Research on soil erosion in Yunnan Province has been carried out for a long time. Chen (1990) discussed the main influencing factors of soil erosion in the Jinsha River basin in Yunnan Province and proposed corresponding prevention and control measures for existing problems. Yue et al. (2003) used remote sensing and GIS technology to divide the soil erosion index system and use the overlay analysis method to investigate soil erosion in the Zhaotong area. Yao et al. (2005, 2006) combined the GIS spatial analysis with traditional statistical analysis with the Lancang River basin in Yunnan Province to study the soil erosion status of the region. Zhou et al. (2005, 2009) and Xu and Zhou (2009) studied the process from a single factor of soil erosion to a later model based on a soil erosion prediction model. Hong et al. (2016) used the indoor artificial simulated rainfall experiment and theoretical analysis to reveal the effect of rainfall intensity, slope and slope length on soil erosion on the Yunnan red soil slope and provided a reference for soil erosion control in the Yunnan red soil area. Yang (2002a,b) and Yang et al. (2002) carried out systematic and in-depth research on soil erosion in the Jinsha River basin in Yunnan Province, and they discussed the relationship between soil erosion control and the sustainable use of land resources (Yang et al., 2004, 2005). Zhang et al. (2004) and Huang et al. (2009) carried out a study on the correlation between soil erosion and soil erosion in the Fuxian Lake watershed. Wang et al. (2016) studied the damage caused by soil erosion in the form of ecological destruction by using the Taojiaxiao River in the Dongchuan District of Kunming city, Yunnan Province, as an example, and proposed conducting research on ecological environment construction in small watersheds, which can improve the local ecological environment. Resilience from disasters can have dividends in terms of economic development and people's lives. Ma et al. (2016) carried out remote sensing monitoring of soil erosion in the Fuxian Lake watershed and determined rainfall was the main influencing factor. The erosion amount of the watershed fluctuated, and it was found that the areas with serious soil erosion were concentrated on the eastern and western sides of Fuxian Lake and on some areas of the southern bank.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66916712

Yang et al. (2016) used soil erosion as one of the basic indicators for constructing a basin-wide land degradation assessment model. The land degradation assessment study of the Fuxian Lake basin was conducted, and it was concluded that the inter-annual variation of land degradation and soil erosion tended to be the same. The correlation between the two was obvious. Zhu et al. (2016) used the case of Lishui County in Yunnan Province as an example to study the soil erosion in the alpine valley area. Based on the spatial differentiation law of regional soil erosion, it was concluded that the unreasonable land use pattern was the main cause of erosion. Ding et al. (2018) estimated the soil erosion in Yunnan Province in 2015 and compared it with the 2004 remote sensing survey data; additionally, the authors carried out dynamic change analysis and concluded that the soil erosion area of the province tended to decrease, among which the areas of mild and moderate erosion reduced significantly.

In terms of erosion models, the RUSLE model is the most commonly used and has a good estimation effect. Scholars have conducted soil erosion studies at the regional, county, watershed and provincial scales in Yunnan Province, but studies have not been conducted in specific administrative and economic regions. In addition, the distribution of soil erosion intensity is used as the research object to discuss. Research on the spatial distribution and agglomeration is also scarce. Therefore, through the study of soil erosion in the CYP, the RUSLE model is used to estimate the regional soil erosion situation from 1980 to 2018.

The objective of the present work was to assess the spatiotemporal variation of soil erosion in the CYP during the 1980-2018 period, using multitemporal remotely sensed images, GIS technology and the RUSLE model, which can provide certain decision support for regional land use planning and eco-environmental engineering management policy formulation.

Materials and methods

Location and description of the study area

The CYP includes the 4 cities of Kunming, Chuxiong, Yuxi and Qujing (*Fig. 1*), and there are 42 counties and urban areas in total. The area is located between 100˚43'-104˚50' E and 23˚19'-27˚03' N. It is adjacent to Guizhou Province and Guangxi Zhuang Autonomous Region in the east, Dali Bai Autonomous Prefecture and Puer city in the west, Honghe Hani Yi Autonomous Prefecture, Wenshan Zhuang and Miao Autonomous Prefecture in the south, and Sichuan Province, Zhaotong city and Lijiang city in the north. The total area is 94,558 km^2, accounting for 24% of the total land area of Yunnan Province. Located in the eastern Yunnan Plateau basin, the terrain is gentle and undulating. The overall terrain is high in the northwest, low in the southeast, and downgraded from the northwest to the southeast. The morphology of each region is widely distributed, and the overall morphology is relatively fragmented (Liu et al., 2017). Located at low latitude and high altitude, the region is controlled by the southwest monsoon and southeast monsoon and is dominated by the mid-subtropical monsoon climate. The region is rich in light energy resources, divided into dry and wet seasons, and rich in heat resources; it has an annual average temperature of 16-22˚C, a summer without heat, and a winter without severe cold. The annual average precipitation ranges from 684.31 mm to 1777.03 mm, and the overall distribution is higher in the southeast and lower in the rest of the region. Red soils and purple soils are the most widely distributed areas in the region. There are many types of soils in the eastern region, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66916712

they are scattered and irregular. Red soils are dominant in the central and eastern regions, while purple soils are distributed in patches in the western regions. Vertically, red soils, yellow soils, yellow brown soils, brown soils and sub-soils are distributed successively from low to high in the mountainous region, and there is also alpine meadow soil. The study area with alpine meadow soil belongs to the subtropical evergreen broad-leaved forest area, mainly in the mid-subtropical evergreen broad-leaved forest zone, and is distributed in a small area of the south subtropical monsoon evergreen broad-leaved forest zone, which is rich in forest resources, with an overall coverage rate of approximately 53.8%.

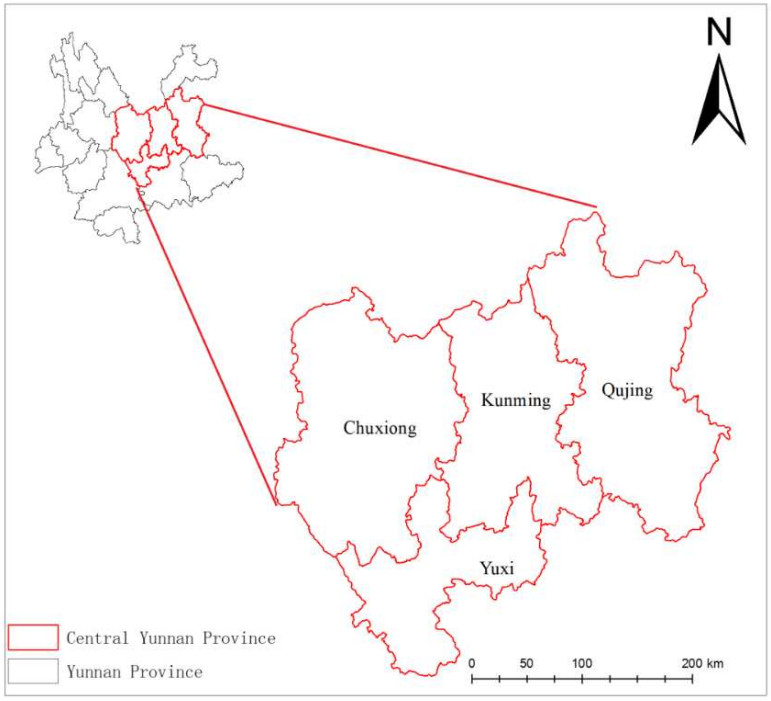

Figure 1. *Research Location Map*

In recent years, with the continuous development of the social economy and the acceleration of urbanization, various environmental protection measures, such as returning grain plots to forest, have been introduced and implemented. Soil erosion in the CYP has also changed, which has a certain impact on the regional ecological environment. By estimating the long time series of soil erosion, there is important ecological and economic value in studying the changing trend of its quantity and spatial distribution.

Data and preprocessing

The data sources mainly include (1) basic geographic information data; (2) historical remote sensing image data; and (3) thematic data.

The basic geographic information data are ASTER GDEM (Advanced Spaceborne Thermal Emission and Reflection Radiometer Global Digital Elevation Model) V2 30 m resolution elevation data, which are freely obtained from the geospatial data cloud (http://www.gscloud.cn/). Historical remote sensing image data mainly come from the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66916712

official website of the National Aeronautics and Space Administration (NASA) (https://search.earthdata.nasa.gov/) and the geospatial data cloud (http://www.gscloud.cn/); most free data were downloaded, and some data, such as Landsat OLI, TM, and MSS, were purchased by the instructor team in advance; the satellite images were taken at 1980, 1990, 1995, 2000, 2005, 2010, 2015 and 2018. The thematic data mainly include meteorological, soil, field survey data and remote sensing survey reports on the soil erosion status in the CYP.

The projection coordinates of the source data of soil erosion factors are set as WGS_1984_UTM_Zone_47N, and the geographic coordinates are set as WGS_1984. According to the research needs and the characteristics of the research area, ENVI 5.3 was used to pre-process the remote sensing images, and the land cover remote sensing classification system and the interpretation mark library were established. The image data of the CYP are classified by the maximum likelihood classification method, and the classification results are superimposed with terrain gradient data to provide the terrain characteristics.

Model description

The Revised Universal Soil Loss Equation (RUSLE), which was an improved form of the Universal Soil Loss Equation (USLE), was used to estimate soil erosion in the CYP. Compared with the USLE, the RUSLE model has a simple structure, a clear physical meaning of parameters, simple calculations, and strong practicability and comprehensiveness.

The mathematical formula of RUSLE is as follows:

$$A = R \times K \times LS \times C \times P \quad \text{(Eq.1)}$$

In the formula, A is the annual average amount of soil erosion per unit area, i.e., the modulus of soil erosion, which is t/(hm^2·a); R is the rainfall erosivity factor, and the international general unit is (MJ·mm)/(hm^2·h·a); and K is the soil erodibility factor, and the international general unit is (t·h)/(MJ·mm). The other factors are dimensionless: among the LS factors of terrain, L is the slope length factor, S is the slope factor, C is the vegetation cover management factor, and P is the soil and water conservation measure factor.

Soil erosion factors

Rainfall erosivity (R) factor

Rainfall erosivity refers to the potential ability of rainfall to cause soil erosion and is the main dynamic factor leading to soil erosion (Fang et al., 2015). Wischmeier and Smith (1958) proposed a classical method for calculating the rainfall erosivity EI model based on the measured data of rainfall erosion. However, this method is limited by the difficulty of completely obtaining the measured data and cannot be popularized. According to the available monthly meteorological data and the applicability of the model in the CYP, the final calculation formula used in this study is as follows (Silva, 2004):

$$R = \sum_{i=1}^{12} 73.989 \times \left(\frac{P_i^2}{P_a} \right)^{0.7387} \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66916712

In the formula, R is the annual rainfall erosivity (MJ·mm)/(hm^2·h·a); P_i is the rainfall (mm) of the i-month; and P_a is the average annual rainfall (mm), which is easy to obtain and has high accuracy in complex terrain areas. Based on the data of 39 meteorological stations in the study area provided by the Kunming, Chuxiong, Yuxi and Qujing meteorological bureaus and 21 supplementary station data obtained from the China Meteorological Data Network (http://data.cma.cn/site/index.html) (*Table 1*, *Fig.2*), the monthly precipitation data of 65 meteorological stations were analyzed by Kring's spherical hemispherical variation function. The model is interpolated, and the annual rainfall erosivity in the CYP is calculated according to the R factor formula. The annual rainfall erosivity in typical years is shown in figures (*Fig. 3*).

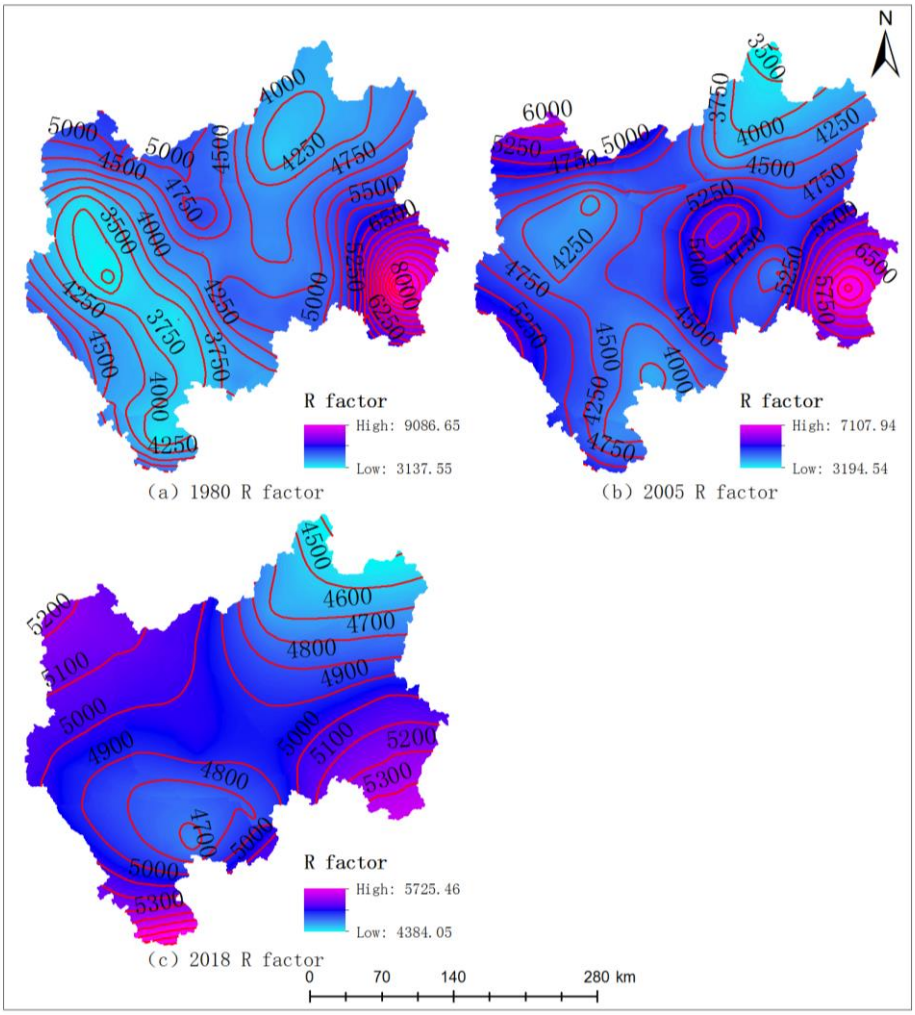

Figure 3. *Spatial distribution of rainfall erosivity R factor in the CYP ((MJ·mm)/(hm^2·h·a))*

Soil erodibility (K) factor

Among the methods for estimating the *K* factor of soil erodibility, the Norit diagram and the EPIC (Erosion-Productivity Impact Calculator) method developed by Williams et al. (1983) are represented. The soil data were provided by the Heihe Planning Data Management Center (http://westdc.westgis.ac.cn) based on the World Soil Database (HWSD). The distribution characteristics of soil texture and organic carbon content are detailed in the study area. Therefore, the productivity model EPIC was used to quantitatively calculate the soil erodibility *K* factor, and the results are revised (Chen et al., 2018) to make the model more appropriate for Chinese soil properties. The formula for calculating the soil erodible factor *K* by the EPIC model is as follows:

$$K_{EPIC} = \left\{0.2 + 0.3\exp\left[0.0256SAN\left(1 - \frac{SIL}{100}\right)\right]\right\}\left(\frac{SIL}{CLA + SIL}\right)^{0.3} \times \left(1.0 - \frac{0.25OC}{OC + \exp\left(3.72 - 2.95OC\right)}\right)\left(1.0 - \frac{0.7SN}{SN + \exp\left(22.9SN - 5.51\right)}\right) \quad \text{(Eq.3)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66916712

The revised formula is as follows:

$$K = -0.01383 + 0.51575K_{EPIC} \quad \text{(Eq.4)}$$

In the formula, K_{EPIC} and K are soil erodibility factors before and after amendment, respectively; *SAN*, *SIL*, *CLA* and *OC* are the percentage of sand, silt, clay and organic carbon in soil, respectively; and *SN = 1-SAN/100.*

The *K* value calculated by this model is reported in US metric units, and the value is multiplied by 0.1317 rpm to convert it into an international unit (t·h)/(MJ·mm), and the soil erodibility *K* factor in the CYP region is obtained (*Fig. 4*).

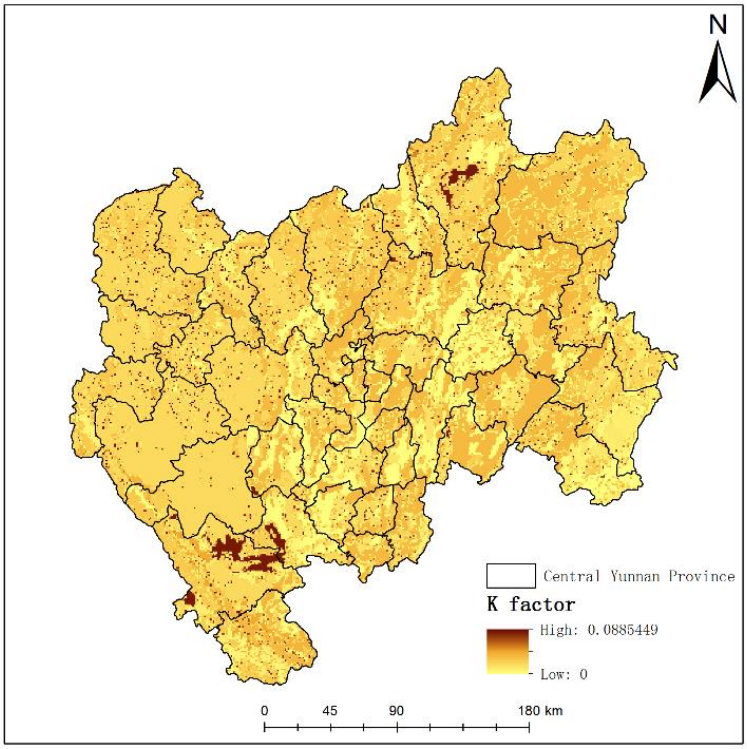

Figure 4. *Spatial distribution of soil erosion K factor in the CYP ((t·h)/(MJ·mm))*

Slope length and steepness (LS) factor

In the topographic *LS* factor, the slope and slope length directly affect the formation and development of the surface soil and the spatial distribution of vegetation, which in turn affects the flow direction, velocity and intensity of surface runoff in the process of surface runoff formation; ultimately, these factors affect the intensity of surface soil erosion. With regard to the calculation of the slope length factor, the method proposed by Wischmeier is more applicable and has higher accuracy; thus, this method is widely used in the field of soil erosion research. Therefore, the formula proposed by Wischmeier and Smith (1965) is used to calculate the *L* factor of slope length in the CYP (*Fig. 5*).

$$L = \left(\frac{\lambda}{22.13}\right)^{\alpha} \quad \text{(Eq.5)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66916712

$$\alpha = \beta / (1 + \beta) \quad \text{(Eq.6)}$$

$$\beta = (\sin\theta / 0.089) / [3.0(\sin\theta)^{0.8} + 0.56] \quad \text{(Eq.7)}$$

In the formula, L is the slope length factor, λ is the slope length, 22.13 is the standard plant slope length (m), α and β are the slope length factor indexes, and θ is the slope.

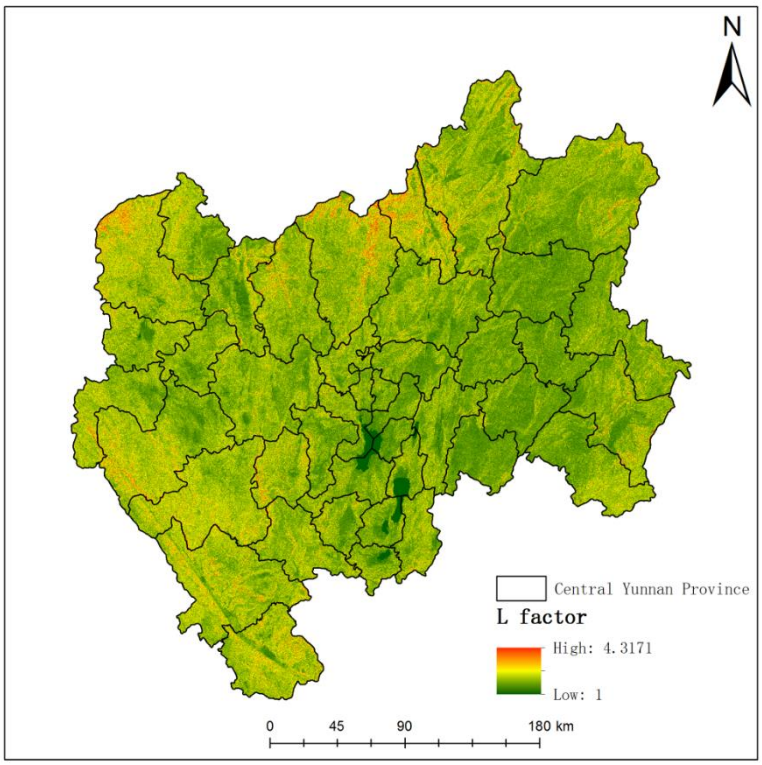

Figure 5. *Spatial distribution of slope length L factor in the CYP*

In a study of the relationship between soil erosion and slope, McCool et al. (1989) established the linear relationship between gentle slope and soil erosion in 1987, and Liu et al. (2000) added the formula for calculating soil erosion in areas with steep slopes. According to the geomorphological characteristics of the study area and combining these characteristics with the results of McCool et al. and Liu et al., the *S* factor of the slope in the CYP is calculated in stages (*Fig. 6*). The formula is as follows:

$$\begin{cases} S = 10.8\sin\theta + 0.03, \theta < 5° \\ S = 16.8\sin\theta - 0.05, 5° \le \theta < 10° \\ S = 21.91\sin\theta - 0.96, \theta \ge 10° \end{cases} \quad \text{(Eq.8)}$$

In the formula, S is the slope factor, and θ is the slope.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66916712

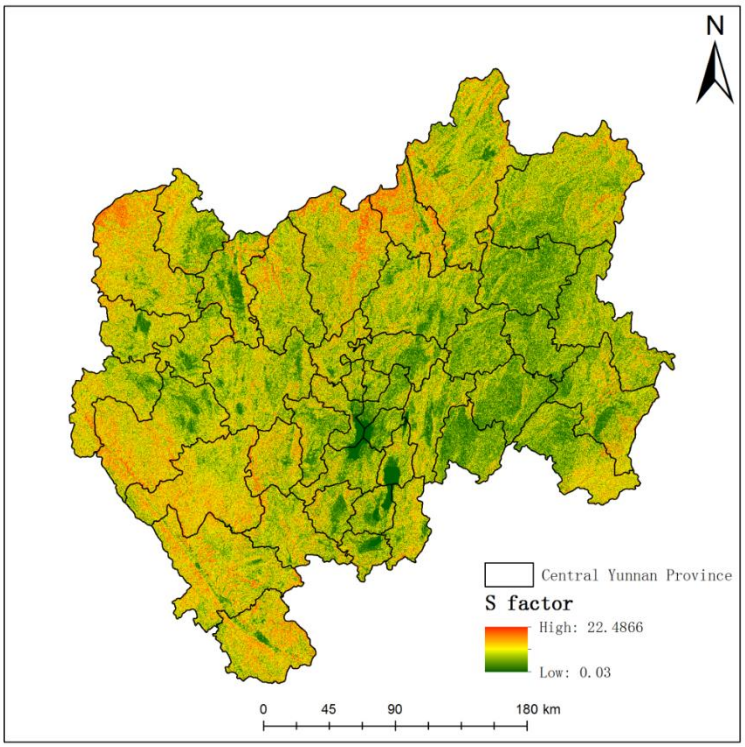

Figure 6. *Spatial distribution of slope S factor in the CYP*

Vegetation cover and management (C) factor

The vegetation cover management *C* factor refers to the standard plot with and without vegetation cover when other conditions are identical, which can reflect the soil erosion caused by different vegetation coverage types. Influence is dimensionless, its value range is [0,1], and its numerical value is directly proportional to the severity of soil erosion. The larger the *C* factor is, the more serious the soil erosion is. In the RUSLE model, factor *C* is susceptible to other factors and has a high sensitivity and variable characteristics.

The calculation of the vegetation cover management *C* factor is divided into three steps: the first step is to extract the normalized difference vegetation index NDVI, the second step is to calculate the vegetation coverage by the NDVI, and the third step is to calculate the *C* factor value of the vegetation cover management from the vegetation coverage.

We used the pixel dichotomy method to obtain the vegetation coverage of the study area and then used the calculation formula established by Cai et al. (2016) to obtain the *C* factor of vegetation cover management in the CYP:

$$F_c = \frac{NDVI - NDVI_{soil}}{NDVI_{veg} - NDVI_{soil}} \quad \text{(Eq.9)}$$

$$C = \begin{cases} 1, 0 \le F_c < 0.096 \\ 0.6508 - 0.3436 \lg(F_c), 0.096 \le F_c \le 78.3 \\ 0, F_c > 78.3 \end{cases} \quad \text{(Eq.10)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66916712

In the formula, F_c is the vegetation coverage (%), *NDVI* is the normalized difference vegetation index, $NDVI_{soil}$ represents the *NDVI* value of no vegetation coverage or bare soil area, $NDVI_{veg}$ represents the *NDVI* value of high vegetation coverage area, and *C* is the vegetation coverage management factor. Through the ArcGIS 10.2 raster calculator, the *C* factor values of the seven years from 1980 to 2018 were calculated in the CYP. The *C* factor values for typical years are shown in figures (*Fig. 7*).

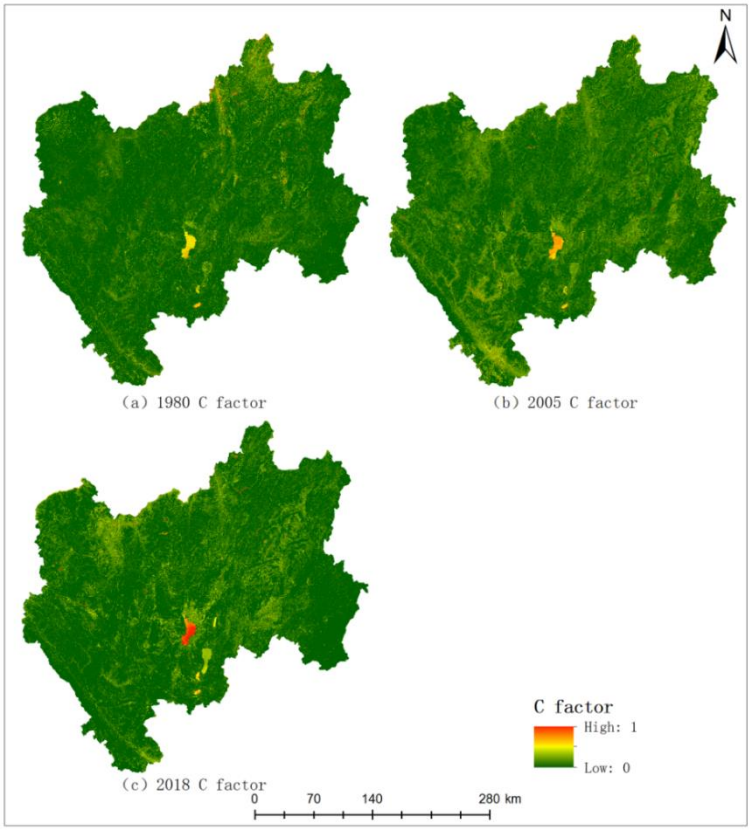

Figure 7. *Spatial distribution of vegetation cover management C factors in the CYP*

Conservation practice (P) factor

The soil and water conservation *P* factor reflects the ratio of soil loss in a certain period of time when the water conservation measures and the standard plots that have not used corresponding measures are in the same situation; the dimension is non-dimensional, and its value is between 0 and 1. Its value is positively correlated with the possibility of soil erosion. A value of 0 indicates that the probability of soil erosion in this area is almost zero and the soil and water conservation measures are good. A value of 1 indicates that soil erosion is very likely in this area and there are no effective soil and water conservation measures that can be taken.

In China, the *P* values of different soil and water conservation measures under certain land use types are generally obtained by comparison methods. However, the *P* values in different regions have large errors, and the values are difficult to determine. Therefore, based on the survey of soil and water conservation status in the CYP, reference is made to the *P* value table of different soil and water conservation engineering measures in China (Wang et al., 1996), the Handbook of the United States Department of Agriculture,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66916712

the land use type map and vegetation cover map and the research results of predecessors. The corresponding *P* values are assigned to the local classes (*Table 2*). The *P* factors for soil and water conservation measures in typical years are shown in figures (*Fig. 8*).

Table 2. *Soil and water conservation measures P factor value*

Land use types	Code	*P* factor value
Paddy field	11	0.15
Dry land	12	slope<5, 0.11; 5≤slope<10, 0.22; 10≤slope<15, 0.31; 15≤slope<20, 0.58; 20≤slope<25, 0.71; slope≥25,0.8

Arbor forest	22	1.00
Grassland	3	1.00
Water area	4	0.00
Construction land	5	0.00
Bare land	61	1.00
Bare rock	62	0.00

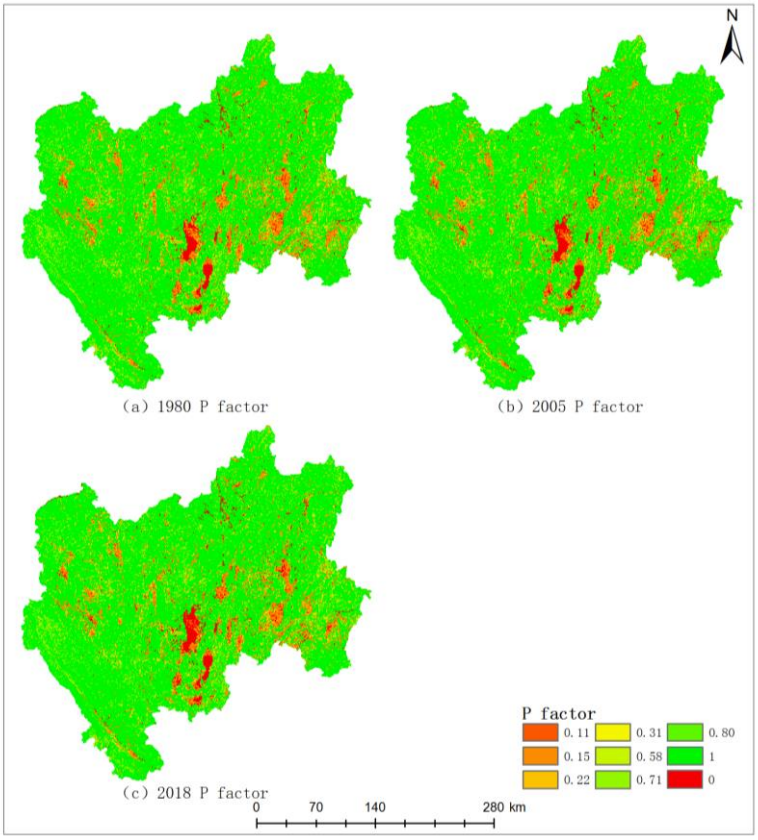

Figure 8. *Spatial distribution of soil and water conservation measures P factor in the CYP*

Creation of soil erosion hazard map

The raster layers of each factor are multiplied in the ArcGIS 10.2 raster calculator by the constant 100 to convert the unit t/(hm^2·a) to t/(km^2·a) to obtain the values in the study area. The generated soil erosion raster data (*Fig. 9*) had a resolution of 30 m.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66916712

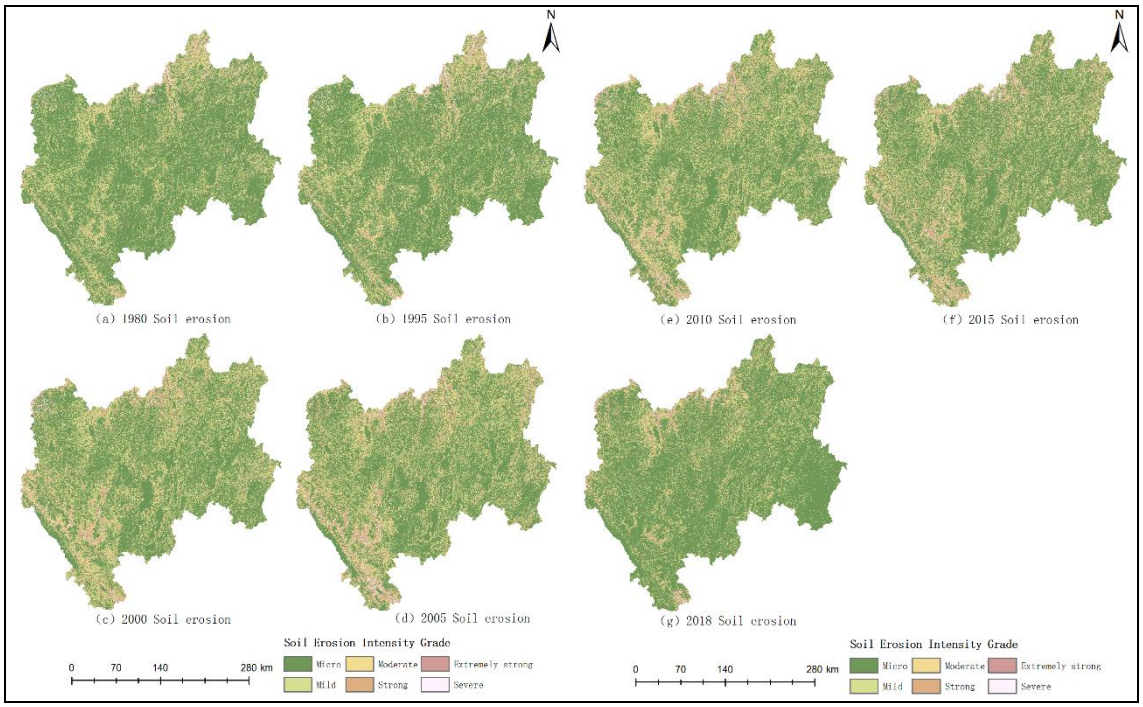

Figure 9. *Spatial distribution of soil erosion intensity in the CYP*

Comparing the estimated soil erosion results of the study area with the remote sensing survey report of the soil erosion status in Yunnan Province in 1999, it is concluded that the soil erosion modulus values in 2000 are larger than those in 1999; additionally, the proportion of each intensity area was more consistent, the total area of soil erosion increased, and the changes that were presented were associated with the objective law.

According to SL190-2007 "soil erosion classification and classification standard" issued by the Ministry of water resources of the people's Republic of China, the soil erosion in the CYP is classified into six levels (*Table 3*).

Table 3. *Classification standard of soil erosion intensity*

Level	Average modulus of soil erosion (t/(km^2·a))	Average loss thickness (mm/a)
Micro	<500	0.37
Mild	500 ~ 2500	0.37 ~ 1.9
Moderate	2500 ~ 5000	1.9 ~ 3.7
Strong	5000 ~ 8000	3.7 ~ 5.9
Extremely strong	8000 ~ 15000	5.9 ~ 11.1
Severe	>15000	>11.1

Spatial autocorrelation of soil erosion intensity distribution

According to the basic law of geographical analysis (Tobler, 1970): "there are corresponding relations between geographical things, among which the closer things are closer than those far away." As a spatial statistical method, spatial autocorrelation can better describe the relationship between geographical objects and measure the degree of aggregation or dispersion among spatial attributes of things.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66916712

General spatial autocorrelation is used to describe the spatial characteristics of spatial element attribute values in the whole area, and reflects the similarity of its neighbor attribute values. It is of great significance for the analysis and description of the distribution characteristics of a specific spatial attribute in the entire area, it is commonly used Moran *I* index, its expression is (Zhang et al., 2007a):

$$I = \frac{n\sum_{i=1}^{n}\sum_{j=1}^{n} W_{ij}\left(x_i - \overline{x}\right)\left(x_j - \overline{x}\right)}{\sum_{i=1}^{n}\left(x_i - \overline{x}\right)^2 \sum_{i=1}^{n}\sum_{j=1}^{n} W_{ij}} \quad \text{(Eq.11)}$$

In the formula, n represents the number of spatial objects, $\overline{x}$ is the attribute mean, x_i and x_j are the attribute values of objects i and j, respectively, W_{ij} is the spatial adjacency matrix of objects i and j, W_{ij}=1, the two are adjacent, W_{ij}=0, the two are not adjacent.

The value range of Moran *I* index is [-1,1], the closer the value is to 1, the closer the attributes between objects are, showing a high value aggregation or a low value aggregation relationship; the closer the value is to -1, it means that the greater difference in attributes between objects; its value is 0, which means that there is no spatial autocorrelation between objects and they are randomly distributed.

Compared with the general spatial autocorrelation, the local spatial autocorrelation is to calculate the spatial correlation between each spatial object in the analysis area and its neighboring objects, calculate the local feature differences in the distribution of spatial objects in the analysis and analysis, and reflect the space in the local area Heterogeneity and instability, the calculation formula is (Zhang et al., 2007b):

$$I_i = \frac{\left(x_i - \overline{x}\right)\sum_{j=1}^{n} W_{ij}\left(x_j - \overline{x}\right)}{\frac{1}{n}\sum_{i=1}^{n}\left(x_i - \overline{x}\right)^2} \quad \text{(Eq.12)}$$

I_i is positive, indicating that the spatial object has similar properties to its neighbors; I_i is negative, indicating that it is different from the neighboring objects.

According to the spatial distribution data of soil erosion intensity grade in the CYP from 1980 to 2018, a 1000 m × 1000 m grid cell was created by using ArcGIS10.2, and the area proportion of each erosion intensity grade in each grid was counted as the data source of spatial autocorrelation analysis.

Results and discussion

Soil erosion factors distribution

The average *R* factor in the CYP is between 4,210.96 and 519.53 (MJ·mm)/(hm^2·h·a). Due to the influence of climate and topography, the spatial distribution is basically bounded by the northeastern and southwestern directions, showing higher *R* values in the southeast and northwest and lower *R* values in the northeast and southwest. Most of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66916712

maximum values are located in the southeastern region, and the maximum value is 9,086.65 (MJ·mm)/(hm^2·h·a), which appeared in 1980; the minimum values are mostly located in the central and western regions. The minimum value was 2,353.77 (MJ·mm)/(hm^2·h·a), which occurred in 2010.

The *K* factor ranges from 0 to 0.0885449, with an average value of 0.0390224, the numerical range is accurate and reliable. In general, the distribution of *K* value is relatively uniform.

The spatial distribution of the *L* and *S* factors of topographic slope length in the CYP is basically consistent with its overall topography, i.e., northwest to southeast inclination, which shows that the adopted calculation method of the *L* and *S* factors can better and quantitatively describe the effect of topography on soil and water loss in the study area.

Soil erosion intensity

Over the past 38 years in the CYP, soil erosion has generally shown a growing development trend. The average soil erosion modulus ranged from 1000.25 t/(km^2·a) to 2064.79 t/(km^2·a), and the multi-year average soil erosion modulus was 1624.47 t/(km^2·a), which represents a mildly erosive state. Overall, soil erosion shows a fluctuating trend. The two turning years were 2005 and 2015. The area of soil erosion first increased and then decreased, with 2005 as the only turning point. The area of soil erosion in 2005 was the largest, reaching 41,056.04 km^2. In 2018, the modulus of soil erosion and the area of soil erosion reached the lowest values. This result is due to the vigorous implementation of the policy of returning farmland to forest and grassland. People's awareness of environmental protection has also increased. Under the guidance of the government, soil and water conservation measures have been continuously improved and implemented, activities that causes ecological destruction have been effectively curbed, and overall, soil erosion has tended to be good.

From the perspective of the relationship between the average area of erosion intensity and the total area of the region in each period, the CYP is dominated by mild soil erosion, with an average annual area accounting for 48.67%, of which the largest proportion was 55.01% in 1980, and the largest area was 18,529.75 km^2 in 2000. The change trend of the area of moderate erosion is consistent with the overall change, and 2005 was the turning point in which the area of erosion transitioned from increasing to decreasing. Except for severe erosion, there is a good correlation between the other grade areas and the total soil erosion area. The correlation coefficients are as follows: mild 0.930; moderate 0.983, which the largest correlation coefficient; strong 0.924; extremely strong 0.929; and severe 0.398, which was the smallest correlation coefficient. From these results, it is possible to estimate the interannual variation of the overall soil erosion status by calculating and analyzing the interannual variation trend of the medium erosion intensity (*Table 4*).

Temporal change in soil erosion

To quantitatively describe the change in the erosion grade in central Yunnan from 1980 to 2018, the transfer matrices of erosion grade between adjacent years and initial years were calculated separately.

From 1980 to 1995, the soil erosion situation deteriorated, and the areas of erosion greater than moderate increased. The moderate erosion area increased most obviously, with an area of 648.47 km^2; the micro-degree and mildness experienced a net decrease, among which the micro-erosion transfer was the largest, with a net decrease of 1,445.32 km^2, and the area converted to mild erosion reached 2,651.27 km^2. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66916712

proportion of unchanged area of strong erosion was the smallest, with 61.72% unchanged, and 26.03% of the original area was converted into extremely strong erosion.

Table 4. *Statistics of area and proportion of different soil erosion intensity grades in the CYP (km^2)*

Year	Mild	%	Moderate	%	Strong	%	Extremely strong	%	Severe	%	A_{mean} ($t/(km^2 \cdot a)$)
1980	15771.02	55.01	6945.71	24.23	2682.65	9.36	1739.45	6.07	1531.25	5.34	1354.95

2018	12461.16	50.16	6748.20	27.16	3382.80	13.62	1832.27	7.38	417.78	1.68	1000.25
Average	16403.81	48.67	8974.18	26.29	4527.26	13.09	2764.07	7.97	1354.02	3.99	1628.47

From 1995 to 2000, soil erosion continued to deteriorate, but the overall rate of erosion enhancement slowed. The area of severe erosion decreased 626.93 km^2, and the micro-erosion decreased to 8,406.05 km^2. The areas of moderate, strong and extremely strong erosion continued to increase, with net increases of 2,941.10 km^2, 2017.18 km^2 and 876.38 km^2, respectively.

From 2000 to 2005, the soil erosion situation was the most severe, and the erosion intensity was mostly converted into strong and extremely strong intensities, with net increases of 1,154.47 km^2 and 1,093.81 km^2, respectively. Under the background of the increase in the area of severe erosion and the continuous reduction in the areas of micro-degree and light erosion, the soil erosion in the CYP is deteriorating. The increased area of strong erosion is mainly from micro-degree and light erosion, which contributed to 1,049.78 km^2 and 1,035.07 km^2, respectively.

From 2005 to 2010, the soil erosion situation improved, and the areas of moderate, strong and extremely strong erosion changed from increasing to decreasing, with net decreases of 841.35 km^2, 1,140.76 km^2 and 879.96 km^2, respectively. The area of mild erosion had the largest increase, reaching 2,780.02 km^2, and its main source of growth was mild erosion, accounting for 38.19% of its original area.

From 2010 to 2015, with the overall situation of soil erosion improving, the area of mild erosion maintained a net growth trend, while the areas of strong, extremely strong and severe erosion rebounded, increasing by 191.26 km^2, 316.19 km^2 and 194.36 km^2, respectively.

From 2015 to 2018, the overall situation of soil erosion was good, and the area of erosion intensity above the micro-degree had a net decrease; thus, the soil erosion status was effectively contained.

Overall, soil erosion in central Yunnan was effectively controlled from 1980 to 2018. The area of mild erosion in the CYP increased to 3,827.88 km^2, and the proportion of the total area of soil erosion increased from 69.68% in 1980 to 73.73% in 2018, representing an increase of 4.05%. The areas of mild, moderate and severe erosion had net reductions of 3,309.87 km^2, 197.51 km^2 and 1,113.47 km^2, respectively. The proportion of these three factors in total soil erosion area changed from 55.01% to 50.16%, with a decrease of 4.85%, from 24.23% to 27.16%, with an increase of 2.93%, and from 5.34% to 1.68%, with a decrease of 3.66%, respectively. The results show that in the process of reducing the areas of mild, moderate and severe erosion, the rate of decreasing the area of mild

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66916712

erosion was the fastest, followed by that of severe erosion, and the deceleration of moderate erosion was slower than that of the former two.

In summary, during the 38 years, the erosion intensity in the CYP showed a weakening trend, but the changes in erosion grade were more complex. The area of mild erosion increased greatly, the intensity of severe erosion decreased significantly, the growth rate of strong and extremely strong erosion slowed, and the mild and moderate erosion decreased each year, which indicated that the intensity of soil erosion in the region decreased significantly. Soil erosion has been effectively curbed, and the overall erosion situation has improved.

Spatial distribution of soil erosion

By comparing and analyzing the soil erosion intensity maps of seven periods in the CYP, it can be seen that the distribution of the soil erosion grades in the mountains and valleys in the north and southwest of the CYP is complex and most grades represent extremely strong and severe erosion; however, in the middle and eastern regions with flatter land, mild erosion is dominant, of which Kunming Basin, Songming Basin, Yuxi Basin and Chengjiang Basin have mild erosion. It can be concluded that the spatial distribution of soil erosion intensity is significantly correlated with the topography in the region.

The spatial distribution of soil erosion intensity changes with time, showing a tendency to first deteriorate and then improve. Before 2005, the area of micro-erosion decreased each year. Starting with a uniform distribution, the area with relatively low terrain and relatively small terrain fluctuations in the southeast direction gradually decreased. In the western high terrain and high terrain fluctuation areas, the degree of soil erosion increased, and the intensity distribution became increasingly complex. After 2005, the micro-erosion surface became increasingly complex. The total erosion area above the mild level showed that the erosion area changed from increasing to decreasing, and the erosion could be effectively curbed.

According to the spatial distribution data of soil erosion intensity in the CYP from 1980 to 2018, the global spatial autocorrelation Moran's I index analysis was carried out based on the erosion intensity grade, and Monte Carlo simulation was used to test the spatial distribution of each erosion intensity. It was concluded that the spatial distribution of each erosion intensity showed a significant positive spatial autocorrelation, and spatial object clustering was obvious.

From 1980 to 2018, the numerical range and annual mean value of the overall Moran's I index of the soil erosion grades in central Yunnan were as follows: micro-erosion 0.62~0.69, 0.66; mild erosion 0.53~0.61, 0.56; moderate erosion 0.54~0.63, 0.58; strong erosion 0.58~ 0.64, 0.61; extremely strong erosion 0.57~0.65, 0.60; and severe erosion 0.43~0.52, 0.48. The Moran's I index of micro-erosion was larger in general, and its spatial aggregation degree was the highest, which indicated that the micro-erosion in the CYP showed a general aggregated distribution during the 38 years; however, the Moran's I index of severe erosion was smaller in general, its spatial distribution was the most dispersed, and it had higher fragmentation.

In the global Moran's I index of the spatial distribution of each grade (*Fig. 10*), except for the fluctuation of extremely strong erosion, the other five grades showed a fluctuating downward trend. This result indicates that the spatial distribution of soil erosion intensity in the CYP has gradually weakened in the past 38 years, and the degree of fragmentation has become increasingly serious. However, the extremely strong erosion shows that the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66916712

spatial distribution of soil erosion intensity is becoming increasingly concentrated. Based on the spatial distribution of regional soil erosion area and its intensity, it can be seen that under the background of a decreasing area of total erosion, the spatial distribution of soil erosion is becoming increasingly dispersed, and the distribution centers are shifting; however, the distribution centers of extremely strong erosion have been located in the north for a long time because of the high elevation and high land level in the region. The large fluctuation of the potential and the high mountains and valleys are conducive to the occurrence of extremely strong erosion, and the prevention and control of soil erosion has not achieved significant results because of the topographic effects. Therefore, the extremely strong erosion shows an increasing trend in terms of the fluctuation in the Moran's I index.

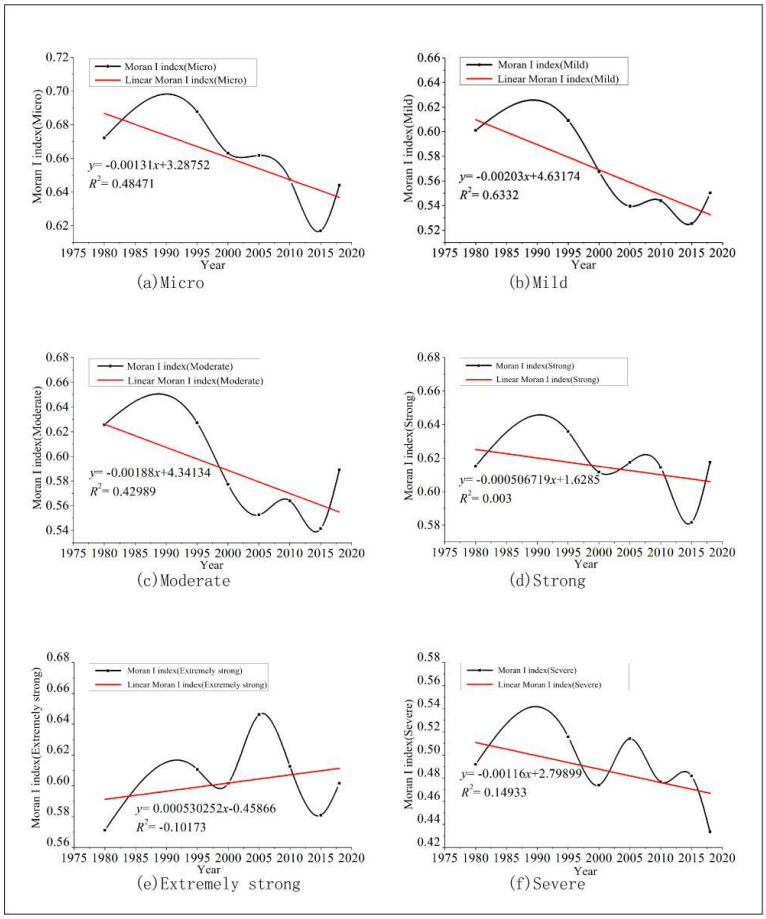

Figure 10. *Soil erosion overall Moran's I index in the CYP*

In general, the CYP region is affected by its overall topography and morphological distribution, there are different degrees of soil erosion in each region, and the spatial distribution is complex. In 2018, the entire region was dominated by micro-erosion, and extremely strong and severe erosion were still high in the western part of the region; however, the erosion area has been suppressed and reduced, and the overall soil erosion situation has improved significantly.

DOI: http://dx.doi.org/10.15666/aeer/1805_66916712

Conclusion

Based on the comprehensive application of remote sensing and GIS technology, the RUSLE model was used to quantitatively characterize the soil erosion factors and the soil erosion status in seven periods for the CYP from 1980 to 2018, and the temporal and spatial changes were analyzed.

(1) Localized soil erosion factors in the CYP. The rainfall erosivity R factor and the topographic LS factor spatial distribution characteristics were more significant. The average R factor was between 4,120.96 (MJ·mm)/(hm^2·h·a) and 5,109.53 (MJ·mm)/(hm^2·h·a), and these values were affected by climate and topography. The spatial distribution changed correspondingly with the regional precipitation, and the overall distribution was more complicated. The spatial distribution of the topographic LS factor was basically consistent with the overall regional topography, e.g., it is inclined from the northwest to the southeast, showing a high numerical distribution in the northwest and a low numerical distribution in the southeast. Its value range is 0.03~97.68.

(2) From 1980 to 2018, the situation of soil erosion in the CYP showed an improving trend. From the aspect of erosion area, using 2005 as the turning point, the area of mild erosion first decreased and then increased, and the area of mild erosion was effectively controlled; from the aspect of the average erosion modulus, the average annual soil erosion modulus was 1,628.47 t/(km^2·a), which was categorized as mild erosion. This pattern experienced two turning points; specifically, the value increased each year from 1980 to 2005, declined from 2005 to 2010, rebounded from 2010 to 2015, and returned to a declining trend from 2015 to 2018. By 2018, the net increase in micro-erosion was three times higher than the increased areas of strong and extremely strong erosion, and these areas accounted for more than 73% of the total area. The overall erosion situation has been effectively contained.

(3) The spatial distribution of soil erosion intensity in the CYP shows a regular change, and its distribution location has a good correlation with regional topographic fluctuations. The erosion intensity above the moderate level is mainly distributed in the mountains and valleys in the north, northwest and southwest of the region. By calculating and analyzing the global Moran's I index of the spatial distribution of the soil erosion intensity from 1980 to 2018, it is further illustrated that the spatial distribution of the soil erosion intensity presents significant positive spatial autocorrelation overall, and spatial object aggregation is obvious. The spatial distribution law of each erosion intensity in the CYP is highly reliable.

In conclusion, from 1980 to 2018, although there were some fluctuations in the area occupied by each intensity grade of soil erosion in the CYP, the overall trend of development had improved. The area of mild erosion continued to increase, and the average soil erosion modulus remained at a low level. The spatial distribution of the soil erosion intensity had significant aggregation and distribution characteristics, and the location was closely related to the topography. Reviewing the whole research process, the delimitation of the range of the R factor of rainfall erosivity and the improvement of the accuracy of land use classification will be the main research topics to focus on in follow-up research; these approaches will enable us to obtain more accurate results of regional soil erosion and provide a more powerful scientific basis for the formulation of regional soil erosion control measures.

Abstract. The symbiotic nitrogen fixation is used to maximum advantage in the case of leguminous crops. It is therefore important to inoculate seeds with relevant strains of bacteria before sowing especially if the crop is to be grown for the first time on the land. A field experiment was done to assess the effect of inoculation with *Bradyrhizobium japonicum* on the growth and yield performance of soybean. Soybean cultivars inoculated with Nitrazon had significantly greater nodule numbers and dry weight of nodules compared to un-inoculated control. The bacterial preparation increased plant lodging and extended their vegetation period. Nitrazon had a positive effect on the number of pods per plant and thousand seed weight. The obtained increase in seed yield was 0.54 $t \cdot ha^{-1}$ compared to the control. Measurements of soil plant analysis development (SPAD) and leaf area index (LAI) showed that the plants were better nourished and had a higher green mass after Nitrazon application. Seed inoculation did not modify the leaf stomatal conductance (Gs). Nitrazon increased total protein content in seeds. The tested parameters were significantly diversified between cultivars and in the years of the study.
Keywords: *nitrogen fixation, soil plant analysis development, leaf stomatal conductance, leaf area index, yield*

Introduction

Soybean is one of the most economically important crops in the world, which results from the high value of its seeds and their versatile use. Soybean production is low in the European Union, but interest in growing this valuable plant has increased in recent years. Watson et al. (2017) reported that this was due to the growing demand for plant protein and the introduction of new high-yielding cultivars with good food and feed seed value. In soybean cultivation, inoculation of sowing material with bacteria fixing free nitrogen from the air is an especially important procedure (Gwata et al., 2004; Dwivedi et al., 2015; Vargas-Díaz et al., 2019). This treatment is particularly recommended when native strains of symbiotic bacteria are not present in the soil or there are too few of them (Solomon et al., 2012; Marinković et al., 2017; Jarecki, 2020). A good solution in this case may be the purchase for sowing material industrially inoculated with symbiotic bacteria (Flajšman et al., 2019) or the purchase of a commercial inoculant and its application to seeds (Kozieł et al., 2013; Pannecoucque et al., 2018). According to Deaker et al. (2004), increasing the amount of inoculant above the commercially recommended dose did not pose a threat and even caused a linear increase in nodulation and yield. Coskan and Dogan (2011) showed that the shape and size of nodules was characteristic of individual legumes. Nodules on soybean roots are usually round and the most effective are the large ones reddish in color inside (*Fig. 1*).

Figure 1. *Cross-section of bacterial nodules on soybean root, a - active, b - inactive (W. Jarecki)*

Numerous studies (Althabegoiti et al., 2008; López-García et al., 2009; Abou-Shanab et al., 2017) have demonstrated that the occurrence of Rhizobium bacteria in soil is common in some regions. In such case, inoculation with commercial preparations may be less effective, because native Rhizobium strains are competitive in establishing symbiosis (Wongphatcharachai et al., 2015; Onishchuk et al., 2017; Iturralde et al., 2019). Torres et al. (2012) also emphasized the need for periodic evaluation of commercial bacterial cultures to guarantee effective symbiosis after seed inoculation. Zhang et al. (2011) indicated in this aspect a high biodiversity and often a unique distribution of Rhizobium communities in individual regions. Giongo et al. (2008) demonstrated a high level for genetic diversity of Bradyrhizobium bacteria, which nodulate soybean in the fields. This information may be useful in experiments on new commercial inoculants better adapted to local environmental conditions. Shiro et al. (2013) observed that *Bradyrhizobium japonicum* and *Bradyrhizobium elkanii*, but also others, are the main Rhizobia nodulating soybeans. Studies by Thilakarathna and Raizad (2017) have shown that local strains of nitrogen-fixing bacteria are often better adapted to local conditions of environmental stress, suggesting great potential for their commercialization. With proper nodulation, soybean plant demand for nitrogen is met at 40-57% (Zimmer et al., 2016) and even up to 60% (Salvagiotti et al., 2008) by biological N_2 fixing. In the discussed case, the need for soybean mineral nitrogen fertilization is ambiguous, especially with proper nodulation (Salvagiotti et al., 2008). Some studies indicated that soybean plants responded favorably to small doses of mineral nitrogen, e.g. in worse environmental conditions (Aboutalebian and Malmir, 2017; Cafaro La Menza et al., 2017; Gai et al., 2017). In turn, Albareda et al. (2009) and Kaschuk et al. (2016) reported that mineral soybean nitrogen fertilization was superfluous in case of proper symbiosis. This also applied to new high-yielding cultivars. Many reports (Zimmer et al., 2016; Leggett et al., 2017; Adjetey and Mbotho, 2019) showed that the use of seed inoculation significantly increased soybean yield compared to controls. In contrast, Abou-Shanab et al. (2017) and Ambrosini et al. (2019) reported that inoculation did not always increase soybean seed yield. The effect of using commercial biological preparations depends on many factors (Abou-Shanab et al., 2017; Kühling et al., 2018; Adjetey and Mbotho, 2019). Suzuki et al. (2014) examined *Bradyrhizobium japonicum* and *Bradyrhizobium elkanii* and showed that the former were more effective at lower temperatures. Interesting results were presented by López-García et al. (2009), which showed that the improvement of soybean nodulation resulted in a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67136724

low, insignificant increase in yield, and nitrogen content in seeds did not change. Albareda et al. (2009) and Narożna et al. (2015) presented imortant studies on the survival of Rhizobium strains in soil in the successive years following soybean cultivation.

The purpose of this research was to determine the influence of nitrogen fixing bacteria on the growth and grain yield of some soybean cultivars, from different maturity groups, in the field conditions of South-East Poland.

Materials and methods

This study was conducted an individual farm in Makowisko (50º3'N 22º47'E), Podkarpackie Voivodeship, Poland (*Fig. 2*), in the years 2017-2019.

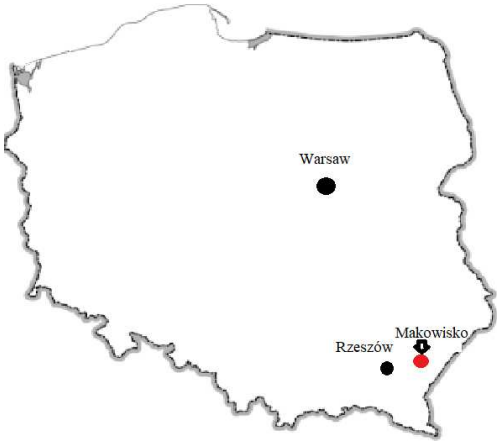

Figure 2. *Location of field experiment*

The first factor in the experiment was the Nitrazon biological preparation containing *Bradyrhizobium japonicum* and a control object - without inoculation. The second factor was soybean cultivars (main plots): Annushka, Lajma, Madlen, Violetta, Atlanta and Smuglyanka (AgeSoya Sp. z o.o., Poland). The cultivars are a high-yieldings recommended for cultivation in the area of the study. The experiment was carried out in four replications in a split-plot design. No soybean was previously grown in the experimental field. Seeds were inoculated according to the manufacturer recommendations (Farma Žiro Ltd., Czech Republic). Inoculation was done just prior to sowing.

The experiment was established on sandy loam soil, Haplic Luvisol (Food and Agriculture Organization of the United Nations, 2015). It was good wheat soil complex. Detailed descriptions of the soil characteristics are given in *Table 1*. Soil sample analysis was carried out at the District Chemical-Agricultural Station in Rzeszów.

Table 1. *Chemical soil properties before the experiment (0-60 cm)*

Years	Humus %	pH 1 mol/L KCl	Nmin kg ha^{-1} DM	P_2O_5	K_2O	Mg
				mg 100g^{-1} of soil		
2017	1.78	6.19	59.4	27.2	35.1	3.7
2018	1.71	5.92	55.1	23.8	24.1	2.8
2019	2.34	5.89	63.0	31.6	28.6	4.9

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67136724

Weather conditions are given according to meteorological data of the Experimental Stations for Variety Testing in Skołoszów. Distance from the experimental field about 12 km.

Sowing of seeds was carried out in the first days of May. The single plot area was 15 m^2. Soybeans were sown with 60 kernels capableof germination per m^2 and a space between rows of 45 cm. Winter wheat served as the forecrop.

NPK fertilization and plant protection treatments are described in detail in the publication Jarecki (2020).

Plant development stages are given according to the BBCH scale (Biologische Bundesanstalt, Bundessortenamtund CHemische Industrie). The full maturity stage of plants (BBCH) was given in days from the date of sowing. Plant lodging assessed before harvest on a scale of 1-9° (1° – the highest plant lodging, 9° – no lodging). The measurement of stomatal conductance of leaves (Gs) was performed with a Meter Porometr SC-1 apparatus (Pullman, USA). Soil plant analysis development (SPAD) was measured with a SPAD 502P chlorophylometer (Konica Minolta, Inc. Japan). Leaf area index (LAI) measurements was performed using a Meter LP-80 AccuPAR apparatus (Pullman, USA). Gs, SPAD and LAI were measured in the BBCH 70 stage.

To assess nodulation parameters, in the flowering stage (BBCH 65), 20 roots were randomly collected from one plot. Then in laboratory the number and dry weight of the nodules were determined.

At physiological maturity stage, 25 plants were collected for measuring the number of pods per plant and thousand seed weight (g). Seed yield obtained from the plots (BBCH 89) was converted into a yield per 1 ha with a moisture content of 15%.

The chemical composition of seeds was determined with the near-infrared spectroscopy (NIRS) method using an FT NIR MPA spectrometer (Bruker, Billerica, USA).

The significance of differences between the characteristic values was found based on Tuckey's halfconfidence intervals, with the significance level $p = 0.05$. Calculations were made using the software Statistica 10 PL (Stat Soft, Inc., Tulsa, USA).

Results and discussion

The weather conditions in 2017-2019 differed from the long-term average. In region, mean annual precipitation is 673 mm and mean annual temperature is 8.4°C. The detailed description of the climatic conditions is given in the *Table 2*.

Table 2. *Weather conditions in the years 2017-2019*

Months	Mean temperature (°C)				Sum of precipitation (mm)

The number of nodules and the dry weight of nodules were significantly higher after the use of bacterial inoculant compared with the control (*Table 3*). On average, 19.9 nodules were found on a single soy root after inoculation Nitrazon, and 0.52 nodules on a un-inoculated control. The highest number of nodules and their highest dry weight were obtained in cultivars Lajma (*Fig. 3*) and Atlanta. The weather conditions had a significant impact on soybean nodulation. In 2018, an average of 14.6 nodules were recorded per root. The fewest nodules and their lowest dry weight were obtained in 2017.

Table 3. *Impact of seed inoculation on nodulation, lodging and maturity of plants*

Specification	The number of nodules	The dry weight of nodules (g)	Lodging (1-9°)	Maturity (number of days since sowing)
Inoculation				
Control	0.52^{b}	0.04^{b}	8.4^{a}	136^{a}

a b

Figure 3. *Lajma cultivar, a – without inoculation, b - with inoculation (W. Jarecki)*

Althabegoiti et al. (2008) reported that commercial soybean inoculant could be used on seeds or in the soil, in which they would be sown. These authors obtained better results in the latter case. Zerpa et al. (2013) obtained the highest number of nodules on soybean roots (17.5 on average) after combined use of two commercial bacterial strain. Nodulation was not found in the control object. Adjetey and Mbotho (2019) demonstrated the efficacy of commercial inoculates, and observed few nodules in control plants. Abou-Shanab et al. (2017) concluded that the presence of native strains of Rhizobium bacteria in soil also

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67136724

caused nodulation on non-inoculated roots (control). The obtained results of soybean seed inoculation by the above-mentioned authors varied depending on the bacterial strain, soil nitrogen content, cultivar and study region. Thuita et al. (2012) report that both the number of nodules on the roots and their weight are significantly dependent on the inoculant used. At the same time, the obtained results were also heavily influenced by the cultivar. Marinković et al. (2018) obtained a varied number and dry weight of nodules on soybean roots depending on the strain of symbiotic bacteria. This provided the basis for selecting the best one for the production of commercial preparations.

In the present study, the application of Nitrazon significantly increased lodging of the plants compared to control. The difference obtained was 0.5°. Plants of the cultivar Smuglanka were characterized by the greatest lodging. Annushka, Lajma and Violetta cultivars were significantly less affected by lodging. In the years of research, the discussed parameter significantly differed. In 2018, plant lodging was the greatest and amounted to 7.7°. The bacterial strain extended the vegetation period by an average of two days compared to control, but this has not been statistically proven. The vegetation period of the studied cultivars ranged from 123 days in the cultivar Annushka to 151 days in the cultivar Smuglanka. Differences in the studied parameter were recorded during the years of the study. Soybean plants reached full maturity after 128 days in 2017 and 145 days in 2018.

The bacterial preparation has significantly increased the number of pods per plant and thousand seed weight. The obtained increase in seed yield was 16.9% compared with the control (*Table 4*). Madlen, Atlanta and Smuglanka were high yielding cultivars. The cultivar Lajma produced a significantly lower seed yield. Seed yield in 2018 was 3.65 t·ha^{-1}, while in 2017 – 3.27 t·ha^{-1}. Therefore, the obtained difference amounted to 11.6%.

Table 4. *Yield and yield components*

Specification	Yield (t·ha^{-1})	The number of pods per plant	Thousand seed weight (g)
Inoculation			
Control	3.19^{b}	29.6^{b}	147.9^{b}
Nitrazon	3.73^{a}	34.1^{a}	153.1^{a}
Cultivar			
Annushka	3.39^{ab}	31.9^{ab}	145.6^{b}

Year			
2017	3.27^{b}	32.8^{b}	141,9^{b}
2018	3.65^{a}	37.9^{a}	156.4^{a}
2019	3.46^{ab}	27.8^{c}	153.2^{a}

Average values for each factor marked with different letters in a column differ significantly ($P < 0.05$)

Macák and Candráková (2013) reported that the number of pods per plant, thousand seed weight and seed yield of soybean were variable in years, while the number of seeds in the pod was stable. Căpățână et al. (2017) obtained an increase in soybean seed yield

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67136724

after inoculation, but only by 3.76% compared to control. Solomon et al. (2012) and Thuita et al. (2012) confirmed that not every strain of *Bradyrhizobium japonicum* provided the expected results. They also added that in the case of soybean, yielding was mainly determined by the selection of proper cultivar. Abou-Shanab et al. (2017) concluded that inoculation of legumes with nitrogen-fixing bacteria did not always result in a significant increase in seed yield. Therefore, recommendations for the use of biological preparations should be related to regional habitat conditions. This was also confirmed by the experiments carried out by Leggett et al. (2017), who showed that the effects of soybean seed inoculation with *Bradyrhizobium japonicum* varied depending on the years of research and the specificity of a given area.

On average, soybean seeds contained 37.5% protein and 19.5% fat. The applied Nitrazon significantly increased protein content in seeds. Crude fat content was not changed compared to control (*Table 5*). The tested cultivars had significantly different content of protein and fat in seeds. The highest total protein content was determined in seeds of the cultivar Violetta and crude fat in the seeds of the cultivars Lajma and Madlen. The chemical composition of seeds was varied during the years of the study.

Table 5. *Chemical seed composition*

Specification	Protein total (% DM)	Crude fat (% DM)
Inoculation		
Control	36.3^{b}	19.6^{a}
Nitrazon	38.7^{a}	19.4^{a}
Cultivar		
Annushka	37.2^{ab}	19.5^{ab}
Lajma	36.7^{b}	20.2^{a}
Madlen	37.7^{ab}	20.0^{a}
Violetta	38.6^{a}	19.4^{ab}
Atlanta	37.6^{ab}	18.9^{b}
Smuglanka	37.2^{ab}	19.0^{b}
Year		
2017	36.8^{b}	20.5^{a}
2018	38.2^{a}	18.2^{b}
2019	37.5^{ab}	19.8^{ab}

Average values for each factor marked with different letters in a column differ significantly ($P < 0.05$)

Zimmer et al. (2016) stated that the use of commercial bacterial strain in soybean cultivation was justified. At the same time, they obtained various effects in the form of an increase in protein yield depending on the study area. Pannecoucque et al. (2018) and Flajšman et al. (2019) reported that commercial preparations effectively increased soybean nodulation, which resulted in an increase in protein content in seeds and protein yield compared to control. Cafaro La Menza et al. (2017) concluded that obtaining high soybean yields, including protein yields, required adequate nitrogen supply. However, with high nitrogen availability, they noted a slight increase in protein content and a decrease in fat in soybean seeds.

Plant nutritional status assessed by the SPAD index was higher after Nitrazon application compared to control. Among the tested cultivars, Annushka was characterized by a high SPAD index, while Atlanta and Smuglanka the lowest. Significant differences in the SPAD index have been shown in plants between 2017 and 2018 (*Fig. 4*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67136724

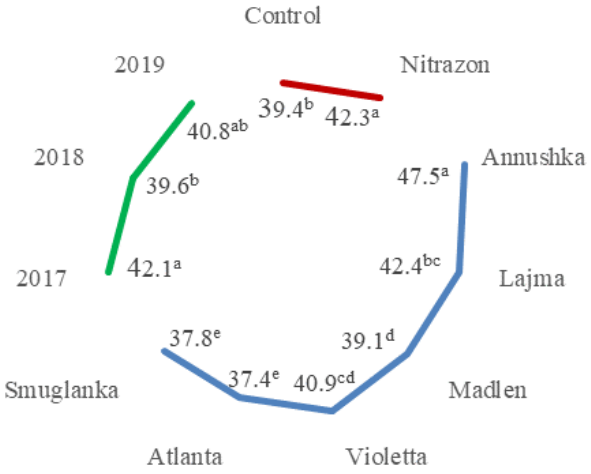

Figure 4. *Soil plant analysis development (SPAD value)*

Thompson et al. (1996) confirmed the usefulness of SPAD measurements for the assessment of chlorophyll content in soybean leaves, but the results were modified by environmental conditions. Fritschi and Ray (2007) believed that SPAD readings were useful, but should have also been supplemented with other measurement techniques. Kühling et al. (2018) reported that the SPAD value was higher after applying the inoculation procedure, but only at the beginning of soybean seed filling phase. In the research of Jarecki et al. (2016), better-fed plants (higher SPAD) were characterized by higher yields, which was confirmed by a strong correlation (r = 0.83). SPAD measurements can therefore be useful for predicting soybean seed yield. Vollmann et al. (2011) added that the assessment of chlorophyll content in leaves also allows to predict the quality parameters of soybean seeds.

Nitrazon significantly increased the LAI index compared to controls. Early cultivars (Annushka and Laima) were characterized by lower LAI values and late cultivars (Atlanta and Smuglanka) by its higher values. Differences in LAI were recorded during the years of the study. The highest LAI was recorded in 2017, while significantly lower in 2018 (*Fig. 5*).

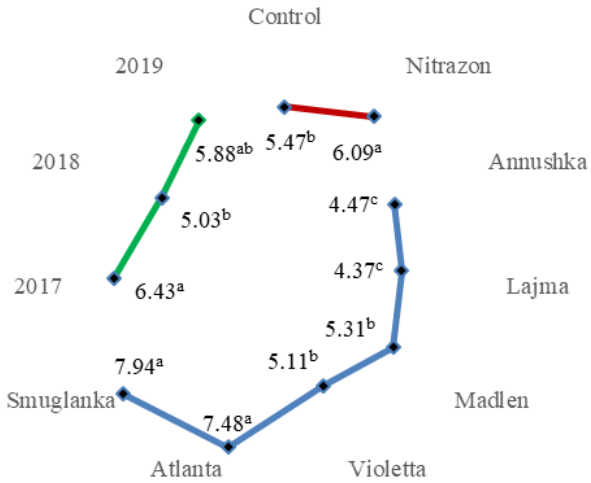

Figure 5. *Leaf area index (LAI)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67136724

Salvagiotti et al. (2008) have argued that the availability of nitrogen, which affects the growth and development of a single plant, largely determines soybean yield. Abou-Shanab et al. (2017) obtained a significantly higher dry weight of soybean plants after inoculation compared to control. However, seed yield did not increase significantly. Zerpa et al. (2013) showed an increase in soy leaf surface after the combined application of two commercial inoculant containing *Bradyrhizobium japonicum*. Single use of the test preparations was less effective. Adjetey and Mbotho (2019) obtained a greater number of leaves in the experiment with soybean after inoculation compared to control; nutrient uptake has also increased. Jarecki et al. (2016) reported that nitrogen availability for soybean plants increased the assimilation surface. However, they did not show a relationship between LAI measurements and seed yield.

The bacterial strain had no effect on leaf stomatal conductance (Gs) compared to control plants. The highest Gs had the cultivar Lajma and Violetta the lowest. In the years of the study, Gs ranged from 561 in 2019 to 836 in 2018 (*Fig. 6*).

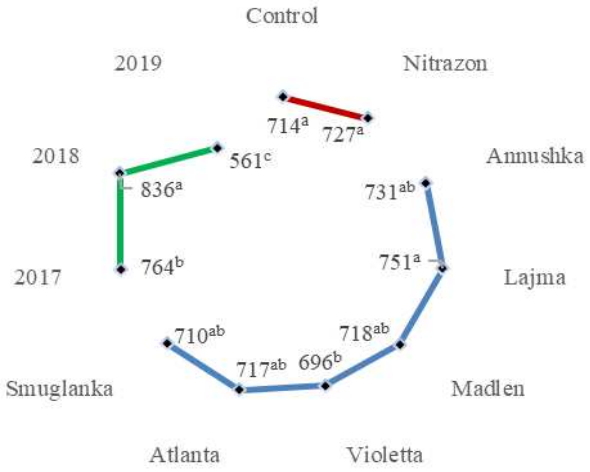

Figure 6. *Leaf stomatal conductance (Gs)*

Yu et al. (2018) believed that the results of leaf stomatal conductance were more accurate when carried out under controlled meteorological conditions compared to field conditions.

Conclusion

In this study, the use of commercial preparation - Nitrazon increased the number and dry weight of nodules on soybean roots compared to control. SPAD and LAI measurements showed that the use of *Bradyrhizobium japonicum* resulted in better nutrition and higher green mass of plants. The inoculation resulted in an increase in the number of pods per plant, thousand seed weight, seed yield, protein content in seeds compared to control. It was shown that the examined traits and parameters varied between cultivars and changed over the years of the study. Low seed yields were obtained in 2017 and high in 2018. Generally, inoculation of soybean seeds with nitrogen-fixing bacteria, can lead to a reduction of the consumption of nitrogen fertilizer in soybean cultivation. In next experiment, it is possible to assess the effectiveness of the commercial soybean seed coating with *Bradyrhizobium japonicum*.

EFFECTS OF LEAD PHYTOTOXICITY ON DIFFERENT PEANUT VARIETIES GERMINATION AND SEEDLING GROWTH

KAYA, A. R.

Department of Field Crops, Agricultural Faculty, Kahramanmaras Sutcu Imam University, Kahramanmaraş, Turkey
(e-mail: alirahmikaya@ksu.edu.tr; phone: +90-344-300-2164; fax: +90-344-300-2002)

(Received 3rd May 2020; accepted 13th Aug 2020)

Abstract. Lead is a highly toxic environmental pollutant for plants and other living organisms, including humans. To determine the effects of lead phytotoxicity on germination and seedling growth of 10 peanut (*Arachis hypogaea* L.) varieties, a study was conducted to screen the influence of different lead nitrate ($PbNO_3)_2$ doses in May 2016 at 25 °C (±2) in the Department of Field Crops Laboratory, Faculty of Agriculture, Kahramanmaras Sutcu İmam University. The treatment was carried out according to the completely randomized plot experimental design with three replications. In the experiment, two pieces of filter paper were placed in each of the 120 sterile petri dishes and then, 25 seeds of each varieties were placed to germinate. After 14 days, some main germination and seedling growth parameters were observed. All the characteristics studied were affected differently by lead doses according to of varieties. Peanut varieties were observed to react differently to lead concentrations due to their different genotypic structure, and some did not have a significant effect on lead doses. Overall, it can be concluded that lead is privative, but plants employ mechanisms to resist it. Thus, further research should be carried out to select and develop cultivars that have superior tolerance to Pb.
Keywords: *germination, lead nitrate ($Pb(NO_3)_2$), peanut (Arachis hypogaea L.), seed, seedling vigor index, toxicity*

Introduction

Peanut (earthnut, groundnut, ground bean) belongs to the Arachis genus, an annual, soil enriching, self-pollinated legume, it is an oilseed, and a member of the Leguminosae family and the Papilionaceae subfamily. It is widely grown in the tropics and temperate regions in six continents between latitudes 40°N and 40°S, from warm temperate to equatorial climates (Konlan et al., 2013; Sharma and Bhatnagar-Mathur, 2006). There are numerous confinements to the productivity of the peanut crop that result in enormous economic losses. Traditional plant breeding practices and methodologies have not been successful in conferring resistance against different biotic and abiotic stresses owing to species restrictions in the natural system. Although it is not sufficiently successful, there is always a need to determine the resistance to abiotic stresses, especially in varieties developed as yield and resistant to certain diseases. Negative effects of non-living factors on living organisms in a given environment can be defined as abiotic stress. There are various types of abiotic stresses such as drought, over-watering, extreme temperatures (cold, frost and heat), salinity and mineral toxicity. Abiotic stresses are the main causes of poor plant growth and reduced plant production in the world (Onaga and Wydra, 2016). Minerals consist of heavy metals that are toxic even to a very low concentrations for both plants and animals. Some heavy metals, such as arsenic, cadmium, mercury, lead and selenium, do not perform any physiological functions known in plants and are called non-essential metals. These metals generally have negative effects on seed germination, plant growth, development, yield and seed quality depending on the plant species. Other minerals such as ferrum, zinc, cobalt,

DOI: http://dx.doi.org/10.15666/aeer/1805_67256738

copper, manganese, molybdenum and nickel are essential elements for the normal growth and metabolism of plants. When the concentrations of these essential elements exceed the optimum level, it may cause poisoning (Mani and Sankaranarayanan, 2018). Environmental conditions' changes influence the biological and physiological reactions of plants. For general growth and development, plants need a variety of mineral elements. These minerals are existing in the soil and absorbed by the roots, a great many of them are transferred to the shoots and then distributed to various organs and tissues of the plant depending on their requirements (Mani and Sankaranarayanan, 2018).

Lead ranks second among all the hazardous heavy metals (Kumar et al., 2012) and is the most common heavy metal pollutant in the environment, according to the Environmental Protection Agency (EPA) (Lamhamdi et al., 2011). Lead inhibits the activity of many enzymes, disrupts mineral nutrition and water balance, alters hormonal status and affects membrane structure and permeability. Lead reduces the photosynthetic rate of plants, thereby limiting plant growth by disrupting the chloroplast infrastructure, reducing chlorophyll synthesis, inhibiting electron transfer, and inhibiting the activities of the Calvin cycle enzymes (Sengar et al., 2008). Lead toxicity causes inhibition of ATP production, lipid peroxidation and DNA damage. In addition, lead strongly inhibits seed germination, root growth, seedling growth, plant growth, sweating, chlorophyll production and water and protein content (Pourrut et al., 2011).

This study deals with the effects abiotic stress due to lead nitrate toxicity concentrations on germination and seedling growth parameters of *Arachis hypogaea* L., and to demonstrate the differences among these 10 varieties.

Material and methods

The study was carried out at 25 °C (±2) in the laboratory of Department of Field Crops, Faculty of Agriculture, Kahramanmaras Sutcu Imam University in May 2016 in Turkey.

In this study, which investigated how lead's phytotoxicity affects germination and subsequent seedling development, 10 (Arıoğlu-2003, Batem-5025, Florispan, Georgia Green, Halisbey, NC-V-II, NC-7, Osmaniye-2005, Sultan and Wilson) varieties of peanuts obtained from Çukurova University Faculty of Agriculture, Department of Field Crops and Osmaniye Agricultural Research Institute were used as materials. The cultivars used in this study, are the major peanut varieties have been registered in Turkey. In addition, all of the varieties planted in Turkey confectionary Virginia type varieties. The most common planted variety is NC-7. Also; There are also local seeds in the form of unregistered farmer populations such as Anamur, Osmaniye, Aydın (Kadiroğlu, 2008).

In this study, healthy and homogenous seeds of 10 peanut varieties were sterilized with 5% NaOCI (sodium hypochlorite) solution for 5 min and then rinsed with tap water. In the study, lead nitrate $Pb(NO_3)_2$ which was used as stress factor was prepared in four different doses as 0, 100, 200 and 400 mg L^{-1}, respectively. In the study, 25 seeds of each variety were sown on to germinate for 14 days in 120 sterile petri dishes, each with two filter papers. During sowing, 20 ml of all concentrations prepared separately were added to each petri dish. The same amount of tap water was added to the petri dishes, which were evaluated as controls. After two days, 15 ml of these solutions were added to each petri dish six times at two-day intervals. The petri dish's

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67256738

lids were closed and placed in growth booths, setting germination rates at the same time each day. In order to assess germination of the seed, seeds with a root formation of 1 mm were considered germinated seeds (Munzuroglu and Geckil, 2002). Germination test was terminated at the end of 14 days when the cotyledon leaves emerged completely. In the study, some basic germination and seedling parameters such as germination percentage, germination index, radicle length, plumule length, seedling length, radicle fresh weight, plumule fresh weight, seedling fresh weight, radicle dry weight, plumule dry weight, seedling dry weight, seedling vigor index and germinated seed number were observed. The germination rate was found by dividing the germinated seeds by the total number of seeds and then multiplying by 100 (Maquire, 1962).

$$Germination\ percentage = \frac{\text{Germinated seeds number}}{\text{Total seeds number}} x100$$

Germination index = ∑Gt/Dt, Gt is the number of germinated seeds in t days; Dt is the number of corresponding germination days (Ertekin et al., 2011).

The length of the seedling was found by measuring the length of the radicle and plumule separately and then adding both lengths (AOSA, 1984).

After measurements of the fresh samples, the samples were kept for 24 h in an oven set at 78 °C, and then analyses of the dry samples were performed (AOSA, 1984).

Seedling vigor index was found by multiplying seedling length by germination percentage (Abdul-Baki and Anderson, 1973; AOSA, 1984).

$$Seedling\ vigor\ index = \text{Seedling length } x \text{ Germination percentage}$$

Statistical analysis of data

All data obtained from the study were processed by SAS (v. 9.0, 2002) statistical package. The analysis of variance (ANOVA) was performed according to the Completely Randomized Experimental Design procedures at significant levels of $p < 0.01$ or $P < 0.05$. To detect the significant differences ($p < 0.01$ or $p < 0.05$) of variables, Least Significant Difference (LSD), a multiple comparison test, was performed. Additionally, the Pearson Correlation analysis was processed to determine the relationship among the observed parameters.

Results and discussion

Germination percentage (%)

In terms of tolerance to increasing lead doses, when the varieties were examined, statistically significant ($P < 0.01$) differences were found among the varieties. The highest germination rate (100%) was obtained from Batem-5025 variety, while the lowest (87.67%) was obtained from Osmaniye-2005 variety (*Table 1*). Differences among the lead doses in terms of their effects on germination rates were found to be insignificant ($P > 0.05$) and it was determined that germination rates ranged between 94.67% and 98.27% (*Table 1*). As shown in *Table 1,* lead doses had different effects on seed germination rates of peanut varieties. It was found that peanut varieties react differently to lead levels due to genotypic differences.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67256738

Germination index

It was seen that there were statistically significant ($P < 0.01$) variations among the varieties in terms of germination indexes. The highest (11.81, 11.77 and 11.70, respectively) germination indexes were determined from Georgia Green, Batem-5025 and Florispan, while the lowest (9.50) was found in Osmaniye-2005. No significant ($P > 0.05$) differences were found among the lead doses in terms of their effects on germination indexes (*Table 1*).

Radicle length (cm)

As can be seen from *Table 1,* in terms of radicle lengths, statistically significant differences ($P < 0.01$) were found among the varieties. The highest radicle lengths were measured from Batem-5025, Wilson and Florispan (5.42, 5.12, and 5.04 cm) varieties, respectively, while the lowest (2.22 cm) was observed from Halisbey varieties. The differences between lead doses were found to be insignificant ($p > 0.05$) in terms of their effect on radicle lengths and it was determined that the radicle lengths obtained from different doses ranged between 3.69 and 4.27 cm (*Table 1*). Due to the different reactions of the varieties to the increased lead doses, the effect of variety and dose interaction on radicle lengths was found to be statistically significant ($p < 0.05$). The highest radicle lengths (6.52 and 6.37 cm) were measured from Georgia Green and Wilson varieties at 100 and 200 mg $Pb(NO_3)_2$ L^{-1} doses, while the lowest (1.78 and 1.83 cm) were observed in Halisbey and Sultan varieties at doses of 200 and 100 mg $Pb(NO_3)_2$ L^{-1} (*Table 1; Fig. 1*).

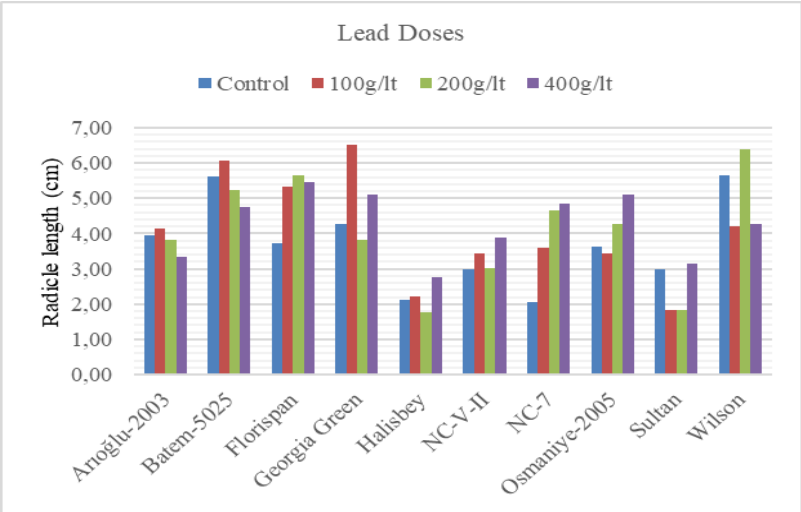

Figure 1. *The interaction of Arachis hypogaea L. varieties' radicle length*

Plumule length (cm)

In the experiment, it was found that there were statistically significant differences ($P < 0.01$) among the varieties in terms of plumule lengths. The highest plumule lengths were seen in Batem-5025 (3.34 cm) and NC-V-II (3.34 cm) varieties, while the lowest was measured from Osmaniye-2005 variety as 2.02 cm. Differences among lead doses were found to be insignificant ($P > 0.05$) in terms of their effects on plumule lengths, and plumule lengths were determined to vary between 2.65 and 2.95 cm (*Table 1*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67256738

Seedling length (cm)

From *Table 1,* it was found that there was a statistically significant ($P < 0.01$) variation among the varieties in terms of seedling lengths. The highest seedling length was observed in Batem-5025 variety as 8.76 cm, while the lowest seedling lengths were seen in Halisbey (4.39 cm) and Sultan (5.08 cm) varieties. As a result of the study, it was found that there were statistically significant ($P < 0.05$) differences among lead doses in terms of their effects on seedling lengths. The highest seedling length was measured as 7.21 cm at 400 mg $Pb(NO_3)_2$ L^{-1} dose, while the lowest was determined as 6.35 cm at the control dose (*Table 1*). The effect of variety and dose interaction on seedling lengths was statistically significant ($P < 0.05$) due to the different responses of varieties to lead doses. The lowest seedling length of 3.69 cm was observed in Sultan variety at 100 mg $PB(NO_3)_2$ L^{-1} doses (*Table 1; Fig. 2*).

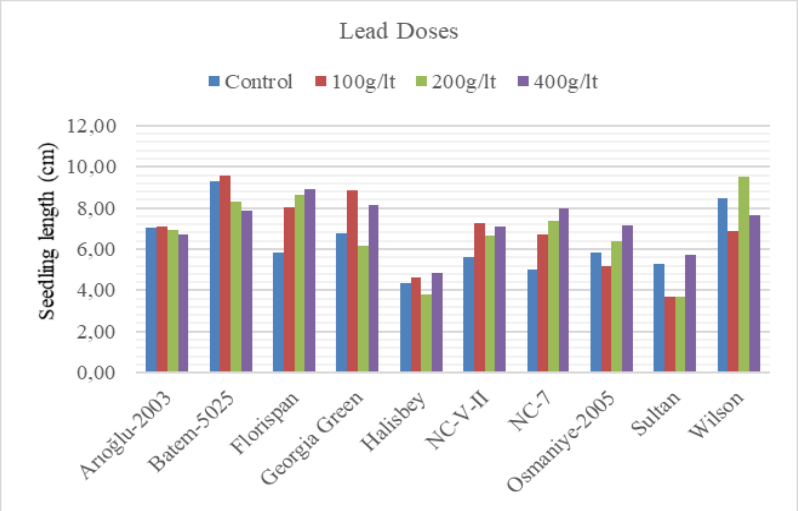

Figure 2. *The interaction of Arachis hypogaea L. varieties' seedling length*

Radicle fresh weight (g)

As indicated in *Table 1,* it was seen that there was a statistically significant ($P < 0.01$) variation among varieties in terms of fresh weights of radicles. The highest radicle fresh weights were observed in Osmaniye-2005 (3.096 g) and NC-7 (2.913 g) varieties, while the lowest was seen in Georgia Green as 1.61 g. Statistically ($P < 0.05$) there were significant variations among lead doses in terms of their effect of radicle on age weights. The highest radicle fresh weight was seen at 400 mg $Pb(NO_3)_2$ L^{-1} dose as 2.442 g, while the lowest (2.032 g) was seen at the control dose (*Table 1*). It was determined that the effects of variety and lead dose interaction on radicle fresh weights were statistically significant ($P < 0.01$). The highest radicle fresh weight (4.18 g) was obtained from Osmaniye-2005 cultivar and 400 mg $Pb(NO_3)_2$ L^{-1} lead dose, while the lowest weights (1.408 and 1.400 g) were detected from Georgia Green and Sultan at 200 and 100 mg $Pb(NO_3)_2$ L^{-1} doses (*Table 1; Fig. 3*).

Plumule fresh weight (g)

In terms of plumule fresh weight, when the varieties were examined, statistically significant ($P < 0.01$) differences were found among the cultivars. The highest radicle

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67256738

fresh weight was observed in Sultan, NC-V-II and Osmaniye-2005 (26.672, 26.627 and 26.141 g) varieties, respectively, while the lowest weights were observed in Florispan (12.675 g) and Georgia Green (14.480 g) varieties (*Table 1*). As seen in *Table 1,* it was determined that increasing lead doses produced significant ($P < 0.01$) different effects on plumule fresh weight. The highest plumula fresh weights (23.112 and 22.563 g) were observed at 400 and 200 mg $Pb(NO_3)_2$ L^{-1} lead doses, while the lowest weights (2.67 and 21.04 g) were determined at 100 mg $Pb(NO_3)_2$ L^{-1} and control treatments (*Table 1*). When the variety and lead dose interactions were examined in *Table 1,* it was observed that the effect interactions on plumula fresh weights were statistically very significant ($p < 0.01$). The highest plumule fresh weights (28.33, 28.26, and 28.32 g, respectively) were observed from NC-V-II, Sultan and Wilson at 100 and 400 mg of $Pb(NO_3)_2$ L^{-1} doses, while the lowest weights (11.601 and 12.011 g) were weighed in Fluorescent and NC-7 varieties from control and 100 mg $Pb(NO_3)_2$ L^{-1} applications (*Table 1; Fig. 4*).

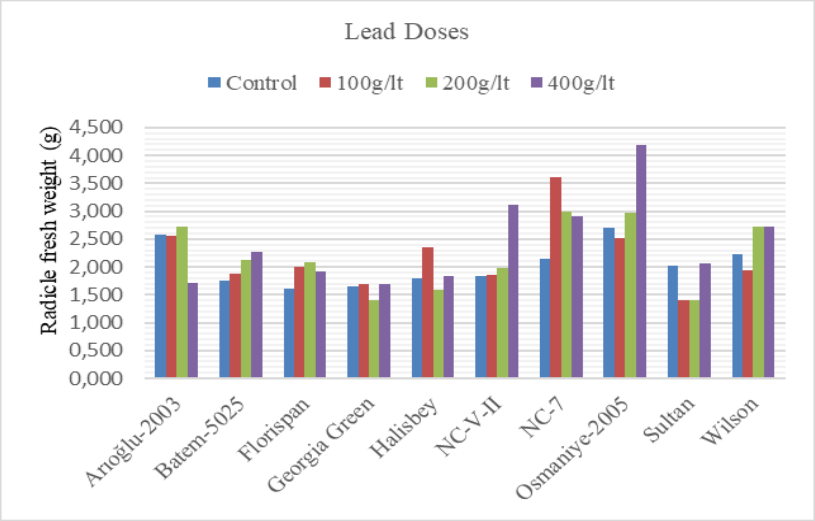

Figure 3. *The interaction of Arachis hypogaea L. varieties' radicle fresh weight*

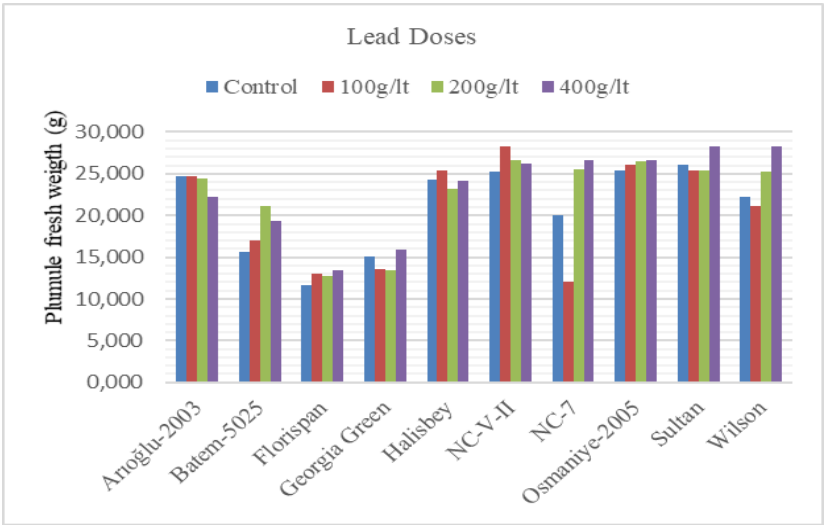

Figure 4. *The interaction of Arachis hypogaea L. varieties' plumule fresh weight*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67256738

Seedling fresh weight (g)

As shown in *Table 2,* the differences among the varieties were found to be statistically significant ($P < 0.01$). The highest seedling fresh weight (29.237 and 28.821 g) was measured in Osmaniye-2005 and NC-V-II cultivars, while the lowest seedling fresh weights (14.581, 16.086, and 20.267 g, respectively) were seen in Florispan, Georgia Green and Batem-5025 cultivars, respectively. There was a statistically significant ($P < 0.01$) variation among the lead doses in terms of their effects on seedling age weights. The highest seedling fresh weights (25.554 and 24.824 g) were obtained from 400 and 200 mg $Pb(NO_3)_2$ L^{-1} lead doses, while the lowest seedling fresh weights (22.850 and 23.071 g) were being observed in 100 mg $Pb(NO_3)_2$ L^{-1} and control applications (*Table 2*). In terms of seedling fresh weights, interactions of varieties and doses have been observed to produce statistically ($p < 0.01$) significant variations. The average fresh weight value of seedlings most affected by stress conditions (13.212 g) was obtained from the control dose of Florispan variety (*Table 2; Fig. 5*).

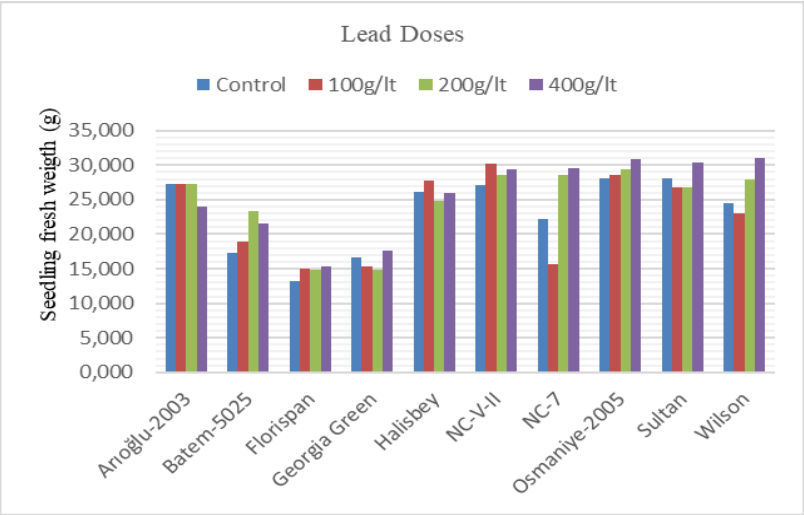

Figure 5. *The interaction of Arachis hypogaea L. varieties' seedling fresh weight*

Radicle dry weight (g)

When the averages of the dry weight of the radicles were examined from the results presented in *Table 2,* it was seen that there were statistically significant ($P < 0.01$) variations among the varieties. The highest radicle dry weight was observed in Osmaniye-2005 variety as 0.549 g, while the lowest dry weight was observed in Batem-5025 variety as 0.373 g. As a result of the analysis of variance, it was determined that lead doses were statistically significant ($p < 0.05$) in terms of their effect on the dry weight of the radicle. The highest radicle dry weights (0.476 and 0.468 g) were obtained from 400 and 200 mg $Pb(NO_3)_2$ L^{-1} doses, while the lowest weights (0.420 and 0.424 g) were determined in the control and 100 mg $Pb(NO_3)_2$ L^{-1} applications (*Table 2*). When the binary interactions were examined in terms of the dry weight of the radicles, it was found that the variety x dose interactions showed statistically significant ($P < 0.01$) variations. The highest radicle dry weight value was obtained from the dual combination of Osmaniye-2005 and 400 mg $Pb(NO_3)_2$ L^{-1} as 0.710 g (*Table 2; Fig. 6*).

DOI: http://dx.doi.org/10.15666/aeer/1805_67256738

Plumule dry weight (g)

As can be seen from *Table 2,* when the averages of plumule dry weights were examined, it was determined that there were very significant variations among the varieties as statistical ($P < 0.01$), while differences between lead doses were found to be insignificant ($p > 0.05$) in terms of their effects on plumule dry weights. The highest plumule dry weights were seen in Sultan (13.349 g) and Osmaniye-2005 (12.653 g) cultivars, while the lowest plumule dry weight was seen in Florispan variety as 5.182 g.

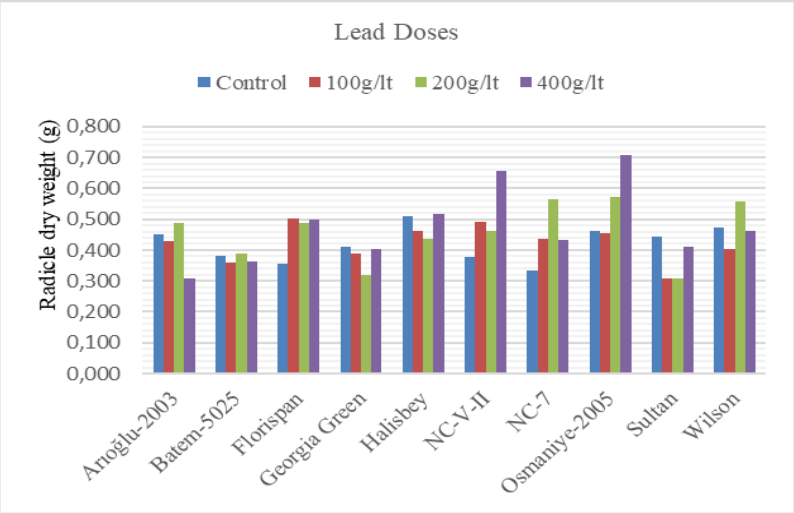

Figure 6. *The interaction of Arachis hypogaea L. varieties' radicle dry weight*

Seedling dry weight (g)

When the averages of seedling dry weights were examined from *Table 2,* it was found that there were statistically significant differences ($P < 0.01$) among the varieties, whereas the differences in lead doses were statistically insignificant ($P > 0.05$). The highest seedling dry weights were seen in Sultan (13.740 g) and Osmaniye-2005 (13.202 g) varieties, while the lowest seedling dry weight was seen in Florispan variety as 5.644 g.

Seedling vigor index

When the averages of seedling vigor indices were examined from *Table 2,* it was found that the differences among the varieties and the differences among the lead doses were statistically significant ($P < 0.01$). According to the results, Batem-5025 varieties had the highest seedling vigor index (875.05), while Halisbey varieties had the lowest seedling vigor index (435.37). The highest seedling vigor index (701.24) was detected at 400 mg $Pb(NO_3)_2$ L^{-1} lead dose, while the lowest seedling vigor index (604.27) was determined from the control application (*Table 2*). Due to the different reactions of the varieties to the lead doses, the effect of variety x dose interaction on seedling vigor indices was found to be statistically significant ($P < 0.01$). It was determined that Sultan variety with the lowest tolerance to lead doses had lowest seedling vigor index (369.05) at 100 mg $Pb(NO_3)_2$ L^{-1}, while Halisbey variety (377.33) was produced lowest seedling vigor index at 200 mg $Pb(NO_3)_2$ L-1 dose (*Table 2; Fig. 7*).

DOI: http://dx.doi.org/10.15666/aeer/1805_67256738

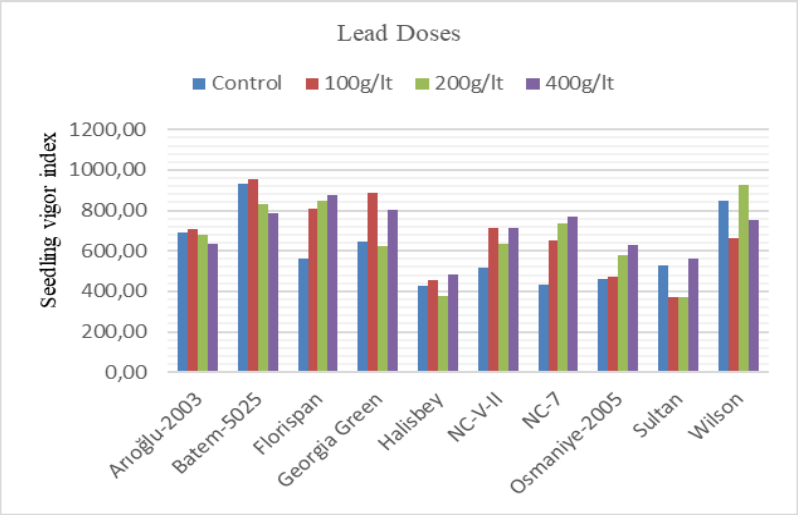

Figure 7. *The interaction of Arachis hypogaea L. varieties' seedling vigor index*

Germinated seed number (number)

In *Table 2,* when the average of germinated seed number, it was seen that there were significant variations ($P < 0.01$) among the varieties and it was determined that the differences between lead doses were insignificant ($P > 0.05$). The highest germinated seed number was observed in Batem-5025 cultivar as 25.00, while the lowest number was obtained in Osmaniye-2005 cultivar as 21.92.

The relationships among the observed characteristics

In the study, a correlation analysis was conducted to reveal the relationships between all investigated properties of peanut varieties subjected to lead concentrations, an abiotic stress factor. The correlations among the all investigated properties are thought to be significant ($P < 0.01$ and $P < 0.05$) due to the widespread and complex lead interactions occurring in the plant organs of different cultivars (*Table 3*). As presented in *Table 3,* it was found that germination percentage, one of the most important attribute, had significant positive correlations ($r = 0.689$ and $r = 0.273$) with the germination index and germinated seed number, but had significant negative correlations ($r = -0.233$ and $r = -0.232$) with germination seed dry weight and seedling vigor index. *Table 3* can be examined for the positive and negative relationship among other characteristics.

Discussion

Germination is the first event in a plant's life and is started by the regulation of enzymatic reactions that activate catabolic and anabolic processes in storage tissues and on the embryonic axis, respectively (Lamhamdi et al., 2011). Germination will be prevented even if a single component of these processes is influenced. Therefore, it is of great concern because of the heavy metal toxicity in the surrounding area and the effects of the abiotic stress conditions on plant growth. Plants under stress conditions are likely to be negatively affected by high concentrations of heavy metals. One known explanation of the effect of heavy metals on plant physiology is that this results in a variety of nutritional disorders (Lamhamdi et al., 2011; Sengar et al., 2008). A high

concentration of lead, one of the most abundant and ubiquitously distributed toxic pollutants (Sharma and Dubey, 2005), may lead to an inhibition in germination, root elongation, seedling development, plant growth, and more than (Sethy and Ghosh, 2013). Although the effect of Pb varies depending on concentration, soil type, soil properties, and plant species (Lakshmi, 2014), Pb toxicity causes a reduction of germination percentage, length and dry mass of roots and shoots (Munzuroglu and Geckil, 2002).

In this study, the effect of increased lead doses on germination and seedling growth parameters were investigated. As seen in *Tables 1, 2* and *Figures 1-7,* lead concentrations had statistically significant different effects on some observed attributes such as radicle length, seedling length, radicle fresh weight, plumule fresh weight, seedling fresh weight, radicle dry weight, and seedling vigor index in peanut varieties. Increased lead doses have been found to cause an increase in the properties studied in some varieties, while a decrease in others. It was determined that peanut varieties react differently to lead concentrations due to their different genotypic structures and that lead doses in some of them do not have any significant effect. In a few varieties' germinations and growth parameters observed were suppressed differentially at all lead treatments. In some varieties, many features have been found to be promoted differently in some lead treatments. Some previous studies have also reported ineffective or positive effects of lead doses up to a certain level on germination parameters in some plants Zaier et al. (2010), however, Pb has often been reported to have negative effects on most plant species (Hussain et al., 2013; Mishra and Choudhuri, 1998; Pourrut et al., 2011; Sethy and Ghosh, 2013). In the present study, as a result of the use of 10 different genotypic varieties of peanut, both positive and negative effects of Pb were determined on the varieties. Similar to the results determined in this study, Islam et al. (2007) reported that at higher concentrations, lead accelerates germination and also causes adverse effects on the length of the radicle and hypocotyl in *Elsholtzia argyi*. Additionally, the results were similar to those of (Xiong, 1998), who studied lead uptake and tolerance of *Brassica pekinensis*. Plant species vary in the level of tolerance to elements for growth but may cause excessive mineral toxicity. These differences can be attributed to variable ion translocation to plant organs. The results of the present

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67256738

findings appear to be a useful indicator for determining the toxic nature and tolerance indices of Pb in *Arachis hypogaea*. Plants differ in their tolerance level to metal stresses. This information can be considered to be a step that contributes to discovering and finding the tolerance limit of *Arachis hypogaea* in lead treatments at different concentrations.

Conclusion

Traditional breeding practices and methodologies of plants have not been successful in providing resistance to different biotic and abiotic stresses due to species restrictions in the natural system. As a result, considering that the germination percentages of some peanut varieties give the highest values, especially at 200 mg L^{-1} lead dose. But, Batem-5025 variety was found to be the most tolerant variety against lead poisoning in terms of germination rate, germination index and importantly seedling vigor index. It is thought that peanut varieties have different mechanisms at the cell level and that these plants work simultaneously with multiple mechanisms, and that further investigation is needed to reveal clearer Pb tolerance and hyperaccumulation. Likewise, among the peanut varieties that have been taken into the test, other breeding studies should be carried out for varieties that show the most resistance to lead toxicity.

Abstract. *Bursaphelenchus xylophilus* became one of the most damaging forest pests in recent years in Hunan province, and caused remarkable losses of pine tree. In order to explore the effect of fire disturbance on the prevention of *Monochamus alternatus* and *B. xylophilus.* forests dominated by *Pinus massoniana* were taken as the object of the study in Daolin town, Ningxiang city, Hunan province, China. Three kinds of forest were selected, such as healthy forest of *Pinus massoniana* (Control Ⅰ), infected forest without prevention(Ⅱ), and infected forest with prevention(Ⅲ). Then, 6 plots were set in every object forest. Three were the control plot, and the other three were treated with prescribed burning. We continuously investigated the number of *M. alternatus* and *B. xylophilus* before and after low intensity prescribed burning. The results indicated that the quantity of female *M. alternatus* in the three kinds of fire disturbance plots were reduced by 88.24%, 75.00% and 94.74%, respectively, while the males were reduced by 77.78%, 81.82% and 88.89% before and after the fire. There were significant differences for the quantity of *M. alternatus* before and after the prescribed burning (P<0.05). The results showed that the prevention efficacy of Ⅱ-2 was the best. Within 10 to 20 days after the fire, the quantity of *B. xylophilus* carried by *M. alternatus* changed significantly. The average quantity of *B. xylophilus* carried by female and male *M. alternatus* dropped from 1135 to 6 and from 397 to 35, respectively. It showed that prescribed burning could reduce the population density *of M. alternatu*s and carrying quantity of *B. xylophilus* of each *M. alternatus*. So prescribed burning could control the spread of pine wilt disease and prevent its outbreak. Prescribed burning has an important theoretical and practical significance in pine wilt disease prevention.

Keywords: *Monochamus alternatus, Bursaphelenchus xylophilus, pine wilt disease, fire disturbance, Pinus massoniana*

Introduction

Pine wood nematode disease, also known as pine wilt disease, is a devastating disease of pine. It can damage more than 50 species of pinus and a few non-pinus species and create huge economic losses (Yang et al., 2003; Gu et al., 2005; Pan, 2011; Lee et al., 2013). *M. alternatus* is the main vector of *B. xylophilus*. Nematodes invade healthy pine trees by feeding of adult beetles and by laying eggs of female beetles. Once the pine tree was infected, it died in a short time (Pajares et al., 2010; Teale et al., 2011; Chen et al., 2012; Shi et al., 2019). Studies had shown that *B. xylophilus* moves to the surface of *M. alternatus* before they fly out of the diseased trees, then it enters the body of *M. alternatus* through the ventral valve (Aikawa, 2008; Chen and Tu, 2012). Therefore, it is very important to control the transmission of pine wood nematode disease.

At present, physical, chemical and biological methods, such as trapping device, black light, wood trapping and killing were mostly used to control the population density of *M. alternatus* and *B. xylophilus* (Sanchez-Husillos et al., 2015; Zhu et al., 2017). Contact stomach toxicity, internal absorption, and agents with strong permeability, such as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67396752

thiophosphorus thiaziamprid, chloramine, phosphorescent milk, etc. were generally used in chemical control like artificial and aircraft spray or trunk injection agent (Zhang et al., 2010; Zhan, 2014).

Biological control was dominated by the release of *Metarhizium anisoplia* and *Beauveria bassiana* as well as natural enemies (such as *Dastarcus helophoroides* and *Sclerodermus* SPP.) (Liu et al., 2007; Yang et al., 2013; Luo et al., 2015). Although scholars had done a lot of research and made great progress in the control of *M. alternatus* and pine wilt disease, there were some limitations in various control theories and technologies. It was difficult to popularize physical control in large areas. Chemical control caused secondary pollution and had a high cost. Biological control was less effective (Chou, 2015). Therefore, in order to prevent the occurrence and spread of pine wilt disease, exploring effective control technologies is necessary. This experiment attempted to control the population density of the vector insects of pine wilt disease by prescribed burning.

Prescribed burning refers to using low-intensity fire to remove undergrowth fuel at certain ecological conditions by planned and purposeful artificial control. It is a technique that achieves certain desired results for one or more goals, such as preventing forest fire, promoting natural regeneration, improving wildlife feed sources and reducing forest pests and diseases. Prescribed burning is an important measure for the healthy management of plantation, which is to take advantage of forest fire and reduce the source of diseases and pests in fuels and dead leaves.

Studies in home and abroad had shown that prescribed burning can reduce large-scale outbreaks of insect pests, and it is now used as a strategy to prevent the occurrence of trunk borer pests (Cui and Tian, 2010). Wang found that it was suitable for *Dendrolimus superans* and *Clostera anastomosis* prevention by low intensity prescribed burning (Wang, 2005). The population density of *D. superans* decreased by 1.793 times in prescribed burning plot compared to control plot, and the rate of trees infected by *C. anastomosis* decreased by 78.56 percentage. Cha et al. (2019) researched the control of *Mycosphaerellalaric-leptolepis* Ito et al. by prescribed burning. Prescribed burning reduced the fallen leaves which were infected by diseases. It can achieve the purpose of reducing and controlling the disease, and the effect of prevention was obvious, the cost of prevention was significantly reduced. Futai (2013) used the technology of prescribed burning to control grey spot, poplar leaf rust and poplar rot, and the average control effect were 76.9%, 83.7% and 79.02, respectively. It showed that the effect was remarkable, and the cost of prescribed burning was 20 times lower than that of chemical control. Han et al. (2003) used prescribed burning to prevent forest diseases, pests and mice in Xiaoxing'an Mountains. The results showed that prescribed burning had a good effect on the pest and leaf disease.

More and more attention had been paid to the research on the effects of prescribed burning on forest pests and diseases. It is well known that high intensity fire wreaks forest ecosystems, while low-intensity fire reduces litter, the combustibility of stand and the source of diseases and insects in the forest. Low-intensity fire promotes the sustainable development of forest ecosystems.

In this study, the technology of low-intensity prescribed burning was set up in the experimental stands. In order to find a new prevention and control technology, we want to study the effect of fire disturbance on the population density of *M. alternatus* and pine wilt disease. It has great significance in the theoretical and technical innovation of pine wilt disease prevention and control.

Materials and methods

Study area

The experiment plot was located in Ningxiang County, Hunan province, with a latitude of 27°55′N to 28°06′N and a longitude of 112°39′E to 112°47′E. It belongs to Hilly landform, the terrain is higher in the northwest and southeast, while there is an alluvial plain in the middle (Huang, 2014). It is characterized by mainland monsoon climate. The alternation of warm and cold air are more obvious, with four distinct seasons. The average annual temperature and the average annual precipitation are about 16.6℃ and 1384.2 mm, respectively. The area is dominated by subtropical evergreen broadleaved forests with a forested cover of 42%. The coniferous forests consist of *Chinese fir* (*Cunninghamia lanceolata* [Lamb.]) and *Pinus massoniana* primarily, and broadleaved forests are dominated by *Phyllostachys heterocycla*, *Schima superba* and *Liquidambar formosana*. These were grouped into pure coniferous, pure broadleaved, and mixed forests. The economic forests are *Citrus reticulata*, *Camellia oleifera*, *Vernicia fordii* and *Sapium sebiferum*.

Experimental design

The trapper consists of an umbrella cover, a circular funnel, a cross baffle and a bug barrel. Attractants (APF-Ⅰ) and the trapper were produced by Fujian Chenkang agricultural and forestry technology co. LTD. In addition, various instruments and materials, such as anatomic tools, gauze, distilled water, hydro extractor, dropper, microscope slide, cover slide and microscope were used in the experiment.

All the plots were located in the middle slope, with a latitude of 28°1′N and a longitude of 112°44′E. The average height of the stand was 7 to 8.5 m, the average diameter at breast height of the stand was 18 to 24 cm, and the average age was 28 to 30 years and the canopy closure was 0.8. There were about 55 *Pinus massoniana* trees in each plot. Three kinds of stands, such as healthy forest (Ⅰ), infected forest without prevention (Ⅱ) and infected forest with prevention (Ⅲ), were selected in the experimental area on 11th April , 2019. Infected forest without prevention meant that there were infected trees in the stands but the infected trees were not removed. Infected forest with prevention meant that there were infected trees, which were cut down and burned. Medicine was applied on the cut hill.

Six plots were set in each experimental stand (*Figure S1*). The control plot and prescribed burning plot were repeated 3 times, so 18 plots were set up and individually numbered in *Figure 1*.

The distance between every two experimental stands was more than a 1000 m, and the distance between each group of plots was at least 50 m. The size of each plot was 30 m×30 m. The stand was a residual stand of *Pinus Massoniana* plantation after being destroyed. There were few trees in understory and shrub layer. A few other broad-leaved tree species were scattered in forest gaps.

The dead tree of pine wilt disease in infected forest was diagnosed with forest symptom. The needles of the whole crown become reddish brown, hanging upside down on the branches, and it was like fire from distant view. Then, we numbered all the dead trees. The prescribed burning plots (Ⅰ-2, Ⅱ-2 and Ⅲ-2) were cleaned up (*Figure S2*). In order to prevent the formation of forest fire weeds, shrubs and branches were cut down (branches of the trunk less than 2.5 m) and a control line with at least 10 m width was set around the prescribed burning plot.

DOI: http://dx.doi.org/10.15666/aeer/1805_67396752

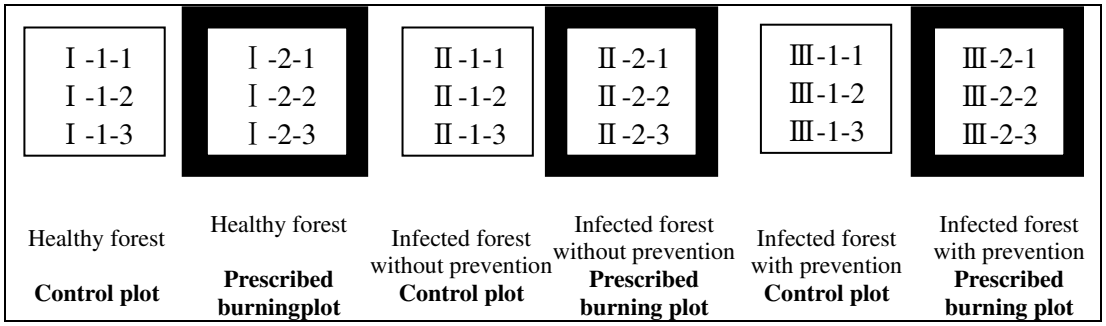

Figure 1. *Experimental design. Note: The black frame was the control line of prescribed burning plot, all of which were 10 m width*

Trappers set up and adult insect observation

In May, 2019, we began trap experiments in 18 plots. The trappers were numbered and hung in the middle of each plot (*Figure S3*). In order to maintain air circulation, weeds, shrubs and branches (which were less than 2.5 m) around the trapper were removed. The trapper was suspended from side branch of the pine tree and the bottom of the trapper was 1.5 m above the ground. To avoid collecting water of the insect bucket, 8 drain holes about 2 mm were drilled at the bottom of the insect bucket. The number of adult beetles of *M. alternatus* were recorded every 10 days during the trapping period, it included the number of females, males and the total *M. alternatus* (*Figure S4*). Numbers of *M. alternatus* which carried *B. xylophilus* were recorded. The number of *B. xylophilus* were recorded, it included the average number of *B. xylophilus* carried by females, males and the total. The attractant was replaced every 20 days.

Experiment of prescribed burning

When it was sunny continuously for five days, and there was no strong wind, we carried out prescribed burning in the non-control plots during the emergence period of *M. alternatus*. Prescribed burning was carried out in the early morning or late afternoon on the 28th June, 2019 (*Figure S5*). The wind direction and wind speed were measured before ignition, then the portable oil-drop igniter was used to light the fire every 1 m in the plot. The fire line was perpendicular to the wind direction, and the combustion effect was checked after the fire.

Identifying the female and male M. alternatus, B. xylophilus isolation

(1) Male and female *M. alternatus* were identified based on the tentacles.

(2) Isolation procedure of *B. xylophilus*: According to the principle of Baermann funnel method, an experiment was designed to isolate nematodes (Cai and Jiang, 2003). We cut up the adult beetle and wrapped debris with 2 layers of gauze, then placed it in a 10 ml centrifuge tube to which 7 ml distilled water was added. The gauze covering the fragments of *M. alternatus* was completely suspended in water (*Figure 2*). It was put aside for 24 hours, then the gauze was removed from the centrifuge tube by forceps. We placed the centrifuge tube in a centrifuge. The supernatant was centrifuged at 3000 R/Min for 3 min, then the supernatant was discarded.

DOI: http://dx.doi.org/10.15666/aeer/1805_67396752

Figure 2. *Bursaphelenchus xylophilus isolation. Note: Laboratory site: Laboratory of Forestry College in Central South University of Forestry and Technology (112°59'35"E, 28°8'15"N)*

(3) Counting *B. xylophilus*: The supernatant was stabillized to 1.5 ml with distilled water and fully shaken to absorb 0.1 ml with a pipette, the liquid was put on a microscope slide, then it was covered by a cover slide. *B. xylophilus* was observed under microscope and counted, the procedure was repeated 5 times. The number of *B. xylophilus* carried by each *M. alternatus* were calculated.

$$A = b \times 15 \qquad \text{(Eq.1)}$$

where, A is the numbers of B. xylophilus (per adult) and b is the average of five observations (per 0.1 ml).

M. alternatus were collected every 10 days from the 23rd May to the 18th July, 2019. *B. xylophilus* carried by *M. alternatus* were isolated and counted according to the above methods.

Statistical analysis

Professional software of Excel 2010 and SPSS 23 were used for data processing. One-way ANOVA of SPSS was used for variance analysis and Duncan's new complex range test was used to compare the difference levels between each treatment.

Results and discussion

Quantity of M. alternatus at different time nodes

The quantity of *M. alternatus* adults in 18 plots before and after the fire were analyzed. The quantity of *M. alternatus* in all kinds of plots before and after the fire disturbance were few, so *M. alternatus* in three kinds of plots were combined for statistical analysis. As time went on after the fire disturbance, *M. alternatus* decreased significantly. It showed that the quantity of *M. alternatus* in 20 days after the fire were lower than that of 10 days after the fire, and the quantity of *M. alternatus* in 10 days after the fire were lower than that of before the fire. There were significant differences of *M. alternatus* in stand at different time nodes ($P<0.05$) (*Figure 3a*).

The results indicated that the quantity of female *M. alternatus* in three kinds of fire disturbance plots were reduced by 88.24%, 75.00% and 94.74%, respectively, while the male reduced by 77.78%, 81.82% and 88.89% before and after the fire. The difference in numbers between males and females were unanimous. The quantity of female *M. alternatus* were larger than male at different time nodes, but there were no significant differences (*Figure 3b*).

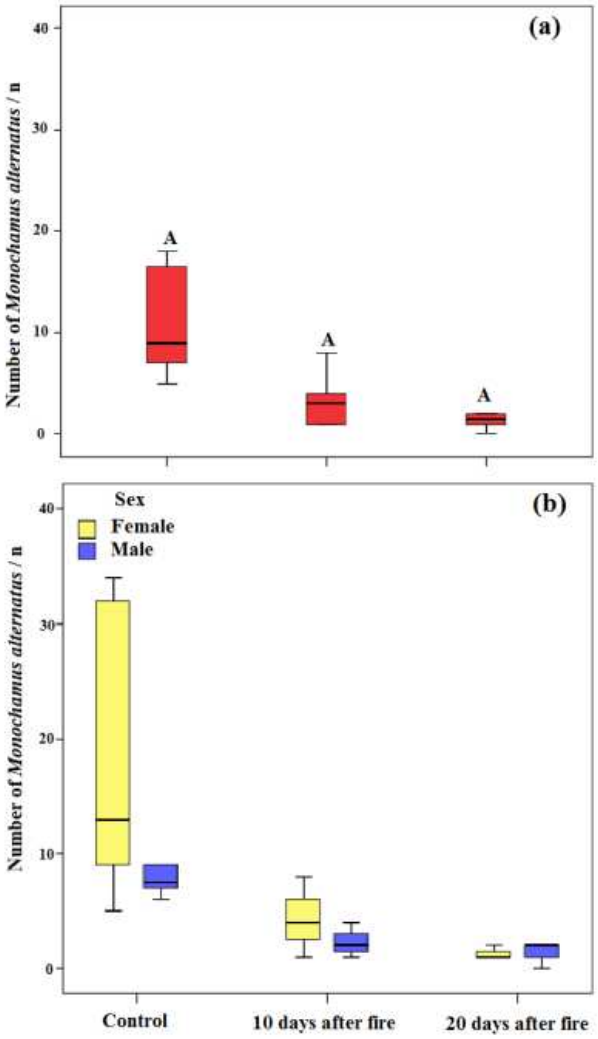

Figure 3. *Changing trend of quantity of M. alternatus at different time nodes. Note: The same letters represent significant differences (One-Way ANOVA of variance, Fish LSD of test, p<0.05). The notes in following figures were the same as in Figure 3*

B. xylophilus at different time nodes in healthy forest

In stands (I), the quantity of *B. xylophilus* at different time nodes decreased with the passage of time after the fire (10 days and 20 days) (*Figure 4a*). Within 10 to 20 days after the fire, *B. xylophilus* changed significantly (P=0.03). However, there were no significant differences of *B. xylophilus*in 10 days after the fire comparing with before and 20 days after the fire. *B. xylophilus* carried by female and male *M. alternatus* decreased with the passage of time after the fire. *B. xylophilus* carried by male *M. alternatus* changed significantly before and after the fire (P<0.05), but there were no significant differences between 10 days after the fire and 20 days after the fire. *B. xylophilus* carried by female *M. alternatus* showed significant differences between 20 days after the fire (6.33±1.97) and before the fire (1209.14±58.07) (P=0.01), and *B. xylophilus* 20 days after the fire were significantly lower than 10 days after the fire (1031.14±50.75, P=0.04) (*Figure 4b*).

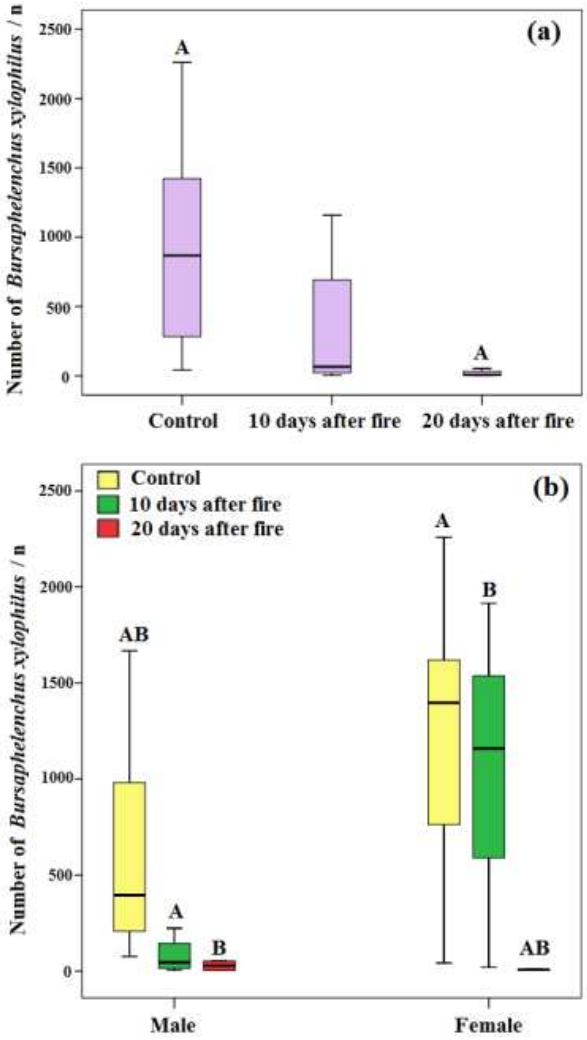

Figure 4. *Significance of B. xylophilus at different time nodes in healthy forest*

B. xylophilus at different time nodes in infected forest without prevention

In stands (Ⅱ), the quantity of *B. xylophilus* 10 days after the fire were significantly higher than in other time nodes (P<0.05), while there was no significant difference between 20 days after and before the fire (*Figure 5a*). *B. xylophilus* carried by female and male *M. alternatus* had the same change trend at different time nodes. *B. xylophilus* carried by male *M. alternatus* were significantly different at different time nodes. 10 days after the fire (316.00±74.17) the number of *B. xylophilus* were significantly larger than that before the fire (119.23±6.77), and 20 days after the fire (54.50±16.53) *B. xylophilus* decreased significantly. *B. xylophilus* carried by female *M. alternatus* were significantly different at different time nodes consistently with male *M. alternatus*. Compared with before the fire, *B. xylophilus* increased significantly 10 days after the fire (P=0.007) and decreased significantly 20 days after the fire (P=0.003). Within 10 to 20 days after the fire, *B. xylophilus* carried by female and male *M. alternatus* in prescribed burning plots were significantly lower than before the fire. The results indicated that prescribed burning could control the spread of pine wilt disease, but the effects do not appear immediately after the fire (*Figure 5b*).

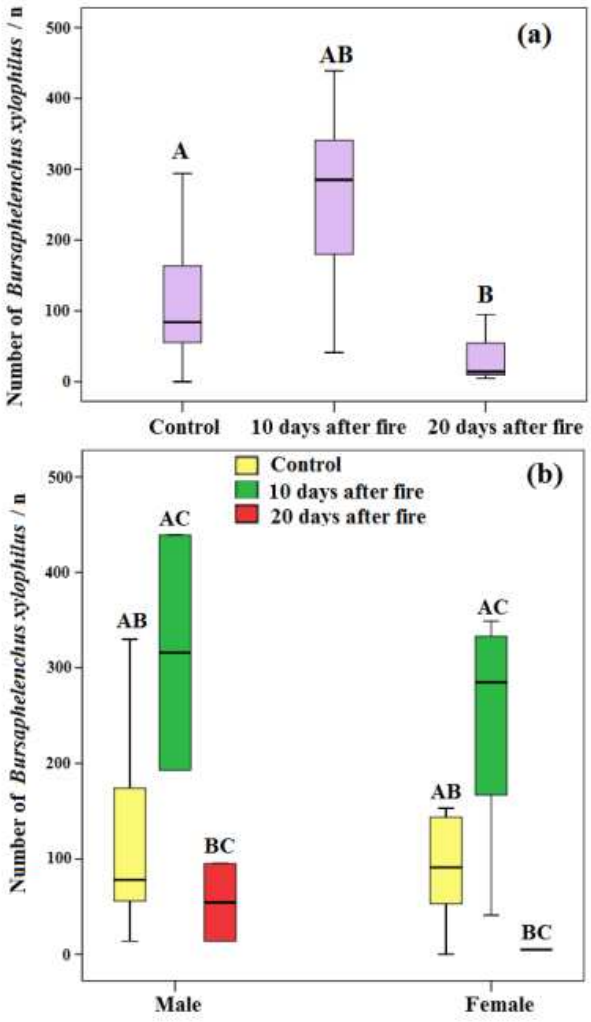

Figure 5. *Significance of B. xylophilus at different time nodes in infected forest without prevention*

B. xylophilus at different time nodes in infected forest with prevention

In stands (Ⅲ), changes of *B. xylophilus* were basically the same as in other stands (Ⅰ) (*Figure 6a*). *B. xylophilus* decreased with the passage of time after the fire in both female and male *M. alternatus*. *B. xylophilus* carried by male *M. alternatus* were significantly lower 20 days after the fire than 10 days after (P=0.012), and before the fire (P=0.000), while *B. xylophilus* did not decrease significantly 10 days after the fire. *B. xylophilus* carried by female *M. alternatus* before the fire were significantly larger than that of 10 days after the fire (P=0.031), and *B. xylophilus* carried by female *M. alternatus* 10 days after the fire were significantly larger than that of 20 days after the fire (P=0.000). There were significant differences among different time nodes (P<0.05) (*Figure 6b*).

Effectiveness of B. xylophilus prevention by prescribed burning

In three kinds of stand, within 10 to 20 days after the fire, *B. xylophilus* carried by female and male *M. alternatus* reduced significantly (carried by female: P=0.01; carried

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67396752

by male: *P*=0.022). The average quantity of *B. xylophilus* carried by female and male *M. alternatus* dropped from 1135 to 6 and from 397 to 35, respectively. It showed that prescribed burning could reduce the population density *of M. alternatu*s and quantity of *B. xylophilus* carried by *M. alternatus*. So it is beneficial to use prescribed burning to control the spread of pine wilt disease and prevent its outbreak (*Table 1*). This was consistent with the findings of Wang et al. (2019) that the amount of *B. xylophilus* carried by female *M. alternatus* were about 1.29 times of male adults.

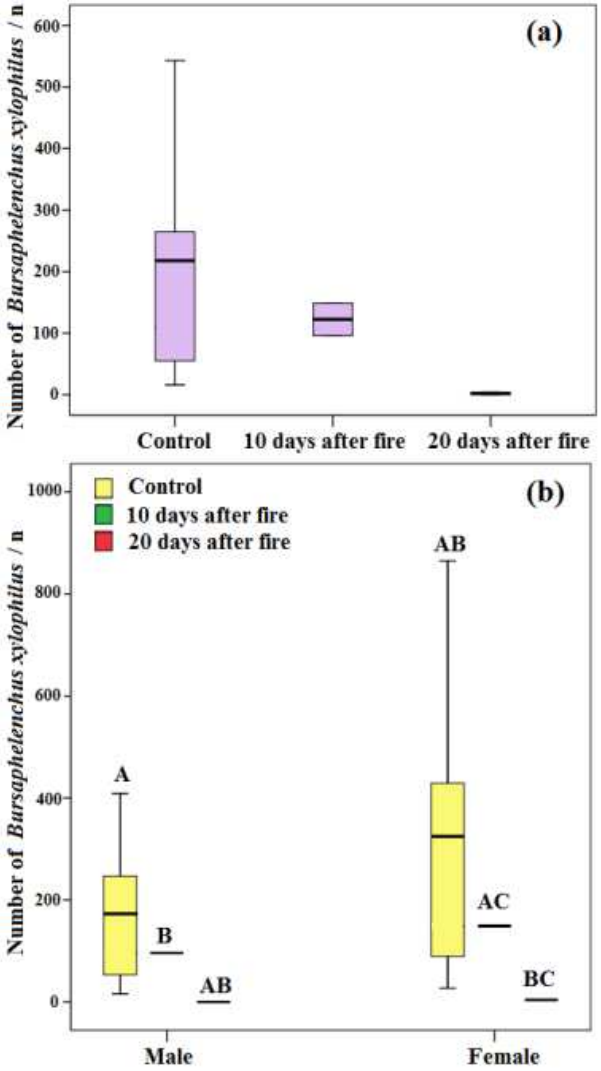

Figure 6. *Significance of B. xylophilus at different time nodes in infected forest with prevention*

Comparison of prevention effectiveness by prescribed burning

The mean number of *M. alternatus* in three kinds of stand were analyzed before and after the fire, the results showed that the quantity of *M. alternatus* in three kinds of fire disturbance plots were reduced, but only stands Ⅱ-2 and Ⅲ-2 reduced significantly (Ⅱ-2: *P*=0.012, Ⅲ-2: *P*=0.026). So it indicated that the prevention efficacy of fire disturbance in plots Ⅱ and Ⅲ were significantly better than in plot Ⅰ, and the prevention efficacy of Ⅱ-2 was the best (*Figure 7*). Whether it was the high

DOI: http://dx.doi.org/10.15666/aeer/1805_67396752

temperature that killed the pupa in the xylem of *Pinus massoniana* or that killed the emergence of adult beetle, or other mechanisms and the comprehensive effect of various factors need further research.

Table 1. *B. xylophilus carried by female and male M. alternatus before and after the fire*

Plots serial	Trapping time	Female *M.alternatus* (n)	*B.xylophilus* carried by female *M. alternatus* (n)	Male *M.alternatus* (n)	*B.xylophilus* carried by male *M.alternatus* (n)
Ⅰ-2	Before the fire	20	1073	9	420
Ⅱ-2		28	740	8	556
Ⅲ-2		19	1593	8	216
Ⅰ-2	10 ~20 days after the fire	2	7	2	29
Ⅱ-2		1	7	2	55
Ⅲ-2		1	4	2	20

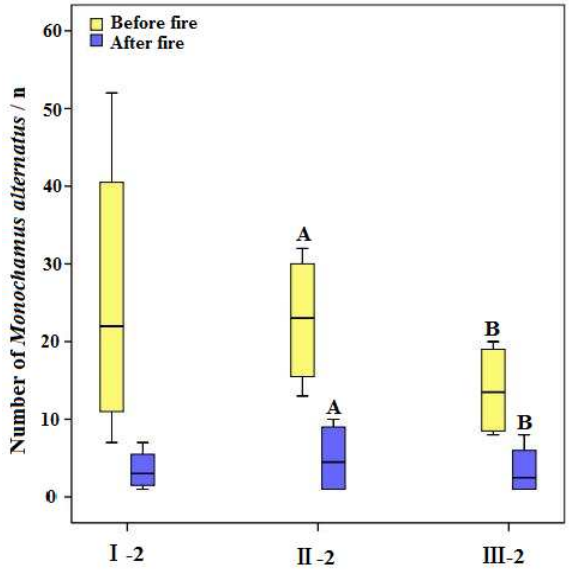

Figure 7. *Significance of M. alternatus in different plots*

Conclusion

In this study, there were no significant changes of *B. xylophilus* carried by female and male *M. alternatus* within 10 days after prescribed burning. However, within 10 to 20 days after prescribed burning, *B. xylophilus* carried by *M. alternatus* decreased significantly. This may be due to that *M.alternatus* in the upper part of the tree were not affected by fire and smoke, so neither *B. xylophilus* carried by *M. alternatus* were affected by fire. However, *M. alternatus* adult beetle, chrysalis and *B. xylophilus* stayed on the lower part of the trunk, thus these were inevitably affected by fire. This explains the sharp drop in the number of *M. alternatus* after prescribed burning, while the reduction in the number of *B. xylophilus* was delayed. In this study, *B. xylophilus* carried by female *M. alternatus* were significantly higher than that by male. The results showed that prescribed burning significantly reduced the population density of *M. alternatus* in *pinus massoniana* forest.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67396752

The control efficacy of prescribed burning in plot (Ⅲ-2) was not as good as in plot (Ⅱ-2), the main reason is as follows: Firstly, it may be due to the occurrence of pine wilt disease. The infected trees had a strong attraction to *M. alternatus*, and the early stage of dead trees of pine wilt disease is often distributed in small groups, so *M. alternatus* are often distributed intensively (Parker et al., 2006). Secondly, the dead trees in the plot (Ⅲ-2) had been cut down and burned on the spot, so the distribution of *M. alternatus* scattered on the plot. The process of burning dead trees released heat and smoke, so *M. alternatus* spread to the surrounding.

It was an innovative research to control pine wilt disease by prescribed burning. The control efficacy is obvious, the cost of control technology is significantly reduced, and the method is simple and easy to operate. It can not only prevent the outbreak of pine wilt disease, but also promotes the transformation of ground litter, reduces combustion of stand and enhances soil fertility. In addition, prescribed burning has low cost, which makes up for the deficiency of existing prevention and control technologies. The technology has broad prospects in application. However, the question of whether high temperature killed the pupa in the xylem of *Pinus massoniana* or it prevented the emergence of adult beetle needs further research along with other questions (such as mechanism and the comprehensive effect of various factors).

