrione content (varying from 68.0% to 47.6%). Similarly, the maximum dissimilarity in the bacterial and fungal genetic structures between the control and 100-fold field rate (FR) treated soil did not exceed 12% and 28%, respectively (Crouzet et al., 2010). This may be due to excessive stimulation of cellular redox processes which reflects an unspecified stress response of the microorganisms in the soil.

Clustering of the DGGE profiles was performed (to elucidate the similarities among the different banding patterns) and the results presented using a dendrogram (Zhang and Fang, 2000). The advantage of this method of presentation was that the coherence in the fingerprinting patterns can be rapidly assessed (Fromin et al., 2002). It can be seen that the 20–100 mg kg^{-1} mesotrione treatments belong to a common cluster which had a similarity among them of over 60%, and 53% difference with the control group profiles (*Fig. 4a*). This showed that the bacterial communities in the soil changed upon addition of herbicide. El Fantroussi et al. (1999) compared the microbial communities in soil treated with three phenylurea herbicides (diuron, linuron, and chlorotoluron) using cluster analysis. They found that the microbial communities were significantly different compared to untreated soil.

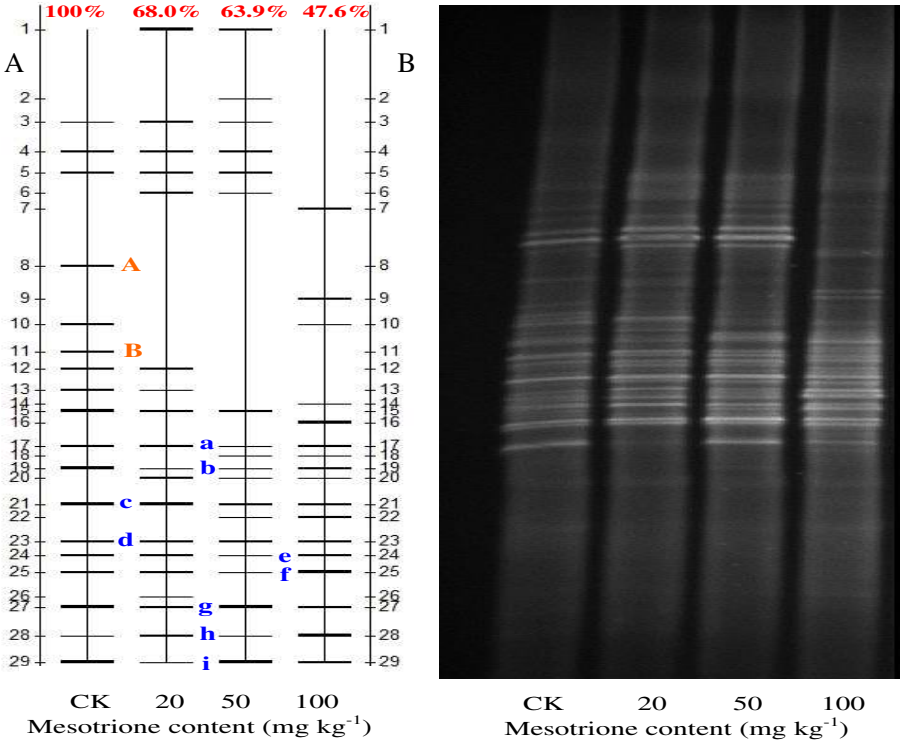

Figure 4. *Comparison of bacterial communities between the control and the three treatments. Note: (A) the analysis results of lane comparison from the DGGE gels using Quantity One V4 4.0.0 software, and (B) DGGE profiles for PCR-amplified fragments of 16 sDNA. A, B, and a-i refer the bands of bacterial DGGE profiles*

To obtain insight into the identities of the major bacterial populations, the discernible DGGE bands in the different mesotrione-treated samples (*Fig. 4b*) were all excised and used for nucleotide sequence analysis. Then, a BLAST search was conducted using the GenBank database to determine their phylogenetic types (*Table 3*). The sequences from bands a, c, and d were found to be closely related to members of the genus *Desulfitobacterium sp*. These are sulfate-reducing bacteria that can grow using meta-chlorinated benzoic acids as electron acceptors and are known to dechlorinate chlorinated phenols and other chlorinated compounds (Yoshida et al., 2007; Jing et al., 2013). The 16S rDNA of the isolated band b closely matched that of *Herbaspirillum sp.* (98%). Bacteria of this genus fall into the β-*Proteobacteria* class and include known nitrogen-fixing endophytes (Doty et al., 2009) and can enhance the phytoremediation of volatile organics and herbicides (Ryan et al., 2008). Band e can be identified (99%) with *Burkholderia caledonica* which had been found to degrade compounds such as herbicides (Hunter and Shaner, 2012), pentachlorophenols (Caliz et al., 2011), and a variety of aromatic hydrocarbons (Stopnisek et al., 2015). Band f showed 100% sequence similarity to a taxonomically unidentified bacterium. Bands g and h were identical to those from strains *Bacillus subterraneus* and *Clostridium sp.*, with 100% similarity. This also showed the capacity of these strains to acclimatize to organic compound pollution. The 16S rDNA sequences of band i were 100% similar to the 16S rDNA sequences of *Bacillus sp*. These bacteria commonly occurred in mesotrione-treated soil and was able to completely and rapidly biotransform mesotrione (Batisson et al., 2009). Biodegradation assays showed that *only* the *Bacillus sp*. strain

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35253541

was able to completely and rapidly bio-transform mesotrione (Durand et al., 2006a, 2006b; Batisson et al., 2009). This is because of the bacterial reductase that is involved in the enzymatic step in which the nitro group of mesotrione is reduced to an hydroxylamine moiety during the degradation process (Durand et al., 2010).

Table 3. *Sequence analysis of bands excised from DGGE gels derived from bacterial 16S rDNA fragments*

Band	Closest organisms in the GenBank database	Accession no.	Similarity (%)
a	*Desulfitobacterium sp.*	AB596883.1	99
b	*Herbaspirillum sp.*	AB769218.1	98
c	*Desulfitobacterium sp.*	AB596883.1	98
d	*Desulfitobacterium sp.*	AB596883.1	97
e	*Burkholderia caledonica*	KM019850.1	99

g	*Bacillus subterraneus*	LN774202.1	100
h	*Clostridium sp.*	JQ420069.1	100
i	*Bacillus sp.*	KJ769178.1	100

Conclusions

The results described in this study show that the treatment of soil with mesotrione was able to stimulate 7.5–92.5% and 27.1–44.4% increase for catalase and invertase activity, while urease activity was inhibited by 11.9–23.2%. CLPPs were obtained that reflect the increase in the amount and rate of carbon utilization of carbohydrate, amino acid polymer and phenolic acid observed in soil subjected to different mesotrione treatments. In contrast, the AWCD of carboxylic and acid amine was inhibited after the application of 50–100 mg kg^{-1} and 20–100 mg kg^{-1} mesotrione, and principal component analysis plots showed that microbial function diversity changed with mesotrione level and each substrate guild. The resulting diversity indices (*H*, *D*, *E*, and *U*) indicate that mesotrione-treated soil had a greater number of more active microorganisms. Our DGGE analysis showed that mesotrione caused slight changes to be made to the biodiversity of the soil bacteria. However, the appearance of some new bands in the DGGE profiles suggests that mesotrione treatment does not have significantly toxic effects on the soil function. In future, it would be useful if further research on the impact of mesotrione could be more integrated with the farming procedures employed, especially herbicide continuous and extensive use. This should provide a more comprehensive understanding of the response of the microbial community in the soil.

Abstract. Knowledge on vegetation dynamics and its response to climate change is important for the sustainability of natural resources and understanding the changes in the ecosystems and its impact on the Earth's environment. We have carried out an analysis of GIMMS (Global inventory modelling and mapping studies) NDVI3g (third generation normalized difference vegetation data), daily temperature (T) and precipitation (P) for the 1982-2015 period based on Linear Regression (LR) analysis, the Mann-Kendall (MK) test with Sen's slope estimator and Kriging interpolation method. We have investigated the spatiotemporal variations of NDVI and climatic factors in the Yangtze River Basin (YRB), China. The relationship between NDVI and climatic factors was also analyzed quantitatively. The results show that the mean NDVI has an increasing trend in all four seasons during 1982-2015, the increasing trend during spring and autumn seasons was higher compared to winter and summer seasons. The response of vegetation dynamics to temperature was more prominent than precipitation. The correlation analysis shows that the mean NDVI had a significant and positive correlation with seasonal temperature, and the correlation coefficients were the highest during spring, followed by winter, summer and autumn seasons.
Keywords: *vegetation variation, NDVI, temperature, precipitation, YRB*

Introduction

Vegetation, as the link between the soil, atmosphere and water, plays an important role in characterizing the energy exchange, carbon cycle and regional human activities (Eugster et al., 2010). Vegetation dynamics has become an indicator of global environmental changes (Qu et al., 2018). In addition, vegetation dynamics (degradation and restoration) can reflect natural evolution and the impact of human activities on the ecological environment (Jiang et al., 2017). Therefore, investigating vegetation dynamics is crucial to protect the ecological environment (Yu and Hu, 2013).

Remote sensing data is one of the most important data sources to monitor vegetation dynamics, which has become a widely used tool in the field of ecological protection due to their advantages, including large coverage area and time savings (Qu et al., 2018). The satellite-based normalized difference vegetation index (NDVI) has been considered to be an effective indicator to monitor vegetation dynamics at regional, continental and global scales (Pinzon and Tucker, 2014). The commonly used NDVI data mainly include NOAA/AVHRR data, EOS/MODIS data and SPOT Vegetation NDVI data. Recently, many scholars have used these datasets to investigate vegetation dynamics at different spatial scales (Peng et al., 2011; Pan et al., 2018). Recent studies show that vegetation activities have increased in the northern mid–high latitudes and vegetation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35433556

stability is changing with the external environment (Nemani et al., 2003; Xu et al., 2013). Climate, especially the factors of temperature and precipitation, has an important impact on vegetation dynamics (Piao et al., 2003; Goetz et al., 2005). In the context of global warming, studies on the relationship between vegetation dynamics and climate change have become hot topics worldwide (Chu et al., 2019; Yao et al., 2019).

Many studies reveal that NDVI showed dramatic spatial variations in response to climate changes (Gong and Shi, 2003; Piao et al., 2015). Ichii et al. (2002) and Xu et al. (2013) found that vegetation dynamics has been strongly influenced by increasing temperature at a global scale. Pan et al. (2018) pointed out that drought possibly has an important impact on the increasing global vegetation browning trend and global vegetation growth is at risk of reversal from greening to browning in the future due to climate warming. Temperature has a positive impact on vegetation dynamics in China (Song and Ma, 2011; Piao et al., 2015). However, the correlation between precipitation and NDVI is characterized by the geographical heterogeneity. Precipitation has a positive effect on NDVI in most dry regions whereas in humid regions, there was a negative correlation between NDVI and precipitation (Wang et al., 2010; Xu et al., 2016). To data, most of the previous studies mainly focused on the correlation between vegetation dynamics and climate factors at annual scale (Zhou et al., 2001). However, climate factors in different seasons might have different impacts on vegetation changes. Therefore, it is meaningful to study the relationship at seasonal scale.

The Yangtze River basin (YRB) is the third-largest river basin in the world. The vegetation cover in YRB plays an important role in regulating ecological balance in China, adjacent areas and even in the world. In the past few decades, the YRB has experienced significant climate change (Cui et al., 2019). The vegetation in the basin has changed obviously (Qu et al., 2018). The present study focused on the spatiotemporal trends of vegetation, as well as its relations with climate factors at annual scale. This paper focuses on long-term vegetation variation and the correlation with climate change at seasonal scale in YRB, which will serve as a reference for further scientific understanding of vegetation dynamics at a large basin scale and provide a reliable scientific basis for vegetation planting and protection. This paper aims to (1) study the spatial and temporal variation of seasonal mean NDVI in YRB during 1982-2015; (2) investigate the correlation between the seasonal mean NDVI and climate factors in YRB; and (3) detect the response of NDVI to climate variables to investigate the major climate factors affecting the vegetation dynamics in YRB.

Materials and methods

Study area

The Yangtze River, with the length of about 6300 km, is the longest river in Asia. The river originates from the Tibetan Plateau (TP) in western China and finally flows into the East China Sea (Zhang et al., 2014). The YRB lies between 91-122° E and 25-35° N (*Fig. 1*) with an area of about 1.8×10^6 km^2 (Niu et al., 2019). The annual average temperature ranges from 12.6 to 28.0°C and annual average precipitation is about 476 mm (Qu et al., 2018). The northern YRB is adjacent to the temperate zone, and the southern YRB is near to the tropical zone (Sang et al., 2013).

DOI: http://dx.doi.org/10.15666/aeer/1802_35433556

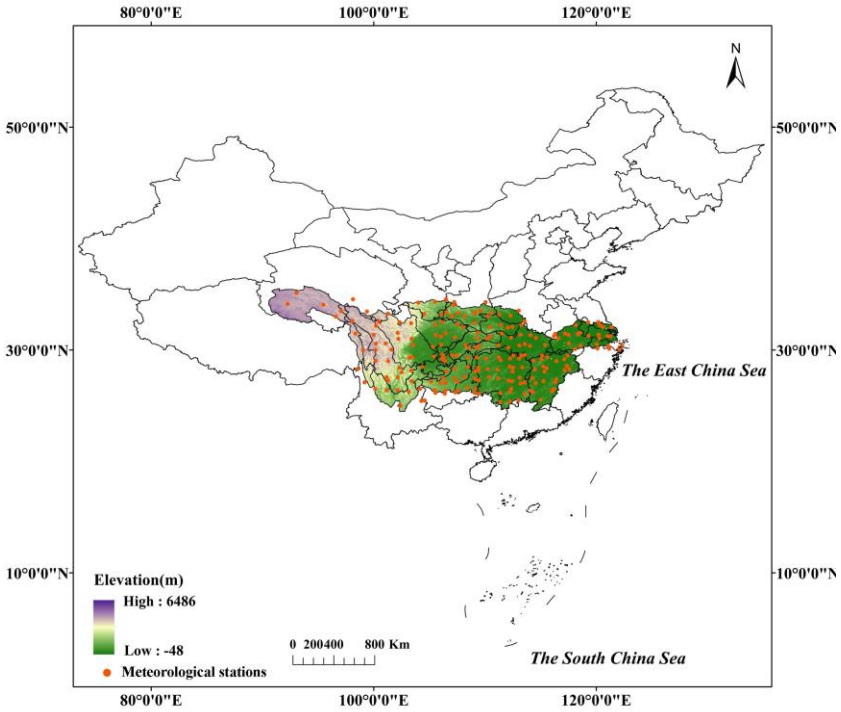

Figure 1. *Location of the YRB in China*

Data

Meteorological data

The daily climate datasets that included temperature (*T*) and precipitation (*P*) were acquired from the Chinese Meteorological Science Data Sharing Service Network. In this study, the daily climate data from 214 meteorological stations in YRB (*Fig. 1*) were used to analyse the variations of temperature and precipitation during the period of 1982-2015.

NDVI data

This study used the GIMMS 3g dataset developed by the NASA Global Inventory Modeling and Mapping Studies group, with a spatial resolution of 8 km and a temporal interval of 15 days (Li et al., 2018). The dataset covering the period from 1982 to 2015 is helpfull for detecting long-term vegetation dynamics at regional and global scales (Qu et al., 2018). To avoid the partial effects from clouds and atmosphere, we calculated a monthly NDVI by Maximum-Value Composites (MVCs) method.

Methods

This study investigates the trends in the annual and seasonal NDVI, temperature and precipitation using the Linear Regression (LR) analysis and the Mann-Kendall (MK) test with Sen's slope estimator.

The linear equation is as follows:

$$y=ax + b, (x=n, n+1 ,..., N) \quad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35433556

where *y* is the trend of NDVI, temperature and precipitation; *x* is the year; *a* and *b* are the slope and intercept respectively; n represents the starting year of the time series.

A positive value of *a* indicates increasing trends, while a negative value of *a* denotes decreasing trends. The significance level (*p*-values) of 10%, 5% and 1% was used for the LR analysis.

In this study, we use the MK test to investigate long-term trends in meteorological data and NDVI time series. This method mainly contains two parameters: Z and β. The standard normal test statistic Z, used for detecting a significant trend of the time series (Cui et al., 2019). The parameter β estimates the slope within the time series.

The correlation coefficients between the NDVI and climatic variables were calculated using Pearson correlation coefficients (Jiang et al., 2017). A prewhitening procedure was applied to the series prior to correlation analysis to improve the accuracy.

Results

Vegetation dynamics in YRB

The mean NDVI during spring (March-May), summer (June-August), autumn (September-November) and winter (December-February) was approximately 0.50, 0.67, 0.56 and 0.41, respectively during 1982-2015 (*Figs. 2a-d*), and increased at the rate of 0.02/10yr (Z_{MK} = 4.12, p < 0.01), 0.002/10yr (Z_{MK} = 0.47, p = 0.58), 0.02/10yr (Z_{MK} = 2.70, p < 0.01) and 0.006/10yr (Z_{MK} = 1.25, p = 0.18), respectively (*Table 1*). A significant turning point (TP) of NDVI during spring, summer, autumn and winter was found in 1996, 1997, 1994 and 1994, respectively (*Fig. 3*), and the abrupt change was statistically significant detected by MK test (*Fig. 4*). The mean NDVI during spring, summer and autumn was 0.47 and 0.52, 0.68 and 0.67, 0.54 and 0.58, 0.40 and 0.41, respectively before and after TP (*Figs. 2a-d*). The seasonal changes in NDVI before and after TP did not reach the statistically confidence level except the trend before TP during summer season (*Table 1*).

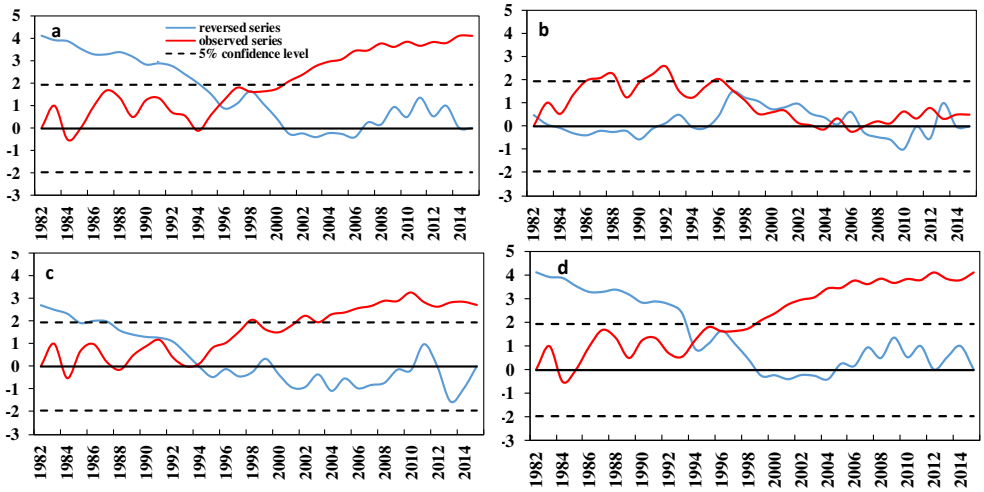

Figure 4. *The significant test of abrupt change in spring, summer autumn and winter NDVI (a, b, c, d) in YRB during 1982-2015*

The seasonal mean NDVI during spring, summer and autumn was generally high over the whole YRB except the north-western dry region and a small part of eastern YRB during 1982-2015 (*Figs. 5a-c*). The mean NDVI during winter was lower over the study area except the south-western and south-eastern YRB (*Fig. 5d*). The seasonal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35433556

changes in NDVI also show strong spatial heterogeneity during 1982-2015 (*Fig. 6*). Parts of the eastern YRB show a significant and continuous increase in vegetation greenness (NDVI ≤0.03/10yr), especially during spring season. However, in most parts of YRD vegetation greenness decrease (NDVI ≤0.03/10yr), especially during summer season. Most parts of the central-south YRB show an increasing trend during spring (NDVI ≤0.05/10yr), and show decreasing trend during winter season (*Figs. 6a, g*). In addition, the mean NDVI in the north-western parts of YRB increase during summer and decrease during autumn (*Figs. 6c, e*).

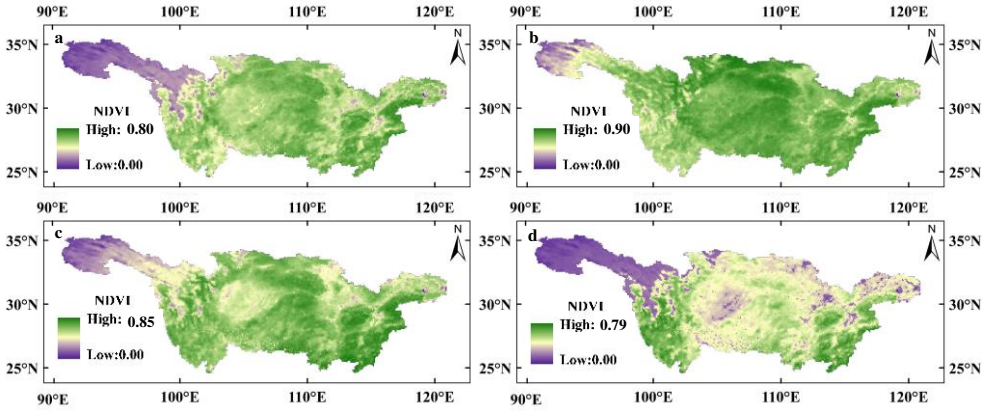

Figure 5. *Spatial distribution of seasonal mean NDVI in YRB during 1982-2015 (spring (a), summer (b), autumn (c) and winter (d))*

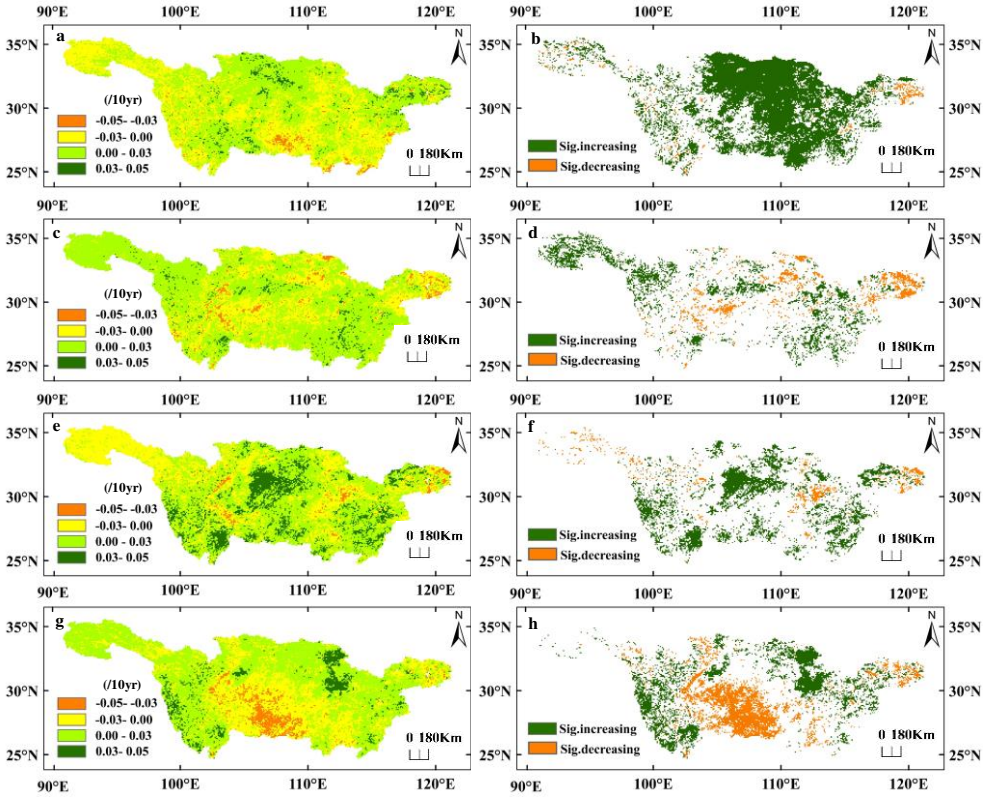

Figure 6. *Spatial distribution of NDVI variation trend in spring, summer autumn and winter (a, c, e, g) and its significant test (b, d, f, h) in YRB during 1982-2015*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35433556

Long-term climate variability in YRB

The seasonal mean temperature during spring, summer, autumn and winter were 14.44, 23.70, 15.33 and 4.40°C, respectively over the whole YRB during 1982-2015 (*Table 2*).

Table 2. *Multi-year means of seasonal NDVI, temperature (T) and precipitation (P) in YRB during 1982-2015*

	NDVI	T(°C)	P(mm)
Spring	0.50	14.44	322.23
Summer	0.67	23.70	518.90
Autumn	0.56	15.33	225.90
Winter	0.41	4.40	108.70

The seasonal mean temperature shows statistically significant increasing trends, and the highest warming magnitude during spring ($p < 0.01$), followed by winter ($p < 0.05$), autumn ($p < 0.01$) and summer ($p < 0.01$) during 1982-2015 (*Table 3*). *Table 3* shows that seasonal mean temperature before TP and after TP also presents an increasing trend in four seasons. The spatial distribution of seasonal mean temperature shows strong seasonal variability (*Figs. 7a-d*): the mean temperature during spring and autumn seasons has a significant increasing trend in the whole YRB, while a decreasing trend during summer and winter seasons was detected in a small part of the YRB (*Figs. 7b-d*). *Figs. 7a-d* also shows the most warming areas in the four seasons were located in the western source region of the Yangtze River and Yangtze River Delta (YRD) due to the rapid population growth and the rapid expansion of built-up areas.

Table 3. *Trend test results of temperature (°C/10yr) and precipitation (mm/10yr) in YRB during 1982-2015, before and after the TP of NDVI trend based on MK and LR analysis*

Seasonal precipitation shows a decreasing trend in the four seasons during 1982-2015 (*Table 3*). However, precipitation presents a significant increasing trend during spring ($p < 0.01$), summer ($p < 0.05$) and winter season ($p < 0.05$) before TP. The spatial variation of seasonal precipitation trend (*Figs. 7e-h*) shows regional differences. The region where precipitation increased was located in parts of the western YRB during spring season (*Fig. 7e*) and in eastern parts of YRB during summer and winter seasons (*Figs. 7f, h*). A decreasing seasonal precipitation was found in located in middle YRB during summer, most parts of YRB during winter season (*Figs. 7f, h*) and in the eastern parts of YRB during spring and autumn seasons (*Figs. 7e, g*).

DOI: http://dx.doi.org/10.15666/aeer/1802_35433556

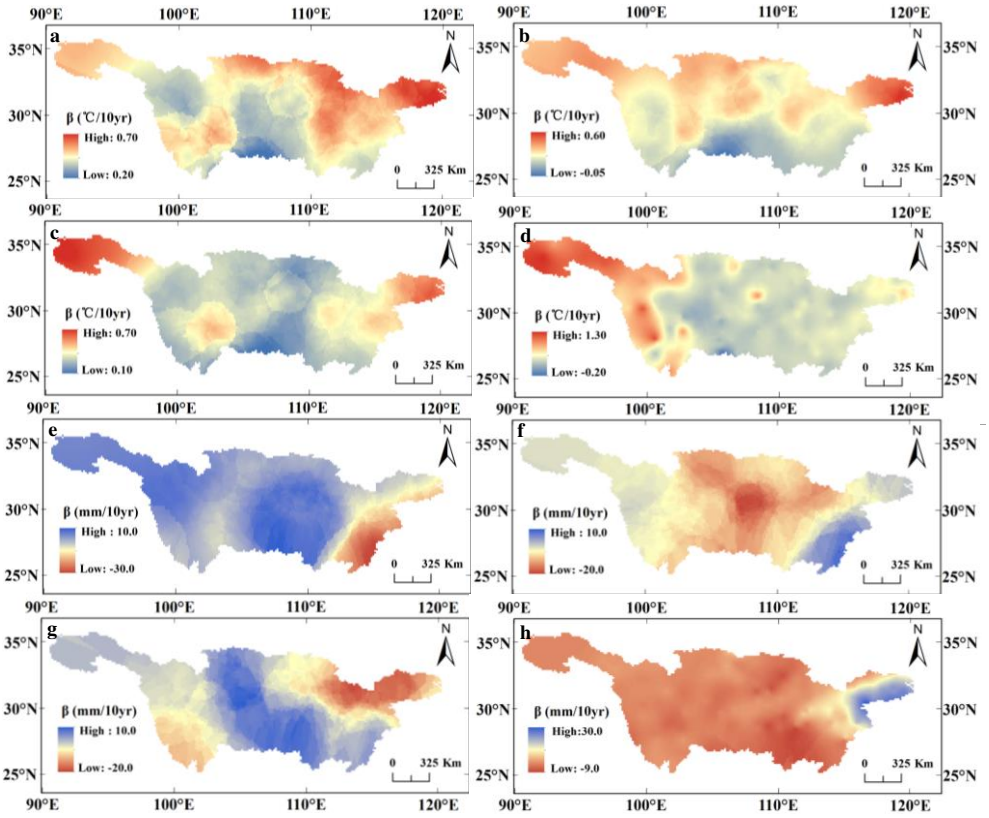

Figure 7. *Spatial distribution of seasonal mean temperature (a-d) and precipitation (e-h) trends in YRB during 1982-2015*

Correlation between vegetation dynamics and climatic variations

Table 4 shows that the mean NDVI had a statistically significant and positive correlation with seasonal temperature, and the correlation coefficients were the highest during spring (R = 0.65, p<0.01), followed by winter (R = 0.50, p<0.01), summer (R = 0.43, p<0.01) and autumn (R = 0.38, p<0.05) seasons. Moreover, the increasing rate of seasonal mean NDVI and temperature during spring season was also the highest during 1982-2015 (*Tables 1, 3*). These results show that climate warming in the beginning of the growing season has a positive effect on NDVI in YRB during 1982-2015. In addition, the mean NDVI shows a significant and positive correlation with temperature during winter season after TP (R = 0.60, p < 0.05) and during summer season before and after TP (R = 0.60, p < 0.01; R = 0.46, p < 0.05). *Fig. 8a* shows a significant and positive correlation between the mean NDVI and seasonal temperature during spring over most of the study area, with the correlation coefficients upto 0.50-0.80. The correlation coefficients in other seasons show spatial heterogeneity. During summer season, the significant and positive correlations were detected in the source region of Yangtze River and eastern YRB, whereas negative correlations were found in parts of the northern and southern YRB (*Fig. 8b*). During autumn season, the correlation coefficients were statistically significantly positive correlation in western and middle YRB, and statistically negative in parts of eastern YRB (*Fig. 8c*). During winter season, the mean NDVI was positively correlated with temperature in the whole YRB, especially statistically significant in the western and southern YRB (*Fig. 8d*).

DOI: http://dx.doi.org/10.15666/aeer/1802_35433556

regions with significant and negative correlation were located in a small parts of the eastern and southern YRB, while those with significant and positive correlation in parts of the northern YRB. During summer and winter seasons, a negative correlation was observed in most parts of YRB, and the correlation coefficients were significant in the eastern and western YRB (*Figs. 8f, h*). During autumn, the significant and negative correlations were observed in the northern, parts of the western and eastern YRB (*Fig. 8g*).

Discussion

Climate change in YRB

Global warming has influenced the climatic pattern of YRB (Cui et al., 2019). The increasing rate of global mean land-surface air temperature was 0.18 ± 0.04°C/10yr in 1951-2012, while the most significant warming was found during 1979-2012, with the highest warming rate of 0.25 ± 0.05°C/10yr (IPCC, 2013). With economic development in China, especially in the past 30 years, the urbanization has been made a large contribution to climate warming (Jin et al., 2015). The amount of urban area rapidly increased from 3376 km^2 to 13073 km^2 in the eastern YRB during 2001-2013. Moreover, a significant and positive correlation existed between land surface temperature and urban area (Yao et al., 2017). Under global warming, the continual increases in temperature in QTP will seriously accelerate the melting of glaciers (Jiapaer et al., 2015). Glacier melt will lead to a drop in river and groundwater recharge, which would be fatal for ecological environment in the source region of Yangtze River due to most vegetation growth relying on rivers and groundwater. Thus local governments should focus on such environments and propose feasible countermeasures to alleviate these risks.

Seasonal precipitation shows a decreasing trend in YRB during 1982-2015. However, a statistically wetting trend was observed in the source region of Yangtze River (Zhang et al., 2017). A similar wetting trend was also found in the western inland river basin and south-eastern China (Zhang et al., 2013). The increase in precipitation is helpful to improve local ecological environments. Recent research reported that the area of the closed inland lake on the QTP has expanded from 2.56×10^4 km^2 to 3.23×10^4 km^2 in approximately the past 20 years, and the number of new lakes reached 99 in approximately the past 40 years, which was mainly caused by a change to a warm and humid climate on the QTP (Zhang et al., 2017).

Variations of NDVI in YRB

This study analysed the spatiotemporal dynamics of seasonal mean NDVI in YRB for the period 1982-2015. The results provide a new understanding of vegetation dynamics in YRB in recent decades. In our past study, we found a significant statistically increasing trend in annual mean NDVI. However, the changes of annual mean NDVI before and after TP (1994) was slight without showing the statistically confidence level (Cui et al., 2019). The spatial distribution of NDVI observed was similar to those of Wang et al. (2015). At seasonal scale, the mean NDVI during spring and autumn increased faster. Earlier study suggested that the vegetation growth in China increased faster during spring (Piao et al., 2003).

Relationship between NDVI and climatic variables

In this study, the correlation analysis between seasonal mean NDVI and temperature/ precipitation was performed. The statistically significant and positive correlations between seasonal NDVI and temperature were generally observed in YRB. These results were consistent with those from Richardson et al. (2010) and Peng et al. (2011). However, it was found in this study that the correlation was negative between NDVI and precipitation over the whole YRB and did not reach a statistically confidence level, which indicated that vegetation growth was least affected by precipitation condition in this region during the study period. A widely accepted viewpoint is that vegetation growth is mainly affected by temperature in humid regions, while precipitation is not a limited factor for vegetation growth due to abundant rainfall (Wang et al., 2015). For example, the climate in the source region of Yangtze River is characterized by lower temperature and relatively abundant precipitation, which indicates that the effect of temperature on vegetation in this region is more than that of moisture (Zhang et al., 2016). Karnieli et al. (2010) found that when energy was the limiting factor for vegetation growth in the North American continent at higher latitudes and elevations, the NDVI was positively correlated with temperature. On the contrary, precipitation for vegetation growth is more important compared to the temperature due to lower rainfall in the arid region (McGwire et al., 2000). The increasing temperature will have a positive impact on vegetation growth by extending growing season and increasing photosynthesis if the temperature ranges from baseline to optimum value (Thornthwaite, 1948; Slayback et al., 2003; Hua et al., 2017). However, vegetation growth will be limited if the increasing temperature exceeds the optimum value (Thornthwaite, 1948). Hence, the regions with higher increasing rate of temperature should pay more attention to protecting ecological environments to mitigate and adapt to climate warming.

Conclusion

In this study, the daily meteorological data (T and P) were used to analyze the spatiotemporal variation of seasonal temperature and precipitation in YRB during 1982-2015. Additionally, the vegetation dynamic and the response to climate change were also investigated. The main findings of the present study are summarized as:

(1) Seasonal mean temperature show significant increasing trend over the whole YRB during 1982-2015 which is mainly attributed to an obvious warming during spring season. The warming rates in the north of the study area were observed to be higher compared to those in the south and the highest warming rate was observed in the eastern YRB with intense human activities and the western source region of Yangtze River in QTP.

(2) The mean NDVI during spring and autumn show significant increasing trends over the whole study area. The seasonal NDVI also shows strong spatial heterogeneity.

(3) The correlation coefficients between the mean NDVI and seasonal temperature (precipitation) were strongly dependent on the season with pronounced spatial difference.

Abstract. Various studies have been conducted on the factors affecting the spatial distribution of terricolous lichen species at regional and landscape scales, yet not on small-scales. In our study, the distribution of lichens was obtained by objective classification and spatial analysis of RGB camera images taken from two different heights by an unmanned aerial vehicle at a reforested area of 1575 m^2. Black pine and cypress are species that have been introduced, while the, native species are oak and mock privet. The total area covered by *Cladonia rangiformis* Hoffm., (26.17 m^2) in the study area was 5 times higher than that covered by the *Cladonia foliacea* (Huds.) Willd. (5.01 m^2). These species were found to be located mostly to the north and sometimes at the east of the tree species. *C. rangiformis* was found under the crown projection area of cypress; however, no such result has been found for black pine, mock privet, and oak. Therefore, tree species affect the distribution of terricolous lichen species. The patch sizes of both of these lichen species fit the power law distribution and demonstrate inhomogeneous spatial distribution in the area. *C. rangiformis* and *C. foliacea* patch size classes generally clustered at short distance (2-2.5 meters) and demonstrated regular distribution beyond this distance.
Keywords: *directional interaction, inhomogeneous distribution, patch-size distribution, unmanned aerial vehicles, Cladonia*

Introduction

Lichens can grow on human-made materials such as fences, tombstones, walls, surfaces of wooden or concrete buildings, just as they can on many natural substrates (Aptroot and James, 2002). The classification of lichens is sometimes based on these substrates; hence the lichens examined in this study are named terricolous lichens since they are located on the ground (Purvis et al., 1992).

The saxicolous lichens on rocks can affect the soil formation process both physically and chemically by weathering the rocks with the acids they produce (Chen et al., 2000; Adamo et al., 2002; Sevgi and Makineci, 2005). Similarly, terricolous lichens contribute to soil formation by changing the physical and chemical properties of the soil by covering it and releasing lichen acids (Asta et al., 2001; Maestre et al., 2011; Gypser et al., 2015; Jackson, 2015). For instance, the terricolous lichens *Cladonia rangiformis* Hoffm., and *Peltigera neckeri* Hepp ex Müll. affect soil mineralization and bacteria growth with the secondary metabolites they produce (Akpinar et al., 2009).

Some studies have been carried out on biological soil crusts (biocrust), including terricolous lichens (Eldridge, 1996, 1999; Martínez et al., 2006; Ochoa-Hueso and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35573576

Manrique, 2011; Ochoa-Hueso et al., 2011, 2017; Pietrasiak et al., 2011; Concostrina-Zubiri et al., 2014, 2018; Gypser et al., 2015). Terricolous lichen cover is positively related to organic carbon, nitrogen, and aggregate stability in soil (Rai and Upreti, 2014). Terricolous lichens take place in different habitats as an important component of the ecosystem and are an indicator of habitat heterogeneity (Will-Wolf et al., 2002a). Besides general distribution in arid, semi-arid ecosystems or cold climate conditions (Eldridge, 1996; Zouaoui et al., 2014), terricolous lichens also prefer the gaps in shrublands and forests in Mediterranean ecosystems (Loppi et al., 2004; Ochoa-Hueso et al., 2011).

Terricolous lichen species require comparatively longer time for dispersal and establishment in the ecosystem (Zouaoui et al., 2014). Elevation and soil type are the leading factors affecting the occurrence of terricolous lichens in large areas (Will-Wolf et al., 2002b; Bowker et al., 2006; Zouaoui et al., 2014). It is also stated that gypsiferous soil is also rich in terms of the diversity of terricolous lichen (Concostrina-Zubiri et al., 2014). In a study conducted in arid and semi-arid ecosystem in Australia, the presence and diversity of terricolous lichen species contributing to the soil crusts is explained through landscape types with non-calcareous soils (Eldridge, 1996). A positive relationship exists between soil pH, Fe, Ca and spatial distribution of lichens and mosses forming soil crusts in the gaps of kermes oak scrubs in semi-arid Spain has been determined (Ochoa-Hueso et al., 2011). The species diversity of terricolous lichen communities of Northern Italy grasslands depends on soil pH, light, and humidity requirements of lichen species (Gheza et al., 2016). Especially some terricolous lichens (*Cladonia* spp.) are limited by light compared to mosses (Tilk et al., 2018).

Unlike studies on factors affecting regional and landscape-level distribution of terricolous lichens, (Pietrasiak et al., 2011; Nelson et al., 2013; Concostrina-Zubiri et al., 2018) there are limited papers on understanding their spatial distribution in small-scale. In the steppe of south-eastern Spain, the microsite created by *Stipa tenacissima* L. may alter the small-scale spatial pattern of *Cladonia convoluta* (Lam.) Anders and *Squamarina cartilaginea* (With.) P. James (Maestre, 2003).

Remote sensing data has been used for determining lichens and biocrusts on a regional scale at deserts and arid areas (Chen, 2005), badlands (Rodríguez-Caballero, 2014), and drylands (Panigada, 2019). RGB, NIR, and hyperspectral images acquired using terrestrial and aerial photography, which are lately often used in other ecology studies, have also been used in lichen studies (Hinchliffe, 2017). However, to the best of our knowledge, this study represents the first application of aerial images in lichen studies at small-scale.

In this study, determining the spatial distribution of terricolous lichens on a small-scale with the RGB images captured by an unmanned aerial vehicle at a reforested degraded forest area was aimed. According to the hypothesis of this study lichen species are expected to a) be distributed inhomogeneously, b) cluster in the area, c) attract each other interspecifically. Lichen size classes are anticipated to fit power law distribution. Determining the effects of tree species, distance from trees, and azimuth of lichen patches cluster centroids on the spatial distribution of terricolous lichens are other objectives of the study.

Materials and methods

Study area

The study area is located in Değirmenköy (Istanbul), northwest Turkey (latitude; 41^0 08’ 11” and longitude; 28^0 03’ 30”) at an altitude of 200 m a.s.l., and the distance

DOI: http://dx.doi.org/10.15666/aeer/1802_35573576

from the sea is 9 km. Mean annual precipitation is 509 mm, and mean annual temperature is 16°C. Presence of summer drought and drops in precipitation in winter show that mediterranean climate is dominant in the area. In 1983, the degraded forest area was reforested with mainly black pine, and cypress trees were planted as road buffer zone. While black pine (*Pinus nigra* J. F. Arnold) and cypress (*Cupressus sempervirens* L.) are species planted into the field, native species are oaks (*Quercus* spp.) and mock privet (*Phillyrea latifolia* L.). Some of the cypress species in the area were cut in 2018 (20 trees) and 2013-2014 (32 trees).

The study area is 1575 m^2 and has a near flat topographic structure (*Figure 1*). In the study area there are 12 black pines, 102 cypresses, 44 oaks, and 29 mock privets (*Table 1*). Black pine is present only along the east side of the area. Among the reforestation species, blackpine has mean height 7.58 m and cypress has 7.56 m, while among the natural species oak has mean height 2.42 m and mock privet 1.70 m. Mean crown projection areas of the trees were 12.01 m^2 for black pine, 5.68 m^2 for cypress, 4.46 m^2 for oak, and 3.55 m^2 for mock privet (*Table 1*).

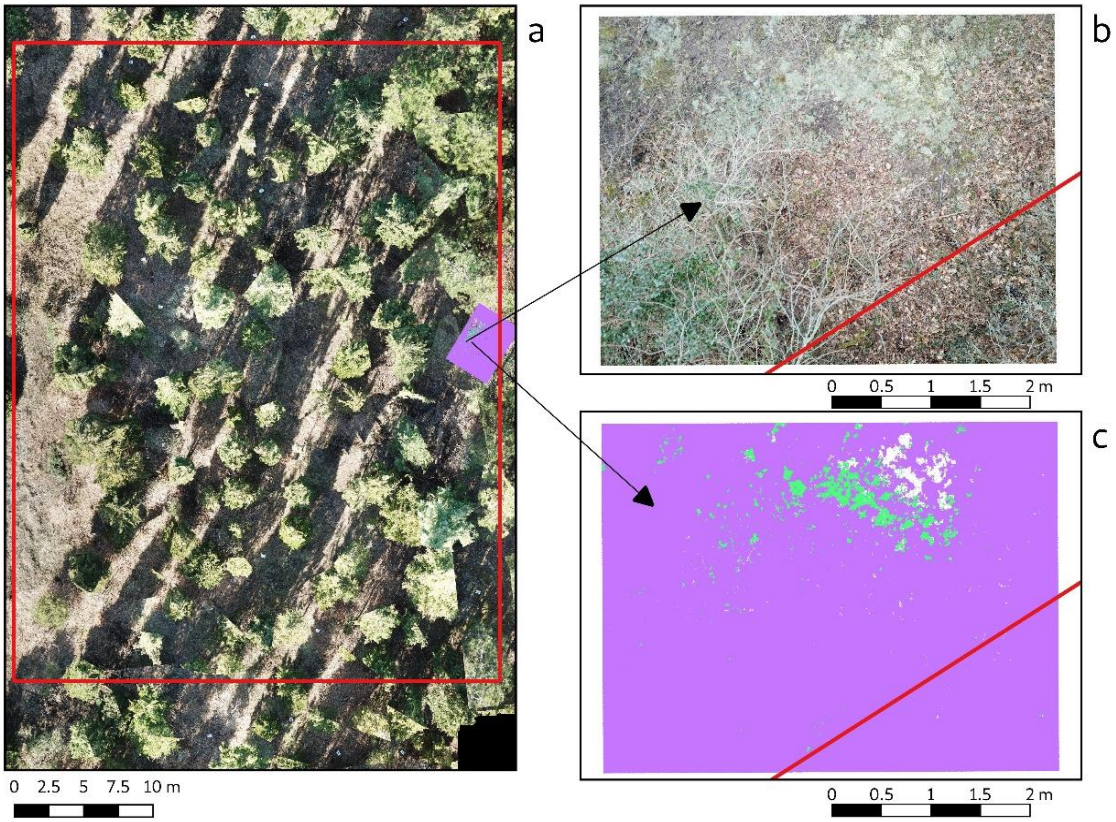

Figure 1. *a) Orthophoto produced from aerial photographs taken from 12 meters height, b) aerial photographs taken from 3-5 meters height, c) classified raster map of lichen species (white pixels: C. foliacea, green pixels: C. rangiformis)*

When the branching structure of the trees is analyzed, it is seen that (except few individuals) black pine and cypress do not ramify down to the breech of the trees; whereas oak and mock privet branch down to the bottom of the trees. Crown base height for black pine is 2.83 m and 0.97 m for cypress on average.

Species data

Three species of terricolous lichens; *Cladonia foliacea* (Huds.) Willd. (Syn.: *Cladonia convoluta* (Lam.) Anders), *Cladonia furcata* (Huds.) Schrad. subsp. *furcata* and *Cladonia rangiformis* Hoffm. were collected from the study area in March 2019. The lichen specimens were treated with a chemical spot test and identified with a stereomicroscope (Nikon SMZ445) according to the keys of references (Hodgetts, 1992; Purvis et al., 1992; Nimis and Martellos, 2004; Eversham, 2015; AFL, 2019; British lichens, 2019; Irish lichens, 2019). Nomenclature of the species mainly follows the Index Fungorum (2019) and MycoBank Database (2019).

Thallus of *C. foliacea* is fruticose when with podetia, but mostly squamulose greenish grey, forming compact mats (Nimis and Martellos, 2004), squamules 4-10 mm x 1-3 mm (Hodgetts, 1992). Thallus of *C. rangiformis is* fruticose, greenish grey to whitish grey, shrubby, (1-3 mm long and broad), forming tuft, (Nimis and Martellos, 2004), podetia 20-60 mm tall (Hodgetts, 1992; Nimis and Martellos, 2004). Thallus of *C. furcata* subsp. *furcata* is fruticose, podetia 20-70 mm tall, forming irregular tufts (Hodgetts, 1992).

C. foliacea was easily noticed in the aerial photos since it has a quite bright color. It was not possible to distinguish *C. furcata* subsp. *furcata* which is mixed with the predominant species in the study area, *C. rangiformis,* in the aerial photos, therefore these two species were considered together, and their mention in the text as *C. rangiformis* should be considered as *C. rangiformis* (+*C. furcata*).

The crown projection of the trees and the shrubs present at the survey area were digitized using the orthophoto generated by aerial photographs taken from 12 m height and the centroids of crown projections were regarded as trees (or shrubs) position coordinates. Minimum enclosing circles surrounding the crown projection were produced and accepted as crown projection (*Figure 2*) and the radius and areas of these circles were calculated (*Table 1*). The plant species were identified, their height and crown base height were measured in the field.

Data collection and preparation for analysis

In regional, landscape, ecosystem and small-scale terricolous lichen studies, data were collected through sampling based surveying in the field such as transect based sampling (Pietrasiak et al., 2011; Bowker et al., 2013), random sampling (Maestre, 2003; Concostrina-Zubiri, 2018; Gutiérrez et al., 2018) or systematic sampling in the field (Ochoa-Hueso et al., 2011; Tilk et al., 2018). In our study, data regarding the lichen population in the study area was collected total count by aerial survey using one of the advanced technology's opportunities, "unmanned aerial vehicle-UAV" with the 12 megapixel resolution RGB camera in March 2019. With this goal in mind, the two-step aerial survey was conducted. First, an orthophoto of the survey area was produced using the photogrammetric method (Open Drone Map, 2019) with images captured from 12 m above the ground through an autonomous aerial photography covering the entire survey area (*Figure 1a*). It has been detected that the spatial resolution of these images (ca. 5 mm) was insufficient in distinguishing lichens. Thereupon new aerial images of lichens with a higher spatial resolution (<=2 mm) were obtained by manual flight of an unmanned aerial vehicle between trees at a height of approximately 3-5 meters above ground.

Since sizes of lichen individuals are rather small, it is very arduous to distinguish them individually in aerial photographs. As a result, lichen patches formed by individual lichens getting together were used as the material in this study. To objectively determine the boundaries of lichen patches from images obtained from a 3-5 meters height, "Trainable Weka Segmentation" (Arganda-Carreras et al., 2017) method was used. 188 aerial photographs were classified in this method, and so objectively determined lichen patches' boundaries were saved as raster data. RGB images captured from 3-5 meters height and the classified raster data (*Figure 1b,c*) were transformed into geo-registered raster data through georectification with the help of the orthomosaic map of the survey area. These geo-registered raster maps were first converted to vector data and then merged to obtain the boundaries of lichen patches as vector maps. The area corresponding to each lichen patch was calculated (*C. rangiformis* n= 25025, *C. foliacea* n= 5598 polygon) and these areas were used to create patch size classes (*Table 2*). In order to use the lichen patches in analysis, their polygon centroids were obtained. In order to investigate the relationships between the lichen patches and trees, lichen patch centroids were clustered.

Table 2. *Total area and number of lichen patches*

size class / species	*Cladonia rangiformis* (cm^2)	*Cladonia foliacea* (cm^2)
VSLP	6.48 (n=18003)	2.09 (n=4226)
SLP	46834.83 (n=4900)	9671.67 (n=1011)
MLP	38617.97 (n=1258)	6823.80 (n=230)
LLP	53010.72 (n=636)	8759.78 (n=101)

DOI: http://dx.doi.org/10.15666/aeer/1802_35573576

patch clusters (hereafter LPC) were generated with a minimum of 5 neighbors in each cluster and a maximum distance of 0.25 meters between LPCs.

Trees and shrubs at a distance below 4 meters to the centers of LPCs were selected. The distances and azimuth values between the center of LPCs and the position of trees and shrubs were calculated (*Figure 3*).

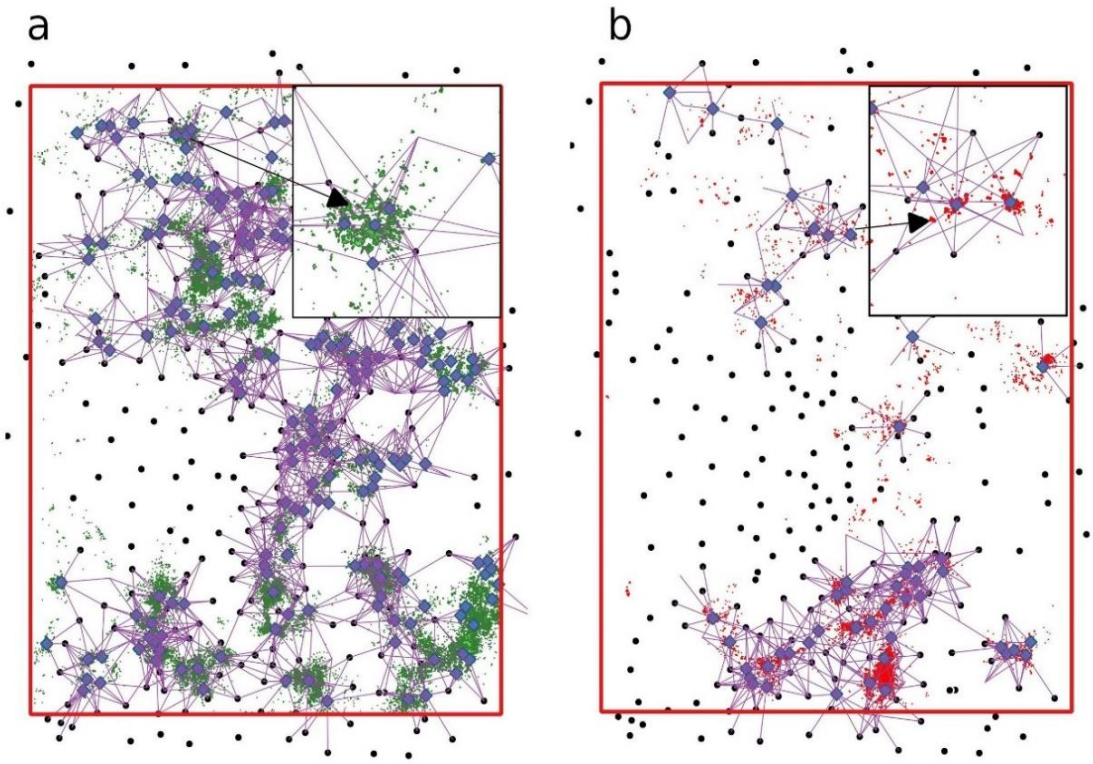

Figure 3. *Hublines for the calculation of azimuth and distance between centers of LPC and position of trees and shrubs; a) C. rangiformis b) C. foliacea*

Statistical Analysis

Since the studied objects were represented areally as lichen patches and the aerial survey was conducted over the entire area, analyses were conducted using a two-tiered approach: a cluster of lichen patches and whole lichen patches. In order to fulfill this objective, the relationships between LPC centers and surrounding trees and shrubs were investigated with circular statistics methods. Whether whole lichen patches fit the power-law distribution was tested and their distribution was inspected using spatial point pattern analyses.

In order to be able to evaluate differences between lichen patches based on their sizes, both lichen patches were sorted into 4 size classes as: Small lichen Patch (SLP) (5-20 cm^2), Middle Lichen Patch (MLP) (20-50 cm^2), Large Lichen Patch (LLP) (50-150 cm^2), Dead Lichen Patch (DLP) (> 150 cm^2). Patches covering areas less than 5 cm^2 (Very Small Lichen Patch) were not used in analyses in order to minimize classification and geometrical accuracy errors.

For analyses regarding the distribution of LPC centers around trees (or shrubs), the circular package (Agostinelli and Lund, 2017) of the R software was employed (R Core

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35573576

Team, 2018). To test whether whole community lichen patches fit power-law distribution (Kefi, 2007; Bowker et al., 2013, 2014) the "poweRlaw" package of the R software (Gillespie, 2015) was used. For the spatial point pattern analysis, firstly whether the lichen distribution is homogeneous was tested with quadrattest (Wang et al., 2010) and it was determined that the distribution is not homogeneous. Therefore the mentioned analyses were conducted inhomogeneously over the entire area (the word inhomogenous is synonymous with the word heterogeneous, but since the word inhomogeneous is used in spatstat package, this word was preferred in our study). The univariate pair correlation function g(r) was employed in order to determine the spatial pattern of the *C. rangiformis* and *C. foliacea*, (Stoyan and Stoyan, 1994; Wiegand and Moloney, 2014) under a inhomogeneous Poisson null model. To detect spatial relationships between lichen pathes in different size classes, and between lichen pathes and trees/shrubs, the bivariate pair correlation functioning $g_{12}(r)$ was used. For spatial point pattern analyses, the "spatstat" package (Baddeley et al., 2015) of the R software was used.

In the followed methodological approach (*Figure 4*) all spatial analyses were performed with Quantum GIS (Quantum GIS Development Team, 2019) and "weka trainable segmentation" FIJI (Schindelin et al., 2012), and all statistical analyses were performed using R (R Core Team, 2018) software.

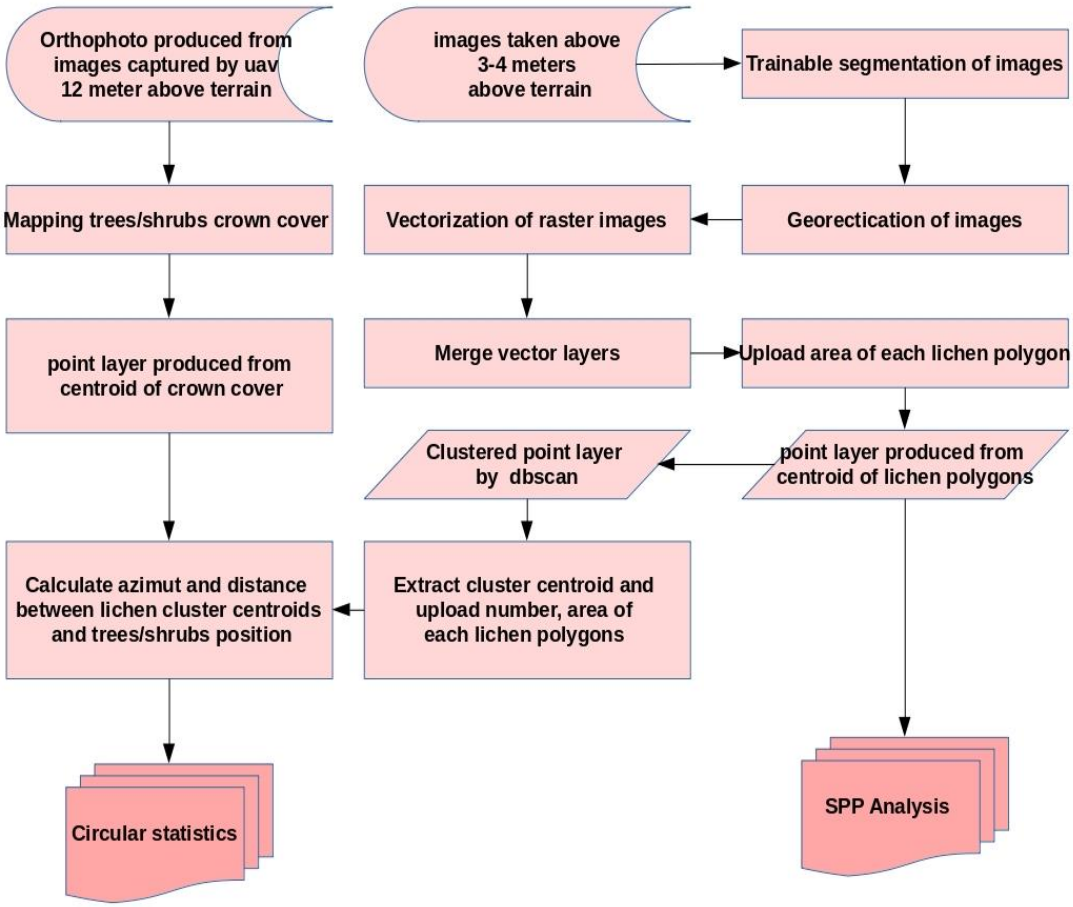

Figure 4. *Workflow of the methodological approach followed in the study*

Results

Cover area of trees (or shrubs) and lichens

In the study area, the crown projection area of black pine, cypress, oak, and mock privets were calculated to be 145.32 m^2, 568.56 m^2, 188.50 m^2, and 105.66 m^2, respectively and the gap area was calculated to be 684.55 m^2. Since the crown projections were intertwined, the total coverage area resulted to be 184 m^2 more than the exact area of the study area.

The total area covered by the *C. rangiformis* (+*C. furcata*) in the study area was 5 times higher than that of the *C. foliacea* (*Table 2*). The total area covered by the lichen species is 31.19 m^2 which lies over 2% of the area. When the total area covered by lichen species were analyzed according to their size classes, 25025 lichen patches in *C. rangiformis*, 5598 lichen patches in *C. foliacea*, and 30623 lichen patches in total were determined (*Table 2*). For both lichen species, the highest lichen patch number was seen in VSLP; however, this size class' total cover is very low (*Table 2*). Among the size classes, DLP was the one with the highest total area, and it was measured 5 times higher for *C. rangiformis* than that for *C. foliacea* on average (*Table 2*).

Cluster of lichen patches analysis

Directional distribution of LPC centers around trees (or shrubs)

For the directional analyses of the lichen patch clusters, SLP, MLP, LLP, and DLP were utilized. In consequence of the conducted clustering process 199 clusters for *C. rangiformis* (*Figure 3a*), and 49 clusters for *C. foliacea* (*Figure 3b*) were determined. The average size of *C. rangiformis* patches was 37.27 cm^2, and the average size of *C. foliacea* patches was 36.57 cm^2. The average distance of lichen patches to cluster centers was 0.74 m for *C. rangiformis*, whereas it was 0.41 m for *C. foliacea*.

When the mean directions of trees and stumps closer than 4 m to LPC centers are considered, *C. rangiformis* LPC centers are located at the north of mock privet, east of oaks, and northeast of stumps (*Figure 5*). *C. rangiformis* LPC centers are located at the north of cypresses until 2.5 m distance, whereas at around 3-3.5 m they are at the northwest (*Figure 5*). Even though *C. foliacea* interaction with trees and shrubs is more erratic, its LPC's are located approximately towards the north of cypress and oak (*Figure 5*).

The amount of trees around *C. rangiformis* LPC centers are higher than those around *C. foliacea* LPC centers (*Figure 5*). The number of trees sorted from high to low at all distances from *C. raniformis* LPC centers are; cypress, stumps, oak, and mock privet (*Figure 5*). Also, while until 2 m stump and cypress individuals amounts are close, after 2 m, cypress amount is ahead (*Figure 5*). For *C. foliacea* cluster centers, the same ranking is: cypress, mock privet, stumps, and oak (*Figure 5*).

Whole lichen patches analysis

Power-law distribution analysis of lichen patches

The fact that lichen patch sizes differ between 0.5 mm^2 and 2.20 m^2 encouraged testing the aptitude of power-law distribution. According to the results of the hypothesis test, the logarithmic values of the number of *C. rangiformis* (p-value=0.38) and *C. foliacea* (p-value=0.44), and their patch-sizes fit power-law distribution (*Figure 6*). It was observed that while the more abundant ones with small lichen patch-sizes fit the

DOI: http://dx.doi.org/10.15666/aeer/1802_35573576

power-law distribution better, the ones with big patch-size are relatively further from power-law distribution (*Figure 6*).

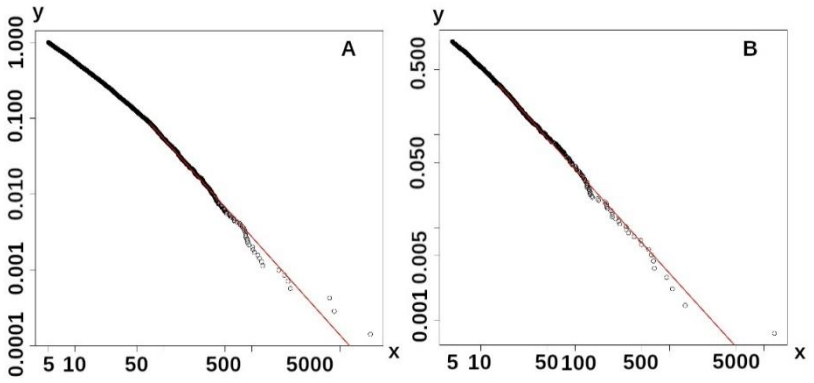

Figure 6. *Cumulative distributions of lichen patches for a) C. rangiformis, b) C. foliacea, shown with logarithmic scales*

Univariate point patterns analysis of lichens patches

According to the results of univariate point pattern analyses, *C. rangiformis* and *C. foliacea* show significant clustering in short distance (*Figure 7a,b*). g(r) values of *C. foliacea* resulted to be higher than the values of *C. rangiformis*. Clustering distance was observed to be same for *C. rangiformis* (r<2.5 m) as *C. foliacea* (r< 2.5 m) (*Figure 7*). When the two species are together, similar clustering was observed in short distance (r<2.5 m) (*Figure 7c*). Besides this, both species demonstrate significant regular distribution after short distance clustering (r>2.5 m).

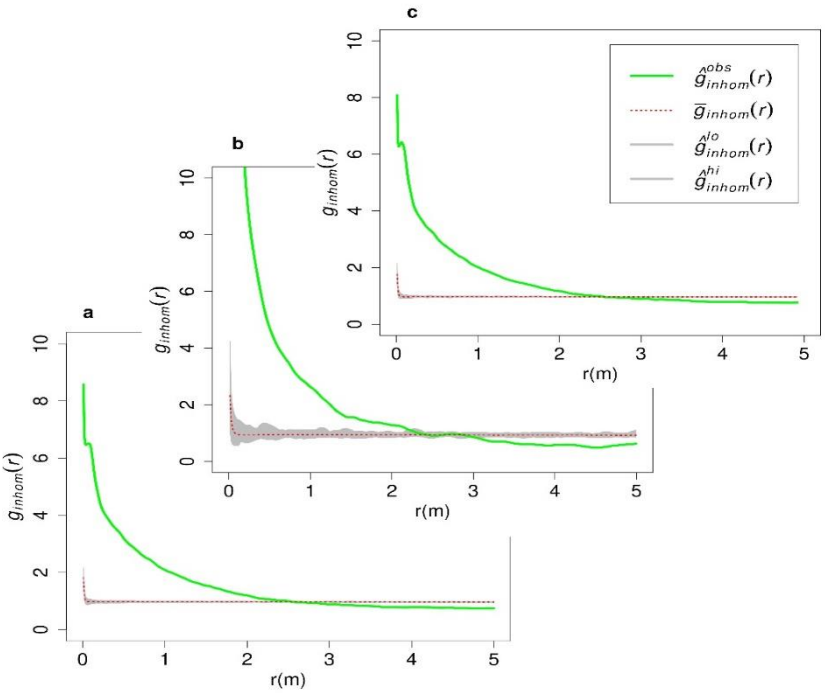

Figure 7. *Univariate point patterns analyses of a) C. rangiformis b) C. foliacea c) whole lichen patches using inhomogeneous pair-correlation function. $g_{inhom}(r)$ = green line; gray areas indicate boundaries of the simulation envelope constructed from 99 simulations of an inhomogeneous Poisson process with inhomogeneity given by kernel smoothed intensity function from a point pattern*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35573576

The patterns created by all size classes of the species, both separately and together, univariate point pattern analyses done according to size classes gave similar results (*Figure 8*). According to the results of univariate analyses conducted considering size classes, random distribution was observed after 1-1.5 meters for *C. foliacea* at LLP and DLP, and after 5 and 6 meters at DLP for *C. rangiformis* (*Figure 8*).

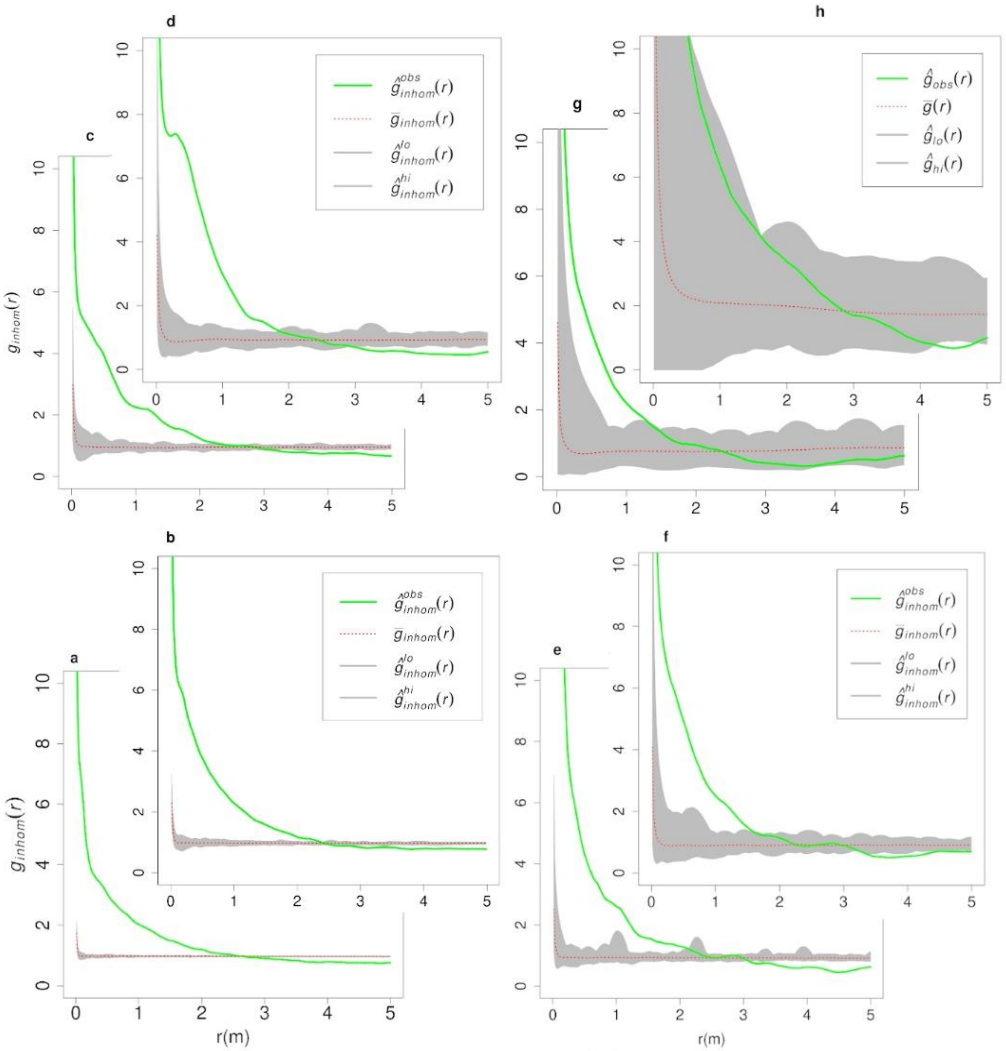

Figure 8. *Univariate point patterns analyses of C. rangiformis based on size class; a) SLP, b) MLP, c) LLP, d)DLP and Univariate point patterns analyses of C. foliacea based on size class e) SLP, f) MLP, g) LLP, h)DLP using inhomogeneous pair-correlation function. $g_{inhom}(r)$ = green line; gray areas indicate boundaries of the simulation envelope constructed from 99 simulations of an inhomogeneous Poisson process with inhomogeneity given by kernel smoothed intensity function from a point pattern*

Bivariate point pattern analysis of lichen patches size classes

SLP of *C. rangiformis* is attracted by other size classes of lichen patches in short distance (r<2 m); however, after this distance (r>2 m), repulsion is observed (*Figure 9*). A similar situation exists between MLP and LLP, between MLP and DLP, and between LLP and DLP (*Figure 9*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35573576

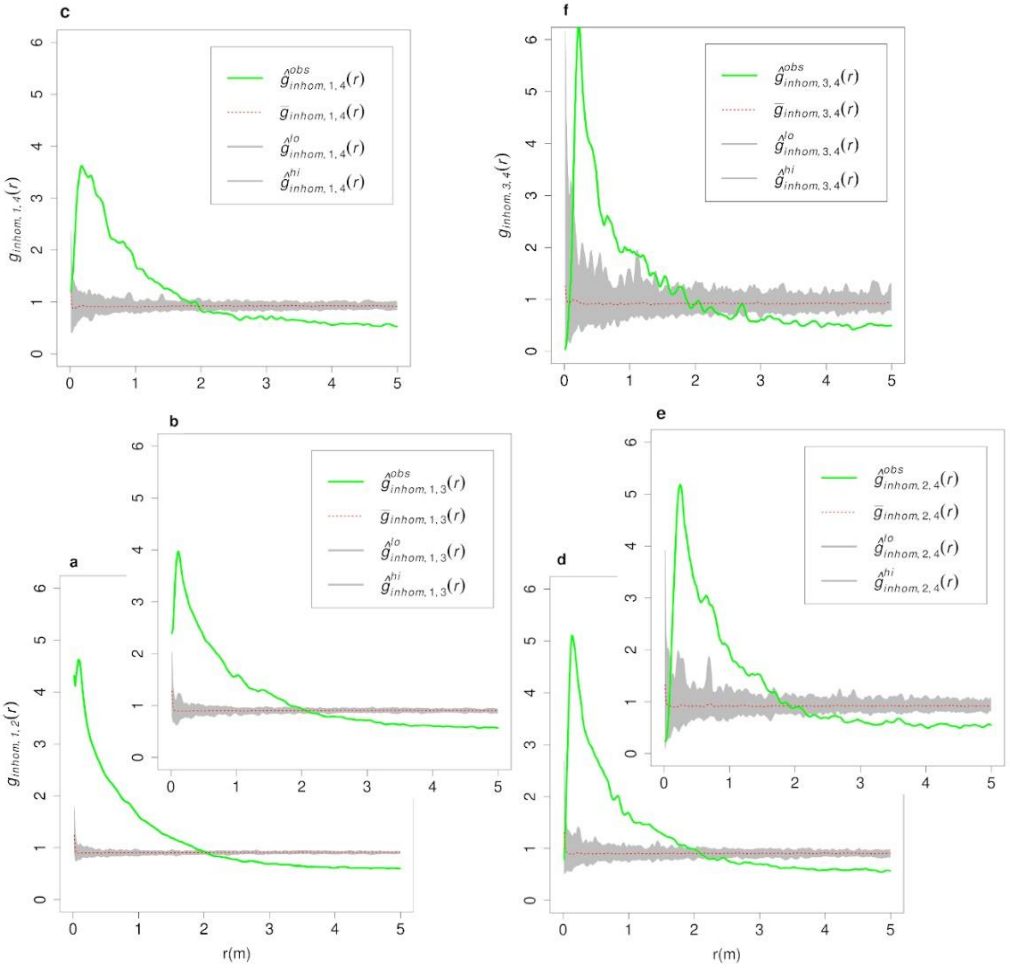

Figure 9. *Bivariate point pattern analysis of C. rangiformis based on a) SLP to MLP, b) SLP to LLP, c) SLP to DLP, d) MLP to LLP, e) MLP to DLP, f)LLP to DLP using inhomogeneous cross-type pair-correlation function $g_{inhom}(r)$ = green line; gray areas indicate boundaries of the simulation envelope constructed from 99 simulations of an inhomogeneous Poisson process with inhomogeneity given by kernel smoothed intensity function from a point pattern*

SLP of *C. foliacea* species is attracted by MLP and LLP in short distance (r<2 m), but after this distance (r>2 m), repulsion is observed. MLP is again attracted by LLP at short distance (r<2 m) (*Figure 10*). Other bivariate analyses were conducted, but since the DLP had n=30 and as a consequence the resulting envelopes were highly irregular, it was not evaluated.

Between *C. rangiformis* and *C. foliacea*, attraction is observed in short distance (r<1.5 m), however after this distance, repulsion is observed (*Figure 11*).

Bivariate point pattern analysis of lichen patches and trees/shrubs

It was determined that both lichen species are repulsed by the cypress (*Figure 12*). Other bivariate analyses were performed, but since n values were very low and therefore the resulting envelopes were irregular they were not evaluated.

Discussion

Factors affecting the distribution of the important genus of terricolous lichens *Cladonia* have been studied for a long time (Yarranton, 1975). *Cladonia* generally can grow on soil, but can also be found in other substrates such as bark, rotting wood, dune system and among moss (Bowker et al., 2006; Osyczka, 2006; Gheza et al., 2016; Tilk et al., 2018; Sevgi et al., 2019). We contributed by investigating the spatial distribution of the species *C. foliacea* and *C. rangiformis* (+*C. furcata*) and their interactions with tree/shrub species. The complicated relationships based on direction and distance between the studied objects were investigated with an aerial survey. These relationships can also be investigated with different re/sampling methods and/or new studies could be done, because the area of such size (1575 m^2) captured aerially is 17500 times the size of the 30 cm x 30 cm (0.09 m^2) sample areas which are widely used in lichen studies. Hence just as different research can be done by resampling this permanent research area, temporal monitoring studies can also be conducted.

In afforestation areas in the Mediterranean region, new species brought into the area through planting and the presence of dominated natural species in the environment affects the distribution of terricolous lichens (Loppi et al., 2004; Concostrina-Zubiri et al., 2018). Similarly, in our study species brought into the area and natural species affected the distribution of terricolous lichens in small-scale. In the spatial clustering of two terricolous lichen species, 199 clusters for *C. rangiformis* (*Figure 3*), and 49 clusters for *C. foliacea* were found. Based on these results, *C. rangiformis* has a higher number of the lichen patches that has joined in size classes and their spatial distribution in small-scale is high. Another evidence that shows this effect more clearly is the mean direction of LPC centers with respect to trees (*Figure 5*). LPC centers are inclined to be on specific sides of tree species even at various distances (*Figure 5*). This inclination is more apparent for the *C. rangiformis*. Both species' cluster centers interacted 'by distance' most with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35573576

cypress, then with other species (*Figure 5*). Oaks and mock privet being fewer in number and them gathering together at specific parts of the area may have made cypress' effects on lichens more obvious compared to other species. Results obtained for the *C. rangiformis* supports previous studies (Loppi et al., 2004).

When the distance from LPC centers at which trees were located was investigated, it has been found that lichen species were found under the crown projection area of cypress; however, no such result has been found for mock privet and oak. While the branching until bottom of oak and mock privet individuals block lights from passing through, the fact that branching begins at 97 cm on average and the branching angle is greater may have allowed more light to pass through the crown. As a result, while lichens with low shade tolerance were not able to disperse beneath the canopy of mock privet and oak, they were able to disperse beneath the canopy of some cypress individuals (Eldridge, 1999). These results are in line with studies which have revealed the negative effects of oak on *Cladonia* species' distribution (Ochoa-Hueso et al., 2011; Goldberg and Heine, 2014). Distribution of *Cladonia* species in open microsites is affected by trees (Crittenden, 1999). Another factor which augments this effect is forest litter (Eldridge, 1999). Although in our study forest litter-related evaluations were not conducted, the dense amounts of forest litter often produced by oak may have contributed in hindering lichens to enter beneath the crown projection area. In our study, besides this effect of oak, it has been determined that there are nearly no lichens in the region where oak is present with mock privet (non-lichen area in the left of *Figure 2*).

Power-law distribution is being utilized successfully in vegetation studies (Kefi et al., 2007) and explains the relationship between epiphytic lichen species diversity and tree diameter (Buckley, 2011). Bowker et al. (2013, 2014) stated that analysis of the patch-size distributions of biological biosoil crusts including terricolous lichens fit power-law distribution. Our study validated that terricolous lichen species' patch sizes directly demonstrate power-law distribution, which is in line with our expectations.

It is thought that the inhomogeneity of lichen distribution arises from the distribution of the trees and shrubs in the area, which proves our hypothesis to be true. It is considered that the intensity and distribution of pine, oak, and mock privet species in the area causes this. It is possible to perform the point pattern analysis of an irregular area by excluding these regions; however, in that case, the reasons behind in-homogeneous distribution and the actual distribution patterns of the lichens would not have been revealed, therefore this method was not preferred.

Considering all lichen size classes together, the occurrence of clustering at short distance (2-2.5 meters) and regular distribution beyond this distance is thought to be related to both the distance among trees in the afforestation area (the average distance of all trees; 1.91 m, the average distance among cypress; 2.44 m) and the fact that lichens form large colonies in the gaps of forest/shrublands by colonization. The highness of the g(r) value of *C. foliacea* results from its clustering in only specific regions of the area. Both *Cladonia* species demonstrating clustering and not distributing randomly goes along with Maestre's (2003) results. However, the random distribution of *C. foliacea* and *C. rangiformis*' large size classes, discovered through the univariate analyses conducted based on size classes, may indicate that they initially disperse randomly in the region. The existence of a positive or negative correlation between lichen patch size classes were investigated using bivariate analyses. According to the results, small size classes in both lichen species show a positive correlation with large size classes at short distance ($r<2$ m);

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35573576

however, after this distance (r>2 m) a negative correlation was observed. This may be due to the effects of colonization, competition for space and nutrition.

The relationship between *C. rangiformis* and *C. foliacea* which is positive at short distance (r<0.5 m), is negative after this distance. The investigation of the bivariate relationship between lichens and trees revealed significant repulsion from cypress trees.

Conclusions

This study has shown that aerial photography can be used for determining the spatial distribution of terricolous lichen species. Captured photographs will allow for comparison with photos taken at a later time period, which will in turn contribute to understanding the spatial distribution of terricolous lichen species over long periods of time. Futher studies should take into consideraiton of spatial modelling of environmental factors (i.e., tree height, crown width, shade, microtopography, soil properties) affecting the spatial distribution of lichens. Also, the effect of herbaceous plants between trees on the spatial distribution of terricolous lichens should be made clear.

Acknowledgements. The authors report that they have no conflicts of interests. We would like to thank to İstanbul Regional Directorate of Forestry and İstanbul Forest Service. Our special thanks are due to Dr. Hatice Yılmaz for her contribution to field studies. The authors are grateful to Lale Yılmaz for the language editing of this paper.

Abstract. Treated waste water (TWW) has been replacing fresh water (FW) partly in irrigation. However, irrigation with TWW can cause soil water repellency that affects infiltration characteristics. In order to determine the water quality index with full consideration taken into infiltration characteristics, one dimensional infiltration experiments were conducted in wettable and repellent sandy loams with TWW irrigation. Five kinds of TWW and one tap water (TW) were chosen. The effect of water quality on the wetting front and cumulative infiltration volume was analyzed. The comprehensive water quality index (ZF) was obtained by principal component analysis. The results show that the water quality has a great effect on the cumulative infiltration and wetting front of wettable soil. The more significant the comprehensive water quality index is, the greater the cumulative infiltration volume and wetting front are. The water quality has a great effect on the cumulative infiltration and no effect on wetting front of repellency soil. Power correlation exists between sorptivety (S) and chemical oxygen demand (COD). Meanwhile, a quadratic polynomial relationship exists between the ratio of S for the wetting front coefficient and ZF, and there is a minimum value in the curve.
Keywords: *soil water repellency, soil moisture, wetting front, cumulative infiltration, COD*

Introduction

Treated waste water (TWW) irrigation has become a common practice in arid and semiarid areas to deal with water scarcity and reduce the consumption of fresh water (FW) (Wallach et al., 2005). However, such irrigation may have an impact on the chemical and hydraulic properties of soils. Long-term TWW irrigation will increase soil organic matter (OM) and form a layer of hydrophobic organic compounds on the surface of soil particles (Chen et al., 2009; Nadav et al., 2012a, 2012b), which will cause soil water repellency. The water drop penetration time (WDPT) of repellent soils could reach 802 s for sandy soils (Mataix-Solera et al., 2011) and 3600 s in clay loam with long-term TWW irrigation (Wallach et al., 2005). The occurrence of water repellency leads to a decrease of soil infiltration rate and water conductivity, which affects irrigation efficiency (Wallach et al., 2005; Leuther et al., 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35773592

The reduction of irrigation efficiency is shown in the decrease of the infiltration rate and the migration rate of wetting front which becomes irregular and unstable during irrigation process. Rye and Smettem (2017) found water repellency reduced the rate of water migration and the evaporation of soil surface water. It is easy to form a preferential flow in repellency soil due to the big difference in the movement of water in horizontal and gravitational directions (DeBano, 2000; Wallach et al., 2008, 2010). The water tends to accumulate on the surface of repellent soil (DeBano, 2000) and cannot infiltrate when the depth of water accumulation is less than the matrix suction of the soil during irrigation (Jordán et al., 2009). However, the above researches mainly aim to obtain the discipline of water movement by FW irrigation in repellent soil. Irrigation water source seldom changes after the soil repellency appears for a long time of TWW irrigation. Therefore, it is very important to study the infiltration law of TWW in repellent soil.

TWW has many components such as grease, OM, suspended solids, salt and so forth (Halliwell et al., 2001). Each component will affect the characteristics of the soil, and then change its infiltration characteristics during the infiltration. Suspended particulate matter and dissolved organic matter (DOM) can clog the soil pores (Vries, 1972; Vinten et al., 1983; Levy et al., 1999). High concentration of sodium ions causes swelling and dispersion of soil clay (Durgin et al., 1984; Frenkel et al., 1992; Levy et al., 1999; Halliwell et al., 2001). Inorganic salt increases the alkalinity and salinity of the soil (Balks et al., 1998; Halliwell et al., 2001; Lado et al., 2009; Bedbabis et al., 2014). These components reduce the pores of the soil, the hydraulic conductivity of the soil and the cumulative infiltration volume. However, some components of TWW can increase soil infiltration in repellent soils. Surfactants alleviates the repellency degree of the soil which increases the cumulative infiltration after a long period of TWW irrigation (Chaney et al., 1986; Fortun et al., 1989; Piccolo et al., 1997; Dekker et al., 2018; Liu et al., 2019). Both characters of irrigated soil and irrigation water quality have great effect on soil water infiltration, and they are always interacting, continuous development and evolution (Sheng et al., 2016). Therefore, selection of right water quality index for different soils is of great significance in irrigation with TWW.

The water quality indexes standards, including biochemical oxygen demand (BOD), chemical oxygen demand (COD), suspended solids, anionic surfactants, pH, total salt, chloride, sulfide, heavy metal content, fecal coliforms, aphid eggs, and so on, have been established for agricultural irrigation all over the world. However, these water quality indexes standards have taken the ecological environmental protection into account, but the impact of irrigation water quality on infiltration characteristics is not considered. There is no uniform comprehensive index, so it is applicative to find a comprehensive water quality index to guild TWW irrigation. The objective of this study was to determining the water quality index of TWW for repellent sandy loam (R) and wettable sandy loam (W) based on irrigation infiltration characteristics.

Materials and Methods

Soil sampling and pretreatment

The soil depth of 0~5 cm shows a certain degree water repellency after long-term TWW irrigation (Wallach et al., 2005; Mataix-Solera et al., 2011). Soil water repellency is not obvious below the depth of 5 cm. The soil samples were collected in 0~5 cm surface sandy loam in the first terrace of Wei River, Yangling (34º18′N, 108º24′E), Shaanxi Province, China. The bulk density, grain-size distribution of the soil was measured by the drying

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35773592

method and Mastersizer 2000 laser particle size analyzer in the laboratory, respectively. The soil, whose bulk density is 1.65 g/cm^3, is composed of 14.4% of clay, 24.7% of silt and 60.9% of sand. Therefore, the soil texture is identified as wettable sandy loam. The soil, after air-drying and impurity removal, was subjected to standard sieving of 10-mesh (2 mm). The soil moisture after air drying and saturated soil moisture were 0.029 cm^3/cm^3 and 0.363 cm^3/cm^3, respectively.

The field water-repellent soil is prone to disturbance in the sampling, which may destroy its original water-repellent characteristics. Therefore, surface active material, octadecylamine ($C_{18}H_{39}N$), is added to wettable soil to obtain a relatively stable water-repellent soil (J&K Scientific Ltd.). Octadecylamine, a white waxy solid crystal with alkalinity, is practically insoluble in water. Its melting point is 52.3°C. The repellency soil was obtained by mixing $C_{18}H_{39}N$ with the air-dried soil sample at a ratio of 0.1 g/kg. Then the mixed soil was placed in an oven at 80°C for 24 hours, and the soil sample was stirred for 5 minutes every 2 hours to make the liquid $C_{18}H_{39}N$ fully mixed with the soil particles (Li et al., 2017). This approach eliminated the confounding time effects associated with unstable water repellency systems and allowed for the identification of basic mechanisms (Carrillo et al., 2000). The relatively stable water-repellent sandy loam was obtained after the whole process. The repellency was determined by water drop penetration time test (WDPT) (Letey, 1969; Dekker et al., 1990). According to the water repellency classification standard proposed the mixed soil is slightly water repellent (Bisdom et al., 1993).

Water sampling and water quality index

The TWW sample was taken from pools under different treatments, namely the catchment, the anaerobic pool, the oxidation pool, the sedimentation pool and the outlet pool, in a domestic sewage treatment plant in China. The reference water is tap water in Yangling, China. The water quality index is given in *Table 1*.

Table 1. *Water quality index of TW and pools under different treatment*

The location of the water	Tap water	Catchment	Anaerobic pool	Oxidation pool	Sedimentation pool	Outlet pool
pH	7.92	7.29	7.31	7.31	7.36	7.07
Electric conductivity(μS·cm^{-1})	143	811	825	811	849	799
Dissolved oxygen(mg·L^{-1})	7.52	0.24	0.43	3.00	4.61	4.03
Total hardness(mmol·L^{-1})	0.89	0.49	0.64	0.61	0.68	0.79
Total alkalinity(CaO mg·L^{-1})	27.96	169.81	176.32	164.37	167.67	153.21
Sodium adsorption ratio a	1.23	6.12	6.16	6.98	6.77	7.01
Turbidity	0	125	187	510	4.77	3.95
Total dissolved substances(mg·L^{-1})	95	226	360	260	412	420
Total suspended solids(mg·L^{-1})	0	170	198	780	325	242

a. The sodium adsorption ratio (SAR) refers to the ratio of the sodium ion concentration to the square root of the mean value of the calcium ion concentration and the magnesium ion concentration in the cation exchange reaction of calcium, magnesium, sodium, etc. The formula of the sodium adsorption ratio is $SAR = \frac{C_{(Na^+)}}{\sqrt{C_{(Ca^{2+})}+C_{(Mg^{2+})}}}$ (Bughici and Wallach, 2016), where, the values are expressed in mmol·l^{-1}.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35773592

There are 12 water quality parameters, including pH, Electric conductivity, dissolved oxygen, total hardness, total alkalinity, sodium adsorption ratio (SAR), turbidity, total dissolved substances (TDS), total suspended solids (TTS), total nitrogen (TN), Chemical oxygen demand (COD) and Biochemical oxygen demand (BOD). Principal component analysis was conducted on each water quality index using SPSS software (v. 21.0, SPSS Inc, 2013) in order to quantitatively evaluate the water quality. First, three principal components are extracted, and then the water quality comprehensive evaluation index is established according to the contribution rate of the characteristic value of each principal component in initial eigenvalues *Eq.1*.

The formula for the comprehensive index of water quality is as follows.

$$Z_F = \frac{\lambda_1}{\lambda_1+\lambda_2+\lambda_3}\cdot F_1 + \frac{\lambda_2}{\lambda_1+\lambda_2+\lambda_3}\cdot F_2 + \frac{\lambda_3}{\lambda_1+\lambda_2+\lambda_3}\cdot F_3 \qquad \text{(Eq.1)}$$

where λ_1, λ_2 and λ_3 are eigenvalues of the first, second and third principal components, respectively. F_1, F_2 and F_3 are the calculated values of the three components, respectively.

Infiltration experiments

The infiltration experiments were carried out in Key Laboratory of Agricultural Soil and Water Engineering in Arid and Semiarid Areas, Ministry of Education, Northwest A&F University, China.

Two kinds of soils (wettable soil and repellency soil) were irrigated by six kinds of water with different quality in one-dimensional water infiltration experiments. The experiments consisted of 12 treatments, and each treatment was repeated 3 times. For convience, in the rest part of the paper, R and W are repellent sandy loam and wettable sandy loam, respectively; R-TW and R-TWW1~5 refer to the six water quality experiment waters that are ranked according to the comprehensive water quality index from small to large. Among them, TW is tap water, R-TWW1 is the water from outlet pool, R-TWW 2～5 are waters from sedimentation pool, catchment, anaerobic pool and oxidation pool, the same below.

The experiment device is shown in *Fig. 1*. The water supply device is a Marriotte bottle to provide a stable water head. The column is 80 cm in height 12 cm in diameter. The bottom of the column is equipped with a 10 cm of quartz sand filter layer to prevent air resistance. The soil sample is loaded into the soil column according to the actual bulk density of 1.65 g/cm^3. The soil is layered into the soil column and each layer is 5 cm. The layers were slightly roughened to prevent delamination. The soil column is 65 cm in height. The soil columns were placed for 24 hours after loading to make the soil moisture distribute evenly. A filter paper is placed on the surface of the soil column to resist the impact of water on the soil. Three paper scales are placed on the column to record wetting front. The water head is 3 cm in the experiments. The infiltration time was recorded using the stopwatch. During the first half hour of the experiments, the Mariotte scale and the wetting front were recorded at 5-min intervals. Subsequently they were recorded at intervals of 10-min from 0.5 h to 1.5 h, and 30-min after 1.5 h.

The Philip model (Philip, 1957) was used to fit the soil cumulative infiltration with time to further analyze the effect of water quality on soil infiltration. The mathematical expression of the model is as follows.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35773592

$$I = St^{0.5} + At \quad \text{(Eq.2)}$$

where, I is the cumulative infiltration, cm; S is the soil sorptivety, cm·min$^{-0.5}$; A is the stable infiltration rate, cm/min; t is the infiltration time, min.

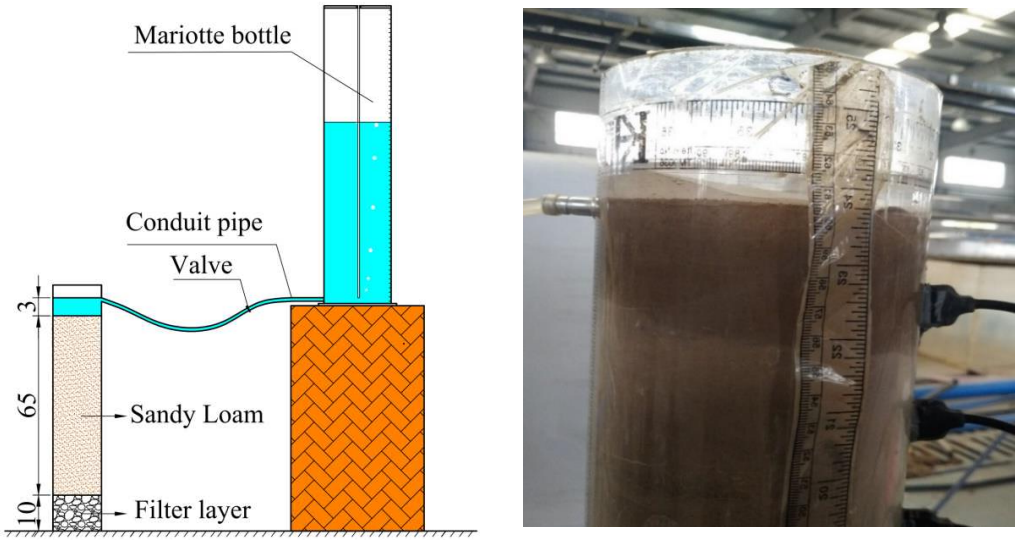

Figure 1. *Laboratory setup of one-dimensional TWW infiltration*

When the infiltration time of the experiment is as short as a couple of hours, the soil sorptivety (S) becomes the main influencing factor of water infiltration. That is, the effect of the stable infiltration rate A can be neglected. Then the *Eq.2* can be expressed as follows.

$$I = St^{0.5} \quad \text{(Eq.3)}$$

Then this paper uses the *Eq.3* to fit the cumulative infiltration and time.

In this study, SPSS 22.0 was used to conduct analysis of variance between means, and significant differences between the treatments were compared by the least significant differences test at a 5% probability, orthogonal design, Standard analysis of variance (ANOVAR) were used to evaluate the effect of the water quality on the infiltration.

Results and Discussion

Comprehensive evaluation result of water quality

Three principal components were extracted using principal component analysis of SPSS. The first principal component eigenvalue has the highest contribution rate of 38.35%. Total dissolved substances, sodium adsorption ratio and conductivity are the main factors of water quality index of the first principal component. The contribution rate of the second principal component eigenvalue is 35.89%. BOD, COD, the total dissolved oxygen, total nitrogen and total hardness are the main factors of the second main component. The total suspended matter and turbidity take up a larger proportion of the third principal component. The cumulative contribution rate of the three principal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35773592

components eigenvalue reaches 95.21%, which can basically represent the information of all 12 water quality indexes. A comprehensive evaluation index is established according to the contribution rate of the eigenvalues as is shown in *Eq.4*.

$$Z_F = 40.29\% \cdot F_1 + 37.70\% \cdot F_2 + 22.02\% \cdot F_3 \quad \text{(Eq.4)}$$

The comprehensive evaluation result of water quality is given in *Table 2*.

Table 2. *Principal component analysis results, the water quality comprehensive index and the naming of water samples*

Water sampling location	First principal component F_1	Second principal component F_2	Third principal component F_3	The water quality comprehensive index Z_F	Levels of TWW
Tap water	-1.812	-0.834	-0.415	-1.136	TW
Catchment	-0.133	1.372	-0.557	0.341	TWW 3
Anaerobic pool	0.197	1.007	-0.388	0.374	TWW 4
Oxidation pool	-0.063	0.117	2.032	0.466	TWW 5
Sedimentation pool	0.809	-0.748	-0.265	-0.014	TWW 2
Outlet pool	1.002	-0.914	-0.407	-0.030	TWW1

According to the water quality comprehensive index, the irrigation waters taken from different locations in the domestic sewage treatment plant are ranked from small to large of Z_F. The comprehensive water quality index of the outlet pool is the smallest, and the oxidation pond outlet is the largest. That might be because TWW needs to add biological bacteria such as nitrates for denitrification and absorption of easily degraded BOD before treated in the oxidation pond. After entering the sedimentation pond, mud and water are separated under the effect of coagulant drugs, and the water quality is greatly improved. For the convenience of the following description, TW represents tap water, TWW1, TWW2, TWW3, TWW4 and TWW5 represent the water of the outlet pool, sedimentation pool, catchment, anaerobic pool and oxidation pool respectively.

Effect of water quality on cumulative infiltration

The variation of cumulative infiltration of wettable and repellent sandy loams under different water infiltration conditions are shown in *Fig. 2*. The cumulative infiltration of different water quality in wettable sandy loam is significant (P value<0.05) (*Fig. 2a*). The cumulative infiltration amount increases with the increase of water quality comprehensive index. That is, the greater the comprehensive water quality index is, the faster the infiltration in wettable soil is. Taking 90 min as an example, the cumulative infiltration amounts of W-TW and W-TWW1~5 are 7.19, 13.13, 13.70, 15.48, 17.18 and 16.02 cm, respectively. When the wetting front reaches the end of 40 cm infiltration, the cumulative infiltration amount is 12.65, 17.3, 17.18, 18.19, 19.96 and 18.21 cm, respectively.

There is a significant difference between TWW and TW during the infiltration of water-repellent sandy loam (*Fig. 2b*). However, the difference among the five groups of TWW is significantly reduced relative to the wettable sandy loam. Taking 90 min as an example, the cumulative infiltration of R-TW and R-TWW1~5 is 6.17, 11.58, 11.74, 12.06, 15.53 and 13.15 cm, respectively. The cumulative infiltration of R-TW and R-TWW1~5 was 10.50, 16.85, 17.36, 17.68, 19.84 and 17.88 cm, respectively at the end of infiltration. Comparing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35773592

Fig. 2a and *Fig. 2b*, it is found that the cumulative infiltration in the water-repellent soil is smaller than that in the wettable soil with the same water quality. Taking W-TWW3 and R-TWW3 as examples, the cumulative infiltration of W-TWW3 is 13.70 cm and the R-TWW3 is 11.73 cm at 90 min. Therefore, it can be inferred that regardless of tap water or sewage water, the water-repellent soil will hinder its water migration and affect its infiltration rate.

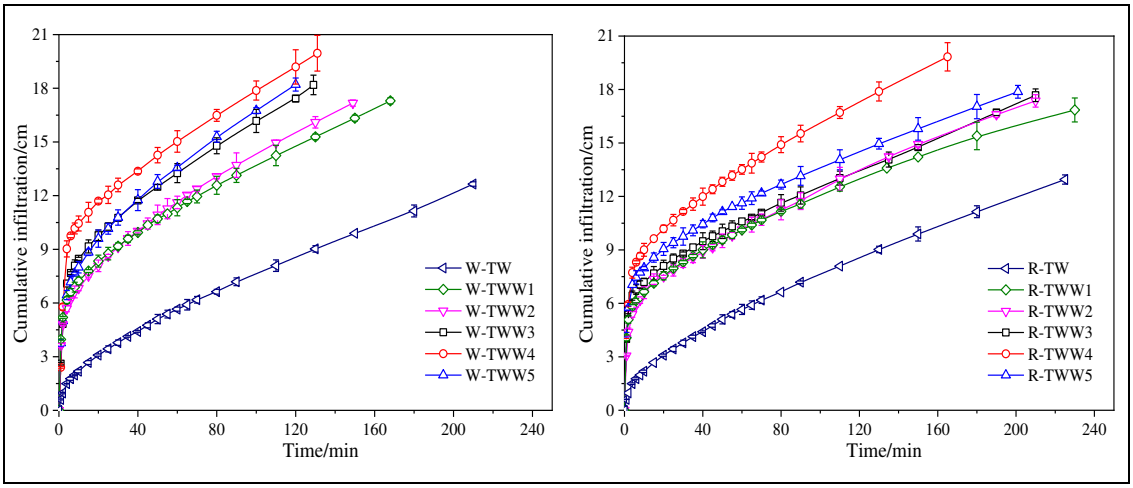

Figure 2. *The cumulative infiltration versus time for different water quality in repellent and wettable sandy loams, (a) Wettable sandy loam, (b) Repellent sandy loam*

Table 3 shows the relationship between the cumulative infiltration and time. The fitting accuracy of the Philip model of TWW infiltration is worse than that of tap water, but the coefficient of determination is greater than 0.7 and the root mean square error is small. Therefore, the curves fit well with the data with high Determination coefficient (R^2>0.988). There is a positive correlation between the infiltration rate and water quality (water from TW, TWW1 to TWW5) of wettable and repellent sandy loams. The infiltration rate of the wettable soil is higher than that of the water-repellent soil with the same kind of water. The regularity of the infiltration rate is the same as the law of cumulative infiltration.

Table 3. *The fitting parameters of the infiltration model*

Soil type	Treatment	Philip formula			Wetting front model		
		Sorptivety S (cm·min$^{-0.5}$)	Determination coefficient R^2	Root mean square error RMSE	Fitting parameter a (cm·min$^{-0.5}$)	Determination coefficient R^2	Root mean square error RMSE
Wettable sandy loam	W-TW	0.776	0.982	0.450	2.652	0.990	0.342
	W-TWW1	1.463	0.809	1.700	2.982	0.994	0.912

DOI: http://dx.doi.org/10.15666/aeer/1802_35773592

Effect of water quality on wetting front movement

The wetting front depth versus time for different water quality in wettable and repellent sandy loams is shown in *Fig. 3*. The variation of the wetting front depth is similar to that of cumulative infiltration in wettable sandy loam (*Fig. 3a*). When different water infiltrates the wettable sandy loam, the greater the comprehensive water quality index is, the greater the depth of the wetting front is at the same infiltration time. The infiltration times of W-TW and W-TWW1~5 are 210, 168, 149, 129, 131 and 120 min, respectively, when the wetting front depth reaches 40 cm in wettable sandy loam. The water quality has little effect on the wetting front depth of repellent sandy loam (*Fig. 3b*). The infiltration times of R-TW and R-TWW1~5 are 210, 168, 149, 129, 131 and 120 min, respectively, when the wetting front depth reaches 40 cm in repellent sandy loam. There is no significance difference between infiltration time and wetting front depth among the different irrigation water quality from TW, TWW1 to TWW5 in repellent sandy loam (P>0.05). The wetting front depth of the water-repellent sandy loam is smaller than that of the wettable sandy loam with the same water quality (*Fig. 3a* and *Fig. 3b*). The infiltration time of the water-repellent sandy loam is greater than that of the wettable sandy loam when the wetting front depth reaches 40 cm.

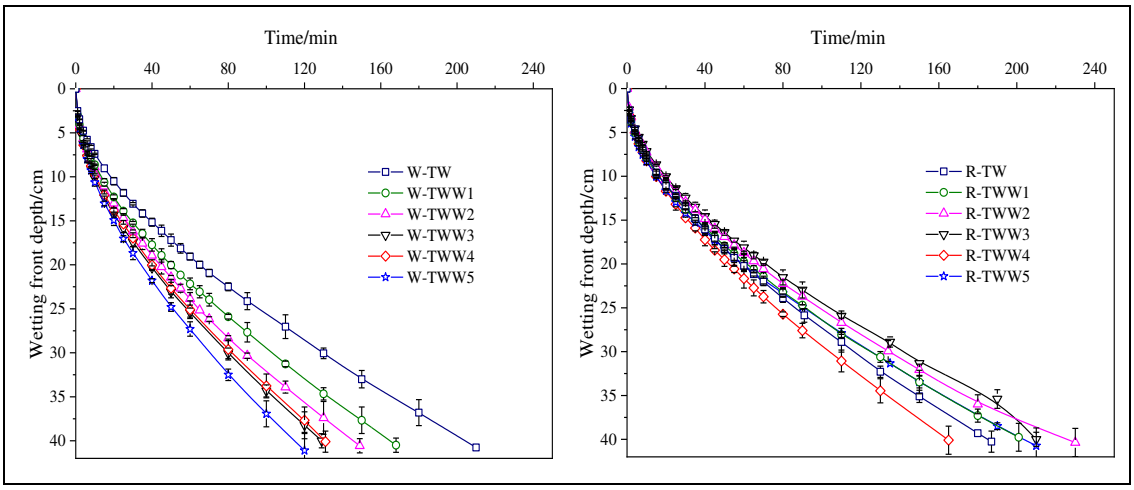

Figure 3. *Wetting front depth versus time for different water quality in wettable and repellent sandy loams, (a). Wettable sandy loam, (b) Repellent sandy loa*

The power function is used to fit the relationship between wetting front depth and infiltration time to analyze the effect of water quality on the soil wetting front. The mathematical expression of the model is as follows:

$$H = at^{0.5} \quad \text{(Eq.5)}$$

where H is wetting front depth, cm; a is the wetting front coefficient, cm·min$^{-0.5}$.

The wetting front model fitting result is given in *Table 3*. The fitting accuracy of the wetting front model (R^2> 0.98, RMSE <1.3) is high. Water quality has little effect on a in repellent sandy loam. The parameter a increases with the increase of the comprehensive water quality index in wettable sandy loam.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35773592

The effect of irrigation water quality on the infiltration is significant (*Fig. 2* and *Fig. 3*). The cumulative infiltration and infiltration rates generally increase with the increase of water quality comprehensive index.

The sorptivety of repellent sandy loam is smaller than that of wettable sandy loam with the same water (*Table 3*). According to the comprehensive water quality index from small to large (TW and TWW1~5), sorptivety decreases by 16.5%, 13.3%, 14.7%, 24.4%, 15.3% and 21.1%, respectively.

The effect of irrigation water quality on infiltration is mainly reflected in the influence of soil solute potential which is closely related to the conductivity in the water quality index. The higher the conductivity is, the greater the soil solute potential is, and the more obvious effect the water has on soil water movement. The electric conductivity value of TW is smaller than TWW (*Table 1*). Therefore, the cumulative infiltration of TWW is larger than that of TW irrigation. The cumulative infiltration shows little difference among the TWW due to the small difference in conductivity among them. It also shows the larger the conductivity is, the greater the cumulative infiltration is. The wetting front depth decreases with the increase of water quality comprehensive index in wettable sandy loam due to the large difference of solute potential. The solute potential is different because TWW contains many solute ions. The wetting front changes greatly with the same cumulative infiltration due to the different solute potential under the same condition of the matrix potential and the gravitational potential.

The water quality comprehensive index has no significant effect on the wetting front in repellent sandy loam because water repellency seriously hinders the water infiltration. So the solute potential caused by the substances contained is smaller than that of the water repellency of both TW and TWW in repellent soil. Therefore, the wetting front has no significance among TW and TWW1~5.

TWW contains many components. It's insufficient to use a single water quality index to analyze the effect of infiltration. For example, the total suspended matter in the water quality index describes the amount of insoluble matter in the water. The suspended matter will deposit on the surface layer or block the soil pores which make the soil surface crust and soil porosity reduction during the infiltration process. Then the soil infiltration rate and the hydraulic conductivity are significantly reduced. It is one of the causes of soil water repellency. However, the effect of suspended matter in TWW on soil pores during the short-term infiltration is not obvious due to the short experiments period in this study. The clogging is weak because of the large particles and soil pores in sandy loam. Soil infiltration rate and hydraulic conductivity decline significantly because the clogging, caused by sewage or TWW irrigation in soils with higher clay content, is obvious (Lado and Ben-Hur, 2009). Therefore, the suspended matter is an important index for long-term irrigation with TWW.

The water movement rate is high in the irrigation of wettable soil with the TWW. The irrigation time must be shortened when the irrigation volume is fixed, or it will cause deep leakage. The TWW contains more polluting ions which may cause groundwater pollution and soil nutrients loss (Lado and Ben-Hur, 2009). However, wetting front is of no difference under the same irrigation time interval in the irrigation of the repellent soil with the TWW. Then the greater the water quality index is, the greater the irrigation volume is. This will cause the water to stay in the upper layer of the soil for a long time, and it is difficult to reach the planned wetting layer of the irrigation design. At the same time, the evaporation of the surface layer increases, resulting in a decrease in water use efficiency. Therefore, the irrigation time should be

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35773592

reduced and high frequency and small flow discharge should be used in order to increase the effective irrigation depth for the soil for high water quality index in repellent soil.

Effect of COD on infiltration parameters

There are many causes of the water repellency in the soil (Bond, 1964; McGhie et al., 1980; King et al., 1981; DeBano, 1981; Jex et al., 1985; Stenstrom et al., 1989; Shakesby et al., 1993, 2006; Dekker et al., 2000; Chau et al., 2012; Jiménez-Pinilla et al., 2016). For sewage water irrigation, water repellency is caused by the increase of the organic matter in the soil (Morales et al., 2010; Chen et al., 2013). In the irrigation with TWW, the oil and grease content in the water has a great influence on the soil water repellency, and the soil water repellency increases with the increase of oil and grease (Travis et al., 2008). As the organic matter in the soil increases, the water repellency of sandy and clay increases. The organic matter in water is measured by COD value. During the infiltration, the organic matter and grease affect the surface tension of the liquid, which in turn affects the interaction between the soil particles and the water molecules. It will affect the capillary force during the movement of soil water. And these can be described by the COD value. The relationship between COD and sorptivety is shown in *Fig. 4*. The relationship between sorptivity *S* and COD is a power function.

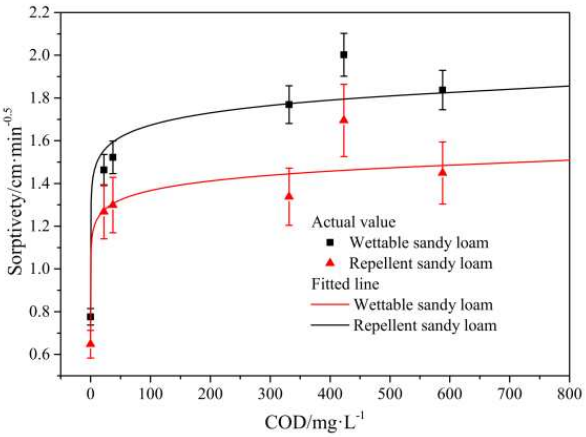

Figure 4. *The relationship between the soil sorptivety (S) and chemical oxygen demand (COD)*

The function is as follows.
Wettable sandy loam:

$$S_w = 1.322 \cdot (\mathrm{COD})^{0.053}, \ R^2 = 0.931 \quad \text{(Eq.6)}$$

Repellent sandy loam:

$$S_r = 1.104 \cdot (COD)^{0.046}, R^2 = 0.955 \quad \text{(Eq.7)}$$

The effect of COD on infiltration is obvious when COD is less than a certain value for wettable and repellent soils. When the COD exceeds the set value, the change of the infiltration rate is small although the COD has a large change.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35773592

With the infiltration change rate of 0.05 cm/min0.5 as the critical point, when the COD value of the irrigation water is greater than 170 mg/L for wettable sandy soil and 140 mg/L for repellent sandy soil, the COD has little effect on irrigation.