Abstract. A completely randomized design experiment was used to determine the effects of aqueous extract of *Moringa oleifera* leaf (AEMOL) on growth, sensory and histology parameters of broiler chickens. Treatment 1 served as the control (antibiotics), Treatment two was given ordinary water ($AEMOL_0$). Treatments 3, 4, 5 and 6 contained 30, 60, 90 and 120 ml of AEMOL per litre of water per day, respectively. Data obtained were analyzed using one-way analysis of variance and mean separation was done using Duncan's test for multiple comparisons. Results showed that the extract influenced ($P < 0.05$) the feed intake and water intake at the broiler starter phase WHILE birds on the control diet had higher values. Finisher phase results showed that final weight, weight gain, feed intake, FCR and water intake were influenced ($P < 0.05$) by the extract with birds treated with 60 ml/l of AEMOL doing better for most parameters except the FCR. All the digestibility and sensory parameters measured were also influenced ($P < 0.05$) by the extract. However, histological parameters measured were not affected ($P > 0.05$) by the extract. It could be concluded that the extract inclusion levels up to 90 ml/l can be used to replace antibiotic growth promoter without compromising the advantages of antibiotic growth promoter.
Keywords: *antibiotics, performance, replace, phytochemical*

Introduction

Broilers are a good source of protein and income to many households and therefore their production attracts the attention of many people. Poultry production remains the most extensive and widely practiced of all livestock enterprises and an important component of socio-cultural and economic development in most countries as well as in food security improvement (Alders, 2005; Dieye et al., 2010). However, the industry in the developing countries is facing some challenges which amongst others include, high feed consumption to gain ratio and high cost of feed due to high prices of feed ingredients (Abbas, 2013). Numerous attempts have been made to overcome these challenges. One of such is the use of antibiotics as growth promoters and to prevent outbreak of diseases (Manyi-Loh et al., 2018), though not without attendant problems such as drug toxicity, residual effects and development of bacterial resistance (Finley et al., 2013). This has led to the ban on the use of antibiotics as growth promoters since

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67536764

2006 by the European Union, thereby shifted attention of researchers to safe alternatives such as the use plants/herbs (phytobiotic) in place of antibiotics. Some plants, such as *Moringa oleifera*, has been found to contain phytonutrients and phytochemicals as secondary metabolites which are physiologically active agents with therapeutic properties as antibiotics. Whereas the human medicinal uses of *Moringa oleifera* has been studied for many years its use in livestock production has received little attention (Nouman et al., 2013). Recently, research is focusing on its possible use to enhance growth, and nutrient utilization as a livestock fodder crop (Nouman et al., 2013). Incorporation of this herb and its products in livestock feeds and water instead of synthetic products have resulted in more rapid gain, higher production and better feed efficiency (Portugaliza and Fernandez, 2012). Other reports have indicated that Moringa oleifera leaves have potential prebiotic and antioxidant effects (Siddhuraju and Becker, 2003; Teixeira et al., 2014; Alabi et al., 2017). The underlying effects of the bioactive compounds in M. oleifera leaves are believed to induce prebiotic effects, bacterial and immune-stimulant activities (Ghazalah and Ali, 2008) resulting in increased productivity of broiler chickens.

Although there are several studies on the use of *Moringa oleifera,* however, there are scanty reports on the use of the aqueous *Moringa oleifera* leaf extract in drinking water to determine its impact on growth performance of broilers in poultry production in Minna, Middle Belt Nigeria. The aqueous extract of *Moringa oleifera* leaf is readily available, accessible and cost effective for use by the farmers and households. The present study was therefore designed to determine the effect of graded doses of aqueous *Moringa oleifera* leaf extract on growth performance, sensory and histopathology of broiler chickens and compare such with antibiotic treated broilers.

Materials and methods

This experiment was conducted at the Teaching and Research Farm of the School of Agriculture and Agricultural Technology, Federal University of Technology, Minna, Niger State. Minna lies within latitude 9° 37′ North and longitude 6° 32′ East. The average temperature in Minna is between 19 to 37 °C with an annual rainfall of 1312 mm. The mean annual relative humidity is between 21 and 73% (Climatetemp, 2016).

Sample preparation

The leaves of *Moringa oleifera* were harvested from Minna town and environs. They were air-dried in order to ease pounding and were subsequently ground to powder using a blender. The leaf powder was soaked in water after which the solution was drained using a 1 mm mesh. The chemical composition of the extract was determined.

Experimental design, treatments and procedures

A total number of 240-day old Hubbard broiler chickens were purchased from B-not Harel hatchery Ibadan, Nigeria. The birds were kept under intensive management for eight weeks. The birds were randomly allocated to six aqueous extract of *Moringa oleifera* leaf (AEMOL) treatments. Treatment 1 served as the control (having the antibiotics), while treatment 2 was given ordinary water to serve as $AEMOL_0$. Treatments 3, 4, 5 and 6 contained 30, 60, 90 and 120 ml of aqueous extract of *Moringa oleifera* leaf (AEMOL) per litre per day of water, respectively (*Table 1*). The treatments

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67536764

were replicated four times and each replicate had 10 birds. All necessary management requirements were strictly followed. Throughout the study, feed was given *ad-libitum*. Each treatment was fed broiler starter diet between day 1 and 21; and broiler finisher diet between days 22 and 56. Water was provided for 20 h and deprived of water for 4 h while placed on treatment dosages (so that the birds can take the treatment dosages).

Table 1. *Aqueous Moringa oleifera leaf extracts (AEMOL) inclusion levels*

Treatments	Inclusion level
AEMOL $_{0+}$	Control (Gendox® 1.25 mg/l)
AEMOL $_{0}$	0 ml/l
AEMOL $_{30}$	30 ml/l
AEMOL $_{60}$	60 ml/l
AEMOL $_{90}$	90 ml/l
AEMOL $_{120}$	120 ml/l

Growth performance

A known quantity of the feed was given to the chickens daily for a period of four weeks with the left over collected every morning (weighed and recorded) throughout the experimental period. The daily feed intake was obtained by subtracting the left-over quantity from the initial quantity offered the previous days. The feed was weighed using weighing balance (RADWAG). The feed conversion ratio (FCR) was calculated as dry matter intake per unit weight gain.

On day 21, digestibility study was carried out. This involves feeding the animals daily with known quantity of feed. A three-day acclimatization period was allowed prior to a four-day collection period. Droppings voided by each bird were collected on a daily basis at 09.00 am. Care was taken to avoid contamination from feathers, scales, debris and feeds. Total faeces voided by each replicate were collected using a collection tray. The faeces was weighed (wet basis) and oven dried at 85˚C until a constant weight was obtained. At the end of the faecal collection the total dry faeces for each replicate was bulked, mixed and 30% of it was weighed and ground to a size that could pass through a 2-mm sieve for proximate analysis. The difference between the nutrients in the feed consumed and the faeces or nutrients in the faeces voided multiply by 100 gives the apparent digestibility coefficient of the feed, i.e. FC (feed consumed) – FV (faeces voided) X100 = apparent digestibility coefficient of the feed.

Sensory evaluation

Meat samples from the breast meat were taken from two birds randomly selected from each of the replicates of the experimental birds and 5 g of salt was added to the meat before being subjected to boiling and frying. Samples of meat from each treatment were collected after removing the flesh from the bone (manually), cut into chops of an average weight of 40 g and labelled for identification. The meat was cooked in a pot with water at a temperature of 65 °C for 30 min using a gas cooker as described by Vasanthakumar et al. (1999). Twenty trained panelists were used in the assessment procedure. They were instructed to chew a sample from each treatment. The scoring was based on parameters stated on the scoring sheet: for appearance, juiciness, flavour, tenderness and overall acceptability. Water was served to the panelists to rinse their

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67536764

mouth after scoring each sample to reduce flavour carryover. The panelists scored each sample on a nine-point hedonic rating scale adopted from Vasanthakumar et al. (1999).

Histopathology

After the completion of the experimental period, the histological analysis was carried out at the histology laboratory of the Faculty of Veterinary medicine, Usman Danfodio University, Sokoto, Nigeria. Two birds per replicate were randomly selected, slaughtered, weighed and examined for respiratory tract gross lesions. Both lungs were removed and weighed. Tissue samples of the liver, lungs, kidney, intestine, spleen and heart were taken and fixed in 10% formalin. The tissues were dehydrated through a graded concentration of ethanol (70, 95 and 100%), cleared in xylene and embedded in paraffin wax. The embedded tissues were stained with hematxylene and eosine for light microscopic examination. Lesions observed were photographed using the Vanox T Olympus photographing microscope as described by Richard et al. (2008).

Lung weight expressed as a ratio of body weight was called the lung: body weight ratio. The thoracic air sacs were assigned gross lesion scores, where 0 = clear, 1 = cloudy, 2 = cloudy with minimal caseous exudate accumulation and 3 = severe caseous exudate accumulation. A 2.5-cm longitudinal hemi-sectioned portion of trachea from each chicken was immersion-fixed in a coded container that was three-quarters full of 10% formalin saline routinely processed, stained with haematoxylin and eosin and examined under light microscope. The severity and distribution of mucosal morphological lesions (loss of cilia, epithelial cell hypertrophy and hyperplasia, inflammation and necrosis) in sections of trachea were recorded. A score was assigned to each lesion and its distribution, which was the sum of A + B, where A represents the severity of the lesion within the section and B represents the distribution of the lesion across the section. For injury distribution, scores were either 0 = no injury, 1 = focal injury, 2 = multi focal injury or 3 = diffuse injury. For each of loss of cilia, epithelial cell hypertrophy/hyperplasia, inflammatory infiltrate and necrosis, a severity score was assigned where 0 = no cells (0%) affected, 1 = < 25% of cells affected, 2 = 25 to 50% of cells affected, 3 = 50 to 75% of cells affected and 4 = > 75% of cells affected. For inflammation, 0 = none, 1 = minimal: if inflammatory cells were directed toward the lumenal epithelium; 2 = mild: if inflammatory cells predominated within the epithelium, and fewer inflammatory cells were found in the lamina propria; 3 = moderate: if inflammatory cells were found scattered throughout the mucosa; and 4 = marked: if sheets of inflammatory cells filled the mucosa.

Data analysis

All data obtained were subjected to analysis of variance (ANOVA) for a completely randomized design. Where differences occurred, they were separated using Duncan's new multiple range test (SAS, 2013).

Results

Proximate and phytochemical composition of Moringa oleifera

The proximate composition of *Moringa oleifera* leaf meal analysis is presented in *Tables 2* and *3*. The dry matter, ether extract, crude protein, crude fibre, ash, and nitrogen free extract contents

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67536764

Moringa oleifera leaf meal contained 0.11 µg/ml of total flavonoids, 9.97 µg/ml of total phenols, 0.26 mg/ml of alkaloids, 1.17 µg/ml of tannins and 245.3 µg/ml of saponins. The aqueous extracts of *Moringa oleifera* leaf contained 0.11 µg/ml of total flavonoids, 10.78 µg/ml of total phenol, 0.21 mg/ml of alkaloids, 5.33 µg/ml of tannins and 22.55 µg/ml of saponins. While the aqueous *Moringa oleifera* residues had 1.22 µg/ml of total flavonoids, 9.70 µg/ml of total phenols, 0.27 mg/ml of alkaloids, 3.83 µg/ml of tannins and 195.3 µg/ml of saponins.

Table 2. *Proximate composition of Moringa oleifera*

Parameters	Percentage composition (%)
Dry matter	94.25
Ether extra	5.50
Crude protein	23.80
Crude fibre	16.57
Ash content	9.75
Nitrogen free extracts	38.63

Table 3. *Phytochemical composition of Moringa oleifera leaf meal, aqueous Moringa oleifera leaf extracts and Moringa oleifera residues*

Parameter	*Moringa* preparations		
	Ground *Moringa oleifera* leaf meal	Aqueous *Moringa oleifera* leaf extracts	*Moring oleifera* residues
Total flavonoids (µg/ml)	0.11	0.11	1.22
Total phenols (µg/ml)	9.97	10.78	9.70
Alkaloids (mg/ml)	0.26	0.21	0.27
Tannins (µg/ml)	1.17	5.33	3.83
Saponins (µg/ml)	245.30	22.55	195.30

Effect of aqueous extract of Moringa oleifera leaf on growth performance of broiler chickens at both starter and finisher phases

Table 4 shows the results of the effects of aqueous extract of *Moringa oleifera* leaf on growth performance of broiler chickens during the starter and finisher phases. The initial, final, growth rate, feed conversion ratio and mortality were not influenced ($P > 0.05$) by AEMOL treatments at the starter phase. However, feed intake and water intake were influenced ($P < 0.05$) by AEMOL treatments.

Birds on the $AEMOL_0$ treatment had the highest feed intake and was significantly ($P < 0.05$) higher than all other treatments which had similar ($P > 0.05$) feed intake values.

Water intake results showed that birds on control and $AEMOL_0$ treatments had the highest water intake, which were significantly higher ($P > 0.05$) than those birds on $AEMOL_{30}$ treatment.

The results of the growth performance at the finisher phase showed that all parameters measured were influenced ($P < 0.05$) by AEMOL treatments except the initial weight and the water intake which were not affected. Birds on AEMOL 60 ml/l had highest final weight and feed intake and were significantly ($P < 0.05$) higher than

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67536764

all the other treatments. Similarly, the weight gain results showed that birds on AEMOL 60 ml/l had significantly ($P < 0.05$) higher value than all the other treatment except for birds on the control treatment. The feed conversion ratio results showed that birds on the control treatment had the best value and was significantly ($P < 0.05$) better than all the other treatments.

^{a,b,c,d,e,f}Means within the same row with different superscripts are significantly different at $P < 0.05$; $AEMOL_{0+}$ contained Gendox® 1.25 mg/l of water, $AEMOL_0$ contained 0 ml of moringa extract/l of water, $AEMOL_{30}$ contained 30 ml of moringa extract/l of water, $AEMOL_{60}$ contained 60 ml of moringa extract/l of water, $AEMOL_{90}$ contained 90 ml of moringa extract/l of water, $AEMOL_{120}$ contained 120 ml of moringa extract/l of water

Effect of aqueous extracts of Moringa oleifera leaf on apparent nutrient digestibility of Hubbard broiler chickens

Apparent nutrient digestibility results are shown in *Table 5*. The apparent nutrient digestibility results showed significant difference in all the treatments in the following order of highest to lowest: $AEMOL_0$, $AEMOL_{90}$, $AEMOL_{60}$, control, $AEMOL_{120}$ and $AEMOL_{30}$ respectively. Similar to the dry matter, the crude fibre digestibility differed significantly in all the treatments in the following order of highest to lowest: $AEMOL_0$, $AEMOL_{90}$, $AEMOL_{120}$, $AEMOL_{30}$, $AEMOL_{60}$ and control, respectively.

The ether extract digestibility results showed that the birds on $AEMOL_0$ treatment had the highest digestibility and their values were significantly ($P < 0.05$) higher than all the other treatments. Birds on $AEMOL_{30}$ and $AEMOL_{90}$ treatments had similar ($P > 0.05$) ether extract values. Similarly, birds on $AMOLE_{60}$ and $AEMOL_{120}$ treatments had similar ($P > 0.05$) ether extract digestibility. Their digestibility values were, however, lower ($P < 0.05$) than those on $AEMOL_{30}$ and $AEMOL_{90}$ treatments. Bird on the control treatment had the least ether extract digestibility and they were significantly lower ($P < 0.05$) than all the other treatments.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67536764

The crude protein (CP) digestibility results showed that birds on $AEMOL_0$ and $AEMOL_{60}$ treatments had the highest CP digestibility and their digestibility were higher ($P < 0.05$) than the ones in other treatments. Birds on $AEMOL_{90}$ had significantly higher ($P < 0.05$) CP digestibility than those on control, $AEMOL_{120}$ and $AEMOL_{30}$ which were all significantly different ($P < 0.05$) from one another.

Birds on $AEMOL_0$ and $AEMOL_{60}$ had similar ($P > 0.05$) NFE (nitrogen free ether) digestibility. Their digestibility values were significantly ($P < 0.05$) lower than those of birds on $AEMOL_{90,}$ control, $AEMOL_{120,}$ and $AEMOL_{30}$ treatments, which were significantly ($P < 0.05$) lower than one another in descending order.

Effect of aqueous extract of Moringa oleifera leaf on sensory evaluation of Hubbard broiler chicken meat

Presented in *Table 6* are the results of the effect of AEMOL treatments on appearance, flavour, juiciness, tenderness and general acceptability. All parameters measured were influenced ($P < 0.05$) by the treatments.

The meat appearance results showed that birds on the $AEMOL_0$, $AEMOL_{30,}$ and $AEMOL_{60}$ treatments had the best appearance ($P < 0.05$), but similar ($P > 0.05$) to meat from birds in $AEMOL_0$ and $AEMOL_{90}$ treatments. Likewise, meat from birds on the control, $AEMOL_{90}$ and $AMOLE_{120}$ treatments had similar ($P > 0.05$) appearance. However, the meat from birds on $AEMOL_{120}$ treatment had least value of appearance.

The results of the meat from birds on $AEMOL_0$, control, $AEMOL_{30,}$ and $AEMOL_{60}$ treatments, their values were similar ($P > 0.05$) in flavour but those on $AEMOL_0$ treatment had the best flavour, and were significantly better than those on $AMOLE_{90}$ and $AEMOL_{120}$ treatments. Meat of birds on control, $AEMOL_{30}$, $AEMOL_{60,}$ $AEMOL_{90}$ treatments had similar ($P > 0.05$) flavour. Meat juiciness results showed that meat form birds on control, $AEMOL_0$, $AEMOL_{30,}$ $AEMOL_{60}$ and $AEMOL_{90}$ treatments were similar ($P > 0.05$) in juiciness values. However, meat of birds from control, $AEMOL_{30}$, treatments and $AEMOL_{90}$ had more ($P < 0.05$) juiciness than those of meat of birds from $AEMOL_{120}$ treatment.

Meat from birds on the $AMOLE_0$ treatment were more tender ($P > 0.05$) than those of birds on $AEMOL_{120}$. However, their tenderness value was similar to those of birds from control, $AEMOL_{30}$, $AEMOL_{60}$ and $AEMOL_{90}$ treatments.

DOI: http://dx.doi.org/10.15666/aeer/1805_67536764

The general acceptability results showed that meat from birds on AEMOL $_0$ treatment were better and more acceptable ($P < 0.05$) than those from other treatments except meat from $AEMOL_{30}$ treatment which had similar values. Birds on control, $AEMOL_{30}$, $AEMOL_{60}$ and AEMOL $_{90}$ treatments had similar ($P > 0.05$) acceptability values and they were however significantly more acceptable ($P < 0.05$) than meat from birds on $AEMOL_{120}$ treatment.

Effect of aqueous extract of Moringa oleifera leaf on histological parameters of Hubbard broiler chickens at finisher phase

Table 7 shows the effect of aqueous extract of *Moringa oleifera* leaf on histological parameters of Liver, Lung, Kidney, Intestine, Spleen and Heart of Hubbard broiler chickens. All organs measured showed no sign ($P > 0.05$) of hypertrophy, hyperplasia, inflammation, necrosis and injury.

Discussion

The Proximate composition of *Moringa oleifera* leaf meal analysis results of dry matter (94.25), ether extract (5.50), crude protein (23.80), crude fibre (16.57), ash (9.75), and nitrogen free extract (38.63) in the present study were contrary to the values obtained by Makkar and Becker (1997) who reported the values as 2.15% of fat content, 27.29% of crude protein, 10.67% of crude fibre, 15% of ash content and 34.08% N.F.E. These differences in the value may be due to the processing methods, the period of harvesting of the plants and the climatic condition as reported by Fuglie (2001). The results also showed that *Moringa oleifera* leaf is considerably rich in protein (23.80%), crude fiber (16.57%) which is similar to the findings of Mabruk et al. (2010) and Zaku et al. (2015). However, the dry matter (94.25%) and ash (9.75%), the fat content (5.50%) and nitrogen free extract content (38.82%) contents in the present study are similar to those reported obtained by Mabruk et al. (2010) and Ogbe and John (2012).

The results also showed that aqueous processing of *Moringa oleifera* leaves do not reduce some the phytochemical properties except for saponin which were reduced. Nityanand (1997) and Akinmutimi (2004) observed similar results and reported that most processing methods employed in improving the food value of non-conventional feedstuffs do not eliminate the anti-nutritional factor substances completely.

AEMOL $_{0+}$ contained Gendox® 1.25 mg/l of water, AEMOL $_0$ contained 0 ml of moringa extract/l of water, AEMOL $_{30}$ contained 30 ml of moringa extract/l of water, AEMOL $_{60}$ contained 60 ml of moringa extract/l of water, AEMOL $_{90}$ contained 90 ml of moringa extract/l of water, AEMOL $_{120}$ contained 120 ml of moringa extract/l of water

The growth performance results in this study is in agreement with the results reported by Portugaliza and Fernandez (2012) which indicated that AEMOL inclusion levels resulted in lower feed and water intake at the starter phase which is also consistent with less water intake in all AEMOL treated groups compare to control and AEMOL$_0$. The reduction in water and feed intake in all AEMOL treated groups compare to control and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67536764

$AEMOL_{0,}$ may have translated to reduced growth performance as recorded in the present study. This is consistent with the findings of Portugaliza and Fernandez (2012). This may be due to the presence of antinutrient substance in the extract as reported by Ramchandra et al. (2019). Ramchandra et al. (2019) reported that chemical such as antinutrients substances present in the diet by themselves or their metabolic products arising in the system, reduce feed intake and thus, interfere with the feed utilization. The present results however, are contrast to the report of Oludoyi and Toye (2012) who reported a significant difference in bodyweight at week 4, between broiler chickens fed diet containing 0, 10 and > 15% MOLM, whereas no significant difference in body weight was observed between pullet groups.

The better final weight, weight gain and feed intake recorded AEMOL60 than in the control group suggests that 60 ml of AEMOL might be an optimal dose of aqueous extract of Moringa oleifera for better broiler growth performance at finisher phase. This is in line with the reports of Kakengi et al. (2003) and Olugbemi et al. (2010) who showed that Moringa oleifera inclusion levels ($AEMOL_{60}$) resulted in an increased body weight gain and feed intake due to high protein content in it. On the contrary, birds on aqueous extract of 120 ml per litre of water had the lowest weight gain despite the high protein content in the extract, suggesting an inverse growth relationship- the higher the dose, the higher the antinutrient contents and less the growth possible.

The higher feed intake at the finisher phase compared to the starter phase might be an indication that the older the birds, has better capacity to manage antinutrient contents. The improved FCR of birds on control could be as a result of the low feed intake recorded by the birds on this treatment group.

The results of sensory properties of broiler meat for the different treatments showed significant difference (appearance, flavour, tenderness, juiciness and general acceptance) among the experimental meat samples. No definite trend was in all the parameters assessed. Aqueous extract of *Moringa oleifera* leaf inclusion levels up to 90 ml/l were similar in the appearance, flavour, tenderness and general acceptability to control and recorded least flavour for $AEMOL_{120}$ treated group suggesting that AEMOL inclusion levels up to 90 ml/l can be used to replace growth promoters in terms of sensory attributes. Additionally, this might mean that poor flavour and tenderness of the meat are produced at inclusion levels above 90 ml/l. The present result is inconsistent with those of Safa et al. (2012) who reported that flavour and juiciness were not significantly influenced by *Moringa oleifera* leaf meal on broiler chickens.

The results of the histological parameters of tissue samples from the liver, lung, kidney, intestine, spleen, and heart of the broiler chickens did not show any adverse effects of administering aqueous extract of *Moringa oleifera* leaf to the broiler birds.

Conclusion

The results of this study showed that aqueous extract of Moringa oleifera leaf inclusion levels up to 60 ml/l can be used to replace antibiotic growth promoter without compromising the advantages of antibiotic growth promoter. Since it is easily available and can be source cheaply, the use may improve cost effectiveness, reduction in feed consumption with improved growth performance. It is recommended that other methods of extraction could be used to see if higher inclusion level will result in better performance.

(Received 10th May 2020; accepted 13th Aug 2020)

Abstract. This investigation was carried out during the two successive seasons of 2016 and 2017 at the private orchard of the modern agriculture company (PICO), El Behera governorate, Egypt, to study the effect of Nitrogen Fixing Bacteria (NFB) and Phosphate Solubilizing Bacteria (PSB) and different rates of N and P as mineral fertilizers (*i.e.* 50% and 75% of recommended dose), compared to the standard recommended mineral fertilization on the growth, yield, fruit quality and leaf mineral contents of Williams banana plants. Results showed that T_8 (50% bio N + 50% bio. P + 50% mineral N and P) and T_7 (100% bio N + 50% bio. P + 50% mineral N and P) enhanced plant growth *i.e.* pseudostem length and perimeter also, it increased bunch weight and yield and improved most physical parameters (*i.e.* finger no./hand, finger length, finger weight, pulp weight, pulp weight and pulp ratio) and chemical characters (T.S.S, total sugar % and reducing sugar %), leaf mineral content (N, P, and K) and chlorophyll a and b were also significantly affected by treatments compared to the control during two season of study. The results suggest that, the utilized biofertilizers can partially substitute the amount of mineral fertilizers, leading to cleaner environment.
Keywords: *P dissolving bacteria, N fixing bacteria, fruit quality, yield, Williams, sustainable agriculture*

Introduction

Banana (*Musa* sp.) is a major crop in tropical and subtropical regions of the world. In Egypt, it represents most important fruit crop after citrus and grapes. It coveres an area of 28667 hectares with production of 1228458 tons in 2017 (FAO STAT). Among Crop management practices, plant nutrition in particular represents one of the major factors influencing banana yield. Moreover, all soils are deficient in N, P and K (Akhtar et al., 2003), besides, soil organic matter contents are low (Abbas et al., 2012) and this is true in new reclaimed lands in Egypt. Fertilization is very important not only to meet the crop requirements but also to improve soil fertility.

Soil microorganisms have enormous role in increasing the availability of accumulated phosphates in the soil for plant by solubilization (Goldstien, 1986; Gyaneshwar et al., 2002; Hamim et al., 2019). Moreover, the microorganisms involved P solubilization as well as better scavenging of soluble P can enhance plant growth by increasing the efficiency of biological nitrogen fixation, enhancing the availability of other trace elements and by production of plant growth promoting substances (Goldstien, 1986). This assumes more important for banana, which is a heavy feeder crop requiring large amount of nutrients (Ganapathi and Dharmatti, 2018).

Williams is one of the most widely grown banana varieties in the world (Xu et al., 2005; FAO, 2018). In Egypt, it is cultivated successfully in newly reclaimed soils for its excellent performance, the large bunch with longer fingers, the excellent taste and high tolerance to transportation (Barakat et al., 2011). Very little information is available on the effect of biofertilizers (Azotobacter chroococcum and Bacillus megatherium var

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67656773

phospahaticum) on this variety under sandy soil condition. Thus, the present investigation was undertaken to study the effect of biofertilizers as ecofriendly, and low-cost alternative fertilizers on growth and yield attributes of Williams banana.

Materials and methods

The present investigation was conducted during two successive seasons (2016 and 2017) in a private orchard of the modern agriculture company (PICO) located at Badr city (30˚36′36.5″N and 30˚45′45.5″ E), El Behera governorate, Egypt (*Fig. 1*). Monthly average of some metrological data during study period of the experimental site is illustrated in *Figure 2*.

Figure 1. *Experimental site location*

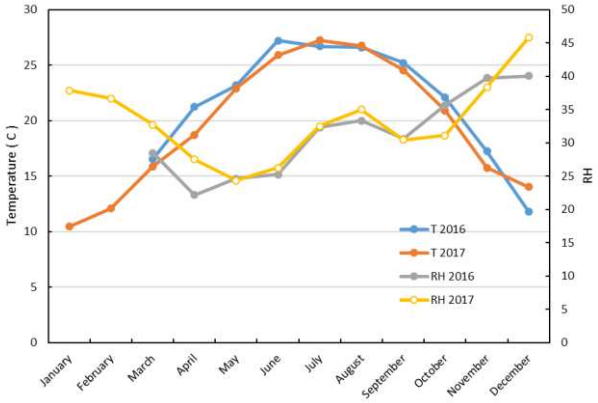

Figure 2. *Metrological data during study period of the experimental site*

At the beginning of the treatments, three soil samples were collected from different sites at 90 cm depth and analyzed as a composite sample for physical and chemical properties according to (Wilde et al., 1985). The analysis of orchard soil is presented in *Table 1*.

Table 1. *Physical and chemical analysis of soil*

Chemical properties							
pH	**E.C (mmhos/cm)**	**Organic matter %**	**Organic carbon %**	**P(available) Meq/L**	**SAR**	**K mg/100g**	**Ca Meq/L**
8.3	0.18	0.68	0.39	24	0.52	0.15	0.8
Physical properties							
Sand (%)		**Loam (%)**		**Clay (%)**		**Density (g/cm3)**	
75		8.75		16.25		1.21	

The mother plants were planted in mid-March at 3.5*1.5 m apart, received 30 m^3 organic matter/Feddan/year. Eight treatments were used; Control treatment fertilized by recommended dose of mineral fertilizers (250, 80 and 480 unite of NPK /4200 m^2/year) in forms of ammonium nitrate (33.5% N), phosphoric acid (80% P_2O_5) and potassium sulfate (48% K_2O), respectively. Two levels of each N and P (100% and 50% of recommended dose) were used in combination with two biofertilizers namely;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67656773

Azotobacter chroococcum (Az14) as nonsymbiotic nitrogen fixation bactria (N.F.B) and Bacillus megatherium var phospahaticum (B6) as phosphate dissolving bacteria (P.D.B). The strains were obtained from Bacteriology Lab, Sakha. Agric. Res. Station. Three kg/ 4200 m^2 from each inoculum was used after mixed with suitable amount of sandy soil and added once at first week of April of each season in crescentic trenches around each plant. The chemical fertilizers were added through drip irrigation system from April to October. The recommended dose of K was applied to all treatments.

The applied treatments were as follows:

T1- Control (100% mineral N, P fertilizers)
T2- 100 % Bio P (P.D.B) +100% mineral N
T3- 100% Bio P + 50% mineral P +100% mineral N
T4- 100% Bio N (N.F.B) + 100% mineral P
T5- 100% Bio N + 50% mineral N +100% mineral P
T6- 100% Bio N +100% Bio P
T7- 100 % Bio N +100% Bio P + 50% mineral N, P
T8- 50% Bio P + 50 % Bio N + 50 % mineral N, P

Vegetative growth measurements

At the beginning of the florescence emergence the following parameters were recorded; Pseudostem length (cm) which was measured from the soil surface up to the petiole of the last emerged leaf. Circumference of pseudostem (cm) at 25 cm above soil surface.

Yield and fruit quality

In mid-February of each season, bunches were harvested at the green maturity stage. At harvest, bunch weight (kg), bunch length (cm), and finger number/hand were recorded, three hands were taken randomly/ bunch/ replicate to estimate fruit physical characters including finger weigh (g), length and perimeter (cm), pulp and peel weight / finger (g) and pulp ratio. Fruit chemical characters were estimated in ripe fingers as total soluble solids in pulp juice (TSS) using hand refractometer as Brix, total titratable acidity percentage as malic acid was estimated using phenolphthalein as indicator according to (AOAC, 1985) and total and reducing sugars (Dubois et al., 1956).

Leaf chlorophyll and mineral contents

Leaf samples were taken from the middle part of third upper leaf blade. Chlorophyll (a and b) content expressed as mg/g fresh weight was determined according to Moran and Porath (1980). Leaf samples were washed and oven dried at 70c to a constant weight. Total nitrogen was determined by using micro-kjedehl (AOAC, 1985). Potassium was measured using a flame-photometer and phosphorus was determined colorimetrically (Chapman and Pratt, 1961).

Statistical analysis

The obtained data in both seasons were statistically analyzed using analysis of variance method as simple experiment in randomized complete block design (Snedecor and Cochran, 1980) using CoStat 6.303, CoHort Software, 798 Lighthouse Ave. PMB 320, Monterey, CA, 93940, USA. Duncan' multiple range test were used for means comparison (Duncan, 1955).

Results and discussion

Growth characters

Considering to height and circumference of pseudostem, data presented in *Table 2* indicate that planta treated with T_2 (100% Bio P (P.D.B) +100% N) recorded the lowest significant pseudostem length in the first season and so in the second season but with no significant difference with T3, T4 and T6. Whereas, the highest pseudostem length was recorded at T_8 (50% Bio P + 50% Bio N + 50% mineral NP), especially in the second season.

Table 2. *Effect of Biofertilizers in combination with different levels of N, P mineral fertilizers on vegetative growth characters*

Treatments	Pseudostem length (cm)		Pseudostem Circumference (cm)	
	2016	2017	2016	2017
T1	200.0a	194.8b	47.25b	49.5bcd
T2	172.5c	187.5d	40.25c	46.25e
T3	184.5b	189.5cd	49.0b	48.5cde
T4	188.3ab	191.3bcd	45.75b	47.25de
T5	199.3a	193.0 bc	49.5b	49.5 bcd
T6	195.0ab	189.5 cd	49.25b	50.25abcd
T7	197.0ab	193.8 b	53. 5 a	50.5 abc
T8	200.5a	198.5 a	55.5a	54.0 a

Means within each column followed by the same letter are not significantly different at $P \leq 0.05$ according to Duncan's multiple range test. T1: Control (100% mineral NP), T2: 100% Bio P (P.D.B) +100% N, T3: 100% Bio P + 50% mineral P +100% N, T4: 100% Bio N (N.F.B) + 100% mineral P, T5: 100% Bio N + 50% mineral N +100% mineral P, T6: 100% Bio N +100% Bio P, T7: 100% Bio N +100% Bio P + 50% mineral NP, T8: 50% Bio P + 50% Bio N + 50% mineral NP

Pseudostem circumference showed significant higher values at T7, T8 in the first season and T6, T7 and T8 in the second season. These results came in line with Abdel Gawad et al. (2017), who reported that height and circumferences of Grande Naine banana pseudostem increased as consequence of biofertilization and feldspar application.

Data in *Table 3* show that, plants treated with T_8 (50% Bio P + 50% Bio N + 50% mineral N, P) gave the highest bunch weight in both seasons, while T_2 (100% Bio P (P.D.B) +100% N) presented the significant lowest value than all tested treatments. In addition, T8 recorded the maximum bunch length and the lowest one registered by T2. These results are in agreement with those reported by Abd El-Naby and Gomaa (2000) and Barakat et al. (2011) who recorded that banana plants supplied with mineral fertilization combined with organic manure improved bunch weight. Also, the results are confirmed by those obtained by Baiea et al. (2015) and Baiea and El-Gioushy (2015) on banana plants.

In both seasons, T_8 (50% Bio P + 50% Bio N + 50% mineral N, P) increased the yield by 2%, 4.1% than the control. Moreover, the rest treatments had intermediate yield among the highest value at T8 (20, 20.4 T) and the lowest one (14.8 ,12.4 T) at T2 (100% Bio P (P.D.B) +100% N) treatment during 1st and 2nd seasons, respectively. In this concern, Mai et al. (2005) observed that number of hands/bunch increased with 50% or 33% recommended dose of N plus Azospirillum phosphate solubilizing

DOI: http://dx.doi.org/10.15666/aeer/1805_67656773

bacteria. Dave et al. (1991), Zake et al. (2000), and Abd el Moniem et al. (2008) found that biofertilization with algal extract significantly improved yield, bunch and hand weight.

Table 3. *Effect of Biofertilizers in combination with different levels of N, P mineral fertilizers on Bunch weight and length and yield*

Treatments	Bunch weight (Kg)		Bunch length (cm)		Yield Ton/ 4200 m^2

Means within each column followed by the same letter are not significantly different at P≤ 0.05 according to Duncan's multiple range test. T1: Control (100% mineral NP), T2: 100% Bio P (P.D.B) +100% N, T3: 100% Bio P + 50% mineral P +100% N, T4: 100% Bio N (N.F.B) + 100% mineral P, T5: 100% Bio N + 50% mineral N +100% mineral P, T6: 100% Bio N +100% Bio P, T7: 100% Bio N +100% Bio P + 50% mineral NP, T8: 50% Bio P + 50% Bio N + 50% mineral NP

With respect to fingers No./hand. the differences among the treatments did not reached the limit of significance in the 1st season (*Table 4*). However, in the 2nd season, T_8 (50% Bio P + 50% Bio N + 50% mineral NP) resulted in increasing the finger No/hand than T3 and T2, the latter presented the significant lowest value than all treatments.

Means within each column followed by the same letter are not significantly different at P≤ 0.05 according to Duncan's multiple range test. T1: Control (100% mineral NP), T2: 100% Bio P (P.D.B) +100% N, T3: 100% Bio P + 50% mineral P +100% N, T4: 100% Bio N (N.F.B) + 100% mineral P, T5: 100% Bio N + 50% mineral N +100% mineral P, T6: 100% Bio N +100% Bio P, T7: 100% Bio N +100% Bio P + 50% mineral NP, T8: 50% Bio P + 50% Bio N + 50% mineral NP

Data presented in *Table 6* show that, in the 1st season acidity percentage was similar in the fruit of T5 (100% Bio N + 50% mineral N +100% mineral P), T6 (100% Bio N +100% Bio P) beside the control plants, while the lowest acidity percentage obtained by T2 (100% Bio P (P.D.B) +100% N). Moreover, in the 2nd season the highest and the lowest value recorded when plants treated with T5 (100% Bio N + 50% mineral N +100% mineral P) and T2 (100% Bio P (P.D.B) +100% N), respectively.

In both seasons the highest fruit TSS as Brix was recorded at T6 (100% Bio N +100% Bio P) and the lowest value presented with T2 (100% Bio P (P.D.B) +100% N). Considering total sugars content, in the 1st season, T6 (100% Bio N +100% Bio P), T7 (100% Bio N +100% Bio P + 50% mineral NP) and T8 (50% Bio P + 50% Bio N + 50% mineral NP) gave the highest significant fruit total sugar content, while plants treated with T2 (100% Bio P (P.D.B) +100% N) had the lowest significant value. Moreover, in the second season T7 (100% Bio N +100% Bio P + 50% mineral NP) and T2 (100% Bio P (P.D.B) +100% N) had the highest and lowest values, respectively.

Fruit reducing sugar percent was significantly improved in response to T8 (50% Bio P + 50% Bio N + 50% mineral NP) in the 1st season as well as, T7 (100% Bio N +100% Bio P + 50% mineral NP) and T8 (50% Bio P + 50% Bio N + 50% mineral NP) in the 2nd season led to significant reduction in fruit reducing sugar value.

Attia et al. (2009) on banana observed that biofertilization increased TSS and decreased acidity.

Leaf chemical composition

Data in *Table 7* show that leaf N, P and K contents were affected by tested combination of mineral and biofertilizer treatments. In both seasons, T7 (100% Bio N +100% Bio P + 50% mineral NP) and T8 (50% Bio P + 50% Bio N + 50% mineral NP) showed to be most effective for inducing the greatest values of leaf N, P and K. Meanwhile, T2 (100% Bio P (P.D.B) +100% N) for leaf N%, T5 (100% Bio N + 50% mineral N +100% mineral P) for P content and T2 (100% Bio P (P.D.B) +100% N), T3 (100% Bio P + 50% mineral P +100% N) for leaf K% presented the lowest values for N, P and K, respectively in both seasons. Different workers have proposed different critical levels of N, P, K which ranged from 1.8- 4, 0.17- 0.29 and 1.66 - 6.4%, respectively (Angeles et al., 1993; Memon et al., 2010) and their levels were increased by biofertilizer.

Chlorophyll content showed no clear trend, however, T7 recorded the highest significant content of chlorophyll a and b of in both seasons.

Conclusion

From the obtained results it can be concluded that integrating biofertilizers (Az14 as nitrogen fixation and B6 as phosphate dissolving bacteria) in fertilization program of Williams banana was beneficial in enhancing the most estimated parameters of banana in terms of yield and fruit quality, moreover T7 and T8 treatments are recommended due to their help in minimizing the application of mineral fertilizer to 50%, which is cost-effective and reducing environmental pollution leading to sustainable agriculture production.

(Received 12th May 2020; accepted 13th Aug 2020)

Abstract. In this study, the physicochemical characteristics of water and soil in conventional and organic rice cultivations are determined. Physicochemical parameters for water and soil samples are assessed by laboratory analysis. Chemical and physical parameters for water quality include temperature, pH, dissolved oxygen (DO), chemical oxygen demand (COD), biochemical oxygen demand (BOD_5), total suspended solids, and heavy metals. Parameters for the physicochemical analysis of soil include pH, particle size distribution, organic carbon, electrical conductivity (EC), cation exchange capacity, and heavy metals. Based on the water quality index, water qualities of conventional and organic rice fields are categorized into Class III. Based on the independent sample t-test, significant differences are observed between conventional rice and organic rice for pH, DO, BOD_5, COD, ammoniacal nitrogen (NH_3-N), arsenic (As), chromium (Cr), iron (Fe), and nickel (Ni) ($p < 0.05$). For soil samples, significant differences are observed between conventional rice and organic rice for pH, organic matter (OM), EC, As, Cr, Fe, and Ni ($p > 0.05$). The results of this study can serve as a guideline and basis for future studies on irrigation water and soil quality in sustainable agricultural management in Malaysia.
Keywords: *Malaysia, physicochemical parameters, rice production, crop management, sustainable agriculture*

Introduction

Malaysia has 688,770 hectares of land for rice cultivation, which produced 2,739,606 metric tons of rice in 2016 (DOSM, 2018). Recently, the tremendous growth in the population has led to an increase in the rice productivity. The need for high rice production has led to the expansion of irrigated areas. As a result, the rice cultivation area has increased, while rice production has decreased from 2014 to 2017. Although the use of hybrid rice varieties introduced by the Malaysian Agricultural Research and Development Institute (MARDI) has overcome some of the issues, the yield is still a factor that limits the increased production level due to bad weather as well as pests and diseases (USDA, 2018). To drive the modernization of Malaysia's agro-food sector, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67756791

rice sector was included in one of the seven specialized industries listed by the National Agro-Food Policy (DAN) 2011–2020. DAN 2011–2020 targets to increase productivity and yields to ensure a sufficient food supply, high-value and sustainable agricultural development. By 2020, the Malaysian government also aims to achieve 80% self-sufficiency in rice (MOA, 2016). Hence, the government has provided several incentives such as subsidized seeds and fertilizers to encourage rice production.

The expansion of irrigated areas has become one of the major challenges in ensuring food security due to the high input used in rice cultivation such as water, fertilizers, and pesticides (Bouman, 2007; Hanafiah et al., 2019). With respect to these issues in rice cultivation, several methods have been explored for the application of less input in rice production, such as aerobic rice cultivation, system of rice intensification, ground-cover rice production system, raising beds, and alternate wetting and drying (Farooq et al., 2009). Moreover, organic cultivation practices have become an alternative to sustainable rice production as these practices avoid the use of synthetic fertilizers and chemical pesticides and exhibit benefits in terms of food security (Champagne et al., 2007; Keawpeng and Meenune, 2012).

Previous studies have independently reported that non-sustainable agriculture techniques can cause water quality problems (Reche et al., 2016; Banch et al., 2020; Bong et al., 2020). Water contamination in rice fields is caused by the chemical substances used for soil fertilization and pest control (Rhee et al., 2011). Iqbal (2011) has reported that pesticides do not exhibit adverse effects due to their low application amount; however, the continuous use of pesticides can slowly disturb the ecosystem and living organisms. Rice cultivation under flooded conditions causes a change in microbial activities from the aerobic to anaerobic fermentation of organic matter in rice fields. Hence, anaerobic respiration can produce substances that can cause the chemical reduction of soil components (Ethan, 2015). However, Haefele et al. (2014) have reported that some negative soil characteristics, including low nutrient reserves and an extremely low cation exchange capacity (CEC), are not considerably affected by flooding.

Water quality index (WQI) is a scale related to a group of parameters that are combined into a single number to determine the overall water quality status at a certain time and location (Yisa and Jimoh, 2010; Leščešen et al., 2015; Ashraf and Hanafiah, 2017; Hanafiah et al., 2018a, 2019). However, the water quality parameters used were varied. Meher et al. (2015) have reportedly utilized 14 parameters for determining the WQI of the Ganges River, including pH, total dissolved solids (TDS), alkalinity, dissolved oxygen (DO), conductivity, and turbidity. On the other hand, Al-Shujairi (2013) has developed WQI to evaluate the water quality of two rivers in Iraq by utilizing seven water quality parameters of pH, DO, TDS, total hardness, biochemical oxygen demand (BOD_5), nitrate (NO_3), and phosphate, respectively.

The physicochemical analysis of soil is another important factor in the agriculture sector for plant growth, crop nutrient management, and soil management. This assessment can aid farmers in managing the nutrient input for crops during cultivation. Several

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67756791

parameters can be employed for the monitoring of agricultural soil, including electrical conductivity (EC), soil organic matter (SOM), and heavy metal analysis. Aimrun et al. (2011) have reported that EC can provide information regarding soil texture, thereby permitting the estimation of the water content. In addition, EC can serve as a proxy for the physicochemical properties of soil, such as SOM, cation content, and CEC (Liu et al., 2011; Li et al., 2013; Wang et al., 2016, 2018). Several studies of soil in paddy fields have been conducted in Malaysia. Aimrun et al. (2011) have conducted a study regarding paddy soil properties and yield characteristics based on EC, while Khairiah et al. (2009) have conducted a study focusing on the heavy-metal content in paddy soil in Kedah. Physicochemical analysis of soil properties in rice fields can serve as a basis and reference to improve the rice cultivation process and reduce the environmental pollution in rice fields.

In recent years, as a result of increasing concerns of environmental pollution due to the application of chemical fertilizers, several efforts have been made to replace chemical fertilizers by organic fertilizers (Zhao et al., 2015; Lenka et al., 2016). Previously, Jat et al. (2015), Singh et al. (2017), and Thakur et al. (2016) have independently reported that organic rice cultivation increases rice production. However, the environmental impact also should be emphasized while simultaneously aiming for high rice productivity to ensure environmental sustainability. Currently, only a few studies on the impact of conventional and organic rice cultivations on the environment in Malaysia have been conducted. Accordingly, it is imperative to conduct a performance evaluation study on the physicochemical characteristics of water and soil for the purpose of increasing the rice yield and sustaining its production to meet the requirements in Malaysia. Hence, this paper aims to determine the physicochemical properties of water and soil for conventional and organic rice cultivations.

Materials and Methods

Samples collection and preservation

The water and soil samples were collected at Sabak Bernam, Selangor, Malaysia, from conventional and organic rice fields (3.684153°N, 101.022841°E) (*Figure 1*). Soil and water samples were collected from six sampling stations consists of conventional and organic rice fields. In total, 18 sampling points were included in the analysis. Water and soil samples were placed in polyethylene bottles and plastic bags, respectively. Water samples were preserved at 4–5°C to minimize biological activity and chemical changes. Soil samples were dried at room temperature in the laboratory before analysis was conducted. For BOD_5 tests, samples were collected using glass bottles wrapped with an aluminum foil to avoid the penetration of sunlight into the bottles. Samples for heavy metal tests were placed in different 50-mL polyethylene bottles. Samples were acidified to a pH less than 2 by the addition of HNO_3 to the samples. All samples that could not be analyzed immediately in the field were preserved following the method recommended by

GEMS (1978) and were transported to the laboratory within 24 h of sampling. *Table 1* summarizes the description of each sampling station.

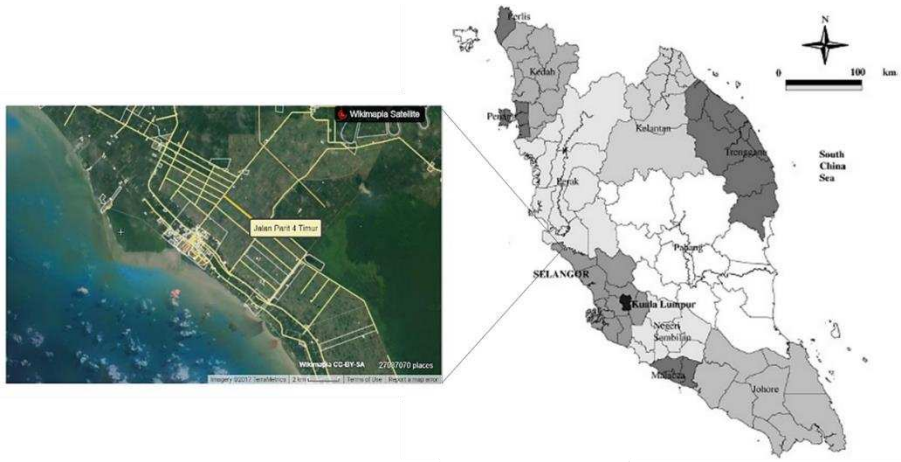

Figure 1. *Location of conventional and organic rice fields for water and soil sampling*

Table 1. *Description of each sample based on the sampling station*

Sampling station	Description
S1; P3	Located at the inlet of conventional rice field.
S2; P2	Located at the conventional rice field. There are paddy planting activities occurred such as fertilizing and pesticide application.
S3; P3	Sampling was done at the outlet of conventional rice field.
T1; Q1	Located at the inlet of organic rice field.
T2; Q2	Located at the middle of organic rice field. There are organic paddy planting activities occurred such as application of effective microbes.
T3; Q3	Located at the outlet of organic rice field.

S = represent water samples in the conventional rice field, T = represent water samples in the organic rice field, P = represent soil samples in the conventional rice field, Q = represent soil samples in the organic rice field

Water quality was analyzed according to temperature, pH, DO, BOD_5, COD, ammoniacal nitrogen, total suspended solid (TSS), and heavy metals. DO values, water temperature, and pH values were measured in situ using a YSI Model 556 Multi Probe system. COD, TSS, BOD_5, and ammoniacal nitrogen were analyzed in the laboratory following American Public Health Associations Standard (APHA, 1998) standard procedures. *Table 2* summarizes the parameters, methodology, and instruments used in this study.

Table 2. *Parameters, applied methodologies, and instruments used in this study for the physicochemical analysis of water and soil*

Parameters	Methodology	Instrument
Water analysis		
Temperature	-	YSI Pro2030 DO Meter
pH	-	pH meter HI8424
Dissolved oxygen (DO)	-	YSI Pro2030 DO Meter
Bio-chemical oxygen demand (BOD_5)	BOD_5	YSI 5000 Dissolved Oxygen meter
Chemical oxygen demand (COD)	Closed reflux	Hach DR 6000 spectrophotometer
Ammoniacal nitrogen	Direct Nesslerization	
Total suspended solid (TSS)	Photometric	
Heavy metals	EPA Method 200.8	Inductively Coupled Plasma Mass Spectrometry (ICP-MS)
Soil analysis		
pH	Was determined in distilled water with ratio 1:2.5 of soil: distilled water	pH meter (DELTA 320 model)
Organic matter	Gravimetric method based on loss on ignition	Oven, furnace, weighting scale
Electrical conductivity	Was determined in saturated extract of gypsum	EC meter Model H 18819 Hanna
Particle size distribution	Pipette method together with dry sieving	Sieve (ASTM)
Cation exchange capacity	EPA Method 9081: Sum of basic cations with acidic cations through summation method	Centrifuge tube and stopper, mechanical shaker, volumetric flask 100mL, Inductively coupled plasma atomic emission spectroscopy (ICP-AES)
Heavy metals	Acid digestion Method 3050B	Inductively Coupled Plasma Mass Spectrometry (ICP-MS)

Water quality analysis

The use of water is classified based on six classes (i.e., class I, IIA, IIB, III, IV, and V) by the Department of Environment (DOE, 2006). To determine the quality of water samples under the National Water Quality Standards for Malaysia (NWQS), WQI was calculated by the following equation *Eq. 1*:

$$WQI = (0.22 \times SIDO) + (0.19 \times SIBOD) + (0.16 \times SICOD) + (0.15 \times SIAN) + (0.16 \times SISS) + (0.12 \times SIpH) \quad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67756791

where,
SIDO = SubIndex DO (% saturation),
SIBOD = SubIndex BOD,
SICOD = SubIndex COD,
SIAN = SubIndex SS,
SIpH = SubIndex pH,
$0 \leq WQI \leq 100$.

Statistical analysis

Statistical analysis was done using the statistical package for social science software (SPSS). Data for physicochemical parameters of water and soil samples were represented as mean values. Independent sample t-tests were conducted to compare the results obtained for the water quality and physicochemical analysis of soil in different rice cultivation systems.

Results and discussion

Physicochemical properties of water in rice fields

Water quality is one of the key factors in the agriculture sector that ensures the healthy growth of crops (Harun and Hanafiah, 2018a, 2018b; Hanafiah et al., 2020; Nizam et al., 2020). The Department of Environment (DOE), Malaysia, has set six parameters to calculate the National Water Quality Index (Alssgeer et al., 2018; Hanafiah et al., 2018b; Ariffin et al., 2019): pH, DO, BOD_5, COD, ammoniacal nitrogen, and suspended solids. *Table 3* summarizes the physicochemical characteristics of water in conventional and organic rice fields.

pH is important for determining not only if a chemical or biological reaction can occur but also the degree of toxicity of some pollutants in water (Basheer et al., 2015). All samples were slightly acidic in the range from pH 5.41 ± 0.12 to 5.86 ± 0.18 for conventional rice fields and from pH 4.24 ± 0.13 to 4.50 ± 0.12 for organic rice fields (*Table 3*). Based on the NWQS for Malaysia, the average pH for conventional rice was categorized into class III, while the average pH for organic rice was categorized into class IV. Hence, the average pH values for conventional and organic rice are within the permissible range for irrigated agriculture. Results obtained from the independent sample t-test revealed a significant difference between conventional and organic rice ($p < 0.001$).

*dissolved oxygen (DO), chemical oxygen demand (COD), biochemical oxygen demand (BOD_5), total suspended solids (TSS), ammoniacal nitrogen (NH_3-N), arsenic (As), cadmium (Cd), chromium (Cr), iron (Fe), manganese (Mn), lead (Pb), zinc (Zn) and nickel (Ni)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67756791

On average, the conventional rice value was 1.24 greater than the organic rice value. pH values for conventional rice fields were greater than those observed for the water samples in organic rice fields due to the application of urea in the conventional rice field. The application of urea in agriculture leads to increased pH (Whalen et al., 2000; Liu et al., 2010). Among conventional rice samples, sample S2 exhibited the lowest pH as the sampling point was located in the rice field, which was related to the decay by stagnant water in the rice field (Lee et al., 2015). pH values reported herein were comparable with those (pH 5.51–5.99) reported previously by Lee et al., (2015). The pH values recorded for water were within the permissible range for irrigation purposes as specified by the DOE.

Average ranges of DO recorded for conventional and organic rice were 4.15 ± 0.14 mg/L to 6.57 ± 0.29 mg/L and 3.45 ± 0.45 mg/L to 5.46 ± 0.41 mg/L, respectively (*Table 3*). Based on the NWQS for Malaysia, the average DO for conventional rice was categorized into class II, while the average DO for organic rice was categorized into class III. Hence, the recorded DO values of water are within the permissible range for irrigation and fishery purposes as specified by the DOE, Malaysia. Results obtained from the independent sample t-test revealed that significant differences are observed between conventional and organic rice ($p < 0.05$). On average, the conventional rice value was 1.08 greater than the organic rice value. Among conventional rice samples, sample S2 exhibited the highest mean DO value, while among organic rice samples, sample T2 exhibited the highest mean DO value due to the location of both samples S2 and T2 in the rice field. Adequate DO is a major indicator for good water quality as DO is crucial for the survival of aquatic organisms. Ariffin et al. (2019) have reported that aquatic life experiences stress if the water oxygen levels drop to less than 5.00 mg/L, and some fish species (e.g., catfish and tilapia) require a minimum DO of 3.00 mg/L for survival. The DO value for conventional rice was greater than that for organic rice due to the depletion of oxygen water by organic materials used in rice farming (Xu et al., 2017). Al-Shami et al. (2010) have reported that DO values for rice fields are greater due to the photosynthesis by algal populations. Moreover, the strong wind and shallow water of rice fields lead to high water turbulence, leading to rich DO (Frei and Becker, 2005; Nugraheni, 2017; Sule et al., 2018).

Table 3 shows the average ranges of BOD_5 recorded for conventional and organic rice were 1.16 ± 0.32 mg/L to 2.48 ± 0.11 mg/L and 0.62 ± 0.35 mg/L to 1.44 ± 0.19 mg/L, respectively. Based on the NWQS, the average BOD_5 for conventional rice was categorized into class II, while the average BOD_5 for organic rice was categorized into class I. Hence, the recorded BOD_5 values of water are within the permissible range for irrigation and fishery purposes as specified by the DOE, Malaysia. Results obtained from the independent sample t-test revealed a significant difference between conventional and organic rice ($p < 0.05$). On average, the conventional rice value was 0.65 greater than the organic rice value. The BOD_5 values for conventional rice were greater than those for organic rice due to the fertilization activity. The highest BOD_5 values were observed for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67756791

sample S2 (conventional rice) and sample T2 (organic rice) due to their sampling location in the rice field. During the cultivation phase, the BOD_5 value increased due to the decay process as well as other contributors such as the fertilizer application, which increased the organic content of water bodies (Hanafiah et al., 2018c). Ariffin et al. (2019) have reported that the nutrient content of chemical fertilizers can lead to the increase in the microorganisms in water, thereby contributing to the high BOD_5 values.

Average ranges of COD recorded for conventional and organic rice were 11.45 ± 3.48 mg/L to 29.88 ± 0.32 mg/L and 27.16 ± 2.02 mg/L to 47.83 ± 2.84 mg/L, respectively (*Table 3*). Based on the NWQS, the average COD for conventional rice was categorized into class II, while the average COD for organic rice was categorized into class III. Hence, the recorded COD values of water are within the permissible range for irrigation and fishery purposes as specified by the DOE, Malaysia. Results obtained from the independent sample t-test revealed a significant difference between conventional and organic rice ($p < 0.01$). On average, the organic rice value was 14.69 greater than the conventional rice value. The COD values for organic rice were greater than those for conventional rice due to the level of organic matter resulting from the organic fertilization of the organic rice field (Ahmad et al., 2014).

Average ranges of NH_3-N recorded for conventional and organic rice were 0.57 ± 0.03 mg/L to 2.44 ± 0.04 mg/L and 0.32 ± 0.03 mg/L to 1.23 ± 0.02 mg/L, respectively *(Table 3*). Based on the NWQS, the average NH_3-N for conventional rice was categorized into class IV, while the average NH_3-N for organic rice was categorized into class I. Hence, the recorded NH_3-N values of water are within the permissible range for irrigation and fishery purposes as specified by the DOE, Malaysia. Results obtained from the independent sample t-test revealed a significant difference between conventional and organic rice ($p < 0.05$). On average, the conventional rice value was greater than the organic rice value by 0.66. NH_3-N values for conventional rice were greater than those for organic rice due to the high application of urea in the conventional rice field. The decay of discharged organic waste in water can lead to the increase in the ammonia concentration (Li et al., 2008; Asman et al., 2017). Yang et al. (2017) have reported that a high pH value for the conventional rice field leads to a high ammoniacal nitrogen value as pH can increase the rate of dissolved ammonia available for volatilization.

Average ranges of TSS recorded for conventional and organic rice were 41.65 ± 0.46 mg/L to 73.17 ± 0.82 mg/L and 45.98 ± 0.65 mg/L to 85.03 ± 3.63 mg/L, respectively as shown in *Table 3*. Based on the NWQS, the average TSS results for conventional rice and organic rice were categorized into class III. Hence, the recorded TSS values of water are within the permissible range for irrigation and fishery purposes as specified by the DOE, Malaysia. Results obtained from the independent sample t-test revealed no significant differences between conventional and organic rice ($p > 0.05$). On average, the organic rice value was 8.93 greater than the conventional rice value. The nature of the muddy condition of rice fields as well as cultivation activities such as ploughing have contributed to high TSS (Al-Shami et al., 2010). Moreover, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67756791

application of organic fertilizers in the organic rice field has increased the density of phytoplankton, thereby contributing to the increase in the TSS (Ahmed et al., 2013).

Results obtained from the independent sample t-test revealed a significant difference between conventional and organic rice for As, Fe, and Ni ($p < 0.01$) and Cr was $p < 0.001$. On average, the organic rice values for As and Fe were greater than the conventional rice values by 0.02 and 2.65, respectively. On the other hand, the average conventional rice values for Ni and Fe were greater than the organic rice values by 0.01 and 0.02, respectively. Harun and Hanafiah (2018a) have reported that the application of chemical fertilizers in the rice field leads to the increase in the heavy metal concentration. Notably, the organic rice field in this study was previously implementing conventional rice cultivation practices. Hence, similar results for heavy metals are observed for conventional and organic rice fields. The highest concentration of Fe was observed in the conventional and organic rice fields. Iron toxicity in lowland rice fields was related to the flooded condition and pesticide application during cultivation (Fageria, 2007).

Nutrients lost from the rice cultivation phase contaminate water bodies. Hence, concerns over the water quality of rice fields have increased in recent decades. The obtained results revealed that the WQI for conventional and organic rice is categorized into class III based on the WQI classification by the DOE, Malaysia. Hence, the WQI is suitable for irrigation and fishery activities. However, for water supply purposes, extensive water treatment needs to be conducted (Halim et al., 2017; Manikam et al., 2019). The results obtained herein were similar to those previously obtained by Ahmad et al. (2014) and Haque et al. (2010). In conclusion, the conventional rice cultivation in the examined rice field follows the permissible rate of fertilizer and pesticide applications. The results obtained herein can serve as a guideline for the future water quality management in rice field studies.

Physicochemical analysis of soil

Physicochemical analysis of soil for conventional and organic rice fields was performed according to parameters such as pH, SOM, EC, particle size distribution, and heavy metal analysis. *Table 4* summarizes the results obtained.

Average ranges of pH recorded for conventional and organic rice were 5.13 ± 0.02 to 5.30 ± 0.01 and 4.20 ± 0.10 to 4.43 ± 0.06, respectively (*Table 4*). Results obtained from the independent sample t-test revealed a significant difference between conventional and organic rice ($p < 0.001$). On average, the conventional rice value was 0.86 greater than the organic rice value. The results obtained herein were comparable with those obtained by Aishah et al. (2010) and Khairiah et al. (2009), with the soil pH ranges within 4.63-5.14 and 4.5–5.0, respectively. In addition, the soil pH values for rice cultivation recommended by MARDI were within the pH range of 5.5–6.5 (Aishah et al., 2010).

DOI: http://dx.doi.org/10.15666/aeer/1805_67756791

In addition, the use of chemical fertilizers has led to the increase in the soil humus, thereby affecting the pH values (Ahmad et al., 2014). Previously, Angelova et al. (2013), Sarwar et al. (2008) and Smiciklas et al. (2008) have reported that the application of organic fertilizers in rice fields leads to the decrease in the pH values as the application of organic fertilizers in organic rice field contributes to the production of organic acids such as amino acids and humid acid during the mineralization of organic materials by heterotrophs and nitrification by autotrophs; hence, a low pH is obtained (Sarwar et al., 2008).

Table 4 shows the average ranges of SOM recorded for conventional and organic rice were 1.90 ± 0.02% to 3.33 ± 0.15% and 2.77 ± 0.15% to 2.77 ± 0.15%, respectively. Results obtained from the independent sample t-test revealed a significant difference between conventional and organic rice ($p < 0.05$). On average, the SOM of organic rice was 0.57 greater than that of conventional rice. The application of an organic fertilizer leads to a high content of organic matter in the soil (Kushwaha et al., 2001; Selvakumari et al., 2001; Smiciklas et al., 2008). Organic matter plays a key role in binding soil particles; hence, soil strength is enhanced. In addition, high organic matter can contribute to the high productivity (Hasan et al., 2020).

Soil EC is the ability of the soil to transmit an electrical charge (Chan et al., 2008). Average ranges of EC recorded for conventional and organic rice were 0.25 ± 0.02 mS/m to 0.35 ± 0.03 mS/m and 0.22 ± 0.01 mS/m to 0.26 ± 0.01 mS/m, respectively (*Table 4*). In this study, EC values were within the range of the suggested EC value (<2.70 mS/m) for rice cultivation in tropical Asia (MAFF, 1970). Results obtained from the independent sample t-test revealed a significant difference between conventional and organic rice ($p < 0.01$). On average, the conventional rice value was 0.073 greater than the organic rice value. In this study, urea was applied in the conventional rice field. The combination of urea and NPK fertilizers can afford a high EC value (Han et al., 2016). Selvakumari et al. (2001), and Smiciklas et al. (2008) have reported that the reading of EC can increase under acidic and alkaline conditions by the application of organic materials to the soil.

Table 4 shows the particle size distribution percentage. Based on the obtained results, the soil samples contain a high percentage of the silt and clay fraction (grain size < 63 μm) for conventional and organic rice fields. Based on the United States Department of Agriculture (USDA), the type of soil for conventional rice and organic rice herein was classified as silty clay loam and silty clay, respectively. Results obtained from the independent sample t-test revealed no significant difference between silt, clay, and soil for conventional and organic rice ($p > 0.05$). Dou et al. (2016) have reported that soil texture as well as the interaction between the water regime and cultivar affect the rice yield. In addition, the high clay soil can contribute to the high yield due to the finer particles of clay soil, which can retain water and nutrients better than sandy soil (Tsubo et al., 2007; Dou et al., 2016; Aboudi Mana et al., 2017).

Results obtained from the independent sample t-test revealed a significant difference ($p < 0.01$) between conventional and organic rice for As, Fe, Ni, and Cr ($p < 0.0001$).

Previously, the organic field in this study was practicing conventional rice farming; hence, the difference between the metal results is nearly the same. The use of chemical pesticides can lead to the increase in the heavy metal content of the rice field (Aimrun et al., 2011; Jamil et al., 2011). Results revealed that among the metals tested, the total Fe content was the highest. However, the value was considered to be less than that reported previously by Khairiah et al. (2009), where Fe values ranged from 254 to 379 mg/kg. Jamil et al. (2011) have reported that flooded conditions in rice fields lead to the precipitation of dissolved Fe. Hence, the oxidized condition of Fe can occur as finely grained hydrous oxides ($Fe(OH)_3$) with a disordered structure; hence, mixing with clays is possible (Khairiah et al., 2009).

Conclusions

In this study, the water quality and soil physicochemical characteristics were assessed by laboratory analysis. We found that water quality measured from the organic and conventional rice fields was classified as Class III. Although similar water and soil quality obtained for all sampling stations from both organic and conventional rice fields, organic farming is a better alternative to overcome the environmental contamination that is caused from the constant utilization of chemical fertilizers. However, future study can be done by considering a longer temporal duration of the water and soil quality measurements for a better understanding of the physicochemical characteristics of water and soil in conventional and organic rice fields in Malaysia.

(Received 12th May 2020; accepted 13th Aug 2020)

Abstract. Surface soil samples were collected from different land use types of the agricultural land in Nam Dinh province, Vietnam to determine the level of heavy metal contamination and identifying potential sources. The farming areas of rice and cereal show similar heavy metal contents, however, the index shows that the content of heavy metals in the aquacultural area is lower compared to the other types. The mean enrichment factor (EF) values of Cr, Cu, Pb, and Zn are less than 1.5, suggesting that these are not a major concern in the research area; whereas, the mean EF values for Cd is higher than 2 and As varies from 5-20 suggest that the pollution of these heavy metals is present in agricultural soil. The data analysis indicates that Cr mainly originates from a natural source; Cd and As have a significant anthropogenic input; Cd, Pb and Zn have a mixed source.
Keywords: *different land use, paddy, cereal, aquaculture, environment*

Introduction

Soil is widely recognized as a pool of nutrients and pollutants, and plays a critical role in socio-ecological stability and national safety (Wu et al., 2018). Human-induced increase of soil contamination with heavy metal input is noteworthy, including atmospheric deposition, irrigation, application of sewage sludge, organic manures, fertilizers, and other soil amendments (Cheng, 2003; Vodyanitskii, 2013; Hou et al., 2014). When heavy metals enter the agricultural soil, they not only degrade environmental quality but they also influence the health of people and other organisms through the food chain (Nabulo et al., 2010). Therefore, it is of great importance to study the characteristics and sources of heavy metal contamination in agricultural soil to protect the environment and human health (Huang et al., 2018; Li et al., 2018).

Agriculture plays a prominent role in Nam Dinh province, with approximately 67% of the land used for agricultural production. It is usually used for 2 paddy rice crops per year equipped with a developed irrigation system (in total 3% of the province area are covered by rivers and channels (Dao et al., 2005). Traditionally, the biggest industry is textile and garment which has been developed since 1889 with French support. The craft production in Nam Dinh, especially bronze and silver casting, has a long tradition. For example, Tong Xa village has been well known for bronze and iron casting in the Red River delta since 1200, Xuan Tien commune with bronze casting and mechanical engineering since 1535, and Van Chang village with iron, steel and aluminum foundry since 1868. According to the data provided by provincial

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67936811

government, there are a total of 71 villages that are specialized on handicraft (e.g. metalworking, food processing, salt production) up to 2018 in Nam Dinh province (Joern et al., 2013). Such production places are most often based on family enterprises located all over the village; therefore, it can be stated that living and working place are rarely distinguished (Dao and Nguyen, 2000). However, all untreated wastewater from industrial and living usages discharges directly open channels or infiltrate into the soil. Previous research shows that water channels in handicraft villages are loaded with heavy metals (Zn, Pb, Cu, Ni, Cd, Cr, and Fe) and cyanides, exceeding the limits by up to 50 times (Le et al., 2003). In recent years, with the increase in population, the industrial sector has achieved prominence. This has resulted in environmental pollution caused by manufacturing activities in industrial zones. Furthermore, the Red and Day rivers receive pollutants from upstream before running across the province. Agricultural activities in the province utilize approximately 300 tons of insecticides per year (Dao et al., 2005), which causes the water to be polluted, that is then returned to the soil via the irrigation network.

Thus far, there has been very little published information on their contaminant level and sources in Nam Dinh province. To better investigate local soil quality, we have used a combined method of enrichment factor (EF) and multivariate statistical analyses with the objectives of analyzing pollution level, characteristics of spatial distribution and identifying potential sources of heavy metals in agricultural soil.

Materials and methods

Study area

Nam Dinh (19°52’ - 20°30’N, 105°55’ - 106°35’E) is a coastal province located to the south of Red river delta with an area of 1,652.6 km² and population of 1,825,771 people; population density is 1,196 people per km². The administrative unit of this province is composed of 9 districts and one city. Nam Dinh is a tropical area experiencing monsoon with hot and humid rain. The average annual temperature is ca. 23 – 24 °C, and the average annual rainfall is ca. 1,700 - 1,800 mm. On average, up to 250 days a year are sunny, with total sunshine hours from 1650 to 1700 h. The province is affected by storms or tropical depressions 4 to 6 times per year.

The river and estuary systems of the Red river and its tributaries (Dao, Ninh Co, Day rivers) have greatly impacted morphological and hydrological characteristics of the region. The terrain is quite flat, gradually dipping to the sea in Northwest - Southeast direction. The formation of this region was historically associated with and the evolution of the Red River Delta. It can be divided into two zones: (1) the low-lying plains with elevations of 0.2 to 3 m above sea level with some exceptions in the northwest (7-100 m above sea level) (Vu Ban, Y Yen, Nam Truc, Truc Ninh and Xuan Truong districts). This region has a high level of agriculture, textile and manufacturing industries; (2) the lowland coastal region including Giao Thuy, Hai Hau and Nghia Hung districts. Running from north to south, Dao river seperates the two regions. In the northern region of the province (My Loc, Y Yen, Vu Ban districts and Nam Dinh city), the water is pumped directly from stagnant canals which is not well circulated and used for irrigation purposes. In the southern region (Nam Truc, Truc Ninh, Xuan Truong, Hai Hau, Giao Thuy and Nghia Hung districts), irrigation water is taken from rivers, which is well circulated because water from upstream flows into the sea.

Samples and methods

Samples

A total of 38 surface agricultural soil samples from different land use types were collected in May, 2018 by grid method (using 10 × 10 km grid). They included 20 samples from paddy field, 12 samples from cereals soil, and 6 samples from aquaculture farm (*Fig. 1* and *Table 1*). The samples were taken at depth of 0-20 cm with volume of 0.5 kg soil by using hand steel drill. Per site, two samples were taken. Samples were packed in plastic bags to send to the laboratory. All samples were dried at 40 °C, then desegregated prior to analysis.

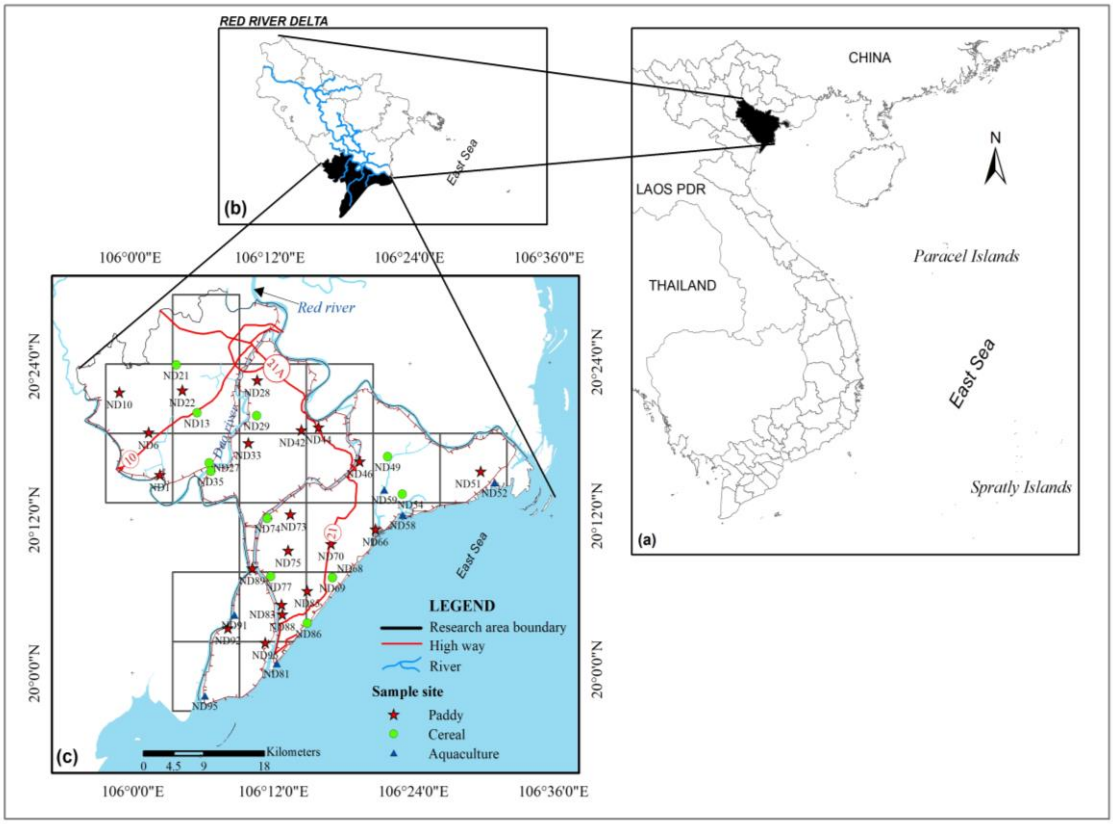

Figure 1. *Map of the study area (a), Red river delta (b), with the sampling sites detailed in (c)*

Methods

For heavy metal analysis, ~ 0.1 g dry soil was weighed into Teflon beakers, in which a mixture of concentrated 2 ml HF – 6 ml HCl – 2 ml HNO_3 were added (Elsorogy et al., 2016), a Teflon watch cover was put in place, and the sample was left at room temperature overnight. On the following day, the sample was digested using a scientific microwave system (Mars 6, USA) with the following heating program: the temperature rises from room temperature to 180 °C in 15 min, keep at 180 °C for decomposition for 30 min, then let solutions cool down to room temperature again. The solution is transferred to the plastic volumetric tube and filled up to the mark by using deionized water. Heavy metals (As, Cd, Cr, Cu, Pb, and Zn) concentration were determined by inductive couple plasma - mass spectrometry (ICP-MS, Agilent 7900). European

Total organic carbon was determined by titration method using Mohr salt $(NH_4)_2Fe(SO_4)_2.6H_2O$ after digestion of the sample by mixture of $K_2Cr_2O_7$-H_2SO_4, which followed the method of ISO 14235:1998. Grain-size distribution of desalted sediments was determined by wet sieving of sand and gravel and by the pipette technique for silt and clay fractions according to Vietnam Standards: Soil quality – Method for determination of particle size distribution (TCVN 8567:2010).

Enrichment factor (EF) is commonly used to discern metal contamination. EF is calculated as follows (*Eq. 1;* Salomons and Forstner, 1984; Sinex and Wright, 1988):

$$A = \frac{\left(\frac{Me}{Al}\right)_{Sample}}{\left(\frac{Me}{Al}\right)_{Background}} \quad \text{(Eq.1)}$$

where $(Me/Al)_{sample}$ is the metal to aluminum (Al) ratio in the samples; $(Me/Al)_{background}$ is the metal to Al ratio in background. Because Al is one of the most abundant elements on the earth and its concentration is generally not influenced by anthropogenic sources, it is commonly used for normalization purpose (Schropp and Windom, 1988). There is little information about heavy metal background values in the Nam Dinh province. Therefore, we adopted the values of upper continental crust (Taylor and McLennan, 1995) as the background values, which are (in $mg.kg^{-1}$): 80,400 for Al; 0.098 for Cd; 25 for Cu; 20 for Pb, and 71 for Zn. For As and Cr, the updated values of 5.7 $mg.kg^{-1}$ and 73 $mg.kg^{1}$, respectively were used (Hu and Gao, 2008). This approach has been widely used to determine the source heavy metal pollution in soil environment (José et al., 2017; Dragović and Mihailović, 2009; Loska et al., 2004).

Multivariate statistical methods such as cluster analysis (CA), principal component analysis (PCA) provide a classification tool based on the relationship between different metals in different sampling points, which can be used to distinguish between the natural and anthropogenic sources of heavy metal (Wang et al., 2019b; Han et al., 2006; Wu and Zhang, 2010; Nguyen et al., 2016a).

Cluster analysis was performed on the heavy metal concentrations and soil properties using SPSS 20.0 software (IBM, USA) using nearest neighbor linkage method based on correlation coefficients. The distance cluster represents the degree of association between elements, the smaller the value on the distance cluster, the more significant the association (Luo et al., 2007).

Principal component analysis using SPSS 20.0 software (IBM, USA) was used in the data set to determine the relationships and common origins between metals. PCA was performed with Varimax rotation with Kaiser Normalization, which facilitated the interpretation of output by minimizing the number of variables that loaded high loads on each component. In this study, all principal factors extracted from the variables were retained with eigenvalues > 1.0, as suggested by the Kaiser criterion (Kaiser, 1960). According to the results obtained from PCA, possible sources of chemical elements were interpreted (Lu et al., 2012).

In this paper, Inverse Distance Weighted which one of tool on ArcGIS 10.5 software is used for interpolating map of heavy metal content. The reclassify the results following the method of equal values to show the distribution of each heavy metal.

Results and discussion

Soil properties in different land use types

Soil properties that could influence the accumulation ability of heavy metals include total organic carbon (TOC), pH, soil grain size, and concentration of aluminum (Al). The variation of these properties in the 38 samples is presented in *Table 2*. From *Table 2* we can recognize that TOC concentration varied among the land use types in Nam Dinh province. Highest TOC content occurred in the paddy soil (TOC_{mean} = 2.99%), which might be related to the tradition of applying organic fertilizers in rice production in this area (Nguyen et al., 2018). The second highest TOC content occurred in the cereals soil (TOC_{mean} = 1.09%), and the least in the aquaculture (TOC_{mean} = 0.58%).

The mean pH value in the studied area was 6.08. The pH values of the sampling sites ranged from 3.87 to 8.05, from extremely acidic to moderately alkaline. According to land use type, the mean pH of paddy soil was 5.6 ± 1.06, close to moderately acidic; the mean pH of cereal soil was 6.8 ± 1.08, near neutral; the mean pH of aquaculture soil was 7.82 ± 0.15, close to slightly alkaline.

Soil grain size varies in each land use type, with sand always being dominant and the mean clay percentage in different types of land use decreases in the order of paddy soil > cereal soil > aquaculture soil in the study area.

Heavy metal concentration in agricultural soil in Nam Dinh province

Heavy metal concentrations in agricultural soil in Nam Dinh province are summarized in *Table 3* and *Figures 2-9*. The mean concentrations of heavy metals in agricultural soil are in decreasing order of Zn > Cr > Cu > Pb > As > Cd. A comparison of the concentrations of heavy metals in the studied soil with the documented data from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67936811

agricultural soil areas in Vietnam show that the contents of As, Cr and Zn are close to previously reported result in the Ba Lat estuary of the Red River (located in Giao Thuy and Xuan Truong districts of Nam Dinh province), while the contents of Cu and Pb are lower 2 to 3 times. In comparison with heavy metal concentration in agricultural soil of Duy Tien district, Ha Nam province, which is also located in Red River delta, we found that the contents of As and Pb in this study are higher 2 and 2.5 times, respectively, while the contents of Cu and Zn are lower. The concentration of As, Cd is higher 5.3 and 1.2 times, respectively while the concentration of Cr, Cu, Pb and Zn is lower in comparison to their counterparts in the upper continental crust.

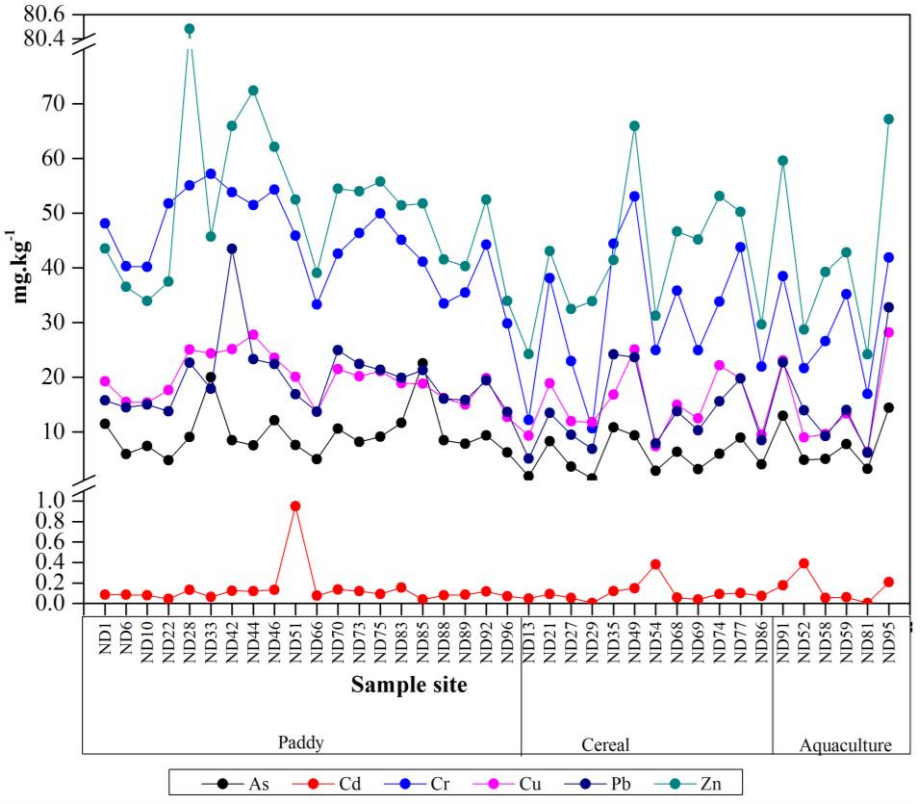

Figure 2. *Spatial variations of heavy metals of the agricultural soil in Nam Dinh province*

Concentrations of metals in soil from different land uses are also presented in *Table 3* and *Figure 3*. In general, paddy soil samples have the highest heavy metal concentration, which was followed by cereal soil samples and aquaculture soil samples. The concentrations of Cd do not exhibit a clear trend. The hotpots of higher Cd contents occurred in Giao Thuy district.

Assessment of heavy metal pollution

The enrichment factor (EF) values can give an insight into differentiating an anthropogenic source from a natural origin. Typically, an EF value of < 1.5 suggests a dominance of natural sources (Zhang and Liu, 2002). Further, EF values can also assist the determination of the degree of metal contamination. Five contamination categories are recognized on the basis of the enrichment factor (Sutherland, 2000; Loska and Wiechula, 2003) (*Table 4*).

The enrichment factors in agricultural soils in Nam Dinh province are shown in *Figure 10* and *Table* 5. It is clear that Cr, Cu, Pb, and Zn have a mean EF less than 1.5, confirming their mainly natural sources except some sites have EF values higher than 1.5 (e.g. ND29, ND35, ND73, ND96). On the other hand, the mean EF values of As and Cd are higher than 2, indicating existence of heavy metal contamination in agricultural soil of Nam Dinh province (Han et al., 2006). In this study, the mean EF values were ranked in the order of As > Cd > Pb > Cu > Zn > Cr. The element Cd has mean EF value between 2 and 5, which was classified as moderately contaminated. The mean EF values of As lie between 5 and 20, which means a significant contamination in this study area.

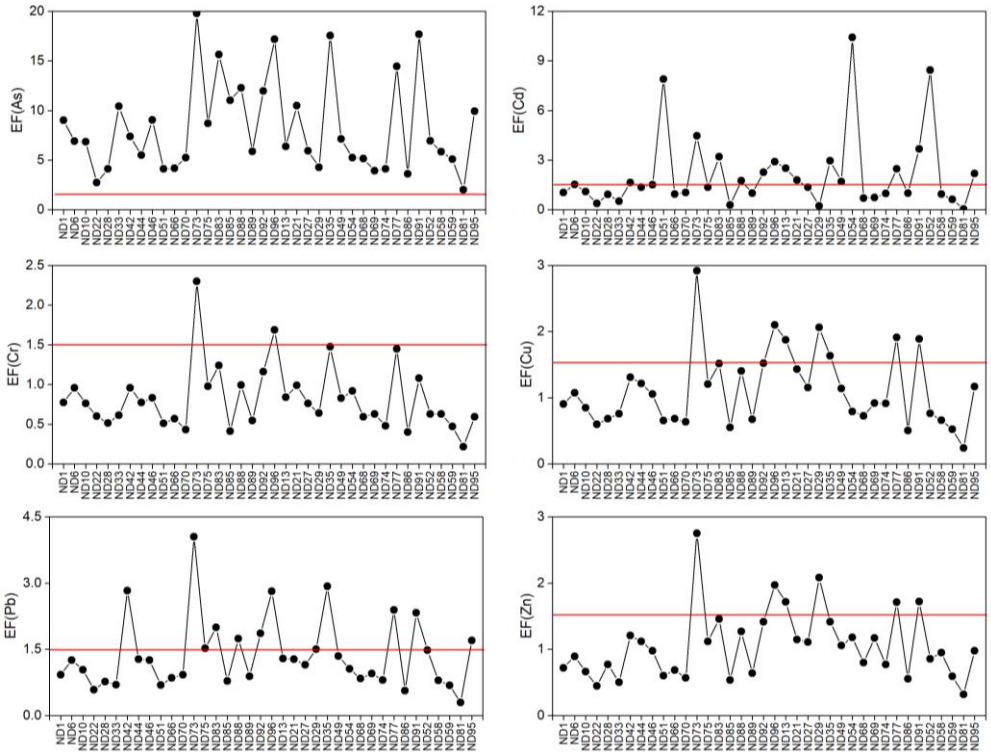

Figure 10. *Spatial variations of EF values of the agricultural soil in Nam Dinh province*

According to land use type and spatial distribution, the smallest mean EF values occurred in aquaculture soil samples, lower 1.4 to 2 times than its in paddy and cereal soil. There is no significant difference in the degree of metal contamination between paddy soil and cereal soil samples. The EF values of As show pronounced higher values in Nghia Hung, Hai Hau, and Nam Truc districts, these sites are localed near industrial zone and traditional handicraft village (e.g. ND88 near to the Thinh Long industrial zone; ND91 and ND92 near to Quy Nhat industrial zone, ND33 near to Dong Quy metal smelting village). The EFs (Cd) show higher in Hai Hau, Nghia Hung and Giao Thuy districts (ND51, ND52, ND54, ND73, ND83, ND92, ND96).

Sources of heavy metal in agricultural soil

Correlation analysis is not only an effective approach to reveal the relationships between heavy metals and soil physicochemical properties, but also an operative way to understand the controlling factors of heavy metals as well as their possible sources

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67936811

(Chai et al., 2015). Correlation analysis reveals diverse relationships between particle size, TOC and pH of soil and heavy metal contents (*Table 6*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67936811

Based on Pearson's correlation coefficients Cr, Cu, Pb, and Zn were found significantly positively correlated with each other ($P < 0.01$). A highly positive correlation ($P < 0.01$) was found between Cu and Zn ($r = 0.91$), Cu and Pb ($r = 0.83$), Cu and Cr ($r = 0.82$), Pb and Zn ($r = 0.80$), Cr and Pb ($r = 0.73$), Cr and Zn ($r = 0.74$), indicating their similar sources. Arsenic has a positive correlation ($P < 0.01$) with Cr, Cu, Pb, and Zn, but these correlation coefficients were relatively weak, i.e., As and Cr ($r = 0.64$), As and Cu ($r = 0.65$), As and Pb ($r = 0.59$), As and Zn ($r = 0.52$). Cadmium does not show correlations with any heavy metals in agricultural soil, suggesting Cd perhaps has different sources or geochemical behaviour.

Soil pH does not show correlations with As, Cd and Pb, however, it shows a negative correlation with Cr, Cu, and Zn (*Table 6*), indicating that neutral soil contains less heavy metals (Chai et al., 2015; Kua et al., 1983; Manta et al., 2002). TOC, Al and silt percentage show a weakly positive correlation with As, Cr, Cu, Pb, and Zn ($p < 0.01$), indicating that these heavy metals are controlled by the contents of organic carbon as well as proportions of finer grain size fractions. Since Cd is not correlated with TOC, Al, and grain size, there exits other factor influencing its contents, which most probably is anthropogenic input.

The results are illustrated in the dendrogram in *Figure 11*, two distinct clusters are identified. The first cluster includes Cu, Zn, Pb, Cr, As and TOC, while Cd cluster into the second group.

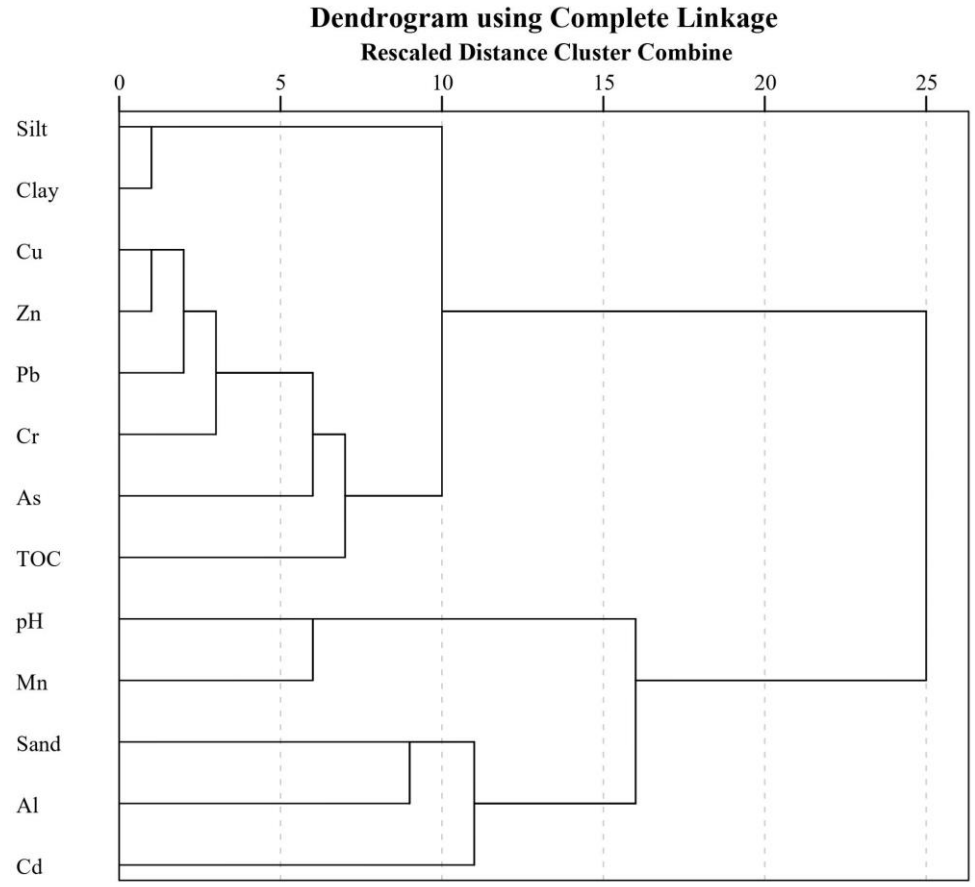

Figure 11. *Hierarchical cluster analysis among particle size and geochemical compositions in topsoil of agricultural soil in Nam Dinh province*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67936811

The results of PCA are presented in *Table 6* and *Figure 12*. The extracted four components with eigen values > 1 explain 75.08% of total variance. The first principal component (PC1) accounts for 43.40% of total variance, showing high positive loadings of Cu (0.91), Zn (0.90), Cr (0.87), Pb (0.85), As (0.75), and medium loading of TOC (0.57) and Al (0.55). The second principal component (PC2) with a variance loading of 20.33% is dominated by the loading clay (0.94) and silt (0.91). The third principal component (PC3) is a less important component, accounting for 11.43 of the total variances, showing positive loading of Mn (0.80), pH (0.86) and Cd (0.28).

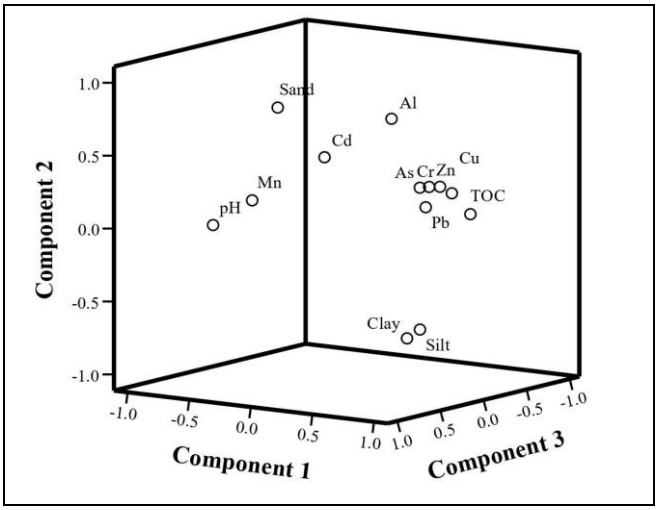

Figure 12. *Principal component analysis loading plots for rotated components of heavy metals and soil properties in Nam Dinh province*

According to the results from cluster and PCA analyses, two groups of elements can be identified: group 1 includes As, Cu, Zn, Pb and Cr, which show affinity with TOC and clay minerals; group 2 include Cd only.

Group 1 can be further subdivided into three sub-clusters. The first one sub-cluster includes Cr element. Since the concentration of Cr in the soil (10.68-57.20 mg/kg) was less than its concentration in UCC (85 mg/kg) and enrichment factor values of Cr were less than 1.5, it can state that Cr originated from natural sources. In addition, a previous study suggested that natural weathering processes are a major factor dominating the amount and distribution of Cr in surface sediments of the Red River, Vietnam, and it has a non-anthropogenic origin in Ba Lat estuary (Nguyen et al., 2016b).

The second sub-cluster includes As. The element As has a weak correlation with other heavy metals in this group, and it has enrichment factor values higher than 2. It indicated that this element has industrial and domestic sources. The main reason for the high enrichment factor values of As could be that the groundwater at these sites contains higher As level, which is commonly used to irrigate agricultural soil. The geology of Red delta shows similarity with the Ganges-Brahmaputra, where high As levels in the groundwater have been reported (Agusa et al., 2005, 2006; Berg et al., 2001, 2007; Chander et al., 2004; Nguyen et al., 2008). The same result was reported in agricultural soils in the Pear River, China (Chai et al., 2004; Huang et al., 2011). Element As was also found in pig and chicken manure, which are often used on the soil as a fertilizer (Zarcinas et al., 2005; Duan et al., 2016; Wang et al., 2019a). In contrast,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_67936811

increased industrial activities, such as chemical and fertilizer production as well as manufacturing in traditional handicraft villages (e.g. metal smelting and processing and painting), might have become additional sources of pollution in recent years.

The third sub-cluster includes Cu, Pb and Zn. These heavy metals have mean enrichment factor values less than 1.5 and they have a close correlation with TOC, silt and Al. These factors indicate a natural origin of Cu, Pb and Zn.

The second group indicates for Cd. Element Cd pollution was possibly caused by anthropogenic wastes, including sewage sludge, wastewater and/or fertilizers and pesticides.

As mentioned above, the EF values of Cd show higher values in Nghia Hung and Giao Thuy, these two districts are coastal districts of Nam Dinh province. These sites are located near the dike, high way, ecotourism zone, and industrial zone (e.g. ND95 near to Thinh Long ecotourism zone, ND51, ND52, ND54 near to the dike). Trinh and Shin (2004) also pointed out that, possible sources of Cd in Red River delta were irrigation water contaminated by inflow of improperly disposed wastewater, sewage sludge that was incorporated in the agricultural soil as an amendment, and vehicle tires.

Conclusions

Heavy metal contents are higher in soils of paddy fields and cereal fields, but lower in aquaculture soil.

According to cluster and PCA analyses, heavy metals can be grouped into two groups. Elements Cu, Pb, Cd, As and Zn have similar geochemical behaviours while Cd is different from them.

According to enrichment factor, elements Cr are mainly from natural source, while Cd and As have a significant anthropogenic input. Elements Cu, Pb and Zn have a mixed source.

Hot spots with high levels of As and Cd pollution are normally located next to industrial zones and traditional handicraft villages. These hotspots should be managed properly in terms of human health.

The effect of land use type on heavy metal concentrations will be discussed deeply in future studies.

(Received 12th May 2020; accepted 13th Aug 2020)

Abstract. In this study, the effects of organic fertilizer forms and doses on the seed germination and seedling growth of rapeseed were investigated. A study was carried out according to the Completely Randomized Experimental Design with three replications. Under liquid seaweed, germination index, radicle fresh weight, and radicle, plumule and seedling dry weights were found to be highest, while germination percentage, radicle length, plumule length, seedling length and germinated seed number proved to be the lowest. In liquid vermicompost; radicle length, plumule length, seedling length, radicle fresh weight, radicle dry weight and seedling vigor index were the highest. The liquid organic fertilizer with plant-derived amino acids proved to be the highest germination percentage value and the lowest radicle length, radicle fresh weigth, plumule fresh weight, seedling fresh weight, and radicle, plumule and seedling dry weight and seedling vigor index. The liquid vermicompost had an effect on increasing the seedling length by encouraging radicle and plumule length of the rapeseed, while liquid seaweed had negative effects on radicle and plumule length. It has been shown an effect to increase seedling fresh weight by promoting seedling growth. It was determined that the liquid organic fertilizer with plant-derived amino acids form encouraged the germination percentage of rapeseed. All tested fertilizers had an inhibitory effect on germination, on the other hand, the fertilizers promoted the seedling growth.
Keywords: *liquid seaweed, liquid vermicompost, organic fertilizer, rapeseed, seedling vigor index*

Introduction

Rapeseed, which can be grown sustainably in two different periods, summer and winter, contains 38-50% fat and 16-24% protein. Rapeseed is an important oil plant. In Turkey; it is also called rapiska, rapitsa and canola (Algan, 1990). Rapeseed oil with a neutral pH level is used as canned and frying oil in the food industry, and its nutritional properties and high boiling point ofconstitute some of its most important features (Tosun and Özkal, 2000). Rapeseed is also used as a raw material in the production of biodiesel with approximately 40% crude oil it contains, and it provides an important contribution to animal nutrition with the remaining 60% pulp.

Rapeseed is very useful in the beekeeping industry as well as in the food industry. It is a good source of food for bees that ensure dust intake from yellow flowers of rapeseed in March-April, when the flowers are scarce (Şeker, 2015). Rapeseed production with these benefits and uses; It ranks third in the world with 75001457 tons of oilseed plants such as soybean, cotton, peanut, sunflower, safflower and sesame. According to 2018 data, the world rapeseed cultivation is 37579575 ha and the yield is 1995.8 kg ha^{-1} (FAOSTAT, 2020).

According to the 2019 data in Turkey in rapeseed cultivation; 52515 ha cultivation, 3430.0 kg ha^{-1} yield and 180000 tons' production, and 61.87% of 111358 tons were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68136828

produced in the West Marmara Region. The highest production is in Tekirdağ province with a ratio of 33.61% with 60497 tons (TURKSTAT, 2020).

Today, urbanization and industrialization have increased, fertile agricultural lands are decreasing, so it is necessary to obtain more products from the unit area in order to meet the nutritional needs of the increasing population. Here, fertilization has become mandatory to regain nutrients lost from the soil.

According to Adolf Mayer, "fertilization is the process of feeding the plant nutrients to the soil in order to increase the yield power of the culture soils and increase the quality and quantity of the product to be obtained. The substances used for this purpose are called "fertilizer" (Kacar, 2013).

Here, in order to increase the production quality of rapeseed, it should not disrupt the structure of the soil, crop rotation should be applied, organic fertilizer should be used, and biological control method which does not spoil the structure of the soil should be used. Human beings have to reestablish the natural balance lost in this ecological system as a result of wrong practices. Organic farming is a production system that is friendly to nature and the environment. It ensures that the soil has a sustainable yield, increases plant resistance, promotes biological methods without using chemicals in plant protection, and aims to increase the quality of the product in production.

Organic fertilization, on the other hand, improves soil yield, sustainability and water-holding capacity, improves soil and accelerates microbial activities (Yüksek et al., 2019). Another important feature of organic fertilizers is that they are a good soil conditioner (Aygün and Acar, 2004). The use of organic extracts (fertilization, plant growth regulators, etc.) has proven effective in improving seed germination and early seedling growth in abiotic stress conditions (Sharma et al., 2014). Seaweed and vermicompost extracts from these organic extracts have found use in seed applications (Demir et al., 2006; Ma et al., 2017; Masondo et al., 2018).

One of these extracts is vermicompost, also known as vermicompost, which is among the soil improvers and nutrients used in organic agriculture. Vermicompost is the process of composting organic waste by worms. The worm fertilizer produced as a result of the vermicompost process consists of completely organic materials, contains plant nutrients and some plant growth hormones. Therefore, it makes it possible to buy more products from the unit area.

Solid worm manure is a product obtained by composting. Liquid worm manure is called processed state of composted manure. So, it is obtained from solid worm manure. Liquid worm fertilizer is an odorless, brown and slightly alkaline (7-9 pH) organic liquid. In liquid worm manure; it contains humates, fulvic acids, amino acids, vitamins, natural hormones, micro and macro elements (N, P, K, O, Ca, Mg, S) found in solid earthworm fertilizer in a concentrated form of soil microorganism spores (Benitez et al., 2000).

Liquid worm fertilizer accelerates the growth and growth of the plant, has no harm on humans, animals and soil, stimulates the root formation of plants and allows them to form strong roots Protects the soil and the plant from harmful pests and pathogens that may occur in the soil. By providing natural immunity to plants, it eliminates the occurrence of disease in parts such as leaves and stems, accelerates flowering in pot plants, and provides faster crop formation in greenhouse plants. When applied to the leaves of the plant, it gives vitality to the leaf and supports the formation of more photosynthesis, accelerates the metabolism of the plant, prolongs the waiting period in storage of plants or nutrients, delays the decay of the plant, it is a form of liquid fertilizer which is highly recommended for use in agriculture. Liquid worm manure is dark colored, high viscosity and has a long

DOI: http://dx.doi.org/10.15666/aeer/1805_68136828

shelf life. It is obtained using various technologies, and and the organic substance is rich in humic and fulvic acid amounts (Yıldırım, 2019). The second of these extracts, seaweed (maxicrop), was obtained from the seaweed called *Ascophyllum nodosum* on the Norwegian coast. There is auxin (indole and derivatives) and cytokinin (zeatin, kinetin, adenine, purine and adenosine) as growth regulators in seaweed. Seaweeds contain macro (0.75% N, 1% P_2O_5, 16% K_2O, 0.20% Mg, 2.90% S) and micro (30 ppm B, 290 ppm Fe, 12 ppm Cu, 56 ppm Zn,) elements. It is also an excellent source of bioactive compounds by growth promoting substances such as seaweeds, essential fatty acids, vitamins, amino acids, minerals, organic osmolites (e.g. betainees) and gibberellins (Spinelli et al., 2010).

Seaweed extracts and suspensions from brown algae are studied in the cultivation of garden plants. Marmarin (seaweed extract) is a biostimulant that increases the production and quality of agricultural products and is widely used in vegetable production (Amanpoor et al., 2011). Seaweed extracts have beneficial effects on plants such as early seed germination, increasing plant performance and yield, high resistance to biotic and abiotic stress and extending the shelf life of seeds. Seaweed extract as an organic biostimulant is one of the applications quickly accepted in horticultural crops due to its beneficial effects. In experimental studies, it has been observed that seedling growth is stimulated by using seaweed extracts (Demir et al., 2006). However, since the high concentration of seaweed can cause loss of yield in the plant, it is necessary to pay attention to the method and duration of application. (Spinelli et al., 2010).

The third of these extracts is a liquid organic fertilizer with plant-derived amino acids. It has a high content of organic matter and contains nitrogen. Therefore, it enables plants to grow faster, bushy and healthier. The liquid organic fertilizer with plant-derived amino acids provide a smooth flowering, promote the number and quality of fruit, shorten the harvest time, provide early crop, increase the resistance of plants against adverse soil and climate factors. Therefore, it is an important liquid organic fertilizer.

In the study, liquid worm manure, liquid seaweed manure, and liquid organic fertilizer forms with plant-derived amino acids were used. It is aimed to determine the encouraging or preventing effects of organic fertilizer forms and doses on the rapeseed (*Brassica napus* L.) seed germination and seedling growth. and liquid organic fertilizer with plant-derived amino acids

Material and Methods

This study was carried out in Kahramanmaraş Sütçü İmam University Faculty of Agriculture, Department of Field Crops, Industrial Plants Laboratory in the climate cabinet in January 2020 in Turkey. In the experiment, healthy and homogenous rapeseed (ES Hydromel variety) seeds were used as material.

The research aimed to investigate the effects of different organic fertilizer forms and doses on the germination and seedling growth of rapeseed using a completely randomized experimental design with three replications, in order to find the most optimal combination.

Three fertilizer forms (OF1: liquid seaweed, OF2: liquid organic fertilizer with plant-derived amino acids and OF3: liquid vermicompost) and six doses (FD1: control, FD2: 1000 ppm L^{-1}, FD3: 2000 ppm L^{-1} FD4: 4000 L^{-1}, FD5: 8000 ppm L^{-1}, FD6: 16000 ppm L^{-1}) were applied. Solutions were prepared by diluting fertilizer doses with tap water. Seeds were placed in petri dishes. After leaving two layers of drying paper on the bottom of each petri dish (90 mm), seven ml of fertilizer doses prepared were added

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68136828

to the drying papers in the petri dish. Surface sterilization was performed in the seeds for five minutes in the solution created with 5% NaOCl (sodium hypochlorite) (Yılmaz, 2015). 25 healthy and similar sized seeds were planted. It is coated with parafilm (PM-992) to prevent water loss in petri dishes. It was allowed to germinate for 14 days in an incubator with a temperature of 25 ± 2 °C. On the 15th day, the seeds were measured for germination and seedling growth (*Figure 1*). The germinated seeds were counted and divided by the total number of seeds and then multiplied by 100 to get the germination rate. Radicle and plumule lengths were measured with calipers. Seedling length was determined by sum of the radicle lenght and plumule lenght. Radicle and plumule were weighed as fresh, and radicle fresh weight and plumule fresh weight were summed and seedling fresh weight was obtained. The samples were then kept for 24 hours at 78 ℃ in the etuv and the dry weight of the radicle and dry weight of the plumula were weighed and the sum of the seedling dry weights were found. As a result of the multiplication of seedling length and germination rate, seedling vigor index was found.

Figure 1. *In the laboratory with climate cabinet, an oven, precision scales, etc., on the 15th day after placing; while seeds are measured for germination and seedling development*

Statistical analysis of data

All data obtained from the study were processed by SAS (v. 9.0, 2002) statistical package. The data were analyzed using analysis of variance (ANOVA) according to the Completely Randomized Experimental Design. Averages were compared by Least Significant Difference multiple comparison test (Stell and Toor, 1980).

Results and Discussion

Averages of the effects of organic fertilizer forms and doses on the seed germination and seedling growth of rapeseed are given in *Table 1* and *Table 2*. According to these tables, fertilizer doses has significantly affected all attributes of germination and seedling. The differences between fertilizer doses, organic fertilezer forms, and their interaction averages were found to be statistically significant for all observed attributes. However, since there was no germination in the OF1-FD6 application, the comparison of the fertilizer x dose interactions averages was performed over 17 values.

*: The mean in the same column, expressed in lowercase and indicated with different letters, is statistically different from each other within the P≤0.05 error limits according to LSD test

**: The mean in the same column, expressed in capital and indicated with different letters, is statistically different from each other within the P≤0.05 error limits according to LSD test

Germination Percentage (%)

It seems that OF2 is more encouraging in terms of germination percentage. The highest germination percentage among fertilizer forms was observed in OF2 with 53.41%, while the lowest germination percentage was obtained from OF1 fertilizer with 43.85%. In fertilizer x dose interaction, the highest germination percentage was observed in OF3-FD1, OF2-FD1, OF1-FD1 and OF1-FD2 (95.11, 95.11, 95.11, and 90.67%, respectively). When the control doses were ignored, the highest germination percentage was seen in OF1-FD2 with 90.67%. Therefore, in addition to seedling growth, liquid seaweed has been determined as a promoter in seed germination. However, the trend of germination percentage at increasing doses in liquid seaweed showed a downward decline. The lowest germination percentage was seen in OF1-FD4 with 17.33% (*Table 1* and *Figure 2*).

Demirkaya (2010), in his study on the effects of seaweed (*Ascophyllum nodosum*) extract applications on the viability and strength of pepper and onion seeds; found that OC (Osmotic Conditioning: Pre-Germination) applications with seaweed extract increase the germination rate of onion and pepper seeds according to the control application. The results are consistent with the highest finding of germination percentage in OF1-FD2 in fertilizer x dose interaction.

Demirkaya (2012), in his another study on the effects of seaweed (*Ascophyllum nodosum*) extract applications on the viability and strength of tomato seeds; found that OK applications with seaweed extract increased the germination rates of the seeds of three tomato varieties compared to the control application. The results are similar to the highest finding of germination percentage in OF1-FD2 in fertilizer x dose interaction.

Yıldırım and Güvenç (2005), in their study on the effect of seaweed extract practices on seed germination in leeks; They found that with the application of seaweed extract to leek seeds, the rate and speed of seed germination increased significantly compared to the control. The results are consistent with the highest finding of germination percentage in OF1-FD2 in fertilizer x dose interaction.

Matysiak et al. (2011), in their study on the effect of seaweed extracts and the mixture of humic and fulvic acid on germination and growth of corn; reported that extracts from seaweeds (Kelpak SL and AlgaminoPlant) stimulate corn seed germination more than humic and fulvic acids (HumiPlant) and increase by 16-19%. The results are consistent with the highest finding of germination percentage in OF1-FD2.

Germination Index

It is seen that OF1 is higher in terms of Germination index average. The highest germination index among the fertilizer forms was seen in OF1 with 3.09, while the lowest germination index was obtained from the OF3 fertilizer form with 2.76. In fertilizer x dose interaction, the highest germination index was found in 8.22 with OF3-FD1, OF2-FD1 and OF1-FD1. The lowest germination index was observed in OF2-FD5 and OF3-FD5 with 0.70 (*Table 1* and *Figure 3*).

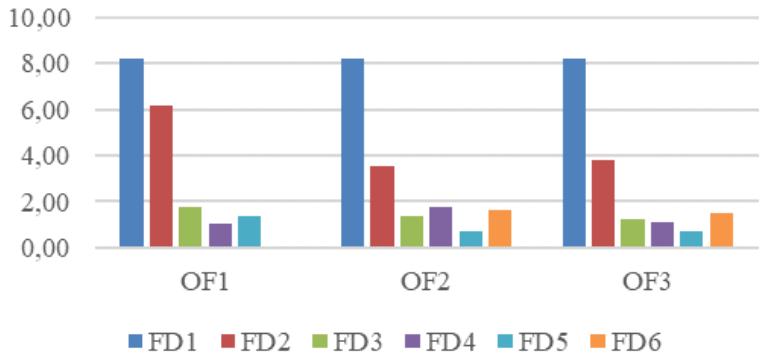

Figure 3. *The interaction of organic fertilizers' germination index*

Yıldırım and Güvenç (2005), in their study on the effect of seaweed extract applications on seed germination in leeks; they found that with the application of seaweed extract to leek seeds, the rate and speed of seed germination increased significantly compared to control. The results are in line with the highest germination index finding in OF1.

DOI: http://dx.doi.org/10.15666/aeer/1805_68136828

Radicle Length (mm)

It is seen that OF3 is more encouraging in terms of the average of the radicle length. Among the fertilizer forms, the highest radicle length was observed in OF3 with 77.17 mm, while the lowest radicle length was obtained from OF2 (37.56 mm) and OF1 (36.78 mm) fertilizer forms. In fertilizer x dose interaction, the highest radicle length was 112.72 mm with OF3-FD1, OF2-FD1 and OF1-FD1. The lowest radicle length was observed in OF1-FD3, OF1-FD4 and OF2-FD4 (3.01, 3.37, and 4.17 mm, respectively) (*Table 1* and *Figure 4*).

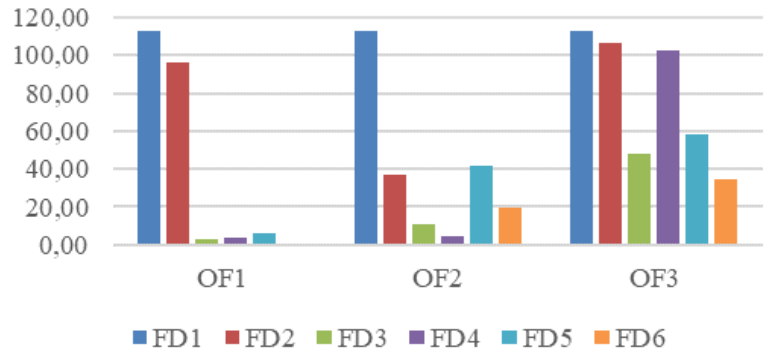

Figure 4. *The interaction of organic fertilizers' radicle length*

Plumule Length (mm)

When plumule length averages are examined, it is seen that OF3 has a more positive effect on plumule length. Among the fertilizer forms, the highest plumule length was 32.56 mm with OF3 fertilizer form. The lowest plumule length was obtained from OF1 fertilizer form with 19.45 mm. In fertilizer x dose interaction, the highest plumule length was observed in OF3-FD2 with 47.55 mm. The lowest plumule length was observed in OF1-FD4, OF3-FD3, OF1-FD3 and OF2-FD4 (6.24, 7.09, 7.22, and 7.68 mm, respectively) (*Table 1* and *Figure 5*).

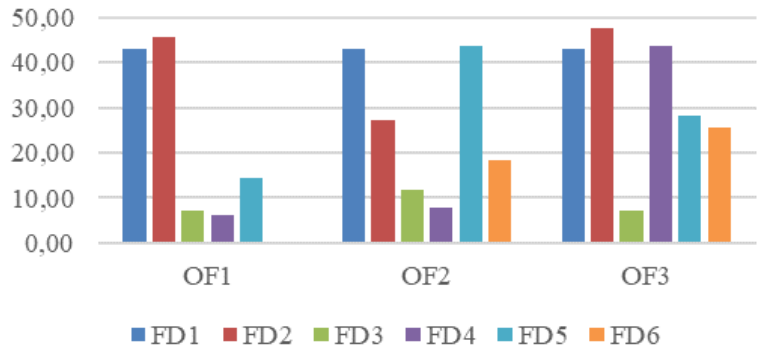

Figure 5. *The interaction of organic fertilizers' plumule length*

Seedling Length (mm)

It is seen that OF3 is more encouraging in terms of Seedling length average. While the highest seedling length was seen in OF3 with 109.72 mm in fertilizer forms, the lowest

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68136828

seedling length was obtained from OF1 fertilizer form with 56.23 mm. In fertilizer x dose interaction, the highest seedling length was observed in OF3-FD1, OF2-FD1, OF1-FD1 and OF3-FD2 (155.93, 155.93, 155.93, and 154.41 mm, respectively). The lowest seedling length was observed in OF1-FD4 OF1-FD3 and OF2-FD4 (9.61, 10.23, and 11.85 mm, respectively) (*Table 1* and *Figure 6*).

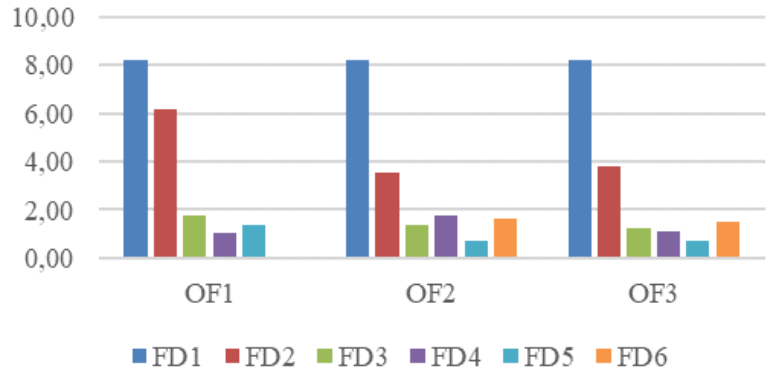

Figure 6. *The interaction of organic fertilizers' seedling length*

Alam et al. (2007), reported that vermicompost and N P K S fertilizers increased the effect of red amaranth on the growth, yield and yield components of red amaranth, and vermicompost application increased the control of vermicompost compared to control applications. The findings support the highest seedling length in OF3.

Radicle Fresh Weight (mg)

It is seen that OF1 and OF3 are higher in terms of radicle fresh weight average. While the highest radicle fresh weights were observed with OF1 (7.58 mg) and OF3 (7.41 mg) among fertilizer forms, the lowest radicle fresh weight was obtained from OF2 fertilizer form with 5.24 mg. In fertilizer x dose interaction, the highest radicle fresh weight was observed in OF1-FD5 with 17.40 mg. The lowest radicle fresh weight was observed in OF2-FD6 with 1.03 mg (*Table 1* and *Figure 7*).

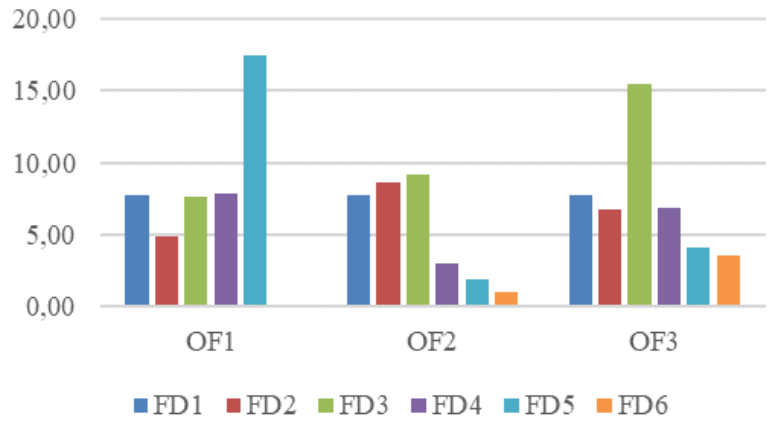

Figure 7. *The interaction of organic fertilizers' radicle fresh weigth*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68136828

Plumule Fresh Weight (mg)

It is seen that OF1 is higher in terms of plumule fresh weight average. While the highest plumule fresh weight was observed in OF1 with 43.832 mg among fertilizer forms, the lowest plumule fresh weight was obtained from OF2 fertilizer form with 28.025 mg. In fertilizer x dose interaction, the highest plumule fresh weight was observed in OF1-FD3 with 71.633 mg. The lowest plumule fresh weight was seen in OF2-FD6 with 15.100 mg (*Table 2* and *Figure 8*).

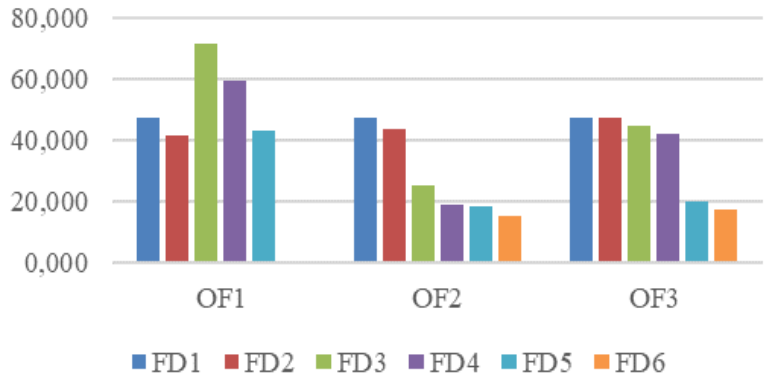

Figure 8. *The interaction of organic fertilizers' plumule fresh weigth*

Matysiak et al. (2011), in their study on the effect of seaweed extracts and the mixture of humic and fulvic acid on germination and growth of corn; reported that extracts from seaweeds (Kelpak SL and AlgaminoPlant) increased corn plumule fresh weight. The results are consistent with the highest plumule wet weight finding in OF1-FD3.

Seedling Fresh Weight (mg)

It is seen that OF1 is higher in terms of seedling fresh weight average. While the highest seedling fresh weight was seen in OF1 with 51.415 mg among fertilizer forms, the lowest seedling fresh weight was obtained from OF2 fertilizer form with 33.270 mg. In fertilizer x dose interaction, the highest seedling fresh weight was seen in OF1-FD3 with 79.233 mg. The lowest seedling fresh weight was observed in OF2-FD6 with 16.133 mg (*Table 2* and *Figure 9*).

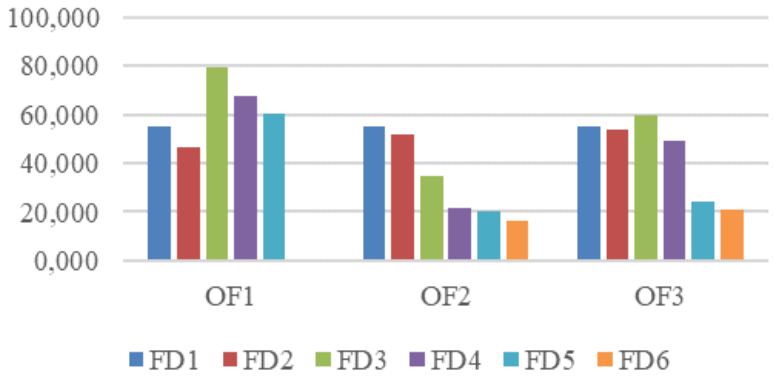

Figure 9. *The interaction of organic fertilizers' seedling fresh weigth*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68136828

Radicle Dry Weight (mg)

It is seen that OF1 and OF3 are higher in terms of the average of radicle dry weight. Among the fertilizer forms, the highest radicle dry weights were seen in OF1 (0.834 mg) and OF3 (0.815 mg), while the lowest radicle dry weight was obtained from OF2 fertilizer form with 0.577 mg. In fertilizer x dose interaction, the highest radicle dry weight was found in OF1-FD5 with 1.914 mg. The lowest radicle dry weight was found in OF2-FD6 with 0.114 mg (*Table 2* and *Figure 10*).

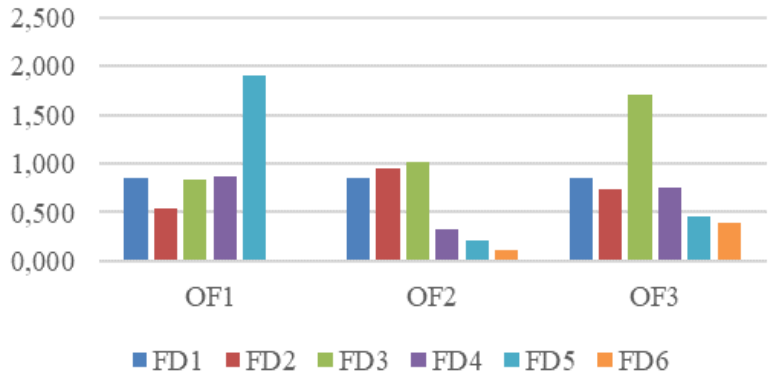

Figure 10. *The interaction of organic fertilizers' radicle dry weigth*

Plumule Dry Weight (mg)

OF1 is higher in terms of plumule dry weight average. While the highest plumule dry weight was observed in OF1 with 4.822 mg, the lowest plumule dry weight was obtained from OF2 fertilizer form with 3.083 mg. In fertilizer x dose interaction, the highest plumule dry weight was observed in OF1-FD3 with 7.880 mg. The lowest plumule dry weight was seen in OF2-FD6 with 1.661 mg (*Table 2* and *Figure 11*).

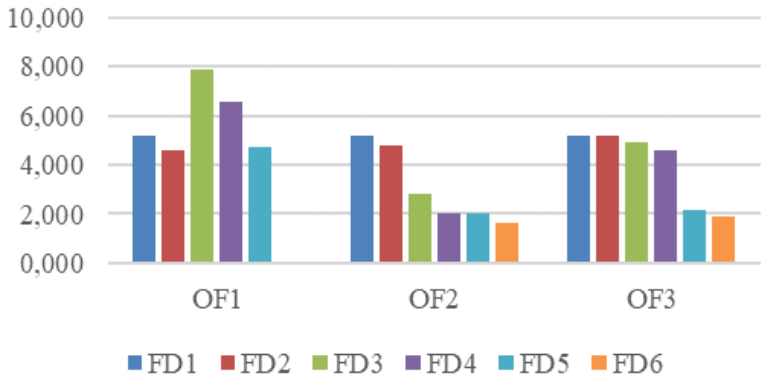

Figure 11. *The interaction of organic fertilizers' plumule dry weigth*

Seedling Dry Weight (mg)

As seen in *Table 2*, OF1 is higher in terms of seedling dry weight average. While the highest seedling dry weight was found in OF1 with 5.656 mg among fertilizer forms, the lowest seedling dry weight was obtained from OF2 fertilizer with 3.660 mg. In fertilizer

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68136828

x dose interaction, the highest seedling dry weight was found in OF1-FD3 with 8.716 mg. The lowest seedling dry weight was observed in OF2-FD6 with 1.775 mg (*Table 2* and *Figure 12*).

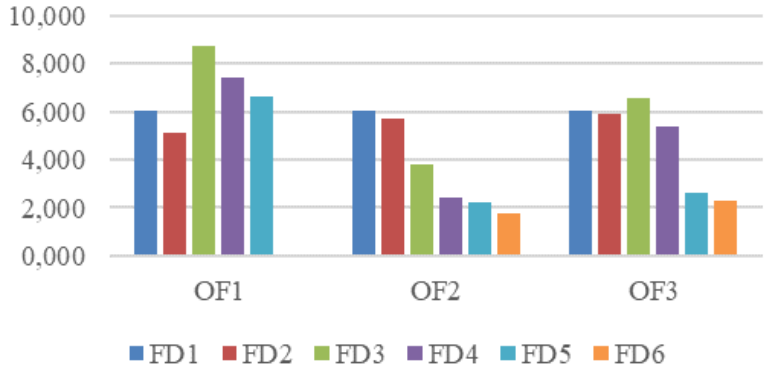

Figure 12. *The interaction of organic fertilizers' seedling dry weigth*

Seedling Vigor Index

It is seen that OF3 is higher in terms of seedling vigor index average. Among the fertilizer forms, the highest seedling vigor index was seen in OF3 with 5933.47, while the lowest seedling vigor index was obtained from OF2 fertilizer form with 4093.27. In fertilizer x dose interaction, the highest seedling vigor index 14848.52 was seen in OF3-FD1, OF2-FD1 and OF1-FD1. The lowest seedling vigor index was seen in OF1-FD4 with 166.84 (*Table 2* and *Figure 13*).

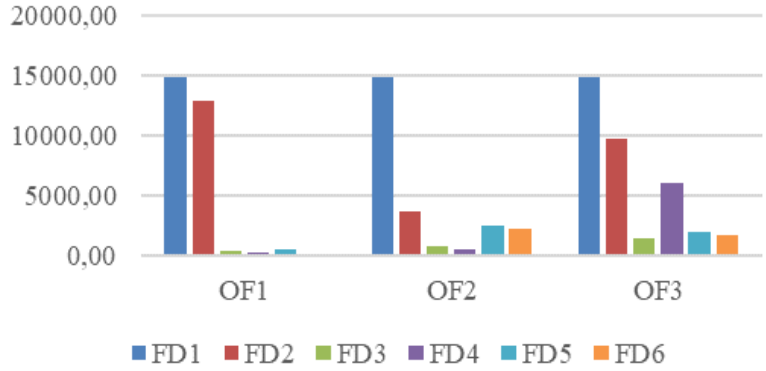

Figure 13. *The interaction of organic fertilizers' seedling vigor index*

Germinated Seed Number (number)

It is seen that OF2 is higher in terms of average of germinated seed number. The highest germinated seed number among the fertilizer forms was seen in OF2 with 13.35, while the lowest germinated seed number was obtained from the OF1 fertilizer form with 10.96. In fertilizer x dose interaction, the highest germinated seed number was observed in OF3-FD1, OF2-FD1, OF1-FD1 and OF1-FD2 (23.78, 23.78, 23.78, and 22.67, respectively). The lowest germinated seed number was found in OF1-FD4 with 4.33 (*Table 2* and *Figure 14*).

DOI: http://dx.doi.org/10.15666/aeer/1805_68136828

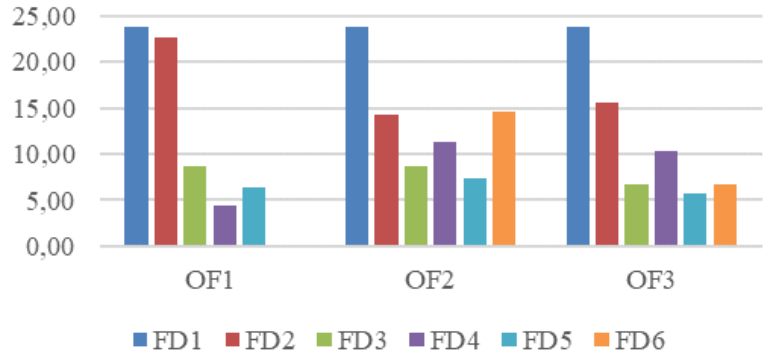

Figure 14. *The interaction of organic fertilizers' germinated seed number*

The relationships among the observed characteristics

In the study, a correlation analysis was conducted to reveal the relationships between all investigated properties of *Brassica napus* L. seeds subjected to organic fertilizer forms and doses. The many of correlations between all the examined properties are considered to be significant (P<0.01 and P<0.05) with different organic fertilizer form doses (*Table 3*). As presented in *Table 3*, one of the most important features is the germination percentage. It was found to have significant positive correlations with GI, RL, PL, SL, PFW, SFW, PDW, SDW, SVI, and GSN (r=0.942, r=0.764, r=0.701, r=0.765, r=0.359, r=0.315, r=0.358, r=0.315, r=0.916, and r=1.000, respectively). *Table 3* can be examined for the positive and negative relationship among other characteristics.

Conclusion

According to the results of the research, it was observed that organic fertilizer forms significantly affect the parameters of rapeseed germination and seedling growth.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68136828

The findings of the study showed that fertilizer x dose interactions were beneficial in determining the inhibitory properties of rapeseed seeds as well as in promoting germination and seedling growth. Although germination percentage, germination index, radicle length, plumule length, seedling length and plumula fresh weight values are highest in control doses; radicle fresh weight, plumule fresh weight, seedling fresh weight, radicle dry weight, plumule dry weight and seedling dry weight values were found to be highest, especially in 2000 ppm L^{-1} doses.

As a summary, while the liquid seaweed 2000 ppm L^{-1} dose application, plumule fresh weight, seedling fresh weight, radicle dry weight and seedling dry weight were highest, plumule fresh weight seedling fresh weight, plumule dry weight and seedling dry weight values proved to be second high values in 4000 ppm L^{-1} dosing application. The liquid vermicompost had an effect of increasing seedling length by promoting both root and shoot length of rapeseed. The liquid seaweed had a negative effect on both root and shoot length of rapeseed, while promoting seedling growth, and had an effect increase seedling fresh weight. The form of liquid organic fertilizer with plant-derived amino acids had a stimulating effect on the germination rate of rapeseed.

There was no germination at the highest applied dose (16000 ppm L^{-1}) of the liquid seaweed. In fertilizer doses; in 16000 ppm L^{-1} application, it was determined that it gave the lowest values in germination index, radicle length, radicle fresh weight, plumule fresh weight, seedling fresh weight, radicle dry weight, plumule dry weight and seedling dry weight, and the application of 16000 ppm L^{-1} fertilizer dose had a negative effect on the germination and seedling growth of rapeseed in organic fertilizer forms investigated.

According to the data obtained in the study, it was observed that the fertilizers of organic origin applied did not have a positive effect on the germination rate and index, but after the germination, it was observed that the seaweed manure had positive and significant effects on seedling growth, while the worm manure had the same effect on the seedling lengths.

In future studies, it is necessary to diversify the studies on organic fertilizers, especially liquid seaweed, which promotes seedling growth, and liquid worm manure, which promotes seedling length. In order to emphasize the importance of these fertilizer forms, it will be important to carry out more studies in different plants, as well as to use other organic fertilizers in these studies to be conducted, to obtain healthier and more accurate data.

(Received 13th May 2020; accepted 13th Aug 2020)

Abstract. This investigation was carried out in the experimental farm and the grain quality laboratory of the Rice Research and Training Center, Kafr El-Sheikh Governorate, Egypt to determine the grain quality characteristics as well as the nutritional value after milling of three Egyptian rice genotypes (*Oryza sativa)* under foliar treatment with different stimulating compounds. A tow-year field experiment was laid out in split-plot design with four replications in the 2017 and 2018 rice growing seasons. Rice genotypes were allocated in the main plot and stimulating compounds in the subplot. After harvesting, 150-gram from each plot was taken to study the following characteristics: hulling, milling, head rice, gelatinous temperature, kernel elongation, amylose content, protein content, carbohydrate content, lipids content, ash, phosphorus, potassium and energy composition. There were significant differences for most of the studied characteristics caused by genotype, stimulating compound and the interaction between the two factors. The results revealed that the grain quality characteristics and the nutritional value of Egyptian rice genotypes can be enhanced by the application of some stimulating compounds such as amino acids and NPK compound fertilizer.
Keywords: *milling recovery, cooking quality, amino acid, ascorbic acid, NPK*

Introduction

Rice (*Oryza sativa*, L.) is considered to be one of the most important stable food crops in Egypt. It plays a critical role in Egyptian food security. Rice is mostly considered a starchy food, but since animal products can be scarce or expensive in Egypt, it is often the most important source of protein in Egyptians diet as well. The Egyptian rice varieties vary in grain quality characteristics as well as nutritional value after milling (Metwally et al., 2016). Those characteristics are not important only to the consumers but, they are important to the marketer and miller. The genotypic variations in grain quality and nutritional value of milled rice are mainly caused by the genetic, environmental and agronomical factors which have been reported as the main responsible for those variations. Singh et al. (2011) found genotypic variations among three Japonica rice cultivars on physicochemical, cooking and textural properties of milled grains. They found that amylose and protein contents of milled rice grains affected significantly the cooked grain quality. Anjum et al. (2007) indicated significant variation in cooking, chemical characteristics and mineral contents among four Pakistani rice cultivars therefore; differences can be exploited by the rice breeders in their hybridization.

Mohapatra and Bal (2006) studied the cooking quality and instrumental textural attributes of cooked rice for different milling fractions of three rice varieties. They

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68296840

found that cooking qualities as well as textural attributes were found to be varied among the varieties. Frei and Becker (2005) reported that rice protein quality is determined by the amino acid composition and its digestibility. Rice protein quality is very high when compared to other crops. Rice has favorable amino acid compositions, a high amount of lysine and a high protein digestibility which makes it a fairly good source of protein in diets where animal protein is limited.

Several researchers have reported that the use of stimulating substances is one of the effective means of improving rice grain quality and enhancing the milled rice nutritional value. Pan et al. (2013) indicated that foliar application plant growth regulators (gibberellic acid, paclobutrazol, 6-Benzylaminopurine) enhanced yield, grain quality characteristics and antioxidant enzyme activities in super hybrid rice. Kamboj and Mathpal (2019) found that foliar application of plant growth regulators i.e. gibberellic acid cytokinin enhanced the translocation of zinc from vegetative parts to the grains of the rice. They also reported a favorable effect of plant growth regulators on protein content in milled grains due to the translocation of synthesized proteins towards grain by increasing longevity of leaves thus resulted in higher grain protein content.

Therefore, the main objective of this study is to test the grain quality characteristics and the nutritional value of three rice genotypes under foliar application different stimulating compounds.

Materials and methods

At the Experimental Farm of RRTC (Rice Research & Training Center), Sakha, Kafrelsheikh Governorate, Egypt (31°5′17″N, 30°56′44″E altitude), a two-year field experiment was conducted to study the behavior of three rice genotypes treated with foliar application of different stimulating compounds. The selected tested genotypes were Sakha108, GZ9399 and GZ10154. Sakha108 is a newly registered variety while GZ9399 and GZ10154 are new promising genotypes. The parentage, type and origin of the studied genotypes are presented in *Table 1*.

Table 1. *Parentage, type and origin of the rice genotypes*

Genotype	Parentage	Type	Origin
Sakha108	Sakha 101/ HR5824-B-3-2-3 //Sakha 101	Japonica	Egypt
GZ9399	Giza178/IR65844-29-1-3-2-1	Indica/Japonica	Egypt
GZ10154	Sakha 105/Sakha 101	Japonica	Egypt

The soil of the experiment was clayey in texture, 8.15 and 8.12 pH, 1.06 and 1.04 dS/m EC, 1.46 and 1.39% organic matter, 23.91 and 24.51 mg kg^{-1} available nitrogen, 15.45 and 14.12 mg kg^{-1} available phosphorus, 346 and 357 mg kg^{-1} available potassium in first and second season respectively.

The different stimulating compounds were control (distilled water), amino acids, NPK 20:20:20, ascobin, vulvic acid, humic acids, and potassium sulphate. Stimulating compounds were applied twice; 20 and 40 days after transplanting (DAT). Amino acid (27.38% mixed amino acids + 9% micronutrients + 2% magnesium), ascobin (13% citric acid, 25% ascorbic acid plus 62% organic materials) and humic acid (65% humic acid + 10% K_2O) were applied at the rate of 1 g L^{-1}. Vulvic acid (50% vulvic acid + 20% organic acid) was applied at 1 ml L^{-1}. NPK (20-20-20) and potassium sulphate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68296840

(50% K_2O) were applied at 2%. 500 letters per hectare was used as spray solution amount for all compounds.

Split-Plot Design with four replicates was used. Rice genotype and stimulating compound treatment were arranged as main plot and sub-plot, respectively. The plot size was 12 m^2. Rice seeds were sown in nursery 2nd and 4th of May for 2017 and 2018, respectively. Transplanted was done after 28 days of sowing nurseries with three to four seedlings per hill, spaced 20 X 20 cm within and between rows. All plots received optimum culture practices.

Grain quality characteristics: milling recovery, gelatinization temperature, kernel elongation and amylose content was estimated according to Cruz and Khush (2000): 150 (g) cleaned rough rice at 14% moisture content was dehulled using an Experimental Huller Machine (Satake - Japan). The brown rice was separated and weighed then the hulling percentage was calculated. The brown rice was milled using MC GILL Rice Miller No.2. (S.K. Appliances – India). The total milled rice was weighed and milled rice percentage was calculated. Whole milled grains were separated from the total milled rice using a rice sizing device SKU: 61-220-50 (Seedburo – USA). The percentage of head rice was calculated.

Six grains of whole milled rice were placed in boxes containing 1.7% KOH and arranged so that the kernels do not touch each. The boxes were covered and incubated for 23 h at 30 °C. The appearance and disintegration of endosperm were graded visually according to the numerical scale of the gelatinization temperature. Kernel elongation was measured using the Micrometer, the length of five milled grains was measured (mm) and their average was determined for each treatment (before cooking). Grains were left in a test tube filled with 30 ml of distilled water for 30 min, then for another 10 min in 98 °C a water tub. After that, the tubes were placed in cold water until reaching room temperature. Grains were lifted from the distilled water, dried (by filter paper), and measured again by graph papers (after cooking). Kernel elongation percentage was calculated as the percentage of grain expanding before and after cooking.