Therefore, the influence of COD on soil water infiltration must be considered. The Farmland Irrigation Water Quality Standard GB5084-2005 in China stipulates that the COD of irrigation water should be less than 200 mg/L for dry crop irrigation. According to this study, considering the effect of COD values on infiltration, we recommend that the COD value should be less than 170 mg/L for wettable sandy soil and 140 mg/L for repellent sandy soil in sewage irrigation.

Effect of comprehensive water quality indicators on infiltration parameters

The effect of water quality on infiltration can be seen from the above research. EC, TSS and COD all have an effect on infiltration. Previous studies focused on the impact of a water quality index on infiltration, but research shows that many water quality indexes affect soil infiltration (Singh et al., 2017; Misaghi et al., 2017; Leuther et al., 2018). Therefore, it is necessary to use comprehensive water quality indicators to analyze the impact of water quality on infiltration. The relationship between Z_F and sorptivety S was shown in *Fig. 5a*. The S of sandy loam increases with the increase of Z_F, and there is a positive linear correlation between them (R^2 is 0.980 and 0.950 for wettable and repellent sandy loams).

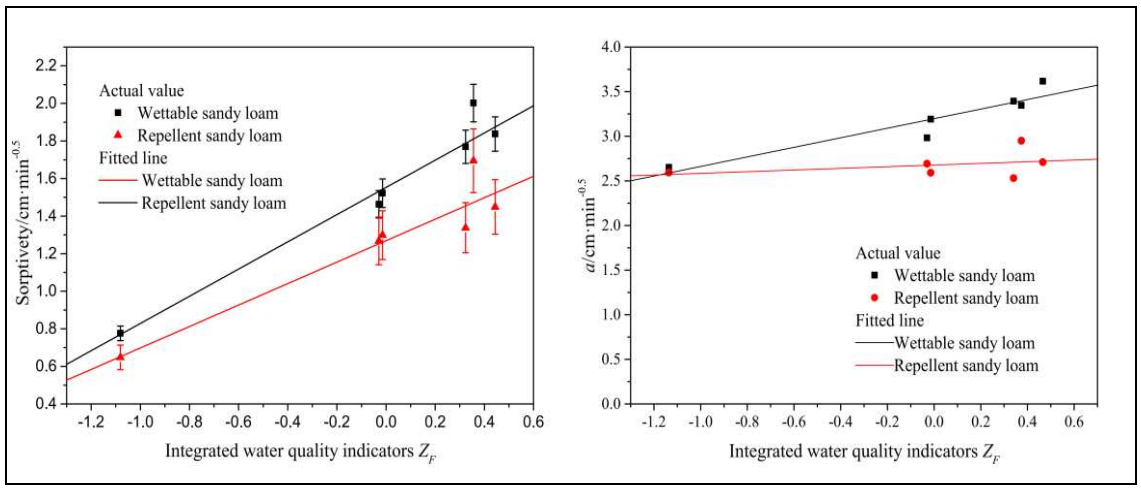

Figure 5. *Relationships between soil sorptivety (S), the wetting front coefficient a and comprehensive water quality index Z_F (a). soil sorptivety, (b) the wetting front coefficient a*

The function is as follows.
Wettable sandy loam:

$$S_{\mathrm{w}} = 1.553 \cdot Z_F + 0.724, \qquad R^2 = 0.980 \tag{Eq.8}$$

Repellent sandy loam:

$$S_r = 1.269 \cdot Z_F + 0.571, \mathrm{R}^2 = 0.950 \tag{Eq.9}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35773592

It can be seen that the larger the comprehensive water quality index is, the faster sorptivety of the soil is (*Eq.8*, *Eq.9*, *Fig. 5a*). The quality of TWW significantly facilitates soil infiltration. However, soil water repellency will lead to a decrease in soil infiltration rate when water infiltrates, and also slow down the tendency of infiltration rate to increase with the increase of the comprehensive water quality index. Soil water repellency will decrease soil infiltration and also slow down the tendency of sorptivety to increase with the increase of ZF. For wettable soils, the water quality of TWW is more significant in increasing soil infiltration. The sorptivety of the wettable sandy loam is larger than that of the repellent sandy loam with the same water quality (*Fig. 2* and *Table 3*). The effect of ZF on sorptivety of the wettable sandy loam is larger than that of the repellent sandy loam. Therefore, it is not advisable to increase the infiltration rate of the soil in order to reduce the irrigation time and simply increase the comprehensive water quality index. The selection of the comprehensive water quality index should be within a reasonable range.

It can be seen that the larger the comprehensive water quality index is, the faster sorptivety of the soil is (*Eq.8*, *Eq.9*, *Fig. 5a*). The quality of TWW significantly facilitates soil infiltration. However, soil water repellency will lead to a decrease in soil infiltration rate when water infiltrates, and also slow down the tendency of infiltration rate to increase with the increase of the comprehensive water quality index. Soil water repellency will decrease soil infiltration and also slow down the tendency of sorptivety to increase with the increase of Z_F. For wettable soils, the water quality of TWW is more significant in increasing soil infiltration. The sorptivety of the wettable sandy loam is larger than that of the repellent sandy loam with the same water quality (*Fig. 2* and *Table 3*). The effect of Z_F on sorptivety of the wettable sandy loam is larger than that of the repellent sandy loam. Therefore, it is not advisable to increase the infiltration rate of the soil in order to reduce the irrigation time and simply increase the comprehensive water quality index. The selection of the comprehensive water quality index should be within a reasonable range.

The relationship between the wetting front coefficient a and Z_F of the sandy loam is shown in *Fig. 5b*. The wetting front coefficient a increases with the increase of Z_F, and there is a positive linear correlation between them for wettable sandy loam. However, Z_F has little effect on the wetting front coefficient a due to the effect of water repellency in repellent sandy loam.

The relationship between the ratio of sorptivety S to the wetting front coefficient a and Z_F is shown in *Fig. 6*. There is a nonlinear relationship between S/a and Z_F. As Z_F increases, S/a shows a minimum point. The minimum point appears near 0.59 and 0.10 for wettable and repellent sandy loams respectively. S/a reflects the volume of water in the wetting body, i.e., the average increase in moisture content in the wetting front range. When Z_F exceeds 0.10 for the water-repellent sandy loam, the increase of S/a indicates that the wetting front coefficient is reduced with the same irrigation volume. That is to say, the increase of irrigation volume does not make the effective wetting depth increase significantly. Therefore, the value of Z_F should be less than 0.10 of TWW when irrigating repellent sandy soil. However, when the minimum Z_F value is around 0.59 for the wettable sandy loam, the water quality indicators have seriously exceeded the agricultural irrigation water quality standards in China, and it is not suitable for irrigation. Therefore, in the irrigation of wettable sandy loam with sewage, it is necessary to consider the impact of crop growth, environment, and long-term

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35773592

irrigation on soil water repellency rather than simply consider its influence on infiltration characteristics.

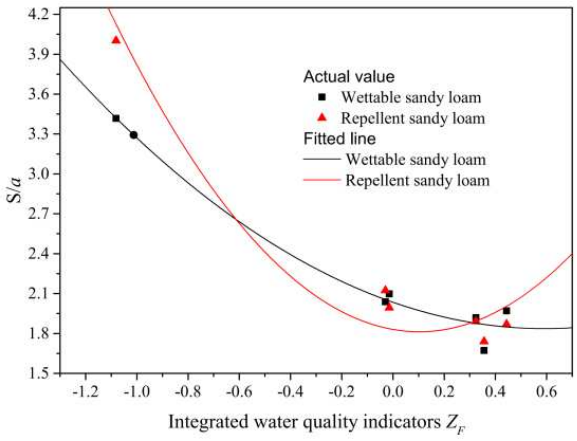

Figure 6. *Relationship between S/a (the ratio of sorptivety to the wetting front coefficient) and comprehensive water quality index* Z_F

Conclusions

Infiltration experiments were conducted on a wettable and a water repellent sandy loam with TWW to determine the water quality index and analyze the effect of water quality on wetting front and cumulative infiltration volume.

(1) The water quality has a great effect on the cumulative infiltration and wetting front of wettable sandy loam. The greater the comprehensive water quality index is, the greater the cumulative infiltration volume and wetting front are. But the water quality has a great effect on the cumulative infiltration but no effect on wetting front of repellency soil. Soil water repellency will decrease soil sorptivety (S). There is a power function relation and positive linear correlation between S and COD, S and Z_F, respectively. Meanwhile a quadratic polynomial relationship exists between the ratio of soil sorptivety S to the wetting front coefficient a and the comprehensive water quality index, and there is a minimum value in the curve.

(2) When both cumulative infiltration and wetting front requirements in TWW irrigation are taken into consideration, COD and Z_F should be less than 170 mg/L and 0.59, respectively, in wettable sandy loam while the two values should be less than 140 mg/L and 0.10, respectively, in repellency sandy loam. However, the study of this paper is relatively macroscopic, the changes in the microstructure between the reclaimed water and the soil pores need to be studied. When the soil water content is same, as the contact angle increases, the matrix suction will continue to decrease, making the soil infiltration rate slow down. Analyzing the relationship between the contact angle and the microstructure of soil pores during soil infiltration is a future research direction.

Abstract. Effective analysis of genotype by environment interactions (GEI) is helpful to screen stable genotypes in a variety of environments. Therefore, the purpose of this study is to test the stability and adaptability of the agronomic traits of maize hybrids from different ecological environments. Thirteen maize hybrids in twenty-six locations over two years (2017-2018) in Huanghuaihai region was conducted to compare the performance and stability of six agronomic traits using AMMI (additive main effect and multiplicative interaction) model and GGE (genotype, genotype × environment) biplot. The analysis of variance through AMMI model showed that genotype (G), environment (E), and GEI had significant effects on agronomic traits. E explains a larger portion of the total variation in grain yield (GY), ear weight (EW) and 100-grain weight (100-GW), to a much higher degree than GEI and G. However, compared to E and G, GEI contributed more to total variation in ear length (EL), kernel row number (KRN) and bald tip length (BTL). Comprehensive analysis of the AMMI model and the GGE biplot results showed that genotypes G2, G3, and G4 had better agronomic performance and stability than other genotypes and are ideal for planting.
Keywords: *genotype by environment interaction, stability, adaptability, agronomic traits, yield, agronomic traits*

Introduction

Maize (*Zea mays* L.) originated in Central and South America and is an important food crop in the world, widely distributed in the United States, China, Brazil and other countries. In China, maize is used as an important food, feed and industrial raw material. The domestic maize cultivation area was 42 million ha with the annual maize production was 260 million tons in 2017 (Wang et al., 2019). Since 2012, maize has surpassed rice and became China's largest food crop variety (Yang et al., 2019). The Huanghuaihai summer maize region is China's largest concentrated maize production area. The annual planting area accounts for more than 40% of the country's total area, and the planting area accounts for about 32% of the country's total planting area, the total output accounts for about 34% of the country's total output. In recent years, the planting area and yield of summer maize in this region have shown a gradual increasing trend, which plays an important role in ensuring national food security (Yue et al., 2018a). The farming system, soil, fertilizer, variety, cultivation management and climatic factors all have different effects on maize yield (Li et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35933614

2019). There is a wide difference in maize yield between the Huanghuaihai region, with an average yield of 5.3 tons/ha, a large area with a high yield of 7.5-9 tons, and a small area with a high yield of 15 tons. For most regions, there is a huge potential for increased production (Huang et al., 2019). High yielding and stable yielding of summer maize has always been one of the research goals of scientists all over the world, and it is also one of the difficulties. Analysis of the high yielding and stability of the representative hybrids, as well as the contribution of various yield components to yield, can effectively guide the production and breeding of maize in the Huanghuaihai region.

Screening and identifying good genotypes are very difficult due to the genotype (G) by environment (E) interaction (GEI). But assessing this interaction is important because it is the primary factor in genotypic performance changes under different environments. The GEI can weaken the association between maize phenotypes and genotype values, and leading to bias in the terms of genotypic effect assessment (Farshadfar et al., 2011; Mohamed, 2013). The GEI can make summer maize genotypes behave differently in different environments, especially in the Huanghuaihai region where the climate is complex and variable (Yue et al., 2019). The selection and breeding of important traits of maize genotypes is complicated by the cross-interaction between hybrids in different environments, and the result is that high-yielding and stable genotypes are easily overlooked (Mulema et al., 2008; Nzuve et al., 2013). In order to breed hybrids that meet people's living needs, it is necessary to systematically evaluate the yield, resistance and quality of the tested genotypes, and obtain basic data on adaptability, high yielding and stability in different ecological regions, comprehensive evaluation and screen out hybrids with excellent yield traits. At the same time, the discriminative power and representativeness of each testing site are evaluated, and the basis for selecting the ideal site for resource and hybrid screening is provided. Multi-environment trials (Mets) is a well-established method for identifying the high yielding and adaptability of different crop varieties. In the Mets, the newly bred varieties were tested according to uniform specifications, and their important characteristics such as high yield, stability, adaptability, stress resistance and quality were comprehensively identified (Navas-Lopeza et al., 2019).

There were many statistical methods for evaluating the GEI, such as, scientists have earlier proposed the coefficient of variation (CV) (Döring and Reckling, 2018), analysis of variance (ANOVA) (Fry, 1992), principal component analysis (PCA) (Perkins, 1972) and linear regression analysis (LRA) (Kang, 1993), but each method has its shortcomings. The coefficient of variation method describes the stability of genotypes, this method can only explain the difference in genotype effects, and does not explain the environmental effects and the interaction between genotypes and the environment. The study of the stability of the variety by linear regression does not reflect the adaptability of the genotype to the environment. The application of analysis of variance to evaluate the adaptability of genotypes cannot analyze the relationship between environmental effects and interaction effects (Blouin et al., 2015). In recent years, with the deepening of research methods, scientists have proposed two analysis methods of the additive main effects and multiplicative interaction (AMMI) model (Gauch, 1988) and the genotype plus genotype by environment (GGE) biplot (Yan et al., 2000) for GEI research. The AMMI model is a graphically unique linear-bilinear model based on a biplot, combining both the ANOVA and the multiplicative model (Yan et al., 2007). The AMMI model is an effective tool for studying genotypic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35933614

stability analysis and distinguishing the environment, and has been successfully applied to the research of various crops (Suwaero et al., 2011; Mortazavian et al., 2014; Ndhlela et al., 2014; Raggi et al., 2017; Mehdipour et al., 2019). The GGE biplot takes into account the G and GE effects and can simultaneously evaluate genotypes and the environments. At the same time, the GGE biplot gives information on the genotype and environment and their relationship, including determining the best variety in a particular environment, the most appropriate environment for a particular variety, and the performance of any two varieties in different environments. Which variety is a high yielding and stable yield. Which environment is conducive to the screening the varieties with high yielding and stable yield (Yan, 2001; Kaya et al., 2006; Dehghani et al., 2017; Oral et al., 2018).

In this study, the multi-environment test was conducted to analyze the yield and yield component traits of 13 tested maize hybrids using the AMMI model and GGE biplot data through the data of 26 test sites for 2 consecutive years, and the genotype-environment interaction effect was evaluated. The actual effect of maize grain yield and yield components, and the comprehensive yield components screen out excellent hybrids. At the same time, the GGE biplot is used to analyze the representativeness and discriminative power of the test sites.

Material and methods

Data of 13 tested genotypes used were maize hybrids recently approved by the National Crop Variety Approval Committee (NCVAC), including one check hybrid Zhengdan958 (G13), were evaluated in 26 locations during two consecutive years (2017-2018 growing seasons) in Huanghuaihai region, and the basic information of tested genotypes is given in *Table 1*. In this study, there were 26 testing sites in the multi-environment trials (Mets), which were derived from seven provinces of Hebei province, Shanxi province, Henan province, Shandong province, Anhui province, Jiangsu province and Shanxi Province. Agro-climatic description and the code of testing sites is given in *Table 2*.

We used the randomized block design with three repetitions in each testing site, and the experimental plot contained five lines (6.7 m long). The width between each line is 0.7 m, and the sowing density was used 7,5000 plants in per hectare which is widely used in local agricultural production. The grain yield (GY) was calculated in the middle three rows of each plot when harvested by manual harvesting. The two side rows were used to sample the ear length (EL), ear row number (ERN), bald tip (BT), kernel weight (KW) and 100-grain weight (100-GW). The fertilization situation of each plot depends on the soil nutrient analysis results of the plot.

Statistical analysis

AMMI model

The formula for the AMMI model was used (Gauch, 1992):

$$y_{ge} = \mu + \alpha_g + \beta_e + \sum_{n=1}^{N} \lambda_n \gamma_{gn} \delta_{en} + \theta_{ge} \quad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35933614

where y_{ge} represents the value of the genotype (g) in the environment (e); μ is the grand mean; is the average deviation of the *g*th genotype from the grand mean; is the average deviation of the *e*th environment from the grand mean; is the *n*th eigenvalue of interaction principal component axis (IPCA); and are the genotypic and environmental principal component score representing the *n*th principal component, respectively; is the error term. The AMMI model can also be used to rank genotypes in accordance with yield stability of the tested varieties. The AMMI stability values (ASVs) calculation can be performed according to the formula of Purchase (Purchase et al., 2000).

$$\mathrm{ASV} = \sqrt{\left[\frac{\mathrm{SS}_{IPCA1}}{SS_{IPCA2}}(IPCA_1)\right]^2 + (\mathrm{IPCA}_2)^2} \quad \text{(Eq.2)}$$

In the formula, SS_{IPCA1} and SS_{IPCA2} are the sum of squares of interaction principal component analysis 1 (IPCA1) and IPCA2, respectively.

GGE biplot

The GGE biplot is called the principal component analysis of environmental centralization. After subtracting the average value of the environment from the original data, the genotype is singularly decomposed in the interaction effect, and the formula as follows:

$$Y_{ge} - y_e = \lambda_1 \xi_{g1} \eta_{e1} + \lambda_2 \xi_{g2} \eta_{e2} + \varepsilon_{ge} \quad \text{(Eq.3)}$$

where Y_{ge} is the value of the *g*th genotype in the *e*th environment; y_e is the yield performance of all genotypes in the *e*th environment; ξ_{g1} and ξ_{g2} are the first and second principal component scores of the *g*th genotype in the *e*th environment, respectively; λ_1 andλ_2 are the eigenvectors of the first and second principal components, respectively; η_{e1} andη_{e2} represent the first and second eigenvector scores of the *e*th environment, respectively; ε_{ge} is the residuals in the model (Balestre et al., 2009).

Data analysis

In this study, the effects of the genotypes, environments and their interactions were calculated by analysis of variance (ANOVA) using Data Processing System (DPS) software (Tang and Zhang, 2013) in the AMMI model. The GGE biplot analysis using the Genstat 64-bit Release (Payne et al., 2013) to select the optimal environments and superior genotypes.

Results

Variations in six agronomic traits

It can be seen from *Figure 1* that the agronomic traits are significantly different. The coefficient of variation of the six agronomic traits is between 5.08 and 77.97%, with an average of 20.18%, and the coefficient of variation of the bald tip length is the largest. Statistics on six agronomic traits of thirteen hybrids in the twenty-six tested environments

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35933614

are shown in *Table 3*. The grain weight varied between 7227.91 and 12321.56 kg/t across environments, the ear length and bald tip length are between 12.85-21.35 cm and 0.00-9.90 cm, respectively. The change range of ear weight and 100-grain weight are between 103.00-214.25 g and 24.25-42.30 g, respectively. The minimum and maximum values of the kernel row number are 12.00 and 17.60, respectively. Further statistical values for six agronomic traits can also be seen from *Table 3*.

The AMMI model analysis

The results of AMMI model analysis exhibited the variations across mega-environments and genotype by environment interaction (GEI) had a significantly differences ($P < 0.001$, $P < 0.01$ and $P < 0.05$) for tested maize hybrid agronomic traits in 2017-2018 (*Table 4*). The genotype (G) and environment (E) of each agronomic trait had very highly significant effects ($P < 0.001$). The GEI effects on grain yield, bald tip length and 100-grain weight also reached very highly significant effects ($P < 0.001$). The GEI effects on ear length exhibited highly significant effects ($P < 0.01$), and there are significant differences ($P < 0.05$) were observed for kernel row number and ear weight. Furthermore, the AMMI model analysis decomposed the SS of GEI into eight interaction principal component axes (IPCAs), of which the first four IPCAs exhibited very highly significant differences ($P < 0.001$) for all agronomic traits. In terms of the ratio of the variance to the total SS, among the three agronomic traits of grain yield, ear weight and 100-grain weight, environmental effects accounted for 57.48%, 66.62% and 50.52% of the total sum of squares, respectively. The GEI as a second main effect contributed to 47.89%, 54.74% and 44.48% of the total sum of squares of ear length, kernel row number and bald tip length, respectively. Among all the six agronomic traits, genotype effects accounted for the lowest proportion. The first four IPCAs explained 64.62%, 70.71%, 65.22%, 84.41%, 69.72% and 62.97% of the interaction sum of squares of grain yield, ear length, kernel row number, bald tip length, ear weight and 100- grain weight, respectively, with IPCA1 contributing 22.23%, 30.82%, 21.30%, 60.42%, 25.74% and 19.71%, in which greater than other IPCAs.

The IPCA values, average performance of the agronomic traits and the ASV values of the tested maize hybrids are presented in *Table 4*. The IPCA value for a specific genotype in the AMMI model indicates the stability of this genotype throughout the environment. The difference in IPCA values (positive or negative) shows the genotype adapted to the specific environment, and the closer the IPCA value is to zero, the more stable the adaptation to the environment (Gerrano et al., 2019). Genotypes vary widely in yield performance between traits. The average grain yield of the genotypes G7 and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35933614

G9 was the lowest and highest in different environments, 9304 kg/ha and 10222 kg/ha, respectively. Other genotypes such as G1, G2, G3, G4, G5 and G8 have higher grain yields. Genotypes G8 and G10 are 16.11 cm and 18.20 cm, which are the worst and best hyrids of ear length, respectively. The performance range of the kernel row number of the tested hybrids was 14.36 to 15.66, which belonged to G4 and G3, respectively. The lightest of the bald tip length is G12, which is 0.38 cm. In contrast, bald tip length of genotype G6 has the highest value of 1.65 cm. Genotypes such as G10 and G5 is the champion of ear weight and 100-grain weight, respectively, and the yield performance is 159.00 g and 36.56 g, respectively.

Table 4. *The performances of IPCA1 to IPCA8 for interaction effect components of 6 agronomic traits of 13 maize hybrids*

IPCA: Interaction principal component axes; ASV: AMMI stability value

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35933614

In the AMMI model, genotypes with lower ASV values are considered to be more stable. Therefore, genotypes G6 and G11 have better stability of grain yield than other maize hybrids. By the same method and so on, the genotypes G3, G2, and G13 have better stability in ear length performance, G4, G1, G8, and G2 belong to the genotypes with better stability of ear row number, genotypes G6, G2, and G5 belong to the hybrids with better stability in bald tip length. We can also see from *Table 4* that genotype G13 followed by G7 and G9 followed by G8, G7, which belong to the hybrids with better stability of ear weight and 100-grain weight, respectively.

The adaptive analysis using GGE biplot

The "who-wins-where" views of the GGE biplot of grain yield, ear length, kernel row number, bald tip length, ear weight and 100-grain weight are shown in *Figure 2a, b, c, d, e* and *f*. The biplot consists of genotypes that are furthest from the origin in the same direction, and all genotypes are included. The biplot is divided into several sectors by vertical lines from the origin to the sides of the polygon, and the test sites fall in different areas in the sector. Test sites in the same sector are considered to have similar yield performance to genotypes, and these sites also belong to the same ecological group. In the same way, genotypes located in the same sector are considered to have similar performance to the environments of this sector. In the biplot, the genotype at the "vertex" position is considered to be the best-performing genotype in this sector (Duma et al., 2019).

GGE biplot analysis showed that the first two principal components (PC1 + PC2) accounted for 54.27%, 54.88%, 46.62%, 77.56%, 49.65% and 59.14% of the total variation in GEI of grain yield, ear length, kernel row number, bald tip length, ear weight and 100-grain weight, respectively. For grain yield, G9, G12, G10, G1, and G2 are connected into a polygon, and the five rays divide the polygon into 5 sectors. The first sector contains the test sites E1, E2, E5, E9, E10, E14, E15, E16, E17, E18, E20, E21, E23, E24 and E25, genotype G9 has the highest yield performance. There are no sites in the second, third, and fourth sectors, indicating that the "vertex" genotypes G12, G10, and G1 of these sectors did not perform well in all the sites. The fifth sector contains the remaining sites, with G2 performing best (*Fig. 1a*). For ear length, PC1 and PC2 in the GGE biplot explained 36.60% and 18.28% of the total variation of GEI, respectively. In this biplot, it can be divided into four ecological groups. The first ecological group contains twelve test sites, environments E2, E4, E5, E6, E7, E8, E10, E12, E14, E16, E19, and E23 fell into the first ecological group, environments E1, E11, E15, E20, E21 and E24 belong to the second ecological group, E13 fell into the third ecological group, and E3 and E9 belong to the fourth ecological group. The genotypes G10, G4, G8 and G12 belong to the champion hybrids of the first to fourth ecological regions, respectively (*Fig. 1b*). For kernel row number, PC1 contributed 31.48% while PC2 accounted for 15.14% of the total variation. This biplot consisted of three ecological group; where E1, E2, E5, E6, E8, E9, E10, E13, E15, E16, E19, E20, E22, E24 and E26 belong to the first ecological group; E23 fell in one group; the remaining sites are combined belong to the third ecological group. Genotype G11 had the highest yielding performance in the first ecological group, G12 was the winner in the second ecological group, whereas genotype G7 was the vertex hybrid in the third group (*Fig. 1c*). For bald tip length, the percentages of 53.10% and 24.46% are attributed to PC1 and PC2, respectively. In this biplot, only two ecological groups were found;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35933614

where E10 and E18 belong to one group; the remaining sites were divided into another group. Genotype G1 and G6 in the first and second ecological group are the vertex genotypes, respectively, which had the most bald performance (*Fig. 1d*). For ear weight, PC1 and PC2 accounted 30.63% and 19.02% of GEI, respectively. GGE biplot for ear weight grouped E2, E4, E12, E13, E14, E15, E16, E18, E19, E21, E24 and E25 as the first group and E1, E5, E6, E7, E8, E10, E20 and E22 belong to the second group. E26 and E1, E9, E9 were found in the third and fourth group, respectively. Genotypes G10, G2, G1 and G5 were found suited for the first to fourth group, respectively (*Fig. 1e*). For 100-grain weight, PC1 accounted for 48.16% of the variation caused by GEI, while PC2 accounted for 10.98% (*Fig. 1f*). Genotype G4 had the highest 100-grain weight performance in E1, E2, E5, E7, E9, E11, E12, E14, E16, E17, E18 and E22. No genotypes fell on E16, indicating that all genotypes did not perform well on E16. Genotype G5 was the top-ranking hybrid at the remaining sites.

Mean performance and stability analysis of the tested genotypes using GGE biplot

The use of the first two principal components axises formed a biplot related to genotypic performance. GGE biplot is an effective tool for assessing two aspects (mean performance and genotypic stability). The longer the vertical line of the genotype relative to axis 1, the lower the stability, and the longer the distance between the genotype and axis 2 (vertical to axis 1), indicated the higher yield (Badu-Apraku et al., 2012). *Figure 3* showed the average environment coordinate (AEC) of the GGE biplot of the agronomic traits of the tested hybrids. Thus, the genotypes G3, G4, G5, G8 and G13 had high grain yield combined with high stability. Genotypes G6 and G11 had good stability, however, these genotypes had no promising performance with grain yield. Based on these interpretations, although G9 has a high grain yield, it has poor stability and is not an ideal genotype (*Fig. 3a*). Genotypes G3, G9, G10 and G11 had longer ear length and good stability, whereas G4, G5 and G12 were highly unstable with longer ear length performance. Genotypes G4 and G5 had higher ear length performance, but had poor stability (*Fig. 3b*). The mean kernel row number of tested genotypes were arranged in the following order: G11 > G5 > G3 > G10 > G2 > G7 > G1 > G4 > G8 > G6 > G13 > G9 > G12. The performance of genotypes G7 and G11 had the worst stability, whereas genotypes G5, G3 and G10 were highly stable with high kernel row number (*Fig. 3c*). Genotype G6 had the highest mean bald tip length, followed by G5, G1, G11, etc.; and G12 had the lowest mean bald tip length. In terms of stability, genotype G2 was the most stable hybrid whereas, G1 was the least stable genotype (*Fig. 3d*). G13 was the most stable genotype with an average ear weight performance. Genotypes G2, G5 and G10 were the most unstable with a high average performance of ear weight (*Fig. 3e*). The biplot showed the ranking of 13 tested maize genotypes based on their average 100-grain weight and stability performance (*Fig. 3f*). The 100-grain weight performance of genotype G5 was the highest and that of G11 was the lowest among all 13 tested genotypes. From the perspective of crop breeding, breeders prefer genotypes with high average yield and high stability as potential ideal genotypes. In the biplot, the more stable genotype should be close to the average environment (the center of the small circle), and it should also have the shortest vector (Bai et al., 2014). Based on this information, although G5 had the highest 100-grain yield performance among all the genotypes, it is still less stable compared with genotypes G7, G8 and G9.

Judging the best genotypes based on the GGE biplot

The concept of 'ideal genotypes' should show high yielding and stability within a mega- environments (Yan and Tinker, 2006). However, we know that ideal genotypes do not exist in reality. Studies have also shown that, compared to average performance and stability, different concentric circles were drawn to help clearly distinguish the distance between each genotype and the ideal genotype, the distance between a genotype and an ideal genotype is also an important parameter for evaluating genotype performance. The closer the genotype is to the center of the circle (the position of ideal genotype), the better the average yield and stability of this genotype. On the contrary, being far away from the center of the circle represents the worst performance of this genotype is defined as the undesired genotype (Erdemci et al., 2018). Based on these, the genotypes G5 and G2 were located on the innermost concentric circle of the biplot, and are closer to the center of the circle than other genotypes. Therefore, these two genotypes (G5 and G2) can be considered as the genotypes closest to the ideal genotypes. In addition, genotypes G6 and G8 were located on the next concentric circle, and these two genotypes were considered desirable genotypes in terms of grain yield. In contrast, genotypes G10 and G12 were located on the outermost concentric circles, which are farther from the center of the concentric circles than other genotypes, may be regarded as undesirable genotypes (*Fig. 4a*). Given that the genotype G10 was located near the first concentric circle and closer to the ideal genotype position, it can be used as the genotype closest to the ideal genotype for evaluation in terms of ear length. Next to genotype G10, compared to other maize hybrids, G9 and G11 were the more desirable genotypes. On the other side, genotype G8 belong to the undesirable hybrid and implying poor performance in all environments (*Fig. 4b*). Genotype G5 belong to the most favorable genotype owing to was closest to the center of the concentric circle, whereas, G12 had the worst performance of kernel row number (*Fig. 4c*).

In the first circle, genotype G15 was found. Therefore, this was an ideal genotype in terms of obtaining a higher average bald tip length and good stability in the tested environments. Genotype G12 was located in the last circle, with the worst average baldness length and general stability compared to other tested maize genotypes (*Fig. 4d*). According to *Fig. 4e,* genotype G10 was highly "ideal", followed by genotypes G4, G5, G9, etc., and these genotypes can be considered as desirable genotypes. On the other hand, G1, G7, G11 and G8 were very poorest for average ear weight, classify them as undesirable genotypes in all environments. Compared with other maize genotypes, G4 fell into the center of concentric circles was ideal genotype, with higher 100-grain weight and good stability. In addition, next to G4 were the genotypes G5, G8 and G9, which were considered as the promising genotypes. In contrast, G11 was the furthest from the center of the circle, followed by genotypes G7, G1, G13, and G2, which were considered the least promising genotypes (*Fig. 4f*).

Discussion

In view of the vast area of the Huang-Huai-Hai region and as the largest area of centralized maize cultivation in China, it is particularly important to test and evaluate the stability and adaptability of different maize genotypes before large-scale planting (Yue et al., 2018). The performance of maize agronomic traits was affected by multiple factors, such as the genotype itself, environmental conditions, and the interaction between genotype and environment. Compared with genotype (G) and environment (E),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_35933614

the genotype by environment interaction (GEI) was the most difficult to grasp and control due to its uncertainty. The expression of many traits, such as crop yield, ear length, 100-grain, etc., were significantly affected by the GEI, and it effects on yield will affected yield stability directly. If the GEI effect was greater, the genotypes' stability was worse. Genotypes with high yielding and stable under multi-environmental trials (Mets) generally had broad adaptability and great value for promotion and utilization, genotypes with poor yielding and unstable but had special adaptability to local environments also had high recommendation. Screening and evaluating high-yielding and stable genotypes in various of environments has been an ongoing challenge for agronomy breeders worldwide (Lin et al., 1992; Alwala et al., 2010). The analysis of the Mets data of most genotypes were based on the data of a single trait (such as yield, quality or resistance), but multiple traits need to be considered simultaneously during the breeding practice. The conclusion based on the comprehensive analysis of single trait components is more important than the conclusion of single trait analysis (Kendal et al., 2016a). According to the analysis of single-yield traits of hybrid maize, only genotype total yield data can be obtained. ear length, ear row number, bald tip length, ear weight and 100-grain weight data and the main factors affecting these data cannot be obtained from the total yield. The purpose of Mets was to identify superior genotypes under different environments. Because of the existence of unpredictable environmental factors, researchers have developed different analytical models (GE, GEI, GGE, AMMI) to explain the effects of genotype, environment, and their interactions. So far, the AMMI model and the GGE biplot were the recommended methods for analyzing the GEI effect across the mega-environments (Kendal et al., 2019). According to reports, the AMMI model was a comprehensive and effective method because it can classify genotypes based on the genotype level combined with the target environment and classify them according to their advantages and disadvantages in different environments. Compared with other methods (such as joint regression methods), this model was a valuable statistical tool for identifying genotypes with specific or broad adaptability, which may be an important advantage of this method. On the other hand, the GGE biplot has been successfully used in Mets of various crops, which can concisely and effectively distinguish the best performing genotypes in the entire environment, so that specific genotypes can be recommended to specific large environments and the yield and stability were fully evaluated (Kendal et al., 2016b).

In this study, the AMMI model analysis indicated that the main effect of G, E and GEI were important among agronomic traits (*Table 5*). By analyzing the proportions of G, E, and GEI of the total variation, the six traits can be divided into two categories. The first category was grain yield (GY), ear weight (EW) and 100-grain weight (100-GW). These three agronomic indicators reflect a phenomenon that the proportion of environment effect was the greatest, followed by GEI and G, which ranged from 3.89-, 11.37- and 2.37-fold the genotype effect for GY, EW and 100-GW, respectively. This suggesting that maize breeders can either choose to set a specific genotype for each environment, or can choose excellent genotypes in a wide range of environments. Correspondingly, ear length (EL), kernel row number (KRN) and bald tip length (BTL) belong to the second category. This type of agronomic traits reflected the largest proportion of the total variation was GEI effect, followed by E and G, which ranged from 2.68-, 6.00- and 2.10- fold the genotype effect for EL, KRN and BTL. It has often been shown in the Mets that agronomic traits variations due to GEI effect exceed that due to genotypes effects (Dehghani et al., 2016).

DOI: http://dx.doi.org/10.15666/aeer/1802_35933614

The effect of GEI on agronomic traits can be confirmed by the ear length of each genotype varied from 12.85 cm (corresponding to G8 at environment E26) to 21.35 cm (corresponding to G11 at environment E18) (*Table 3*), it was shown that the ear length performance of 13 genotypes in 26 environments had considerable variation. Further analysis of the AMMI model, in the face of different parameters, because of the stability analysis using multiple IPCA numbers, it was better than the stability analysis using the first IPCA score. Hence, combined with the ASV results in this study, G9 had a higher performance of GY, but the worst stability. However, G6 had the best stability, the GY was moderate. According to comprehensive analysis, genotypes G2, G3, G4 and G8 were high yielding with outstanding stable in GY. Similarly, genotypes G2, G3 and G4 also showed better agronomic performance and stability in agronomic traits, like EL, KN, GTL, EW and 100-WG compared with other genotypes. In production practice, genotypes with showing good adaptability in agronomic traits across all the environments were favored by plant breeders. Conceptually, successful genotypes not only had high agronomic trait values, but also showed good stable performance in different ecological environments (Mohammadi et al., 2017). However, we should not ignore those genotypes that had special adaptability to individual environments. For instance, genotypes showed higher EL (i.e. G8 at environment E13 and G12 at environments E3, E9), genotype G5 showed higher EW at environments E3, E9 and E11. Because of the existence of GEI, both the AMMI model and GGE biplot could well explore the variations in Mets data, and the two methods had proven to be similar in practice, which leads to basically the same conclusion (Mitrovic et al., 2012; Vaezi et al., 2017; Yue et al., 2020).

Conclusions

This result of research revealed that agronomic traits like GY, EW and 100-GW of tested maize hybrids were highly influenced by E effect, followed by GEI effect and G contributed the least, other agronomic traits EL, KRN and BTL were highly influenced by GEI effect, followed by E effect and G. For the maize agronomic traits GY, EL, KRN, EW and 100-GW, the larger the field performance value, the more the breeder likes, but the BTL was just the opposite. The results of the GEI study indicated that the environments in this research had an opposite effect on genotypes performance. For instance, genotypes G2 and G5 had opposite results for 100-KW in the tested environments. Genotypes G2, G3 and G4 showed the best performance and stability in agronomic traits. These genotypes could be considered as the desirable hybrids with similar ecological region. It turns out that the AMMI model and GGE biplot were approximately equal for the analysis results of this study, and thus the conclusions of the genotypes with the highest agronomic performance and stability were basically the same. Considering the enormous impact of environment and genotype by environment interactions on agronomic traits of summer maize hybrids, maize breeders across China are encouraged to conduct further experiments in more seasons and elsewhere in agro-climatic regions.

(Received 17th Dec 2019; accepted 23rd Mar 2020)

Abstract. Increasing the efficiency of phosphorus (P) fertilizers is very important for using natural sources as well as minimizing possible environmental risks. Therefore, the effects of P, applied as mono-ammonium phosphate (MAP) in different forms (liquid and granule) and soil amendment containing humic-fulvic acids (HA + FA), on the growth and P uptake of model plant bread wheat (*Triticum aestivum* L. cv. Adana-99) and vertical movement of P in a calcareous soil were investigated. The application of P in a liquid form enhanced both P uptake and shoot growth in comparison to its granule form. However, HA + FA application had no effect on either P uptake or plant growth. Although the HA + FA did not affect biomass yield, it had a strengthening effect on vertical movement, even for P applied as a granule. The application of P in liquid form not only increased P movement in the soil but also enhanced the P nutritional status of wheat. In conclusion, the results, in a supportive manner to formerly obtained limited results, showed that the application of P containing liquid fertilizers, in comparison to granular ones as well as HA + FA addition might increase the efficiency of P fertilizers; and thus enhance yield and minimize the environmental concerns, as well.
Keywords: *nutrient efficiency, fluid, granule, phosphorus uptake, soil amendment*

Introduction

Increasing human population together with incorrect and unconscious consumption of natural resources necessitates a specific need to increase crop productivity per area. That is why the main objectives of today's agriculture are as follows: i) raising of crop yields to higher levels and ii) sustainability. Increasing the agricultural production to maximum levels will be possible by either expanding production areas or obtaining better yields per area. Since a further increase in existing agricultural areas does not seem feasible/possible, obtaining a higher yield per area appears to be the real target. One of the most critical factors that may ensure higher yields per area in a sustainable manner is sustainable plant production practices. As a well-known phenomenon, nutrient deficiencies are in the forefront among factors limiting the development of sustainable plant production (Fageria and Baligar, 2005) and 30-50% of the total increase in world food production since the 1950s has come about due to fertilizer additions (Stewart et al., 2005).

Agricultural production depends on phosphorus (P), which is a non-renewable natural resource derived from phosphate rocks (Cordell et al., 2009). However, a conflict exists with regard to how many years the available phosphate resources will last. While van Kauwenbergh (2010) opined that existing phosphate rocks reserves would be exhausted in 300-400 years or more, others emphasize that they would only last for 50-100 years (Cordell et al., 2009).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36153626

As it is well recognized, P has the highest far-reaching effect after nitrogen (N) in both natural and agricultural ecosystems among fertilizer nutrients (Brady and Weil, 2008). However, approximately 5.7 billion ha of agricultural land on Earth contains P lower than the optimum level (Mouazen and Kuang, 2016).

Soil organic matter, pH, and exchangeable and soluble aluminum (Al), iron (Fe), and calcium (Ca) affect the availability of P for plant growth (Ulrich and Schnug, 2013). Since the mobility of P in soils is limited and, what is considered worse, exposed to fixation at high rates, plants cannot use it effectively. Plants can use only 10-25% of the P in fertilizers applied to the soil during the application season (Syers et al., 2008). In such a way, plants in the year of application use only a few portions of P in fertilizers, and the effectiveness of any residual P fertilizer decreases with time (Lombi et al., 2004a, b).

Alkaline soils represent a very significant part of the agricultural production area of the world (Holloway et al., 2001). According to the Food and Agriculture Organization (FAO), almost 800 million ha of soils worldwide are calcareous and mainly located in arid or semi-arid climates of both hemispheres (FAO, 2001). In general, high pH, clay, lime, and low organic matter are known as factors limiting the availability of P in soils (Gallet et al., 2003; Franson et al., 2003).

In calcareous soils, the application of fluid forms of P fertilizers results in higher P mobility (Lombi et al., 2004 a, b) and availability (Holloway et al., 2001). In the andisols and oxisols, as well, greater P diffusion is observed with the fluid form in comparison to the granular one (Montalvo et al., 2014), However, in contrast to calcareous soils, the liquid form of P does not have an enhancing effect on P availability in andisols and oxisols - lability and solubility (Montalvo et al., 2014).

It is well-known that the addition of soil amendments such as HA + FA may have positive effects on plant growth (Arjumend et al., 2015; Canellas and Olivares, 2014; Quilty and Cattle, 2011) and support the root development (Canellas and Olivares, 2014; Quilty and Cattle, 2011). Also, this application may increase the mobility/availability of fertilizer P (Zhen-Yu et al., 2013) and its recovery (Delgado et al., 2002).

For the above-mentioned reasons, it was evident that studies aimed at increasing the efficiency of P containing fertilizers may have outstanding contributions to plant production, thereby quelling the environmental concerns. Therefore, using a subsoil known for its low P availability and low P fertilizer use efficiency due to high pH, clay content, lime, and few organic matter, two experiments were designed. In the first experiment, to view the effects of different forms of MAP (fluid or granular) and soil amendment (HA + FA) applications on growth and P uptake, a pot experiment was set up using bread wheat (*Triticum aestivum*) as a model plant. Also, a column experiment was set up to analyze the effects of the above-mentioned variants on vertical P transport.

Materials and methods

Experimental soil and basal fertilization

The soil material used in the present work was clayey (63.5% clay, 19.6% sand, 16.9% silt), calcareous (17.8% $CaCO_3$), alkaline (pH 7.5), and low organic matter containing (0.12% OM) subsurface soil. The available P and potassium (K) contents of soil were found to be 1.5 kg $P_2O_5 \cdot ha^{-1}$ and 462 kg $K_2O \cdot ha^{-1}$, respectively.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36153626

The experimental soil was fertilized with the following rates of basal nutrients (in $mg \cdot kg^{-1}$ soil): 200 N (as NH_4NO_3 + [MAP]), 100 K (as K_2SO_4), 5.0 Fe (as Fe(III)EDDHA, 2.5 Zn (as $ZnSO_4 \cdot 7H_2O$), 2.5 Mn (as $MnSO_4$), and 1.0 Cu (as $CuSO_4 \cdot 7H_2O$). As mentioned earlier, the soil had very low P availability, so a basal P fertilization was also included in the amount of 5.0 $mg \cdot kg^{-1}$ soil as TSP. Since varied amounts of NH_4-N came from different rates of MAP, after subscription of those NH_4-N amounts from the total N (200 $mg \cdot kg^{-1}$ soil), the rest of it was added using NH_4NO_3.

Fertilizer forms, HA + FA, and P uptake - Experiment I

In this part, a pot experiment was conducted in a growth chamber under controlled climatic conditions [light:dark periods, 16:8 h; temperature (light:dark), 22:18 °C; relative humidity (light:dark), 60:70%; photosynthetic flux density, 250 μmol $m^{-2}s^{-1}$] to view the effects of fertilizer forms and their application rates, presence of HA + FA mixture as soil amendments on plant growth, and P uptake using pots contained 1 kg of soil in each. For this, a bread wheat cultivar (*Triticum aestivum* L cv. Adana-99) was used as a model plant. While MAP-P was added at three rates (0, 25, 50, and 100 mg $P \cdot kg^{-1}$ soil) as either granule or fluid, HA + FA mixture was applied at two rates (0 and 125 mg $[HA + FA] \cdot kg^{-1}$ soil) using a commercial product (TKI-Hümas, Coal Enterprises Association of Turkey). The HA + FA mixture, together with other basal nutrients (given above) was mixed with soil. Thereafter, all of the granular and fluid MAP applications were performed 2.5 cm below the soil surface shortly before sowing. While granule numbers were kept equal for each rate of P (6 granules per pot) to eliminate the effect of spatial variations, liquid applications were performed in 50 mL of distilled water. After sowing five seeds per pot, seedlings were thinned to 3 $plants \cdot pot^{-1}$. Every two days, pots were regularly weighed and watered at 50% of the field capacity for the first week and 75% for the following weeks. At the end of the 30-day experimental period, the shoots were harvested, dried at 65 °C, weighed, and dry ashed; then, P concentrations were determined. After the above-ground parts were cut off, the roots in pots were washed carefully with deionized water, and dried at 65 °C to measure their dry weights. Thereafter, their P contents were determined as well.

Fertilizer forms, HA + FA, and vertical P transport - Experiment II

A disrupted soil column experiment was designed to investigate the effects of fertilizer forms and HA + FA on the vertical transport of P in soil. Here, columns prepared with an inner diameter of 6.9 cm and a height of 23 cm were used (*Fig. 1A*). In the middle of the 0-5 cm, 5-10 cm, 10-15 cm, and 15-20 cm sections below the first 3 cm from the top, there were 4 mm holes in which soil solution sampling sticks of 2.5 mm diameter existed. The columns were filled with soil subjected to incubation with 5 or 100 mg $P \cdot kg^{-1}$ soil, with or without application of HA + FA at 125 mg HA + $FA \cdot kg^{-1}$ soil level for two weeks, at a bulk density of 1.1 $g\ cm^3$. In the experiment, the application forms were a granular and fluid MAP, and the application dose was 100 mg $P \cdot kg^{-1}$ soil. Both types of MAP were employed 2.5 cm below the soil surface, and deionized water was added to the columns until they reached field capacity. Twenty-four hours after application, the samples of soil solution were taken using soil solution samplers (Rhizone Sampling), which were made of a porous plastic material (*Fig. 1B*) and sucking them with the help of vacuum tubes. Since the pore diameters of the samplers are 0.15 μm, the P measured in the solutions obtained is deemed to be colloid-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36153626

free soil solution P (McDowell and Sharply, 2001; Shand et al., 2000). Since the sophistication of experimental design (especially solution sampling step) would not let us have multiple replicas in *Experiment II*, statistical analysis was *not applicable*.

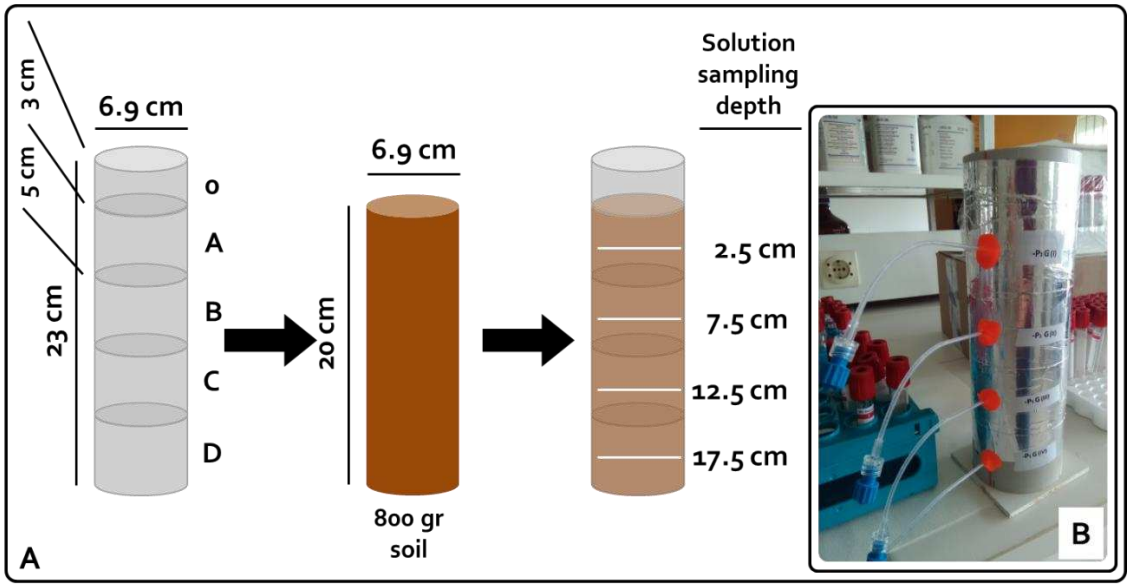

Figure 1. *Experimental design of fertilizer forms, HA + FA, and vertical P transport experiment. (A) Design of a column and solution sampling points in it and (B) a column ready for sampling*

Statistics

All the values obtained in *Experiment I* were subjected to analysis of variance using the statistical package software 'SPSS STATISTICS 20'. Since there was no statistical effect of HA + FA recorded for each parameter measured, traits with or without HA + FA application were evaluated separately. The averages of measured parameters with different traits were compared using the Duncan test at the probability level of $P \leq 0.05$, and the differentiating averages were shown with different characters.

Results

Fertilizer forms, HA + FA, and P uptake - experiment I

Plant growth

Even though soils fertilized with a basal P level of 5 mg $P \cdot kg^{-1}$ soil, due to shallow Olsen P level of soil, were used in the experiment, the control plants showed very severe P deficiency symptoms. On day 24, grayish-brown necrosis, which was different from typical P deficiency symptoms such as growth regression in shoot growth and purpling on old leaves, was visible. As the symptoms on control plants became severe, the experiment was terminated on day 30.

The plant observations at harvest showed that P application, together with increments in P rates, had a positive effect on plant growth. In *Table 1*, there are some growth parameters such as shoot and roots dry weights and root-to-shoot ratios. As given in this

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36153626

table and *Figure 2*, the P applied in the fluid form of the MAP showed a statistically important higher effect on the shoot growth of plants compared to the ones supplied with the granular MAP. Compared to plants provided with the fluid MAP, root/shoot ratios, an indicator of P nutrition of plants, of plants fertilized with granule MAP in both the presence and absence of HA + FA were higher, and this was statistically important (*Table 1*). Although increasing P application rates had a positive effect on both shoot and root dry weights of bread wheat, HA + FA mixture used as soil amendments did not affect plant growth (*Table 1*). Also, *Figure 2* taken on the day of harvest shows that independent of HA + FA application, tillering density and stalk thickness was higher in plants supplied with a fluid MAP than granule MAP.

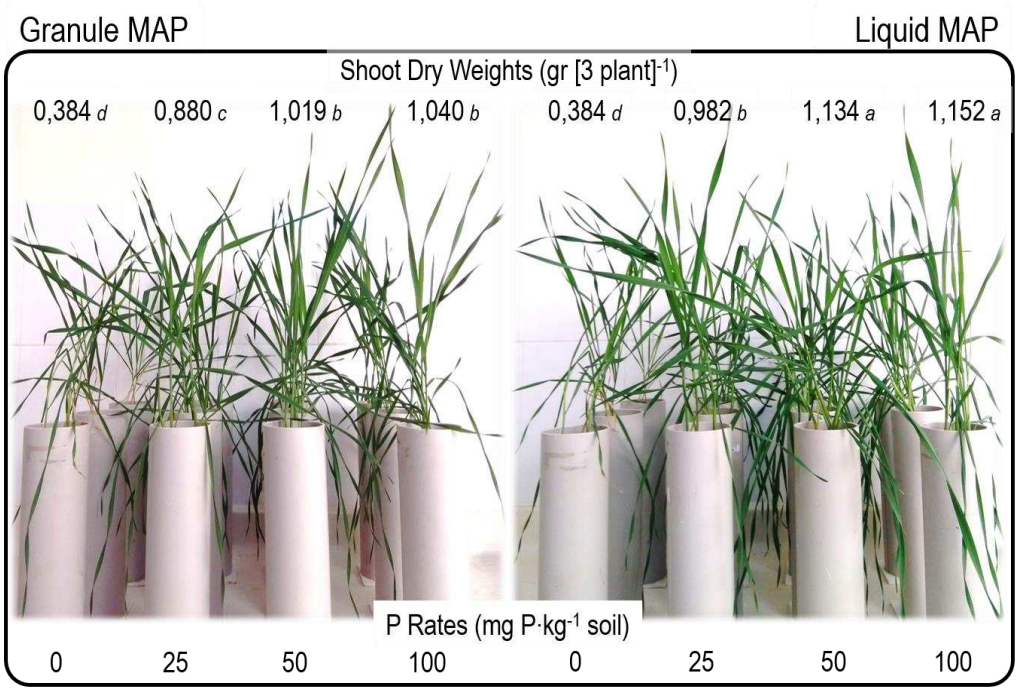

Figure 2. *Shoot dry weights and growth of model plant bread wheat grown with fluid or granule forms of the MAP and different P rates (- [HA + FA]). Dry weight values are means of three independent replicates. For each trait, numbers with different letters are significantly different from each other at $p < 0.05$, according to ANOVA and Duncan's test*

Phosphorus uptake

As clearly seen in *Table 2,* independent of the application form of MAP-P and HA + FA addition, increasing rates of P moved the P contents per shoot or root dry matter up in comparison to the control plant. However, this increment was more evident for the plants grown with fluid MAP, and the effect was statistically significant as well. Even the P concentration in the shoot of plant supplied with the fluid MAP at the lowest P rate was higher than granule applications at all P levels without HA + FA (*Table 2*). Parallel to this, when plants were supplied with HA + FA, the P concentration in the shoot of plants supplied with the fluid MAP at the lowest P rate was similar to plants provided with granule MAP at the highest P rate and higher than the other two lower P rates (*Table 2*).

As a result of better growth and higher P uptake, independent of the application forms of MAP and HA + FA application, increasing rates of P enhanced the P content

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36153626

per shoot, roots, and whole plant in comparison to control plants (*Table 3*). Moreover, with or without soil amendment application, the P content per shoot, roots, and whole plant in plants grown with fluid or granule form of MAP considered together, it was seen that plants supplied with fluid ones had higher P contents and this difference was statistically significant (*Table 3*). The P content per plant with or without HA + FA application showed that there was no difference among the plants.

Fertilizer forms, HA + FA, and vertical P transport - Experiment II

The results of the disrupted soil column experiment, which was conducted to investigate the effects of fertilizer forms and rates and HA + FA on the vertical transport of P in the soil, are displayed in *Table 4*. As mentioned above, the columns prepared with an inner diameter of 6.9 cm and a height of 23 cm were used (*Fig. 1A*), and P was applied either as fluid or granule to the horizontal mid-point of the top cylinder. After a 24-h incubation period, the soil solution samples were taken from the middle of each cylinder using a soil solution sampler to analyze them for P (*Fig. 1B*).

Table 4 shows the P concentrations in soil solution samples. As it is clearly reflected, the vertical movement of MAP-P, which was applied as granule with or without HA + FA application, was much lower than when it was applied as fluid. In the columns supplied with the granule MAP-P and no soil amendment, and in the soil solution samples taken from 7.5 cm and deeper, no P was measurable, showing bordered movement of P (*Table 4*). However, even in the soil solution samples taken from the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36153626

mid-point (15 cm away from application point) of the bottom-standing cylinder of columns, the P could be measured 24 h after application. Phosphorus could be detected even in the soil solution samples taken 5 cm below application points of columns pre-cultured with HA + FA and to which the granule MAP-P was applied, as opposed to columns precultured without HA + FA.

Table 4. *The P concentrations in the soil solution samples taken from the application points and vertically 5, 10, and 15 cm away from them in the columns pre-cultured 5 or 100 mg P·kg^{-1} soil and with or without HA + FA for two weeks*

Pre-culture (mg kg^{-1} soil)		**Fertilizer form**	**P concentration in soil solution (µg mL^{-1}) The position of sampling stick (cm from the top of soil surface**			
HA + FA	P		2.5	7.5	12.5	17.5
–	5	Granule	6.34	0.00	0.00	0.00
	100		19.24	0.00	0.00	0.00
	5	Fluid	2.91	1.31	1.00	0.26
	100		3.87	4.18	0.50	0.00
+	5	Granule	5.87	1.37	0.00	0.00
	100		5.09	1.15	0.00	0.00
	5	Fluid	1.29	1.10	0.30	0.10
	100		1.97	7.26	1.60	1.20

Moreover, the mobility of P in the columns supplied with the fluid MAP and pre-cultured with HA + FA and 100 mg P·kg^{-1} soil was even better than columns without HA + FA; even the solution samples taken from 15 cm away from application point contained higher P concentrations. However, there were no apparent differences in the P movement of soils pre-cultured with different amounts of P within a given form of MAP fertilizer.

Discussion

According to Fageria and Baligar (2005), one of the essential details that cause problems in sustainable crop production is the inadequacy of nutrient element(s). The nutrient capital of soils is not unlimited and should be renewed depending on the amounts of nutrients removed from the land. In addition to this renewal, the primary aim involves minimizing the risk of environmental contamination and maximizing the contribution of plant nutrients to vegetative production by ensuring the most effective use of the nutrients by plants.

Although the most critical roles of P in vegetative life are energy transfer and storage, it is also found in the structure of many components, which are essential for growth and development, such as nucleic acids, nucleotides, coenzymes, phospholipids, phosphoproteins, and sugar phosphates (Vance et al., 2003). Incongruity involves an increase in the shoot growth of model plant wheat with the P application as well as an increase in P rates (*Table 2*) fitted well in those roles of P in plant nutrition. However, gray-brown necrosis and very severe growth regression differed from the typical P deficiency symptoms of regressive growth and purpling in old leaves (Snowball and Robson, 1983) of control plants cultivated on the experimental soil with very low

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36153626

available P being observed. The reason for this might be the problems encountered with the use of photosynthesis products and that occur in severe P deficiency (Carstensen et al., 2018). Moreover, independent of HA + FA application, the higher roots-to-shoot ratios of plants supplied with granule MAP in comparison to the plants provided with the fluid form of MAP (*Table 3*) may be an indicator of severe P deficiency (Andrews et al., 1999; Zhang et al., 2012).

Although increasing rates of P increased both shoot and roots growths, the soil amendment application had no positive effect on plant growth (*Table 3*). This result was in contrast to the results of those studies in which the HA + FA mixture had positive effects on plant growth (Arjumend et al., 2015; Canellas and Olivares, 2014; Quilty and Cattle, 2011). The possible reason for this might be the termination of the experiment after 30 days, as the control plant showed fast and severe P deficiency stress due to very low organic matter content (0.12%) or very low Olsen P in the soil. It is a well-known phenomenon that the root growth is very active on P uptake (Wang et al., 2016), and HA + FA supports the development of root growth (Canellas and Olivares, 2014; Chunhua et al., 1998; Quilty and Cattle, 2011). Due to the limited volume of soil in a narrow design pot, the superior effect of HA + FA application on root growth in comparison to plants grown without HA + FA might have been prevented, since the roots of plants grown without HA + FA application could easily reach to the nutrients in the pots.

Consistent with a study carried out in the calcareous soils of Australia by Holloway and colleagues (2001), the plant observations as well as the shoot dry weights (*Table 1*) obtained from the harvested plants on the 30th day after planting indicated that fluid P improved the plant development relative to granule. As mentioned before, roots/shoot ratio is an indication of P nutrition in plants, as it increases when they suffer from P deficiency (Andrews et al., 1999; Zhang et al., 2012). Accordingly, the model plant wheat supplied with no P or granular MAP-P, irrespective of soil amendments application, had higher root-to-shoot ratio values than plants supplied with fluid MAP-P with the same rates of granule ones (*Table 1*). It is well known that P moves in soil with diffusion (Marschner, 2012), and its application in fluid form in calcareous soils showed higher mobility and distribution than its granular forms (Lombi et al., 2004a, b). Therefore, the higher root/shoot ratios of plants, grown with granule MAP-P as in control plants and in comparison to plants fertilized with fluid MAP-P (*Table 1*), might be the higher P deficiency stress as a result of limited P mobility in case of granular MAP-P application. Lower P concentrations in the shoots of plants supplied with granular MAP-P compared to the plants grown with the same rates of the fluid MAP (*Table 2*) also supports the argument. This result is consistent with the knowledge that P applied to the band as a fluid responds better than in the granular form (Holloway et al., 2001). However, although they had found a supporting effect of fluid P application on grain yield of wheat in the field conditions, they did not observe any increase in P concentrations in the leaf tissue (Holloway et al., 2001).

According to the growth parameters (*Table 1*) and P nutritional status (*Tables 2* and *3*) of model plant wheat, the application of P as fluid instead of granular improved its mobility in the soil (*Table 4*). In the common opinion, while the P precipitation occurs at high concentrations of soil solution P, the P adsorption takes place at low levels (Castro and Torrent, 1998; Saavedra and Delgado, 2005). Therefore, it might be assumed that the precipitation of Ca-phosphates arises in the soil surrounding fertilizer granule where the P concentration is higher than the bulk soil (Holloway et al., 2001;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36153626

Lombi et al., 2004a, b). So, the reason for higher mobility (or longer vertical movement) of P applied as the fluid MAP (*Table 4*) might be less Ca-phosphate precipitation in comparison to the granular MAP application. However, in contrast to calcareous soils, although the liquid form of P may increase the mobility of P in andisols and oxisols, it does not have an enhancing effect on P availability - lability and solubility (Montalvo et al., 2014). It is known that organic compounds may decrease the P fixation capacity of soils (Brady and Weil, 2008), and humates can bind P (von Wandruszka, 2006). Parallel to this, the application of HA + FA caused an increment even in the mobility of P applied in the granular form. This result fits well with the results of a study showing that HA application supports the movement of MCP-P to long distances, thereby increasing its mobility (Zhen-Yu et al., 2013).

Moreover, in a survey conducted by Delgado et al. (2002), the soil amendment with HA + FA increased the recovery of fertilizer P. However, in that study, they had tested extremely high amounts of HA + FA (from 1000 to 5000 mg [HA + FA]·kg^{-1} soil) which were much higher than applied in practice. Also, all the experiments related to the mobility of P in soils had been conducted during an extended incubation period (Delgado et al., 2002; Lombi et al., 2004a, b; Zhen-Yu et al., 2013), but in the present work, we analyzed the mobility of P in a period as limited as 24 h.

Conclusions

Our study, propelled by limited previous research activities, showed that liquid forms of P containing fertilizers might increase the efficiency of P fertilizers, expanding both P mobility and availability in soils with high $CaCO_3$ and clay. As a natural result of it, the P application in the form of the fluid MAP led to higher uptake of P than plants supplied with the granular MAP. Therefore, under suitable conditions/regions, the growers may prefer liquid forms of P containing fertilizers to ensure higher yields and protect the environment from the hazardous effect of excess P. However, to test the actual contribution of this phenomenon, additional experiments are needed under field conditions. Moreover, the addition of HA + FA enhanced the mobility of P in the soil in both forms of MAP, in particular, fluid form of it. Although such an amendatory effect of HA + FA on P mobility existed, its application did not play a decisive role in either the growth or P uptake of the model plant. The reason for this might be the extreme behaviors of experimental materials such as soil with extremely low OM and plant available P or very narrow designed pots. Further detailed experiments are required to clarify this point.

Acknowledgments. The present manuscript was prepared using the results of Şeyhmus Dündar's MSc thesis, which was granted by the Scientific Research Projects Coordination Unit at Çukurova University.

(Received 19th Dec 2019; accepted 24th Mar 2020)

Abstract. The study was carried out under rainfall conditions during the 2011-2012 and 2012-2013 growing seasons in Diyarbakir province of Turkey. The experiment had designed as a randomized block design with 3 replications. The aim of the study was to determine the lines that were superior in terms of yield and quality to the varieties. The experimental material consisted of 20 bread wheat lines and 5 standard varieties. According to the results of variance analysis; significant differences were observed between genotypes in all features at 1%. Grain yield (GY) had a significant positive relationship with test weight (TW), and a significant negative relationship with wet gluten (WG). Also, grain hardness (GH) (PSI: Particle size index) had significant negative relationship with TW, and a significant positive relationship with plant height (PH) and heading time (HT). 4 lines in grain yield, 3 lines in test weight, 1 line in protein content, 4 lines in zeleny sedimentation and 1 line in wet gluten showed superior performance than all standards. It is concluded that the G19 and G24 lines may be candidates for registration.
Keywords: *correlation, grain hardness, protein content, wet gluten*

Introduction

Wheat has been a main source of nutrient throughout the ages, and it continues to strengthen its role in human life. 23.4 million hectare of agricultural land is cultivated in Turkey, It is reported that the area allocated for agricultural activities except fallow areas is 66.4%. Also, it is reported that cereal sowing amount has 71% share in this area and wheat cultivation takes first place among cereals in proportion (TSI, 2018).

The center of origin of wheat in the world and also the first place where wheat and barley cultivation is made is called fertile crescent. Southeast Anatolia Region is located in fertile crescent region. So, of Turkey it is considered to have a significant track record in wheat breeding and commissioning culture of wheat (Cıvgın, 2016; Aktas, 2017).

Central Anatolia Region in wheat production in Turkey takes first place with rate of 33.5%. Southeastern Anatolia Region ranks second in wheat production with a rate of 16.5% (TSI, 2018). Diyarbakir is one of the important provinces of Southeastern Anatolia Region in wheat production. 1.1 million tons of wheat is produced in Diyarbakir. This amount constitutes 3.5% of the total wheat production in Turkey (TSI, 2018). The annual per capita wheat consumption in Turkey is over 200 kg. Due to the high daily consumption per capita and being one of the most important caloric sources of Turkish people, wheat maintains its strategic importance (Morgounov et al., 2016).

It has been reported that the amount of protein in the grain is affected significantly by environmental conditions (climate, fertilizer amount, irrigation, etc.) and also the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36273638

inheritance factor is an important determinant on quality parameters in wheat grown in both irrigated and rainfall conditions (Grausgruber et al., 2000; Souza et al., 2004).

It is emphasized that the amount of protein in bread wheat is important in determining quality. However, since the amount of protein alone is not sufficient, it has been reported that the amount of sedimentation and gluten should be taken into account (Gooding et al., 2003). Plant breeders aim to develop genotypes with high grain yield, quality and ability to adapt to different environments (Kendal and Sener, 2015).

With this purpose, study was conducted in Diyarbakir conditions in Turkey. After comparing the wheat lines of abroad origin with registered varieties in terms of yield and quality characteristics, the lines that can be high performance candidates were determined.

Materials and methods

The study was carried out under rainfall conditions in Diyarbakir province of Turkey in 2011-2012 and 2012-2013 growing seasons with 5 standard varieties and 20 advanced bread wheat lines (*Fig. 1; Table 1*).

Figure 1. *Experiment location's place in the Turkey map*

In the first year of the study, rainfall was below the average of long years, while in the second year there was rainfall above the average of long years (*Fig. 2*).

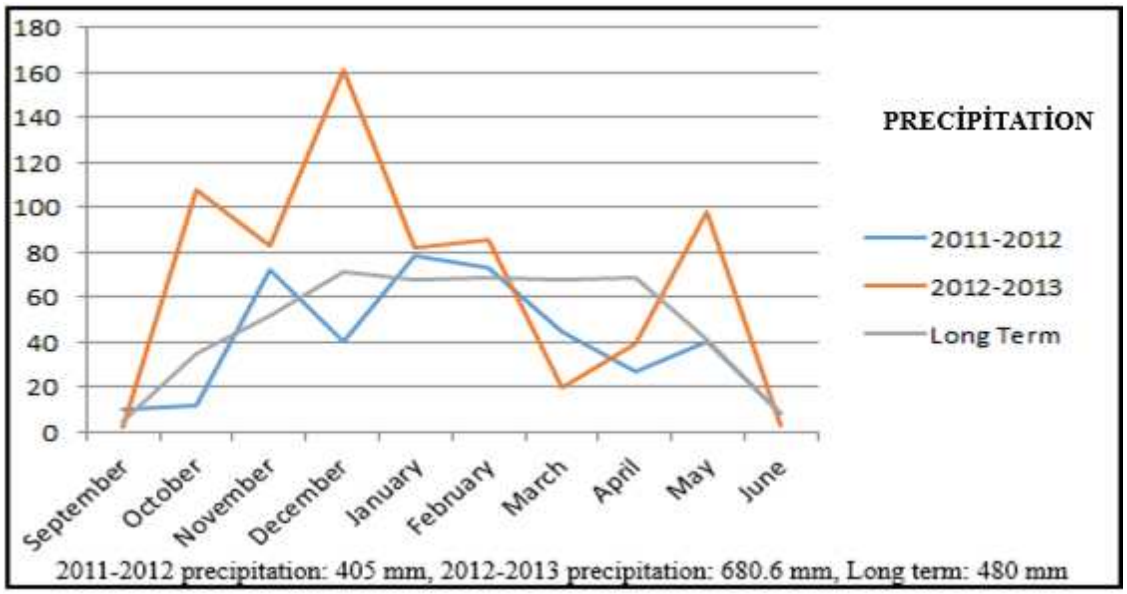

Figure 2. *The amount of precipitation of Diyarbakir's in 2011-2012 and 2012-2013 growing seasons and long terms (mm)*

However, it was determined that the amount of precipitation was not reflected to the grain yield at the expected level since the distribution of rainfall was irregular on months basis.

In the first year of the study, the average temperatures based on months were below long years. However, the second year has been more than long years (*Fig. 3*).

The experiment was conducted in randomized block design with 3 replications. All of the lines used in the study are of spring nature. Additionally, Pehlivan winter, Sagittario alternative, Nurkent, Cemre and Adana-99 varieties are of spring character. 450 seeds were sowed in the square meter and the size of the parcel was 6 m^2.

DOI: http://dx.doi.org/10.15666/aeer/1802_36273638

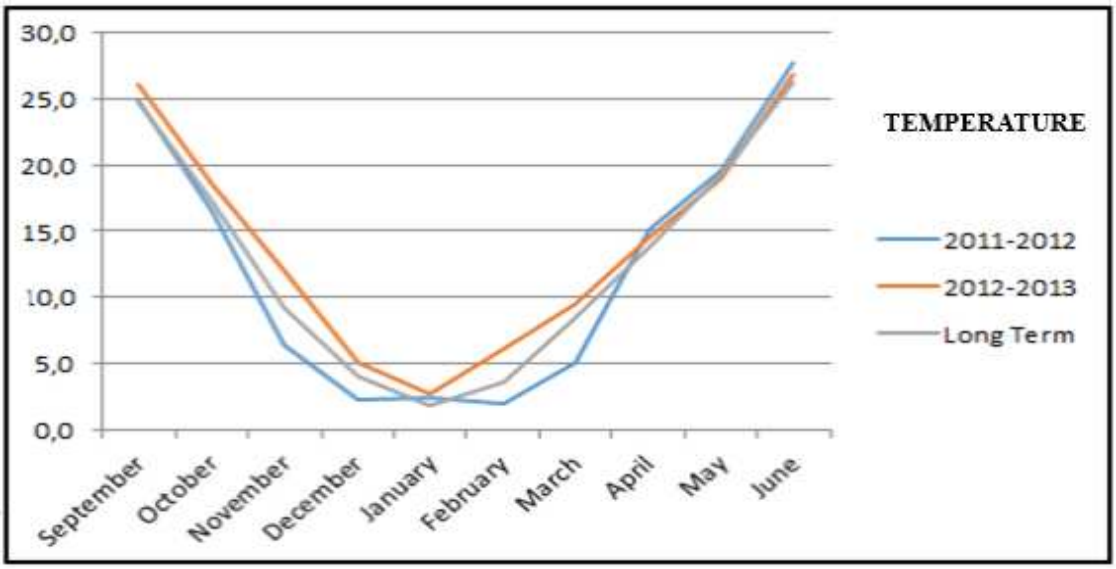

Figure 3. *Average temperature of Diyarbakir's in 2011-2012 and 2012-2013 growing seasons and long terms (°C)*

The amount of fertilizer to be used in the experiment was calculated over 120 kg ha^{-1} pure nitrogen (N) and 60 kg ha^{-1} pure phosphorus (P_2O_5). Half of the total nitrogen and all of the phosphorus were used with sowing and the remaining half of the nitrogen was given at the end of the tillering period. Experiment was sowed in the first week of November and harvesting was done with the combine harvester in the second week of June. The study area is 37° 56 north latitude and 43° 15 east longitude and has a height of 599 m. It is determined that the soil formation class is clayey, the salt content is 0.25%, PH: 7.8, the amount of organic matter is 0.68% and the saturation rate with water is 77%. (Anonymous, 2013).

In the study, heading time (HT) was determined as the number of days as of January 1, taking into account the date when 50% of the plants in each parcel were spiked. When determining plant height (PH), 10 plants were randomly selected per plot. Then, the length from soil level to the highest spikelet except for awns was measured in cm. Grain yield (GY) was determined by turning the yield in kg ha^{-1} after the whole parcel was harvested. When determining the thousand grain weight (TGW), 100 seeds were counted 4 times and weighed on a 0.01 precision scale, then averaged and multiplied by 10 and determined in grams.

To determine the test weight (TW), the seed obtained from each parcel after harvest was weighed after being put into a 1-L container and its weight was multiplied by 100. Protein content (PR) was determined with the Near Infrared Model 6500 device according to the AACC 39-10 method (Anonymous, 1990). Amount of zeleny sedimentation (ZS) ICC-No. according to the 115 was determined (Anonymous, 1982). Wet gluten (WG) ratio was determined by the Glutomatic 2200 device according to ICC standard 155/1 method (Anonymous, 1994). Grain hardness (GH) (Particle size index) was made according to the AACC 39-70 A method (Anonymous, 2000). In the research, variance analysis of the data was performed with JMP 13.0 statistical package program. Differences in mean values were examined by LSD test ($p \leq 0.01$ or $p \leq 0.05$) (Gomez and Gomez, 1984).

Results and discussion

According to the results of ANOVA analysis, of squares mean and significance levels of the investigated features are given in *Tables 2* and *3*. In terms of other features, except for grain yield (n.s.) and zeleny sedimantasyon (5%), between years were observed significant differences at the level of 1%. In addition, except for grain hardness, it is seen that the responses (YxG) of genotypes by years are different from each other (*Tables 2* and 3).

In the study, the average values of heading time are given in *Table 4*. The average experiment of heading time was 119.4 days. While the early heading genotypes were G14 (115.3 days) and G22 (115.3 days), in terms of heading time means, Pehlivan (124.0 days) was the late heading genotype. In terms of heading time, it was determined that all lines were earlier heading than the earliest heading standard cultivar (Adana-99; 121.2 days).

Because temperature stress is an important problem in the Southeastern Anatolia Region, early heading genotypes not exposed to heat stress are preferred. In this case, early heading varieties rather than late heading varieties are in demand (Tekdal and Yildirim, 2017). In the selection study, early heading and medium early heading varieties were selected. Kiseleva and Salina (2018) reported that many genes interact for determination of heading time in bread wheat. Also, they emphasized that the genes that affect the heading time of wheat are not studied sufficiently, but the number of studies is increasing day by day.

Average plant height was determined as 99.4 cm. Cemre cultivar had the longest plant length with 110.8 cm and Sagittario cultivar had the shortest plant height with 80.8 cm (*Table 4*). In studies conducted on wheat under different conditions, it was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36273638

determined that heredity had a significant effect on plant height. In addition, climate, soil structure and agronomical application (fertilization, soil processing, etc.) has been reported to be effective on plant height (Caierao, 2006).

In terms of grain yield, the experiment average was 6765 kg ha^{-1} and G24 (7449 kg ha^{-1}) line had the highest grain yield. In terms of grain yield, 4 lines passed the standard variety with the highest grain yield (Cemre; 7187 kg ha^{-1}) (*Table 4*). It has been reported that grain yield and quality parameters in wheat are generally affected by genotypes, environmental conditions and genotype environment interaction. (Barutcular et al., 2016; Kizilkeci, 2019).

The average experiment for test weight was 81.7 kg hl^{-1}. In addition, G14 (83.1 kg hl^{-1}), G18 (83.1 kg hl^{-1}) and G21 (83.1 kg hl^{-1}) lines by share the same group and were the highest test weight (*Table 5*). In terms of test weight, 3 lines showed higher performance than the highest standard variety (Adana-99; 83.0 kg hl^{-1}) (*Table 5*). In a

DOI: http://dx.doi.org/10.15666/aeer/1802_36273638

study conducted on bread wheat in India conditions, it was reported that the weight of test ranged from 70.0 to 84.6 kg hl^{-1}. In this study, the results were similar since the average test weight was 81.7 kg hl^{-1} (Panghal et al., 2019).

Av: Average

Cemre (40.1 g) cultivar took the first place in terms of thousand grain weight (*Table 5*). In a study carried out in bread wheat related to thousand grain weight, it was reported that thousand grain weight ranged between 29.6 and 53.8 g, and the average was 40.7 g. In this study, a thousand grain weight ranged between 32.8 and 40.1 g. The average of the experiment was 35.7 g. The results of the studies are similar (Panghal et al., 2019).

The average of protein content was 13.5%. The highest protein content was obtained from G9 (14.1%) line. In addition, the highest value in terms of protein content of the varieties used as standard in the study was obtained from Sagittario cultivar with 14.0%

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36273638

(*Table 5*). Karaman (2019), in his study based on precipitation conditions in bread wheat has reported that the average protein rate is 14.5%. Also, there is a significant relationship between protein content and grain hardness. This has been reported to result from the strong interaction between carbohydrates and proteins. This result was confirmed by our study. (*Table 5*) (Preston, 1998; Dobraszczyk et al., 2002; Pasha et al., 2010; Baslar et al., 2012).

The average amount of zeleny sedimentation was 28.5 ml and the G12 (35.1 ml) line have the highest sedimentation amount. In addition, it was determined that 4 lines had higher sedimentation amount than the highest standard variety (Sagittario; 31.6 ml) (*Table 6*). In the study of Koçak et al. (1992), the sedimentation value ranged from 18.8 to 43.8 ml, reported that the hereditary effect in sedimentation is higher than the effect of environmental factors. The obtained values are similar to our findings. It is emphasized that the amount of sedimentation is of great importance in determination of protein quality in bread wheat (Peterson et al., 1992).

The mean of wet gluten ratio was found to be 30.0%, while G9 (31.6%) and Sagittario (31.5%) had the highest value by sharing the same group (*Table 6*). It has been reported that wet gluten ratio in bread wheat is important and the amount of gluten formed as a result of swelling of gliadin and gluten, which are subcomponents of protein, by absorbing water, is affected significantly by environmental conditions. The researchers reported that wet gluten content varied between 11.3 and 45.2% (Keçeli et al., 2017).

In the study, the mean experiment value of grain hardness was found to be 51.5 (PSI). Nurkent (46.3 PSI) had the hardest grain type and Cemre (61.3 PSI) had the softest grain type. In the interpretation of the grain hardness parameter, it is interpreted that the grain hardness increases with decreasing PSI value and decreases with increasing PSI value (Sahin et al., 2017). According to this, G13 (45.1) was found to be the genotype with the highest grain hardness. G4 (46.5), Nurkent (46.3), G11 (46.6), G14 (45.2), G19 (46.4), G21 (45.7) and G22 (45.4) lines were also good genotypes for grain hardness (*Table 6*). Because grain hardness is positively associated with protein *(Table 7).*

Grain hardness (PSI) parameter is important in bread wheat. Especially when flour is obtained from hard wheat, starch damage is more than soft wheat. It was emphasized that this was not preferred by bakers. Also, dough made from a high damaged starch content flour was reported to have more water-holding capacity (Khan and Shewry, 2009; Sahin et al., 2017).

Correlation analysis

Respect to correlation analysis, there was a positive correlation between grain yield and test weight and a negative correlation with wet gluten ratio. While test weight increased, wet gluten ratio and grain hardness (PSI) values were found to decrease. Thousand grain weight was found to be inversely related to protein content and wet gluten ratio. In addition, the content of protein and wet gluten was found to be inversely related to the amount of zeleny sedimentation (*Table 7*). This situation is contrary to the literature. Because many researchers have reported that the amount of zeleny sedimentation positively correlated with protein content and wet gluten ratio (Surma et al., 2012; Keceli et al., 2017).

This may be due to the low protein quality despite the high protein content of the genotypes or vice versa. Additionally, grain hardness (PSI) was positively correlated with heading time and plant height. Kılıç et al. (2014) obtained similar results in their study.

Conclusion

In the study, early heading cultivars were found to be prominent in terms of grain yield and test weight. However, it was determined that the same situation was not observed in terms of quality parameters. It was found that there was a positive correlation between grain yield and test weight and a negative correlation with wet gluten. There was a negative correlation between grain hardness (PSI) and test weight and a positive correlation between plant height and heading time. G1, G14, G19, G24 for grain yield, G14, G18, G21 for test weight; G9 for protein ratio and wet gluten amount, G2, G7, G11, G12, for zeleny sedimentation outperformed all standards. In the study, it is determined that the lines which are superior to standard varieties in terms of one or a few features should be taken into consideration in grain yield or quality-oriented breeding studies. It was concluded that G19 and G24, which have superior features, can be registered candidates. In the future, if collaboration with modern breeding (molecular) is done, genotypes of superior will be studied and the results will shed light on future research.

Abstract. In China, the distribution area and ecological function of *Potamogeton pectinatus* have been adversely affected by aquaculture. To evaluate the effects of omnivorous fishes on submerged plant recovery in cultured lakes, growth responses of *Potamogeton pectinatus* to disturbance by three such fishes (gold fish (*Carassius auratus*), common carp (*Cyprinus carpio*), and yellow catfish (*Pelteobagrus fulvidraco*)) were analyzed. Three stocking densities (low, medium, and high) were selected for each fish species. Fish stocking obviously increased total nitrogen, total phosphorus, conductivity, and total dissolved solids and decreased dissolved oxygen and pH of the water. Fish species had significant effects on plant height, root length, root dry weight, and aboveground dry weight, which were the lowest after *Cyprinus carpio* treatment. Stocking density had significant effects only on root length, root dry weight, and aboveground dry weight. The fish species, stocking density, and their interaction had significant effects on total dry weight and biomass allocation. The total dry weight and root:aboveground part values were significantly lower after *Cyprinus carpio* treatment than after the other treatments. Therefore, the dominant fish species should be scientifically assessed before restoring submerged vegetation, and fish stocking density needs to be controlled to promote submerged macrophyte establishment in cultured lakes.
Keywords: *cultivated lakes, aquaculture, ecological restoration, stocking density, aquatic plants*

Introduction

Submerged macrophytes are the dominant primary producers in lake ecosystems, and they play important roles in stabilizing embankments, purifying water, and providing shelter for other aquatic organisms (Zhang et al., 2017, 2019; Ge et al., 2018). In China, the distribution area of submerged macrophytes in many freshwater lakes has been greatly reduced due to human activities (Fang et al., 2006; Zhang et al., 2017). The lakes have gradually shifted from a macrophyte-dominated state to a phytoplankton-dominated state (Wu et al., 2019), and the ecological service function is seriously degraded. In addition to factors such as land use change, dam construction, and eutrophication, aquaculture is often considered to be a major reason for the degradation of submerged macrophytes in lakes (Wang et al., 2005; Fang et al., 2006; Wu et al., 2019).

In China, aquaculture is an important part of fisheries. Aquaculture production in the country accounts for 60.5% of the total production worldwide (Mo et al., 2018).

DOI: http://dx.doi.org/10.15666/aeer/1802_36393649

However, high fish production in China is mainly achieved through high-density farming. For more economic benefits, many cultured lakes generally stock a high density of fish. Previous studies have shown that high-density stocking of herbivorous or omnivorous fishes can affect submerged plants directly or indirectly (Pipalova, 2006). The direct effects mainly include direct feeding and physical damage by the fishes, for example, grass carp (*Ctenopharyngodon idellus*) can directly graze on the rhizomes, shoots, and stems of submerged plants, resulting in the decline of aquatic plant resources (Hanlon et al., 2000; Domingues et al., 2017), and the foraging activities of some bottom fishes such as common carp (*Cyprinus carpio*) and tilapia (*Oreochromis mossambicus*) which often uproot submerged macrophytes (Chen and Guo, 2005). The indirect effects are mainly attributable to the activities of the fishes. After fish stocking, the suspended matter in the water increases, and more nutrients (such as N and P) are released into the sediment, leading to decreased water transparency and overpopulation of algae and, thus, inhibition of the growth of aquatic plants (Pipalova, 2006; Wang et al., 2016; Hansen et al., 2019).

Recently, the negative impacts of aquaculture have received widespread attention. To restore lake environments, ecological restoration projects have been conducted in many cultured lakes in China (Gu et al., 2018). However, the growth response of aquatic plants affected by different fish disturbances has rarely been reported, and it is difficult to provide a theoretical basis for the restoration of aquatic plants in cultured lakes. Therefore, in this study, we selected three omnivorous fishes, (*Carassius auratus*, *Cyprinus carpio*, and *Pelteobagrus fulvidraco*) that are commonly cultured in lakes in China to determine the growth responses of *Potamogeton pectinatus* to disturbances by the different fishes at different stocking densities. Although all the three fishes are omnivorous, *Pelteobagrus fulvidraco* mainly feeds on benthic invertebrates and is less active and causes minimal disturbance in the water body; *Carassius auratus* mainly feeds on plants and shows relatively strong activity; and *Cyprinus carpio* mainly feeds on both animals and plants and may cause the strongest disturbance to the water body. Therefore, we hypothesized that the growth responses of *Potamogeton pectinatus* to disturbances by the different fish species may be different, and its growth was the worst when disturbed by *Cyprinus carpio* at high stocking density.

Materials and methods

Experimental design

Potamogeton pectinatus L. is a perennial submerged macrophyte that can reproduce via vegetative fragments, underground stems, and seeds. On July 22, 2018, similar fragments of *Potamogeton pectinatus* (35-cm-long apical shoots without developed roots) were collected from Baiyangdian Lake, Hebei Province; transferred to the Baiyangdian field station (N: 115°59′30.31″; E: 38°50′37.12″); and randomly cultivated in rectangular plastic pots (40 cm × 15 cm × 20 cm). Each plastic pot contained 10 cm of the substrate (obtained from Baiyangdian Lake). The nutrient content of the substrate (dry weight) was determined to be 1.64 mg g^{-1} N, 0.52 mg g^{-1} P, and 24.53 mg g^{-1} organic matter. Each rectangular plastic pot had 12 seedlings, and three pots were placed in a cement pond (2.0 m × 2.0 m × 1.8 m) as three replicates. A total of 10 cement ponds were used in this study. Lake water was added to each cement pond. The total nitrogen (TN) and total phosphorus (TP) in the water were 0.980 and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36393649

0.048 mg/L, respectively; the temperature, dissolved oxygen (DO), conductivity (Cond), total dissolved solids (TDS), and pH in the water were 28.9℃, 7.70 mg/L, 904 uS/cm, 587.9 mg/L, and 8.90, respectively. The water depth was initially maintained at 100 cm to promote the survival and growth of the seedlings. After half a month, the water depth in the cement pond was increased to 150 cm, and two plants from each pot with large differences in plant size were removed, so that the average plant height of the remaining 10 seedlings was maintained at about 135 cm.

Three omnivorous fishes (*Carassius auratus*, *Cyprinus carpio*, and *Pelteobagrus fulvidraco*) were used, and all of them were captured from Baiyangdian Lake. For each fish species, individuals with a weight of about 100 g were selected. Three stocking densities were selected for each fish species: high density (HD), medium density (MD), and low density (LD); correspondingly, the number of fishes for the three treatments was 15, 10, and 5, respectively, and the total weight was 1500, 1000, and 500 g, respectively. On August 9, 2019, the three fish species at different stocking densities were placed randomly in each pond. The cement pond with no fish was used as control group. During the experiment, if a fish was found dead, it was replaced with a fish of similar size. No fish were fed throughout the experiment. At the end of the experiment, the temperature, DO, Cond, TDS, and pH were measured using a portable multi-parameter water quality analyzer (YSI Professional Plus, USA). The transparency of the water body was measured using a Secchi disc. The TN and TP of the pond water were determined using standard methods (Lu, 2000).

Data analyses

The experiment ended on September 22, 2018. All plants were harvested from the plastic pots, and plant height and root length were measured with a meter stick. Then, the plants were divided into root and aboveground (including stems and leaves) parts and dried in an oven at 80℃ for three days. The dry weight (DW) of the roots, aboveground parts, and whole plants was determined. Two-way analysis of variance (ANOVA) was used to analyze the effects of the fish species and stocking density on plant height, root length, aboveground DW, root DW, and total DW of *Potamogeton pectinatus*. The normality and homogeneity of all the variables were tested before ANOVA. For variables that satisfied the homogeneity, Tukey's HSD multiple comparisons were used to test for differences between groups, whereas Tamhane's T2 method was used for unequal variances (Li et al., 2018). All analyses were performed using Excel and SPSS 13.0 software.

Results

Physiochemical parameters

At the end of the experiment, the physiochemical parameters in the different treatment groups showed some differences (*Table 1*). The TN, TP, Cond, and TDS in all the treatments were obviously higher after fish stocking and transparency was obviously lower than the control. Small differences in the water temperature were observed in all the treatments. The DO and pH in all treatments with stocked fish (except for *Pelteobagrus fulvidraco* at LD) were lower than the control values.

Morphological parameters

The fish species had significant effects on plant height, root length, root DW, and aboveground DW of *Potamogeton pectinatus*, and the values of all four parameters were the lowest after *Cyprinus carpio* treatment (*Table 2*; *Fig. 1*). The root DW and aboveground part DW were lower than the control values after fish stocking; however, the plant height and root length did not show similar trends (*Fig. 1*).

Table 2. *Two-way ANOVA of the effects of fish species, stocking density, and their interactions on plant height, root length, root dry weight (DW), and aboveground DW of Potamogeton pectinatus*

Source of variation	Plant height	Root length	Root DW	Aboveground DW	Total DW	Ratio
Fish species	77.19**	45.62**	64.25**	35.66**	42.29**	3.87*
Stocking density	0.78	5.65**	11.76**	22.86**	23.32**	4.57*
Fish species × Stocking density	3.70**	6.78**	14.70**	4.37**	5.16**	9.13**

Note: * $P < 0.05$; ** $P < 0.01$

The stocking density had significant effects on root length, root DW, and aboveground DW of *Potamogeton pectinatus*; however, it had no significant effects on plant height (*Table 2*). With the increase in stocking density, the root length, root DW, and aboveground DW of the plants showed a significant decrease (*Fig. 2*). The highest values of all three parameters were observed in the control group, whereas the lowest values were detected in the HD treatment groups (*Fig. 2*). In addition, the fish species and stocking density had significant interactions with respect to all four morphological parameters (*Table 2*).

Biomass allocation

Fish species, stocking density, and their interactions had significant effects on the total DW and root:aboveground part values (*Table 1*), which were significantly lower in the *Cyprinus carpio* treatment groups than in the other two fish groups and control group. Although the total DW values after *Carassius auratus* and *Pelteobagrus fulvidraco* treatments were lower than the control values, the ratio was not significantly different among the three groups (*Fig. 3*). With the increase in stocking density, the total DW and ratio showed a tendency to significantly decrease, and both were the lowest after HD treatment (*Fig. 4*).

Discussion

In China, fishery plays a very important role in socio-economic development. With the rapid development of freshwater aquaculture fisheries, many freshwater lakes and reservoirs in China are being used intensively (Gu et al., 2018). In 2015, freshwater aquaculture production from the lakes and reservoirs account for 18% of the total freshwater aquaculture in China (Fisheries Bureau of the Ministry of Agriculture, 2016). Although aquaculture has made great advances in China, its negative impacts on the environment have also received increased attention. The most significant negative impacts are the deterioration of water quality and degradation of aquatic plants because of high-density aquaculture. In this study, the TN, TP, Cond, and TDS were obviously higher in all the treatment groups than in the control group after fish stocking; however, water transparency was obviously lower in all the treatment groups than in the control group. This is consistent with the results of other studies, which indicates that fish stocking increases disturbance to aquatic plants and accelerates the release of nutrients in the sediment (Pipalova, 2006; Wang et al., 2016; Hansen et al., 2019). The *Cyprinus carpio* treatment groups showed the lowest transparency and highest nutrient content at the same stocking density, whereas the *Pelteobagrus fulvidraco* treatment groups showed the opposite trend (*Table 1*). This may because, of the three fish species, *Cyprinus carpio* disturbs water bodies and aquatic plants to the greatest extent.

Changes in morphology and biomass allocation because of external disturbances are adaptive strategies developed by aquatic plants during long-term evolution (Lytle and Poff, 2004; Merritt et al., 2010; Zhang, 2013). The results of this study show that the fish species and stocking density had significant effects on the morphological parameters and biomass allocation of *Potamogeton pectinatus*, and the morphological parameters differed in response to fish disturbance. The plant height was significantly higher in the *Pelteobagrus fulvidraco* and *Carassius auratus* treatment groups than in the control group, whereas the plant height was significantly lower in the *Cyprinus carpio* treatment groups than in the control group. This may be mainly because the transparency of the water body gradually decreases with an increase in fish disturbance. To a certain extent, *Potamogeton pectinatus* can increase its height to avoid the lack of underwater light; however, excessive disturbance significantly inhibits the growth and survival of the plant. Many studies have shown that light availability is the main factor that determines the growth of submerged plants. Aquatic plants tend to produce taller shoots, which is associated with decreased investment in the belowground part in response to decreased light availability (Strand and Weisner, 2001; Zhang et al., 2013; Li et al., 2018). In this study, the root length of the plants after the three different fish treatments was lesser than that of the plants in the control group, which indicates that *Potamogeton pectinatus* reduced root investment after the stocking of omnivorous fishes. The root:aboveground part value was significantly lower in the *Cyprinus carpio* groups than in the control group and other two fish groups (*Fig. 3*); this suggested that the *Cyprinus carpio* groups caused the largest disturbance, and the plants in the *Cyprinus carpio* groups invested more resources into aboveground parts than those in the other groups.

The plant height in the different treatment groups did not demonstrate any significant differences as the stocking density increased, but the root length and root:aboveground part values significantly decreased (*Fig. 2*). The reason for the similar plant heights may be mainly attributable to the shallow water depth in the cement ponds during the experiment (always maintained at 150 cm), which limited the space for plant growth.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36393649

The significantly decreased root length and root:aboveground part values indicated the active adaptation of *Potamogeton pectinatus* to gradually increasing external disturbances. In addition, regardless of the stocking density, the total DW, root DW, and aboveground DW values significantly decreased and were the lowest in the *Cyprinus carpio* treatment groups. This may be mainly due to the reduced branch number and stem diameter of *Potamogeton pectinatus* after the fish stocking, which is an active adaptation to weak light conditions caused by the fish stocking. Other studies on the morphological responses of emergent or submerged plants in low light environments have also reported similar findings (Stand and Weisner, 2001; Zhang, 2013; Wang et al., 2018).

Changes in the fish community structure will inevitably affect other aquatic communities and the structure and function of the entire lake ecosystem (Gu et al., 2018; Zhen et al., 2018). A previous study on some temperate lakes has shown that the ultimate cause for the transition from a macrophyte-dominated state to a phytoplankton-dominated state is changes in the fish community structure (Brönmark and Weisner, 1992). Therefore, appropriate regulation of fish resources is very important for lake management and submerged plant restoration. To date, studies on the relationships between fish and aquatic plants mainly focused on herbivorous fishes, especially grass carp (Garner et al., 2013; Domingues et al., 2016). Some studies have indicated that irrational stocking of grass carp often leads to the disappearance of many submerged macrophytes in freshwater lakes (Chen and Guo, 2005; Wang et al., 2016; Zhen et al., 2018). However, our study showed that, although the consumption of submerged macrophytes by omnivorous fishes was lower than that by the grass carp, the effects of different omnivorous fishes on the growth of submerged macrophytes have significant differences. For the restoration of submerged plants in cultivated lakes, in addition to reducing the adverse effects of some herbivorous fishes (such as grass carp) on submerged macrophytes, the adverse disturbances caused by omnivorous fishes (such as *Cyprinus carpio*) need to be considered. On the basis of the results of this study, we suggest strict control of the number of *Cyprinus carpio*, appropriate control of the number of *Carassius auratus*, and relaxed control of omnivorous fishes (such as *Pelteobagrus fulvidraco*) that do not cause much disturbance to submerged macrophytes.

Conclusion

Both the fish species and stocking density had significant effects on the growth of *Potamogeton pectinatus*. Generally, the disturbance caused by *Cyprinus carpio* was the greatest, and the disturbance caused by *Pelteobagrus fulvidraco* was the lowest. With the increase in stocking density, the disturbance gradually increased. To a certain extent, *Potamogeton pectinatus* can adapt through changes in the morphological parameters or biomass allocation, but excessive disturbance by fishes significantly inhibits the growth and survival of the plant. Therefore, the dominant fish species should be scientifically assessed before the restoration of submerged vegetation, and appropriate control of fish stocking density is necessary to promote the establishment of submerged macrophytes in cultured lakes. Finally, more field studies are required to determine the joint or single effects of dominant fishes with different feeding habits on the growth of submerged macrophytes and provide a quantitative basis for the restoration of submerged macrophytes.

Abstract. The nutritional composition of fish muscle is an important reference data for the design of fish feed formulae. However, the nutritional composition of the muscle of Chinese hook snout carp has not been analyzed at present. In addition, considering the obvious individual difference between male and female Chinese hook snout carp, there may also be significant difference in nutritional composition. To provide a reference for the feed formula design of artificially cultured Chinese hook snout carp, the muscle nutrient composition of five wild male and female individuals was analyzed in this study. Our results showed that water, crude protein, crude fat, and crude ash contents had no significant differences between male and female fish. Although there was no significant difference in the contents of most amino acids between male and female fish, the contents of flavored amino acids, essential amino acids and total amino acids in male fish muscle were significantly higher than those in female fish muscle. The proportion of saturated fatty acids, monounsaturated fatty acids, and polyunsaturated fatty acids was 1.37:1:1.80, and most of fatty acids showed significant difference between male and female fish.

Introduction

Chinese hook snout carp (*Opsariichthys bidens* Günther) is one of the most widely distributed small Asiatic cyprinids. It generally occupies fast-flowing mountainous steams (Perdices et al., 2005; Fu et al., 2012). However, due to habitat destruction caused by human activities and overfishing, the natural resources of the fish decreased dramatically in recent years (Chen, 2015).

To avoid extinction of wildlife resources due to over hunting, it is an important and feasible way to establish artificial breeding technology instead of the market demand for the wildlife resources (Chen, 2015; Xiang et al., 2018). For example, only in a Chinese county, Anhua County, 26505 kg of commercial adult Chinese hook snout carp and 994000 fries produced in 2012. However, although the nutritional composition of fish muscle is an important reference data for the design of fish feed formulae (Schaeffer et al., 2012), and a large number of studies have been reported on the nutritional composition of fishes (e.g. Hang et al., 2001; Xu et al., 2005; Lou et al., 2010; Liu et al., 2010; Yang et al., 2010), the nutritional composition of the muscle of Chinese hook snout carp has not been analyzed yet. In addition, considering the obvious individual difference between male and female of Chinese hook snout carp, there may also be significant difference in nutritional composition.

The lack of nutritional composition of muscle seriously limits the development of feed formula and the efficiency of artificial propagation and cultivation of Chinese hook snout carp. For example, to provide more suitable feed for the parent fish of Chinese hook snout carp in the breeding stage, it is necessary to clarify the nutritional requirements of the male and female fish, and the muscle nutritional components of the male and female fish provide an important reference data for the development of such feed. To provide a reference for the feed formula design of artificial cultured Chinese hook snout carp, the muscle nutrient composition of wild male and female Chinese hook snout carp was analyzed in this study.

Materials and Methods

Sample collection

The Chinese hook snout carp samples were collected from Chetianjiang Reservoir, Anhua, China (27.85° N, 111.60° E) on March 15. The fish samples were transported to the laboratory by oxygenation and then fasted for 1 days. Each 5 male and female samples with the same size (approximately 50 g of each fish; *Fig. 1*) were selected and anesthetized 5 min using 100 mg/L of neutralized MS222 (tricaine methanesulfonate, Sigma-Aldrich, Germany) (Tuo et al., 2020). Then, the muscles on both sides of the back above the lateral scale below the dorsal fin were dissected for the determination of nutritional components.

Figure 1. *Photos of male (A) and female (B) Chinese hook snout carp*

Analysis of nutrients

Dry matter content was determined by 105°C constant temperature and atmospheric pressure drying method. Crude protein content, crude fat content, and crude ash content was determined by Kjeldahl nitrogen method, Soxhlet extraction method, and muffle

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36513658

furnace burning method respectively according to previous studies (Saalah et al., 2010; Sun et al., 2011).

Amino acids were measured by a L8800 amino acid analyzer (Hitachi, Japan) (Sun et al., 2016). Fish oil was extracted by Soxhlet extraction (Ozogul et al., 2012). Composition of fatty acids was measured using a 6890-5973N gas chromatography - mass spectrometer (Agilent, USA) (Mazurek et al., 2017).

Data analysis

The data were showed as mean ± standard deviation (S.D.) (Jiang et al., 2019). Independent *t*-test was conducted to test statistical difference between different groups using R software with basic packages (Everitt and Hothorn, 2010; Horton and Kleinman, 2011). Results with $p \leq 0.05$ were considered statistically significant (Ni et al., 2019).

Results

Contents of the crude protein, crude fat, and crude ash in male Chinese hook snout carp muscles were 17.23 ± 1.54%, 2.71 ± 0.61%, and 1.32 ± 0.10%, respectively. Contents of the crude protein, crude fat, and crude ash in female fish muscles were 16.71 ± 0.99%, 2.23 ± 0.92, and 1.36 ± 0.02%, respectively (*Fig. 2*). Water content in muscle was no significant difference between the male and female fish (independent *t*-test, $t = 0.90$, $p = 0.38$). No significant difference of crude protein (independent *t*-test, $t = 0.49$, $p = 0.64$), crude fat (independent *t*-test, $t = 1.38$, $p = 0.18$), and crude ash (independent *t*-test, $t = 1.20$, $p = 0.25$) contents in muscle between male and female Chinese hook snout carp was found.

Figure 2. *Nutritional compositions in muscle of male and female Opsariichthys uncirostris bidens Günther (% wet weight)*

Among the amino acids in the muscle of male and female Chinese hook snout carp samples, the highest amino acids were glutamic acid, proline, aspartic acid and lysine, all of which were more than 1.5 g in 100 g of muscle (*Table 1*). Only content of cystine in the muscle of male fish was significantly higher than that of female (independent *t*-test, $t = 3.16$, $p = 0.01$; *Table 1*). Although there was no significant difference in the contents of most amino acids between male and female fish, the contents of flavored amino acids, essential amino acids and total amino acids in male fish muscle were significantly higher than those in female fish muscle (*Table 1*).

The saturated fatty acids detected in the muscle of the Chinese hook snout carp samples were c13:0, c14:0, c15:0, c16:0, c18:0 and c20:0. Methyl palmitate (c16:0) was the major saturated fatty acids, which accounted for 68.18% of the saturated fatty acids (*Table 2*). This result was similar to those reported in other fishes (Lv et al., 1995). The main monounsaturated fatty acids were c16:1n-9 and c18:1, which accounted for 80.08% of the monounsaturated fatty acids (*Table 2*). The main polyunsaturated fatty acids were c22:6n-4, which accounted for 58.57% of the polyunsaturated fatty acids (*Table 2*). The proportion of saturated fatty acids, monounsaturated fatty acids, and polyunsaturated fatty acids was 1.37:1:1.80 (*Table 2*). Although the concentration distribution of various fatty acids in muscle of male and female fish was similar, the contents of most of fatty acids in muscle were significant differences between the male and female Chinese hook snout carp samples, in which c15:0 and c18:1 in male muscle were more than one time than those in female, while c27:2n-3 in female muscle was more than one time than that in male (*Table 2*).

Discussion

There is a close relationship between the nutritional composition of fish muscle and its feeding habits (Wang et al., 2010a). Generally, contents of crude protein and crude fat in muscle of carnivorous fishes are higher than those of herbivorous fishes, while the content of crude ash is lower than that of herbivorous fishes (Wang et al., 2010a). Our results showed that the content of crude protein in the Chinese hook snout carp was higher than that of yellow catfish (*Pelteobagrus fulvidraco*) (Jiang et al., 2013) and Qinling lenok (*Brachymystax lenok*) (Xu et al., 2010), lower than that of *Phoxinus lagowskii* (Zhang et al., 2013), and closed to that of *Neosalanx brevirostris* (Jiang et al., 2011) and other carnivorous fishes (Sun et al., 2008; Jiang et al., 2013). These results implied that the muscle of Chinese hook snout carp contained high protein level and conformed to its carnivorous attribute.

Sex is one of the most important factors that affect the composition of muscle nutrients in fish (Jiang et al., 2011; Zhang et al., 2013). Although contents of most of amino acids in muscle are significant difference between male and female *Neosalanx brevirostris* (Jiang et al., 2011) and *Silurus asotus* (Jiang et al., 2012), our results showed that only cystine content was significant difference between male and female Chinese hook snout

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36513658

carp, which was consistent with previous report in *Pelteobagrus fulvidraco* (Jiang et al., 2013). However, contents of most of fatty acids were significant differences in muscle between male and female Chinese hook snout carp, which was consistent with previous reports in *Neosalanx brevirostris* (Jiang et al., 2011).

Fish species is an important factor affecting the nutritional composition in muscle. Choi et al. (2008) reported that the protein in the muscle of *Sophorae fructus* is composed of a total of 18 different kinds of amino acids, and the contents of saturated fatty acids, monounsaturated fatty acids, and polyunsaturated fatty acids in the muscle of *Sophorae fructus* are 24.94%, 32.40%, and 32.86%, respectively. Our results showed that the contents of saturated fatty acids, monounsaturated fatty acids, and polyunsaturated fatty acids in the muscle of were 28.38%, 20.78%, and 37.46%, respectively. In addition, culture patterns, food sources and fish strains affect the compositions of fish nutrients (Wang et al., 2010b; Zhou et al., 2014).

Conclusion

In conclusion, contents of the crude protein, crude fat, and crude ash in male Chinese hook snout carp muscles were 17.23 ± 1.54%, 2.71 ± 0.61%, and 1.32 ± 0.10%, respectively. Contents of the crude protein, crude fat, and crude ash in female fish muscles were 16.71 ± 0.99%, 2.23 ± 0.92%, and 1.36 ± 0.02%, respectively. No significant difference of the crude protein, crude fat, and crude ash was detected between male and female fish. Although there was no significant difference in the contents of most amino acids between male and female fish, the contents of flavored amino acids, essential amino acids and total amino acids in male fish muscle were significantly higher than those in female fish muscle. The proportion of saturated fatty acids, monounsaturated fatty acids, and polyunsaturated fatty acids was 1.37:1:1.80, and most of fatty acids were significant difference between male and female fish. However, the influence of feed formulae designed according to our results on the reproduction and growth of Chinese hook snout carp should be further studied.

Abstract. *Picea schrenkiana var. tianshanica* (*PSVT*) is an endemic tree species in Xinjiang, and serves as windbreak and soil consolidation, to ensure the stability of ecological environment. To efficiently and quickly grasp the ecological status of *PSVT* and the stability of forest ecosystem, we used images of different resolutions (GF-2 (1 m), GF-1 (8 m), GF-1 (16 m), Landsat 8 (30 m)) combined with field survey data, and performed multi-resolution segmentation to select the best segmentation scales. Based on the spectrum, texture and terrain factors, the canopy closure inversion of *PSVT* was performed to select the characteristic factors suitable. Then, we applied three object-oriented methods (i.e. support vector machine (SVM), classification and regression tree (CART), and nearest neighbor classification (NNC)) to classify the forest land. The result shows that the near-infrared (NIR) band is highly independent and makes an important contribution to the optimum index factor (OIF), in which the real-time adjustments of segmentation results are made to achieve better effect. There is a significant relationship between textural features of each band. The canopy closure estimation model performs better with a combination of spectral, terrain, and texture factors. Compared to CART and NNC models, SVM classification achieved better accuracy.
Keywords: *multi-resolution segmentation, remote sensing, environmental factors, canopy closure, supervised classification*

Introduction

Picea Schrenkiana var. tianshanica (*PSVT*) is a unique tree species in Xinjiang that is important to the wind resistance, soil stabilization, and overall stability of the ecological environment. The fast and efficient monitoring of forest resource information (Fernandez et al., 2019) and changes has become an important basis for scientific management and the efficient use of forest resources. Canopy closure (Perea et al., 2019; Adepoju et al., 2020), an important aspect of forest information surveys, reflects the growth status and density of forests, and plays a very important role in forest monitoring, so it is widely used in forest resource information surveys and forest ecology evaluations.

With the increasing number of satellite image sources, high-spatial-resolution remote-sensing images now contain more abundant spectral, spatial, shape, and textural information (Abdulhakim, 2019). Using only the spectral information of a single image will very likely cause the problems of "same substance and different spectrum" and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36593681

"different substance and same spectrum" (Gilcher et al., 2019). The reasonable and effective selection of image data sources along with spectral factors, textural information, and terrain factors is very important for ensuring the accuracy and classification of canopy closure. Object-oriented methods can make better use of detailed information regarding an image's spectrum, space, shape, and texture (Baatz, 2000; Hofmann, 2001; Sun, 2009; Guo, 2012). For instance, Baatz (2000) and Hofmann (2001) conducted extensive experiments and research on high-resolution remote-sensing images and proposed a method for processing target features and an object-oriented classification. Hofmann (2001) used an object-oriented method to process IKONOS remote-sensing images to effectively classify buildings and highways. Piazza (2016) used aerial imagery to produce a graphic drawing of the tropical rain forest area in southern Brazil, and compared object-oriented and pixel-based classification methods. Guo (2012) took HJ-1 image and used an object-oriented method to effectively classify forest land information in Mentougou district, Beijing. Based on IKONOS images, Sun (2009) used the object-oriented and pixel-based fuzzy classification methods to extract urban-forest-park land in Fuzhou. Data with different resolutions often require different classification methods (Maas, et al., 2019). The canopy closure of a forest stand is used to achieve effective and precise forest classification (Donato et al., 2019), and the relationship between the internal information and depression in images has been widely studied. Linear regression modeling is performed, using the measured value of the degree of sample depression as the dependent variable (Rajasekhar et al., 2019) to obtain the correlation between the image feature factor and the degree of depression. Finally, the precise classification of a forest is realized based on its canopy closure.

In this study, we investigated the effects of spatial resolution on forest classification accuracy and selected the appropriate classification model based on images with different resolutions. Combining field survey data from GF-2 (1 m), GF-1 (8 m), GF-1 (16 m), and Landsat 8 (30 m) images, we established a canopy closure estimation model, selected sensitive feature factors, and used the classification and regression tree (CART), nearest neighbor classification (NNC), and support vector machine (SVM) methods to classify the *PSVT*. Then, we compared the accuracies of the different classifiers. Our aim in this work was to explore the effect of using data with different spatial resolutions and different classification methods on the precision of forest classification.