Amylose content was determined by weighing accurately 100 mg of sample into 100 ml volumetric flask then carefully adding 1 ml of 95% ethanol and 9 ml 1 N Na OH. The mixture was heated for 10 min in a boiling water bath to gelatinize the starch; then cooled, and the content made up to volume 100 ml with water. Pipette 5 ml portion of the gelatinization starch solution, 1 ml of 1 N acetic acid, and 2 ml of iodine solution were added and made up to a volume of 100 ml with distilled water. The content was shaken and stands for 20 min before reading the transmission at 620 nm by Spectronic 1201 Spectrophotometer (Milton Roy, USA)**.**

Protein, carbohydrate, lipids, ash, phosphorus and potassium determination in rice grain: Plant samples were taken from the grain after milling (50 g of milled rice). All plant samples were placed in paper bags and oven-dry at 70 °C for 48 h. Grain samples were ground to powder and digested according to the method of Chapman and Pratt (1961) before chemical analysis as follows: the nitrogen content of milled grains was determined by using the Microkieldahl method (Jackson, 1967) to calculate protein content. Total carbohydrate was calculated by difference as mentioned by Fraser and Holmes (1959). Lipids was determined according to A.O.A.C. (2000). The phosphorus content of milled grain was determined using Spectronic 1201 Spectrophotometer (Milton Roy, USA) following the procedures of Watanabe and Olsen (1965). The Potassium content of grain was determined using Elico CL378 Flame Photometer

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68296840

(RHYS international LTD, India) according to Peterpurgski (1968) method. The energy composition was calculated according to A.O.A.C. (2000) and Singh and Singh (2019).

The data was subjected to analysis of variance (ANOVA), and the differences among treatments' means were compared by Duncan's Multiple Range Test ($P < 0.05$) and multiple F. test according to Duncan (1955). The Simple correlation coefficient (r) among the nutritional properties of milled rice grains was generated using pooled values of two seasons. All statistical analyses were done using Costat Statistical Software - CoHort Software.

Results and discussion

There were marked differences in milling recovery characteristics due to genotype, stimulating compound and the interaction between the two factors (*Tables 2* and *3*). Sakha108 recorded the highest values of hulling percentage and head rice percentage. The highest percentage of milling was observed by the rice genotype GZ10154. The differences among rice genotypes may be due to the genetically inherited variants. Zhao et al. (2018) identified GS9 (Grain Shape Gene on Chromosome 9) gene by map-based cloning. GS9 regulates grain shape and hull thickness by altering cell division.

The application of different stimulating compounds enhanced significantly milling recovery characteristics. The highest percentages of hulling, milling and head rice were noted with foliar application of amino acid followed by NPK 20,20,20. Regarding the interaction effect between genotype and stimulating compound, the studied rice genotypes responded differently to the stimulating compound application. Sakha108 recorded the highest percentages of hulling and head rice under the amino acid foliar application. While the highest percentage of milling was recorded by GZ10154 rice genotype treated with amino acid. Pan et al. (2013) found that foliar application plant growth regulators improved the rice milling recovery characteristics. Gharieb et al. (2016) indicated that application of Ascobin (13% citric acid, 25% ascorbic acid and 62%organic materials) three times as foliar application increased hulling, milling and head rice percentages.

The Gelatinous temperature, kernel elongation and amylose content were varied the rice genotypes by stimulating compounds application (*Tables 4* and *5*). GZ9399 recorded the highest values of gelatinous temperature and the lowest values of kernel elongation and amylose content. The highest amylose content and kernel elongation were observed by the rice genotype GZ10154. The variations among the studied genotypes in cooking qualities may be due to the differences in their shape, thickness and surface area. Mohapatra and Bal (2006) suggested that surface area and thickness of the rice grain are important factors in deciding the diffusion of water during cooking. GZ9399 has lower amylose content and higher gelatinous temperature and kernel elongation which suggests that amylose content plays a significant role in deciding the cooking quality of rice.

Starch is the main component of milled rice grain. It is made up of two starchy fractions: amylose and amylopectin. After cooking, rice grains with high amylose content are dry, fluffy, separate and hard, while those with low amylose content are glossy, soft and sticky. So, Amylose content is considered to be one of the most important predictors of the eating quality of cooked rice. Milled rice cultivars may be generally classified based on their apparent amylose content into waxy (1-2%), very low (2-12%), low (12-20%), intermediate (20-25%) or high (>25%) (Bao, 2012). Based on the results, the studied genotypes under the current study belong to low amylose content rice types that meet the Egyptian consumers' preferences. The significant variation in amylose content among the studied genotypes could be attributed to the genetic background of those varieties.

Foliar application of different stimulating compounds increased significantly gelatinous temperature, kernel elongation and amylose content. The highest values of gelatinous temperature, kernel elongation and amylose content were observed with the application of amino acid followed by NPK 20,20,20. Concerning the interaction effect between genotype and stimulating compound, GZ9399 recorded the highest values of gelatinous temperature and kernel elongation under the amino acid foliar application. While the highest percentage of amylose content was recorded by GZ10154 rice genotype treated with amino acid.

Data in *Tables 6* and *7* revealed significant differences among rice genotypes, stimulating compound and the interaction for protein, carbohydrate and lipids content percentage in both seasons. GZ10154 recorded the highest values of protein content and the lowest values of carbohydrate and lipids. The highest values of carbohydrate content were recorded by GZ9399. Lipids content was significantly higher in Sakha 108 than the other genotypes. Zhao et al. (2018) indicated that GS9 Gene on Chromosome 9 acts as a transcriptional activator to regulate rice grain protein content and appearance quality. Anjum et al. (2007) and Singh and Singh (2019) found genotypic variation in protein, carbohydrate and lipids content percentage among different rice varieties.

The application of different stimulating compounds increased significantly the contents of protein and lipids over control treatment. Foliar application of NPK recorded the highest values of protein content while amino acid foliar application produced the highest values of lipids content. There are highly significant differences in protein, carbohydrate and lipids content percentage with respect to genotype X stimulating compound interaction suggesting that the three rice genotypes responded differently to stimulating compound application. Foliar application of NPK to GZ10154 gave the highest content of protein. Application of amino acid to Gz9399 and Sakha108 recorded the highest values of carbohydrate and lipids respectively. Khan et al. (2016) found that application of plant growth regulators (gibberellic acid, indole acetic acid and kinetin) significant increase in soluble protein contents of two rice cultivars. These results found in accordance of Kamboj and Mathpal (2019).

The ash, phosphorus and potassium contents in milled rice grains differed significantly among genotypes and stimulating compounds, with a significant interaction (*Tables 8* and *9*). Ash content was higher in GZ9399 followed by GZ10154 without any significant difference between them in the second season. Sakha 108 recorded the highest content of phosphorus and potassium. Similar variations pattern has been reported earlier for rice genotypes by Anjum et al. (2007) and Singh et al. (2011). Singh and Singh (2019) found a genetic diversity of five rice varieties in mineral contents of rice grains. Stimulating compounds foliar application increased the content of ash, phosphorus and potassium in milled rice grains compared to control. Amino acid foliar application produced the highest values of ash content. Phosphorus content was higher in NPK treatment compared with other treatments. Potassium sulphate treatment increased significantly potassium content over the other treatments.

Regarding the interaction effect, ash content was higher in GZ9399 under the application of amino acid in both seasons. Phosphorus content in Sakha 108 rice milled grain was higher with the foliar application of NPK. The application of potassium sulphate to Sakha 108 produced the highest content of potassium. Pan et al. (2013) reported that foliar application of different stimulating compounds could enhance the lodging resistance and increase root biomass and root activity to improve phosphorus and potassium accumulation in milled grains of two rice cultivars.

Figure 1 shows that the amounts of energy vary significantly among the different genotypes. The amounts in GZ9399 and GZ10154 were slightly higher than Sakha108. These variations are mainly due to genetic diversity. The application of different stimulating compounds increased energy amount in milled rice grains. The application of amino acid recorded the highest composition of energy for the three rice genotypes. Data in *Table 10* indicated that energy composition in milled rice grain had significant and positive correlations with each of lipids ($p = 0.05$), ash ($p = 0.01$) and phosphorus ($p = 0.01$) concentrations in milled grains. These results explain the superiority of amino acid application.

Conclusion

The foliar application of different stimulating compounds enhanced rice grain quality characteristics as well as the nutritional value of milled grains. The application of different stimulating compounds enhanced the translocation of assimilates to milled grains. Amino acid foliar application showed marked increases in the studied characteristics compared to other treatments. There were noticeable differences in grain quality characteristics and the nutritional value of milled grains among the studied genotypes. Finally, greater attention should be paid to grain quality characteristics in Egyptian rice production to meet Egyptian consumer preferences. Thus, more studies should be done to improve the grain quality characteristics of the Egyptian rice varieties.

Abstract. The paper presents the epizootic situation of African swine fever in Polish territory from the official confirmation of the first case to the end of 2019. In Poland, there is a genotype II of the virus, the transmission of which is associated with its appearance in Georgia in 2007, followed by its spread to the northwest and subsequent appearance in European countries. During the virus period, an annual increase in the number of cases found in feral domestic pigs and outbreaks in pigs was observed. It was not until 2019, when 2,477 cases were diagnosed, that the virus prevalence stabilized in wild boars and the number of outbreaks in pigs more than doubled compared to 2018. Depopulation of boars carried out during this period, indicated as the primary source of danger, did not bring the expected results. Administrative preventive measures have also failed. The current epizootic situation as well as the appearance of the virus even in places more than 300 km away from its earlier statements is a confirmation that wild boars are not the basic vector in the spread of ASFV. At the same time, during the disease occurrence, in samples of wild boars shot from regions where the virus appeared, the presence of antibodies increased in the following years. Seropositivity of wild boars indicates the initial phase of viral endemicity in these regions. This creates another epizootic threat, as these animals may become asymptomatic carriers that may infect other individuals in the wild. In the current situation, it seems necessary to develop clear biosecurity principles for pig farms. These principles should also cover all individuals who may become viral mechanical vectors in the environment. Enforcing compliance with biosecurity rules developed in all areas of activity related to pigs and wild boars should be a priority in limiting the spread of ASFV and its possible eradication in Poland.
Keywords: *wild boar, domestic pig, virus, prevention, biosecurity*

Introduction

The African swine fever virus (ASFV) is a DNA virus that belongs to the *Asfavirus* species of the family *Asfarviridae*. It causes acute viral haemorrhagic disease of pigs and wild boars, usually ending in death, therefore it poses a serious threat to pig production all over the world. Its properties provide it with very high resistance to inactivation by physical and chemical agents, which means that under optimal conditions it can be pathogenic for up to 6 years. The disease is characterized by clinical symptoms and sectional changes similar to the acute form of classical swine fever, in particular high fever, significant splenomegaly, high degree of ecchymosis and up to 100% mortality. In connection with the ban on the treatment of sick animals and the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68416856

lack of vaccines against ASF, the disease is only combated by administrative methods, by killing infected herds and introducing strict biosecurity rules and by limiting, by shooting, the wild boar population as the primary virus reservoir in the natural environment (Markowska-Daniel and Pejsak, 2014; Pejsak and Truszczyński, 2017b; Fila and Woźniakowski, 2020).

The African swine fever virus in Poland was first found on February 14, 2014, based on samples from a wild boar that was found dead in the Sokole County, about 1 km from the border with Belarus. This case was confirmed by the European Reference Laboratory (EURL) for ASF in Valdeolmos, Spain, on February 18, 2014. On February 17, 2014, a second fallen boar was found near the border with Belarus (Pejsak et al., 2014a). In the following months of 2014, further cases of the virus were confirmed. They occurred only in the border belt of the Podlaskie Voivodeship reaching up to 10 km inland, along a length of about 50 km along the border with Belarus (Flis and Nestorowicz, 2019; Woźniakowski et al., 2016). The conducted phylogenetic analyzes showed that in all cases the virus was found in genotype II, i.e. identical as in other Eastern European countries, and showed 99.95% identity of nucleotides with the Georgia 2007/1 strain (Mazur-Panasiuk et al., 2019a; Śmietanka et al., 2016). Genotype II has also been confirmed by ASFV (African swine fever virus) studies conducted in Belgium in 2018. However, the entire genome sequence of ASFV Belgium 2018/1 showed 15 differences for overall sequence identity at the nucleotide level. A comparison of all available sequences of the entire genome of the virus occurring in Eastern European countries as well as in ASFV in China indicates that these genomes are almost identical with a probability of 99.9% (Forth et al., 2019; Gilliaux et al., 2019). These data confirm previous reports on the possible direction of virus transmission to Eastern European countries through Georgia and the Caucasus since 2007 and further towards north-eastern Europe (Flis and Nestorowicz, 2019; Markowska-Daniel and Pejsak, 2014; Pejsak et al., 2014a, b; Pejsak and Piekut, 2018).

Since the appearance of the first cases of virus occurrence, the Polish authorities together with veterinary services have undertaken a number of administrative activities introducing further provisions and guidelines to contribute to limiting the possibility of its transmission to new areas (Flis, 2019). This was mainly due to the lack of experience in the scope of the possibility of the virus spreading and the role of wild boars in its transmission to new areas, with varying levels of density of this species and the impact of hunting pressure. Therefore, initially two main hypotheses were adopted. The first of them said that the disease would rapidly spread westwards, while the second indicated the possibility of very rapid extinction of the disease due to the high virulence of the virus, which will naturally lead to depopulation of wild boars. It soon turned out that these hypotheses in Poland's environmental and social conditions did not work. Therefore, actions were taken to exterminate wild boars by hunting. It was related to the fact that the wild boar was indicated as the basic vector of virus spread to new areas (Flis and Kołodziejski, 2019; Flis, 2020; Pejsak et al., 2018b; Probst et al., 2017).

Undoubtedly, in Poland's environmental conditions, wild boars constitute the primary reservoir of the virus (Flis and Nestorowicz, 2019; Flis and Kołodziejski, 2019; Pejsak et al., 2018b). Therefore, high population density rates have an impact on the increase in the possibility of the virus traveling in the environment, where it spreads in a diffusive manner, i.e. without human intervention (Śmietanka et al., 2016; Pejsak and Truszczyński, 2017b). In addition, in border zones, the spread may also be partly dependent on the occurrence of the virus in neighboring countries (Flis and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68416856

Nestorowicz, 2019; Flis, 2020; Markowska-Daniel et al., 2011). Assessment of the geographical pattern of virus spread indicates that wild boars can be a virus vector to areas not far away from the sites of its previous findings. This is due to the fact that the virus in the natural environment has clear connectivity with habitats, without a tendency to dynamically move over time. In the natural environment, regardless of the season, it spreads with an average pace of 1-2 km per month (Abrahantes et al., 2017; Depner et al., 2016; Podgórski and Śmietanka, 2018).

The aim of the study was to analyze the epizootic situation of African swine fever in Poland in terms of the preventive measures taken so far, including measures related to the depopulation of wild boars and its impact on the spread of the virus from its appearance, i.e. from February 2014 to the end of 2019. The analysis included virus cases found in feral pigs and outbreaks in pigs in individual years of the study period, as well as a geographical model of virus spread and indication of possible vectors related to transmission to diverse environments, including pig-keeping farms, which will allow for the development of further groups of activities preventive measures in the scope of limiting the possibilities of ASFV transmission to new areas.

The presented data include only officially reported cases in which the presence of ASFV has been confirmed in laboratory tests. Certainly, some of the fallen boars are not found and remain in the natural environment, constituting a reservoir for the virus. In addition, there may also be situations where a dead boar is found and the case has not been reported. The number of these wild boars is difficult, and even impossible to determine precisely. Information from conducted search campaigns, during which the boar's dwelling places are meticulously penetrated, indicates that these are not common cases. Thus, the number of such cases does not affect the results presented.

Materials and methods

Material

The research material was the data of the Main Veterinary Inspectorate. They concerned officially identified cases of African swine fever virus in feral pigs since 2014, when the virus was first detected until the end of 2019. These data come from monitoring studies from every wild boar shot in the danger area (blue zone), restricted area (red zone) and protection area (yellow zone). These data also include the results of tests for the presence of ASF from every dead boar, regardless of the cause of death from all over Poland. Samples are taken from all wild boars from car collisions. In addition, they are also collected from fallen boars found occasionally, by persons staying in the wild boar's habitat, as well as from those found as part of organized search for fallen animals. Depending on the method of obtaining biological material, different samples are taken. Blood is collected from the boars shot. This is done by hunters or other persons authorized by district veterinarians. On the other hand, if dead pigs are also able to take blood samples, and if the carcasses are already in a state of decay, samples are taken from internal organs, mainly spleen, possibly kidneys or lungs. In cases of highly advanced degradation, samples are taken from the bone marrow.

Analyses

The collected material was tested on an ongoing basis in the national reference laboratories for ASFV, to which samples collected in the field were delivered. Two

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68416856

diagnostic methods are used in these tests. The first of these involves an ELISA test (Enzyme-Linked Immunosorbent Assay) to detect anti-ASFV antibodies. The second study is based on the molecular method of qPCR (real-time PCR - Ingezim PPA COMPAC, Ingenasa, Spain), i.e. a polymerase chain reaction to detect and identify ASFV genetic material. Soft tissues or bone marrow are also examined by real-time PCR. Each positive or doubtful sample in the ELISA was tested by a confirmatory indirect immunoperoxidase (ITP) technique that shows higher sensitivity than the ELISA. This method is recommended by EURL for ASF (CISA-INIA Valdeolmos).

Material development

On the basis of the obtained data, the dynamics of virus transmission and the geographical pattern of its spatial distribution in individual years were compiled. The prevalence index in wild boars was also calculated. It represented the percentage of positive cases found to the total number of wild boars tested. Also presented are data obtained from the National Veterinary Institute in Pulawy regarding the number of seropositive wild boars, which allowed determining the percentage of such animals in relation to the number of tested animals. Also presented is a geographical model of the possibility of the virus spreading to new areas through environmental vectors such as wild boars and indirect vectors. mechanical, related to multidirectional human activity. An analysis was also made of the dynamics of the number of wild boars in terms of the level of hunting exploitation of the population of this species, which is directly related to the occurrence and spread of the virus in the natural environment and potential possibilities of reaching pig farms. Data on numbers and hunting of wild boars were obtained from the Polish Hunting Association.

Results

Occurrence of ASF virus in Poland

In the period from 2014, when the virus was found in Poland for the first time, the number of cases found in wild boars tended to increase (*Fig. 1*). However, a very dynamic increase of over 9 times occurred in 2017 when 741 cases were found. In the following year, a further more than 3-fold increase in cases was observed, while in 2019 there was a relative stabilization compared to the previous year. Slightly different tendency of outbreaks was observed in pigs. In the first two years, the number of outbreaks was small. There was a dynamic increase in the number of outbreaks in 2016-2018. In turn, in 2019 there was more than a 2-fold decrease compared to the previous year. The spatial distribution of the virus occurrence in individual years indicates a clear tendency of its spread towards the west and a bit slower, though successive towards the north and south (*Fig. 2a-f*). In the subsequent years of virus incidence, the number of wild boars covered by the ASF testing increased (*Table 1*). In 2014, 15,881 samples from wild boars were tested, and in 2019 77812 samples. In the initial 5 years, the prevalence index increased every year from 0.19 in 2014 to 5.56 in 2018 (*Fig. 3*). In 2019, despite the largest number of samples tested, this indicator dropped to 3.18.

Almost from the very beginning of the virus in Poland, ASFV antibodies were found during laboratory tests (*Table 1*). This indicates that these individuals have been in contact with the virus. The first such case was already recorded in December 2014. The percentage of seropositive wild boars increased with the increase in the number of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68416856

samples and the virus cases found. It is difficult to clearly indicate whether these animals had contact with a small dose of the virus and the immune system generated immunoglobulins, which meant that the virus did not lead to death, or whether these individuals contracted the virus. The possibility of acquiring antibodies from the mother in utero or with colostrum is also not fully known, and the results of the study also show their occurrence in young wild boars.

Routes and directions of ASFV spread in wild boar

From the very beginning of the appearance of the virus in Poland, it spread mainly in the natural environment, which was confirmed by subsequent cases of the virus in boars in this region. The main areas were related to the border belt, where the virus spread to subsequent areas along the eastern border of Poland and successively occupied further areas to the west. In this case, it is undeniable that the main vector of the virus was certainly infected with wild boars or their corpses. In border areas, it could certainly also be cross-border migrations of infected wild boars (*Fig. 4*).

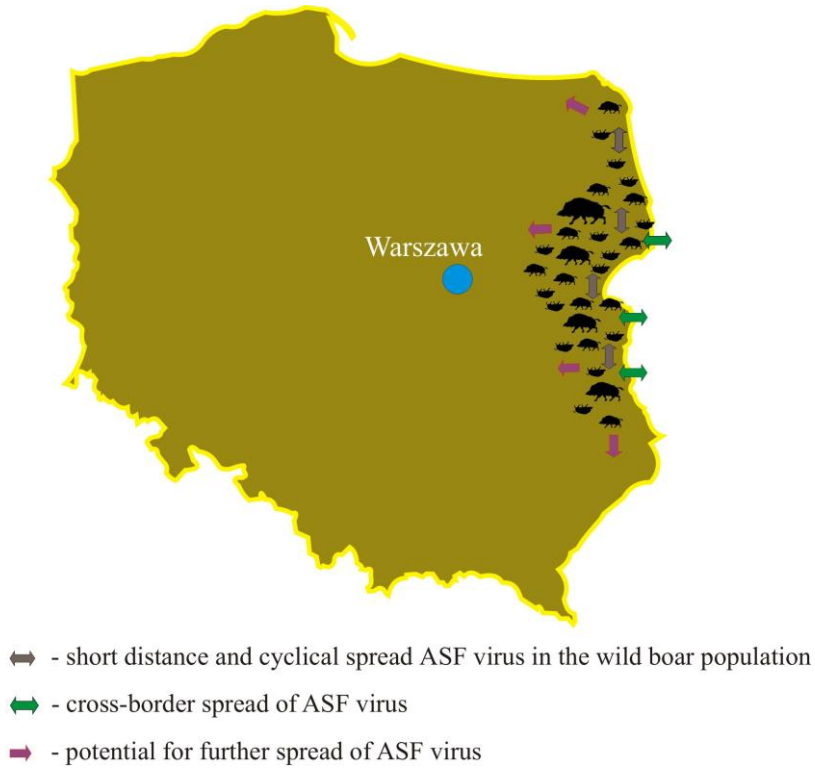

Figure 4. *Geographic pattern of short-distance ASF virus movement in determined wild boars by environmental factors in Poland in the years 2014-2016*

However, starting from 2017, there was an unexpected spread of the virus to new areas, quite distant from the sites of earlier statements. The first of them were around Warsaw, and the next regions of northern Poland, just off the Kaliningrad region. Cross-border migration of feral pigs was indicated as the main reason for the emergence of a new region of virus occurrence, just off the northern border, quite far away from its

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68416856

current sites. However, the appearance of the virus near Warsaw cannot be equated with any wild boar migration. At most, two hypotheses were mentioned. The first of these was about transporting the unexplored carcass of a wild boar from areas where the virus had not yet been officially diagnosed and could have been present in the environment and the boar was infected. The second, more likely, said that unconscious human activity and the introduction of the virus into new areas contributed to this by failing to follow biosecurity principles when moving from areas where the virus was already present in the natural environment (*Fig. 5*).

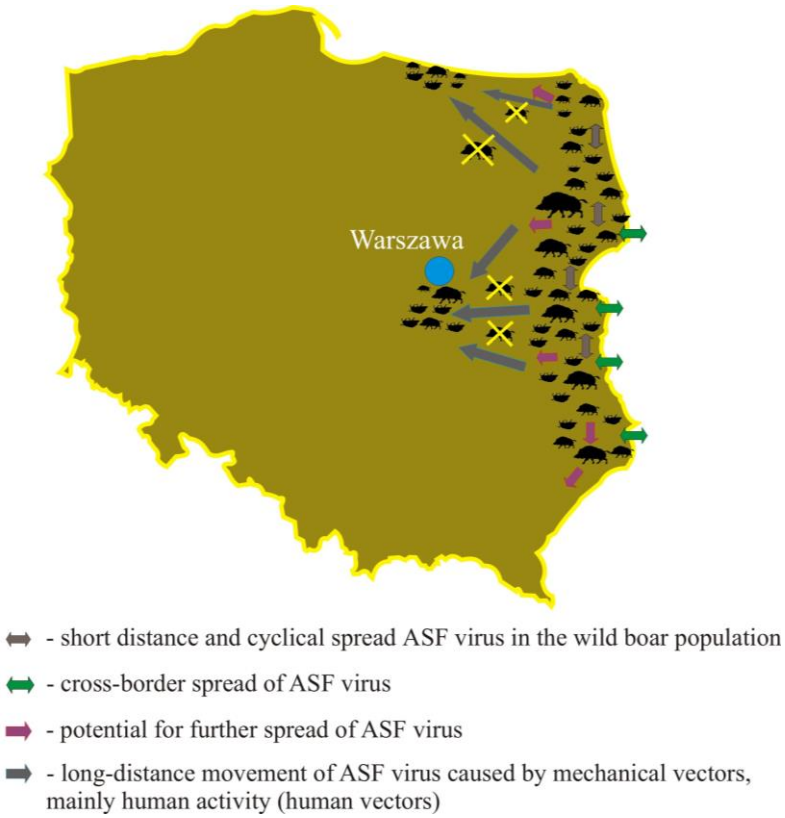

Figure 5. *Geographic pattern of short and long-distance ASF virus movement in determined wild boars by environmental factors and human vectors in Poland in the year 2017*

Another case of virus transmission to new, very remote areas was recorded in Poland in 2019, when the virus was diagnosed in a dead boar, near the town of Slawa on Tarnowskie Lake in southwestern Poland (*Fig. 6*). The determined distance in a straight line from the most westerly case in places of earlier virus occurrence in boars and pigs in the eastern and central part of Poland was slightly over 300 km. Thus, there is no epidemiological and, above all, geographical link with existing virus cases. This is another confirmation that mechanical vectors, mainly humans, play a key role in virus transmission.

Routes of ASF virus entry into pig-keeping farms

In Poland, 246 outbreaks in pigs have been reported since the appearance of the ASF virus. In the initial period, the outbreaks were few and were found in small farms,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68416856

holding a few pigs each. This was mainly due to the way pigs were kept and fed, and thus the lack of any biosecurity. Along with the extension of the range of occurrence, outbreaks also appeared on larger farms. The successively increasing losses reached hundreds or even thousands of pigs, which were slaughtered and disposed of. In total, during the period 2014-2019, 67415 pigs were slaughtered and disposed of, which generated huge economic losses. Regardless of the type of farms in which there were outbreaks, although the paths of virus penetration were not always recognized and described in detail, in most cases they were associated with a mechanical vector associated with human activity. There is no reason to conclude, which is also logical for the wild boar to drag the virus into the farm, including the piggeries. In addition, the aspect related to virus neutralization in facilities where sick pigs were kept was not fully understood. Thus, in areas where the virus was present, the infection could have a two-way nature, and the virus could circulate between farms and the environment.

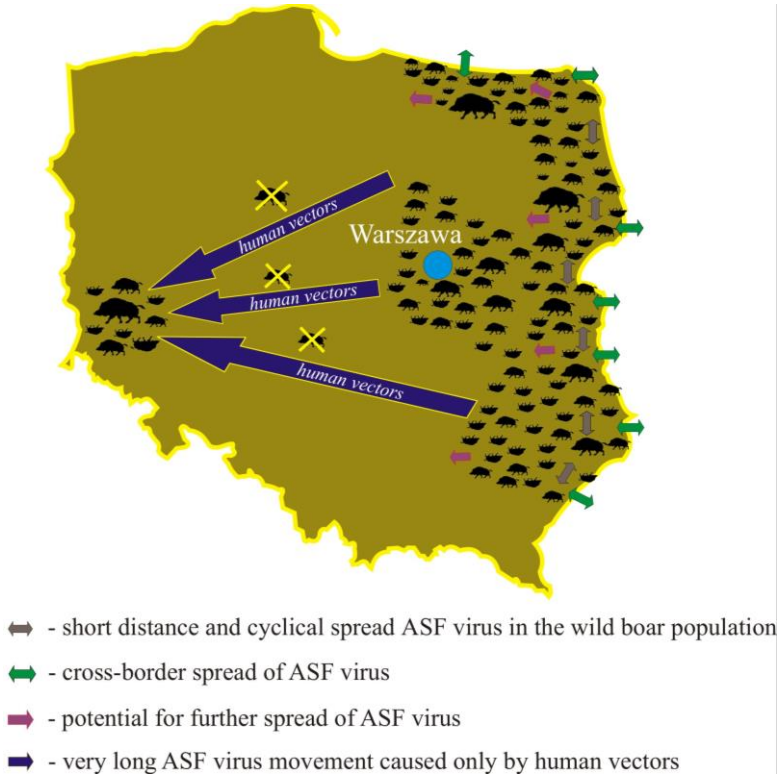

Figure 6. *Geographic pattern of short and very long-distance ASF virus movement in determined wild boars by environmental factors and human vectors in Poland in the year 2019*

Preventive actions

Even before the virus was officially confirmed in Poland, the first administrative and preventive initiatives were undertaken. In January 2014, guidelines were issued regarding the rules of conduct aimed at preventing the virus from entering the territory of the Republic of Poland. However, less than a month after this, the virus was officially confirmed and these guidelines became pointless. The next package of rules of conduct was released in March 2014 and contained a number of guidelines for pig farmers. It included guidelines on farm biosecurity rules and the possibilities for pigs to move. At that time, the wild boar was defined as the main virus vector in terms of its

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68416856

transferability to pig-keeping farms. It is worth emphasizing that these guidelines in the initial period of implementation introduced a total ban on hunting boars.

In the following years, further programs were introduced to detect early infections by the African swine fever virus and to increase knowledge about this disease. In these programs, the approach to wild boars changed radically, and the guidelines contained in them pointed to the need for depopulation of this species. What is more, in addition to hunting, compulsory (sanitary) shots were implemented based on the decisions of the Veterinary Inspection, as well as cash bonuses for shots carried out. These guidelines also introduced the mandatory search for fallen wild boars and the rules of conduct of hunters during hunting and after shooting in the field of biosecurity. Although they introduced clear guidelines for the biosecurity of pig farms, in many cases they were not followed, as confirmed by the inspections carried out. Such activities contributed to reducing the number of wild boar populations, which were indicated as the main source of virus transmission to farms. Further guidelines on the depopulation of wild boars, due to massive hunting conducted since 2017, caused a drastic decrease in the number of wild boars (*Fig. 7*). Arguments regarding wild boars as the primary source of threat to pig farming were not entirely correct, as the depopulation carried out in no way affected the number of cases and the possibility of the virus spreading to new areas as well as the number of outbreaks on pigs on farms.

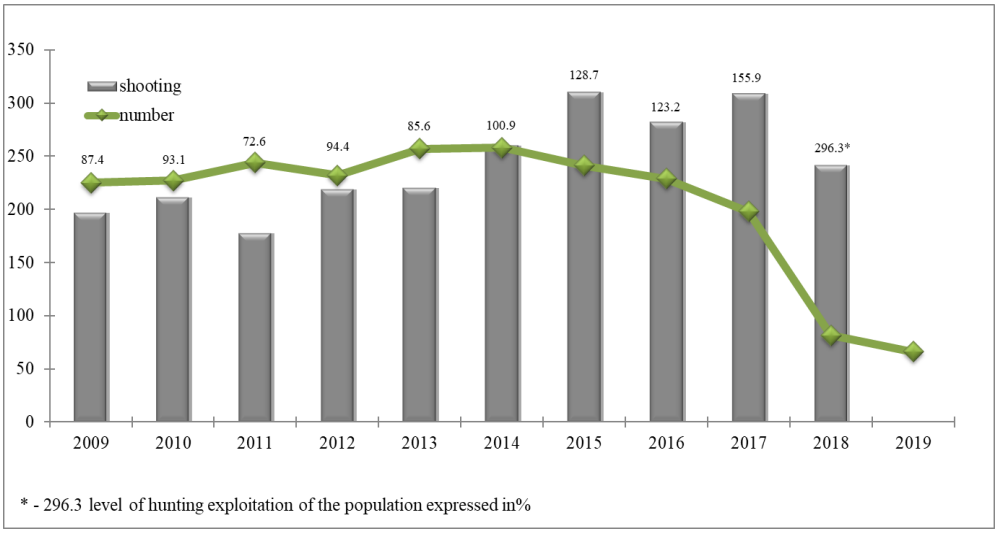

Figure 7. *Numbers and hunting of wild boars (thousand individuals) in districts leased by the Polish Hunting Association in the last decade*

Discussion

African swine fever as an infectious disease, causing almost 100% mortality in porcine animals (Suidae), poses a serious threat to the European and global pig market. Starting from 2007, he expanded the range of his presence to include Eastern European countries, and in subsequent years his successive expansion towards Western Europe occurs. Due to the fact that currently no vaccine is available, the only way to combat and thus limit further spread is to follow the principles of biosecurity (Markowska-Daniel and Pejsak, 2014; Pejsak et al., 2018b; Mazur-Panasiuk et al., 2019b).

The presented epizootic situation in Poland indicates that the boar remains the primary reservoir of the virus in the natural environment, but it is not the main vector of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68416856

its spread. At the same time, all administrative measures taken so far to combat and limit the transmission to new areas have not yielded any results (Flis, 2019; Pejsak et al., 2018b). It was determined by the speed of virus transmission in the natural environment. Research in this area indicates that the virus, regardless of the season of the year and environmental conditions, spreads at an average rate of about 1-2 km per month (Abrahantes et al., 2017; Depner et al., 2016; Podgórski and Śmietanka, 2018). This is also confirmed by the results of Russian studies, which highlighted the lack of dependence of the epidemic in pigs and wild boars, as they were independent of each other. At the same time, the authors of these studies indicate a high probability of infecting wild boars through various by-products associated with breeding and keeping pigs (Vergne et al., 2017).

The increase in the spatial development of the virus in Poland in the years 2014-2019 has shown that there are certainly different directions of infection in both wild boars and pigs. The presented results indicate almost unambiguously that the key role is played by wild boars, however, other transmission routes should not be underestimated, especially to pig-keeping farms, including a number of factors referred to as mechanical vectors. Some tick species from the *Ornithodorus* genus may play an important role in transmitting the pathogen. Although in European conditions these ticks do not occur in the natural environment, this route of transmission should not be underestimated, even by importing accompanying animals susceptible to this group of arachnids. As a rule, they are asymptomatic carriers of the virus, however, ASFV can replicate in their body and survive up to five years, being a potential source of infection for a sensitive species (Arias et al., 2018; De Carvalho Ferreira et al., 2014; Galindo and Alonso, 2017; Fila and Woźniakowski, 2020; Plowright et al., 1969). Some species of flies may also be involved in the transmission of the virus, which may be mechanical vectors of the virus, transferring it within 24 h through blood infected with the virus, as well as infection may occur orally by ingestion by animals infected with the virus (Galindo and Alonso, 2017; Baldacchino et al., 2013; Mellor et al., 1987; Olesen et al., 2018b). The possibility of transmission of the virus through mammals and birds of prey, as well as scavengers, which can be mechanical vectors of the spread of the virus is not fully understood. German studies conducted on carcasses of dead boars have shown that both birds and mammals, including domestic dogs, have had contact with carrion, and thus these animals may be mechanical viral vectors (Probst et al., 2017). In the case of virus transmission to pig-keeping farms, a key role may also be played by feed contaminated with pathogen, coming from fields and meadows, not quarantined (Guinat et al., 2016; Thomson, 1985).

The development of the epizootic situation in Poland during the 6 years of the presence of the ASF virus shows that the virus occurs in the natural environment, where its only reservoir is wild, but the basic vector of virus spread is the human factor. This is confirmed by its transmission to the areas around Warsaw (Mazur-Panasiuk and Woźniakowski, 2019; Pejsak et al., 2018a), or the appearance in Western Poland at a distance of 300 km, from earlier places of its finding (Flis, 2020). Also cases of its appearance in other European countries (Czech Republic, Belgium) distant hundreds of kilometers from places of its occurrence in this period (Forth et al., 2019; Gilliaux et al., 2019; Flis and Kołodziejski, 2019). Confirmation of the thesis that mechanical vectors play a key role in virus transmission in Poland are data from other European countries. In the case of the Czech Republic, the virus vector was workers from Eastern Europe,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68416856

while the Belgian case was associated with the transport of carcass of an infected wild boar by hunters from Lithuania (Flis and Nestorowicz, 2019).

There is also no doubt that wild boars remain the primary reservoir of the virus. However, taking into account the behavior of this species and the fact of the emergence of new cases of the virus in areas quite distant by places of earlier statements, it is impossible to agree with the thesis that it is boars that are the main factor associated with the spread of the virus to new areas (Flis, 2020; Flis and Nestorowicz, 2019; Keuling et al., 2009; Schultz et al., 2019b). Therefore, one of the priority tasks in the field of prevention in the spread of the virus is to comply with the principles of biosecurity resulting from the introduced veterinary regimes (Flis and Kołodziejski, 2019; Pejsak et al., 2018a). This is confirmed by the analysis of the spatial spread of the virus in Poland. They point to the need for more effective prevention and control measures in areas of permanent virus prevalence during the epidemic season, in pigs in summer and in wild boars in winter. It is also necessary to permanently assess the level of risk of spreading the virus (Lu et al., 2019).

In ASFV transmission, some role may be played by wild boars, which have been in contact with the virus and have infected it. The number of such animals during the period of virus occurrence in Poland is gradually increasing, and this is confirmed by the presence of antibodies in the tissues of these animals. These animals mainly come from areas where the virus has been around for a long time. Thus, they can be asymptomatic carriers of the virus. However, there is no evidence that every seropositive animal is a long-term virus carrier (Ståhl et al., 2019). A similar trend in the growing number of seropositive wild boars occurs in Estonia, where their incidence is definitely higher in those regions where the virus was the first to appear (Schulz et al., 2019a). Research results from Poland and the Baltic States show that there is a positive correlation between the time of infection and the occurrence of seropositive individuals (Martínez-Avilés et al., 2020). Such a course of the disease may be the beginning of its endemic in these regions (Schulz et al., 2019a). Also studies in pigs who have recovered from an acute ASF infection in the Netherlands have shown that these pigs can transmit the disease to other individuals through direct contact (Eblé et al., 2019). Research on the possibility of virus transmission through the environment in which virus infected pigs euthanized, conducted in Poland, Podlasie, showed that the introduction of healthy pigs to the same pens the next day led to the development of the disease in one week. Only at least 3 days quarantine eliminated virus transmission to subsequent individuals through a contaminated environment (Olesen et al., 2018a). Thus, in the current conditions of multi-directional possibilities of virus transmission to new areas, both in Poland and other European countries, farms keeping pigs should be almost isolated from the outside world. This is due to the fact that the virus is introduced to farms via indirect transmission paths, with a lack of biological security (Nurmoja et al., 2018; Pejsak and Truszczyński, 2018).

In the scope of preventive actions, elements related to the utilization of all remains of dead animals by specialized rendering companies with the principles of biosecurity are extremely important. This applies to both pigs and wild boars or their remains remaining in the wild. Therefore, one of the most important preventive elements in wild boars should be searching for dead animals, their utilization and proper disinfection of places where carrion was found (Flis, 2020; Flis and Kołodziejski, 2019; Halasa et al., 2016; Pejsak and Truszczyński, 2017a; Pejsak and Woźniakowski, 2017).

Conclusion

The presented data regarding the epizootic situation associated with the occurrence of the ASFV virus on the territory of Poland clearly indicate that despite the administrative and preventive measures taken in the field of virus eradication, they did not bring the expected results. During the period of six years, the virus spread to almost half of Poland's territory. Analysis of the geographical pattern of virus spread indicates that mechanical vectors, and mainly multidirectional human activity, play a key role in its transmission to new areas. Previous efforts in the field of depopulation of feral pigs considered both as a reservoir and as a virus vector have failed. Although the density of wild boar population is an important element in virus transmission within neighboring groups, it does not play a key role in its transmission to new, quite often remote areas from the sites of previous statements. Wild boar is also not directly related to the transmission of the virus to pig farms. Nevertheless, in Polish conditions, regardless of population density, wild boars remain the only reservoir of the virus in the natural environment.

Due to describing the next possibilities of virus transmission to new areas through the so-called mechanical vectors should be focused on searching for dead animals, as well as their remains at various stages of decomposition, as well as their removal from the environment and thorough disinfection of their locations. All such activities reduce the germ reservoir in the environment, and thus the possibility of its further transmission. The knowledge and observance of biosecurity rules by pig farmers, as well as hunters and other people staying in places of potential occurrence of boars or their periodic concentration should be absolutely binding. The possibility of limiting the use of the environment should also be considered, especially in places susceptible to the occurrence of wild boars. The effect of this initiative should be to limit further possibilities of spreading the virus among wild boars and result in limiting its further transmission to new areas. New fast and comprehensive solutions should also be sought to combat the virus, especially in areas where it appears for the first time. The Czech case is the best confirmation that decisive action may limit transmission possibilities and even lead to virus eradication.

It is also necessary to conduct further research on the possibilities of virus transmission to new areas through diverse vectors, both environmental and those associated with human activities. These studies should focus on determining the magnitude of the impact of human-dependent factors in the spread of the virus, and on this basis indicate the possibility of developing methods to minimize anthropogenic factors that have a significant impact on further transmission of the virus. The research aimed at determining the role of wild boars in the spread of the virus, as well as determining the level of density of the wild boar population guaranteeing the inhibition of virus transmission from the environment to farms keeping pigs are also significant.

(Received 18th May 2020; accepted 13th Aug 2020)

Abstract. The purpose of this study was to compare the soil properties of an adjacent natural forest, clay mine spoil and mine site reclaimed with Stone pine (*Pinus pinea* L.). Bulk density, sand, silt, clay, pH, electrical conductivity (EC), nitrogen (N), carbon (C) and C/N ratios of soil samples taken from three different soil depths (0-5, 5-15 and 15-30 cm) were determined and compared. Furthermore, the mass, N and C contents and C/N ratios of the forest floor were determined in the Stone pine plantation and natural forest. Almost 24 years after the establishment, 6.79 ton/ha forest floor mass was found in the Stone pine plantation, while it was found to contain 2.71 ton C/ha and 0.04 ton N/ha, which were significantly lower than those in the natural forest. In general, with some exceptions (EC in 0-5 and 5-15 cm, and bulk density in 15-30 cm), there were significant differences on the soil properties. Sand and clay contents varied substantially depending on the material and mixture. The soil C (1.5-2.1%), N (0.05-0.06%) and pH (5.34-5.69) in the Stone pine plantation significantly increased. Despite these properties, this shows that rehabilitation with plantation will take a much longer time compared to the natural forest area.
Keywords: *afforestation, carbon, nitrogen, pH, restoration*

Introduction

Mine production and mining operations have been exponentially increasing across the entire world. Open pit sites in particular lead to drastic degradation of soil and land. Mining activities have disruptive effects on the ecosystem, and affect the physical, chemical and biological soil properties of mining sites. First the plant cover is destroyed, then fertile top soil layers are removed from the site through major excavations, and the soil is compacted and destroyed due to the sue of heavy duty vehicles to open large pits created as a result of deep slopes. Moreover, soil organic matter disappears substantially and the material becomes too poor in terms of plant nutrients including primarily nitrogen. This is especially important for the restoration of sites after mining operations (Shrestha and Lal, 2011; Frouz et al., 2015; Gu et al., 2019).

DOI: http://dx.doi.org/10.15666/aeer/1805_68576874

Most of the mineral and natural resources are located in forestlands around the globe (Burton and Macdonald, 2011). Mineral extraction and processing in forestlands lead to their destruction at a large extent (Burton and Macdonald, 2011) and turning forestlands into mining sites lead to extremely harmful changes in the ecosystem and soil (Ahirwal and Maiti, 2016). Such practices increase the pressure on forest areas (Gençay et al., 2018).

It is essential to rapidly restore severely destroyed areas after mining activities (Frouz et al., 2015). Plantation is the most commonly used method to restore abandoned mining sites. However, mining tailings-spoils that have very poor physical, chemical and biological properties and levelled mine soils usually inhibit plant existence and growth (Asensio et al., 2013; Rodríguez-Vila et al., 2016). The use of forest tree species among the plant species is a common way while it requires selecting the appropriate species (Mukhopadhyay et al., 2013).

Moreover, different tree species have different restorative properties (Mukhopadhyay et al., 2013). Therefore, it is crucial to determine the improvements and changing properties after establishing plantations for the restoration and reclamation of mining sites. Comparison with adjacent control sites is a preferred way to demonstrate the rehabilitative power of the treatments conducted (Shrestha and Lal, 2011; Liu et al., 2017; Gu et al., 2019). There are several studies regarding the rehabilitative features of tree species for mine sites (Juwarkar et al., 2010; Mukhopadhyay and Maiti, 2011; Gu et al., 2019).

The main physical and chemical soil properties played a determining role in these studies. Bulk density and soil texture type (sand, silt and clay contents), which are among the main soil properties identified, have an important impact on hydro-dynamic properties of the soil, are also important parts of soil quality parameters (Kantarcı, 2000; Yuan et al., 2017) and important for plant development (Asensio et al., 2013). In addition to organic soil and forest floor mass, carbon and nitrogen contents of forest floor (Walmsley et al., 2019) in the restored mining sites, presence of soil carbon and nitrogen are important criteria for biological activity and soil fertility (Frouz et al., 2013; Ahirwal and Maiti, 2016). Besides, soil acidity (pH) and electrical conductivity (EC) have an impact in many soil chemical processes while they also have biological effects (Mukhopadhyay et al., 2013; Mosseler and Major, 2017).

This study was conducted in order to determine the change in soil properties caused by clay mining activity and the effect of Stone pine (*Pinus pinea* L.) plantations in mine spoils after the termination of clay mining. To this end, the study was designed to compare the soil properties at different depths (0-5, 5-15 and 15-30 cm) and the existing forest floor of three different sites, which included the abandoned clay mine spoil, the adjacent clay mine reclaimed with 24-year old Stone pine (*Pinus pinea* L.) plantation and the adjacent natural forest.

Material and method

Research area

The research area was located in Şile-Istanbul in the northwest of Turkey (N41°08'07"-41°08'16"; E29°27'11"-29°27'21"). The clay mine site studied in the research and its surroundings are in the south of Istanbul-Şile Highway, while it is 53 km to Istanbul and 17 km to Şile. The distance of the research area to the sea (Black Sea) is around 6.5 km in air distance. As regards the topography of the research area, it is situated on peneplain, its elevation is 115-150 m (*Fig. 1*).

DOI: http://dx.doi.org/10.15666/aeer/1805_68576874

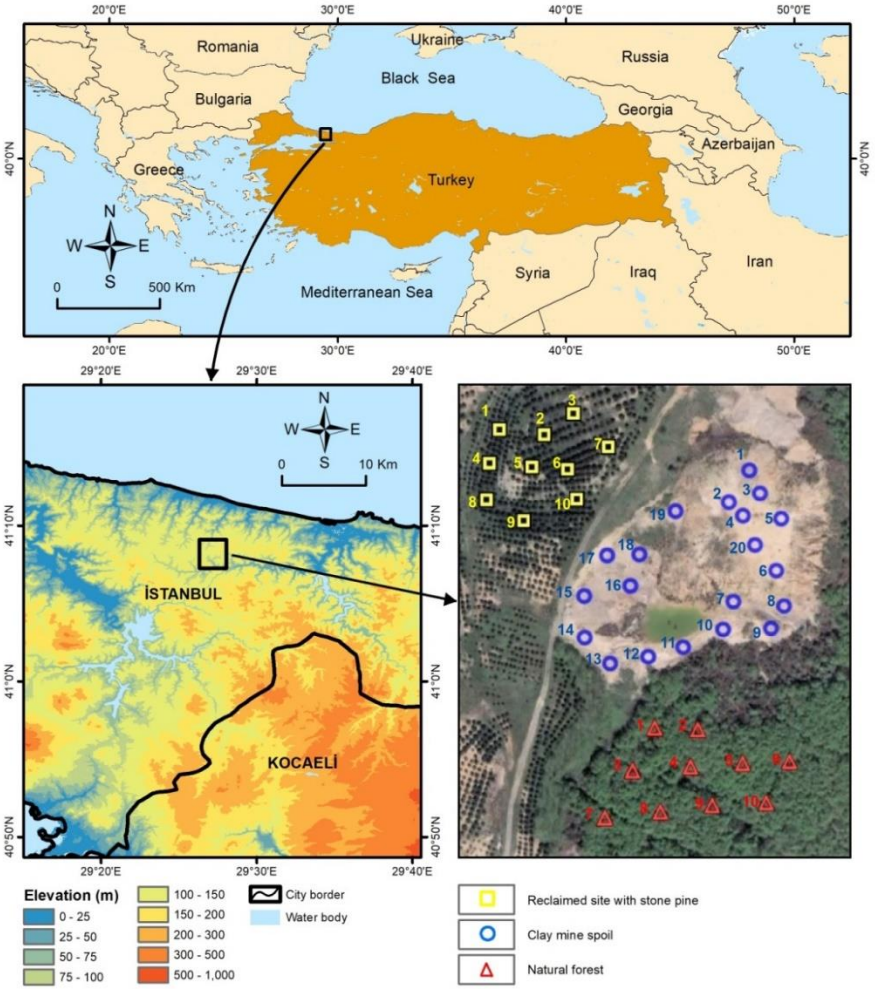

Figure 1. *Location of study area*

As for its geological structure, Neogene sediments are common in the site, while mainly sandy layers are located on the surface and clay is found in the lower layers (Ertek et al., 1998; Demir et al., 2016). In the geological literature of Turkey, Şile (Istanbul) Neogene Basin is referred to as a storage of natural industrial raw materials, which supplies 90% of industrial clay demands in Turkey (Sezer, 2006). Brown forest soil is the common soil type in the natural forests where land degradation did not occur.

Transition climate between the Mediterranean climate and Black Sea Climate is dominant in the research area. According to the data of Şile Meteorology Station, its mean annual precipitation is 929 mm. Its mean annual temperature is 13.6 °C, mean monthly minimum temperature is -3.8 °C in February, mean monthly maximum temperature is 31.8 °C in September and relative humidity is 80.5% (Sezer, 2006). The natural forest from which sample plots were selected is an oak coppice forest and includes mainly *Quercus petraea* as the dominant species, while *Fagus orientalis, Castenae sativa* and *Sorbus torminalis* are the other tree species included in the mixture in some of the sample plots. In addition to these species, *Quercus robur, Quercus frainetto, Alnus glutinosa, Acer campestre, Fraxinus excelsior, Carpinus betulus, Tilia tomentosa, Populus tremula, Corylus avellana, Cornus mas, Mespilus germanica,*

DOI: http://dx.doi.org/10.15666/aeer/1805_68576874

Buxus sempervirens are the other tree or shrub species distributed in the forests in this region (Dönmez, 1979).

Sampling and methods

This study was conducted to determine the effect of Stone pine (*Pinus pinea* L.) plantation introduced for the rehabilitation of the clay mine spoils after clay extraction operations on soil properties in three different adjacent sites including 1) the clay mine spoil 2) clay mine site reclaimed with Stone pine plantation and 3) natural forest. The Stone pine plantation was established by direct planting method without any rehabilitation or laying topsoil almost 24 years ago (determined according to the annual growth ring samples taken from the trees) on top of the mining tailings-spoils. The huge pits in the clay mine tailings site were filled and the site was leveled and abandoned. In the adjacent natural forest land, *Quercus petraea* of coppice origin which protects its natural structure is the dominant species. Adjacent sites were selected for common site characteristics (*Fig. 2*).

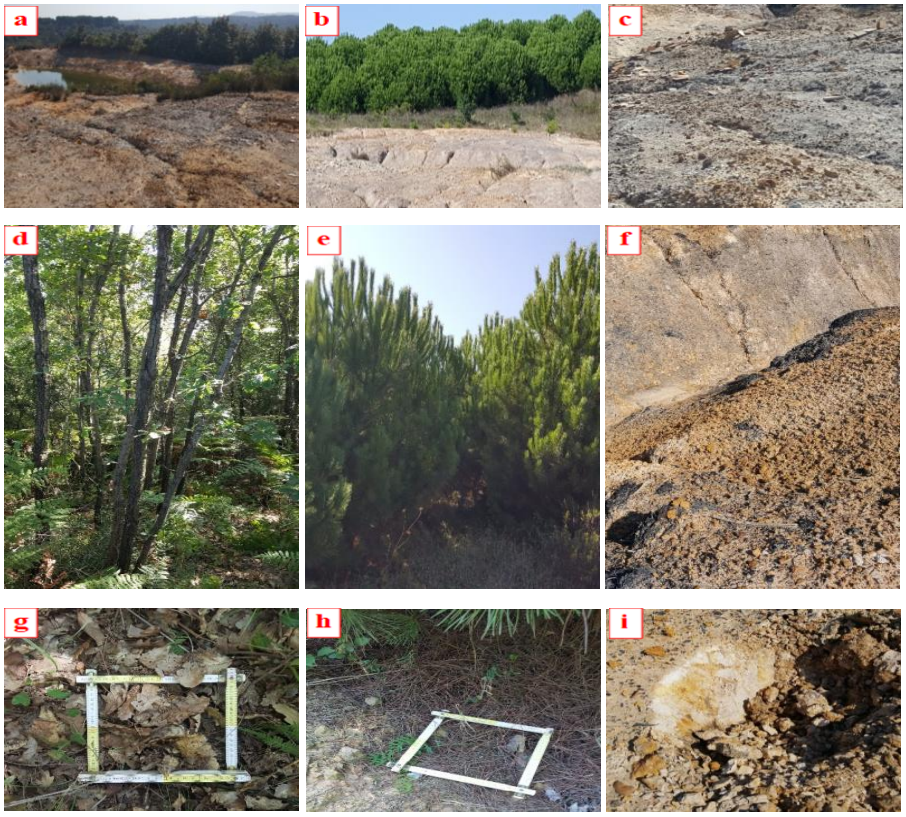

Figure 2. *Pictures from research sites, a) transect view on clay mine spoil and natural forest, b) transect view on clay mine spoil and Stone pine plantation, c) a part from clay mine spoil, d) natural forest, e) Stone pine plantation, f) different surface layers of clay mine spoil, g) forest floor of natural forest, h) forest floor of Stone pine plantation, i) heterogeneity structure of clay mine spoil*

The number, diameter (dbh) and height of the trees were determined in 10 sample plots of 5x5=25 m^2 in the natural forest and of 4x3=12 m^2 from the Stone pine plantation because plantation has same planting distance (4x3 m). The density, average

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68576874

diameter (dbh) and height of the trees in these sites are presented in *Table 1*. The mean age of the Stone pine plantation was found to be 24 years according to the annual ring samples collected from a tree in each sample plot of the plantation.

Table 1. *Density, average diameter (dbh) and height of trees on sample plots*

Characteristics	Natural forest	Stone pine plantation
Tree number (ha)	3760 ± 1053	3250 ± 264
Diameter (dbh) (cm)	8.08 ± 1.39	9.39 ± 1.18
Height (m)	6.98 ± 1.09	4.45 ± 0.63

± standard deviation, Stone pine (*Pinus pinea* L.) plantation age: 24 ± 2, main species in natural forest is oak (*Quercus petraea* L.)

The soil samples were collected from 10 plots in the natural forest and Stone pine plantation and 20 plots in the clay mine spoils site (*Table 2*). We selected more sampling points from mine spoils site to represent the area because the mine site is more heterogeneous (*Figs. 1-2*). Soil samples for bulk density were collected from these three sites at depths of 0-5 cm, 5-15 and 15-30 cm in the selected plots that could represent the overall site during the field studies. Moreover, forest floor samples were collected from areas of 1/4 m^2 in from each sample plot in the natural forest and Stone pine plantation with 5 repetitions (*Fig. 2*). As the forest floor did not cover the entire soil surface contrary to the one in the natural forest, the percentage of forest floor coverage was determined in plantation. This value was found to be 51.3% on average, while the coverage percentage of each site was averaged to their total forest floor mass.

The soil samples collected from the area for bulk density were air dried, ground in a mortar, screened through a 2-mm sieve and fine soil fraction (<2 mm) and stones were removed. The samples were oven dried at 105 °C till constant weight and their weight in unit bulk was found. Then, based on these weight values, the amount of fine soil (<2 mm) per hectare was calculated for each depth layer (0-5, 5-15 and 15-30 cm). The particle diameter (sand, silt and clay contents) in the soil samples prepared for analysis was analyzed with Bouyoucos hydrometer, soil reaction (pH) was analyzed with pH-meter containing glass electrode in a solution mixed with distilled water at a ratio of 1/2.5; salinity (electrical conductivity, EC) with salinity meter in a solution mixed with distilled water at a ratio of 1/5; organic carbon with Walkley-Black wet oxidation method and the total nitrogen with semi-micro Kjeldahl method (Karaöz, 1989a,b). To prepare the forest floor samples for analysis, they were dried at 70 C° till constant weight. The dried samples were weighed and the amount of forest floor mass in areas of 1/4 m^2 was calculated. Based on these values, forest floor masses per hectare was found. Then, the forest floor samples were ground to be prepared for analysis while their carbon and nitrogen contents were determined with Leco Truspec 2000 CN analysis device by dry combustion method.

Amounts per hectare were determined on the basis of the carbon and nitrogen concentrations of forest floor and soil found through analyses. Then the similarities and differences between the sites were compared with Analysis of Variance (ANOVA) for each data obtained through analysis results and calculations while the features found to be significant according to the analysis of variance were evaluated with Duncan post-hoc test due to inequality of the numbers of sample plots and sampling points among sites. As there was no forest floor on the mine spoil, the forest floor characteristics of the Stone pine plantation and the natural forest were compared with 2-independent samples t test. IBM SPSS STATISTIC 20 for Windows computer software package was used for the statistical evaluation of the data. Base ANOVA results were presented in *Appendix Tables 1-3*.

Results

Forest floor characteristics

The mass of forest floor in the Stone pine plantation (6.79 ton/ha) was much lower than the one in the natural forest (28.07 ton/h). The carbon concentration of the forest floor was almost the same in both sites (around 40%), while the nitrogen concentration was higher in the oak-dominated natural forest (0.81%) compared to the Stone pine plantation (0.51%). The carbon content per hectare was almost 4 times higher in the natural forest than in the Stone pine plantation due to the high amount of forest floor mass in the natural forest. The nitrogen content was found to be 0.04 ton/ha and 0.22 ton/ha, respectively, for the Stone pine plantation and the natural forest. C/N ratio was determined to be higher (94.21) in the Stone pine plantation where the nitrogen content was lower although both sites had a very similar carbon content (*Table 3*).

Soil properties

The soil sand content ranged from 81.25% to 88.25% in the natural forest, which was markedly higher compared to the other two sites. The clay mine spoil was found to have the lowest soil sand content, which was 38.05-43.25%. The soil clay content was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68576874

much lower in the natural forest compared to the other two sites and ranged from 7.23% to 11.35%. The clay mine spoil had the highest soil clay content, ranging from 41.50% to 43.13% (*Table 4*). When the sites were compared as regards the texture type of soil, the main soil texture type was loamy sand in the natural forest while it was heavy clay in the clay mine spoil. The soil texture in the Stone pine plantation was mainly sandy clay.

± standard deviation, means within rows following by the same letter are not statistically different at 0.05 significance level in Duncan Post-Hoc Test

The mean soil bulk density was found to be statistically significantly different and lower in the natural forest compared to the other two sites at depths of 0-5 and 5-15 cm. At these two depths, the highest mean soil bulk density was found in the clay mine spoil whereas the lowest was in the natural forest. At the deepest layer which was 15-30 cm, there was no statistically significant difference between the sites as regards mean soil bulk density (*Table 4*).

As for soil pH; it was statistically significantly different in the clay mine spoil compared to the other sites at three depths, which was lower compared to the soil pH in the Stone pine plantation and natural forest (*Table 4*). There was no statistically significant difference as regards mean soil EC between the three sites at depths of 0-5 and 5-15 cm. The soil EC was higher in the clay mine spoil (389.28 µs/cm) at the depth of 15-30 cm compared to the other two sites, which was statistically significantly different (*Table 4*).

There was a statistically significant difference in soil carbon and nitrogen concentrations between three sites at all depths. The highest carbon and nitrogen concentrations at all depths were found in the natural forest while the lowest values were found in the clay mine spoil. The soil carbon and nitrogen concentrations in the Stone pine plantation were in the range between the values of the other two sites. The carbon and nitrogen concentrations at the depth of 0-5 cm where the values are the highest are ranked from the highest to the lowest as follows: 0.390 - 4.092%, in the natural forest; 0.056 - 2.060% in the Stone pine plantation, and 0.029 - 1.292% in the clay mine spoil (*Table 4*). As for C/N ratio, there were statistical differences at all three depths between the natural forest, Stone pine plantation and mine spoil. The lowest C/N ratio for all depths was found in the natural forest while the highest was found in the mine spoil (*Table 4*). The total carbon storage per hectare was statistically significantly different in three different sites at all three depths in parallel to soil carbon content. At the depth of 0-30 cm in all sites, the total carbon storage per hectare was ranked from the highest to the lowest as follows: 85.814 ton/ha (15.078 + 29.876 + 40.860) in the natural forest, 59.944 ton/ha (12.222 + 20.371 + 27.351) in the Stone pine plantation, and 40.366 ton/ha (7.927 + 14.906 + 17.533) in the clay mine spoil. The highest nitrogen storage per hectare at the depth of 0-30 cm was found as 6.555 ton/ha (1.464 + 2.498 + 2.593) in the natural forest followed by the Stone pine plantation with 1.990 ton/ha (0.338 + 0.650 + 1.002), while the lowest was found to be 0.990 ton/ha (0.182 + 0.377 + 0.431) in the clay mine spoil, which was similar to total carbon storage (*Table 4*).

Discussion

Forest floor

The forest floor from the tree species planted in mine sites provide important benefits including primarily nutrients such as carbon and nitrogen (Frouz et al., 2013). Similar results were obtained in this study as regards forest floor carbon and nitrogen concentrations, which were consistent with the previous studies. Polat (2010) found that the forest floor carbon concentration in Stone pine plantations ranged from 39% to 55% at different layers. Keskin and Makineci (2009) reported that the mean forest floor organic carbon content ranged from 38% to 51% and nitrogen content from 0.5% to 0.8% in coal mine sites reclaimed with Stone pine plantation trials in Istanbul-Ağaçlı. The forest floor carbon concentration in the natural oak forest was also similar to the ones reported by other studies. For example, the forest floor carbon ranges from 39% to 44% across different oak stands in Turkey and their forest floor nitrogen concentration is approximately 1% (Akburak, 2013; Çakır, 2013; Makineci et al., 2015). Walmsley et al. (2019) reported that the nitrogen concentration was 0.53% and 0.36%, respectively, in the forest floor of oak (*Quercus robur*) and pine (*Pinus* spp.) planted in mine sites and biological activity was lower in the forest floor with high C/N ratio like as for pine species.

Forest floor accumulated in 24 years in the Stone pine plantation, which was found to cover around 50% of the soil due to planting density. Our observations and findings revealed that decomposition of Stone pine forest floor was not fast on clay mine spoils. Poor decomposition may be the result of poor physical soil properties, high bulk density and high clay content leading to poor water and air drainage conditions as well as slower biological activity of the severely acidic substrate. Moreover, high C/N ratio of Stone pine forest floor lead to slow decomposition. Similarly, previous studies reported that the forest floor of Stone pine plantations decomposed slowly under limited conditions such as mine sites and dunes (Keskin and Makineci, 2009; Polat, 2010; Abdalmoula et al., 2019). Forest floor decomposition and carbon to nitrogen ratio vary depending on several factors such as habitat and the chemical properties of the forest floor (Kantarcı, 2000; Treschevskaya et al., 2019).

Soil properties

Soil texture, sand, silt, clay ratios

As a significant difference between the sites as regards soil type as one of the physical soil properties, the soils in the natural forest had a very high sand content while the other sites had a high clay content. The significant difference between sand contents was because the natural structure of the geological material in the forest was sandy. Large pits are created as this material is removed during surface mining. After the mine is abandoned, the excavated clay mine tailings-spoils mix with the material from different depths having different physical properties to use this very heterogeneous material to level the site. Natural soil mixes due to excavation, stockpiling, and replacement operations because of the reclamation activities during and after mining. Therefore, a material that has very different properties than the natural forest structure is formed.

In a similar study, Mosseler and Major (2017) found that one of two adjacent mining tailings sites had a high soil clay content while the another was an abandoned shale overburden site. Two different Salix species (*Salix discolor* and *Salix eriocephala*) were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68576874

tried in those sites. The clay content was found to be higher than 42% in the site with high soil clay content while the shale overburden site had a higher sand content (67.2%) (Mosseler and Major, 2017). Contrary to our results, Shrestha and Lal (2011) and Yuan et al. (2017) reported that the reclaimed mine site had a higher sand content and they associated it with the high sand content of the material. However, they also reported that clay content increased depending on weathering in the reclaimed sites in the following years compared to the initial years. These findings show that different results can be obtained depending on the structural characteristics of the material. The research area in our study was a clay mine spoil which had a high clay content. On the contrary, the soil in the natural forest had a higher sand content.

Bulk density

The bulk density at all three depths in the study was significantly higher in the Stone pine plantation and clay mine spoil compared to the natural forest. The highest mean bulk density (<2 mm) was found to be 1316 g/l. There was a significant difference between the Stone pine plantation and mine site spoil. High bulk density is an expected result in reclaimed mine sites, which is increased due to the compaction of the soil by heavy duty vehicles during the leveling of the soil (Ussiri et al., 2006). Moreover, the material is highly mixed in mine sites and areas reclaimed on mine spoils and has different physical properties. In our study, it can be suggested that increased organic carbon content especially at the topsoil layer (0-5 cm) in the plantation did not reach the level that could change the soil bulk density. In this case, the heterogeneous physical properties of the mixed material are the determining factor. Increased bulk density an important physical soil property for plant growth because it affects water retention capacity and drainage conditions by decreasing soil pore volume (Asensio et al., 2013).

Several studies have reported that organic carbon content is low in mine sites and soil bulk density increases due to compaction and properties of the material (Keskin and Makineci, 2009; Sever and Makineci, 2009; Ahirwal and Maiti, 2016; Gu et al., 2019). Shrestha and Lal (2011) reported that soil bulk density at the depth of 0-15 cm in reclaimed mine sites was 54% higher than the one in the protected areas. Ussiri et al. (2006) stated that soil bulk density can be as high as 1.82 Mg m^{-3} in reclaimed mine sites due to the compaction of the soil by heavy duty vehicles, Maiti (2007) reported that bulk density was 2040 g/l at the topsoil layer of non-reclaimed mine sites and 1760 g/l in reclaimed mine soil. Besides, Ganjegunte et al. (2009) did not find any difference in bulk density between the reclaimed site and protected area at the depth of 0-30 cm.

pH and EC

Soil chemical properties which include pH, EC, C, N and C/N ratio are affected substantially by mining and reclamation activities.

Acidic soil reaction was usually observed in all sites whereas very low pH values were measured in the mine spoil. Soil pH was higher in the Stone pine plantation at each depth compared to the other sites. Because the mixed material has a completely different character in mine sites, pH might vary significantly due to the heterogeneous structure. In fact, Rodríguez-Vila et al. (2016) reported that pH varied in a wide range from 2.7 to 9.03. Changing pH is an expected result after plantation while soil pH tends to increase in reclaimed sites (Ussiri et al., 2006; Chatterjee et al., 2009; Liu et al., 2017; Gu et al., 2019).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68576874

Depending on soil pH values in acidic soils, soil EC is usually low and salinity problem is not expected for plant growth. Besides, difference between the sites only at the depth of 15-30 cm was significant. Soils with low pH usually have low salinity (Mosseler and Major, 2017).

Soil pH and EC variations are affected by the properties of the geological materials of the sites and those of the material that is formed after mining operations. Carbonates, lime, different dissoluble chemical compounds contained in these material and chemical contamination with the material have an important impact on pH (Shrestha and Lal, 2011; Mukhopadhyay et al., 2013). Additionally, Yuan et al. (2017) reported that substances contained in the decomposed litter (humic acid, organic acid and fulvic acid) also affected soil pH.

C and N

Mine spoils usually have a very low organic matter-carbon content. Treschevskaya et al. (2019) reported that almost the whole soil organic matter disappeared due to mining operations, while Akala and Lal (2001) stated that 70% of soil organic matter disappeared. Soil carbon is very important as the main source of soil nutrients, for soil ecology and its biological properties, climate change and carbon balance as well as improvement of water retention and drainage conditions. It is indeed the main subject of several similar studies. Moreover, nitrogen is a primary nutrient for all living organisms and organic matter is the main source of nitrogen in terrestrial ecosystems. In this scope, low organic carbon content in mine sites to be reclaimed is important as it limits plant growth and nutrition. However, increased carbon content in a reclaimed site is a crucial indicator of the improvement of the site.

Organic carbon and nitrogen contents at three depths were significantly different in the sites studied in this research, which increased in mine spoil, Stone pine plantation and natural forest, respectively. The main reason for increased nitrogen content must be the high organic carbon content. This result demonstrated that Stone pine could adapt to the poor environment of the mine spoil and can grow after plantation, which supplied organic matter to the soil. However, the organic carbon and nitrogen concentrations were nearly half of the values in the natural forest even in 24 years after plantation, which indicated that a long time was needed for development. Because of huge degradations on soil and land via surface mining activities, the natural forest soil differs in nature from the one being remediated. Also, it is not possible to reach the same level of soil health status under the plantation at all. Liu et al. (2017) reported that although soil organic matter increased through reclamation after mining operations, it required a long time even decades for it to reach the levels under natural conditions. Cui et al. (2012) stated that it required more than 40 years. In some circumstances, the species of trees planted in mine reclamation sites have important effects on the soil but the question if these effects are the result of the properties of the material or the characteristics specific to the tree species could not be answered (Józefowska et al., 2016).

Slow decomposition due to high C/N ratio as a result of forest floor properties is another possible reason for low organic carbon content in Stone pine plantations. Similarly, Yuan et al. (2017) reported that soil organic carbon and nitrogen increased in reclaimed mine sites, C/N ratio changed very differently but reclaimed mine sites had a higher C/N ratio.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68576874

Similar results have been demonstrated by similar studies on Stone pine plantations. For example, organic carbon concentration in Stone pine plantations was reported to be 0.07-0.56% (Atmaca and Yılmaz, 2006), 0.30% (Kizildag et al., 2012) and 0.6 – 7.0% (Kılcı et al., 2000). In addition, organic carbon content was found to be 0.13-2.74% and nitrogen content to be 0.02-0.407% in reclaimed coal mine sites with Stone pine plantations (Keskin and Makineci, 2009).

Soil organic carbon and nitrogen may vary highly in natural oak forests. In fact, various studies revealed that soil carbon content was 0.02-10.5% in natural oak forests, and thus nitrogen and C/N ratio might differ substantially (Akburak, 2013; Çakır, 2013; Makineci et al., 2015).

Conclusion

The most important conclusion of the study is that Stone pine could survive and growth on mine spoils that have very poor physical and chemical properties under the ecological conditions of the research area. Moreover, 24 years after plantation, soil organic carbon sequestration has been limited despite the forest floor accumulation under Stone pine. Soil carbon and nitrogen contents in the plantation are still half of the natural forest and it requires a long time for restoration.

The extent of such changes and differences may vary depending on the type of mineral, mining method, substrate properties, selected tree species, habitat conditions and etc. Furthermore, reclamation technique may also result in differences. The land was just leveled; soil laying, nutrient supplementation, fertilization or any other soil rehabilitation were not performed. The limitation of the study was that only a limited number of sampling was performed and it was sampled just once. There is a need for further studies to collect more information about the reclamation of these sites through sampling a larger area with higher repetitions.

(Received 19th May 2020; accepted 13th Aug 2020)

Abstract. Phytoremediation is currently an area of trending research due to its huge potential as a sustainable substitute for traditional methods of restoring contaminated sites. It is a profitable and ecological alternative to mechanical and chemical remediation techniques used worldwide. An increase in soil, water, and air pollution has severely disturbed an ecosystem functions and poses a huge threat to the natural and agricultural environment as well as public health. Remediation of the contaminated environment is one of the paramount concerns of the world. Hence this article deliberates on the general problems of pollutants linked to phytoremediation techniques of organic and inorganic contaminants, especially agrochemicals, petroleum, and explosive compounds. The paper also reviews a systematic assessment of the recent progress in the phytoremediation of contaminants in a natural and agricultural environment. Additionally, we highlight the benefits and limitations of phytoremediation along with a brief clarification of the resilient mechanistic removal of contaminants by a three-phase method. Finally, the perspective of biotechnological approaches in remediation is also suggested; taking into consideration the future of synergistic remediation approaches and genetically improved plants to enhance phytoremediation.
Keywords: *hyperaccumulation, pollutant, phytoextraction, phytotransformation, phytovolatilization*

Introduction

Phytoremediation is a term related to ecological restoration technology that takes plants as the main source. Therefore, phytoremediation can be explained as using plants (shrubs, trees, aquatic plants, and grasses) and associated microorganisms for the elimination, degradation, or separation of contaminated sites in an environment (Ossai, 2019; Chirakkara, 2015; Bruneel, 2019). Different approaches have been employed to remediate contaminated sites, but phytoremediation is well-thought-out as a possible alternative, effective, ecologically friendly, and best likened to other outmoded physicochemical methods (Burges et al., 2018; Rajput et al., 2019).

During the process of phytoremediation, compounds that can be remediated include (i) organic waste (ii) metals (iii) inorganic substances (iv) agrochemicals (v) metalloids (vi) radiochemical elements (vii) petroleum hydrocarbons (viii) explosives and (ix) chlorinated solvents (Cristaldi et al., 2017; Misra, 2019; Abdel-Shafy and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68756904

Mansour, 2018). The key sources of organic and inorganic pollutants occur naturally but others are a result of the use of fuels, solvents, and pesticides. Several organic and inorganic compounds are harmful and connected to health issues worldwide (Dixit et al., 2015; Li et al., 2017). These pollutants are on the rise within the environment through several activities in agriculture (pesticides, herbicides), industry (chemicals, petrochemicals), spillage (fuel, solvents), wood processing, and military activities (explosives, chemical weapons), etc. (Tripathi et al., 2020). Many contaminants within the agricultural soils can cause a substantial amount of damage to plant growth, soil ecological functions, and human health (Cai et al., 2019; Ngole-Jeme and Fantke, 2017). For instance, nitrobenzene impedes soybean seed growth and initiate genotoxicity in the cells of its root tip (Guo et al., 2010). There are also varied contaminants generally in soils or areas to be remediated, which contain trace elements and organic chemicals. Even though this is still a herculean task, many groups have faced action recently on contaminated soil phytoremediation (Gutiérrez-Ginés et al., 2014; Xu et al., 2019).

The extreme pressures from organic and inorganic waste and the magnitude of contamination have caused widespread concern as intentional or unintentional exposure of these materials poses a major threat to the environment and public health (Cristaldi et al., 2017; Rajput et al., 2019). Also, the events and mishaps of these contaminations worldwide have drawn the attention of the general public. Progressively, more people are alarmed and as a result, researchers are in search of the most effective remedies to curb these pollutions. The Soil Pollution Prevention and Control action plan by countries like China in 2016 was estimated to cost US$90 billion, aiming to utilize and develop effective remediation methods (Hou and Li, 2017). Conversely, these approaches do have some disadvantages such as high cost in operation and mobilizing contaminated material to the site of treatment which intensifies the risk of secondary contaminations.

Many techniques have evolved in the past decades intending to restore sanity to our environment and a wide acknowledgment of these methods is on the basis that it is an environmentally friendly method and a cheaper approach to get rid of contaminants. Currently, the extent of studies that have employed phytoremediation techniques to clean and reduce environmental pollution is increasing (Dixit et al., 2015; Rodriguez-Narvaez et al., 2017). However, despite several reports by many authors on the issue of remediation, there is still missing information regarding materials on the possible antagonistic or synergistic effects of diverse contaminants and their cross-accumulation or detoxification in both natural and agricultural environment.

Here, we:

- Provide an overview of phytoremediation of contaminants from agrochemicals (pesticides/fertilizers), petroleum compounds, explosive compounds, and inorganic compounds.
- Discuss the challenges in phytoremediation methods and also try to suggest an improvement in the biotechnological approaches for future research perspectives to enhance the phytoremediation of organic and inorganic pollutants.

This paper, we believe will provide a critical and extensive review of studies in natural and agricultural environment specifically in addressing the recent literature regarding remediation of organic and inorganic compounds.

Phytoremediation techniques

Phytoremediation has great promising as a natural on-site treatment with solar energy capable of treating the land and a vast area of moderately contaminated sites. Contrasting other kinds of remediation, plants grown for ornamental purposes in gardens and landscaping projects have become an important tool in recent years (Liu et al., 2018; Dodangeh et al., 2018; Cheng et al., 2017; Ranieri et al., 2016). Besides being attractive to the environment, some of these ornamental plants accumulate or decompose pollutants when they grow in soil polluted by heavy metals and organic pollutants (Liu et al., 2018). Just like heavy metals, an organic pollutant in plants is remediated by several natural biophysical and biochemical processes. Trees with large roots and high transpiration rates, such as *Populus* (*Populus spp.*) or *Willow* (*Salix spp.*), are well-known in the phytoremediation process (Srivastav et al., 2018). Such plants have a multiplicity of effects on these toxic compounds. They can be fixed, stored, volatilized, and converted to varying degrees (or even mineralized) or a combination of the processes which are conditional on the particular compound, environmental conditions, and plant genotypes. Phytoremediation remains a widely used method; however, if a cautious selection of the best appropriate plants and proper agronomic methods are not used appropriately, there could be a lack of control and plant availability. The mechanism that plants use to promote remediation (*Fig. 1*) includes plant extraction, plant degradation, plant stabilization, plant volatilization, and rhizosphere decomposition.

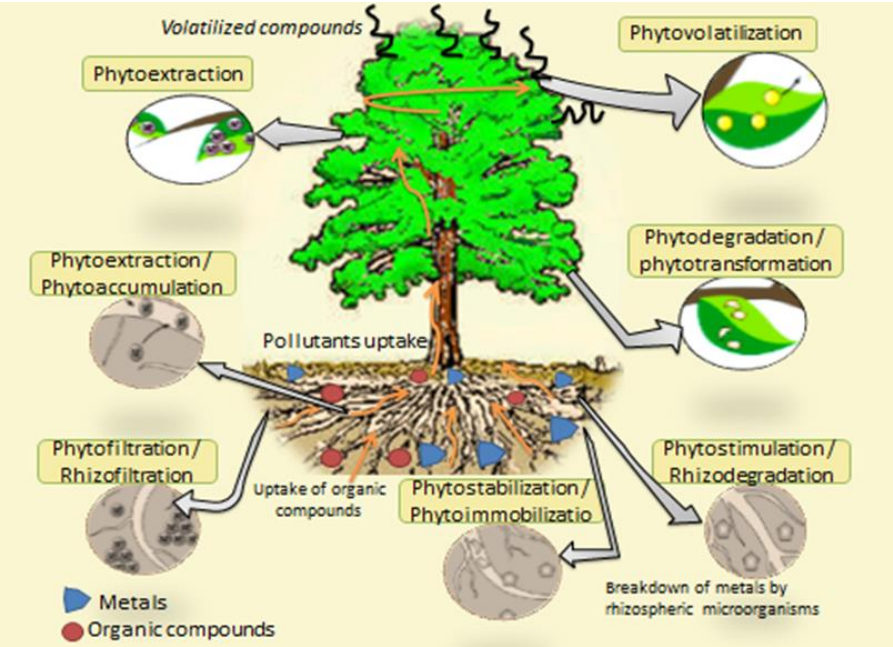

Figure 1. *Presentation of phytoremediation of organic and inorganic pollutants from a contaminated environment (adapted from Favas et al., 2014; Avensblog, 2020)*

Phytodegradation (phytotransformation)

Phytodegradation (also known as phytotransformation) involves the uptake of organic contaminants to be decomposed (metabolized) or mineralized in plant cells by certain enzymes. These include nitroreductase (through the decomposition of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68756904

nitroaromatic compounds), dehalogenase (through the decomposition of chlorinated solvents and pesticides), and volatile enzymes (involved in the decomposition of aniline) (Kumar et al., 2018). Plant species such as Populus and Sage are illustrations of plants with these enzyme systems (Leung et al., 2019; Feng et al., 2017). For instance, Chen et al. (2016) reported that the Armoracia rusticana possess the ability to degrade benzophenone within its tissues. These green plants are classified as the biosphere 'green liver'. Also, a current study employed phytotransformation for organic compounds like insecticides, chlorinated solvents, herbicides, inorganic nutrients, and munitions (Kumar et al., 2018).

Phytostabilization (phytoimmobilization)

Phytostabilization or phytoimmobilization is an in situ technology whereby toxic compounds are integrated into the root cell wall lignin to form non-toxic substances, hence decreasing the existence of pollutants in the natural and agricultural environment (Khalid et al., 2017; Mahar et al., 2016). Metals are precipitated in insoluble forms under the direct action of root exudate and subsequently enter the soil medium. The main challenge relating to this technique is the avoidance of the concentration of pollutants and suppressing their dispersion in soil (Favas et al., 2014; Ali et al., 2013; Fan et al., 2017). Studies conducted by Khalid and coworkers (Khalid et al., 2017) have referenced a great number of examples of plants grown for this purpose which are but not limited to species of the genera *Haumaniastrum*, *Eragrostis*, *Ascoliepis, Gladiolus*, and *Alyssum*. These plant species can also contribute to phytostabilization owing to their capability to release a greater number of chelating agents. Other research studies (Lebrun et al., 2018) showed that in phytoimmobilization, unclean soil is covered with vegetation that is resistant to high applications of harmful elements, thereby limiting soil erosion and the leaching of pollutants within groundwater. These substances immobilize pollutants, inhibiting their uptake and reducing their mobility in soil. As a result, plants with stabilizing potential play an essential role in polluted areas of agricultural production and vegetation restoration (Eskander and Saleh, 2017; Saha et al., 2017). It is reported (Eskander and Saleh, 2017), that these substances were known to immobilize pollutants, prevent absorption, and thereby decrease their movement in the soil. This accounts for why plants with phytostabilization potential are very valuable for mining, waste, and vegetation restoration in contaminated sites. Similarly, Yadav and colleagues (Yadav et al., 2018) have also revealed that phytostabilization is very useful in removing inorganic contaminants, from soil contaminated with Arsenic (As), Copper (Cu), Lead (Pb), Zinc (Zn), Cadmium (Cd), Chromium (Cr) and other metals in their sediments.

Phytovolatilization

Phytovolatilization is the capability of some green plants to engross certain metals/metalloids and later release them through vaporization. Some ions groups like IIB, VA, and VIA in the periodic table (especially mercury (Hg), selenium (Se), and As) are being taken by the roots, transformed into non-toxic forms and later volatilized into the atmosphere (Limmer and Burken, 2016). Conversely, the disadvantage of phytovolatilization lies in the fact that toxic compounds discharged into the atmosphere can undergo precipitation and re-deposit back into the environment, as this will give rise to other toxic substances (Nikolić and Stevović, 2015). Examples of plant species from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68756904

studies (Ali et al., 2013; Mani and Kumar, 2014) include *Stanleya pinnata* and *Astragalus bisulcatus* or transgenic plants (with bacterial genes) such as *Liriodendron tulipifera, Brassica napus, Arabidopsis thaliana*, or *Nicotiana tabacum*. This method can also be applied to tackle organic compounds and other heavy metals like Se and Hg.

Phytoextraction (phytoaccumulation, phytoabsorption or phytosequestration)

This mechanism refers to the absorption of pollutants by roots, followed by displacement and accumulation in air particles. Phytoextraction technology as reviewed by Parmar et al. (2015) involves the eradication of contaminants from soil, groundwater, or surface water by living plants. This technique according to research by Sarwar et al. (2017) is mainly engaged in the remediation of soils polluted by metals (Cd, Nickel (Ni), Cu, Zn, Pb), however, it could also be used for other elements (such as Se, As) and organic compounds. This method favors hyperaccumulator species (which will be discussed in this paper) that can maintain a great absorption of exact metals in their air portions (0.01-1% dry weight, depending on the metal) (Parmar, 2015). Phytoaccumulation, also called phytoextraction or hyperaccumulation, reported by Xiao et al. (2017) uses cationic pumps and sorption to remove metals, salts, and organic compounds from the soil by absorbing water available to plants. The process commences by sowing the metal-accumulating plant in metal-polluted soil and coupled with extensive agricultural practices. Many authors (Van der Ent et al., 2013; Xiao et al., 2017; Reeves et al., 2018) have proposed *Elsholtzia splendens, Alyssum bertolonii, Thlaspi caerulescens* and *Pteris vittata* as known examples of hyperaccumulating plants of Cu, Ni, Zn/Cd, and As respectively. Several plant species near metal mining areas as stated by Saxena et al. (2020) thrived in soils heavily contaminated with metals, hence for remediation of contaminated areas, it is necessary to select the kind of plants which can absorb and transport metals in various conditions. However, some soils are highly contaminated hence the elimination of metals through this method will save an uncertain amount of time.

Phytofiltration

This technique uses plants to absorb distillate and/or precipitate contaminants, especially radioactive elements, and heavy metals, from the environment through the root structure or further submerged organs. In this process, Parmer and Singh (Parmar, 2015) reviewed that plants are stored in a hydroponic system through which wastewater passes and is "filtered" by the roots (rhizofiltration) or other structures that can absorb and concentrate pollutants (hyperaccumulators) or tolerate pollutants for the best results. Phytofiltration remediates metallic substances like Cu, Ni, vanadium (V), Cr, Pb, including other radionuclides such as caesium (Cs), strontium (Sr) and uranium (U). Nevena et al. (Cule et al., 2016) in an experiment used the ornamental plant (*Canabis indica*) to remediate Pb in wastewater. Their findings showed that the removal rate was 81.16% higher. The authors (Cule et al., 2016) supported the idea that terrestrial plants are most appropriate for rhizofiltration than aquatic plants and that *C. indica* is best used in rhizofiltration methods or floating islands for treatment of water polluted with Pb. Zhang et al. (2005) researched on the efficiency of Cu removal from contaminated water by *Elsholtzia argyi* and *Elsholtzi splendens* in hydroponics. Their results demonstrate that *Elsholtzia argyi* showed better Cu phytofiltration (removal rate of 50-90%) than *Elsholtzi splendens* (removal rate of 45-80%), which was linked with better

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68756904

capability to higher Cu concentrations and translocation to shoots. One could infer that various physicochemical properties of plant species are factors in the choice of plant for phytofiltration. This technology is capable of dealing with industrial discharge, agricultural runoff, and mine drainage. Several authors have indicated some promising examples of such plants as *Brassica juncea*, *Helianthus annus*, *Fontinalis antipyretica*, *Phragmites australis*, and some species of *Salix*, *Populus*, *Lemna,* and *Callitriche* (Van der Ent et al., 2013; Bonanno and Cirelli, 2017; Favas and Pratas, 2016; Tatar et al., 2019).

Rhizodegradation (phytostimulation)

Rhizodegradation or phytostimulation is the breakdown of organic compounds in the soil through the microbial activity of the root (rhizoshere) (Echereme, 2018). This is improved biodegradation of contaminants by a particular plant species root-associated fungi and bacteria (Ali et al., 2013; Khalid et al., 2017). There are free-living, symbiont mycorrhizal fungi that are associated with plant roots and are significantly more beneficial for the production and biochemical availability of nutrients such as cobalt (Co), Cu, Zn, Ni, nitrogen (N), phosphorus (P), potassium (K), sulphur (S) and Calcium (Ca) through the extensive hyphal network (Sarwar et al., 2017). In research by Jiang et al. (2017), it was demonstrated that bacterial species, for instance, *Pseudomonas*, *Acinetobacter*, *Bacillus*, and *Cupriavidus* improved their environmental adaptability and was resistant to Pb, Cd, and Cu in rhizospheric soil around the plant. The authors deduced that *Boehmeria nivea* L. (known to be evolving around chemical refineries) was improved by increased concentrations of the particular microorganisms (Jiang et al., 2017). Also, the plants themselves can release biodegradable enzymes. The microbial association in the rhizosphere is heterogeneous due to the changing spatial distribution of nutrients, but species of the genus *Pseudomonas* are the organisms largely connected with the root (Ali et al., 2013; Singh and Singh, 2016; Salem et al., 2018). The death of plants ought to be considered and agronomic methods must be used to reduce it by timely planting in the growing period, digging a hole in diameter, and feasibly filling it with unpolluted plant soil, for better survival of trees, thus bringing a greater efficiency of phytoremediation.

Phytodesalination

According to literature, this is a recently informed remediation approach that removes saline from internal salts. Studies have reveals that the efficacy of *Suaeda maritima* and *Sesuvium portulacastrum* in eradicating and accumulating sodium chloride (NaCl) from highly salty soil, has demonstrated to be very effective (Ali et al., 2013; Kumar et al., 2019b). Phytodesalination may possibly occur in parallel with phytoremediation of heavy metal contaminated soils in arid regions, increasing the prospect of this process. Halophytes (salt-tolerant plants) have been suggested (Padmavathiamma, 2014) to naturally adjust to cope with environmental stresses, such as heavy metals and other organic contaminants (Padmavathiamma, 2014). Iniyalakshimi (Iniyalakshimi, 2019) also found that *S. portulacastrum*, which has high sodium and chloride absorption ability may be a possible candidate for reducing secondary salinization due to irrigation with sodium-rich industrial wastewater (Fan et al., 2019). Taken together, this indicates that *S. portulacastrum* (SpSOS1 and SpAHA1) coordinates to alleviate salt toxicity by cumulating the efficiency of Na + extrusion to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68756904

maintain K + homeostasis and defend the plasma membrane from oxidative harm induced by salt stress. In a current study (Lastiri-Hernández et al., 2020), the capacity of halophytes species namely; *Bacopa monnieri* (L.), *Sesuvium verrucosum* Raf. and *Wettst* was assessed to increase their chemical properties in saline soil for 240 days in a field. It was also reported that the association of these plants has a phytodesalination ability of 1.21 t Naþ ha1 and this served to prepare the conditions for the crop growth (Lastiri-Hernández et al., 2020). This technology involves an enzymatic breakdown of pollutants, relevant for soil, groundwater, or surface water, and sediment sludges. This process is an impressive kind from phytoextraction, even though it has its drawbacks. Some of these drawbacks could include the duration of the process, the properties of the soil (salinity, sodicity and porosity), the number and the initial weight of the plant species.

Phytoremediation of organic contaminants

Currently, phytoremediation is offered as a cost-effective method to remove many kinds of organic contaminants such as petroleum products, aromatic hydrocarbons (BTEX), chlorinated solvents, explosives, and cyanides as aforementioned (Hattab-Hambli et al., 2020).

Furthermore, one of the largest environmental disasters was in the Gulf of Mexico, which had a major impact on the ecosystem and human health (Sandifer et al., 2017; Singleton et al., 2016; Schaum et al., 2010; Han and Clement, 2018; Babcock-Adams et al., 2017; Eklund et al., 2019). Crude oil kills small invertebrates, destroying soil biological life thereby rendering such polluted soils habitable to only anaerobic bacteria. Phytoremediation, as a natural, solar energy-driven in situ method, has great potential for treating soils and large areas of moderately contaminated areas. Plants are carefully selected and appropriate agronomic methods are used to properly manage phytoremediation of organic pollutants (Schwitzguébel, 2017). Phytoremediation can restore, balance a stressful environment due to the natural, synergistic relationships between plants, microorganisms, and the environment. Further, during the in-situ phytoremediation process, organic matter, nutrients, and oxygen are added to the soil through the metabolic processes of plants and microorganisms, thereby improving the quality and texture of the clean area (Schwitzguébel, 2017; Wiszniewska et al., 2016).

Phytoremediation of agrochemicals

The predominant misuse of agrochemicals over several years has polluted the agricultural and natural environment. These chemicals cause various damages to agricultural lands, various water bodies, and other land-dwelling organisms.

Various organic compounds (OCs), for example, organochlorine pesticides (OCPs) and other agrochemicals are extremely toxic and persistent in the environment (Sun et al., 2018).

The potential use of alfalfa, tomato, sunflower, and soybean species to remove endosulfan from the soil was studied by Mitton et al. (2016). Their research results showed that, except soybean, the phytoextraction rate of all other species at 60 days increased with the decrease of soil pesticide levels. Sunflower plants had the highest phytoextraction rate (2.23%), followed by tomato (1.18%), soybean (0.43%), and alfalfa (0.11%). In additional research (Zhao, 2018), the dissemination of dichloro diphenyl trichloroethane (DDT) residues in agricultural soils in southwestern Ontario, Canada,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68756904

was also studied to determine the degree of degradation of tomato plants. The DDT concentration in tomato fruits was 211.75 ug/kg, which was lower than the prescribed value. Consequently, tomato fruits are eligible and valued, and may be a potential choice for future field research. In a study (Qu et al., 2017) involving atrazine-contaminated lake sediments, spiked watermilfoil (*Myriophyllum spicatum*), and curled algae (*Potamogeton crispus*) were opened to 0.10 mg atrazine kg-1 soil at a decreased rate of 76.15% and 75.65% respectively in comparison to Atrazine's decline of 46.3% non-cultivated soil.

To correct these contaminations, researchers have essentially used consortia of various bacterial strains, such as atrazine and deisopropylrazine (Fan and Song, 2014) via rhizodegradation/phytostimulation of agrochemicals from agricultural environment. From a biotechnological point of view, bacterial strains can also be used to decompose certain pesticides, such as the one Myresiotis et al. (2012) used to remediate the soil contaminated with hydrochloride, metribuzin, acidobenzolar-S-methyl, propamocarb, thiamethoxam and napropamide. Phytoremediation of pesticides is affected by some factors. Their low bioavailability in soils might confine the attainment of this technology.

Large numbers of plants have been tested to proficiently accumulate pesticides and some of these plants are listed in *Table 1*. The capacity of these plants to uptake pesticide residues varies greatly between plant species (Handford et al., 2015; Romeh, 2015). These plants are widely used because of their significant role in agriculture and gardening and as a result of these good prospects for the accumulation of innumerable organic pollutants, they are therefore generally considered phytoremediation plants (Singh and Singh, 2017).

Significant interactions can occur between different pollutants in a polluted environment. When there is soil-to-plants absorption, the accumulation potential is affected by various plant properties such as water absorption potential and root depth/structure (Eevers et al., 2017). When pesticides are trapped in plant root tissues, they can be immobilized in the roots or transferred to an aerial portion of the plant where the analytes can be stored, metabolized, or evaporated (Eevers et al., 2017). In general, the objective of effective phytoremediation is not only phytoaccumulation but also the degradation of pollutants in plant tissues as this can be done with or without endophytic bacteria.

Phytoremediation of explosive compounds

After World War II, the commissioning and removal of weapons at military factories brought about the pollution of the agricultural environment and other biological systems with explosives like 2,4,6-trinitrotoluene (TNT), hexahydro-1,3,5-trinitro-1, 3,5 triazine (RDX) and octahydro-1,3,5,7-tetranitro-1,3,5,7-tetraazocin (HMX) (Taylor, 2017; Srivastava, 2015; Sheehan et al., 2020; Aguero and Terreux, 2019). These compounds are the most widely distributed organic explosive contaminates found in nature. The use of explosives during military exercises and operations leads to large-scale environmental pollution, in which case the ecological balance is disturbed (Ndibe et al., 2018). As a consequence of their manufacturing and disposal practices, these explosives with their transformation products are major pollutants in soils, ground and surface waters worldwide. For instance, ammunition contamination in the 1920s in Verdun, France, still posed a danger to public health (Rylott and Bruce, 2019; Gorecki et al., 2017).

Source (common English name): https://en.wikipedia.org/wiki/ (accessed on April 7, 2020)

Explosives are sensitive to a xenobiotic, and their survival in an environment is dangerous for living organisms; as they can migrate through aboveground soils,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68756904

polluting groundwater (Taylor, 2017). Despite the devastating effects of pollution on environmental and human health, the global market for explosives was forecast to grow from $ 23.8 billion in 2017 to $ 31.2 billion by 2022, therefore lucrative, clean-up methods are required instantly (BCC, 2018). There are innumerable practices connected with the conversion of explosive pollutants by plants. RDX has been described (Hannink et al., 2002) to have minor toxicity than TNT. Additionally, it can translocate within plants, and consequently, these compounds can be stored in various parts of the plants.

In the USA (Virginia Commonwealth University), a study by Via et al. (2016) was conducted to investigate the impacts of explosives polluted soils using ecological metrics in an experimental minefield on vegetative communities. Their results showed that RDX and TNT contaminated plots had shifted in dominant functional traits, suggesting an influx of more tolerant species as a result of new tolerant species filling open niches in contaminated plots (Via et al., 2016). In another study (Kiiskila et al., 2015), many agricultural and ornamental important plants were examined for their capability to remediate TNT and RDX in barley (*Hordeum sativum*), Soybean (*Glycine max*), alfalfa (*M. sativa*), chickpea (*Cicer arietinum*), maize (*Zea mays*), sunflower (*Helianthus annuus*), pea (*Pisum sativum*), and ryegrass (*Lolium multiflorum*) species. Furthermore, Das (2017) reported the two most effective species for TNT uptake- *Eurasian watermilfoil*, *Myriophyllum spicatum*, and vetiver grass as well as *Chrysopogon zizanioides*. For RDX phytoremediation, reed canary grass, rice, and fox sedge showed good promise, although degradation of RDX in the plant tissue is limited (Kiiskila et al., 2015). Conversely, there are limitations to this new technology. It is only effective when treating shallow soils, ground, and surface waters. Plants can also efficiently remove pollutants only close to the root zone since phytotoxicity is also a drawback to this methodology.

Phytoremediation of petroleum compounds

Economic growth and industrialization have led to increased emissions of petroleum hydrocarbons (PHC) and trace elements (TE). Due to their tenacity in an environment and various toxicological effects on living things, they are well-thought-out to be the greatest toxic pollutants in the world (Marchand, 2018). Most chemical contaminated soils are linked with the release of petroleum products into the environment. The intensification of global oil and gas activities, including oil exploration, drilling, production, land storage, and transportation has also increased the menace of crude oil spills and outflows (Okotie et al., 2018). Due to health problems, these water bodies and land contaminated with crude oil are often not suitable for domestic and agricultural uses (Tang and Angela, 2019a).

However, the exploration of crude oil has brought economic development, especially in developing countries (like Ghana, Nigeria, Niger etc.), but the natural and agricultural environment in these countries has also been damaged by the negative effects of these oil industries (Ngene et al., 2016). For instance, water resources in the Niger Delta are no longer fit for human drinking, but oil exploration in Nigeria cannot be stopped as 90% of Nigerian foreign currency earnings come from crude oil exploration (Okotie et al., 2018; Adekola et al., 2017; Siakwah, 2018). In addition to the detrimental effects of the oil industry in our environment, various reports (Ramirez et al., 2017) points out its negative impacts on human health as well. These are psychological problems initiated by crude oil leakage, respiratory tract irritation, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68756904

blood disorders (Ramirez et al., 2017; Taheri et al., 2018). Sylvia reported that contaminated sites pose a risk to human life owing to severe health complications caused by unreceptive health effects from introduction to oil-soil contamination (Adipah, 2019).

Phytoremediation is said to be a slowly developing process that can clean the environment for a long time. This method is also influenced by external parameters, including type and leaching of pollutants, soil chemistry, and photosynthesis (Lim et al., 2016) and water-related effects on conservation and weather conditions. Exposure of plants to organisms and pollutants for a longer period reduces their ability to uptake contaminants (Zabbey et al., 2017). In current research by Viesser et al. (2020), three bacteria were isolated namely; *Bacillus thurigiensis*, *Bacillus pumilus*, and *Rhodococcus hoagie*. These were able to use petroleum hydrocarbons as the sole carbon during vitrodegradation assays. The authors found that *R. hoagii* had the highest efficacy of petroleum consumption, attaining 87% of degradation after only 24 h of cultivation.

Another experiment (Heidari et al., 2018) was conducted to study the effect of oil-contaminated soil on *Echinacea purpurea* with four concentrations of crude oil. The results depicted that this plant has a possibility for removing TPHs, up to 45.5% at 1% crude oil contamination. The authors further reported that *E. purpurea* is a widely - spread species that can be commendably used for phytoremediation of ≤ 10000 mg kg^{-1} crude oil-contaminated soil. Other studies suggested that the faster-growing flora (e.g. grass species) are plants that effectively restore polycyclic aromatic hydrocarbons (PAH) in contaminated soil (Srivastav et al., 2018; Kumar et al., 2019a). The adsorption properties of TPH ought to be investigated as it aids to reduce the concentration of organic material in the soil. Thorough remedial studies have to be carried out not only to assess the effectiveness of the repair but also to investigate and implement the potential for secondary pollutants.

These studies demonstrate that agricultural lands with low rates of oil contamination allow the growth of plants. Furthermore, previous studies in phytoremediation of contaminants have not focused so much on petroleum hydrocarbons rather all attention has been on heavy metals remediation (Tang and Angela, 2019b), hence further studies must be focused on this area.

Inorganic contaminants

Inorganic materials belong to man-made environmental activities, for instance, smelting, mine drainage, chemical, and metallurgical processes, and also natural processes. These sources release inorganic pollutants usually in the form of minerals such as metals, salts, and natural substances (Masindi and Muedi, 2018; Fayiga et al., 2018). Heavy metal contaminants are usually brought about by human activities, but natural and biological contaminations are also common such as erosion and volcanic activity, mining pollution over time; which causes toxic particles release in vegetation nutrients and forest (Banunle, 2018). These contaminants are poisonous since they sometimes accumulate in the food chain (Masindi and Muedi, 2018). Pb, Co, Cd and other toxic heavy metals cannot be biodegraded, so they can be distinguished from other pollutants, but they can accumulate in plants, even if the concentration is relatively low, it can cause various diseases and diseases. Higher levels of essential and non-essential heavy metals in the soil may inhibit plant growth and cause toxic symptoms in most

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68756904

plants (Ochonogor, 2014). Several remediation techniques for inorganic compounds are known in literature but phytoremediation stands out.

Phytoremediation of inorganic contamination

Phytoremediation of inorganic contaminants comprises three technologies, plant extraction (similarly known as phytoextraction/phytoaccumulation), root filtration (rhizofiltration), and plant stabilization (phytostabilization) (Chirakkara et al., 2016; DalCorso et al., 2019). In phytoextraction as aforementioned, heavy metals within the soil are absorbed by the roots of the plants, transferred to the ground part, and accumulated in the soil. The contaminants do not decompose, but remain in roots and/or plant tissue (Chandra et al., 2017). After harvesting plant parts containing inorganic contaminants, it is advisable to keep them in a safe place for discarding. It is reported according to some authors (Banunle, 2018; Sharma, 2018) that the amount of contaminated plant material treated is relatively small compared to the amount of contaminated soil treated with in situ remediation techniques. There are differences in rhizofiltration from the phytoaccumulation, as this is applied to contaminants dissolved in shallow, underground, or wastewater (Chirakkara et al., 2016).

In the process of rhizofiltration of plant root, inorganic contaminants will be adsorbed in the roots or deposited on the roots (Makombe, 2018; Makombe and Gwisai, 2018). The fixation of pollutants in the root zone by the effects of soil chemistry, microbiology, and physics are also referred to as phytostabilization (Touceda-González et al., 2017). Some soils are so severely contaminated hence metals removal using plants would take an impractical expanse of time. Therefore, the normal practice is to select drought-resistant, fast-growing fodder or plants which will be able to grow in metal-contaminated and nutrient-deficient soils.

Hyperaccumulation process by some plant species

The remediation techniques noted here is plant extraction (phytoextraction), identified as phytoaccumulation, where residues of pollutants are taking by plant roots and transferred to other parts of the plant. Some metals are more deadly than others (e.g. arsenic, cadmium is less toxic) for instance cobalt, nickel, chromium, mercury, and selenium are very toxic even in small quantities (Masindi and Muedi, 2018). Plant extraction according to Rascio and Navari-Izzo (2011) can be accomplished by removing high concentrated contaminants from the soil, such as using hyperaccumulators; uptake of low concentrations of extracts while maintaining high growth status as in *Populas sp*. (Nissim et al., 2018). Subsequently, phytostabilization removes contaminants and reduces their leaching from the soil by reducing crop roots. Roots can also be an important material for transforming harmful metals into low-toxic forms (Ali et al., 2013). Additionally, damage to plants depends on the microorganisms that come with the root system and the enzymes that are secreted by the root to clear the germs and then remove them by absorption and transpiration.

The roots that accumulate higher concentrations of iron in each tissue are higher; and so, their habitat is acknowledged as hyperaccumulators (Srivastav et al., 2018). Qatari plants reported in recent studies by Al-Thani (2019) are the most candidates for active phytoremediation of contaminated compounds of such nature. Considering that monitoring is employed, *Phragmites australis*, *Typha domingensis*, *Amaranthus spp.*, *Nerium oleander*, and *Ricinus communis* are noted as important species of plant for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68756904

successful ecological remediating and conserving a healthy environment (Al-Thani, 2019). *Table 2* summarizes some examples of plant species and their metal accumulation capabilities that have been tested for phytoremediation studies. In general, different methods of phytoremediation have potent characteristics which make them suitable for diverse soil and water pollution remediation. These methods of study are delimited by duration, nonetheless it supports the capability of selected phytoremediation plants to be considered (Tang and Angela, 2019a). For phytoremediation through phytoaccumulation, the shoot must be obtained after uptake. The shoot can be burned or otherwise destroyed (Valipour et al., 2015).

Table 2. *Some plant species used in the hyperaccumulation of metals and their accumulation capacity*

Plant species	Family	Polluted medium	Metals	Metal accumulation capacity (mg kg-^{1}DW)	Phytoremediation mechanism and metal accumulation compartment	References
Blue stool (*Noccaea caerulescens*)	Brassicaceae	Water	Pb	1,700–2,300	Rhizofiltration (aerial parts/root)	Dinh et al., 2018

Benefits and limitations of phytoremediation technology

Phytoremediation does not only have advantages but also disadvantages that need to be considered when using this technique. Economically it is cost advantageous, but tracking results can be time-consuming and more of these are elaborated in *Table 3*. Choosing the technique that can recover multiple pollutants at once is tough (Srivastav et al., 2018). The concentration of contaminants and the occurrence of extra toxins should not exceed the tolerance of the plants used. It is not easy to choose plants that effectively remove various impurities. In applying this technique, these limitations and the likelihood of these pollutants entering the food chain should be considered.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68756904

Table 3. *Benefits and limitations of the phytoremediation technology of compounds (Dhanwal et al., 2017; Ashraf et al., 2019)*

Benefits	Limitations
Application	
It can be employed in situ, i.e., on-site removal of contaminants, whether within the soil, water, or groundwater	It is mainly applicable to the top layer of the soil and mine tailings
It is very effective at sites where low amount/toxic contaminants are present	It offers limited applicability to diverse kinds of wastes, especially with high-level toxicity wastes
Cost factor time factor	
It offers lower labor expenditures and reduced cost in operations	Plant deaths may occur in highly toxic sites which could increase the cost of the process
It comes with low investment cost and minimal equipment requirement (constitutes substantial savings)	Mostly there is incomplete removal of contaminants with long-term low performance
Contaminants can be recovered from the plant tissues and offer an opportunity for commercialization	Good cultivation practices and maintenance is required to avoid accidents
Performance	
It can be used for remediating soils that are nonproductive for agricultural purposes	The effectiveness of this remediation process is affected by seasonal factors
It has the potential to treat sites polluted with more than one type of pollutant	A good considerate of the performance and physiological changes of plants in response to different varieties of wastes is needed
Impact on the environment and population	
It is aesthetically pleasing and widely accepted by the public community	There is the possibility of bioaccumulation of pollutants in the food chain
It can reduce erosion of soils, especially thinner inorganic soils	There is the possibility of introduction and spreading of undesirable invasive species of plants
It is nondestructive, nonintrusive, highly biologically active, therefore have a very low environmental impact on soil and water	Proper discarding of plant matter is required with proper risk assessment
It reduces leaching of particulate substance and spreading of toxicants	

Interaction of phytotransformation, phytoextraction, and phytovolatilization technologies

Phytotransformation, otherwise known as phytodegradation, as aforementioned is the decomposition of organic contaminants released by plants: the action of compounds (like enzymes) is produced by plants (Saleem, 2016). There is the degradation of organic pollutants into simple compounds that integrate within plant tissues to encourage plant growth. Restoration of sites by phytotransformation relies on the direct uptake of contaminants via a medium and buildup in the plant (Abdullah et al., 2020). Plants absorb hydrocarbons and extra complex organic molecules and then metabolize or mineralize them through sunlight-driven chemical reactions (Schwitzguébel, 2017). For instance, some enzymes can break down waste from ammunition (explosives), chlorinated solvents, or herbicides. This technology can similarly be used to get rid of noxious waste from petrochemical and storage sites, fuel leakages, leachate stacking,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68756904

and agrochemicals (Kumar et al., 2018). To successfully implement this technique, the transformed compounds accumulated in the plant must be non-toxic or less harmful than the parent compound. Hybrid *Poplars* are proven in research to convert TCE into trichloroethanol, dichloroacetic acid, and trichloroacetic acid which is partially mineralized into CO_2 (Leung et al., 2019; Feng et al., 2017). Here, organic pollutants and heavy metals are being investigated too. Soil conditioning, including chelating agents, may be needed to break the compounds that connect pollutants with soil particles to encourage their uptake by plants (Verma, 2017; Franchi and Petruzzelli, 2017). In some cases, plant transformation is used in cooperation with other restoration techniques or as an improving technique (Mustapha and Lens, 2018).

The discharge of volatile contaminants into the atmosphere via plant leaves refers to phytovolatilization as previously described and is a form of phytotransformation (Limmer and Burken, 2016). Even if the discharge of contaminants into the atmosphere might not attain the full clean-up goal, phytovolatilization treatment may be ideal merits to the long-term properties of the soil and the danger of groundwater contamination (Limmer and Burken, 2016). In literature, phytovolatilization is generally considered beneficial because it usually dilutes atmospheric pollutants and undergoes photochemical degradation. In this technology plants is not just a research area of traditional organic pollutants but also an important research area for other contaminants that occur naturally in the soil and roots of plants. Phytovolatilization of many inorganic and organic contaminations in the natural and agricultural environment is usually observed. Studies by Arya et al. (2017) on the phytovolatilization of pollutants have shed light on ways by which many pollutants are evaporated from plants. In phytovolatilization, certain organic contaminants become volatile in plants and then become evaporated. Compounds having a low octanol-air partition coefficient (log Koa b 5) are reported as been more volatile in plants (Limmer and Burken, 2016). Research conducted by Nwaichi et al. (2015) showed that plant can promote the migration and/or degradation of carbon monoxide in the soil; just like *Fibrristylis littoralis* which is employed for the biological regeneration of agricultural soil polluted by crude oil (up to 92% PAH, shelf life 90 days). Moreover, compounds that cannot be transferred to plants owing to being hydrophobic can still be absolved in plant tissues during particle deposition or air distribution over the soil (Limmer and Burken, 2016). But, the relative prominence of various remediation techniques remains unclear, especially for less studied connections (Limmer and Burken, 2016).

Phytoextraction interactions with phytovolatilization are two methods of removing organic contaminants and detoxification in agricultural soils. It has been reviewed in this paper that phytoextraction removes soil contaminants by concentrating them on parts of the harvested plant. Previous research studies (Izinyon and Seghosime, 2013; Sun et al., 2018) have unraveled *Zucchini* (*Cucurbita pepo*) as a good organic compound storage medium for agricultural land. The mechanistic interaction of phytoremediation involving phytotransformation, phytoextraction, and phytovolatilization technologies is illustrated in *Figure 2.*

Future perspectives in biotechnological enhancement for phytoremediation

Recent studies have offered the physiological and molecular technique of remediation to improve remediation and the cleanup of the agricultural and natural environment. Food waste being used has also helped to control the proper management

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68756904

of food/vegetables/fruit. This gives plants the natural ability to absorb, decompose, or concentrate pollutants from soil, water, and air. Contaminants and toxic metals are the core objectives in phytoremediation

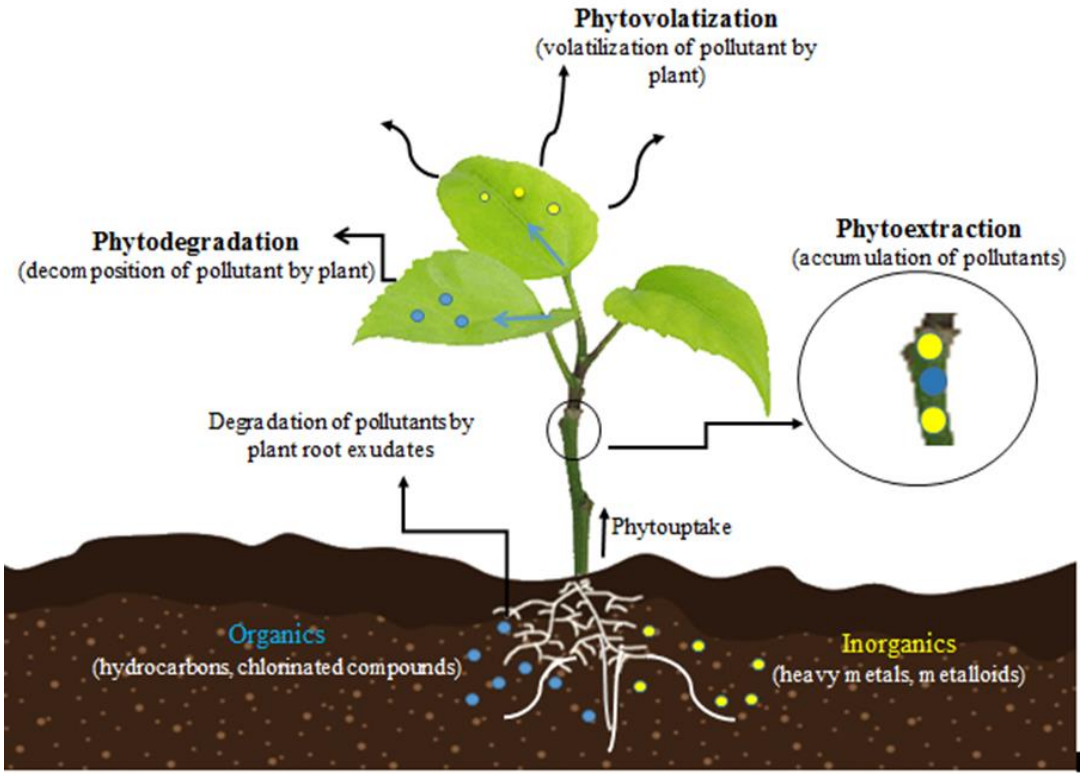

Figure 2. *Mechanistic overview of 3-phase phytoremediation process*

Plant-microbial assisted interaction

Plant and rhizosphere microorganisms are generally employed to remediate contaminated land. Under this mechanism, plants work together to promote soil regeneration through the action of roots and soil microorganisms. Microorganisms utilize root metabolites (secretions), which in turn allow plants to benefit from microbial processing/mineral dissolution (Asemoloye et al., 2019). Plants can absorb pollutants from the soil and transfer them to themselves, while microorganisms mainly decompose pollutants. With the introduction of transgenic techniques, microorganisms and plants can progress to better degrade pollutant. Nonetheless, the use of inherently improved organisms in many countries, different political and moral issues, and related legal power limits the effectiveness of the application. It is well known that microorganisms play key roles in the decomposition of toxic substances as they help in the elimination of undesirable molecules in the environment (Maier and Gentry, 2015). As microbiology evolves, biologists hire the smallest living things on earth to clean and remediate highly oil-contaminated ecosystems. Undoubtedly, microbes are a viable and unused resource for novel environmental biotechnologies (Gaur et al., 2018). Plant growth in a contaminated field often improves soil quality by increasing microbial populations and organism diversity, plus adding organic matter to the soil. Biological

DOI: http://dx.doi.org/10.15666/aeer/1805_68756904

treatment (mainly microbial decomposition) is a natural way of eradicating contaminants by decomposing contaminated nutrients. Soil microorganisms can be tested aerobically (aerobic biodegradation) or anaerobically (aerobic biodegradation). Organic compounds through biological treatment have been effectively performed on agricultural land under natural conditions (Girma, 2015; Odukkathil and Vasudevan, 2016). Plant in combination with microbes efficiency can be enhanced by mixing, aerating, and adding nutrients, for example, heterotrophic bacteria are employed to clean agricultural soils contaminated with crude oil (Odukkathil and Vasudevan, 2016). An important condition is the presence of microbes with sufficient metabolic potential. Microbes can be native to the infected area (biostimulation) or insulated from the subsequent area (bio-augmentation) (Varjani and Upasani, 2019; Salimizadeh et al., 2018). If these microorganisms are present (Nishiwaki et al., 2018), the biodegradation of contaminants can be sustained by providing sufficient nutrients, moisture, and oxygen. Other variables, for example, salinity are usually out of control. The destructive potential of microorganisms for various pollutants has been previously reported (Mishra et al., 2020; Chen et al., 2019), namely; hydrocarbons, pesticides, and furans for many compounds, including PCBs, PAHs, DDT, and others. The application of the pesticide in the soil can cause problems because according to Abatenh et al. (2017), biological methods are appropriate for conditions where the pesticide is not harmful to microorganisms and plants employed for remediation. Compared to other biological methods, microbiological re-purification is considered to be the most effective method, but high molecular weight hydrocarbons, with low adsorption and solubility, limit their availability to microorganisms (Koshlaf and Ball, 2017). Microbe-assisted phytoremediation can be also carried out by stimulation via inoculation with pesticides degrading microorganisms (Mitton et al., 2012). It is reported that microorganisms can secrete enormous amounts of surfactants and enzymes, hence it is possible for pesticides to undergo extracellular degradation due to these secreted enzymes (Sharma et al., 2018; el Zahar Haichar et al., 2014).

A study by Balcom et al. (2016) reported the potency of microorganisms to metabolize micropollutants such as xenobiotics during the process of wastewater treatment.

These include the concentration of contaminants and chemical nature, the physicochemical properties of the surroundings, and their availability to microorganisms (Koshlaf and Ball, 2017; Bharathi et al., 2017). Due to various factors, monitoring and improving the biological treatment procedure is a challenging system. These factors consist of the microbial populace that can decompose the contaminant and environmental factors (temperature, soil type, pH, nutrient uptake, and oxygen or other electrons) present (Abatenh et al., 2017; Kothe, 2015). The non-existence of information concerning the effects of several environmental factors on the proportion and the extent of biodegradation creates uncertainty.

Nano-phytoremediation enhancement

Nano-phytoremediation involves a combined application of nanotechnology and phytoremediation to decontaminate the environment. Nanotechnology improves the efficacy of phytoremediation. Nanotechnology can provide an environmentally friendly alternative to remediation and management without harming nature. Nanoparticles are used to remediate soil and water contaminated by heavy metals, organic and inorganic pollutants (Srivastav et al., 2018). A variety of plants, bacteria, and fungi in studies

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68756904

(Mallikarjunaiah et al., 2020) also enhance their ability to accumulate very high concentrations of metals, which are also recognized as hyperaccumulators. Plant species used in nano-plant engineering cleaning (nano-phytoremediation) technology to decontaminate contaminated soil include the application of phytoremediation techniques (for instance, phytodegradation, phytoextraction, phytostabilization) and nanoparticle.

Due to the high efficiency of pollutants remediated by plants using this technology, numerous reports (Srivastav et al., 2018) have shown that various nanoparticles/nanomaterials significantly detoxify or restore contaminated soil from organic, inorganic, and heavy metal pollutants. Nano zerovalent iron (nZVI), bimetallic nanoparticles (Pd/Fe) and magnetite nanoparticles (nFe3O4), according to the literature (Alonso et al., 2018) may rapidly decompose organic pollutants such as atrazine, chlorpyrifos, trichloroethylene (TCE), pentachlorophenol, pyrene, polychlorinated biphenyls, lindane, 2,4-Dinitrotoluene and ibuprofen from the contaminated soil environment.

Studies by Pillai and Kottekottil (2016) reveals that plant species (*Cymbopogon citratus*) and nanoparticle (nZVIs) can be used to remediate Endosulfan pollutant at an efficiency rate of 86.16 ± 0.09 (%). Souri and coworkers (Souri et al., 2017) also reported that Arsenic (As) pollutant was removed using plant (*Isatis cappadocica*) and nanoparticle (SANPs) at 705 ppm and 1188 ppm accumulate in roots and shoots, respectively. A recent study by Ma and Wang (Ma and Wang, 2018) proves that 82% of Trichloroethylene pollutants can be remediated by a combination of Fullerene (nC60) and *Populus deltoids* from the environment. The success of phytoremediation, or more precisely the phytoextraction, depends on the hyperaccumulator specific to the particular pollutant. Preferably, researchers (Srivastav et al., 2018) suggest that the nano-phytoremediation must be able to accumulate excess contaminants (organic, inorganic, and heavy metals), specifically in the aboveground part (sinking potential). It ought to be a fast-growing plant with high biomass (growth and productivity). The use of selected nanoparticles significantly increased plant growth and treatment with nano augmentations improves the efficiency of phytoremediation and significantly removed pollutants from the soil (Pillai and Kottekottil, 2016).

Despite the many benefits, we obtain from this combination of technology; research on phytoremediation using nanomaterials is very scanty. So far, only microcosm studies (Simonin and Richaume, 2015) have been carried out, so future studies need to use more realistic studies and a better understanding of field practicals is needed.

Genetic engineering enhancement

Genetically improved technology creates effective means of plants and microbes combined with systems of bacterial-plant remediation. Combined cultivation of contaminant sources and individual microbes, whole cells, living plants and plant wastes, food, agriculture, and forestry wastes plays key roles in reducing the content of heavy metals in mining locations to bring a good return to agriculture or the natural environment. Similarly, genetic manipulations of plant hosts in microbial communities can improve phytoremediation capabilities (Tripathi et al., 2020). This includes isolation of bacteria and gene integration that direct the production of specific enzymes thus resulting in degradation of pollutants using the transport of modified organisms and an increase in the number of responsible microbial species in the host system. Biotechnology (genetic engineering) from a previous research study (Dhanwal et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68756904

2017) can be engaged to attach one or more active accumulator genes from higher plants into smaller plants, thereby increasing the final biomass. Novel catalytic enzymes can be used in present biotechnology for soil remediation; new microorganisms can be a replica with precise degrading genes for active hydrocarbon degradation (Asemoloye et al., 2019).

Currently, genetically improved plant species are produced using genetic engineering techniques and are used for a plant in remediating soils contaminated with methyl mercury, a neurotoxic agent (Dhanwal et al., 2017). Conversely, modern biotechnological advances, for instance, the new omic revolution, the emergence of nanotechnology, and the innovation of new catabolic genes, may improve the competence of bioremediation and its applicability in removing soil pollution. To identify plant traits that depend on a particular combination of several genes; for instance, a quantitative map of the trait loci between zinc-tolerant (*Arabidopsis helleri)* and non-zinc-tolerant (*Arabidopsis lyrate)* hybrids identified several genomic regions, and combining them explains why more than 42% of the plant was tolerance to zinc (Nahar et al., 2017). Arabidopsis and Transgenic tobacco are some examples of the genes of transgenic bacteria merB and merA (Dhanwal et al., 2017) that have the potential to eliminate mercury from the soil. Studies have shown that transgenic plants combined with bacterial genes can transform the herbicide Simazine into different non-toxic forms (Azab et al., 2016). Nahar et al. (2017) also reported the *Arabidopsis thaliana* AtACR2 gene (encoding arsenic reductase 2) which was cloned and transformed into the tobacco genome (*Nicotiana tabacum*). The results obtained showed that transgenic tobacco has a higher tolerance to arsenic than wild tobacco.

For genetic manipulation, the use of bacteria is employed to assist plant remediation. Therefore, several strains of bacteria and fungi are known to degrade these compounds (Gilani et al., 2016). In another study, Gilani et al. (2016) identified 14 species of *Pseudomonas* and isolated them from the soil as the organisms that could degrade chlorpyrifos. Many of these soils have been contaminated with a mixture of pollutants let us say pesticides (Barchanska et al., 2019). Therefore, preserving the steadiness of genes transferred to a host is a very difficult task (Tripathi et al., 2020), and there are signs that recombinant organisms with certain characters often lose their efficacy to degrade some contaminants.

Improvements in omics technology provide opportunities for isolating and cultivating such useful microorganisms and studying non-cultivable organisms. The next-generation of sequencing technology can provide an ideal method for analyzing microbial communities (Van Dorst et al., 2016). Although the higher nutrient content in the artificial medium usually restricts oligotrophic bacteria (i.e microorganisms that require only a small amount of nutrients) and prefers copiotrophs bacteria (i.e. microorganisms that grow under nutrient-rich conditions), therefore, it is similar to the new cultivation technology of the natural environment is closing the gap between culturally dependent methods and culturally independent techniques (Van Dorst et al., 2016; Ferrari et al., 2011).

Conclusion

Biotechnological integration may provide a crucial step towards the development viability of the remediation of the ecosystem. However, there is a need for more research into understanding the mechanisms underlying plant-microbial interactions of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_68756904

the rhizosphere. Further exploration is also required to develop the kinetics and simulations for synergistic degradation procedures and their field applications. Additionally, developments in bioremediation are expected to focus on ways to provide conditions that promote plant growth and microbial activity in the soil to enable bioavailability and degradation of organic and inorganic compounds.

Since phytoremediation research is actually interdisciplinary, we recommend the following:

a) Plant breeders, biotechnologists, physiologists, agronomists, soil scientists, biochemists, and environmentalists must work together to produce robust methods to develop genetically modified plants and enhance the potential of existing plants for better contaminant control.
b) In transgenic research on phytoremediation, future research should be feasible to solve the problem of mixed pollution that occurs in many contaminated locations to remove mixed or complex pollutants.
c) Future research should also focus on making better use of metabolic diversity, not only for plants, but also for a better understanding of the complex interactions between pollutants in the rhizosphere, plant roots, soil, and microorganisms (bacteria and mycorrhizae).

(Received 20th May 2020; accepted 14th Aug 2020)

Abstract. This study clarified the applicability of micro-sprinkler irrigation under plastic film (MSPF) in a greenhouse and finding the optimal micropores group spacing and capillary arrangement density. The effects of different micropores group spacing (L1: 30 cm micropores group spacing, and L2: 50 cm micropores group spacing) and capillary arrangement density (C1: one pipe for one row, C2: one pipe for two rows, and C3: one pipe for three rows) with the MSPF on the growth, quality, yield (Y), and water use efficiency (WUE) of tomato were studied. A completely randomized trial design was used, and drip irrigation under plastic film and micro-sprinkler irrigation were used as controls. The results showed that MSPF in a greenhouse can lead to saving water, increase yield, and improve crop quality. Compared to 50 cm micropores group spacing, 30 cm was better for tomato growth and also increased fruit quality, yield, and WUE. Considering our results comprehensively, the combination of one pipe for two rows under a micropores group spacing of 30 cm is recommended as technical parameters for greenhouse tomato cultivation under MSPF in arid and semi-arid sandy loam soils.

Introduction

The development of facility agriculture has provided a powerful guarantee for vegetable production in arid and semi-arid sandy loam soils of northwest China. However, the irrigation water used for facilitating agriculture in this region mainly originates from groundwater, and the resulting groundwater resource exploitation has exacerbated the water crisis in these arid and semi-arid areas; therefore, it is urgently required to mitigate the excessive use of irrigation water in this region (Du et al., 2014). Therefore, the realization of a more efficient utilization of water resources has become the current research hotspot in this region. As a common irrigation method for the greenhouse tomato (*Solanum Lycopersicum* L.) in this area, drip irrigation offers the advantages of water-saving, fertilizer-saving, and labor-saving. It has been widely used on tomato, pepper, melon, and other crops (Liu et al., 2012; Zhang et al., 2017; Wang et al., 2018a). Because of the existence of sediment, chemical precipitates, or biomass in the irrigation water body, the emitters in the drip irrigation system clog easily, resulting in decreased irrigation uniformity, accompanied by decreased crop yield and an increased cost (Yu et al., 2010; Feng et al., 2018). Drip irrigation belongs to local irrigation, and the soil wetting body per unit area of tillage layer is limited, which greatly hinders the development of the crop root system (Michelakis et al., 1993; Zhou et al., 2017).

As one of the many development forms of drip irrigation, micro-sprinkler irrigation is an irrigation form, where sprinkler (micro) pores are arranged in groups on the wall of a thin-walled drip irrigation plastic pipe (flat strip after coiling) (Zhang et al., 2009). The emitter energy dissipation structure is removed. Under identical working pressures, the flow velocity of micro-sprinkler irrigation is about 15 times larger than that of labyrinth drip irrigation. This results in strong sediment-carrying capacity and anti-clogging performance of the micro-sprinkler irrigation. This technique can solve the clogging

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69056926

problem of drip irrigation emitters (Yu et al., 2010; Feng et al., 2018). At the same time, the flow rate of a single group of micro-sprinklers is much higher than that of drip irrigation, which easily increases the ratio of the horizontal and vertical migration distance of soil moisture peaks, and improves the uniformity of the soil wetting body and the water per unit area of tillage layer (Ould et al., 2001; Del et al., 2020). Micro-sprinkler irrigation offers the advantages of decreasing the restriction of horizontal root growth and short irrigation duration (Man et al., 2014; Li et al., 2019a). Therefore, micro-sprinkler irrigation has been used for winter wheat, summer corn, lawn, seedlings, and other crops, where it has achieved good results (Man et al., 2014; Baram et al., 2018; Fletcher et al., 2018; Li et al., 2018a). However, the shape, area, and uniformity of soil wetting in a micro-sprinkler irrigated area are affected by the wind speed. In addition, problems, such as difficulty to control weeds and high damage rate of micro sprinklers currently obstructs micro-sprinkler irrigation treatment (Man et al., 2014, 2017; Li et al., 2019b).

The development of facility agriculture provides a good environment for the application of micro-sprinkler irrigation, since it offers flat land, no wind indoors, and short capillary laying distance (Tsitsimpelis et al., 2016). However, the space of facility agriculture is relatively closed, and micro-sprinkler irrigation water spray atomization easily increases air humidity. High temperature and high humidity have been shown to facilitate crop diseases and insect pests (Gómez-Rodríguez et al., 2003; Er and Gökçe, 2004; Camara et al., 2017), resulting in less use of micro-sprinkler irrigation in facility agriculture. Plastic film mulching provides a solution for the application of micro-sprinkler irrigation in facility agriculture. Plastic film mulching can restrain the water jet of micro-sprinkler irrigation, decrease spray water atomization and ineffective water evaporation, and help to improve irrigation water use efficiency (WUE) (Massatbayev et al., 2016; Wang et al., 2019a). Therefore, the combination of micro-sprinkling irrigation and film mulching technology, and the use of multiple groups of small micro-pores beneath the film can compensate for the shortcomings of the micro-spray pipes used in the greenhouse. This technique is called micro-sprinkler irrigation under plastic film (MSPF, *Fig. 1*). The exploration of MSPF is of great significance to enrich the greenhouse micro-irrigation technology system, expanded the scope of the application of micro-sprinkler irrigation, and decrease the water needed for crops, and increases both the yield and quality of crops.

Figure 1. *Micro-sprinkler irrigation under plastic film (MSPF)*

The tomato is one of the main vegetables grown in facility agriculture in the arid to semi-arid areas of northwest China. The tomato has rich nutritional value and is the main cash crop with which local farmers increase their income (Malherbe and Marais, 2015;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69056926

Liu et al., 2019). The greenhouse tomato in this area belongs to sparse planting crops. Based on its unique planting structure pattern, the selection and arrangement of orifice flow directly changes the soil water distribution and indirectly affects the WUE and investment cost of tomato plants. The orifice flow position on the capillary pipe (i.e., dripper spacing) and the orifice flow position between the capillary pipe (i.e., capillary arrangement density) are two aspects of the orifice flow position. Therefore, for the sustainable development of the greenhouse tomato industry in this region, it is important to determine the optimal position of the orifice flow position on the capillary pipe and the orifice flow position between the capillary pipe. These values will enable the best balance between increasing production and improving quality while reducing the use of irrigation water. Previous studies on drip irrigation showed that the confluence time of the wetting peaks at two adjacent dippers was shorter at identical dipper flow rate. Moreover, the surface wetting shape of soil moisture under two adjacent emitters was approximately rectangular when the emitter spacing decreased from 80 to 30 cm (Ould et al., 2001; Elmaloglou and Diamantopoulos, 2010). The more uniform the wetting body was, the more irrigation water use could be decreased and irrigation WUE increased (Xu et al., 2012; Sui et al., 2018). When the dipper spacing increased from 15 to 30 cm, the yield of onions first increased and then decreased (Enciso et al., 2007). The smaller the capillary arrangement density is, the more uniform the horizontal water content distribution will be, and the higher the crop dry matter accumulation and yield will be. However, the higher capillary arrangement density easily increases the investment cost. This is also not conducive for the improvement of vegetable flavor, nutrition, and WUE (Bozkurt et al., 2006; Chen et al., 2015; Zhou et al., 2017; Liu et al., 2019; Lv et al., 2019; Yang et al., 2019).

At present, relevant research mainly focused on the orifice flow position on the capillary pipe (i.e., dripper spacing) and the orifice flow position between the capillary pipe (i.e., capillary arrangement density) in the drip irrigation capillary with small flow. However, few studies investigated the influence of the change of the orifice flow position on the capillary pipe (i.e., micropores group spacing) and orifice flow position between the capillary pipe (i.e., capillary arrangement density) on greenhouse crops using MSPF. In production practice, yield is the goal pursued by farmers, quality is the demand of users, and WUE is the core of the effective utilization of agricultural water resources (Wang et al., 2019b). Sufficient soil moisture can increase yield, but fruit quality and crop WUE will both decrease, while profit loss will increase when too much water is used (Luo and Li, 2018). It remains difficult to optimize quality, yield, and WUE. The technique for order preference by similarity to an ideal solution (TOPSIS) method provides a solution for multi-objective decision-making optimization. It has been widely used to comprehensively evaluate both the advantages and disadvantages of the tomato irrigation system. Luo and Li (2018) takes tomato yield, quality and water use efficiency as evaluation indexes, uses principal component standard deviation method to obtain each index weight, and establishes a comprehensive evaluation model based on weighted TOPSIS combination to select the best irrigation mode and irrigation quantity. Liu et al. (2019) used the yield, quality, and WUE of tomato as evaluation index, where the weight of each index was made equal to 1 by an artificial method. A comprehensive evaluation model based on weighted TOPSIS combination was established to optimize the best irrigation frequency and irrigation quantity. At present, the TOPSIS method is relatively rarely applied for comprehensive benefit evaluations of MSPF.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69056926

Therefore, compared with drip irrigation and micro-sprinkler irrigation, this study explored the applicability of MSPF in the greenhouse. The responses of tomato growth, quality, yield, and WUE to different micropores group spacing and capillary arrangement density were investigated. In addition, a comprehensive benefit evaluation model of greenhouse tomato quality, yield, and WUE was established by the TOPSIS method to optimize different treatments. The combination model of micropore spacing and capillary arrangement density was obtained for the best quality, yield, and WUE of tomato plants under MSPF. This paper enriched the data on tomato micro-irrigation technology systems in arid and semi-arid sandy loam soil of facility agriculture. Data support and a theoretical basis are provided for water-saving, yield increases, and improved quality of facility agricultural crops in this area by using greenhouse experiments and multi-objective optimization data analysis.

Materials and methods

Experimental site and management

The experiment was conducted from March 27, 2019, to July 23, 2019, in a greenhouse at the Modern Agricultural Science and Technology Exhibition Center of Xi'an City, Shaanxi Province, China (108°52°E, 34°03°N). It has a warm temperate semi-humid continental monsoon climate. The soil is sandy loam, and the mass fractions of sand, silt, and clay are 63.9%, 29.63%, and 6.47%, respectively. The average bulk density of the 1.0 m soil layer was 1.48 g/cm^3, the water holding capacity of field weight was 27.40%, and the depth of groundwater table on the site exceeded 30 m. The content of organic matter, total phosphorus (P), total potassium (K), total nitrogen, available nitrogen, available P, and available K in the plough layer before sowing were 15.53 g/kg, 10.12 g/kg, 2.01 g/kg, 1.36 g/kg, 70.45 mg/kg, 112 mg/kg, and 85.23 mg/kg, respectively. The irrigation water originated from groundwater, the pH of which was 6.8, the chemical oxygen demand (COD) was 53.2 mg/L, the anionic surfactant content was 3.2 mg/L, and the chloride content was 0.48 mg/L.

The greenhouse (85 m long and 15 m wide) was oriented from north to south. The tomato variety 'Jingfan 401' (Jingyan Yinong Seed Sci-tech Co. Ltd., Beijing, China), with a 50 cm row spacing and a 40 cm plant spacing, was planted on a ridge. The length of the ridge was 3.4 m and the width was 1.2 m. The irrigation plot is shown in *Fig. 2*. The distance between each plot was 4 m; one 1.0-m deep building waterproof film made up of styrene-butadiene-styrene block copolymer was buried in the middle to prevent the horizontal infiltration and movement of soil moisture, thus avoiding their effect on other plot experiments. Tomato plants were topped when the four-eared fruit were retained and the field management measures, such as fertilisation, irrigation, and pesticides, were kept similar in all treatments. The source of irrigation water in the region was groundwater. To ensure the survival of seedlings on the day of planting, the irrigation was unified with reference to the local tomato planting experience. Spring tomatoes were planted on 27 March 2019 and irrigation treatment was initiated on 4 April 2019. The irrigation treatment was continued until 15 July 2019 and tomatoes were completely harvested on 25 July 2019. Autumn tomatoes were planted on 23 August 2019, irrigation treatment was continued between 30 August 2019 and 17 January 2020, and tomatoes were complete harvested on 30 January 2020. The micro-sprinkler pipe of MSPF (Hebei Plentirain Irrigation Equipment Technology Co., Ltd., Hebei, China) adopts three thin-walled oblique micropores with a diameter of 32 mm and a micropore diameter of 0.8 mm.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69056926

The micropores group spacing is shown in the experimental design (*Table 1* and *Fig. 3*). Drip irrigation under mulch (CK1, Hebei Plentirain Irrigation Equipment Technology Co., Ltd., Hebei, China) with thin-walled labyrinth tooth channel was selected as control. The geometric parameters of the channel were 54.3 × 1.1 × 0.83 mm, the distance between emitters was 30 cm, and the emitter flow rate was 2 L/h. Micro-sprinkler irrigation (CK2, Hebei Plentirain Irrigation Equipment Technology Co. Ltd, Hebei, China) adopted three thin-walled oblique micropore pipes with a diameter of 32 mm and a micropore diameter of 0.8 mm an was also used as control. The micropores group spacing was 10 cm.

8	CK2	Micro-sprinkler irrigation	10	one pipe for two rows	

Experimental design

Two factors were set up in this study: micropores group spacing L (*Fig. 3*) and capillary arrangement density C (*Fig. 4*). Of these, the micropores group spacing (L) used two levels: 30 cm (L1) and 50 cm (L2); the capillary arrangement density (C) used three levels: one pipe for one row (one capillary pipe irrigated one crop, C1), one pipe for two rows (one capillary pipe irrigated two rows of crops, C2), one pipe for three rows (one capillary pipe irrigated three rows of crops, C3). One pipe for two rows were used for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69056926

both CK1 and CK2 control treatments. A total of eight treatments were implemented, each of which was repeated three times, for total of 24 test areas (*Table 1*).