Materials and methods

Study area

The study area is located in the middle of the Tianshan Mountains (Dilixiati et al., 2019), 110 km southwest of Urumqi (86°46′ E–86°57′ E, 43°16′ N–43°26′ N). The total forest farm area is approximately 10444 hm^2 with a woodland core area 5116 hm^2. The terrain in the study area is complex, with high terrain in the south and low terrain in the north. The altitude ranges between 1700 and 3200 m. Topographic changes are obvious, and the slope mainly ranges between 10° and 40°. A wide range of rivers flows within the forest farm, with the Toutunhe River flowing from south to north, and small tributaries flowing throughout the area. The drinking water of local herders is mainly from these rivers. The annual precipitation in the study area is unevenly distributed. The annual average precipitation is about 600 mm, with great seasonal differences. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36593681

concentrated precipitation in summer and autumn accounts for a large proportion of the precipitation over the whole year. The annual average temperature is 3 °C, and the average temperature in July is 14 °C (Aizezitiyuemaier et al., 2019). The total annual sunshine is 1300 h, and the frost-free period lasts 140 d. *Figure 1* shows the specific location of this area, with the forest mainly distributed on the northeast and northwest slopes, comprising mainly grasses and *Picea Schrenkiana var. tianshanica* (*PSVT*), and the soil of the forest being ordinary taupe forest soil. As the main dominant conifer species in Xinjiang mountain forests (Li et al., 2019), *PSVT* comprises an important part of the northern forest. It also plays an irreplaceable role in the conservation of water resources (Liu et al., 2019), maintaining both the water and soil and the ecological balance of the Xinjiang oasis.

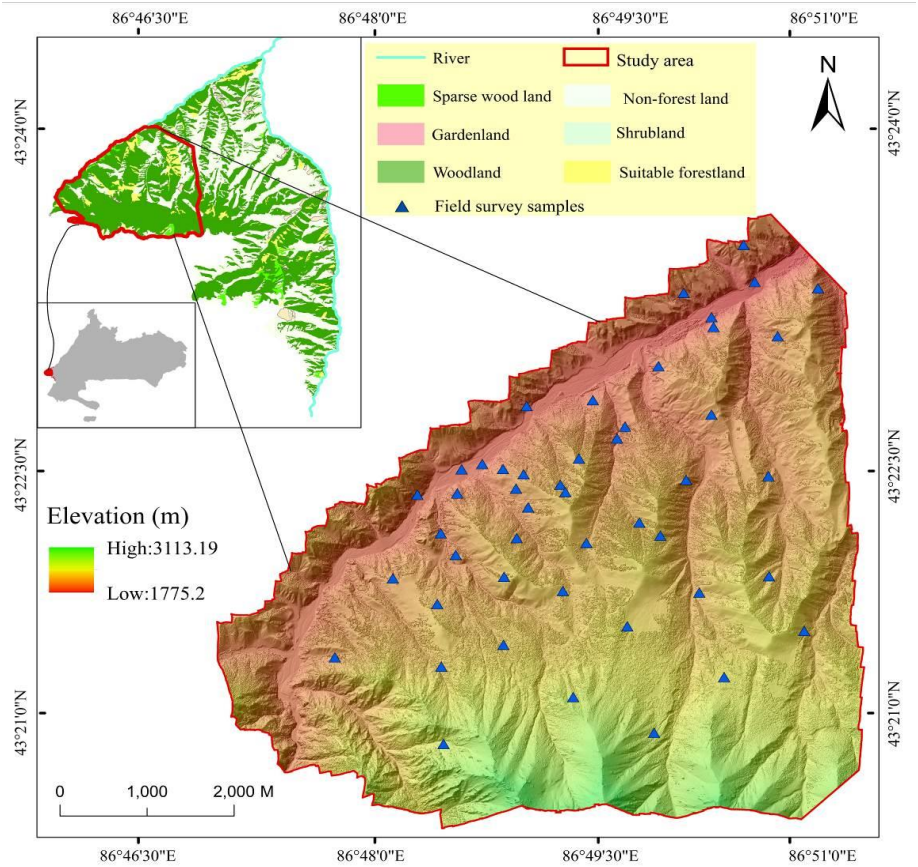

Figure 1. *Study area showing study plots and forest types*

Data and processing

Remote sensing data

Data with different scales reflect the spatial heterogeneity of forest stands. In this study, we used remote-sensing images with four scales, including GF-2 (1 m), GF-1 (8 m), GF-1 (16 m), and Landsat 8 (30 m). According to multispectral satellite imagery data in the study area (*Table 1*), we performed extensive pre-processing, including radiometric calibration, atmospheric correction, orthorectification, projection definition, cropping, and image fusion. We then used these satellite remote-sensing images to invert the canopy closure for classification experiments.

Field survey data

The field data mainly included data from 47 plots with the dimensions 30 m × 30 m surveyed from July to September 2017 (*Fig. 2*), including their latitudes and longitudes, along with their wooden height, crown width, slope, aspect, elevation, and canopy closure. We used GPS to record the center point of the sample square and the positions of the four corner points and matched the measured sample plots with the corresponding remote-sensing images. The measurement process of the canopy closure was as follows: First, we set the sample points and captured images of five crowns with the Win SCANOPY canopy analyzer, include center point, 2 diagonal lines formed by southeast-northwest and northeast-southwest. Then, we used Win SCANOPY 2016 software to calculate the light transmission porosity of the five canopy images, using the mean value as the true value of the measured light transmittance in the ground field. To eliminate the influence of shrubs and weeds on the canopy measurements, we set the height of the fisheye lens to 1.5 m. Using the Win SCANOPY 2016 software to analyze the fisheye photos, we obtained two measures of light transmittance porosity, the gap fraction and the openness. The openness measure eliminates the effect of nonlinear projection on the transparency of the canopy to generate a result equal to the true canopy transparency. Therefore, we used the openness measure as the canopy transparency.

Methods

Multi-scale segmentation

Multi-scale segmentation, an algorithm based on region segmentation, performs bottom-up segmentation of target image data. The objective is to gather one or more groups of pixels with similar features to identify a set of regions and thereby obtain different image objects as carriers for the next image classification. In the process of segmentation, a different level of network structure is established and each segmentation is based on the image object layer of the following layer for segmentation, which is then merged in the segmentation process. The segmentation parameters mainly include the segmentation scale and weight factor. Spectral and shape factors and smoothness and tightness factors are two important pairs of parameters in multi-scale segmentation. The sum of the spectral and shape factors is equal to 1, and that of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36593681

smoothness and tightness factor is also 1, so the reasonable adjustment of parameters has an important impact on multi-scale segmentation.

Best factor index (OIF) method

We used the best factor index (OIF) method (Goodchild, 1995; Singh, 2013) to select the bands of the GF-2 (1 m), GF-1 (8 m), GF-1 (16 m), and Landsat 8 (30 m) images. By calculating the standard deviation of each of the four types of data and the correlation coefficients between the bands, we could select the band combination most suitable for the region. This is because the standard deviation indicates the amount of information contained, and the correlation coefficient between each band reflects the independence of the image data and their degree of redundant information. To calculate the OIF, we use *Equation 1:*

$$OIF = \frac{\sum_{i=1}^{n} Y_i}{\sum_{i=1}^{n} \sum_{j=i+1}^{n} |Y_{ij}|} \quad \text{(Eq.1)}$$

where n is the band of the remote-sensing images, Y_i is the standard deviation of each band, and Y_{ij} is the correlation coefficient between band i and band j.

Principal component analysis (PCA)

We used the PCA algorithm to reduce the number and dimensions of the feature factors and improve processing efficiency (Lin et al., 2004). First, we analyzed the correlation between individual feature factors, after which we used the variance matrix to orthogonally rotate the load matrix of the feature factors and select the factors with a load factor of 0.85 or higher in each principal component. The selected feature factors were then used as independent variables to construct the canopy-closure estimation model. PCA not only ensures that unrelated comprehensive factors can be extracted to minimize the loss of information, but also reduces the spatial dimensions.

Multiple stepwise regression

Multivariate stepwise linear regression is the basic modeling method used in regression modeling, whereby the model selects the variable x_1 that has the most significant effect on the dependent variable among all the n independent variables. Then it selects the variable $x_2 \ldots x_1$ with the most significant effect on the dependent variable among the remaining n-1 independent variables. In this way, $x_2 \ldots x_n$ establishes a multivariate equation, and another multivariate equation is established for significant x_1, x_2, … x_m variables. Next, the model selects and verifies all the independent variables that have a significant effect on the dependent variable. The multivariate stepwise linear regression equation (*Eq. 2*) is:

$$y = k + ax_1 + bx_2 + cx_3 + \ldots + nx_m \quad \text{(Eq.2)}$$

where k is a regression constant term, a, b, c…n are the regression coefficients, and x_1, x_2, … x_m are the significant independent variables.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36593681

Classification method and accuracy evaluation

We used three methods to classify forest land and compare the classification results (Wang et al., 2019; Wei et al., 2019), including CART, NNC, and SVM. CART, a common classification method (Cai et al., 2019), uses the Gini Index to select the best test variable. It achieves fast classification and has strong practicability. NNC classifies by determining the distance between sample objects, with the degree of membership of a sample determining the classification accuracy. SVM improves the generalization ability of a model by reducing the amount of sample error by transforming the sample space into a high-dimensional space and then constructing an optimal classification hyperplane as the decision surface. In this study, we correlated the main evaluation indicators, i.e., overall accuracy, mapping accuracy, and user accuracy, based on the confusion matrix method. Using the coefficient of determination (R^2), root mean square difference (RMSE) (*Eq. 3*), and estimation accuracy (EA%) (*Eq. 4*), we could determine the accuracy of the different types of canopy-closure models, and using the confusion matrix to calculate classification accuracy, include overall accuracy (OA) (*Eq. 5*), user accuracy (UA) (*Eq. 6*), and producer accuracy (PA) (*Eq. 7*).

$$RMSE = \sqrt{\frac{\sum_{i=1}^{n} (s_i - y_i)^2}{n}} \quad \text{(Eq.3)}$$

$$EA = (1 - \frac{RMSE}{Ave(y_i)}) \times 100\% \quad \text{(Eq.4)}$$

$$OA = \frac{TP + TN}{T} \quad \text{(Eq.5)}$$

$$UA = \frac{TP}{TP + FP} \quad \text{(Eq.6)}$$

$$PA = \frac{TP}{TP + FN} \quad \text{(Eq.7)}$$

y_i, s_i represent the measured and estimated values, respectively; Ave(y_i) are the average values of the samples, and n is the number of samples; TP is the correctly extracted objects; FP is the incorrectly extracted objects; TN is the non-samples that are correctly rejected; FN is the samples that are not detected.

Results

Canopy features extraction

Vegetation index factor

When considering the spectral features (Twisa and Buchroithner, 2019; Brabant et al., 2019), we selected three vegetation indices, the ratio vegetation index (RVI),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36593681

normalized vegetation index (NDVI), and the transformed normalized difference vegetation index (TNDVI) (*Table 2*). The RVI changes significantly with changes in the vegetation coverage. When the coverage exceeds or is lower than 50%, the sensitivity of the RVI to vegetation increases or decreases, which reflects the vegetation coverage. NDVI, which is derived from RVI by simple nonlinear normalization, reflects the growth of the vegetation and the effective coverage, and effectively eliminates the influence of atmospheric radiation to show the same trend as shown by the vegetation coverage (*Fig. 3*). TNDVI is mainly used to adjust the NDVI when the sensitivity of the vegetation coverage is higher or lower, and it more intuitively reflects the comprehensive condition and growth of vegetation.

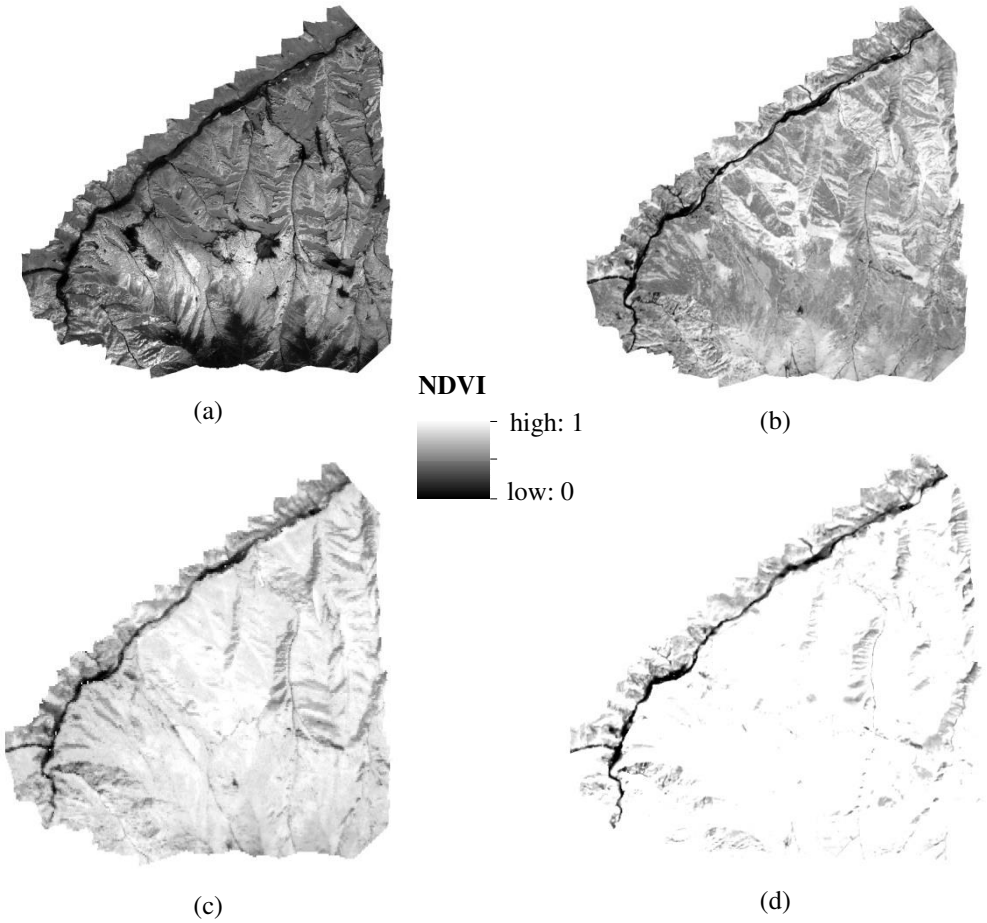

Figure 3. *Vegetation index features of remote-sensing images. (a) GF-2 (1 m); (b) GF-2 (8 m); (c) GF-2 (16 m); (d) Landsat 8 OLI (30 m)*

Terrain and shadow index factor

Due to the height angle of the sun, the height of the object itself, and the varied topography in the study area, a remote-sensing image will contain more shadows, which can affect the estimation of the canopy closure in the study area. Using ENVI 5.3 software, we found the slope, slope direction, and height of the study area to have a direct impact on the canopy closure of the stand and the extraction of the shadow index,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36593681

slope, aspect, and height of the image. In particular, the shadow index is the ratio of the fourth to the third band based on the image data.

Table 2. *Alternative factors for vegetation index*

Modeling factor	Calculation formula
Ratio vegetation index (RVI)	$RVI = \frac{DN_{NIR}}{DN_R}$
Normalized vegetation index (NDVI)	$NDVI = \frac{NIR - R}{NIR + R}$
Conversion vegetation index (TNDVI)	$TNDVI = \sqrt{\frac{DN_{NIR} - DN_R}{DN_{NIR} + DN_R + 0.5}}$

R: Red band; NIR: Near infrared band

Texture factors

The simple use of spectral features will result in a large loss of spatial information of the image, whereas the addition of textural features can make full use of the spatial information. In the same kind of remote-sensing images, the textural features of different canopy regions can differ, with the texture of a canopy with a larger canopy closure being more uniform and that with a smaller canopy closure being less uniform. Choosing the right type of textural feature will greatly improve the accuracy of canopy estimation. The gray level co-occurrence matrix (GLCM) (Haralick, 1973) describes the correlation and spatial structures of pixel pairs based on the spatial relationship of the gray values of an image. GLCM is the most commonly used method used for textural analysis. In this study, we used the GLCM to extract eight textural features from Tianshan spruce forest images in the study area. *Figure 4* shows the specific textural feature factors and extraction results.

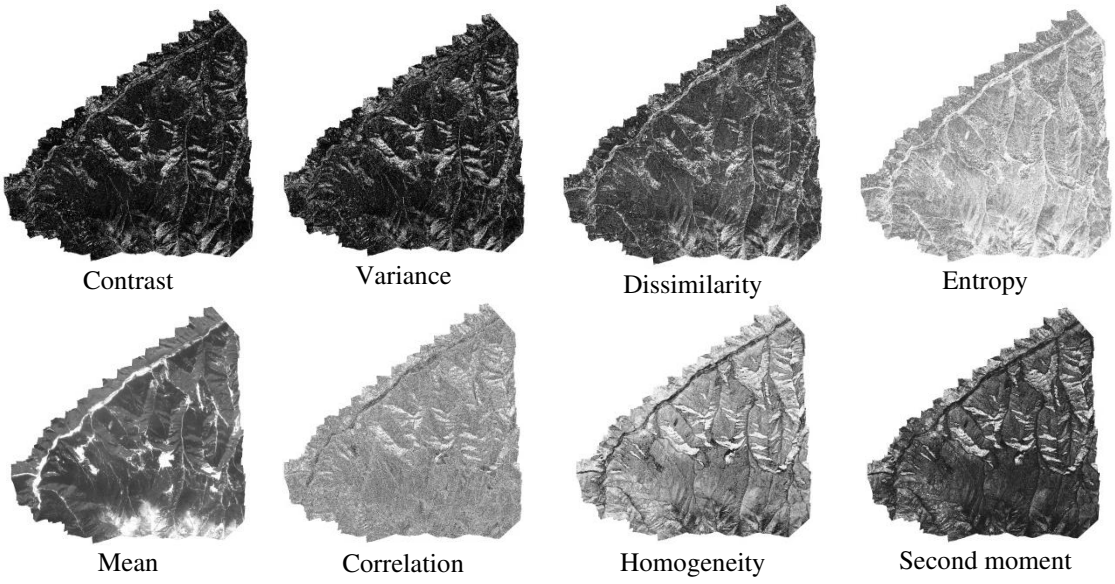

Figure 4. *Textural features of band 1 of GF-2 remote-sensing image*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36593681

Multi-resolution segmentation

Each band of multispectral remote-sensing data with different spatial resolutions contains different amounts of information. Using the weight ratio method, the spectral information of these different bands can be biased or discarded to improve the segmentation efficiency and effect of different remote-sensing images. In this study, we used the OIF method to compare and screen the bands by calculating the standard deviation of each band and the correlation coefficient between bands in the remote-sensing images with different spatial resolutions. When the standard deviation between the bands is larger, the correlation coefficient between the bands will be smaller, and the more information is contained in the band, the stronger is the independence of the data.

In *Table 3* we can see that for band combination GF-2 (1 m), the highest OIF value is the combination with band 234. Compared to the band combinations 123, 124, and 1234, it can be seen that when the 1st and 2nd bands are fixed, the 4th band is introduced, and the OIF value is increased from 64.357 to 74.392, and when the 234 band combination is fixed, band 1 is introduced to the band combination, and the OIF value is reduced from 78.665 to 67.15. For GF-1 images (8 m), when the first and second bands are fixed, the fourth band is introduced, and the OIF value does not change significantly. When the band combination 234 is fixed, band 1 is introduced to the band combination, and the obtained OIF value is significantly reduced from 69.014 to 55.134. For GF-1 images (16 m), when the 1st and 2nd bands are fixed, the 4th band is introduced, and the OIF value does not increase significantly. When the band combination 234 is fixed, band 1 is introduced to the band combination, and the obtained OIF value is significantly reduced from 68.836 to 47.402. For Landsat 8 images (30 m), in the band combination (*Table 4*), the combination of the 146th and 456th bands has a higher OIF value.

Table 3. *GF data OIF values of each combination band*

Combined band	123	124	134	234	1234
GF-2 (1 m)	64.357	74.392	76.811	78.665	67.165
GF-1 (8 m)	51.233	52.736	59.236	69.014	55.134
GF-1 (16 m)	44.987	47.496	57.246	68.836	47.402

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36593681

In short, for remote-sensing image data with different resolutions, the image information contained in the near-infrared band is rich, the image information contained in this band is relatively independent, and the contribution to the OIF is also obvious. In addition, to extract forest land information, the near-infrared band shows high reflectivity of the vegetation, which has obvious benefit for the extraction of forest land information. When setting the weight of the split band and the weights of the GF-2 (1 m), GF-1 (8 m), and GF-1 (16 m) bands, we set the data to 0 (band 1), 1 (band 2), 1 (band 3), and 2 (band 4). For Landsat 8 (30 m), we set each band weight to 0 (band 1), 1 (band 2), 0 (band 3), 1 (band 4), 2 (band 5), 2 (band 6), and 1 (band 7).

In the multi-resolution segmentation process, the segmentation scale can either too small or too large, which will affect the accuracy of the target object classification. As such, it is important to set the optimal segmentation scale for different image data in the target region to ensure that the multi-resolution segmentation can effectively segment different remote-sensing data, which lays the foundation for information extraction and classification of different images. Depending on the target of the extracted features, the types of bands involved in the segmentation will differ, so no single classification method can be used. Using eCognition Developer 9.0, we scaled and processed the remote-sensing data with four different resolutions, and intercepted some regions with richer terrestrial types to compare the segmentation effects of different data sources, categories, and scales.

In terms of GF-2 (1 m), GF-1 (8 m), GF-1 (16 m), and Landsat 8 (30 m), we set the segmentation scale from 90, 65, 30, and 20 respectively (Zhang et al., 2015), with a step size of 5, and simultaneously set the compactness and smoothness of the remote sensing data with different resolutions to be 0.5, to study and analyze the spectrum and shape factors. Specifically, the compactness value is set to be 0.5 (remain unchanged), the initial value of the shape factor is set to 0.1, and we increase the shape factor from 0.1 to 0.8 with a step size of 0.1, to conduct the multi-scale segmentation experiments in turn (Zhang et al., 2014). After several experimental comparisons, we obtained the optimal segmentation scales for GF-2 (1 m), GF-1 (8 m), GF-1 (16 m), and Landsat 8 (30 m), which are 115, 85, 55, and 35, respectively. We set the shape and compactness of the weighting factors to 0.3, 0.5, 0.3, 0.5, 0.5, 0.6, 0.2, and 0.5, respectively, and achieved superior results for each image (*Fig. 5*). The results indicate that the topography of the study area comprises mostly natural landforms, and that most of the features are Tianshan spruce forest land and grassland, which means the shape factor accounts for only a small proportion and the spectral factor accounts for a large proportion.

With respect to the band weights of the remote-sensing image bands, during the segmentation process, we set different band weights for different remote-sensing data from the same research area. In this study, we calculated the standard deviation and correlation coefficient of each band based on remote-sensing data with different spatial resolutions, and used the OIF value to determine the best combination of bands for performing image segmentation. From the analysis, we found that the combination of different bands of the remote-sensing images with the same resolution and the same bands of images with different resolutions yielded different OIF values. The correlation coefficient is relatively small between the near-infrared band (NIR) and other bands in the remote-sensing image data. The independence of the band information is also strong, and the contribution rate to the OIF value is also large. When segmenting the Tianshan spruce forest based on GF-2 (1 m) remote-sensing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36593681

data, when the weights of the first, second, third, and fourth bands are set to 0, 1, 1, and 2, respectively, and the division scale, shape, and compactness factor are respectively set to 115, 0.3, and 0.5, the obtained segmentation result is optimal. For GF-1 (8 m), when the weights of the 1st, 2nd, 3rd, and 4th bands are set to 0, 1, 1, and 2, respectively, and the division scale, shape, and compactness factors are set to 85, 0.3, and 0.5, the best image segmentation is obtained. For GF-1 (16 m) data, we set the weights of the first, second, third, and fourth bands to 0, 1, 1, and 2, respectively, the scale selection to 55, and the shape and compactness factors are to 0.5. At 0.6, the segmentation results are the best. For Landsat 8 (30 m) remote-sensing images, we set the weights of the 1st, 2nd, 3rd, 4th, 5th, 6th, and 7th bands to 0, 1, 0, 1, 2, 2, and 1, respectively. When the shape and the compactness factor are 0.2 and 0.5, the image segmentation effect is the best.

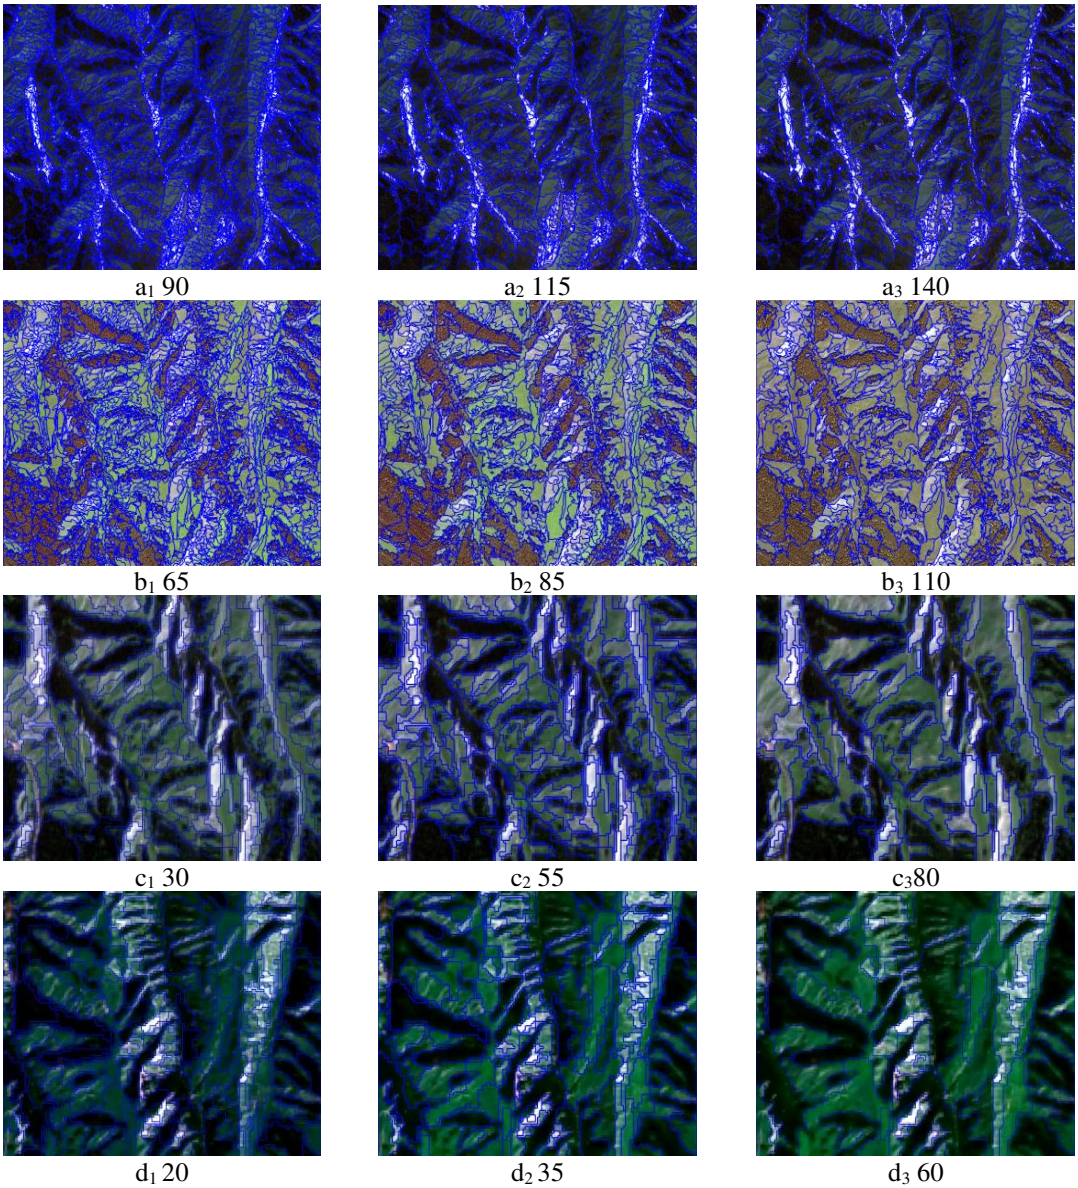

Figure 5. *Maps of multi-scale segmentation effects of remote-sensing data with different resolutions. a_1, a_2, a_3 are GF-2 (1 m) images, b_1, b_2, b_3 are GF-1 (8 m) images, c_1, c_2, c_3 are GF-1 (16 m) images, d_1, d_2, d_3 are Landsat 8 (30 m) images*

Canopy closure simulation

Next, we conducted an experiment using the GF-2 (1 m), GF-1 (8 m), GF-1 (16 m), and Landsat 8 (30 m) images. Using the image and feature factor variables, we constructed a canopy-closure estimation model based on the measured values of the canopy closure in the field, and then evaluated its accuracy. We calculated 39 features related to the spectra, texture, shape, topography, and shadow index. Spectral factors included the NDVI, RVI, TNDVI, SI; topographic factors including the slope, aspect, and altitude; and textural factors including the mean, variance, homogeneity, contrast, dissimilarity, entropy, second moment, and correlation. Using SPSS 19.0 software, we performed correlation analysis of the 39 extracted feature factors and the measured canopy-closure values, and selected the factors with a small correlation. As independent variables, we used spectral and topographical features, textural features, spectral and topographic features + textural features, and used canopy closure as the dependent variable. We used the multi-step regression method to construct the canopy closure model. In *Table 5*, the fit of the canopy-closure regression model based on the spectral, topographic features and texture features is significantly better than that achieved when using a single spectrum, topographical features, or textural features. R^2 and corrected R^2 reflect degree of advantages for simulation results.

To test the universality of the estimated model, we tested its accuracy. The remaining 15 test samples were used in three regression models to obtain predicted canopy-closure values, and we calculated the RSME and EA (%) of each group. As can be seen from *Table 6,* the determined coefficient of the estimation model based on textural features is better than that based on spectral and topographic features, the determined coefficient of the estimation model based on spectral, topographic, and textural features is significantly improved, and the estimation accuracy is greatly improved.

Object-oriented classification

According to the image features in the study area and the actual survey results for GF-2 (1 m), GF-1 (8 m), GF-1 (16 m), and Landsat 8 (30 m), these four kinds of images were segmented at multiple scales. We selected the image objects at the optimal segmentation scale and established classification levels. We used the NNC, SVM, and CART methods to classify the forest land. According to the classification standards and the actual conditions of the study area, with reference to land-use classification standards, we divided the ground objects within the study area into six categories, including buildings, water, shrub land, grassland, bare land, and forest. We then divided the forest land into dense forest land, middle wood land, and sparse wood land according to the degree of canopy closure. *Figure 6* shows the results of classification based on four kinds of images using NNC, SVM, and CART methods, respectively, a1, a2, a3, a4 are the results of using CART classifier; b1, b2, b3, b4 are the results of using NNC classifier; c1, c2, c3, c4 are the results of using SVM classifier.

The evaluation of accuracy is a key step in remote-sensing image classification. In this study, we selected a total of 200 sample verification points in the study area to evaluate the accuracy of the three image-classification methods. To calculate their accuracies, we constructed a confusion matrix. The selected sample verification points were mainly derived from field sampling points, drone aerial sampling points, a distribution map of a second-class survey of forest resources, and forest phase maps of the study area. *Tables 5-8* list the classification accuracies of these methods for GF-2 (1 m), GF-1 (8 m), GF-1 (16 m), and Landsat 8 (30 m) images, respectively.

As shown in *Table 7,* in terms of overall accuracy, the classification accuracy of the SVM method was 84.50%, which is better than those of the other two classification methods. This result demonstrates that classification based on the SVM method is more suitable for forest land classification of GF-2 (1 m) remote-sensing images. Regarding SVM's classification accuracy for different land types, the classification accuracies of buildings and sparse forests were the best, and those of middle and dense forests were good. The best classification result for middle and dense forests were also obtained by the SVM method, with user accuracies of 96.67% and 85.71% and mapping accuracies of 90.63% and 73.0%, respectively.

Table 7. *Accuracies of three classification methods of GF-2 (1 m)*

Type	NNC		CART		SVM	
	UA	PA	UA	PA	UA	PA

For the GF-1 (8 m) image classification, the SVM method also achieved a higher accuracy of 84.01%, which is 10% higher than that of the other two methods. When classifying middle and dense forests, the classification result for dense forest was relatively good, but that for middle forest was poor. Better classification results for dense forests was achieved by the CART and SMV methods, with user accuracies of 93.70% and 93.02% and mapping accuracies of 92.97% and 93.75%, respectively. In the classification of bare land, the NNC method obtained relatively good results, with a user and mapping accuracies of 64.29% and 69.23%, respectively (*Table 8*). The SVM method achieved better recognition of shrub land, with user and mapping accuracies of 71.43% and 62.50%, respectively.

Table 8. *Accuracies of three classification methods for GF-1 (8 m)*

Type	NNC		CART		SVM	
	UA	PA	UA	PA	UA	PA

For GF-1 (16 m) images, the classification of sparse forest land by the SVM method was also the best. The classification accuracy of the SVM method for dense forest was higher than that for middle-closed forest land for both user and mapping accuracy, i.e., higher than 80% (*Table 9*). The NNC method made obvious misclassifications and misjudgments in this category, which also occurred for bare land and shrub land, yielding only a fair classification accuracy.

Table 9. *Accuracy of three classification methods for GF-1 (16 m)*

Type	NNC		DTC		SVM	
	UA	PA	UA	PA	UA	PA
Buildings	100.00	100.00	100.00	100.00	100.00	100.00
Grassland	60.00	50.00	42.86	70.00	50.00	46.67
Water	100.00	100.00	100.00	85.71	77.78	80.00
Bare land	57.14	61.54	42.86	46.15	50.00	53.85
Shrub land	31.25	62.50	39.41	62.50	66.67	50.00
Dense forest land	96.10	57.81	89.62	74.22	88.89	81.25
Middle wood land	48.62	41.67	33.33	16.67	49.17	58.33

OA	58.00		68.00		72.50	

For Landsat 8 (30 m) images, in terms of overall accuracy (*Table 10*), the NNC classification accuracy was 73.50%. Compared with the CART and SVM methods, the NNC accuracy was 4.5% and 12% higher, respectively, which indicates that the NNC method is more suitable for forest land classification in the area. Regarding the classification accuracy for different land types, those for buildings and sparse forests were the best, and that for moderately closed forest land was fair. The classification accuracy of dense forest by NNC was the best, with user and mapping accuracies of 92.44% and 85.94%, but the classification accuracies of bare land and shrub land were low.

Table 10. *Accuracy of three classification methods of Landsat 8 (30 m)*

Type	NNC		CART		SVM	
	UA	PA	UA	PA	UA	PA
Buildings	100.00	100.00	100.00	100.00	100.00	100.00

In summary, in terms of overall classification accuracy, the best classification effect was achieved for GF-2 (1 m) remote-sensing images, and the worst for Landsat 8

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36593681

(30 m) remote-sensing images. The overall classification accuracies for the GF-1 (8 m) and GF-1 (16 m) images were 78.83% and 66.17%, respectively, which indicates that the classification accuracy of forest land in the study area depends to some degree on the spatial resolution of the image. Regarding classification methods, when using the CART method for classification, the overall classification accuracies for GF-2 (1 m), GF-1 (8 m), GF-1 (16 m), and Landsat 8 (30 m) remote-sensing images were 72.50%, 79.50%, 68.00%, and 69.00%, respectively. However, the classification method that is most suitable for the study area varies with the data source. In terms of GF-2 (1 m) images, our results indicate that the best classification for this study area is the SVM method, followed by the NNC and CART methods. For GF-1 (8 m) and GF-1 (16 m) images, the best classification method was SVM, followed by NNC. For Landsat 8 (30 m) images, the best to worst classification methods are the NNC, CART, and SVM methods.

Discussion

Superiority and summary

High-precision land use/cover remote sensing classification mapping is widely used in precision agriculture, vegetation ecology, wetland water quality, urban heat island, mineral resources, atmospheric environment, and other research fields. In this study, multi-source data was based on agreement analysis and refined classification (Jung et al., 2006). Compared with traditional remote sensing forest land classification methods, the object-oriented method can not only make full use of the spectral information of remote sensing images, but also can add texture information, shape information, and custom information according to the classification of ground features to more accurately compare effective extraction and classification of target features (Judah and Hu, 2019). In the case of determining the optimal segmentation scale, the selection of remotely sensed images that do not use spatial resolution and the use of different object-oriented classifiers will have a certain impact on the classification effect. Therefore, a reasonable selection of remotely sensed images to determine the spatial resolution of data and classification method has become the key to the fine classification of forest land types.

From the perspective of the spatial resolution of remote sensing images, when the resolutions of remote sensing images are 1 m, 8 m, 16 m, and 30 m, their average overall classification accuracy is 80.00%, 78.83%, 66.17% and 68.33% It shows that the higher the resolution, the higher the classification accuracy of the image. This is because the high-resolution images contain more feature information and categories, and the information utilization rate is higher, which leads to the improvement of the classification accuracy of the image. However, in practical applications, although the classification of images with a resolution of 1 m and 8 m is good, but because of the large amount of data it contains, the processing time is long, and the process is more complicated, you can choose to ensure certain accuracy Fast processing speed of 16 m and 30 m images.

From the perspective of the classification method, the classification method that is most suitable for the study area varies with different data sources. For example, in the GF-2 (1 m) remote sensing image, the classification effect of the study area is better by the support vector machine method, followed by the nearest neighbor method and the decision tree method; for the medium resolution GF-1 (8 m), GF-1 (16 m) remote sensing image, the effect is better is support vector machine, the worst is the nearest

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36593681

neighbor method; in Landsat8 (30 m) remote sensing image, the classification effect is the nearest neighbor classification, decision tree classification Support vector machine method.

This is due to a series of reasons such as different study areas, different image data sources, and the scale selected during segmentation. As a result, for each data source, the forest land classification method that is most suitable for the region is different. Due to the particularity of geographical location and terrain in this study area, the distribution of forest stands is complex. Different classification methods have been adopted for different data sources. It can be seen from the accuracy analysis that the adopted classification method has certain effectiveness and reliability, which meets the requirements for extraction of *Picea Schrenkiana var. tianshanic*a (*PSVT*).

Limitation and outlook

This study comprehensively uses the spectrum, terrain, texture, shape and other information contained in the image to estimate the canopy closure model and forest land classification of the study area (Amani et al., 2017; Dendoncker et al., 2007), which has certain limitations. (1) The study area is small, and large-scale verification and improvement are needed in other areas to ensure the universality of the estimation model. (2) The accuracy of results is affected by landscape heterogeneity in the study area. Therefore, although this research has made important progress in remote sensing classification mapping of land use/cover based on multi-source data, many follow-up studies need to be completed to obtain the best results. (3) In the future more attention should be paid to the fusion between different classifiers, because it is difficult for a single type of classifier to classify all the forest types better.

For example, the target classification system can be further refined. This study divided *PSVT* into eight main types: building, water, shrubland, middle woodland, grassland, bareland, dense woodland, sparse woodland. Specifically, these types are high generalizations of actual land types, avoiding as much confusion as possible due to the complexity of classification. However, in view of the particularity of forest areas, reasonable attention should be paid to *PSVT* resources in follow-up studies.

Conclusions

Taking GF-2 (1 m), GF-1 (8 m), GF-1 (16 m), Landsat 8 (30 m) images combined with field survey data, and performed multi-resolution segmentation to select the best segmentation scales. Based on the spectrum, texture and terrain factors, the canopy closure inversion of PSVT was performed to select the characteristic factors suitable for different images. Then, we applied three object-oriented methods (i.e. the support vector machine (SVM), classification and regression tree (CART), and the nearest neighbor classification (NNC) methods) to classify the forest land. The conclusions show that (1) the near-infrared (NIR) band is highly independent and makes an important contribution to the optimum index factor (OIF), in which the real-time adjustments of segmentation results are made to achieve better effect. (2) In the canopy-closure estimation model, a combination of the spectrum, terrain remote-sensing factors, and textural feature factors yields the best result. For GF-2 (1 m) images, the combination of the four characteristic factors SI, Con_2, Con_3, and Con_4 yields the best estimation model. The model estimation accuracy is an EA of 89.82%, an RMSE of 0.079, and a determination coefficient R^2 of 0.868. (3) In terms of GF-2 images, the classification performs better when using the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36593681

SVM method, which achieved an overall classification accuracy of 84.5%, thereby being an effective classification method for the forest land types in the study area. In terms of their economics and practicality, each data source has its own advantages.

Additionally, forest canopy estimation algorithm can be further developed. As there are many variables introduced, and there is a strong correlation between the texture feature factors, it is important to find a reasonable and effective modeling method. With the improvement of image resolution, the influence of the shadow index on the estimation of occlusion is getting larger and larger. Due to the differences in the selected remote sensing images or the differences in the ecological and geographical environments in different regions, the factors for estimating canopy closure in different regions should take into account the actual local conditions.

(Received 2nd Jan 2020; accepted 26th Mar 2020)

Abstract. Potato (*Solanum tuberosum*) is the fourth most important food crop worldwide, but soil-borne diseases lead to serious decline of potato yield and quality. Rhizosphere microbiota (RM) play an important role in the health of potato. However, the number of reports on the RM of potatoes with soil-borne diseases is still insufficient. To explore the correlation between RM and the potato soil-borne diseases, 3 rhizosphere samples of potatoes with blackleg disease (PBD), bacterial wilt (BW), and healthy controls were collected from a Chinese potato base and analyzed by Actinomycetes culturing and culture-free high-throughput sequencing technology. Our results showed that the amount of Actinomycetes in the healthy control was higher than that in the PBD and the BW. The RM composition of the healthy control was significantly different from that of the PBD and the BW. The increased bacterial species in the PBD group mainly concentrated in Firmicutes, while those in the BW mostly belonged to Betaproteobacteria. Soil pH and content of organic matter (OM), available phosphorus (P) and available potassium (K) were most significantly positively correlated with the bacteria that were enhanced in the healthy potato RM. The results implied that the RM of diseased potatoes were significantly different from the healthy controls, and moderately improved the soil pH, OM, P and K probably aid in the prevention of the PBD and the BW through regulating the RM.
Keywords: *high-throughput sequencing, potato blackleg disease, bacterial wilt, soil physicochemical indicators, soil-borne bacterial diseases*

Introduction

Potato (*Solanum tuberosum*) is the crop with the fourth largest planting area worldwide, following rice, corn and wheat (Bera et al., 2015). However, potato diseases, especially soil-borne bacterial diseases, have caused serious reduction in yield and quality (Mao et al., 2019). The soil-borne bacterial diseases have caused 22% of global potato loss, and the loss reaches to 65 million tons per year (FAO, 2008; Mao et al., 2019).

Potato blackleg disease (PBD) and bacterial wilt (BW) are two common soil-borne bacterial diseases. PBD is caused by *Pectobacterium atroseptica* and mainly damages the base of stem and tuber of potato. It can occur from seedling stage to late growth stage and storage period. In seeding stage, symptoms usually begin to appear when the plant height is 15-20 cm. The symptoms are that the leaves are chlorotic and yellow flowers roll up, the internodes of the plants are shortened, the tissues above the stem base are black and rotten, and eventually wilt and die (Mao et al., 2019). Potato BW is a destructive bacterial disease caused by *Ralstonia solanacearum*. The BW plants withered in the early daytime and returned to normal at dusk. Leaves remained green and did not turn yellow. Later stem rotted with mucus, and finally withered and died. Generally, the disease begins at the middle stage of plant growth, resulting in serious yield reduction (Jiang et al., 2017). In addition, the pathogens of the above diseases can

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36833691

invade the potato disability tissues to survive in winter. High temperature and humidity promote the diseases (Mao et al., 2019).

There are many rhizosphere microorganisms, such as bacteria and fungi, which play an important role in the nutrition and health of plants. For instance, the amount of actinomycetes in rhizosphere soil is collected to soil microecological balance (Chen et al., 2013; Zheng et al., 2016; Mao et al., 2019). Soil actinomycetes could inhibit soil-borne diseases of crops in potato-maize intercropping system (Zhao, 2013). Additionally, Ma et al. (2015) reported that change of soil microbial species in pepper root was related to its pathogenesis. These studies provide a direction for prevention and control of plant bacterial diseases through regulating the composition of rhizosphere microbiota (RM). However, there still are few comparative studies on the RM compositions of PBD, BW, and healthy potatoes, which implements the prevention of bacterial diseases of potato through regulating the composition of RM.

To elucidate the composition characteristics of the RM of potatoes with BW, PBD, and healthy controls for providing reference information to control the BW and PBD, the community structure of rhizosphere soil microorganisms of diseased and healthy potatoes were collected and analyzed using Actinomycetes culturing and culture-free high-throughput sequencing technology. The results could provide important reference for biological control of the potato soil-borne diseases.

Materials and methods

Sample collection

Potato rhizosphere soil samples were collected from the Jiuhua Potato Base in Huidong County, Huizhou City of China (22.86° N, 114.93° E) on September 20, 2017. The elevation of sampling sites was 11.03 m. A total of 9 rhizosphere soil samples including 3 samples of PBD, 3 samples of BW, and 3 healthy controls (*Fig. 1*), were collected according to our previous description (Mao et al., 2019). Diagnoses of PBD and BW were conducted according to previous descriptions (Jiang et al., 2017; Mao et al., 2019).

Determination of soil physicochemical indicators

Rhizosphere soil pH, content of organic matter (OM), alkali-hydrolyzable nitrogen (N), available phosphorus (P) and available potassium (K) in the rhizosphere soils was measured according to previous reports (Xiong et al., 2008; Shen et al., 2013).

Amount counting of actinomycetes

Amount counting of actinomycetes in the rhizosphere samples was conducted according to a previous report (Guan et al., 2018). Briefly, ten grams rhizosphere soil of each sample was weighted and added into a triangular bottle containing 90 ml sterile water and glass beads, then the triangular bottle was shaken for 20 min with 150 r/min at 28 °C to obtain the 10^{-1} suspension of rhizosphere soil. The 10^{-2}, 10^{-3}, and 10^{-4} gradient suspensions were prepared by the 10-fold dilution method. Each 100 μL suspension was added to the Gauze's synthetic medium No. 1 and the humic acid medium, then was inversely cultured 7 days at 28 °C to count the colony forming units (CFUs). Two replicates were set up in each sample. The CFUs in per ml were calculated (*Eq. 1*) as follows:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36833691

$$CFUs = N_{two} \times DM \times 10 \quad \text{(Eq.1)}$$

where N_{two} was the average colony number of two repeats, and *DM* was the dilution multiplier.

Figure 1. *Photos of healthy potatoes (A), potatoes with potato blackleg disease (B) and bacterial wilt (C), and symptoms of the diseases (D). PBD, potato blackleg disease; BW, bacterial wilt*

RM DNA extraction and high-throughput sequencing

DNA of RM was extracted using CTAB method according to previous reports (Fang et al., 2015; Ni et al., 2017). Then the DNA was purified using a DNA fast purifying kit (Dingguo Changsheng, China). One μL of each DNA sample was used to measure purity and concentration by a NanoDrop 2000 micro-spectrophotometer (Thermo, USA).

The V4 hypervariable region of the 16S rRNA gene was amplified using the 515F and 806R primers with sample-specific barcodes (Douglas et al., 2014; Li et al., 2017). PCR reaction mixture and the thermal cycling conditions were as reported in Li et al. (2017). The PCR producted were mixed at equimolar ratios and purified using an AxyPrep DNA gel extraction kit (Axygen, China), then sequenced using the Illumina MiSeq platform at BIG (China) and 250 bp paired-end reads were generated (Douglas et al., 2014).

The raw sequences were filtered for quantity control, merged, and assigned to each sample according to previous descriptions (Magoc and Salzberg, 2011; Huang et al., 2018; Xiang et al., 2018; Ni et al., 2019). The remaining sequences with > 97% similarity were assigned to the same operational taxonomic unit (OTU) using USEARCH v7.0.1090 (Edgar, 2013). Then the chimeric OTUs were detected and removed using UCHIME v4.2.40 (Edgar et al., 2011), the remaining OTUs were used as valid OTUs for subsequent analysis. The representative sequence of each OTU was annotated by RDP classifier v2.2 with reference to Greengene gg_13_8 dataset. The alpha-diversity indices were calculated using mothur v1.31.2.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36833691

The sequences were submitted to the Genome Sequence Archive (https://bigd.big.ac.cn/gsa/) database under accession number subCRA001900.

Data analysis

The results are presented as the mean ± standard error for each group. Principal component analysis (PCA) of OTUs was conducted using R ade4 package. Kruskal-Wallis rank sum test was conducted using R. Boxplots were drawn using R ggpubr package. Circular layout was drawn using R Statnet and circlize packages. LDA effect size (LEfSE) analysis (Segata et al., 2011) was conducted at Galaxy platform (http://huttenhower.sph.harvard.edu/galaxy/). Parametric multivariate analysis of variance (Per-MANOVA) was conducted using R vegan package.

Results

Amount differences of actinomycetes in RM between healthy and diseased potatoes

Amounts of actinomycetes in the RM of the healthy control, the PBD, and the BW were 16.52×10^5, 6.18×10^5, and 7.58×10^5 CFU/g in the humic acid medium, respectively; and those were 23.38×10^5, 7.72×10^5, and 6.23×10^5 CFU/g in the Gauze's synthetic medium No.1, respectively (*Fig. 2*). Although no significant difference was found (Kruskal-Wallis rank sum test, $\chi^2 = 5.60$, $p = 0.061$ for humic acid medium; $\chi^2 = 5.42$, $p = 0.066$ for Gauze's synthetic medium No.1), the amount of actinomycetes in the healthy control was much higher than those in the PBD and the BW, suggesting that the amount of actinomycetes had a positive effect on maintaining the ecological balance of the potato RM.

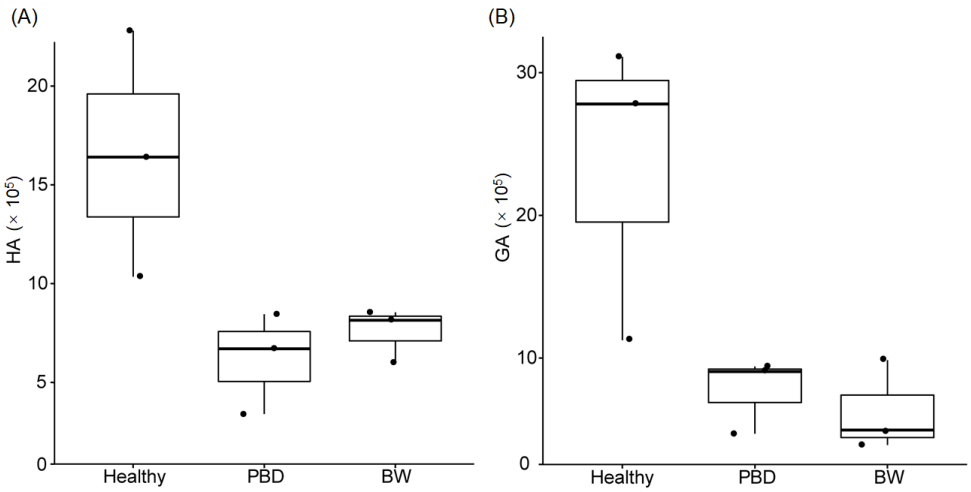

Figure 2. *Boxplots shows the amount differences of actinomycetes in different rhizosphere microbiota of potato. HA, humic acid medium; GA, Gauze's synthetic medium No.1. PBD, potato blackleg disease; BW, bacterial wilt*

Significant difference of RM between healthy and diseased potatoes

After removing low-quality and chimerism sequences, total of 263173 (29241.44 ± 365.93) merged sequences were obtained from the 9 samples. Total of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36833691

4096 (2200.56 ± 65.63) OTUs were detected under 97% sequence similarity. PCA result showed that the microbiota from the healthy control were significantly distinguished to PBD and BW groups, but those from PBD and BW groups did not distinguish to each other (Per-MANOVA, $F = 2.121$, $p = 0.045$; *Fig. 3A*). Although it has been reported that the alpha-diversity of RM of diseased potatoes was significantly decreased, no significantly decrease in the alpha-diversity of RM of diseased potatoes was found in the present study (Kruskal-Wallis rank sum test, $\chi^2 = 2.40$, $p = 0.301$; *Fig. 3B*).

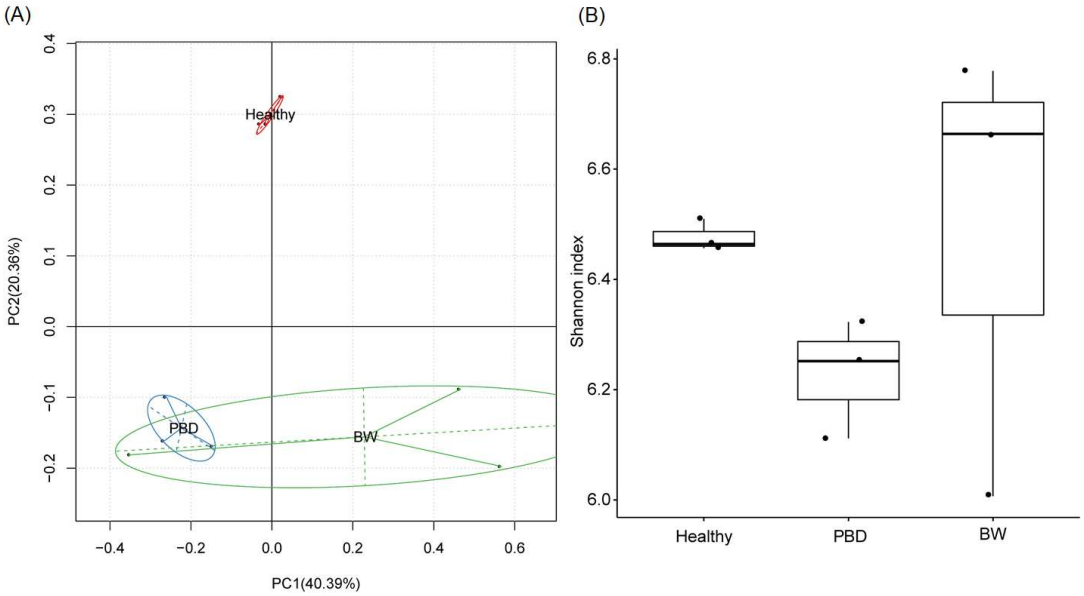

Figure 3. *PCA profile (A) shows the differences between the healthy, PBD, and BW groups; and boxplot (B) shows the Shannon index between the groups. PBD, potato blackleg disease; BW bacterial wilt*

Except rare tags (0.98 ± 0.08%) that could not ascertain their classification, other tags were classified into 50 phyla. However, only 15 phyla - Acidobacteria, Actinobacteria, Bacteroidetes, Chlorobi, Chloroflexi, Crenarchaeota, Euryarchaeota, Firmicutes, Gemmatimonadetes, Nitrospirae, Ploteobacteria, TM6, TM7, and Verrucomicrobia - dominated the microbiota, which contained 96.19 ± 0.32% of the high-quality analyzed sequences (*Fig. 4A*). Except TM6 (Kruskal-Wallis rank sum test, $\chi^2 = 6.489$, $p = 0.039$), other phyla were not detected significant difference between the groups. In addition, no significant difference was detected in TM6 between the groups through pairwise comparison using Wilcoxon test (*Fig. 4B*).

Considering there was a significant difference at OTU level between the healthy and diseased groups (*Fig. 3A*), we screened significantly different OTUs using LEfSe method. Our results showed that the increased bacteria in the PBD group mainly concentrated in Firmicutes, such as *Paenibacillus*, *Sporosarcina*, and *Caloramator*, while those in the BW group mainly concentrated in Betaproteobacteria, such as *Novosphingobium*, and *Rubrivivax*. Comparing with the two diseased groups, the bacteria species in the healthy controls mainly concentrated in Chloroflexi and Proteobacteria, such as *Anaerolinea*, *Desulfovibrio*, and *Geobacter* (*Fig. 5*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36833691

To analyze potential impacts of soil chemical indices on the RM OTUs, we analyzed their correlation and screened the significantly correlated soil chemical indices and the OTUs. Our results showed that soil pH, and soil content of OM, P and K mainly significantly positive correlated with the OTUs that significantly higher in the RM of heathy potatoes (*Fig. 5*). These results implied that moderately improved the soil pH, and content of OM, P and K probably aid in the prevention of PBD and BW through regulated the RM.