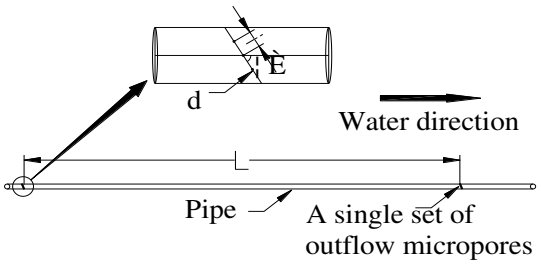

Figure 3. *Schematic diagram of micropores group (inside) spacing structure parameters. Note: diameter of micropore is d=0.7 mm; The internal spacing of the micropores group spacing was i =0.4 cm; The Angle of micropores is =68°; The micropores group spacing is L*

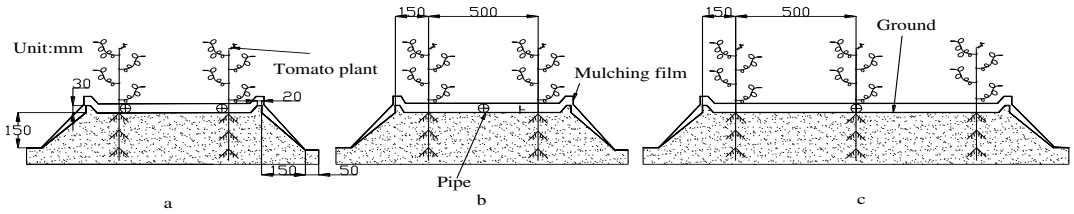

Figure 4. *Schematic diagram of capillary arrangement density (a: one pipe for one row; b: one pipe for two rows; c: one pipe for three rows)*

The irrigation amount was controlled on the basis of the cumulative evaporation from a 20-cm diameter standard pan (E_{pan}, DY.AM3, Weifang Dayu Hydrology Technology Co., Ltd., Shandong, China) following Dinc et al. (2018) and Liu et al. (2013). The evaporation amount was measured at 08:00 am every 5 d. The irrigation amount was evaluated after the measurement. The W of irrigation quota was calculated according to Formula (*Eq.1*), and the irrigation times and amounts were recorded (*Fig. 5*).

$$W = A \times E_{pan} \times k_{cp} \quad \text{(Eq.1)}$$

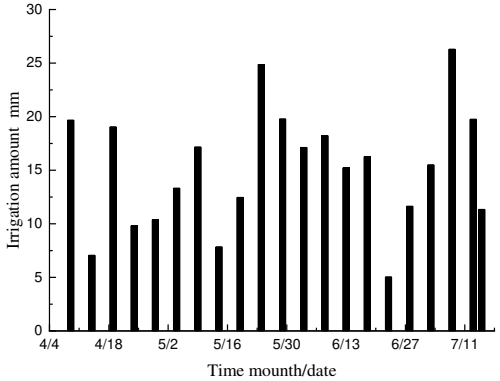

Figure 5. *Irrigation records*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69056926

In the formula: E_{pan} represents the evaporation within the interval of two irrigation, basing on the cumulative evaporation from a 20 cm diameter pan (mm); A represents the capillary control area (mm), and k_{cp} represents the crop- pan coefficient. In this paper, adopting adequate irrigation mode, the crop- pan coefficient of k_{cp} is 1.0 (Zhu et al., 2020).

Measurements and computational methods

Growth

The growth-related indexes were measured at 26, 51, 73, and 110 days after planting, and three plants were randomly selected from each plot. Plant height (PH) was measured with a ruler (Ma and Upadhyaya, 2016); the stem diameter (SD) was measured with electronic Vernier calipers at the base stem (Ma and Upadhyaya, 2016), and the leaf area index (LAI) was measured by AccuPARLP-80 canopy analyzer (Decagon Devices, Inc., Pullman, Wash. USA).

Three tomato plants were randomly selected in each plot, the stem of the plant was assumed as the center, and a hole was dug with a straight diameter of about 0.2 m and a depth of about 0.4 m to obtain the root system of the plant. Rhizosphere soil was carefully shaken off and the residual root system was slowly washed to remove the soil, using a weak water flow. Then, the root system and soil were placed on a 100-mesh steel screen during flushing to minimize root loss. After washing, the root system was dried in an oven at 105 °C for 15 min, followed by drying at 75 °C to constant weight. Finally, the dry matter mass of the root system was obtained.

Quality

Fruit shape, flavor, and nutritional indexes are the main three factors of tomato quality. Three tomato fruits were randomly selected in each plot when the tomatoes were ripe at the first stage. Individual fruits were homogenized to determine the fruit flavor and nutritional indexes.

Shape indices: The weight of single fruit (SFW) was measured using precision 0.01 g electronic scale. Vertical diameters (VD) and transverse diameters (TD) of the fruit were measured using vernier calipers.

Flavor indices: The total soluble solids (TSS) was measured using a hand-held refractometer with automatic temperature compensation (PR-32α Atago, Tokyo, Japan); the total soluble sugar (TSU) was measured using anthrone method (Decruyenaere et al., 2012). The soluble solid content (SSC) was measured using anthrone method (Liu et al., 2019). Titratable acids (TA) were determined by diluting an aliquot of the blended fruit and titrating against 0.1 mol/L NaOH using phenolpthalein as an indicator. Titratable acids (TA) content was determined by diluting an aliquot of the blended fruit and titrating against 0.1 mol/L NaOH by using phenolphthalein as an indicator. TAs were estimated by mL aliquot of blended fruit (Gould, 1992). Sugar/acid ratio (SAR) was determined by dividing the soluble sugar concentration by titratable acid.

Nutritional indices: the soluble protein (SP) content was measured using Coomassie Brilliant Blue assay (Liu et al., 2019). The vitamin C (VC) was calculated by the classical titration method with 2,6-dichlorophenol indophenols sodium salt solutions (Liu et al., 2019). Lycopene (LY) was extracted with 2% dichloromethane and petroleum as solvents to enhance its solubility and the absorption at 502 nm was measured using ultraviolet spectrophotometer (Cefali et al., 2015).

Yield and water use efficiency

During the maturation period, 4 tomatoes were randomly selected from each plot and the quality of mature tomatoes was measured using an electronic scale. After obtaining yield per plant, the yield per hectare was derived.

Time-domain reflectometry soil moisture sensor (TRIME-PICO-IPH, IMKO, Inc., Ettlingen, Germany) was used to measure the soil volume moisture content of 0–10, 10–20, 20–30, 30–40, 40–50, 50–60, 60–70, and 70–80-cm soil layers. It was measured once before and after each growth period. Two monitoring points were selected in each district as shown in *Figure 6* (monitoring point 1 was arranged at the outflow micropore; monitoring points 2 was arranged at distance m between the two groups of micropore in the vertical flow direction, where m = 25 cm). Water consumption (ET_a) and crop water use efficiency (WUE) were calculated using formula (*Eq.2*) and (*Eq.3*), respectively (Du et al., 2017).

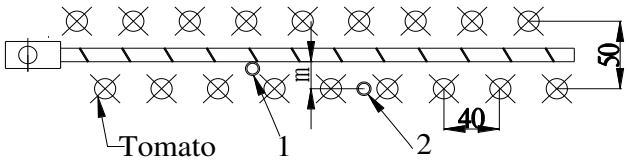

Figure 6. *Schematic diagram of capillary and TRIME pipe arrangement (unit: cm)*

$$ET_a = I \pm 1000 \times H \times (\theta_{t1} - \theta_{t2}) \quad \text{(Eq.2)}$$

In the formula, ET_a represents crop water consumption during growth period (mm); I represents the irrigation quota of crop growth period (mm); H represents the depth of the wetting layer with plan (H = 0.8 m); θ_{t1} and θ_{t2} represent 80-cm average soil volumetric water content at times $t1$ and $t2$ (cm^3/cm^3), respectively.

$$WUE = Y/ET_a \quad \text{(Eq.3)}$$

In the formula, WUE indicates crop water use efficiency (kg/m^3); Y indicates crop grain yield (kg/hm^2).

Standardization and homogenization of raw data

In order to eliminate the influence of different evaluation indices dimensions, first standardize the data, and at the same time, in order to ensure that the evaluation indices has the same direction, it is also necessary to carry out the same chemotactic treatment of the data, reference to "Effect of planting row spacing and irrigation amount on comprehensive quality of short-season cultivation tomato in solar greenhouse in northwest china" (Wu et al., 2018), which is convenient for the selection of reference vectors when constructing the comprehensive benefit evaluation model by TOPSIS method.

Data analysis

Data was tested for normal distribution, which was followed by evaluation of the differences between groups, using SPSS22.0 (IBM Crop., Armonk, NY, USA). F test was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69056926

used and the significant level was set to $P < 0.05$. OriginPro2019 (Origin Lab Corporation, Northampton, MA, USA) was used to draw plots. Except for special annotations, the data are visualized by showing averages ± standard deviations.

Results

Effects of different treatments on plant height, stem diameter, and leaf area indexes on plant growth of tomato

Table 2 shows the effects of different treatments on PH, SD, and LAI of tomato. With progressing tomato growth, PH and LAI increased first and then decreased, while SD increased. The PH, SD, and LAI of L1C2 were higher than those of CK1 and CK2 by 7.34% and 0.13%, 8.32% and 4.69%, 22.95% and 2.76%, respectively. With decreasing capillary arrangement density, PH, SD, and LAI of tomato decreased, and no significant difference was found between C1 and C2 ($P > 0.05$). C1 and C2 were significantly higher than C3 by about 10.64% and 7.15%, 8.35% and 7.10%, 24.97% and 17.14% ($P < 0.05$), respectively. The PH, SD, and LAI of 30 cm tomato were 1.04, 1.03, and 1.14 times that of the 50 cm micropores group spacing.

Table 2. *Experimental factor and design Effects of different treatments on PH, SD and LAI*

Effects of different treatments on tomato quality

In terms of fruit shape indexes (*Table 3*), compared with CK1 and CK2, SFW, VD, and TD of L1C2 increased by 28.38% and 5.66%, 11.70% and 4.69%, 14.43% and 1.67%, respectively. Under the same irrigation amount, with decreasing capillary arrangement density, the SFW, VD, and TD of tomato followed a decreasing trend, and decreased by about 34.10%, 16.38%, and 9.98%, respectively. The SFW, VD, and TD in the 30 cm micropores group spacing were 1.20, 1.04, and 1.10 times higher than that of the 50 cm micropores group spacing.

In terms of fruit flavor indexes (*Table 3*), compared with CK1, the TSS, TSU, and SAR of L1C2 decreased by 0.32%, 3.30%, and 0.31%, respectively. Compared with CK2, the TSS, TSU, and SAR of L1C2 increased by 20.00%, 12.35%, and 26.63%, respectively. The spacing of micropores significantly affected the TSS of tomato ($P < 0.05$), and the capillary arrangement density significantly affected both TSS and SAR ($P < 0.05$). In the micropores group with 30 cm spacing, TSS, TSU, and SAR were 1.06, 1.04, and 1.02 times higher than that of 50 cm spacing. Under the same irrigation amount, TSS, TSU, and SAR increased by 15.38%, 10.30%, and 23.75%, respectively, with decreasing capillary arrangement density.

In terms of fruit nutritional indexes (*Table 3*), compared with CK1, L1C2 tomato flavor indices SP, VC, and LY decreased by 0.12%, 0.08%, and 2.67%, respectively; compared with CK2, these increased by 0.02%, 18.39%, and 9.40%, respectively. The micropores group spacing significantly affected the VC of tomato ($P < 0.05$), and the capillary arrangement density significantly affected the SP, VC, and LY ($P < 0.05$). In the 30 cm micropores group spacing, SP, VC, and LY were 1.05, 1.13, and 0.99 times as much as that of the 50 cm spacing. Under the same irrigation amount, the SP, VC, and LY increased by 8.72%, 16.07%, and 13.28%, respectively, with decreasing capillary arrangement density.

Effects of different treatments on water consumption, yield, and water use efficiency of tomato

Compared with CK1, the water consumption and yield of L1C2 was significantly higher than 8.46%, 19.39% ($P < 0.05$), and there was no significant difference in the improvement of WUE (10.03%, $P > 0.05$; *Fig. 7*). Compared with CK2, there was no significant difference in the increase of L1C2 yield (4.69%, $P > 0.05$); however, the water consumption was significantly decreased by 8.01% ($P < 0.05$) and WUE was significantly increased by 13.87% ($P < 0.05$). Compared with L1C1, L1C3, L2C1, L2C2, and L2C3, the yield and WUE of L1C2 increased by 0.99% and 0.99%, 47.18% and 47.18%, 13.69% and 13.69%, 24.74% and 24.74%, as well as 52.08% and 52.08%, respectively. At the same time, the micropores group spacing and capillary arrangement density significantly affected yield and WUE ($P < 0.05$), and the interaction of both factors had significant effects on WUE ($P < 0.05$). With decreasing capillary arrangement density, the water consumption, yield, and WUE of tomato decreased. The yield and WUE of C1 and C2 were significantly higher than those of C3 by about 39.85% and 34.76%, 32.10% and 31.94% ($P < 0.05$); however, there was no significant difference in yield and WUE between C1 and C2 ($P > 0.05$). The water consumption, yield, and WUE of the 30 cm micropores group spacing were 1.01, 1.14, and 1.13 times higher than that of the 50 cm micropores group spacing.

Optimal evaluation of comprehensive benefit of tomato quality, yield and water use efficiency based on the technique for order preference by similarity to an ideal solution method

The SFW, VD, TD, TSS, SP, TSU, VC, LY, SAR, yield, and WUE of tomato were selected as evaluation variables in *Table 4*. Firstly, these 11 indexes were weighted by Criteria Importance Though Intercrieria Correlation (CRITIC) method (*Table 4*). The calculation method is referred to the "effect of planting row spacing and irrigation amount on comprehensive quality of short-season cultivation tomato in solar greenhouse in northwest China" (Wu et al., 2018). The comprehensive benefit evaluation model is constructed by the TOPSIS method (*Table 5*), and the calculation method is referred to "optimizing irrigation frequency and amount to balance yield, fruit quality and WUE of greenhouse tomato" (Liu et al., 2019). The order of weight obtained by the CRITIC method was as follows: Yield > SFW > SAR > WUE > VD > LY > VC > TSS > TD > TSU > SP, among which, the yield weight was highest (0.150). The evaluation results of the TOPSIS comprehensive benefit evaluation model showed that the comprehensive benefit of L1C2 was best (C*i* = 0.939), followed by L1C1. The comprehensive benefit of drip irrigation under mulch ranked 4th, and micro-sprinkler irrigation ranked 3rd.

Discussion

Effects of irrigation methods on quality and yield of greenhouse tomato

The yield and WUE of tomato plants under MSPF were 19.39% and 10.03% higher compared with drip irrigation under plastic film (*Fig. 7*). This may be because the flow rate of MSPF was about 45 times higher than that of the single group with drip irrigation under plastic film and identical working pressure. Under identical irrigation amount, the flow rate of the single group of MSPF exceeded that of drip irrigation with smaller orifice flow, and the irrigation time was shorter, so that the ratio of soil water horizontal to vertical migration distance increased. The larger surface wetting area increases the wetting volume and irrigation uniformity per unit area of the tillage layer, and decreases the deep transport of soil water (Topp, 1969; Zotarelli et al., 2009; Elmaloglou and Diamantopoulos, 2010; Selim et al., 2013). The average soil volume moisture content of the 0-40 cm soil layer under MSPF was 9.34% higher than that of drip irrigation under plastic film (*Fig. 8*) and root dry matter accumulation (*Fig. 9*). This provided a strong guarantee for the stable yield of greenhouse tomato (Ould et al., 2001), resulting in higher yield of tomato under MSPF. However, because of the large surface wetting area of MSPF and the vigorous growth of tomato plants, soil water evaporation was further intensified. Compared with drip irrigation under plastic film, the water consumption of tomato under MSPF increased by 8.46% (*Fig. 7*). The yield increase of MSPF (19.39%) was about 2.29 times that of its water consumption (8.46%); therefore, the WUE of crops under MSPF was higher than that of drip irrigation under plastic film. This study found that TSS, TSU, SAR, SP, VC, and LY of MSPF decreased by 0.32%, 3.30%, 0.31%, 0.12%, 0.08%, and 2.67% compared with drip irrigation under plastic film. This may be due to the higher moisture content of tomato fruits under MSPF and excessive water dilution of fruit flavor and nutrition index content per unit mass. This is consistent with previous studies, which showed that with increasing irrigation water, the soil volume and water content increased, which reduce the tomato fruit flavor and nutritional content (Topp, 1969; Meek et al., 1992; Li et al., 2020).

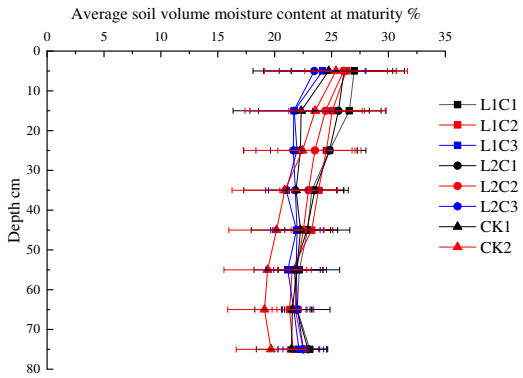

Figure 8. *Average soil volume moisture content in different treatments at mature stage (70 days after transplant). Note: the data are all average ±standard deviation in the figure*

Compared with micro-sprinkler irrigation, the yield of tomato under MSPF increased by 4.69%, because the micro-sprinkling irrigation water flows through the capillary pipe and is sprayed out through the micropore water flow on the capillary pipe wall. The spray height reached more than 1 m under normal working pressure. The spray water flow could

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69056926

easily be atomized and increase air humidity, thus resulting in tomato canopy humidity as high as 70%, which is 1.56 times higher than that of MSPF (*Fig. 10*). Previous studies have shown that high-humidity environments can easily cause leaf moisture condensation, leaf cell rupture, decreased leaf photosynthesis, limited dry matter accumulation, and delayed fruit morphological development (Mortensen, 1992; Panchal et al., 2016). It is also possible that under the same amount of irrigation, part of the water is used to increase air humidity, which decreases soil water infiltration. The average volumetric moisture content of the 0-40 cm soil during the mature period was 7.48% lower than that of MSPF (*Fig. 8*). The lower soil volumetric moisture content decreased the increase of tomato yield. This study found that the WUE of tomato under MSPF was significantly higher (by 13.87%) than that of micro-sprinkler irrigation. This may be because the yield of micro-sprinkler irrigation was lower than that of MSPF, and the water consumption of tomato under MSPF was significantly lower than that of micro-sprinkler irrigation (by 8.01%; *Fig. 7*). This study also showed that the related indexes of tomato flavor and nutrition in micro-sprinkler irrigation were lower than those of MSPF. This may be due to the atomization of water droplets in micro-sprinkler irrigation, which increases air humidity and decreases the temperature difference between day and night in the greenhouse; these effects are not conducive to the accumulation of tomato flavor and nutritional indexes (Max et al., 2009; Luo et al., 2016; Sun et al., 2016).

Effects of micropores group spacing on quality and yield of greenhouse tomato

This study found that the PH, SD, LAI, and yield of tomato plants with the 30 cm micropores group spacing were better than that of those with 50 cm (*Table 2*). Maybe, the influence of the change of micropores group spacing with MSPF on the soil wetting body is similar to that of dripper spacing with drip irrigation under plastic film, and a phenomenon of intersection of wetting peaks between two groups of adjacent micropores on the capillary pipe was identified. The difference is that under the same working pressure and amount of irrigation, the single group flow of MSPF is higher than that of drip irrigation. Moreover, a larger flow rate easily increases the ratio of horizontal to vertical migration distance of soil water wetting peak. Shortening the confluence time of adjacent wetting peaks is beneficial to the overall deep transport of soil water between the two groups of micropores in the capillary, and improves the soil volume moisture content and irrigation uniformity in the tillage layer per unit area (Ould et al., 2001; Del et al., 2020). Diameter measurement showed that the 30 cm micropores group achieved better tomato maturity than that of the 50 cm micropore group, the average soil volume moisture content of the 0-40 cm soil layer increased by 1.60% (*Fig. 8*), and the higher soil volume moisture content of the tillage layer provided a strong guarantee for tomato growth (Abdelhafeez et al., 1975; Silveira et al., 2020). This is consistent with the conclusion that PH, SD, LAI, and yield of pomegranate, as studied by Meshram et al. (2019), were higher than that of 50 cm.

The present study showed that micropores group spacing had a significant effect on tomato yield. Wang et al. (2005), did not find a significant difference in cucumber yield between 50 and 30 cm drippers spacing when drip irrigation was used, which may be due to the different amounts of irrigation in their experiment. In this study, the irrigation amount was controlled by evaporation pan, and the cumulative amount of irrigation was 353 mm, while Wang controlled the lower limit of soil irrigation and irrigated 385 mm during the growth period. Enciso et al. (2007) found no significant difference in onion yield under different dripper spacings, and the conclusion that the micropores group spacing had a significant effect on tomato yield, as found in this study, is also inconsistent. Because the maximum spacing of dripper set by Enciso was 30 cm (which was much smaller than 50 cm in this study), the soil water distribution was uniform, and could not easily cause yield differences because of drought stress on crops (Ould et al., 2001; Jiménez et al., 2010). Furthermore, the WUE of micropores group spacing at 30 cm was 1.13 times higher than that of 50 cm (*Fig. 7*). It is possible that the soil volume of the tillage layer with a micropores group spacing of 30 cm is moist and uniform, and there is no obvious high water and bottom water area, which can accurately and in time meet the water demand of plants (Li et al., 2018b), resulting in a significant increase in tomato yield. At the same time, the water consumption of the 30 cm micropores group spacing did not significantly increase (*Fig. 7*), and finally showed a significant improvement in WUE (Wang et al., 2005; Li et al., 2019c). Elmaloglou and Diamantopoulos (2010) suggested that decreased dripper spacing can shorten irrigation duration and improve irrigation efficiency, which is consistent with the conclusion that reducing the micropores group spacing to 30 cm can improve WUE.

Previous studies found that too high or too low soil moisture can decrease the contents of soluble solids, VC, and lycopene (Wu et al., 2018). This study showed that the flavor and nutrition of tomato with the 30 cm micropores group spacing were better than that of 50 cm, indicating that the soil moisture distribution at 30 cm micropores group spacing was more suitable spacing for greenhouse tomato under MSPF. This study also found that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69056926

micropores group spacing had a significant effect on tomato TSS, which was inconsistent with the conclusion of Enciso et al. (2007) who reported that dripper spacing had no significant effect on onion solids. The reason for this difference is mainly because all water required by tomato plants originated from irrigation water, while Enciso's onion water requirements were also met by rainfall, which could provide similar irrigation water and optimal soil moisture conditions in all treatments.

Effects of capillary arrangement density on tomato quality and yield in greenhouse

The study of the capillary arrangement density of tomato in the greenhouse showed that the PH, SD, LAI, yield, and water consumption of tomato plants decreased with decreasing capillary arrangement density. Because the same single group flow rate, micropores group spacing, and irrigation amount were used, the higher the capillary arrangement density, the higher the amount of flow per unit area. This makes it easy to increase the surface wetting area, which is conducive to the overall decreasing movement of surface soil moisture and decreases the deep migration of soil moisture. The average soil volume moisture content of one tube and two rows of tillage layer (0-40 cm) was significantly higher than that of one tube and three rows (*Fig. 8*). The higher soil volume moisture content in the higher tillage layer provides a strong guarantee for the growth and stable yield of tomato (Tracy et al., 2013).

With the decrease of capillary arrangement density, a lower surface wetting rate can easily reduce soil ineffective water evapotranspiration, and the lower LAI decreases leaf transpiration, resulting in decreased tomato water consumption. Wang et al. (2018a) found that the yield of tomato under greenhouse drip irrigation increased first and then decreased with decreasing capillary arrangement density. This was inconsistent with the decreasing trend the tomato yield showed in this study, which was mainly because of the different of soil types and irrigators used, and possibly also because of differences of capillary arrangement density used for drip irrigation. In this study, the arrangement of one tube and two rows was the maximum spacing of Wang's drip irrigation. With regard to the differences of tomato yield between three tubes for four rows and one tube and two rows with MSPF, further experiments are needed. The bermudagrass yield of Cantrell et al. (2009), the spring wheat yield of Lv et al. (2019), and the maize yield of Bozkurt et al. (2006) for drip irrigation decreased with decreasing capillary arrangement density. This conclusion is consistent with the conclusion of tomato yield with MSPF in this study.

Furthermore, TSS, TSU, SP, VC, and LY increased with decreasing capillary arrangement density (*Table 3*), which may be because under the same irrigation amount, the smaller the capillary arrangement density was, the longer the irrigation duration was. This aggravated the deep soil water transport and decreased the soil volume moisture content per unit area, thus resulting in a decrease of tomato fruit moisture content and increases of TSS, TSU, SP, VC, and LY concentration per unit weight tomato fruit (Patanè and Cosentino, 2010; Wang et al., 2018a,b). Wang et al. (2018a) found that the SAR of muskmelon in northwest China increased with decreasing capillary arrangement density under drip irrigation, which was consistent with the conclusion of SAR of tomato fruit in this study. This indicates that the effect of capillary arrangement density of micro-sprinkler irrigation on tomato taste was consistent with that of drip irrigation in this area.

Conclusions

Under the same amount of irrigation, the spring and autumn tomato growth, fruit morphology, yield, and WUE were better with MSPF than with drip irrigation and micro-sprinkler irrigation. Improvements were about 7.34% and 0.13%, 8.32% and 4.69%, 22.95% and 2.76%, 28.38% and 5.66%, 11.70% and 4.69%, as well as 14.43% and 1.67%, respectively. Compared with drip irrigation under plastic film, no significant decreases in fruit flavor and nutrition were found. TSS and VC were significantly higher than that of micro-sprinkler irrigation by about 20.00% and 19.39%, indicating that MSPF was suitable for greenhouse tomato irrigation. With decreasing capillary arrangement density, tomato growth, fruit shape, yield, and WUE decreased, while tomato fruit flavor and nutrition increased. Compared with 50 cm micropores group spacing, 30 cm was beneficial for tomato growth, fruit quality, yield, and WUE. The comprehensive benefit evaluation model of tomato quality, yield, and WUE by the TOPSIS method and the comprehensive evaluation results of yield and WUE identified the L1C2 treatment as better. With the goal of improving WUE and low-cost investment without significantly reducing yield, it is recommended to use a combination of one pipe for two rows with a micropores group spacing of 30 cm in arid and semi-arid sandy loam soils. This study provides a theoretical basis and data support for the large-scale promotion of MSPF. While the presented results describe the optimum irrigation if the row spacing is 50 cm, but it remains an open question that the further experiments are needed to investigate other row spacings.

ANALYSIS OF HOST PREFERENCE AND RELATIONSHIP OF APHID SPECIES AND THEIR PARASITOIDS IN WHEAT FIELDS AND SURROUNDING AREAS, IN DIYARBAKIR AND ŞANLIURFA PROVINCES, TURKEY

BAYRAM, Y.

Ministry of Agriculture and Forestry, General Directorate of Food and Control, 06110 Ankara, Turkey
(e-mail: yunusb04@yahoo.com)

(Received 22nd May 2020; accepted 14th Sep 2020)

Abstract. This study was carried out to investigate the relationship and host preference of aphids and their parasitoids on different host plants in Diyarbakır and Şanlıurfa provinces in 2014-2015. In this study, 24 aphid species belonging to 18 genera, 10 parasitoid species belonging to 6 genera and 20 plant species belonging to 8 families were evaluated. Biodiversity Pro V7 package program was used for diversity cluster analysis and to determine similarity between host plant species, aphids and their parasitoids. *Lysiphlebus fabarum* (Marshall) and *Praon volucre* (Haliday) were observed as the most active parasitoids, with preference of five different aphid species, while the remaining aphid species were parasitized by the other parasitoid species. However, *Aphelinus paramali* (Zehavi & Rosen) was found to be specifically parasitizing only one aphid species. The highly parasitism percentage of 10 parasitoid species over 24 different aphid species and their complex relationship in wheat fields and surrounding areas, provided a wonderful natural balanced of biodiversity and possibility to control of aphids in Southeast Anatolia Region. The results of this study will provide useful knowledge in order to introduce biological control possibilities under the framework of integrated pest management.
Keywords: *crops, weeds, diversity, aphids, natural enemies, parasitism, biological control, IPM*

Introduction

Winter wheat, (*Triticum aestivum* L.) is main crop in Turkey and constitutes 3.5% of the world wheat area (Anonymous, 2018a). This area also accounts for 20% of total cultivated farmland in Turkey (Anonymous, 2018b).

Aphids among other insects are the main pests causing the highest damage to wheat production at approximately 30% yield loss per year (Webster and Kenkel, 1999). There are nearly 4,400 aphid species belonging to 599 genera in the Aphidomorpha (Hemiptera) superfamily in the world, 3,706 species of which live in the Palearctic region (Remaudière et al., 2006; Blackman and Eastop, 2020; Favret, 2020). Many studies have been conducted to determine the number of aphid species in Turkey and according to these studies, 558 aphid species belonging to 8 subfamilies of Aphidoidea were determined in Turkey (Düzgüneş et al., 1982; Görür et al., 2012; Şenol et al., 2014; Kök et al., 2016; Akyürek et al., 2019; Özdemir, 2020).

The locomotive sector of the Southeast Anatolia Region is agriculture. 3.2 million ha of 7.5 million ha area in the region is suitable for agricultural activities. Currently, 93.6% of red lentils, 96.3% of pistachios and 35.3% of wheat, are supplied from this region (Anonymous, 2020). Various studies related to aphids and natural enemies on wheat have also been carried out in this region (Bodenheimer and Swirski, 1957; Tuatay and Remaudiere, 1964; Tuatay, 1988; Kıran, 1994; Elmalı and Toros, 1994; Ölmez, 2000; Yüksel, 2003; Şimşek et al., 2005; Remaudiere et al., 2006; Ölmez Bayhan et al., 2012, 2013; Aslan, 2013; Bayram and Bayhan, 2013, 2016; Bayram et al., 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69276939

Aphids are able to transmit plant viruses directly or indirectly from secondary host plants to main crops (Kennedy et al., 1962). Therefore, it should be well known to understand the presence secondary host plants such as early growing plants, weeds or uncultivated plants as much as main crops for estimating aphid damage and their ability by carrying viruses from one plant to another (Bayram et al., 2018).

Aphid species generally live on their host plant species in colonies. Aphids change their host plants as facultative or obligate and this change includes two (dioeciously species) or more (heteroecious species) host plants. Although there is no clear relationship between main crops and secondary host plants, there is a clear explanation that main crops and secondary host plant species are classified under the same genus and the same families (Kristoffersen, 2003). Host preferences of aphid individuals are affected by numerous factors such as the structure of plant surface, as well as plant color and odor. Some specific substances such as phenols, alkaloids and oils affect aphid feeding and host plant preference (Özdemir, 2013).

As it is difficult to control aphids and chemical control is not a sustainable or environmentally friendly method, studies generally have been focused on alternative control strategies such as biological control, biotechnical control and cultural measures. There are many studies about aphid parasitoids (Kıran, 1994; Ölmez, 2000; Kavallieratos and Lykouressis, 2000; Kavallieratos et al., 2001; Praslićka et al., 2003; Legrand et al., 2004; Aslan, 2013; Bayram and Bayhan, 2013, 2016; Bayram et al., 2018). Investigation on host preference and relationship between aphids and parasitoids is one of the most important points for establishing a comprehensive control strategy. Therefore, this study was carried out to investigate host preference and relationship of aphids and parasitoids on wheat and neighboring habitats.

Materials and Methods

Field studies

Studies were carried out in wheat growing areas and neighboring habitats randomly, from different fields in 2014 and 2015 in Diyarbakır (Yenişehir and Kayapınar central counties) and Şanlıurfa (Akçakale, Siverek counties) provinces (*Figure 1*). Aphid colonies consisting of both live and mummified aphids were collected together with their host plants. Field studies were conducted during April, May and June by examining and sampling shoots, plants, leaves, branches and trunk of each plant once a week, while in November and February months by sampling once a month, with irregular controlling of 70 different locations. Each sample was placed in a plastic container and brought to the laboratory for rearing.

Laboratory studies

Studies were established under controlled conditions (25±3°C, 70% ± 10% RH and 16:8 L:D) in climatic rooms. Samples were examined daily for emerged aphids and parasitoids. Both adult aphids and parasitoids were preserved in 70% ethanol for subsequent identification. The slide mounting technique was mainly based on the method of Hille Ris Lambers (1950). The specimens were studied using a LEICA DM LB2 compound light microscope and morphological characters were measured using LAS 4.1 version software. Measurements of morphological characters were made according to Blackman and Eastop (2020).

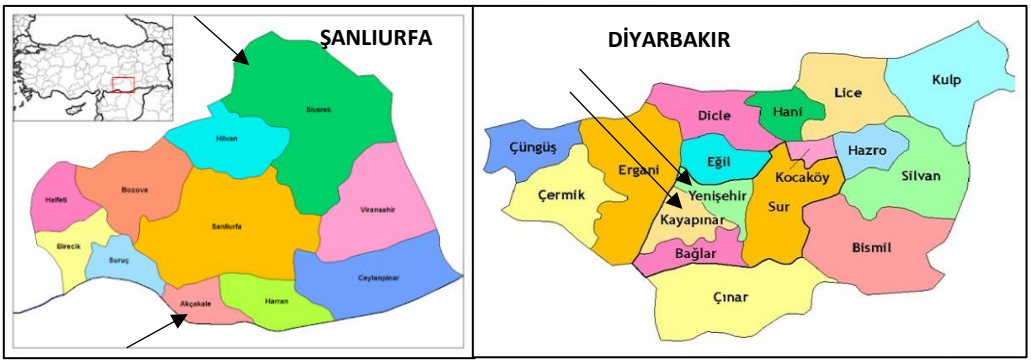

Figure 1. *Map of Diyarbakır and Şanlıurfa provinces in which field studies were carried out*

Host plant species

Wheat fields and the nearest area around these fields were examined carefully and plant samples were taken together with mummified aphids to laboratory for identification. Secondary host plants such as uncultivated plants and weeds around wheat fields were identified by Prof. Dr. Bekir BÜKÜN (Dicle University, Faculty of Agriculture, Plant protection Division) and Erdal ATEŞ (Plant Protection Research Institute, Diyarbakır). Identification studies of host plants, aphids and their parasitoids were published by Bayram et al. (2018).

Preparation and identification of aphids and parasitoid specimens

Aphids and parasitoids were examined and separated under a binocular and were placed into small bottles or tubes with 70% alcohol. The tubes and bottles with aphids and parasitoids were recorded with required information and prepared for identification. The colors of aphid mummies were also recorded, considering that they could be useful for identification and classification. Selected fresh specimens of aphids were immersed in 75% ethanol and preserved for future identification. Adult parasitoids were preserved in 96% ethanol. Some specimens were mounted on slides. Aphids were removed from their host plant with a small soft brush and put into a tube which contained 70% alcohol. The preservation techniques were mainly based on the method of Hille Ris Lambers (1950). The morphological terminology used as key for parasitoid species identification was based on (Sharkey and Wharton, 1997; Kavallieratos and Lykouressis, 2000; Kavallieratos et al., 2001) literatures. Aphid species were identified by specialist Dr. Işıl Özdemir (Central Plant Protection Research Institute, Ankara). Parasitoid species were identified by specialist Zeljko Tomanoviç (University of Belgrade, Faculty of Biology, Serbia).

Cluster analysis of host plants, aphids and parasitoids

Jaccard similarity index (Magurran, 2004) was used for determining the faunal similarity of host plant families from which aphids were obtained and Biodiversity Pro V7 package program (Biodiversity Pro. 1997), which is a statistical package program for Windows PC, enabling many measures of diversity to be calculated for a dataset of taxa by samples, was used for determining cluster analysis of aphid similarity from which parasitoids were obtained.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69276939

Determination of the amount of emerging parasitoid individuals and parasitized aphid species

Mummified aphids and plant samples were collected from different locations randomly. These samples were recorded and each of the samples was separated in the laboratory. Plant materials with mummified aphids were taken into plastic boxes and required information was recorded on the boxes. The cover of the plastic boxes was cut as widely round and closed with tight textured nylon muslin to provide ventilation. The samples were kept for at least 14 days and controlled daily until parasitoid adult emerged. Each sample was followed separately and parasitoid exit recorded according to parasitoid and aphid species. The obtained data determined the total number of parasitoid exit for each aphid species and the number of aphid species parasitized by the same parasitoid species.

Results and Discussion

The cluster similarity analysis of main crops (wheat) and surrounding host plants and uncultivated plants in terms of hosting aphids was shown on *Figure 2*. *Alopecurus myosuroides* Hudson*, Carduus crispus* L.*, Cirsium vulgare* (Savi) Airy-Shaw.*, Daucus carota* L. var. *carota, Galium aparine* L.*, Orobanche* sp. and *Sonchus oleraceus* L., host plants were determined as specific host plants for obtaining aphid species. However, other host plant species such as; *Amaranthus retroflexus* L.*, Avena fatua* L.*, A. sterilis* L.*, Centaurea solstitialis* L.*, Lolium perenne* L.*, Onopordum acanthium* L.*, Papaver rhoeas* L.*, Silybum marianum* (L.) Gaertn, *Triticum aestivum* L. Emd., *T. durum* Desf., and *Vicia sativa* L., were determined as unspecific host plants for obtained aphid species and these aphid species could feed on other host plants at a certain rate. *Lens culinaris* Medicus and *Lupinus albus* L., plant species hosted the same aphid species (*Figure 2*).

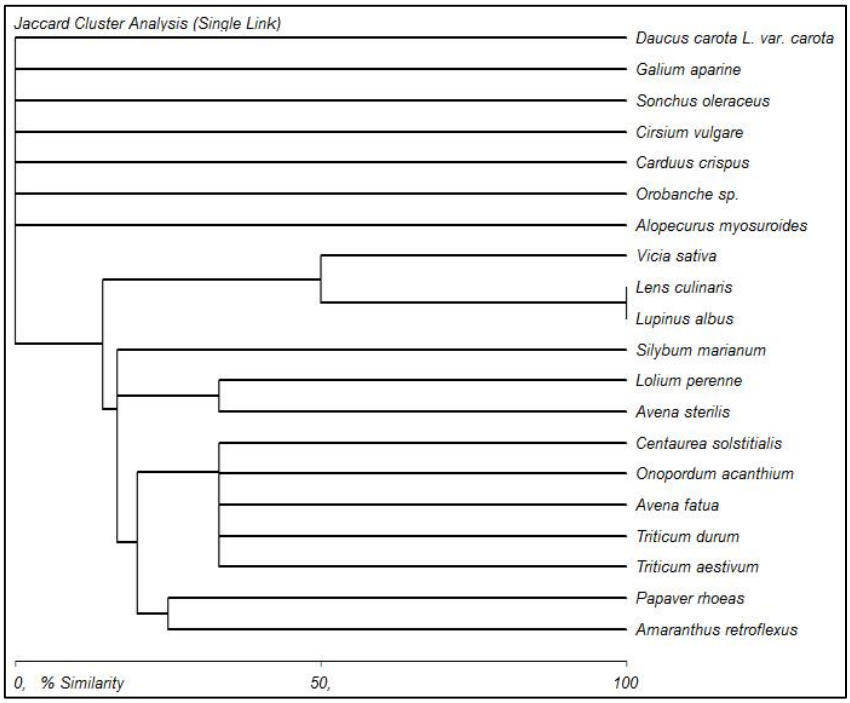

Figure 2. *Similarity of cereals and uncultivated plant species in terms of hosting aphid species*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69276939

The cluster similarity analysis of aphids in terms of host plant preference was shown on *Figure 3*. *Aphis gossypii* Glover, *A. galiiscabri* Schrank, *Diuraphis noxia* (Kurdjumov), *Dysaphis foeniculus* (Theobald), *Hyperomyzus lactucae* (L.), *Smynthurodes betae* Westwood and *Uroleucon (Uromelan) jaceae* (L.) aphid species fed on certain host plant groups and those host plant species weren't preferred by the other aphid species. *Uroleucon cichorii* (Koch) and *Capitophorus elaeagni* (deI Guercio) aphid species preferred the same host plant. However, the other aphid species could tend to prefer the same host plant species in different rates. The percentage of similarity of host plant preference of *Anoecia corni* (Fabricius), *Aphis fabae* Scopoli, *Aulacorthum solani* (Kaltenbach), *Lipaphis erysimi* (Kaltenbach), *Macrosiphum euphorbiae* (Thomas), *Metopolophium dirhodum* (Walker), *Myzus* (*Nectarosiphon*) *persicae* (Sulzer), *Sipha* (*Rungsia*) *maydis* Passenger, and *Uroleucon* sp., was 50%. The percentage of similarity of host plant preference for other aphid species such as; *Aphis craccivora* Koch, *Brachycaudus (Acaudus) cardui* (L.), *B. helichrysi* (Kaltenbach), *Rhopalosiphum maidis* (Fitch), *R. padi* (L.) and *Sitobion avenae* (Fabricus) was less than 50% (*Figure 3*).

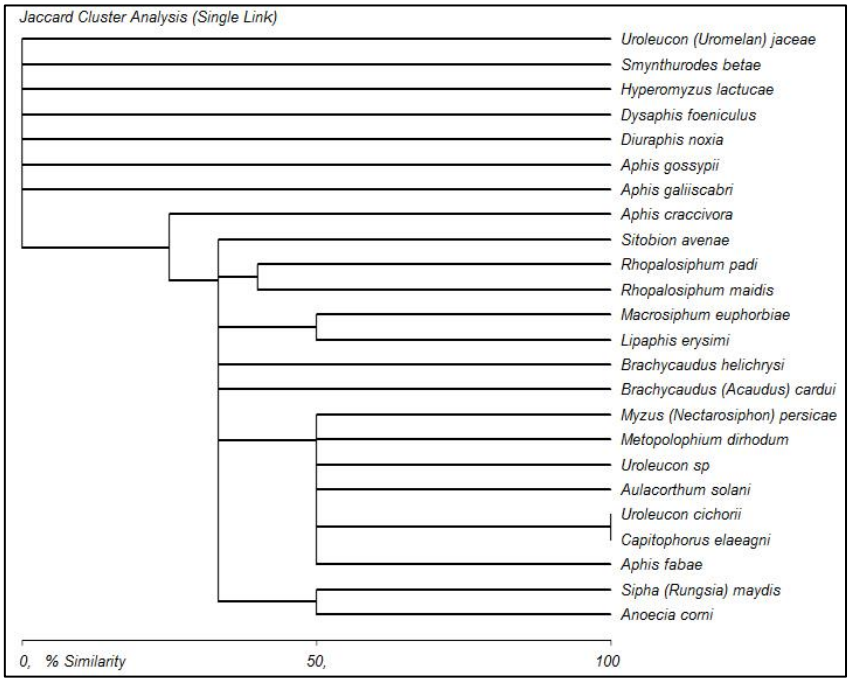

Figure 3. *Similarity of aphid species in terms of host plant preferences*

The cluster similarity analysis of parasitoids in terms of aphid preference was shown on *Figure 4*. Parasitoid species that parasitizing *Rhopalosiphum maidis, Hyperomyzus lactucae, Brachycaudus helichrysi* and *Aphis gossypii* aphid species were tending to prefer only one aphid species. However, the other parasitoid species could tend to prefer different aphid species at a certain rate. *Lipaphis erysimi, Diuraphis noxia* and *Aulacorthum solani* aphid species were parasitized by the same parasitoid. *Uroleucon cichorii, U. (Uromelan) jaceae, Rhopalosiphum padi, Macrosiphum euphorbiae* and *Aphis galiiscabri* aphid species were parasitized by one parasitoid (*Praon volucre* Haliday). *Myzus (Nectarosiphon) persicae* and *Dysaphis foeniculus* were parasitized by the same parasitoid (*Lysiphlebus fabarum*). *Brachycaudus (Acaudus) cardui, Aphis fabae,*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69276939

and *A. craccivora,* aphid species were also parasitized by the same common parasitoid species (*Figure 4*).

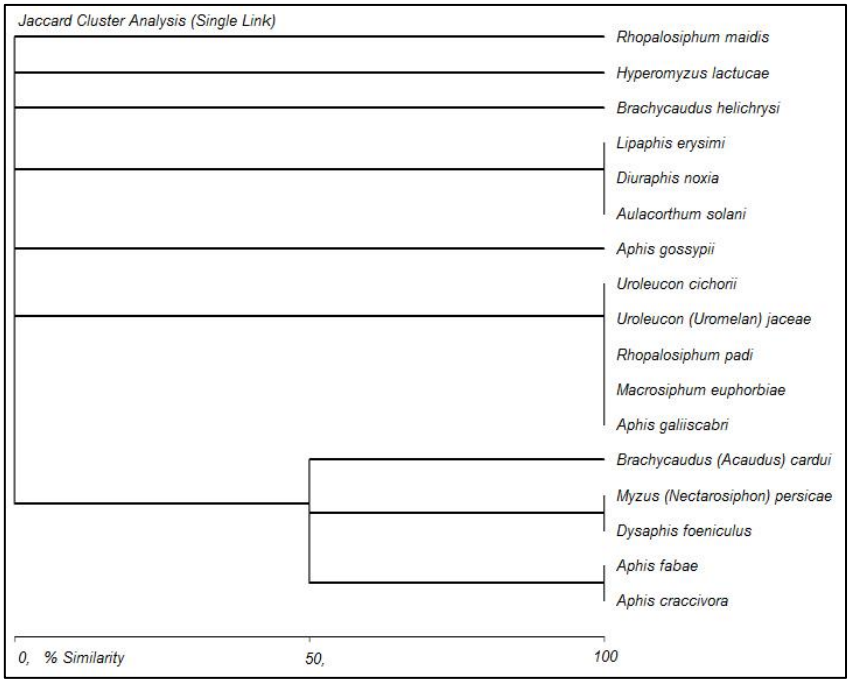

Figure 4. *Similarity of parasitoid species on aphid species*

The cluster similarity analysis of parasitoid species and the number of emerging parasitoid individuals and parasitized aphid species were shown on *Figure 5* and *Figure 6*. It was observed that certain parasitoid species such as *Praon volucre, Diaeretiella rapae* (M'Intosh)*, Aphidius rhopalosiphi* de Stefani-Perez*, Aphidius matricariae* Haliday and *Aphidius colemani* Viereck were specialized on certain aphid species. *Binodoxys acalephae* (Marshall)*, Lysiphlebus fabarum* (Marshall) and *Aphidius ervi* Haliday tended to prefer common aphid species. The other parasitoid species *Lysiphlebus testaceipes* (Cresson) and *Aphelinus paramali* Zehavi & Rosen were parasitizing the same aphid species (*Figure 5*). It was revealed that *L. fabarum* is parasitizing *Brachycaudus (Acaudus) cardui*; *Praon volucre* is parasitizing *Uroleucon cichorii, U. (Uromelan) jaceae, Rhopalosiphum padi, Macrosiphum euphorbiae* and *Aphis galiiscabri*; *Aphidius ervi* is parasitizing *Myzus (Nectarosiphon) persicae*; *Aphidius rhopalosiphi* is parasitizing *Rhopalosiphum maidis*; *Aphidius matricariae* is parasitizing *Brachycaudus helichrysi*; *Lysiphlebus testaceipes*; and *Aphelinus paramali* is parasitizing *Aphis gossypii*; and *Diaeretiella rapae* is parasitizing *Diuraphis noxia* (*Figure 5*).

Praon volucre was found the most effective parasitoid both in terms of obtaining parasitoid individuals (147 individuals) and having the ability of parasitizing 5 different aphid species. *Lysiphlebus fabarum* also has a high parasitizing tendency towards many different aphid species (5 species) and it has a high parasitizing capacity (110 individuals) (*Figure 6*). Although those five aphid species were parasitized by the other parasitoid species (*Binodoxis acalephae*, *Aphidius ervi*), *Lysiphlebus fabarum* has a high parasitizing capacity and tendency of so many different aphid species including ability of highly competitive. *Diaeretiella rapae* parasitized three different aphid species, while

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69276939

Aphidius rhopalosiphi parasitized two different aphid species. *Aphidius ervi, A. colemani, A. matricariae, Aphelinus paramali and Lysiphlebus testaceipes* parasitoid species were obtained only from one separate aphid species (*Figure 6*).

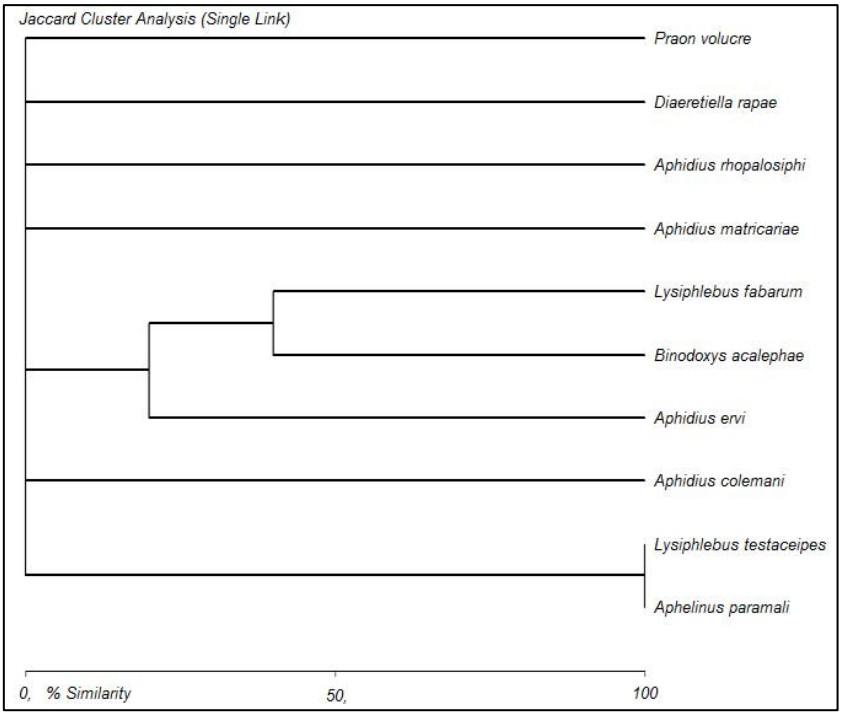

Figure 5. *Similarity of parasitoid species in terms of aphid preferences*

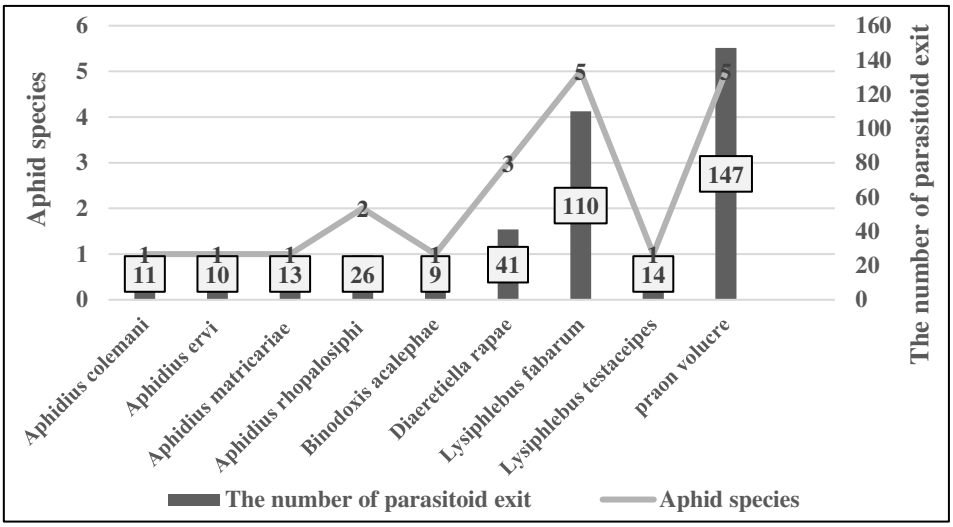

Figure 6. *The number of emerged parasitoid individuals and the number of aphid species parasitized by the same parasitoids*

According to former studies conducted in the world related to host plants, aphids and their parasitoids; Nine aphid species [*D. noxia, M. dirhodum, R. maidis, R. padi*, *S. graminum* Rond., *Sitobion avenae, S. fragariae* (Walker), *Sipha elegans* del Guercio and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69276939

S. maydis] were determined in wheat fields of Yugoslavia (Petrović, 1996). In Southeastern Europe 422 host plant species, 208 aphid species and 122 parasitoid species, 115 of which belonged to Aphidiinae genus were identified and 561 parasitoid-aphid relations were described (Kavallieratos et al., 2004). The relationship of *S. avenae* and *Aphidius rhopalosiphi* in spring, autumn and winter months in Belgium revealed that the fields where the parasitoid were available, the aphid population decreased rapidly and lasted at a low level (Legrand et al., 2004). Four aphid parasitoid species belonging to Aphidiidae family in the Angola region were determined. While *D. rapae* and *Ephedrus persicae* Froggatt parasitoid species were determined as cosmopolitan species. *Aphidius platensis* Brethes was obtained from some domestic aphids or some materials that collected from out and *A. camerunensis* Mack was only determined on some *Sitobion* species (Stary and Van Harten, 1972). The most dominant aphid species were *Aphis fabae* and *Cirsii acanthoidis* Börner, while the most related parasitoids were *L. cardui* (Marshall), and *L. fabarum* on *Cirsium arvense* (L.) in Czechoslovakia (Stary, 1986). Four parasitoid species (*A. ervi, A. eadyi* StarýFebGonzález & Hall, *A. picipes* (Nees) and *P. barbatum* Mackauer) were found on pea aphid in Yugoslavia, and *A. ervi* was found as the most dominant species (Tomanović et al., 1996). Eight new aphid species with their host plants, including 12 Aphidiinae parasitoids, four of which new record was reported in Serbia and Montenegro (Tomanović, 2000). *A. ervi*, *A. uzbekistanicus* Luzhetzki, *A. rhopalosiphi* and *P. gallicum* Starý were found as the most intense parasitoid species in the wheat fields of Southern agro-eco systems of the Pannonia region (Tomanović and Brajkovic, 2000). A new aphid parasitoid species *Praon uroleucon* Tomanović & Kavallieratos, identified in Yugoslavia, and this parasitoid species parasitize *Uroleucon* aphid species on *Carduus acanthoides* L., host plant (Tomanović et al., 2003). Seven aphid parasitoid species (*Aphidius uzbekistanicus*, *A. ervi*, *A. picipes, A. rhopalosiphi*, *Ephedrus plagiator* Nees, *Praon volucre* and *P. gallicum*) were determined in wheat fields of Slovakia (Praslićka et al., 2003).

Aphid parasitoids generally hibernate in diapause in winter as prepupae in mummified aphids in the regions where the temperature is mild (climate, weather). By the migration of aphids from one host to another host plant habitat with summer or in the warmer season conditions, seasonal diapause of parasitoids also could be observed (Minks and Harrewijn, 1988). Stary (1964) reported that the relation between dioecious aphids and their parasitoid is even more complex. These aphid species always change their habitats throughout the season from primary host plants to secondary host plants due to their migration behavior. Therefore, their parasitoids habitat also changes throughout the season depending on the migration of aphids. In this case, any dioecious aphid could be parasitized by different parasitoid species complex according to its habitat type. For example, *Brachycaudus cardui* aphid species could be found on the edges of wooded areas and in the parks on *Prunus spinosa* L., and *P. domestica* L. host plants in spring or in winter and parasitized by *Ephedrus plagiator*, while this species migrates towards the end of spring or at the beginning of summer on weeds such as *Carduus* sp. and *Arctium* sp., and parasitized by *Lysiphlebus fabarum* and *Lipolexis gracilis* Forster. However, Monoecious aphids even if migrating to other plants for feeding purposes, they do not change their habitat types throughout the season. Therefore, studies revealed that these aphid species generally parasitized by the same parasitoid species.

According to the former studies conducted in Turkey about host plants, aphids and their parasitoids; 13 aphid species, 5 parasitoid species and 21 predator species were determined in the wheat fields of Konya province (Elmalı, 1993). 10 aphid parasitoids

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69276939

belonging to 6 genera were determined on weeds areas of Ankara province (Güz and Kılınçer, 2005).

According to the former studies conducted in Southeastern Anatolia Region, five aphid species *Sitobion avenae*, *Rhopalosiphum padi*, *R. maidis*, *Schizaphis graminum* and *Myzus persicae* and two parasitoid species *Lysiflebus faborum* and *Ephedrus plagiator* were determined in the wheat fields of Southeastern Anatolia Region (Kıran, 1994). In addition, 24 aphid species belonging to 18 genera, 10 parasitoid species belonging to 6 genera were determined in wheat and surrounded areas on 20 host plants belonging to 8 families in Southeastern Anatolia Region (Bayram et al., 2018).

By this study, the cluster analysis of similarities and differences of host plants, aphids and parasitoids was evaluated. Since there are many host plant samples, aphids and parasitoid species, it is hard to exactly differ their relation with each other, or to evaluate each element separately. While some aphid species preferred one host plant species, the other aphid species preferred more host plant species and two or more aphid species could be seen over the same host plant species as well.

The aphid species are generally a significant food source both for parasitoids and predator. While some aphid parasitoids which are so specific and representing the isolated complexes have no relation in the food chain, the other aphid parasitoids have a more complex relationship. *Lysiphlebus fabarum* and *Praon volucre* were found very active having both abilities of parasitizing five different aphid species and reproductive capacity. However, *Aphelinus paramali* was found specified only one aphid species. The difference of the host plant change or the presence of main crops and uncultivated host plant species, in connection with aphid host series determine the composition of parasitoid species and their percentage into this composition. The parasitizing activity of 10 parasitoid species over 24 different aphid species and their complex relationship with the highly parasitizing rate is a wonderful natural balance in wheat fields and surrounded areas of Southeastern Anatolia Region (Bayram et al., 2018). Sometimes main crops are not available in the environment, so the presence of uncultivated plants or weeds around the main crops is a good opportunity for reproduction of first generations of aphid colonies on these host plants and also an integrative element for first generation of parasitoids which is emerging at the beginning of spring and lying eggs to aphid colonies. The richness of biodiversity guarantees the sustainability of not only the aphid living, but also the beneficial insects living. Although Monoecious aphids migrate to other plants for feeding purposes, they do not change their habitat types throughout the season, so Monoecious aphids are generally parasitized by the same parasitoid species.

The same as harmful organisms, beneficial insects also could not survive in the pesticide used areas. However, the environment that has not been treated with pesticides such as weeds or uncultivated areas are suitable both for pests and for beneficial insects to survive. These areas are good reservoirs and provide a perfect biodiversity. The reason for numerous cereal aphid species kept below the threshold of economic damage depends on these herbaceous plants in the vicinity of grain fields. The relationship of aphids and their parasitoids depend on vegetation diversity of the same or different areas. The availability of these flowering weeds before the vegetables, cottons or other cultivated crops planted in early spring, provides an opportunity for parasitoids to feed on these flowering weeds together with aphids and then migrate to other cultivated areas (Bayram et al., 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)

Conclusion

This study has aimed to investigate the host preference and relationship between aphids and their parasitoids on different host plants growing on wheat fields and surrounding areas in Turkey, in order to help develop biological control methods.

Although chemical control is primary resort for pest control in main crops, uncultivated plants, or weeds around main crops are not treated with chemicals, so these plants are reserving so many pests and beneficial insects as well. In Southeastern Anatolia Region wheat production is getting mature at the beginning of summer, so aphids could give damage to only some local points with some limited colonies which are formed at the edge of the fields. Except for any extra situation there is no needs for chemical control. Producers also do not use chemicals for aphid control in wheat fields, and the use of some chemicals against Sunnpest suppresses aphid population as well.

The presence of many aphid species, the richness of parasitoid species and their effectiveness, tendency and complex relationship over many aphid species in main crops, and uncultivated host plants and weeds are valuable and helpful resources for suppressing aphid population by using these beneficial insects. The survival of these parasitoids is useful not only for the wheat production, but also for suppressing the aphid populations in other secondary products. This resource should be well protected by avoiding unnecessary pesticide usage and by educating growers for increasing their awareness about the importance of beneficial insects. The analysis of interaction of host plants, similarities and differences among host plants, aphids and parasitoids, and determining the most active and common parasitoid species will be a useful knowledge in the framework of biological control and integrated pest management.

Future studies should focus on the protection as well as the production, reproduction, preservation of these beneficial insects and their transition to secondary host plants following wheat main crop. The possibilities of using these beneficial insects for controlling aphid species in corn, vegetables, fruits and industrial plants which are cultivated in the summer should be investigated. Opportunities should be sought to preserve this natural enemy in the Southeastern Anatolia Region, to survive and to benefit throughout the year. Usually weeds are not liked, whereas it should be taken into consideration that these weeds are a good habitat for beneficial insects to survive, and these plants that grow by themselves around wheat fields should not be destroyed.

Acknowledgements. I am thankful to Dr. Mustafa ÖZDEMİR (Central Plant Protection Research Institute, Ankara) for his contribution about using biodiversity program and analysis.

(Received 22nd May 2020; accepted 20th Aug 2020)

Abstract. In this study, the extractive substances of *Hedera helix* L. (forest ivy) wood and bark, naturally found around Filyos Stream in the Çaycuma district of Zonguldak, were investigated, for both ground-creeping individuals and for those clinging to Oriental plane (*Platanus orientalis* L.). The samples taken from the wood and bark of the plants were compared. According to the results of wood hexane experiments, linoleic acid (26.98%) was the most abundant in normal wood samples. In the same experiments on bark, while linoleic acid (25.40%) was determined to have the highest content in normal *H. helix*, palmiteloic acid (17.09%) was the most abundant compound in plants clinging to trees. In acetone:water (95:5,v:v) extract experiments on wood, the penetrating ivy wood contained the greatest amount of α-D-glucopyranoside (58.47%). Based on acetone:water (95:5,v:v) experiments on bark samples, sucrose (35.94%) had the highest content in normal bark.
Keywords: *ivy, oriental plane, lipophilic extractives, hydrophilic extractives, fatty acids*

Introduction

The morphology and anatomy of plants change with enviromental factors. The physiological events that enable the growth, reproduction, survival behaviors, metabolism, and geographical distribution of plants are significantly influenced by the physical, chemical, and biotic factors of the surrounding environment (Lambers et al., 2008).

Hedera helix L. (forest ivy), an evergreen and clinging plant belongs to the *Araliaceae* family. It is located in forests and bushes with its fast polyploid capacity Although, it has a fast height increment the diameter increase slowly (Mandade et al., 2010). It can climb up to 30 m high by adhering strongly on solid surfaces with the help of adventitious roots where its root diameter can reach 20 cm (Brendler et al., 2003; Horz and Reichling, 2003; Schnitzler and Heuze, 2006; Stavretovic, 2007). The plant's ability to adhere to surfaces depends on the secretion of an adhesive composing of 60-85 nm diameter spherical nanocomposite polysaccharide and nanoparticles (Xia et al., 2010; Burris et al., 2012).

The leaves of *Hedera helix* L. are used in medical treatments. The main compounds found in the leaves are α-hederin and hedefracoside C with strong antioxidant activity (Gülçin et al., 2004). These compounds belong to the saponin group. Saponins have steroid or triterpenoid structure, and are usually used in disease treatment (Küçükkurt and Fidan, 2008; Mingjun et al., 2008; Fazio et al., 2009; Yollu, 2015; Muşmula et al., 2017). Also, *Hedera helix* L. is used extensively in traditional medicine due to its analgesic and anti-inflammatory properties (Mandade et al., 2010; Uddin et al., 2011).

Because of its climbing properties, it is also used for landscaping in walls, fences.

In its natural habitat this plant covers the ground area and it is described as “normal ivy” in this study (*Figure 1*), also, it embraces many tree species. Oriental plane (*Platanus orientalis* L.) is one of the tree species embraced by ivy (*Figure 2*).

Figure 1. *Normal ivy (Hedera helix L.) in its natural habitat*

Figure 2. *Penetrated ivy (Hedera helix L.) to Oriental plane (Platanus orientalis L.)*

Oriental plane (*Platanus orientalis* L.), a member of the *Platanaceae* family and *Platanus* L. genus, can live up to 500-2000 years. *Platanus orientalis* L. natural distribution areas include Southern Europe and Southwest Asia, particularly the forests of Turkey and Iran (Davis, 1982; Anşin and Özkan, 2006; Zencirkiran and Erken, 2012). Naturally, they are typically found near the streams of forest and riversides; unnaturally, they are often used as ornamental plants and shade trees in cities and villages (Doğu, 2002).

In the chemical composition of the wood, the main components of the cell wall are polymer compounds, such as cellulose, hemicelluloses, and lignin. At the same time, the wood also contains extractives with lower molecular weights (Gindl and Teischinger, 2003; Papadopoulos, 2005; Dönmez and Dönmez, 2013). Most of the chemical groups found in wood are also seen in the bark with varying amounts. Generally, the content of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69416948

the extractive substance in the bark is higher than that in the wood of the same tree (Sjöström et al., 1981). The extractives affect several properties of the tree, such as texture, odor, taste, and color. Extractives are lipophilic and hydrophilic substances that are soluble in neutral solvents (Fengel and Wegener, 1989; Sjöström, 1993; Holmbom, 1999). Lipophilic extractives, which are soluble in dichloromethane, ether and some hydrocarbon solvents, consist mostly of fats, fatty acids, resin acids and sterols. Comparatively, hydrophilic extractives are substances like carbohydrates, lignans, phenols, stilbens and chalkones that are soluble in polar solvents like water, alcohol and acetone (Holmbom, 1999). These chemicals are now being extracted for different industries, such as pharmaceutical, cosmetic, and food industry (Dönmez, 2018).

According to Yaman (2009), *Hedera helix* L.'s effect on the anatomical structure of *Platanus orientalis* L. is incidental. After a certain period of time on the tree, it was concluded that the invader cannot cause detrimental damage to the tree. In this context, compounds in the tree's wood support normal growth and both species can actually benefit (*Hedera helix* and *Platanus orientalis*). On the other hand, the literature regarding the chemical composition of *P. orientalis* on *H. helix* is out of our knowledge.

In this study, it was aimed to investigate chemical composition, especially extractive substances, of *Hedera helix.* Both normal and penetrating on *Platanus oreintalis* was analysed for the first time, thus, this work provides a novel source in literature.

Materials and Methods

Materials

Both normal grown ivy and the ivy penetrating to the oriental plane were used as study material. Both wood and bark samples were taken, with three replicates, from Filyos Stream in the Çaycuma district of Zonguldak in April 2019, where the altitude was 40 m (41°22'56"N, 32°5'13"E). The sampling area can be seen in *Figure 3*. Cross-sections of the samples were prepared according to TAPPI standards. All samples were stored at -24 °C until analyses. Wood was first debarked, and the bark was cut into small pieces. All samples were freeze-dried and ground by a Wiley mill into 1-mm (Ekman, 1983).

Figure 3. *The sampling area*

Extraction

Approximately 10 g of grounded wood and bark from each sample was successively extracted first with n-hexane and then with acetone:water (95:5, v:v) in a soxhlet. Samples were weighed before and after extraction to determine the extractive yield. 100

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69416948

ml aliquots of extractives were removed using rotary evaporator, followed by gravimetric analyses (Dönmez et al., 2016). For gravimetric analyses, 10 ml aliquot was evaporated to dryness, i.e, constant weight, leaving a film of extractives in the solvent container. All results, given in mg/g, were calculated from freeze-dried samples. The appropriate amount of mixture was evaporated under nitrogen prior to silylation. The extracts obtained from hexane and acetone:water (95:5, v:v) were injected into GC-MS to identify the lipophilic and hydrophilic components.

Chromatographic analyses of the extracts

Chromatographic analysis of the extracts was carried out using a Shimadzu GC-2010 gas chromatograph equipped with an MS-QP 2010 mass spectrometer (Shimadzu Corporation, Kyoto, Japan). The instrument was equipped with a column, Rxi-5Sil MS (30 m × 0.25 mm i.d. × 0.25 μm film thickness; Restek, Bellefonte, PA, USA); the temperature program was as follows, from 60 °C (1 min) to 280 °C at 2 °C/min; injection temperature, 280 °C; the carrier gas was He with a flow rate of 1 mL/min; the injection mode was split (10:1); the MS temperature was 280 °C.

Results and Discussion

Wood and bark of the normal ivy and ivy penetrating to the oriental plane were analyzed by GC-MS to determine lipophilic and hydrophilic components after extraction with different solvents. In both normal and penetrated ivy wood, hexane-soluble extracts were found to be lower than acetone:water (95:5, v:v) extracts. In comparison, the amount of hexane-soluble extracts in penetrated ivy wood was almost 50% higher than that in normal wood. Specifically, hexane extracts were determined to be 37.46 mg/g in penetrated ivy bark, 28.31 mg/g in normal, 3.22 mg/g in penetrated ivy wood, and 2.30 mg/g in normal wood. The amount of acetone:water-soluble extracts was found to be 31.31 mg/g in normal bark, 28.44 mg/g in penetrated ivy bark, 5.79 mg/g in normal wood, and 6.32 mg/g in penetrated ivy wood. In hexane extracts, the increase of 40% in wood and 32% in bark samples of *H. helix* penetrating to the oriental plane tree were determined compared to normal *H. helix*. In addition, a 9% increase in wood samples of *H. helix* penetrating to the oriental plane tree compared to normal grown wood, on the contrary, a 10% decrease in the penetrated wood compared to normal grown wood was observed in acetone-water extracts.

After isolating hexane-soluble extracts, the lipophilic components in wood and bark samples were obtained via a wiping process, then transmitted to vials and analyzed by GC-MS. The amounts of soluble substances were calculated gravimetrically and are shown in *Table 1*; lipophilic and hydrophilic components are displayed in *Table 2* and *Table 3*, respectively.

Wood and bark samples were taken from the same tree due to concepts of the value of environmental factors such as the area where plants are located in their growing areas. So, the extractive substances in normal ivy and in ivy penetrating to oriental plane, wood and bark were compared.

In hexane extracts, the highest component in normal and penetrating wood samples was linoleic acid (26.98%, 22.49%, respectively). Moreover, in bark samples, while linoleic acid (25.40%) was determined as the highest in normal *H. helix*, palmiteloic acid (17.09%) was the most abundant compound in penetrating tree. When observed in terms of components, the highest amount of the components in both normal and

DOI: http://dx.doi.org/10.15666/aeer/1805_69416948

penetrating *Hedera helix* was the same while different components come to the fore in bark samples.

In the wood samples, acetone:water (95: 5, v: v) extract experiments to determine the structure and amount of hydrophilic components, sucrose (47.10%) was determined as the highest in normal *Hedera helix* wood while α-D-Glucopyranoside (58.47%) was the dominant compound in penetrating wood. In addition, sucrose had the highest amount both in normal and penetrating bark of *H. helix*, i.e. 35.94%, 43.15%, respectively.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69416948

Conclusion

Lipophilic and hydrophilic components of normally grown ivy and ivy penetrating to oriental plane tree in Turkey were obtained by extraction with hexane and acetone:water solvents. Analysis of the extractives were performed by GC-MS. Herein, the wood and bark of normal and penetrating ivy plants grown around Filyos Stream in the Çaycuma district of Zonguldak (Turkey) have been examined for the first time. It was determined that the amount of fatty acids in the bark of ivy is high. In order to evaluate this plant in industrial areas, more comprehensive studies should be done. On the other hand, this study provides a source for future research on the chemical analysis and influence of ivy penetration on plane tree wood and bark, providing a basis for the comparison and evaluation of similar conditions.

PRIMING WITH MORINGA (*MORINGA OLEIFERA* LAM.) LEAF EXTRACT BOOSTS THE GROWTH AND PHYSIO-BIOCHEMICAL ATTRIBUTES OF LEAD-STRESSED FENUGREEK (*TRIGONELLA FOENUM-GRAECUM* L.) SEEDLINGS

AL KHAZAN, M. M.

Department of Biological Sciences, Faculty of Science, University of Jeddah, Jeddah, KSA
(e-mail:mmalkazan@uj.edu.sa)

(Received 7th Jun 2020; accepted 20th Aug 2020)

Abstract. Lead (Pb) is a potentially toxic environmental concern, affecting all forms of life on the planet. However, moringaleaf extract (MLE) attained enormous attention owing to its high phytohormones, antioxidants and essential nutrient contents. To evaluate the potential of MLE in alleviating the phytotoxicity of Pb on fenugreek seedlings, a pot experimentwas conducted at the laboratory of Biological Sciences Department, Jeddah University. The uptake of Pb by fenugreek seedlings negatively affected growth rate, chlorophyll content, soluble sugars, enzymatic and non-enzymatic antioxidants, availability of the macronutrients (N, P, Ca, K), as well as K/Na ratio. Contrastingly, H_2O_2, MDA, soluble proteins and Mg content were increased. Seed priming in the aqueous MLE significantly ameliorated the ionic and osmotic deteriorations resulting fromPb uptake by fenugreek seedlings.MLE potentially retrieved seedling growth, balanced carbon and nitrogen metabolism, decreased the ROS-induced oxidative damage, in addition to sustaining ionic and osmotic homeostasis in Pb-stressed fenugreek seedlings. To sum up, the present study proved MLE as a potent eco-friendly approach to counteract Pb-phytotoxicity.
Keywords:*metalpollution, Moringaoleifera, stress markers,antioxidantpotential, ionic homoeostasis*

Introduction

Lead (Pb) is one of the most hazardous non-essential heavy metals in any ecosystem, it accumulates in excessive concentrations due to its non-degradable nature(Mahaffey, 1990).Lead pollution can originate from many sources like leaded gasoline, agro-fertilizers, mining processes, stoneware, boat constructing, paints, pipes manufacturing, batteries, artificial limbs, colorants, ink industry and traffic exhausts(Karri et al., 2008). Exposure of plants to lead stress results in damaging effectstotheir morphology, growth, biochemistry, ultrastructure, photosynthesis,productivityand quality. The deteriorations caused by lead stress are time, dose and growth-stagedependent. Several reports revealed that lead exposure had resulted in reduced germination ratio, biomass production, protein content (Hussain et al., 2013), photosynthetic activity, lamellar organization of the chloroplast (Hu et al., 2007) and yield criteria (Sobhy et al., 2019). Moreover, Pb stress triggered the increase in the level of some stress markers like membrane leakage, lipid peroxidation (MDA), H_2O_2 and $OH^{\bullet}$ radical in wheat (*Triticum aestivum* L.) seedlings (Sobhy et al., 2019). The same authors reported that the activities of particular antioxidant enzymes (SOD, CAT and POD) were increased in wheat seedlings due to up-regulation of the decoding genes.

On the organelles level, lead toxicity had been proven through the damage of cristae, enlargement of mitochondria, distortion of endoplasmic reticulum, damageddictyosomesand irregular darknuclei in different plant cells (Sandalio et al., 2001).

Fenugreek (*Trigonellafoenum-graecum* L.) is a self-pollinating annual forage leguminous plant (Family: *Fabaceae*) native to the Eastern Mediterranean region but is widely distributed in various parts of the world (Abdel Latef et al., 2017). The plant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69496967

possesses a long taproot, long erect cylindrical stem and trifoliate leaves with inversely ovate leaflets. After blossoming, the plant produces long pods with 10 to 20 angular-flattened seeds. Many factors, like farming practices, climatic conditions, use of herbicides and fertilizers, irrigation systems and genotypes, affect seed yield and quality of fenugreek (Pavlista and Santra, 2016). Choudhary et al. (2012) reported that number of pods/plant and number of seeds/pod in fenugreek subjected to Pb-stress were decreased in a dose-dependant manner.

Traditionally, fenugreek leaves and seeds have been used extensively in the treatment of various ailments (Basch et al., 2003). It has been used for centuries in folkloric medicine as a hypocholesterolemic, antidiabetic, antineoplastic, antitumor, antioxidative, anti-inflammatory, antiulcerogenic, antihypotriglyceridemic and antipyretic substance (Dixit et al., 2010; Xue et al., 2011). The therapeutical activity of fenugreek has been attributed to a variety of metabolites such as vitamins, amino acids, fatty acids, saponins (neogitogenin, disogenin, gitogenin, saponaretin, homorientin, neogigogenin and trigogenin) polysaccharides, fibers, fixed oils, flavonoids, and alkaloids (trigonelline and choline) (Yoshikawa et al., 1997).

The natural phyto-extracts of some algae, weeds, and plant species have been ascribed to be effective tools in ameliorating the deteriorations caused by various biotic and abiotic stressors.Saad-Allah and Nessim (2016) reported that the aqueous extract of the seaweed *Halimedaopuntia* potentially augmented cadmium toxicity in rocket plant (Eruca sativa Mill.) via improving the water content, photosynthesis efficiency and water-soluble osmolytes. Also, Hegazi et al. (2015)concluded that the extract of *Ascophyllumnodosum* seaweed functioned as an anti-salinity agent through the upregulation of some antioxidant enzymes level and enhancing the uptake of some essential macronutrients.In the meantime, Rady et al. (2013)affirmed that salt imposed common bean(*Phaseolus vulgaris*L.) seedlings exhibited an improved growth rate by seeds pre-soaking in the leaf extract of *Moringaoleifera*.The extract had increased the antioxidative, osmoprotective and ion uptake potentials of NaCl-stressed seedlings. Likewise,Abdel Latef et al. (2017) studied the response of salt-stressed fenugreek seedlings to the foliar application of fresh moringa leaf extract. They concluded that the interruption in the growth rate of stressed fenugreek had been resumed through the enhanced metabolic activity, minerals uptake and up-regulation of some salt tolerance genes. In the present study, we aimed at assessing the morpho-physiological, antioxidant and nutritional status responses of lead-stressed fenugreek seedlings to seed priming in the powdered moringa leaf extract.

Materials and Methods

Preparation of aqueous moringa leaf extract

The fully expanded and healthy fresh moringa(*Moringaoleifera* Lam.) leaves were collected from the streets of Jeddah city, KSA during the summer season (August 2019). The collected leaves were washed several times with tap water then once with distilled water and dried in an electrical oven at 60°C till constant weight. The dried leaves were ground using an electric mixer and sieved through a 0.2 mm sieve. The aqueous extract of moringa leaves was prepared by soaking of 50 g of the powdered leaves in 1L of the distilled water in a 2L Erelnimerflask. The flask was placed on a rotary shaker (180 rpm) for 24 hours then the extract was filtered through Whatman No1 filter paper to get rid of leaf tissues and the supernatant was taken and used in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69496967

preparation of two different concentrations (2.5 and 5.0%) of the aqueous extract. The prepared extracts were placed in the fridge at 4°C until the time of use.

Growth conditions and treatments

Seeds of fenugreek (*Trigonellafoenum-graecum*L.) were obtained from the Ministry of Environment, Water and Agriculture, Mecca branch, Kingdom of Saudi Arabia (KSA) and chosen for superficial homogeneity of size and shape. The seeds were disinfected in 5% Clorox for 4 minutes with stirring then washed with distilled water. The seeds then were separated into 2 groups; the first was soaked in distilled water for 24 hours as a control and the second was primed by soaking either in2.5 or 5.0% of aqueous moringa leaf extract (MLE) solutions for 24hours. Thereafter,10 seeds of every treatment were sown in plastic pots (25 cm diameter and 18 cm depth) filled with 8 kg of clay-sandy soil (2:1 w/w) and four pots were used as a replica for each treatment. Seeds were irrigated with tap water and left to grow for 5 days, before the treatment with Pb stress, under normal environmental conditions (10 hours photoperiod at 28/16°C±2 day/night and 62% relative humidity) at the laboratory of Biological Science Department, Faculty of Science, Jeddah University, KSA. The Pb stress was applied as lead acetate (100 mMPb$(CH_3COO)_2$ solution), while the 5-days old seedlings were irrigated once at 70% field capacity with tap water (the sub-lethal concentration of Pb$(CH_3COO)_2$ (100 mM) was previously determined in a preliminary experiment). The freshly harvested 25-days old seedlings were separated into roots and shoots, washed thoroughly with tap water several times followed by deionized water,and stored at -80°C. For dry matter analysis, the plant samples were oven-dried at 60°C till constant weight. Three replicates were utilized for each treatment of all the experiments.

Growth parameters

The collected 25-days old seedlings were used to assess Pb toxicity through measuring growth criteria (lengths, fresh and dry weights of both roots and shoots).

Photosynthetic pigments

The third fully-expanded leaf in each seedling was selected to estimate chlorophyll a and b by Arnon (1949) method and carotenoids by Horvath et al. (1972) method. Concisely, 0.1 g of fresh leaves were extracted in 85% cold acetone, whereas the absorbance was measured using a UV/visible spectrophotometer and expressed as mg/g fw.

Soluble sugars and protein estimation

The total free sugars fraction in dry leaves and roots of fenugreek was estimated using the phenol-sulfuric acid method (Dubois et al., 1965) with glucose as a standard sugar. Protein fraction was assessed using Bovine serum albumin (BSA) as a standard protein by the method of Bradford(1976). The quantified sugars and proteins were expressed as mg/g dw.

Hydrogen peroxide and lipid peroxidation quantification

Hydrogen peroxide(H_2O_2) content of fresh fenugreek leaves was estimated by the method given byVelikova et al. (2000). TheH_2O_2content of leaves was calculated using the extinction coefficient (0.28 $\mu M^{-1}cm^{-1}$) and expressed as µmol/gfw.Malondialdehyde (MDA) in fresh leaf homogenates was estimated according to the method ofHeath and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69496967

Packer (1968) by the aid of thiobarbituricacid(TBA) using the extinction coefficient (155 mM^{-1} cm^{-1}) and expressed as nmol/gfw.

Enzymatic activity assay

Fresh leaves (0.5 g) were homogenized in pre-chilled 0.1MK-phosphate buffer (pH 6.8) containing 0.1 mM EDTA. Homogenates were centrifuged at10000 rpm for 15 min and the resultant supernatant was used for enzymes assay.

The activity of CAT(catalase) wasmeasured by the method of Havir and McHale (1987). The decline in H_2O_2 was monitored spectrophotometricallyat 240 nm and the activity was calculated using the molar extinction coefficient 36 x 10^3 mM^{-1} m^{-1} and expressed as µM/g fw. min^{-1}.

POD (peroxidase) activity as assessed in the leaf extracts using 7.2 mMguiacol and the reddish-brown color development was monitored using a UV/vis spectrophotometer at 470 nm. POD activity was expressed asµM/g fw min^{-1} based on the molar extinction coefficient of26.6 mM^{-1} cm^{-1}(Kato and Shimizu, 1987).

APX(ascorbate peroxidase) activity was determined using a mixture of 0.5 mM ascorbic acid, 0.1 mM H_2O_2, K-phosphate buffer and 1 mM EDTA-sodium salt (Nakano and Asada, 1981). The decrease inascorbateabsorbance at 290 nm and APX activity was calculated as µM/g fw. min^{-1}using the extinction coefficient of 2.8 mM^{-1} cm^{-1}.

Polyphenol oxidase (PPO) activity of leaf homogenates was determined as described by Kumar and Khan (1982)in a mixture of 100 mM K-phosphate buffer and 100 mMcatechol. Sulfuric acid (2.5 N) was used to stop the reaction and the absorbance of the developed purpurogallin was measured at 495 nm. PPO activity was expressed as µM/g fw min^{-1}using the extinction coefficient of catechol (22.6$mM^{-1}cm^{-1}$).

Radical scavenging and total antioxidant capacity

The free radicals scavenging activity of the root and shoot ethanolic extracts was evaluated using the technique adopted by Hatano et al. (1988). A 0.1 ml aliquot of each extract was well vortexed with 3 ml of 36 x 10^{-2}% 1,1-diphenyl-2-picrylhydrazyl (DPPH˚) radical in methanol and kept for 30 min in dark. The bleaching in DPPH color by the extracts was monitored at 417 nm using UV/vis. spectrophotometer and the activity was expressed as a percentage.

The total antioxidant capacity (TAC) of the extracts was estimated using 3 ml of phosphomolybdate reagent (0.6 mol. $L^{-1}H_2SO_4$, 28 mmol L^{-1} sodium phosphate and 4 mmol L^{-1}amm.molybdate) and 300 µL of the extracts. The contents were boiled at 95°C for 90 min, cooled and the absorbance was recorded at 765 nm. The TAC was reported in µg/g dwusing ascorbic acid as a standard (Ahmed et al., 2012).

Mineral ions content

The dry plant root and shoot samples were wetly digested by a mixture of 70% $HNO_3$and 30% H_2O_2(5:2 v/v). The concentrations of Ca, Mg, K, Na and Pbin the digested samples were quantified using an inductively coupled plasma-opticalspectrophotometer(Polyscan 61E, Thermo Jarrell-Ash Corp., Franklin, MA, USA) at the Central Lab of Jeddah University.Nitrogen and phosphorus were calorimetricallyestimated in the samples digest by the assay of Allen et al. (1974) using Rochelle reagent for N and molybdenum blue method for P against their standard

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69496967

calibration curves. The mineral content of root and shoot samples was expressed as mg/g dw.

Statistical analysis

The experimental results were expressed as a mean of three replicates ± the standard error (SE). The obtained data were statistically analyzed(ANOVA test) using SPSS software (V20) and the variations between means were evaluated using the LSD test at 5% level. All the experimental values were compared to the control treatment.

Results

Growth parameters

In the current study, fenugreek seedlings treated with 100 mMlead acetate exhibited evident toxicity symptoms reflected as a reduction in growth parameters as shown in *Fig. 1*. Compared with the control, Pb stress resulted in a significant reduction in the fresh and dry weights of both shoot and root. The presoaking of fenugreek seeds in aqueous moringa leaf extracts (MLEs) was considerably effective in increasing the growth parameters of non-stressed fenugreek seedlings, but non-significantly alleviated the growth reduction mediated by Pb; whereas the degree of alleviation was dose-dependent. Compared to Pb treatment, priming in 5% MLE was the most valuable and slightly increased the growth parameters offenugreek seedlings.

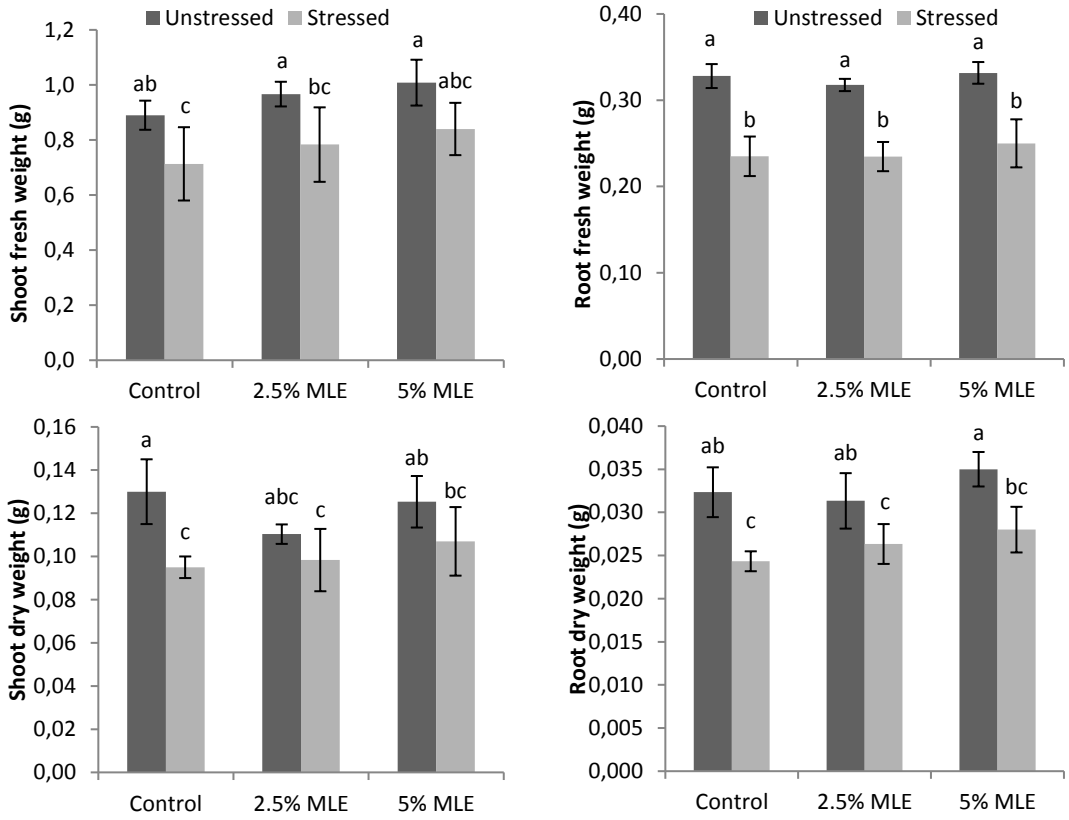

Figure 1. *Growth parameters of Pb-stressed and pre-soaked in MLE (0.0, 2.5 and 5%) fenugreek seedlings. Different letters indicate significant differences at 5% level and the error bars represent SD*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69496967

Photosynthetic pigments

The application of Pb was extremely destructive concerning photosynthetic pigments as observed in *Fig. 2*. The leaves content of Chla andChl b were significantly declined with percentages of 26.47and 49.50%, respectively compared to the control. Meanwhile, carotenoids content was significantly increased following lead treatment, the percentage of increase was 27.11% as compared to the control. The priming with MLE triggered an enhanced response and ameliorated Pb-stress by raising the level of chlorophyll content and lowering that of carotenoids to a significant level as compared to Pb treatment. Compared to Pb stress, 5% MLE had a more pronounced impact by increasing chlorophyll a and b contents and lowering carotenoids content.

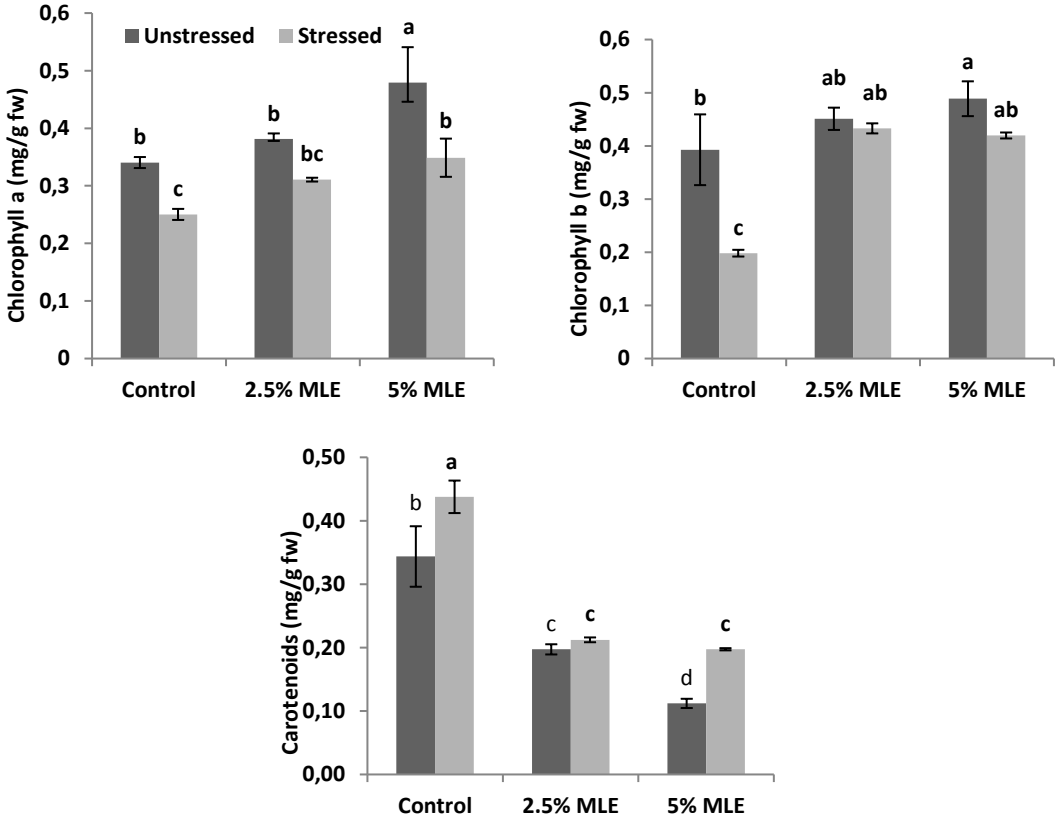

Figure 2. *Photosynthetic pigments of Pb-stressed and pre-soaked in MLE (0.0, 2.5 and 5%)fenugreek seedlings. Different letters indicate significant differences at 5% level and the error bars represent SD*

Soluble sugars

The total soluble sugars content of thefenugreek seedlings root and shoot was significantly affected by Pb-stress as represented in *Fig. 3*. The exposure to 100 mM lead acetate had lowered fenugreek root and shoot sugar content, but the effect was more pronounced on the root, as the reduction was with percentages of 43.12 and 11.90% in root and shoot, respectively, compared with the control. However, priming in MLE had declined the sugar content in fenugreek root and shoot. The most evident decline was observed at 5% MLE in the root and 2.5% MLE in the shoot. The combined

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69496967

interactions of Pb and MLE non-significantly affected soluble sugar contents of both root and shoot, comparable to Pb-stress.

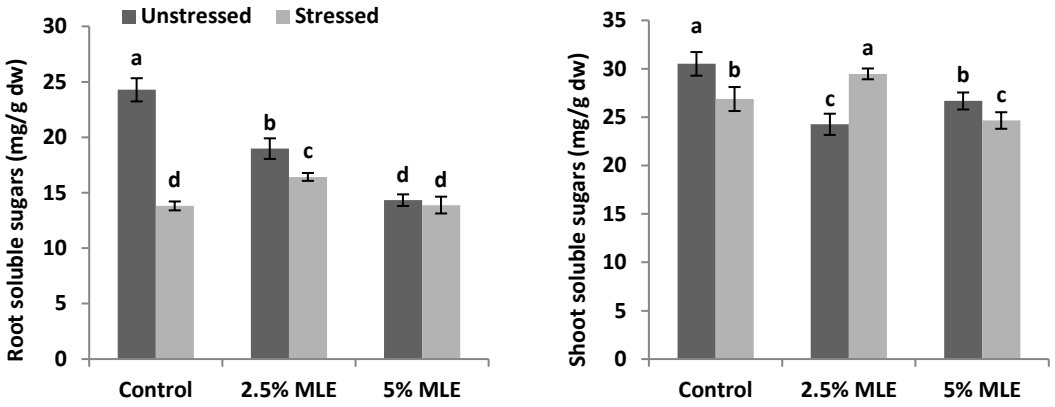

Figure 3. *Soluble sugars content in roots and shoots of Pb-stressed and pre-soaked in MLE (0.0, 2.5 and 5%) fenugreek seedlings. Different letters indicate significant differences at 5% level and the error bars represent SD*

Soluble proteins

Contrasting to soluble sugars, the soluble protein content of fenugreek seedlings was significantly increased as affected by lead treatment (*Fig. 4*). The achieved increment in protein level was 46.24 and 113.75% in root and shoot, respectively, relative to the control's content. Likewise, MLE treatments have increased the content of proteins in fenugreek seedlings compared with the control, especially 2.5% dose in roots and 5% in shoots. Meanwhile, the priming in MLEs was effective in decreasing the soluble protein content of Pb-stressed fenugreek seedlings, but the level still close to or slightly higher than that of the control.

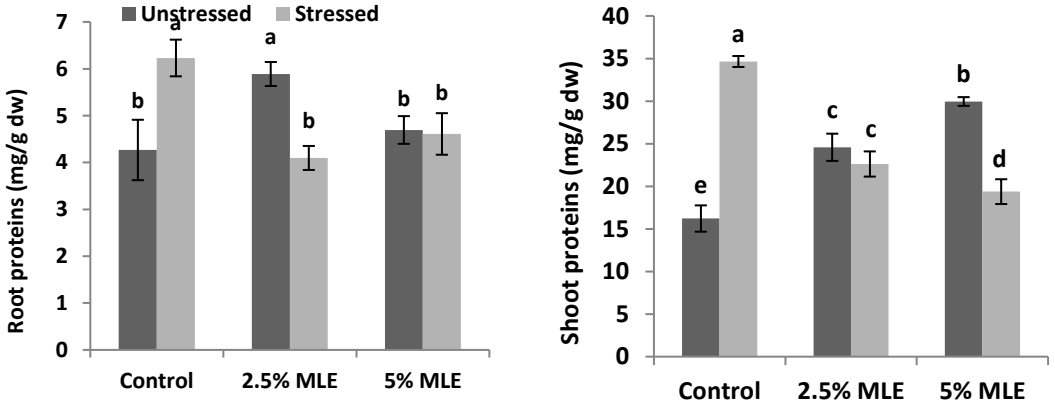

Figure 4. *Soluble proteins content in roots and shoots of Pb-stressed and pre-soaked in MLE (0.0, 2.5 and 5%) fenugreek seedlings. Different letters indicate significant differences at 5% level and the error bars represent SD*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69496967

Stress indices

Hydrogen peroxide (H_2O_2) and malondialdehyde (MDA) contents in the leaves of fenugreek seedlings were significantly affected by the applied dose of lead stress (*Fig. 5*). Irrigating fenugreek seedlings with 100 mMPb-acetate triggereda reasonable increment in the oxidative stress markers;H_2O_2 and MDA, in the leaf tissues, compared to the control. The applied dose of Pb acetate showed 43.24 and 47.90% increase in the level of H_2O_2 and MDA, respectively, relative to the control levels. Nevertheless, seed pre-soaking in MLE effectively lowered the leaf content of both stress markers;H_2O_2 and MDA, in fenugreek leaves, particularly 2.5% MLE. Likewise, the pre-treatment with MLE efficiently ameliorated the deleterious impact of Pb-stress on fenugreek seedlings.

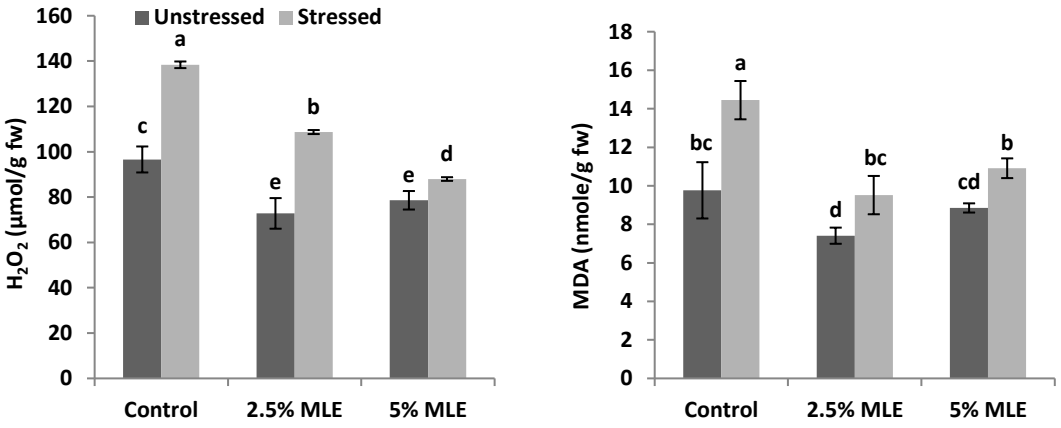

Figure 5. *Stress markers (H_2O_2 and MDA) of Pb-stressed and pre-soaked in MLE (0.0, 2.5 and 5%) fenugreek seedlings. Different letters indicate significant differences at 5% level and the error bars represent SD*

Enzymatic activity

The activities of catalase (CAT), peroxidase (POD), ascorbate peroxidase (APX) and polyphenol oxidase (PPO) in fenugreek leaves were significantly affected by lead and aqueous moringa leaf extract (MLE) treatments (*Fig. 6*). As for CAT, the exposure of fenugreek seedlings to 100 mMPb resulted in 47.32% decline in CAT activity, compared with the control. Additionally, both MLE treatments caused a sharp decline in CAT activity(53.36 and 53.68% with 2.5 and 5% MLE, respectively). The combined interactions betweenPb and MLE showed the least CAT activity throughout the experiment.

Nonetheless, POD activity showed a 20.84% rise following Pb exposure, but non-significantly affected by both MLE treatments, either as single treatments or combined with Pb stress, compared with the untreated control. Likewise, Pb stress significantly affected APX activity, as it caused a 31.59% increase compared to the control. Both, 2.5 and 5.0%MLE treatments non-significantly diminished APX activity relative to the control activity, 5.95 and 13.69%, respectively. Combined interaction of Pb and MLE was concentration dependant. The low dose (2.5%) slightly declined APX activity, but the higher dose (5.0%) reasonably increased its activity, compared to their stress counterparts.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69496967

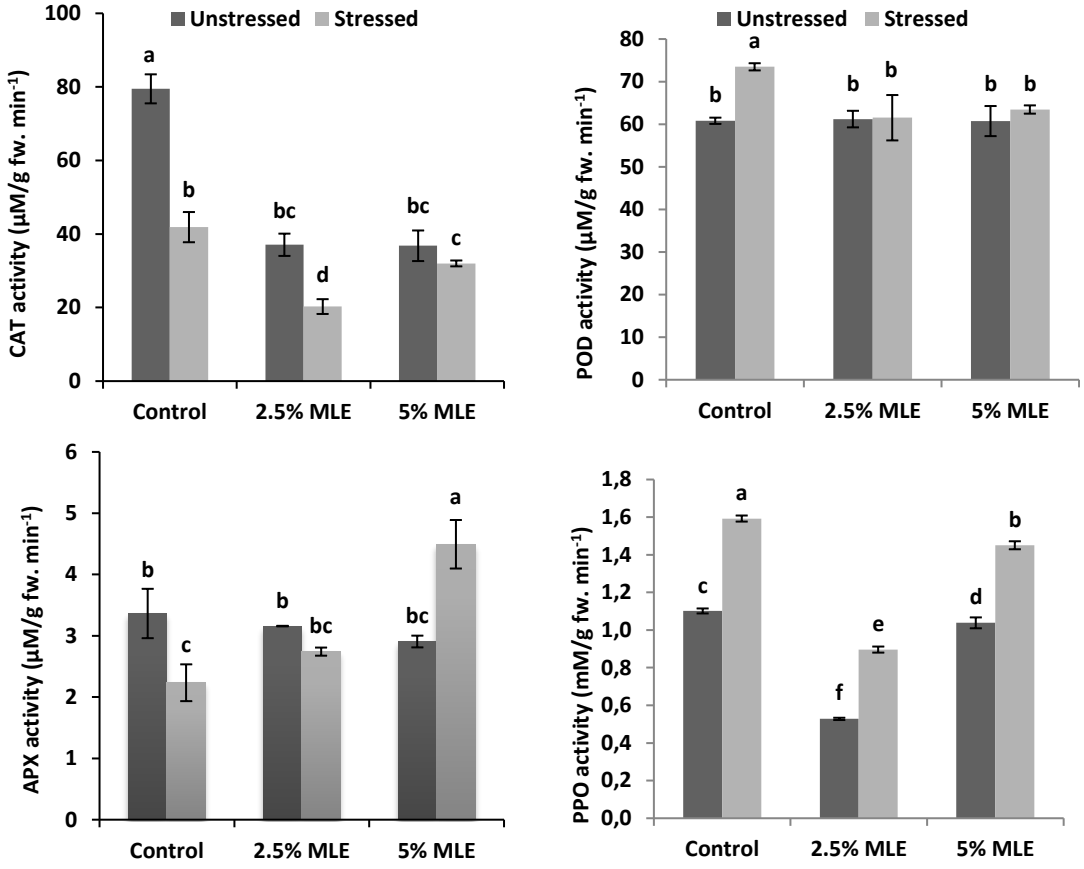

Figure 6. *Enzymatic activities (CAT, POD, APX and PPO) of Pb-stressed and pre-soaked in MLE (0.0, 2.5 and 5%) fenugreek seedlings. Different letters indicate significant differences at 5% level and the error bars represent SD*

Like POD, PPO activity was markedly induced (44.54%) by Pb treatment. However, both MLE treatments; 2.5 and 5.0%,showed a pronounced decrease in PPO activity in comparison with the untreated control, particularly the low dose (49.09 and 5.45%, respectively). Combined treatments of Pb and MLE significantly enhanced PPO activity, compared to single MLE treatments, but the activity still lower than that of Pb sole treatment.

Free radical scavenging activity

The free radical (DPPH) scavenging activity of fenugreek root and shoot ethanolic extracts was significantly affected by Pb and MLE treatments (*Fig. 7*). Treatment of fenugreek seedlings with 100 mMPb-acetate non-significantly lowered the DPPH activity of the root and the shoot extracts (3.79 and 11.33%, respectively). However, the effect of MLE on DPPH activity was dose-dependent. Priming in 2.5% MLE significantly increased the DPPH activity in both root and shoot of fenugreek extracts (33.67 and 18.83%, respectively), but priming in 5.0% MLE resulted in a 16.15 and 19.26% decrease in the DPPH activity of root and shoot extracts, respectively.

The interactive combinations of MLE and Pb treatments decreased the scavenging activity of fenugreek ethanolic root and shoot extracts, except for the mutual treatment with both Pb-acetate and 5.0% MLE in case of the shoot, this treatment remarkably

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69496967

decreased the DPPH activity of the ethanolic extract, compared to the sole Pb treatment. All in all, the DPPH scavenging activity of fenugreek shoot extracts was higher than those of the root under all treatments.

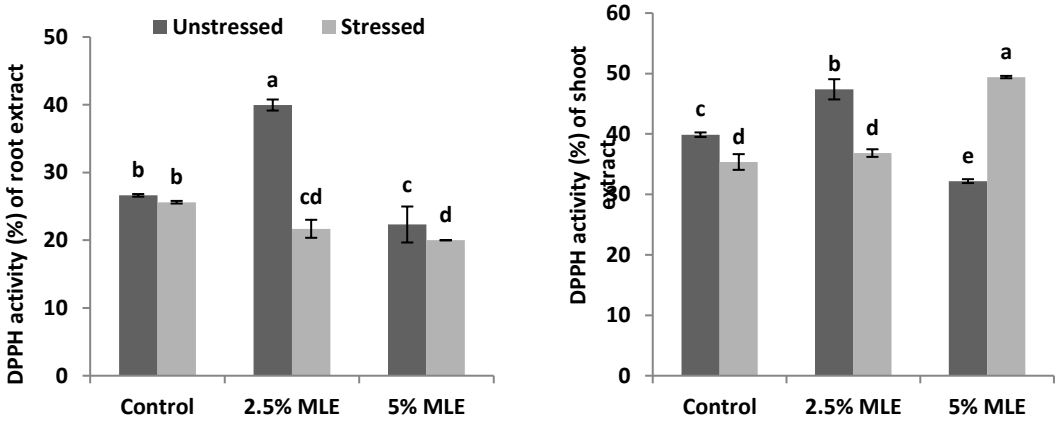

Figure 7. *DPPH free radical scavenging activity of root and shoot ethanolic extracts of Pb-stressed and pre-soaked in MLE (0.0, 2.5 and 5%) fenugreek seedlings. Different letters indicate significant differences at 5% level and the error bars represent SD*

Total antioxidant capacity

The phosphomolybdateassay is used as a criterion for total antioxidant capacity (TAC) in fenugreek root and shoot ethanolic extracts (*Fig. 8*). The TAC of root extract was not affected by Pb treatment, however, that of the shoot extract was slightly decreased, compared to the non-stressed counterparts. The TAC of the root extract was significantly raised by priming in 2.5% MLE, however priming in 5.0% MLEdid not affect the TAC, compared to the control treatment. As for shoot ethanolic extract, 2.5% MLE did not affect TAC but 5.0% MLE addressed a slight decrease inTAC, comparable to the control treatment.

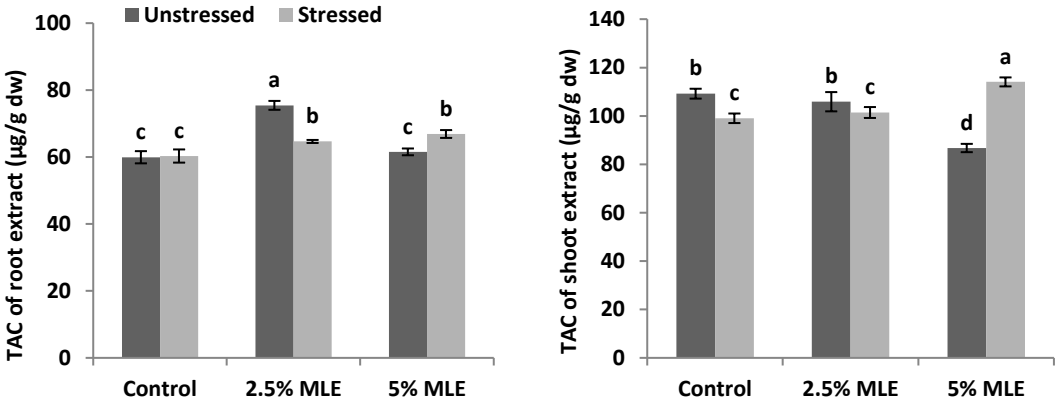

Figure 8. *Total antioxidant capacity (TAC) of root and shoot ethanolic extracts of Pb-stressed and pre-soaked in MLE (0.0, 2.5 and 5%) fenugreek seedlings. Different letters indicate significant differences at 5% level and the error bars represent SD*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69496967

The interactive treatments of Pb-acetate and MLE were concentration dependant. The low concentration of MLE (2.5%) decreased the TAC, but the high concentration (5.0%) increased it in the root and the shoot extracts, relative to the individual lead-exposed treatments.

Elemental content of fenugreek root

The contents of N, P, Ca, Mg, K, Na and Pb, as well as K/Na ratio in the roots of fenugreek grown under Pb-stress and pre-soaked in MLE were determined and tabulated as mg g^{-1}dw (*Table 1*). Treatment with Pb-acetate resulted in a pronouncedaccumulation of Pb ions in theroots of stressed-untreated fenugreek seedlings as compared with the control. Comparable withPb treatment, priming with2.5 and 5.0%MLE distinctly declined the Pb content of fenugreek. Likewise, the levels of Mg and Na were increased as affected by lead stress, but the priming with MLE lowered their accumulation to values relatively near to the control. However, N, P, and K contents, as well as the ratio of K/Na, were decreased by the exposure of fenugreek to Pb stress, but Cacontent relatively remained unaffected by Pb treatment. Fenugreek priming with MLE significantly increased the root content of N, P, and K ions of Pb-stressed fenugreek, supporting improved ionic homeostasis and enhanced root growth.

Table 1. *Ion concentrations (N, P, Ca, Mg, K, Na, and Pb) in the root of Pb-stressed fenugreek seedlings pre-treated with 2.5 and 5.0% MLE. Different letters in the same column represent significant variations at 0.05 level*

Elemental content of fenugreek shoot

The contents of N, P, Ca, Mg, K, Na and Pb,in addition to K/Na ratio in the shoots of fenugreek grown under Pb-stress and presoaked in MLE were estimated and represented as mg g^{-1}dw (*Table 2*). Treatment with Pb-acetate resulted in an evident uptake of Pb ions into thefenugreek shoot system as compared with the control. Comparable with Pb-stress, priming with2.5 and 5.0%MLE distinctly declined Pbcontent (57.14 and 71.42%, respectively)in fenugreek shoot. Similarly, Na level increased as affected by Pb-stress, nevertheless,pre-soaking in MLEslightly decreasedNauptake into fenugreek shoot. On the other hand, other minerals (N, P, Ca, K, andK/Na ratio) were observably decreased by fenugreek exposure to Pb-stress, but Mg content relatively increased as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69496967

affected byPb treatment. Fenugreek priming with MLE significantly increased the shoot content of N, P, Ca, Mg, and K ions of Pb-stressed fenugreek, contributing to ionic homeostasis in the stressed fenugreek seedlings.

Table 2. *Ion concentrations (N, P, Ca, Mg, K, Na, and Pb) in the shoot of Pb-stressed fenugreek seedlings pre-treated with 2.5 and 5.0% MLE. Different letters in the same column represent significant variations at 0.05 level*

Discussion

Globally, plants are endangered by the increased human, industrial and agricultural activities, particularly after the industrial revolution in the past century. One of the most challenges faced by plants is heavy metals pollution. Lead (Pb) was reported as a potential heavy metal, neither possess any role in cellular metabolism nor essential for plant growth and development (Nas and Ali, 2018), although it is simply uptaken and accumulated within various plant parts. The declined fenugreek growth by lead exposure in the current study could be ascribed to the extensive phytotoxicity represented in the distortion of cellular structures, ionic imbalance, reduced chlorophyll synthesis, induction of ROS over-accumulation and hormonal imbalance(Kumar et al., 2012). As one of the heavy metals, Pb impairs the hydrolysis and the translocation of carbohydrates leading to reduced plant growth (Kuriakose and Prasad, 2008).

On the other hand, the study results demonstrated that moringa leaf extract (MLE) pretreatment significantly improved the growth rate of Pb-stressed fenugreek seedlings. These results are in agreement with those of Latif and Mohamed (2016) in salt-stressed common bean and Abdel-Latef et al. (2017) in salt-stressed fenugreek. These results affirmed thatMLE could be considered growth-promoting due to its high content of growth-regulating substances (zeatin), antioxidants (ascorbate, phenols and carotenoids) and essential nutrients (Yasmeen et al., 2013). Those authors concluded that MLE induces the endogenous hormonal level causing improved plant growth in the presence and/or absence of any other stressful factor. Additionally, Taiz and Zeiger (2010) reported that MLE is an excellent source of cytokininswhich promote many physiological processes in the growing plants as chlorophyll biosynthesis, cell division and cell elongation.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69496967

The induced reduction in chlorophyll content by Pb is considered as a common consequence of ROS mediated chlorosisdue to the impairment of chlorophyll biosynthesis and induction of chlorophyll degradation (Desoky et al., 2018). The study results showed a significant reduction in chlorophyll (a+b) content in Pb-stressed fenugreek leaves. Furthermore, chlorophyll b was reported to be more sensitive to lead stress than chlorophyll a. The powerful inhibition in the activity of α-amino levulinate dehydrogenase; a key enzyme in chlorophyll biosynthesis, by lead ions was reported to be the main cause of chlorophyll decline as a result of lead exposure (Prasad, 1996). Other reports showed that lead restrainschlorophyll biosynthesis by decreasing the uptake of some essential ions like Mg and Fe (Nas and Ali, 2018). Lead destroys the photosynthetic apparatus because it has high affinity towards protein nitrogen and sulfur ligands (Ahmed and Tajmir-Riahi, 1993).Sofy et al. (2020)reported that lead stress reduced the total chlorophyll content and disrupted the chloroplast ultrastructure of maize leaves. They attributed that to the increased levels of lipid peroxidation and membrane leakage, in addition to the interaction of lead with-SH group in chlorophyll biosynthetic enzymes.

Priming of fenugreek seeds in MLE provoked a protective mechanism for the growing seedlings against lead stress. This was apparent during this study through the improved chlorophyll content of lead-stressed fenugreek seedlings. Yasmeen et al. (2013) also previously reported that MLE improved the total chlorophyll content of wheat plants subjected to salt stress. Moreover, Latif and Mohamed (2016) reported that the foliar spray of common bean plants with MLE significantly improved the chlorophyll content of salt-stressed plants. They attributed this effect to the high content of macronutrients in MLE such as magnesium, which is a main constituent of chlorophyll. Other reports showed that the high content of cytokinins, particularly zeatin, in MLE prevent early senescence, producing large leaf area with high chlorophyll content (Elzaawely et al., 2017) through upregulatingcytokinindependantisopentenyltransferase, which is a key enzyme in the biosynthetic pathway of chlorophyll.

Carotenoids, as main antioxidant molecules, were significantly boosted by lead stress. Similar results were obtained by Lim et al. (2012) in buckwheat(*Fagopyrum esculentum*Moench.) subjected to salt stress, they attributed this increase to the induction of themevalonate pathway to induce the biosynthesis of abscisicacid (ABA) to improve the plant tolerance to salt stress. Also, Zaid et al. (2020)reported that carotenoids content highly increased by the exposure of menthol plants (*Mentha piperita* L.) to cadmium stress. The excessive accumulation of carotenoids under abiotic stress conditions was attributed to their capability to scavenge ROS, in addition to providing photoprotection against photooxidation of photosynthetic reaction centers (Gururani et al., 2015). Moreover, carotenoids were reported to offer protection to thylakoid membrane lipids, quenching singlet oxygen and chlorophyll triplet excited state (Li et al., 2012).Consequently, the increased carotenoids provide protection to the photoassimilating apparatus against Pb-stress.

Pre-treatment of fenugreek with MLE significantly reduced the level of carotenoids in the leaves of Pb-stressed fenugreek seedlings. Our results are in harmony with those obtained by Abd El-Mageed et al. (2017) in squash. The declined level of carotenoids in fenugreek subjected to Pb-stress might be due to the accompanying antioxidant properties in the aqueous MLE, as it has been reported to be a rich source of natural antioxidants such as flavonoids, ascorbic acid, carotenoids and phenolics(Siddhuraju

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69496967

and Becker, 2003). These antioxidant molecules could offer protection to the stressed fenugreek seedlings, allowing it to harness the mevalonate pathway in the production of other essential molecules sustaining plant growth under stress conditions.

The results of this study revealed that Pb-stress down-regulated the accumulation of soluble sugars in the root and the shoot of fenugreek seedlings. This reduction was ascribed to the loss of chlorophyll, inhibition of photosynthetic enzymes (like RUBP carboxylase/ oxygenase) and reduced leaf area in stressed plants (Pandey et al., 2001), in addition to the increased respiration rate to adapt with the high energy demand (John et al., 2008).

The single treatment with MLE resulted in decreasing the soluble sugar content of Pb-stressed fenugreek seedlings, but the combined interaction of Pb and MLE slightly affected their content, compared to Pb treatment. Free soluble sugars function as anti-stress osmoregulators and their decrease in response to priming with MLE could be attributed to the fact that this extract containsvariousosmoregulators, like proline and soluble sugars (Abd El-Mageed et al., 2017), which improve the vigor, cellular turgidity, and water use efficiency of stressed plants. Accordingly, these plants direct the photosynthates into the production of other imperative compounds like structural sugars and essential secondary metabolites.

In comparison with the control, soluble proteins content of fenugreek seedlings root and shoot was significantly increased in response to Pb and MLE treatments. The increased protein accumulation in response to lead toxicity has been previously reported in wheat (Lamhamdi et al., 2011) and grass pea (*Lathyrus sativus* L.) (Brunet et al., 2009). Such accumulation of proteins may protect plants against Pb-stress through sustaining cellular redox like ascorbate, glutathione and phytochelatins make (Jiang and Liu, 2010). Lamhamdi et al. (2011)postulated that increased protein accumulation under Pb-stress could be a direct consequence of stimulating specific stress proteins. Increasing of total soluble protein content in stressed plants by using MLE has been previously approved in snap bean (*Phaseolus vulgaris* L.)(Elzaawely et al., 2017). Those authors accredited the increase in protein to the increased nitrogen concentration due to MLE treatment. Moreover, the increased protein biosynthesis could be explained by the availability of antioxidant compounds in the extract, providing protection to the metabolic machinery involved in protein biosynthetic pathway.

The current investigation revealed a prominent increment in lipid peroxidation (MDA) and H_2O_2 accumulation in the leaves of fenugreek seedlings exposed to Pb-stress, substantiating Pb-induced oxidative damage in fenugreek seedlings.Wang et al. (2012) found that eelgrass(*Vallisnerianatans*L.) showed an increased production of MDA and H_2O_2 as a result of Pb treatment. They explained this effect by the deteriorationscaused by the excessive generation of ROS through the frequent creation of fatty aldehydes and short-chained alkanes caused by Pb ions. Likewise, Ahamed and Siddiqui (2007) confirmed ROS generation due to lead toxicity, causing oxidant/antioxidant-balance disturbances, and lipid metabolism alternation. However, MLE-treated fenugreek plants counteracted oxidative damage through the decreased generation ofMDA and the accumulation of H_2O_2. This could be caused by the high content of antioxidant compounds, vitamins and cytokinins in MLE, in addition to the induction of antioxidants, like ascorbate, phenols and anthocyanins, in the stressed plant tissues (Batool et al., 2016).

Lead is well-known to be a redox inert-metal, causing excessive ROS generation via disrupting cellular oxidant/antioxidant balance (Zulfiqar et al., 2019). To meet oxidative injury, plant have developed several enzymatic and non-enzymatic molecules. In the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69496967

present investigation, catalase (CAT) and ascorbate peroxidase (APX) activities decreased in fenugreek leaves by receiving 100 mMPb-acetate. This might be a consequence of the severe oxidative damage imposed by Pb(Erdei et al., 2002). Verma and Dubey (2003) reported that the Pb-induced decline in CAT and APX activities arise from ROS-mediated inactivation of these enzymes, enzymes-synthesis decline, or enzyme subunits assembly modification. On the contrast, peroxidase (POD) and polyphenol oxidase (PPO) activities were raised following Pb-treatment. The probable explanation of the increased POD activity is the dependence of fenugreek in eliminating the rapidly accumulated H_2O_2on this enzyme, to compensate for the diminishedCAT activity. Similar results were obtained by Sobhy et al. (2019) in wheat and Hou et al. (2019) in bamboo grass(*Pogonatherumcrinitum*Thunb.).PPO has been established as a key enzyme in the photosynthetic apparatus, and it can provide and evidence for heavy metals accumulation in various plant species (Lavid and Tel-Or, 2001). The exposure of plants to Pb-stress has been correlated with the increased activity of PPO, due to its crucial role in respiration, oxidation-reduction reactions, and synthesis of phenol-containing molecules like lignin(El-Beltagi et al., 2016).The declined activity of antioxidant enzymes, except for POD which remained unchanged, as consequence of pre-treating fenugreek with MLEpull the awareness to the ability of this extract, owing to its elevated antioxidative capacity, to eliminate the generated ROS, so there is no need for the upregulation of enzymatic antioxidant machinery, and the plant could sustain its normal growth based on the high content of antioxidants in MLE (Yasmeen et al., 2013).

Under normal growth conditions, plants produce specific secondary metabolites, some of which can scavenge ROS. However, the scavenging potential of these metabolites has been reported to decrease under stress conditions (Ahmad et al., 2016). In the current study, Pb-stress resulted in decreased radical scavenging (DPPH) activity and total antioxidant capacity (TAC) in fenugreek roots and shoots.Tripathi et al. (2016)attributed that the increased Pb-stress mediated accumulation of $H_2O_2$and MDA is the main cause of the antioxidant potential decreasing in the stressed plants. MLE presoaked fenugreek seedlings showed a mitigating response to Pb-stress in terms of DPPH and TAC at the low concentration (2.5%), but the higher concentration (5.0%) non-significantly affected the non-enzymatic antioxidant status of fenugreek.Yasmeen et al. (2013) stated that the high content of cytokinins in MLE was behind its effectiveness in ameliorating environmental stresses via quenching ROS. Moreover, the reason may be due to the reduced absorption and transfer of lead tofenugreek tissues.

Pb-stress was demonstrated to increase the uptake of Pb and Na ions, disturbing the uptake and mobility of essential minerals (N, P, Ca and K), reducing K/Na ratio and interrupting ionic and osmotic homeostasis. Transport of Pb to the plant cells occurs through the cation channels on plasma membranes, especially Ca channels, causing other nutrients deficiency, hindering water uptake and deterioration of membrane integrity (Lamhamdi et al., 2011). Therefore, the decreased content of essential nutrients could be considered as a consequence of intensive membrane deteriorations as a direct effect of Pb ions or the generated ROS. The decreased level of essential macronutrients after Pb-exposure results in the decreased growth rate of fenugreek seedlings, which may be correlated with reduced cell division and elongation, as well as metabolic redox imbalances.

The high content of essential nutrients in MLE promoted high ionic homeostasis in tissues leading to higher levels of essential macronutrients (N, P, K and C) supporting the normal growth of Pb-stressedfenugreek. The balanced ionic status of MLE-treated plants

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69496967

promoted fenugreek seedlings to sustain membrane integrity, ionic homeostasis, water use efficiency and antioxidant capacity, consequently improved growth. Several authors adjudged enhanced ionic status of stressed plants following MLE treatment (Yasmeen et al., 2013; Abdel-Latef et al., 2017).

Conclusion

Being a heavy metal, lead negatively affected growth rate, photosynthetic pigments, nitrogen metabolism, antioxidant status and ionic homeostasis in fenugreek seedlings. Seed priming with moringa leaf extract (MLE) is a cost-effective and eco-friendly approachthat could be used to improve Pb-resistance in fenugreek by modulating nitrogen metabolism, antioxidative machinery, ionic homeostasis with decreased Pb and Na concentrations, thereby promoting enhanced growth rate under stress conditions. However, further studiesare recommended to elucidate the phytochemical constituents of MLEand the mode of action of this extract in modulating metal-stressed plants growth.

Abstract. Sowing naked seeds is generally preferred in arid and semiarid regions. This research aimed to find the optimal dimensions for both pelleted and naked seeds based on seed distance in rows and field emergence irrigation setting in sugar beet (*Beta vulgaris* L.) cultivation under the environmental conditions of Central Anatolia in Turkey. For comparison, the research considered two field emergence irrigation conditions, namely, irrigated and non-irrigated, at 8 and 17 cm seed distances within rows for naked seeds of two dimensions: N3.25-Ø4.50 and N3.00-Ø3.50 mm and for pelleted seeds of five dimensions: P3.50-Ø3.75, P3.75-Ø4.00, P4.00-Ø4.25, P4.25-Ø4.50, and P4.50-Ø4.75 mm. The results showed that the highest beet yield and refined sugar content were 66.67 and 10.31 t ha^{-1}, respectively, obtained in the plot that was irrigated and drilled with N3.00-Ø3.50 mm seeds at 8 cm sowing distance. The lowest values were obtained from the non-irrigated plot that was drilled with P4.50-Ø4.75 mm seeds at 17 cm sowing distance in all conditions. In field emergence irrigation conditions, planting pelleted seeds from 3.50 to 4.25 mm in dimension or 0.25-0.75 mm in thickness at row distances of 8 and 17 cm can be concluded to be the optimum application.
Keywords: *sugar beet, seed pelleting, germination, field emergence irrigation, row space, quality indicators*

Introduction

Decreasing the manual labor and increasing machinery operations by as much as possible are among the goals of sugar beet (*Beta vulgaris* L.) farming. In practice, considerable progress has been achieved with machinery operations except for thinning and singling. Reducing manual labor generally depends on three factors: uniform and healthy seedling rows, uniform seedling distribution, and adequate weed control (Draycott, 2006). Achieving a uniform seedling distribution and the optimum plant density depends on the seed specifications, proper cultivation, and sowing technique. The application of suitable mechanical and chemical weed control is also important to ensure a high yield and quality (SBGG, 2016).

Sugar beet is generally planted at 8 cm seed distance in a row and at 45 cm distance between rows by using precision drilling machines; a singling distance of 20-25 cm is applied in Turkey. In addition, planting at 45 cm row spacing and at the desired seed spacing within a row can be carried out with the use of pneumatic drilling machines. The optimum plant frequency to obtain the highest yield and quality has been determined to be between 70000 and 90000 plants ha^{-1} (Hozayn et al., 2013; SBGG, 2016). The forward speed of the drilling machine is one of the major factors affecting the sowing quality; a forward speed of 4.5-5 km h^{-1} seems to provide the most appropriate seed distribution. A high speed causes an irregular seed distribution, changing the depth settings and leaving

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69696979

the seeds on the soil surface. The planting depth is also a major factor in yield and quality. Sugar beet seeds must be sown at a depth of 2-4 cm and should be checked continuously during sowing. Further, proper planting facilitates the subsequent hoeing and harvesting process (Hozayn et al., 2013).

Spacing is the distance between two successive seeds in a row. Misses (voids) refer to the absence of a seed where there should be one theoretically, that is, where the spacing is more than 1.5 times the theoretical seed spacing. Multiples (doubles) refer to the presence of two or more seeds where there should only be one, that is, where the spacing is less than 0.5 times the theoretical seed spacing (Lammers et al., 2015). One seed within targeted rows and single seedling germination in each cell are desired in sugar beet cultivation. To achieve these goals, it is important to use precisely calibrated pelleted and naked seeds. The vast majority of sugar beet seeds sown in Turkey consist of naked genetic monogerm seeds. Genetically monogerm sugar beet seeds belonging to different varieties are processed and calibrated according to sizes of 3.25-Ø4.50 mm at the Turkish Sugar Factories Corporation seed processing plant. They are then delivered to farmers after being treated with one insecticide (imidacloprid or thiamethoxam), two fungicides (hymexazol and thiram) against disease and pests. The variety of seeds produced by private seed companies can be bought from the market and sown according to the preference of farmers (TSFAS, 2019).

In recent years, an increase has been observed in the number of producers sowing pelleted genetically monogerm seeds, called thin pelleted seeds, 3.50 to 4.00 mm in dimension. The smoother surface and more spherical structure of pelleted seeds result in a more precise seed distribution in a row, especially when precision sowing machines are used. Also, larger amounts of pesticide may be mixed into the coating material depending on the naked seeds, thus increasing the efficacy of pesticides against both pests and diseases. On the other hand, seed pelleting increases the costs and decreases the amount of field emergence in some regions where arid and semi-arid climate conditions prevail and during years of arid climate and with insufficient rainfall periods, especially just after drilling in spring. The germination rate of naked sugar beet seeds delivered to farmers by the Turkish Sugar is required to be at least 85% (TSFAS, 2019). Although the standard naked seeds satisfy this requirement, the rate may decrease to 68% after pelleting (Duan and Burris, 1997).

Pelleting of sugar beet seeds is done after polishing, dimension measurement, and separation by weight. To prepare the seeds for pelleting, one or all of these processes are carried out depending on the physical characteristics of the seed lot to be used. The pre-cleaning dimension of harvested seeds is generally between 3.25 and 6.00 mm. The seed size is decreased to 3.25-Ø3.50 mm by polishing before the pelleting process (Draycott, 2006). Polishing is the process of correcting the disk-shaped, jagged outer surface of beet seeds and obtaining the desired dimension by chipping the pre-pelleting of the seed outer surface (pericarp). Thinning of the pericarp by polishing increases the water intake and germination speed. After polishing, the seed units are passed through a multilevel sieve with round holes; seeds that are too small to be pelleted are removed, whereas those that are too large are polished again. Next, the seed units are passed through a sieve with oval holes, and those with multiple embryos are separated (Draycott, 2006). The remaining seeds are separated by weight and assessed by an X-ray test; those found to be 100% full are then sent to the pelleting units. Pellet sizes of 3.50-Ø4.75 and 3.75-Ø4.75 mm are widely preferred in Europe; only Finland and Sweden use pelleted seeds in the range of 4.00 to 5.00 mm. The thickness of the pelleting material increases

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69696979

the seed weight by an average of 180% (between 150 and 200%) or by 0.50-0.75 mm (Draycott, 2006). In Turkey, a pellet thickness of 0.50 mm is generally applied.

The pelleting process consists of four stages (*Fig. 1*). During seed pelleting, naked seeds are pelleted with a mixture of clay, wood flour, and adhesive. The process is done in rapidly rotating cylindrical boilers; inside the drums, water and the pelleting powder are sprayed onto the seeds. After that, the seeds are dried, and the water in the pelleting material is removed by evaporation, thus turning the pelleted seed into a hard pellet (KWS, 2020). Turkey has no domestic production of the sugar beet seed pelleting material, which is currently sourced from abroad.

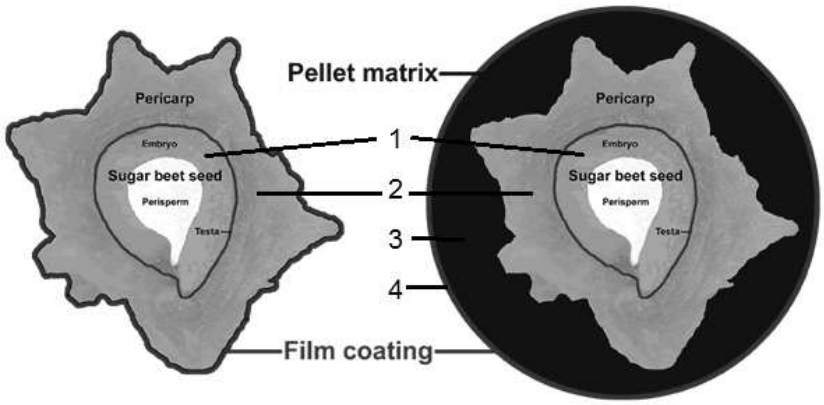

Figure 1. *Sectional view of the pelleted seed*

In this study, it was aimed to determine the most suitable seed type and seed coating thickness for high yield and quality by comparing uncoated and coated sugar beet seeds under different of sowing distances and with and without emergence irrigation conditions.

Materials and methods

This research was carried out at the Sugar Institute in the Eskişehir (39°47′N, 30°31′E), Etimesgut (39°56′45″N, 32°40′10″E), and Ilgın (38°16′45″N, 31°54′50″E) experimental stations over a three-year period from 2012 and 2014 in Turkey. The soil textures in the three locations were silty-clayey and clayey, and the regional climatic characteristics were arid and semi-arid. During the vegetation period of sugar beet, the total annual precipitation in April-August period is given in *Fig. 2* and the average temperature values by months are given in *Table 1*. Climate data (temperature, precipitation) in the test fields were taken hourly by the automatic climate station in the test regions. In the three-years period, the three regions had similar mean rainfall rates despite their different geographic locations. Although there are minor differences in regions, the temperature between June-August periods was 15-25°C that were desired for the development of sugar beet.

The field used for sowing was prepared first by using a subsoiler, after which a disc harrow was used to clean the preplant wheat stubble in preparation for planting in autumn. The field was ploughed after the application of all the potassium fertilizer and two thirds of the phosphorus fertilizer according to the soil analysis. The seedbed was prepared with the combined use of a cultivator, harrow, and rotary harrow, which supplied the remaining one third of the phosphorus fertilizer and half of the nitrogen fertilizer in spring. The remaining half of the nitrogen fertilizer was applied before the first hoeing. According to

the soil analysis, 120-170 kg ha^{-1} of nitrogen, 50-100 kg ha^{-1} of phosphorus, and 70-100 kg ha^{-1} of potassium were present in the soil as pure substances at varying rates by region and year.

Field tests were carried out by applying a randomized split plot design in four replications. The experimental plots were 10 m long and 4.5 m wide, and the seeds were planted in the plots at 10 rows each with 45 cm row spacing. The total trial area was 4977 m^2, the sowing plot was 45 m^2, and the harvest plot was 20 m^2. The main plots consisted of areas under field emergence irrigated and non-irrigated conditions, and the subplots were planted at 8 and 17 cm planting distances with naked seeds of two different dimensions: N3.25-Ø4.50 and N3.00-Ø3.50 mm pelleted seeds of five different dimensions: P3.50-Ø3.75, P3.75-Ø4.00, P4.00-Ø4.25, P4.25-Ø4.50 and P4.50-Ø4.75 mm. In the plots with a seed drilling distance of 8 cm, the beets were manually thinned to 20-25 cm at the 4-6 leaf stage. In the plots with a drilling distance of 17 cm, the beets were singled and but not thinned even if there were more than one seedling in the queue (*Fig. 3*).

Figure 3. *General view of the parcels and plants in the trial area*

In the study, 15 mm water was applied to the plots which will be applied emergence irrigation by sprinkler irrigation method immediately after sowing. According to the needs of sugar beet 6-7 irrigation was made and approximately 100-150 mm water applied in each irrigation during the vegetation period.

Genetic monogerm sugar beet seeds, called "Giraf," from SESVanderhave (Belgium) were used in the study. A mechanical precision drilling machine manufactured by Turkish Sugar was used for sowing in the trial plots. The seed pelleting and classification processes were done at the BETA Agriculture and Trade Co. seed processing plant in Merzifon (*Fig. 4*). First, the raw seed dimension of 3.00-6.00 mm was decreased to 3.00-3.50 mm by polishing, after which the seeds were pelleted. Then, the pelleted seeds were passed through sieves with round holes of 4.50, 4.25, 4.00, 3.75, and 3.50 mm and divided into five groups. The pelleted seeds in these groups and the naked seeds were then sprayed with pesticide, painted with the company's promotional color, and packaged. *Table 2* shows the average mass of 1000 seeds according to the seed dimension.

U: uncoated seed, C: coated seed

Both pelleted and naked seeds were treated with thiram (3.2 g active ingredient/1 kg seed) and hymexazol (3.5 g active ingredient/1 kg seed) to protect against fungal disease and imidacloprid (9 g active ingredient/1 kg seed) to protect against underground pests (wireworms, springtails, and millipedes) and flea beetles (Kaya and Gürkan, 2011). Seed germination tests of all seed plots used in the trial were carried out in a laboratory (*Table 2*).

For the germination tests, at least 100 seeds from each test subject were placed in germination containers laid on a flat folded filter paper. Each container was sprayed with 40 ml of water in the application with four replications. The number of seeds germinated after 4^{th} and 14^{th} days was counted in a germination room kept at a constant temperature of 20-22°C under a 16 h light/8 h dark cycle (ISTA, 2019).

The duration of field emergence is usually 14 days from the date of sowing on. However, the counts were done weekly from the beginning to the completion of the field emergence. The plant emergence rate was determined as the proportion of the total number of plants counted after complete plant germination to the amount of seed thrown per unit area based on the sowing distance in a row and between rows (Lammers et al., 2015).

After the harvesting, the beets were washed, weighed, and sampled for laboratory analysis with the use of a fraise hob. The amount of dry matter was measured with the Anton Paar Abbemat 500 refractometer manufactured in Germany. The sugar content was considered as the percentage of polar sugar (P). The amount of polar sugar was determined by extracting 26 g of beet pulp with 178.2 ml of aluminum sulfate ($Al_2 (SO_4)_3$) liquor, after which polar meter readings were taken. The amounts of sodium (Na), potassium (K), and α-N were determined by the Anton Paar Betalyser system applying flame photometry principles. The refined sugar content (RSC) and refined sugar yield (RSY) was obtained by calculations (Reinefeld et al., 1974).

Variance analysis and F-tests were applied to the results. No comparisons were made when the F-value was found to be non-significant. Duncan's multiple comparison method was used when the F-values were significant.

Results and discussion

Field emergence

The germination power of the seed varieties was found to be 99% in laboratory conditions (*Table 2*). Water is one of the most important factors in the germination of all

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69696979

plants. After sowing, achieving rapid seed germination and plant emergence depends on having appropriate soil weathering during sowing and maintaining adequate moisture in the soil. Sugar beet is a plant which is extremely sensitive to water. It should be considered to obtain a high yield and quality of sugar beet during the sowing period from April to mid-September.

Based on the combined results over the three-year study period, higher field emergence was obtained from the irrigated plots than from the non-irrigated ones (*Table 3*). In particular, pelleted seeds of P3.50-Ø3.75, P3.75-Ø4.00, and P4.00-Ø4.25 mm showed a considerable advantage in field emergence under both irrigated and non-irrigated conditions. The total annual rainfall and the amount of precipitation showed a variation during the vegetation period (from April to August). The highest average rainfall in the period from April to August was measured in 2013 and the lowest in 2014 (*Fig. 2*). Therefore, field emergence irrigation may be necessary to ensure germination and field emergence exactly from year to year after sowing even if adequate rainfall is not being taken before sowing.

Beet yield

Considering the mean values, a higher beet yield was obtained in the plots in which field emergence irrigation was applied. In the irrigated plots, better results were achieved at 8 cm sowing distance than at 17 cm; in the non-irrigated plots, similar yield values were obtained for both sowing distances. The average beet yield was 61.71 t ha^{-1} in the irrigated plots, compared to 57.85 t ha^{-1} in the non-irrigated ones (*Table 4*, *Fig. 5*). The difference between these yields was statistically significant ($P<0.01$).

Regarding the beet yield based on sowing distance in a row, a value of 60.67 t ha^{-1} was obtained at 8 cm and 58.89 t ha^{-1} at 17 cm. The difference between these yields was also statistically significant ($P<0.01$) (*Table 4*).

The differences in yield according to the dimension of the pelleted seeds, except for those P4.50-Ø4.75 mm, were not significant. When considering average values; the

DOI: http://dx.doi.org/10.15666/aeer/1805_69696979

highest value was obtained as 61.22 t ha^{-1} with P3.50-Ø3.75 mm seeds. However, the highest yield of 66.67 t ha^{-1} was obtained in the irrigated plot sown with N3.00-3.50 mm seeds at 8 cm distance; the lowest value of 44.77 t ha^{-1} was obtained in the non-irrigated plot sown with 4.50-4.75 mm seeds at 17 cm distance (*Fig. 5*).