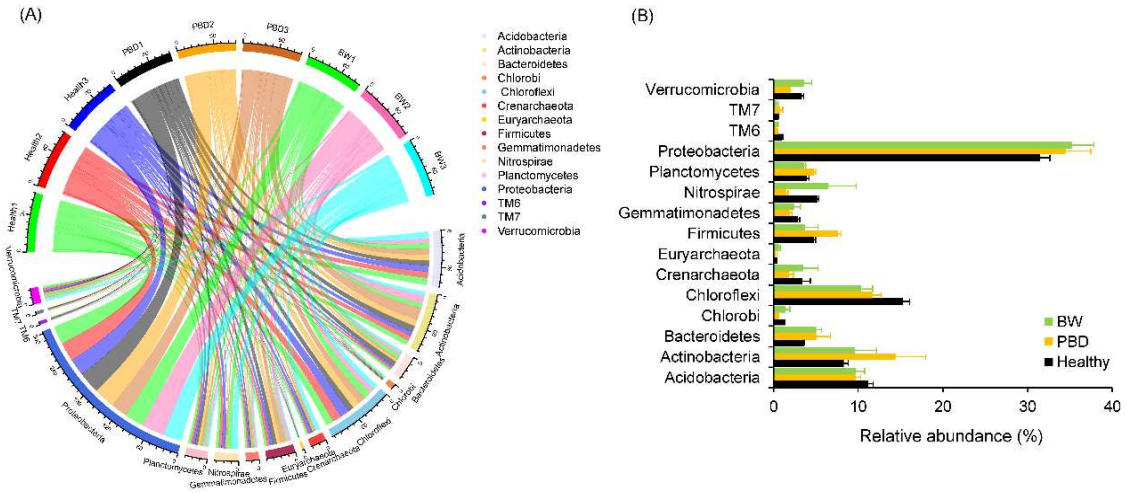

Figure 4. *Circular layout (A) and bar plot (B) show the distribution of dominant phyla in potato rhizosphere microbiota. PBD, potato blackleg disease; BW bacterial wilt. The error bars showed the standard errors of the relative abundances of the dominant phyla*

Discussion

Previous reports showed that amount of actinomycetes in the healthy potato RM was higher than that in the diseased potatoes (Chen et al., 2013), which implied that the actinomycete abundance has a positive effect on maintaining soil microecological balance and improving crop disease resistance. In present study, we also found that the amount of actinomycetes in the healthy potato RM was slightly higher than the diseased potatoes (the PBD and the BW groups). However, it is still need to further verify whether actinomycetes can effectively prevent the occurrence of potato bacterial diseases.

Our previous study showed that the PBD was closely related to the composition of the RM, and found *Flavobacterium*, *Acinetobacter*, *Dickeya*, *Sphingobacterium*, and *Myroides* were more abundance in the RM of the PBD than the healthy potatoes, while *Bacillus*, *Rhodophlanes*, *Kaistobacter*, and *Pedobacter* were less abundant in the PBD (Mao et al., 2019). In the present study, we found the increased bacteria in the PBD group mainly concentrated in Firmicutes, such as *Paenibacillus*, *Sporosarcina*, and *Caloramator*, while those in the BW group mainly concentrated in Betaproteobacteria, such as *Novosphingobium*, and *Rubrivivax* (*Fig. 5*). The inconformity was probably caused by sampling time and position, as season and geography are the two major factors that impact the compositions of soil microbiota and RM (Schloter et al., 2000; Wang et al., 2015).

Soil physicochemical indices play an important role in balancing the plant RM and preventing disease outbreaks (Zaccardelli et al., 2012; Vilvert et al., 2014; Wang et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36833691

2015; Gudeta et al., 2016; Bonanomi et al., 2018; Liu et al., 2019). Soil pH, content of P and K are highly correlated with the occurrence of plant diseases (Anderson et al., 1990; Sun et al., 2004; Burdon et al., 2014). Our results showed that properly increasing soil pH, and P and K content could help to increase relative abundances of the OTUs that were significantly enhanced in the healthy potato RM, and presumably helped to prevent PBD and BW, which was consistent with production practice that improvs potato disease resistance through using the plant ash and P and K fertilizers. Plant ash riches in minerals, which can provide K for potato seeding, and plant ash is alkaline, which can improve the rhizosphere soil pH.

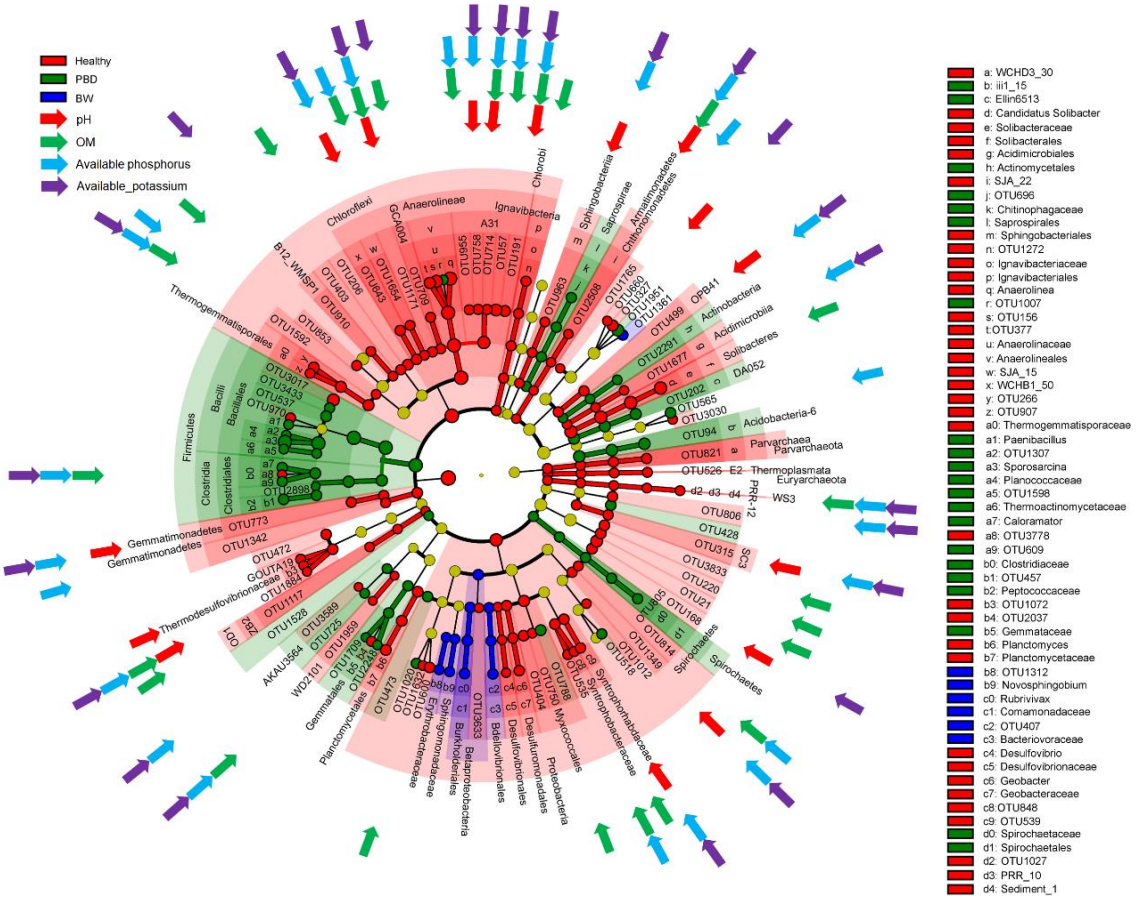

Figure 5. *LDA effect size (LEfSE) profile showed the significantly taxa between the PBD, BW, and healthy potatoes. PBD, potato blackleg disease; BW bacterial wilt. The arrows showed the OTUs that significantly positively correlated with soil chemical indices*

Conclusion

In conclusion, there were significant differences in the structure of RM between the healthy and diseased potatoes with PBD and BW. The occurrence of the PBD and the BW is closely corrected to the potato RM. Moderately improved the soil pH, and content of OM, P and K probably aid in the prevention of PBD and BW through regulated the RM. However, how to improve the soil pH, and the content of OM, P and K, and the mechanism to prevent the PBD and BW still need to be further studied and assessed, respectively.

Abstract. Despite there is a rich literature base that strives to characterize and understand the influencing factors of landscape ecology, the fact that we still know very little about the ecological impact in the road overlap areas. Taking the upstream area of the Minjiang River of Fujian Province in China, as a case, quantitative landscape metrics were employed to analyze the forest landscape fragmentation and degradation associated with road networks in five zones, including the whole landscape (WL), non-road effect zone (NREZ), road effect zone (REZ), mono-road effect zone (MONREZ) and multi-road effect zone (MULREZ). Our findings showed that 5.4% of the forest landscape within the REZ experienced changes from 2007 to 2015, while only 4.1% in the NREZ. Landscape metrics also identified more scattered habitats in the REZ than in the NREZ. As a result, these leaded to more severe forest landscape degradation in the REZ. Notably, the outcomes showed that the landscape pattern in the MULREZ has been more affected by road networks than the REZ and the MONREZ. Furthermore, the growing rate of landscape degradation from 2007 to 2015 in the REZ was about 1.2 times higher of the NREZ.
Keywords: *sub-tropical forest, road effect zone, fragmentation, landscape degradation index, landscape pattern*

Introduction

As the element of social development and economic prosperity, road networks tend to occupy a growing percentage of land surface worldwide (Gutiérrez and Urbano, 1996; Wang et al., 2007; Patarasuk, 2013). Development of road network increases accessibility and mobility, meanwhile opening land for resource extraction and other human activities, thus aggravating human interference on ecosystems (Jaeger et al., 2007; Selva et al., 2011). This negative impact on the environment may occur at multiple spatial scales from local to global (Forman, 1998; Coffin, 2007). At the local scale, individual road segment change the ecological process of the landscape, resulting

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36933711

in the increased abundance of invasive species, alternating hydrologic flows, and blocking the movement for animals (Forman, 1998). At the landscape scale, road network causes habitat fragmentation and degradation by creating high contrast linear edges, removing, alternating or subdividing the continuous forests into pieces (Hawbaker et al., 2005; Mehdipour et al., 2019). Moreover, landscape speeding changes associated with road network extensions often aggravate habitat fragmentation and degradation (Liu et al., 2014). However, most researches on the effects of roads on ecosystems have examined them at separate scales, few studies have integrated multiple scales in their observation. At the local scale, previous studies have focused on biodiversity conservation, such as traffic mortality, animal movement patterns, species distributed patterns, and species invasion (Spooner et al., 2004; Gibbs and Steen, 2010; Bordadeágua et al., 2011). At the landscape level, landscape structure, pattern and cover change dynamics have been quantified using geographical information system (GIS) tools. Considering the complexity and irreversibility due to the cumulative and time-lagged effects of road network on biodiversity (Selva et al., 2011), conservation evaluations on a local scale are far from comprehensive due to the lack of related knowledge (e.g. the habitats' alternations or forest displacement), while landscape-level analyses, such as landscape transitions, often have limited ecological meanings for biodiversity, owing to number of land cover classes restricted by satellite imagery (Wimberly and Ohmann, 2004; Fu et al., 2010; Li et al., 2010). For example, typical analysis of road effect on landscape pattern based on previous studies usually does not distinguish among forest categories, instead they view on "forests" as an implicitly homogenous category, thereby ignoring variations between forests and their effects on the ecological processes (Wang et al., 2007; Patarasuk, 2013; Angelstam et al., 2017). Only a few of studies on road disturbances subdivided forests into coniferous forest, mixed forest and broad-leaved forest (Freudenberger et al., 2013; Liang et al., 2014). Fortunately, the implement of Forest Resources Inventory Program in China involves an intensive survey of permanent sampling plots, thus establishing an extensive database covering many aspects of the forest resources at the biome level, such as forest type, and tree species type (Ren et al., 2011; Xie et al., 2011). This large database provides an excellent and unique opportunity to assess forest composition at the finer level. In this study, we classified landscape into relatively homogeneous forest types to address the environmental heterogeneity across the region basing on the dominant tree species (group) at the patch level, then relating patterns of forest change with road network. This combining the biome level (sampling plots) with the patch level (spatial information) datasets in an analysis of forest landscape structure overcomes the deficiencies of local-scale empirical studies and landscape-scale studies separately (Redo et al., 2012).

Although biodiversity exists at the multiple levels (e.g. genetic, species, population, community, ecosystem, and landscape level) (Lindenmayer et al., 2000), all levels of biodiversity could be enhanced from improved connectivity and stability of forest from a landscape-level perspective (Forman, 1998). In this context, landscape structure, fragmentation and connectivity should be included into the biodiversity indicator system (Liu et al., 2014; Karadağ and Şenik, 2019), e.g., the efficiency of biodiversity conservation is often assessed by landscape metrics representing the spatial structure in a quantitative manner (Sowińska-Świerkosz and Soszyński, 2014). Such landscape metrics consist of a set of indexes at the patch, class and landscape levels, which are always calculated for both administrative borders (Hargis et al., 1998) and for different

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36933711

kinds of natural units, such as a park (Peng, 2019) or a watershed (Syrbe and Walz, 2012). They are also used to suggest the level of anthropogenic interference in landscape (Moser et al., 2007).

Habitat fragmentation and the subsequent effects of roads have been widely studied in America (Airey, 1992; Mcgarigal et al., 2001; Forman et al., 2002) and Europe (Jaeger et al., 2007; Freudenberger et al., 2013; Psaralexi et al., 2017), while similar research has just begun in China (Forman et al., 2002; Li et al., 2010). Since the implementing of the government's reform policy, China's road network construction has made brilliant achievements during the past four decades. As one of the most developed regions in China, Fujian Province also experienced rapid development in the construction of road infrastructure during 2007 and 2015, and in the coming years, more roads will be built to improve the accessibility for the region according to the provincial strategic plan. Moreover, Fujian Province is also one of the four major forest regions in China, with the highest forest coverage rate (66.8%, 2018) in the country (http://lyt.fujian.gov.cn/). It is noteworthy that a recent study indicated that active transformations occur among forest cover types with high conversion rates (e.g. from primary and secondary forest to planted forests) in this region (Zhang et al., 2010; Hansen et al., 2014), which can lead to the reduction of forest biodiversity and carbon storage of forest biomass (Carnus et al., 2006; Stephens and Wagner, 2007). Therefore, the direct and underlying driving forces of such landscape dynamics need to be further investigated in the upcoming studies to habitat conservation (Zhang et al., 2010). Especially, with the expansion of the road network, more and more roads are built parallelly, e.g., parallel roads of different levels are very common here; moreover, the numbers of road intersections increase greatly. These both lead to the overlapping and overlapping road effect zones. However, quantitative research on the impact of these zones on the landscape is still lacking. Thus, researches on the ecological effects of road network, especially of road overlap areas, on the forest landscape structure and degradation will have significant practical applications for this region.

Taking a typical forest landscape in the sub-tropical region, the upstream area of the Minjiang River, Fujian Province, as a case, we hypothesized five zones in this paper firstly, including the whole landscape (WL), non-road effect zone (NREZ), road effect zone (REZ), mono-road effect zone (MONREZ) and multi-road effect zone (MULREZ). Then, different rates and trajectories of forest cover changes among these zones were compared in this study. Specified, the objectives are: (1) investigate the effects of the road network on forest landscape structures (habitat fragmentation, connectivity and heterogeneity) in the five zones; (2) comprehensively evaluate the forest landscape degradation dynamics in the five zones by a comprehensive index (landscape degradation index, LDI); (3) examine whether the 'scaling up' level of human disturbance on ecosystems exists in the MULREZ zones.

Materials and methods

Study area

The study area, the upstream area of the Minjiang River (26°5′N, 117°5′E) is in a catchment basin between the Wuyi Mountains and the Daiyun Mountains, the skeletons of the terrain in Fujian Province, China. The area belongs to a typical sub-tropical forest. In the study area, 82.7% of the land area was covered by forest in 2007 and was selected as the study site, with total area of 672 km^2. Three reasons make it suitable for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36933711

this study: (1) intensive extensions of road network in recent years, e.g. Quan-Shan and Yong-Ning express ways, have enforced biodiversity in this region to be subjected to severe disturbances by these roads; (2) this area is located in the upper reaches of the Minjiang River, therefore, the water quality of these rivers highly depends on the protection the forests in the study area; (3) the mixed forest with Chinese fir, pine and hardwood is a major type in the southeastern China, and of national and international importance in terms of its provision of both plant diversity and community stability of the ecosystem.

Data sources

The road data was digitized as a vector map based on the transportation maps of Sanyuan District in 2015. According to the study by Liu et al. (2008) the roads were divided into six categories (*Fig. 1a*): (1) first level (expressway), (2) second level (national roads), (3) third level (provincial road), (4) fourth level (county road), (5) fifth level (country road) and (6) sixth level (the other main road).

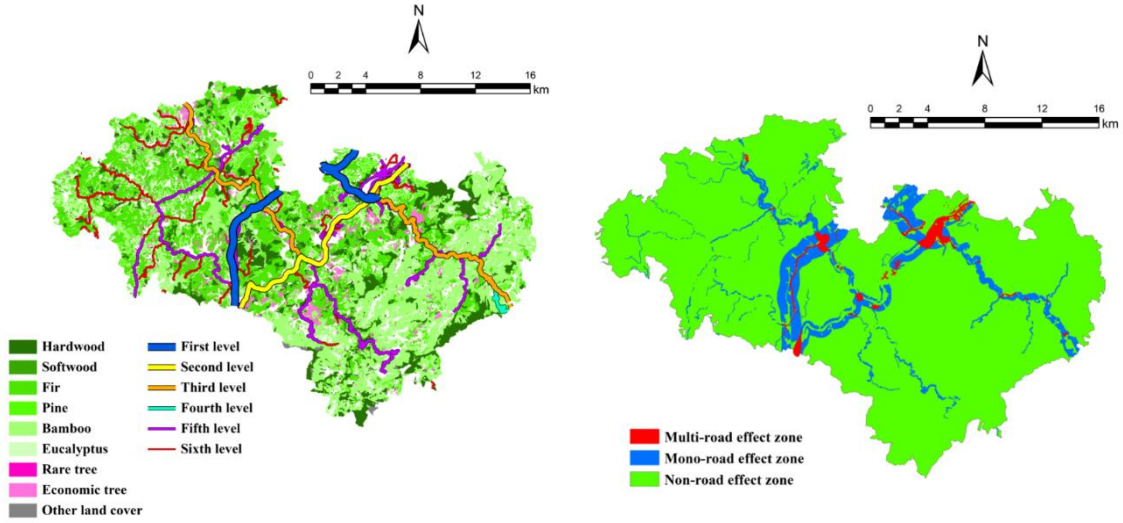

Figure 1. *(a) Road network of study area, (b) study zones, including multi-road effect zone (MULREZ), non-road effect zone (NREZ), mono-road effect zone (MONREZ), road effect zone (REZ) is composed of MONREZ and MULREZ, and whole landscape (WL) is composed of NREZ and REZ*

The forest landscape maps were derived from Forest Resources Inventory Databases (vector maps) for 2007 and 2015, collected from the local forestry department. In China, the database is the second type of forest resource survey based on forest management units such as state-owned forest farms, nature reserves, forest parks, or county-level administrative areas, to meet the needs of forest management plans, overall design, forestry zoning, and planning and design. The outcome of the survey is the establishment and update of forest resource inventory database, which is the basis for forestry engineering planning and design and forest resource management, is also an important basis for formulating regional national economic development plans and forestry development plans, implementing forest ecological benefit compensation and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36933711

forest resource asset management, and guiding and standardizing forest scientific management. The database is prepared and updated yearly by the combining of field investigation (*Fig. 2*) and remote sensing. Sample plots systematically located on 1-by-1 km grid cells across the study area and are used for remote sensing verification as well (see (Xie et al., 2011) for detail). The database provides miscellaneous information at the landscape pixel level, such as land type, terrain factors, vegetation type, and dominant tree species so on.

Figure 2. *Field investigation*

Landscape classification

In this study, we classified the forests into nine categories according the dominant tree species (i.e., with the highest percentage in quantity of all individuals) of each biome when mapping forest landscapes. The nine categories of forests were fir, pine, rare tree, softwood, hardwood, Eucalyptus, bamboo, economic tree and other land cover (*Table 1*). Then, transitions between forest cover categories between 2007 and 2015 were calculated using area tabulation tool of ArcGIS software for each studied zone.

Definition of road effect zones and zones

The first-, second-, third-, fourth-, fifth- and six-level roads were buffered at 1000 m, 500 m, 250 m, 100 m, 50 m and 25 m, respectively, depending on the impact degree on the ecosystems (Wang et al., 2007; Liu et al., 2014). A minor portion of buffer zones of different level roads overlapped each other. Theoretically, these overlapped areas are more accessible than others, with more chances to be interrupted. In this context, it is interesting to better understand several fundamental questions. Are these areas more vulnerable? Is the 'scaling up' level of human disturbance on ecosystems in these areas higher than that of the other? To answer these questions, the road effect zone was separated into mono-road effect zone and multi-road effect zone here, thus as a whole five zones were hypothesized in this study, including WL (672 km^2), NREZ (607 km^2), REZ (65 km^2), MONREZ (62 km^2) and MULREZ (3 km^2) (*Fig. 1b*). Then, landscape metrics for these five zones were calculated respectively for the comparisons of their Landscape change, habitat fragmentations, isolation, heterogeneity and landscape degenerations between 2007 and 2015.

DOI: http://dx.doi.org/10.15666/aeer/1802_36933711

Table 1. *Description of the nine classes of forest cover*

Forest cover classes	Classification criteria	Biomes
Fir	Taxodiaceae family species	*Cunninghamia lanceolata*
Pine	Pinaceae family species	*Pinus massoniana*, *P. elliottii*, *P. taeda*, *Tsuga chinensis* var. *tchekiangenesis*
Rare tree	The first reference list of the main rare species in Fujian Province (2007), compiled by the Fujian Province Department of Forestry	*Cinnamomum camphora*, *Phoebe bournei*, *Fokienia hodginsii*, *Taiwania cryptomerioide*, *Liquidamba formosana*, *Cryptomeria fortunei*
Softwood	Hard timber trees, are generally more durable and denser than softwoods or soft timbers although not all are harder than softwoods the main differences between them are botanical, these types of trees have broader leaves than soft timber trees	*Paulownia chinense*
Hardwood		*Castanopsis* species, *Schima superba*
Eucalyptus	Plants of *Eucalyptus* (Myrtaceae family)	*Eucalyptus grandis*, *E. citriodora*
Bamboo	The woody bamboos	*Phyllostachys edulis*, *Dendrocalamus olhami*, *D. latiflorus*
Economic tree	Those where the main management emphasis is on forest products rather than timber, such as fruit, bark, leaves, tree sap, branches, flower buds and tender sprouts	*Citrus maxima*, *C. reticulate*, *C. mollissima*, *Camellia oleifera*, *C. Sinensis*, *Magnolia officinalis*, *Vernicia fordii*
Other land cover	Other forest covers apart from the above, besides which non-forest covers are included in this category in the 2015's landscape	2007: shrub land and minor forest; 2015: shrub land, minor forest, no standing forest and non-forest

Calculation of landscape change rate

Landscape change rate (LCR) indicates the transfer rate between all landscape types in a study period in a region, and can be used to characterize the intensity of landscape type transformation in a particular region (e.g., a road buffer zone) in order to find a hot spot for change. It can be calculated as follows (*Eq. 1*):

$$LCR = \frac{\sum_{i=1}^{n} \Delta LA_{i-j}}{\sum_{i=1}^{n} LA_i} \times 100 \quad \text{(Eq.1)}$$

where, *LCR* is the landscape change rate (%) of the integrated landscape during the study period, LA_i is the total area of the initial landscape type *i*, $\Delta\ LA_{i\text{-}j}$ s the area of landscape type *i* converted to the landscape type *j* during the study period.

Calculation of landscape degradation

The Fragstats software presents the most comprehensive overview of the landscape metrics, which are algorithms that quantify the specific spatial characteristics of three hierarchical levels: patch level, class level and landscape level (Šímová and Gdulová, 2012). To investigate the effects of road network extensions on landscape structure, we measured commonly used landscape metrics to analyze the habitat changes for each landscape using the Fragstats 3.4 program (Mcgarigal and Marks, 1995; Mcgarigal et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36933711

al., 2001). Among which, area related indices were calculated to describe the features of patches, such as mean patch area (AREA_MN), standard deviation of patch area (PSSD) and coefficient variation of patch area (AREA_CV). Number of patch (NP), patch density (PD), edge density (ED), and mean fractal dimension index (FRAC_MN) were used to examine habitat fragmentation at the class level. The isolation, connection and heterogeneity of the entire landscape were indicated by landscape level metrics: aggregation index (AI), contagion index (CONTAG) and Shannon's evenness index (SHEI). For the formulas and detailed descriptions of all landscape indices, please refer to reference (Mcgarigal and Marks, 1995; Mcgarigal et al., 2001).

Quantitatively measuring the fragmentation, isolation, connection and heterogeneity of the entire landscape have been extensively applied to the analysis of landscape pattern using landscape metrics (Turner et al., 2003). However, these metrics were calculated as separate indicators in the most of the landscape structure studies (Tinker et al., 1998; Mcgarigal et al., 2001), with little contribution to the comprehensive comparisons of different ecological processes between different landscapes. In this context, an integral index, LDI, was selected to evaluate the landscape pattern as a whole. LDI measures the fragmentation and the stability of the entire landscape, which is proportionally composed of a series of metrics, such as AREA_CV, PD, ED, FRAC_MN, CONTAG, AI and SHEI. The formulas were given by the following expressions (Wang et al., 2007; *Eqs. 2-4*).

$$LFDI = aAREA\_CV + bPD + cED + dFRAC\_MN \quad \text{(Eq.2)}$$

$$LSI = \sqrt[3]{CONTAG \times SHEI \times AI} \quad \text{(Eq.3)}$$

$$LDI = LFDI/LSI \quad \text{(Eq.4)}$$

where the LDI includes landscape fragmentized degree intensity (LFDI) and landscape stability index (LSI); *a, b, c* and *d* are the weights of the indexes of AREA_CV, PD, ED, and FRAC_MN, which is 0.27, 0.26, 0.24 and 0.23 respectively (Wang et al., 2007).

We assumed that in a region with relatively homogeneous biophysical interference, higher value of LDI indicates higher level of anthropogenic interference (e.g., road network, cutting) in the habitats, which, in turn, influences the abundance and distribution of plant and animal species (Geneletti, 2003; Eigenbrod et al., 2008).

Results

Forest landscape composition and dynamics in different senarios

For the whole landscape, NREZ and REZ occupied 90.3% and 9.7% of the study area respectively. In the REZ, MONREZ and MULREZ occupied 95.0% and 5.0%, respectively (*Fig. 3*).

Figure 2 also indicated that forest landscape changes were active during the study period in all the zones. 5.4% of the landscape in the REZ experienced forest cover change between 2007 and 2015. By contrast, only 4.1% of the landscape in the NREZ was transformed between 2007 and 2015. In the REZ, 5.6% of the landscape experienced forest cover change in the MONREZ, while it was unexpectedly that only 2.3% of the landscape was transformed in the MULREZ between 2007 and 2015.

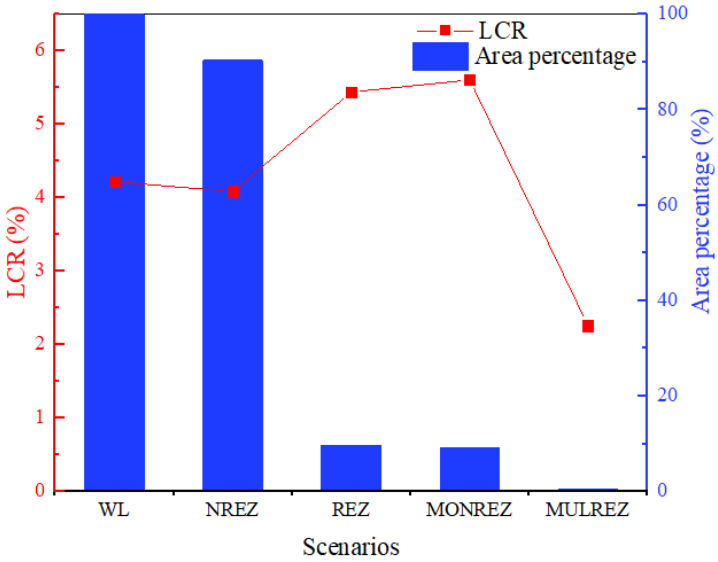

Figure3. *Proportion of each zone and its landscape change dynamics. The curve represents the landscape change rate of d different zones (left Y-axis); the columns represent the area proportion of each zone to the total area of the study area (right Y-axis). LCR is landscape change rate*

Figure 4 showed the forest landscape compositions and dynamics from 2007 to 2015 for the five zones. The dominant forest cover classes were fir and bamboo, predominating in 34.1% and 31.7% in 2007, and 32.7% and 31.7% in 2015, respectively, in the WL zone. Compared to the NREZ, the REZ had a relatively smaller proportion of bamboo, accounted for 21.5% and 21.7% of the area, respectively in 2007 and 2015. On the contrary, the proportion of fir and economic tree in the REZ were about 5% higher than that in the NREZ in the both years. Furthermore, it was worth to mention that the proportions of other land cover in the REZ (especially in the MULREZ) were uncommonly several-fold beyond those in the NREZ.

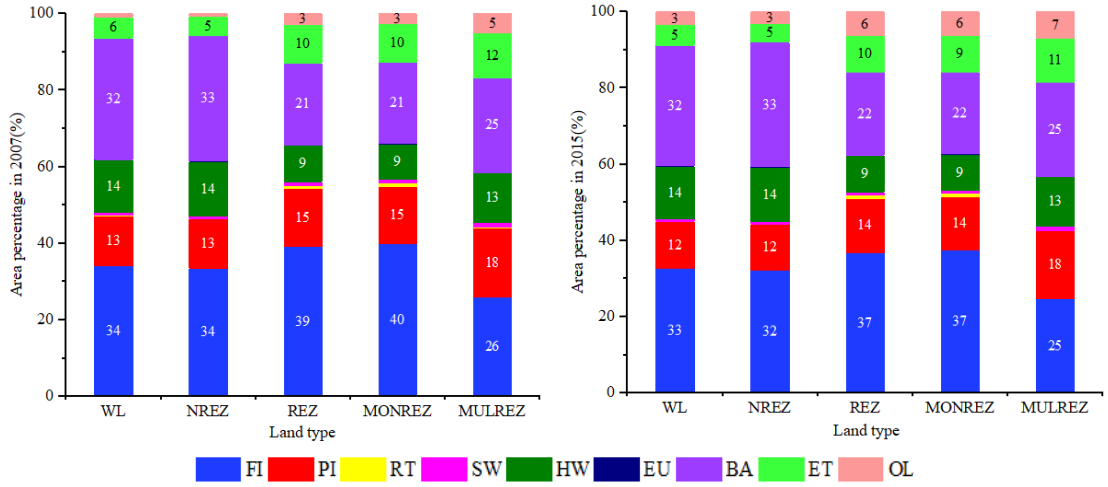

Figure 4. *Forest landscape composition in each zone. The nine categories of forests were Fir (FI), Pine (PI), Rare tree (RT), Softwood (SW), Hardwood (HW), Eucalyptus (EU), Bamboo (BA), Economic tree (ET) and other land cover (OL). The numbers on the columns indicates the percentage of each landscape in each zone*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36933711

Figure 5 indicated that, in all the zones, bamboo and hardwood showed high stability during the studied period, fir, pine, softwood and economic tree decreased steadily, while eucalyptus and other land cover increased dramatically over time. Between 2007 and 2015, fir in the NREZ was reduced by 4.0% of its area, while the reduction increased to 6.1% in the REZ; the proportion of pine was also slightly reduced by 6.7% and 5.5% in the NREZ and REZ, respectively. The opposite trend was observed in other land cover, which increased more than four times in the NREZ, whereas, only increased 127.0% in the REZ. Eucalyptus also increased 22.8% and 74.2% in the NREZ and REZ, respectively. Simultaneously, the change of rare tree showed a different trends and directions in different zones. Specifically, in the NREZ zone, the area of rare tree increased, while in the case of road zones (i.e., REZ, MONREZ, MULREZ), the area of rare tree species decreased, especially all the area of rare tree was encroached in the MULREZ zone.

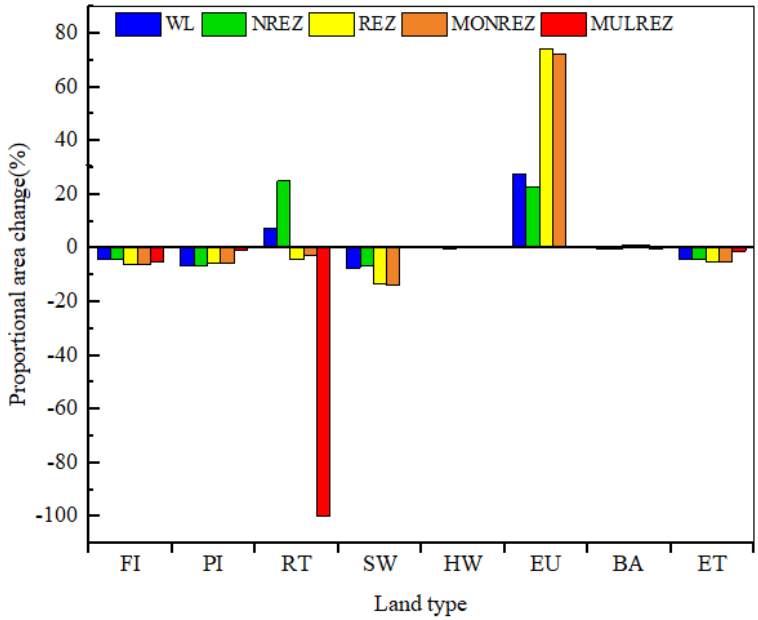

Figure 5. *Forest landscape change dynamics in each zone during 2007-2015*

Forest landscape patterns and dynamics in different scenarios

Table 2 showed the calculated results of the landscape metrics for the years of 2007 and 2015. In this studied case, the AREA_MN index in the NREZ (10.853-12.150 ha) was much higher than that of the REZ (2.989-3.215 ha) (P-value = 0.000), which indicated that the forest landscape structure of the NREZ was much more stable, and distinguished by a number of larger area patches. The PD index was substantially higher in the REZ (31.102-33.461) than that in the NREZ (8.231-9.214) (P-value = 0.000), especially in the MULREZ (80.021-81.571) even ten times or so as much as that in the NREZ (P-value = 0.000). Analogically, the ED index in the REZ (71.410-77.496) was significantly higher than that of the NREZ (57.372-61.697) (P-value = 0.000), moreover, MULREZ had a greater ED than the former two as well. These findings clearly indicated that the landscape spatial structure in the REZ (especially in the MULREZ) was much more fragmented than that in the NREZ.

DOI: http://dx.doi.org/10.15666/aeer/1802_36933711

The AI and CONTAG values were close in all the zones, with the highest in the NREZ, and then in the REZ, followed by the MULREZ. The study results showed that patch types with a similar area (lower AREA_CV and PSSD values) in the REZ were generally much more dispersed than those of the NREZ. The SHEI value was bit higher in the REZ (0.742-0.770) (P-value = 0.005), much higher in the MULREZ (0.835-0.843) (P-value = 0.000) than that in the NREZ (0.683-0.712). This finding confirmed a lower landscape diversity of the REZ than that of the NREZ.

Number of patch (NP), mean patch area (AREA_MN), standard deviation of patch area (PSSD), coefficient variation of patch area (AREA_CV), patch density (PD), edge density (ED), mean fractal dimension index (FRAC_MN), aggregation index (AI), contagion index (CONTAG) and Shannon's evenness index (SHEI), landscape degradation index (LDI)

Figure 6 showed that the trends of the landscape metrics between 2007 and 2015 were relatively unanimous in all the zones, indicating a decreasing trend as the increasing intensity of road disturbance, in order of WL, NREZ, MONREZ and REZ and MULREZ.

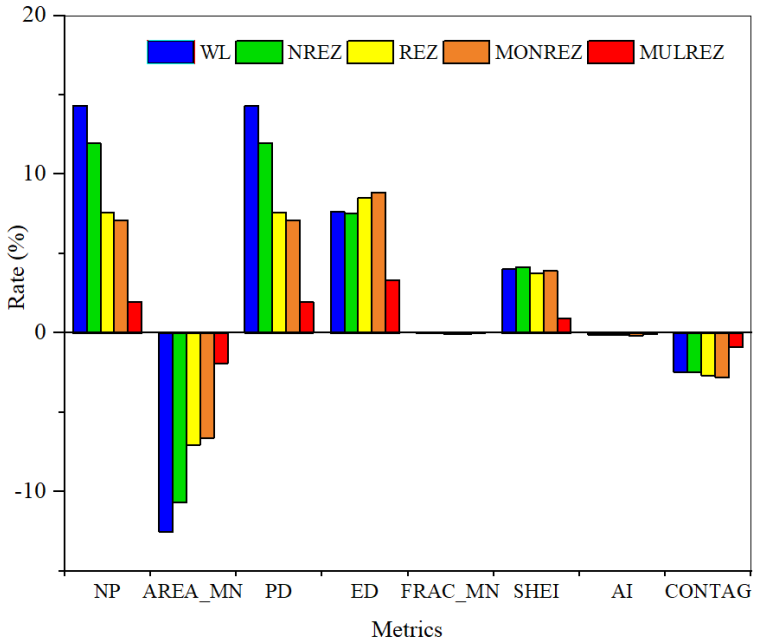

Figure 6. *Change rates in landscape metrics in each zone (2007-2015)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36933711

Forest landscape degradation and dynamics in different scenarios

The dynamics of the landscapes showed that the fragmentations of the landscape structures were obviously strengthened under the disturbance of road network (*Table 2*). In *Figure 7,* the composite index of landscape fragmentation (LFDI) also showed that the degree of fragmentation of forest landscape increases with the increase of road disturbance intensity, moreover, the trend was relatively stable for the index of LSI. Referring these results directly to identify the level of degradation of the entire landscape requires the analysis of the LDI. In this case, the LDI was significantly higher in the REZ (1.621-1.742) than that in the NREZ (1.193-1.122), and the MULREZ (2.459-2.522) had much higher LDI than MONREZ (1.672-1.797). Furthermore, the growing rate of landscape degradation from 2007 to 2015 in the REZ was about 1.2 times as that in the NREZ, however, the change rate in the MULREZ was relatively low (*Fig. 8*). This finding confirms that road networks have broken the landscape into pieces and resulted in fragmented ecosystems and complicated ecosystem structures, eventually accelerating the degradation of the ecosystem.

Discussion

Landscape transitions

As a permanent modification of the landscape, road network threatens the existing habitats and the wildlife populations depending on it, e.g., interrupting ecological flows, inhibiting interior species, and promoting landscape fragmentation (Forman, 1998). Landscape fragmentation is a breakup to transform a continuous habitat into smaller, more dispersal patches, which can impose destructive and irreversible consequences on regional biodiversity (Trakhtenbrot et al., 2005). Such negative impacts of road network have been hot topics in the study of landscape ecology and biodiversity conservation (Zhu et al., 2006; Benítez-López et al., 2010). In this study, we detected considerable transitions among different forest landscapes types in each zone. Though landscape dynamics patterns varied through zones, most of the changed forest cover was transformed into other land cover in all the zones. However, the key differences were that the percentages (the area changed to other land cover divided by the total area experienced change in each zone) were significantly higher in the REZ (67.4%) than that in the NREZ (60.9%) (*Table A1* in the *Appendix*). Moreover, the MULREZ was among the most surprising zone, in which more than 80% of the forest cover change happened to shift into other land cover. In the NREZ, gain of other land cover area was largely from fir, which accounted for more than 60% of the total area gained by other land cover in the study periods; while, in the REZ, the gain of other land cover was from relatively diversified forest covers, among which fir, pine and economic tree accounted for 38.5%, 10.0% and 8.6% of the total area gained by other land cover, respectively. All these findings indicated that the forest covers have suffered greater human disturbance in the REZ (MULREZ in particular) than in the NREZ. Previous studies on the ecological impacts of road network at the landscape level, with no effort identifying habitat changes among forest types, which have limited ecological meanings to devise more effective strategies for biodiversity conservation (Li et al., 2010; Patarasuk, 2013). In this study, we overcame these difficulties by conducting a Forest Resources Inventory Database-based analysis of changes in forest landscape, stratified

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36933711

by dominant species in respective biomes, which it very helpful in identifying the dynamics of forest landscape changes from a finer scale.

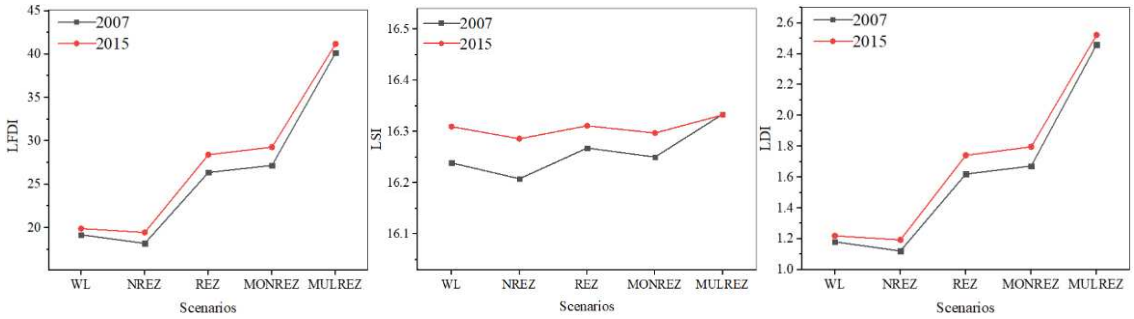

Figure 7. *Landscape degradation dynamic in each zone (2007-2015)*

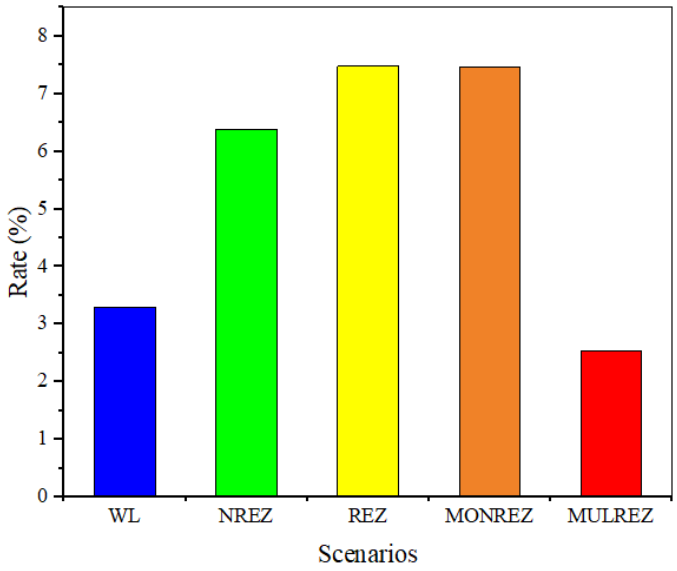

Figure 8. *Change rate of landscape degradation index from 2007 to 2015*

Landscape degradation

In our study, it was obvious that the landscape metrics varied greatly across different zones, revealing that the landscape spatial structure in the REZ (especially in the MULREZ) was much more fragmented than that in the NREZ, and a lower landscape diversity in the REZ than that of the NREZ. This finding indicates a higher level of interference imposing on the forests in the REZ, leading to the increasing of habitat fragmentation and isolation, the decreasing of heterogeneity in forest landscape near roads. Our results agree with previous researches, documenting habit fragmentation causing by the changes of landscape patterns near road corridors (Hawbaker et al., 2005; Liu et al., 2008), which have been reported as a contribution to the declining in forest species (Arnold et al., 1995; Mcintyre, 1995). However, different from many of these studies (Heilman et al., 2002; Liu et al., 2014), we further separated the REZ into two segments, i.e., MONREZ and MULREZ. Our result indicated that the level of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36933711

habitat fragmentation and isolation in the MULREZ was much higher than that of the MONREZ, implying that there exists superimposed effect of the roads on the forest landscape.

For the change ratios between 2007 and 2015, landscape fragmentation indices (NP, AREA_MN, PSSD, PD and ED) had larger values than landscape stability index (AI, CONTAG and SHEI). In all the zones except the MULREZ, the rates of change of NP, AREA_MN, PSSD, PD and ED indices were 7.1~14.3%, 6.6~12.5%, 10.3~30.5%, 7.1~14.3% and 7.5~8.9%, respectively, while those for the AI, CONTAG and SHEI indices were -0.2~-0.1%, -2.8~-2.5% and 3.8~4.2%, respectively (*Table 2*). The relatively major changes in landscape fragmentation and relatively minor changes in overall landscape structure of the forest may be attributed to the high rate of persistence in area size of each forest category between 2007 and 2015, while a relatively rapid transition intra/inter- these cover categories occurred. This provided a good reason for us to classify landscape into forest types basing on the dominant tree species.

As landscape fragmentation indices concerned, the change ratios of NP, AREA_MN, PSSD, and PD in the NREZ were higher than those in the REZ, while it was versa for the change ratios of ED. Similarly, the comparisons of the change ratios for landscape stability indices also showed a bidirectional diagram between the NREZ and the REZ. Though, much greater in habitat fragmentation and landscape degradation was evident on the REZ, more significant changes of habitat fragmentation were detected in the NREZ between 2007 and 2015. Also, an unexpected outcome of the study was the lowest change ratios of such indices in the MULREZ. The reasons are followed: the study area has always been a key base of forestry industry in Fujian Province, a large proportion of forest is designated as suitable for commercial timber use. Therefore, logging often happens in the currently designated as suitable timberlands, which as a result is sufficient to cause rather dramatic changes in landscape structure. These can be proved by the fact that more than 60% of the total area changed has been converted into other land cover (shrub land, minor forest, no standing forest and non-forest) in all the zones (*Table A1*). Therefore, the increase in other land cover was partly caused by frequent regeneration failures or time-lagged regenerations following clear-cut logging in the study area. This implies that both road network extensions and forest management practices lead to the increasing of landscape degradation in all the zones, with a higher change rate in the REZ in the study area.

Several indices have been developed to quantify the influence of road disturbance on landscape structure (Mcgarigal et al., 2001; Liu et al., 2014). Most of the current indices focus on habitat fragmentation, isolation, connection or heterogeneity separately, without joint consideration of comprehensive evaluation of these landscape metrics. In this study, LDI, an approach that combines these measures of landscape metrics, was employed to examine the disturbance of road network on landscape. An expected outcome was that the LDI in the REZ was higher than that of the NREZ, and showed an aggravated influence on the forest landscape in the REZ during the study period. Thus, in the REZ, habitat fragmentation may switch from being predominantly internally driven (i.e., logging) to being predominantly externally driven (i.e., road construction). Simultaneously, remnant patches become more and more isolated, thereby resulting in further ecological degradation across the landscapes.

These findings are consistent with other studies from the Rocky Mountains (Reed et al., 1996; Mcgarigal et al., 2001) and the north-central Wyoming (Tinker et al., 1998), which documented that forests were more highly fragmented from roads than from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36933711

clear-cuts. However, we also found that the change ratios of some landscape metrics were higher in the NREZ than in the REZ, these can be explained by the following reasons other than logging mentioned above: (1) Roads provide access and allow landscape pattern to change during the construction and in the early stage, however these changes may be constrained by environmental factors such as topography in the later period after road been built (Hawbaker et al., 2005). In this case, land use changes near roads may be mediated by the constrain of the topographic feature prevailed with the mountain terrain in the study area; (2) a large portion of forest buffer belts were designed for various ecological purpose (e.g. conservation of water and soil, prevention of traffic noise, protection of slope and greening of road), where logging and constructing cannot occur frequently.

Extensions and limitations

As described by different authors, the simple landscape metrics, e.g., NP, ED, PD and AREA_MN, are the most suitable indices to analyze landscape structure (Frohn and Hao, 2006; Šímová and Gdulová, 2012), so the cutting and fragmentizing effect of road networks on landscape can be revealed from the changes of such landscape metrics (Sowińska-Świerkosz and Soszyński, 2014). The ED is among a positive index identifying the level of provision of habitats for alien plants, posing a great threat to the existence of native species. Still more important is the dissecting effect of road network, the ED value has also been proven to be crucial for local hydrologic and erosion effects and downstream peak-flow and sediment impacts (Forman, 1998; Uuemaa et al., 2009). In our case, the ED values of REZ were greater than those of NREZ, and the differences incline to be enlarged during the study period. This finding shows that biodiversity in the REZ and water quality in the watersheds has been subjected to severe disturbances by these roads during the study period.

Yet, it is insufficient to assess landscape changes due to road network disturbances within a specific zone/a fixed temporal extent using landscape metrics (Liu et al., 2008), because the extent of REZ may be different for different regions (Forman et al., 2002), moreover, effects of roads on landscape may vary over time (Forman, 1998), while the analysis performed here to the five zones was in the same period and the REZ was at a fixed spatial scale. Such approach does not give answer if a particular stage is up surging for the landscape changes near roads, and if the effects of road network on landscape vary with different extents of REZ. Moreover, the road network has continued to expand over time, and although the overall change has been small, we have failed to consider the impact of new roads on the landscape during the study period.

Conclusions

Our results showed that there were obvious different forest landscape structures and their dynamics between the NREZ and REZ during the study periods, so the LDI did. In addition, we found that the change ratio of LDI value in the REZ was much higher than that in the NREZ, while it was versa for some landscape fragmentation indices. This is because the high rate of persistence in area size of each forest category between 2007 and 2015, while a relatively faster transition intra/inter- these cover categories occurred in the NREZ. These results indicate that the potential effects of road network on biodiversity maybe severer than the direct effects of logging, while logging may be also an important factor contributing to the habitat fragmentations in the study area. And it

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_36933711

also shows the necessity of the landscape classification according to the dominant tree species, which will provide more finer information on forest cover change.

Our result indicated that the level of habitat fragmentation and isolation in the MULREZ was much higher than that of the MONREZ, implying that there exists superimposed effect of the roads on the forest landscape. While, an unexpected outcome of the study was the lowest change ratios of landscape metrics in the MULREZ during the study period. The reasons were still unclear so far as from our study. Therefore, we suggest that further investigations should be carried out for this region and beyond by conducting a gradient analysis with changing road buffer zones and a comparison analysis across time periods (e.g., pre- and post- construction of a road). Furthermore, it is also necessary to further quantify forest landscape structure, such as forest edge dynamic and landscape connectivity, analyze the underlying causes of these habitat changes, and to evaluate the effect of such active forest change in this area on carbon emission, which will help to prevent adverse impacts of human dimensions on biodiversity and climate warming. Finally, understanding how the spatial distribution of road networks affects forest landscape pattern should take at least the following factor into account: control for bias that arises when observable biophysical (e.g., topography) and artificial (e.g., logging and mining) factors affect both which landscapes are in REZ and which are in NREZ.

Acknowledgments. This research was funded by the National Natural Science Foundation of China (No. 41901221 and 31971639), to which we are very grateful. We are also very grateful for the support provided by the Natural Science Foundation of Fujian Province, China (No.2019J01406 and 2019J01430). Finally, many thanks to the Forestry Bureau of Sanyuan District, Fujian Province, China for providing us with a validation dataset.

Abstract. Heavy metals can remain in nature for a long time without deterioration and their concentration in the environment is constantly increasing. In addition, some may have toxic or carcinogenic effects even at low concentrations, while some others which act as micronutrients can have toxic effects for humans at high concentrations. Therefore, determining heavy metal concentrations is of great importance towards identifying risk zones and risk levels. The main sources of heavy metals are industrial plants where heavy metal ores are processed. In this study, the Combine Magnesite operating in Russia which entails -"processing and mining of magnesite ore"- was examined for Mg, Al, Fe, Mn and Ca concentrations by analysing the samples taken from the 1- and 2-year-old needles of scots pines grown at 1, 3, 10 and 25 km distances. As a result of the study, it was determined that the concentrations of heavy metals subject to the study vary depending on the distance, especially the Mg concentration which exhibited a significant decrease the farther the trees were. We determined that the concentrations recorded in the 2-year-old needles at almost all points were higher than the 1-year-old needles, and could even exceed this difference several times.
Keywords: *pollution, Satkinsky Combine Magnesite, forest, Mg, Al, Fe*

Introduction

With the rapid increase in the world population, industrial activities have witnessed an identical rise, and the air pollution which increased in parallel with these activities has reached dangerous levels (Cetin and Sevik, 2016a, b; Cetin et al., 2017,2020; Turkyilmaz et al., 2020; Bozdogan Sert et al., 2019; Ozel et al., 2019; Kaya et al., 2019; Cetin, 2019; Zeren Cetin and Sevik, 2020). So much so that today air pollution has become a global problem that causes millions of deaths annually (Cetin, 2016a, b, c, 2017, 2019; Bozdogan Sert et al., 2019; Cetin et al., 2018a,b, 2019a, b; 2020).

Industrial activities are the biggest culprit for air pollution (Shahid et al., 2017). Although mineral resources are extremely important for socio-economic development, mineral extraction and its use in different industrial processes play a leading role in increasing environmental pollution, and air pollution in particular (Li et al., 2014; Goix et al., 2015; Niazi and Burton, 2016).

The change in heavy metal pollution can be determined by direct and indirect methods. The direct approach is expensive, and the direct impact of atmosphere

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37133727

pollution on the ecosystem cannot be determined, and data about the measurement period cannot be examined (Yucedag et al., 2019a, b, c; Cesur, 2019; Gemici et al., 2019). These methods often require expensive measuring instruments and carry a higher risk of contamination than biomonitors. The use of biomonitors in the determination of air pollution is an inexpensive and easy method and provides more reliable data on the periodic changes of heavy metal concentrations (Aricak et al., 2019a, b). Plants that grow in areas with heavy pollution show heavy metals concentrations in the body, branches and hands, and show the increase in heavy metal concentrations in the air over time (Turkyilmaz et al., 2019; Bozdogan Sert et al., 2019). Therefore, instead of the direct detection of heavy metal pollution, biomonitors are frequently used (Sevik et al., 2019a; Cetin et al., 2018a, 2019 a, b, 2020; Turkyilmaz et al., 2019; Bozdogan Sert et al., 2019; Cetin, 2019; Ozel et al., 2019).

In this study, we aimed to determine the change of pollution level depending on distance and pointer age by using 1 and 2 wet hands of scotch pines grown in different distances around a process and mining of Magnesite ore operating in Russia.

Materials and methods

In the conditions of modern cities, aerotechnogenic pollution is a permanent environmental factor that has a negative impact on the environment and human health. One of the objects of large foci of destruction of forest vegetation is located in the Southern Urals in the Chelyabinsk region city Satka the Combine Magnesite in Russia, (the GPS coordinates of 55°6'10.663" N and 58°58'27.53" E) (*Fig. 1a, b*). Experimental sites (ES) were planting trees created in rows in 1980-1983. Employees of the Botanical Garden in order to study the suitability of soils for reforestation in various zones of magnesite pollution. ES are located at different distances from the Combine.