* U: uncoated seed, C: coated seed

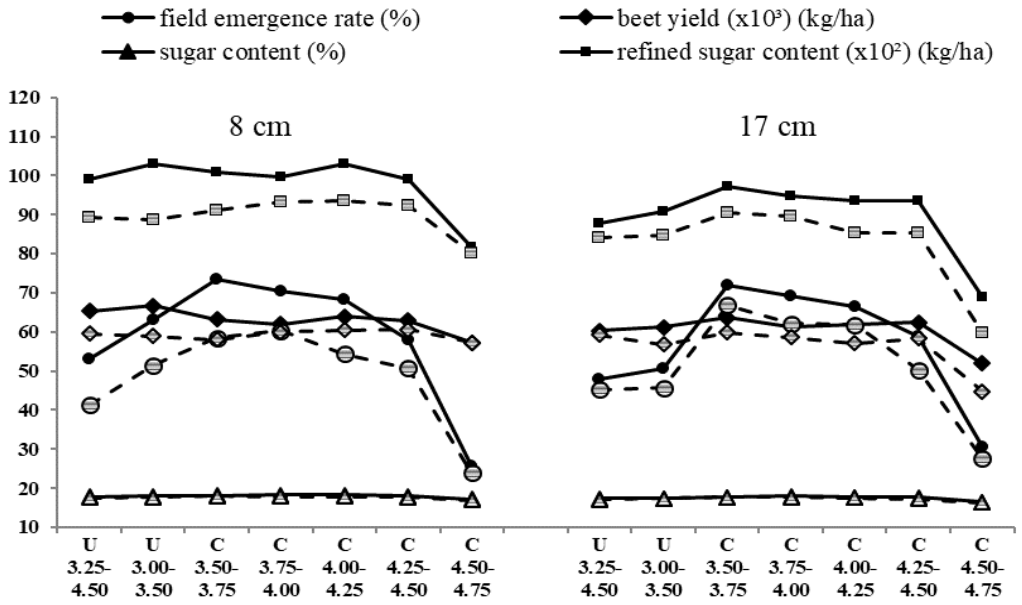

Figure 5. *Quality data's obtained from plots (means of 3 years and 3 locations, dashed is non irrigated values)*

Sugar content

Higher sugar content was obtained in the irrigated plots and at a sowing distance of 8 cm compared with the other plots (*Fig. 5*). The average sugar contents were determined as 17.72% in the irrigated plots and 17.49% in the non-irrigated ones. The difference between these values was found to be statistically significant (P<0.01).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69696979

Regarding the sugar content by sowing distance in a row, 17.63% was obtained at 8 cm and 17.58% at 17 cm. The difference between these values was not statistically significant (*Table 4*).

The highest sugar content obtained based on seed dimension was 17.98% for P3.75-Ø4.00 mm seeds. Although the differences in sugar content between the seeds P3.50-Ø3.75, P3.75-Ø4.00, and P4.00-Ø4.25 mm in dimension were not significant, the differences between these subjects and the others were significant ($P<0.01$). The highest sugar content of 18.31% was obtained in the irrigated plot sown with P3.75-Ø4.00 mm seeds at 8 cm distance, whereas the lowest value of 16.32% was achieved in the non-irrigated plot sown with P4.50-4.75 mm seeds at 17 cm distance (*Table 4*, *Fig. 5*).

Refined sugar content

Similarly to the beet yield and sugar content, a higher refined sugar content was obtained in the irrigated plots and at 8 cm sowing distance compared to the other plots (*Table 4*, *Fig. 5*). The average refined sugar content in the irrigated plots was 9.38 t ha^{-1}, compared to 8.64 t ha^{-1} in the non-irrigated ones. The difference between these values was statistically significant ($P<0.01$).

Regarding the refined sugar content by sowing distance in a row, a value of 9.15 t ha^{-1} was obtained at 8 cm and 8.87 t ha^{-1} at 17 cm. The difference between these values was statistically significant ($P<0.01$).

The highest refined sugar contents were 9.49 and 9.44 t ha^{-1}, respectively, for the seeds P3.50-Ø3.75 and P3.75-Ø4.00 mm in dimension. The differences between seeds based on pelleting thickness were not significant. The highest refined sugar content was 10.31 t ha^{-1}, obtained in the irrigated plot sown with N3.25-3.50 mm seeds at 8 cm distance; the lowest value was 5.98 t ha^{-1}, achieved in the non-irrigated plot sown with P4.50-4.75 mm seeds at 17 cm distance (*Table 4*, *Fig. 5*).

In the statistical evaluations carried out in the three years of the research, location and year interactions were found. In essence, it is normal to have this type of interaction because the location and years differ in properties. However, since the results obtained in three years and three locations are parallel to the applied methods, the methods were evaluated over the averages.

Although it is not statistically significant in these three years, better results were observed comparing the irrigated plots to the non-irrigated ones with 8 cm sowing distance to 17 cm all of the three locations and years. A significant difference between irrigated and non-irrigated plots was found in the beet yield at Ilgın in 2014 ($P<0.05$), the sugar content at Etimesgut in 2012 ($P<0.05$), and the refined sugar content at Ilgın in 2012 ($P<0.05$) and 2014 ($P<0.01$) (*Table 5*). The difference between sowing distances of 8 and 17 cm was not significant in all the years and locations.

Regarding the difference between seed pelleting thicknesses by year and location, seeds P3.50-Ø3.75, P3.75-Ø4.00, and P4.00-Ø4.25 mm in dimension showed better results in all locations. The difference between the seeds P3.50-Ø3.75, P4.00-Ø4.25 mm in dimension and the other treatments were significant in terms of beet yield, sugar content, and refined sugar content ($P<0.05$, $P<0.01$) (*Table 5*).

Seed germination is controlled by environmental factors (light, temperature, water). The field emergence rates of the seed variety and in the specific region have to be known to determine the optimal sowing distance in a row. In this research, the average field germination rates at three different experimental stations was determined as 58% in irrigated plots and 50% in non-irrigated plots. These values are representative of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69696979

Central Anatolian Region and show the average levels in Turkey. This rate is lower than the level of 76% in the United Kingdom (BBRO, 2020). The data indicate that sowing at a distance of up to 17 cm can be done in similar circumstances. Larger sowing distances are discouraged because they present a higher risk under climate conditions of arid and semi-arid countries as well as Turkey. On the other hand, sowing sugar beet seeds at 8 cm distance in a row and adjusting to 20-25 cm by thinning and singling ensure a high yield and quality despite the lower field emergence in Central Anatolia, where sugar beet is cultivated intensively (Çakmakçı and Oral, 1995; Tuğrul et al., 2012). The 8 cm sowing distance also provided the best results in this study. However, in many areas, farmers do not carry out the necessary thinning and singling because they think it will decrease the number of plants in the field. Eventually, more frequent seedlings prevent the development of sugar beets (Draycott, 2006).

Conclusions

In this study, field emergence irrigation was shown to significantly increase the beet yield and quality in the conditions of Central Anatolian Region which has arid and semi-arid climate in Turkey. Thus, taking into account the climatic conditions after sowing, proper irrigation scheduling would be beneficial to the level of 15-20 mm in the soil condition of the absence of enough moisture. In particular, field emergence irrigation is of great importance in ensuring sufficient emergence when sowing pelleted seeds.

In conclusion, frequent beet rows fail to achieve adequate growth and cause yield loss to the farmers. On the other hand, labor costs also seem to be a growing problem every year. Considering these reasons, if the field and seedbed preparation is carried out at the right time by the appropriate technical quality, and the climatic conditions are suitable, beets can be sown at 12 and 17 cm distances. Increasing seed pelleting thickness reduces remarkably the field emergence, yield and quality. In this case, the seeds P4.50-Ø4.75 mm in dimension, which have the thickest pellet, are not suitable in similar arid and semi-arid climatic conditions. The P4.25-Ø4.50 mm seeds, which have the second thickest pellet, provided better results for C5; however, pelleting with this thickness is considered to be risky. Besides their high field emergence, the seeds pelleted

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69696979

P3.50-Ø3.75, P3.75-Ø4.00 and P4.00-Ø4.25 mm in dimension provided a high yield and quality due to their advantages of allowing uniform and high-dose pesticide application. The seeds pelleted 3.50 to 4.25 mm in size were considered to be of the appropriate thickness to obtain the best results. The results indicate that, given the regional climatic conditions, besides planting naked seeds at 8 and 17 cm sowing distances, the best results are obtained by sowing seeds pelleted 3.50 to 4.25 mm in dimension and 0.25-0.75 mm in thickness under irrigated conditions.

Nowadays due to global warming, many regions where sugar beet is grown are under the problem of drought in the spring season or the problem of obtaining sufficient water with rainfall or both. For this reason, continuing trials with thinly coated or uncoated seeds are among the important issues, especially in areas where the water required for germination of seeds and sprouts of the plants to reach the soil surface cannot be adequately met with rains.

Abstract. A food network model of the Tian-E-Zhou Oxbow ecosystem in the Yangtze River was established by combining fishery resource data with other aquatic biological data. The ecosystem can be divided into seven discrete trophic levels, and nutrient flow occurs mainly between the trophic levels I-V. The average material transfer efficiency of each trophic level was 10.5%, there were no obvious key species in the system, and large aquatic plants had the largest key index (-0.173). The matter and energy recirculation ratio in the system was low, while the values of other indicators such as system connection index (CI), system omnivore index (SOI), Finn's cycle index and Finn's mean path length were all at a low level, indicating that the Tian-E-Zhou Oxbow ecosystem was at an early stage of development. Finally, based on the food network model, the environmental carrying capacity of the Yangtze finless porpoise in the Tian-E-Zhou Reserve was calculated as 0.207 t/km^2, counting about 89 individuals.
Keywords: *ECOPATH with ECOSIM, trophic modeling, energy flow, food web, ecosystem*

Introduction

Capacity originates from the logistic equation of population ecology. It was originally a term in animal husbandry management and has now become an important concept in wildlife management. Leopold (1933) was the first to propose the definition of capacity to be the maximum number of wild animals allowed to survive in an environmental condition. Later, a number of scholars successively proposed the definition of tolerance. For example, Edwards et al. (2013) defined the capacity as the maximum population quantity that can be obtained in the habitat under the environmental conditions favored by the animals within a specific time interval (usually 1 year) without the occurrence of ecosystem degradation and damage to animal quality. Over the years, the carrying capacity concept has been used to describe the growth limits of natural populations, account for resource use by rising human populations and make environmental management decisions (Chapman and Byron, 2018). Animals exist in specific habitats, and changes in habitat conditions will directly or indirectly affect the survival and reproduction of these animals and the sizes of the populations. Therefore, the carrying capacity is not a long-term stable value and will change with changes in various

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69816994

ecological factors in the habitat. It becomes a relative constant only for a specified period (Storch and Okie, 2019).

ECOPATH is a mass-based, static, and ecosystem-based model that takes all trophic levels of the ecosystem into account and is mainly used to simulate ecosystem status and internal energy flows (Zhu et al., 2020). Researchers have evaluated carrying capacity through the ECOPATH model based on the assumption that the carrying capacity value is reached when the population increase made the model unbalanced (Byron et al., 2011; Ferreira et al., 2018). This approach represents an advance in that it places the organism at an ecosystem level to assess the carrying capacity. ECOSIM allows for the temporal exploration of potential impacts of a further increase in population based on dynamic species interaction, and has been used for carrying capacity evaluation (Gao et al., 2018; Outeiro et al., 2020).

The Tian-E-Zhou Oxbow is an ex-situ reservation. Five Yangtze finless porpoises (*Neophocaena asiaeorientalis asiaeorientalis*) were moved there in 1990. After years of development, a population of about 60 finless porpoises was present in the site in 2015 (2015 census data). The water area of the Tian-E-Zhou Oxbow has shrunk in recent years due to climate change and the development of the surrounding shoals. In addition, the water quality in the oxbow has been deteriorating. It is, therefore, necessary to calculate whether the population of the Yangtze finless porpoise has reached the saturation state. If the population density is too high, measures should be taken to improve the habitat. Therefore, the assessment of carrying capacity is of vital importance for both species protection and habitat protection in the reserve.

In order to achieve this goal, we built a nutrition ecosystem network channel model (ECOPATH) in Tian-E-Zhou Oxbow with Yangtze finless porpoise population, fishery resources survey database, and other aquatic biological resources survey data. The ecosystem characteristics and energy flow regularity of the Tian-E-Zhou Oxbow were systematically analyzed, the carrying capacity of the Yangtze finless porpoise was estimated and the main factors affecting the carrying capacity were analyzed.

Materials and Methods

Study area

The Tian-E-Zhou Oxbow (112°31'-112°37' E, 29°46'-29°51' N) is located on the northern bank of the Yangtze River about 20 km downstream of Shishou City, Hubei Province, central China (*Fig. 1*). It is oxbow shaped and was originally the main channel of the Yangtze River. It was formed by the natural cutting and straightening of the Yangtze River in 1972. The oxbow is 20.9 km long, with a water surface width of 0.2-1.5 km, average water depth of 4.5 m, and a total area of about 20 km^2.

Model description

In this study, the ECOPATH method was used to construct the nutrition network model in the Tian-E-Zhou Oxbow ecosystem. This method was originally proposed by Polovina (1984) of the Hawaii Institute of Oceanography in the United States and was used to describe the biological production and food digestion processes of aquatic ecosystems in a stable state. Subsequently, combined with the ecological theory of energy analysis of Ulanowicz (1986), it gradually developed into a method of quantitative analysis of ecosystem structure and function.

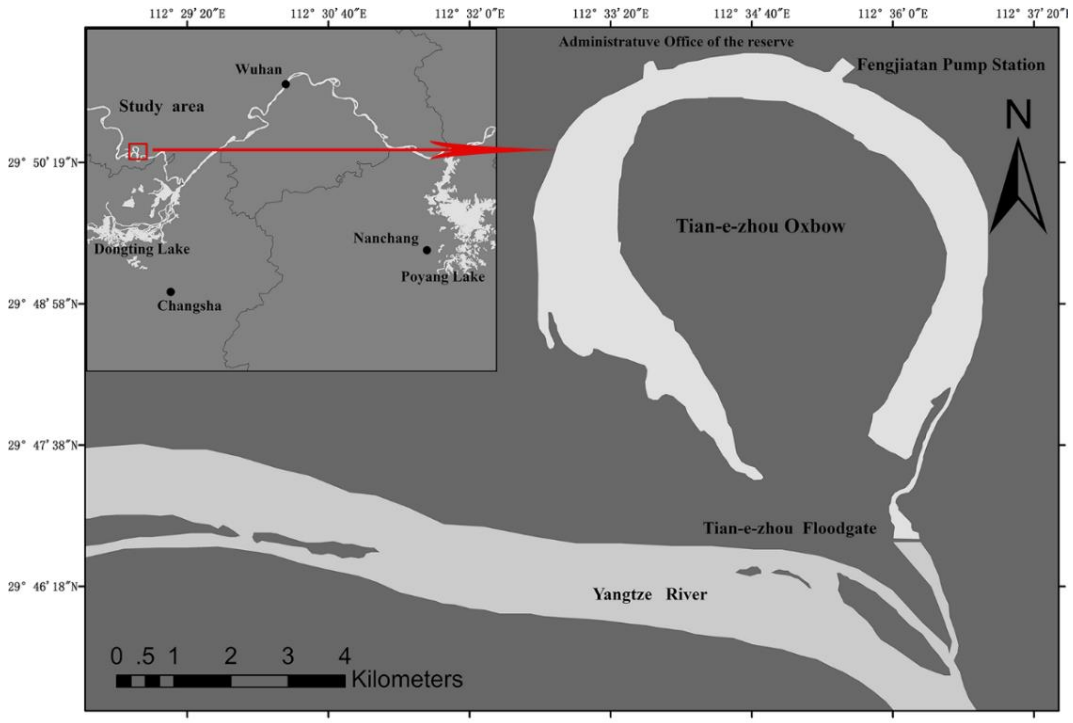

Figure 1. *Location of the study area*

The ECOPATH model defines that an ecosystem is composed of a series of ecologically related functional groups, all of which can combine to cover the process of energy flow in an ecosystem. The model assumes that the energy input and output balance of each functional group can be described by the following formula (Christensen et al., 2008):

$$\boldsymbol{B_i \times (P/B)_i \times EE_i - \sum_{j=1}^{n} B_j \times DC_{ji} - Y_i - B_i = 0} \qquad \text{(Eq.1)}$$

In type, the $\boldsymbol{(P/B)_i}$ is the ratio of functional group i production and biomass, $\boldsymbol{(Q/B)_j}$ for predation function group j consumption and the ratio of biomass, $\boldsymbol{DC_{ji}}$ prey for functional groups of the predator functional group j I always prey on quantity proportion, $\boldsymbol{\sum_{j=1}^{n} B_j \times (Q/B)_j \times DC_{ji}}$ on behalf of the functional groups were all in the amount of functional groups feeding.

The ECOPATH model needs to input the basic parameters including biomass $\boldsymbol{B_i}$, biological turnover ratio $\boldsymbol{(P/B)_i}$, consumption and biomass ratio $\boldsymbol{(Q/B)_i}$, the ecological efficiency of $\boldsymbol{EE_i}$, food nutrition matrix $\boldsymbol{DC_{ji}}$ and total catches a $\boldsymbol{Y_i}$. Any one of the first four parameters can be unknown. The other parameters are calculated by the model, but $\boldsymbol{EE_i}$ is the best to have as an unknown quantity, because the parameters are difficult to measure directly. The latter two parameters, namely food composition $\boldsymbol{DC_{ji}}$, and catch quantity $\boldsymbol{Y_i}$, require input.

The results of the biomass and ecological network analysis indicators total system throughput (TST) (Ulanowicz, 2012), biomass, primary production, respiration, transfer efficiency (Christensen and Walters, 2004), Connectance index, Finn's cycling index

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69816994

(Finn, 1976), system omnivory index and Finn's mean path length were downloaded from ECOSIM and ECOSIM network analysis in ECOPATH (Christensen et al., 2005; Behera et al., 2020).

The data source

In this study, the biomass data of finless porpoises were obtained from the population census in 2015. Fish data were obtained from the fish catch and hydroacoustic survey in October 2014, and the other data were obtained from the biological resources survey of the reserve in 2011 as well as published literature and scientific investigation reports on the Tian-E-Zhou Oxbow (e.g., Wang et al., 2012; Sun et al., 2013; Ma et al., 2014).

Functional group division

First, the main biological groups or species in the Tian-E-Zhou Oxbow ecosystem were divided into 18 functional groups according to their biological and ecological characteristics, namely, classification status, nutritional type, individual size, and the water layer they occupied (Christensen et al., 2005; Guo et al., 2013; Li et al., 2018). Species of significant ecological or economic value that needed to be analyzed separately were treated as functional groups for easy study. See *Table 1* for the names of each functional group and the main categories it includes. Among them, the detrital functional group was necessary to construct the nutrition network model. The two functional groups of large aquatic plants and phytoplankton belong to the primary producers, while the remaining 15 functional groups are all consumers, covering the primary consumers, secondary consumers, and top consumers. The defined 18 functional groups can cover the entire process of energy flow in the oxbow ecosystem.

Table 1. *Classification of functional groups within Tian-E-Zhou Oxbow ecosystem*

Number	Functional group	Species composition
1	Finless porpoise	*Neophocaena asiaeorientalis asiaeorientalis*
2	Snakehead fish	*Channa argus*, *Siniperca chuati*
3	Topmouth culter	*Culter alburnus*, *Culter dabryi*, *Culter mongolicus*
4	Catfish	*Pelteobagrus fulvidraco*, *Pelteobagrus eupogon*, *Silurus asotus*, etc.
5	Common carp	*Cyprinus carpio*
6	Crucian carp	*Carassius auratus*
7	Small pelagic fish	*Hemiculter leucisculus*, *Hemiculter bleekeri*, *Toxabramis swinhonis*, *Hyporhamphus intermedius*, *Coilia brachygnathus*, etc.
8	Small bottom fish	*Pseudorasbora parva*, *Rhinogobius giurinus*, *Abbottina rivularis*, *Sarcocheilichtys nigripinnis*, *Rhodeus ocellatus*, *Pseudorasbora parva*, etc.
9	Silver carp	*Hypophthalmichthys molitrix*
10	Bighead carp	*Aristichthys nobilis*
11	Bluntnose bream	*Megalobrama amblycephala*, *Parabramis pekinensis*, *Ctenopharyngodon idellus*
12	Other fish	*Xenocypris davidi*, *Squaliobarbus curriculus*, etc.
13	Shrimp and Crabs	*Macrobrachium nipponense*, etc.
14	Zoobenthos	Mollusca, Insecta, Oligochaeta, etc.
15	Zooplankton	*Rotifer*, *Cladocera, Copeoda*, etc.
16	Phytoplankton	*Phytoplankton*
17	Macrophyte	plants
18	Detritus	Decayed animal and plant, etc.

Parameter settings

Yangtze finless porpoise

The biomass of Yangtze finless porpoise was obtained according to the population census data in the reserve in 2015. The P/B coefficient and Q/B coefficient refer to the setting coefficient of other ECOPATH models and the harbor porpoise of the same family and close weight, respectively 0.02 and 15 (Nurhakim, 1979; Plaganyi and Butterworth, 2005).

Fish

The total biomass of fish was obtained from 2014 hydroacoustic and catch survey data. According to the results of the hydroacoustic survey (unpublished data), the volume density of fish in the Tian-E-Zhou Oxbow was 0.18 Ind./m^2, which was converted to 0.81 Ind./m^2 of biomass. The P/B value of fish is derived from the following formula (Beverton and Holt, 1957; Pauly, 1980):

$$F = Y / B \quad \text{(Eq.2)}$$

$$P / B = Z = F + M \quad \text{(Eq.3)}$$

$$M = K^{0.65} \times L_{\infty}{}^{-0.279} \times T_c{}^{0.463} \quad \text{(Eq.4)}$$

Y and B represent catch and fish biomass, respectively. While F and M stand for fishing mortality and natural mortality, respectively, K is the parameter of the Von Bertalanffy growth equation, $\boldsymbol{L}_{\infty}$ and is the asymptotic value of the body length of the Von Bertalanffy growth equation, K and $\boldsymbol{L}_{\infty}$ are obtained by a FishBase database query. T is the average annual water temperature (℃).

The Q/B coefficient of fish is obtained by the empirical formula of Palomares and Pauly (1998).

Shrimp and crab

The biomass P/B and P/Q values of shrimp and crab were referenced to freshwater lakes or reservoirs in the Yangtze River basin at the same latitude (Halfon et al., 1996; He et al., 2000; Christensen et al., 2000; Deng et al., 2014).

Benthic and plankton

The biomass of benthic fauna, zooplankton and phytoplankton was based on the 2011 survey data of aquatic organisms, averaging 14.03 t/km^2, 16.2 t/km^2 and 32.4 t/km^2, respectively. The P/B and Q/B coefficients were obtained by referring to results from other lakes at the same latitude or by estimating the P/Q coefficients (Yan and Liang, 2003; Liu et al., 2007; Zeng et al., 2011).

Detritus

Detritus includes both bacterial and organic detritus, and the bacterial biomass is estimated at 17.5% of the phytoplankton biomass according to Heymans et al. (2004), and this result can be used generally. The biomass of organic debris was estimated by referring to the linear model proposed by Pauly et al. (1993).

Model debugging

Because the ECOPATH model builds a steady-state system model, the energy flow budget for each functional group must be balanced. First, ecological nutrition efficiency EE = (feed intake + catch)/ production. The sum of predation and catch in a functional group should be greater than 0 and less than its production, so 0<EE<1. The EE value of the functional group under high predation or fishing pressure in the system can be close to 1. Some underutilized functional groups usually have low EE values. Second, the respiration rate of each functional group must be greater than 0, and the R/B coefficient (the ratio of respiration rate to biomass) of fish should be between 1 and 10. Finally, the P/Q coefficient of the functional group represents the ratio of production to consumption, which is generally distributed between 0.1 and 0.3 in ecology, but may be less than 0.1 for some vegetative functional groups. When running the ECOPATH model, if these conditions are not met, the model cannot achieve balance or will lack the necessary biological significance. The researcher can then repeatedly adjust other input parameters in an appropriate range of settings, such as B, P/B, or Q/B, and the composition of food, to find the equilibrium that has the actual meaning of the optimized parameter values while debugging steps of the specific reference (Christensen et al., 2008).

Result

Model output parameters and ecological significance

After the ECOPATH food web model of the Tian-E-Zhou Oxbow ecosystem had been balanced from 2011 to 2014, its basic parameters were summarized in *Table 2*. Since the biomass accumulation and migration of each functional group were all 0 in this study, the ecological nutrient conversion efficiency EE reflects the degree to which the production of each functional group is utilized by predation and fishing. It can be seen from *Table 2* that the EE values of channa Argus, silver carp, and bighead ranged from 0.769 to 0.831, indicating that they were highly utilized, which was consistent with the annual catch of the oxbow. The EE value of small pelagic fish was 0.823, mainly due to the influence of the feeding pressure of the Yangtze Finless porpoise. The EE value of zooplankton was as high as 0.918, which was related to silver carp and bighead. Phytoplankton, large aquatic plants, and detritus were not utilized to a high degree (EE values were 0.21, 0.35, and 0.035, respectively).

Overall features of the Tian-E-Zhou Oxbow ecosystem

The total system throughput (TST) of the aquatic ecosystem of Tian-E-Zhou Oxbow was 19271.490 t/km^2/year, the total production (TP) of the system was 8977 t/km^2/year, and the total primary productivity (TPP) was 8486.625 t/km^2/year, accounting for 94.53% of the total production (*Table 3*).

The ratio of total primary productivity (TPP) to total respiration (TR) of the system (TPP/TR) is an important indicator of system maturity. Generally, the value of TPP/TR in a mature ecosystem is close to 1, while TPP/TR>1 in a developing system. TPP/TR<1 for systems exposed to organic pollution (Odum, 1971). The TPP/TR=18.131 (*Table 3*) indicates that the Tian-E-Zhou Oxbow ecosystem is still a developing system.

The connection index (CI) and System omnivory index (SOI) are indicators of the complexity of the connections within an ecosystem, and the CI and SOI are higher, meaning that the system within the greater the chance of a variety of nutrients can be

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69816994

reused. The ecosystem is a more stable and mature system of CI index between the functional groups, and the SOI index value is close to 1 (Odum, 1971; Christensen, 1995). The CI and SOI indices of the Tian-E-Zhou Oxbow were 0.267 and 0.262 (*Table 3*), respectively, indicating that the degree of aggregation and stability among the functional groups of the ecosystem was low.

Finn's mean path length, FML	2.271	2.271	

Note: V1 is means the current status of the system (2011-2015); V2 is means the status at ecological carrying capacity for the Yangtze finless porpoise. The calculation method of all parameters is based on Christensen et al. (2005)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69816994

Finn's circulation index (FCI) is the ratio of the circulation flow to the total flow in the system, and Finn's average path length (FML) is the average length of each cycle through the food chain. The higher the proportion of material recycling, and the longer the food chain through which the nutrient flow passes, the higher the system maturity (Christensen, 1995). The FCI and FML of the Tian-E-Zhou Oxbow ecosystem were 2.488% and 2.271 (*Table 3*), respectively, indicating that the water area had low material and energy recirculation ratio, short flow path, and the system was in the early stage of development.

Nutrient-level structure and material energy flow of the Tian-E-Zhou Oxbow ecosystem

The trophic levels of each functional group in the Ecosystem of Tian-E-Zhou Oxbow were divided into 7 discrete trophic levels (*Table 4*). It can be seen from the table that detritus and two primary producers completely occupy the nutritive grade I. The vegetative or omnivorous consumer functional group mainly occupied the trophic level II and III, among which zooplankton completely occupied the trophic levels II. Carnivorous fish and the functional group of the Yangtze finless porpoise mainly occupied the III and IV nutritional grades, and a small amount occupied the V and VI nutritional grades; the trophic level was completely dominated by the Yangtze finless porpoise. According to the specific flow distribution of each discrete trophic level, the nutrients in the Ecosystem of Tian-E-Zhou Oxbow mainly flowed between the first five discrete trophic levels. The traffic for the Ⅵ and traffic Ⅶ nutrition levels was very low, less than 1%, and can be ignored.

Table 4. *Trophic level decomposition of the functional groups in Tian-E-Zhou Oxbow ecosystem*

Functional group	Trophic level						
	Ⅰ	Ⅱ	Ⅲ	Ⅳ	Ⅴ	Ⅵ	Ⅶ
Finless porpoise			0.484	0.474	0.0387	0.00280	0.000022

Detritus	1.000						

The total flow of a trophic level is the sum of the flux of all substances flowing through it per unit time. The total capacity of each trophic level is affected by respiration, arrests, food intake, catches, and the amount of debris. The transfer efficiency of each trophic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69816994

level is equal to the ratio of the sum of its food intake and catch to the total flow, indicating the efficiency of utilization of the trophic level in the ecosystem. The energy flow process among different trophic levels in the Tian-E-Zhou Oxbow is shown in *Fig. 2*. Trophic level I includes phytoplankton and detrital functional groups, so the energy flow process of the Tian-E-Zhou Oxbow ecosystem can be divided into the grazing food chain and the detrital food chain. After the two food chains were merged, the transfer efficiency of trophic levels II, III, IV, V, VI, and the two food chains in the Tian-E-Zhou Oxbow ecosystem, in turn, were 9.0%, 11.9%, 11%, 10.9%, 10.2%, and 5.3%, respectively, with a total average conversion efficiency of 10.5% (*Table 5*).

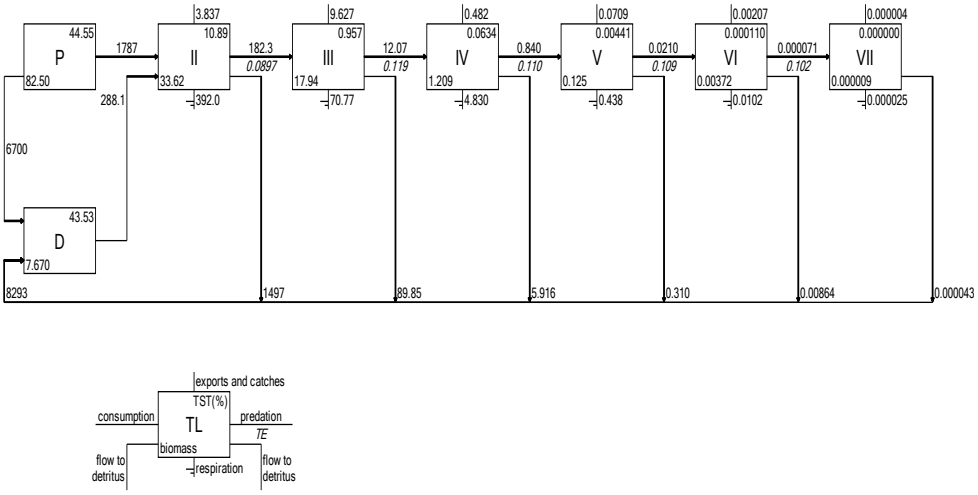

Figure 2. *Trophic flows transferred along trophic levels in Tian-E-Zhou Oxbow ecosystem*

Detrital pathway conversion efficiency: 11.2%						
Total conversion efficiency: 10.5%						

The carrying capacity of theYangtze finless porpoise in the Tian-E-Zhou Oxbow

The Yangtze finless porpoise is the top predator of the Tian-E-Zhou Oxbow ecosystem and a major conservation target of the Reserve. As the population continues to grow, it may cause a significant change in the energy flow of the Tian-E-Zhou Oxbow ecosystem. According to the definition of the carrying capacity in this study, when the population of the Yangtze finless porpoise in the ecosystem gradually increases, the predation pressure on its food resources is bound to increase, resulting in EE greater than 1. Then, the ecosystem is destroyed, and the model is out of balance. At present, the population is the carrying capacity of the Tian-E-Zhou Oxbow. In the iterative process, the biomass

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69816994

(population number) of the finless porpoise continuously increased. When it increased to 0.207 t/km^2, the model was not balanced. At this time, EE >1 in the upper-middle and upper small fish functional groups was >1 (*Table 6*). Therefore, it is estimated that the average biomass of the finless porpoise supported by the Tian-E-Zhou Oxbow ecosystem is 0.207 t/km^2 (about 89 individuals).

Table 6. *Changes in Tian-E-Zhou Oxbow ECOPATH model while estimating the carrying capacity of Yangtze finless porpoise*

Frequency	The biomass of the Yangtze finless porpoise(t/km^2)	EE of Small pelagic fish	Changes in the model
1	0.138	0.823	Balance
2	0.148	0.838	Balance
3	0.158	0.874	Balance
4	0.168	0.900	Balance
5	0.178	0.926	Balance
6	0.188	0.952	Balance
7	0.198	0.977	Balance
8	0.208	1.003	No balance
9	0.207	1.001	No balance
10	0.206	0.998	Balance

Discussion

The Tian-E-Zhou Oxbow was originally the channel of the Yangtze River, which naturally curved and straightened. It was seasonally connected to the Yangtze River; however, after the completion of the Tian-E-Zhou Oxbow floodgate in 1998 (*Fig. 1*), it was cut off from the Yangtze River, so its ecosystem features are similar to lakes or small reservoirs. Due to the lack of large aquatic plants, the total flow was only 62.62 t/km^2 year^{-1}, which was much lower than the total flow of phytoplankton (8424 t/km^2 year^{-1}) (*Fig. 2*). Because the biomass of herbivorous fish is very small, the primary producer of the grazing food chain in the Tian-E-Zhou Oxbow ecosystem is the phytoplankton. However, the detrital food chain is also a significant energy flow channel, and the detrital energy flow accounts for 45% of the total flow of the system. In *Fig. 2*, we found that the total amount of organisms flowing into the debris of the biological chain finally reached 8290 t/km^2 year^{-1}, indicating that there was still a large quantity of nutrients left in the Tian-E-Zhou Oxbow ecosystem. This nutrient load has caused the deposition of a large amount of unused debris at the bottom of the water body, increasing the endogenous pollution and resulting in a nutrient excess and the emergence of a large amount of phytoplankton. The main fish species, including free-range silver carp, bighead, and a large number of silver carp, are caught every year. It can also be seen from *Fig. 2* that the output of nutrient grades II (3.837 t/km^2 year^{-1}) and III (9.627 t/km^{2}year^{-1}) is the largest, and they are the main exporters.

According to the ecosystem development described by Odum (1971) and Christensen (1995), TPP/TR is >1 in the immature ecosystem and will approach 1 when the ecosystem becomes mature. The Ecopath model has been constructed for many lakes to assess the maturity of aquatic ecosystems. The TPP/TR ratio was 18.13 in the Tian-E-Zhou Oxbow ecosystem (*Table 3*). This ratio was higher than that of most lakes in China, including Shangshe, Gehu, Dianchi, Chaohu, Taihu (Jia et al., 2012; Li et al., 2013, 2019; Shan et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69816994

al., 2014; Kong et al., 2016). That may because the Tian-E-Zhou Oxbow was cut off with Yangtze River in 1998 and belongs to a relatively young lake.

The average conversion efficiency of the general ecosystem was approximately 10% (Lindeman, 1942), while the conversion efficiency between the trophic levels of the Tian-E-Zhou Oxbow ecosystem was 10.5% (*Table 5*), which is relatively close. However, the conversion efficiency between grade I and grade II in primary producers is low (8.7%) (*Table 5*), which may be due to a suboptimal proportion of silver carp and bigheads, resulting in a loose connection between functional groups. On the one hand, the filter pressure of silver carp on phytoplankton is low; on the other hand, the pressure of bighead, which is large, is high, which leads to less feeding of phytoplankton by the bighead, which will lead to the overgrowth of phytoplankton which cannot be fully utilized, and there is the risk of "bloom". Therefore, it is suggested that the stocking ratio of silver carp and bighead in the Tian-E-Zhou Oxbow should be adjusted to a level that is beneficial to the stability of the ecosystem.

By improving the conversion efficiency of residual nutrients and the ecosystem characteristics of the Tian-E-Zhou Oxbow, the aim is to improve the habitat quality of the Yangtze finless porpoise and expand the carrying capacity of the oxbow to accommodate the porpoise and protect the population more effectively. In this study, the carrying capacity of the Tian-E-Zhou Oxbow for the finless porpoise was 0.207 t/km^2, accounting for about 89 individuals (*Table 6*). According to this study (*Table 2*), the biomass of the small fish is the main factor affecting the carrying capacity of the habitat for the finless porpoise.

The carrying capacity is a fundamental feature of wildlife conservation biology that influenced by many factors. For example, in aquatic ecosystems, the primary productivity of the animal habitat determines the amount of plant growth available, and plant growth is under the influence of various physical and chemical factors in the water (Hobbs et al., 1985). The availability of plants is closely related to the limitation of the mobility of aquatic animals (Hobbs et al., 1982). The efficiency determines the primary consumers of resources, layer upon layer, top determines the number of consumers. The purpose of estimating the carrying capacity of the Tian-E-Zhou Oxbow for the Yangtze finless porpoise is to determine the capacity of the system from the perspective of energy balance. The ECOPATH model itself does consider the biological growth changes at each trophic level; it only takes fixed parameter values and does not take into account the spatial changes. Therefore, there is still a shortage of biological variables, such as life history. The carrying capacity is a process of dynamic change that can be influenced by both population and habitat changes of species. Therefore, dynamic changes that cannot be described by the static model need to be considered when calculating the carrying capacity. However, the estimation method of carrying capacity used in this study can provide a referential calculation method for the selection of future protected areas, which can help determine the carrying capacity of ex-situ reserves for the Yangtze finless porpoise.

Conclusion

In this study, a food web model of the Tian-E-Zhou oxbow ecosystem was developed based on the EwE modeling framework. The aim is to use the model to estimate the ecological carrying capacity of the Tian-E-Zhou oxbow ecosystem for the Yangtze finless porpoise. The model shows that the material and energy recycling was low, together with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69816994

a low connectance index (CI), system omnivory index (SOI), Finn's cycled index, and Finn's mean path length, indicating that the Tian-E-Zhou ecosystem is an immature ecosystem and still at its development stage. Finally, based on the ECOPATH model, the carrying capacity of the Tian-E-Zhou reserve for Yangtze finless porpoise was 0.207 t/km^2, accounting for about 89 individuals. The ecological capacity of target species in the Tian-E-Zhou ecosystem is determined on the basis of mass balance, without further consideration for spatial changes and life history. The set of parameters used to determine the ecological carrying capacity is one of the possible parameter combinations that can achieve similar results. This model is open for further improvement. In addition, DNA barcoding for prey identification or a combination of DNA-barcoding and stable isotope analyses may further elucidate the energy flow of the Tian-E-Zhou ecosystem as well as enable proper evaluation of the carrying capacity of Tian-E-Zhou reserve for the Yangtze finless porpoise.

Abstract. Grazing exclusion by fence was often used in the management of grassland ecosystems. However, the direction and the strength of effects of grazing exclusion on grassland vegetation characteristics and community diversity are currently disputable. In addition, little research was conducted on the effects of grazing exclusion on vegetation phenology. In this study, we aim to determine the effects of grazing exclusion on vegetation characteristics, community diversity and vegetation phenological periods. For this, we performed a fencing experiment in three grassland types in Mongolia. Each grassland type was set by two treatments: grazing exclusion and freely grazing. We found that grazing exclusion generally increased vegetation height regardless of grassland type. In contrast, variations of vegetation cover caused by grazing exclusion were not consistent in three grassland types. Grazing exclusion decreased species richness and Shannon diversity. However, community evenness varied little without grazing disturbances. Grazing exclusion advanced the vegetation phenological periods in three grassland types. This study fills the knowledge gap of the effects of grazing exclusion on vegetation characteristics, community diversity and vegetation phenological development in Mongolian grasslands. Other management strategies like rotational grazing and reseeding are encouraged to be used in tandem with grazing exclusion to restore Mongolian rangelands.
Keywords: *vegetation cover, species richness, Shannon-Wiener diversity, phenological periods, grassland type*

Introduction

Grasslands are an important component of terrestrial ecosystems and greatly influence provisions of ecosystem services like food supplies, biodiversity maintenance and climate regulation (Solen et al., 2019). Grasslands sustain nomadic peoples and facilitate the production of livestock (Kemp et al., 2013). However, increasing anthropogenic activities, in particular livestock volume and the resulting overgrazing often cause grassland degradation, especially in arid and semi-arid regions (Ahlborn et al., 2020; Bosch, 1989). Overgrazing significantly alters the community structure through decreasing vegetation cover and species diversity (Mysterud, 2006). Simultaneously, overgrazing has important management implications, since it leads to great losses of economic resources and threatens plant diversity (Stein et al., 2016).

To restore degraded grassland ecosystems, grazing exclusion by fence is a useful management practice (Xiong et al., 2016). Fencing can be regarded as a direct reference to determine the benefits of grazing removal on ecosystem services and functioning in grasslands (Davies and Boyd, 2019). Nevertheless, grazing gradient experiments focus

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69957009

on ecological consequences of livestock grazing intensity (Stein et al., 2016). Degraded grasslands enter self-recovery state in case grazing activities are forbidden for a suitable period (Golodets et al., 2010). A large number of researches have been conducted to examine effects of grazing exclusion on vegetation characteristics and diversity under different grazing regimes (Augustine et al., 2017; Koch et al., 2017; Sagar et al., 2019; Yao et al., 2019). Grazing exclusion by fence often increases vegetation height and cover (Li et al., 2014; Zhu et al., 2016a). However, the findings are not consistent in terms of plant diversity. Palatable plant species may benefit from fencing owing to their fast tissue regrowth (Guo et al., 2016). Grazing exclusion may decrease richness of grazing avoided species since slow growing tissue constrains their competition capacity (Rota et al., 2016). In addition, the response of community diversity to grazing exclusion is largely determined by fencing time. Grazing history strongly affects the forage quality of grasses (Adler et al., 2004). Long-term grazing exclusion by fence generally has negative effects on the community diversity owing to density effects (Wu et al., 2009; Yao et al., 2019). Short-term grazing exclusion is beneficial for the community vegetation diversification since most of plant species rapidly grow without grazing (Zhang and Zhao, 2015). Oppositely, grassland species richness and diversity were also found to increase under the condition of long-term grazing exclusion (Sagar et al., 2019; Zhu et al., 2016a). Several studies show that grazing exclusion by fence plays little role in maintaining grassland plant diversity (Koch et al., 2017; Xiong et al., 2016). These fencing experiments were implemented in different grassland types characterized by specific combinations of plant species. Diverse responses of plant species to grazing exclusion largely shape the structure and the diversity of grassland communities. However, it needs to be strengthened for effects of grassland type and their interaction with grazing removal time on characteristics and the diversity of vegetation communities. Nevertheless, several long-term grazing exclusion experiments have been carried out to explore these effects (Goheen et al., 2018; Irisarri et al., 2016).

Besides vegetation characteristics and community diversity, grazing exclusion also strongly affects vegetation phenological development. Key aspects of vegetation phenology such as green up, seeding and flowering have profound implications for restoration of degraded grasslands. Short-term grazing exclusion advances the phenology of *Kobresia pygmaea* (Zhu et al., 2016b). Moreover, grazing alters the flowering probability of the short-lived perennial *Cirsium vulgare* (Marco and Silvertown, 2014). Annual grass species in the ungrazed plots flower earlier than in the grazed ones (Bergmeier, 1998). However, different species have distinctive sensitivities and subsequent phenological response to grazing exclusion. In addition, the consequences of grazing for the same species are likely to vary across different grassland types, which are characterized by site-specific grazing history and vegetation community properties (Stahlheber and D'Antonio, 2013). Therefore, currently available work needs to be strengthened towards clarifying the effects of grazing exclusion on the vegetation phenology.

To fill the above-mentioned knowledge gap, the study was conducted in three grassland types of Mongolia, namely meadow, mountain steppe and dry steppe. Grasslands occupy 83.4% of the land area in Mongolia, while the nomadic people are the majority among population (Li et al., 2005). Livestock grazing is a traditional land use form of the Mongolian grasslands (Ahlborn et al., 2020). With an increase of the population, most grasslands in Mongolia are experiencing overgrazing and an increased threat of degradation (Wang et al., 2020). Restoring the degraded grasslands is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69957009

necessary for a long-term utilization of natural resources in the vast grassland region. Although a grazing restriction has been implemented for a period in this area, little is known about effects of grazing exclusion on vegetation characteristics, community diversity and vegetation phenology. We examined the response of these factors to grazing exclusion through performing a 6-10 years enclosure trial and addressed the following questions: (1) How does grazing exclusion by fence affect vegetation characteristics and community diversity in Mongolian grasslands? (2) Is the impact of grazing exclusion dependent on grassland type? (3) How does vegetation phenology respond to grazing exclusion?

Materials and methods

Study site

Three grassland types, namely dry steppe (47°12' N, 108°44' E), mountain steppe (48°17' N, 108°43' E) and meadow (48°11' N, 108°26' E), are located in the southeast of the Ulaanbaatar on the Mongolian Plateau (*Fig. 1*). According to historical climatological data from 1993 to 2002, mean annual temperature is 1.2 ℃, with the highest mean daily temperature in July (21.4 ℃) and the lowest temperature in January (-22.9 ℃). Mean annual precipitation is less than 200 mm. More than 50% of annual precipitation occurs during the vegetation growing season (June to September). The soil of the area is mostly composed of burozem and of a high calcium content. The vegetation communities in three grassland types are characterized by various combinations of dominant species: *Potentilla anserine*, *Carex duriuscula*, *Carex pediformis*, *Carex coriophora* and *Taraxacum cerataphorum* in the meadow; *Potentilla acaulis*, *Aster alpinus, Festuca lenensis, Carex pediformis* and *Stipa baicalensis* in the mountain steppe; *Artemisia frigida*, *Allium bidentatum*, *Artemisia adamsii*, *Kochia prostrata* and *Astragalus galacitites* in the dry steppe. Most plant species in the area green up in late April and senesce in late October. The average grazing intensity is 7 large stock units per 100 ha in the meadow and the mountain steppe, while a heavier grazing intensity occurs in the dry steppe with a value of 11 large stock units per 100 ha. One large stock unit could be simply deemed as 1 cow.

Experimental design

To examine effects of grazing exclusion on vegetation characteristics, community diversity and vegetation phenology of the Mongolian grasslands, the enclosure was set up to completely exclude livestock grazing in the meadow from 2009, the mountain steppe and the dry steppe from 2013 (*Fig. 2*). We set one enclosure in each grassland type. Each enclosure covered an area of 0.1 ha (50 m × 20 m). Three sites of the enclosure were selected over a homogeneous area and had similar geographical conditions like slope, elevation and soil types. A freely grazed area was selected as the control treatment nearby the enclosure of each typical grassland. That is, each grassland was carried out by two treatments: grazing exclusion by fence (GE) and freely grazing (FG). In 2013, we randomly sampled ten quadrats (1 m × 1 m) of fenced plots in the mountain steppe and the dry steppe respectively. Similarly, we chose ten quadrats (0.5 m × 0.5 m) of fenced plots in the meadow, where grasses were much denser. The quadrats in the fence had a distance of 5 m to fence margins to minimize edge effects. Simultaneously, ten quadrats were separately sampled in grazed plots for three grassland types. The quadrats in grazed plots had the same distance of 20 m to the corresponding ones in fenced plots. We used a bootstrapping method to sample 3 quadrats from 10 for both fenced and grazed plots in each grassland. We performed the implementation 10 times in three grassland types respectively. We found that a small number of quadrats depicted well general changes in vegetation cover regardless of treatments and grassland type (see *Table A1* in the Appendix). Thus, we separately determined three quadrats in the dry steppe, the mountain steppe and the meadow. Then we sampled the same quadrats in the following years. We used the same quadrats to weaken confounding effects of abiotic factors like soil properties on the vegetation communities. Effects of grazing exclusion on grassland communities were often studied from a taxonomic perspective. Thus, the number, the height, vegetation cover and phenology of plant species, as well as the number of species individual were investigated in each quadrat at the end of August (late in the growing season) of every year. We measured vegetation cover through visual estimates. Vegetation height was determined from the surface of ground to reproductive leaves or branches. The number of plant species was recorded according their vegetation cover in one quadrat. Specifically, we set a standard of the cover more than 0.05 to identify whether the species should be counted. We elaborately investigated 108 quadrats in a 6 consecutive years experiment (3 quadrats × 2 treatments × 6 years × 3 grassland types). Moreover, we tried to examine the response of vegetation palatability to grazing exclusion. We classified all the plant species into two categories according to their palatability for livestock: palatable species (grass species and sedge species) and non-palatable species (forb species, Artemisia species and leguminous species) (Yao et al., 2019). We showed palatability-related results of the vegetation characteristics and the community diversity under treatments of grazing exclusion and freely grazing (see *Table A2* in the Appendix). This aims to offer a mechanistic and supplementary interpretation of grazing exclusion effects on grassland communities.

We examined the response of vegetation to grazing exclusion in terms of phenology. Vegetation phenological periods were divided into five stages: germination, growth, bud, flower and seeds. The five periods were assigned with sequential numbers from 1 to 5 respectively. Categorization of the phenological stages followed the system of Moore et al. (1991). In case certain species had different values of phenological periods for one enclosure, the phenological period corresponding to the largest cover ratio

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69957009

(cover of one species divided by total cover of all species in one quadrat) among quadrats was determined as the phenology of the species. Then we evaluated the phenological period of the same species inside (ungrazed) and outside (grazed) the enclosure for three grassland types. To quantify effects of grazing exclusion on the vegetation phenological period, we established an evaluation index of relationship change of phenological stages (*EIRCP*) to describe phenological differences between fenced plots and grazed plots. The index was calculated according to *Equations 1* and *2*.

$$APS = \frac{\sum_{i=i}^{n} PS_i}{n} \quad \text{(Eq.1)}$$

$$EIRCP = \frac{APS_{inside} - APS_{outside}}{4} \quad \text{(Eq.2)}$$

PS_i denotes the phenological period of species i; APS denotes the average phenological period of all species inside (ungrazed) or outside (grazed) the enclosure; The number 4 represents the maximum phenological differences between inside and outside the enclosure. We assumed that it is impossible for the case that the phenological stage is 5 (seeds) in the fence plot, while the stage is 1 (germination) in the grazed plot. If EIRCP is larger than 0, then it means the vegetation phenology advances; If EIRCP is smaller than 0, then it means the vegetation phenology delays. The value of ERCIP ranges from -1 to 1.

We thereafter calculated the distribution of EIRCP relative to 0 in each grassland type. In addition, we provided species proportions in terms of phenological changes for three grassland types (see *Fig. A1* in the Appendix).

Data analysis

Vegetation characteristics of grassland communities were evaluated in terms of plant height and vegetation cover. Richness index (the number of plant species), Shannon-Wiener diversity index (*H'*) and Pielou evenness index (*E*) were calculated for each quadrat.

$$Richness = S \quad \text{(Eq.3)}$$

$$H' = -\sum_{i=1}^{S} P_i(lnP_i) \quad \text{(Eq.4)}$$

$$E = \frac{H'}{lnS} \quad \text{(Eq.5)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69957009

P_i denotes the cover ratio of species i to total species; H' denotes Shannon-Wiener index; E denotes Pielou evenness index.

We used Wilcoxon signed rank test to assess differences of the vegetation characteristics and the community diversity between grazing exclusion and grazed treatments within each year for three grassland types. Statistical analyses were performed using R software (R-core-Team, 2017).

Results

Response of vegetation characteristics to grazing exclusion

Grazing exclusion by fence significantly increased vegetation height for all three grassland types (*Fig. 3*). However, the height varied differently with grassland type. It was with a substantially higher height without grazing than the grazing scenario for the meadow, and a comparatively lower height than that of the other two grassland types under grazing treatment. Grazing exclusion generally did not facilitate the increment of vegetation cover. The response of vegetation cover to grazing also varied with grassland type. Grazing exclusion increased the cover in the dry steppe while decreased the cover in the meadow and the mountain steppe. In addition, the effect was only significant in the dry steppe. There was no clear inter-annual tendency of grazing exclusion induced variations of vegetation height and cover.

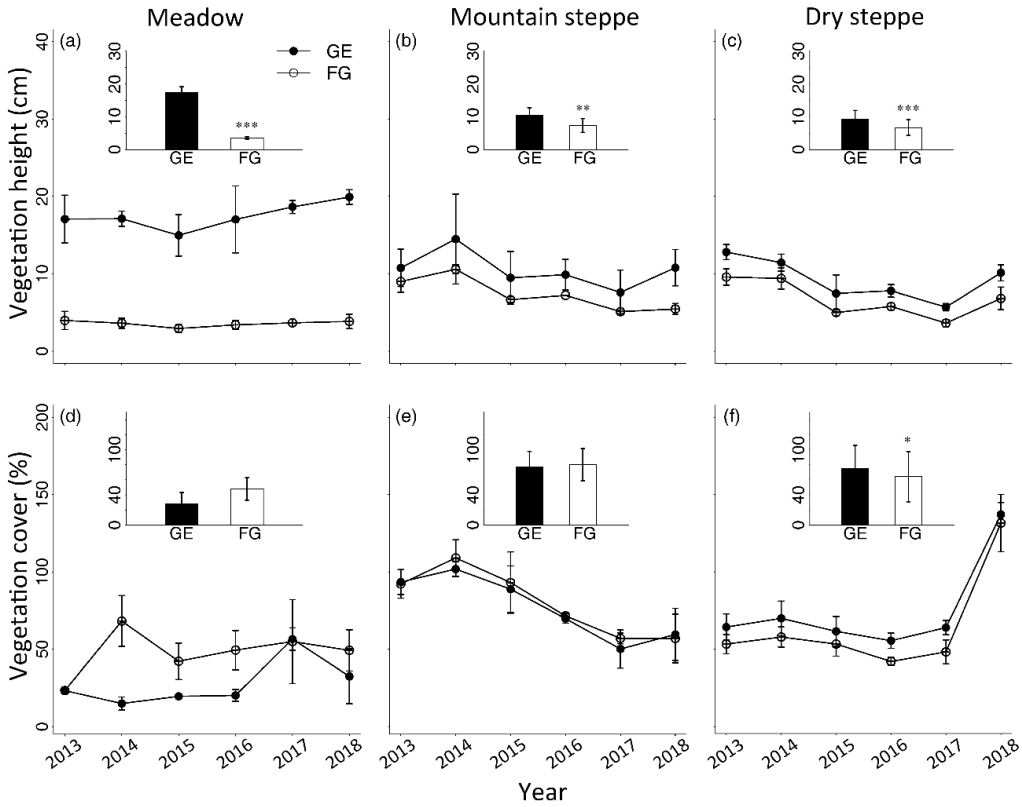

Figure 3. *Vegetation height (a, b, c) and cover (d, e, f) under two treatments: grazing exclusion by fence (GE) and freely grazing (FG) of three grassland types from 2013 to 2018. Scatter plots show time-series variations of vegetation characteristics. Bar plots attached show the average value of six years. Error bars are shown by standard deviation. Letters within bar plots indicate differences with a significant level ($P < 0.05$) between two treatments*

Response of community diversity to grazing exclusion

Grazing exclusion generally had negative effects on the species richness and the Shannon diversity in three grassland types (*Fig. 4*). Species richness in fenced plots significantly differed from that in grazed plots. Similarly, the effect of grazing exclusion suited well in terms of Shannon diversity in the meadow and the dry steppe, but performed weakly in the mountain steppe. No obvious differences of the community evenness were found between fenced plots and grazed plots. The inter-annual effects of grazing exclusion on the community diversity were lack of regularity for three grassland types.

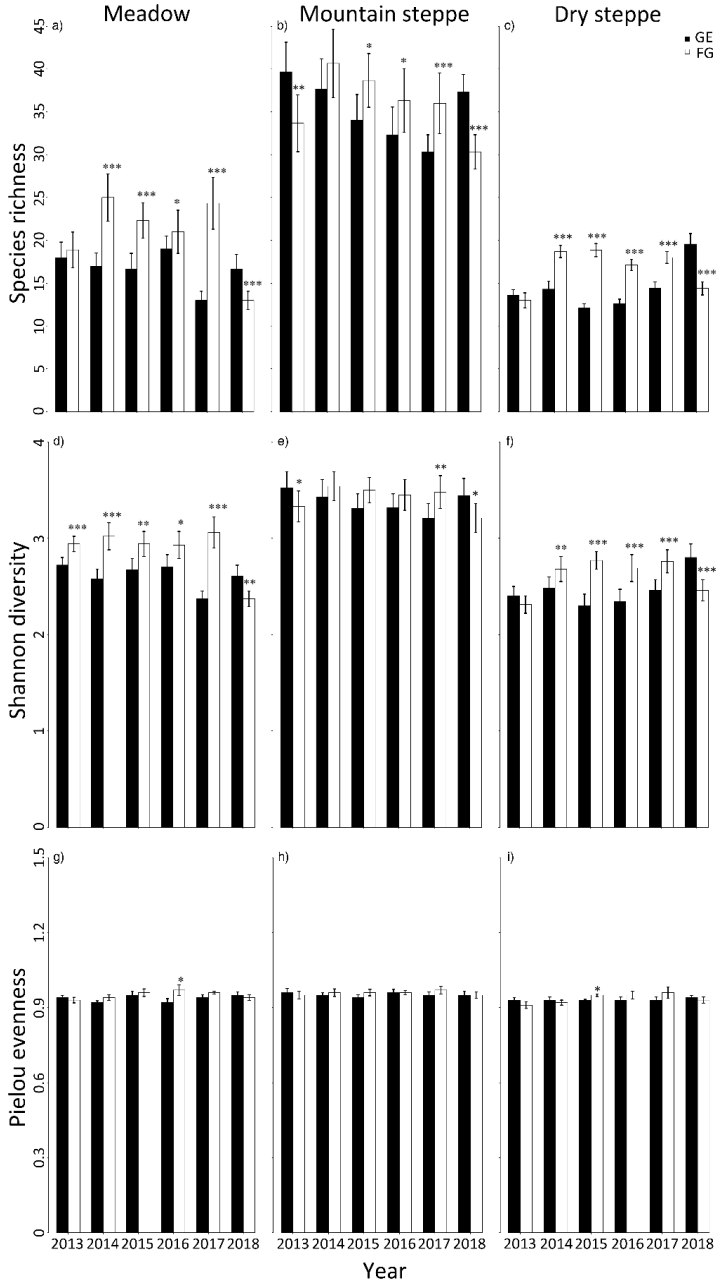

Figure 4. *Species richness (a, b, c), Shannon-Wiener diversity (d, e, f) and Pielou evenness (g, h, i) under treatments of grazing exclusion by fence (GE) and freely grazing (FG) in three grassland types from 2013 to 2018. Response of phenological characteristics to grazing exclusion

Grazing exclusion by fence generally advanced vegetation phenological stages in three grassland types (*Fig. 5*). However, the phenology of the meadow and the mountain steppe vegetation postponed by 0.02 and 0.19 respectively in 2014. In addition, the positive phenological variations tended to be greater in the meadow than other two grasslands. Dry steppe vegetation often had earlier phenological stages than that of mountain steppe.

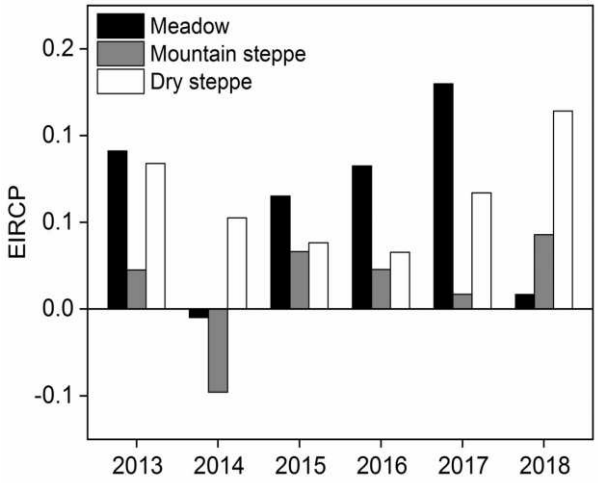

Figure 5. *Vegetation phenological changes (fenced plots vs. grazed plots) in three grassland types from 2013 to 2018*

Discussion

Livestock grazing is an important and direct way influencing grassland communities (Stein et al., 2016; Weiss and Jeltsch, 2015). Fencing is often considered as a useful tool to explore grazing exclusion effects on vegetation communities (Zhu et al., 2016b). Understanding the direction, the magnitude and mechanisms of grazing exclusion effects on vegetation communities greatly improves grassland management practices (Wang et al., 2014). In this study we focused on the response of aboveground vegetation indices to grazing exclusion by fence. Even though belowground parameters like soil properties and nutrients are also sensitive to grazing exclusion in Mongolian grasslands (Wang et al., 2019). Vegetation characteristics and diversity have been widely used to assess effects of grazing exclusion on grassland communities. However, the assessment is missing in Mongolian grasslands. Our study showed that grazing exclusion increased vegetation height and advanced vegetation phenological stages, but decreased community diversity. The effect of grazing exclusion varied with grassland type.

Vegetation characteristics response to grazing exclusion in three grassland types

Grazing exclusion by fence generally facilitated an increment of vegetation height for three Mongolian grasslands. This finding is in line with other fencing experiments in grasslands (Deng et al., 2014; Li et al., 2014), since tall plants are sensitive to livestock grazing (Díaz et al., 2007). In addition, positive changes in vegetation height induced by grazing exclusion did not exhibit a clear regularity of inter-annual variability. Grazing exclusion did not increase vegetation cover in the meadow and the mountain steppe, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69957009

significantly increased the cover in the dry steppe. The finding verifies different responses of vegetation cover to grazing exclusion across various steppes in Mongolian rangelands (Khishigbayar et al., 2015). Vegetation cover was more vulnerable to harsher environments. Fencing might stimulate a greater increment of the cover in the dry steppe. In addition, the meadow had a longer time since enclosure. This might explain a larger difference of vegetation cover between fenced and grazed plots. Recovery of vegetation cover is a lasting procedure. Li (2014) found vegetation needed 6 years to recover after grazing exclusion by fence in a degraded grassland in northeast China. For some savanna ecosystems these shifts can take many years (Goheen et al., 2018). Other management strategies like reseeding and fertilization may be performed to increase survival rates of plant species, thereby leading to an enhancement of vegetation cover. Moreover, variations of vegetation cover may be largely constrained by local climatic conditions. General arid environments in Mongolia hinder the restoration of vegetation cover. We further found that grazing exclusion positively affected vegetation cover of palatable species in the meadow and the mountain steppe, while the effect was not available in the dry steppe (see *Table A2* in the *Appendix*). This indicates that analyses from a perspective of functional groups aid us to comprehensively understand effects of grazing exclusion on vegetation characteristics. The communities were further found to be generally composed of unpalatable species across years in three grassland types (see *Table A2* in the *Appendix*). Palatable species are preferably selected by livestock (Guo et al., 2016). The result suggests that overgrazing in historical periods led to a decreased quality of forage grass and the dominance of unpalatable species in Mongolian grasslands. Thus, palatable species grow rapidly. Grazing history can impact the response of rangeland community cover and diversity to grazing management (Vermeire et al., 2018).

Community diversity response to grazing exclusion in three grassland types

We found that grazing exclusion had negative effects on the species richness and Shannon-Wiener diversity in three Mongolian grasslands. This is consistent with the findings in other grassland ecosystems (Wu et al., 2009; Yao et al., 2019; Zou et al., 2016). However, other studies showed contradictory results compared with ours (Sagar et al., 2019; Zhang and Zhao, 2015; Zhu et al., 2016a). Grazing leads to an occurrence of empty space, which allows more species to live on it. Grazing may also create the heterogeneity of habitats and thus benefits species coexistence (Guo et al., 2018). Another possible reason for the lower diversity in fenced plots is that grazing exclusion prevents seeds in freely grazed areas into the small fenced area (only 0.1 ha). Pielou evenness was found to be little controlled by grazing exclusion. Several studies have indicated that short-term grazing exclusion may be essential and important for improving species diversity (Jing et al., 2014; Xiong et al., 2016). Long-term fenced plots are likely to form climax species. This intensifies species competition for light and water resource, and thus decreases plant diversity (Zhu et al., 2016a). However, our results showed that the community diversity decreased in fenced plots regardless of years. This is not in line with typical discussions of fencing time impact on the community diversity. From a perspective of grassland management, grazing exclusion by fence is not an effective approach for restoring the diversity of the whole community in the degraded Mongolian grasslands. Moderate or rotational grazing rather than grazing exclusion by fence may be a better choice, since grazing weakens the dominance of certain undesirable species, allows the persistence of grazing-adapted

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_69957009

species and thus promote species coexistence (Stahlheber and D'Antonio, 2013). Fencing treatment could be regarded as a scenario without disturbances, while freely grazing scenario was full of disturbances. Both scenarios may correspond to a lower species diversity level based on intermediate disturbance hypothesis (Connell, 1979). We found that grazing exclusion had positive effects on the richness of palatable species in the meadow and the mountain steppe, while the effect did not exist in the dry steppe (see *Table A2* in the Appendix). This indicated that grazing exclusion improved the palatability of vegetation communities, but was constrained by water availability. Empirical and simulation studies show that the diversity of grasses is susceptible to interactions of livestock grazing and aridity (Guo et al., 2018; Rota et al., 2016).

Vegetation phenology response to grazing exclusion in three grassland types

Vegetation phenological stages tended to be earlier in fenced plots of three Mongolian grasslands in terms of the whole community. Grazing exclusion treatment stimulates the growth of shallow-rooted plants (Zhu et al., 2016b). Plants in Mongolian grasslands are assumed to have short roots to utilize water resource in the upper soil layer, since local arid environment does not allow much water to infiltrate into deep soil layers. Grazing exclusion can also lead to soil desiccation induced by an increase of water required by non-grazed plant species (Bergmeier, 1998). Moreover, the phenological development of taller plant species is less constrained by water availability than that of lower ones (Dorji et al., 2013). We further found that phenological periods of species differed in their response to grazing exclusion (see *Fig. A1* in the *Appendix*). Specifically, certain number of species had no changes or even negatively altered for phenological stages in fenced plots. This provides species-specific evidence for restoring degraded grasslands. In future, it is necessary to investigate soil moisture and temperature under grazing exclusion and grazed treatments in Mongolian grasslands, to obtain a general and mechanistic explanation of grazing exclusion effects on vegetation phenology. We are aware that the measurement of vegetation phenology in several days is not enough to assess its response to grazing exclusion, since we cannot identify how many times of grasses were eaten by livestock. Moreover, the regrowth of grazed plants was not adequately considered.

Conclusion

Our study shows that grazing exclusion by fence significantly affects vegetation characteristics and community diversity. The effects are strongly modulated by grassland type. Grazing exclusion by fence is not an effective way to restore the vegetation cover and the diversity of plant communities in degraded Mongolian grasslands. However, grazing exclusion may play a positive role in promoting the growth of palatable species. Appropriate alternative management practices, such as rotational grazing, reseeding and fertilization, should be considered for the grassland restoration. In addition, factors influencing vegetation phenology need a further study in Mongolian rangelands.

APPENDIX

Determining the number of quadrats

We found that mean vegetation cover of selected three quadrats was generally similar with that of ten quadrats regardless of treatments and grassland type. In addition, resampling based on the bootstrapping method little influenced mean vegetation cover of randomly combined three quadrats. Thus, three quadrats well depicted general changes in vegetation cover. We finally determined fixed three quadrats based on a rule of minimum differences between mean vegetation cover of three quadrats and that of total ten quadrats for each treatment and each grassland.

10	23.54	24.13	94.98	92.45	62.43	52.37
Mean value of ten quadrats	23.29	23.34	93.41	92.16	64.29	53.30

Response of vegetation community palatability to grazing exclusion

Vegetation height of palatable species was higher than that of unpalatable species in the meadow and the mountain steppe. In contrast, this showed an opposite trend in the dry steppe. The richness of unpalatable species was much greater than that of palatable species. Vegetation cover indicated a similar trend. However, the cover dominance of unpalatable species did not exist in the meadow. In addition, grazing exclusion by fence generally increased the cover ratio and the richness of palatable species in the meadow and the mountain steppe. The effect was not available for the dry steppe. The richness of unpalatable species decreased in fenced plots compared to grazed ones in three grassland types.

Table A2. *Vegetation height (H) and richness (R) of palatable species (P) and non-palatable species (NP), as well as cover ratio (CR) of palatable species to the community under treatments of grazing exclusion by fence (GE) and freely grazing (FG) in three grassland types from 2013 to 2018*

Species distributions of phenological changes

Species with negative phenological variations were generally the minority of grassland communities. Grazing exclusion advanced species phenological stages. However, the effects did not show a clear inter-annual regularity.

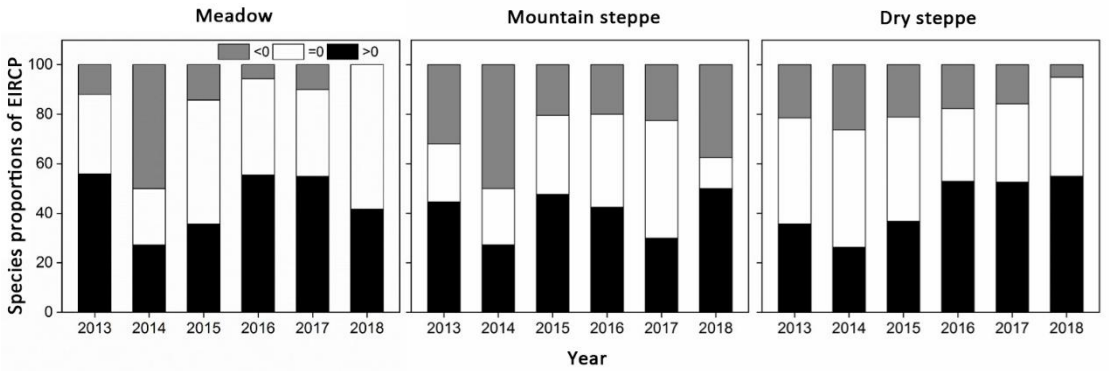

Figure A1. *Species proportions of phenological changes (fenced plots vs. grazed plots) in three grassland types from 2013 to 2018. The expression "<0" denotes negative phenological variations; The expression "=0" denotes no phenological variations; The expression ">0" denotes positive phenological variations*

(Received 19th Oct 2018; accepted 5th Dec 2018)

Abstract. *Aegilops tauschii* Coss. (2n=2x=14, DD) is a problematic weed and has contributed in the D genome of common wheat. The genetic diversity among 40 Chinese populations were evaluated by microsatellites marker and morphysiological traits. Dry weight biomass showed variation while in the case of plant height high variation was found between populations. We determined 27 alleles by using eight primers with an average of 3.37 allele per locus. The maximum polymorphism information content (PIC) was 0.63 with an average of 0.20 and maximum allele frequency was 1.00 with an average of 0.88. Cluster analysis divided *Aegilops tauschii* into different groups, which showed obvious genetic difference between these populations. This study will be helpful for weed management and wheat crop breeding program.
Keywords: *Aegilops tauschii, molecular marker, genetic diversity, morphysiological trait, microsatellites*

Abbreviations: PIC: Polymorphism Information Content

Introduction

(*Aegilops tauschii* Coss.) (*Ae. tauschii*) has a troublesome effect on wheat crop growing areas of China (Dudnikov, 2000; Zhang et al., 2007). It is native to tropical Asia to temperate Asia and Europe (Wei et al., 2008). It has infested about 330,000 hectares (Zhang et al., 2007) of winter wheat in different provinces including Shanxi, Shandong, Henan, Shaanxi, Inner Mongolia, Jiangsu and Hebei in China. Moreover, due to insufficient prevention and limitation of control strategies, the spreading pace of this weed tremendously damage winter wheat productivity, particularly in the main wheat producing regions. *Ae. tauschii* distributed from the Mediterranean region; present in Syria, Russia, Kazakhstan, Afghanistan, Pakistan, Turkey, all the way to Iran and extending to the eastwards of Yili Valley of Xinjiang in China (Li, 2005). Iran and Yili valley of Xinjiang were usually familiar with the center of the origin of *Ae. tauschii*. *Ae. tauschii* is recognized in natural habitats for its world distribution, whereas subspecies (strangulate) of *Aegilops* is native to south-western Caspian Iran and Afghanistan (Ogbonnaya et al., 2005; Wang et al., 2013; Kalia et al., 2016). Some scientists also proposed that *Ae. tauschii* presented in the Yellow river region in China was introduced with common wheat through trade along the Silk Road (Li and Mo, 2004; Zhao, 2007).

Ae. tauschii involved in the origin of the hexaploid wheat. Moreover, crop breeding has resulted in genetic diversity among the hexaploid wheat and *Ae. tauschii* populations. On the base of the morphological parameter, decidedly less genetic differentiation in the D genome of the wheat crop exists (Zahra et al., 2010). Due to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70117020

genetic similarity of *Ae. tauschii* with wheat, it may have an essential role in wheat crop improvement (Knaggs et al., 2000). Through hybridization, many useful biotic and abiotic stress resistance genes of *Ae. tauschii* can be utilized in wheat variety improvement programs (Hsam et al., 2001).

Genetic diversity can assessed by phenotypic (physiological and morphological parameters) and microsatellite markers (AFLP, RFLP, and SSR). Morphological parameters of crops are useful for introductory assessment because of their rapid range for diversity (Majidi et al., 2009; Sun et al., 2014). Molecular markers used to evaluate the genetic diversity because of their polymorphism, reproducibility, co-dominance, and simplicity (Roder et al., 1995). In molecular markers, simple sequence repeats (SSR) are universal and commonly used for genetic diversity evaluation (Vieira et al., 2016). Furthermore, SSR markers are more critical for crop improvement (Mian et al., 2005). *Aegilops* species possessing the D genome could be rich abiotic sources. Molecular markers have been used in several studies to assess genetic diversity among different populations (Roy et al., 2006). Genes from *Ae. tauschii* can be utilized in wheat variety improvement programs (Hsam et al., 2001).

In China, *Ae. tauschii* is a problematic weed and competes for resources from the early stage until maturity stage in wheat. It is scattered in more than ten provinces all across the country. Due to morphological similarities with the wheat crop, it is difficult to be controlled with herbicides. It is known that DD genome of *Ae. tauschii* has a rich source of potential variability. For genetic diversity of *Ae. tauschii* populations collected from five different provinces of China were assessed by using morphysiological traits and fluorescent dye-labeled SSR markers. The results of this study will be beneficial to both weed management and wheat breeding.

Materials and methods

Forty populations of *Ae. tauschii* seeds were used from five different provinces (Henan, Shaanxi, Shandong, Hebei, and Shanxi) of China (*Table 1*, *Fig. 1*). The experiment was conducted at the greenhouse of the Institute of Plant Protection, Chinese Academy of Agriculture Sciences, Beijing, China. Each population was replicated four times following a completely randomized design for pot experiment. Plants floated over half-strength Hoagland's nutrient solution (Hoagland and Arnon, 1950). Sixty days after sowing, plant height (cm) and dry weight biomass (g) were recorded. For SSR analysis, plant leaves were taken and stored at -80ºC for DNA extraction. DNA was isolated from leaves by plant kit (TIANGEN). DNA purification and quantification were carried out following Shah et al. (2009). SSR primers were designed by BATCHPRIMER3 (*Table 2*).

Table 1. *Aegilops tauschii populations collected from different provinces of China*

Name of province	Population Collection
Henan	10
Shaanxi	3
Shandong	10
Hebei	12
Shanxi	5

Polymerase chain reactions (PCRs) were carried out in 20 μL reactions comprising 40 ng of genomic DNA 1 μL, 0.6 μM of each forward and reverse primer, 7.8 μM of ddH_2O and 10 μM of PCR master mix. The PCR profile consisted of denaturation at 95°C for 10 min, followed by 35 cycles of 95°C for 30 sec, 45°C-60°C (depending on primers) for 30 sec and 72°C for 2 min, with a final extension at 72°C for 10 min. The genetic diversity of these populations were analyzed by using eight SSR fluorescent markers by capillary electropherogram.

Statistical analysis

Means, variances and coefficient of variances for plant height and dry weight biomass were measured by Statistix-8.0. For molecular data, allelic size was determined by using GeneMarker version 2.2.0 (Applied Biosystems). PowerMarker 3.1 was used to determine the allele amplification, allele frequency and polymorphism information content. Phylogenetic tree was drawn by PowerMarker MEGA 3.5.

Results

Means, variances and coefficient of variance in 40 *Ae. tauschii* populations showed variation in dry weight biomass and plant height (*Table 3*). Different populations have a different coefficient of variance in plant height, with maximum 12% and minimum 1.8%. In dry weight biomass, maximum and minimum coefficient of variance were recorded 25% and 3% in different populations. Analysis of variance in plant height and dry weight biomass showed a relationship between populations, but some populations showed variation as compared with others in these two traits. Populations 6, 9, and 23 showed variation in plant height (*Fig. 2*), and populations 23 and 26 showed variation in dry weight biomass (*Fig. 3*). Amplification of eight primers in *Ae. tauschii* showed 27 alleles with an average of 3.37, maximum polymorphism information content (PIC) was 0.63 with the average of 0.20, and allele frequency ranges 0.41 to 1 with an average of 0.88 (*Table 4*). D genome microsatellite markers revealed the allelic range in the Chinese *Ae. tauschii* populations and has extended and showed polymorphism.

On the base of cluster analysis (*Fig. 4*), 40 populations of *Ae. tauschii* were divided into three groups (I-III). Furthermore, the genetic relationships between populations elucidated by a dendrogram. Group I has six populations from Shanxi, Henan, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70117020

Shandong, showing their similar genetic background. Group II clusters have 26 populations of *Ae. tauschii* from Shaanxi, Shandong, Hebei, Henan, and Shandong provinces. The populations collected from Shaanxi, Henan, Shanxi, and Shandong were present in-group III. These results illustrated that the populations in the same group have a similar genetic background.

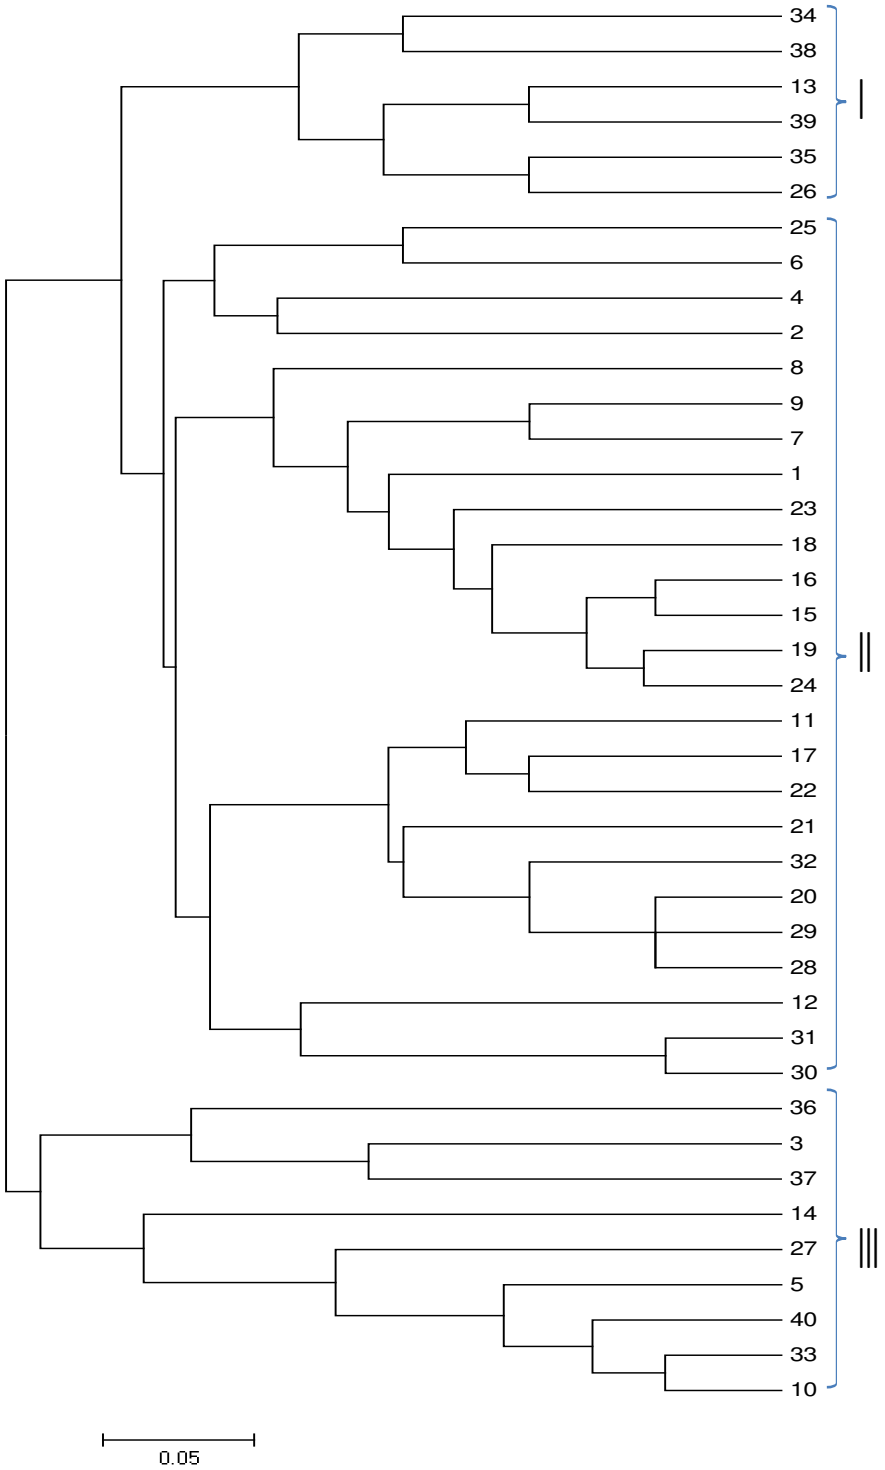

Figure 4. *Genetic relationship determined by PowerMarker (MEGA 3.5) cluster analysis based on the similarity coefficient of 40 populations of Ae. tauschii.*

Discussions

The results showed the significant effect of *Ae. tauschii* on the genetic diversity by using morphysiological traits and SSR markers. Fifty-five populations of *Ae. tauschii* showed variances on the base of the morphysiological characteristics (Naghavi et al., 2007). Based on data recording plant height, some populations showed a close relationship with each other while populations 3 and 15 showed variation. Zara et al. (2010) and Ojaghi et al. (2010) reported high diversity in *Ae. tauschii* on the base of plant height, which is a little larger than ours. In our results, dry weight biomass showed close relationships between populations while in some populations showed variations. Zaharieva et al. (2003) reported higher genetic diversity in three species of *Aegilops* on the base of different morphological traits. Agronomic traits are available for wheat improvement and showed a high level of genetic diversity (Giuliani et al., 2009). Knaggs et al. (2000) reported that morphysiological characteristics of *Ae. tauschii* could be used in crop improvement varieties. Similarly, in the case of many studies, they believe that seed collection belongs to geographic regions in morphological diversity. Many studies showed that morphological and physiological parameters are not in compliance with the genetic diversity, while molecular markers cover a large part of the genome including coding and noncoding parts (Semagn, 2002). Our results showed that on the base of the molecular marker relationship between *Ae. tauschii* was obvious, while the genetic difference is present.

Genetic diversity based on morphological and physiological parameters were not confirming like SSR markers. No relationship was present between morphological and physiological parameters with genetic diversity (Tahernezhad et al., 2010). In microsatellite markers, simple sequence repeats (SSR) revealed higher genetic diversity in populations. A high level of polymorphisms and average allelic richness showed a high level of genetic diversity in crops. SSR markers also confirmed the phenotypic evaluation of populations (Zaharieva et al., 2003). The result on the base of eight SSR primers and morphological traits showed genetic diversity between populations. Obtained results were confirmed by Naghavi et al. (2007) with a PIC value of 9.21 and an allelic range of 6-15 that was achieved by the SSR marker and it could be helpful for a breeder in a crop breeding program. Results on the base of eight primers showed genetic diversity between populations. In the evaluation of the genetic diversity in Iranian *Ae. tauschii* populations using 13 microsatellites, a total of 66 alleles were amplified with PIC value of 0.65 (Saeidi et al., 2006). In our study, maximum (PIC) was 0.63 (*Table 4*) with the mean of 0.20, that was lower than 0.82 (Naghavi et al., 2007). Similarly, the genetic diversity of 46 *Commelina communis* populations using 12 SSR markers were assessed with an average PIC value of 0.20 (Yang et al., 2018). PIC values showed variation because they depended on (GT) content, number allele per locus, and type of motifs (Roder et al., 1995). Amplification of wheat SSR primers in *Ae. tauschii* (DD) showed similar regions between *Ae. tauschii* and wheat genome (Zhang et al., 2004). Microsatellite markers from the D genome revealed allelic amplification which showed polymorphism in *Ae. tauschii* populations of China. Allelic amplification showed a high level of genetic diversity in *Ae. tauschii* populations of Iran (Saeidi et al., 2006). This showed the relationship between populations and subdivisions in groups showed diversity. Amplification of universal wheat primers in *Ae. tauschii* of China showed the close relationship between wheat and *Ae. tauschii* (Pestsova et al., 2000).

Bibi et al. (2009) and Akhundova (2010) reported genetic variation among wheat populations using microsatellite markers with an allelic range of 2-4. SSR markers in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70117020

wheat populations were reported with 3.6 alleles per primer (Ahmad, 2002; Almanza-Pinzon et al., 2003). Genetic diversity among wheat populations were studied with 21 SSR markers, which had an allelic range of 2-6, genetic similarity coefficient variation ranged from 0.45-0.90, and an average PIC value was 0.47 (Singh et al., 2006). Cluster analysis showed that populations from the same geographical region were present in the same group and their division in groups showed diversity. Populations from the same region have a great chance of being descended from a similar ancestor. On the basis of the genetic similarity coefficient, *Ae. tauschii* was divided into different groups. Cluster analysis divided *Ae. tauschii* (Iranian populations) into different groups and reported a high level of genetic variation between populations (Zahra et al., 2010).

Conclusion

Studying of *Ae. tauschii* populations of China by using molecular markers and morphysiological parameters has an essential role in wheat crop improvement. It is evident through molecular marker that *Ae. tauschii* will be helpful for crop breeding programs. Cluster analysis divided *Ae. tauschii* populations into three groups, which showed diversity and its different origins. High PIC value, allele amplifications and major allele frequency in some primers showed that specific parts of *Ae. tauschii* could be a valuable source for wheat crop improvement. Due to a rich source of potential variability, *Ae. tauschii* may perform vary when herbicides are applied in different wheat-growing areas. The results obtained from the study will help to weed management strategies in these regions.

(Received 20th Feb 2020; accepted 25th May 2020)

Abstract. Severe human health risks can be caused by consuming vegetables contaminated by heavy metals (HMs); thus, assessing the HM uptake by these plants is important. The current work was performed to construct a regression model for predicting the concentration of ten HMs in four tissues of *Phaseolus vulgaris* (roots, stems, leaves and pods) based on their concentration in a soil-sludge mixture, soil organic matter (OM) and soil pH. For pods, the regression equation with the highest coefficient of determination ($R^2 = 0.99$) and model efficiency ($ME = 1.00$) but the lowest mean normalized bias ($MNB = 0.01$) was that of cobalt. For leaves, the equation with the highest R^2 (0.90) and ME (0.92) but the lowest MNB (0.001) was that of molybdenum. Comparable findings were obtained for molybdenum in the stems and manganese in the roots. All t values that assessed the difference between the actual and predicted values of the ten HMs in the four tissues were nonsignificant. Thus, these models could be used as a risk assessment tool for *P. vulgaris* cultivated in soil-sludge combinations.
Keywords: *bioconcentration factor, prediction modelling, sewage sludge, translocation factor, vegetable crops*

Introduction

Contamination of cultivated lands by heavy metals (HMs) due to severe human impacts (such as industrial effluents, sewage sludge, chemical fertilizers and pesticides, untreated irrigation water contaminated by wastewater and mining activities) represents a hazardous global problem (Ramadan and Al-Ashkar, 2007). Some HMs are essential to plants at low concentrations (e.g., Zn, Mn, Fe and Cu), but others pose a toxicity risk to living organisms (e.g., Ni, Cd, Pb, As, Hg and Cr). Therefore, many studies have evaluated the risks associated with the accumulation of HMs in soil-crop systems (Belaid et al., 2012; Galal, 2016; Farahat et al., 2017; Jamali et al., 2007, 2009; Zhao et al., 2010).

Although HMs occur in different forms in the soil, only the dissolved forms are available for uptake by plants (Aydinalp and Marinova, 2003). The adsorption and desorption properties of soil are among the main factors that limit the bioavailability of HMs for plants (Krishnamurti et al., 1999). Some soil factors, such as pH, organic matter (OM), and Fe and Mn oxides, influence the adsorption and desorption of HMs in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70217039

soil (Usman et al., 2008). In view of this, soil pH has a significant negative correlation with the mobility and availability of HMs in soil solution, with acidity increasing the availability of HMs and alkalinity having a decreasing effect (Du Laing et al., 2008; Novotná et al., 2015; Zeng et al., 2011).

Consequent to the treatment of drainage water resulting from municipal and industrial activities, sewage sludge (SS) is produced as an organic byproduct that has excess macro- and micro-nutrients (Eid and Shaltout, 2016). Approximately 1.3 billion tons of SS is produced by cities globally per annum, and this is predicted to expand to 2.2 billion tons globally per annum by 2050 worldwide (Hoornweg and Bhada-Tata, 2012). Thus, there is consideration for how such quantities of SS can be disposed of safely to ensure it does not impact the environment (Eid et al., 2017) with the best means indicated as landfills and land application (Li et al., 2018). Some studies have indicated that the mixing of cultivated soil with certain amounts of SS has an enhancing effect on soil fertility and plant nutrients (Aráujo et al., 2007). Many studies (Singh and Agrawal, 2008, 2010; Grotto et al., 2015; Rehman et al., 2018; Asgari Lajayer et al., 2019) reported that SS could be added as a valuable fertilizer that improves the growth and yield of plant crops. However, this practice may lead to a risk to humans and the environment because of the presence of HMs that could contaminate soil and water, cause phytotoxicity, and the entry of such contaminants into the food supply (Mamais et al., 2000; Dolgen et al., 2007; Singh and Agrawal, 2007). The degree of danger is dependent on the quantity of SS applied, its structure, the crop species used and the conventional controls employed (Latare et al., 2014).

To reduce the toxicity levels of HMs and their movement through the food chain, it is important to assess the impact of soil variables on the availability and uptake of HMs by plants (Zeng et al., 2011). Regression models are useful mathematical tools for predicting the concentration of HMs in crop plants using certain soil factors such as HMs, pH and OM (Waegeneers et al., 2011). Comparable equations were constructed for barley (Adams et al., 2004; Novotná et al., 2015; Eid et al., 2020a), broad bean (Eid et al., 2019), carrot (Legind and Trapp, 2010; Bešter et al., 2013), cauliflower (Kumar et al., 2019), celery (Wang et al., 2004), chicory (Bešter et al., 2013), Chinese cabbage (Zhang et al., 2016), cucumber (Eid et al., 2018a), endive (Bešter et al., 2013), *Eruca sativa* (Eid et al., 2020b), garden pea (Eid et al., 2020c), hop (Novotná et al., 2015), lettuce (Legind and Trapp, 2010), maize (Tudoreanu and Phillips, 2004; Yang et al., 2013; Novotná et al., 2015), onion (Bešter et al., 2013), potato (Bešter et al., 2013; Novotná et al., 2015), rapeseeds (Novotná et al., 2015), red beet (Bešter et al., 2013), rice (Zeng et al., 2011; Rafiq et al., 2014), rye grass (Tudoreanu and Phillips, 2004), soy bean (Tudoreanu and Phillips, 2004), spinach (Wang et al., 2004; Eid et al., 2018b), tomato (Ramadan and Al-Ashkar, 2007; Bešter et al., 2013), wheat (Adams et al., 2004; Chaudri et al., 2007; Novotná et al., 2015; Eid et al., 2020d) and zucchini (Bešter et al., 2013). However, differences in soil, climate, SS composition and management factors require more specific estimates for different climatic regions or different cropping systems (Binder et al., 2002). Therefore, for safe crop production, it is important to evaluate the toxic levels of the HMs in the soil by establishing regression equations between the HMs in the plants on the one hand and those in the soil supporting the plants on the other hand (Eid et al., 2020d).

The kidney bean (*Phaseolus vulgaris* L.) is a herbaceous annual leguminous plant that has a long history of cultivation (Gentry, 1969). *P. vulgaris* is an annual plant belonging to family *Fabaceae* that originated in Central-South America. It is an erect or

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70217039

twining plant with compound leaves (each with three leaflets), and its flowers are usually white to purple in colour. Its pods are long, narrow, and straight or slightly curved, with pointed tips. The size and colour of its seeds are variable. The pods are cooked in immature stages, leaves are edible, and dried seeds are cooked and sometimes fried in oils as a salad (Huxley, 1999; Tindall, 1978). *P. vulgaris* is the most important food legume for direct consumption in the world (Jones, 1999). It was therefore selected for assessment in this research study. To the best of the authors' knowledge, no regression models are available for the uptake of HMs by *P. vulgaris* grown in soil amended with SS. Therefore, the present study was carried out to develop a mathematical model for predicting the potential uptake of HMs by *P. vulgaris* after growing it in an agricultural soil with different rates of SS addition under greenhouse conditions. Such models are suitable for assessing the severe impact of cultivating some vegetable crops in soil mixed with different amounts of SS.

Materials and methods

Materials and experimental design

White seeds of *P. vulgaris* (Strike, Seminis Vegetable Seeds, Inc., St. Louis, USA) were obtained from a local market in Abha City, Saudi Arabia. The soil used in the experiment was collected from nearby cultivated fields at a depth of 0-20 cm (Lat.: 18° 14′ 36.37″ N, Long.: 42° 33′ 58.25″ E), while the SS was obtained from the municipal sewage treatment station in Abha (Lat.: 18° 13′ 59.19″ N, Long.: 42° 31′ 16.35″ E). This station treats some 41,275 m^3 day^{-1} wastewater and produces 90 tons day^{-1} dry SS (Eid et al., 2017). Soil and SS samples were air dried for 2 weeks, ground and passed through a 2-mm sieve.

The experiment was performed in the greenhouse of the Biology Department, King Khalid University, Abha. Based on a preliminary experiment, the SS was mixed with agricultural soil at concentrations of 0, 10, 20, 30, 40 and 50 g kg^{-1}. Each treatment consisted of six plastic pots (each with a 6-L volume, filled with four kg of the respective treatment, and planted with ten equally sized seeds). The experimental units were arranged following a completely randomized design (CRD). The seeds were sown (directly after mixing the soil with SS) on the 4th of January 2018 for a period of 57 days under a natural day/night regime, irrigated using tap water as required with the soil water holding capacity (SWHC) in each pot varying between 40-50% and weeded manually as needed. The SWHC was determined and maintained on a volume basis using the following formula (*Eq. 1*):

$$\text{Volumetric SWHC (\%)} = (\text{depth of water in cm} / \text{depth of soil in cm}) \times 100 \quad \text{(Eq.1)}$$

Fifteen days after sowing, the emerged plants were manually thinned to one individual in each pot.

Sample analysis

Plant materials were harvested on 1 March 2018, then cleaned under running tap water, separated into four tissues (roots, pods, stems and leaves), dried for one week at 60 °C, powdered in a plastic mill and stored for later use. For physicochemical analyses, post-harvest soil samples were air-dried for two weeks, ground and passed through a 2-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70217039

mm sieve. Dried powders (pre- and post-harvest soil and SS samples) were analysed for OM using the loss-on-ignition method at 550 °C for 2 h (Wilke, 2005), while pH was measured in 1:5 soil:water extracts (Allen, 1989).

For HM estimation, 0.5-1.0 g of each dried powders and plant sample was digested following the mixed-acid digestion method (HNO_3 and $HClO_4$; 3:1, v/v). A microwave sample preparation system was used for digestion (PerkinElmer Titan MPS, PerkinElmer Inc., USA). Blank samples were used to verify the accuracy of the digestion procedure and the subsequent analyses. Ten HMs (Cd, Co, Cr, Cu, Fe, Mn, Mo, Ni, Pb and Zn) were estimated by inductively coupled plasma optical emission spectrometry (Thermo Scientific iCAP 7000 Plus Series; Thermo Fisher Scientific, USA) as outlined by Allen (1989). The detection limits of the HMs (in $\mu g\ l^{-1}$) were as follows: 6.0 for Ni; 2.0 for Co, Cr and Cu; 1.0 for Fe, Pb and Zn; 0.3 for Mn; and 0.1 for Cd and Mo. The settings of the instrument and the conditions of operation were as specified by the manufacturer. Standard solutions with known concentrations of the ten HMs were prepared for system standardization.

Quality assurance and control

Certified reference material (tomato leaves, SRM 1573a) was used to verify the accuracy of HM estimates. The reference material was digested and analysed using the methods applied to the *P. vulgaris* samples. Digestion and measurement of the ten HMs were performed in triplicate. Accuracy was assessed by comparing the actual concentration with the certified value and then expressed as a percentage. Recovery rates had a range of 95-104% for SRM 1573a.

Data analysis

Before performing the one-way analysis of variance (ANOVA-1), the distribution of the HM, bioconcentration factor (BCF) and translocation factor (TF) data was tested for normality using the Shapiro-Wilk W test and for homogeneity of variance using Levene's test; when necessary, the data were log-transformed. The HM data for *P. vulgaris* tissues were subjected to an ANOVA-1 to evaluate the differences among *P. vulgaris* tissues. Significant difference between means among the four tissues were identified using the Tukey's HSD test at $p < 0.05$. The BCF determines the capacity of a plant, such as *P. vulgaris*, to accumulate an HM in its roots (Galal et al., 2017) and is calculated using the following formula (*Eq. 2*):

$$BCF = C_{Root} / C_{Soil} \quad \text{(Eq.2)}$$

where C_{Root} is the concentration of an HM in the root ($mg\ kg^{-1}$) and C_{Soil} is its concentration in the soil ($mg\ kg^{-1}$). In addition, the TF determines the ability of *P. vulgaris* to translocate an HM from the root to each of the stem, leaf and pod (Eid and Shaltout, 2016) and is calculated using the following formulas (*Eqs. 3, 4* and *5*):

$$TF_{Stem} = C_{Stem} / C_{Root} \quad \text{(Eq.3)}$$

$$TF_{Leaf} = C_{Leaf} / C_{Root} \quad \text{(Eq.4)}$$

$$TF_{Pod} = C_{Pod} / C_{Root} \quad \text{(Eq.5)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70217039

where C_{Root}, C_{Stem}, C_{Leaf} and C_{Pod} are the concentrations of an HM in these tissues (mg kg^{-1}). The BCFs and TFs data were subjected to an ANOVA-1 to evaluate the differences among the ten HMs. Significant difference between means among the ten HMs were identified using the Tukey's HSD test at $p < 0.05$. Pearson's simple linear correlation coefficient (r) was estimated for the BCF of a certain HM in the plant tissues with soil pH and soil OM. The same coefficient was determined to assess the relationship between the plant HMs and soil HMs, pH and OM.

Eighteen observations from the dataset for each of the root, stem and leaf were selected randomly as a validation dataset. The other eighteen observations were used to establish the regression models for predicting the HM contents in *P. vulgaris* tissues, based on some soil variables used as independent variables (pH, OM, Cd, Co, Cr, Cu, Fe, Mn, Mo, Ni, Pb and Zn). The number of individuals that produced pods was twelve (in treatments with concentrations of 10 and 20 g kg^{-1} only); thus, six observations were used as a validation dataset, while the other six observations were used in the regression procedure. Following Novotná et al. (2015) and Yang et al. (2013), the OM content, pH value and HM content of the soil are considered the most important factors with which to explain plant HM concentrations. The general equation of the model was established using the following formula (*Eq. 6*):

$$C_{Plant} = a + b \times C_{Soil} + c \times pH + d \times OM \quad \text{(Eq.6)}$$

where C_{Plant} is the concentration of a given HM in any *P. vulgaris* tissue; C_{Soil} is its concentration in the soil; OM is the soil organic matter content (%); and a, b, c and d are the regression coefficients.

Model quality was evaluated using the coefficient of determination (R^2), model efficiency (*ME*), model strength (*MNAE*) and model bias (*MNB*) using the formulas by Novotná et al. (2015) (*Eqs. 7, 8* and *9*):

$$ME = 1 - (\sum (C_{Model} - C_{Measured})^2 / \sum (C_{Measured} - C_{Mean})^2) \quad \text{(Eq.7)}$$

$$MNAE = (\sum (|C_{Model} - C_{Measured}| / C_{Measured}))/n \quad \text{(Eq.8)}$$

$$MNB = \sum (C_{Model} - C_{Measured}) / \sum C_{Measured} \quad \text{(Eq.9)}$$

where C_{Model} is the predicted concentration of an HM given by the model, $C_{Measured}$ is the actual HM concentration, C_{Mean} is the mean of the actual HM concentrations, and n is the number of observations. Student's t-test was applied to assess the significance of the difference between the predicted concentration of an HM in a tissue and its actual value in the same tissue. All these analyses were carried out in SPSS 15.0 (SPSS, 2006).

Results

For prior testing of the quality of the used agricultural soil and SS, the OM, pH value, and concentrations of ten common HMs were analyzed. The data presented in *Appendix 1* show that the agricultural soil from the study region is poor in fertility because it contains less than 1% OM. The pH of this soil is 8.7 (basic), which reduces the availability of most nutrients (Sharma et al., 2017). The HM concentrations in the agricultural soil ranged between a minimum of 1.1 mg kg^{-1} for Mo and a maximum of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70217039

42,400 mg kg^{-1} for Fe; while in the SS they have a range of 0.9 mg kg^{-1} for Mo and 24,100 mg kg^{-1} for Fe (*Appendix 1*). In addition, the concentration of 5 HMs (Cd, Co, Fe, Mn and Mo) are higher in the agricultural soil than in the SS, while the reverse is true regarding the other 5 HMs.

After plant harvesting, the pH values of the soil-sludge mixture were alkaline, with a range of 6.8 - 8.5, a mean of 7.5 and a coefficient of variance (CV) of 7%; the OM ranged between 1 and 9%, with a mean of 5% and a CV of 47% (*Table 1*). The concentrations of the ten HMs in the soil descended as follows: Fe > Mn > Cr > Zn > Ni > Co > Cu > Pb > Cd > Mo. Iron had the highest mean concentration of 41,878 mg kg^{-1}, while Mo had the lowest mean concentration of 1 mg kg^{-1}. Regarding the plant tissues, most of the HM concentrations were lower in the pods than in the other tissues, except Co, Mo and Ni (*Table 2*). In contrast, the HMs were more abundant in the roots than in all the areal tissues, except Mo. In descending order, the ten HMs in the three areal tissues were Fe > Mn > Zn > Mo > Ni > Cu > Cr > Co > Pb > Cd, while those in the roots were Fe > Mn > Zn > Cr > Cu > Ni > Co > Mo > Pb > Cd.

The BCFs and TFs were < 1 for most HMs, except the BCFs of Mn (1.07), Mo (6.12), Pb (1.03) and Zn (1.25) and the TFs of Mo (2.53-4.57) in the three areal tissues (*Table 3*). In addition, the BCFs and TFs varied among the studied HMs (*Table 3*). Correlations were significant and negative between the BCFs of all ten HMs and soil pH, with the highest *r*-value of 0.89 for Mn and the lowest of 0.37 for Pb (*Fig. 1*), but significant and positive between the BCFs and soil OM, with a maximum *r*-value of 0.84 for Mn and a minimum of 0.36 for Pb (*Fig. 2*).

F-value	128.7***	101.8***	83.4***	24.7***

F-values represent one-way ANOVA, degrees of freedom = 9. Means in the same column followed by different letters are significantly different at $p < 0.05$ according to Tukey's HSD test. ***: $p < 0.001$

With a few exceptions, the correlation between an HM in the four tissues and the same HM in the soil was significant and positive (*Table 4*). In addition, significant negative correlations were detected between soil pH and only some HMs in the pods ($r = -0.76$ with Co, -0.67 with Mo, -0.89 with Ni and -0.81 with Zn, $p < 0.001$) but between soil pH and all HMs in the other three tissues. In contrast, soil OM showed the reverse trend with some HMs in the pods and all HMs in the other three tissues.

Correlations between the measured and predicted HM values, with high R^2, high *MEs* and low mean *MNAEs*, reflected the goodness of fit of the model. Additionally, the presence of a non-significant difference (*p*-value) between the measured and predicted concentrations of the HMs indicated good performance of the developed model. For the pods, the regression equation that had the highest R^2 (0.99) and highest *ME* (1.00) but the lowest *MNB* (0.01) was that of Co. For the leaves, the equation with the highest R^2 (0.90) and highest *ME* (0.92) but the lowest *MNB* (0.001) was that of Mo. Similar results were obtained for Mo in the stems and Mn in the roots (*Table 5*). Applying a *t* test that assessed the significance of the differences between the actual and predicted values of the ten HMs in the four tissues revealed that the differences were nonsignificant ($p > 0.05$).

Discussion

The soil-sludge combination supporting *P. vulgaris* was slightly alkaline (pH = 7.5). High soil pH is known to enhance the adsorption of many HMs, thus decreasing their solubility in soil solutions (Chaudri et al., 2007; Zeng et al., 2011). The adsorption and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70217039

desorption properties of soil are among the factors affecting the mobility and availability of HMs (Krishnamurti et al., 1999). Both properties are associated with soil pH, OM, clay minerals and oxidation-reduction status (Antoniadis et al., 2008; Usman et al., 2008). Significant negative correlations were detected between soil pH and most of the estimated HM concentrations in the four tissues of *P. vulgaris*. Zhao et al. (2010) reported that this soil factor plays a vital role in determining the solubility and availability of soil HMs.

In contrast, soil OM had significant positive correlations with most of the estimated HM concentrations in the tissues of the studied species. OM content plays an important role in determining the availability and mobility of HMs in soils, and it helps provide organic chemicals to the soil solution that act as chelates to increase HM availability to plants (Zeng et al., 2011). Decomposition of soil OM forms soluble organic-HM complexes and consequently more bioavailable HMs (Antoniadis and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70217039

Alloway, 2002). Therefore, SS must be applied carefully under appropriate conditions to reduce the accumulation of HMs in soil and consequently their transfer to plant tissues.

The build-up of HMs in plants is a complex process that depends on various soil properties, SS composition and application rate, species phenology and physiology, rhizosphere biochemistry, climatic factors, chelating effects and chemical speciation of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70217039

HMs (Dolgen et al., 2007). The root system is considered the main accumulator of HMs and filter for HM uptake; it slowly accumulates HMs (particularly if present in high concentrations), thus preventing or diminishing their transport to the above-ground biomass (Eid and Shaltout, 2016; Sawidis et al., 2011). The findings of the present study confirm this observation, as almost all the estimated HMs were higher in the roots of *P. vulgaris* than in its stems, leaves and pods.

Singh et al. (2004) reported that the hyper-accumulation of HMs in a root system may be ascribed to complexation of HMs with sulfhydryl groups, resulting in less HM translocation to the shoot system. Furthermore, higher accumulation of an HM in the root of a certain plant than in its above-ground tissues may occur because the root is the first tissue to come into contact with HMs; therefore, greater accumulation occurs there (Eid and Shaltout, 2014). In a plant such as *P. vulgaris*, this is a preferential behaviour that prevents toxic levels of HMs from occurring in the edible shoot parts, particularly the pods, which are cooked in immature and dried stages (Huxley, 1999; Tindall, 1978).

The three HMs with the highest concentrations in the four tissues of *P. vulgaris* and the supporting soil-sludge mixture were Fe > Mn > Zn, suggesting their easy uptake as a result of their higher levels in the soils and because they are essential for the growth of the studied plant (Dolgen et al., 2007; Lopes et al., 2012). In contrast, Pb and Cd tend to accumulate poorly in plant tissues and, if their uptake occurs, they accumulate in the root system (Latare et al., 2014).

The addition of SS to cultivated soil often leads to soil pollution by HMs and HM accumulation and phytotoxicity in the food supply (Yilmaz and Temizgül, 2012). The HM contents in the soil mixed with SS in the current work, except the Cd and Fe contents, were in the normal range reported by Allen (1989) and Kabata-Pendias (2011). In addition, most of the HM concentrations in *P. vulgaris* tissues were not in the critical ranges proposed by Kabata-Pendias (2011); however, some of them were within the normal range reported by Allen (1989) (e.g., concentrations of Cu, Fe, Mn, Pb and Zn). Thus, although the mixing of cultivated soil with SS may be practical for some crops, it might not be practical for others, such as *P. vulgaris*. Nevertheless, regular checking of HM levels in crop products that are cultivated in soil mixed with SS is recommended to avoid toxic effects of HMs in the food chain.

The BCF (root:soil ratio) is a rough estimate of HM uptake but reflects fewer details about site conditions (Zeng et al., 2011). In the current work, soil pH had a negative effect on BCF values, while soil OM had a positive effect. Significant negative *r* coefficients between soil pH and BCF of HMs in the root system of *P. vulgaris* could be interpreted in the view that alkalinity decreases the availability of HMs in soil solutions while acidity increases their availability (Du Laing et al., 2008; Novotná et al., 2015; Zeng et al., 2011). In addition, the presence of significant positive *r* coefficients between soil OM and BCF of HMs in the root system of the studied plant may be interpreted in the view that OM increases HM mobility in soil and HM uptake by plants (Singh and Agrawal, 2010). This finding is comparable to that of some previous related studies (Boshoff et al., 2014; Chaudri et al., 2007; Zeng et al., 2011). The BCF was < 1 for some metals (e.g., Fe, Cr, Ni, Cd, Co and Cu), which means that either the accumulation capacity of the root system was low for these HMs or they were transferred in low concentrations (see Novotná et al., 2015). In contrast, the BCF was > 1 for Mn, Mo, Pb and Zn, which means that *P. vulgaris* is a hyper-accumulator and may be used as a phytoremediator for these metals. Regarding the TF (aerial

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70217039

tissue:root ratio), all the values were < 1, except that for Mo, which means that the root is an effective bio-filter for these elements, while it is less effective for Mo.

Regression models are complex approaches with which we can predict the HM contents in plant tissues using some soil variables, e.g., HMs, pH and OM (Chaudri et al., 2007; Waegeneers et al., 2011). The results of the studied species indicated that the constructed models performed well for most of the estimated HM concentrations in the tissues of *P. vulgaris*, taking into account the parameters that indicate the high performance of the models (R^2, *ME*, *MNAE* and *p*-value). All the measured soil factors (HM, pH and OM) consistently contributed to HM concentrations in the plant tissues. Similar findings were reported by other investigators (e.g., Bešter et al., 2013; Boshoff et al., 2014; dos Santos-Araujo et al., 2017; Gan et al., 2017).

To the best of the researchers knowledge, to this day, no study has been performed where regression models have been developed to forecast of HMs uptake by *P. vulgaris* from the soil amended with SS. The mathematical models for the uptake of HMs by the roots, stems, leaves and pods of *P. vulgaris* constructed here are comparable to those produced for some other crops cultivated in soil amended with SS. For example, the variability (R^2) in Cd in the tissues of cucumber was 49-76% (Eid et al., 2018a), in garden pea was 25-67% (Eid et al., 2020c), in *Eruca sativa* was 49-81% (Eid et al., 2020b), in spinach was 83-88% (Eid et al., 2018b), compared with 44-61% for the *P. vulgaris* tissues. In their study on the Cd models of some vegetables, Bešter et al. (2013) reported R^2 values of 41% for tomato and 90% for endive. Regarding the same element, Boshoff et al. (2014) reported an R^2 range of 10-47% for *Urtica dioica* and 31-38% for *Agrostis* and *Poa* species. In Brazil, dos Santos-Araujo et al. (2017) recorded an R^2 of 45% for lettuce and 47% for carrot. A possible reason for the lower R^2 values of some HM models in previous studies (*Table 6*) may be the large number of replicates used in model construction which results in a large amount of noise in the datasets that may influence the predictive ability of the models (Römkens et al., 2004). The pollution levels, physico-chemical characteristics of the soil at the sampling sites, soil texture, soil microbial activity, soil types with different origins and mineralogy, distinct land management practices and analytical methods used in digestion of sample materials (Du Laing et al., 2003, 2009; Kabata-Pendias, 2011) could be other reasons for the different R^2 values between HM models.

n: number of samples, R^2: coefficient of determination

Conclusion

The HM concentrations in the different tissues of *P. vulgaris* showed that most of the investigated HMs were accumulated in the plant roots rather than in the other tissues. The SS is a rich source of OM, can increase solubility of soil HMs, and therefore the use of SS as amendment must be applied carefully to avoid the accumulation of these HMs in the soil and their transfer to plants. All the TFs values were less than unity, except that for Mo, which means that the root is an effective bio-filter for these HMs, while it is less effective for Mo. Prediction models for HMs concentrations proved that pH, OM and HMs concentrations of the soil were good predictors for the uptake of HMs by *P. vulgaris*. These models functioned well and demonstrated great levels of efficacy and low rates of error, and can be employed in examining *P. vulgaris* plants grown in soil amended with SS. Applying the *t* test, there are no significant differences between the actual and predicted values of the ten HMs in *P. vulgaris* tissues, which reflect the best-fitting of these equations for predicting the uptake of these HMs. An

extended field study for several growth seasons using the same SS may be required to confirm whether the repeated application of SS causes environmental problems in the future. Additionally, in future work, this study could be extended to investigate the microbial effects of SS application on soil quality and plant growth. Also, investigations of suitable methods for SS treatments are needed before the application in the agricultural system to avoid the health and environmental hazards.

RESPONSES OF SULFUR AND PHOSPHORUS DOSES ON THE YIELD AND QUALITY OF FENUGREEK (*Trigonella foenum-graecum* L.)

ÖZYAZICI, G.

Department of Field Crops, Faculty of Agriculture, Siirt University, Siirt, Turkey
e-mail: gulenozyazici@siirt.edu.tr; phone: +90-533-221-8208

(Received 24th Feb 2020; accepted 9th Jul 2020)

Abstract. This study was conducted to determine the effects of sulfur and phosphorus doses on the yield and quality of fenugreek in Siirt, Turkey, in the 2016-2017 and 2017-2018 growing seasons. Field trials were designed in a factorial complete block design with three replications at the experimental fields of the Agricultural Faculty of Siirt University. In the study, plant height (cm), first pod height (cm), the number of pods (pod plant^{-1}), the number of seeds in the pod (seed pod^{-1}), pod length (cm), thousand-seed weight (g), seed yield (kg ha^{-1}), protein content (%) and trigonelline content (%) were determined. All of the growth and yield parameters, except for plant height and pod length, were significantly affected by sulfur fertilization. All the parameters were affected by phosphorus fertilization. The highest seed yield (2224 kg ha^{-1}) and trigonelline content (1.26%) were obtained under 30 kg S ha^{-1} and 90 kg P ha^{-1} applications.
Keywords: *Trigonella foenum-graecum, fertilizer, medicinal plants, seed yield, trigonelline*

Introduction

Nowadays, due to the many side effects of synthetic and chemical drugs, trending towards alternative medicine or complementary medicine is gradually increasing. Medicinal and aromatic plants used for this purpose can be found in Turkey among many other countries, mainly by gathering from the natural flora. Therefore, medicinal plants of the desired quantity and quality cannot be obtained. This situation brings up the production of medicinal and aromatic plants with increasing the usage area.

Fenugreek (*Trigonella foenum-graecum* L.) which is grown for its seeds, fresh shoots, and leaves and is an important multi-purpose plant, one of the oldest known to have medicinal and aromatic properties. It has Mediterranean and Asian origin, and is an annual plant belonging to the Leguminosae family (Baldemir and İlgün, 2015; Bienkowski et al., 2016), containing about 50 species, and 45 of these species are found in the natural flora of Turkey (Davis, 1982; Beyzi et al., 2010). India is the world's largest producer of fenugreek, and it is also grown in South Asia, the Middle East, Far East, China, Iran, Pakistan, Turkey, the Mediterranean region, Europe, North Africa, Australia, Canada, the USA, and Argentina (Basu et al., 2019).

Fenugreek is a plant that has economic value in food, feed, medicine, and cosmetics. Fenugreek seeds are used in traditional medicine in the treatment of diabetes and cancer, as a natural dyestuff in the cosmetics industry, in animal feeding, as a coating material of some products in the food industry, and in making spices (Boeker, 1963; Baytop, 1984; Arslan et al., 1989; Hornok, 1992; Akgül, 1993; Küçük and Gürbüz, 1999; Soylu et al., 2000; Kızıl and Arslan, 2003; Tunçtürk et al., 2011; Abd Elhamid et al., 2016). It is also used as a green manure plant since it is a legume plant, and it has been reported to play a role in improving the physical and chemical properties of the soil (Abdelgani et al., 1999).

Phosphorus (P), which fulfills many functions related to plant growth, development, and metabolism and is essential for young tissues and cannot be renewed, is the most crucial macronutrient element after nitrogen. It is also called the key to life because it regulates many metabolic activities of plant life. If sufficient P is given to the plant, it causes rapid growth and increases plant resistance. In the case of P deficiency, plants stop and slow down the growth of the above-ground organs and accelerate the root growth. P, which also plays an essential role in increasing the yield of legumes by increasing biological activities such as nodulation, nitrogen fixation, nutrient uptake in the soil and in the rhizosphere environment, alleviates adverse effects of drought on physiological parameters in plants (Kacar and Katkat, 2007; Turan and Horuz, 2012; Yadav et al., 2014; Singh and Singh, 2016; Gezgin, 2018).

Generally, the properties of soils in Turkey affect the uptake of soil phosphorus by plants negatively (high pH, high lime content, low organic matter content, high clay content). It is very important to apply appropriate amounts of P to legume plants or to increase the availability of soil phosphorus, according to the results of soil analysis (Gezgin, 2018). Legumes' benefiting from soil phosphorus also differs according to its species and varieties (Gökmen Yılmaz et al., 2017).

Elemental sulfur (S) is a natural material and can be applied to increase the availability of plant nutrients and to reduce deficiencies in calcareous and alkaline soils (Manesh et al., 2013). Sulfur has vital importance in the activation of the process of photosynthesis, carbohydrate metabolism, and certain enzyme systems in plants; it can increase plants' seed and oil yields and protein contents. It is considered to be an essential nutrient in the vitamin and amino acids synthesis of legume plants. Sulfur is found in cysteine, cystine, and methionine, among the amino acids, and in the composition of proteins. It is necessary for chlorophyll formation (Lal et al., 2015). It accelerates root growth and nodule formation (Tonguç et al., 2017; Bolat and Kara, 2017). It has been reported that the amount of nitrogen fixed by legumes increases with the treatment of sulfur, and as a result of this, soil fertility improves (Mohamed El-Sayed Ali, 2018).

The reduced use of fossil fuels in the world and in Turkey and the widespread use of sulfur-free fertilizers have caused sulfur deficiency to emerge as a factor limiting the yield in plant production. Sulfur affects nitrogen utilization efficiency, and adverse effects of sulfur deficiency are observed on the growth of plants, chlorophyll amount, photosynthesis capacities, yield, and yield parameters (Tonguç et al., 2017). Sulfur positively affects not only the above-ground organs of plants but also the root growth, just like phosphorus. As a matter of fact, in the soybean plant given sulfur, the number and weight of side roots, the number and weight of nodules in which nitrogen fixation occurred were reported to increase significantly (Zhao et al., 2008). In beans, plant weight, the number of branches, the number of pods, the number of grains per plant, thousand-seed weight, harvest index, and yield were indicated to significantly increase in comparison with unfertilized plants (Tonguç et al., 2017).

This study was conducted to determine the effects of sulfur and phosphorus doses on the yield and quality characteristics of fenugreek (*T. foenum-graecum* L.).

Materials and methods

The study was carried out between 2016-2018 under the ecological conditions of Siirt province located in the Southeastern Anatolia Region of Turkey, which has a

DOI: http://dx.doi.org/10.15666/aeer/1805_70417055

semi-arid climate. Siirt is located at 37° 58' 7.37" N and 41° 51' 3.87" E coordinates with 894 m altitude (*Figure 1, Figure 2*).

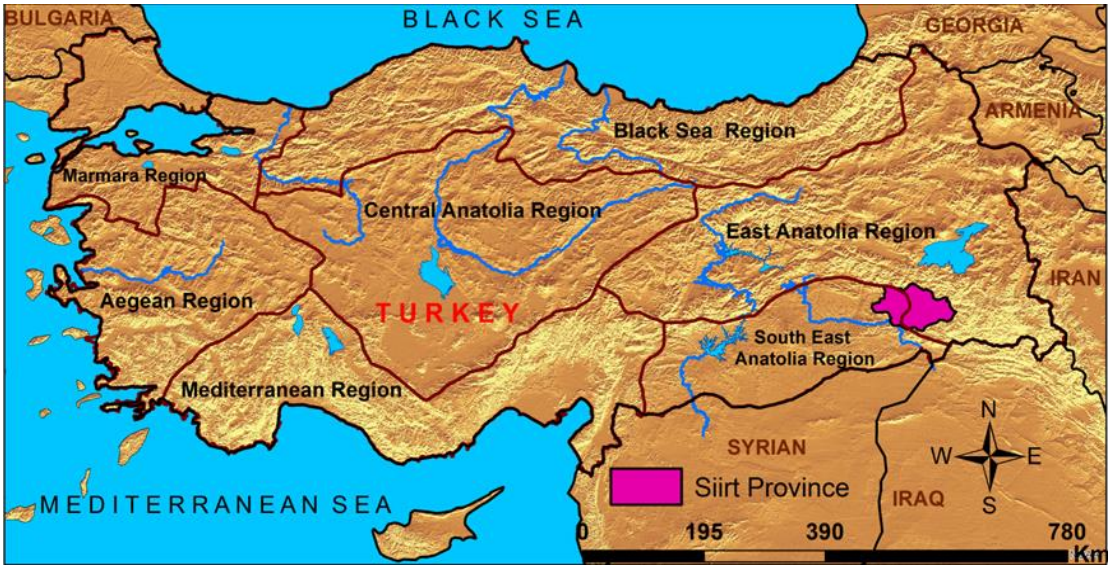

Figure 1. *Location of the study area in Turkey*

Figure 2. *A photo of the research area*

In the second year of the study, less precipitation (522.8 mm) occurred in comparison with the first year (574.2 mm), while the long-term annual precipitation was 634.1 mm. While the highest precipitation occurred in March and April during the 2016-2017 vegetation period, the highest precipitation was recorded in May during the 2017-2018 vegetation period (*Table 1*). The mean temperature during the study years and the long-term mean temperature (38 years) were 11.2 °C, 13.8 °C, and 11.4 °C, respectively *Table 1* (Anonymous, 2018).

In the study, some physical and chemical analysis results of the soils taken before establishing the field trial were presented in *Table 2*. In the first year (2016-2017), the trial area soils were loamy textured, and they were clay-loam textured in the second year (2017-2018); both trial area soils were slightly alkaline, salt-free, their lime content was "medium calcareous," the organic matter content was "low," and the available potassium (K) content was "sufficient". The available P content of the soils in the first year was determined to be "very little," and the available P content of the soils in the second year was determined to be "low" (*Table 2*).

*: Analyses were carried out in Siirt University, Science and Technology Application and Research Center Laboratory

As the plant material in the study, fenugreek (*T. foenum-graecum* L.) seeds, belonging to the "Konya population" and seeded locally in the Central Anatolia Region of Turkey, were used.

In this study, the field trial was established as three replications in randomized blocks according to the factorial trial design. In the study, 4 different sulfur doses (S_0= 0, S_{10}= 10, S_{20}= 20, and S_{30}= 30 kg S ha^{-1}) and 4 different phosphorus doses (P_0= 0, P_{30}= 30, P_{60}= 60, and P_{90}= 90 kg P_2O_5 ha^{-1}) constituted the subject of the study. Elemental sulfur was used as the source of sulfur fertilizer, and triple superphosphate (43-44% P_2O_5) was used as the source of phosphorus fertilizer. According to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70417055

research subjects, both fertilizer forms were mixed by applying them to the soil before seeding.

The seeding process was performed manually on 14 November 2016 in the first year and on 17 November 2017 in the second year on the grooves opened with the help of a marker. In the study, row distance was 30 cm and parcel distance was 100 cm. Each parcel constituted from four rows, while length and width of the parcels were 3 meter by 1.2 meter each with a total area of 3.6 m^2 per parcel. Sowing norm was 30 kg ha^{-1}, and sowing was done manually in rows opened with the help of a marker. Weed control was performed mechanically by hand several times in both years. At the harvest, two border rows and 50 cm from each side were excluded to eliminate border effects.

Plant height, first pod height, pod length, the number of pods per plant, and the number of seeds per pod were determined in 10 plants randomly selected in each parcel before harvest. The harvest was carried in the entire plot area, excluding borders in the first week of July in both years. The harvested plants were dried in the shade for 3-4 days, and seed yields were calculated per hectare. Crude protein determination in seeds was performed by the Kjeldahl nitrogen determination method, and trigonelline analysis was performed by the HPLC method. In trigonelline analysis was used Agilent TC-C18 (ODS 25 cm * 4.6 mm) column. Column temperature was maintained at 27 °C and the flow rate of the mobile phase was kept at 1 ml per min. The changes in absorbance at wavelength 210 nm were recorded with UV detector. The peak area was calibrated to trigonellin content with a standard.

The data were analyzed by JMP statistical software. A homogeneity test was applied to the data obtained from the study. According to the results of the homogeneity test, they were subjected to combined variance analysis (ANOVA) according to the factorial trial design in randomized blocks. According to the F-test results, differences between the groups were determined by the LSD multiple comparison test. In the study, the correlation coefficients of the pairwise relationships between the examined properties were calculated (Yurtsever, 1984; Düzgüneş et al., 1987).

Results and discussion

Plant height

In the study, the effect of S doses on the plant height of fenugreek was statistically insignificant, and according to S doses, plant height varied between 62.4-65.2 cm as the mean of P doses and years. The effect of phosphorus doses on plant height was determined to be statistically significant at the $p<0.01$ level. This difference occurred between the P_0 and P_{30} doses of phosphorus and its P_{60} and P_{90} doses. In this study, in which plant height increased according to P doses, the highest plant height was determined in P_{60} (65.2 cm) and P_{90} (66.3 cm) P doses. When the interaction of SxP was examined, the highest plant height was determined in the S_0P_{90} application as 70.1 cm, but no statistically significant difference was found between it and S_0P_{60}, $S_{10}P_{60}$, $S_{10}P_{90}$, $S_{30}P_0$, and $S_{30}P_{90}$ applications. The lowest plant height was measured in unfertilized parcels (control). SxP interaction was determined to be statistically significant ($p<0.01$) (*Table 3*). When the studies on this subject were reviewed, increasing P applications were reported to increase plant height, similarly to the results of our study (Halesh et al., 2000; Khiriya et al., 2001; Nehara et al., 2006; Meena et al., 2012; Mehta et al., 2012; Verma et al., 2014; Srivastava et al., 2015; Ahmad, 2017; Basu et al., 2019).

First pod height

In the fenugreek plant, S and P doses had a statistically significant effect on the first pod height at the $p<0.01$ level. The highest first pod height was measured in plants in parcels not treated with S, and no statistically significant difference was found between the other S doses. In other words, increased S doses did not affect the first pod height (*Table 3*). Tunçtürk et al. (2011) reported that the highest first pod height was obtained in the dose of 40 kg S ha^{-1} and that contrary to the results of our study, the first pod height increased with increasing S doses. It is thought that seeding time and genotype differences may be effective in this difference in the literature. As a matter of fact, Babagil (2010) stated that the first pod height is a property that is significantly affected by genotype and environmental factors. When the results of phosphorus doses were examined, as the mean of years and S doses, the lowest first pod height (38.6 cm) was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70417055

measured in parcels not treated with phosphorus fertilizer, while the P_{30}, P_{60}, and P_{90} doses of phosphorus were statistically in the same group and yielded the highest values (*Table 3*). In the studies conducted on fenugreek, the highest first pod height was determined in 40 kg P ha^{-1} by Khiriya and Singh (2003) and in 30 kg P ha^{-1} doses by Tunçtürk (2011), Nehara et al. (2006) reported that increased phosphorus doses increased yield properties.

Pod length

While the effects of S doses on pod length were statistically insignificant in the fenugreek plant, the effects of P doses were significant at the $p<0.01$ level. The pod length varied between 14.8-15.5 cm according to sulfur doses. The pod length was observed to increase in parallel with the increasing P doses. The highest pod length was measured to be 16.1 cm at P_{90} dose, and the lowest value was measured in the control parcel (14.2 cm) (*Table 3*). Similarly to our results, Khiriya et al. (2001), Khiriya and Singh (2003), Bhunia et al. (2006), and Meena et al. (2012) reported that increased P doses increased the pod length.

Number of pods

The statistical analysis results demonstrated that S and P doses and SxP interaction had significant effects on the number of pods per plant at the $p<0.01$ level. In the study, the number of pods was determined to increase in the fenugreek plant depending on the increase in S and P doses. In both fertilizer applications, the highest values were determined at the highest fertilizer doses (*Table 4*). In the studies conducted by Kumar (2011) on pea and by Nawange et al. (2011) on chickpeas, it was reported that increasing phosphorus and sulfur applications increased the number of pods.

The number of pods per plant was reported to vary between 7.7-8.5 by Tunçtürk (2011), between 30.6-33.0 by Meena et al. (2012), between 46.73-50.72 by Lal et al. (2015), between 6.4-8.6 by Srivastava et al. (2015), and between 11.6-23.1 by Mitoo et al. (2018). The reason for the number of pods per plant obtained in this study to be higher than these values in the literature may be differences in genotype, soil, climate, and cultural practices.

When the SxP interaction was examined, the highest number of pods was obtained from $S_{30}P_{60}$ and $S_{30}P_{90}$ applications, while the lowest number of pods was obtained from the S_0P_0 application (*Table 4*).

Number of seeds per pod

When sulfur applications were examined, it was observed that the number of seeds per pod increased up to S_{20} dose (15.59 seeds) depending on the increase in S doses, and after this dose, it was observed that it decreased statistically significantly. This difference between sulfur doses was statistically significant at the $p<0.01$ level. In terms of phosphorus doses, the number of seeds per pod increased with increasing P doses. Although the highest value was obtained to be 15.85 seeds at P_{90} dose, the difference between P_{90} and P_{60} doses (15.62 seeds) was statistically insignificant. This difference between phosphorus doses was determined to be statistically significant at the $p<0.01$ level. According to the sulfur x phosphorus interaction, the lowest number of seeds per pod was in S_0P_0 interaction (12.40), and the highest values were determined in $S_{20}P_{90}$, $S_{20}P_{30}$, $S_{20}P_{60}$, $S_{30}P_{60}$, $S_{30}P_{90}$, S_0P_{90}, $S_{10}P_{90}$, $S_{10}P_{60}$, and S_0P_{60} interactions. SxP

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70417055

interaction was determined to be very important in terms of the number of seeds per pod ($p<0.01$) (*Table 4*). Srivastava et al. (2015) reported that the number of seeds per pod varied between 13.20-16.60 and that the application of phosphorus increased the number of seeds per pod in the fenugreek plant. Mitoo et al. (2018) stated that the number of seeds per pod varied between 11.67-15.07 and increased with increasing phosphorus and sulfur applications.

Thousand-seed weight

The results of the statistical analysis showed that S doses had a significant effect on the thousand-seed weight at the $p<0.05$ level and P doses at the $p<0.01$ level. When *Table 4* was examined, the highest thousand-seed weight among S doses was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70417055

determined at S_{20} (13.83 g) and S_{30} (13.84 g) doses. However, no statistically significant difference was determined between them and S_{10} (13.65 g) S dose (*Table 4*). Ramkishor and Kumawat (2015) stated that different doses of S applied to the fenugreek plant had significant effects on the thousand-seed weight, and that the application of 40 and 60 kg S per hectare increased the thousand-seed weight compared to control subjects. Srivastava et al. (2015) obtained the highest thousand-seed weight to be 13.75 and 13.76 g at the 40 and 80 kg ha^{-1} P doses, respectively. Tunçtürk et al. (2011) stated that the thousand-seed weight was significantly affected by S application in the first year and that the highest thousand-seed weight was obtained to be 18.8 g at dose of 40 kg ha^{-1}. The increased P doses increased the thousand-seed weight in the fenugreek plant. While the lowest thousand-seed weight was determined at P_0 dose (12.90 g), the highest thousand-seed weight was determined at P_{90} dose (14.45 g) (*Table 4*). Tunçtürk (2011) reported that P doses increased the thousand-seed weight, and the highest thousand-seed weight was obtained from 60 and 90 kg ha^{-1} P (17.8 g and 18.0 g) applications. The highest thousand-seed weight was determined by Sammuria and Yadav (2008) from 40 and 60 kg ha^{-1} P application (11.62 g and 11.74 g, respectively), and by Mitoo et al. (2018) to be 9.98 g from 40 kg ha^{-1} P application, which was the highest dose.

Seed yield

The variance analysis results showed that S and P doses and SxP interaction had significant effects on seed yield at the $p<0.01$ level (*Table 5*). When *Table 5* was examined, it was determined that the highest seed yield was obtained to be 2224 kg ha^{-1} from the $S_{30}P_{90}$ application, and the lowest seed yield was obtained to be 1038 kg ha^{-1} from the S_0P_0 application. As P and S doses increased, seed yield was determined to increase in fenugreek. In both fertilizer applications, the highest seed yields were determined at the highest fertilizer doses. As the mean of years and P doses, the highest fenugreek seed yield with the sulfur application was obtained to be 1822 kg/ha (S_{30}), and as the mean of years and S doses, the highest fenugreek seed yield in phosphorus fertilizer applications was obtained to be 1810 kg ha^{-1} (P_{90}) (*Table 5*). Many researchers stated that the phosphorus element is necessary for energy transfer in plants and that the yield, and above ground and root development of the plant are adversely affected in P deficiency or excess (Kacar and Katkat, 2007; Singh and Singh, 2016). Tunçtürk et al. (2011), Lal et al. (2015), Ramkishor and Kumawat (2015), Singh Manohar et al. (2017), and Verma et al. (2017) reported that increasing sulfur doses increase seed yield, and Halesh et al. (2000), Tunçtürk (2011), and Meena et al. (2012) reported that increasing phosphorus doses increase seed yield in the fenugreek plant.

Protein content

In the study, the effects of S and P doses on the protein content of fenugreek seed were found to be statistically significant ($p<0.01$). In terms of sulfur doses, as the mean of years and P doses, the highest protein ratio was determined at S_{30} (26.0%) dose and the lowest at S_0 (25.3%) dose. In terms of phosphorus doses, increasing P doses increased protein content in fenugreek, but statistically, P doses, except for P_0, were in the same group (*Table 5*). Baldaneeya Nitesh (2018) and Tunçtürk et al. (2011) stated that they determined the highest protein content at a dose of 40 kg ha^{-1} S. Mehta et al. (2012) reported that although increasing P doses increased protein content, there was no

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70417055

difference between 20 and 40 kg ha^{-1} P doses. Tunçtürk (2011) also reported similar results.

Trigonelline content

The effects of S and P doses and SxP interaction on the trigonelline content of fenugreek seeds were found to be significant at the $p<0.01$ level (*Table 5*). When *Table 5* was examined, the highest trigonelline content was determined in $S_{30}P_{90}$ (1.26%), but there was no statistically significant difference between $S_{30}P_{60}$ (1.22%) and $S_{20}P_{90}$ (1.21%). On the other hand, as both S and P doses increased, trigonelline content was observed to increase (*Table 5*). Kan et al. (2007) stated that applied different phosphorous fertilizer sources did not change the trigonelline content, that trigonelline

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70417055

content varied between 0.86-1.26%, and that ecological factors might be effective on the trigonelline content. Dar et al. (2015) reported that a 40 kg P ha^{-1} application increased the trigonelline content. Mutlu (2011) reported in the study conducted in fenugreek of different origins that the trigonelline content varied between 0.66-1.40%. The trigonelline content obtained in this study was higher than the values reported by Akgül (1993) (0.36%), Mehrafarin et al. (2010) (0.20-0.36%), and Mathur and Yadav (2011) (0.27%).

Relationships between the ınvestigated properties

The simple correlation coefficients showing linear relationships between the seed yield per plant and the investigated properties were presented in *Table 6*. The correlation analysis revealed that the seed yield was positively and significantly correlated with the number of pods per plant (r= 0.703**), pod length (r= 0.334**), the number of seeds per pod (r= 0.509**), and thousand-seed weight (r= 0.571**). Increases that occurred in these properties caused significant increases in the plant seed yield. The highest correlation coefficients in terms of seed yield were determined in the relationships between the number of pods per plant, the number of seeds per pod, and thousand-seed weight. Parchin et al. (2019) stated that there was a positive relationship between the number of pods per plant and seed yield.

Table 6. *Correlation coefficients related to pairwise relations between the seed yield and other properties*

	2	**3**	**4**	**5**	**6**	**7**
1. Plant height	0.274**	0.094	0.218*	0.243*	0.104	0.154
2. First pod height	-	0.280**	0.080	0.068	0.110	0.078
3. Number of pods per $plant^{-1}$		-	0.391**	0.478**	0.436**	0.703**
4. Pod length			-	0.343**	0.321**	0.334**
5. Number of seeds per pod^{-1}				-	0.299**	0.509**
6. Thousand-seed weight					-	0.571**
7. Seed yield						-

*: Significant at the p<0.05 level, **: Significant at the p<0.01 level

A positive and significant relationship was determined between plant height and the first pod height. Positive and significant relationships were detected between the number of pods per plant and pod length and between the number of seeds per pod and thousand-seed weight. Positive and significant relationships were found between the thousand-seed weight and the number of pods per plant and between pod length and the number of seeds per pod. The number of pods per plant was stated to be the most important factor affecting seed yield in many studies (Şehirali, 1980; Pooran-Chand, 1999; Amini et al., 2002; Kumar Singh et al., 2019, Singh et al., 2019), and finding the number of pods per plant as the most leading factor in this study supports the other literature on this subject.

Conclusions

This study, which was carried out under the ecological conditions of Siirt province located in the Southeastern Anatolia Region of Turkey, which has a semi-arid climate, revealed the importance of sulfur and phosphorus fertilizers when an evaluation was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70417055

made in terms of yield and some quality criteria. Increased sulfur and phosphorus doses positively affected all of the investigated properties. When an evaluation was made in terms of yield and yield components, 30 kg S and 90 kg P doses could be stated to be suitable for per hectare. However, it was revealed that studies involving further increasing doses of both elements should be performed due to the linear increase determined in yield and quality properties in parallel to the increasing sulfur and phosphorus doses.

(Received 29th Feb 2020; accepted 9th Jul 2020)

Abstract. This study aimed to reveal the effect of different levels of leonardite and nitrogen fertilizer applied to the soil on seed yield and some quality parameters of black cumin (*Nigella sativa* L.). The study was carried out in the Southeastern Anatolia Region of Turkey between the years 2016-2018. In the study, 4 different doses of leonardite and nitrogen fertilizer were administered. In the study, the highest plant height and number of branches were found in L_2N_{90}, the highest number of capsules was found in L_2N_{60}, and the highest number of seed per capsule was found in L_2N_{60} and L_3N_{60}. As a result of the study, the highest seed yield was obtained from L_2 and L_3 doses of leonardite and from N_{60} dose of nitrogen. It was determined that the fixed oil ratio, essential oil ratio contained in the black cumin seeds, and essential oil components parallel with the increase in leonardite and nitrogen doses. It was concluded that leonardite, a soil conditioner, could be used in black cumin cultivation under semi-arid climate conditions and that 2000 kg ha^{-1} leonardite and 60 kg ha^{-1} nitrogen could be applied to improve the yield and quality of black cumin.
Keywords: *soil conditioner, thymoquinone, seed yield, Nigella sativa, essential oil, fixed oil*

Introduction

The blackcumin is a annual herbaceous plant from the Ranunculaceae family. It is distributed over a wide area from southern and eastern shores of Indian continent to mediterranan basin (Egypt and Turkey) (Seyyedi et al., 2015; Kılıç and Arabacı, 2016). It has 12 species distributed in Turkey. *Nigella sativa* and *Nigella damascena* species are commonly cultivated (Baydar, 2013). One of the most famous books in the history of medicine by İbn-i Sina, the author of "El Kanun Fi‟ ttıb", states that black cumin stimulates metabolism, prevents drowsiness and fatigue, regulates body energy and restores vitality lost by disease (Nasr, 2008). The seeds of black cumin have high economic value and contain fixed oil, essential oil, protein and carbohydrates. It also contains nigellidin, nigellisin and nigellimin in alkaloids in seeds (Baydar, 2013).

Black cumin is an important spice species and have high production especially in East and Southeast Asia. There is no specific report of production area and amount for black cumin, but for spice production India, China and Turkey leads world production (Dessie et al., 2020).

Humic acids, which are among the most important components of humic substances, are heterogeneous natural resources with high molecular weight and colors varying from yellow to black (Akıncı, 2011), and they have significant benefits in terms of both improving soil properties and agricultural production such as increasing the cation exchange capacity of the soils and neutralizing the pH of the soil (Stevenson, 1994), making plant nutrients bound to soil colloids available (Yılmaz, 2007), slowing down the evaporation of water in the soil (Akıncı, 2011; Sesveren and Taş, 2018), improving soil microflora (Larcher, 2003; Calvo et al., 2014; Li et al., 2019), improving plant growth, yield, and quality (Sharif et al., 2002; Esringü et al., 2015; Selladurai and Purakayastha, 2016; Çöl and Akınerdem, 2017; Ahmad et al., 2018), and increasing the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70577075

uptake of mineral elements in plants (Mackowiak et al., 2001; Eyheraguibel et al., 2008; Khaled and Fawy, 2011). Leonardite constitutes the raw material of humic acids that are classified as soil conditioners (Pekcan et al., 2018). Leonardite, which is a sedimentary rock formed by the changes of plant and animal remains during a period of millions of years (Pekcan et al., 2018), is an all-natural organic material that has not reached the level of coal (Sesveren and Taş, 2018). The use of materials such as leonardite to increase the organic matter content of the soil, especially in agricultural soils containing low organic matter with an intense polyculture production pattern, takes an important place nowadays.

It was reported that humic acid applications in *Brassica napus* ssp. *oleifera* L. plant had positive effects on plant height, the number of sub-branches attached to the main stem, the number of capsules in the main stem, the number of seeds per capsule, thousand grain weight, seed yield, oil ratio, and oil yield properties (Gürsoy and Kolsarıcı, 2017), that better tuber yields were obtained with humic acid and fulvic acid applications in the potato plant especially in dry and cool periods (Wadas and Dziugieł, 2019), and that potassium fertilizer and humic acid doses applied in increasing amounts in *Helianthus annuus* L. plant had significant effects on the yield and yield components and mineral content of the plant (Yağmur and Okur, 2017). Similarly, it was determined that the tuber yield in potato (Şanlı et al., 2013), wheat grain yield (Kolay et al., 2016), rye dry matter yield (Adiloğlu et al., 2017) increased in parallel with the increase in leonardite doses.

Obtaining high yields and quality products in agricultural production depends on giving the nutrients needed by the plant to plants in the appropriate period and dose, along with the accurate and timely implementation of many other cultural practices. In this sense, nitrogen (N) is the primary element among nutrients that are absolutely essential for many cultivated plants. The unconscious and excessive use of fertilizers, which are the most important inputs of agricultural activities, is shown to be one of the most important causes of soil pollution nowadays, and high doses of fertilizer applications also lead to toxic accumulation in plants, the inhibition of the intake of some other nutrients, and of course, economic losses. Therefore, the determination of nutrient needs of cultivated plants in different ecologies and the preparation of fertilization programs according to the soil analysis results constitute the most important branches of sustainable agriculture techniques.

Moreover, it is necessary to carry out cultural application techniques that minimize agricultural inputs such as fertilizer. For this purpose, it is essential to use soil conditioners such as leonardite in plant production, especially in agricultural soils where soil organic matter is low and, consequently, the intake of nutrients is prevented, and to reveal the interaction with other nutrients, and to show its effects on product yield and quality. In this study, it was aimed to reveal the effect of leonardite and nitrogen fertilizer applied to the soil at different levels on seed yield and some quality parameters of black cumin.

Materials and methods

The study was carried out between 2016-2018 under the ecological conditions of Siirt province located in the Southeastern Anatolia Region of Turkey, which has a semi-arid climate. Siirt is located at 37° 58' 7.37" N and 41° 51' 3.87" E coordinates with 894 m altitude (*Figure 1, Figure 2*).

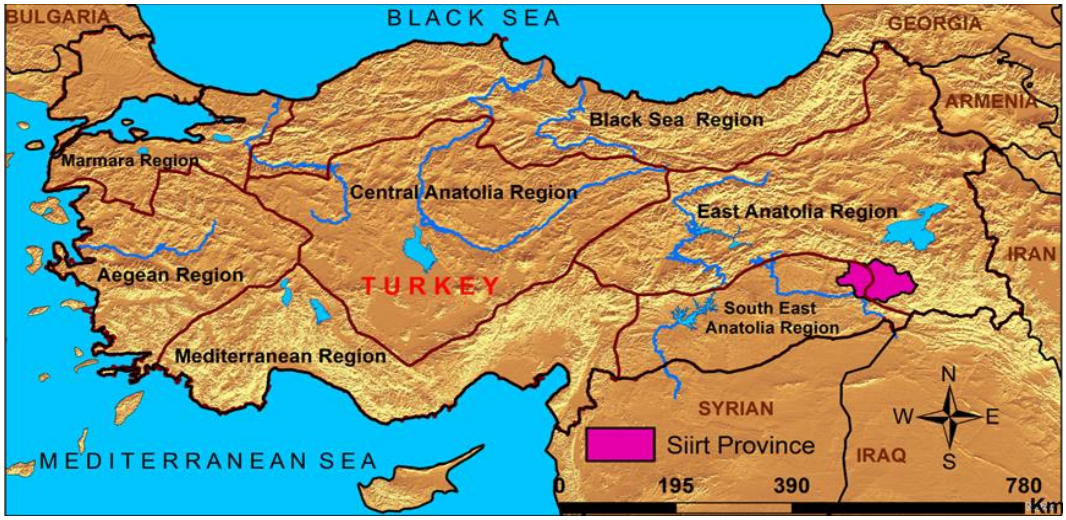

Figure 1. *Location of the study area in Turkey*

Figure 2. *A photo of the research area*

In the second year of the study, less precipitation (522.8 mm) occurred in comparison with the first year (574.2 mm), while the long-term annual precipitation was 634.1 mm. While the highest precipitation occurred in March and April during the 2016-2017 vegetation period, the highest precipitation was recorded in May during the 2017-2018 vegetation period (*Table 1*). The mean temperature during the study years and the long-term mean temperature (38 years) were 11.2 ºC, 13.8 ºC, and 11.4 ºC, respectively (*Table 1*) (Anonymous, 2018).

*: 1980-2018

In the study, some physical and chemical analysis results of the soils taken before establishing the field trial were presented in *Table 2*. In the first year (2016-2017), the trial area soils were loamy textured, and they were clay-loam textured in the second year (2017-2018); both trial area soils were slightly alkaline, salt-free, their lime content was "medium calcareous," the organic matter content was "low," and the available potassium (K) content was "sufficient." The available P content of the soils in the first year was determined to be "very little," and the available P content of the soils in the second year was determined to be "low" (*Table 2*).

*: Analyses were carried out in Siirt University, Science and Technology Application and Research Center Laboratory

As the plant material in the study, black cumin (*N. sativa* L.) seeds, belonging to the "Isparta population" and seeded locally in the Mediterranean Region of Turkey, were used.

In this study, the field trial was established as three replications in randomized blocks according to the factorial trial design. In the study, 4 different leonardite doses (L_0= 0, L_1= 1000, L_2= 2000, and L_3= 3000 kg ha^{-1} leonardite) and 4 different nitrogen doses (N_0= 0, N_{30}= 30, N_{60}= 60, and N_{90}= 90 kg N ha^{-1}) constituted the subject of the study. “Leonagro” was used as the source of leonardite, and urea (46% N) was used as the source of nitrogen fertilizer. The content of the leonardite material is given in *Table 3*. According to the research subjects, both fertilizer forms were mixed by applying them to the soil before seeding.

pH	Humic + Fulvic acid (%)	Organic Matter (%)
6-8	40	40

The seeding process was performed manually on 15 November 2016 in the first year and on 17 November 2017 in the second year on the grooves opened with the help of a marker. In the study, row distance was 30 cm and parcel distance was 100 cm. Each parcel constituted from four rows, while length and width of the parcels were 3 meter by 1.2 meter each with a total area of 3.6 m^2 per parcel. Sowing norm was 30 kg ha^{-1}, and sowing was done manually in rows opened with the help of a marker.Weed control was performed mechanically by hand several times in both years. At the harvest, two border rows and 50 cm from each side were excluded to eliminate border effects.

Plant height, number of branches, number of capsules, number of seed per capsule, seed weight were determined in 10 plants randomly selected in each parcel before harvest. The harvest was carried in the entire plot area, excluding borders in the first week of July in both years. The harvested plants were dried in the shade for 3-4 days, and seed yields were calculated per decare. Thousand seed weight, fixed oil and essential oil analysis were performed. For the fixed oil percentage grinded samples were dried at 105 ºC for 3 hours and 10 g sample was fed into a Soxhlet apparatus (SOXTHERM® 2000). The extraction was performed on a water bath at 60 ºC for 4 h with 200 mL petroleum ether. For the essential analysis percentage; seeds dried at 35 ºC in room were crushed bu using grinder. Distillation process was carried out using the Clevenger apparatus. Distilled water (250 ml) was used, and 25 g crushed fruit were watered with 250 ml distilled water (1:10). Distillation lasted for approximately 5 h at boiling point. The essential oil collected at the end of distillation was measured in mL and calculated as % (v/w). The essential oil components of black cumin seed were determined using Headspace GC-MS. Crushed black seed samples was taken 1 g and placed in a 25 mL Chromacol Headspace vial. The vial was heated in a Triplus RSH Headspace oven for 90 minutes at 120 °C. The heated Headspace was sent from the vial to the GC-MS with an injection volume of 2.5 mL. The analysis was carried out in a Trace 1310 gas chromatograph equipped with an ISQ single quadrupole mass spectrometer (Thermo Fisher Scicentific, Austin, TX). The procedure was set to an initial temperament 60 °C for 10 min, then ramp at 1 °C/min to 140 °C, 1 min in 140 °C, then ramp at 15 °C/min to 230 °C and finally 5 min in 230 °C. The ion source and detector temperature was 220 °C and 220 °C, respectively. Separation of sample was performed on a Thermo TG-WAXMS GC column (60 m x 0.25 mm ID x 0.25 µm) using helium as carrier gas at 1.2 ml/min. Mass spectral scan range was set at the rate of 55–550 (amu). Peak identification was conducted by comparison of the known components stored in the NIST Demo, Wiley7, Wiley9, redlip, mainlip, WinRI.

The data were analyzed by JMP statistical software. A homogeneity test was applied to the data obtained from the study. According to the results of the homogeneity test, they were subjected to combined variance analysis (ANOVA) according to the factorial trial design in randomized blocks. According to the F-test results, differences between the groups were determined by the LSD multiple comparison test (Yurtsever, 1984).

Results and discussion

Plant height

According to the results of a two-year study, the effects of leonardite and nitrogen fertilizer doses on the plant height of black cumin were found to be statistically significant at a level of $p<0.01$ (*Table 4*).

The plant height values increased in parallel with the increase in leonardite and nitrogen doses, and the highest plant height was measured at the highest doses of both leonardite and nitrogen. In the study, when the interaction of organic material and nitrogen doses was evaluated together, according to two-year averages, the highest plant height value was obtained in L_2N_{90} (68.38 cm) subject, and the lowest values were found in L_0N_0 (50.37 cm) subject. LxN interaction was found to be statistically significant at a level of $p<0.01$ (*Table 4*).

Nitrogen is an essential plant nutrient that promotes vegetative growth in plants. Therefore, nitrogen fertilizer applications affect plant height. In their studies carried out with black cumin, Shah (2004), Özgüven and Şekeroğlu (2007), Tuncturk et al. (2012), Yimam et al. (2015), Muhammad et al. (2017), Kızılyıldırım (2019), and Sultana et al. (2019) reported that plant height values increased in parallel with the increase in nitrogen fertilizer doses and/or plant height was positively affected by nitrogen dose applications, similarly to the results of our study.

It has also been reported in the results of many studies that organic material applications such as humic acid and leonardite, which is a source of humic acid, improve the soil properties, and therefore, plant height is positively affected in plants (Laz, 2011; Demirkıran et al., 2012; Betül et al., 2016; Eleroğlu and Korkmaz, 2016; Çöl and Akınerdem, 2017; Yağmur and Okur, 2017).

In the study, the difference between the years was also found to be significant, and the highest plant height values were determined in the second year of the study (*Table 4*). These differences in plant height values between the years can be explained by the difference in precipitation regimes over the years.

Number of branches

With respect to the number of branches, the effects of N doses alone were found to be statistically significant ($p<0.01$), while the effects of leonardite doses were found to be insignificant. As an average of leonardite doses, the highest number of branches was statistically found in N_{60} (3.75 unit plant^{-1}) and N_{90} (3.81 unit plant^{-1}) nitrogen doses that constituted the first group, and the lowest values were found in other doses of nitrogen. In the study, when LxN interaction was examined, while the highest value for the number of branches was found in L_2N_{90} (3.95 unit plant^{-1}) subject, the lowest value was found in L_0N_0 (3.53 unit plant^{-1}) subject (*Table 4*).

According to the results of the two-year study carried out with black cumin by Tuncturk et al. (2012), it was reported that nitrogen fertilizer doses increased the number of branches and that the difference between 40-80 kg nitrogen applications per hectare in terms of the number of branches was insignificant. While Özgüven and Şekeroğlu (2007) reported that the highest number of branches was obtained from 90 kg N ha^{-1} application dose among nitrogen fertilizer dose applications, Kızılyıldırım (2019) and Sultana et al. (2019) reported that it was obtained from 100 kg N ha^{-1} and 60 kg N ha^{-1} application doses, respectively. These results in the literature were found to be relatively compatible with the results of our study.

Number of capsules

With respect to the number of capsules per plant, while the effects of N doses alone were found to be statistically significant ($p<0.01$), the effects of leonardite doses were insignificant. As an average of leonardite doses, the highest number of capsules was found in N_{60} (6.56 unit plant^{-1}), and the lowest number of capsules was found in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70577075

control subject in which nitrogen fertilization was not applied (N_0) with 4.92 unit plant^{-1}. In the study, when LxN interaction was examined, the highest values for the number of capsules were statistically found in L_0N_{60} (6.85 unit plant^{-1}) and L_2N_{60} (6.92 unit plant^{-1}) subjects that constituted the first group. The lowest number of capsules per plant was found in L_0N_0 subject with 4.70 units. In the study, LxN interaction was found to be statistically very significant ($p<0.01$) (*Table 4*).

The number of branches per plant affects the number of capsules obtained per plant (Tuncturk et al., 2012). Indeed, in our study, nitrogen doses increased the number of branches, and consequently, more capsules were produced by plants. In their study, Tuncturk et al. (2012) investigated the effects of different nitrogen doses (0, 20, 40, 60, and 80 kg N ha^{-1}) in black cumin and reported that the number of capsules per plant increased up to the nitrogen dose of 60 kg N ha^{-1}, that the highest number of capsules was achieved with 7.5 capsules at this dose according to the average of two years, and that there was a statistically significant decrease in the number of capsules after 60 kg N ha^{-1} nitrogen dose. These results were in parallel with the results of our study. It was also reported in some other studies (Özgüven and Şekeroğlu, 2007; Rana et al., 2012; Yimam et al., 2015; Kızılyıldırım, 2019) that the number of capsules in black cumin increased depending on the level of nitrogen fertilizer.

Number of seeds per capsule

According to the results of the two-year study, the effects of leonardite and nitrogen fertilizer doses on the number of seeds per capsule in black cumin were found to be statistically significant at a level of $p<0.01$. When the two-year data were considered, the number of seeds per capsule increased in parallel with the increase in leonardite doses, and as an average of nitrogen doses, the highest and lowest values were obtained at L3 dose (92.52 seeds) and L_0 dose (62.32 seeds), respectively (*Table 5*). The positive effect of leonardite on the number of seeds per capsule can be explained by its contribution by improving the soil structure. Namely, humic substances such as leonardite serve as a reserve in terms of elements such as carbon, nitrogen, Sulphur, and phosphorus, therefore, in the study soil where soil organic matter was quite low (*Table 2*), it was considered that leonardite, known as the soil conditioner, made some plant nutrients in the soil available to plants, and consequently, flower and seed formation increased. Gürsoy and Kolsarıcı (2017) reported that humic acid doses in the soil covered with leonardite increased the number of seeds per capsule in the colza plant.

When the effects of nitrogen levels were evaluated, it was determined that the number of seeds per capsule increased up to N_{60} nitrogen dose and decreased statistically significantly after this dose and that the highest value for the number of seeds per capsule, as an average of leonardite doses, was found at N_{60} nitrogen dose with 100.69 seeds. The lowest values in terms of the number of seeds per capsule were found at N_0 dose (53.81 seeds) (*Table 5*). As in the results of our study, Shah (2004) and Mollafilabi et al. (2010) reported in their study on black cumin that there were significant decreases in the number of seeds per capsule after a certain level of nitrogen. In their study carried out with the datura plant, Esendal et al. (2000) reported that the number of seeds per capsule increased in parallel with the increase in nitrogen doses. On the contrary, Tuncturk et al. (2012) and Kızılyıldırım (2019) determined that nitrogen fertilizer levels in black cumin did not affect the number of seeds per capsule and that the number of seeds per capsule varied between 52.4-55.1 and 110.70-126.73,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70577075

respectively, depending on the levels of nitrogen fertilizer applied. Unlike these data in the literature, significant differences between nitrogen doses in terms of the number of seeds per capsule in our study can be explained by the fact that the soil-plant nutrition relationship occurred differently in terms of nitrogen and other plant nutrients depending on the soil and climatic conditions, in addition to different varieties used.

When LxN interaction was examined, the highest value for the number of seeds per capsule was statistically obtained from L_3N_{60} (114.77 seeds) and L_2N_{60} (112.75 seeds) applications, which constituted the first group. The lowest value was found in L_0N_0 (42.97 seeds). In the study, the highest values for the number of seeds per capsule were found in the second year of the study as an average of leonardite and nitrogen doses.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70577075

With respect to the number of seeds per capsule, the difference between the years ($p<0.05$) and LxN interaction ($p<0.01$) were found to be statistically significant (*Table 5*).

Seed weight capsule

The effects of leonardite and nitrogen fertilizer doses on the seed weight capsule in black cumin were found to be statistically significant at a level of $p<0.01$. When the two-year data were considered, seed weight capsule increased in parallel with the increase in leonardite doses, and as an average of nitrogen doses, the highest values were obtained at L_3 dose (0.54 g) and L_2 dose (0.53 g), respectively (*Table 5*). The highest seed weight capsule value was 0.56 with N_{90} nitrogen doses as an average of leonardite doses (*Table 5*).

Thousand-seed weight

In the study, nitrogen doses had a statistically significant effect at a $p<0.01$ level on the thousand grain weight of black cumin, and the highest thousand seed weight values were found at other nitrogen doses (N_{30}, N_{60}, and N_{90}), except for the control (N_0) subject. The effects of leonardite applications were found to be significant at a $p<0.01$ level (*Table 5*). The highest thousand seed weight value was obtaned from L_2 (2.35 g), followed by L_3 (2.32 g) leonardite doses. In the studies carried out by Başalma (1999) in the colza plant, by Esendal et al. (2000) in the datura plant, and by Ashraf et al. (2006) and Muhammad et al. (2017) in black cumin, the researchers determined that nitrogen fertilizer doses significantly increased thousand grain weight compared to the control. On the other hand, Tuncturk et al. (2012) and Kızılyıldırım (2019) reported that no significant differences were observed between nitrogen fertilizer doses in terms of thousand grain weight in black cumin.

Seed yield

In the study, when the effects of leonardite applications were examined, the highest seed yield, as an average of nitrogen doses, was statistically found at L_3 (1673.3 kg ha^{-1}) and L_2 (1645.8 kg ha^{-1}) leonardite doses included in the first group. In terms of seed yield, the lowest results were obtained at L_0 and L_1 doses. This difference between leonardite applications was found to be statistically very significant ($p<0.01$) (*Table 6*). It was considered that leonardite applied to the soil prevented the evaporation of water in the plant root zone and conserved the water in the soil, and consequently, drought and temperature stress occurred, and it increased the effectiveness of the existing water in the soil under the climate and soil conditions of Siirt province. Accordingly, the application of leonardite in these and similar soils, which are low in organic matter, plays a role in the conversion of plant nutrients in the soil into receivable form and increases the efficiency of the use of nutrients by plants. Therefore, humic substances such as leonardite have indirect effects on the yield increase in plants by increasing the uptake of minerals. In our study, it was considered to be effective on the increase in the seed yield of black cumin, depending on the increase in leonardite doses. Similar studies carried out in different plants on this subject support the results of our study. For example, it was reported that humic acid dose applications increased the seed yield in colza (Gürsoy et al., 2016) and tuber yield in the potato plant (Çöl and Akınerdem, 2017) compared to the control, that leonardite applications increased the tuber yield in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70577075

potato (Şanlı and Karadoğan, 2011) compared to the control, and that leonardite applications increased the amount of dry matter and the levels of some macronutrients (Adiloğlu et al., 2017) in the rye (*Secale cerale* L.) plant compared to the control.

L_0= Control, L_1= 1000 kg ha^{-1} leonardite, L_2= 2000 kg ha^{-1} leonardite, L_3= 3000 kg ha^{-1} leonardite, N_0= Control, N_{30}= 30 kg ha^{-1} nitrogen, N_{60}= 60 kg ha^{-1} nitrogen, N_{90}= 90 kg ha^{-1} nitrogen, ^{1}: The difference between the means indicated by the same letter in the same column and group is not significant, CV: Coefficient of variation, ns: Not significant, *: $p<0.05$, **: $p<0.01$

When the effects of nitrogen doses alone were examined, as an average of leonardite doses, the highest seed yield was found to be 1922.5 kg ha^{-1} at N_{60} dose, and the lowest seed yield was found to be 1072.1 kg ha^{-1} at N_0 dose, and seed yield decreased significantly at N_{90} dose. With respect to seed yield, this difference between nitrogen fertilizer doses was found to be statistically significant at a $p<0.01$ level (*Table 6*). It was also reported in the results of some studies that nitrogen fertilization in black cumin

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70577075

had significant and positive effects on seed yield. When these studies were reviewed, it was reported that the highest seed yield in black cumin was obtained from 60 kg N ha^{-1} nitrogen dose under the ecological conditions of India (Shah, 2004), Çukurova-Turkey (Özgüven and Şekeroğlu, 2007), Van-Turkey (Tuncturk et al., 2012), Ethiopia (Yimam et al., 2015), and Eskişehir-Turkey (Sağlam, 2018), from 30-60 kg N ha^{-1} nitrogen dose under the conditions of South Korea (Ashraf et al., 2006), from 30 kg N ha^{-1} nitrogen dose in the ecology of Iraq-Sulaymaniyah (Muhammad et al., 2017), and from 80 kg N ha^{-1} nitrogen dose under the climatic and soil conditions of Kahramanmaraş-Turkey (Kızılyıldırım, 2019).

It can be said that the results of our study are generally compatible with these data in the literature. The fact that nitrogen doses have different effects in different ecologies in terms of the seed yield of black cumin can be explained by different physical and chemical properties (especially organic matter) of soils where the study was carried out, along with the genotypic difference of the plant material used.

In the study, the difference between the years in terms of seed yield was also found to be statistically significant ($p<0.05$), and the highest values, as the average of leonardite and nitrogen doses, were found in the second year of the study (*Table 6*). It was considered that this difference between the years in terms of seed yield was due to differences in precipitation and temperature between the years.

In the study, although the LxN interaction was found to be statistically insignificant, it was remarkable that the seed yield was high in the treatments in which leonardite and nitrogen fertilizer were applied together at increasing ratios (e.g., such as L_2N_{60} and L_3N_{60}) (*Table 6*), which was considered as a significant result in that soil-conditioning organic materials such as leonardite increase the effectiveness of chemical fertilizers.

Fixed oil

One of the most critical factors that determine the seed quality in black cumin is the fixed oil ratio (Akgül, 1993). In the study, it was observed that leonardite applications increased the fixed oil ratio in the seeds of the black cumin plant. It was determined that this increase was statistically very significant at a ($p<0.01$) level compared to the subject without leonardite application (L_0) and that the highest values were obtained from other applications, except for L_0. The fixed oil ratio of black cumin varied between 37.02-37.50% along with leonardite applications (*Table 6*).

When nitrogen fertilizer doses were examined alone, it was determined that the fixed oil ratio of black cumin seeds increased in parallel with the increase in nitrogen doses and that the highest fixed oil ratio was obtained from N_{90} nitrogen dose with 37.96% as an average of leonardite doses. This difference between nitrogen fertilizer doses in terms of fixed oil ratio was found to be statistically significant at a $p<0.01$ level (*Table 6*).

While the fatty acid composition of seeds varies by species and genotypes (Karaca and Aytaç, 2007), different cultural applications in the planting-harvesting process (Küçükemre, 2009; Arslan et al., 2011; Kulan et al., 2012) and the ecological (Karaca and Aytaç, 2007) and topographic (Yüksek et al., 2016) differences also affect the oil ratio. In this sense, different results were obtained with respect to the effects of nitrogen fertilization on the fixed oil ratio consisting of saturated and unsaturated fatty acids. For example, it was reported that different doses of nitrogen fertilization did not generally affect the fixed oil ratio in black cumin (Shah, 2004; Özgüven and Şekeroğlu, 2007; Kızılyıldırım, 2019). On the contrary, it was reported that significant differences

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70577075

occurred between nitrogen fertilizer doses in terms of fixed oil ratio in the fennel (*Foeniculum vulgare* Mill.) plant (Tunçtürk et al., 2011) and oil ratio in the safflower (*Carthamus tinctorius* L.) plant (Katar et al., 2012).

It was considered that the emergence of significant differences between leonardite and nitrogen applications in terms of fixed oil ratio in the research soil, where soil organic matter, and accordingly, the amount of nitrogen in the soil were low, was affected by the increased availability of plant nutrients and the synergistic relationship between some nutrients. Nevertheless, it was reported that black cumin seeds contained fixed oil at ratios varying between 21.83-40.58% (Akgül, 1993; Türker and Bayrak, 1997; Kalçın, 2003; Kulan et al., 2012; Ertaş, 2016; Selicioğlu, 2018; Kızılyıldırım, 2019), and it was observed that the fixed oil ratio values obtained as a result of leonardite and nitrogen applications in our study were within these limits in the literature.

Essential oil

In the study, both leonardite and nitrogen fertilizer doses had statistically very significant ($p<0.01$) effects on the essential oil of black cumin seeds. While the highest essential oil in leonardite applications was found at L_2 and L_3 doses (0.30% and 0.29%, respectively) as an average of years and nitrogen doses, the highest essential oil in nitrogen fertilizer applications was found at N_{60} (0.30%) and N_{90} doses (0.31%) as an average of years and leonardite doses (*Table 6*).

According to the result of the study, it was observed that leonardite applications and nitrogen fertilizer applications, also known as organic fertilizer sources, increased the essential oil of black cumin seeds. Our results obtained by nitrogen fertilizer dose applications were found to be consistent with the results obtained by Türközü (2005), Özgüven and Şekeroğlu (2007), and Kızılyıldırım (2019). For example, in some other studies in which nitrogen fertilizer applications were performed, Yıldırım and Kan (2006) and Tunçtürk et al. (2011) reported that nitrogen fertilizer doses had no effect on essential oil in fennel, contrary to the results of our study.

Essential oil components

Essential oil components obtained by the Headspace GC-MS analysis of black cumin essential oil are presented in *Table 7*. A total of 6 components were found in black cumin essential oil. The main component of black cumin essential oil is thymoquinone. In our study, the effects of leonardite and nitrogen doses alone and together on thymoquinone content were found to be statistically significant ($p<0.01$). Accordingly, it was observed that the composition of thymoquinone of the essential oil of black cumin seeds increased in parallel with the increase in both leonardite and nitrogen doses and that the highest values were obtained at high doses. Indeed, this situation also manifested itself in the LxN interaction, and the highest thymoquinone content was found in L_3N_{90} subject by 47.09% (*Table 7*). Another major component of black cumin essential oil is P-cymene, and leonardite and nitrogen doses had a very significant ($p<0.01$) effect on P-cymene content. The highest P-cymene content and the lowest P-cymene content were found at L_3 dose by 41.66% and at L_0 (41.27%) leonardite dose, respectively, as an average of years and nitrogen doses. When the effects of nitrogen doses alone were reviewed, the highest P-cymene content and the lowest P-cymene content were found at N_{90} dose by 43.11% and at N_0 nitrogen dose by 38.67%, respectively, as an average of years and leonardite doses (*Table 7*).

In the study, other components found in black cumin essential oil were beta-pinene, sabinene, limonene, and linalool. It was determined that the amounts of these components were affected by leonardite (except for sabinene) and nitrogen dose applications and that the components generally had the highest values at the highest leonardite and nitrogen doses (*Table 7*).

In other studies on black cumin, the main component was determined to be p-cymene (47.4%, 49.06%, and 43.58%, respectively) by Orchid et al. (2004), Ashraf et al. (2006), and Toma et al. (2010). Moretti et al. (2004), Orchid et al. (2004), Toma et al. (2010), and Harzallah et al. (2011) determined that thymoquinone ratios in black cumin essential oil were 3.8%, 20.8%, 1.65%, and 0.79%, respectively. On the other hand, Akgören Palabıyık and Aytaç (2018) reported that black cumin oil contained thymoquinone by 67.7% as essential oil components, followed by carvacrol by 8.4%, and junipene by 4.8%. In our study, the main component of black cumin essential oil was thymoquinone by 45.41%. The fact that the main components of black cumin essential oil were different from some studies may also be due to different climatic characteristics along with the different genotypic features of the plant material used. Namely, the fact that the temperature is high but the amount of precipitation is low especially in May and June (*Table 1*) was considered to lead to a high amount of thymoquinone. A similar situation was also indicated by Akgören Palabıyık and Aytaç (2018), and Herlina et al. (2017) reported that high temperature had an effect on high thymoquinone content.

Conclusions

According to the results of this study carried out under semi-arid climatic conditions, the applications of leonardite, known as a soil conditioner, and nitrogen fertilizer doses significantly affected the seed yield and yield components of black cumin. The highest seed yield was obtained from 2000 kg ha^{-1} leonardite and 60 kg ha^{-1} nitrogen applications. If some amount is waived in terms of essential oil and components of essential oil, the L_2N_{60} application can be recommended with respect to yield and quality.

(Received 2nd Mar 2020; accepted 7th Jul 2020)

Abstract. This study examined the effect of effluent water from an intensive fish farm on rice (*Oryza sativa* L.) grown under aerobic condition in Hungary. During the experiment four treatments were used: T_1 - effluent water; T_2 - effluent water supplemented with gypsum; T_3 - effluent water diluted with surface water and supplemented with gypsum; T_C - control treatment. A number of quality parameters (TKW - thousand kernel weight, MQP - milling quality parameters, MC - mineral content) of the selected Hungarian rice variety (M 488) were studied. While, in the TKW test no statistically significant difference was found between the treatments, MQP test showed that there was a statistically significant difference between treatments in the percentage of whole polished (white) rice. The highest percentage was in T_C with 68.5%, T_1, T_2, and T_3 had 60%, 61.1% and 59.12%, respectively. The analytical analysis of MC highlighted, that the Ca and Na contents in rice seeds were not affected by the treatments, however, under T_3 a statistically significant decrease in the P, K and Mg contents of rice seeds was observed. Altogether, irrigation with fish farm water affects some quality parameters of the chosen rice variety in different ways, this effect can remain stable while reducing stress levels.
Keywords: *effluent water, environment, rice quality, water saving, water stress*

Introduction

One of the necessary conditions for obtaining a high quality crop is associated with water quality that meets the standards of irrigation (Suarez, 2011; Limjuco et al., 2016). Currently, climate change and water scarcity make it difficult for farmers to access quality irrigation water (Deressa et al., 2011; Chand and Kumar, 2018). These are undesirable limiting stress factors for the growth, development, and productivity of plants (Wang et al., 2006). Stresses, such as drought and high salinity in irrigation water can damage life cycle of plants, change cell size, disrupt gas exchange, and ultimately reduce yield (Bongi and Loreto, 1989; Rhodes and Nadolska-Orczyk, 2001; Tenhaken, 2015; Chowdhury, 2016; Joshi et al., 2016; Dresselhaus and Huckelhoven, 2018).

Many researchers have focused on alternative resources, such as wastewater in order to eliminate the existing shortage and to provide plants with the necessary water in a timely manner (Haruvy, 1997; Toze, 2006; Drechsel and Evans, 2010). Since they are rich in chemical composition, in some cases, these waters can be used as fertilizers (Rahimi et al., 2012; Ryu et al., 2012). It is also possible to make some progress in increasing productivity through the use of wastewater for irrigation (Khan et al., 2009). Another progressive aspect of this is the opportunity of reuse of wastewater, which in most cases is directly discharged into rivers, seas and oceans (Nair, 2008; Kamal et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70777088

2008). Eventually, this reuse will lead to environmental protection and minimization of potential damage. For instance, in recent decades, it was noted that an increase in the number of fish farms due to the disposal of waste into natural water resources has led to a disruption in the chemical and environmental balance of the water (Jones, 1990). According to a study by Ruiz-Zarzuela et al. (2009) in Northeast Spain, water from fish farms leads to a decrease in pH and dissolved oxygen in the river, which could affect water quality and aquatic life. However, the application of effluent water from fish farms in agriculture may be more suitable. According to Castro et al. (2006) the application of effluents from fish ponds greatly increased tomato yields in Northeast Brazil. Abdelraouf et al. (2014) reported in their study in Egypt, drainage water of fish ponds could be a good option for saving current water resources.

Changes at the global level, as well as existing problems also affect rice (*Oryza sativa* L.) cultivation. Rice is one of the most water-demanding crops among cereals and is the main agricultural crop that satisfies the nutritional needs of a large part of the world's population (Vergara, 1991; Muthayya et al., 2014). In addition, as the number of people increases, the demand for this product increases too (Khush, 2005). According to some researchers, the use of aerobic rice systems, which is considerably more water-efficient than the traditional method, can be an advantageous method in conditions of water scarcity (Bouman et al., 2002; Pinheiro et al., 2006). But another important factor in this event is related to the quality and yield of rice. Thus, in this study, our aim was to identify the effect of effluent water from fish farm on the development of aerobic rice by studying the qualitative characteristics and parameters of the mineral composition. In addition, we also focused on taking another step to the reduction of water demand and environmental pollution to improve a complex agricultural system.

Materials and methods

The experiment was conducted at the National Agricultural Research and Innovation Centre, Research Institute of Irrigation and Water Management (NAIK ÖVKI) Lysimeter Station in Szarvas, Hungary (46°51'48"N, 20°31'39"E). Possible changes of effluent water from the intensive catfish farm on rice was explored during the experiment. For that purpose Hungarian rice variety named M 488 was planted in 16 gravitation lysimeters under aerobic condition in May 2019. The treatments were applied by a micro sprinkler irrigation method and with four replications. The applied experimental design has been shown in *Figure 1*. Generally, lysimeters are devices used to study the dynamics of water, evapotranspiration and changes of other substances in the soil (Lanthaler, 2004). However, the reason for choosing gravitation lysimeter was to create aerobic conditions for the plants and at the same time to separate them from the vertical and horizontal effects of the surrounding environment and soil.

The non-weighted, backfilled gravitation lysimeters at the NAIK ÖVKI have the volume of 1 m^3 and each of them has a surface of 1 squaremeter. Four lysimeters were installed into one block together (one treatment in irrigation studies). The bottom 10 cm of the lysimeter is a layer of gravel to collect percolated water in case of heavy rain or high amount of irrigation. The plants have 80 cm of soil for the development. The type of soil in the lysimeters was vertisol (expansive clay). The plant density was set to 40 plants/m^2 (*Figure 2*).

The numbers in the cells represent the identification number of the gravitational lysimeters. M 488 – Hungarian rice variety*

Figure 2. *Lysimeter experiment of rice developed with different quality of irrigation water*

Four types of treatments have been applied during the experiment: T_1 - effluent water; T_2 - effluent water supplemented with gypsum; T_3 - effluent water diluted with surface water and supplemented with gypsum; T_C - control treatment, water from oxbow, which is a section of the Körös River in eastern Hungary. The chemical parameters of treatments are listed in the *Table 1*.

Seeds were sown on May 22, 2019. On the first and second irrigation days (22nd of May and 7th of June) all plants in lysimeters were irrigated with river water, only after that they were irrigated on the basis of treatments. On July 4, 0.5 kg of fertilizer (NH_4NO_3 + $CaMg(CO_3)_2$) was applied (84.4 kg N*ha^{-1}), and pesticides were not used during the experiments. The total applied irrigation water was 200 mm. Irrigation time and amount of used water are shown in the following *Table 2*.

Meteorological data were measured using meteorological equipment (Agromet-Solar automatic weather station, Boreas Ltd., Hungary) that was installed next to the experimental field. Rainfall during the growing season was 303.7 mm (*Table 3*).

After the harvest (24th of September, 2019) and standard post-harvest operation (cleaning, drying, and storing) basic tests – Thousand Kernel Weight (TKW), Milling Quality Parameters (MQP) and Mineral Content (MC) of rice seeds were analysed (*Table 4*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70777088

Table 4. *Conducted test and used equipments*

№	Conducted tests	Used equipments (methods)
1	Moisture content	Sartorius MA45
2	Thousand Kernel Weight (TKW)	1) Sartorius BP221S 2) Satake THU Laboratory Husker
3	Milling Quality Parameters (MQP)	Satake TM05 Test Mill laboratory
4	Analysis of Mineral Content (MC)	1) Thermo Scientific Solaar M6 atomic absorption spectrophotometer 2) Thermo Scientific ICAP 6000 ICP-OES

In order to begin those tests, moisture content of rice seeds from every sample was defined. At the beginning, the grains of each sample were divided into tiny particles, then by using Sartorius MA45 moisture analyser moisture content was found. The average moisture content was computed after the replications of four measurements.

For Thousand Kernel Weight (TKW) test, 100 paddy seeds were counted from each sample and weighed on Sartorius BP221S analytical balance. Afterwards, husk of seeds was removed by using Satake THU Laboratory Husker equipment and cargo (brown) rice weighed. The obtained results were multiplied by 10. After four replications of tests, the average TKW of paddy and cargo rice was determined.

100 g of rice from each sample was prepared for Milling Quality Parameter (MQP) analysis. First, a husk layer of seeds removed and cargo rice was weighed. Later, by using Satake TM05 Test Mill laboratory equipment brown rice was polished and the results were weighed. Subsequently, the percentage whole and broken white (polished) rice were calculated. The experiment was repeated five times and the average value is defined. According to the following formulas, the results were calculated (Lapis et al., 2019):

$$\%\, Cargo\ rice = \frac{weight\ of\ brown\ rice\ (g)}{weight\ of\ paddy\ rice\ (g)} * 100 \qquad \text{(Eq.1)}$$

$$\%\, Polished\ rice = \frac{weight\ of\ polished\ rice\ (g)}{weight\ of\ paddy\ rice\ (g)} * 100 \qquad \text{(Eq.2)}$$

$$\%\, Whole\ p.rice = \frac{weight\ of\ whole\ p.rice\ (g)}{weight\ of\ paddy\ rice\ (g)} * 100 \qquad \text{(Eq.3)}$$

Mineral Content (MC) test involves determination of amount basic minerals (Ca, Mg, K, Na, and P) in rice grains. In order to carry on analyses, paddy rice from each sample were hulled with Satake THU Laboratory Husker and brown rice received. After standard procedures, every sample was wet digested in 6 ml HNO_3 and 2 ml H_2O_2. One day later, the samples were kept in a microwave oven at a temperature of 180 °C for 1.5 hours. Afterwards, samples were analysed by using AAS and ICP-OES (NAIK ÖVKI Laboratory of Environmental Analytics, Szarvas, Hungary).

Based on standard methods, Ca, Mg, K and Na content were measured by Thermo Scientific Solaar M6 atomic absorption spectrophotometer. Determination of P was done with Thermo Scientific ICAP 6000 ICP-OES inductively coupled plasma atomic emission equipment, according to MSZ EN ISO 11885:2000 international and Hungarian standard.

The collected data were subjected to the analysis of variance (ANOVA) using IBM SPSS software (version 22). The significant differences among mean values were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70777088

determined with the Tukey test at 5% level of probability. In condition of violation of homogeneity of variances (Levene's test, $p<0.05$), Games-Howell post-hoc test was set under the terms of Welch test ($p<0.05$).

Results and discussion

Moisture content

The general idea behind of controlling moisture content of paddy seeds to receive moisture content below 14% (International Rice Research Institute, 2013). For the experiments, samples were placed in storage room in unmonitored condition. Although, conducted experiments were done moisture free basis, in our experiments we also got results less than 14% in all samples. The moisture content of samples under T_1, T_2, T_3 and T_C was 7.97%, 7.46%, 7.69%, 7.28%, respectively.

Thosand Kernel Weight (TKW)

One of the main indicators of the vitality, quality, and productivity of rice seeds is associated with TKW (Wu et al., 2018). In many cases, the TKW of rice grains in cultivation under flooding conditions is greater than in aerobic rice systems, however, it may vary depending on the rice cultivar (Castaneda et al., 2003; Reddy et al., 2010). The results of our experiments (*Table 5*) show, in both paddy seeds and cargo seeds, the highest TKW between treatments was observed with T_1. Nevertheless, the result of statistical analysis indicated non-significant differences between treatments ($p>0.05$). The absence of such a statistically significant difference specifies a similar reaction of rice to all treatments.

Table 5. *Thousand kernel weight of paddy and cargo seeds of rice developed with different quality of irrigation (Szarvas, 2019)*

Treatment		TKW of paddy seed (g)	TKW of cargo seed (g)
T_1	Average	22.15a	17.88a
	CI	[21.54; 22.76]	[17.4; 18.35]
T_2	Average	22.0a	17.68a

	CI	[21.17; 21.78]	[17.19; 17.37]

T_1 - effluent water, T_2 - effluent water supplemented with gypsum, T_3 - effluent water mixed with surface water and supplemented with gypsum, T_C - river water (control). CI - confidence interval (lower and upper bound). Values with the same letter are not significantly different at $p<0.05$

Milling Quality Parameters (MQP)

The importance of rice milling is mainly related to the percentage of whole white rice (Dhankhar et al., 2014). On the one hand, if it is connected with the tradition of consumption, on the other hand, it is closely connected with marketing goals (Dela Cruz and Khush, 2000; Zhou et al., 2019). Usually, most consumers before buying a product,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70777088

pay attention not only to the shape of the rice, but also to the colour and aroma of the rice (Rachmat et al., 2006). While in our experiment in the analysis of cargo rice percentage and polished (white) rice percentage, apparent differences were not found, in the percentage of whole polished rice there were statistically significant differences between treatments (*Table 6*). T_1, T_2, and T_3 had a statistically similar results ($p>0.05$), 60%, 61% and 59.12%, respectively. However, the highest percentage of whole polished rice was observed in the control treatment (68.5%) and this difference was statistically significant ($p<0.05$) between T_1, T_2, and T_3. According to the initial assumption, this difference between the results is due to the chemical composition between the control and the other treatments. One of the main indicators of the effluent water from intensive fish farm is that it contains a lot of sodium. Usually, rice cultivated under aerobic conditions and irrigated at regular intervals is subject to abiotic stresses (Jabran et al., 2017). This sensitivity to abiotic factors manifests itself as a reduction in a number of plant parameters (Singh et al., 2012; Kato and Katsura, 2014). The high salt content in the water prevents the plant from absorbing the water it needs (Ghosh et al., 2016). The greatest challenge is when the temperature is high, which causes the plant to become more stressed (Clermont-Dauphin et al., 2010; Mishra et al., 2015; Ali et al., 2019). Although the response to salinity may vary depending on the rice variety, increasing the salinity level of irrigation water at all stages of cultivation can significantly affect rice (Castillo et al., 2007; Fraga et al., 2010; Chang et al., 2019). This may ultimately affect the quality of the rice seeds.

Table 6. *Milling quality parameters of cargo and polished seeds of rice developed with different quality of irrigation (Szarvas, 2019)*

T_C	Average	78.8a	72.9a	68.5b
	CI	[77.86; 79.74]	[71.29; 74.51]	[66.92; 70.08]

T_1 - effluent water, T_2 - effluent water supplemented with gypsum, T_3 - effluent water mixed with surface water and supplemented with gypsum, T_C - river water (control). CI - confidence interval (lower and upper bound). Values with the same letter are not significantly different at $p<0.05$

Salinity also has a direct effect on the protein content of rice grains, where protein loss can increase the rice seed breakage (Leesawatwong et al., 2004; Balindong et al., 2018). Since the decrease in protein content in salt-sensitive rice varieties is observed more distinctly (Billah et al., 2017). Moreover, according to Rao et al. (2013), salinity in the soil is another reason for the decline in head rice recovery.

Mineral Content (MC)

The content of Ca in all treatments had a statistically similar ($p>0.05$) result (*Table 7*). Analogous results were also noted in Na content. While there was no statistically significant difference in Mg content between the control and T_1, T_2, T_3, the difference

DOI: http://dx.doi.org/10.15666/aeer/1805_70777088

between T_3 and T_1, T_2 was statistically significant ($p<0.05$). P and K content in T_3 was lower compared to the control and T_1, T_2, which was a statistically significant difference ($p<0.05$).

Table 7. *Average mineral content in M 488 rice seeds, (Szarvas, 2019)*

The high salt content in irrigation water creates stressful conditions and negatively affects the mineral metabolism in plants (Subekti et al., 2020). In our experiments, since the salinity level was normal in control, there were no obstacles to the absorption of P, K from water. Compared to T_1, T_2, the salt content in T_3 was lower, however, due to the low P, K in T_3, the content of P and K in the brown seeds may be lower. It should be noted that under stress, the development of the roots decreases, and the absorption of minerals is weakened (Hu and Schmidhalter, 2005; Hakim et al., 2014). In general, in each part of the plant a different amount of mineral accumulates (Sperotto et al., 2017). In other words, the low transportation and accumulation of minerals in T_3 can be associated with a high salt content and a low content of P, K. Furthermore, despite the low content of minerals in control, because of optimal regime, there was no interfere to the transportation of minerals.

Conclusion

Limited water resources, problems with the use of existing water resources, droughts and various global climatic phenomena require the use of alternative irrigation methods. In the current experiment, an analysis of the quality of rice irrigated with water discharged from an intensive fish farm was made. The study showed that both the direct use of intensive fish farm water (T_1) and supplemented with additives (T_2, T_3) does not adversely affect TKW and MC of rice grains (excluding P and K during T_3 irrigation), but reduces percentage of whole polished rice. Based on general ideas, the influence of direct use of intensive fish farm water (T_1) or supplemented with additives (T_2, T_3) on the quality indicators of the studied rice variety (M 488) under conditions of minimizing the harming effects of all the stress factors is stable. Although the most important determining factor

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70777088

is the amount of irrigation water and the total number of irrigation applications, to further clarify these conditions and the effect of effluent water on the development of aerobic rice, more quality parameters and more genotypes would be necessary in the upcoming experiments. But effluent water from the intensive African catfish farm could be utilized for irrigation purposes what can hinder the negative effects (mainly nutrient content) of this water for the natural water bodies. Finally, the use of effluent water in a more complex agriculture system, such as agroforestry, can also provide a natural solution for the utilization of effluents and also for the restoration and conservation of natural water resources.

(Received 6th Mar 2020; accepted 2nd Jul 2020)

Abstract. The influence of Miswak (*Salvadora persica* L.) that is made from arak on the oral microbiome signatures of 6- to 12-year-old Saudi children was studied. Deep sequencing was done for the V3-V4 regions of bacterial 16S rRNA. Sequence tags were assigned to 291 OTUs (operational taxonomic units) across samples with ≥ 97% similarity. The results indicated that factors like ethnic background and/or geographic origin can influence differences in healthy oral microbiome signatures. The results indicated some changes in the overall structure and diversity of oral microbiome. At genera level, there are five abundant phyla. At the species level, there are two opportunistic pathogens and the unassigned species as well as bacteria of the Proteobacteria family significantly decreased, the unassigned species belonging to the two genera increased due to swaking. The high abundance of *Streptococcus* and *Megasphaera* genera and low abundance of *Veillonella* genus are biomarkers of good oral hygiene as the first two genera (producer) can catabolize carbohydrates to the useful short-chain organic acids in biofilm formation, while the third (consumer) relies mainly on the fermentation of organic acids. These results shed light on the possible anti-microbial and anti-inflammatory properties of Miswak in addition to the role in removing plaque. In summary, we claim that Miswak is an excellent natural toothpaste for maintaining good oral hygiene, especially for children.
Keywords: *oral microflora, dysbiosis, Streptococcus, Megasphaera, Veillonella, organic acids*

Introduction

The human body contains ~100 trillion bacterial cells representing 1000 bacterial species or more. This bacteriome influences important parameters in human health including immune response, nutrient absorption, body weight, etc. (Gill et al., 2006; Pflughoeft and Versalovic, 2012). Although most of these bacterial species promote human health, others contribute to human illness (Greenblum et al., 2012; Ley, 2010). Other reports indicate that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70897138

the type of bacteria is not the only factor affecting human health, but the global microbiome balance was proved to have influence on human health (Huttenhower et al., 2012; Methé et al., 2012). Therefore, it is important to detect the normal symbiotic bacterial community that holds the healthy performance in human and how dysbiosis of this community encounters for diseases (Costello et al., 2009; Qin et al., 2010; Turnbaugh et al., 2009).

The mouth cavity is the major gateway to the human body, which influences the gastrointestinal microbiome and subsequent status of human health (Meurman, 2010). Dysbiosis of oral bacteriome has been linked with several life-threatening disorders including cardiovascular disease, stroke, pneumonia, etc. (Awano et al., 2008; Beck and Offenbacher, 2005; Joshipura et al., 1996, 2003; Offenbacher et al., 1998; Seymour et al., 2007). Simon-Soro et al. (2018) indicated that combined assessment of host response along with host oral microbiome can reveal clusters of health and disease. This indicates that oral microbiome can offer biomarkers of oral health (Alcaraz et al., 2012) and disease (Gomez and Nelson, 2017). Simon-Soro and colleagues also indicated that susceptibility to oral disease can be influenced by host immune factors, with emphasis to those existing in saliva. The latter contains a complex mixture of innate anti-microbial proteins and adaptive immune mediators with a significant impact on the microbial colonization of the oral cavity (Hancock et al., 2016; Mookherjee and Hancock, 2007). Previous reports indicate the high diversity among oral microbiomes of healthy individuals (inter-individual variation) (Aas et al., 2005; Nasidze et al., 2009), but little is known about the link between the structure and diversity of the oral microbiomes of healthy individuals in different ethnics/geographic regions (Mason et al., 2013). Interestingly, Nasidze and colleagues (Nasidze et al., 2009) indicated that normal saliva microbiome differs as we go further from the equator. In addition, saliva microbiome differs due to the human lifestyle and diet (Nasidze et al., 2011).

Salvadora persica L., also known as Miswak, is a tooth (or chewing) stick that is recommended by Prophet "Muhammad". *Salvadora persica* belongs to the family Salvadoraceae and order Brassicales (*Table 1*). This plant is a well-branched evergreen tree, with soft yellow wood, that is capable to tolerate severe abiotic stresses (Haque and Alsareii, 2015; Khatak et al., 2010). The World Health Organization (WHO) has recommended the use of this stick as a natural toothbrush for healthy oral hygiene (WHO, 1984). The plant is known to contain important chemical constituents such as vitamin C, alkaloids, trimethylamine, tannins, saponins, organic sulphur compounds, lignan glycosides, etc. (Ohtani et al., 1992). Besides, the plant possesses a number of bioactive compounds with important pharmacological properties (Aumeeruddy et al., 2018). These properties include anti-microbial, anti-oxidant, anti-ulcer, anti-inflammatory, and anti-tumor activities besides being recently feasible in several biotechnological applications (Lebda et al., 2018).

Table 1. *The taxonomic classification of Salvadora persica*

The present study aims at detecting the influence of swaking with *Salvadora persica* L. (Miswak) for one month on maintaining or restoring healthy oral microbiome in Saudi children and assessing the possible protective effects against human opportunistic pathogens.

Materials and methods

Recruitment of participants and sample collection

The study was approved by the Ethics Committee of King Abdulaziz University Hospital (KAUH, Jeddah, Saudi Arabia) under number 066-16 in 2018 and written informed consent was obtained from parents of all participant children. All participant children received oral examination and those with a history of immunosuppression or systemic diseases, use of medications that reduce saliva flow, or exposure to anti-microbials in the previous three months were excluded from the study. A total of 10 Saudi children were selected based on the pervious criteria with age ranging from 6 to 12 years old. Children have used Miswak once a day for one month. The saliva samples were collected before (BEF) and after (AF) swaking in Oragene-DNA (OG-500) Self-Collection kit (DNA Genotek Inc., Canada) and mixed with stabilizing reagent in the collection tubes per manufacturer's instructions and stored at 4 °C.

DNA extraction and partial 16S rRNA gene sequencing

Genomic DNA was extracted using the QIAamp® DNA Mini kit (Qiagen®51306; Hilden, North Rhine-Westphalia, Germany) according to the manufacturer's instructions. DNA purity was evaluated via A260/A280 ratio using NanoDrop 7000 Spectrophotometer (Thermo Fisher Scientific, Waltham, MA, USA), and DNA integrity was checked by 1% agarose gel electrophoresis. PCR amplification of the V3-V4 regions of bacterial 16S rRNA was performed using the universal primers 338F (5′-ACTCCTACGGGAGGCAGCA-3′) and 806R (5′-GGACTACHVGGGTWTCTAAT-3′). PCR program was the following: initial denaturation at 95°C for 5 min; 25 cycles of denaturation at 95 °C for 30 s, annealing at 56 °C for 30 s, and extension at 72 °C for 40 s; and final extension of 72 °C for 10 min. Amplicons were run on agarose gel (1.2%), then gel-purified using DNA Gel Extraction kit (Qiagen, Hilden, Germany) according to the manufacturer's instructions. Amplicons were, then, shipped to Beijing Genome Institute (BGI) in China for library construction and deep sequencing on Illumina Miseq platform to recover ~300 bp pair-end reads of the V3 and V4 regions. The ends of each read were overlapped to generate high-quality, full-length reads. The resulted sequencing data has been deposited in the European Nucleotide Archive (ENA) (https://www.ebi.ac.uk/ena/submit/sra/#studies) under the project number PRJEB27276.

16S dataset processing and statistical analysis

Sample size estimation was performed to determine the probability that the samples are representative (Motulsky, 2010). The raw sequencing data were analyzed using the Quantitative Insights Into Microbial Ecology 2 (QIIME2) package v.2018.11; (https://qiime2.org) (Bokulich et al., 2018; Bolyen et al., 2019). V3-V4 16S rRNA sequence reads were trimmed using trimmomatic software (Version 0.33) and merged into single sequences using FLASH (Version 1.2.10). Merged sequences were filtered to remove the low-quality sequences. The latter are the reads shorter than 110

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70897138

nucleotides, reads truncated at any site with an average quality score of < 20 over a 50-bp sliding window, or the truncated reads that were shorter than 50 bp. Only sequences that overlapped for more than 10 bp were assembled. The unique sequence set was linked to tags and classified into operational taxonomic units (OTUs) with a cutoff of 97% identity using the *de novo* OTU selection strategy. We retained only OTUs with at least 0.01% mean relative abundance, as predominant. OTUs were ranked by the relative abundance values as x- and y-axis, then the rank curve was drawn by software R (Version 3.1.1). Taxonomies were assigned by the RDP classifier (Version 2.2) (Cole et al., 2013) against the Human Oral Microbiome Database (Chen et al., 2010) (HOMD RefSeq, Version 13.2) and the Greengenes database (version 13.8: 16S rDNA database, http://qiime.org/home_static/dataFiles.html) with a confidence threshold of 0.7. Chimeric sequences were removed using Usearch (Version 8.0).

Alpha diversity was assessed by Shannon and Simpson indices that were calculated by Mothur (v1.31.2), and the corresponding boxplot of alpha diversity and rarefaction curve were drawn by software R (Version 3.1.1). Drawing rarefaction curve was based on calculating OTU numbers of the extracted tags (in multiples of 500) and detecting the maximum depth (no. reads) permitted to retain all samples in the dataset. Sequences were extracted randomly according to the minimum sequence number for all samples, and the extracted sequences formed a new 'OTU table biom' file. To detect the beta diversity within and between groups, the weighted and unweighted UniFrac distances were calculated (Lozupone et al., 2011) and plotted *via* principal coordinate analysis (PCoA) using package 'ade4' of software R (Version 3.1.1). UniFrac uses the system evolution information to compare the composition of community species between samples. The results can be used as a measure of beta diversity. It takes into account the distance of evolution between species, and the bigger the index, the greater the differences between samples. The UniFrac is divided into weighted UniFrac and unweighted UniFrac of which the weighted UniFrac considers the abundance of sequences, while unweighted UniFrac gives more weight on species presence/absence.

Heat maps were generated using the package 'gplots' of software R (Version 3.0.3) (https://github.com/talgalili/gplots). At phylum level, all species were used to draw the heat map and taxa of which abundance was less than 0.5% in all samples were classified as 'others'. To minimize the differences degree of the relative abundance value, the values were all log transformed. The representative sequences were aligned against the Silva core set. Representative OTU phylogenetic tree was constructed using the QIIME 2 (v.2018.11) built-in scripts including the fast-tree method for tree construction. The tags with the highest abundance of each genus was chosen as the corresponding genus representative sequences, and genus level phylogenetic tree was obtained by the same way as the OTU phylogenetic tree. Then, the phylogeny tree was imaged by R phylogenetics packages. Venn diagram was drawn by Venny (http://bioinfogp.cnb.csic.es/tools/venny/), while differences in the relative abundances of taxa at the phylum, genus and species levels were analyzed using Metastats (Paulson et al., 2011). PERMANOVA was used to test significance among values. All statistical tests were two-sided, and P value ≤ 0.05 was considered significant. Benjamini-Hochberg false discovery rate (FDR) correction was used to correct for multiple hypothesis testing where applicable. A GitHub repository link (https://github.com/shandley/Microbiome-Analysis-Using-R.git) providing the applied codes was added.

Results

Statistics of oral 16S rRNA sequence datasets

In the present study, the oral microbiome was detected for a group of 10 Saudi children (subjects) who used Miswak as a natural toothpaste. Illumina MiSeq was used in analyzing 20 salivary samples based on the 16S rRNA. Statistics of the raw data description and its processing is shown in *Table 2*. The average sequence length per read was 297 bp across different samples ranging from 293 to 300 bp. A total of 2,305,029 clean sequence reads were generated across subjects before and after swaking with average read numbers of 116,476 and 114,027 per subject, respectively (*Fig. 1*). A total of 2,241,369 tag-linked sequences were generated across subjects before and after swaking with average read numbers of 113,346 and 110,791 per subject, respectively. While, a total of 1,700,687 sequence tags were generated across subjects before and after swaking with average read numbers of 86,072 and 83,995 per subject, respectively (*Fig. 1*). These sequence tags were assigned to 291 OTUs (operational taxonomic units) across samples with ≥ 97% similarity. A summation of 4,147 OTUs for the 20 samples were generated with an average of 207 OTUs per sample ranging from 146 to 257 OTUs and averages of 206 and 208 OTUs per subject before and after swaking (*Figs. 2* and *A1*). The overall number of OTUs before swaking (BEF) was 289, while 282 after swaking (AF). The results for the number of observed species (number of OTUs) per subject indicated increases in four subjects, while resulted in decreases in five subjects and no change in one subject (*Fig. 2*).

Table 2. *Statistics of data generated from deep sequencing for 10 Saudi children before (BEF) and after (AF) swaking for one month*

Sample ID	Reads length (bp)	Raw data (Mbp)	N base (%)	Low quality (%)	Clean data (Mbp)	Data utilization (%)	Raw reads	Clean reads	Read utilization (%)

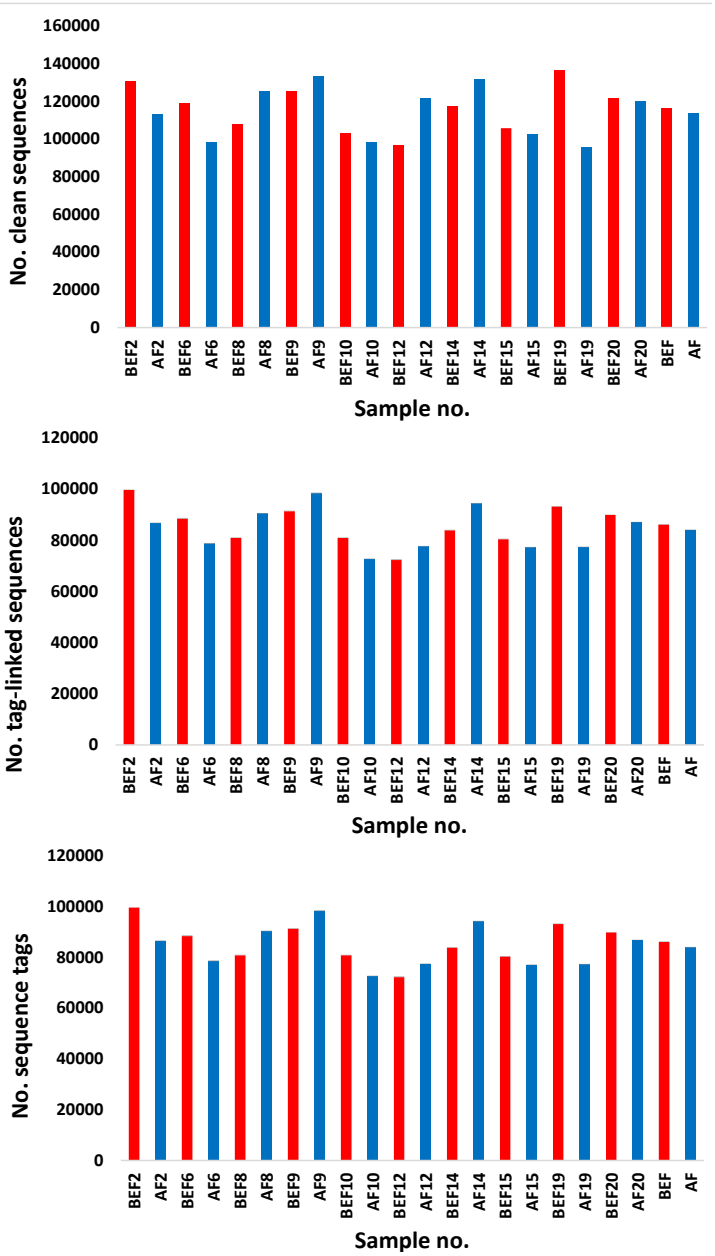

Figure 1. *Comparison among numbers of clean and tagged sequences along with the recovered sequence tags at the sample and group levels before (red) and after (blue) swaking for one month to sequences statistics. BEF = before swaking, AF = after swaking*

Diversity and rarefaction curve analysis

Description of observed species detected from OTU annotation is shown in *Table A1*. Alpha diversity was applied to analyze complexity of species. Shannon and Simpson indices as alpha diversity measures indicated no significance between BEF and AF groups (*Fig. 2*). Shannon and Simpson values reflect the species diversity of the community at both species' richness and evenness levels. But Shannon index comprises more weight on sequence richness, while Simpson index comprises more weight on evenness. With the same species richness, the greater the species evenness, the greater the community diversity. Alpha diversity per subject indicated increases in six subjects

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70897138

due to swaking for one month in terms of Shannon measures (*Fig. 2*). Almost opposite results were detected in terms of Simpson measures (*Fig. 2*). These results indicated that the use of Miswak has resulted in increased microbial species richness and decreased species evenness. In other words, Miswak likely changed the overall structure of oral microbiome during such a short period of treatment. Alpha diversity at the group level showed much higher diversity in AF group due to swaking than BEF group (*Fig. 3*). However, further prolonged studies might be required to prove whether salivary bacterial diversity is related to oral hygiene status, especially after swaking, or not.

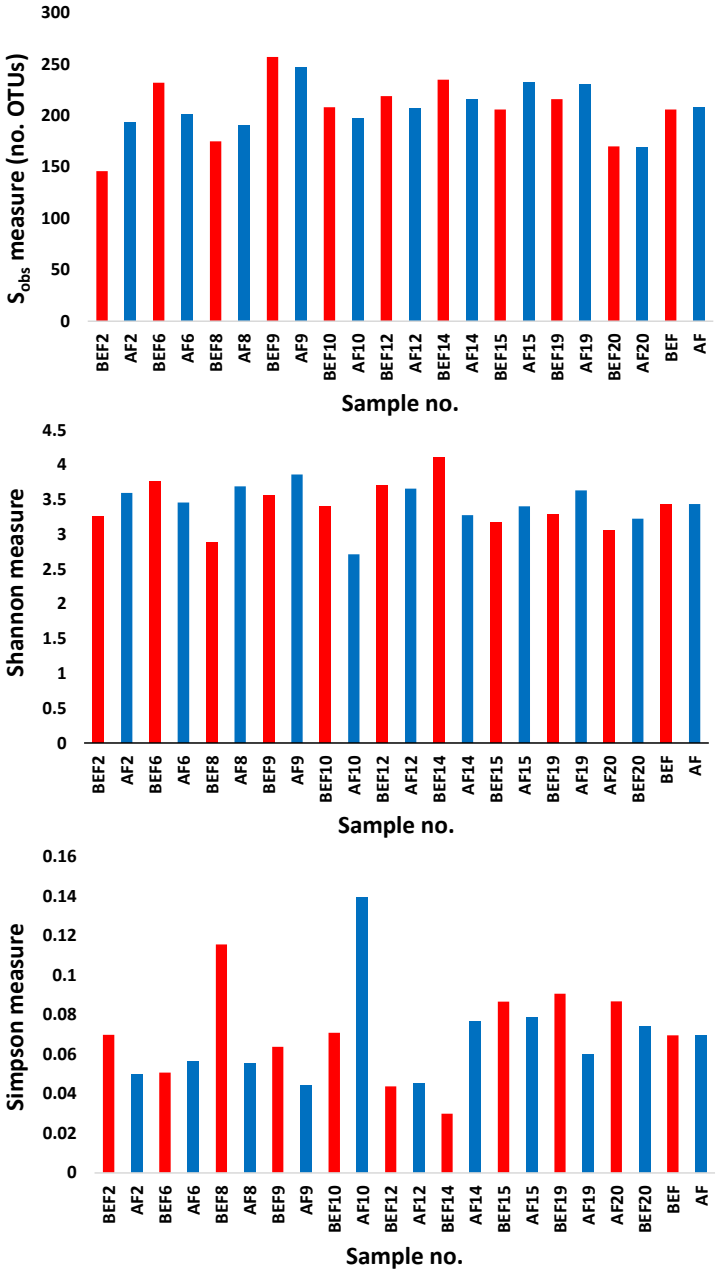

Figure 2. *Alpha diversity measures at the sample and group levels before (red) and after (blue) swaking for one month to describe number of species (OTUs) per sample or group, sample or group richness (Shannon index) and evenness (Simpson index). BEF = before swaking, AF = after swaking*

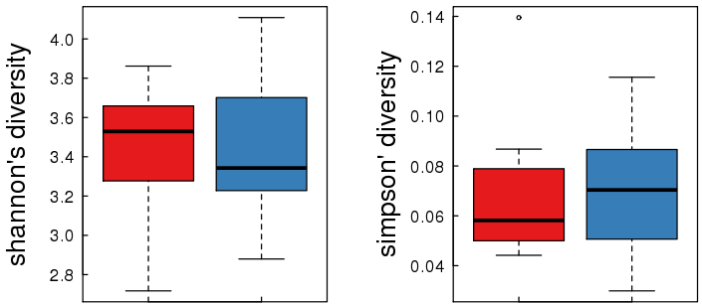

Figure 3. *Alpha diversity indices as boxplots to describe richness and evenness at the group level of the samples before (red) and after (blue) swaking for one month*

Rarefaction curves based on stacked number of OTUs (*Fig. 4*) were analyzed in order to describe the maximum depth permitted to retain all samples in the dataset for studying taxonomic relative abundance and to evaluate if produced data is enough to cover all species in the microbial community. When the curve tends to drop (*Fig. 4*) or no longer climbs, this indicates that the produced data is enough for further analysis. The more the curve continues to climb with increasing sequencing reads, the higher the complexity will be in samples, i.e., there will still be species uncovered by the sequencing data. The two rarefaction measures indicated that the maximum number of sequences reads to be used for further analysis of taxonomy abundance is 72,000 (*Fig. 4*).

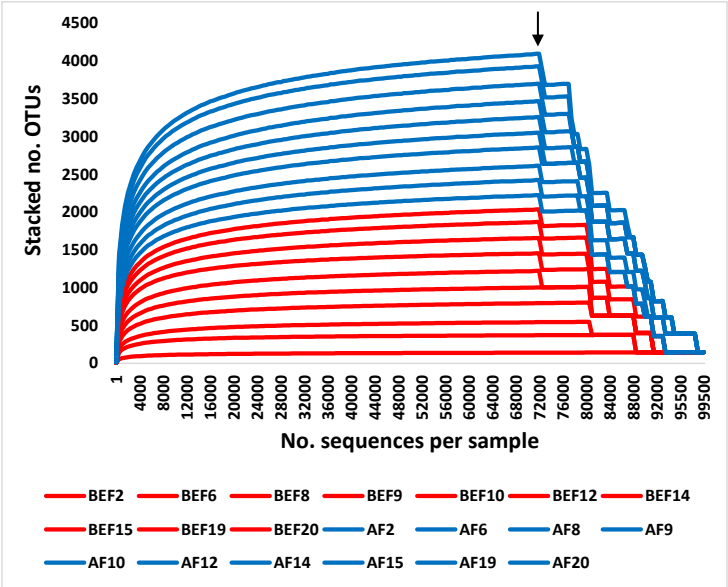

Figure 4. *Stacked number of OTUs as rarefaction measures to describe the maximum depth permitted to retain all samples in the dataset for studying taxonomic relative abundance. The arrows indicate the suitable sample size for analyzing taxonomy abundance (72,000 sequence reads). BEF = before swaking, AF = after swaking*

In order to display the diversity and differences of OTU composition in different samples and groups, principal coordinate analysis (PCoA) was used (*Fig. 5*). PCoA summarizes factors mainly responsible for this difference. When similarity is high, the two groups are closely located. Based on the OTU abundance information, the relative

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70897138

abundance of each OTU in each sample and group was calculated, thus the PCoA of OTUs was plotted (*Fig. 5*). The PCoA plot partially showed a similar tendency in the distances within and between groups. The diversity of BEF subjects was higher towards PCoA 2 direction (PC2), while diversity of AF subjects was higher towards PCoA 1 direction (PC1). Overall, the diagram showed that mean value of BEF group was localized in the positive directions of PCoA 1 and PCoA 2 (PC1 and PC2), while that of AF group was localized in the negative directions (*Fig. 5*). These results indicated that the microbiome signatures of the two groups differed due to swaking, while holding relatively similar microbiome compositions as the swaking time of the experiment was short.

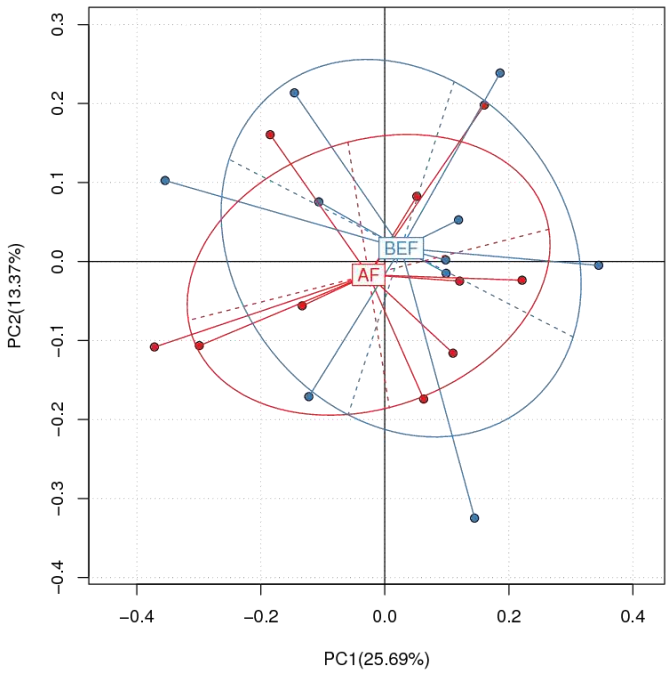

Figure 5. *PCoA based on OTU abundance of different samples. Blue box indicate sample mean before swaking. Red box indicate sample mean after swaking for one month. X-axis is the first principal coordinate and Y-axis is the second. Numbers in brackets represent contributions of PCoAs to differences among samples. A dot represents each sample, and different colors represent different groups*

Oral microbiomes at phylum and genus levels

Phylogenetic tree describing taxonomic groups of oral microbiomes at phylum and genus levels are shown in *Figure 6*. A phylogenetic tree is a branching diagram showing the inferred evolutionary relationships among various biological taxa based upon similarities and differences in their physical or genetic characteristics. The evolutionary distance between taxa is closer if the branch length is shorter. Besides the taxa composition and abundance analysis, phylogenetic tree could clarify the species evolutionary relationship further. The results indicated that the most common phyla are Actinobacteria (seven genera), Bacteroidetes (six genera), Firmicutes (28 genera), Fusobacteria (two genera), Proteobacteria (11 genera), Sphirochaetes (one genus), Synergistetes (two genera) and Tenericutes (two genera) (*Fig. 6*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70897138

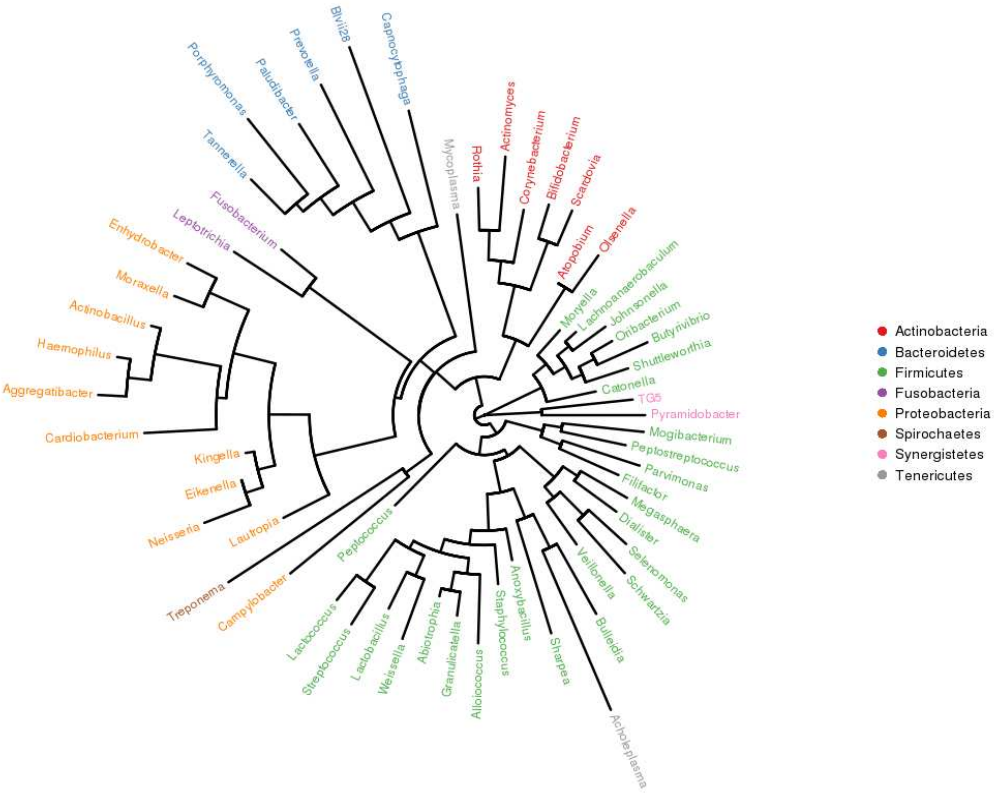

Figure 6. *Genus level phylogenetic tree of oral microbiome. Genera with the same color belong to the same phylum*

Abundance of individual OTUs across samples was also studied in which OTUs with number of sequences over 10,000 were considered highly abundant (*Fig. 7*). This criterion was met by a number of 29 out of the 219 OTUs (*Table A2*). These selected OTUs are OTU1-OTU12, OTU14, OTU15, OTU17, OTU20, OTU21, OTU23, OTU25-OTU29, OTU32, OTU33, OTU37, OTU40, OTU193 and OTU261. *Table A2* also indicates richness of these OTUs for different samples before and after swaking. Description of these selected highly abundant OTUs in terms of taxonomy of their phyla, genera and/or species is shown in *Table A3*. The results of *Table A3* indicate that the highly abundant OTUs belong to five of the previously mentioned phyla (e.g., Bacteroidetes, Firmicutes, Proteobacteria, Fusobacteria, Actinobacteria) in addition to the recently discovered phylum of Saccharibacteria, previously known as TM7. These results are consistent with those of log-scaled percentage heat map at the phylum level (*Fig. A2*). A heat map is a graphical representation of data where the individual values contained in a matrix are represented as colors.

The five highly abundant phyla included a number of 25 genera/species (*Table A3*). The latter include assigned and unassigned species of genera *Prevotella* and *Porphyromonas* of Bacteroidetes; *Streptococcus*, *Veillonella*, *Gemella*, *Megasphaera*, *Clostridium* and *Granulicatella* of Firmicutes; *Haemophilus*, *Campylobacter*, *Neisseria, Moraxella* and *Pasteurella* of Proteobacteria; *Fusobacterium* and *Leptotrichia* of Fusobacteria; while *Rothia* of Actinobacteria. However, no genus/species information is available for the new phyla Saccharibacteria TM7-3 because, up to date, these bacteria is culture-independent.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70897138

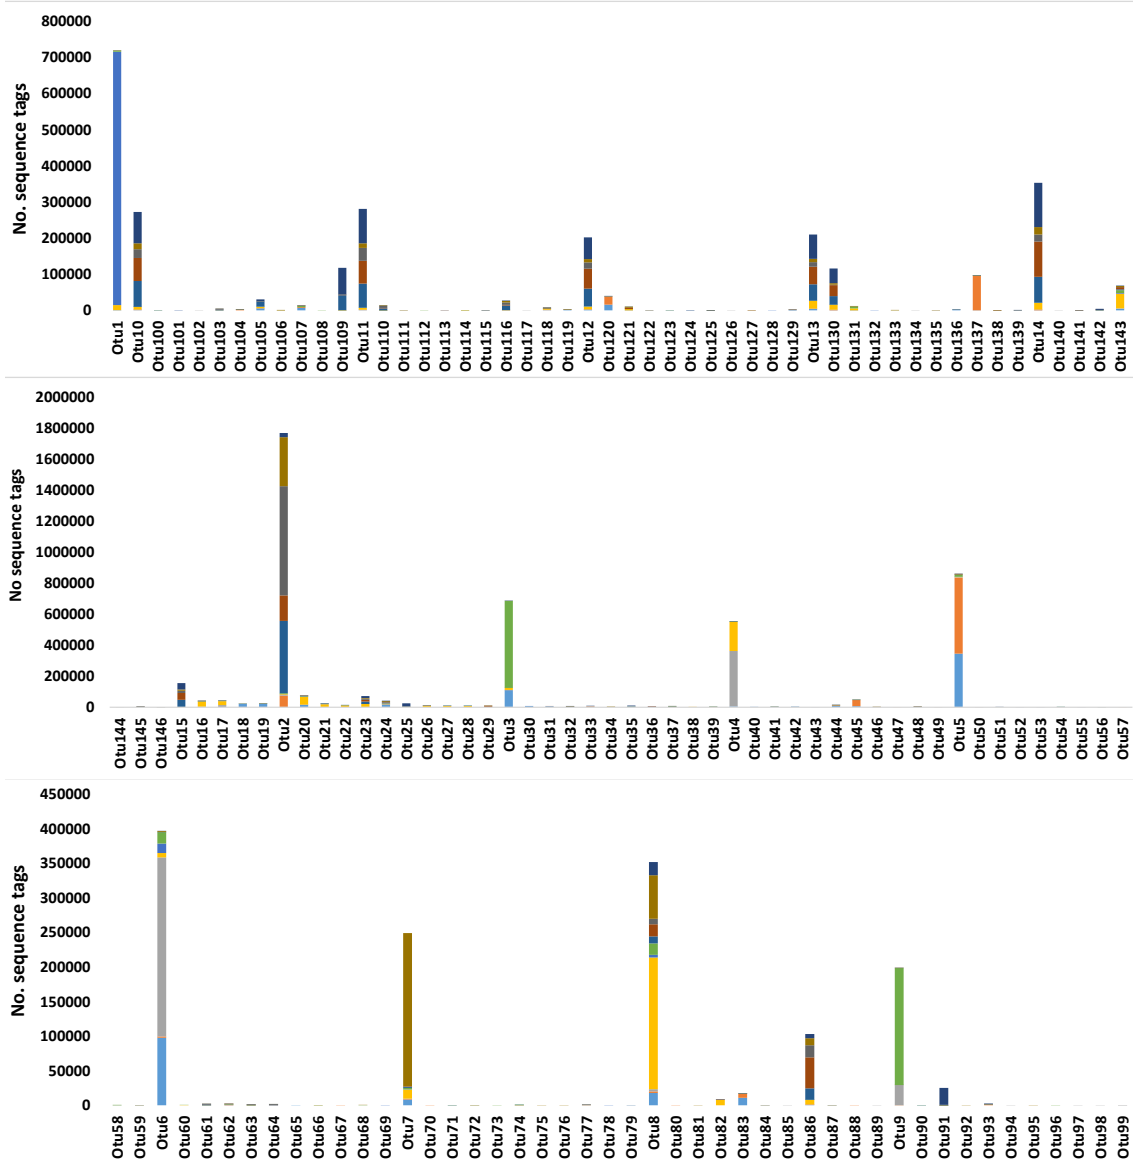

Figure 7. *OTU abundances across samples*

At the genus level, *Streptococcus* was the most abundant genus, with *S. infantis* as the most abundant species, followed by *Veillonella* (mainly *V. dispar*), *Prevotella* (mainly *P. melaninogenica*), *Haemophilus* (mainly *H. parainfluenzae*), *Rothia* (mainly *R. mucilaginosa*), *Neisseria* (mainly *N. subflava*), *Fusobacterium*, *Campylobacter* and the candidate phyla *Saccharibacteria* (*Table A3*). These results are consistent with those of log-scaled percentage heat maps at genus and species levels (*Figs. A3* and *A4*). Many of the highly abundant genera (e.g., *Veillonella, Campylobacter*, *Clostridium*, *Prevotella*, etc.) and species (e.g., *V. dispar*, *H. parainfluenzae*, *R. mucilaginosa*, etc.) are opportunistic pathogens and reflect the lack or the poor hygiene that requires attention, especially at childhood period.

Venn diagram indicated the existence of 280 common OTUs in both the BEF and AF groups (*Fig. 8*). The number of OTUs uniquely found in BEF group was nine representing the taxonomic groups *Streptococcus* spp., *Aggregatibacter*,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70897138

Veillonellaceae, *Prevotella* spp., *Pyramidobacter piscolens*, *Bifidobacterium* spp., *Bulleidia* spp., *Prevotella* spp. and *Streptophyta I*), while two (*Actinobacillus* spp. and *Kingella* spp.) in AF group. Each of these taxonomic groups were present in only 1-2 samples, while only *Streptococcus* spp. was present in five BEF samples. However, this result was not considered affective because the number of sequences for the specific OTU of this taxa (e.g., OTU138) is as little as 72. Thus, the 11 group-specific OTUs were not considered effective in distinguishing between the two groups or in detecting the influence of swaking for one month on children oral microbiomes (*Fig. 8*).

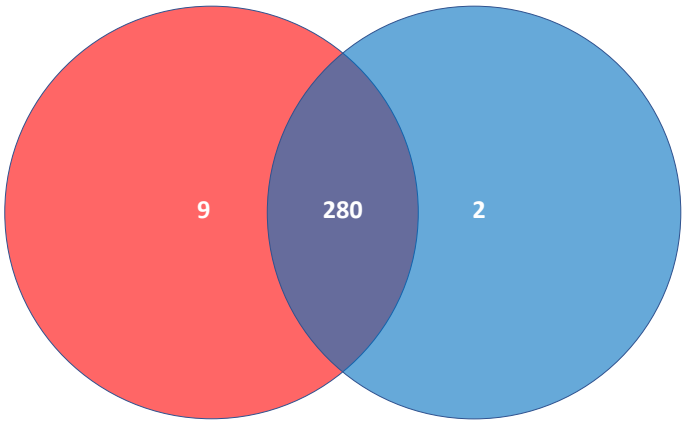

Figure 8. *Venn diagram describing the unique (nine for BEF and two for AF) and shared OTUs (280) between the two groups of samples before (red) and after (blue) swaking for one month. BEF = before swaking, AF = after swaking. The nine BEF OTUs involve OTU138, OTU181, OTU224, OTU232, OTU243, OTU257, OTU260, OTU266 and OTU 267. The two AF OTUs involve OTU127 and OTU269. The other OTUs (280) are shared between the two groups with different relative abundances*

Differential abundance of microbes due to swaking for one month

Differential abundance of microbes of different subjects before and after swaking for one month was studied at phylum, genus and species levels (*Figs. 9, 10* and *11,* respectively). Weighted Unifrac diversity distances within subjects indicated major changes in microbiome signature due to swaking in six out of the ten subjects, while unweighted Unifrac diversity distances within subjects indicated major changes in only two subjects. We did not consider the unweighted Unifrac results as the number of diverged subjects is less than four. As indicated earlier, prolonged swaking time might result in higher distances at the weighted and unweighted Unifrac levels. A number of 12 phyla, 27 genera and 21 species showed considerable changes within each subject's microbiome due to swaking (*Figs. 9, 10* and *11,* respectively). Overall, phyla Actinobacteria and Bacteroidetes decreased, while Firmicutes increased due to swaking for one month.

Statistical analysis for the highly abundant OTUs recovered from oral microbiomes with number of sequences over 10,000 indicated significant increases due to swaking across subjects in two OTUs referring to unassigned species of the genera *Streptococcus* and *Megasphaera* (*Fig. 12; Table A4*), while significant decreases in five OTUs referring to opportunistic pathogens *Veillonella dispar* and *Rothia mucilaginosa*; unassigned species of genera *Campylobacter* and *Prevotella* as well as bacteria of the family Pasteurellaceae (*Fig. 13; Table A4*).

Discussion

Oral microbiome significantly affects overall human health. It is organized as biofilms adapted to every niche within the mouth. This biofilm has fundamental role in host homeostasis and the protection against oral as well as gastric diseases (Ismail et al., 2009; Kau et al., 2011).

Normally, the predominant bacteria in saliva are commensal and produce enzymes that degrade biofilm matrix polymers (Kaplan et al., 2004; Pereira et al., 2012) Poor oral hygiene can lead to changes in microbial communities and cause dental caries and periodontal disease that seriously affect children's overall life-time health status (Marsh, 2003; Prabhu and John, 2015). Therefore, it is important to detect oral microbe biofilm signatures in healthy and infected individuals in order to develop preventive strategies, especially in childhood.

Earlier studies indicated that changes in the microbiome balance might have a more important influence on human health than a distinct microbial species being either beneficial or harmful (Huttenhower et al., 2012; Methé et al., 2012). Although a distinct microbial species might not be harmful in its primary habitat, oral bacteria were linked with systemic, life-threatening disorders including cardiovascular disease, pneumonia and stroke (Awano et al., 2008; Beck and Offenbacher, 2005; Joshipura et al., 2003; Joshipura et al., 1996; Seymour et al., 2007). Oral microbiome is highly divergent among healthy individuals as several ecological factors, such as life style, external environment and oral hygiene, can contribute to this divergence (Aas et al., 2005; Crielaard et al., 2011; Nasidze et al., 2009; Sheiham and Watt, 2000).

Other factors include ethnic background and/or geographic origin (Aas et al., 2005; Ledder et al., 2007). Several bacterial genera/phyla fundamentally influence human oral health/disease status. They include *Actinomyces* spp., *Gemella* spp., *Granulicatella* spp., *Veillonella* spp., *Haemophilus* spp., *Capnocytophaga* spp. and TM7. For example, early colonization of *Veillonella* spp. and existence of phylum TM7 guide the development of microbial biofilm communities (Liu et al., 2012; Periasamy and Kolenbrander, 2010). As indicated earlier, *Streptococcus* was the most abundant genus in oral micrbiomes of Saudi children regardless of swaking, followed by *Veillonella*, *Prevotella*, *Haemophilus*, *Fusobacterium*, *Rothia*, *Neisseria*, *Campylobacter* and the candidate phyla *Saccharibacteria* (*Table A3*). These results are consistent with previous studies of the human oral microbiota (Hoffman et al., 2018; Li et al., 2014; Takeshita et al., 2014).

High-throughput technologies are employed in detecting microbiome signatures in different human organs and their relation to disease risk/status (Gao et al., 2017; Jo et al., 2017). The approach of the cost-efficient, high-throughput characterization of the human microbiome relies on the use of microbial 16S ribosomal RNA (rRNA) gene sequence that is considered as a barcode of microbes, either culturable or unculturable (Ahn et al., 2011). Such an approach can provide new insights into the diversity, normal microbial signatures and health/disease status (Ahn et al., 2011; Belda-Ferre et al., 2012; Johansson et al., 2016; Zhou et al., 2016). Many problems raised when isolating oral bacterial DNA from clinical samples due to the lack of bacterial lysis uniformity, particularly for gram-positive bacteria (Lazarevic et al., 2013). Although Vesty et al. (2017) recommended the use of enzymatic lysis method for bacterial DNA extractions, Garbieri et al. (2017) recommended the use of commercial DNA extraction kits. We have chosen the QIAamp® DNA Mini kit (Qiagen®51306; Hilden, North Rhine-Westphalia, Germany) for extracting high-quality oral bacterial DNA. Another problem lies in the choice of the hypervariable regions (V1-V9) of 16S rRNA gene that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70897138

adequately and reliably detect oral microbiome signatures. Besides, it is important to know the proper database for OTU annotation. Based on the most recent studies, the 16S V3-V4 regions of oral microbiome were successful in detecting accurate microbial signatures and in providing adequate phylogenetic assignment (Furquim et al., 2017; Jiang et al., 2016; Yu et al., 2017). Accordingly, we have chosen the V3-V4 regions for analyzing the oral microbiome. We have also chosen the Greengenes (version 13_8: 16S rDNA database, http://qiime.org/home_static/dataFiles.html) (DeSantis et al., 2006) and Human Oral Microbiome (HOMD, http://www.homd.org/) (Chen et al., 2010) databases for annotating the oral microbiome sequences.

The influence of swaking on human oral microbiome was statistically studied on the 29 most abundant families, genera and species (*Table A4*). The overall results indicated that swaking for one month resulted in the significant increases of the unassigned species of the genera *Streptococcus* and *Megasphaera* (*Table A4; Fig. 12*) and the significant decreases of the bacteria *Veillonella dispar* and *Rothia mucilaginosa*; unassigned species of genera *Campylobacter* and *Prevotella* as well as bacteria of the family Pasteurellaceae (*Table A4; Fig. 13*). Although extremely abundant, *Streptococcus anginosus* (previously known as *Streptococcus milleri*) and *S. infantis* showed insignificant increases due to swaking (*Table A4*). Otherwise, the influence of Miswak was arbitrary for the other highly abundant taxa with no specific pattern across subjects. Although it resides in normal flora of the oral cavity, *Streptococcus anginosus* is considered as a strong virulent pathogen (Liu et al., 2018). It is speculated that the significant increase of oral *Streptococcus anginosus* associates with periodontal diseases (Drucker and Green, 1977; Liu et al., 2018; Rawlinson et al., 1993). *Streptococcus infantis* is a microbe that lives mainly in the human upper respiratory tract and usually found in healthy mouths, e.g., free of or are at low risk of tooth decay (http://www.ncbi.nlm.nih.gov/pmc/articles/PMC2444020/, http://www.ncbi.nlm.nih.gov/pmc/articles/PMC3472979/).

Miller et al. (2017) showed an increased evidence that the commensal acetaldehydogenic microorganism *Rothia mucilaginosa* can be an opportunistic pathogen in immune-compromised hosts, while Amer et al. (2017) indicated that the increased abundance of *R. mucilaginosa* is linked to oral leukoplakias from lingual sites. Elevated levels of *R. mucilaginosa* was also shown to be associated with human endocarditis, meningitis and peritonitis (https://en.wikipedia.org/wiki/Rothia). Amer et al. (2017) also indicated that the increased levels of *Campylobacter concisus* is associated with severe dysplasia. *Campylobacter* spp. is the main cause of food poisoning (campylobacteriosis) affecting up to 1% of the world (https://en.wikipedia.org/wiki/Campylobacter). Recently, Liu et al. (2018) detected high abundance of *Prevotella intermedia* in saliva of gout and hyperuricemia (HUA) patients and suggested that abundance of this bacterial species is linked with gum inflammation and the progression of periodontitis. This conclusion complements a previous one made by Kamma et al. (1994). As for the bacteria of the family Pasteurellaceae, it was recently reported to be associated with caries in young children living in a rural province in China (Xu et al., 2018). The significant decreases of *Rothia mucilaginosa*, *Campylobacter* spp., *Prevotella* and Pasteurellaceae due to swaking in the present study (*Fig. 13*) can be considered as biomarkers of good hygiene in children.

Most of the normal commensal oral bacteria benefit the host through the production of various metabolites. They mostly include short chain fatty acids, vitamins, co-factors and other metabolites (Nallabelli et al., 2016). However, there is a strong reverse action

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_70897138

of the two colonizers, e.g., *Streptococcus* and *Veillonella* in oral cavity bacteria (Hoffman et al., 2018). Mashima et al. (2017) indicated that unassigned species of *Streptococcus* spp. decreased, while *Veillonella dispar*, *V. parvula* and unassigned species of *Veillonella* spp. increased with poor oral hygiene status. *Streptococcus*, a facultative anaerobe and an initial colonizer, is able to catabolize (and transport) carbohydrates to short-chain organic acids, e.g., lactic acid and pyruvic acid (Cotter and Hill, 2003). On the other hand, *Veillonella*, an obligate anaerobe and subsequent colonizer, is unable to catabolize sugars, thus, it relies mainly on the fermentation of organic acids to propionic and acetic acids, carbon dioxide, and hydrogen (Delwiche et al., 1985). It is reported that oral *Veillonella* depends on organic acids produced by oral *Streptococcus* (Mashima and Nakazawa, 2014; Palmer et al., 2006). The proximity of the producer/consumer shuttle is important in such metabolite transfers (Mashima and Nakazawa, 2014; Palmer et al., 2006). Organic acids participate mainly in biofilm formation due to the action of *Streptococcus* (Periasamy and Kolenbrander, 2010). Anaerobic environment promotes growth of *Veillonella* due to the prior growth of aerobic and facultative organisms that results in an increased plaque thickness to yield conditions suitable for anaerobic growth (Ritz, 1967). The growth of *Streptococcus* may be inhibited by anaerobic conditions that favor the growth of *Veillonella*. Therefore, the high abundance of *Veillonella* in salivary microbiome is considered as a biomarker of poor oral hygiene and occurrence of caries in children (*Fig. 14*). Pharmacological studies indicated that Miswak possesses anti-microbial, anti-plaque and anti-inflammatory activities that makes it useful in defeating plaque (Lebda et al., 2018). The latter potential activities align with our results in terms of the decrease of *Veillonella* spp., the bacteria that favors the accumulation of plaque. *Veillonella* was also found in higher proportion in caries or periodontal subjects (Zhang et al., 2015; Zhou et al., 2016).

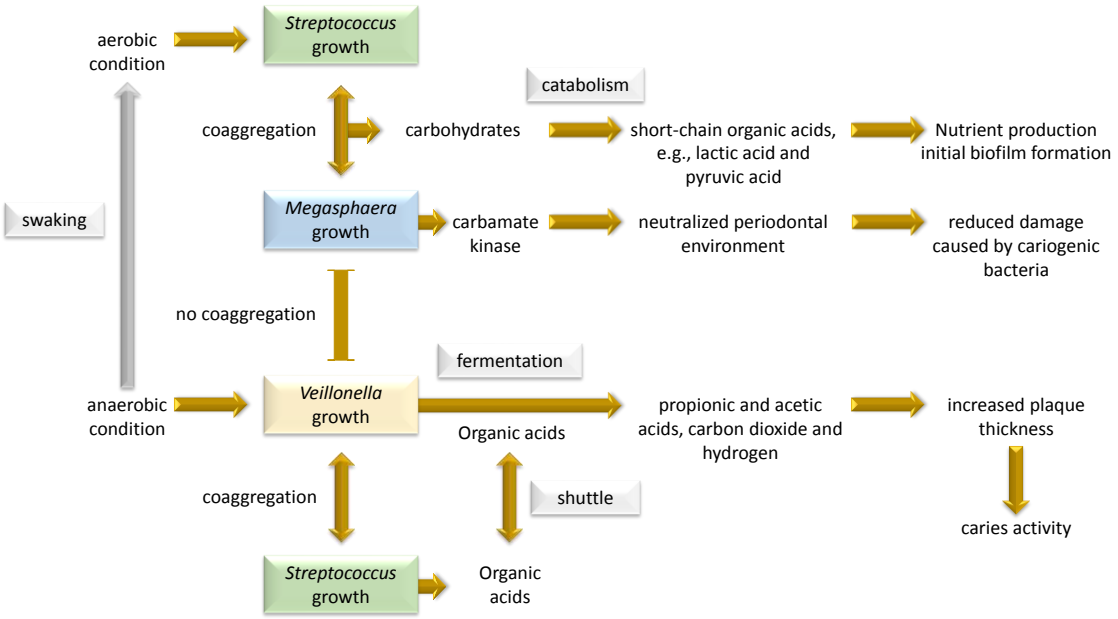

Figure 14. *Roles of the three genera Streptococcus, Veillonella and Megasphaera and possible influence of swaking on oral hygiene*

DOI: http://dx.doi.org/10.15666/aeer/1805_70897138

Conclusion

In general, we claim that swaking hinders the anaerobic condition required for *Veillonella* growth, thus favors the aerobic condition that promote *Streptococcus* growth. Our results also indicate parallel significant increases of the unassigned species of the genera *Streptococcus* and *Megasphaera* (*Fig. 12; Table A4*). Interestingly, *Megasphaera* spp. strain DISK18, a nonpathogenic species, was recently reported to coaggregate with *Streptococcus* during oral early colonization but not with *Veillonella* (Nallabelli et al., 2016). It is speculated that genera *Megasphaera* and *Veillonella* compete for coaggregating with *Streptococcus* due to homology of surface receptors of these two genera (Kreth et al., 2009; Nallabelli et al., 2016). Whole genome sequencing of the *Megasphaera* strain showed a lack of virulence genes, that are associated with oral pathogenesis, or genes encoding collagenase or gelatinase. The latter indicates that *Megasphaera* unlikely participates in periodontal disease. Instead, this bacteria harbors carbamate kinase that participate in neutralizing the periodontal environment, thus, reduce the damage caused by cariogenic bacteria (*Fig. 14*). In summary, we consider Miswak as an excellent natural toothpaste with differential influence on oral microbiome that makes it feasibly useful for maintaining good oral hygiene, especially for children. Future studies on the new selected species are still required in order to support the results of the present research.

Acknowledgments. The authors Acknowledge Prof. Khalid M. Al-Ghamdi, the head of Department of Biological Sciences, Faculty of Science, King Abdulaziz University, Jeddah, KSA, for providing physical and logistic support for this study.

Table A1. *Description of observed species detected from OTU annotation across subjects and swaking*

OTU no.	OTU abundance	Taxonomy
Otu2	235993	Bacteria; Firmicutes; Bacilli; Lactobacillales; Streptococcaceae; Streptococcus; Streptococcus_infantis
Otu1	195394	Bacteria; Bacteroidetes; Bacteroidia; Bacteroidales; Prevotellaceae; Prevotella; Prevotella_melaninogenica
Otu3	163677	Bacteria; Firmicutes; Clostridia; Clostridiales; Veillonellaceae; Veillonella; Veillonella_dispar
Otu4	92051	Bacteria; Proteobacteria; Gammaproteobacteria; Pasteurellales; Pasteurellaceae; Haemophilus; Haemophilus_parainfluenzae
Otu11	58531	Bacteria; Fusobacteria; Fusobacteriia; Fusobacteriales; Fusobacteriaceae; Fusobacterium
Otu8	58093	Bacteria; Actinobacteria; Actinobacteria; Actinomycetales; Micrococcaceae; Rothia; Rothia_mucilaginosa
Otu32	50183	Bacteria; Firmicutes; Clostridia; Clostridiales; Veillonellaceae; Veillonella; Veillonella_dispar
Otu14	46624	Bacteria; Firmicutes; Bacilli; Gemellales; Gemellaceae
Otu6	40872	Bacteria; Proteobacteria; Betaproteobacteria; Neisseriales; Neisseriaceae; Neisseria; Neisseria_subflava
Otu5	39815	Bacteria; Proteobacteria; Epsilonproteobacteria; Campylobacterales; Campylobacteraceae; Campylobacter
Otu12	34029	Bacteria; Firmicutes; Bacilli; Lactobacillales; Streptococcaceae; Streptococcus
Otu10	33068	Bacteria; TM7; TM7-3
Otu7	32641	Bacteria; Firmicutes; Bacilli; Lactobacillales; Carnobacteriaceae; Granulicatella
Otu29	29782	Bacteria; Proteobacteria; Betaproteobacteria; Neisseriales; Neisseriaceae; Neisseria
Otu261	27911	Bacteria; Proteobacteria; Betaproteobacteria; Neisseriales; Neisseriaceae; Neisseria; Neisseria_cinerea
Otu17	23783	Bacteria; Bacteroidetes; Bacteroidia; Bacteroidales; Prevotellaceae; Prevotella; Prevotella_pallens
Otu15	22697	Bacteria; Bacteroidetes; Bacteroidia; Bacteroidales; Prevotellaceae; Prevotella
Otu25	20994	Bacteria; Bacteroidetes; Bacteroidia; Bacteroidales; Porphyromonadaceae; Porphyromonas
Otu21	18426	Bacteria; Bacteroidetes; Bacteroidia; Bacteroidales; Paraprevotellaceae; Prevotella
Otu20	17155	Bacteria; Fusobacteria; Fusobacteriia; Fusobacteriales; Leptotrichiaceae; Leptotrichia
Otu37	14672	Bacteria; Firmicutes; Clostridia; Clostridiales; Veillonellaceae; Megasphaera
Otu27	13910	Bacteria; Firmicutes; Bacilli; Lactobacillales; Carnobacteriaceae; Granulicatella
Otu26	13468	Bacteria; Bacteroidetes; Bacteroidia; Bacteroidales; Prevotellaceae; Prevotella; Prevotella_nanceiensis
Otu9	13242	Bacteria; Proteobacteria; Gammaproteobacteria; Pseudomonadales; Moraxellaceae; Moraxella
Otu40	13051	Bacteria; Firmicutes; Clostridia; Clostridiales; Veillonellaceae; Veillonella
Otu33	12906	Bacteria; Bacteroidetes; Bacteroidia; Bacteroidales; Paraprevotellaceae; Prevotella
Otu193	12432	Bacteria; Proteobacteria; Gammaproteobacteria; Pasteurellales; Pasteurellaceae
Otu23	11707	Bacteria; Firmicutes; Clostridia; Clostridiales
Otu28	10024	Bacteria; Bacteroidetes; Bacteroidia; Bacteroidales; Paraprevotellaceae; Prevotella; Prevotella_tannerae
Otu109	9878	Bacteria; Proteobacteria; Gammaproteobacteria; Pasteurellales; Pasteurellaceae; Haemophilus
Otu49	9750	Bacteria; Proteobacteria; Gammaproteobacteria; Pasteurellales; Pasteurellaceae; Actinobacillus; Actinobacillus_parahaemolyticus
Otu18	9704	Bacteria; Bacteroidetes; Bacteroidia; Bacteroidales; Prevotellaceae; Prevotella; Prevotella_nigrescens

Table A3. *Taxonomy and description of the highly abundant OTUs recovered from oral microbiomes of children regardless of swaking*

Phylum	Genus/Species	Description	OTUs
Bacteroidetes	*Prevotella* spp.	A genus of gram negative anaerobic bacteria. Some strains are present in humans, including *Prevotella denticola*. They are predominantly oral and can be opportunistic pathogens [1].	15,21,33
	Prevotella melaninogenica	A species of bacterium in the normal flora of the upper respiratory tract. It is formerly called *Bacteroides melaninogenicus*, is a gram-negative, anaerobic, rod-shaped bacterium that inhabits the oral cavity. It is an important human pathogen in various anaerobic infections [2].	1
	Prevotella pallens	A genus of gram-negative bacteria. *Prevotella* spp. are members of the oral, vaginal, and gut microbiota and are often recovered from anaerobic infections of the respiratory tract [3].	17
	Prevotella tannerae	An obligately anaerobic, non-spore-forming, nonmotile, gram-negative, rod-shaped bacterium that was isolated from the human gingival crevice [4].	28
	Prevotella nanceiensis	A novel species isolated from human clinical samples, e.g., blood cultures, lung abscess pus, broncho-alveolar lavage fluid, obligately anaerobic, non-spore-forming, non-motile, gram-negative coccoid and short rods [5].	26
	Porphyromonas spp.	Associated with severe and chronic periodontal (tissues surrounding and supporting the tooth) diseases. Progression of the disease is caused by colonization by this organism in an anaerobic environment in host tissues and severe progression results in loss of the tissues supporting the tooth and eventually loss of the tooth itself [6].	25
Firmicutes	*Streptococcus* spp.	First isolated in 1924 from human carious (cavities) lesions and is the main cause of tooth decay. This organism thrives in a bacterial community known as a dental plaque which forms on the surface of teeth. This organism has also been implicated in cases of infective endocarditis [7].	12
	Streptococcus infantis	A species of alpha-haemolytic streptococci. It has been isolated from human tooth surfaces and pharynx [8].	2
	Veillonella spp.	Well known for its lactate fermenting abilities. They are a normal bacterium in the intestines and oral mucosa of mammals. In humans they have been rarely implicated in cases of osteomyelitis and endocarditis [9].	40

DOI: http://dx.doi.org/10.15666/aeer/1805_70897138

Phylum	Genus/Species	Description	OTUs
	Veillonella dispar	A member of the normal human oral microbial community [10].	3,32
	Gemella morbillorum	Previously known as *Streptococcus morbillorum*, is an anaerobic, gram-positive coccus which is a component of the normal flora of the human gastrointestinal tract and the human oral microflora [11].	14
	Megasphaera spp.	A commensal genus of Firmicutes classified within the class Negativicutes as a member of the Clostridia. *Megasphaera* spp. reside in the human genitourinary tract. It has not yet been characterized using traditional methods, or the species name has not yet been validly published [12].	37
	Clostridium spp.	Distinguished from the Bacilli by lacking aerobic respiration. They are obligate anaerobes and oxygen is toxic to them [13].	23
	Granulicatella spp.	A facultatively anaerobic gram-positive, non-motile, non-sporulating bacterium. It is part of normal human oral flora and is thought to be a cause of endocarditis [14].	7
	Granulicatella adjacens	Formerly called *Streptococcus adjacens* or *Abiotrophia adiacens*, a species of gram-positive, non-motile, non-sporulating cocci isolated from the throat flora, urine and blood of patients with endocarditis [15].	27
Proteobacteria	*Haemophilus parainfluenzae*	A slow-growing gram negative bacteria that is a normal part of the human oropharyngeal flora. It is a cause of endocarditis in children [16].	4
	Campylobacter spp.	The leading cause of bacterial food poisoning (campylobacteriosis) in the world, and is more prevalent than *Salmonella enteritis* (salmonellosis). Severe health and economic problems are a result of widespread infections that affect up to 1% of the population [17].	5
	Neisseria spp.	A nonpathogenic, commensal bacterium closely related to the pathogenic *Neisseria meningitidis*. Of the 11 species that colonize humans, only two are pathogens, *N. meningitidis* and *N. gonorrhoeae* [18].	29
	Neisseria subflava	Commonly isolated from the oral and respiratory tract of humans. This bacterium can be an opportunistic pathogen and has occasionally been isolated from cases of endocarditis or bacteremia [19].	6
	Neisseria cinerea	Isolated in Germany from the nasopharyngeal mucosa of a healthy human [20].	261
	Moraxella spp.	Part of the commensal flora of the upper respiratory tract. It is also recognized as the cause of a variety of human infectious diseases including acute otitis media and sinusitis, which occur primarily in infants and young children [21].	9
	Pasteurella spp.	One of the first pathogens ever studied, and is named after Louis Pasteur, who used it in his vaccination studies in the 1880s. This organism usually resides in the mucous membranes of the intestinal, genital, and respiratory tissues and is an opportunistic pathogen [22].	193
Fusobacteria	*Fusobacterium* spp.	Belongs to the normal microflora of the human oral and gastrointestinal tracts. It is a very long and slender spindle-shaped bacillus with sharply pointed ends that is characterized by the ability to invade soft tissues. Although not considered a major dental pathogen on its own, this anaerobe facilitates the aggregation and establishment of several other species including the dental pathogens *Porphyromonas gingivalis* and *Bacteroides forsythus* [23].	11
	Leptotrichia spp.	An anaerobic, gram-negative rod bacteria. It is a constituent of normal oral flora. Leptotrichiabuccalis can be clearly identified using live blood analysis in dark field. They have a distinct form, which separates them from other rod forms [24].	20
Actinobacteria	*Rothia mucilaginosa*	A gram-positive, cocci-shaped bacterium that inhabits the oral cavity. The bacterium is considered an opportunistic pathogen and has been associated with endocarditis, meningitis, and peritonitis [25].	8
Saccharibacteria (TM7-3)	N/A	A major lineage of Bacteria, or a candidate phylum known solely through environmental 16S rRNA sequences as no species had been grown in the lab [26].	10

Abstract. Salinity stress is considered to be the most damaging type of abiotic stress, with devastating effects on wheat production. Abscisic acid (ABA) is a plant hormone that plays an important role in inducing the plant's response to abiotic stresses. Based on the structures of ABA, pyrabactin (PYR) and coronatine (COR), a target chemical compound, B2, was designed in this study. In a previous study, B2 enhanced drought tolerance in wheat by enhancing the ROS capacity, which was achieved by improving the antioxidant enzymes activity and the osmotic adjustment ability. Furthermore, it had a significant effect on improving photosynthesis and increasing the endogenous hormones in wheat under stress conditions. Two wheat cultivars (*Triticum aestivum L.*), JIMAI22 (JM22) and SHANNONG12 (SH12), were grown under hydroponic conditions to explore the effect of B2 in mitigating salt stress. The results showed that B2 had a function analogous to ABA, especially at a concentration of 0.1 μmol·L-1. Under a salinity stress of 150 mM NaCl, treatment with 0.1 μmol·L-1 B2 increased the leaf water content in both wheat cultivars, improving their photosynthetic efficiency and the antioxidant enzyme activity. Moreover, B2 enhanced the expression level of ABA-responsive genes (*TaABAOH2*, *TaNCED1*, and *TaAREB3*). Furthermore, it enhanced the expression level of salt-responsive genes (*TaMYB3R1* and *TaERF3*). Moreover, B2 also induced the endogenous plant hormone (ABA) signaling pathway, which led to an improvement of the salt tolerance in the wheat cultivars.
Keywords: *abscisic acid alternatives, salt stress, ABA and salt-responsive genes, hormonal signaling antioxidant, Triticum aestivum*

Introduction

Wheat is recognized as one of the most commonly cultivated food crops throughout the world and the primary source of proteins and carbohydrates. Current wheat production does not meet the demands of a rapidly growing global population. While plant breeders are working hard to improve wheat production, it is difficult to achieve the required production level due to complex issues, especially abiotic stresses (Jatoi et al., 2011; Moaveni, 2011).

Currently, soil salinity and drought are considered the most damaging abiotic stresses, affecting overall agricultural production. Salinity plays a crucial role in limiting plant production, especially in barren and semi-barren regions (Ashraf et al., 2004; Hussain et al., 2009). The main cause of salt stress in crops could be the use of saline water for irrigation purposes, due to the excessive amount salt in the ground water. Plants have internal mechanisms that help them realize the incoming stresses and regulate their physiological and metabolic processes accordingly to face the calamities (Zhang et al., 2006).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71397157

The plant root system rapidly senses the salt stress, which reduces the plant growth. In the short term, the water availability to the plant is hindered by increasing osmotic stress due to a high salt content, while in the long term, it is hampered by the raised ion toxicity, causing a nutrient deficit in the cytosol (Munns, 2005). A high salt concentration leads to a shortage in plant water uptake, even in well-watered soil, due to a reduction in the osmotic potential of the soil solutes, which makes it difficult for the plant roots to absorb water from the soil solution (Rengasamy, 2006). A high level of salinity also substantially reduces the pigment content of the leaves (Al-Sobhi et al., 2006).

High concentrations of NaCl, such as 125 mM and 150 mM, have a completely inhibitory, rather devastating, effect on most of the wheat cultivars (Amor et al., 2005), as most of the growth processes are badly affected. Growth rates and biomass production are efficient indicators to evaluate the level of the stress caused by salt and a plant's ability to resist it (Amor et al., 2005).

The higher salinity concentrations show clear effects on root and shoot lengths, since the roots are directly exposed to salt. A high level of NaCl causes a reduction in root and shoot development due to its toxic effects and an imbalanced nutrient uptake by plants. It also inhibits root elongation and development by reducing the water uptake by plants.

High salt concentrations decrease the water potential of plants and affect the water availability for the plant physiological functions (Jakab et al., 2005). The osmotic stress, as a result of salt accumulation, leads to a reduction of water absorption through roots and hence creates a water deficit in wheat leaf (Rahnama et al., 2010).

One of the main defense strategies in plants is their antioxidant system. This includes enzymatic and non-enzymatic compounds, which act as detoxification agents, scavenging toxic free radicals and helping the plants overcome destructive oxidative stress (Parida et al., 2004; Li et al., 2011). The major antioxidant defense enzymes are superoxide dismutase (SOD), catalase (CAT) and peroxidase (POD). SOD can scavenge the toxic O2- radicals, and its enzymatic action results in the formation of H_2O_2, which is subsequently converted to H2O by POD (Li et al., 2011).

ABA is one of the plant hormones that has the ability to regulate the plant physiological responses. It is known as a stress hormone because of its rapid accumulation in response to stresses and its mediation of stress responses, which helps plants to overcome stresses (Zhang et al., 2006). Exogenous ABA application accumulates proline by activating its biosynthesis and inhibiting its degradation pathways, which in turn plays a protective role in salt-stressed plants through scavenging free radicals (Wang et al., 2017). Recent studies show that plant growth responses to abiotic and biotic stresses can be regulated by plant hormones. These hormones have interrelated growth, inducing or inhibiting activities, which leads to a modulation of different plant biosynthesis and physiological responses (Peleg and Blumwald, 2011).

High plants have developed strategies to understand stress signals and modulate the specific stress-responsive gene expressions to acclimate to the stress conditions. Many genes induced by stress have been identified, such as key enzymes of the ABA biosynthesis pathway, osmotic adaptation proteins, cell protective enzymes and transcription factors (TFs). TFs, including AP2/ERF proteins, ABA responsive element (ABRE)-binding proteins and MYB, which play an important role in controlling stress-related gene expressions. Previous studies declare that different ERF members play various functions in plant responses to abiotic stress (Rong et al., 2014).

DOI: http://dx.doi.org/10.15666/aeer/1805_71397157

To synthesize the B2 compound, the sub active structure splicing method of integrating ABA, Pyrabactin (PYR), and coronatine (COR) was used, based on the similarities of the amide structure of COR and the sulfonamide-structure of PYR (Zhou et al., 2019) (*Fig. A1* in the *Appendix*).

In a previous study, B2 enhanced drought tolerance in wheat by enhancing the ROS capacity, which was achieved by improving the antioxidant enzymes activity and the osmotic adjustment ability. Furthermore, it had a significant effect on improving photosynthesis and increasing the endogenous hormones in wheat under stress conditions (Zhou et al., 2019).

Jimai22 is widely known as salt tolerant genotype (Dugasa et al., 2019) however Shannong12 was used as test material as it is not investigated for its salinity tolerance previously.

In the present study, the efficiency of compound B2 in enhancing wheat tolerance to salinity stress was investigated. This was because the function of this compound is analogous to that of ABA. The study was conducted to observe the morphological and physiological changes, occurring in different wheat cultivars. Moreover, the variation of the expression level of the related genes, with the use of B2 under high saline conditions, was also investigated.

Materials and methods

Wheat seedlings preparation and salt stress treatment

The experiment was conducted in Research Institute China Agricultural University, Beijing, China. Wheat seeds were sterilized by soaking them in 5% sodium hypochlorite solution for 10 min. The seeds were then washed 3–4 times with distilled water and planted in a plastic net, placed in a hydroponic box. At the one-leaf stage, after germination, the seedlings were transferred into plastic hydroponic boxes, containing Hoagland solution (Hoagland and Arnon, 1950). All the growth-boxes were placed in a greenhouse, set at 22–25 °C, 50% humidity and 14 h light and 10 h dark conditions, with a light intensity of 400 $mol \cdot m^2 \cdot s^{-1}$. Two wheat cultivars, Jimai22 (JM22) and Shannong12 (SH12), were grown to study their performance. After 48 h, when the seedlings were at the two-leaf stage, the chemical compound B2 and ABA treatments were applied by soaking the roots in the treatment solutions for 48 h. The ABA concentration was 0.01 $\mu mol \cdot L^{-1}$. B2 was added to the concentrations of 0.1 $\mu mol \cdot L^{-1}$, 0.01 $\mu mol \cdot L^{-1}$ and 0.001 $\mu mol \cdot L^{-1}$. After the treatment, the seedlings were transplanted into Hoagland nutrient solution. Five days later, seedlings were transplanted into Hoagland nutrient solution, containing 150 mM NaCl for salt stress treatment. For the purpose of conducting different analyses, leaf samples were taken from the seedlings, including those under the normal conditions (NC) and NaCl treatments. The treatments were replicated three times, average values of five seedlings were used for each replicate, and samples were collected for physiological measurements or RNA extraction.

Plant growth and biomass accumulation

For the measurement of fresh weight and dry matter accumulation, shoot, and root were separated and weighed for their fresh weight. The shoot and root dry weight was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71397157

recorded after drying in hot air oven at 65 °C for 72 h. All the related traits were recorded after eight days of planting.

Root characteristics

Three plants from each treatment were selected, shoot and roots were separated. The roots of each plant were scanned, (the roots of the same plant were submerged in a water tray to ensure separation of roots and to reduce their overlap, and the roots were scanned by using Epson photo scanner (Epson, Long Beach, CA). Scanned images of roots of respected treatments were analyzed using WinRHIZO Pro image analysis software (Regent Instruments, Inc., Quebec City, QC) to calculate the total root length (sum of the lengths of all roots from the same plant), root volume and total root surface area.

Relative water content (RWC)

Three leaves from each treatment were taken for relative water content (RWC) measurement. The fresh leaf weight (FW) was recorded. The leaves were then dipped in distilled water, for 24 h. The leaves were taken out of the water to record the turgid weight (TW). To record the dry leaf weight (DW), the leaves were dried in an electric oven, set at 65 °C for 72 h. The relative water content (RWC) of the leaves was calculated as per the formula given by Cornic (1994).

Antioxidant enzymes extraction and assays

The supernatant, used for the detection of SOD, POD and CAT activities, was according to the protocol described by Parida et al. (2004), where 0.5 g of leaf tissue was homogenized in 4 mL of 50 mM sodium phosphate buffer (pH = 7.0), containing 1% (w/v) PVP, 0.1 mM EDTA-Na_2, 1 $mM \cdot L^{-1}$ iso ascorbic acid and 0.05% (w/v) Triton X-100 in an ice bath. The homogenate was centrifuged at 12000 rpm and 4 °C for 15 min.

The soluble proteins content was quantified using the Bradford (1976) method, absorbance values, obtained by a standard curve was prepared with bovine serum albumin.

ABA was extracted and purified using the methods of Bollmark et al. (1988) and Yang et al. (2001) with some modifications. Quantifications were conducted using the ELISA approach. The mouse monoclonal antigens and antibodies, used in ELISA, were produced at the Phytohormones Research Institute China Agricultural University (checked and proven).

Malondialdehyde (MDA) and hydrogen peroxide (H2O2) content

For the determination of lipid peroxidation in shoots was done by, thiobarbituric acid (TBA) test, which determines Malondialdehyde (MDA) as an end product of lipid peroxidation (Heath and Packer, 1968). Fresh leaf material (500 mg) was homogenized in 5 ml 0.1% (w/v) TCA solution. The homogenate was centrifuged at 10000× g for 20 min, and 0.75 ml of the supernatant was added to 1.5 ml of 0.5% (w/v) TBA in 20% TCA. The mixture was incubated in boiling water for 30 min, and then reaction stopped by placing the reaction tubes in an ice bath. Then the samples were centrifuged at 10000×g for 5 min, and the absorbance of the supernatant was recorded at 532 nm. The value for non-specific absorption at 600 nm was subtracted. The amount of MDA–TBA complex (red pigment) was calculated from the extinction coefficient 155 mM^{-1} cm^{-1}.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71397157

$$\text{MDA (nmol g}^{-1}\text{ fresh weight)} = (\text{Abs532} - \text{Abs600})/155 \quad \text{(Eq.1)}$$

H_2O_2 levels were determined according to Alexieva et al. (2001). The absorbency of the supernatant was recorded at 390 nm. The content of H_2O_2 was given on a standard curve.

Proline content

Free proline content in shoots of wheat seedling was extracted with 3% sulfosalicylic acid and centrifuged at 12 000×g. An aliquot was mixed with glacial acetic acid and acidic ninhydrin for 30 min at 100 °C. The reaction was terminated in an ice bath, and chromophore was extracted with five mL of toluene. The chromophore-containing toluene was warmed to room temperature, and absorbance was recorded at 520 nm (Bates et al., 1973).

Determination of photosynthetic parameters

Photosynthetic speed using a portable photosynthetic apparatus LI-6400 (LI-Cor Inc, Lincoln, NE, USA) to measure the photosynthesis rate, stomatal conductance, intercellular CO_2 concentration and transpiration rate. Measurement conditions: leaf surface temperature: 25-28 °C, light intensity 1000 μmol/m^2 s, flow rate 500 mL/s. Each treatment was repeated 3 times, and the newly developed leaves of the seedling leaves were selected at the measurement site.

Statistical analysis

Two separate experiments were done each one contains one cultivar using complete randomized design (CRD) was used with three replications for each treatment. Analysis of variance (ANOVA) was carried out using Proc Mixed of SAS package version 9.2 (SAS 2008) and means were compared by Duncan's multiple range test at 5% level of probability (Steel and Torrie, 1980).

Extraction of RNA and quantitative RT-PCR

Total RNAs were extracted from the leaves using an Easy Pure Plant RNA Kit (Trans Gene Biotech, Beijing). A Nano-Drop2000 spectrophotometer was used to determine the concentrations. Two μg of the total RNA was used to synthesize cDNA, as per the method described in detail by Zhou et al. (2019). Each sample had three independent replicates, and each replicate had three biological repetitions. The $2-\Delta\Delta Ct$ formula of Livak and Schmittgen (2001) was used to calculate the relative expression level, where reference gene was β-actin gene (Gene Bank ID: AB181991.1) (*Table A1* in the *Appendix*).

Results

B2 effect on plant growth and biomass accumulation, root characteristics and relative water content (RWC) under salt stress

Significant differences were found among different treatments, according to statistical analyses, in terms of the plant dry weight and root/shoot ratio of wheat seedlings under salinity stress conditions.

The data regarding the total plant dry weight of seedlings pretreated with B2 showed that cv. JM22 had a 36.8% increase, and cv. SH12 had a 22.7% increase, in plant dry

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71397157

weight (compared with the control) under salt stress conditions. An increase in the root dry weight was also observed due to the pretreatment of B2. Compared with the control, an increase of 56.7% and 35.2% in the root weight was found for cv. JM22 and cv. SH12, respectively, under high saline conditions. Moreover, a significant increase of 20.8% for cv. JM22 and 14.8% for cv. SH12, in terms of the root/shoot ratio, was also observed in the seedlings pretreated with 0.1 μmol·L-1 B2 under salt stress conditions (*Table 1*). On the other hand, the lower concentrations of B2 were not effective under salinity conditions for both wheat cultivars, while the 0.001 μmol·L-1 B2 was effective, compared with the control, in cv. JM22 under normal conditions (NC) in terms of the total dry weight and the root dry weight traits.

The data clearly showed that the seedlings treated with ABA or B2, with different concentrations, performed better under salt stress, compared with the untreated ones. It was also observed that 0.1 $\mu mol \cdot L^{-1}$ B2 not only increased the total root length but also enhanced the total root volume and root total surface in JM22 and SH12 (*Table 1*).

The plant physiological state can be reflected by the relative water content (RWC) of the leaves under salt-stressed conditions. *Table 1* shows that the cv. SH12 leaves of seedlings treated with B2 0.1 and 0.001 $\mu mol \cdot L^{-1}$ had a substantially higher RWC than the control plants, while the cv. JM22 leaves of seedlings treated with B2 0.1, 0.01 and 0.001 $\mu mol \cdot L^{-1}$ had a significant improvement in RWC under the same concentration of salt. Additionally, ABA-treated seedlings had a significant improvement in both cultivars. ABA and B2 enhanced the RWC of both wheat cultivars, SH12 and JM22, under both saline and non-saline conditions.

Based on the preliminary presented data 0.1 $\mu mol \cdot L^{-1}$ of B2 was the best effective concentration among the three investigated concentrations. Therefore, the other two concentrations of B2 were excluded from the following experemints.

Influence of B2 on wheat leaf endogenous ABA level

Under the salinity stress conditions, the ABA endogenous hormone level increased significantly with B2 treatment. The ABA content in leaves, for the treated seedlings (with 0.1 μM B2 and ABA), increased, compared with the control, and the endogenous ABA content increased by 88% and 22% in JM22, respectively, and increased by 106% and 76% in SH12, respectively (*Fig. 1*).

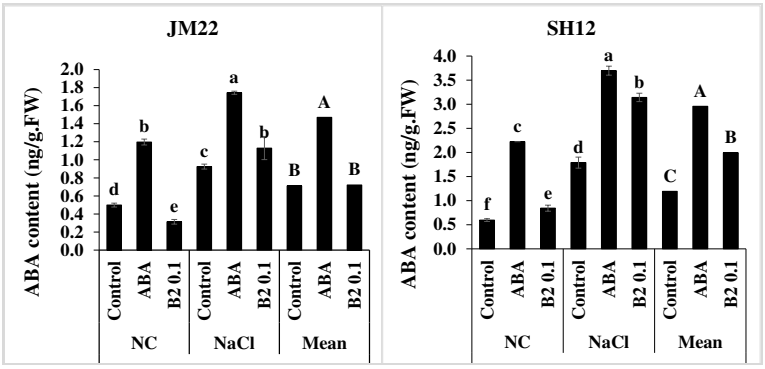

Figure 1. *Effect of B2 on the content of endogenous hormone ABA in both wheat cultivars Jimai22 and Shannong12. Normal conditions (NC), under salt stress (NaCl) and the mean of each treatment under both conditions (Mean). The data are expressed as the mean ± SE of three replicates. Means are compared using Duncan's test at 5% level of significant. Bars labeled with same letters are not significantly differ from each other*

B2 effect on the wheat leaves soluble protein content under high salinity levels

After going through the salt stress, the recorded plant content of soluble protein was higher in B2- and ABA-treated leaves, compared with the control. It increased significantly, by 17% in cv. JM22 and 31% in cv. SH12 B2-treated seedlings, in comparison with the control seedlings, while it increased by 9 and 15% in JM22 and SH12, respectively, in ABA-treated seedlings (*Fig. 2*). Pre-treatment with both

DOI: http://dx.doi.org/10.15666/aeer/1805_71397157

0.1 μmol·L^{-1} B2 and ABA efficiently enhanced the wheat leaf content of soluble protein under high saline conditions.

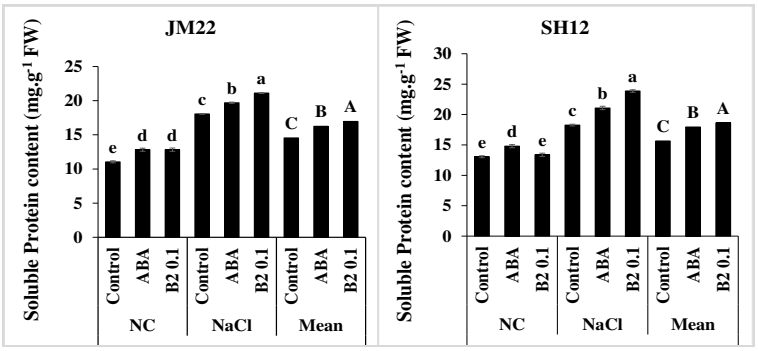

Figure 2. *Effect of B2 on the soluble protein content in both wheat cultivars Jimai22 and Shannong12. Normal conditions (NC), under salt stress (NaCl) and the mean of each treatment under both conditions (Mean). The data are expressed as the mean ± SE of three replicates. Means are compared using Duncan's test at 5% level of significant. Bars labeled with same letters are not significantly differ from each other*

B2 influence on the antioxidant enzymes activity under saline conditions

Three days after the salt application, the antioxidant enzyme activity was analyzed. The antioxidant activity of CAT, SOD and POD enzymes was obviously affected by salt stress. The SOD activity significantly increased due to B2 in the leaves of both wheat cultivars. The rate of increase was 17 and 18% for cv. JM22 and cv. SH12, respectively. Furthermore, there was a significant enhancement in the POD activity, where the rate of increase reached 16% in cv. JM22 and 23% in cv. SH12. Additionally, the antioxidant enzyme CAT activity increased significantly in both cv. JM22 and cv. SH12, at 15 and 10%, respectively. In addition, ABA significantly enhanced the antioxidant enzyme activity of SOD, POD and CAT in both cultivars, JM22 and SH12, and the rates of increase were 23 and 16% for the SOD activity, 17 and 8% for the POD activity and 34 and 30% for the CAT activity, respectively, compared with the untreated seedlings under the saline condition (*Fig. 3a, b, c*).

Proline content

After application of salt stress, it was notable that the plant content of proline become higher in leaves. It increased significantly by 14% and 15% in JM22 and SH12 treated seedlings with B2 and 19% and 26% with ABA compared with the non-treated seedlings in the same concentration of salt (*Fig. 4*). Pre-treatment with both 0.1 μmol·L^{-1} B2 and ABA could efficiency enhance leaves content of proline in both cultivars of wheat crop under the high-level salt conditions.

Lipid peroxidation and ROS accumulation

Under salt stress conditions, data clearly presented that ABA and the chemical compound B2 have improving effect on MDA in both wheat cultivars JM22 and SH12, both treatments successfully decreased the MDA level by 16% and 33% with ABA treatment and 14% and 30% with B2 treatment in both JM22 and SH12 respectively (*Fig. 5a*).

Both ABA and B2 treatments had significantly showed lower accumulation of H_2O_2 in salt conditions. Where, ABA and B2 reduced the level of H_2O_2 in both wheat cultivars leaves, the decreasing rate were 29% and 44% with ABA and 32% and 71% with B2 in JM22 and SN12 respectively (*Fig. 5b*).

Effect of B2 on wheat leaf photosynthetic rate under salinity stress

The data showed that seedlings treated with ABA or B2 had a high photosynthesis rate, as compared with the control treatment, while growing under salt stress conditions. The photosynthesis rate of ABA- and B2-pretreated seedlings increased by 43 and 39% in cv. JM22 and by 37 and 28% in cv. SH12, respectively, compared with the non-treated seedlings under a high salinity. Additionally, there was a notable effect of ABA and B2 on wheat leaf stomatal conductance and transpiration rate under salt stress in both the cultivars. Moreover, there was a significant increase in B2-treated seedlings in both indicators, Stomatal conductance (Sc) and Transpiration rate (Tr), in the wheat cultivar, SH12, under salt stress conditions, and it increased by 84 and 68%, respectively, while the effect was not notable in JM22 under the stress conditions. On the other hand, the increase rate was not significant for ABA-treated seedlings in both indicators, Stomatal conductance (Sc) and Transpiration rate (Tr), in both SH12 and JM22 (*Fig. 6a, b, c*).

Effect of ABA and B2 on the expression of salt and ABA-responsive genes

With the B2 and ABA pre-treatment of wheat seedlings, the expression level of salt-responsive genes (i.e., *TaERF3* and *TaMYB3R1*), along with the ABA-responsive genes

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71397157

(i.e., *TaABAOH2, TaNCED1*, and *TaAREB3*), increased significantly under salt stress. However, the time for each gene to reach the highest expression level was different, depending on the treatment and cultivar. The expression level of *TaERF3* increased with B2 and ABA treatments, compared with the control, under salt stress, based on time. Here, B2 was comparable with ABA in terms of the increase in the expression level of the mentioned gene. In cv. JM22, B2 increased *TaERF3* expression at 12, 24, 48 and 72 h, and its effect was higher than that of ABA from 24 to 72 h (*Fig. 7a, b*). However, in cv. SH12, the significant increase started at 6 h for the treatment with both B2 and ABA (*Fig. 7d*). On the other hand, an initial increase in the expression level of *TaMYB3R1* was seen in cv. JM22 at 3 h due to ABA treatment. However, the expression dropped down with time (*Fig. 7c*). In the case of cv. SH12, *TaMYB3R1* expression increased linearly at 24, 48 and 72 h due to the effect of B2, unlike the nonlinear influence of ABA (*Fig. 7d*). Under salt stress, B2 improved the expression level of *TaABAOH2* in cv. JM22 and cv. SH12, especially at 72 and 24 h, respectively (*Fig. 8e, f*). Furthermore, like ABA, B2 enhanced the expression level of *TaNCED1* in cv. JM22 at 72 h and significantly enhanced the expression of the same gene in cv. SH12 at 24 h (*Fig. 7g, h*). The effect of B2 and ABA was almost similar on the expression of *TaAREB3* in cv. JM22, which reached its peak at 72 h. However, in cv. SH12, only ABA affected the gene expression at 12 h, with no significant effect of B2, compared with the control (*Fig. 7i, j*).

Discussion

Soil salinity and drought are considered to be the most damaging abiotic stresses affecting agricultural production. It has previously been reported that ABA affects plant growth and development and has a role in plant responses to abiotic stresses, including salt, cold and drought stresses (Zhu, 2002).

Under saline conditions, applying a proper concentration of ABA enhances the salinity tolerance and increases the growth rate in sorghum and rice crops (Gurmani and Bano, 2007). Shoot fresh and dry weight decreases with an increase in salinity, but the application of ABA decreases the inhibitory effect of salt on shoot weight to some extent. The root weight of wheat also increases, if the seed is pretreated with ABA (Gurmani and Bano, 2007). These previous studies are in accordance with the present study. Here, both the treatments of ABA and B2 enhanced the total dry weight, root/shoot ratio, and root growth rate.

The plant physiological state is reflected by the relative water content (RWC) of its leaves. The reduction of the leaf water potential (LWP) and relative water content (RWC) were significantly moderated by ABA treatment under saline conditions. Additionally, ABA priming enhanced the RWC and LWP of salt-acclimated plants under subsequent salt stress. This indicates that ABA helps in maintaining a better water status of wheat plants under salinity stress (Davies and Zhang, 1991). The positive effect of ABA-induced antioxidant activity and the reduction in oxidative stress was further manifested by an increase in RWC, plant growth and membrane stability index (Gong and Li, 1998).

In this study, both B2 and ABA promoted the RWC of both wheat cultivars. In accordance with these observations. B2 enhanced the root growth, and plant total fresh and dry weight, leading to an improved water absorption capacity of wheat seedlings and hence an improved RWC (Karcher et al., 2008).

ABA accumulation in plant cell decreased the level of Na^+, regardless of whether these plants were salt acclimated. The endogenous ABA content notably increased with the salt treatment. A reduced Na^+ concentration and increased ABA level were caused by the combination of salt acclimation and ABA priming. ABA wheat plant priming improves the endogenous ABA content, which leads to a reduction in Na^+ uptake and accumulation (Davies and Zhang, 1991).

In the present study, the endogenous ABA level increased under salinity conditions. This indicates that B2 induced ABA accumulation in wheat plants. It also contributes to antioxidant enzyme's resisting system regulation and osmotic stress adjustment and enhancement, thus reducing oxidative damage.

One of the main defense strategies in plants is their antioxidant system. This includes enzymatic and non-enzymatic compounds, which act as detoxification agents of toxic-free radicals and therefore help the plant to overcome the destructive oxidative process

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71397157

(Li et al., 2011; Zhang et al., 2016). The major antioxidant defense enzymes are SOD, CAT, and POD. POD decomposes H_2O_2 through the oxidation of co-substrates, such as phenolic compounds and/or other antioxidants, whereas CAT breaks down H_2O_2 into H2O and O2 (Mittler, 2002; Li et al., 2011). An increase in SOD activity decreases free radicals, especially superoxide radicals that harm cell membranes, increase plant tolerance to oxidative stress and scavenges O_2^- radicals (Manjili et al., 2012).

Many studies indicate that the antioxidant system has a critical role in plant resistance to oxidative damage caused by salinity stress (Mittler, 2002; Xie et al., 2008; Qiu et al., 2014). Therefore, improving the antioxidant enzyme activities in plants results in an enhancement of the plant tolerance to salt stress. ABA has a positive effect in inducing the POD, SOD, and CAT activity in wheat plants exposed to a high salt stress (Davies and Zhang, 1991). ABA has a positive effect on adaptation responses in wheat (Agarwal et al., 2005).

The present results show that B2 mimics ABA and can enhance the scavenging capacity of reactive oxygen species (ROS) by improving the antioxidant enzymatic activities in wheat seedlings under saline conditions. Therefore, B2 could diminish the oxidative damage, which was also confirmed by the improvement in the soluble protein level, SOD, POD, and CAT, which led to the enhancement in the osmotic adjustment potential of the wheat seedlings.

Plants show many physiological and biochemical responses to cope the environmental abiotic stresses such as the accumulation of proline (Delauney and Verma,1993). In fact, free proline accumulates in a wide variety of higher plants, such as tobacco, soybean, barley, wheat and rice (Yoshiba et al.,1999). Proline play a major role in free radical scavenging, adjusting cell osmotic and a compatible solute that protects enzymes (Verbruggen et al., 1993). The metabolism of proline is essential for the plant stress resistance (Hare et al.,1999). Furthermore, it has been confirmed that accumulation of proline in cells improve osmotic and salt stress tolerance in transgenic plants (Kavi-Kishor et al., 1995; Zhu, 2002), although there also existed the regards that proline was an alternative result from adaptive or detrimental processes responding to osmotic stress (Larher et al., 2003). Proline also has a main function as protecting the enzymes from dehydration and salt accumulation (Thomas, 1990), and because of increasing abscisic acid concentration in response to various stresses (Unyayar et al., 2004), it seems that abscisic acid spraying increases proline content as a defense mechanism. ABA increased the proline content of flag leaf in the high salt level conditions (Flower and Yeo, 1989).

One of the ABA functions is enabling the plant to rapidly respond to salt stress by inducing stomatal closure. This is achieved through the modulation of the cytosolic $CA2^+$ concentration, which leads to the depolarization of the guard cell, as a result of an improved ABA level (Wang et al., 2017). It has been proved that salt causes the inhibition of photosynthesis, which could be due to stomatal or non-stomatal limitations. Gas stomata conductance (gs) decreases significantly due to salt stress, while ABA application improves the gs level in wheat plants under saline conditions (Davies and Zhang, 1991).