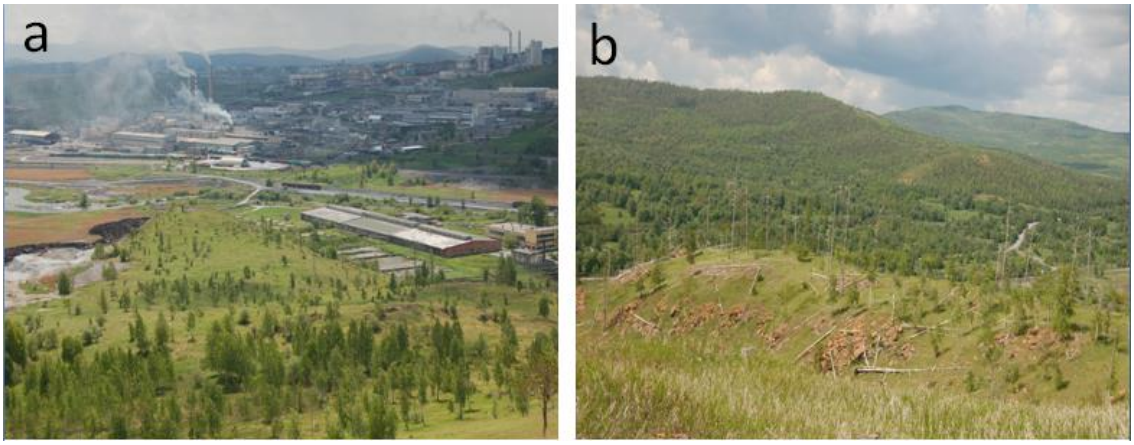

Figure 1. *Satkinsky Combine Magnesite (a) and the surrounding forests (b)*

In the pollution gradient to the northeast, in the direction of the prevailing winds from the emission source, the following areas are located: ES-2 at 1 km from the plant in the zone of strong influence, ES-5 at 3 km - zone of average influence and ES-4 at 10 km - zone of weak influence at the Combine Magnesite. Near the village of Sibirka settlement area (conditional control) - 25 km south of the Combine in background

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37133727

conditions is located Control. During planting of *Pinus sylvéstris* L., peat was deposited at ES-2 and ES-5 at a layer of 2 cm. Peat was not added to the site at ES-4. The type of forest in all ES is the Scots pine (*Fig. 2*).

The raw material for the production of sintered Pericles powders is raw magnesite. High-carbonate feedstock is burned in such a way that raw magnesite of Satkinsky groups of deposits (fractions 0–40 mm) is loaded into a rotary kiln. After burning natural magnesite, a large amount of caustic dust is formed which undergoes repeated burning. When burning dust, a large amount of flue gases, carbon monoxide, alkali, fluorine and sulfuric anhydride, nitrogen oxides are released into the atmosphere. Near the Combine Magnesit and within a radius of 1.5–2 km, the forest completely died (*Fig. 1b*). The maximum volumes of magnesite dust into the atmosphere in 1963 reached 182.5–328.5 thousand tons per day. In 1978, new electrostatic precipitators were installed at the plant, and dust emissions dropped to 70–90 tons per day.

Figure 2. *Location of experimental sites depending on the Combine Magnezit*

Samples were taken from the ends of the longest lateral branches of the trees at the designated points on the source of pollution by cutting branches with a needle. Under the conditions of the region, the pine needles can remain on the tree for two years and with the help of the formed nodes. The cut branches were then cut according to their age, and the shoots formed in the last year were classified as 1 year, shoots formed in the previous year were classified as 2 years, and labelled by packaging. This classification process in trees such as pine, spruce and fir has also been used in different studies (Turkyilmaz et al., 2018c; Cobanoglu, 2019; Kececi, 2019). The needle samples used in the study were collected at the end of the 2018 vegetation season and the study was carried out in 5 replications.

Heavy metal analyses

The samples, which were classified and labeled in the laboratory, were stored and air dried for 15 days. The air-dried samples were then dried in a drying oven at 45 °C for a week. Experiments were started for heavy metal analysis in dried samples on the same day. Plant samples were pulverized and were weighed as 0.5 g and put into tubes designed for microwave. 10 mL of 65% HNO_3 were added to the samples. During this process, the fume cupboard was used. The prepared specimens were then burnt at 280 PSI pressure in a microwave and at 180 °C for 20 min. The tubes were removed from the microwave after being processed and left to cool. Deionized water was added to the cooled samples and tubes were filled until 50 ml was completed. The filtered solutions were analyzed for heavy metal concentrations of Mg, Al, Fe, Mn and Ca using GBC Integra XL–SDS-270 ICP-OES.

Statistical analyses

The obtained data were evaluated with the help of SPSS package program, variance analysis was applied to the data and homogeneous groups were obtained by applying the Duncan test to the values having at least 95% confidence level differences statistically. The obtained data is simplified and tabulated and interpreted.

Results

The change in Mg levels according to distance and pointer age was determined and mean values and P value obtained by analysis of variance, error rate and groupings formed as a result of the Duncan test are given in *Table 1*.

Table 1. *The element of Mg (ppm) of the change depending on distance and needle age variance*

Distance	1 Age needle	2 Age needle	P value	Error
1 km	3659.24 Ad	4566.64 Bd	42.598	0.000
3 km	2907.08 Ac	4179.28 Bc	50.364	0.000
10 km	2687.33 Ab	2902.48 Bb	9.415	0.007
25 km	2282.17 Aa	2597.37 Ba	12.012	0.003
P Value	65.505	83.040		
Error	0.000	0.000		

It is statistically different from the values contained in different groups, starting with the letter A-a, the numerical value grows

When the results of the table are examined, it is observed that the concentration changes of Mg element are statistically significant ($p < 0.001$). When the average values and Duncan test results are examined, it is seen that Mg concentration decreases significantly in both 1-year-old and 2-year-old needles depending on the distance, Mg concentration values determined at 25 km distance are more than 1.6 times of Mg concentration values determined at 1 km. It is seen that the changes in all distances in terms of pointer age are statistically significant ($p < 0.01$ in 1 and 3 km at other distances $p < 0.001$), and the values determined in 2-year-old needles at all distances are higher than those determined in 1-year-old needles.

The letters A, B, a, b, c, etc. means according to Duncan's test results; show that the group is located. It is statistically different from the values contained in different groups, starting with the letter a, the numerical value grows

Al-element concentration in both 1- and 2-year-old needles is statistically significant ($p < 0.001$), but it is difficult to say that there is a linear relationship between distance and Al concentration when the mean values and groupings formed by Duncan test are examined, because, the lowest value is determined at 10 km and the highest value is 25 km at both 1-year and 2-year-old needles. As a result of the variance analysis, it was observed that the changes in all distances were statistically significant ($p < 0.001$) in terms of pointer age, and the values determined in the 2-year-old needles were higher than those determined in the 1-year-old needles. In fact, it was calculated that this difference was quite high and the difference, which was 1.75 times at a distance of 25 km, could reach up to 3.12 times.

The change of Fe element according to distance and pointer age was determined and P values, error rate and groupings resulting from Duncan test obtained from mean values and variance analysis are given in *Table 3*.

Table 3. *The element of Fe (ppm) of the changing depending on distance and needle age*

Distance	1 Age needle	2 Age needle	P value	Error
1 km	66.56 Ac	110.41 Ba	21.641	0.000
3 km	55.20 Ab	156.48 Bb	224.086	0.000

According to the analysis of variance, the change of Fe element concentration depending on distance was statistically significant ($p < 0.001$ in 1-year-old needles and $p < 0.01$ in 2-year-old needles). According to the average values and Duncan test

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37133727

results, it can be said that Fe concentration decreases in 1-year-old needles while it is difficult to say that there is a significant change in 2-year-old needles. As a result of variance analysis, it was seen that the changes in all distances were statistically significant ($p < 0.001$) in terms of pointer age, and the values determined in 2-year-old needles were higher than those determined in 1-year-old needles. In fact, this difference is quite high, ranging from 1.6 times to 2.9 times.

The variation of Mn element according to distance and pointer age was determined and the mean values and P value obtained by analysis of variance, error rate and the groupings formed as a result of Duncan test are given in *Table 4*.

Table 4. *The element of Mn (ppm) of the changing depending on distance and needle age*

Distance	1 Age needle	2 Age needle	P value	Error
1 km	40.95 Ab	77.78 Bb	28.326	0.000
3 km	65.52 Ac	100.52 Bc	62.199	0.000
10 km	28.18 Aa	48.10 Ba	13.131	0.002
25 km	95.42 Ad	169.47 Bd	81.932	0.000

Error	0.000	0.000		

The letters A, B, a, b, c, etc. means according to Duncan's test results; show that the group is located. It is statistically different from the values contained in different groups, starting with the letter a numerical value grows

It was determined that the concentration of Mn element was statistically significant ($p < 0.001$). However, it is difficult to say that there is a linear relationship between distance and Mn concentration when the mean values and the groupings formed by Duncan test are examined because the lowest value is determined at 10 km and the highest value is 25 km at both 1 year and 2-year-old needles. As a result of the analysis of variance, it was found that the changes in all distances were statistically significant ($p < 0.01$ at 10 km distance, $p < 0.001$ at other distances) in terms of pointer age, between 5 and 1.9 times.

It was determined that the concentration of Mn element was statistically significant ($p < 0.001$). However, it is difficult to say that there is a linear relationship between the distance and the Mn concentration because the lowest value is determined at 10 km and the highest value is 25 km at both 1 year and 2-year-old needles. ($P < 0.01$ at 10 km distance, $p < 0.001$ at other distances) in terms of pointer age. Between 5 and 1.9 times.

According to the variance analysis results, are given in *Table 5,* it was found that the change of Ca element depending on distance was statistically significant ($p < 0.01$) in both 1 and 2 year old needles, and when the mean values and Duncan test results were examined, it was found that there was an inverse relationship between Ca concentration and distance. As a result of the analysis of variance, it was found that the changes in all distances were statistically significant ($p < 0.001$) in terms of pointer age, and the values determined in 2-year-old needles were 1.9 times to 2.3 times higher than those in 1-year-old needles.

Discussion

The concentrations of Mg, Al, Fe, Mn and Ca elements in the 1 and 2-year-old needles of the scots pine grown around 1, 3, 10 and 25 km distances around the "process and mining of magnesite ore" were determined. Although many studies on heavy metals have studied some of these elements, it is noticeable that in general, studies focus on elements such as Pb, Ni, Cd, Cr, Zn, Co (Turkyilmaz et al., 2019, 2018a, b, c, d; Sevik et al., 2019b). The reasons that these elements may cause toxic effects and are carcinogens even at low concentrations can be shown as the main factors in the prominence of these elements (Turkyilmaz et al., 2019, 2018a, b, c, d; Saleh, 2018). Some recent studies are shown that conform the temporal changes in magnesite pollution released by the factory to the air (Blanár et al., 2019; Pišút and Pišút, 2006).

However, the studies show that although micronutrients such as Mn and Fe, which are considered in this study, are necessary, they can create harmful effects at high levels (Shahid et al., 2017). Fe and Al are defined as carcinogenic to humans (Goney, 2018). In addition, it is stated that the elements that are required as a nutrient can cause serious health hazards if taken by mouth or respiration (Batır, 2019). For example, Mn, which reaches people through the food chain, causes hallucinations, fatigue, insomnia, weakness, forgetfulness and nerve damage by causing damage to the respiratory system and brain, and may cause Parkinson's, lung embolism and bronchitis, and impotence in men (Pak, 2011; Mossi, 2018). It is therefore very important to monitor the concentrations of these elements in the air.

The results of the study show that Mg concentration decreases significantly depending on the distance. In studies conducted to date, it has been shown that the concentration of heavy metals in plants decreases as they move away from the source (Turkyilmaz et al., 2018c; Aricak et al., 2019a, b). However, as a result of the study, no linear relationship was found between distance and concentration decrease in other elements. This has been demonstrated in other similar studies and it has been stated in many studies that there is no significant difference between the distance to the source of pollution and the concentration of heavy metals (Mossi, 2018; Saleh, 2018; Sevik et al., 2019a).

There are two possible explanations for this situation. The first is that the source of pollution is not a source of pollution in terms of these elements. The second explanation is that the change in heavy metal concentration in plants is a complex mechanism that has not been fully solved under the influence of many factors (Sevik et al., 2019b; Turkyilmaz et al., 2019). Indeed, studies show that heavy metals can be transported

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37133727

hundreds of kilometers away from their original source (Shahid et al., 2017). However, the accumulation of heavy metal concentrations in plants is shaped by the interaction of many factors and their sub-factors (Mossi, 2018; Turkyilmaz et al., 2018b, c).

Studies carried out to this day have shown that the diffusion of heavy metals in the atmosphere and entry into the plant is a very complex process. The heavy metal accumulation potential of the plants grown in the same environment as well as plant species and plant organ, organelle structure, physico-chemical properties of metals, organelle morphology and surface area, organelle surface texture and size, plant habitus, duration of exposure to heavy metal and amount of particulate matter (Pearce et al., 2006; Xu and Zhou, 2008; Schreck et al., 2012).

The accumulation of heavy metals in the plant is closely related to environmental conditions. It is stated that there is a significant relationship between the entry of heavy metals into the plant and especially air humidity and precipitation (Shahid et al., 2017; Ozel, 2019). In addition, environmental factors directly affect plant growth and there is a significant relationship between plant growth and heavy metal uptake. Therefore, the introduction of heavy metals into the plant and its accumulation in organs are shaped under the interaction of many factors and their sub factors (Shahid et al., 2017; Aricak et al., 2019a).

The study shows that the concentration of all elements subject to the study at 2-years-old needles is higher than their concentration at 1-years-old needles at all distances. This can be explained by the longer exposure of the 2-year-old needles to the same environmental conditions and therefore to heavy metals. Similarly, similar results were obtained from studies on different aged needles on the same plant (Turkyilmaz et al., 2018c; Cobanoglu, 2019; Kececi, 2019).

Although a number of studies have been conducted on the use of plants as biomonitor for monitoring heavy metal pollution in the air, it is not yet possible to determine which plants are most suitable for monitoring heavy metal concentrations. There are many reasons for this, but the most obvious is the limited number of plants, since it is very difficult and costly to work with many plants at the same time. The studies can be done by comparing 8-10 plants at most and in this case only the plants subject to the study can be compared with each other. However, studies show that there is a very high-level difference between the species growing in the same environment (Mossi, 2018; Sevik et al., 2019a, b; Saleh, 2018).

The first question to be answered is which kind of heavy metal pollution should be used. Lichen and algae are the most important plant groups in biomarkers for heavy metal pollution.

Bryophytes covering these plants, especially algae, have been used as biomonitor since the 1970s (Ayres et al., 2006; Harmens et al., 2010). However, one of the biggest problems in using lichen and algae as biomonitors is that it is not easy to determine how long these plants have been exposed to pollution. Therefore, it is not known clearly how long any concentration of metal accumulates, and this results in questioning the reliability of the data obtained (Cobanoglu, 2019).

In deciduous high-structured plants the problem of time is relatively eliminated. Because the foliage in these plants occurs at the beginning of the vegetation season, which is in the spring and is exposed to air pollution, i.e. heavy metals, until the leaves are shed. Therefore, the amount heavy metals accumulation in the leaves can be known. Therefore, deciduous plants are often used to monitor heavy metal pollution (Anicic et al., 2011; Petrova et al., 2014; Mossi, 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37133727

By using deciduous plants as biomonitors, the amount of heavy metals deposited on the leaves during the vegetation period of the year in which the samples collected can be determined. However, as much as the determination of the concentration of heavy metal is possible, it is extremely important to determine the change of this concentration depending on the year. Few studies have been conducted to determine the amount of heavy metal accumulation in plants in the past years. Rather, the studies are done on the trunks of trees by taking samples from annual rings. This type of sampling usually involves the analysis of heavy metals deposited on annual rings in the trunks of trees (Panyushkina et al., 2016; Xu et al., 2017; Turkyilmaz et al., 2018b, c). This method is not suitable for sustainable monitoring because trees need to be cut down.

In some variegated species, the leaves can remain on the plant for many years. However, there is a problem in interpreting what heavy metal concentration means because the leaf age is not known in these studies. However, in many types of hands, the hands remain on the tree for a few years, and it is possible to know the age of hands by the means of the nodes formed. In addition, since the hands of these plants are exposed to the same environmental conditions outside the vegetation season, the accumulation in the old hands can be much higher (Cobanoglu, 2019; Kececi, 2019). As a matter of fact, in this study, it was found that the concentrations obtained in the 2-year-old hands were much higher than the 1-year-old hands.

Heavy metals can enter the plant through root or leaf uptake, but it is very difficult to distinguish whether heavy metals in the plant's internal tissues are taken from the soil or atmosphere, because both intake pathways can work simultaneously (Pourrut et al., 2013; Shadid et al., 2017). Therefore, it is thought that leaves are the most suitable organs especially for monitoring heavy metal pollution in the air. Because the leaves are the most exposed to heavy metal pollution in the air and are affected most by them due to the entry of air through their stomata during photosynthesis (Cetin et al., 2019a,b, 2020; Turkyilmaz et al., 2018c; Shahid et al., 2017; Saleh, 2018).

There is also a significant relationship between heavy metal accumulation in the plant and particulate matter in the air. Studies show that the interaction of fine particles with plant leaves is especially important in contamination with heavy metals (Temmerman et al., 2012; Schreck et al., 2012). Particulate matter acts as a pharynx for heavy metals in the air, and the concentration of heavy metals in these organs can vary significantly with the adherence of particulate matter contaminated with these heavy metals to plant surfaces and especially leaves (Mossi, 2018; Turkyilmaz et al., 2018d). Heavy metals in the air may accumulate in plant leaves by leaf transfer following precipitation of atmospheric particles on leaf surfaces. The potential for absorbing nutrients, water and metals from leaf parts of plants has long been recognized. However, information about the uptake of metal by plant leaves from the atmosphere is very limited (Shahid et al., 2017). To date, there have been few studies on leaf or pointer ages in determining the concentration of heavy metals in the past (Turkyilmaz et al., 2018c; Cobanoglu et al., 2019; Kececi, 2019).

Heavy metal accumulation in plants varies significantly on organ basis. However, there are many factors that affect this accumulation. Particularly with the adhesion of particulate materials contaminated with heavy metals to plant organs, heavy metal concentrations in these organs increase significantly. Adhesion of particulate materials contaminated with heavy metals causes heavy metal concentrations to be quite high, especially in the bark of trees with cracks. However, heavy metal concentrations in branches, leaves and fruits other than this vary significantly by species. In the wood,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37133727

which is located in the interior of the tree and does not have a direct connection with the external environment, many heavy metal concentrations remain at lower levels (Sevik et al., 2020a, b, c).

As a result, there are many factors that affect the penetration and accumulation of heavy metals in the air. These factors include plant species, rainfall and moisture content, plant habitus, organelle structure, type of heavy metal and interaction with the plant (Sevik et al., 2019a; Aricak et al., 2019a) There are also many factors that may directly or indirectly affect the concentration of heavy metals. For example, the change in heavy metal concentration depending on plant species has been demonstrated in many studies (Sevik et al., 2019a, b, c, 202a, b, c; Saleh, 2018; Erdem, 2018; Bozdogan Sert et al., 2019; Cetin et al., 2019a). However, it can be expected that the heavy metal concentrations in the subspecies, forms, varieties and origins of the plant will be at different levels. Because, studies show that many phenological, morphological and anatomical structures change depending on these characteristics (Yucedag et al., 2019a; Cetin et al., 2018a; Sevik et al., 2019c). In this case, it is inevitable that plant metabolism changes and this affects heavy metal absorption (Shahid et al., 2017; Sevik et al., 2019a, b).

Heavy metal absorption in plants is also closely related to plant metabolism (Shahid et al., 2017; Sevik et al., 2019a, b). Therefore, the stress level of the plant significantly affects plant metabolism (Sevik and Cetin, 2015; Yigit et al., 2016), plant origin (Sevik and Topacoglu, 2015), and the genetic structure of the plant (Hrivnak et al., 2017), and many other factors such as heavy metal absorption and thus heavy metal concentration. However, the factors affecting the accumulation of heavy metal concentrations in plants and their effect levels have not been clearly determined yet. Therefore, studies on this subject should be continued, diversified and increased.

Conclusions

We have attempted to determine the change of some heavy metal concentrations depending on the distance to the point which is thought to be the source of pollution and the age of the pointer in *Pinus sylvestris* L. whose needles can remain on the tree for a few years. The results of the study showed that Mg concentration decreased significantly in relation the distance. Considering that the source of pollution is "processing and mining of magnesite ore", this result is very logical and also shows that *Pinus sylvestris* L. needles are very suitable for monitoring the change of Mg concentration in the air.

One of the most important results of the study is that the concentrations obtained in the 2-year-old needles in all elements are significantly higher than in the 1-year-old needles. This can be explained by the fact that older needles are exposed to heavy metals in the air longer than younger needles. According to this result, the needles of trees such as *Abies* and *Picea,* whose needles can remain on the trees for up to 8-10 years and the age of the pointer can be calculated clearly, can be good biomonitor in monitoring the recent heavy metal pollution.

No connection between the distance and the Al, Fe, Mn and Ca could be observed, but sometimes those concentrations were lower close to the factory. This shows that there is no direct connection between the source of pollution and the elements, and the source of these elements is probably soil. It is suggested that the source of these elements should be determined clearly by doing soil analysis in further studies.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37133727

It has been determined that Mg concentration varies significantly depending on the distance to the source. While the concentration of Mg in 1-year-old hands taken at a distance of 1 km from the source is 3659 ppm, it decreases to 2907 ppm at 3 km distance, 2687 ppm at 10 km distance and 2282 ppm at 25 km distance. In the 2-year-old hands, the concentration of 4566 ppm in 1 km distance to the source decreased to 4179 ppm at 3 km, 2902 ppm at 10 km and 2597 ppm at 25 km. However, in order to determine how much of this decrease originates from air and how much from soil, it is recommended to make measurements in soil samples and evaluate the results comparatively.

(Received 14th Jan 2020; accepted 13th Apr 2020)

Abstract. Niyang River is the second largest tributary of the Yarlung Tsangpo River on the Tibetan Plateau. To establish the controlling factors of water quality in the river basin, this paper explores the hydro-chemical features of the major ions in the river water, and evaluates the water quality and health risk of trace elements. Multiple advanced technical instruments were adopted for our exploration including, the principal component analysis (PCA) and Water Quality Index (WQI). The hydro-chemical results show that the major ions in the river mainly originate from the weathering of rocks, with Ca-Mg-HCO_3 being the dominant type of hydro-chemical facies. Through PCA-based water quality assessment, we learned that the trace elements of Tl, Hg, Cd, Mo, Ti, U, As, Cr, Pb, Rb, Li, Sr, Ba, Fe and Al mostly come from rock weathering and groundwater leaching, while Cu, Zn and Mn are mainly attributable to natural and human sources. According to international and domestic standards, virtually no trace element surpassed the permissible limit, and the WQI values were basically low across the river basin, indicating that the river water is suitable for drinking directly.
Keywords: *Water Quality Index, trace elements, Niyang River, dissolved ion chemistry, principal component analysis*

Introduction

Water is one of the most important resources on the Earth. However, freshwater only makes up 2.5% of the total volume of the world's water. The Tibetan Plateau has an abundance of water resources, which greatly affect the local economy and ecology (Huang et al., 2008; Qu et al., 2019). Hailed as the water tower of Asia, the plateau is the source of the ten largest rivers on the continent, such as the Yangtze River, the Yellow River and the Nujiang River (Huang et al., 2010, 2008; Wu et al., 2005; Xu et al., 2019). Among the various rivers on the Tibetan Plateau, more than 20 rivers have a catchment greater than 10, 000 km^2 (Guan and Chen, 1980). The largest catchment (>240, 000 km^2) belongs to the Yarlung Tsangpo River (Jiang et al., 2015; Zeng et al., 2018). On the Tibetan Plateau, the most important tributary of the Yarlung Tsangpo River is the Niyang River, the catchment of which catchment is larger than 10,000 km^2 (Liu et al., 2018). The existing studies on this river mainly focus on the potential effects of global warming on the chemical weathering of rocks in the catchment and on the eco-environmental changes

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37293740

in the downstream (Liu et al., 2018; Yu et al., 2019). There is little report on the water quality in the Niyang River, from the perspectives of major ions and trace elements.

Water quality reflects the potential of river water to serve drinking and production purposes. It is generally agreed that the water quality of rivers is influenced by human factors (e.g. mining, wastewater discharge, and land use changes) and natural processes (e.g. rock weathering, grassland degradation, and glacier melting) (Huang et al., 2015; Wijesiri et al., 2018; Chen et al., 2019; Haldar et al., 2019; Jahin et al., 2020). For instance, rapid economic growth, which is accompanied by intense human activity, can push up the pollutant content in water systems, while rivers in pristine areas maintain good water quality (Wijesiri et al., 2018; Haldar et al., 2019). Under global warming, the pollutants accumulated in glaciers are released into the rivers, reducing the water quality (Huang et al., 2008). However, it is very difficult to assess the water quality of rivers in a comprehensive manner, because of the complex interplay between human factors and natural processes.

In recent years, both anthropogenic factors and natural processes are posing a serious threat to the water quality of the Niyang River. About 94, 000 people now live along this water course, and economic activities (e.g. mining, agriculture and tourism) have been in full swing in the downstream. In addition, the water chemistry in the catchment is being changed by the growing volume of meltwater and rainwater. Through the above analysis, this paper aims to identify the chemical features of river water, assess the controlling factors of water quality, track the source of trace elements, and evaluate the water quality in the Niyang River basin. First, water samples were collected from the Niyang River and its major tributaries. Then, the major ions and trace elements were analyzed in the water samples. In addition, the suitability of the water samples as drinking water was evaluated based on multiple water quality indices. The research results shed new light on water management and health protection on the Tibetan Plateau.

Materials and Methods

General situation of research area

The Niyang River (92°10'-94°35'E; 29°28'-30°31'N) originates at 5,000 m above the sea level (m a.s.l.) from the Cuomuliangla, west of the Mila Mountain, China's Tibet Autonomous Region (TAR). With a catchment of 17, 679 km^2, the river flows 307.5 km from west to east, before entering the Yarlung Tsangpo River at 2,920 m a.s.l. The elevation difference between the source and confluence is up to 2,080 m (Zhang et al., 2009). Being the second largest tributary of the Yarlung Tsangpo River, Niyang River is of great importance to the regional water balance on the Tibetan Plateau. The annual runoff of river is estimated to be 17.23 billion m^3. Meltwater and rainwater contribute to 47 and 40% of the annual runoff, respectively (Wang, 2011). The precipitation in the river basin is unevenly distributed, and largely controlled by the warm current in the Indian Ocean and the cold current from the north. The mean annual rainfall stands at 650 mm, 90% of which occurs in the summer months from June through September. The climate in the river basin changes significantly with the elevations. The annual mean temperature rises from 7.6℃ in the upstream to 8.6°C in the downstream.

The river basin has a complex lithology. The bedrocks are mainly composed of granite, diorite and granodiorite. The dominant minerals include mica, feldspar and quartz. Quaternary deposits are widely developed on both banks of the river. Located in the downstream of the Niyang River, the Bayi District is home to more than 39,000 people,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37293740

serving as an important agricultural base on the Tibetan Plateau (Li, 2009). Every year, a large volume of agricultural and domestic wastewater is discharged into the river. What is more, fertilizers and pesticides are widely applied in this district to guarantee the agricultural output (Shi, 2015).

Experimental methods

In August, 2018, water samples were collected at 10 cm below the water surface from the Niyang River and its major tributaries (*Fig. 1*). The physical and chemical compositions of the samples are reported by Liu et al. (2018). The temperature (T), electrical conductivity (EC) and pH of the samples were measured in-situ by a Multi 3630 IDS multi-parameter portable meter (WTW, Germany). The alkalinity of the samples was obtained through Gran titration analysis in the field, using 0.02 mol/L HCl. The water samples were processed by 0.45 μm cellulose acetate (CA) membrane filters, and then stored in pre-cleaned polyethylene bottles. The filtrate was divided into two parts: one part was used directly for anion analysis (e.g. SO_4^{2-}, F^-, Cl^-, NO_3^-), and the other was acidified to pH < 2 with ultrapure 1:1 HNO_3 for cation analysis (e.g. Na^+, K^+, Ca^{2+}, Mg^{2+}, SiO_2). The cations were analyzed by inductively coupled plasma atomic emission spectroscopy (ICP-OES) system (Vista MPX, US), while the anions were measured by ionic chromatography (IC), using an ICS-90 IC system (Dionex, US). The contents of trace elements were obtained through inductively coupled plasma mass spectrometry (ICP-MS) system (Agilent 7700X, US). The contents of anions, cations and trace elements were all measured in The State Key Laboratory of Environmental Geochemistry, Institute of Geochemistry, Chinese Academy of Sciences. The measurement reproducibility was determined through repeated analysis, showing ± 5% precision for the anions, cations and trace elements. For all the samples, the calculated total anion charge TZ^- was balanced by the total cation charge TZ^+ within the analytical uncertainties, and the normalized inorganic charge balance (NICB) fell within ± 5% are reported in Liu et al. (2018).

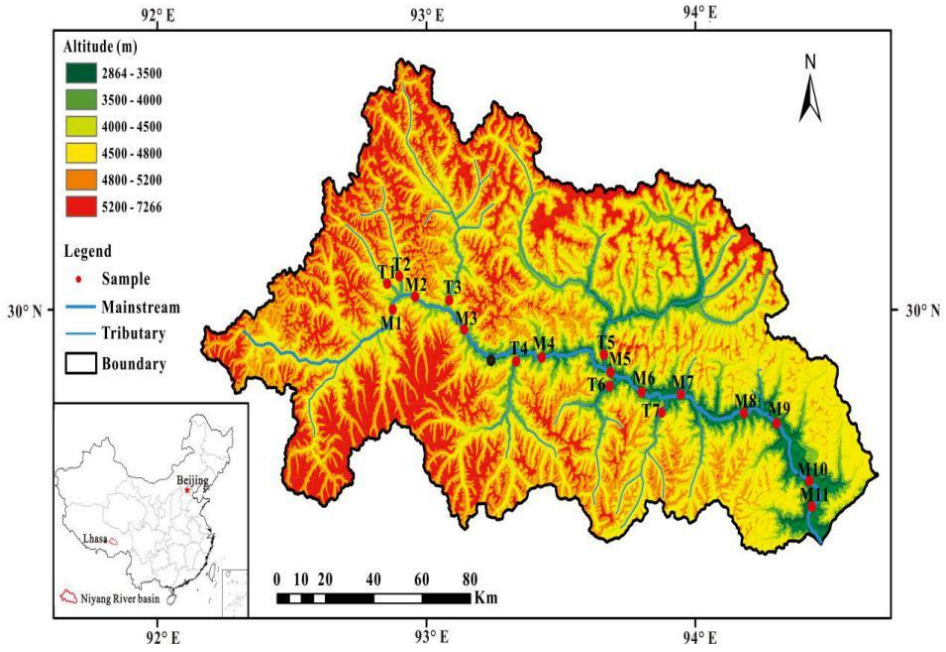

Figure 1. *Sampling location map of Nyang River. Modified from Liu et al. (2018)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37293740

Statistical methods

Pearson correlation analysis was performed to disclose how different trace elements influence the water quality. If the Pearson correlation coefficient (r), is greater than or equal to 0.7, then the two variables have a strong correlation; if $0.4 < r < 0.7$, then the two variables have a moderately strong correlation; if $r \leq 0.4$, then the two variables have a weak correlation (Gidey and Amanuel, 2018).

The Water Quality Index (WQI) was introduced to evaluate the combined effects of several toxic elements considered detrimental to the aquatic ecosystem (Qu et al., 2019):

$$WQI = \frac{1}{n}\sum_{i=1}^{n} A_i = \frac{1}{n}\sum_{i=1}^{n} C_i/Q_i \quad \text{(Eq.1)}$$

where C_i (μg/L) is the content of the i-th toxic element in the water sample; Q_i (μg/L) is the content limit of the i-th toxic element specified by the World Health Organization (WHO, 2011) and the Chinese national standard (GB) (MOH and SAC, 2006). According to the WQI value, the pollution level was divided into four classes: $WQI \leq 1$ (Class 1, unpolluted); $1 < WQI \leq 2$ (Class 2, slightly polluted); $2 < WQI \leq 3$ (Class 3, moderately polluted); and $WQI > 3$ (Class 4, heavily polluted) (Qu et al., 2019).

Results and Discussion

Characterization of the major ions of Niyang River systems

As mentioned before, the chemical compositions of the water in the Niyang River basin are reported in Liu et al. (2018). The pH of the water samples varied from 8.08 to 7.71, indicating the mild alkalinity of the water in the river basin. Due to the specific hydrology and geology, the major ion contents of the Niyang River were lower than those of other rivers in the world (*Fig. 2*). The total dissolved solids (TDS) of the samples ranged from 51.7 to 112 mg/L, averaging at 81.7 mg/L. This is far lower than the global mean level of 120 mg/L (Wetzel, 1975). In the mainstream of the Niyang River, the TDS decreased from 112 mg/L in the upstream to 72.3 mg/L in the downstream, owing to the dilution effect. The Ca^{2+} accounts for 60.5-80% of all cations (TZ^+) in the water samples, followed by Mg^{2+} (10.8-34.9%), Na^+ (3.58-8.74%) and K^+ (0.67-1.9%), while HCO_3^- accounts for 60.2% of all anions (TZ^-) in the samples, followed by SO_4^{2-} (36.4%).

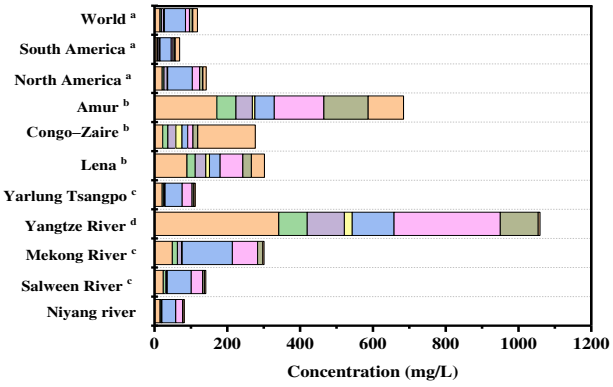

Figure 2. *Average concentrations of major ions in Niyang River and other rivers of the world. Data source: a. Wetzel (1975); b. Gaillardet et al. (1999); c. Huang et al. (2011); d. Chetelat et al. (2008)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37293740

To evaluate the hydrogeochemical facies and types of the samples, the relative equivalent proportions of major ions were plotted as ternary diagrams. As shown in *Fig. 3*, the data clustered near the [Ca^{2+} + Mg^{2+}] peak (*Fig. 3a*) and the HCO_3^- peak (*Fig. 3b*), suggesting the water in the Niyang River basin belongs to the type of Ca-Mg-HCO_3 river water. This is similar to that in the Yangtze River (Chetelat et al., 2008), but differs from that of the Wujiang River (Han and Liu, 2004) and the Yellow River (Fan et al., 2014).

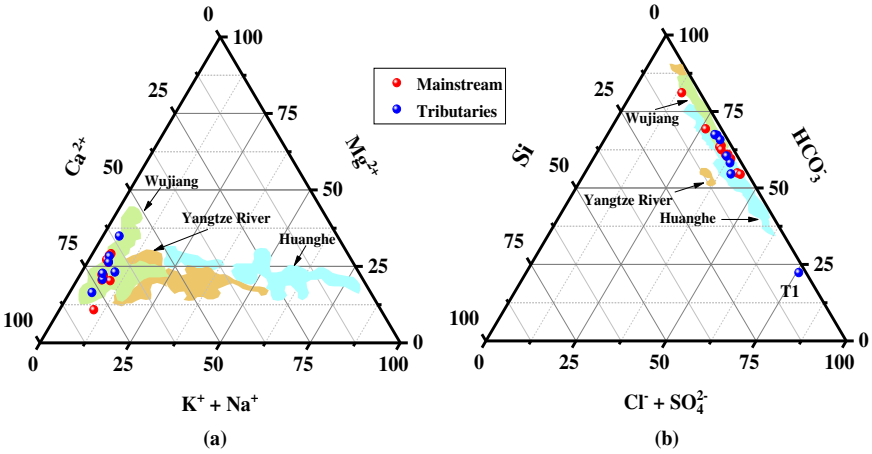

Figure 3. *Ternary diagram of the relative equivalent proportions of major cations (a) and major anions (b) for the river waters, indicating that the Niyang River was dominated by Ca^{2+} and HCO_3^-*

Major sources and controlling factors of the ions

The major elements dissolved in river water generally come from precipitation, groundwater leaching, human inputs (e.g. agriculture, industry and urbanization), and chemical weathering of rocks (e.g. silicate, evaporite, carbonate, and sulfide) in the catchment (Meybeck and Ragu, 1997; Gaillardet et al., 1999). On the Tibetan Plateau, the meltwater and rainwater are the two leading sources of the major elements in rivers (Hasnain and Thayyen, 1999). Zhang et al. (2003) calculated how much atmospheric inputs contribute to the total cations based on the measured ion/Cl^- ratio in rainwater in Lhasa region, assuming that rainwater has the lowest Cl^- content measured in the catchment (Ding et al., 2017). In the Niyang River basin, the lowest Cl^- content was observed at the site T-2 (3.30 μM). According to Liu et al. (2018), the atmospheric inputs contribute to 5.5-12.9% of the total cations, with an average of only 8.0%. Thus, the contribution of atmospheric inputs to the major ions of our samples is very limited. Considering the major impact of human activities on water chemistry via wastewater input (Sun et al., 2017), it is necessary to evaluate the contribution of human inputs to the major ions in the water samples. In many large rivers, NO_3^-, among the dissolved ions, is generally associated with anthropogenic sources (Chetelat et al., 2008). In our water the NO_3^- content was below the global mean value of 21.7 μM (Meybeck, 1987). According to Liu et al. (2018), the human activities are responsible for 0-0.5% of all cations. Hence, the human inputs also have a limited contribution to the major ions in our samples. TDS contents and low weight ratios of [Na^+]/[Na^+ + Ca^{2+}] and [Cl^-]/[Cl^- + HCO_3^-]. This means the dominant source of major ions in the Niyang River catchment is the chemical weathering of rocks. In general, the Mg^{2+}, Ca^{2+} and HCO_3^- in our samples are most likely

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37293740

to originate from the weathering of carbonates and silicates, while the K^+, Na^+, SO_4^{2-} and Cl^- from the weathering of silicates and the dissolution of evaporites. To identify which type of rock weathering controls the ions in the water samples, the plotted the mixing diagrams of the Na-normalized of Ca^{2+} versus HCO_3^- and Ca^{2+} versus Mg^{2+} for identifying three endmembers of carbonates, silicates and evaporates. As shown in *Fig. 4*, our water samples were close to the carbonate endmember in the mixing diagrams, indicating that the weathering of carbonate is crucial to the major ion chemistry of the river water.

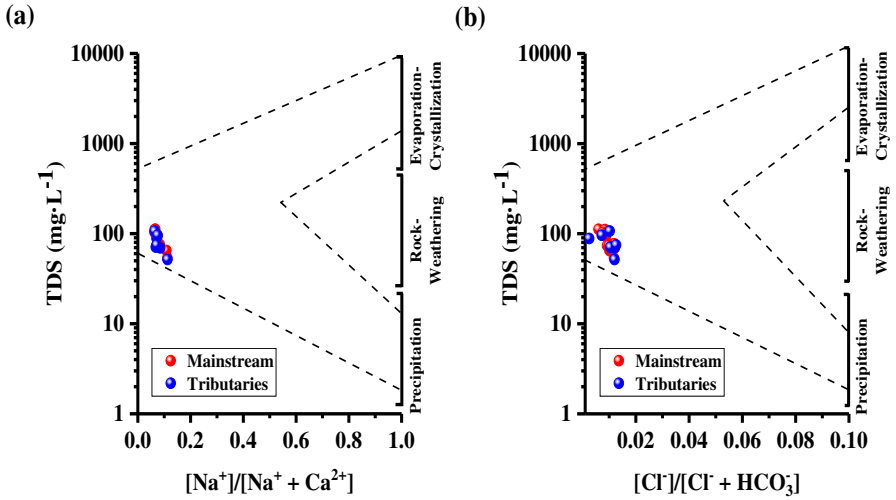

Figure 4. *Gibbs diagram (weight ratios) of major ion compositions in Niyang River basin*

This conclusion echoes with the previous results on the rivers in other parts of the High Himalaya region (Wu et al., 2008; Jiang et al., 2018; Zeng et al., 2018), and is supported by the relatively high mean $[Ca^{2+} + Mg^{2+}]/[Na^+ + K^+]$ molar ratios of 7.62 and mean $[HCO_3^-]/[Na^+ + K^+]$ molar ratios of 9.28. The molar ratios confirm that the river basin is dominated by the weathering of dolomite and calcite minerals in *Fig. 5*.

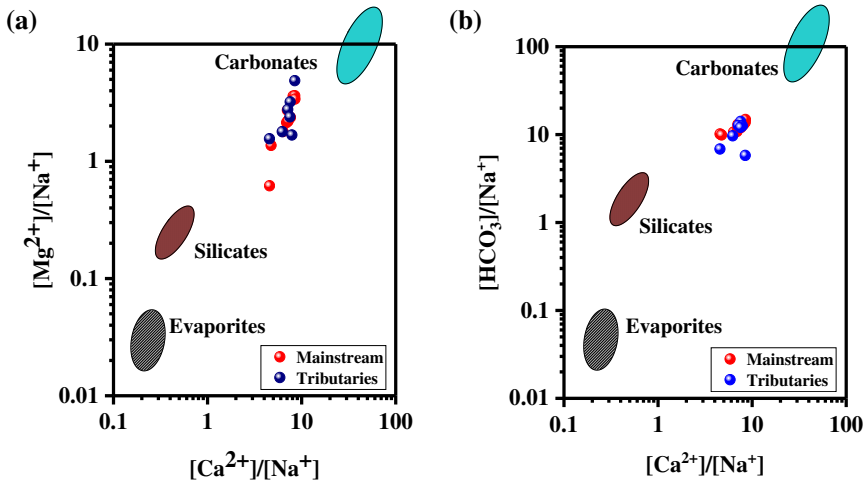

Figure 5. *Mixing diagram of the Na-normalized molar ratios of (a) Ca^{2+} versus Mg^{2+} and (b) Ca^{2+} versus HCO_3^- in the Niyang River basin. The data for the three endmembers, i.e., carbonates, silicates and evaporites, are obtained from Gaillardet et al. (1999)*

Dissolved trace elements and water quality assessment

Dissolved trace elements

Despite their excessively low content (<1 mg/L), the trace elements play an important role in human health (Xiao et al., 2019). This subsection discusses the features and possible sources of trace elements in our water samples, and assesses their risks to the residents in the river basin in *Table 1*.

na, not determine

The Niyang River has fewer dissolved elements than most rivers around the world. The contents of trace elements were extracted to identify the correlations and covariances between varying sample parameters through the principal component analysis (PCA). Three main parameter clusters were observed in the PCA loading-plot (PC1, PC2 vs PC3) in *Fig. 6*, which represent 74.0% of the total variances in the data of river waters. The Sr, Cu, Cr, Al, Fe, Ti, and Pb in PC1 had the highest loadings among the PCs, which explains

DOI: http://dx.doi.org/10.15666/aeer/1802_37293740

33.1% of the variance. This is supported by the positive correlation among these elements (*Table 2*): the correlation coefficients of Cu and Pb, Al and Fe, and Cr and Pb were 0.975, 0.952, 0.944 and 0.971, respectively. Meanwhile, the Cd, Mn, Zn, Rb and Tl in PC2 could explain 26.6% of the variance; the Mo and Hg in PC3 was responsible for 14.2% of the variance.

DOI: http://dx.doi.org/10.15666/aeer/1802_37293740

Overall, the contents of trace elements in samples varied with the differences in the weathering of rocks, groundwater supply, rainwater and human inputs (Tatsi et al., 2015; Qu et al., 2017). In the Niyang River systems, Fe and Al mainly come from the weathering of chlorite and calcite (Yokoo et al., 2004), Cu, Zn and Mn mostly originate from mineral exploration, due to the abundance of mineral deposits (e.g., manganese ore, copper ore and lead zinc ore) in the river basin (Lü et al., 2019). As shown in *Table 2*, Tl and Cd had a positive correlation coefficient of 0.93, suggesting that the two trace elements are both attributable to mining and meltwater (Tatsi et al., 2015). Note that the heavy metals Mn and Zn at site T-I were 13 times and 128 times more concentrated than those in other rivers (Gaillardet et al., 1999), respectively, reflecting the major contribution of the human activity of metal mining.

Water quality assessment

The water quality indices of our samples were compared against the drinking water standards of the World Health Organization (WHO) (WHO, 2011) and the GB (MOH and SAC, 2006). The comparison shows that most of the Al, As, Ba, Hg, Pb, Tl, Cr, Cu, Fe, Mo, Sr and Zn in our samples were below the lower limits of toxic elements for drinking water. As shown in *Table 1*, the trace element contents and the Water Quality Index (WQI) were relatively high in the upstream of the Niyang River, owing to high evaporation and limited precipitation. Across the river basin, the WQI values ranged from 0.03 to 0.4, except for the relative high WQI at site T-1. The latter is attributable to the mineral exploration at the site. Therefore, almost all samples from the river basin belong to the unpolluted class.

The Niyang River supplies agricultural water to the entire Bayi District. More than half of the population in that district live along the water course. The tourism and agriculture are booming along the river. This research reveals that water in the Niyang River is still undisturbed, because the impacts from agriculture and industrial activities (mining) are mitigated by the strong dilution and buffering capacity of the river. However, the boom in tourism, coupled with the mining activities, will put heavy burdens on the water quality in the region. The degradation of water quality is foreseeable, due to the intensified weathering of rocks and growing human activities in the river basin. Therefore, the local government should implement strict environmental regulations on solid waste and waste water treatment.

Conclusions

In the context of sustainable development, water quality is an important environmental issue across the globe, especially in the Tibetan Plateau, the water tower of Asia. This paper mainly explores the geochemistry features of major ions in the Niyang River, and assesses the water quality in the river basin. It is learned that the water chemistry in the river is greatly affected by the natural process of rock weathering, with Ca-Mg-HCO_3 being the dominant type of hydro-chemical facies. Under the alkaline aquatic environment, the river basin has low contents of trace elements, which originate from bedrock weathering. Through water quality assessment, the rivers water in the basin was found safe for direct drinking, for no trace element surpasses the lower limit in international and domestic water quality standards, except for Mn and Zn at site T-I. However, the elemental abundances in the air, soil, and water of the river basin may be perturbed by the growth in economy, human activities (e.g. mining and wastewater

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37293740

discharge) and natural processes (e.g. rock weathering). Considering the potential damages of this possibility to human health and the essential role that rivers on the Tibetan Plateau play in terms of water resources of Asia, the region should consistently monitor the pollutant loads and implement pollutant control in the rivers, e.g. increasing of the sampling and adding the analysis of water quality parameters.

Abstract. Plant-microbial bioremediation is an efficient way to treat heavy metal contaminated soils. In order to reveal the potential mechanisms of ectomycorrhizal fungi mutualistic symbiosis for remediating heavy metal contaminated soils, the masson's pine associated with ectomycorrhizal fungi (*Suillus luteus*) and control treatments (plant roots without ectomycorrhizal fungi) were planted in a Pb and Zn contaminated mining area in the south of China. The results showed that the growth of masson's pine seedlings were significantly higher in the treated group than in the control group. The bioconcentration factor (BCF) of heavy metals inoculated with *Suillus luteus* was 1 to 5 times higher than that of those in control group. However, the translocation factor (TF) of heavy metals in treated group decreased by 50% compare to the control group. Both selenium and potassium content significantly improved the functions of oxidation and stress resistance in symbiotic systems. The activity of the urease and alkaline phosphatase in the soil was significantly improved in treated group. The soil available N, P and K contents, and the ratio of C/N was increased compared to the control. In conclusion, the ectomycorrhizal fungi could improve soil physicochemical properties, and enhance nutrient absorption by the plants, which would be favorable to the growth of plants in the soil contaminated with heavy metals.
Keywords: *bioremediation, heavy metal toxicity, enzyme activities, mycorrhiza, symbiosis systems*

Introduction

Soils may be contaminated by the accumulation of heavy metals through emissions from the rapidly expanding mine tailings. The water and soil erosion caused by deforestation in abandoned mining area had polluted the surrounding soil with heavy metals severely, which resulted in impacts on the growth and development of wild life, plants and human activities in central south of Hunan, China (Ayangbenro and Babalola, 2017; Huang et al., 2012). To remediate hazardous pollutants of heavy metal ions have attracted more attention (Li et al., 2019).

There were many methods reported to restore or remediate heavy metal contaminated soil, for example, physcio-chemically, to fix available heavy metals in soils by means of welding, stabilizing, excavating and electrodynamics, so that the effective concentration (EC) of heavy metals were reduced to harmless level (Sheoran et al., 2011; Wuana and Okieimen, 2011). However, these methods would inevitably damage the natural structure of soil by adding curing agent. Also the improper storage

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37413755

of the contaminated soil after curing might result in secondary pollution. In contrast, the bioremediation method constructed by plant roots and ECM fungi was environmentally friendly. The symbiotic system could immobilize, accumulate and transfer excessive heavy metals through the absorption of water and nutrients in soil (Ma et al., 2019; Guo et al., 2020).

Many reports, in recent years, showed that the heavy metal contaminated soils, such as abandoned mining areas and tailings reservoir areas, did harm to the growth and development of plants considering the physiologically and the survival of herbaceous plants (Zhang and Ji, 2019; Zhang et al., 2018). However, some woody plants such as Fagaceae (Tam, 1995; Sozoniuk et al., 2019) or Pinaceae (Wang et al., 2019) coexisted with ectomycorrhizal (ECM) fungi, which could supply the host plants with water and nutrient (Colpaert, 2008), and promote these plants to survive in the toxicity of heavy metals in mining areas (Lalancette et al., 2019). According to Jentschke and Godbold (2000), the roots of almost all forest tree seedlings rely on mycorrhizal fungi, which could shift the absorption and translocation of heavy metal stress in roots system and ameliorate the toxicity of heavy metals to the aboveground of host plants (Jentschke and Godbold, 2000). Compared with the plants inoculated without ECM fungi, *Pinus sylvestris* inoculated with six strains of ECM fungi immobilized larger numbers of zinc in the roots, and limiting the transportation of zinc to the host plants of *Pinus sylvestris* (Colpaert, 2008). As well as Sousa et al. (2012) mentioned that ECM fungi (*Suillus bovinus*) would improve shoot development of *Pinus pinaster* seedlings up to 30% exposure to the soil contaminated by Cd, and the accumulation of Cd in the aboveground parts of the seedlings inoculated with *S. bovinus* seedlings also increased (Sousa et al., 2012). Other studies also showed that masson's pine inoculated with ECM fungi was more tolerant to higher concentrations of heavy metals than the non-ECM fungi inoculation, and ECM fungi had a great effect on the absorption and fixation of heavy metals (Huang et al., 2012).

Masson's pine, a pioneer tree species with large biomass, is regarding as an important timber and industrial material tree species that has ectomycorrhizal in southern China (Sun et al., 2010). Masson's pine exhibits many advantages, such as fast growth, high yield, strong adaptability to drought-stressed soils, and high potential for the phytoremediation of soils that contaminated by heavy metals (Wang et al., 2019; Zhang et al., 2017). Therefore, masson's pine was considered to be an appropriate reforestation tree species in heavy metal contaminated soils in abandoned mining tails area. *Suillus luteus* could form symbiotic systems with masson's pine (Zhang et al., 2017), *Larix principis-rupprechtii* (Huai et al., 2003), P*icea abies* (Krznaric et al., 2009a), *Pinus sylvestris* (Yin et al., 2014) and so on, and could increase the absorption of nutrients and water, and then promote the growth of symbiotic plants (Luo et al., 2014). However, so far, the effect of ECM fungi on the improvement of host plant remediation potential and adaption under excessive stress of heavy metals in soil are not very clear.

In this study, the effects of masson's pine inoculated with or without ECM fungi on soil properties were investigated. The objectives of the study were 1) the characteristics of absorption, accumulation and transportation of heavy metals and nutrients of masson's pine inoculated with *Suillus luteus* compared to the control (without ECM fungi) in the mining areas contaminated soil by lead-zinc; 2) to address the mechanisms of mycorrhiza and plant mutualistic symbiosis system on the soil physicochemical properties and the activities of enzymes in masson's pine rhizosphere.

Materials and methods

Experimental site

The experimental site is located in an abandoned lead-zinc mining tails of mountain Manao in the southeast of Chenzhou city, Hunan Province, China (*Fig. 1*). *Miscanthus* sp, *Equisetum ramosissimum, Elsholtzia cypriani* are the dominate plants species growing in the abandoned mining tails area that are seriously polluted by lead (Pb) and zinc (Zn) heavy metals. The area is at the northern foot of middle section of the mountain Nanling (13°08′00″~113°08′30″E, 25°35′00″~25°44′00″N). It is a continental subtropical monsoon humid climate, with distinct four seasons, abundant sunshine and the rainfall, but unevenly distributed. As "hometown of non-ferrous metals", the mountainous and hilly are rich in mineral resources, have less arable land and water. Due to extensive mining, there is a series of problems such as soil erosion, eco-environment deterioration, and heavy metals pollution. Therefore, the native plant species, such as *Koelreuteria paniculata*, *Sapium sebiferum*, *Pinus massoniana* Lamb, and *Quercus*, growing in the polluted site are endangered. It is urgently needed to protect and reforest plants and tree species in the whole area, particularly the mining tailings.

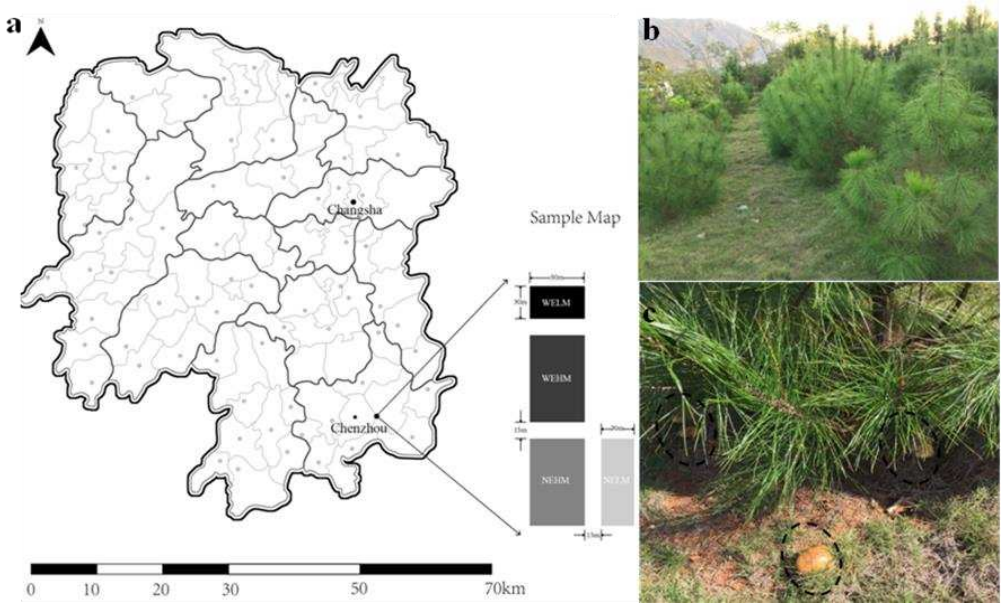

Figure 1. *Location of the study area and plot setting. (Note: a refers to the experimental site, b refers to the growth condition of masson's pine, and c refers to the sampling site inoculated with Suillus luteus; the capital letter WELM refers to low heavy metals contaminated soil inoculated with ECM fungi, WEHM refers to high heavy metals contaminated soil inoculated with ECM fungi, NELM refers to low heavy metals contaminated soil inoculated without ECM fungi, NEHM refers to high heavy metals contaminated soil inoculated without ECM fungi)*

Experiments design

The plants used in this experiment were two-year-old masson's pine seedlings inoculated with and without ECM fungi, which were provided by Hunan academy of forestry. The seedlings inoculated with EMC were cultivated by the way of Yu et al. (2020). At the end of 2016, the masson's pine seedlings inoculated with ECM fungi (WE) and without inoculation (NE) were planted in two polluted areas with two different levels of Pb and Zn

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37413755

contamination degree in soil, the low heavy metal contaminated soil (LM) and the high heavy metal contaminated soil (HM). The polluted soils combine with the treatment inoculated with ECM fungi (WE) named as WELM, WEHM, and the polluted soils inoculated without ECM fungi (NE) named as NELM, NEHM. There was no polluted soil (NM) based on the Pb and Zn contaminated degree below the Hunan background and national standard II (see *Table 1*) with NE treatment only (names as CK) in the experiment. There were three replications in both LM and HM soils. Before the experiment to set up, we have measured the no polluted soil samples with WE and NE treatments, and we found that no significant difference between the treatment and control. So that there were three WELM, three WEHM, three NELM, three NEHM, and three NENM of the treatments, the total of 15 sampling plots in the experimental study, and each plot included 3 trees. The heavy metal contents in different plots were showed in *Table 1*.