ABA has a photosynthesis regulation function in wheat plants adapted to salt through the regulation of non-stomatal parameters. ABA plays an effective role in the plant's resistance to salt stress by decreasing the water loss and adjusting the osmotic stress through stomatal control. ABA priming treatment improved the carbon absorbance and water use efficiency of the adapted wheat plants under salt stress (Davies and Zhang, 1991).

It is well known that the salt-induced inhibition of photosynthesis is attributed to stomatal and non-stomatal limitations (Wang et al., 2017). It might be that ABA improves the photosynthesis of wheat plants under salt stress due to the regulation of some other non-stomatal parameters. Nevertheless, stomatal control by ABA appears to be an efficient strategy for decreasing water loss and the negative effects of osmotic stress, caused by salinity (Wang et al., 2017).

A comparison of the influence of both ABA and B2 analogues on the expression of some genes related to salt stress and the ABA response was also performed. The effect of B2 on the expressions of these genes was found to be similar and sometimes superior to that of ABA, which reflected its efficiency as a stress regulator. However, the activation of gene expression was mainly based on the gene, time, and cultivar. The results showed that B2, like ABA, simulated the expression level of all the studied genes. In addition, among the tested genes, some were involved in drought and salt stress, such as transcription factor *TaERF3* (Zhang et al., 2007a), which was previously isolated and characterized in wheat. This transcription factor may directly regulate the expressions of different stress-related genes by interacting either with their promoters or with other TFs (Buttner and Singh, 1997; Zhang et al., 2007b). Additionally, *TaERF3* may indirectly regulate the expression of other stress-related genes involved in proline and chlorophyll accumulation, redox homeostasis (H_2O_2 reduction), and stomatal closure, which consequently become the induction of abiotic stress tolerance (Rong et al., 2014). It is well known that ERF proteins possess a vital role in regulating the expression of specific stress-related genes. Moreover, ERF subfamily members were primarily involved in biotic stresses as well (Berrocal et al., 2002; Onate et al., 2007; Chen et al., 2008). On the other hand, recent studies show that ERF members are also involved in diverse functions in plant responses to abiotic and biotic stresses (Rong et al., 2014). MYB proteins play multifunctional roles in the regulation of gene expressions (Rosinski and Atchley, 1998; Jin and Martin, 1999). For instance, they control the cell shape and morphogenesis involvement in abiotic and biotic stress responses to ABA (Cai et al., 2011). The *TaMYB3R1* gene expression was up-regulated, and its expression remained high under both cold and salt stresses. This suggested that *TaMYB3R1* may take part in abiotic stress regulation in wheat. In the present study, the *TaMYB3R1* gene was affected by ABA and B2, based on the time and plant genotype. However, B2 was more efficient than ABA in enhancing the gene expression in cv. SH12 in a linear mode through time. This result proved that the novel analogue (B2) has a good influence in enhancing stress tolerance in wheat.

Conclusions

From this study, it is apparent that B2 and ABA have a similar performance in improving the active oxygen radical scavenging efficiency by improving the antioxidant enzyme activity and enhancing the osmotic adjustment ability in wheat under salt stress. Moreover, the photosynthesis rate and the plant endogenous ABA content also increased, which confirms that B2 has a special regulating physiological mechanism. Suggestion that the findings could be beneficial in eradicating the salt stress problem in agricultural field crops is premature. Further studies should be performed to explain the effect of B2 on other crop plants such as rice since it considered as the main food crop in China, and investigate the effect of B2 based on the molecular analysis.

(Received 10th Apr 2020; accepted 29th Jul 2020)

Abstract. Parkinson's disease (PD) is a common associated motor dysfunction nervous system disease. Low-level occupational mercury vapor exposure is a commonly known critical factor that increases the risk of PD. Dental amalgams, used for dental restoration, are a major source of mercury exposure for people. However, the relationship between PD and the use of amalgam fillings (AMFs) has yet to be clarified. This paper of retrospective case–control aimed to examine the relationship between AMF use and the risk of PD; it analyzed Taiwan's NHIRD (National Health Insurance Research Database) based on population administrative database, for the 2000-2013 period. For the case and control groups, Charlson Comorbidity Index, age, urbanization level, sex and monthly income were all matched by a propensity score method for a 1:1 ratio; 5712 cases and 5712 controls participated in this study. This results of case–control based on nationwide population revealed no significant association between PD and AMF in Taiwanese people. This result provides meaningful implications despite being statistically not significant.
Keywords: *dental amalgam, mercury, NHIRD, nationwide population, case-control study*

Introduction

Parkinson's disease (PD) is a neurodegenerative disease. The incidence rate among women aged younger than 60 years is 8.6 per 100,000 people; this figure increases to 29 and 78.4 per 100,000 people among women aged 60–69 and 70–79 years old, respectively. The incidence rate among men aged younger than 60 years is 11.1 per 100,000 people; this figure increases to 49.5 and 140.7 among those aged 60–69 and 70-79 years old, respectively (Van Den Eeden et al., 2003). The risk and prevalence rate of PD increases with age (Bower et al., 1999; Baldereschi et al., 2000). With respect to prevalence rate, PD, as a progressive neurodegenerative disease, is second only to Alzheimer's disease (Wirdefeldt et al., 2011). The main clinical symptoms of PD are mostly associated with motor dysfunction—including rigidity, resting tremor, bradykinesia, and postural instability (Frank et al., 2006; Davie, 2008). Generic and environmental risk factors may cause the dopaminergic neurons death in the brain, where these dead neurons, in turn, inhibit the neural pathways from the basal ganglia to the motor cortex (Davie, 2008).

Dental amalgams are a common dental filling material with a 50% mercury content. Traditional low-copper amalgams have a copper content lower than 6%. The high-copper dental amalgams in the 1960s were developed with a copper content of 8%–10% (Haque et al., 2019). In high-copper dental amalgams, mercury is more soluble under acidic conditions relative to its low-copper counterpart (Okabe et al., 2003). High-copper amalgams, because of the amount of mercury vapor released from it (Bengtsson and Hylander, 2017), has a higher corrosion rate and longer corrosion time relative to early amalgams that contain metal composites.

DOI: http://dx.doi.org/10.15666/aeer/1805_71597165

Autopsy reports have demonstrated that dental amalgam fillings (AMFs) cause mercury accumulation in the human body (Mutter, 2011). AMF use has been found to correlate with mercury content in the brain and kidney tissues (Eggleston and Nylander, 1987; Nylander et al., 1987; Barregård et al., 1999; Guzzi et al., 2006) and to positively correlate with mercury content in the blood and urine (Kingman et al., 1998; Zimmer et al., 2002; Levy et al., 2004). A recent epidemiological study with 2137 participants revealed that relative to those who had not, people who had had 7 or more of their teeth filled with AMF had a 30%–50% higher mercury content in their urine (Dutton et al., 2013).

The pathogenesis of PD has yet to be elucidated. Several case reports and epidemiological studies have indicated that exposure to certain metals long-term (e.g., aluminum, manganese, copper, iron, mercury, lead, zin, and those in amalgams) is a potential factor of risk for PD. The PD development may be associated with the dose of mercury exposure (Ngim and Devathasan, 1989). However, studies have also determined that working in jobs involving long-term exposure to manganese, mercury, or aluminum has no effect on PD development (Semchuk et al., 1993; Vieregge et al., 1995). Accordingly, to control the incidence rate of PD, the study used the Database of National Health Insurance Research Database (NHIRD) to investigate the relationship between PD development and amalgam use.

Materials and Methods

Study Design and Data Source

The data used in this paper were collected from the 2010 Longitudinal Health Insurance Database (2010LHID), a publicly accessible database compiled by Taiwan's National Health Research Institutes. LHID2010 contains raw insurance claims data and registration documents for 2000–2013, including the information of 1 million people selected randomly from beneficiaries registered compulsory National Health Insurance (NHI) procedure in Taiwan, which covered 99.9% of the Taiwanese population in 2010 (Charlson et al., 1987). The present study defined diagnoses corresponding to the ICD-9-CM (International Classification of Diseases, Ninth Revision, Clinical Modification). Because data from the LHID 2010 were used for research and were deidentified secondary data, therefore the consent of written informed was not required.

Control Groups and Selection of Case

This study limiting is the adult population, the present case–control study excluded those aged younger than 20 years, those who had withdrawn from the NHI procedure, or those with missing data in the 2010LHID. Additionally, only individuals who had received three or more consensus diagnoses of PD were included in the sample to improve the diagnostic effectiveness for PD in the LHID2010. Propensity score matching by a 1:1 ratio was performed to conditionally select participants in the population for comparison according to urbanization level, the Charlson Comorbidity Index (CCI) (Charlson et al., 1994), age, socioeconomic status, and sex. The CCI ranges from 0 to 3, with a high CCI indicating a high risk of mortality for a particular patient (diabetes, hypertension, etc.) (Charlson et al., 1987). *Figure 1* illustrates the research process.

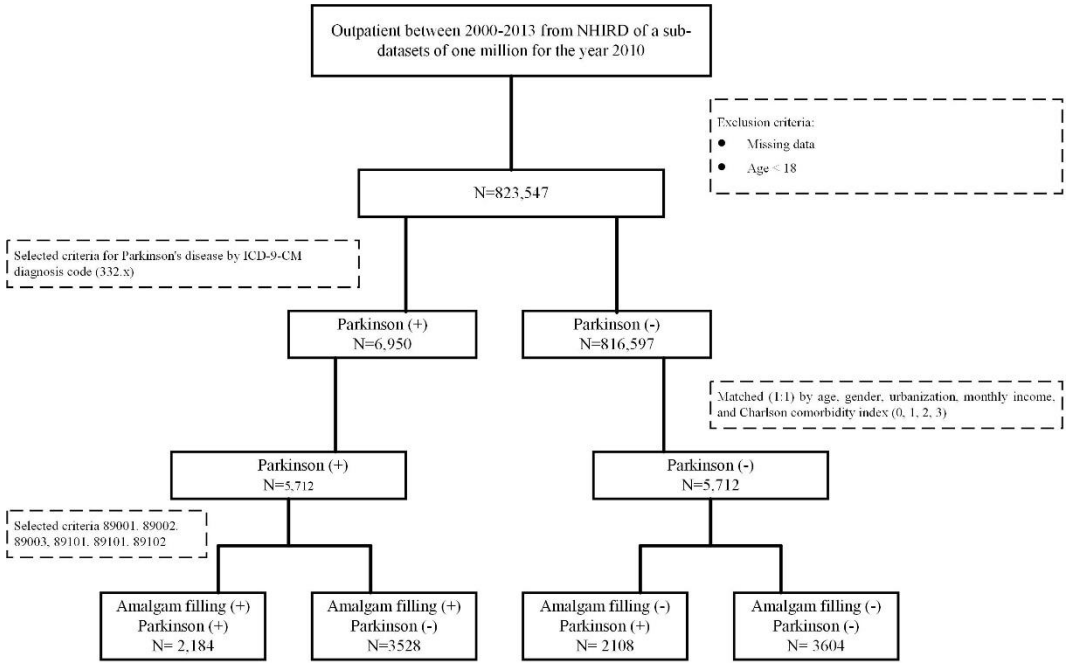

Figure 1. *The flowchart of the study*

Exposure Assessment

This study identified patients, from the LHID2010, who had received AMF-related treatments according to the following procedure codes: Dental amalgam fillings (89001C, 89002C, 89003C) and other dental treatments (89101C, 89102C, 89103C) (*Table 1*). Confounding factors—namely age, urbanization level, CCI, socioeconomic factors, and sex—were included in the analysis (*Figure 1*).

Table 1. *The amalgam filling codes*

Dental amalgam fillings		Other dental treatments	
Code	**Treatment**	**Code**	**Treatment**
89001C	Amalgam restoration for single-face.	89101C	Amalgam restoration for single-surface in specific cases.
89002C	Amalgam restoration for two-face.	89102C	Amalgam restoration for two- surface in specific cases.
89003C	Amalgam restoration for three-face.	89103C	Amalgam restoration three-surface in specific cases.

Statistical Analysis

SPSS 18 (International Business Machines Corporation, Chicago, IL, United States) was used for data analyses. For the continuous variables, this study used Student's *t*-test; for categorical variables, this study used a chi-square test, and the odds ratio (OR) for calculating between the control and case groups; and multiple logistic regression was used in a stratified analysis. All results are presented in terms of the OR and 95% confidence interval (95% CI). Sex, region of residence, age, CCI, and income were adjusted for in the analyses. Statistical significance was defined when the p-value was <0.05.

Result

This study recruited 5712 cases and 5712 controls. As listed in *Table 2*, the average age was 76.87 ± 11.73 years old; 5806 (50.82%) and 5618 (49.18%) of them were women and men, respectively. The case and control groups did not significantly differ with respect to their demographic characteristics, specifically their sex, region of residence, CCI, age, urbanization level, and monthly income ($P > 0.05$).

Discussion

As far as authors' know, the present study is the first to examine the association between PD and AMF based on a large-scale population-based database and tracking time 13 years. The results revealed no positive correlation between AMF and PD. To ensure accurate PD diagnosis, this study recruited only patients with at least three PD diagnoses. The effectiveness of the PD diagnoses was validated through the NHI system of conducting regular verification of diagnoses; such verification is part of the NHI's treatment guidelines to ensure that health insurance claims are legitimate. The findings of this registry-based study are significant and meaningful.

Dental amalgams of all types contain mercury, which is released in the form of mercury vapor. Mercury's toxicity can cause cell damage through the increased production of free radicals (Olivieri et al., 2000). Heavy metals are suspected to cause the generation of free radicals, which increases oxidative stress in neurons, which, in turn, causes PD. Usually, nervous system diseases are the body accumulation of heavy metals or associated with environmental exposure. Heavy metals can affect the basal ganglia in the brain, which causes physical derangement through damaging neurons in the substantia nigra pars compacta. PD is a highly common motor disorder (Montgomery, 1995). Case reports and epidemiological studies have reported long-term exposure to mercury to be a potential risk factor for PD (Ngim and Devathasan, 1989), whereas some studies have revealed no association between the two (Semchuk et al., 1993; Vieregge et al., 1995). In the present study, PD and AMF use were not positively correlated. This is attributable to possibly differing levels of mercury exposure in occupational exposure than in exposure from AMF use. Mercury can leach out from the surface of AMFs when chewing and tooth brushing. However, this study did not assess the extent of exposure to mercury vapor in patients using AMFs.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71597165

This study has some limitations. First, the NHIRD provides no data on family medical history, symptoms, PD severity, dietary habits, and the brand and formula of amalgam used; such missing information makes the analysis robust, especially with regard to controlling for confounders. Second, the procedure codes in the NHI did not indicate the positions of AMFs. Third, this study did not collect information on the use of other metal dental restoration implements (e.g., dental inlays or crowns) from the NHIRD. Fourth, propensity score matching cannot cope with unobservable confounders, which limits the analysis of this study.

Conclusions

On the basis of results for a nationwide population, the present study revealed no association between PD and AMF in Taiwanese people. Dental amalgams are a potential source of environmental mercury exposure, and it must be investigated as a possible contributor to mercury-induced neurotoxicity. An in-depth risk–benefit analysis on the use of AMF must include the effects, service life, and performance of dental amalgams. Overall, despite dental amalgam fillings use very widespread, the safety data of dental amalgam fillings safety are inadequate. Most reassurance is provided for Parkinson's disease in this study. The further, most in need investigation are effects and neurodegenerative diseases on children and infants.

Abstract. A field experiments was conducted at the Wenxi experimental site of Shanxi Agriculture University, China. A study was designed to evaluate the effect of different planting density and tillage conditions, spike, protein content, protein yield and grain yield of dryland wheat cultivar (Liangxing-99). The five doses of nitrogen application included were the following: 150 kg·hm^{-2}, 225 kg·hm^{-2}, 300 kg·hm^{-2}, 375 kg·hm^{-2}, and 450 kg·hm^{-2}. The nitrogen rate/amount has extremely significant effects on the number of ears, thousand-grain weight and yield and water use efficiency of winter wheat. Nitrogen absorption and fertilizer productive efficiency significantly were increase by 50% and 51%, respectively, while nitrogen harvest index, the number of ears and yield significantly increased by 22%, 46% and the yield by 25%, 55%. The water use efficiency significantly increased by 33%. The treatment significantly improved grain albumin 13%, gliadin 14%, gluten protein 17%, total protein 14%, and grain/alcohol ratio 3%; wet gluten content increased by 23%, water absorption by 14% and, the softening degree was reduced. Improving nitrogen uptake at different growing stages, ultimately increased yield and improved quality. GS activity of flag leaf was closely related with the total grain protein, glutenin, and gliadin content at the middle filling stage. Wide space sowing in Jinnan area was beneficial and increased water consumption during the growth period, also tiller dynamics, promoted nutrient operation, and increased yield and grain protein content.
Keywords: *plant height, leaf ratio, protein content, tiller dynamics, water consumption, yield of dryland wheat*

Introduction

Wheat (*Triticum aestivum* L.) is one of the most important food crops in the world and it is also an important food crop in China. Wheat production has an important role in the national economic production of China. Improving yield and quality in production has always been an important task for wheat cultivation workers. The yield and quality of wheat are affected by varieties, environmental factors and cultivation measures (Mao et al., 2015). The arid and semi-arid area of the Loess Plateau is typically rainfed and 60% of the dryland area is under wheat cultivation (Jin et al., 2007). The cropping system of the Loess Plateau is mainly a mono-cropping of winter wheat with a 3-month fallow during the rainy summer season (Deng *et al.,* 2006). Most studies in the field of water and N (nitrogen) have only focused on soil water and Nitrogen fertilization (Li et al., 2009). High yield of good quality is based on the used agro-technical measures. One of the most important agro-technical measures is optimal nutrient provision. Insufficient precipitation during the growth stages of wheat and shortages of irrigation water in dryland wheat producing areas are major constraints to high yield (Lei et al., 2017). Nitrogen is a nutrient of high importance for plant growth, development and grain quality assurance, but it is also one of the most mobile plant nutrients in the soil

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71677188

(Myrbeck et al., 2014). Nitrogen fertilization is a common practice to increase food production, but its performance depends on soil water status (Turner et al., 2005).

Despite many years of research effort there is still no accurate method available for determining how much fertilizer N can be applied to intensively managed cereal crops to obtain high target yields, maintain adequate soil fertility and minimize environmental risk (Zhu et al., 2006; Robertson et al., 2009). Although emerging evidence indicates that integrated use of manure and chemical Nitrogen fertilizer is a feasible approach to improve winter wheat production and water use efficiency (WUE) in the Loess Plateau (Liu et al., 2012). Winter wheat yield and biomass are dependent on water availability (Kang et al., 2002).

Crop yield and soil nitrate-N residue (NR) have been shown to increase after long-term N fertilizer application, and at the same time nitrate residue (NR) and its accumulation in soil have been attracting increasing attention. The results from a typical rain fed area of southern Spain showed that the NR in soil increased with time, mostly it accumulated in the 30-60 cm soil layer (López et al., 2013). In a wheat maize system in North China, the NR at harvest was as high as 221-275 kg N ha^{-1} in the 0-90 cm soil layer and 213-242 kg ha^{-1} in the 90-180 cm soil layer (Ju et al., 2006). Available water and nitrogen are considered the most limiting factors in wheat production in most parts of the world, especially in arid and semi-arid region (Gonzalez et al., 2010).

Therefore, precipitation stored in the soil during the summer fallow period after wheat harvest is utilized by the subsequent crop and crucial for the success of cropping in the Loess Plateau (Zhang et al., 2007; Schlegel et al., 2017).

Water storage in soil has been affected by the different management practices such as tillage and fertilizer application (Grigoras et al., 2012). Winter wheat yield has been increased by the application of fertilizer but it also resulted in increasing soil water depletion and formation of dry subsoil layer especially in the high land areas (Yan et al., 2015). Hence, for sustainable wheat production, it is crucial to seek management practices for improving water-and N-use efficiency (Fu et al., 2014).

Supplemental irrigation and Nitrogen fertilizer application are required to match soil water stress and stabilize yields (Tavakkoli et al., 2004). It was also found that utilization of more nitrogen decreased breaking strength of the second internode significantly (Berry et al., 2000). Reducing spring nitrogen could reduce the height of gravity and increased stem strength by increasing both stem diameter and wall width (Crook et al., 1995). The highest Nitrogen uptake in the growth period occurred from reviving stage to anthesis stage. The proportion of Nitrogen accumulated in leaf and stem was high before the anthesis stage and the accumulated Nitrogen rate in stem reached peak at the anthesis stage (Zhao et al., 2006). Recent technological advances have focused on the simultaneous and synergistic improvement of several factors including water use, nitrogen efficiency, yield and grain quality (Parry et al., 2011).

Nitrogen (N) was a key element for plant nutrition. Applying N and P (phosphorus) fertilizers and other management practices increased the yield of wheat but in some cases these show adverse effects due to severely limiting irrigation (El Mejahed and Aouragh, 2005). Nitrogen use efficiency can be increased by combining fertilizer, soil, and water management. Two main approaches can be undertaken: increasing the use of N during crop growing season and decreasing the losses of N by applying optimum doses (Cui et al., 2010). At the early filling stage, GS activity of flag leaf was closely related with the total grain protein, glutenin, and gliadin content, while at the middle filling stage, GS activity of flag leaf was closely related with glutenin/gliadin (glu/gli) (Yu et al., 2009).

The objective of this study were to find the best sowing method and optimize doses of nitrogen level to increase the yield and quality of winter wheat crop. Wide space sowing (WSS) with 300 kg·hm-^{2} in Wenxi Shanxi area was beneficial to the growth and development of winter wheat, improved nitrogen uptake at different growing stage, ultimately increased yield and improved quality. The WSS was beneficial and increased water consumption during the growth period, also tiller dynamics, promoted nutrient operation, and increased yield and grain protein content.

Materials and methods

Description of experimental site

Field experiment was performed at the Agriculture Research Station of Shanxi Agriculture University (35°200N, 111°170E), in Wenxi county, Shanxi Province of China. The experimental site was located in the southeast of the Loess Plateau. The southeast of the Loess Plateau is a typical semi-arid region with an average annual rainfall of 450-630 mm, of which 60-70% precipitation falls in July-September, the altitude is 450-700 m and the annual average temperature is 11-13 °C. This region is characterized by a semiarid climate which receives 491 mm of average annual precipitation, 12.9 °C annual mean temperature, and 2242 h of annual sunshine. The straw was returned to the field after the previous stubble corn was harvested and planted on the 25th October, 2017 and harvested in early June the next year. The soil in the test site adopts the Chinese soil classification standard and belongs to calcareous cinnamon soil. See *Table 1* for the soil fertility parameters of the 0-20 cm soil layer.

Table 1. *Soil nutrient properties from experimental location*

Soil nutrients	2016-2017	2017-2018
Organic matter (g kg^{-1})	12.07	12.61
Total nitrogen (g kg^{-1})	0.86	0.88
Alkali-hydrolysis nitrogen (mg kg^{-1})	36.42	44.07
Available phosphorous (mg kg^{-1})	16.26	10.71
Available potassium (mg kg^{-1})	218.76	188.87

Precipitation distribution

Natural precipitation was the main source of water for crop cultivation in this area, with precipitation mainly concentrating in July-September, which was the fallow period of wheat. Precipitation during experimental years and long-term average of 13 years are given in *Table 2*. Total precipitation in 2016-2017 was 406.3 mm during winter wheat growth period and it was 165.4 mm in the fallow periods. In 2017, precipitation before flowering was more than average in 2017. In 2017-2018, total precipitation was 416.6 mm, and precipitation during growth was 198.3 mm. Precipitation from sowing to wintering and jointing to maturity was abundant.

Experimental design and treatments

The experiment, a typical winter wheat-summer fallow, was started with the winter wheat season, covering 2 successive wheat crops at the same experimental plot. The seeds of winter wheat (*Triticum aestivum* L.) cultivar 'Liang xing-99' were obtained from Wenxi Agriculture Jinnan. Wheat stubble of 20–30 cm from the previous wheat crop was left in field to reduce evaporation and to increase organic carbon content in soil. The two factors split-plot design was adopted, with nitrogen rate as the main factor and nitrogen density as sub-plot factor. The sowing methods were wide space sowing (WSS). The details of the machinery and sowing techniques are given in *Figure 1* in with five nitrogen level (150 kg·hm^{-2}, 225 kg·hm^{-2}, 300 kg·hm^{-2}, 375 kg·hm^{-2}, and 450 kg·hm^{-2}). The plot area was 75 m^2 (2.5 m × 30 m), and it was repeated three times. The straw was returned to the field after the previous stubble corn was harvested and planted on the 25th October, 2017. Before planting, 150 kg·N·hm-^{2}, 150 kg·P_2O_5·hm-^{2}, 90 kg·K_2O·hm-^{2}, jointing topdressing 90 kg·N·hm-^{2} were applied, harvested on the 10th June, 2018 (*Fig. 2*).

Measurement: determination of agronomic traits

Plant height and leaf area

Twenty (20) plants with uniform growth and representativeness were taken at each growth stage and the plant height was measured; at the same time the length, width and number of green leaves of the second leaf were measured.

For the determination of leaf area, the length and width of the second leaf and total number of leaves were calculated. Leaf area was measured using the following formula:

$$\text{Leaf area} = \text{length} \times \text{width} \times \text{number of green leaves} \times 0.85 \quad \text{(Eq.1)}$$

where 0.85 was the adjustment factor. Then leaf area index (LAI) was calculated by dividing the leaf area (cm^2) by the ground surface area.

Sowing method	Sowing technique	Line spacing	Tillage
Wide space sowing (WSS)	2BMF-12/6, tillage, auto-fertilization	Line space: 22-25 cm	Sub-soiling, rotary tillage

Figure 1. *Field preparation at experimental site of Shanxi Agricultural University*

Dry matter quality

Twenty (20) plants with uniform growth and representativeness were taken at each growth stage and placed in an 80 °C oven for 30 min and then dried at 80 °C to constant weight.

Determination and calculation of plant nitrogen content

After drying and pulverizing each organ of the plants the nitrogen content was measured by H_2SO_4-H_2O_2-indigo blue colorimetry. Nitrogen accumulation, running volume and nitrogen efficiency were calculated with reference to Xue et al. (2017). Twenty (20) plants from each plot were collected randomly for the measurement of plant nitrogen concentration at jointing, anthesis and maturity. Plant samples and grains were oven-dried at 105 °C for 30 min and then at 75 °C for 48 h for dry weight. Dry plant samples were cut to 4-5 cm length and ground using plant ball mill (FZ102, Beijing, China). Dry grains were also ground to powder using FZ102 mill. Ground samples of 0.25 g were digested with H_2SO_4-H_2O_2, and then total nitrogen concentration was determined using the standard indophenol-blue colorimetric method (Meyer et al., 1983). Calculation of nitrogen accumulation and translation and nitrogen efficiency were carried out as follows (Przurj et al., 2003):

Plant nitrogen accumulation amount = plant dry weight × plant nitrogen concentration;

Contribution of pre-anthesis organs nitrogen translation amount to grain = pre-anthesis organs nitrogen translation amount / grain nitrogen accumulation × 100%;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71677188

Nitrogen uptake efficiency (kg' kg^{-1}) = plant nitrogen accumulation amount / nitrogen fertilizer amount;
Nitrogen use efficiency (kg' kg^{-1}) = grain yield / plant nitrogen accumulation amount;
Nitrogen productive efficiency (kg' kg^{-1}) = grain yield / nitrogen fertilizer amount.

Figure 2. *Field preparation use fertilizer machine site of Wenxi*

Determination of total tiller and effective tillers rate

The total number of tillers was investigated at the jointing stage and the number of fertile tillers were counted at late grain filling stage. The number of tillers was calculated from the area of 1 m^2 at 3 random points from each plot and average at each plot was the number of stem and tillers. The effective tiller rate was calculated as the proportion of main stem and tiller at jointing stage to the number of effective panicles at maturity.

Grain to leaf area ratio

Grain to leaf ratio was calculated according to Feng et al. (1999), using *Equations 2* and *3*:

$$\text{Grain number to leaf area ratio} = \frac{\text{total number of grain per unit area}}{\text{total leaf area on the same plot at booting stage}} \quad \text{(Eq.2)}$$

$$\text{Grain weight to leaf ratio} = \frac{\text{grain weight (mg) per unit area}}{\text{total leaf area on the same plot at booting stage}} \quad \text{(Eq.3)}$$

Total leaf area was taken from the same plot at booting stage (cm^2).

Determination of soil moisture

Soil was drilled from 0-300 cm depth with soil drill at sowing, wintering, jointing, flowering and maturity stages. The soil was divided into 20 cm layers and soil water content and soil water storage were determined.

The soil water storage was calculated by methods as described by He et al. (2009):

$$SWSi = Wi \times Di \times Hi \times \frac{10}{100} \quad \text{(Eq.4)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71677188

where SWS_i is the soil water storage capacity (mm) of the i-th soil layer; W_i is the soil water content (%) of the i-th soil layer; D_i is the soil bulk density (g cm^{-3}) of the i-th soil layer; H_i is the thickness of soil layer (cm). The soil water content and soil bulk density were both measured using the oven-drying method Gardner et al. (1986):

Water consumption

Water consumption in wheat fields was measured using a simplified formula as described by Noor et al. (2020):

$$ET = P - \Delta S \quad \text{(Eq.5)}$$

where P is the effective precipitation (mm) during that stage and ΔS is the reduction of soil water storage at each stage and was measured as $\Delta S = S_1 - S_2$, where S_1 and S_2 were the soil water content at the beginning and at end of the stage, respectively. Whereas, runoff and drainage were considered negligible.

The water consumption intensity (CWR, mm d^{-1}) was calculated as:

$$CwR = \frac{ET_i}{d} \quad \text{(Eq.6)}$$

where ETi is the water consumption (mm) of wheat in each growth stage and d is the number of days in the growth stage.

Determination of spike number

Comparison of the spike of interest with the model spike occurs in an n-dimensional vector space, which dimensions are defined by the total spikelet number of the spike of interest. The geometrical difference in GYDAS between the two spikes is based on the scalar product of these two vectors:

$$\cos\measuredangle\left(\vec{a}, \vec{b}\right) = \frac{\vec{a} \cdot \vec{b}}{|\vec{a}| \cdot |\vec{b}|}, \quad \text{(Eq.7)}$$

Plant density

Seeds were sown at a density of 225 × 104 ha^{-1} in rows 20 cm apart between September 28 and October 30 from 2016 to 2018.

Biomass and yield

At maturity, the number of panicles per unit area, the average number of grains per panicle and weight of 1000 grains were investigated from 50 plants per plot, and plants from 20 m^2 area were harvested to calculate economic yield. For determining the aboveground dry biomass, plant samples were kept at 105 °C for 30 min, and then oven dried at 75 °C for 12 h until constant weight.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71677188

Determination of grain protein and component content

At maturity period 30 ears were burned at 105 °C for 30 min, dried at 80 °C to constant weight, crushed with a DE-100 g mini high-speed universal grinder produced by Zhejiang Hongjingtian Industry and Trade Co., Ltd and a continuous extraction method was used to determine the protein content of the grains.

Determination of kernel quality

The MJZ-II type gluten index tester was used to determine the wet gluten content and the micro dough LAB 2800 micro flour analyzer was used to determine the flour characteristics.

Statistical analysis

Data subjected to analysis of variance (ANOVA) and SAS 9.0. Charts were constructed using Microsoft Excel 2007. Mean values were calculated and significance of the difference between treatments was tested by LSD (least significant difference) method at the significance level of $P = 0.05$.

Results

Soil water consumption

Table 3 shows that with the increase of the seeding amount, the water consumption during the growing period and the proportion of water storage water consumption tend to increase and then decrease. The seeding amount was 300 kg·hm^{-2}, which is the highest, and the water consumption during the growing period was 369.48 mm. The water consumption ratio of water storage was 40.72%, and the water consumption ratio of precipitation and irrigation water showed a trend of decline and then increased, and reached the lowest value when the seeding amount was 300 kg·hm^{-2}. It can be seen that the wide sowing amount of 300 kg·hm-^{2} was conducive to increasing the water consumption during the growth period and the proportion of stored water consumption, and reducing the proportion of water consumption and irrigation water consumption. The water consumption ratio of precipitation and irrigation water was significantly reduced. Compared with sowing, the water consumption during growing stage and water storage under even sowing the proportion of water increased and the proportion of water consumption in precipitation and irrigation decreased. Wide space sowing and increased the water consumption during the growth period and soil water consumption ratio.

Table 3. *Effects of seeding rate on soil water consumption ratio at 0-200 cm depth from different water sources of winter wheat*

Seeding rate (kg·hm^{-2})	Soil water consumption in the growing stage (mm)	Soil water consumption ratio (%)	Precipitation consumption ratio (%)	Irrigation consumption ratio (%)
150	447.71 ^{c}	37.84 ^{c}	48.76 ^{a}	13.40 ^{a}
225	451.13 ^{b}	38.31 ^{c}	48.39 ^{a}	13.30 ^{a}
300	469.48 ^{a}	40.72 ^{a}	46.50 ^{c}	12.78 ^{c}
375	459.96 ^{b}	39.49 ^{b}	47.46 ^{b}	13.04 ^{b}
450	447.68 ^{c}	37.83 ^{c}	48.76 ^{a}	13.40 ^{a}

Effects of seeding rate on soil water consumption plant height and leaf area of dryland wheat

The effects of nitrogen rate on soil water consumption on plant height and leaf area of winter wheat from 2016 to 2017 were as follows, the plant height was significantly the highest when the sowing amount was 375 kg·hm^{-2} in the wintering period from 2017 to 2018, the plant height was significantly the highest when the sowing amount was 450 kg·hm^{-2} in the wintering period; in the two years, when the sowing amount was 300 kg·hm^{-2}, the plant height was significantly the highest from the elongation stage to the maturity stage and the plant height was significantly the lowest when the sowing amount was 150 kg·hm^{-2} (*Fig. 3*). In those two years, when the sowing amount was 300 kg·hm^{-2} the leaf area was significantly the highest in each growth period and the leaf area was significantly the lowest when the sowing amount was 150 kg·hm^{-2}. It can be seen that the increase of sowing volume (150-300 kg·hm^{-2}) was beneficial to the increase of plant height and leaf area of wheat.

Effects of seeding rate on soil water consumption amount and on population dynamics of WSS dryland wheat

Effects of nitrogen rate on soil water consumption in wintering stage examined throughout two years can be seen in *Figure 4*. Group with 375 kg·hm^{-2} sowing amount showed the highest tailoring and had a significant jointing stage, mature stage and sowing quantity. Group 300 kg·hm^{-2} showed the highest tiller number in the growth period (2016 to 2017), and the flowering period and mature period reached significant level (2017 to 2018), the sowing quantity of different levels the nitrogen level of 150 kg·hm^{-2} tiller number was lowest significantly. Lower sowing quantity of the wide space sowing (WSS) was 300 kg·hm^{-2}, which was conducive to the formation of tiller number and yield.

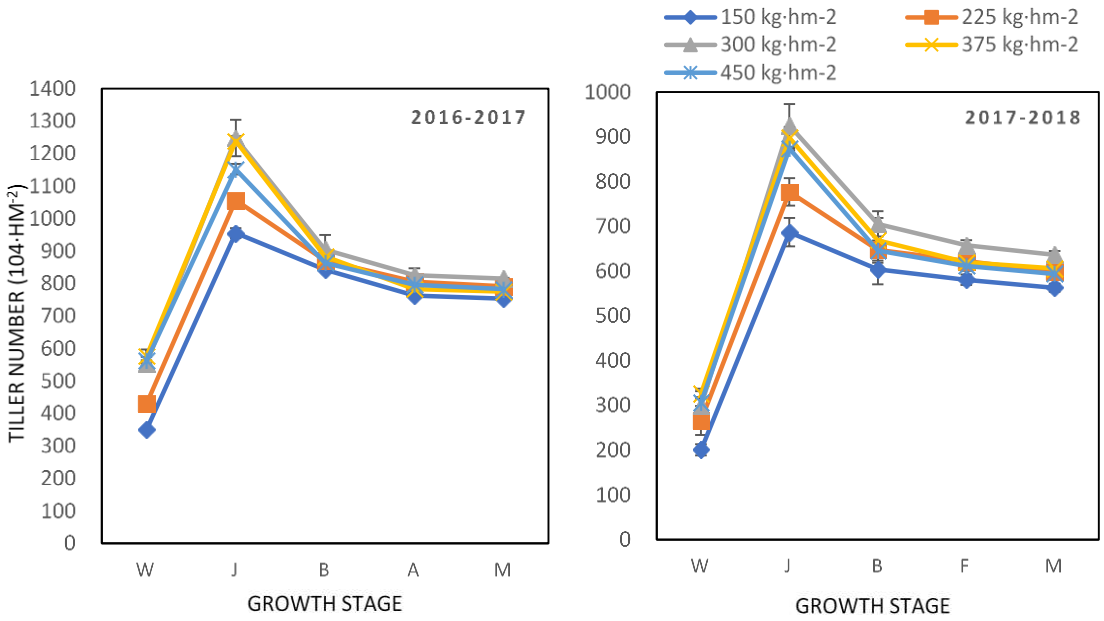

Figure 4. *Effects of seeding rates on water consumption of tiller dynamics at different growth stages of dryland wheat. W, J, B, F, A, and M indicate Wintering, Jointing, Booting, Flowering, Anthesis and maturity W-J: Wintering to jointing, Oct 1 to Apr 10; J-B: Jointing to Booting, Apr 11 to May 10; B-F: Booting to Flowering, May 11 to May 25 B-A: Booting stage to anthesis, May 26 to Jun 10; A-M: Anthesis to maturity, Jun 12 to Jun 19. Effects of seeding rate on dry matter accumulation characteristics of winter wheat

Effects of nitrogen rate on dry matter accumulation characteristics are shown in *Table 4*. The results show that with the increase of sowing amount the dry matter mass of the plants increased first and then decreased in each growth period and the highest sowing amount was 300 kg·hm^{-2}. During the wintering period and booting period the dry matter quality of the plants was the highest when the sowing amount was 300 kg·hm^{-2}, but there was no significant difference from 225 kg·hm^{-2}, when the sowing amount was 450 kg·hm^{-2}. During the flowering period and maturity period the dry matter quality of the plants was the highest significantly when the sowing amount was 300 kg·hm^{-2} and the difference was not significant when the sowing amount was 225 kg·hm^{-2}. It can be seen in *Table 4*, that it is beneficial to improve the dry matter quality of the plants especially in the late growth period, when the down sowing quantity of the WSS is 300 kg·hm^{-2}.

Effects on agronomic characters at maturity stage

Agronomic characters (*Table 5*) show that the Nitrogen rate was 300 kg·hm^{-2}, with the longest ear length (7.51 cm), which was not significantly different from 375 kg·hm^{-2}. The number of pregnable spikelet was the highest (13.87), and the number of non-pregnable spikelet was the lowest (1.17). The number of pregnable spikelets can be increased and the number of non-pregnable spikelets can be reduced when the wide space sowing amount is 300 kg·hm^{-2}, which is ultimately beneficial to the formation of yield.

Table 5. *Effects of seeding rate on agronomic characters at maturity*

Effects of seeding rate on nitrogen uptake at different growing stages

The effect of seeding rate on nitrogen uptake at different growing stages of winter wheat is presented in *Table 6.* The results show that with the increase of sowing amount the nitrogen accumulation of plants in each growth period showed a trend of increasing first and then decreased and reached the maximum at 300 kg·hm^{-2} and it was also observed that with the increase of sowing amount the contribution rates of nitrogen accumulation before flowering and nitrogen accumulation before flowering on grains increased first and then decreased reaching the highest at 300 kg·hm^{-2} and the nitrogen accumulation after flowering and nitrogen accumulation after flowering had no significant effect on the contribution rates of grains.

Effects of seeding rate on pre-anthesis accumulated nitrogen translocation and nitrogen accumulation amount after anthesis of winter wheat

Effects of seeding rate on pre-anthesis accumulated nitrogen translocation and nitrogen accumulation amount are presented in *Table 7.* With the increase of sowing amount, the accumulation of nitrogen in each growth stage showed a trend of first increasing and then decreasing, reaching the highest at 300 kg·hm^{-2}. The sowing methods mainly promote the operation of nitrogen accumulation before flowering to increase the contribution rate to grains, among which WSS was better.

Table 7. *Effects of seeding rate on pre-anthesis accumulated nitrogen translocation and nitrogen accumulation amount after anthesis of winter wheat*

Effects of seeding rate on nitrogen use efficiency (NUE) of winter wheat

The nitrogen use efficiency (*Table 8*) shows that with the increase of sowing amount the nitrogen absorption efficiency and nitrogen fertilizer production efficiency first increased and then decreased and reached the highest at 300 kg·hm^{-2}, while the nitrogen utilization efficiency first decreased and then increased with no significant effect on the nitrogen harvest index. It can be seen that when the lower sowing amount was 300 kg·hm^{-2}(WSS), it was beneficial and the accumulation of nitrogen in each growth period increased along with the contribution rate of nitrogen running amount with grains before flowering and the nitrogen absorption efficiency and nitrogen fertilizer production efficiency improved.

Table 8. *Effects of seeding rate on nitrogen use efficiency (NUE) of dryland wheat*

Seeding rate (kg·hm^{-2})	N uptake efficiency (kg·kg^{-1})	N use efficiency (kg·kg-^{1})	N productive efficiency (kg·kg^{-1})	Nitrogen harvest index
150	0.88^{d}	45.44^{a}	39.98^{c}	0.83^{a}
225	1.07^{b}	40.14^{d}	42.95^{b}	0.83^{a}

450	0.94^{c}	43.98^{b}	41.34^{bc}	0.82^{ab}

Effects of seeding rate yield and composition of dryland wheat

The effects of seeding rate yield and composition are presented in *Table 9*. The results show that with the increase of sowing amount, the panicle-number and yield show a trend

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71677188

of increasing first and then decreasing. When the sowing amount is 300 kg·hm^{-2}, the panel-number is the highest significantly, reaching 636.00×104·hm^{-2} and the highest yield is 7158.30 kg·hm^{-2}, but there is no significant difference from 375 kg·hm^{-2}. The number of panicle grains was the highest when the sowing amount was 300 kg·hm^{-2}, but there was no significant difference from 150 kg·hm^{-2} and 375 kg·hm^{-2}. The difference of 1000-grain weight in the range of 300-450 kg·hm^{-2} was not significant. It can be seen that the appropriate sowing amount is the key to increase the wheat yield, and the excessive or low sowing amount is not conducive to the formation of yield, and the number of ears is the key factor affecting the formation of yield. The appropriate sowing amount under wide space sowing is 300 kg·hm^{-2}.

Table 9. *Effects of seeding rate and N input on yield components of dryland wheat*

Seeding rate (kg·hm^{-2})	Ear number (10^4·hm^{-2})	Grain number per spike	1000-grain weight (g)	Yield (kg·hm^{-2})

Effects of seeding rate on protein and component contents of mature grains

The protein and component contents of mature grains are presented in *Table 10*. The results show that with the increase of sowing amount the contents of grain protein components and protein yield first increased and then decreased. The yield of grain albumin, globulin and protein was significantly the highest when the sowing volume was 300 kg·hm^{-2} and the content of altoprotein, glutenin, grain/alcohol ratio and protein was the highest but there was no significant difference from that of 225 kg·hm^{-2}. It can be seen that the seed size of 300 kg·hm^{-2} was beneficial and increased the content of protein and components in grains.

Table 10. *The protein components and protein yield of wheat under different nitrogen rate*

DOI: http://dx.doi.org/10.15666/aeer/1805_71677188

amount of nitrogen accumulated before flowering yield panicle number, 1000-grain weight, protein content and grain/alcohol ratio. The yield was positively correlated with panicle number and positively correlated with panicle grain number and 1000-grain weight. The protein content was positively correlated with the amount of nitrogen accumulated before flowering and the grain/alcohol ratio.

Discussion

Wheat production in Hugong Township, Wenxi region are facing great challenges due to scant water supply and nutrient deficit. Due to the sparse and deep groundwater resources, rainfall is the sole water source for wheat production in the Loess Plateau, which is limited (200-600 mm) and unevenly distributed. 30%-40% of annual rainfall occurs during winter wheat growing season, whereas most of the rain falls between July and September, which is concurrent with the summer fallow between two growing seasons of winter wheat (Li et al., 2015). Water stress is the main limiting factor for wheat production in Loess Plateau and other arid and semiarid regions (Liu et al., 2007). The growth of winter wheat plants depends on the soil water stored by rainfall during summer fallow season (60-70%) and growing season (30-40%). The roots of rain fed winter wheat are not able to utilize water from deeper soil layers and ground water (Li et al., 2017). Hence, the limiting precipitation during growth season means that winter wheat must utilize soil water stored from precipitation during fallow season (Xue et al., 2019).

Effect of seeding rate on Soil water consumption

In addition, nitrogen also significantly affects crop yield under water deficient conditions. Winter wheat under water deficient conditions, supplying post-anthesis nitrogen fertilizer increases grain yield by decreasing the sink limitation and not by increasing source strength (Madani et al., 2010). Therefore, nitrogen fertilizer has no relation with sesame phonological traits under higher rainfall areas, whereas in drought-prone areas, zero fertilization might flower earlier than the fertilized one. Taller plants (116 cm), higher LAI (0.78), higher branches per plant (8.7), and TDM per plant (32.7 g) were obtained with the application of 100 kg·N/ha in Nigeria (Haruna et al., 2011). Nitrogen could influence leaf area, active life span, chlorophyll content, tuber size and tuber bulking time to affect yield (Goffart et al., 2008). The use of wide range precision sowing method under the condition of corn straw mulch significantly improved water use

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71677188

efficiency and reduced water consumption (Liu et al., 2015). The soil water storage capacity of 0-300 cm soil layer with full membrane soil hole sowing increased during sowing jointing and grouting and the water consumption intensity increased during sowing jointing water use efficiency increased. (Hou et al., 2017). Compared with conventional sowing, the total water consumption under wide space sowing increased and water use efficiency increased (Li et al., 2015). The yield and yield parameters were significantly affected due to application of nitrogen and irrigation water. For higher yield, it is better to apply nitrogen at the stem elongation and heading unless it is not irrigated with minimum amount of water (Cao et al., 2008a).

The effect is better and the percentage of soil water consumption in the 0-200 cm soil layer under wide space sowing is significantly higher than in other sowing methods and the water consumption during the growth period and water use efficiency under (WSS) are increased. The increase of 17% and 33% may be due to the uneven distribution of the roots in the upper layer of conventional seeding which caused the root density between individual plants to be much lower than the density of the roots in the row. This caused the soil moisture to be lost in the manner of soil evaporation. The individual growth and nutrient movement of wheat during the whole growth period has a very important influence on the formation of grain yield (Chu et al., 2018), there was a significant negative correlation between nitrogen accumulation and nitrogen use efficiency and a significant positive correlation between nitrogen absorption efficiency and nitrogen use efficiency. This study shows that wide space sowing can significantly increase plant nitrogen accumulation at various growth stages and the contribution rate to grains is mainly increased by the amount of nitrogen before flowering, which is consistent with previous research results (Xue et al., 2017). Nitrogen absorption efficiency, nitrogen fertilizer production efficiency and nitrogen harvest index significantly improved, but the mechanism that affects nitrogen operation by wide space sowing needs further study. The number of spike grains per spike and thousand grain weight are the elements of yield formation. Dang et al., 2015 showed that compared with the traditional sowing method, the use of wide precision sowing increased the number of ears by 5%, the number of ears by 5%, the weight per thousand by 3%, and the yield increased by 12%. The number of ears and yield showed a very significant positive correlation. There was a significant positive correlation between ear number and thousand-grain weight and yield. It can be seen that wide space sowing (WSS) mainly increased yield by increasing ear number which is the same as that of (Li et al., 2012). The yield is significantly positively related to the water consumption during the growth period and the nitrogen accumulation before flowering. Wide space sowing has high water consumption during the growth period and high nitrogen before bloom which promotes nutrient absorption and operation and increases yield. In addition the broad soiled sowing population structure is reasonable, significantly increasing the number of tillers in the middle and late stages of reproductive growth, along with ear length, and the number of fertile spikelet's, while it significantly reduces the number of infertile spikelet's, increases the leaf area in the later stages of growth and increases growth stages. The accumulation of dry matter is conducive to the increase of yield.

Effect of seeding rate on the regulation of quality

The technical quality of wheat is a very complex character, applied technologies and agro-ecological conditions. The high content of mineral nutrition, especially nitrogen, affects the quality of the process. These results showed that higher N rate has a positive

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71677188

effect on wheat grain quality. Higher density provides a greater number of primary tillers per square meter, which causes the formation of grains with larger size and mass. These grains have a more favorable ratio of storage proteins and starch, which requires better quality. In crops with a lower density, a greater number of secondary tillers are created, which produce small grains with less weight and lower quality. These results agree with those of Geleta et al. (2002). From our results, we conclude that the application of slurry had small but significant influences on yield and quality compared to mineral fertilization. This effect was also found by Sieling et al. (1997).

Quality parameters investigated in this paper significantly depended on applied nitrogen doses. The application of an increased nitrogen fertilization dose caused an increase of quality traits. The highest increase of sedimentation value and wet gluten content established in N3 variant when applied 120 kg ha^{-1} of nitrogen, which agree with our previous results (Zecevic et al., 2005). By analysis of variance, it was established that both of the analyzed quality traits significantly depended on genotypes and investigated years. Interactions between genotypes, applied nitrogen doses and years were also highly significant, which means that new genotypes positively reacted to nitrogen application (Guarda et al., 2004). Research showed that the use of wide stubble sowing can make wheat individuals grow robustly which can significantly increase the bulk density and hardness of wheat grains, significantly improve water absorption wet gluten content and sedimentation value and significantly increase the maximum resistance of dough, the standard value of power and flour quality, but has no significant effect on flour protein content and dough ductility (Wang et al., 2012). Some studies have shown that the amount of nitrogen before flowering affects wheat grain protein content. It has a large regulatory effect (Desai et al., 1978) and some studies have shown that the contribution of nitrogen accumulation and operation amount before and after flowering to grain protein varies from species to species. The protein content has a regulating effect and the nitrogen accumulation after flowering mainly has a regulating effect on the grain protein content in medium protein varieties. There was a significant positive correlation between protein content in grains and nitrogen accumulation before flowering, and a significant or very significant positive correlation with grain/alcohol ratio, wet gluten content, water absorption, and quality of powder maps. The grain/alcohol ratio is an important index for evaluating the quality of wheat (Zou et al., 2006). The grain/alcohol ratio is related to water consumption during growth, nitrogen accumulation before flowering, wet gluten content, water absorption, dough formation time, and flour. There is a significant or very significant positive correlation between the mass numbers in the prime image. It can be seen that increasing the water consumption during the growth period and the amount of nitrogen accumulation before flowering are conducive to increasing the protein content of the grain, increasing the grain/alcohol ratio and ultimately facilitating the formation of quality. Under this test condition, the use of (WSS) is the most beneficial to improve the grain quality indicators such as protein and component content, grain/alcohol ratio, wet gluten content, water absorption, dough formation time and stabilization time.

Effect of seeding rate on the regulation of yield amount

Dry land wheat that sowing amount in open field was 354 × 104 hm^{-2}, and 245 × 104 hm^{-2} on the film was good for improving grain yield (Feng et al., 2013). Suitable seeding rate for wide space sowing is 105 kg·hm^{-2}. At this time, the highest yield of wheat is 13% higher than that of conventional precision sowing and the highest yield is 8643 kg·hm^{-2}.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71677188

A research work by Cao et al. (2008b) showed that the suitable nitrogen rate under trench sowing was 150 kg·hm^{-2} and the yield at this time was 8644 kg·hm^{-2}. Under the conditions of this experiment the interaction effects of the sowing method and the sowing amount were analyzed: the sowing method, sowing amount, sowing method × the sowing amount had a significant effect on the number of ears, grain number, thousand-grain weight yield, and water use efficiency of winter wheat. Among them the most important influence on yield was the sowing method followed by the sowing amount; the most important effect on water use efficiency was the sowing amount, followed by the sowing method. The suitable seeding capacity for (WSS) was 300 kg·hm^{-2}, the yield at this nitrogen amount was 7158 kg·hm^{-2} and the water use efficiency was 14.2%; the suitable seeding capacity for trenching was 300 kg·hm^{-2}. The yield at this sowing rate was 6343 kg·hm^{-2} and the water use efficiency was 13.4%; the suitable nitrogen rate for uniform sowing was 375 kg·hm^{-2} and the yield at this sowing rate is 6780 kg·hm^{-2}, the suitable sowing capacity for conventional sowing is 225 kg·hm^{-2}, the yield at this sowing capacity was 5832 kg·hm^{-2} and the water use efficiency was 13.7%. It can be seen that the appropriate nitrogen amount should be selected according to different nitrogen rate. Under this experimental condition, the matching nitrogen amount of (WSS) was 300 kg·hm^{-2}, which is conducive to the improvement of grain yield and water use efficiency. It is suitable for the local sowing method and volume.

Effect of seeding rate on N input yield components and accumulation characteristics of dryland wheat

Constructing a reasonable population structure, that is individuals can fully absorb water, light, heat and nutrient resources, promote the healthy growth of individuals, coordinate the contradictions between individual groups and it is extremely important for the coordination of wheat yield and quality (Bhatta et al., 2017; Lin et al., 1996). Nitrogen rate can affect the nitrogen accumulation and translation of winter wheat. Rational close planting of wheat is beneficial to increase nitrogen accumulation amount, so as to realize synergistic improvement of grain yield and nitrogen utilization efficiency. Enhanced nitrogen accumulation in winter wheat requires seeding rate at an appropriate density. Previous study indicated that with irrigation the winter wheat plant density increased from 270 to 405 m^{-2}, nitrogen use efficiency (NUE) increased significantly mainly due to increasing root length density and enhanced nitrogen uptake (Dai et al., 2014).

Wheat grain nitrogen mainly comes from the redistribution of pre-anthesis nitrogen translocation amount from various organs, accounting for about 53.0%, 80.8% of grain nitrogen (Geleta et al., 2002). According to them the increase of nitrogen volume, the leaf area index (LAI) of Guomai 301 in the flowering stage gradually increased, the dry matter accumulation in the flowering stage increased first and then decreased and the number of ears and yield increased first and then decreased. Under the conditions of this experiment, the relevant analysis of factors related to yield formation shows that the water consumption during the growth period, the number of ears, the 1000 grain weight and the yield have a significant or very significant correlation and the nitrogen rate was 300 kg·hm^{-2}. In the period the water consumption and the proportion of stored water consumption increased and the water consumption and irrigation water consumption decreased and the output gradually increased with the increase of the nitrogen amount. Increasing the sowing volume within a certain range increased the nitrogen accumulation in the above ground, the nitrogen utilization efficiency decreased and the nitrogen utilization increased first and then decreased (Zhu et al., 2018).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71677188

A research by Zhang et al. (2015) showed that increasing planting density within a certain range increased nitrogen accumulation and absorption efficiency in the above-ground area and reduced nitrogen use efficiency. Wang et al. (2012) showed that with the increase of planting density, the nitrogen harvest index, grain accumulation and nitrogen content gradually decreased, and the contribution rate of nitrogen transport from vegetative organs to the grain during the flowering period showed an upward trend. Plant nitrogen accumulation wave, nitrogen absorption and utilization rate and nitrogen fertilizer partial production efficiency showed a trend of rising first and then decreasing. Xue et al. (2017) showed that increasing the sowing amount increased the amount of nitrogen accumulation in various organs before flowering and the contribution of nitrogen accumulation in leaves glumes and cobs to flowering increased before flowering. This study showed that with the increase of nitrogen rate the nitrogen accumulation of plants in each growth stage showed a trend of first increase and then decline and the contribution rate of nitrogen accumulation before flowering and the amount of nitrogen accumulation before flowering showed first contributions to grains. It reached the highest at 300 $kg \cdot hm^{-2}$. It can be seen that when the wide space sowing rate is 300 $kg \cdot hm^{-2}$, it is beneficial to improve accumulation of nitrogen in each growth period, increasing the contribution rate of nitrogen operation before flowering with grain, improving nitrogen absorption efficiency and nitrogen fertilizer production efficiency, are beneficial to plant nutrient operation. Adjusting the nitrogen rate to build a reasonable population structure, promoting wheat's absorption of soil moisture and nitrogen affect plant nutrient operation and thereby form protein in the grain. In the range of 245 ~ 330 × 104 hm^{-2}, the grain protein content increased first and then decreased with increasing planting density. Under the conditions of this test a correlation analysis was performed and the protein content was extremely significantly positively correlated with the nitrogen accumulation and the grain/alcohol ratio before flowering. The change trend of first increase and then decrease reached the highest at 300 $kg \cdot hm^{-2}$, which may be due to the plant population under the nitrogen amount, low intercellular CO2 concentration, strong nitrogen metabolism, flag leaf GS and GOGAT activity, and grain GS activity. The GOGAT activity of the grain during the early grain filling period is high, the nitrogen accumulation is high before the flowering operation and finally the grain protein content increases (Wang et al., 2014).

Conclusion

Under this experimental condition, the matching nitrogen amount of WSS was 300 $kg \cdot hm^{-2}$, which is conducive to the improvement of grain yield and water use efficiency. It is suitable for the local sowing method and volume. Sowing methods are beneficial to the increase of winter wheat grain yield. Correlation analysis showed that there was a very significant positive correlation between yield and water consumption during the growing period, and nitrogen accumulation before flowering. Wide sowing increased water consumption during the growing period, and nitrogen transportation before flowering increased tiller number, leaf area in late growth period, dry matter accumulation in each growth period, and ear length. The water consumption during the growing period increases, the nitrogen accumulation and operation before flowering increases, the grain protein and component content increases, the grain/alcohol ratio increases, The effect of wide space sowing with 300 $kg \cdot hm^{-2}$ is the most obvious, and it is conducive to increasing water consumption in the growing period, increasing nitrogen accumulation in each growing period, and improving flowering. The amount of pre-nitrogen operation increases with the

contribution of grains, improves nitrogen absorption efficiency and nitrogen fertilizer production efficiency, and promotes plant nutrient operation.

Abstract. The Clearfield® Rice Production System (CPS) technology successfully manages weedy rice infestation and increases rice production in Malaysia. However, there were concerns on the recurring presence of weedy rice in the CPS fields in recent years, suspecting that weedy rice has become resistant to the imidazolinone (IMI) herbicide. This research was designed to evaluate the occurrence of herbicide resistant weedy rice in the CPS fields. A total of 17 weedy rice biotypes were collected and assessed for resistance to IMI (imazapic + imazapyr) during germination and vegetative stages using different herbicide concentrations. Different dosages of IMI herbicide only reduced germination rate by ~30% but significantly decreased the weedy rice seedlings' viability. Low viability rate for commercial (13.9±13.8%) and double (7.3±4.1%) herbicide dose indicated application of IMI herbicide as pre-emergence herbicide was effective to control weedy rice. The application of IMI herbicide at later stage after the recommended period increased weedy rice escape potential in the CPS fields by 64.7% to 76.5% for one- and two-dose applications, respectively. There is a possibility that weedy rice in Malaysia has developed certain levels of resistance towards IMI herbicide. Stringent ecological risk evaluation of CPS is needed to mitigate the development of herbicide resistant weedy rice in the future.
Keywords: *Clearfield® rice, direct-seeding, herbicide application, herbicide resistant, weed management*

Introduction

Weedy rice (*Oryza sativa* L.) is one of the notorious weed species in rice granaries all over the world. In most rice agroecosystem, the spread of weedy rice becomes significant mainly after the shift from rice transplanting to direct seeding (Azmi and Karim, 2008; Chauhan, 2013). The herbicide-tolerant Clearfield® rice technology (Croughan, 2003) provides an option to control weedy rice in rice agroecosystems using imidazolinone herbicides. An herbicide-tolerant rice cultivar from Clearfield® Rice Production System (CPS) was introduced to Malaysian rice farmers in 2010 as the current best solution to combat weedy rice especially in direct-seeding system (Azmi et al., 2012). This imidazolinone tolerant variety (IMI-TR) rice was developed by crossing United States IMI-TR Line No. 1770 with local cultivar, MR220, using a conventional breeding technique (Azmi et al., 2012). Introduction of CPS as a pilot study in Seberang Perak rice granaries has become popular to other rice growing states (i.e., Selangor and Kedah) because of the success of this system to control many grasses weed species including weedy rice while boosting rice production (Sudianto et al., 2013).

This system used imidazolinone (IMI) herbicide (a.i. imazapic + imazapyr) which is a selective herbicide that inhibits the ALS enzyme and the three amino acid branched

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71897199

chains: isoleucine, leucine, and valine. It stops protein synthesis, and eventually, kills any susceptible plants (weeds) including weedy rice (Azmi et al., 2012; Sudianto et al., 2013). This system reported to increase yield production by 5 to 8 times (Azmi et al., 2012). Despite the current popularity of CPS in most major rice granaries in Malaysia, Sudianto et al. (2013) has listed four major challenges for this system to become sustainable in Malaysia including the evolution potential of the weedy rice to be resistant to the herbicide application.

Low levels of natural hybridization were known to occur between the rice cultivars and weedy rice with gene flow generally ranges from 0.003% to 0.25% (Gealy, 2005; Shivrain et al., 2008). Engku et al. (2016) also observed that Clearfield®-weedy rice hybrids can occur within 5 m distance. IMI resistant weedy rice populations were reported in the United States after two cropping seasons (Burgos et al., 2008, 2014) and similar events were reported in other countries adopting similar CPS technology (Gressel and Valverde, 2009; Busconi et al., 2012; Scarabel et al., 2012; Rosas et al., 2014). Unfortunately, Malaysia has high potential risks of gene flow and evolution of resistant weedy rice populations because of multiple cropping of rice in a year and freezing temperatures, which would reduce the density of volunteer plants, do not occur (Shivrain et al., 2008; Burgos et al., 2014).

Despite various reports of gene flow and IMI-tolerance weedy rice in the world, there are still limited reports or evidences on weedy rice IMI resistant status in Malaysia. A preliminary study at three townships in Kedah reported that there is high likely that weedy rice has developed resistance to IMI herbicide at various level (Hamdani et al., 2015) based on the weedy rice escapes in CPS rice fields in these areas (Jaafar et al., 2014). Dilipkumar et al. (2018) reported the resistant biotype of weedy rice in Malaysia can be 2.1 to 2.8 times more resistant than the Clearfield® rice itself. Harun et al. (2018) also reported the farmers concern on the recurring weedy rice existence in the CPS fields and the potential of weedy rice resistance to IMI herbicide.

Herbicide resistance in weed population is heritable and in fact is evolution in action (Baki, 2010). This attribute indicates that weed exposure to herbicides is less likely to cause mutation but rather, an herbicide resistance weed (HRW) arises from natural selection of genetic variants possessed among weed populations (Barret and Schluter, 2007; Neve et al., 2009). Weeds in ecosystems always retain a certain level of genetic diversity to survive in a balance ecosystem until a new stress imposing to the population (Novoplansky, 2009). This instituting extra pressures to nature to inevitably response with the landscape shifts. Weeds did not change to become resistant; instead the fittest genotype was selected to survive in a changed environment (Ammann, 2000; Gressel, 2000; Gienapp et al., 2008; Heap, 2019). This study was designed to evaluate the resistant status of weedy rice from various populations collected from CPS rice fields.

Materials and Methods

Weedy rice collection

Seeds from a total of 17 different weedy rice biotypes were sampled during harvesting period in October 2016 at rice fields in Sawah Sempadan (3°25'35.0724" N, 101°10'36.1704" E) in the state of Selangor, Malaysia. Weedy rice samples were randomly selected from high weedy rice infestation fields. These weedy rice biotypes were selected due to observation of weedy rice presence despite the Clearfield® Rice Production System (CPS) has been practiced in the fields for the past six years.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71897199

Communication with field owners indicated that selected fields during sample collection were planted with Clearfield® rice MR220CL2 for two consecutive seasons. Weedy rice seeds were hand-threshed and placed into an individual paper bag. Seed samples were air-dried at room temperature for 3 days (d) before placed in a -4ºC refrigerator for further experiments (to test for resistance to IMI herbicide). Conventional local rice cultivars MR220 and Clearfield® rice MR220CL2 certified seeds were obtained from the Muda Agricultural Development Authority (MADA).

Seed bioassay with imidazolinone (imazapic + imazapyr) herbicide treatments

The resistant of weedy rice seeds to IMI (a.i. imazapic + imazapyr) herbicide was tested by standard germination method using a half (75 g a.i. ha^{-1}), single (150 g a.i. ha^{-1}), and double (300 g a.i. ha^{-1}) doses of herbicide application. A sample of ~30 seeds from each weedy rice biotype was distributed in standard petri dishes (9-cm petri dish diameter) with a Whitman no. 1 filter paper in an incubator set at 40ºC overnight to break the dormancy. This will eliminate the possibility of false negative germination data.

Seeds on each petri dish with three replications were then wetted with ~5 ml concentrated of IMI herbicide using 2.2 g/L concentration for two doses, commercially concentrated 1.1 g/L for single-dose application and 0.56 g/L herbicide concentration for a half-dose application. The seeds for control treatment was applied with distilled water. Samples were placed in an incubator set at 30ºC and 100% relative humidity in the light. Germinated seeds were determined by the emergence of radical or coleoptiles. The viability of germinated seedlings was determined based on the seedling appearances as viable (green in colour) and non-viable (white/non-pigmented). The germination rate and number of the viable seedlings were counted at 1, 3, 5, 7, 10 and 14 d after imbibition.

Weedy rice growth response to imidazolinone (imazapic+imazapyr) herbicide

After-ripened (dormancy released) seeds from all collected weedy rice biotypes and two cultivated rice were germinated in a 30ºC incubator for 7 d. The seedlings were transplanted into pots (40 cm x 40 cm x 25 cm dimension), with 30 plants per pot. The pots were filled with clay soil mixed with growth medium and placed in water containers (60 x 120 x 15 cm dimension) in a greenhouse at Rimba Ilmu, Institute of Biological Sciences, University of Malaya (3°13'N, 101°66'E). The experimental lay out was arranged in a Complete Randomised Design (CRD) with three replications for every weedy rice population and treatment. The seedlings were carefully thinned to 25 per pot during the 2-leaf stage.

The IMI herbicide at 1.1 g/L (150 g a.i ha^{-1}) concentration replicating the commercial dose (one-dose) was applied to the plants at 2-leaf stage (3 d after transplanting) using hand-held spray. The plant response (injury and death) to the treatment was recorded for every three days after the herbicide application. Plants with >50% of the total leaves retained green pigmentation were considered survive from herbicide application. The second application of herbicide was applied to the plants at 21 days after first application with an increased concentration dosage to 2.2 g/L (double dose from commercial recommended dose or 300 g a.i. ha^{-1}) and the plant response was recorded for the subsequent three days. No application of herbicide for control treatment. A total of nine (9) morphological traits were recorded for all weedy rice populations from the control treatment (*Table 1*). All materials were grown with natural temperature, humidity, and day length in the greenhouse during the experiment. The water level in the pots were kept at 5 cm depth throughout the experiment.

[a] Traits evaluated; PH, plant height measured in cm; SH, seed shattering percentage (%); PT, panicle type; PC, color of the pericarp; FE, flag leaf type; HC, hull color; HD, days to heading; AN, presence of awn; SW, 1000 seed weight (g)

Data analysis

The germination rate and growth response data were analysed as a one-way factorial, with different dosage of herbicide treatments as the factor. The variation was tested with ANOVA to detect difference between treatments and means were compared by Tukey's test using the SAS GLM procedure and Tukey option (SAS Institute, 2011). The level of significance was set at $p < 0.05$.

Results

Effects of imidazolinone (imazapic + imazapyr) herbicide application during germination stage

The average germination rate for different dosages of IMI-herbicide (imazapic+imazapyr) application after 7 d of herbicide treatments showed that half- (93.14±6.46%) and one- (90.97±7.52%) dose applications were significantly higher than the double-dose (72.57±9.43%) application (*Fig. 1*). Daily record of germination rate also displayed that weedy rice in the half- and one-dose treatments reached nearly full germination capacity at 4 d after imbibition while the double-dose treatment showed slower rate at 5 d after imbibition. At this pre-emergence treatment (germination test), imazapic+imazapyr only reduced ~10% and ~30% germination percentage under commercial- and double-dose herbicide applications, respectively indicating that this herbicide has limited effect on the germinability of weedy rice. Under controlled condition (germination with distilled water), all weedy and cultivated rice recorded near 100% germination rate (*data not shown*). However, this germination data cannot be an indication of resistant level in weedy rice because the fate of survival of the seedlings to

DOI: http://dx.doi.org/10.15666/aeer/1805_71897199

maturity are yet to be determined. Therefore, the pigmentation of the seedlings was observed to determine the seedlings potential viability.

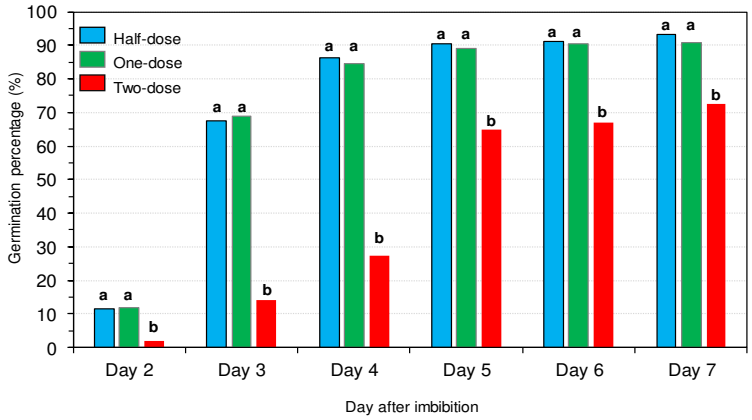

Figure 1. *Cumulative germination percentage recorded for 7 d after imidazolinone herbicide treatment at half (1.1 g/L), single (2.2 g/L), and double (4.4 g/L) herbicide concentration represented by blue, green and red column bars, respectively. Bars with the same letter show no significant difference ($p<0.05$) within the treatments*

Viability of seedlings post germination after IMI-herbicide treatments at different dosage was determined by the green pigmentation of the seedlings 14 d after imbibition (*Fig. 2*). Seedlings developed normal (green) pigmentation after treatments were counted as 'survived' from herbicide treatment and considered resistant towards the herbicide treatment while unpigmented (white color) seedlings were considered not be able to endure through maturity. The seedlings viability percentage was significantly reduced over the increment of herbicide dosage (*Fig. 3*). Increment from half-dose to one-dose significantly ($p<0.001$) decreased seedlings survival by 45.8% while two-dose herbicide treatment decreased seedlings survivability by 64.8% ($p=0.0017$).

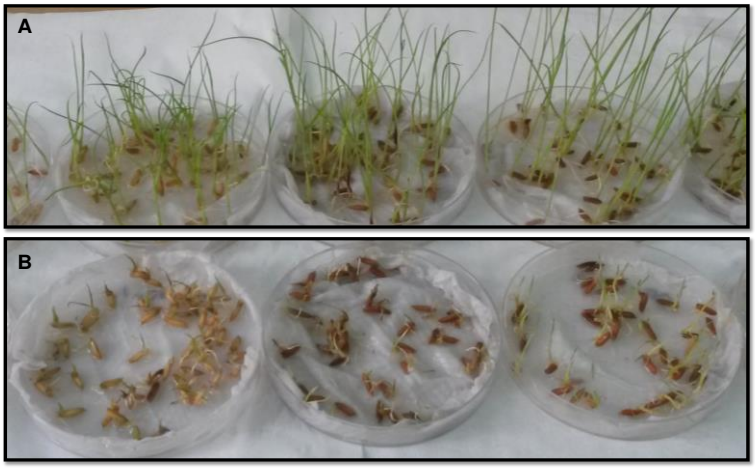

Figure 2. *Weedy rice seeds' response towards pre-emergence imidazolinone herbicide treatments. The seedlings' viability was determined based on green (A) and white (B) appreances to indicate viable and non-viable seedlings, respectively*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71897199

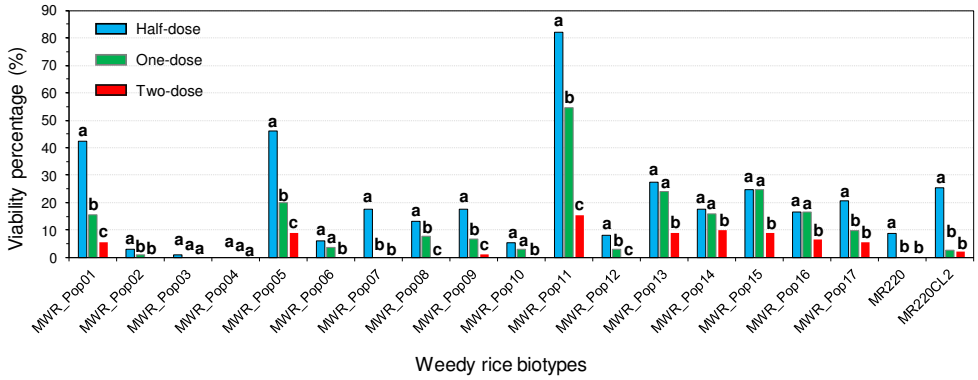

Figure 3. *Percentage of seedlings viability for each weedy rice biotypes after 14 d of imidazolinine herbicide treatments at half (1.1 g/L), single (2.2 g/L), and double (4.4 g/L) herbicide concentration represented by blue, green and red column bars, respectively. Bars with the same letter show no significant difference ($p<0.05$) within the treatments*

At half dosage of IMI-herbicide, average percentage of viable seedlings ranged from 1% to 82% while weedy rice MWR_Pop04 displayed no seedlings developing green pigmentation (*Fig. 3*). This indicates that this weedy rice population was the most susceptible population towards IMI herbicide. Application of IMI-herbicide at one-dose displayed three weedy rice populations were fully controlled (susceptible) at this application rate. Additional five weedy rice biotypes displayed susceptibility towards the herbicide when the dosage was increased to double the recommended dosage (*Fig. 3*).

Current recommended dosage of IMI herbicide with herbicide concentration of 150 g a.i. ha^{-1} only successful to control 23.5% of weedy rice biotype samples as pre-emergence herbicide. Despite relatively low percentage of viable seedlings (13.9±13.8%) for the remaining 13 populations, weedy rice has developed a degree of resistance to potentially escape current herbicide dosage. At an increased dosage, IMI herbicide can control half of the weedy rice population but the remaining still maintaining low level of resistance ranging from 1.1% to 15.6%. Weedy rice MWR-Pop11 displayed the most resistant population with 54.44 and 15.56% of its seedlings survived the herbicide treatments at one- and two-dose application, respectively. Clearfield® rice MR220CL2, an imidazolinone tolerant rice, displayed 25.56%, 2.67%, and 2.22% seedlings viability percentage after herbicide application at half-, one- and two-doses, respectively.

Weedy rice growth response on imidazolinone herbicide application

The effects of IMI herbicide to weedy rice growth varied between biotypes (*Fig. 4*). A total of 11 (64.71%) weedy rice biotyeps responded to one-dose herbicide application after 3 d with mortality ranging from 1.4% to 6.4%. The mortality rate was gradually increased over time for the majority of the populations except for four biotypes (MWR_Pop03, MWR_Pop12, MWR_Pop13, and MWR_Pop17) which showed stagnant mortality below 10% starting at day 15 and two populations (MWR_Pop15 and MWR_Pop16) have all plants survived commercial dose of IMI herbicide. At 21 d after one-dose herbicide application, weedy rice populations MWR_Pop06, MWR_Pop07, MWR_Pop08, and MWR_Pop11 showed high susceptibility to the herbicide treatment where all individuals died from the treatment.

DOI: http://dx.doi.org/10.15666/aeer/1805_71897199

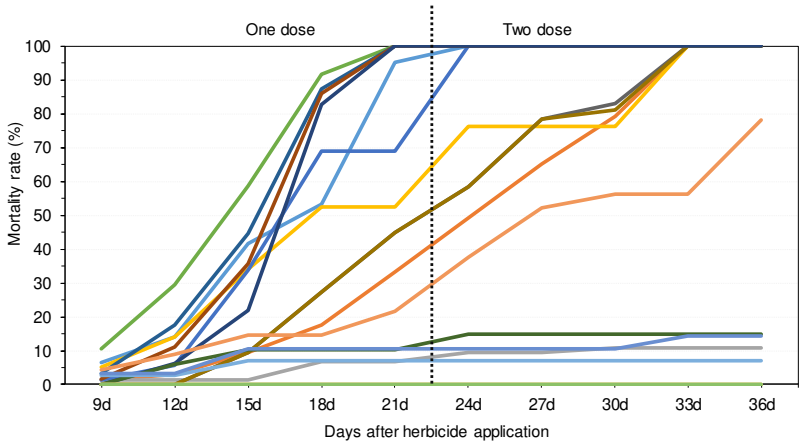

Figure 4. *Effects of imidazolinone herbicide on mortality rate to 17 weedy rice biotypes over time. Vertical dotted line indicates the time of the two-dose herbicide concentration application*

The increase dosage of herbicide after 21 d to two-dose affected the other six weedy rice biotypes where MWR_Pop01 and MWR_Pop05 reached 100% mortality seven days after the 2-dose treatment while MWR_Pop02, MWR_Pop04, MWR_Pop09, and MWR_Pop10 died at day 37 (*Fig. 4*). The increased mortality rate of MWR_Pop14 however stopped at 78.3%. The remaining weedy rice biotypes showed no effect (survived) or stagnant mortality rate for both application dosages.

Clearfield® rice variety MR220CL2 showed complete resistant towards IMI herbicide of both dosages while commercial variety MR220 displayed total susceptible to the herbicide (*Fig. 5*). A total of two weedy rice biotypes (MWR_Pop15 and MWR_Pop16) showed similar resistant pattern with Clearfield® rice. *Figure 4* also showed that IMI herbicide can have total control to only 23.52% and 35.29% of the weedy rice biotypes for one- and two-dose applications, respectively. The remaining 41.18% of the weedy rice biotypes showed certain degrees of resistance towards herbicide application ranging from 4.74 to 100%.

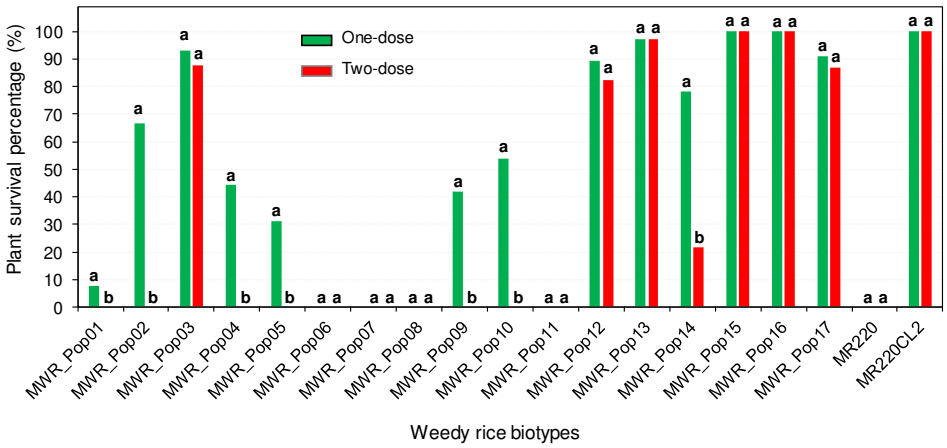

Figure 5. *The growth response (survival rate) of weedy and cultivated (MR220 and MR220CL2) rice after imidazolinine herbicide treatments at commercial (150 g a.i. ha^{-1}), and double (300 g a.i. ha^{-1}) herbicide concentration represented by green and red column bars, respectively. Bars with the same letter show no significant difference ($p<0.05$) within the treatments*

Discussion

It is high likely that several weedy rice biotypes in Malaysia have already 'evolved' to be resistant to imidazolinone herbicide (a.i. imazapic + imazapyr) possibly from consequential conferment of resistant genes from Clearfield® rice to weedy rice (Shivrain et al., 2008; Jaafar et al., 2014; Dilipkumar et al., 2018). Different weedy rice biotypes from this study showed wide variation of IMI herbicide responses to the weed during pre-emergence (*Figs. 1,3*) and post-emergence (*Figs. 4,5*) herbicide applications at various dosage. This confirmed that sampled weedy rice biotypes have various degrees of resistant towards IMI herbicide. This variation might be caused by accidental and/or voluntary hybridization between IMI tolerant cultivated rice with weedy rice in the Clearfield® rice fields.

Engku et al. (2016) reported the potential gene flow between Malaysian Clearfield® rice (MR220CL1 and MR220CL2) to various weedy rice biotypes producing resistant progenies in the F_1 population. The hybridization introduces gene flow and subsequently increases genetic diversity and heterogeneity of the hybrid weedy rice populations (Chang, 2003), initiating hybridization-differentiation cycles of next generations (Gu et al., 2004; Mispan et al., 2013). This increases genotypic selection for adaptive/survival traits (Mispan et al., 2013; Zhang et al., 2017; Qiu et al., 2017) which later expand the probability of survival potential from selection pressure due to continuous IMI herbicide application (Kuk et al., 2008; Dilipkumar et al., 2018).

Viability percentage of the seedlings for herbicide treatment as a pre-emergence application at half-dose (21.4±19.6%), commercial dose (13.9±13.8%) and double-dose (7.3±4.1%) rate (*Fig. 3*) indicates the application of IMI herbicide as pre-emergence herbicide might help in managing weedy rice at the early stage. Imidazolinone herbicide reportedly to have a slight effect on the percentage of seed germination in chickpea but a significant shift down in the speed of germination (Hoseiny-Rad and Jagannath, 2011). This is in line with the stewardship guideline for the Clearfield® Production System (CPS) to apply the recommended herbicide only between 0 to 7 d after sowing (DAS). High percentage of imazapic (52.5%) - one of active ingredients in IMI herbicide - acting as pre-emergence herbicide might contribute to this action (Dilipkumar et al., 2018).

However, this study showed that MR220CL2 (imidazolinone tolerance variety) seeds also affected by the pre-emergence application (*Fig. 5*) if the seeds were directly sowed before pre-germination. The usage of IMI herbicide as pre-emergence herbicide could be more effective in transplanting method especially with an increased dosage from the commercial rate. However, the environmental impact of regular usage and high dosage of this herbicide need to be properly assessed because the current CPS practice showed potential herbicide leachate and carryover in the rice field soil (Bzour et al., 2019).

The application of IMI herbicide as a post-emergence herbicide can increase the potential of weedy rice to escape the CPS. Only 23.5% of weedy rice sampled populations can be fully controlled (susceptible) by commercial dosage and additional 35.3% were controlled by 2-dose. The low formulation rate of imazapyr (17.5% or equivalent of 38.5 g a.i. ha^{-1}) as a post-emergence herbicide in the herbicide will increase the probability for diverse weedy rice populations to survive. Dilipkumar et al. (2018) reported that imazapyr can control resistant biotype of weedy rice at 4,995 g a.i. ha^{-1}. This wide margin creates ample window for weedy rice to adapt in the CPS environment and consequently become resistant to the herbicide through spontaneous mutation over time (Tan et al., 2005; Sales et al., 2008; Kuk et al., 2008).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_71897199

Unfortunately, disobedience of some farmers to follow the CPS guidelines and stewardships has been reported (Dilipkumar et al., 2018; Harun et al., 2018) and personally observed. This include practicing CPS for more than three consecutive seasons in the same field, late application of recommended herbicide at 10 to 15 DAS, and reducing the herbicide dosage to cut input cost.

Continous application of same herbicide will enhance selection pressure for resistant weedy rice. Previous experience in Malaysia already reported that continuous use of phenoxy herbicides since late 1980s has caused the weed species shift to graminaceous species including weedy rice in Malaysia rice granaries (Baki, 2006; Baki and Shakirin, 2010; Mispan et al., 2019). Late application of IMI herbicide will reduce herbicide efficacy which leads to weedy rice survival (Dilipkumar et al., 2018). This study also showed that reducing herbicide dosage will significantly increase seedlings survivability (*Fig. 3*), consequently facilitate weedy rice escape in the rice fields.

Conclusion

This research demonstrated diverse weedy rice biotypes in one of the rice granaries in Malaysia have developed various degrees of resistant towards IMI herbicide (a.i. imazapic + imazapyr). Intervention strategies are required to ensure the sustainability of the CPS technology in the country (Dilipkumar et al., 2018). Understanding the escape mechanism of weedy rice from herbicide application and their adaptation strategies from dynamic changes of agronomic practices in rice cultivation is needed to offer valuable insights into weedy rice management strategies in the future. Malaysia will face ecological risks of continuous weedy rice adaptation in favor to its survival if no stringent ecological risk evaluation including the screening and mitigation strategies to break the selection of herbicide resistant weedy rice in the CPS system (Sudianto et al., 2013; Mispan et al., 2019).

Abstract. Organic acids are influenced by many factors, such as season variations, water levels, vegetation and others. In the study, the rhizosphere soils of lakeshore plants in Poyang Lake, Chaohu Lake and Wuchang Lake in China were sampled under different water level fluctuations, and the amounts of organic acids were measured. Water level fluctuations affect the temporal and spatial characteristics of rhizosphere organic acids. The annual average of the total amount of organic acids in the rhizosphere soil of lakeshore plants in Wuchang Lake was higher than that in the other lakes. The seasonal variations in the amounts of organic acids were the same in the three lakes. The total amounts of organic acids in the rhizosphere soils at high water level sites were higher than those in the low water level sites of the three lakes. The effects of the interactions of season variations and water level fluctuations on the amount of organic acids in the rhizosphere were significant. The results revealed that the lake types changed in response to anthropogenic influence; Wuchang Lake, as a quasi-natural lake, suffered from much more human pollutants than Chaohu Lake as a reservoir-like lake and Poyang Lake as an intermittent lake.

Introduction

A suitable water level is an important factor for maintaining the structure, function and biological integrity of lake ecosystems (Coops et al., 2003; Wantzen et al., 2008; Leira and Cantonati, 2008). Water level fluctuations are defined as the differences or changes in the water level within a period of time and are influenced by many factors, such as the water storage capacity, rainfall, and human factors involved in dam, highway and railway construction (Beckmann et al., 2005; Wang et al., 2007). Water level fluctuations have an important influence on the diversity of aquatic organisms; many studies have shown the effect of water level fluctuations on the digestion and retention of pollutants, the stabilization of the lakeshore, the maintenance of the water self-purification capacity, and the support of regional biological communities (Naiman and Décamps, 1997; Venkatachalam et al., 2005). For instance, water level fluctuations were found to influence the mobilization and transformation of nutrients such as nitrogen, phosphorus

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72017214

and chlorophyll a, as well as the diversity of phytoplankton and zooplankton (Sherr et al., 2003; Zhang et al., 2013; Liu et al., 2018). However, few studies have focused on the relationship between water level fluctuations and the root-soil environment, especially the effect of water level fluctuations on organic acids in rhizosphere soil.

Low molecular weight organic acids, such as citric acid, oxalic acid, and malic acid, are three of the most active forms of carbon in the plant-rhizosphere-soil interface and have great importance in physiological and biochemical processes, such as microbiological activity, nutrient acquisition, and the detoxification of heavy metals (Bais et al., 2006; Keiluweit et al., 2015; Chen et al., 2017). Numerous studies have shown that the allocation, transformation and exudation characteristics of organic acids are important mechanisms in response to environmental stresses. For instance, the roots of dicotyledonous species such as lupine (*Lupinus albus* L.), rape (*Brassica napus* L.) and alfalfa (*Medicago sativa* L.) exuded large amounts of organic acids under phosphorus deficiency; this organic acid mobilizes the insoluble phosphorus compound in rhizosphere soils, which increases the release of inorganic phosphorus and promotes phosphorus uptake (Haichar et al., 2014; Zhao and Wu, 2014; Baetz and Martinoia, 2014). Lakeshore plant species such as umbrella sedge and *Pistia stratiotes* adapt to phosphorus deficient environments via the regulation of the composition and amount of root-exuded organic acids (Zhang et al., 2019a,b). The roots of three lakeshore plants, *Canna indica*, *Zizania aquatic* and *S. warburgii Seemen* exude many organic compounds, mainly low molecular weight organic acids and aromatic proteins in root exudations; furthermore, the amount of such exudates was found to have a positive correlation with the biomass of the three plants (Lu et al., 2009). The mangrove *Kandelia candel* exudes high amounts of formic acid, butyric acid, malic acid, citric acid and lactic acid, and these low molecular weight organic acids increased the release of available heavy metals in wetland sediments (Lu et al., 2007). The composition and amount of organic acids in rhizosphere soils via root exudation can directly influence many biological processes in the rhizosphere-soil-plant interface under environmental stresses (López-Bucio et al., 2000; Zhao and Wu, 2018). Therefore, investigation of the composition and amount of organic acids in rhizosphere soils of lakeshore plants will provide important information on nutrient acquisition, heavy metal detoxification and plant growth.

In the present study, the composition and amount of organic acids under different water level fluctuations in different seasons were investigated in the rhizosphere soils of lakeshore plants in three different lakes in the lower-middle reaches of the Yangtze River basin of China. Furthermore, the effects of the physicochemical parameters of the rhizosphere soils on the amounts of organic acids were analyzed, and the responses of organic acids in different lakes under different water level fluctuations were investigated.

Materials and Methods

Study areas

Three lakes, Poyang Lake (PYL), Chaohu Lake (CHL) and Wuchang Lake (WCL), in the middle and lower reaches of the Yangtze River that are affected by human disturbance were investigated (*Fig. 1*). PYL is located in Jiangxi Province, and CHL and WCL are located in Anhui Province. The three lakes are at relatively low elevations. CHL and WCL are regulated by the Yuxi and Wanhe sluices, which were constructed as a consequence of human disturbance, and the water surface areas of PYL have been greatly reduced. The climate of three lakes is a typical subtropical monsoon climate characterized by hot and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72017214

rainy summers and cold and dry winters. The high temperature period is concentrated in July and August, the rainy season is from April to June, and the cold season occurs in January and February. The annual precipitation and annual air temperature at PYL, CHL and WCL are 1600.0 mm, 995.7 mm and 1299.6 mm, and 17.2 °C, 16.1 °C and 16.5 °C, respectively (Zhang, 2013; Zhang et al., 2018).

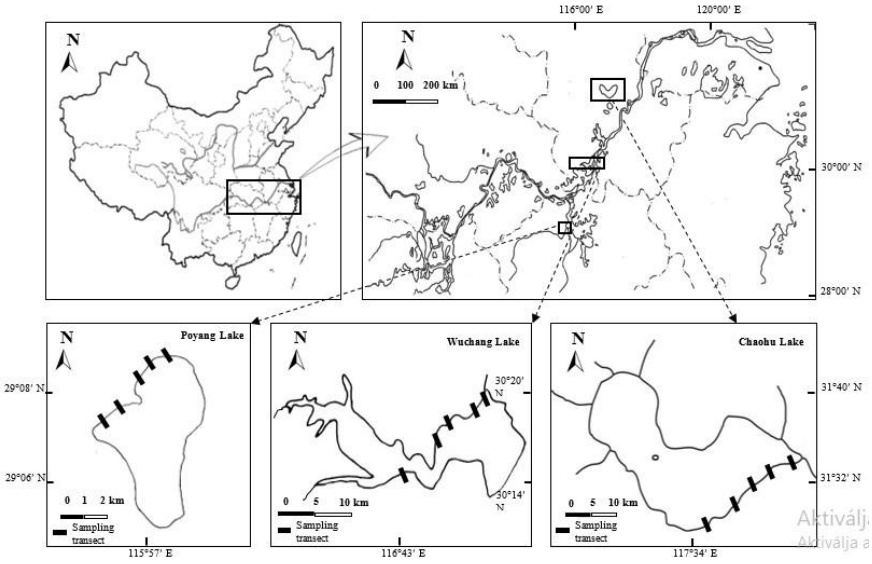

Figure 1. *Study area and soil sampling sites of three lakes*

PYL with a mean bottom elevation is 14.67 m amsl, and the water levels are low and stable with a mean water depth of less than 1.0 m. The mean bottom elevation of CHL is 5.0-6.0 m above mean sea level (amsl), and the water level is often maintained at 7.5-8.0 m amsl. The annual average water level of CHL was raised about 1.5 m after the building of the sluice (Zhang et al., 2014). The mean bottom elevation of WCL is 10.0 m amsl, and the water level is often controlled at 11.5 m amsl. The main uses of WCL are for aquaculture and flood control (Zhang et al., 2016). The other limnological parameters of the three lakes are shown in *Table 1*.

Table 1. *Limnological parameters of the three lakes. Note: Data are from Wang and Dou (1998), Zhang (2013), and Zhang et al. (2018)*

	Poyang Lake	**Chaohu Lake**	**Wuchang Lake**
Area (km^2)	30	769.6	100.5
Mean water depth (m)	0.70	2.69	3.43
Maximum water depth (m)	4.43	3.77	4.31
Annual precipitation (mm)	1600	995.7	1299.6
Annual air temperature (°C)	17.2	16.1	16.5
Recharge coefficient of lake	-	12.0	10.8
Catchment area (km^2)	-	9258	1083.7
Volume (m^3)	-	20.7×10^8	3.45×10^8

The floristic composition along the shores of the three lakes are significantly different (Zhang et al., 2015, 2016). The vegetations along the shores of CHL and PYL are relatively simple, and the dominant species of the lakeside zone near CHL is mainly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72017214

Cynodon dactylon, while *Carex sp*. is the dominant species in PYL. The floristic composition along the shore of WCL are relatively diverse, with *Cynodon dactylon* and *Carex sp.* covering some of the area, and the wild emergent aquatic plant species *Zizania latifolia* having a large distribution area.

Rhizosphere soil sampling

The rhizosphere soils of the lakeshore plants around lakes that exhibited three different types of fluctuations were investigated in the summer of 2016 (August, Summer), the autumn of 2016 (November, Autumn), the winter of 2017 (February, Winter) and the spring of 2017 (May, Spring). The main vegetation that grew in the soil samples were *Cynodon dactylon* in CHL, *Carex sp.* in PYL, and *Zizania latifolia* in WCL. The sections with limited artificial interference were selected in the three lakes, the five typical sample points were evenly distributed throughout this section, ranging from the lowest perennial average water level to the highest perennial average water level of the lake, which were called 1, 2, 3, 4 and 5 successively. The distance between two adjacent sample points remained equal. According to the water level fluctuations of the three lake types in the normal hydrological year 2015, water levels in these lakes are higher in winter and spring, and low in late spring to early summer, which is opposite to the natural condition (Zhang et al., 2018). Therefore, the elevations of the sample points in PYL were 14.75 m (PYL1), 15.56 m (PYL2), 16.38 m (PYL3), 17.19 m (PYL4) and 18.00 m (PYL5). The elevations of the five sample points in CHL were 8.15 m (CHL1), 8.61 m (CHL2), 9.07 m (CHL3), 9.52 m (CHL4) and 9.98 m (CHL5). The elevations of the sample points in WCL were 10.82 m (WCL1), 11.52 m (WCL2), 12.22 m (WCL3), 12.91 m (WCL4) and 13.61 m (WCL5).

The rhizosphere soil samples were randomly collected in triplicate in the three different lakes owing to the obvious lakeshore plant layer. The soil samples were collected always at the same site, the sampling sites of WCL, CHL and PYL were shown in *Figure 1*.

The soils within 0.5 cm from the root system were collected after excavating the roots and the aboveground parts of plants following the method described by Gollany et al. (1997), and the rhizosphere soil samples were divided into two parts.

One part was stored at -24 °C as fresh soil. The other part was dried and sieved through 2 mm mesh, and the soil physicochemical parameters, such as pH, moisture content (MC), soil organic matter (SOM), total nitrogen (TN) and total phosphorus (TP), were determined. The pH and MC were measured by the potentiometric method and the oven-drying method, respectively; SOM was measured by the $K_2Cr_2O_7$ titration method; the TN and TP contents were measured using the Kjeldahl method and molybdenum blue colorimetry, respectively (Lu, 2000).

Extraction and purification of organic acids in rhizosphere soils

A total of 5 g of fresh rhizosphere soil samples with the root chips, residues and others large particulate matter removed were placed in a 50 mL Erlenmeyer flask, and 25 mL 0.1% H_3PO_4 extracted solution was added. The soils and the extracted solution were mixed with a glass rod, the mixed soil solution was oscillated for 2 h; then, the mixture was transferred to a 50 mL centrifuge tube. The tube underwent centrifugation at 10000 r min^{-1} for 10 min; then, the supernatant was collected and passed through a 0.22 μm water phase filtration membrane.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72017214

The solutions containing organic acids were collected and passed through a cation exchange column (12 mm × 15 mm) filled with 5 g of Amberlite IR-120B resin (H^+ form, Alfa Co.). Afterward, these solutions were passed through an anion exchange column (12 mm × 15 mm) filled with 3 g of Dowex 1 × 8 resin (100 mesh to 200 mesh; OH^- form; Acros Co.). The solutions were evaporated under rotary conditions of 40 °C after steaming to nearly dry, and the residue was obtained in 1 mL water for a quick rhizosphere soil sample test.

Determination of the amounts of organic acids in rhizosphere soils

The amounts of organic acids, including oxalic acid (OA), citric acid (CA), malic acid (MA), tartaric acid (TA) and succinic acid (SA), in the rhizosphere soils of the three lakes were analyzed by Waters Acquity H-Class ultra-performance liquid chromatography coupled with a four element pump system, automatic injection system, ultraviolet detector system, solvent system and chromatography column system (Zhao et al., 2019). The standard samples of OA, CA, MA, TA and SA were obtained from Sigma-Aldrich-Fluka (ref. 02288, 27488, 75688, 251380, and S7501, respectively). The concrete analytical conditions were the following: chromatography column, BEH C18 column (2.1 mm i.d. × 500 mm, 1.7 μm); eluent solution, 10 mM KH_2PO_4 solution (adjust pH to 2.20±0.10 by 1 mol L^{-1} H_3PO_4 solution); flow rate, 0.30 mL min^{-1}; temperature of the chromatography column, 30 °C and injection volume, 1 μL. The eluent solution and analyte were filtered using a 0.22 μm membrane and then ultrasonically degassed before use.

Statistical analysis

All experiments were performed in triplicate with the same treatment independently replicated. Statistical analyses of data were carried out by one-way ANOVA, two-way ANOVA and bivariate correlations. Significance was assigned at the $p < 0.05$ level with Duncan's test. All analyses were conducted using SPSS 17.0 (SPSS Inc., Chicago, IL, USA).

Results

Soil physicochemical parameters

The pH values were significantly different among the three lakes in the same season; the difference in MC was not significant in winter but exhibited significant differences in the other three seasons; SOM, TN and TP were not significantly different, except for SOM and TN, which were higher in PYL than in WCL and CHL in spring (*Table 2*). MC was not significantly different in the four seasons in WCL, while the other soil parameters were different (*Table 2*). The pH in autumn and winter was lower than that in spring and summer, while MC, SOM, TN and TP were not significantly different in CHL and PYL (*Table 2*).

The total amount of organic acids in the rhizosphere soil of lakeshore plants in different seasons

The total amount of organic acids (ToA), including OA, CA, MA TA and SA, in the rhizosphere soil of the lakeshore plants in winter was lower than that in the other three seasons in the three lakes, which was higher in summer than in the other three seasons in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72017214

CHL and PYL and was highest in WCL (*Fig. 2*). The ToA in WCL was significantly higher than that in CHL and PYL during the same season (*Fig. 2*). The annual averages of the total amounts of organic acids in WCL, CHL and PYL were 2.783 mg kg^{-1}, 1.668 mg kg^{-1}, and 1.954 mg kg^{-1}, respectively.

The effect of water level fluctuations on the characteristics of the ToA in the rhizosphere soil in different seasons

The seasonal variations in organic acids in the rhizosphere soil were significant at the different water levels in the three lakes, as shown in *Fig. 3*. At the different water level fluctuations, the ToA was between 0. 607 mg kg^{-1} and 6.817 mg kg^{-1} in WCL, which was highest in summer, and lowest in winter, and the ToA at high water levels, such as at WCL3, WCL4, and WCL5, was higher than that at low water levels, such as WCL1 and WCL2 (*Fig. 3*). At the different water level fluctuations, the ToA was between 0.712 mg kg^{-1} and 3.798 mg kg^{-1} in CHL. The ToA had was not significantly different in the sites with low water level fluctuations, including CHL1 and CHL2, in the different seasons; however, the ToA values were higher at the sites with high water level fluctuations, including CHL4 and CHL5. The ToA was the maximum at CHL4, which was two-fold higher than that at CHL1 in the all seasons except winter (*Fig. 3*). The ToA in the sites with different water level fluctuations in PYL was between 0.410 mg kg^{-1} and 3.909 mg kg^{-1}. The seasonal variations in the amount of organic acids were the following: summer > autumn > spring > winter. The ToA at PYL4 was higher than that at the other sites.

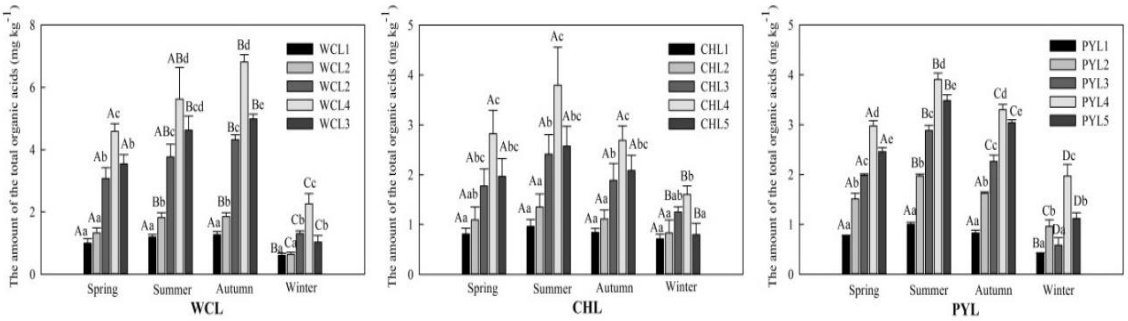

Figure 3. *The effect of water level fluctuations on the characteristics of the total amounts of organic acids in rhizosphere soil in different seasons in the three lakes. Note: Columns with bars indicate means ± SD (n= 3). The different capital letters indicate a significant difference in the four seasons under the same water level fluctuations in the same lakes at p<0.05. The different lowercase letters indicate a significant difference in the water level fluctuations in the same season in the same lakes at p<0.05. The proportions of the five organic acids in the rhizosphere in different seasons in the three lakes

The contributions of OA, CA, MA, TA and SA to the ToA in the three lakes differed in the different seasons. The proportions of the five organic acids varied with season in WCL, and the proportion of CA increased, which accounted for 40% in winter (*Fig. 4*). The dominant organic acids were CA and MA in CHL, and the proportion of CA and MA was over 60% in all four seasons (*Fig. 4*). CA, MA and SA were the dominant organic acids in the rhizosphere soils of PYL, accounting for more than 75% of the ToA, especially more than 90% in winter (*Fig. 4*).

The interaction of seasonal variation and water level fluctuations with the characteristics of organic acids in rhizosphere soil

The effect of the interaction of the seasonal variation and water level fluctuations on the characteristics of the amounts of five organic acids and the ToA in rhizosphere soil of lakeshore plants in three lakes was significantly different based on the two-way ANOVA. The mean square value was between 0.002 and 4.839, and the F value was between 5.602 and 123.355 in the three lakes (p<0.001) (*Table 3*). The mean square value or F value of ToA in WCL was higher than that in PYL and CHL, which indicated the effect of interaction of seasonal variations and water level fluctuations on WCL was stronger than that on other two lakes (*Table 3*).

The correlations between the amounts of organic acids and environmental factors in the three lakes

Table 4 shows the correlations between the amounts of organic acids and physicochemical parameters of rhizosphere soils such as pH, MC, SOM, TN and TP in the three lakes. The amount of one organic acid exhibited a linear correlation with the other organic acids and the ToA. The Pearson correlation coefficient (R) ranged from 0.502 to 0.963 in the rhizosphere soils of lakeshore plants in the three lakes (p <0.01). The soil parameters had different influences on the amount of organic acids in the rhizosphere soils of lakeshore plants in the three different lakes. There were no significant differences between the amounts of five organic acids or the ToA and MC, SOM, TN and TP, except for the significant difference between TN and OA (p<0.05). There were highly negative linear correlations between the individual organic acids or the ToA and pH (p<0.01), except for the nonsignificant difference between TA and pH (p>0.05) in PYL. In CHL, the soil physicochemical parameters included pH, MC and SOM, and the individual organic acids or the ToA exhibited significant differences. The differences between the individual organic acids or the ToA and TN were highly significant (p<0.01), except for the nonsignificant difference between TA or SA and TN (p>0.05). Meanwhile, there was no significant difference between the individual organic acids or the ToA and TP (p>0.05), except for the highly significant differences between OA and TP (p<0.01). In WCL, the soil physicochemical parameters, including MC, SOM, TN and TP, exhibited a negative linear correlation with the individual organic acids or the ToA (p<0.01), while pH had an influence on the amounts of MA, TA and SA.

Discussion

The influence of lake types on the amount of organic acids

According to the different water level fluctuation patterns, the lakes in this study area could be divided into three types (Zhang, 2013). WCL is a quasi-natural fluctuating lake, which includes most lakes and some barrier lakes, and the water level fluctuations are similar to those of the Yangtze River. CHL is a reservoir-like fluctuating lake, which is mainly obstructed by other lakes and maintains a high water level all year round. The water level decreases due to irrigation or flood storage from April to June. PYL is an intermittent fluctuating lake, which is similar to floodplains and maintains stable low water levels most of the time, except in the high water level period at the Yangtze River trunk stream.

The composition and content of organic acids in the rhizosphere soil of the different lakes were different, and the annual average values of the ToA varied greatly. The annual average ToA in WCL was higher than that in PYL and CHL, which indicated that the carbon storage capacity in the rhizosphere soil of the quasi-natural lake wetland was higher than that in the intermittent lake and reservoir-like lake. The amount of organic acids in rhizosphere soils responded to the carbon storage and transformation capacities (Jones et al., 2009; Kuzyakov and Razavi, 2019). Due to the limited variations in the water level fluctuations and limited anthropogenic impacts, the carbon storage capacity in the rhizosphere soils of the WCL was higher than that in the CHL and PYL. CHL, as a reservoir-like lake, has a large amount of runoff, and the water that is stored in the lake is not enough to meet the demands because of the large amount of industrial and agricultural water consumption in the region, leading to the loss of carbon in rhizosphere soils. Hence, the annual average organic acid values were low in this lake. Furthermore, the dominant plant species and their distribution in the three lakes influenced the amount of organic acid in the rhizosphere. *Zizania latifolia*, as the dominant species in WCL, had the maximum biomass; *Carex sp*., as the dominant species in PYL had intermediate biomass, and the biomass of *Cynodon dactylon*, as the dominant species in CHL, was minimal (Zhang et al., 2018). The photosynthetically fixed carbon increased as the biomasses of these annual or biennial herbaceous plants increased. The carbon transformation increased from the aboveground parts (leaf, stem) to the belowground parts (root), resulting in an increase in root-exuded organic acids in the rhizosphere soils, which explained the higher ToA in the rhizosphere of quasi-natural lakes such as WCL than in the other two types of lakes.

The variational characteristics of the amount of organic acids under water level fluctuations in four seasons

The effects of seasonal variations on the amount of organic acids in the rhizosphere soil were evident, and the effects were irrelevant of the lake type. The amounts of organic acids were higher in summer and autumn than in spring and winter in the three lakes, resulting from the rapid growth and strong photosynthesis of wetland plants in summer and autumn, when plant roots exuded much more organic acids to rhizosphere soils. Due to the weak photosynthesis and low water level, the organic acid storage in the rhizosphere soil was low in winter (Wu and Zhao, 2013).

The amounts of organic acids at the sites with different water level fluctuations were different, and these were not related to the lake type. The amounts of ToA were higher at the sites with high water level fluctuations than that with low water level fluctuations.

DOI: http://dx.doi.org/10.15666/aeer/1805_72017214

These differences not only were relevant to the above-mentioned factors, such as photosynthesis and biomass, but also may be related to other factors, such as the soil sample location and root morphology. Previous studies have shown that the root morphological parameters such as root length, root density, root volume, and root surface area at the sites with low water fluctuations were lower than those at sites with moderate and high water fluctuation levels (Zhang et al., 2018). These findings were consistent with the variation characteristics of organic acids in rhizosphere soils in this study. The root morphological parameters were positively correlated with the amount of organic acids in the rhizosphere soils of lakeshore plants. When the root morphological parameters were high, much more root organic acids were exuded into the rhizosphere soils.

The differences in dominant organic acids

The dominant types of organic acid were different in the three lakes. These were CA, MA and SA in PYL and CA and MA in CHL. In WCL, the distributions of the five organic acid contents were average, and only the CA content was higher in the high water level area. CA is the dominant organic acid among the three lakes in our study, which is the main organic acid in the Krebs cycle, not only accumulates in plant organs and tissue, but also is released into the rhizosphere via root exudates (Sweetlove et al., 2010; Araújo et al., 2012; Yu et al., 2017).

The correlation between the amount of organic acids and the soil physicochemical parameters

There were significant positive correlations among the amounts of organic acids in the three lakes, which indicated that a single organic acid was not exuded into soils, while multiple organic acids exuded simultaneously into the rhizosphere soil through the plasma membrane via diffusion and anion channels (Ryan et al., 2001; Adeleke et al., 2017; Silva and Lambers, 2020). There was a negative correlation between the amount of organic acids and pH, which indicated that an increase in the amount of organic acids led to an increase in H^+ release, decreasing the pH; however, this condition did not change the adsorption sites. MC and SOM had the same influences on the amount of organic acids, which included no influence on the amount of organic acids in PYL, a positive influence in CHL, and a negative influence in CHL because of the different heights of the water level fluctuations. TN and TP, as indicators of pollution sources, had limited impacts on the release of organic acids in PYL and CHL because the two lakes were greatly affected by human activities and exhibited low release of organic acids. TN and TP exhibited significant negative correlations with the amount of organic acids in the rhizosphere soil of WCL, which indicated that an increase in the exogenous input of nitrogen and phosphorus decreased the amount of organic acids in the rhizosphere soil. Thus, WCL, as a quasi-natural lake, was greatly influenced by human activities, and this lake may be converted to another type of lake and lose the function of the natural wetlands.

Conclusion

The organic acids of rhizosphere soil in different types of lakes were influenced by many factors, such as season variations, water levels, vegetations and the soil

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72017214

environment. The annual average amount of the total organic acids in the rhizosphere soil in the quasi-natural WCL was higher than that in the intermittent PYL and reservoir-like CHL, which was related to the vegetation density, photosynthesis and root morphological parameters of WCL. The seasonal differences in the amounts of organic acids were independent of lake type, and the amount of organic acids in the three lakes in winter was lower than that in the other three seasons. The dominant organic acids were different, and CA was the dominant organic acid in the three lakes. The CA accumulation in plant tissue can promote the release into rhizosphere soil. There were positive correlations among the amounts of organic acids in the three lakes. pH exhibited a negative correlation with the amount of organic acids. MC and SOM had no effect on the amount of organic acids in PYL, a positive effect in CHL and a negative effect in WCL. TN and TP had a greater impact on the amount of organic acids in WCL than in PYL and CHL, which would lead to changes to WCL as a result of anthropogenic influence.

In future studies, it will be necessary to consider the following two points: first, quantitatively analyze the organic acids characteristics in plant-rhizosphere soil- aquatic environment, the carbon distribution and transfer of organic acids should be focused via stable carbon isotope tracer technology. Second, in order to better understand the function of organic acid in plants especially root-exuded organic acids, the heavy metal concentration, nutrition such as phosphorus and nitrogen, and microbial activities should be investigated in rhizosphere soil-aquatic environment, and discuss the influence of anthropogenic intake pollution source.

Acknowledgements. The authors are grateful to all the people who provided assistance in rhizosphere soil sampling and the measurement of the organic acids. The study was supported by the National Natural Science Foundation of China (Grant No. 41501028), the Key Science and Technology Program of Anhui Province (Grant No. 17030701057), the Natural Science Foundation of Anhui Province (Grant No. 1908085QD149), and the Key Natural Science Research Projects of Universities in Anhui Province (Grant No. KJ2018A0374).

Abstract. At the regional scale, many studies have been devoted to the construction of biomass models to improve the accuracy of regional biomass estimation, while only a few studies were carried out to investigate spatial influence. Therefore, the current research examined the spatial autocorrelations as well as variations between forest biomass and forest variables using 419 forest biomass plots sampled in the Guizhou Province in the year 2010. Besides, 4 global models, including the ordinary least squares model (OLS), linear mixed model (LMM), spatial lag model (SLM), spatial error models (SEM), together with geographically weighted regression model (GWR, the local model), were fitted to the associations of forest biomass with basal area, height and age of the stand. As suggested by our findings, distinct spatial autocorrelations as well as variations exist between forest biomass and these variables. OLS is not appropriate for modeling. SLM and SEM efficiently accounted for the spatial autocorrelations within model residual; however, they were unable to manage spatial heterogeneities. However, LMM and GWR, which had combined spatial variations as well as dependence during the modeling process, performed well in data fitting and response variable predicting. Of them, GWR reduced spatial heterogeneity to a greater extent than LMM.
Keywords: *linear mixed model, spatial lag model, spatial error model, geographically weighted regression*

Introduction

It is of crucial importance to estimate the forest biomass to understand source dynamics and atmospheric carbon sinks (Brown and Lugo, 1984). To be specific, forest biomass, particularly that is located in the subtropics, accounts for a leading global carbon emission source. In order to evaluate the ecological quality and the effectiveness of forestry construction and to provide decision-making for promoting rational use of energy and forest management, the large-scale study of forest biomass and its spatial distribution is necessary (Rodríguez-Veiga et al., 2016).

Forest biomass has been frequently predicted based on the timber volume data extracted via the forest inventories, for which, field plots were used for statistical sample collection to directly measure the forest parameters (such as breast height diameter, height, as well as tree species). Forest biomass estimation methods are continuously improving with the advancement of research. Thereafter, timber volume is converted into the above-ground biomass through the application of the biomass expansion factor (BEF) where timber volume information is obtained (Brown and Lugo, 1984). Fang et al. (2001) improved the BEF method for forest biomass estimation overcoming the shortcoming of static conversion parameters of the BEF method improving the biomass-volume model and providing a more accurate calculation of the parameters for various dominant tree species. Remote sensing methods, often used to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72157232

estimate large-scale forest parameters (Patenaude et al., 2005; Ploton et al., 2017), can hardly accurately estimate spatial distributions due to the limited sensitivity of the selected satellite sensors to forest parameters (Benson et al., 2016; Ghosh et al., 2018). Different technical means and auxiliary data were employed to improve the estimation precision. Remote sensing methods also use process models, which have a perfect theoretical foundation and clear physical meaning; however, they require more complex data sources as input parameters (Chiesi et al., 2011).

As we all know, forest biomass information is usually extracted across the huge geographic areas, which leads to distinct differences of topographic characteristic, species abundance and compositions, as well as vegetation coverage; as a result, the carbon storage and forest biomass among the different locations are also different (Liu et al., 2014). The neighbor locations are similar to each other, but the remote locations are not similar. This can be explained by two aspects of spatial effects, spatial heterogeneity (non-stationarity of space), together with spatial autocorrelation (namely, spatial dependence) (Anselin and Griffith, 1988). Of them, spatial heterogeneity represents the instability of structure that manifests as the systemically altering model variables or the diverse response functions. Meanwhile, spatial autocorrelations are those correlations of the random variable value in a region with identical variable values in adjacent regions. Ignoring spatial heterogeneity and spatial autocorrelation lead to false significance test results, inferior predictions (Anselin and Griffith, 1988), as well as damaging influence on modeling and data analytic results (Páez and Scott, 2005). In recent years, the indexes of global and local spatial autocorrelations, such as Geary's C, Moran's I, Getis'G*, and Getis'G, are extensively utilized for measuring spatial autocorrelation degrees across different regions (Boots, 2002; Páez and Scott, 2005; Fu et al., 2014). Several statistical regression approaches have been adopted in incorporating the spatial autocorrelations to model the associations across variables, including the spatial error model (Lichstein et al., 2002), spatial lag model (Anselin, 1993), spatial Durbin model (Overmars et al., 2003), spatial filter model (Borcard and Legendre, 2002), and linear mixed model (Zhang et al., 2009), and others (Dormann et al., 2010). Spatial heterogeneity represents the function of spatial scales that are referred to as the measuring units. A variety of regression approaches are developed for modeling the local alterations in the complicated associations of spatial random variables, including random coefficient model (Fotheringham and Brunsdon, 1999), spatial expansion approach (Anselin, 1992), multilevel modeling approach (Duncan, 1997; Jones1997), and spatial adaptive filtering approach (Gorr and Olligschlaeger, 1994). Recently, the geographically weighted regression (GWR) is increasingly used for exploring spatial heterogeneities (Fotheringham et al., 2002; Zhang et al., 2004; Liu et al., 2014).

The GWR is the local regression model that can effectively solve spatial nonstationarity. The parameters of each sample are estimated by using the locally weighted least square method and the spatial location is taken into account in the estimation process. In other words, GWR offers diverse regression modeling parameters of a localized model in every region to incorporate the locoregional spatial variation into the modeling processes. Therefore, it is becoming an important method to detect the non-stationarity of space and has been showing better performance than ordinary models when applied to many fields such as social economics (Öcal and Yildirim, 2010; Wang et al., 2019), geography (Erdoğan, 2010), soil (Song et al., 2019; Li et al., 2020), environment (Qin et al., 2019) and forestry (Propastin, 2012; Lin et al., 2018; Monjarás-Vega et al., 2020). Consequently, in the forestry fields, the influences of vegetation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72157232

competition, micro-environment, and growth potential; besides, effects of managing activities on carbon storage and forest biomass are assessed, analyzed, simulated and visualized (Liu et al., 2014; Zhen et al., 2013), while the study about spatial influence in modeling forest parameters is still rare, especially in regional scale (Liu et al., 2014).

The current research analyzed forest biomass for its spatial distribution in the Guizhou Province of southwest China. Typically, this study aimed to achieve the following objectives: (1) to use five models, including the ordinary least squares (OLS) model, the spatial lag model (SLM), the spatial error model (SEM), the linear mixed model (LMM), together with the geographically weighted regression model (GWR) fitting forest biomass information; (2) to analyze and compare these five models for their performances; and (3) to evaluate model residues for spatial autocorrelation as well as spatial heterogeneity.

Materials and methods

Study area

Guizhou Province (103°36′E to 109°35′E and 24°37′N to 29°13′N) is located in southwest China (*Fig. 1*) with a total land area of 176128 km^2 and 57% forest coverage rate. 92.5% of the whole province is mountainous and hilly, with an average altitude of 1100 m. This area is of subtropical monsoon climate. Affected by mountainous terrain, the weather conditions are variable. The average annual temperature is 10~18 ℃, the annual precipitation is 1,000~1,500 mm, the relative humidity is above 70%, the annual sunshine hours are 1300 h, and the frost-free period is about 270 d (Editorial Committee of Guizhou Forest, 1991). Affected by climate, soil and mountainous terrain, the vegetation types in the province are diverse. The central and northern parts of the country are dominated by mid-subtropical evergreen broad-leaved forests, while the southern part is a south-subtropical evergreen broad-leaved forest. The middle-eastern part is humid forest and the western part is semi-humid forest. Cold and warm sub alpine coniferous forests are distributed in high altitude areas, while intrazonal karst evergreen deciduous broad-leaved mixed forest and secondary deciduous broad-leaved forest are distributed in limestone and dolomite mountains (Editorial Committee of Guizhou Forest, 1991).

According to the forest management plan of Guizhou province (2016-2050) and our study aims, the study area was divided into six ecological geographical sub-regions. The details are presented in *Table 1* and *Figure 1*.

Table 1. *The six ecological geographical sub-regions of Guizhou province*

Code of sub-regions	Name of sub-regions
A	The low-middle mountain sub-region of *Pinus massoniana*, bamboo and broad-leaved mixed forest for soil and water conservation
B	The low-middle mountain sub-region of *Pinus massoniana* and broad-leaved forest for dual-purpose of precious large-diameter timber
C	The high-middle mountain sub-region of *Pinus yunnanensis, Pinus armandii, Cryptomeria fortune* and broad-leaved mixed forest for soil and water conservation
D	The middle mountain sub-region of *Pinus massoniana*, broad-leaved mixed forest for special purpose
E	The low mountain sub-region of *Cryptomeria fortune* forest for fast-growing and high-yielding timber
F	The middle mountain sub-region of *Cryptomeria fortune, Pinus yunnanensis* and broad-leaved forest for dual-purpose of precious large-diameter timber

Data

For the current research, the utilized stand as well as tree data were extracted based on 6 locations in the year 2010 from 419 permanent sample plots, including 283 Arbor plots (666.67 m^2 per plot), 51 bamboo plots (100 m^2 per plot), and 85 shrub plots (16 m^2 per plot), observed via the Chinese National Forest Inventory (CNFI), together with the Guizhou Provincial Forestry Department. The topographical descriptors and geographical locations were also collected for every plot. In addition, the stand as well as tree parameters were determined and analyzed for describing the slope (°), elevation (m), numbers of tree species and trees of every species, as well as diameter at breast height in cm (DBH, > 2 cm for bamboo and shrub plots, > 5 cm for Arbor plots), and living tree height in m (HT). In addition, additional stands as well as tree variables were subsequently calculated based on unit hectare, which included the tree number per hectare (TPH) (trees/hm^2), the living tree volume per hectare (m^3/hm^2), the mean living tree age (year), the basal area of trees per hectare (BA, the accumulated area in cross-section determined based on the breast height (1.3 m) for each tree within one stand) (m^3/hm^2), the average height of living trees (H), and vegetation coverage (%). The 1-year meteorological data were extracted based on 77 weather stations Guizhou Province in the year 2010 and Kriging interpolation was conducted with the data for obtaining the precipitation and temperature information for each sample plot. In each arbor plot, the biomass models based on the Guizhou province universal biomass equation were used (Zeng et al., 2011). The tree species, without a clear corresponding model, were referred to as the approximate dominant tree species (group) parameters. In each Bamboo plot, the biomass models were calculated according to Tian (2011) and that of the shrub plot was calculated according to Liu et al. (2009).

Theoretical background

Ordinary least squares (OLS)

Assume there are diverse *n* observations regarding the response variable y, together with *p* predictor variables x. The association of y with x is regressed based on OLS (*Eq. 1*):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72157232

$$y = x\beta + \varepsilon \quad \text{(Eq.1)}$$

where, β stands for the unclear fixed-effects parameter vector, whereas ε indicates the model error term following a normal distribution N (0, σ^2). Thus, the OLS estimator is acquired through (*Eq. 2;* Littell et al., 2006)

$$\hat{\beta} = (X'X)^{-1}X'Y \quad \text{(Eq.2)}$$

It is supposed that, the association given based on *Equation 1* is constant or universal within the geographical area.

Linear mixed model (LMM)

The LMM represents a special case of generalized linear models, which is presented in the form of *Equation 3:*

$$y = X\beta + Z\gamma + \varepsilon \quad \text{(Eq.3)}$$

in the formula, y stands for the response variable vector, x represents the fixed-effects predictor matrix, β indicates the unclear fixed-effects model coefficient vector, whereas Z suggests the given random-effects design matrix, γ represents the unclear random-effects parameter vector, while ε stands for a random error term. The following assumptions are given: (1) E (γ) = 0 and Var (γ) = G represents the random-effects covariance matrix; (2) E (ε) = 0 and Var (ε) = R suggests the model residual covariance matrix; (3) Cov (γ, ε) = 0; meanwhile, (4) γ and ε show normal distribution. Besides, variance y is calculated based on V = ZGZ′ + R, which is predicted through establishing the design matrix Z of random-effects and indicating the G and R covariance structures. Generally speaking, OLS has not been deemed as the optimal parameter prediction approach, whereas the maximum likelihood approaches are frequently adopted for obtaining γ and β (Littell et al., 2006).

Spatial lag model (SLM)

The SLM represents the formal spatial diffusion procedure, which obtains great spatial data dependences (Anselin, 1993, 2001). Generally, SLM is appropriate for assessing the spatial dependence presence and strength. To be specific, SLM is completed through incorporating one spatial lag term for dependent variable y to that OLS model (*Eq. 1*) mentioned above, as shown below (*Eq. 4*):

$$y = X\beta + \rho Wy + \varepsilon = (1 - \rho W)^{-1}X\beta + (1 - \rho W)^{-1}\varepsilon \quad \text{(Eq.4)}$$

where *W* represents the row-sum weight matrix after standardization processing, *W*y stands for the response variable that is lagged spatially, ρ indicates the spatial autocorrelation variable with normal distribution N (0, $\sigma^2 I$), and *I* denotes the identity matrix. For response y, its value in every region depends on the x in a specific region and in adjacent regions based on spatial multiplier $(1-\rho W)^{-1}$. It should be noted that, according to *Equation 1,* ε becomes correlated with predictor variable (namely, the spatially lagged *W*y). As OLS is not an appropriate parameter prediction method any

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72157232

more, since it will produce ineffective and biased predictions, while the maximum likelihood approach is adopted.

Spatial error model (SEM)

It is assumed in SEM, that spatial autoregressive procedure takes place within error term only, rather than within response or predictor variables (Anselin, 1993, 2001). This is because that, the variables with spatial correlation or spatial region boundaries that do not coincide with the practical behavior units are eliminated (Graaff et al., 2001). SEM is recognized to be the special regression using one non-spherical error term, and this approach is suitable to examine the possible spatial autocorrelation effect induced by using the spatial data, regardless of the model spatiality. SEM combines OLS regression model with the spatial autoregression model within an error term ε, as shown below (*Eq. 5*):

$$y = X\beta + \varepsilon = X\beta + \lambda W\varepsilon + \xi = X\beta + (1 - \lambda W)^{-1}\xi \quad \text{(Eq.5)}$$

In the formula, W stands for the row-sum weight matrix after standardization, $W\varepsilon$ represents the error term with spatial lag, λ indicates the spatial autocorrelation variable, whereas ξ suggests the ordered error term with normal distribution N (0, $\sigma^2 I$), and I denotes the identity matrix. For y, its value in every region is subjected to influences of error in every region based on spatial multiplier $(1-\lambda W)^{-1}$. Nonetheless, different from β, λ has been identified to be the nuisance variable, and this factor itself is not the focus, yet it is of necessity for correcting spatial dependencies. For y, its average value is independent from error spatial dependence, and that maximum likelihood approach has been used to estimate the parameters.

Geographically weighted regression (GWR)

The GWR is extended based on the conventional regression that allows variations, in this way, the regression coefficient is location-specific, and does not represent a universal estimate (Fotheringham and Brunsdon, 1999). The possible GWR model is shown below (*Eq. 6*):

$$y = \beta_0(u_i, v_i) + \sum_{k=1}^{p} \beta_k(u_i, v_i) X_k + \varepsilon \quad \text{(Eq.6)}$$

In the formula, y stands for a response variable, whereas X_k represents diverse p predictor variables (k = 1, 2, …, p), and β_0 (ui, vi), β_1 (ui, vi), …, β_p (ui, vi) suggests those regression coefficients for the kth predictor variable and ith location. εi stands for a random error term with normal distribution N (0,$\sigma^2 I$), and I denotes the identity matrix. Generally, GWR aims to estimate the above-mentioned coefficients for every independent variable x in every geographical region i using neighbors within a given bandwidth and weighted least-squares regression. Those GWR model parameters in every region i in the matrix are predicted according to the following formula (*Eq. 7*):

$$\hat{\beta} = (X'W_iX)^{-1}X'W_iY \quad \text{(Eq.7)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72157232

where W_i stands for the (m × m) diagonal matrix of spatial weights; X indicates the [m × (n + 1)] matrix of independent parameters, in which n is the explanatory variable number; whereas Y represents the (m × 1) matrix of dependent variables.

The weighted function is used to determine the weighted approach, and it is adaptive or fixed (Mcmillen, 2004). With regard to the size of adaptive kernel, every point weight is determined based on the Gaussian function (*Eq. 8*):

$$W_{ij} = \exp(-\frac{1}{2}(\frac{d_{ij}}{r})^2) \quad \text{(Eq.8)}$$

In the formula, d_{ij} stands for the Euclidean distance of an estimated site i compared with a sampling site j, r stands for the parameter of bandwidth. Notably, the selection of bandwidth within the as-mentioned GWR model represents a critical factor that affects the results of regression analysis. At present, both the corrected Akaike information criterion (AICc) and cross-validation approaches have been extensively utilized for determining bandwidth.

Model specification

The current research aimed was to examine forest biomass for its spatial distributions as well as patterns using the regression models. In every plot, forest biomass was used as the dependent response parameter (ton/hm^2). The stand as well as tree parameter number was analyzed and screened through gradual regression to be model predictors, including the tree basal area per hectare (BA), stand age (Year) and stand height (m). *Table 2* shows the baseline variable data.

Table 2. *Baseline variable data adopted in the current research*

Variable	Plot number	Average	Maximum	Minimum	Std
Biomass (t/hm^2)	419	51.25	261.57	0.01	47.25
Basal area (BA, m^2/hm^2)	419	161962.70	772947.11	477.59	126107.37
Age (Year)	419	20.83	98.00	0.00	15.06
Height (m)	419	8.79	25.00	0.24	5.44

The multiple linear model shown below was adopted for regressing the forest biomass relative to 3 estimators (Basal area (BA)), stand age and stand height) using OLS, SLM, SEM, LMM as well as GWR models:

$$Biomass = \beta_0 + \beta_1 \cdot BA + \beta_2 \cdot Age + \beta_3 \cdot Height + \varepsilon \quad \text{(Eq.9)}$$

where β_0, β_1, β_2, and β_3 stand for the regression coefficients predicted based on statistics, whereas ε is model residual that represents the heterogeneity of observed forest biomass compared with the predicted one. OLS model was adopted to be the model comparison benchmark in the current research. In LMM model, seven regions were used to be fixed effects, and covariance matrix R was used to model those spatial autocorrelations across various sample plots in those seven regions. For both SLM and SEM models, distance bandwidths performed better than k-nearest neighbors as spatial weights. For the GWR model, the best bandwidth size was 30 km determined according to the golden section

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72157232

search (automated) and adaptive bisque kernel function, because it has a higher coefficient of determination (R^2) and lower residuals than other methods. Meanwhile, for those five models, model residuals were determined based on global Moran's Z- and I-values, with the bandwidths range of 5-45 km at an interval of 5 km, which described the pooled spatial autocorrelations within those model residuals at a variety of spatial scales. Specifically, local Moran's I-value, an index for local spatial autocorrelation (LISA), was calculated according to the best bandwidth (30 km) in every model residual for OLS, LMM, as well as GWR (Boots, 2002). Meanwhile, Z-value is used as the standard deviation (SD). At a significant level of $\alpha = 0.05$, $Z > 1.96$ and $Z < -1.96$ indicate that the model residual has significant spatial autocorrelation, and $-1.96 < Z < 1.96$ indicates otherwise. Intra-block spatial variances, illustrating the local spatial variability, were computed for the above-mentioned five model residuals, and the block size was 5-30 km at an interval of 5 km (Zhang et al., 2009). It is assessed based on the fact that 1/2 GWR coefficients should fall in the range of Q1 (25% quartile) to Q3 (75% quartile), whereas approximately 68% normally distributed LMM or OLS coefficients must fall in the range of 1 SD. The studied association might be not fixed spatially when inter-quartile range was > 1 SD of an equal global variable for the GWR local coefficients (Fotheringham et al., 2002; Zhang et al., 2004).

In this research, we aimed to examine model errors for their spatial heterogeneity and autocorrelation using the above 5 regression methods to fit the associations of biomass with relevant variables, but not to develop a predictive regional forest biomass model. Then, Akaike's Information Criterion (AIC), R^2, and mean squared error (MSE) summation were adopted to evaluate the pooled model fitting effect. Moreover, the LMM and OLS models were fitted using SAS 9.3 (SAS Institute Inc., 2011). In addition, SLM and SEM were fitted using GeoDa software (Anselin et al., 2006; GeoDa Center for Geospatial Analysis and Computing, 2009), while GWR 4.0 software (Nakaya et al., 2009; Department of Geography, Ritsumeikan University, Kyoto, Japan) was used to fit GWR model.

Results

Model fitting

The model fitting data of those five regression models adopted in this study are displayed in *Table 3*. As observed, OLS model had good data fitting effect (R^2 was 0.91) when not considering the independence assumption violation. With regard to SLM model, it adopted those spatially lagged dependent variables to be the predicting variables, so as to calculate spatial autocorrelation; meanwhile, SEM model managed spatial autocorrelation within a model error term (residuals). Besides, SLM and SEM performed better in data fitting (larger R^2, smaller MSE, smaller AIC, and lower global Moran's I (Z)) than the OLS models. For SME model, those tested values [Lagrange multiplier (LM) (error), as well as robust LM (error)] were relatively high relative to those for SLM model, indicating that the SEM model was better (*Table 4*).

According to *Table 3*, LMM performed well in data fitting (higher R^2, lower MSE, lower AIC, and lower global Moran's I (Z)) than OLS, SLM, and SEM. However, the best fit was observed for the GWR model that had greater ^{R2}, smaller MSE, lower AIC, and lower global Moran's I (Z) and SH%. As suggested by Z-values, for SLM and OLS models, their model residuals displayed distinct spatial autocorrelations ($Z > 1.96$, $\alpha = 0.05$). Nonetheless, for SEM, LMM and GWR models, their model residuals

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72157232

displayed no distinct autocorrelations ($-1.96 < Z < 1.96$, at $\alpha = 0.05$) indicating a reduction in the spatial autocorrelation.

Table 5 lists the model coefficient estimates, standard errors (SE), as well as p-values for three predicting factors. Each model coefficient was deemed to be of statistical significance upon $\alpha = 0.05$ in all the five models. For local models, their means for 2 regression coefficients were similar to those for global counterparts (*Table 5*). In addition, the inter-quartile range for GWR model, local intercepts, BA coefficients, age coefficients and height coefficients did not fall within the scope of ± 1 SD of those other four models, indicating the non-stationary and/or different association of forest biomass with those 5 predicting factors. However, the GWR model generated the geographically different model coefficients (a model coefficient set was generated in every region). *Figure 2* illustrates the spatial variations for GWR model coefficients, which shows that the association of forest biomass with those three predicting factors are different at different study locations. Generally speaking, local intercepts were negative over the study area, Age coefficients were positive across our study locations, whereas age and height coefficients were either positive or negative based on different regions. Local intercepts were smaller within the eastern study locations while larger across the northern and southern study locations. BA coefficient was opposite to that of local intercepts, larger in the east, but smaller in north and west. The values of age coefficients were smaller in west and south, and larger in north and east, while age coefficients were smaller in north and south, and larger in the central region. As demonstrated from *Figure 2*, those magnitudes and signs for such regression coefficients depended on the geographical location, suggesting the region-specific influences of those three tree predictors on the forest biomass. The coefficient shows a positive value indicating a positive impact on forest aboveground biomass, otherwise it is a negative contribution. The trend between coefficients distribution was similar indicating their impacts on estimating forest aboveground biomass have regional similarity, and vice versa.

Spatial autocorrelation and heterogeneity in model residuals

Compared with OLS model, the rest four models generated markedly lower global Moran's *I*- values (*Table 5*). Generally, GWR model generated negative values, while SLM, LMM and SEM generated positive values. *Figure 3* shows spatial correlation diagram for model residuals of those five models, with the lag distance ranging from 5 to 45 km. For OLS model, its residuals displayed great spatial autocorrelation compared with those for other models at every tested lag distance. For SLM model, its residuals behaved similar to that of the OLS model but had smaller values across the lag distances (*Fig. 3*). The LMM and SEM models generated similar Moran's *I* values (<0.05) among various lag distances. For GWR model, its model residual showed no significant spatial autocorrelation (Z-value < 1.96) across the range of lag distances and approached zero especially at larger spatial scales (15–45 km).

Figure 3 also shows the intra-block within model residuals representing mean local spatial variation of a known block size. As observed, OLS, SLM, as well as SEM models had remarkably greater and relatively the same intra-block sizes. The GWR had the smallest intra-block local spatial variance among the various block sizes, and then LMM model ranked the second place. Nonetheless, the different intra-block variability across those five models were low at the block size interval of 5 km. It became greater and approached one stable value with the increase in block size.

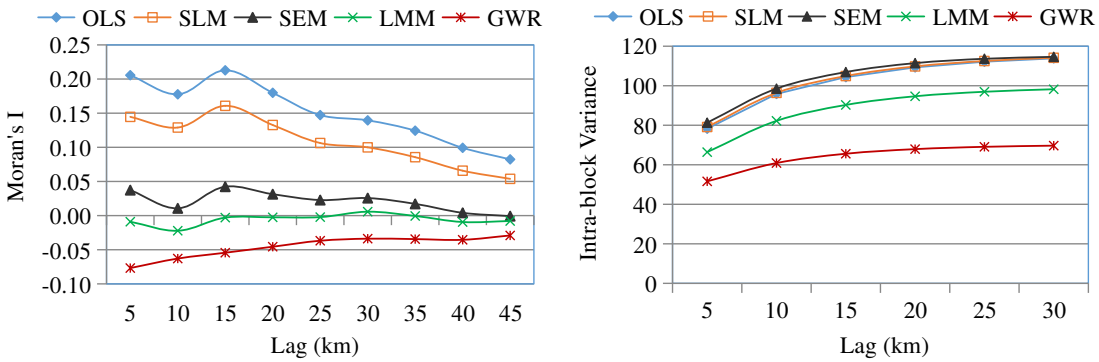

Figure 3. *Correlogram and intrablock variance of the five model residuals*

To illustrate the spatial details of residual autocorrelations, distributions of the Local Moran's *I* at 30 km spatial scales were computed for residuals from each of the five models (*Fig. 4*). It was observed that the local Moran's *I* values of OLS model residual were greater, which were positive (black circles) among the study region, which indicated that OLS model under-predicted or over-predicted the clusters (hotspots). SLM had similar spatial patterns for those 3 plots, and the local Moran's *I* values were greater and more positive (black dots), which indicated that the negative or positive model residuals were clustered. SEM produced few hot spots compared with those of SLM and OLS models. In contrast, the LMM and GWR models produced lower values,

Discussion

Model variables and coefficients

In our study, three variables, basal area, stand age, stand height were selected to estimate forest biomass. They all had statistically significant effects on the amount and distribution of forest biomass. In both global and local models, the three variables were the most important stand variables for our study area. The model coefficients of the three variables were all positive (*Table 4*), indicating that larger basal area, stand age and stand height would sequester more biomass in the forests, which is consistent with most studies (Mani and Parthasarthy, 2007; Cannell, 1984; Fang, 2001).

Other factors, including the temperature and precipitation data, were also considered as variables, but their influence was not significant. Our study also showed that the relationship between basal area and forest biomass was better than the relationship between DBH (diameter at breast height) and forest biomass. That is basal area explained 85% of the model, age explained 3%, height explained 3% (data not shown). Brown (2002) found that DBH alone explained more than 95% of the variation in above ground carbon content in tropic forests. Liu et al. (2014) also selected DBH as the main variable when estimating forest carbon stock of north forests in Heilongjiang province. However, Basal area has been used more frequently as a surrogate for biomass and carbon in tropical forests (Mani and Parthasarthy, 2007; Sagar and Singh, 2006), and often has been found to be the best predictor of biomass in combination with the mean tree height at the stand level (Cannell, 1984; Masera et al., 1997). Fang (2001) improved BEF for forest biomass estimation, which using only a simple linear relationship between biomass and volume when taking into account the influence of forest age, because other factors, site conditions, climate factors, etc., are already included in the volume. Basal area, stand age, stand height used in our study is the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72157232

explanation of this information including density, forest age, and site conditions. In many studies, shrubbery and bamboo plots often not be included or be estimated using other methods instead of BEF when forest biomass is estimated (Guo et al., 2013). Owing to the investigation standards of shrubbery and bamboo plots are different from those of arbor forests, for their starting DBH usually lower. And forest types and tree species in Guizhou province are diverse. At present, the volume equation of over 30 tree species including *Pinus massoniana*, *Cunninghamia lanceolata*, *Pinus yunnanensis* and *Pinus armandii* and so on have been established, while there is no corresponding volume equation for other tree species whose volume equation have not been established. And the volume equation also varies with the region. To avoid the impact of volume calculation errors on biomass modeling, this study established the relationship between three variables, namely basal area, stand age and stand height, with forest biomass, which not only avoided the trouble of establishing biomass according to different tree species, but these three variables also reflected the factors of volume, environment and other factors of the sample plot. In addition, the purpose of this study is to attach more importance to reveal the influence of spatial correlation and heterogeneity of biomass distribution on model fitting than the biomass model itself. Facts have proved that the three variables, basal area, stand age, and stand height are feasible for the estimation of regional forest biomass, and the model has a high explanatory degree with R^2 of the least square model reaches 91%.