Table 1. *Heavy metals content of soil in different planting areas of masson's pine (mg/kg)*

Soil type	Pb	Zn	Cu	Cd	Mn
CK	20.93	87.47	23.69	0.13	686.10
LM	602.35	400.93	44.93	0.32	1222.93
HM	2555.20	496.75	57.52	0.473	2010.83
Hunan background	29.7	94.4	27.3	0.17	–
National standard II	≤ 250	≤ 200	≤ 150	≤ 0.30	–

CK refers to no heavy metal polluted soil without ECM fungi; LM refers to the low heavy metal contaminated soil; HM refers to the high heavy metal contaminated soil

Plant growth determination and sampling

From June 2017 to May 2019, the plant heights, ground diameters, crown width and annual branch length of masson's pine were measured. Meanwhile, three root, stem and leaf samplings of each masson's pine inoculated with ECM fungi (including WELM and WEHM), without ECM fungi (including NELM and NEHM) and CK treatment were collected, and the root, stem and leaf samplings from each plot was mixed into one sample, respectively, we totally got 15 root samplings, 15 stem samplings, and 15 leaf samplings. Then, heavy metals and nutrient element contents were determined. Notably, root samplings of each plant were carefully excavated by soil core sampler (φ108 mm × φ100mm × 130mm), the soil attached to the root surface was took as rhizospheric soils, and the depth of sampling was 10 to 20cm.

Soil sampling

The soil samples were taken in each plot before the seedlings of masson's pine planting and the soil physicochemical properties were measured (*Table 1*). Two years after planting the seedlings of masson's pine, root samplings of each plant were carefully excavated and the soil attached to the root surface of masson's pine was collected and packed in a sealed plastic bag. The gravel, plant litter and other visible impurities were removed. The sampled soil was divided into two categories: one was stored in refrigerator at -20 ℃ for the determination of soil enzyme activities of the soil, and the other one was air-dried at room temperature for the determination of soil physicochemical properties.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37413755

Determination of soil physicochemical properties

The soil was dried in oven at 70 ℃ for 48 h for measuring water content. Took 1 g soil dissolved in 5 ml distilled water and shaken for 30 min, and was measured by glass electrode (Sartorius PB-10). Soil total carbon (TC) and total nitrogen (TN) were determined by element analyzer (VarioEL III, Germany). The available phosphorus (AP) in soil was extracted by sodium bicarbonate and determined with molybdenum-blue method, the available potassium (AK) was determined by flame spectrophotometry, and available nitrogen (AN) was measured by means of alkaline hydrolysis diffusion method (Bao, 2000).

Determination of total heavy metal concentrations in plants and soils

The dried plants were divided into two parts, belowground part and aboveground (stem and leaf) parts. After smashed, both of 0.3 g plant and soil samples were weighed accurately, then digested by microwave acid digestion (EPA 3051; USEPA, 2004). The heavy metal concentrations were determined by Inductively Coupled Plasma Emission Spectrometer (ICP-MS, X-7, Thermo Electron, Waltham, MA, USA) (Zhao et al., 2013). All samples were repeated for three times and then took the average value was taken.

Determination of soil enzyme activities

The activity of catalase was defined as decomposing one milligram of soil hydrogen peroxide every 30 min, and determined by ultraviolet spectrophotometry. A unit (μ) of urease active was defined as producing the mass of NH_3-N by hydrolyzing 1 g soil for 1 min, and determined by sodium phenol-sodium hypochlorite colorimetry. The activity of alkaline phosphatase was defined as producing the mass of phenol with 1 g of soil after 24 h, and determined by disodium phosphate colorimetric method. The activity of sucrose enzyme was defined as producing the mass of glucose with 1 g of soil after 24 h, and determined by 3, 5 dinitrosalicylate colorimetric method (Guan et al., 1986).

Statistical analysis

The means of the growth vigor of masson's pine, the absorption of heavy metals and nutrient elements, and soil physicochemical properties had been compared within Microsoft s Excel (Office' 2000), One-way analysis of variance (ANOVA) and The correlation between the soil physicochemical properties and plant nutrients was performed to determine the effects of above factors by using SPSS (version 19.0; SPSS, Chicago, IL, USA)

Results

Effects of ECM fungi on the growth of masson's pine

The mean height, ground diameter, annual branch length and crown width of masson's pine seedlings inoculated with/without EMC and the control in different contaminated soils are shown in *Figure 2*. The mean height and annual branch growth of seedlings with NE treatment were decreased compared to the no polluted soil treatment (CK), especially, there was a significantly difference in plant height ($P < 0.05$) (*Fig. 2a*). Seedlings of WELM treatment have improved the mean plant height, annual branch length, ground base diameter and crown width than in others

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37413755

($p < 0.05$). The mean ground diameter of seedlings in WELM and WEHM plots were increased by 53.12% and 43.38%, respectively, compared to the NELM and NEHM plots (*Fig. 2b*).

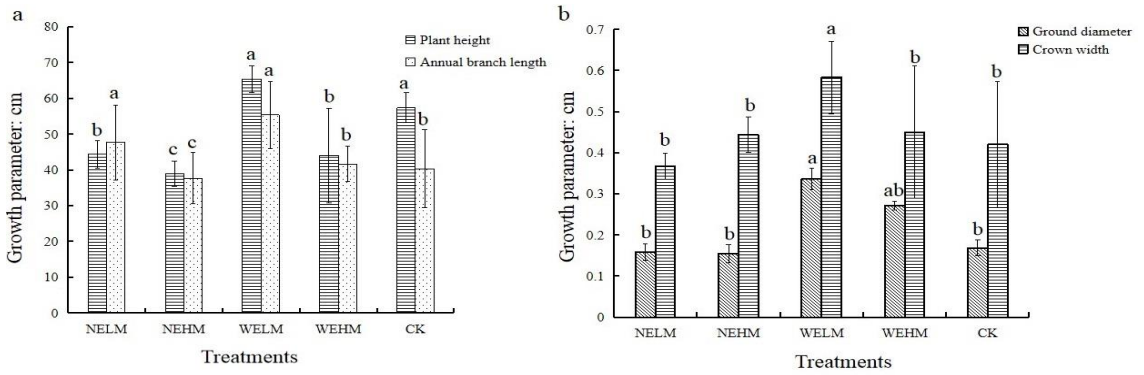

Figure 2. *Effects of ectomycorrhizal fungi on the growth of masson's pine. (Note: a refers to the plant height and annual branch length, and b refers to the plant ground base diameter and crown width; the capital letter CK refers to no heavy metal polluted soil without ECM fungi, WELM refers to low heavy metals contaminated soil inoculated with ECM fungi, WEHM refers to high heavy metals contaminated soil inoculated with ECM fungi, NELM refers to low heavy metals contaminated soil inoculated without ECM fungi, NEHM refers to high heavy metals contaminated soil inoculated without ECM fungi; means followed with same letters are not significantly different by Tukey's test multiple comparison at $p < 0.05$, mean ± standard error of three measurements)*

Effect of ECM fungi on accumulation and transportation of heavy metals in masson's pine

The distribution of heavy metal concentrations of masson's pine in different treatments were analyzed (*Table 2*). The results showed that accumulation of heavy metals of Pb, Zn, Cd, Cu and Mn in WE treatment was higher than that of NE in the plant roots ($p < 0.05$). The translocation factor (TF) of Pb was 0.93, and the bioconcentration factor (BCF) of the root was 0.09 in NEHM plot, which was nearly reach to that of CK (TF = 1.26, BCF = 0.55). However, the TF and BCF of Pb in WEHM plots were 0.51 and 0.44, respectively; the TF was about 45% while the BCF was almost five times of that in NE treatment. The accumulation of Zn, Cd, Cu and Mn in the roots of WE treatment was increased by 1 to 2 times, while TF was significantly decreased compared to the NE soil.

Effects of ECM fungi on the absorption and distribution of nutrient elements in masson's pine

The results showed that the TF of selenium in WELM and WEHM treatments were 2.33 and 1.57 times higher than that of NELM and NEHM treatments, respectively (*Table 3*). The Iron (Fe) in the root system was significantly increased in WEHM treatment, while decreased in aboveground part, especially, in the plant leaves ($p < 0.05$). In soil with the same degree of pollution, the average content of N and P of the plants in the WE treatment plant were higher than that of NE treatment, but the content ratio of the belowground part to the underground part was lower in WE treatment than that in NE treatment ($p < 0.05$), except for the N content of NELM and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37413755

WELM. The content of K in the plant is lower in WE treatment than that in NE treatment, while the TF of K is higher in WE treatment than that in NE treatment.

Effect of ECM fungi on physicochemical properties of soil

The physicochemical properties of soil were changed significantly between WE and NE treatments (*Fig. 3*). The water content of soil was increased by 84% in WELM and 45% in WEHM treatment than that in NE treatment, respectively. The available N content was increased by 64% in WELM and 13.3% in WEHM than that in NE treatment, respectively. The C/N ratio of the soil in WE treatment changed greatly, especially in WELM soil, and the soil C/N is about 22% higher than that in NE treatment. The contents of P and K in WELM plot was significant increased compared to CK. The highest N content was found in WE treatment of the soil ($p < 0.05$). The overall results showed that the inoculation of ECM fungi could significantly improve the soil structure and physicochemical properties.

The capital letters CK refer to no heavy metal polluted soil without ECM fungi, WELM refers to low heavy metals contaminated soil inoculated with ECM fungi, WEHM refers to high heavy metals contaminated soil inoculated with ECM fungi, NELM refers to low heavy metals contaminated soil inoculated without ECM fungi, NEHM refers to high heavy metals contaminated soil inoculated without ECM fungi; means followed with same letters within column are not significantly different by Tukey's test multiple comparison at $p < 0.05$, mean ± standard error of three measurements

Effect of ECM fungi on soil enzymes

Soil enzyme plays an important role in recycling of nutrients, which is closely related to soil microorganisms and plant community structure. It is a sensitive index to evaluate soil fertility and soil quality. The results showed that the enzyme activity in WE treatment was significantly different from that of control treatment (CK) and NE treatment ($p < 0.05$) (*Table 4*). The urease and alkaline phosphatase contents in WE treatment was significantly higher than that of NE treatment ($P < 0.05$), while there was no significant different in catalase and sucrase content among different treatments.

The correlation between the soil physicochemical properties and plant nutrients

The correlations between the soil physicochemical properties of soil and the contents of macro nutrients in masson's pine seedlings were analyzed (*Table 5*). The results showed that there were correlations between soil physicochemical properties and the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37413755

accumulation of macro nutrient. The soil pH correlated negatively with all the nutrient elements of plant, excepting the K. Especially, the significantly negative correlation was found between the concentration of N and soil pH (*Table 5*). The soil water content was positively correlated with plant Se, N, P elements, while the negatively correlation was found between soil water content and the plant Fe and K (*Table 5*). There was positive correlation of N and P between the plants and the LM and HM soils, while the content of K in plant was negatively correlated with the available K content in the soil. The results of correlation analysis of soil enzymes and soil physicochemical properties showed that urease had a significantly negative relationship with soil pH, while there was no significant relationship between the soil urease and bulk density (*Table 5*). Both Urease and alkaline phosphatase positively correlated with soil nutrient elements. Sucrase negatively correlated with the soil properties (excepting the soil pH and the soil bulk density), especially with the available nitrogen (N) and phosphorus (P) contents of the soil. Altogether, plants inoculated with ECM fungi could increase the activities of catalase, urease and alkaline phosphates and therefore improved the soil physicochemical properties.

Discussion

Tolerance and adaptability of ECM fungi on masson's pine seedlings in mining area

Soil bioremediation based on plant-microorganism symbiotic system has become a hot topic of researches (Kurzawova et al., 2012; Becerra-Castro et al., 2012). Many studies have shown that herbaceous plants have a strong ability to absorb and accumulate heavy metals (Leguizamo et al., 2017; Xue et al., 2014). In recent years, researchers have also tried to use woody plants with larger amount of biomass for forest restoration (Shi et al., 2011). For example, Shukla et al. (2011) chose five species of woody plant for the phytoremediation of heavy metals of sludge dumps in India, and the results showed that all the five plants had high bioconcentration factor for different metals and the remove rate of heavy metals were from 14.05 to 70.22% (Shukla et al., 2011). It is worth noting that many plant species largely rely on mycorrhizal fungi, which enhance nutrient uptake and protect against environmental stresses (Krznaric et al., 2009a), especially in the heavy metal contaminated stress (Adriaensen et al., 2006; Krznaric et al., 2009b).

In our research, the growth parameters, height, lateral branches and the ground diameter of the masson's pine inoculated with ECM fungi were significantly higher than those of the control and the masson's pine inoculated without ECM fungi during the experimental study in the mining area (*Fig. 1*). Moreover, masson's pine inoculated with ECM fungi could enhance the accumulation of heavy metals (*Table 2*), and the absorbed metals such as Pb, Zn, Cd, Cu, Mn elements were immobilized in roots system, which reduced the transportation of heavy metals to the aboveground part and alleviated the toxicity of heavy metals to the plant (*Table 3*). Our result was consistent with Reddy et al. (2016) that growth performance of plants was improved significantly inoculated with ectomycorrhizal fungi (*Pisolithus albus*) in the stress of Cu and Cd, which proved that ectomycorrhizal fungi could help plants to adapt to the heavy metal stress environment (Reddy et al., 2016). Similar results were also reported by other ectomycorrhizal fungi studies where heavy metals transfer to the host plants was significantly reduced (Krznaric et al., 2009b; Colpaert et al., 2005). Mycorrhizal fungi contribute not only to the uptake and detoxification of various environmental pollutants including heavy metals, but also to plant nutrition (Perotto and Martino, 2001). The result was consistent with our results that ECM fungi inoculation could promote the plant absorption and accumulation of essential elements Fe, N, P, K, and Se in the aboveground and underground parts of masson's pine under heavy metals stress in soil. The Se element could enhance the activity of plant antioxidant enzymes and the resistance of heavy metals stress.

Effects of ECM fungi on nutrient elements and soil enzyme in heavy metals contaminated soils

Soil enzyme is the most important catalyst of all biochemical reactions in soil biological activity (Nannipieri et al., 2018), and it is the most active bioactive substance in the degradation, transformation, and mineralization of soil organic matter (SOM) thereby maintaining energy flow and change the composition and structure of nutrient elements in soil, which was of great significance to plant growth (Sinsabaugh, 2010), and further alleviate the stress of the environment to the plants (Angelovičová et al., 2015).

In our study, the ECM fungi could activate the soil urease and the phosphatase, and increased the available nitrogen and the phosphorus contents in the soil for the plants to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37413755

uptake it. Furthermore, the enzyme activities had significant negative correlation with soil pH, and positively correlated with available N, P, and K contents in soil, while the soil pH had significantly negative correlation with the N, P contents in plants, so that there was a significantly positive correlation between N, P contents in masson's pine plants and urease and alkaline phosphates in soil. ECM fungi could form mutual symbiotic system with majorities of plants' roots (Burke et al., 2011), and play a vital role in enzyme activities which correlated with nutrient absorption such as nitrogen and/or phosphorus (Eichlerová et al., 2015). Previously studies shown that ECM fungi could expand the absorption area of plant roots through hyphae, and then increase the nutrient uptake in plant rhizosphere, especially in soil available P (Cairney, 2011; Köhler et al., 2018). According to Taniguchi et al. (2008), the inoculation of ECM fungi significantly increased the growth of plants, which significantly related to the content of phosphorus, the ratio of nitrogen to phosphorus and plant rhizosphere soil phosphatase (Taniguchi et al., 2008).

Conclusions

In this study, we investigated the effects of masson's pine inoculated with ECM fungi (*Suillus luteus*) on soil physicochemical properties by evaluating the soil bulk density, water content, soil available nutrients and soil pH. The heavy metals accumulation and translocation in multi-metals of mining areas was also analyzed. The results showed that the masson's pine inoculated with ECM fungi growing in the heavy metals contaminated soils increased the growth of masson's pine in ground base diameter, annual branch length and crown width. Soil enzymatic activities were significantly improved in the mutualistic symbiosis systems of *Suillus-Pine*, especially the activities of urease and alkaline phosphatase, indicating the potential to obtain more nutrient elements. An immobilization of Pb, Zn, Cd, Cu, Mn was observed in the roots of plant inoculated with S*uillus luteus*, and correspondingly decreased the translocation of heavy metals in the plants' roots may due to the detoxification. Two enzymes decreased the soil pH and increased the soil available of N, P, K contents, enhancing the growth of masson's pine. Our results provided the information to understand the adaptation and bioremediation of plants mycorrhizal to detoxify the heavy metals from the environment, and provided a theoretical basis in allocation and transformation of heavy metals in the case of multi-metals contaminated soil in mining area.

Considered that, future research should pay more attention to the difference of rhizosphere microbial community diversity in different contaminated sites and its influence on the restoration effect of heavy metals.

(Received 9th Dec 2019; accepted 24th Mar 2020)

Abstract. Cadmium (Cd) is one of the most notable heavy metals because of its high mobility and toxicity towards plants. In the present study, we aimed to evaluate the effect of cadmium on growth, physiological parameters, anatomical changes and phenolic compounds content in *Phaseolus vulgaris* L plant. Seedlings were exposed to cadmium at 0.25; 0.5 and 1 $g.l^{-1}$ for 21 days. Results indicated that cadmium significantly decreased percent seed germination, embryonic radical elongation, plant dry weight, stem/root length and numbers of leaves and lateral roots. Cadmium also induced a decrease in chlorophyll and protein content with all treatments; however, sugar and proline increased significantly with 1 $g.l^{-1}$. Total phenolic content increased by around 43% and 32% in the above ground part and roots respectively. Flavonoids, flavonols, hydrolysable tannins and condensed tannins showed a significant increase with higher cadmium concentration. Cadmium also changed plant root and stem anatomy; a decrease in both number and size of xylem vessels and a delay in xylem differentiation were observed.
Keywords: *cadmium, Phaseolus vulgaris L., growth, histological changes, phenolic compounds*

Introduction

Modern agro-ecosystems have continually received ever-increasing cadmium (Cd) pollution from several domestic and industrial activities, as well the agricultural application of phosphate fertilizers, sewage sludge and irrigation water contaminated with this element; leading to soil Cd contamination and increased Cd uptake by plants grown in those mediums (McLaughlin et al., 2006; Escudey et al., 2007). Cadmium can be found in soils, reaching levels of approximately 1 $mg.kg^{-1}$ for most of surface soils (Kabata-Pendias, 2000). It is relatively easily available for plant uptake because it is predominantly found in soil solution or bound to solid phase systems (Verbruggen et al., 2009).

In plants, exposure to cadmium induces phytotoxicity symptoms, such as biomass reduction, inhibition of root elongation (Gratao et al., 2009) and causes a reduction of several physiological processes including photosynthesis, respiration and transpiration (Seregin and Ivanov, 2001; He et al., 2017; Yazdi et al., 2019), seed germination (Chugh et al., 1995; Fattahi et al., 2019) and interferes with uptake, transport, and distribution of essential and non-essential mineral elements, especially in the form of Cd^{2+}(He et al., 2017). Cd toxicity triggers the over-accumulation of reactive oxygen

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37573774

species, ultimately resulting in oxidative stress in plants (Cuypers et al., 2011; Anjum et al., 2015; Gupta et al., 2017)

Antioxidant molecules produced by plants as a response to Cd uptake, are considered a defense mechanism to metal stress. In this context, many studies have shown the radical scavenging properties of phenols, mainly by yielding electrons (Michalak, 2010; Cruces et al., 2015; Manquián-Cerda et al., 2016). Plants exposed to heavy metal stress have been observed to exude high levels of phenolic compounds (Posmyk et al., 2009; Mongkhonsin et al., 2016; Manquián-Cerda et al., 2018).

The harmful effects of Cd in soils include also anatomical changes such as variation in root tissues organization, development of apoplastic barriers (Vaculík et al., 2012), structural changes in plant's vascular system (Barcelo et al., 1988).

Common bean (*Phaseolus vulgaris* L.) is one of the most important grain legumes worldwide; it is a valuable food source for humans around the world and accounts for higher consumption and economic importance. This crop is potentially exposed to Cd due to a component of fungicide and fertilizer formulations and amendment that is commonly used in agriculture throughout the word.

The purpose of this study was to evaluate Cd effect on: (i) morphological and physiological parameters, (ii) polyphenol accumulation in seedlings, (iii) root and stem structure in order to obtain detailed picture of Cd-induced structural disorders in vessels. It should help to explain responses of common bean to Cd stress.

Materials and methods

Plant material, treatments and growth conditions

Study was done in Algeria northern Africa under laboratory conditions. Common bean (*Phaseolus vugaris* L.) Djadida genotype commonly cultivated there was used. Seeds were selected, surface-disinfected using 0.1% sodium hypochlorite (NaClO) for 10 min, rinsed and soaked in distilled water at room temperature for 12 h. Seeds were then germinated in sealed plastic dishes with moistened filter paper at 25 °C in dark for 3 days. Uniform seedlings were selected and transplanted to pots containing mould with 16 h light and 8 h dark cycle at average day/night temperature of 25 °C/20 °C and average relative humidity of 75%, watered as needed according to field capacity calculated in gram of water per gram of soil and afterwards, till the end of the experiment for 21 days. The following treatments were considered: (1) 0.25 $g.l^{-1}$ of Cd, (2) 0.5 $g.l^{-1}$ of Cd, (3) 1 $g.l^{-1}$ of Cd. The Cd concentration was supplied us $CdCl_2$ water solution. For control experiment, Cd was omitted.

Seed germination and root elongation test

This test serves to verify the effect of cadmium on seeds germination. After selection and disinfection, seeds were placed in boxes containing filter paper moistened with cadmium solution at different concentrations 0.25 $g.l^{-1}$, 0.5 $g.l^{-1}$, 1 $g.l^{-1}$ and control moistened with distilled water. In each box 50 seeds were putted at 25 °C temperature in dark, with three repetitions for each concentration. Seeds were watered as needed by distilled water during 7 days.

To calculate the germination rate, we counted seeds sprouted per box every day until the seventh day, knowing that germination is positive when its radical reaches 5 mm in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37573774

length. After the seventh day of seed germination, radical's length of germinated seeds was measured on cm.

To obtain percentage of germination, we used the formula:

$$G(\%) = (\text{number of germinated seeds / total number of seeds}) \times 100$$

Morphological parameters

The different studied parameters are: Stem height and root length measured in cm; number of leaves and lateral roots. After sampling, roots were separated from above-ground part of plants and dried at 80 °C temperature for 48 h and weighed until we obtained a fixed weight in order to have the dry matter yield per pot.

Determination of tolerance index

Tolerance index (TI) was calculated as a ratio of the mean dry weight of plants grown in presence of Cd and mean dry weight of control plants. TI values lower than 1 suggests that plants are stressed due to metal pollution. Whereas, TI values equal to 1 indicate no difference relative to control treatments. Also, TI values higher than 1 indicate that plant is a hyper accumulator (Audet and Charest, 2007).

Biochemical and physiological parameters

Photosynthetic pigments determination

For photosynthetic pigments (chlorophyll *a* and *b*, carotenoids) analysis, fully developed trifoliate leaves were extracted with 80% acetone. Pigments contents were determined spectrophotometrically (spectrophotometer Shimadzu UV 1800) at following wavelengths: 663, 646 and 470 nm and calculated according to Lichtenthaler and Wellburn (1983).

Total soluble sugars

Leaves were used for soluble sugar determination; extraction was done with 80% (v/v) ethanol. Sugar content of resulting solution was determined following to Dische (1962) using anthrone reagent. Absorbance was measured at 620 nm. Standards of glucose were prepared and analyzed in the same way to obtain a calibration curve. Soluble sugars content was calculated as mg glucose equivalent g^{-1} FW.

Total protein content

The protein content in leaf tissue was determined according to Bradford (1976), Fresh leaves were homogenized and extracted with 5 mM buffer Tris-HCl, pH 7.2, 0.25 M sucrose and 1 mM $MgCl_2$. The extract was incubated with Bradford reagent in darkness. Absorbance was measured at 595 nm and the amount of proteins was expressed in equivalents of BSA bovin serum albumin (mg eq. BSA g^{-1} FW), used as standard.

Proline content

Proline content was determined following to Bates et al. (1973), using ninhydrin reagent. The absorbance was measured at 520 nm. Reference standards of proline were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37573774

prepared and analyzed in the same way to obtain a calibration curve. Results were expressed on $\mu g.g^{-1}$ DW.

Estimation of phenolic compounds

Phenolic compounds were extracted from shoot and roots dried samples of *Phaseolus vulgaris* L. The amount of total phenolics in the extract was determined using Folin Ciocalteu reagent as described by Meyers et al. (2003). Absorbance was measured at 750 nm and the results expressed in equivalents of gallic acid (mg eq. GA g^{-1} DW), used as standard.

Colorimetric aluminum chloride method was used for flavonoids and flavonols determination, using optimized protocols established by Bahorun et al. (1996); Kumaranand Karunakaran (2007a, b), respectively. Absorbance was measured at 430 and 440 nm respectively, and the amount of flavonoids and flavonol were expressed in equivalents of Quercetin (mg eq. Q g^{-1} DW), used as standard.

Hydrolysable tannins content was determined as described by Mole and Waterman (1987) and was quantified according to standard curve prepared for tannic acid. Results were expressed in equivalent of tannic acid (mg eq. TA g^{-1} DW).

Condensed tannins contents were determined following the method described by Swain and Hillis (1959). The absorbance was measured at 500 nm. The amount of condensed tannins was expressed in equivalents of catéchin (mg eq. CAg^{-1} DW), used as standard.

Anatomical study

At day 21 from sowing, samples were taken for light microscopy study. Sections were performed on fresh plants. Cross sections were made on the main root (1 cm of the collar; area of lateral roots), and those of stem are represented between first and second internodes. Samples were cut with a vibratome in order to obtain 100-µm transverse sections; fresh sections were collected and stained with iodine green carmine as described in Locquin and Langeron (1978).

Specimens were analyzed using a light microscope (optika B-350, Italy) using ×100 and × 400 magnifications, light micrographs were acquired by a digital camera and the images were processed and archived with TS view software version 6.2.4.5, tucsen imagin technology.

Statistical analyses

All data presented are the mean values of tree replicates ± standard deviation (SD). Statistical analysis was carried out by student analysis at 5%, 1% and 0.1% significance level, using statistical software package STATISTICA version 8.0

Results

Effect of Cd on germination and root elongation

Smaller number of seeds germinated in comparison with control variant was identified when Cd was added. Percent seeds germination was affected by different cadmium concentrations, it was lowered by about 68% with 0.25 $g.l^{-1}$ of metal, 84% with 0.5 $g.l^{-1}$ and 98% with 1 $g.l^{-1}$ Cd concentration ($p < 0.05$*) in contrast to control (*Fig. 1A*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37573774

However, elongation of embryonic radical was impaired by about 70%, 87%, 91% (*Fig. 1B*) by 0.25; 0.5 g.l^{-1} and 1 g.l^{-1} Cd respectively ($p<0.01$**) compared to control.

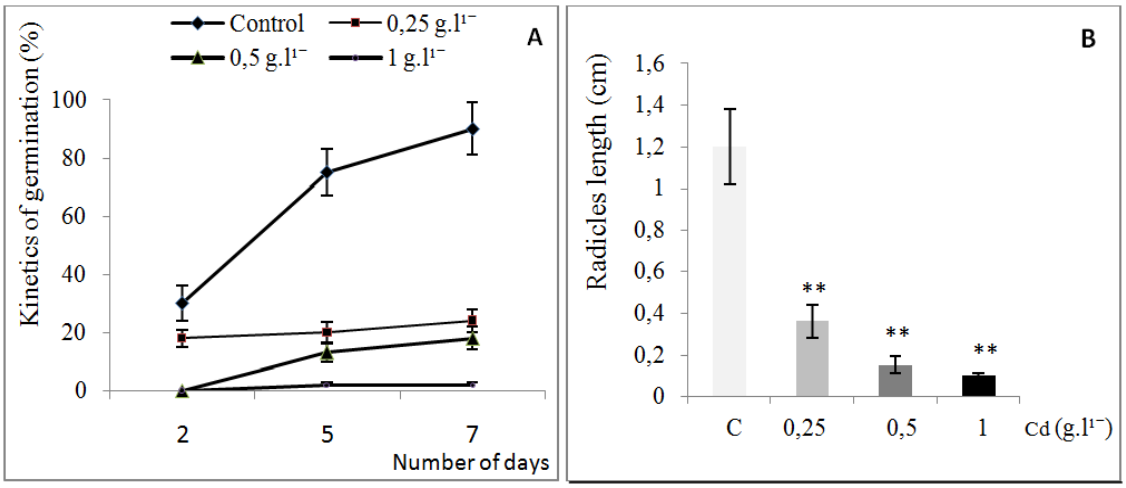

Figure 1. *Effects of cadmium (Cd) on (A) germination kinetics, (B) radicles length of common bean seeds (Phaseolus vulgaris L.). Results represent the mean ± SE (n = 3) (*p < 0.05, **p < 0.01, ***p < 0.001 according to Student test)*

Effect of Cd on plant growth

Morphological changes in *Phaseolus vulgaris* L. plants treated with concentrations of Cd showed leaf chlorosis, growth inhibition; stem weakening and dark brown root tips. We noted that 21-day-old, bean seedlings on polluted soil developed all aerial organs but shorter compared to control plants. Dark brown root tips and reduced growth are the most common physiological effects of heavy metal exposure in plants (Ovečka and Takáč, 2014). Stem and main root length is 68.58% and 71.43% shorter respectively in bean plants grown in 1 g.l^{-1} Cd concentration compared with those of controls (*Fig. 2A*); in this same concentration, bean plants had 50% fewer leaves and 20% fewer lateral roots per plant (*Fig. 2B*). The above ground part-roots dry weight and TI which represent relative plant growth were adversely affected by Cd concentrations; they decreased gradually with increase of Cd concentrations. This decrease was around 77.27% in above ground part length, and 47.97% in roots length comparing to their respective control under 1 g.l^{-1} Cd (*Fig. 2C*). According to results shown in *Table 1,* Tolerance Index of bean plants is less than 1 for all Cd concentrations in both part of plant, this confirmed a net decrease in biomass and suggests that *Phaseolus vulgaris* L. plants are stressed.

Treatment with 0.5 and 1 g.l^{-1} of Cd elicited significant decrease in all growth parameters as compared with control value ($P<0.05$ *), except for lateral roots number and roots dry weight; no changes were observed.

Table 1. *Value of tolerance index of bean plants according to Cd concentrations*

	Cadmium treatments		
TI	0.25 g.l^{-1} Cd	0.5 g.l^{-1} Cd	1 g.l^{-1} Cd
Above ground part	0.65	0.34	0.22
Roots	0.82	0.58	0.52

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37573774

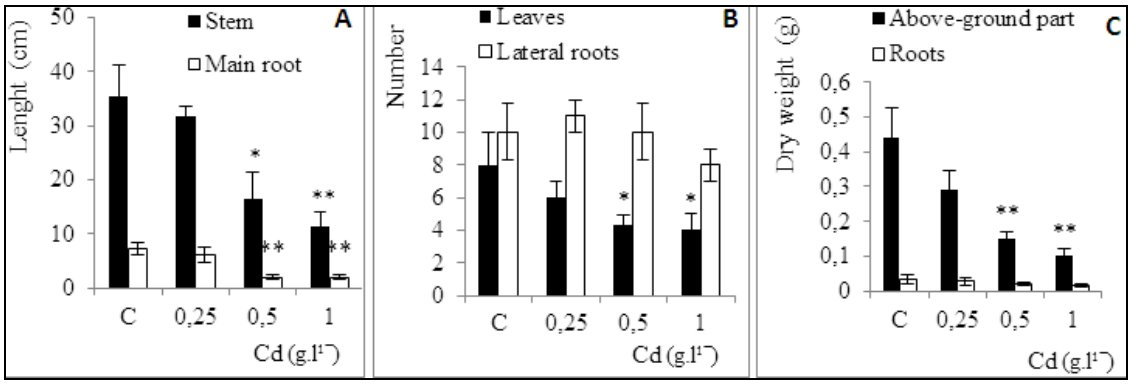

Figure 2. *Effects of cadmium (Cd) on (A) stem and main root length, (B) leaves and lateral roots number, and (C) dry weight of common bean seedling (Phaseolus vulgaris L.). Results represent mean ± SE (n = 3) (*p < 0.05, **p < 0.01, ***p < 0.001 according to Student test)*

Biochemical and physiological parameters

Cd treatment results in decline in chlorophyll content with increasing Cd concentrations. Chl *a* decreased significantly (P<0.01**) under all treatments till 56.87% compared to control. However, Chl *b* decrease was significant only under 1 g.l^{-1} Cd (p<0.05*) till 31.19% compared to control (*Fig. 3A*). When total carotenoids content showed a decrease reaching their lowest value under 1 g.l^{-1} Cd treatment (p<0.05*) in contrast to control (*Fig. 3B*).

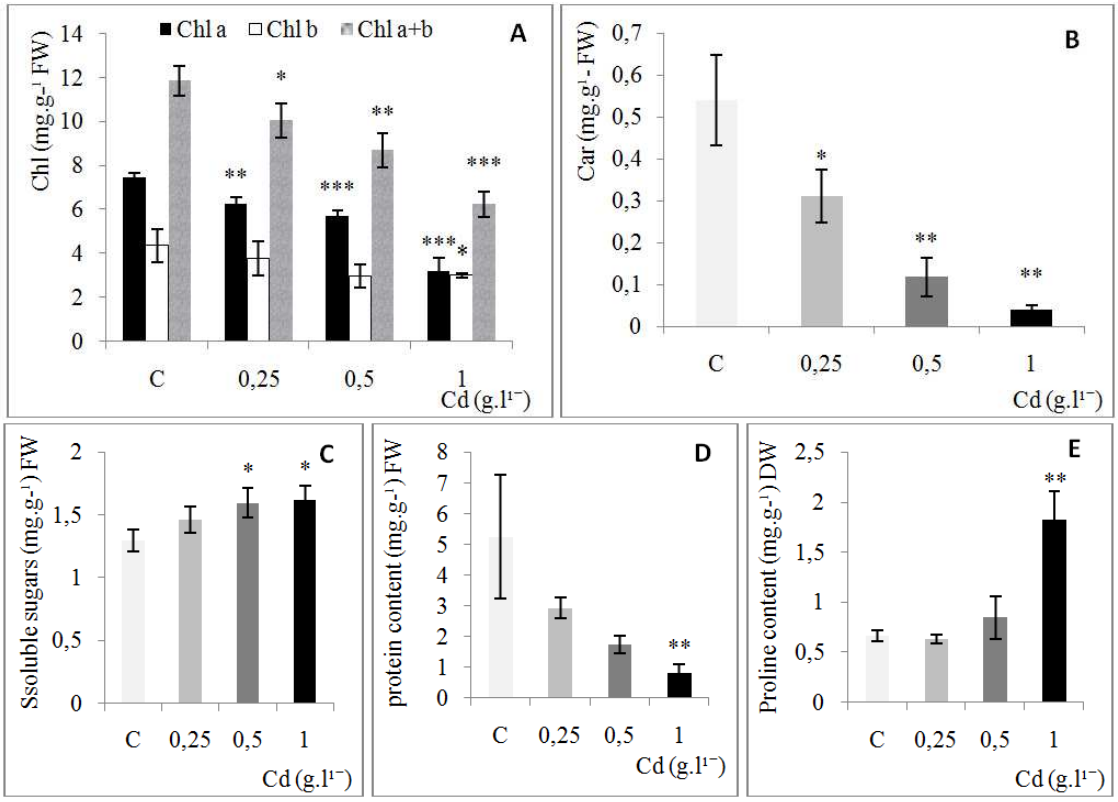

Figure 3. *Effects of cadmium (Cd) on biochemical parameters of common bean seedling (Phaseolus vulgaris L.). Results represent the mean ± SE (n = 3) (*p < 0.05, **p < 0.01, ***p < 0.001 according to Student test)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37573774

It is obvious from *Figure 3C* that total soluble sugars content, appeared to increase under Cd treatment; increase was significant under 0.5 and 1 $g.l^{-1}$ Cd ($p<0.05$*) as compared with control value, it reached 24.80%.

Bean plants exhibited a significant decrease in proteins content with 1 $g.l^{-1}$ Cd concentration ($p<0.01$**) reaching 84.67% compared to control (*Fig. 3D*) when proline appeared to increase progressively with increase of Cd concentrations till 63.80% with 1 $g.l^{-1}$ Cd concentration ($P<0.01$*) (*Fig. 3E*).

Changes in phenolic compounds

Phenolic content in *Phaseolus vulgaris* L. extract is shown in *Figure 4*. Increasing levels of Cd markedly increased synthesis of these metabolites in all treatments in both above ground part and roots ($p<0.05$*) in contrast to control, aside from roots hydrolysable tannins. The rates of increase were till 43, 63, 58, 106, 239% in above ground part, and till 32, 34, 65, 31 and 20% in roots for total phenolics, flavonoids, flavonols, hydrolysable tannins and condensed tannins respectively.

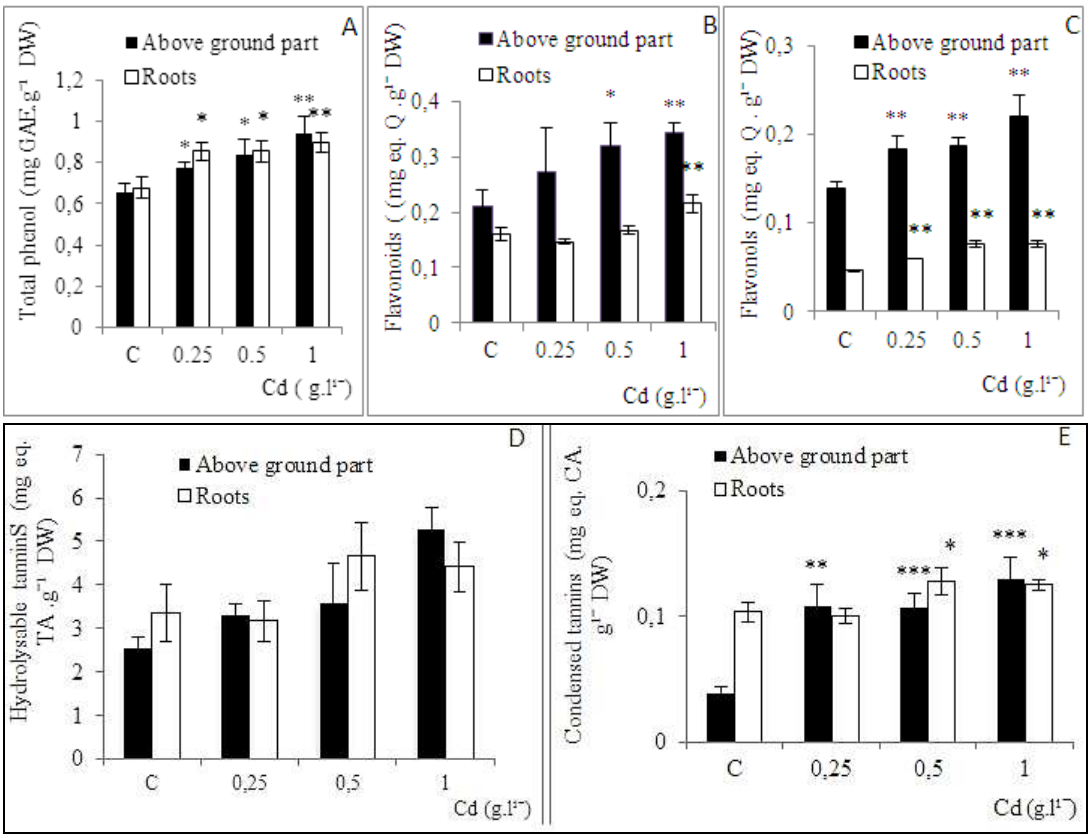

Figure 4. *Effects of cadmium (Cd) on phenolic compounds content of comman bean seedling (Phaseolus vulgaris L.). Results represent the mean ± SE (n = 3) (*p < 0.05, **p < 0.01, ***p < 0.001 according to Student test)*

Anatomical study

Our results showed that stem (*Fig. 5A, B, C, D*) and root (*Fig. 6A, B, C, D*) diameter sections were similar in control and all Cd treatment plant samples, with slight flattening of stem section. Cortex cells are similar in size in all samples; however, there

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37573774

was a slight enlargement of cortex zone in primary roots and stem that had been exposed to Cd. At high magnification (*Figs. 5E, F, G, H, 6E, F, G, H*), a decrease of both number and size of xylem vessels in root and stem sections was observed and xylem differentiation appears retarded in plants grown in presence of Cd. which probably led to a decrease in raw sap flow.

Development of plant led to progressive disappearance of cortical parenchyma resulting to medular lacunae formation in plants stem; our results showed that medular lacunae diameter decreased with increase of Cd concentration till its disappearance with 1 $g.l^{-1}$ Cd concentration (*Fig. 5*), which suggests a delay in development of bean plant. In addition, sections showed appearance of secondary tissues in control, in contrast these tissues were retarded in plants grown with Cd treatment with a high number of cambial cells (*Figs. 5E, F, G, H, 6E, F, G, H*).

In root, higher Cd concentrations can result in rhizodermis disintegration in some location of root, but lateral root initiation was observed in all samples (*Fig. 6A, B, C, D*).

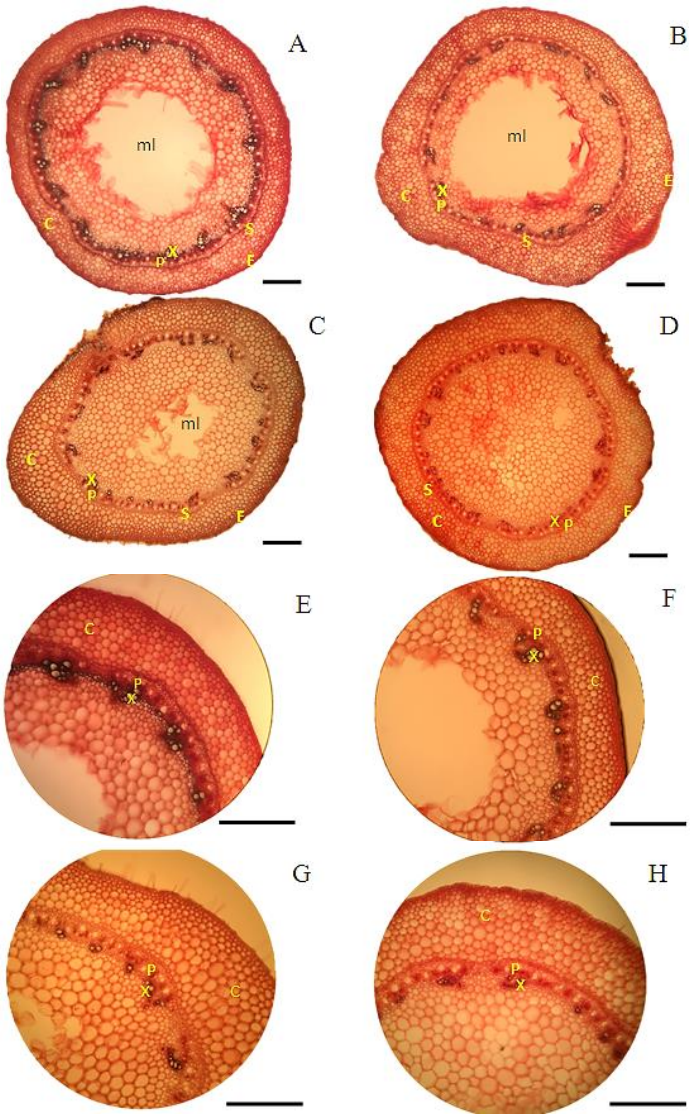

Figure 5. *Light micrographs of control (A, E) and Cd-treated plants: 0.25 $g.l^{-1}$ (B, F); 0.5 $g.l^{-1}$ (C, G); 1 $g.l^{-1}$ (D, H) showing transversal stem sections. C: cortex, X: xylem, P: phloem, S: sclerenchyma, E: epidermis, ml: medular lacunae; Scale bar, 500 µm*

Discussion

Effect of Cd on germination and root elongation

Seed germination and root elongation tests are frequently used for assessing heavy metal phytotoxicity (Wang and Keturi, 1990; Munzuroglu and Geckil, 2002). Our results indicated significant inhibition of seed germination and root elongation under Cd stress which is in agreement with previous results of Li et al. (2005) on *Arabidopsis thaliana*. Hsu and Chang-Hung Chou (1992) reported that among heavy metals tested, Cd showed more toxicity to seed germination of *Miscanthus*, Fattahi et al. (2019) also

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37573774

indicated that the increase in Cd concentrations led to an increase in germination time and a reduction in germination percentage.

According to Kranner and Colville (2011), Cd hamper water uptake inhibiting seed germination, and prolonged their dormancy under room temperature, Munzuroğlu et al. (2008) demonstrate that the inhibition of germination was related with abscisic acid accumulation in seeds. In addition, starch is the most abundant stored material in seeds used in germination after being degraded by enzymes such as amylase; so, inhibition of specific enzymatic reactions by heavy metals causes a negative effect on germination (Ko et al., 2012).

Effect of Cd on plant growth

Plant growth is one of the best indicators to evaluate plant response to environmental stress. Cadmium stress is a major environmental factor which induces various phytotoxicity symptoms such as stunted growth, root browning, chlorosis, necrosis and cell apoptosis (Chang et al., 2013; Zemanová et al., 2015; Younis et al., 2018a).

Our experimental data revealed that cadmium stress inhibited the growth of bean plants; similar behavior was reported by Yazdi et al. (2019), who found that seedlings of lettuce treated with low doses of Cd (100, 200, and 300 $\mu g.g^{-1}$ perlite) had phytotoxic effects. In addition, Younis et al. (2018a) reported that (*Phaseolus vulgaris*) treated with (10^{-6}, 10^{-3}M Cd) showed a significant decrease in growth parameters. The same result was observed in research conducted on three Miscanthus species (Guo et al., 2016). Growth inhibition could be attributed to inhibiting photosynthesis, respiration, water and nutrient uptake by Cd (Dias et al., 2013; Xue et al., 2013). The production of various forms of reactive oxygen species under inductive oxidative stress due to heavy metals presence, results in retardation of plant growth that could eventually led to plant death (Loi et al., 2018). It has been proposed that inhibition of root and shoot growth in presence of heavy metals may be mainly due to abnormal cell division as well as interference of heavy metals with cofactors that play a vital role in photosynthesis, respiration and protein synthesis in root and shoot of plants (Volland et al., 2014).

Biochemical and physiological parameters

Cadmium treatments cause a decrease in pigmentation of common bean shoots wich is in accordance with results of Molnarova et al. (2012) on *Sinapis alba* shoots., Younis et al. (2018a) on *P. vulgaris* L., Yazdi et al. (2019) on *Lactuca sativa* Linn. and Chen et al. (2019) on *Kandelia obovata*.

Decrease in chlorophyll content is attributed to inhibition of chlorophyll synthesis either by affecting key enzymes synthesis such as d-aminolevulinic acid dehydratase (ALA-dehydratase) and proto-chlorophyllide reductase (Stobart et al., 1985; Van Assche and Clijsters,1990), or indirectly by induction of Fe deficiency by inhibiting Fe(III) reductase and seriously affecting photosynthesis (Alkantara et al., 1994; Lang et al.,1995; He et al., 2017). Cd is also known to enhance chlorophyll enzymatic degradation (Somashekaraiah et al., 1992).

Sugars are involved in many mechanisms of biotic or abiotic stress response, their action in abiotic stress is very wide, they can act as an osmoprotectants by stabilising cellular membranes and maintaining turgor (Peshev and Ende, 2013) or as antioxidant molecules (Keunen et al., 2013).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37573774

Our results indicate that Cd treatment led to an increase in total soluble sugars content in common bean. Similar results have been reported by Li et al. (2013) on wheat plants and Vezza et al. (2018) on soybean plants under Zn and As stress, respectively. Contrary to these results, reducing sugar content was observed in *Phaseolus vulgaris L.* under Pb and Cd stress (Bhardwaj et al., 2009; Younis et al., 2018a). In fact, cadmium induced perturbation in metabolism of carbohydrates by modulating their enzymes activities and causes sugar accumulation (Devi et al., 2007; Mishra and Dubey, 2013)

Protein content is inversely proportional to Cd concentrations, it decreases with Cd increasing. This is may be due to enhanced protein hydrolysis either by increased protease activity (Palma et al., 2002; Melnichuk et al., 1982) or by fragmentation of proteins due to toxic effects of reactive oxygen species. In fact, denaturant ion of functional and structural proteins is known as a result of reactive oxygen species (ROS) production in cells under stress conditions (Davies et al., 1987; Bowler et al., 1992). Moreover, decrease in protein content can also be attributed to their slowdown biosynthesis due to a decrease in nitrate reductase activity (Fresneau et al., 2007). Similar effects have been showed in several other plant species under Cd stress (Tamas et al., 1997; John et al., 2008; Aslam et al., 2014) or in *Phaseolus vulgaris* L. Plant (Bhardwaj et al., 2009; Younis et al., 2018a).

Proline has always been considered as a biomarker of drought or salt stress. Actually, several studies associated its accumulation with heavy metal stress (Alia and Pardha, 1991; Choudhary et al., 2007; Vezza et al., 2018; Younis et al., 2018a). Proline promotes photosynthetic activity, water status, antioxidative enzymes activities (Zouari et al., 2016) and assures osmotic adjustment at cellular level (Kasai et al., 1998). According to Alia and Pardha (1991), increase in proline level could be either due to its fresh synthesis and/or due to decrease in its utilization in stressed plants. Li et al. (2013) reported that accumulation of proline is due to ornithine pathway involving in OAT (ornithine d-aminotransferase) stimulation a biosynthesis enzyme of proline; on the other hand, a decrease in GK (glutamate kinase) and PDH (proline dehydrogenase) activities involved in catabolism of proline.

Changes in phenolic compounds

Oxidative stress is an important mechanism of cadmium toxicity (Smeets et al., 2005). Plants use a complex antioxidant defense system to prevent oxidative damage and keep reactive oxygen species concentrations within a narrow functional range (Ozgur et al., 2013). The primary components of this system include non-enzymatic radical scavengers among them carotenoids, flavonoides, and phenolic compounds. These components keep plant cells away from oxidative damage by scavenging ROS (Schafer et al., 2002). A better understanding of underlying antioxidant mechanisms mediated by phenolic compounds is necessary to develop strategies for contaminated crop soil.

Phaseolus vulgaris L. grown under Cd treatments showed a significant increase of phenolic compounds and total flavonoids contents in both parts of plant. Under heavy metal stress, phenolic compounds can act as transition metal ions chelators, ROS scavengers (Vollmannova et al., 2014; Manquian-Cerda et al., 2016) and can suppress lipid peroxidation by breaking radical chain reactions during lipid peroxidation (Arora et al., 2000; Sakihama and Yamasaki, 2002).

Chen et al. (2019) reported that the activity of Shikimate dehydrogenase (SKDH), cinnamyl alcohol dehydrogenase (CAD), and polyphenol oxidase (PPO) increased at the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37573774

meantime when total phenolic compounds increase in *Kandelia obovata* exposed to higher concentrations of cadmium (Cd) and zinc (Zn), which indicate that Cd and Zn play a previously unrecognized but major role in phenolic compounds synthesis, transport, and metabolism. Kovácik et al. (2006) affirmed that activation of the phenylalanine ammonia-Liaza (PAL) enzyme is the main cause of increase in the phenolic metabolits concentration, since it is the main biosynthetic pathway of phenolic compounds. Increase of total phenolic compounds under Cd pollution has been reported in several plants, including *P. vulgaris* (Manquian-Cerda et al., 2016; Mongkhonsin et al., 2016; Younis et al., 2018b; Chen et al., 2019).

Flavonoids are frequently induced by abiotic stress especially by heavy metals and promote roles in plant protection (Grace and Logan, 2000; Dai et al., 2006). Biological and antioxidant activities of flavonols, among others quercetin, have been proven (Tsai et al., 2002). Posmyk et al. (2009) reported that at 0.5 mM Cu^{2+} stress, anthocyanins concentration increased and that anthocyanins synthesis was the effective strategy against ROS generated by Cu^{2+} stress. Flavonoids are known that are inhibitors of lipoxygenase enzyme, which converts polyunsaturated fatty acids to oxygen-containing derivatives (Nijveldt et al., 2001).

Posmyk et al. (2009), Mongkhonsin et al. (2016) and Younis et al. (2018b) examined common bean plant treated with metals such as Cu and Cd, and reported an increase in flavonoids concentration in both shoots and roots.

In the present study, Cd led to a marked increase of tannins. Tannins have great anti-oxidant capacities due to their phenol nuclei. According to Bruneton (1999), hydrolysable tannins are ROS and superoxide anion scavengers and are very good proton donors to ROS produced during peroxidation, resulting in more stable tannic radical formation. Tannins are known to remove heavy metals from solutions using green technology (Sun et al., 2019). Oo (2009) reported that the metal ions could interact with hydroxyl groups of mangrove tannins through an ion exchange and/or complexation process.

Anatomical changes

Plant anatomy is known to be sensitive to physical and chemical conditions, like Cd pollution area. Anatomical changes in response to Cd have been long reported (Barcelo et al., 1988; Lux et al., 2011; Pereira et al., 2018) on *Phaseolus vulgaris*, *Zea mays L.* and, *Solidago chilensis* respectively.

Presence of Cd in soil causes a decrease of both number and size of xylem vessels and a slight enlargement of cortex zone. As mentioned by Maksimovic et al. (2007), the enlargement of cortical tissues had a functional role by decreasing radial flows of water and solutes showed in maize with Cd and Ni pollution. Little information is available on development of central cylinder cells and tissues under Cd stress; this topic requires more attention, especially considering the importance of xylem translocation in regulating cadmium movement from roots to aerial tissues (Lux et al., 2011).

Our result were in accord with Aloni (1987), Barcelo et al. (1988) and Vazquez et al. (1992) who reported that Cd reduces cell division and differentiation in vascular cylinder of Cd-treated bean plants, which seems essential for both production of cambium and cambium cells differentiation into vessels and fibers leading to poor development of vascular bundles. Moreover, the differentiation of cambium to these conducting elements depends on phytohormones like auxins and cytokinins (Aloni, 1987; Bhalerao et Bennett, 2003). Lower auxin concentrations, result in slower differentiation and therefore fewer

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1802_37573774

vessels (Aloni, 1988). It seems that Cd stimulates Auxin degradation (Chaoui et al., 2005). Cytokinins seem crucial for formation and maintenance of cambial cells (Fukuda, 2004), furthermore Cd may decrease cambium size and fiber differentiation in stems by inhibiting cytokinin export from roots (Aloni, 1982).

Cd exposure had not any effect on diameters of bean roots, which is in concordance with Vázquez et al. (1992). However, higher Cd concentrations can result in rhizodermis disintegration in some location of root, similar abnormal effects have been also described in tomato (Gratão et al., 2009).

Conclusion

The present study showed clearly that Cd had negative impact on seed germination, plant growth and caused several physiological and biochemical modifications in *Phaseolus vulgaris* L. Furthermore, it resulted in noticeable effects on phenolic compounds contents as antioxidant response to Cd. It is supposed that the revealed anatomical changes in xylem under Cd impact hamper fluid movement from root to shoot and are one of the reasons of nutrients decrease and pollutants translocation from roots to shoots. It might be a tolerance to abiotic stress limiting Cd impact on plant.

For future studies, evaluation of Cd effect on phenolic compounds profile and non-enzymatic antioxidants seems to be important.