OLS, SLM, SEM, and LMM global models remained unchanged among the studied regions, however, their coefficients were insufficient for the accurate description of three predicting factor effects on the forest biomass across various local regions. To be specific, GWR model offered the local model coefficients, and they were observed by the GIS technique to observe more details about on the association of forest biomass with the predicting factors (*Fig. 2*). Clearly, those predicting factors had different influences on forest biomass, depending on the different locations. For GWR model, its local model coefficients offered more details about the effects of micro-site variation and managing measures on forest biomass and tree growth. It would help to plan the management and make a decision (Lu and Zhang, 2012; Zhen et al*.,* 2013). In view of the above analysis, GWR can be combined with remote sensing data to improve the accuracy of traditional models for estimating forest parameters, and in addition, the forest parameters can be further predicted and validated through each Reflectivity Pixels from remote sensing model and remote sensing data can be used to predict the spatial distribution of and a relatively more accurate spatial distribution map can be draw (Propastin, 2012; Chen, 2012). However, the distance between sampling points, the number of samples could influence the estimation of GWR model, and even the influence of outliers, weak data problem and even lack of independence weaken and limit its application (Zhang et al., 2004; Zhang and Shi, 2004; Shi et al*.,* 2006).

Spatial autocorrelations as well as heterogeneities within the model residuals

Our results indicated that when considering spatial autocorrelations within model residuals, SLM, SEM, LMM, and GWR obtained a significant improvement over the traditional OLS model, which resulted in a biased hypothesis tested according to model coefficient. Particularly in that figure of local Moran's *I*, those spatial autocorrelations in residuals showed obvious characters. Across the entire study area, for OLS model, the local Moran's *I* values for its residuals were mostly positive (presented as "hot spots") while that of other models, especially the GWR model residuals were mostly negative

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72157232

(presented as "cold spots"). Zhang et al. (2009) obtained similar conclusions while studying the relationship between DBH and tree height using these spatial regression models. As suggested by Moran's *I* and LM tests (*Table 4*) for the model residuals (*Fig. 3*), SEM model showed higher suitability to manage spatial autocorrelations than SLM. Therefore, spatial autocorrelations are the troublesome things due to model misspecification rather than the dependent variable being influenced by the values of the neibouring dependent variables (Luo et al., 2016). Though SLM and SEM models allowed for direct and effective correction for spatial autocorrelations among data corrected spatially, they were unable to manage spatial heterogeneity, as shown by those intra-block variance patterns among various block sizes like those for OLS model (*Table 3*; *Fig. 4*). Data fitted by LMM model were superior to those fitted by SLM and SEM, which offered a larger number of spatial autocorrelations in the expected model residuals (*Table 4*; *Fig. 3*), like in other reported studies (Zhang et al., 2009). LMM model, one of the global models, is also used to manage spatial correlation through 2 manners, including adjustment and characterization. Of them, the adjustment manner obtains the rate estimates for response variables using EBLUP, the global kriging in Geostatistics, whereas the characterization manner estimates the spatial covariance variables, such as semivariogram range, partial still, and nugget (Ozdenerol, 2006). LMM used the exponential spatial covariance structure, like geographical weight function in GWR model, to calculate those spatial weights for adjacent forest plots. As a result, LMM model emphasized the "local" data determined based on those semivariogram variables, so as to provide a large number of expected spatial autocorrelations and heterogeneities in model residuals relative to other global models.

According to other research (e.g., Zhang et al., 2009; Kupfer and Farris, 2007), GWR model accommodates the spatial heterogeneity in the meantime of markedly reducing the spatial autocorrelation within model residuals (*Fig. 3*). GWR, the local spatial model, adopts the moving window across an observation set distributed spatially to produce a model coefficient set based on data subsamples surrounding certain points spatially (Páez and Scott, 2005). Although GWR does not merge the spatial autocorrelation during the process of modeling, since it assumes a normal distribution N $(0, \sigma^2 I)$ in model error term. Besides, the GMR model definitely considers the spatial locations and emphasizes the local variations regarding the associations among variables. It is precisely due to the above characteristics of GWR, it represents an efficient approach in the mountainous regions with complicated terrains (Wang et al., 2020). The GWR model can be improved according to the need of the research. For example, Propastin (2012) extended the GWR model to develop a geographically altitudinal weighted regression (GAWR) model for managing altitudinal (vertical) as well as spatial (horizontal) instabilities in estimating the aboveground biomass for a rainforest region in tropics. Therefore, considering the diversity and complexity of forest ecosystems, GWR offers the highly precise visual data for afforestation planning and management measures with cost- and labor-effectiveness as long as it is properly applied (Zhang et al., 2009; Liu et al., 2014).

Conclusion

It is concluded that basal area, stand age, stand height were closely associated forest biomass in our study. They were the explanation of density, forestage, and site conditions. The distinct spatial autocorrelations as well as variations exist between

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72157232

forest biomass and the variables, thus the OLS was not appropriate for modeling. SLM and SEM efficiently accounted for the spatial autocorrelations within model residual, but insufficient to deal with the problem of spatial heterogeneity. In contrast, the LMM and GWR incorporated the spatial dependence and variation into modeling processes, and consequently, fitted the data better and predicted the response variable more accurately. Therefore, in the presence of obvious spatial variations and autocorrelations between dependent and independent variables, and spatial regression models such as LMM, especially GWR should be considered.

Abstract. Forage species composition, biomass production and carrying capacity potential are primary indicators of rangeland conditions. The article aimed to assess the changes occurring in forage species composition, biomass production and carrying capacity of different grazing sites with relation to seasonal variation by using the benchmark and biomass methods in Yabello rangeland, Southern, Ethiopia. Results indicated that the species abundance and height showed significant variation across the sampling site in relation to seasonal difference. *Chloris roxburghiana, Cenchrus ciliaris* and *Chrysopogon aucheri* grass species were shown to be dominant and registered the highest average single species coverage and biomass yield for all grazing sites. The grazing vegetation index value of conserved grazing site were shown higher value 62.8% and 64.4% during rainy season and 48% and 54.7% during dry season from open communal and woody plant infested grazing site respectively. 76.7% and 90.9% higher biomass production was observed from ranch grazing site as compared to open-communal and woody covered grazing area, respectively. The carrying capacity variation within ranch grazing site was 77%, 76% and 76.7% greater from open-communal grazing site and 92.7%, 86.4% and 90.9% greater from woody plant infested grazing site compared during rainy season, dry season and yearly average value respectively.
Keywords: *abundance, stoking rate, production, palatability value, height*

Introduction

Forage species play an important role in livestock feeding in arid and semi-arid regions (Arzani et al., 2006), and also improve ecosystem services for the welfare of pastoral societies. Biomass of forage in rangelands is mainly determined by the amount of, distribution and duration of rainfall, effects of invasive alien species, livestock grazing intensity and other anthropogenic factors (Kassahun, 2008; Lemus, 2010). Recently, most pastoral areas of Ethiopia, including the Yabello rangelands, have been exhibiting a shift from herbaceous species to woody plants, a feature that is accompanied with some degree of degradation resulting from overgrazing, expansion of cultivation, also frequent drought and settlement resulted in decline in forage biomass and carrying capacity (Gemedo-Dalle et al., 2006; Oba et al., 2008; Angassa and Oba, 2010; Angassa, 2014). The Yabello pastoralists have been practicing transhumance to counter seasonal fluctuations in forage and water availability (Angassa and Oba, 2010; Habtamu, 2013; Takele et al., 2014). The factors that have been reported to affect the forage production and carrying capacity of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72337253

rangelands are caused due to seasonal variability (Snyman, 1998), species variation (Arzani et al., 2008), soil nutrient status of production location (Tessema et al., 2011), grazing pressure (Adisu, 2009) and mismanagement aspects (Van der et al., 2005). In the semi-arid Yabello rangeland, this translates into seasonal shortages of forage and low carrying capacity of rangelands (Alemayehu, 2006), further hindering sustainable livestock production and affecting the socio- economic of the pastoralist livelihood (Herlocker, 1999; Gemedo-Dalle et al., 2005; Bikila et al., 2014).

Assessment of rangeland based on forage biomass productivity was used to sustainable rangeland management through balancing the livestock population with an amount of forage production, that used to reduce further degradation (Ganskopp and Bohnert, 2001; Arzani et al., 2006; Keno and Suryabhagavan, 2018). The Yabello pastoralists have been known to exist since before the thirteenth century (Oba and Kotile, 2001) and have adapted the local knowledge to manage their range land from different threating factors like drought, invasive plant species, overgrazing and other anthropogenic factors (Oba and Kotile, 2001; Teshome et al., 2012). Assessing forage productivity and carrying capacity are key factors of rangeland inventory and monitoring programs which are highly required for the sustainability of natural resources (Galt et al., 2000; Tsegaye et al., 2010; Lemus, 2010; Abdella, 2010; Bikila et al., 2014; Hailu, 2017; Cheng et al., 2017; Meshesha et al., 2019). Land use evaluation is an important tool in making decisions in planning type of animals to be used and land suitable to them accordingly based on their specified requirements, preference and predictors of specific activates (Mligo, 2009; Lin et al., 2010; Tamrat and Stein, 2015; Bikila et al., 2016; Siraj and Abdella, 2018). The productivity and carrying capacity of Yabello rangeland is degrading and decreasing ultimately (Habtamu, 2013). Since, Yabello rangeland is a depleted range area, the assessment of present potential of the range resource is important in order to plan its sustainable development. However, there is not enough information available on the effect of invasive plant infestation on native grass species, forage biomass production and therefore carrying capacity of the study area. Therefore, in this study we examined the change of herbaceous species ground cover, forage production and carrying capacity in the Yabello rangelands of southern Ethiopia.

Materials and methods

Study area

The study was conducted at Yabello district in the Borana zone of Southern Ethiopia using both ranch, communal and woody grazing site (*Fig. 1*). The site was selected because it is one of the most arid parts of Borana zone and, therefore, the pastoral communities of this district are the most vulnerable to the rangeland degradation due to overgrazing because of the large number of livestock population and bush encroachment. Yabello is located at 566 km south of Addis Ababa along Addis – Moyale road. The total area of district is 15,430 km^2 of which 68% (10,492 km^2) is rangeland and it is located between 4°30′55.81″ and 5°24′36.39″ north latitudes and between 7°44′14.70″ and 38°36′05.35″ east longitudes (Gemedo-Dalle et al., 2015). The altitude is about 1000-1500 m, with a maximum altitude of 2000 m. The rainfall of the area is characterized as bi-modal. Most (73%) of the rainfall occurs in March to May, which is called the long (gaana) rainy season, and the remainder (27%) occurs in September to November, which is called the short rainy (hagaya) season (Gemedo-Dalle et al., 2015).

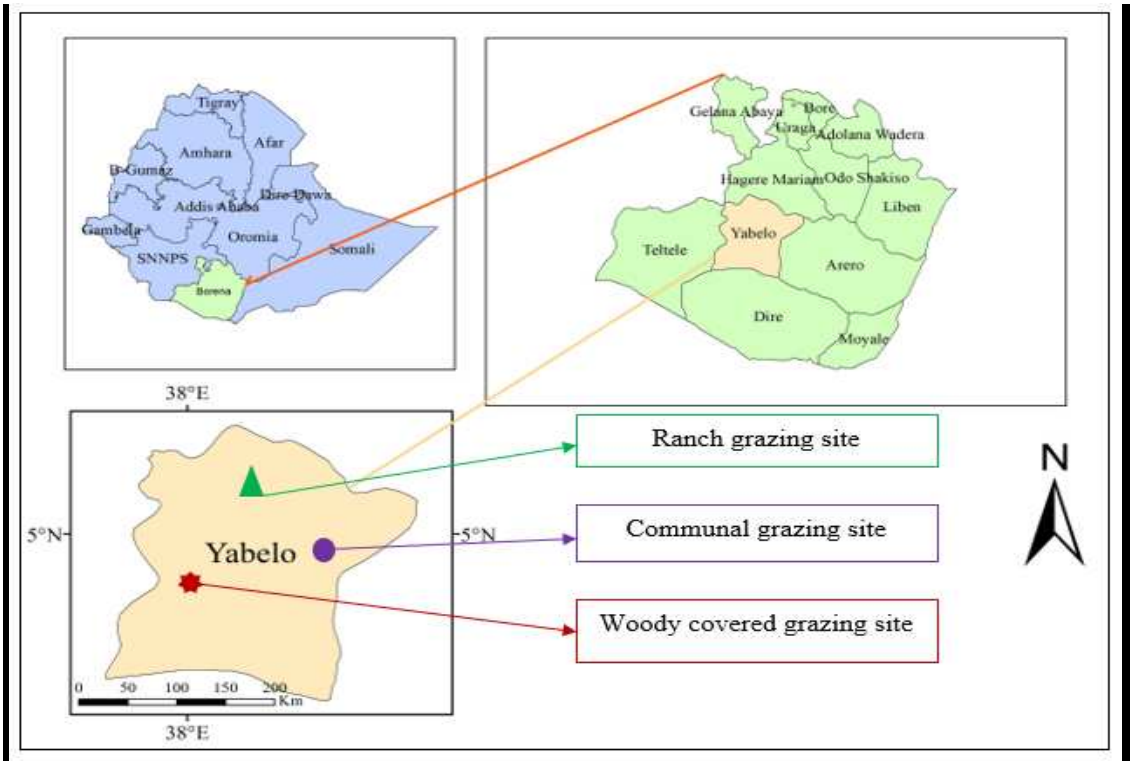

Figure 1. *Location of the study area*

The mean annual rainfall is recorded between 450-700 mm (Angassa, 2014) while the mean annual temperature varies from 19-24°C with little seasonal variation (*Fig. 2*). The potential evapotranspiration is 700-3000 mm (Billi et al., 2015). The soil in the study area includes, 53% red sandy loam soil, 30% black clay, and volcanic light-colored silt clay and 17% silt and the vegetation is mainly dominated by encroaching woody species, and those that frequently thinned out including *Senegalia mellifera*, *Vachellia reficiens* and *Vachellia oerfota* (Coppock, 1994). According to the latest census conducted in 2015, the national census reported that the total population for this district was 70,501, of whom 36,246 were men and 34,255 were women; 4,874 or 6.91% of this population includes urban dwellers. Cattle, goats, sheep, camel, mule, donkey and horse are the main reared livestock species.

Data collection methods

Sampling species composition and forage biomass production

In order to quantify the forage composition and biomass dynamics in different grazing land types, above ground herbaceous was collected and biomass measurement was conducted. Within each rangeland grazing type, one linear 5 km transect was assigned and six 25 * 25 m^2 sampling plots were systematically placed at 500 m interval at each grazing site in total 3*3= 9 plots. And within each plot three were (3) 5 * 5 m^2 sub plots randomly assigned in total 3*3*3= 27 subplots. Finally, five (5) 1 * 1 m^2 quadrants in total 3*3*3*5= 135 quadrants were assigned by throwing randomly to the back side in order to minimize any biases resulting from selective placement within each sub plot for herbaceous and grass species sample collection. All the above ground forage samples were harvested by using cutter and collected in paper bags. The fresh weight of forage sample was measured in the field with a scale.

Samples were taken to Yaballo Pastoral and Dryland Agriculture Research Center soil laboratory and oven dried for 24 h at 105°C to determine the biomass. Then the dry matter was measured after 24 h of drying and converted into kilogram per hectare (kg/ ha), and the proper use factor (PUF) have been taken as 30% to calculate available forage (Sintayehu, 2006; Meshesha et al., 2019). Thereafter, dry matter (DM) biomass and livestock carrying capacity were determined by the following procedures described by Niguse, 2008 and grazing vegetation index percentage (GVI) methods. Identification of the grass species were done in the field with the help of field identification keys and plates, using Flora of Ethiopia books, and Addis Ababa University national herbarium (Elmore et al., 2000; Gemedo-Dalle et al., 2005). Data collection on grass species sampling was commenced twice per year, in the dry season (January-February 2019) and in the rainy season (March-May 2019) at the time when grass species were identified easily and peak biomass were recorded. Field data was collected with three replications for each season.

Grazing site vegetation index, height and palatability of grass species

The grazing site vegetation index (GVI) valuing each study site (*Fig. 3*) was analyzed using both percentage coverage (PC) of each species within each sampling plot and in combination of ecological index values (EIV) (Vorster, 1982; Solomon et al., 2006). The EIV and palatability value (PV) of grass species was recorded by direct observation of the grazing livestock, semi-structured focus group discussion and field on site explanation of the local pastoralists with a total of 110 participants (71 males and 39 females) and identification was carried out with the help of elder pastoralist and district experts. The participants were selected based on their experience, direct linkage of livestock rearing, age, year spent on the study site and based on recommendation of experts in addition with their voluntarism. For this study the EIV was grouped into four (4) classes with its value, namely: decreasers = 10; increaser I=7; increaser II = 4; Increaser III = 1 (Solomon et al., 2006). PC value of each species was calculated.

The PV was also grouped in to four (4) classes and values were assigned, like: highly palatable = 8; Moderately palatable = 6; less palatable = 4 and unpalatable = 2. The percentage composition of grass species in each class was summed up, after which the sum for each class was multiplied by EIV and PC value. These amounts were then totaled to give the vegetation index. For our case we also calculated the grand total score of our benchmark grazing site and the most probable maximum assuming that all species were grouped under decreases. The average height of each individual grass species at each grazing site were measured both

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72337253

during February and May for dry and rainy season respectively when the two seasonal features clearly and at the time where grass species were identified easily and peak biomass were recorded. And the field data collected with three replications for each season.

Figure 3. *Picture representation of sampling site*

Carrying capacity determination used ranch grazing site as the benchmark

To determine grazing capacity with the benchmark method, the GVI percentage, obtained from either the ecological index or grazing value index, was used. It also incorporated the average annual rainfall for the grazing site. The equation used for this method was described below at *Eq. 1* (Niguse, 2008; Habtamu, 2013).

$$CC\ (AU/ha) = \{[-0.03 + 0.00289 \times GVI\%] + [(RF - 419.7) \times (0.000633)]\} \quad (Eq.1)$$

where, CC = Carrying capacity in animal unit per hectare (AU)/ha, GVI = grazing vegetation index in % of the benchmark rangeland, RF = Average annual rainfall for the grazing site.

Carrying capacity determination using the biomass method

This method described by (Moore and Jung, 2001), uses the grass biomass per hectare to determine the grazing capacity for animal units (AU) for one year. It assumes that one AU consumes 11.25 kg grass per day (2.5% of its body mass of 450 kg). The method also includes a utilization factor 0.30 (30%) depending on the recommendation for savanna rangelands including Borana and calculated using *Eq. 2* given below (Habtamu, 2013).

$$CC = \frac{d \div [DM \times Uf]}{r} \quad (Eq.2)$$

where, **CC** = Carrying capacity in AU/ha, **d** = number of days in the year (or period to be grazed), **DM** = dry matter (biomass) in kg/ha, **Uf** = utilization factor (0.3), **r** = daily dry matter required by one grazing animal (2.5% of bodyweight), which is 11.25 kg for an AU (450 kg grazing animal (cattle).

Statistical analysis

The rangeland productivity, livestock, carrying capacity, palatability value, percentage cover, height data were analyzed by means of Microsoft Excel program and descriptive statistics in the Statistical Package for Social Sciences (SPSS) to generate descriptive statistics. Significant differences evaluation at $P < 0.05$ were done by using analysis of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72337253

variance (ANOVA) used to analyse difference with regards to different grazing site and seasonal variation and Principal Component Analysis (PCA) was performed on the complete dataset to reduce its complexity and get a better understanding of the underlying vegetation structure.

Results and Discussion

Grass species composition of rangeland

A total of 23 grass species were identified and recorded using both their scientific and local name. The species and their average coverage for the different grazing site are presented in *Table 1*. *Chloris roxburghiana*, *Cenchrus ciliaris* and *Chrysopogon aucheri* grass species showed dominance and registered the highest average single species coverage in both season across all grazing sites and highly abundance at communal and woody grazing site. This is because of high resistance capacity of species during overgrazing and competent features with woody plant species, as a result this species are highly recommended for rehabilitation of degraded rangeland. Results showed that there was a significant difference ($P<0.05$) in most grass species coverage across different grazing sites both during rainy and dry season. And among the total 23 grass species that were found in the study area, in ranch grazing site, coverage of 20 and 19 species was above 1%, abundance of 2 and 1 species was below 1% and the remaining 1 and 3 species did not exist in the grazing site during rainy and dry season respectively (*Table 1*).

Note: * = significant, ** = highly significant, + = indicates grass species present with cover <1%, - = indicates grass species absent, Rs = rainy season, Ds = dry season

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72337253

At the communal grazing site, abundance of 15 and 14 species was above 1%, 5 and 3 species were below 1% and the reaming 3 and 6 species did not exist in the grazing site both rainy and dry season, respectively. On woody covered grazing site, 15 and 10 species were found with a coverage above 1%, 4 and 5 species were below 1% and the reaming 4 and 8 species did not exist in the grazing site both at rainy and dry seasons, respectively. As we have seen from *Table 1*, even if the species was found in all grazing site, its abundance showed declined pattern from conserved ranch grazing site to open communal and woody covered rangeland site.

And also, seasonal variation had a great impact on the grass species occurrence and abundance based on our result and past reported data (Han et al., 2013). Almost all, grass species showed increasing trend during rainy season and decreasing trend during dry season, with the exception of *Cyperus bulbosus, Sporobolus pellucidus, Harpachne schimperi* and *Eragrostis papposagrass* species that showed increasing trend of their abundance during dry season as compared to rainy season. From this we can understand that this grass species had the capacity to resist rainfall security and will be recommended for rangeland rehabilitation in the aera where more frequent drought occurred, and this result is in agreement with the data reported by Han et al., 2013.

In general, from this study we can observe that grass species existence and abundance had a direct influence and it is linked with grazing land type. That is grass coverage was higher in well managed ranch rangeland site and showed great decreasing rate both in abundance and total absence in the non-managed open communal and woody plant infested grazing site. This told us random grazing trend and bush infestation of rangeland had a great impact on both the composition and mass of herbage species and this had a direct influence on the livelihood of livestock pastoralists as well as the economy of both the local people and the whole country. This finding on the pattern of species composition showed an opposite trend that data reported by (Lanta et al., 2009), whose studies indicated that excluding herbage from livestock grazing decreases species richness and increases it under conditions of grazing pressure. The spatial distribution and composition of grass species in relation to seasonal variation as assessed by the component analysis of PCA is provided (*Fig. 4*). The first two PCA component axes cumulatively explained 97.7% of the total variance in species, which shows that the two components have accounted for most of the species types composition in the rotated space.

Grazing site vegetation index of rangeland

Concerning the grazing system, we used a well-managed and conserved government ranch site as our benchmark in order to analyze the ecological status of grass species. We used two variations, one relies on the ecological index value classification (decreasers and increasers) of grasses and the other percentage occurrence value of each species are calculated above (*Table 1*). The recorded multiplicative value is in the 'Score' columns. In most studies a grand total was assumed as 900-1000 for the benchmark site (excellent rangeland condition) (Marake et al., 2019), but in our case the grand total value was obtained by collecting and analyzing all the grass species existed on the site that was a highly conserved and well managed government ranch site. The percentage difference between these two sites (i.e. the well managed ranch and non-managed open communal and woody covered grazing site) represents the ecological index value (EIV).

In *Table 2* above the EIV indicated the assigned values rather than classified groups. That is, 10= for decreasers; 7= for increaser I; 4= for increaser II and 1= for increaser III. In this case, grouping of grass species under decreasers and increasers was conducted based on their

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72337253

basal area coverage percentage conducted in *Table 1* above in combination with direct field observation of their occurrence and abundance in each grazing site and past trends of the species based on elder pastoralist information obtained during focus group discussion and field assistance and grouped as follows: abundance greater than 20% under decreasers, 15-20% under increaser I, 10-14% under increaser II and with abundance less than 10% under increaser III (the same technique used by Baars (2002)).

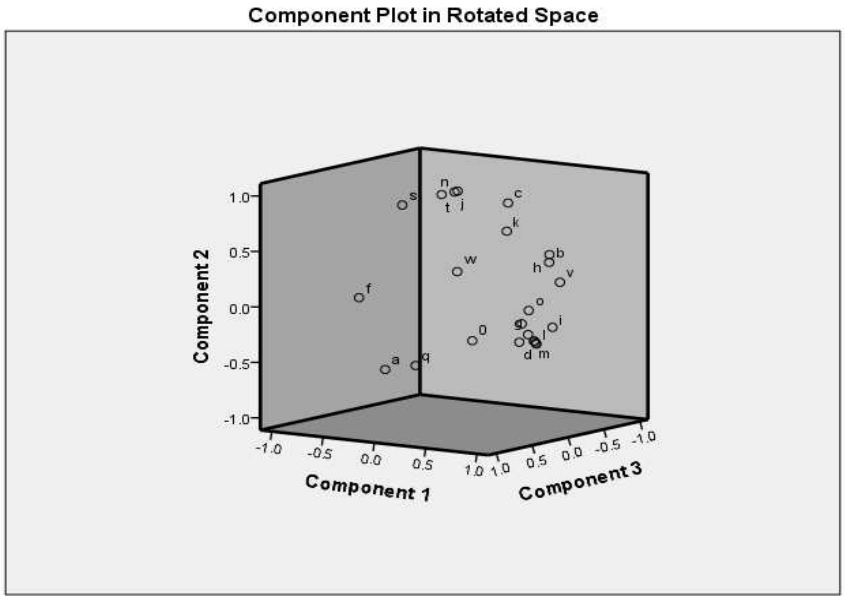

Figure 4. *PCA component analysis of grass species based on occurrence frequency with in each grazing site in relation to seasonal variation. (a=Chrysopogon aucheri, b=Dactyloctenium aegyptium, c=Xerophyta humilis, d=Aristida kenyensis, e=Eragrostis capitulifera, f=Harpachne schimperi, g=Leptothrium senegalense, h=Melinis repens, i=Themeda triandra, j=Digitaria milanjiana, k=Chloris roxburghiana, l=Digitaria naghellensis, m=Panicum maximum, n=Bothriochloa insculpta o=Cenchrus ciliaris, p=Pennisetum mezianum, q=Eragrostis papposa, r=Sporobolus discosporus, s=Grewia tenax, t=Grewia tenax, u=Cyperus sporobouls, v=Cyperus bulbosus, w=Sporobolus pellucidus)*

In the ranch grazing site, 39.1% and 30.4% of grass species were grouped under decreasers, 17.4% and 4.3% of grass species under increaser I, 0% and 13% of grass species under increaser II and 43.5% and 39.1% of grass species under increaser III during rainy and dry grazing season, respectively. In the open-communal grazing site, 13% and 17.4% of grass species were grouped under decreasers, 13% and 0% of grass species under increaser I, 8.7% and 21.7% of grass under increaser II and 52.2% and 34.8% of grass species under increaser III during rainy and dry grazing season, respectively. At woody plant infested grazing site, 17.4% and 13% of grass species were grouped under decreasers, 0% and 4.3% of grass species under increaser I, 4.3% and 0% under increaser II and 60.9% and 47.8% of grass species under increaser III during rainy and dry grazing season, respectively. And the average ratio of each grass species category was: in ranch grazing site, 34.8%, 13%, 8.7% and 43.8% of grass species were grouped under decreasers, increaser I, increaser II and increaser III, respectively.

DOI: http://dx.doi.org/10.15666/aeer/1805_72337253

In open-communal grazing site, 17.4%, 8.7%, 17.4% and 43.8% of grass species were grouped under decreasers, increaser I, increaser II and increaser III, respectively. At wood plant infested grazing site, 17.4%, 4.3%, 4.3% and 56.5% of grass species were grouped under decreasers, increaser I, increaser II and increaser III, respectively. From this ratio, we can understand that decreasers grasses were highly abundant in rangelands in a good condition for grazing (ranch), but decreased in number when the rangeland was over-grazed or infested by woody plant species. With regard to GVI value, the conserved grazing site (ranch) showed higher value such as 62.8% and 64.4% during rainy season and 48% and 54.7% during dry season compared with unmanaged open-communal grazing site and woody plant infested grazing site respectively (*Table 2*). And also, ranch grazing site showed 57.2% and 60.8% higher grass species composition from communal and woody grazing site during assessing the yearly GVI value.

Palatability classification of rangeland grass species

Classification of grass species based on palatability value (PV) at different grazing site was recorded by directly observing the grazing livestock in the field for two different seasons. These field observations were further confirmed from knowledge gathered from pastoralist and local experts. In order to calculate the degree of palatability, we simply focus on grazing site variation. There were no visible differences based on the morphological grass parts preferred by livestock. This is may be because of all grass species in our study area have showed almost similar morphological and phenological palatability features. And this observational result is in agreement with the data reported by Marake et al. (2019). Results regarding palatability value of existing grass species in our study rangelands revealed great variation in Palatability rate (*Table 3*).

In ranch grazing site, among the total 22 identified grass species (*Table 1*), 3 (14%) species grouped under highly palatable (Hp), 5 (23%) under moderately palatable (Mp), 8 (36%) under less palatable (Lp) and 6 (27%) under unpalatable (Up). At ranch grazing site most species grouped under less palatable grass species, this is due to the well managed grazing area that the grazers have the chance to access different forage source grass species, as a result their preference of grazing become diverse and not focused on a certain grass species. In the open-communal grazing site, among the total 21 identified grass species (*Table 1*), 7 (33%) species were grouped under highly palatable (Hp), 9 (43) under moderately palatable (Mp), 5 (24%) under less palatable (Lp) and no species were grouped under unpalatable (Up) grouped. In the woody infested grazing site, from the 19 grass species identified (*Table 1*), 6 (31%) species were grouped under highly palatable (Hp), 10 (53%) under moderately palatable (Mp), 3 (16%) under less palatable (Lp) and no grass species remain as unpalatable. From this we can understand that, in the degraded grazing site all species that can be preferable for grazing, because there is scarcity of forage source and no species remain unpalatable if the rangeland faced degradation.

In general, the palatability rating score (highly palatable and moderately palatable) were found to be the highest in the woody area (84%), followed by the open- communal grazing site (76%) and lastly on the ranch (37%) and the rating scores of the other two species categories (less palatable and unpalatable) were found the highest in the ranch area (63%), followed by open-communal grazing site (24%) and lastly woody infested grazing site (16%). This is because of accessibility of variety of species and no scarcity on the properly utilized and managed grazing site (ranch) and the current study is directly in line with the data reported by Solomon et al., 2006.

Grass species height of rangeland

The height of grass species recorded from the study sites also showed a significant variation across the grazing site and presented below in *Table 4*.

The grass species collected from the sampling site showed height variation across the grazing site difference with relation to seasonal influence. Grass species height in woody covered grazing site was found the shortest as compared to ranch and communal grazing site and in the ranch grazing site all grass species showed a better height among other sites. This difference in height could possibly be due to less vigour associated with herbage under woody vegetation cover as a result of light competition effect. This may cause species to easily break in case of environmental disturbances like grazing and wind, hence not able to grow tall to the heights comparable to those with no light shade effect in open grass land area.

In general, the impact of unmanaged livestock grazing and infestation of woody plant species showed significant ($P<0.05$) variation with regards to livestock forge species growth on the grazing site, so that species heights in a well-managed ranch site significantly showed a better growth performance than those in over-grazed and woody infested range site. However, as we have seen from *Table 4*, the height of herbage species

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72337253

Chrysopogon aucheri, Chloris roxburghiana and *Cenchrus ciliaris* showed great resistance across all sampling sites and served as a main source for forage for livestock throughout the year. According to the data obtained directly from our field investigation and also from both direct interview and focal group discussion of the local communities those grass species had high resistance capacity and recommended for further degraded range land rehabilitation method either through reseeding or direct planting of it. Our data were directly supported by the study conducted by Yeneayehu et al. (2020), on effects of vegetation cover, grazing and season on herbage species composition and biomass in the case of Yabello rangeland, Southern Ethiopia.

Grass species biomass production of rangeland

In the current study, only grass species that are identified and available to animals for grazing are classified as forage. Data were collected in rainy (May) and dry season (February). Comparison of means for forage biomass production (kg/ha) and grazing status of the three (3) grazing sites (ranch, open-communal and woody covered) during the study period was given in *Fig. 5* below. According to the results, total biomass production from ranch grazing site were 4,584 and 1,890 kg/ha, from open-communal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72337253

grazing site were 1,053 and 453 kg/ha and from woody covered grazing site were 336 and 256.2 kg/ha were recorded during rainy and dry season, respectively. Seasonal variation showed significant impact on the biomass production of rangeland across all grazing sites. 58.8%, 57% and 23.8% higher biomass production was observed during rainy season at ranch, open-communal and woody covered grazing site, respectively. This is due to rainfall is the primary determinant factor for forage production both in the conserved and degraded rangeland area.

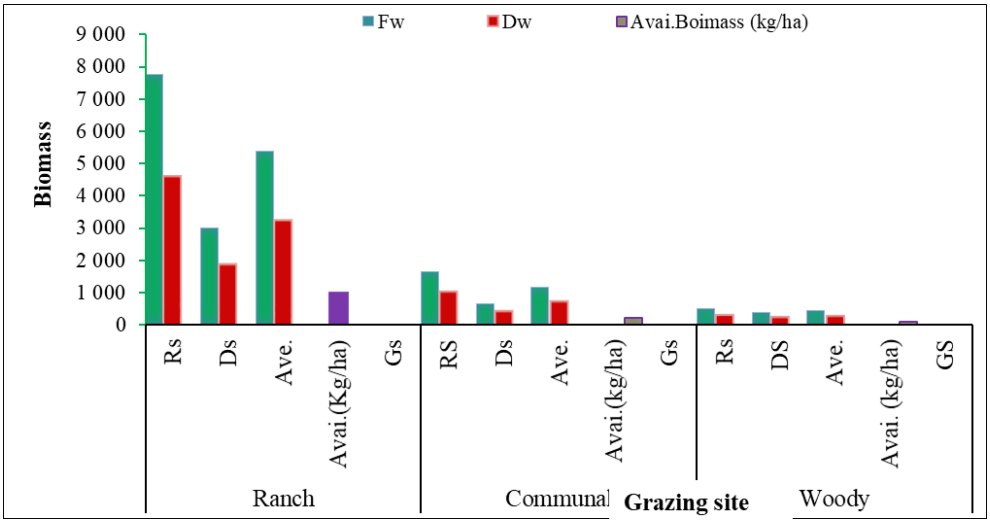

Figure 5. *Seasonal forage biomass production (kg/ha) and grazing status of range sites of the Yabello rangeland. (Note: Fw= fresh weight(kg), Dw= dry weight (kg) Rs = rainy season, Ds= dry season, Ave= average biomass (kg/ha),Avai= availbale biomass (averge dry mass* Uasble factor (0.3)) , Gs = grazing status of the grazing site, 10= repersentes slightly grazing, 4 = represents overgrazing)*

The biomass production rate during dry season also showed the same reduction trend across all grazing site. Overall forage productivity was also high during rainy season across the three grazing sites. Average biomass was higher at well managed grazing site (ranch) as compared to others, that is 3,237 kg/ha, 753 kg/ha and 296.1 kg/ha at ranch, open-communal and woody covered grazing site, respectively. That means, 76.7% and 90.9% higher biomass production was observed from open- communal and woody covered grazing area, respectively. The available forage biomass with a useable factor of 30% recorded from each grazing site was 971.1 kg/ha, 225.9kg/ha and 88.8 kg/ha from ranch, open-communal and woody covered rangeland grazing site, respectively.

Based on the total available biomass production and field observational results the grazing status (Gs) of ranch grazing site was well managed and livestock grazing was done through planned and programed way and the status was under very good condition. It used as a demonstration sample site for different rangeland management practice and awareness creation was conducted at the district and classified as slight grazing category. Whereas, the rest were grouped under overgrazing category (*Fig. 4*) above. Since, rainfall is the major determinant factor for rangeland biomass production, the productivity measured and reported here in our result should be interpreted with caution and it is expected to be valid in an average annual rainfall amount of around 605 mm (which is the case of the data obtained from the Ethiopian metrological authority, for the year 2019

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72337253

in our study area) and our conclusions agree with the data reported by Alemayehu (2006), Sisay (2006) and Elias (2007).

Carrying capacity of the rangeland

In this study, carrying capacity was calculated by two methods: (I) using GVI value calculated for each season and yearly for each grazing site (*Table 2*) and the average rainfall for the year 2019 used ranch grazing site as our benchmark and (II) by using biomass method.

Carrying capacity of rangeland using ranch grazing site as benchmark

According to our results showed at *Table 5* and *Fig. 6* below the seasonal and overall carrying capacity of degraded rangelands such as open-communal and woody covered grazing site was low as compared to the ranch grazing site. The carrying capacity during rainy season was 11.22 ha/AU/Y and 11.2 ha/AU/Y, in dry season was 11.27 ha/AU/Y and 11.24 ha/AU/Y with an average overall carrying capacity was 11.24 ha/Au/Y and 11.23 ha/AU/Y for open-communal and woody covered grazing site, respectively.

Table 5. *Carrying capacity of Yabello rangeland at different grazing sites (as benchmark method)*

Grazing site	season	GVI value (%)	Average RF (mm)	CC (ha/AU/y)	CC (AU/ha/Y
Communal	Rs	62.8	605	(-)11.22	0.08919
	Ds	48	605	(-)11.27	0.08872
	Ave.	55.4	605	(-)11.24	0.08894
Woody	Rs	64.4	605	(-)11.2	0.08921
	Ds	54.7	605	(-)11.24	0.08892
	Ave.	59.6	605	(-)11.23	0.08907

Note. Rs= rainy season, Ds= dry season, Ave.= average, GCI= grazing condition index, ha/AU/Y= hectare per animal unit per year, AU/ha/Y= animal unit per hectare per year (Note. To convert AU/ha to ha/AU, divide 1 by AU/ha value (Abdullah et al., 2017)

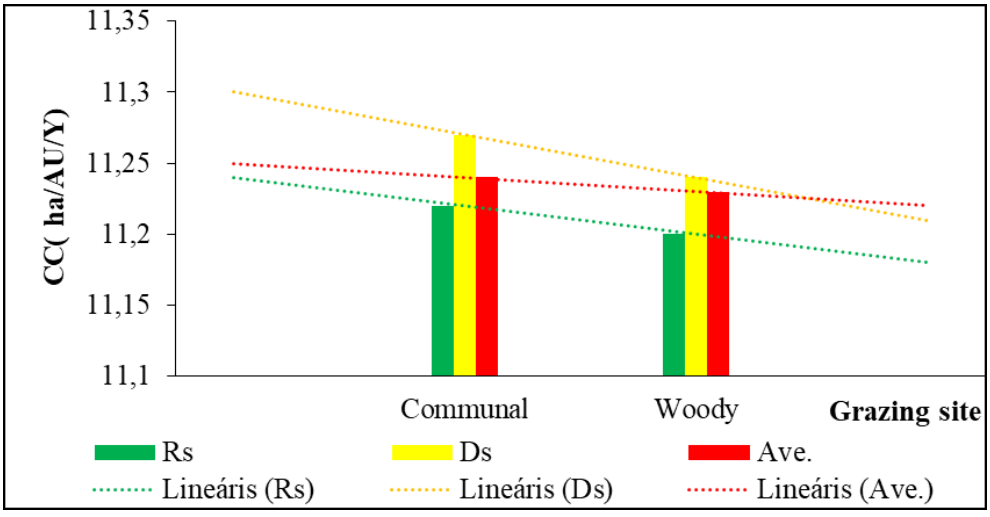

Figure 6. *Carrying capacity comparison of grazing sites (communal and woody) during different seasons*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72337253

The negative (-) sign at *Table 5* indicated the carrying capacity difference as compared with the ranch site. That means, the carrying capacity of the degraded grazing sites were less by 11 ha/AU/Y when compared with the conserved ranch grazing site. In other words, in order to support equal number of livestock overgrazing rate would have been zero or no overgrazing would have been observed in ranch grazing site, while in the case of open-communal and woody grazing site the overgrazing rate would have been 11 ha/AU/Y. That means the degraded grazing area was exposed to overgrazing 11 times higher than the normal or recommended capacity that can support. From this we can understand that in order to support equal number and type of livestock it would be needed additional 11 times grazing site area in case of degraded (open-communal and woody infested) grazing site.

In general, from this result does not mean that the carrying capacity of grazing site both at rainy and dry season were equal. Instead, the dry biomass production at rainy season was higher and it is clear that during rainy season the carrying capacity of Yabello rangeland was better across all grazing sites. Therefore, biomass productivity ultimately decreased due to overgrazing and infestation of woody invasive plant species leading to poor carrying capacity. Our result is in agreement with the data reported by Solomon et al. (2007) for the same study site using different method.

Carrying capacity by biomass method

This technique clearly provided visible and clear information about the impact of seasonal variation and overgrazing on biomass productivity potential and carrying capacity across the grazing site.

Carrying capacity value ranged between the interval 2.99 to 53.40 ha/AU/Y or 0.33 to 0.019 AU/ha/Y with the average yearly value of 4.23 to 46.24 ha/AU/Y or 0.24 to 0.022AU/ha/Y (*Table 6*). When we have seen seasonal carrying capacity difference across the grazing site 58.7%, 57% and 23.7% better carrying capacity potential was observed from ranch, open-communal and woody covered grazing site, respectively during rainy season as compared with dry season. Based on this we can concluded that, it is crucial to analyze the vulnerability of pastoral livelihoods to combined threats within a risk-prone environment and developed adaptation strategies to reduce the impact of drought on their livestock and our result is highly constituent with the data reported by Habtamu (2013), Angassa and Oba (2010) and Bat et al. (2016).

Table 6. *Carrying capacity of Yabello rangeland at different grazing site (Biomass method)*

Grazing site	Season	Biomass Kg/ha	Available biomass Kg/ha	CC ha/AU/Y	CC AU/ha/Y	Grazing status value
Ranch	Rs	4,584	1,375.2	2.99**	0.33	10
	Ds	1,890	567.0	7.24**	0.14	
	Ave.	3,237	971.1	4.23**	0.24	
Communal	Rs	1,053	315.9	13.00**	0.077	4

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72337253

The maximum carrying capacity was observed at well managed (ranch) grazing site throughout the year (both in rainy and dry season). That was 2.99 ha/AU/Y, 7.24 ha/AU/Y and 4.23 ha/AU/Y at rainy season, dry season and in yearly, respectively. The carrying capacity potential of ranch grazing site showed higher values of 77%, 76% and 76.7% compared to open-communal grazing site, and 92.7%, 86.4% and 90.9% compared to woody-plant infested grazing site during at rainy season, dry season and yearly respectively. The reason for the low carrying capacity potential of non-conserved grazing site (communal and woody) is that degradation resulted from overgrazing and infestation of woody plant species in combination with both climatic and anthropogenic factors. And the current status of open-communal and woody grazing site is under degradation because of overgrazing (*Table 6*). Overall, the rangeland of Yabello showed overgrazing and changed to non-usable stage because of serious degradation, which challenges the survival rate of livestock, livelihood of the pastoral community and the economy of the country.

Conclusion

Based on our overall results, we clearly understood that the seasonal variation and grazing site management difference had a great influence on the available grass basal area coverage, height, biomass production and carrying capacity potential of rangeland. It helps to put a baseline data for decision how it is valuable to conserve and manage grazing site based on the data recorded from our benchmark site, since plant cover, dry mass and carrying capacity are the primary indicators for how a certain range land site would be used sustainably without further deterioration. In Yabello rangeland the pastoralists community are more challenged because of the factors like overgrazing, invasive plant species infestation, frequent drought and other climatic and human factors caused for rapid decline of biomass production and carrying capacity rate. The main target to quantify the change of optimal grazing site with relation to grass basal cover, biomass production, growth height performance and carrying capacity was to create awareness with in the community and the scholars with regards to how to conserve further degradation by incorporating scientific techniques and applying practical immediate managerial decision. The forage biomass production in Yabello area is primarily determined by the inconsistence variability of rainfall and rapid infestation rate of woody plant. The overall biomass production in the rangeland was not adequate to meet the requirements of the tropical livestock unit in the area. There is a big difference between the conserved and non- conserved grazing site due to the ultimate influence of overgrazing and woody plants. However, this study was preliminary, based on the result we highly recommend that subsequent ecological studies should be conducted on spatial and temporal variations of forage production. The productive potential of rangelands is not the same across the study site and carrying capacities are needed to be periodically reviewed to accommodate any changes in land resources, or environment. There is a severe problem of overgrazing that leads to year-round stress on grazed species. Therefore, the adjustment of stocking rate is compulsory and planned grazing should be introduced and implemented to release the stress over grazed species.

(Received 1st May 2020; accepted 13th Aug 2020)

Abstract. Eco-environmental vulnerability is one of the challenges of Teltele rangeland Southern, Ethiopia. This research aimed to analyzing change of grassland area to bush covered area via remote sensing method using NDVI values, temperature, perception, land use change and the local community background knowledge from 1990-2015. The eco-environmental Vulnerability Integrated Index (EVSI) for each class,1990-1995, 1995-2000, 2000-2005, 2005-2010 and 2010-2015 shows an upward trend. That is 1.59, 2.61, 2.91, 2.67 and 2.8 respectively for each interval. The higher EVSI value, is the more serious impact of eco-environmental vulnerability or encroachment of the bush plant coverage. Based on the NDVI data, the net change in open bare grazing area to bush covered vegetation over the past 25 years was 43.2%. The key factor in the rapid encroachment of bush vegetation was the frequency of drought (El Niño), causing a decline in the population of pastoralist community of Teltele were faced with poverty due to their livelihood. As a result, trend of livestock population dynamics shows a decreasing in the pattern. Based on the current results, the design of the scientific management techniques for eco-environmental vulnerability and raising awareness in the local community will be the priority area for further studies.
Keywords: *NDVI, invasive species, degradation, pastoralist, remote sensing*

Introduction

Environmental vulnerability has been defined as a significant impact observed due to the variation of the mean state of climate relevant variables such as temperature, precipitation and wind over a period of time (IPCC, 2007) and exposure to climate change, sensitivity and adaptive capacity (IPCC, 2001) and became a major threat to humanity (Watson et al., 1998; O'Brien and Levchenko, 2000). Mainly in Africa, the impact of vulnerability to climate change is difficult compared to other developed countries, because of the lack of economic, development and institutional capacity (IPCC, 2001; Sithole and Murewi, 2009). Poverty, human diseases and high population density with high demand for food, water, and livestock forage are among the major impact due to climate change (Davidson et al., 2003; Thomas et al., 2000; Masike and Urich, 2008). Arid and semi-arid environments of most part of the world including Ethiopia, mainly characterized by high inter-annual rainfall variability and reoccurring

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72557278

droughts (Ellis and Swift, 1988; Mogotsi et al., 2012) which are likely to be exacerbated by climate change (IPCC, 2013). And also, the Teltele rangeland, Southern, Ethiopia highly faced such climate impact like drought and flooding. In the rangeland areas livestock production sector as a livelihood option is one key sector which will bear the brunt of these climatic conditions fluctuation (Stige et al., 2006; Sithole and Murewi, 2009).

Livestock rearing and farming are the most important source of income for the people lived in arid and semi-arid rangeland area in most parts of the world. In most rangeland area of Ethiopia, including Teltele rangeland livestock rearing is the direct source of income for local pastoralist communities (Bongers and Tennigkeit, 2010). It is a home for the livestock production sector as a woreda and national level with 95% of the family income source rely on livestock in the area (Tache and Oba, 2010). According to report of different studies (Li et al., 2012; Shapiro et al., 2017), estimated direct contribution of livestock production in lowland pastoral systems of Teltele in combination with other part of Ethiopia to agricultural growth domestic product (GDP) and national GDP to be 39 and 17%, respectively. The area supports more than 70,500 families with an annual population growth rate of 2.5–3% (Dalle et al., 2015). Livestock production dominated by the Borana breed and it was been the major source of livelihood for Teltele pastoralists. This breed is one of the most productive, fast-growing and fertile as compared with other indigenous cattle breeds in Ethiopia (Elias et al., 2015). Cattle, goats, sheep, camel, mule, donkey and horse are the main livestock species reared on the study site. According to central statically agency report in, 2014 to 2015 there were a total of 499,719 (197,876 cattle, 185,846 goat, 105,158 sheep, 4 horses, 65 mule, 9,704 donkey and 1,062 camel) livestock population were recorded in Teltele rangeland. Livestock play a crucial role in the subsistence economy, culture and religion of pastoralists in Teltele rangeland, and represent both social capital and an insurance against disaster (Angassa and Oba, 2008). Teltele pastoralists are used their indigenous knowledge for rangeland and water resource management strategies.

Now adays, threatening factors mainly due to environmental and socio-economic changes may severely affect ecosystem services of the rangelands, such as forage supply and carrying capacity potential in worldwide and also highly happened in Ethiopia rangeland area, particularly in Teltele rangeland (UNEP, 2009; Augustine, 2010; Brink et al., 2014). Climatic factors like drought and unpredictable rainfall have a huge impact on the rangeland's vegetation status and its productivity (Neely et al., 2009; UN, 2011). In several part of Ethiopia, including Teltele, mean annual precipitation is projected to decrease by 10 to 20% (Haile et al., 2010; Elias et al., 2015) and climate change is therefore, expected to threaten the pastoralist livelihoods. Under which local circumstances, changing rainfall characteristics may limit the ability of pastoralists to secure their livelihood sustainably if they depend only on local forage resources is an open question (Angassa and Oba, 2008). Drought also one of the major causes for rapid encroachment of Bush plant species, since this species can easily adaptive potential with environmental change as compared with native plant species. The vulnerability of pastoralists is becoming severe due to the recurrent occurrence of climate change, due to both climatic and anthropogenic factors and caused the declining of carrying capacity of the rangelands (Sulieman and Elagib, 2012). Therefore, it is crucial to monitor and analyze the vulnerability of pastoral livelihoods of the pastoralists and develop adaptation strategies to reduce its impact both economic and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72557278

social aspects (Funk and Browny, 2006; Fensholt et al., 2012). Traditionally, many pastoralists have used the installation and movement of their herds near the trading center, areas accessible to forage and water points as an adaptive method when climate change like drought occurred (Morton, 2010; Thornton et al., 2009; Sulieman and Elagib, 2012).

Furthermore, the issues like government policies, frequent impact of climate change, the increase of both livestock and human population and other political issue from time to time limits this traditional movement of the pastoralists and this make the degradation of Teltele rangeland severe in combination with climate change factors. As a result, the Teltele livestock practice, quantity and quality practice were affected by chronic interactions stocking rate and environmental variables like rainfall, soil erosion and invasive plant species encroachment and its impact is not understood and quantified yet. In order to monitor the change in vegetation, NDVI data (focused on pixel change) in combination with climate data (rainfall and temperature) evaluation was mandatory (Gu et al., 2008). However, to date, there is no any documented study data about the impact of environmental vulnerability of Teltele rangeland and associated communities entirely dependent on the rangeland. This become one of a major gap for substantiable rangeland management through balancing grazing capacity and maintain livestock performance. So, the main objectives of this study were to: (1) analyzing spatial-temporal patterns of vegetation change due to eco-environmental vulnerability by using normalized difference vegetation index (NDVI) satellite data and climatic data, (2) evaluating the effect of change in climate parameters on livestock population dynamics and (3) assessing the strategies employed by the Teltele pastoralists to reduce impact of climate cahnge. The basic question of the study was, how does environmental change become a major cause for bush encroachment in the rangeland area? How encroachment of bush plant species effect on the rangeland productivity? Simply stated, the null hypotheses of this study were: (1) environmental change does not any role for rapid encroachment of bush plant, (2) Push plant species does not have any effect on rangeland forage productivity and (3) there is no any effect on livestock population due to environmental variability.

Materials and methods

Study site

The study was conducted in Teltele Woreda of Borana zone, Southern, Ethiopia (*Fig. 1*) which covered an area of 15,430 km^2 of which 68% (10,492 km^2) is rangeland. The site was selected because it is one of the most arid parts of Borana zone and therefore, pastoral communities in this region are the most vulnerable to climatic variability. It is located 666 km south of Addis Ababa, the capital city of Ethiopia. It lies approximately between 04° 56’ 23”N latitude and 37° 41’ 51”E longitude and the altitude are about 496 m to 1500 m, the maximum altitude of 2059 m. The annual mean temperatures vary from 28 °C to33 °C with little seasonal variation. The rainfall of the site is characterized as bi-modal. Which is the 60% of rainfall occurs from March to May, and 27% from September to November with high temporal and spatial fluctuations (*Fig. 2*) (Dalle et al., 2015). The potential evapotranspiration is 700-3000 mm (Billi et al., 2015). The soil in the study site includes, 53% red sandy loam soil, 30% black clay, and volcanic light-colored silt clay and 17% silt and the vegetation mainly dominated by encroaching woody species, and those that frequently thinned,

include *Senegalia mellifera*, *Vachellia reficiens* and *Vachellia oerfota* (Gemedo et al., 2005; Coppock, 1994). According to the latest 2015 national census report a total population of the study site was 339,460 in total (22/km^2) and of whom 179,518 men and 159,942 women. And 50,944 (15%) of its population are urban dwellers and the remaining 288,516 (85%) of the population are living in the rural area mainly on livestock rearing activity.

Dataset

This study combined multispectral satellite remote sensing data, in-depth fieldwork surveys and rangeland use policy analysis linked with rangeland vegetation change source. It seeks to compile some of the perceptions and experiences of local communities and individuals who are on the frontlines of climate change. The traditional weather patterns of the area, historical trends (1990-2015) in climatic variables (temperature and rainfall) collected from Ethiopian meteorological authority (EMA, 2015) and using geographical information system (GIS) and remote sensing (RS) data in order to analyze eco-environmental vulnerability. To monitoring the spatial and temporal variation in vegetation in the study area, we used the annual average of third Generation Standard Difference Vegetation Index (NDVI3g) data (1990-2015). Then from the general precipitation, temperature and NDVI data derived from the Global Inventory Modeling and Mapping Studies (GIMMS) with 8 km grid resolution of Ethiopia, we resample our study area to digital elevation model of 300 m resolution in order to get our focusing site data with high resolution, because we only need the satellite data of our study (Teltele) rangeland site (*Fig. 3*). For NDVI grid cell values we simply took the maximum, minimum and an average annual mean value in order to reduce disturbance in the trends, such as those attributable to bare soil and sparsely vegetated areas (Slayback et al., 2003; Wang et al., 2011). Vegetation maps of the Teltele district in 1990-2015 were obtained from the remote sensing data with spatial scale 1:100,000. The Landsat TM imageries acquired in five-year interval 1990-1995, 1995-2000, 2000-2005, 2005-2010, 2010-2015 and also changes from 1990-2015 were used for range land vegetation pattern and degradation assessment and the characteristic of Landsat used for analysis was described in *Table 1*. These years were chosen because of the availability of data, the quality of the images, and in order to compare the changes with in equal time intervals. And also, further, verification was done through interviews and semi-structured focal group discussions with the local pastoral community and stakeholders for the accuracy of the rangeland current status and vegetation degradation images analyzed by using ArcMap 10 software.

Socio-demographic profile of the respondents

To understand the level of pastoralists awareness on the changing climate, the types and nature of the impacts, the changing climate variability has had on the livestock production, the coping strategies that pastoralists have employed in reaction, as well as the existence of external support to help the pastoralists adapt to the climate change impacts was collected through both informal and formal group discussion with pastoral community, individual and key informant. Interview questionnaire were composed of both structured and unstructured questions and basically focused on the issues such as: How climate change trend looks like on the study area, its influence on the grazing lands and local communities, the possible causes, the main problems of climate change on the range land, traditional coping mechanisms and extension service provided against these condition were explored. The discussion was used as a means of creating awareness in the pastoralist's community, generating ideas regarding issues related to rangeland management and coping mechanisms. In order to obtain a representative sample data for the study site, both stratified and clustered sampling methods were applied for all pastoralists and stakeholder selection. Since, the pastoralists commonly live in scattered way, rather than nuclear clustering of households was necessary.

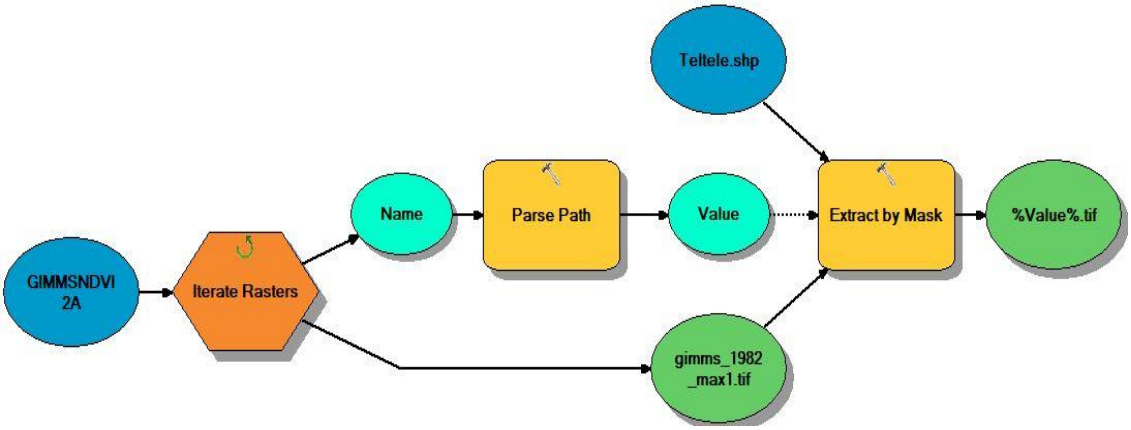

Figure 3. *Schematic representation of the model we used to extract and resample our study area data*

Table 1. *Characteristic of Landsat used for LULC change analysis*

Data	Year of acquisition	Bands/color	Resolution (m)	Spectral resolution/bands
Landsat Thematic Mapper (TM)	1992, 1995, 2000, 2005, 2010, 2015, 2019	Multi-spectral	300	Band 1-5: 0.45-1.75 Band 6: 10.4-12.5 Band 7: 2.08 – 2.35

A total of 104 (69 males and 35 females) head of households were interviewed. From this key informant purposefully selected based on age (>35), experience, training participation and way of better life based on the recommendation of the local people and stakeholders (n = 20 in total, 14 males and 6 females) with addition of 4 government official worker stakeholders (3 males and 1 females) from different sectors (livestock, agriculture, tourism and meteorology), and the remaining 80 (52 males and 28 females) were selected randomly based on the our clustering. The total number of sampling population was mainly depending on our time and budget, but we tried to made it representative of the study site. Such approaches have proven effective with Ethiopian pastoralists like Teltele because these people place very high cultural value on livestock and have well developed mental skills to track animal inventories (Solomon and Coppock, 2002). The trends of the priority livestock (cattle, goat, sheep and camel) population dynamics and production performance indicators, such as birth rates, death rates and off-take rates for each livestock species, was collected from statistical abstracts of Teltele district, southern Ethiopia for the last twenty-five (25) years. The general framework methodology we adopted to identified the change of precipitation, temperature and the vegetation index change using NDVI was summarized in *Figure 4*.

Analysis of eco-environmental vulnerability change trend

In order to understand the cause of vegetation change in the study area, the general trend of environmental viability was assessed through both interview and group discussion with the local communities in addition to the satellite data. Spatial analyses of vegetation, precipitation, temperature and NDVI change were done using ArcMap

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72557278

10.3.1. Study site statistics function was used to extract NDVI values of the Regions of Interest (ROIs) from corresponding vegetation types for all months from January to December for the years 1990-2015. The data were coded, tabulated and analyzed using Microsoft excel and SPSS. The data collected from the officials and key informants were analyzed through descriptive narration and also using SPSS based on the research questions. Then, the Eco-environmental Vulnerability Integrated Index (EVSI) for each category was calculated using *Equation 1*.

$$EVSI_j = \sum_{i=1}^{n} P_i \times \frac{A_i}{S_j} \quad \text{(Eq.1)}$$

In this formula, n = is the number of degradation level (in our case n = 4, that was described under result section in *Table 3* and *Fig. 9*), EVSIj = the EVSI in unit j, A_i = the occupied area of degradation level i in analysis unit j (area of pixel for each level or assign number), Sj = the area of analysis unit j (total area of analysis), and P_i = is the leveled or assign number value of level i (in our case i = 1, 2, 3, 4) (Gunnula et al., 2011; Yang et al., 2016; Xu et al., 2010; Ainong et al., 2006).

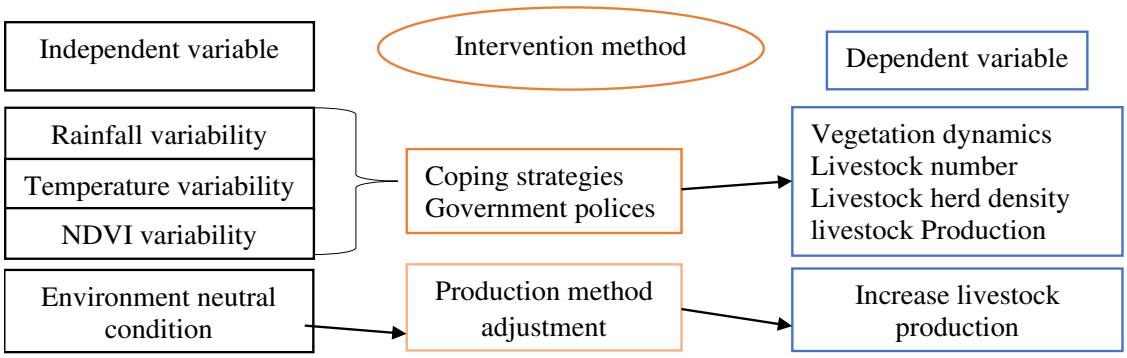

Figure 4. *Conceptual framework for this methodology (developed by Author, 2020)*

Results and discussion

Socio-demographic characteristics of the respondents

The respondents' gender, occupation and level of education were some of the main demographic feature's that the authors considered for this study to remove the biased from our data.

During data collection we also tried to considered the gender proportion into account within the participants. But, in the area and in the country in general, the activity of field work including farming, livestock rearing and other outside activity mainly performed by male household, whereas, females are mostly focused on housework including keeping children, prepared food and others. As a result, the experience and knowledge about rangeland status mostly obtained from male households. However, we tried to included and balance gender involvement during our data collection i.e. 66% of males and 34% of females of the total number of participants. This distribution made it possible to understand the perception and coping method of adaptation to climate vulnerability of male and female pastoralists. Then, the level of education is one of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72557278

basic factors on the socio-economic practice within a family and as we have seen from *Figure 5,* the majority of pastoralists (78%) were illiterate followed by primary education (11%) level. This is because of the educational system was still not well exercised and adapted, due to lack of awareness about the value of being educated and these leads the community did not enforce to accesses the infrastructure with in the pastoral community based on the data obtained from the respondents. And also, to some extent, the situation has occurred in some way to other parts of the country. As a result, most of the livelihood community that depends on livestock occupation has been dispossessed, and this was the major factor that caused most of the pastoralists source of income to depend on livestock rearing (66%) followed by running their own business beside it (19%). Considering, their educational level, our questioners were focused on their experience observation and impacts based on their expectation, rather than scientific explanation.

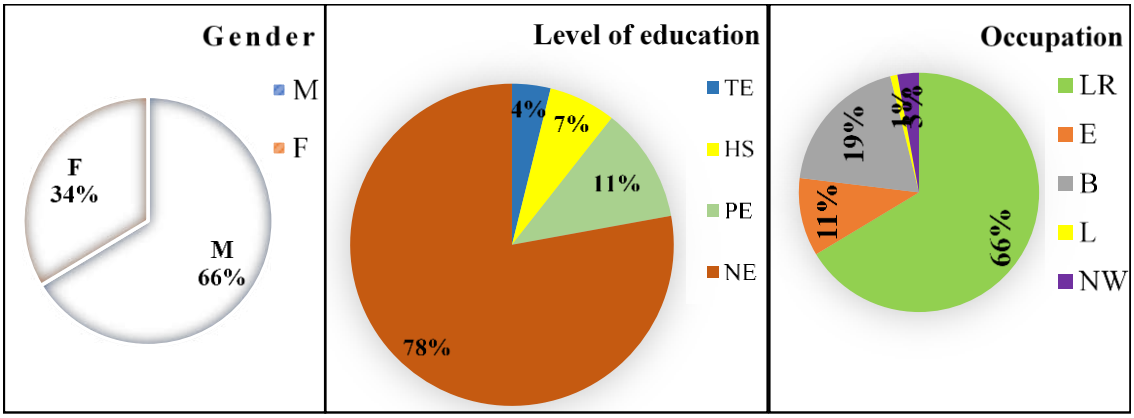

Figure 5. *Distributions of respondent's demographic characteristics. (M = male, F = female, TE = tertiary education (college and university), HS = high school, PE = primary school, NE = not educated, LR = livestock rearing, E = employment, B = business, L = labor work, NW = Not known work)*

Analysis of eco-environmental vulnerability

Trend, pattern and impact of environmental vulnerability based on respondent's Perception

In order to understand the trend, pattern and followed impact of climate change (mainly rainfall and temperature) from their experience and daily activities, respondents were asked the following basic questions: (1) Is there any change observed in the recent year? (2) What was the nature of the change? (3) what was the impact of the change? And (4) What is the possible reason that cause the change? Their ideas and response were described in *Figure 6* and *Table 2*.

From *Figure 6* we clearly understand that majority of the respondents confirmed the occurrence of climate change (93.3 and 89.4%), trends of change (97.1 and 92.3%) and its associated impact (98.1% and 84.6%) for both rainfall and temperature respectively. Respondents mentioned that climate change was significant impact on forage production and water availability in the rangeland, that affected their livestock health and caused death and a decrease in the number and of productivity, which had a direct effect on their livelihoods.

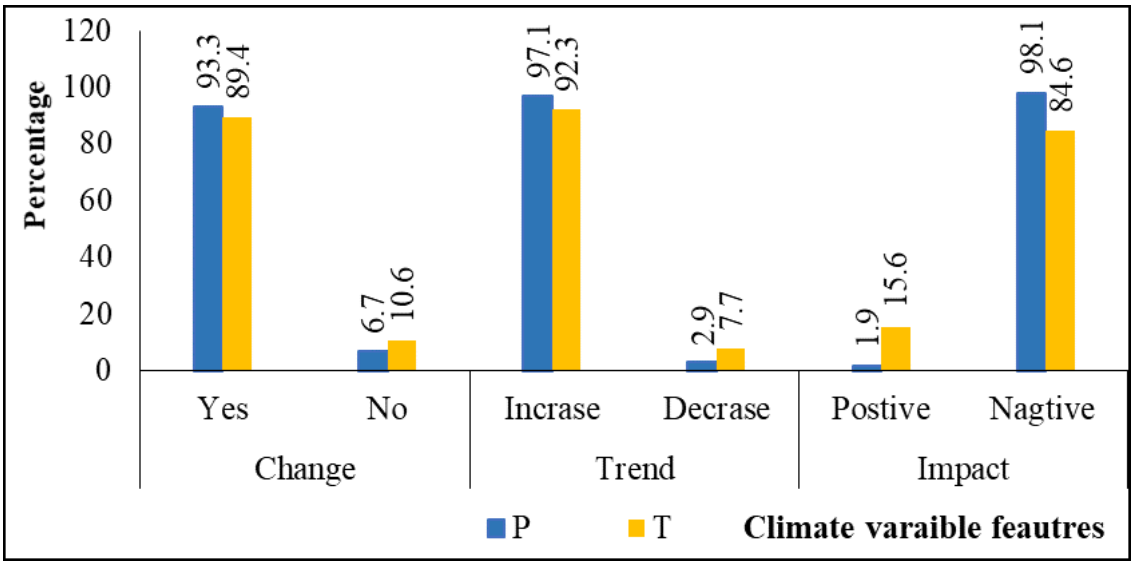

Figure 6. *Respondents data with trend, pattern and impact of eco-environmental vulnerability. P = precipitation, T = temperature*

Table 2. *Drivers that cause climate change in Teltele rangeland*

No.	Possibilities	Number of respondents (n)	Percentage (%)
1.	Drought	24	23.0
2.	Increase population number	16	15.4
3.	Poor social- interaction	7	6.7
4.	Bush encroachment	35	33.7
5.	Gods plan and nature	6	5.8
6.	Government policies	11	10.6
7.	Insects and disease	5	4.8
	Total	**104**	**100**

With regards to the major drivers of impact of climate change on vegetation in Teltele rangeland, the bush encroachment ranked as the primary reason (33.7%), followed by drought (23%) and increase of the population both human and livestock in the district (15.4%) without additional land provided (*Table 1*). Government policies have also had their own impact on the livelihood of pastoralists in Teltele, which promote transformation of rangeland into cultivated land and restrict the movement of pastoralists who were traditionally used to coping climate change impact. Not only this but also government policies also caused for the introduction and expansion of invasive plant species on the rangeland area due to a reason for watershed activates before scientifically assessed its long-term impact. Most of the invasive bush species on Teltele rangeland introduced and expanded due to the above-mentioned reason. And also, the policies restricted from eradicated all invasive plant species from the rangeland by the local communities in the name of forest deforestation activates and punished the one who participated on such activity. Further, free movement of pastoralists for searching food for their livestock from one area to another area was restricted and enforced them to spent in specific grazing area for a long period of time and caused both degradation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72557278

and scarcity of forage for their livestock. Both productivity of rangeland and their livestock decline and faced for poverty and scarcity of food. As a result, such government policies on the study area became caused for climate change and degradation of rangeland because of rapid encroachment of non-native spices. But there is still a big gap under the term of climate change, rather the pastoral community thought that it was due to God's plan and to the nature which could be intended to punish us. This was an indicator of community's low awareness of the climate change with which the whole world is grappling with and our data are consisted with the data reported by Han et al. (2008).

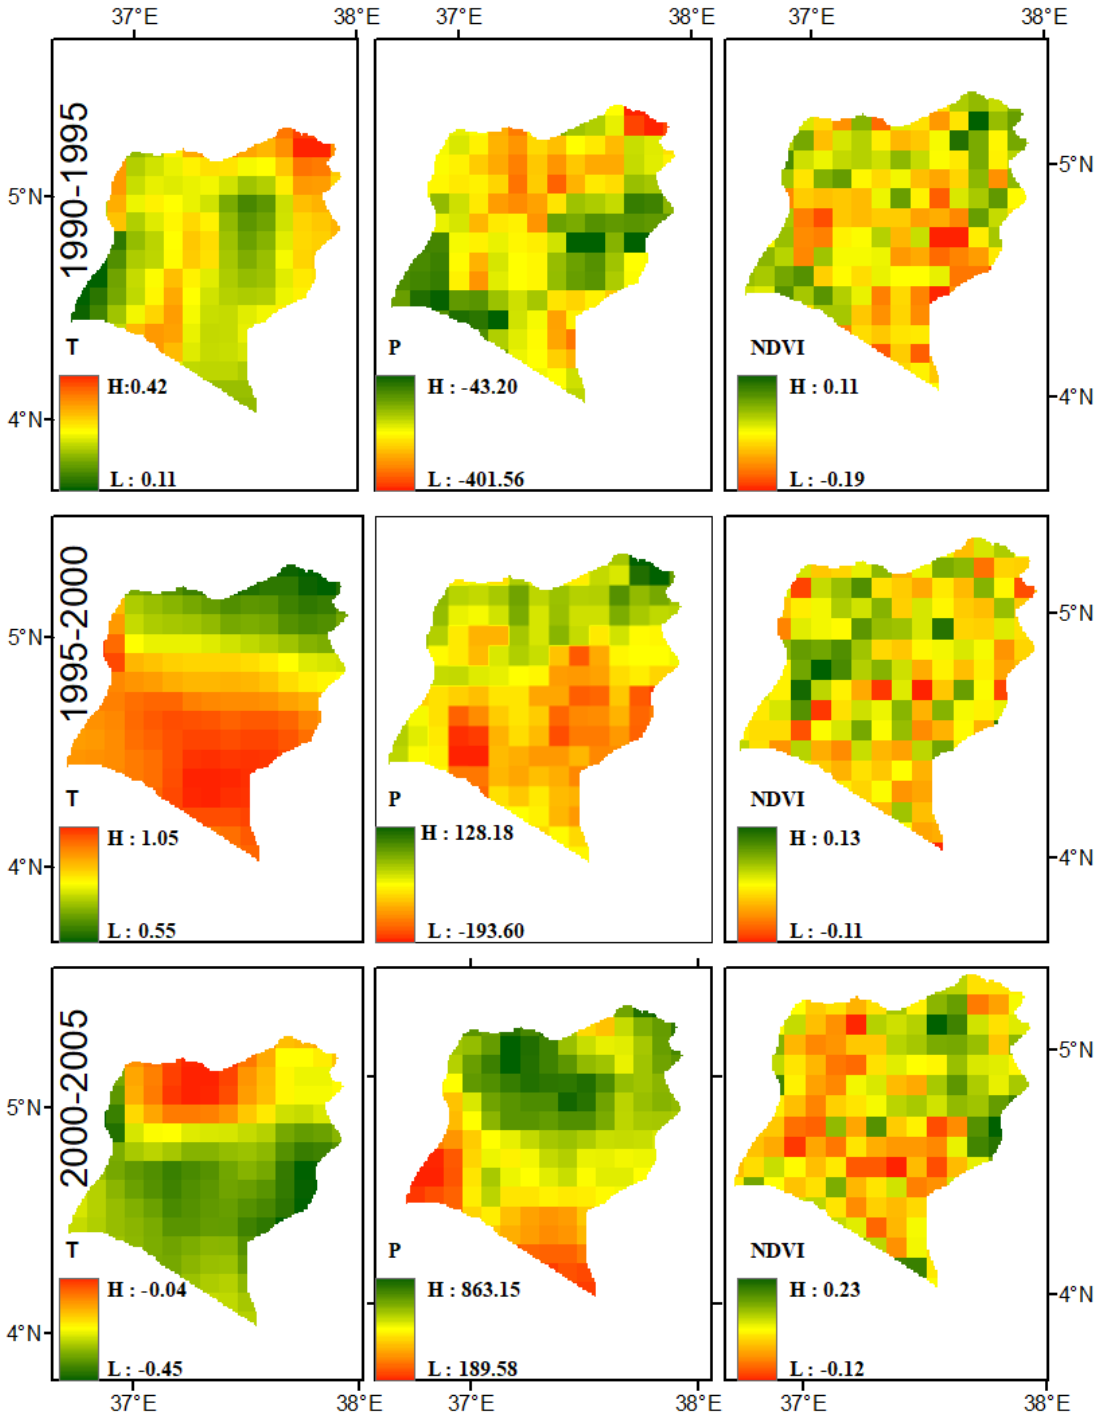
Effect of climate change on vegetation pattern

Among the major driving factors of vegetation degradation in arid and semi-arid rangeland area like Teltele, a frequently occurrence of climate change, mainly a decrease in rainfall pattern and increase of temperature. The remote sensing data from these results indicated that the annual temperature was going to increase on an alarming scale and on the contrary annual rainfall rate shows a decline trend (*Figs. 7* and *8*). This told us in the vegetation of arid and semi-arid rangeland that the eco-environmental vulnerability was high and resulted in vegetation degradation and followed the decline of livestock population dynamics and faced a change in the pastoral livelihoods. Then, our result directly related to the data reported by Lin et al. (2013). In the pasture rangeland of Teltele, the frequency of eco-environmental vulnerability creates favorable conditions for rapid encroachment of invasive bush plant species which compete with the native grass species. And the grazing rangeland area was becoming changed to bush covered non-grazing area (*Fig. 7*) and leads to scarcity of forage for livestock. Comparing the level of degradation of vegetation dynamics from 1990-2015, the significant open degraded area was observed in during the study period from 1995-2000, which major part of area were bare due to high drought occurrence especially in 1999 what is called El Niño occurred (1.05 °C increasing was recorded), but in 2010-2015, this open degraded area was becoming encroached by bush plant species and change to green area. The vegetation greenness changed from 1990-2015 showed appositive value. From this we can understand that in Teltele rangeland encroachment rate of invasive bush plant species was significantly rapid due to eco-environmental vulnerability of the area. Currently, this is the big challenge for pastoralist community to covered all rangeland site and also their farming area.

From *Figures 7* and *8* we can clearly understand that both precipitation and temperature variability had significant impact on the rangeland vegetation index in Teltele. The trend of temperature change from 1990-2015 showed a positive value both the highest (1.32 °C) and lowest (0.83 °C) recorded value. The rainfall pattern also showed both positive highest value (206.14 mm) and negative lowest value (-190.10 mm) and this told to us the maximum amount of rainfall showed an increased pattern and that cased for flooding and caused for rangeland degradation. Whereas, the lowest yearly recorded rainfall showed a decline trend and since lowest rainfall is very essential for vegetation growth and also for recharge ground water table that is important for increasing both water and forage availability for livestock. But the normal rainfall distribution became decline and this is the real cause for degradation in Teltele rangeland happened currently. In the period between 2000 and 2005 the rainfall distribution was recorded highest both yearly maximum (863.15 mm) and minimum (189.58 mm) and the highest flooding that highly degraded the rangeland area was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72557278

recorded and at the sometime encroachment of bush plant species got favorable reached highly occupied most part of the rangeland (highest NDVI value = 0.23) and less competition from native plant species (*Fig. 7*). The net change of both highest and lowest recorded temperature value in Teltele rangeland from 1990-2015 was showed significantly increasing pattern. The mean highest rainfall value trend also showed an increasing and this up normal maximum rainfall amount caused for rapid degradation of rangeland soil and other resource, but the normal or minimum rainfall distribution showed a decreasing trend. Therefore, net changing trend of rangeland vegetation greenness also showed variation with related to highest and lowest value.



http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72557278

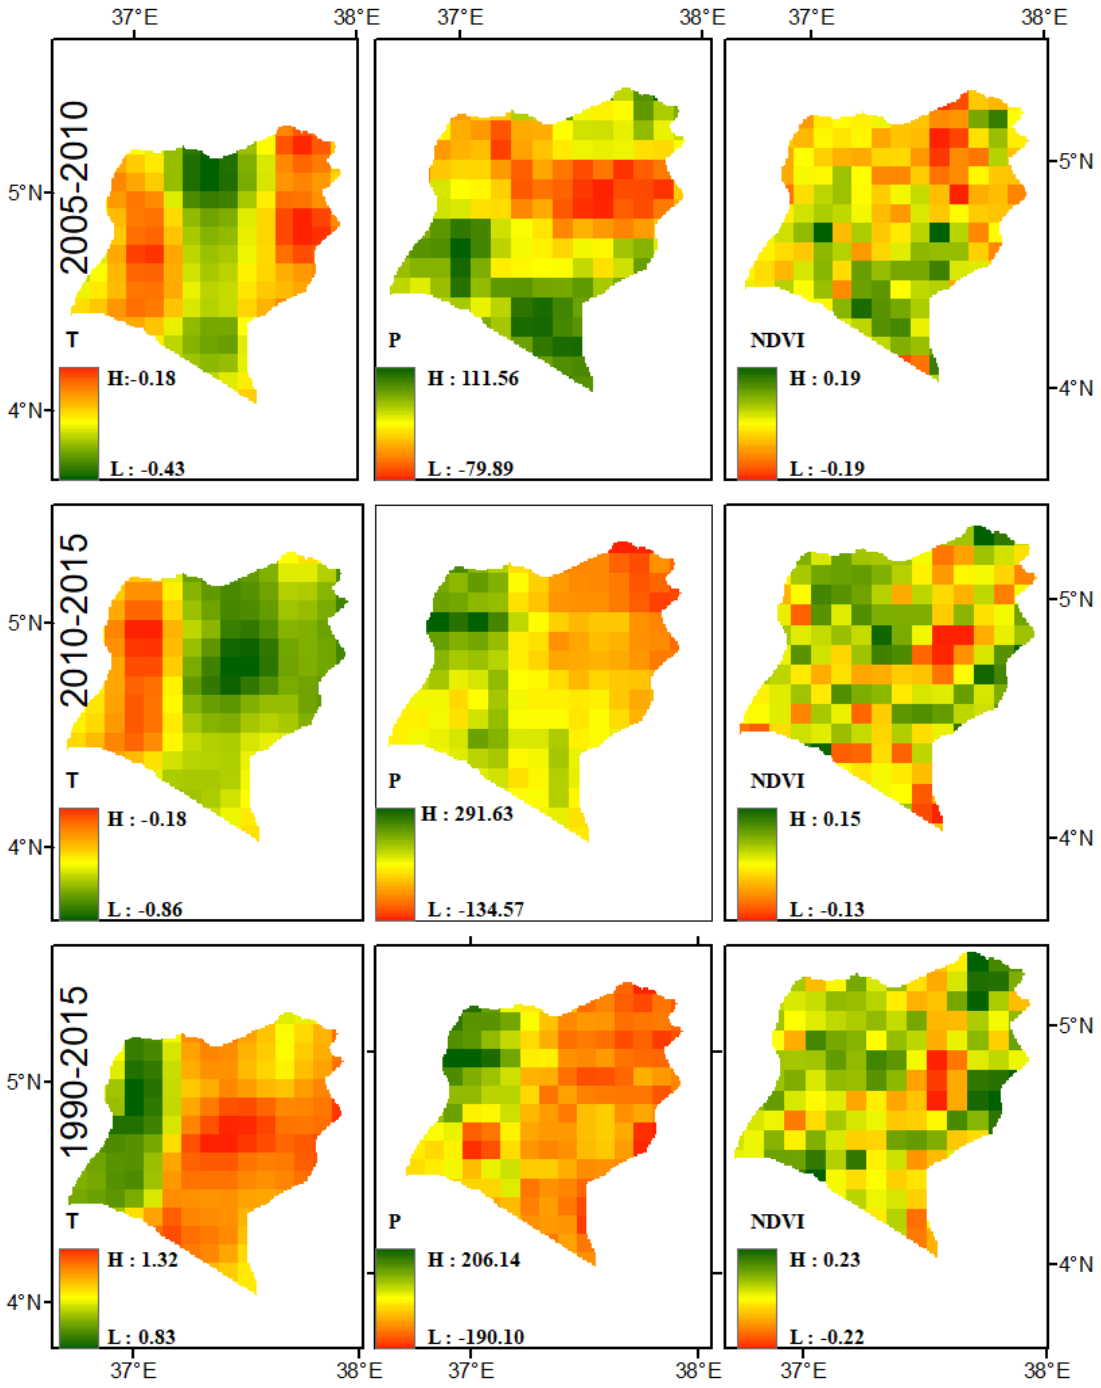


Figure 7. *Temperature, precipitation and NDVI change trends for Teltele rangeland from 1990-2015, T = temperature, P = precipitation, H = high value, L = low value*

The highest NDVI greenness value highly related with encroached bush plant species that occupied major area and easily detected by satellite data, showed appositive value (0.23) indicated that rapid encroachment of non-native spices on the Teltele rangeland. Whereas, the lowest NDVI value showed a decreasing trend (-0.22) and this highly related with the grazing grass species and showed a decline due to the mentioned eco-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72557278

environmental factors. This variation depends on the fluctuation patterns of climate change (rainfall and temperature). Mostly, if the temperature was low and rainfall was high (2000-2005), the rangeland vegetation index (NDVI) value was high. Since, the rangeland vegetation phenology was high during the periods of heavy rainfall. The general trend of the vegetation index dynamics of the Teltele rangeland with respect to the slope analysis, was calculated based on *Equation 1* given by Yang et al. (2016) and Xu et al. (2010) using the mean NDVI value. Based on the calculated result, the Teltele rangeland had a positive (0.0055) slope value. Rangeland with a positive slope value indicate an increasing trend, while those with a negative slope value indicate a decrease trend of vegetation greenness (Cai et al., 2014). Climate change is the main driving force both either directly and indirectly for change of vegetation index, especially in the arid and semi-arid rangeland like Teltele. For instance, for rapid encroachment rate of bush plant species climate impact is the major root cases.

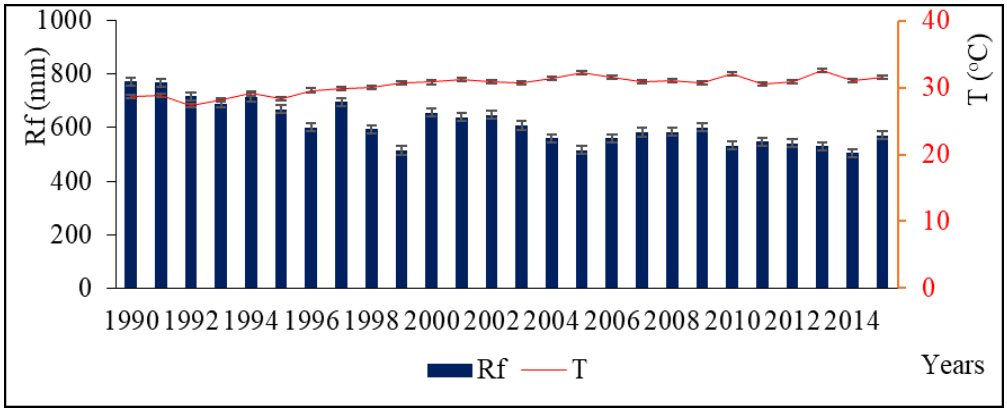

Figure 8. *Annual mean (±SE) rainfall and temperature for Teltele rangeland from 1990-2015, Rf = rainfall, T = temperature*

However, most of eco-environmental vulnerability studies focused only on the numerical change value (Amting, 1997) without considering the spatial variation of the rangeland. From our result, we can understand that the eco-environmental venerability of vegetation dynamics varies according to the slope variation. A rangeland sites with higher slope or elevation value and sites with flat were not equally impact on climate change. This means that slope steepness influences on the disturbance of livestock and human activity and the disturbance was highly observed at flat rangeland site. In addition, a combination effect of climate change was less at the highest slope, that is why the vegetation dynamics was shown a better rate at highest elevation site. The human activity and livestock disturbance in combination with climate change significantly increased the rate of rangeland degradation and showed high vegetation index change. Our result is entirely in agreement with the data reported by Potapov et al. (2008), Yi et al. (2014) and Herrmann et al. (2005).

Vulnerability grade

To scale up the observation of degradation level of our study, we used the histogram as a graphical tool to explore the statistical distribution of the classes and clusters in the attribute space (Apan, 1997) and the axes represents our categorical interval NDVI values. Taking the year from 1990-1995 as our baseline for classification since during

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72557278

this year interval, we observed the maximum level of degradation as a result, we used it as our reference to classify our interval scale (*Fig. 9*).

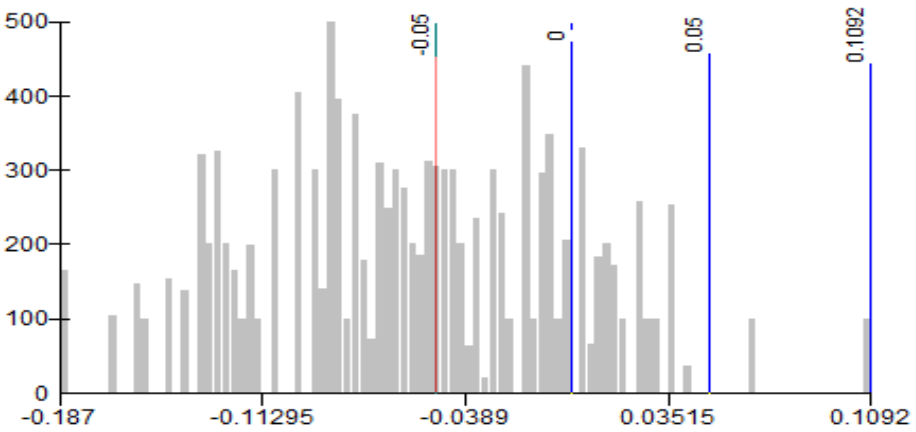

Figure 9. *Degradation distribution histogram of the integrated index of eco-environmental vulnerability from 1990-1995*

Based on the NDVI value classified in *Table 3,* the eco-environmental vulnerability integrated index for each year interval (combined in five years) the degradation level of Teltele rangeland was clearly analyzed and generate based on remote sensing data (*Fig. 10*).

In order to understand the eco-environmental vulnerability change trend in Teltele rangeland area, the value of EVSI was calculated based on *Equation 1* and described in *Table 4*.

Table 3. *Eco-environmental vulnerability classification interval in Teltele rangeland (based on Fig. 9)*

Degradation level	Assign number	NDVI value	Level characteristics
Over degradation	1	< -0.05	Open bare degraded rangeland area
Moderate degradation	2	0-(-0.05)	Relatively the bare degraded rangeland area sparsely covered by bush plant species
Moderate improvement	3	0-0.05	almost 50% of the degraded bare rangeland area covered by bush plant
High improvement	4	> 0.1092	More than 75% of the degraded bare rangeland area covered by bush plant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72557278

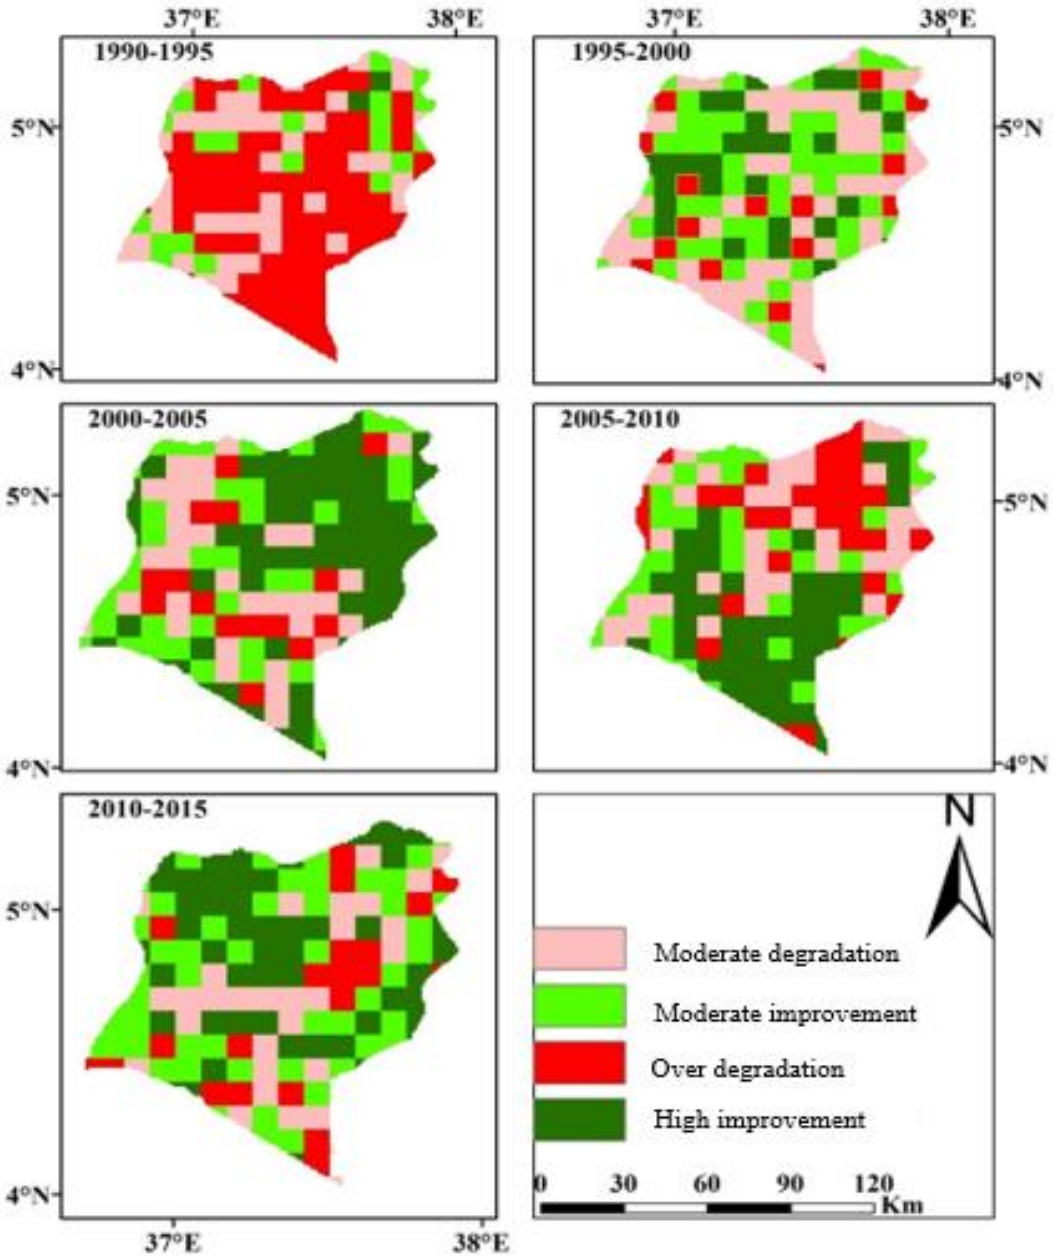

Figure 10. *The degradation distribution of eco-environmental vulnerability level in Teltele rangeland from 1990-2015*

When we have seen the general trend of eco-environmental vulnerability from *Table 4,* the rangeland situation between the time interval from 1990-1995 with an EVSI value 1.59 showed a better status from encroachment of bush plant species than the vulnerability status from 1995-2000, 2000-2005, 2005-2010 and 2010-2015 which have an EVSI value 2.61, 2.91, 2.67 and 2.8 respectively. The higher EVSI value indicated the more serious impact of eco-environmental vulnerability and the lower EVSI value indicated that impact of eco-environmental change is not that much significant (Ainong et al., 2005). The majority of rangeland area occupied by non-native bush plant species that is highly competent with the native grass species and caused rapid decline of forage biomass in our Teltele rangeland.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72557278

The pattern of degradation level or the rangeland area occupied by the invasive bush plant species looks like: (1) from 1990-1995, level 1 degradation was highest (57%) followed by level 2 (27.2%), level 3 (14.2%) and level 4 (1.6%). This indicated that the major degraded Teltele rangeland area during from 1990-1995 was bare area and was not occupied by the current rapid encroached bush plant species, (2) from 1995-2000 the major bare degraded area of the rangeland encroached by the bush plant species and the degradation level goes from level 1 to level 2, i.e. level 1(10.7%), level 2 (35.7%), level 3 (33.5%) and level 4 (20.1%) and this indicated that majority of bare area replaced by encroached non-palatable plant species, (3) from 2000-2005 the major encroachment rate (level 4) of bush plant species was observed (40.7%) followed by level 2 (24.1%) and level 3 (23.4%). This is because of the occurrence of a severe drought called El Niño in 1999 which facilitates the encroachment rate of bush plant species while the native grass species was highly degraded, due to effect of drought, high competition with those encroached plant species and overgrazing, (4) from 2005-2010, the encroachment rate showed an increasing trend and the local community tried to adopt the intervention techniques to reduce the degradation impact of bush plant species like mechanical cutting and others. That is why the level 1 bare area showed an improvement as compared to 1995-2000 and 2000-2015. The area coverage (in %) of each degradation level was in level 1(19.6%), level 2 (25.5%), level 3 (20.8%) and level 4 (34%), (5) from 2010-2015 the level of encroachment trend of bush plant also showed an increasing trend, level 4 (31.8%), level 3 (32.9%), level 2 (20.9) and level 1 (14.4%). Thus, this was due to the drought (El Niño) occurrence of in the Teltele rangeland during 2014 that offered an opportunity for the rapid encroachment rate of bush plant species and high degradation of the native grass species in the study area.

Livestock population dynamics

The livestock population dynamic data was collected from the district livestock office and from the respondents based on type, breed, age, sex and purpose possessed by the local communities from 1990-2015. In order to easily manage the data during analysis we, simply took five (5) year interval data (i.e. 1990, 1995, 2000, 2005, 2010 and 2015 data) and tried to see how the change looks like.

The livestock population trend from 1990-2015, showed a decline rate across in almost all livestock species found in the study area, with the exceptional of the donkey (+ sign indicates that population increment from year to year) as we have seen from *Table 5*. Then, the reduction rate was high between 1995-2000 and 2000-2005 as compared to data from other years for all species. Because of the high incidence of drought (El Niño) in the study area in 1999 and high disease occurrence during 2004 in the study site respectively, there was a loss of more livestock population through die, due to lack of forage source, water availability and diseases. The expansion of farming practices is also another major cause of declining numbers of livestock, because of loss of pasture area and this also supported by government policies which state that every livelihood should keep their own livestock in his/her own grazing site near to his/her settlement area, and not allocate more communal grazing land and mobilization from one area to another for grazing. Thus, the government has divided the communal rangeland area for independent young community for farming practice, therefore, the number of livestock per household level should be reduced. Donkey species became increase in a unique manner compared to other species found in the study area, which is also due to the impact of climate change. During the drought period the pastoral

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72557278

community collected forage and water from far distance for their livestock and for themselves. And for this purpose, donkey used as the main transportation method which is main cause for the increment of their number. From 1990-2015, the net change of livestock number was 29%, indicating that a 29% reduction of livestock number was observed as compared to the livestock population number of 2015 with 1990.

Table 5. *Total number of each livestock species from 1990-2015 in Teltele*

Livestock population dynamics across household

Livestock population dynamics in average, across the total households found in Teltele district was shown in *Figure 11*. In order to calculate the livestock number per household, we collected the total human population data from the national census reported of Teltele district for the mean value of each 5-year interval 1990-1995 (30,156), 1995-2000 (38, 412), 2000-2005 (49,480), 2005-2010 (57,609), 2010-2015 (70,501) and divided the total number of livestock population corresponding with each year. Both the total livestock number per household level and pattern of total population number within the district was showed sharp decline trend. Livestock holdings were laid with an average of 23.44, 17.6, 11.7, 9.3 and 8 head per household from 1990-2015 each five-year interval respectively, with a net decline of 65.9% overall. This is due to direct and indirect impact of climate change, like the drought that faced the livestock for forage and water scarcity and caused for death and un planned selling of the pastoralist to their livestock to cope up from the impact. Our data directly linked with the data reported by Solomon and Coppock (2002) stated that cattle deaths were mainly due to malnutrition and starvation, with only a few due to disease, predation or other factors because of climate change impact in Borana rangeland with part of our study site.

Association of rainfall variability with livestock dynamics

The variability of rainfall in combination with other factors had a direct impact on the livestock population in the study area (Bao and Wang, 2000). The frequent fluctuation in both temperature and rainfall has also become an emergency cause of insects and other related factors that cause disease and loss of livestock in Teltele district.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72557278

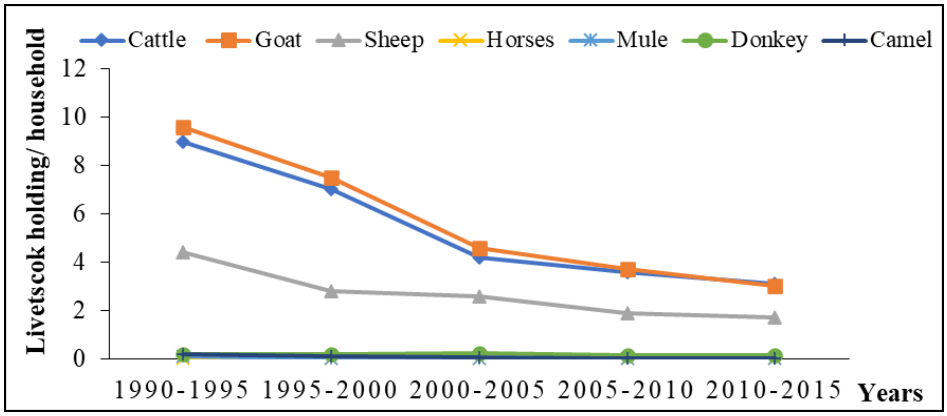

Figure 11. *Mean value of livestock population dynamics (average number of head/household)*

As we see in *Figure 12,* livestock population decreased with the decrease in rainfall, but failed to show a significant relationship with mean annual rainfall, because of the coping strategies taken by the pastoralist community. Our result was found to be consistent with the data reported by Stige et al. (2006), Angassa and Oba (2007) and Alemayehu and Fantahun (2012). Since livestock population in the Teltele district depends mainly on the natural resource (both forage and water) found in the communal grazing area, this makes the impact of rainfall significant in combination with other factors.

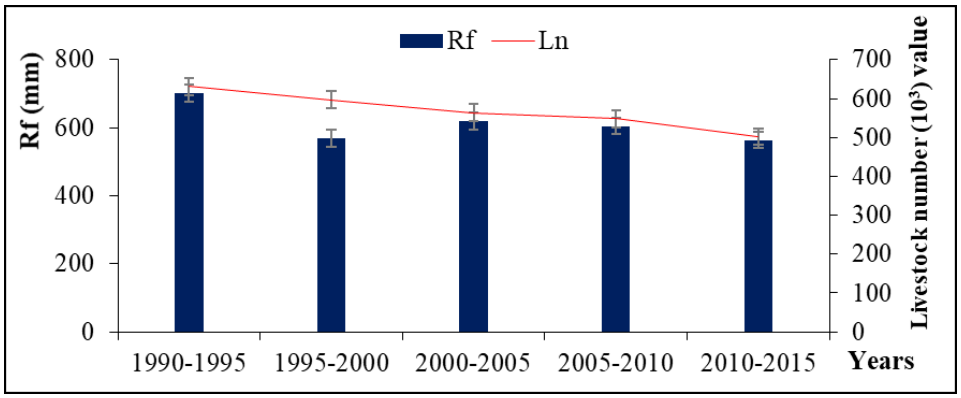

Figure 12. *Association of mean (±SE) annual rainfall and livestock population number, Rf = rainfall, Ln = livestock number*

Correlation analysis of precipitation with grazing livestock population number

Amount of precipitation was a major impact on the productivity and general vegetation status of rangeland and highly effect on the health of the grazing site. And also, the number of livestock highly rely on the amount and distribution of precipitation both directly in indirectly. As a result, perception and livestock number had showed a significant positive correlation to each other (*Fig. 13*).

The linear regression correlation trend showed that precipitation and livestock population number had significantly ($R^2 = 0.5934$) positive relationship. Further, we can understand that, higher rangeland rainfall value confirmed better biomass production and used to satisfy the forage demand of grazing animal and resulted high number of grazing livestock population.

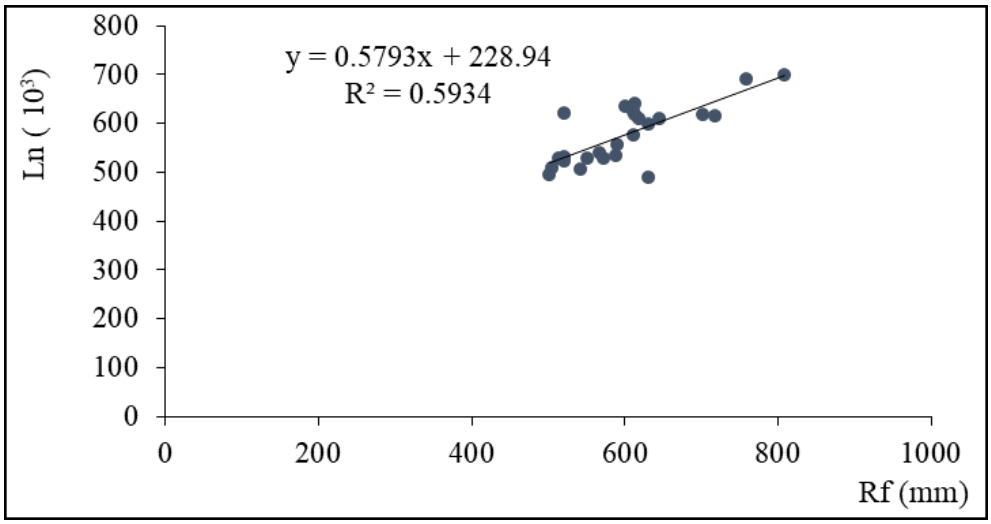

Figure 13. *Correlations between rainfall and livestock number at Teltele rangeland, Rf = rainfall, Ln = livestock number*

Coping strategies to climatic variation on the study site

The techniques used by the local community to adapt to climate change, survive or reduce its impacts and overcome this difficult condition depend mainly on factors like: rangeland condition, livelihood income background, educational level, institutional and social network, capacity and accessibility of infrastructures such as market, road and other services (IPCC, 2007). Due to the lack of accessibility and awareness in the Teltele pastoralists community, the implementation of coping strategies was weak compared to other parts of the country. The major coping techniques listed by the local community for each possibility of climate change and how many of them applied that technique based on the respondent's data were presented in *Table 6*.

The respondents mentioned the above coping strategies listed in *Table 6*, that were implemented during climate change, mainly when strong drought (El Niño) occurred, that caused for a great impact on both the livestock and human life. During drought time the priority action taken by the pastoralists were migration or mobility to search better water and forage (77%), Sale their livestock (69%) and transport water and forage from remote area (60%) respectively. To rehabilitate rangelands infested by bush encouragement clearing or thinning the area (87%), diversified the livestock that have the capacity to eat the bush plant (69%) and used as a source of energy and income (57%) were among the priority action taken by the local communities based on the respondents data. Peace building practice through the local elders (96%) was also the primary solution used by the community to solve conflict or poor social-interactions when happened. Livestock diseases were also another challenged issue that was happened linked to climate change. The use of traditional medicine in combined with the modern (94%), was the priority action taken by the local community followed by isolating the infected animal from the herd and made it stay at home for follow-up. Moreover, to avoid further infection of the disease, selling livestock was prohibited and taken as the next strategies that was implemented in Teltele district pastoralist during climate change. Our result was highly in line with the data reported by Kgosikoma and Batisani (2014).

Table 6. *Coping strategies used by the local communities to reduce climate impact*

No.	Drivers	Coping techniques used by the community	Frequency (%)
1	Drought	Migration or mobility to search better water and forage	77
		Conserving water through wells	38
		Transport water and forage from remote area	60
		Enclosing pasture land	39
		Sale their livestock	69
		Using water supplied by NGO Diversified their livestock to tolerate drought	29
2	Bush infestation	Clearing or thinning	87
		Burning the rangeland	24
		Used as source of income (charcoal)	57
		Herd diversification	69
3	Poor social interaction	Engaging peace building through local elders	96
		Assign local guards and take immediate action	29
		Developed traditional assets	73
		Apply government policies	75
4	Insects and disease	Using both traditional and modern medicine	94
		Isolating sick animal from the herd	76
		Reporting the case to the government	34
		Dealing with market bans and sell the livestock	48

Conclusion

Our study focuses on the impact of the eco-environmental vulnerability of the Teltele rangeland and evaluates the current situation of the encroachment of bush plant species. The eco-environmental vulnerability was analyzed using NDVI3g time series data, rainfall and temperature records. As revealed in this analysis, the variation of vegetation greenness, changes through NDVI value showed a direct correlation with the variability of rainfall and temperature. This means, that if the mean value of temperature was high, the NDVI value showed a decline, whereas if the mean rainfall value was high, the NDVI value showed high value. Thus, this tell us there is a significant relationship NDVI positively with rainfall and negatively with temperature. However, during the time when high rainfall was occurred and flooding, rangeland area became degraded and NDVI value also not significantly high related with amount of rainfall, due to consequence of degradation instead of greenness the rangeland site. Further, the rangeland vegetation showed a better status, when the rainfall was at normal standard and not caused for further degradation in the form of flooding compared with dry season. The degradation level of Teltele rangeland showed an upward trend between 1990 and 2015 mainly due to the encroachment of invasive bush plant species that almost occupied the entire rangeland area. The frequent fluctuation of both rainfall and temperature creates an appropriate condition for a rapid encroachment of invasive bush plants and, on the contrary the native grass species degraded at an alarming rate and this is the major challenge for semi-arid rangeland in Africa including Ethiopia now days. Further, the livestock population in Teltele area decreased from time to time, for this encroachment of bush plant species due to frequent drought as the primary factor based

DOI: http://dx.doi.org/10.15666/aeer/1805_72557278

on the data obtained from both NDVI and the respondents. The local pastoral communities have enough information on the level of impact of eco-environmental vulnerability and practice different coping strategies to further reduce the influence on their livelihoods, but the scientific understanding still shown a gap and this is due to the lack of awareness. Therefore, based on our results, we highly recommend that the design the scientific management techniques for eco- environmental vulnerability and awareness within the local community be the priority for further studies.

Acknowledgements. The authors wish to thank the University of Chinese Academy of Science and CAS-TWAS fellowship program that provide funding and the PhD Scholarship for the first author. They also acknowledge the African Great Green Wall Adaptation Technical Cooperation Research and Demonstration (2018YFE0106000), Science and Technology Partnership Program, Ministry of Science and Technology of China (Grant No. KY 201702010), and International cooperation and Exchanges NSFC (Grant No. 41861144020) financial support to do this paper and the CAS Key Technology Talent Program support, also our great thanks go to the local community and stakeholder of the Teltele district for giving us the basic information that are still the challenge for them for our next research step. Once again, Yabello Pastoral and Dryland Agricultural Soil Research Center deserve many thanks for providing us the laboratory and other facilitates while conducting our experiment.

Funding. This study received financial support from CAS-TWAS fellowship program and African Great Green Wall Adaptation Technical Cooperation Research and Demonstration (2018YFE0106000), Science and Technology Partnership Program, Ministry of Science and Technology of China (Grant No. KY 201702010), and International cooperation and Exchanges NSFC (Grant No. 41861144020).

Availability of data and materials. All the data generated or analyzed during this study are included in this published article and publicly available.

COPROLOGICAL STUDY OF GASTROINTESTINAL PARASITES IN DAIRY CATTLE IN SULAYMANIYAH PROVINCE, KURDISTAN REGION, IRAQ

ARAM, A. M.

Department of Microbiology, College of Veterinary Medicine, Sulaimani University, Iraq
e-mail: aram.mohammed@univsul.edu.iq; phone:+964-770-157-1306

(Received 4th May 2020; accepted 16th Sep 2020)

Abstract. Gastrointestinal (GI) parasitic diseases are a serious problem in cattle management, and one of the most significant reasons for economic losses incattle for developing countries. This study aimed to assessthe prevalence of helminth and protozoan infection of gastrointestinal tract in local dairy cattle in Sulaymaniyah province of Iraq.A total of 1,376rectal fecal specimens of local dairy cattle were randomly collected in different regions of Sulaymaniya province. Direct fecal smear, saturated sugar flotation technique, and simple sedimentation method, were used to detect the parasitic stages in the coprological specimens.The overall prevalence rate was 60.46%.The single and mixed parasite infection rates were 37.21% and 23.25%, respectively. The infection rates of protozoa, nematodes, trematodes, and cestodes were 58.14%, 18.60%, 15.11%, and 3.48%, respectively. Among all parasites, *Eimeria* spp. (29.07%) was the most abundant one, followed by *Buxtonella sulcata* (18.60%) and *Strongyle* nematodes (17.44%). There was significant variation in the prevalence rates of nematodes and protozoa between various age categories and distributional regions. The results indicated that improved management system and proper anthelmintic treatment strategies should be applied in the regions to diminish the high incidence of GI parasitismin local dairy cattle.
Keywords:*prevalence, helminthes, protozoa, livestock,fecal analysis*

Introduction

Parasitosis is one of the biggest issues affecting livestock especially cattle of all age and breed categories (Rafiullah et al., 2011;Awraris et al., 2012). The endoparasites intervene with dietary status, growing process and byproductsof the cattle population (Pilarczyket al., 2009; Awraris et al., 2012; Khan et al., 2013).

The animals' gastrointestinal tract holds a broad range of parasitic protozoa and helminthes, which cause sub clinical and clinical parasitic infestation. These internal parasites inauspiciously affect the health conditions of animals and cause great economic impacts on the livestock industry (Wimmer et al., 2004; Bilal et al., 2009).

In the case of rearingfarm animals for food production, investigations that aid in evaluating the economic impacts caused by parasitic infestation are significant, particularly in smallholder farming structures in developing countries (Perry and Randolph, 1999; Sahoo et al., 2002). As parasites may cause clinical and nonclinical parasitism leading to economic losses, the purpose of veterinarians and producers is to avoid parasitism via goodhusbandry,adequate nutrition, control of epidemiological factors, and effective therapeutic treatment (McDermottet al., 1999; Kaewthamasornand Wongsamee, 2006).

Although the numbers of studies havereported the prevalence of gastrointestinal (GI) parasite of ruminants inIraq (Al-Taee et al., 2011; Nassrullah, 2011; Nasrullah et al., 2014; Minnat, 2014; Al-Zandee et al., 2016; Hassan et al., 2018; Al-Robaiee et al., 2019), there is no published study available related to GI parasites of cattle in the province of Iraq. Thus, the objective of the current studywas to record the prevalence of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72797287

GI parasites among local dairy cattle in different regions of Sulaymaniyah province.The recorded data will provide fundamental knowledge of GI parasite infection levels in the province and it could be supportive for control strategies.

Materials and Methods

Study area and sample population

This study was conducted in Sulaymaniyah province, Kurdistan Region, north-east of Iraq. It is located between 35°04′- 36°30′ latitude and 44°50′- 46°16′ longitude. The area is characterized by seasonal rainfall from October to May, and inadequate farmer awareness about the husbandry and control of the endoparasites in the ruminants. Cattle population in the study regions (Penjwen, Chwarta, Said Sadq, and Piramagroon) is estimated to40,355 according to the data recorded by Sulaymaniyah Veterinary Directorate in December 2015.

A total of 1,376 rectal fecal specimens of local dairy cattle, involving560 calvesand 816 cows, were randomly collected from different regions of Sulaymaniyah province. Among these samples, 200 were collected from Penjwen, 330 from Chwarta, 470 from Said Sadq, and 376 from Piramagroon. The samples were stored at 4 °Cuntil parasitological assessment. The age groups of cattle were sorted as calves (under1 year old) and cows (above 1 year old).The sampling period was begins from March to August 2018.

Parasitological analysis

Fecal specimens were analyzed for the existence of helminth eggs, protozoan oocysts and cysts,applying the simple flotation technique using saturated sugar solution (Sheather's sucrose solution). A simple sedimentation procedure was utilized to find the ova of flukes and some other nematodes and cestodes, whose ova do not recover in a saturated sugar solution. For diagnosis of protozoan trophozoites, the direct fecal smears were performed. The parasitic stages were identified based on morphological keys (Urquhart et al., 1994; Zajac and Conboy, 2012; Kandasamy et al., 2013).

Statistical interpretation

The data calculated by Chi-square (X^2) test using SPSS® software V.25. The probability values below 0.05 were considered statistically significant.

Results

Out of 1,376 fecal samples examined, the overall infestation rate of GI parasite was60.46%. The single and mixed parasite infection rates were 37.21% and 23.25%, respectively with statistically significant differences. *Eimeria* spp. was the most dominant parasite that recognized in majority of multiple infections (*Table 1*).

This study found that the highest prevalence ofprotozoan infection was (58.14%), followed by nematodes (18.60%), trematodes (15.11%), and cestodes (3.48%).There was significant variation in the prevalence rates of nematodes and protozoa between various age categories and distributional regions (*Table 2; Fig. 1; Fig. 2*).

[a]No. = total number of examined cattle, [b]No.= number of infected cattle

It was recorded three kinds of protozoan cysts/oocysts or trophozoites in the examined fecal samples, namely *Eimeria* spp. (29.07%), *Buxtonella sulcata* (18.60%), and *Cryptosporidium* spp. (10.46%). The prevalence of *Eimeria* spp. in calves (35.89%) was statistically higher than in cows (24.38%), while *Cryptosporidium* spp. was significantly lower in calves (6.96%) than cows (12.86%). The increasing prevalence of *B. sulcata* associated with an expansion in age.

In the current investigation, the recognized nematode eggs included *Strongyle* nematodes and *Toxocara vitulorum. Strongyle* nematode (17.44%) was the most predominant species detected in local dairy cattle, and the commonness in Piramagroon was fundamentally higher than those in other regions. *T. vitulorum* was recovered in 16 cattle.

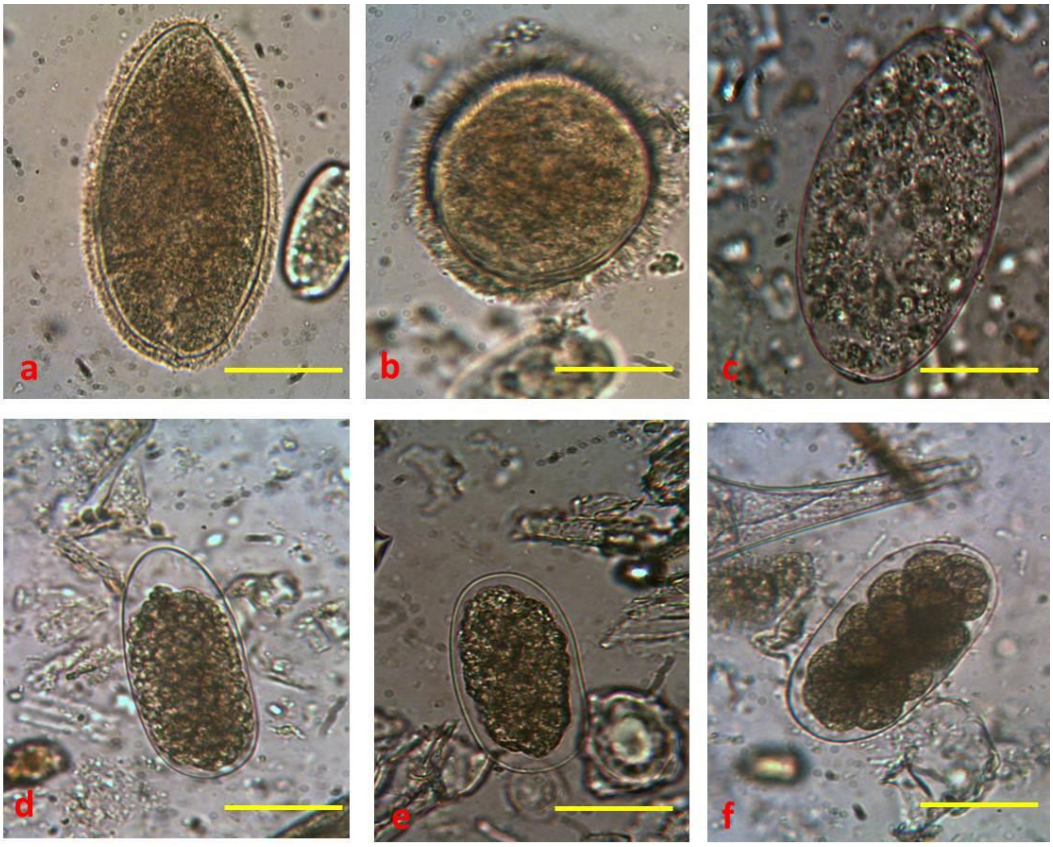

Figure 2.*Fecal smears of cattle under the X40 objective microscope, scale bars are 100 µm:a. Buxtonella sulcata (trophozoite);b.Buxtonella sulcata (cyst); c. Paramphistomum cervi (egg); d.;e.;f. Strongyle type(eggs)*

The infection rate of trematodes (15.11%) was comparatively lower than that of nematodes and protozoa. The identified trematodes involved *Paramphistomum cervi* (5.81%), *Fasciola* spp. (5.81%), and *Dicrocoelium dendriticum* (3.48%). There was apparent variation between different age groups and different regions for these flukes infection.

The prevalence of tapeworms (3.48%) was markedly lower than that of other parasites. *Moniezia* spp. eggs only recovered among infected cattle. There was no obvious difference between age categories of cattle; however, the prevalence rates in Piramagroon and Said Sadq regions were statistically higher than those in Chwarta and Penjwen areas.

Discussion

Control of GI parasitic diseases in livestock requires comprehensive information about the epidemiology, field management, and environmental conditions such as rainfall and temperature. The numbers of protozoan oocysts and helminth eggs developed inside the host animals vary according to the parasite species, degree of host susceptibility,the health,and immune status of the animals (Sharma and Busang, 2013).

Gastrointestinal nematode diseases of cattle continue to be a limitation on the proficient raising of cattle all through the world. In much less developed agricultural

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72797287

systems, parasitic infections may also cause serious clinical signs, such as stunted growth, tissue edema, and diarrhea (Gasbarre et al., 2001).Indeed in well-managed herds with no signs and symptoms of parasitism, the existences of GI parasites restrict the growth inyoung animals and diminish milk production in growing-up bovines (Hawkins, 1993).In Sulaymaniyah province of Iraq, infections triggered by GI parasites are predominant in small ruminants since of the helpful local weather for the transmission of infection (Nassrullah et al., 2014).

With this study, the findings demonstrated highly GI parasitic infections in cattle (60.46%) in the Sulaymaniyah province of Iraq. The results are consistent with other reports from a number of countries (Regassa et al., 2006; Tung et al., 2012; Huang et al., 2014; Hussain et al., 2014; Hamid etal., 2017).These high levels of infection rate have reflected the lack of success from the de-worming program and highlighted ineffective husbandry.

In present research recorded a high prevalence of protozoan infection (58.14%). This finding was similar to the consequence of the studies mentioned by Tung et al. (2012) and Huang et al. (2014).During the current study, a significantly higher proportion of calves (35.89%) were infectedwith *Eimeria* spp. than cows (24.38%). A recent investigation carried out in Sri Lanka has also recorded the similar findings (Gunathilaka et al., 2018). This might be due to the excessive humidity and reasonable temperature encourages the survival and sporulation of the oocysts. As their immunity is additionally lower than the adult cattle, calves might bemore susceptible to coccidian diseases (Bilal et al., 2009).*B. sulcata* infection was the second most dominant protozoan infection found in 18.60% of the local dairy cattle in the present study, and the increasing prevalence correlated with the rising in age. This finding was lower than the results of a previous research performed in Iraq (Al-Bakri et al., 2010).Fox and Jacobs (1986) showed that the quantity of carbohydrate in the food would affect the population growth or decrease of *B. sulcata*. The variation in the prevalence of infection may be due to differentfactors, such as environment, farm management practices and stress factors.*Cryptosporidium* spp. was the third protozoa recorded 10.46% of cattle with a significantly higher prevalence of infection in cows compared to calves. However,Roy et al. (2006) indicated calves to be most susceptible to infection and they also actas reservoirs.

According to the results of the current investigation, nematodes infected 18.60% of local dairycattle. The infection rate was markedly lower than a recentstudy conducted by Hamid et al. (2017).Improper antihelmintic administration, poor husbandry, or the evasion of immune responses might accelerate the risk of nematode infection.

In this study, *P. cervi* (5.81%)and *Fasciola* spp. (5.81%) were the most abundant trematodes followed by *D. dendriticum* (3.48%).On the contrary, this result was higher than that registered by Tung et al. (2012). Environmental pollution may be one of the factors that reduce the number of snail population in the areas.Additionally, feeding fresh grass contaminated with metacercaria to their cattle from farmers could increase the risk of trematode infection.

During this research, *Moniezia* spp. was infected a very low proportion of cattle. A similar observation was reported by Jittapalapong et al. (2011). The variation in the prevalence rate of monieziasis between distributional regions may be due to the distribution of intermediate host, the free-living soil mites on pasture, in these regions.

Conclusion

To the best knowledge, this is the first report on prevalence of GI parasites in Cattle in Sulaymaniyah province, Iraq.This study showed a high rate of GI parasites in cattle and it was concluded that GI parasite was common and endemic in the study areas. In addition to that, *Eimeria* spp. and *Strongyle* nematodes were the most abundant parasites recovered in the cattle. The farmers should apply improved management systems and regular de-worming treatments for controlling and prevention of parasitic diseases. Future investigations are essential to evaluate the economic impact of GI parasites in the study regions.

Acknowledgements. The author would like to thank the Sulaymaniyah Veterinary Directorate, Sulaymaniyah province, Kurdistan Region, Iraq for its facilities provided. The author also wishes to great thanks the owners of selected cattle farms in the study regions.

Abstract. Formation of serpentine flora and vegetation is primarily influenced by local geology and they represent an extraordinary area for botanical research studies (from both taxonomical and ecological perspective). During a sixteen-year research of serpentine terrain flora of the Ibar river middle-stream valley in northern Kosovo and Metohija, the existence of 882 taxa grouped into 83 families and 386 genera has been proven. The collected serpentine flora was analysed on taxonomical, ecological and phytogeographical basis. Out of the total number of identified taxa, 73 (8.27%) are endemic, sub-endemic, relict and endomorelic. 31 taxa belong to a group of internationally significant vascular plants. Of these, 14 taxa have been protected by CITES Convention. The taxonomic structure of the serpentine flora of the Ibar river middle-stream valley is compared to the serpentine flora of Mt. Studena and Goleš Mt. (parts of Ibar serpentine massive).
Keywords: *floristic composition, Ibar serpentine massif, endemism, floristic similarity, Serbia*

Introduction

Serpentine is technically a mineral, but the same word is often used for all ultramafic rocks, the soils that form from them, and the unique ecosystems that form on them (Harrison and Rajakaruna, 2011). Serpentine is a ferromagnesian silicate mineral which contains high concentrations of nickel (Ni) and often chromium (Cr) and cobalt (Co) in a form available for plants (Westerbergh and Saura, 1992). Serpentine soils are often deficient in plant essential nutrients such as nitrogen (N), phosphorus (P), potassium (K), and sulfur (S) (Rajakaruna and Boyd, 2014), while ratio of calcium (Ca): magnesium (Mg) is less than 1.0, and pH values range from basic to ultrabasic (Brooks, 1987; Selvi, 2007; Pavlova, 2007; Bani et al., 2013). Owing to this chemical composition, Novák (1926) described serpentine ranges as "dead rocks". Serpentine soils are typically recognized on the landscape as patchily distributed rock outcrops with stunted vegetation (Anacker, 2014). Serpentine outcrops are often steep and comparatively rocky, making them particularly vulnerable to erosion, which results in shallow soils (Brady et al., 2005) and stony structure (Kurt et al., 2013).

The serpentinite is rather unfavorable to plant growth, and its physical conditions also are inhospitable for many plants (Bani et al., 2013). However, plants would not be

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72897322

what they are, if they weren't able to conquer any tolerably suitable substratum by adapting to it (Vasić and Diklić, 2001). Plants adapted to grow under these constraints are called serpentinophytes (Selvi, 2007), distinguished by characteristic structural-morphological adaptations (Stevanović and Jakovljević, 2014); they posses capacity for removal and accumulation of metals (Branković et al., 2017). Many serpentine species are xeromorphic, and water deficiency has been suggested as another stress factor of many serpentine soils (Tumi, 2013). The serpentine flora contains both basophilous and acidophilous plants (Marin and Tatić, 2001). Vegetation growing on serpentinised rocks is often reduced in height, biomass, and ground cover (Gavrilović et al., 2017).

Ultramafic outcrops (also called "serpentine"), formed during tectonic movements, are widespread but sparse, covering roughly 3% of the Earth's surface (Guillot and Hattori, 2013). The largest serpentine areas in Europe are in the Balkans (Stevanović et al., 2003), with an estimated size of over 1,300 km^2 (Pustahija, 2011).

The serpentine areas on the Balkan Peninsula traverse discontinuously from the northwest to central Bosnia, over western and central Serbia, Metohija, Albania, Epirus and northern Thessaly all the way to the Island of Evia, Greece (Stevanović and Jakovljević, 2014). In Bulgaria serpentine areas are smaller and scattered (Pavlova, 2010), distributed in Soutwestern & Central Bulgaria (Stevanović et al., 2003). It should be emphasized that the floristic opulence of these habitats increases with the serpentinites of western and central Serbia, over Albania to northern Pindo and the Evia Island, Greece (Stevanović and Jakovljević, 2014).

In the territory of Serbia the largest serpentine surfaces are located in its western and central regions, as well as in Kosovo and Metohija territory, covering about 250000 ha (Stevanović et al., 2003). These serpentine zones are distinctly delimited from the adjacent surrounding regions with a different geological substratum (e.g., limestone) (Dudić et al., 2007). Kosovo, as a part of the Balkan, hosts an ultramafic area of 487 km^2 within its territory (Salihaj et al., 2018). The largest complexes of serpentine in Kosovo region are found in the valley of the Ibar River and the same are continued in a discontinuous chain through Koznica Mt. and Goleš Mt. to the southwest of Kosovo (Krasniqi and Millaku, 2007). The Ibar serpentine massif stretches along the middle course of the Ibar River and represents a link in the extension chain of the serpentines in Bosnia-Zlatibor and the Ibar gorge-Albania direction (Prodanović et al., 2008). The identified age ranges from post-trias to lower jurassic.

The serpentine terrains of northeastern Kosovo, i.e. the middle stream of the Ibar river, have been rarely visited and floristically researched, which resulted in scarce scientific literature (Pavlović, 1967; Rexhepi, 1979, 1992; Krasniqi et al., 1981; Ranđelović et al., 1982; Krivošej et al., 1993, 1995-1998; Tatić and Krivošej, 1997). A more thorough exploration of this area was started in 2003 by Prodanović, whose work resulted in publishing new chorological data on the flora of Kosovo and Metohija, and entire Serbia (Prodanović, 2007; Prodanović et al., 2004, 2008, 2010, 2012, 2013, 2018; Krivošej et al., 2003, 2011, 2013). However, a comprehensive study involving all vascular serpentine flora in the Ibar valley has not been published so far.

This paper presents a synthesis of all research studies performed in these area, both literature data and intensive field study data, starting from 2003 up to the present days. Its aim is to compile a complete checklist of floristic diversity of this area, analyse it on taxonomical, ecological and phytogeographical base and to compare the flora of two serpentinite regions in central Kosovo and central Serbia. It would be a significant scientific contribution to taxonomic and ecological studies of flora in whole Serbia.

DOI: http://dx.doi.org/10.15666/aeer/1805_72897322

Only a good knowledge of floristic diversity may initiate the procedures that may lead to preserving and protecting rare and endangered and internationally important species in these areas.

Materials and Methods

Study area

The intensive research studies of serpentine terrain in middle stream of the Ibar river started in March 2003 and continued till today. The researched area covers terrains in the Ibar river canyon north of Kosovska Mitrovica towards the administrative boundary of Kosovo and Metohija and central Serbia and a 50 km long village area of Donje Jarinje (*Fig. 1*). It should be emphasized that this highway more or less follows the Ibar river course. The actual length of the investigated area, due to naturally winding river course, is much bigger.

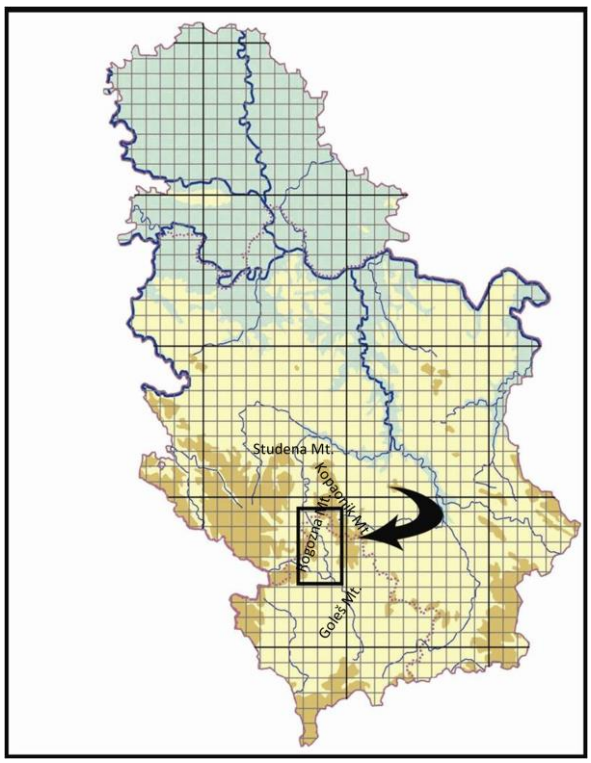

Figure 1. *Geographical position of investigated area in Serbia (UTM 10x10 sq km)*

The geographic relief of the Ibar river middle stream valley may be characterized as mountainous region – the Mountains of Rogozna, Kopaonik and Mokra raise up in the direction of the Ibar river canyon and they provide the main landscape characteristics to Kosovska Mitrovica basin. The altitude on the researched terrain varies between 500 and 900 meters above sea level. The climate of the Ibar river middle steam is defined as moderate –continental. The average air temperature is 10.2 ^{0}C. The researched area belongs to the zone with limited precipitation rate, around 614 mm.

The researched area in north Kosovo and Metohija covers the position between the Mesian and Illyrian provinces, since the Ibar river represents the farthest eastern

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72897322

boundary of the Illyrian province. Due to this herbal-geographic position complex floristic and vegetation relations occur.

Data collection

The floral material was collected in the wider area on both sides of the river, through the gorge. The collected material was processed on usual ways for herbariums and stored in the Herbarium of the Institute for Natural Conservation of Serbia (a department in Belgrade) and some specimens are stored in the Herbarium of the Institute of Botany and Botanical Garden "Jevremovac", University of Belgrade (BEOU). The contemporary literature has been used for plant determination. The nomenclature used for all the registered species in the area under investigation was adjusted to comply with Euro+Med Plantbase (2006) and The Plant List (2013). The floristic catalogue is arranged in alphabetical order of families and genera.

The floristic elements for phytogeographic analyses have been processed and analyzed in line with herbal-geographic classification of Stevanović (1992a). The well-known Raunkiaer system (1934) amended by Stevanović (1992b) for Serbian conditions, has been used for the classification of life forms. Checklist of Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), as well as International Union for Conservation of Nature (IUCN) were used to determine the category of internationally significant and endangered species.

For the analysis of the similarity of flora in the researched area in the Ibar river valley and Studena planina/Mt. Studena and Goleš Mt., as parts of the Ibar serpentine massive, Sørensen's (1948) similarity index was used.

Results and Discussion

Taxonomic analysis of the flora

Biologically, serpentine sites frequently host a depauperate flora compared to the surrounding regions (Obratov-Petković et al., 2006). Serpentine habitats are important centres for floristic differentiation and speciation (Stevanović et al., 2003) distinguished by high number of endemics. Considering the fact that the serpentine terrains with the insufficiently developed soil and unfavourable water and mineral regime, and high levels of magnesium, iron, nickel and chrome are "inhospitable" for floral development, the total number of 882 identified taxa in the investigated area still show floral treasure (Prodanović et al., 2008).

During a 16-year research of serpentine terrain flora of the Ibar river middle-stream valley, 882 taxa (species, subspecies) has been identified, which represent about 25% of total flora of Serbia. They have been grouped into 83 families and 386 genera (*Table 1*). Class *Polypodiopsida* is presented by 8 families and 13 taxa. Only two species of *Pinopsida* can be found. Floristically speaking, the richest class is *Magnoliopsida* with 867 taxa. The greatest number of taxa is noted in family *Compositae* (105), followed by *Leguminosae* (86), *Poaceae* (66), *Lamiaceae* (51), *Brassicaceae* (50), *Caryophyllaceae* (49) which coincides with the most numerous families in the flora of entire Serbia (Stevanović et al., 1995).

Viola reichenbachiana Boreau	Prodanović, 2007	early dog-violet, pale wood violet

A vast majority of genera belong to the familiy *Compositae* (51), followed by *Poaceae* (38), *Apiaceae* (26), *Brassicaceae* (24), *Leguminosae* (24), *Lamiaceae* (22). Among the genera the most species rich are *Trifolium* (17) followed by *Carex* (16), *Euphorbia* (14), *Veronica* (14), *Vicia* (13), *Lathyrus* (12), *Hieracium* (11), *Centaurea* (8), *Medicago* (8), *Rosa* (7) etc. The dominance of the genera *Trifolium, Vicia* and *Lathyrus* (*Leguminosae* family) is most likely conditioned by the higher presence of areas under xerothermic meadows and pastures as well as thermophilic rocks in the study area. Genus *Carex* is on second position. This is explained by the fact that species within this genus require moist habitats, which were abundant in the investigated terrains, on the banks of river Ibar, as well as streams flowing into the river. Genera *Trifolium* and *Carex* are also dominant in serpentine complexes in Eastern Rhodopes (Bulgaria) (Pavlova et al., 2004).

31 taxa in total have been recorded in this area for the first time and they present a novelty for the flora of Kosovo and Metohija and entire Serbia. The records for most of these were first published in Prodanović et al. (2004, 2008, 2010, 2012, 2013, 2018).

Life-form spectrum and phytogeographical analysis

The analysis of life forms indicates domination of hemicryptophytes (48.29%) (*Fig. 2*). The significant representation of therophytes (21.99%), is typical for the serpentine floras, where the plants are adapted to ensure reproduction within a short period of time under stress conditions (Brooks, 1987). Other herbal life forms are present in smaller numbers, geophytes (10.54%) phanerophytes (8.27%), chamaephytes (6.91%), scandentophytes (1.81%) etc. Such biological spectrum is characteristic for the Balkan Peninsula, as well as for the territory of Serbia (Diklić, 1984).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72897322

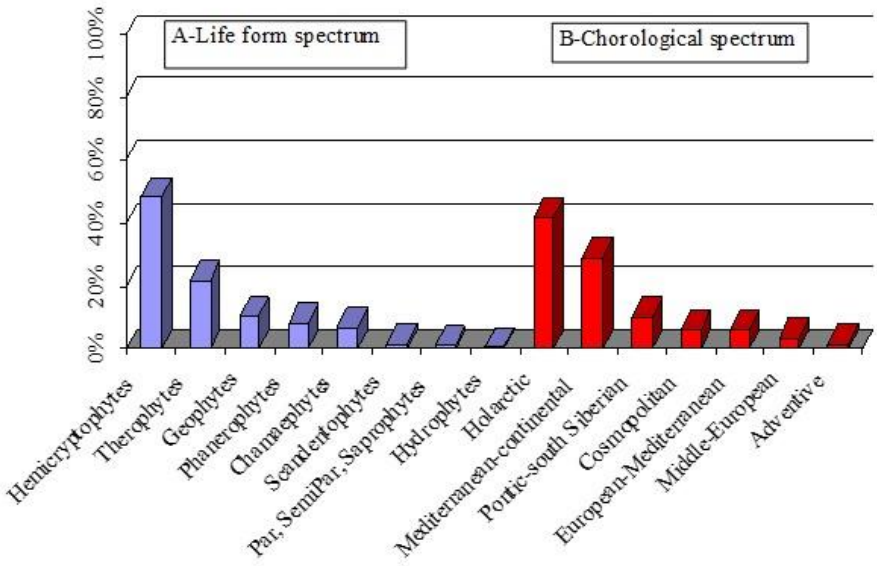

Figure 2. *Life form spectrum (A) and chorological spectrum (B), by basic area types, of the serpentinite flora in the middle course of the Ibar river valley*

The chorological floristic analysis indicates that this is an area with interim holarctic-Mediterranean character (*Fig. 2*). Holarctic areal type with 369 taxa (41.83%) is the most presented on the terrain, followed by Mediterranean – continental areal type (29.18%) and pontic – south Siberian areal type (10.31%), cosmopolitan areal type (6.45%) as well as central European –Mediterranean (6.23%). The least reported species in the serpentine terrains of the Ibar river valley are Middle European dispersion areal type and Adventive areal type. The presence of plants belonging to Adventive areal type indicates anthropogenic influence, which is present in settlements around river banks, as well as around main roads and local rural roads. Xeromorphic species are predominant due to conditions for their growth on serpentine soil.

Endemism and internationally significant vascular plants

Serpentine habitats are the most important endemic regions in the world and also called "geological islands" (Kurt et al., 2013). Despite the shallow active layer of serpentine soil, biodiversity is high with a great number of interesting local and regional endemics (Shuka and Hallaçi, 2010). It is estimated that the total number of endemic plants in the Balkans is bigger than 2200 taxa. 300-350 (15-16%) taxa of this number have been identified on the serpentine background; 123 of them are obligate serpentine endemics (Stevanović et al., 2003).

Due to diverse physical and geographical characteristics, the Republic of Serbia has a considerable number of endemic plant taxa. Centres of endemism are located in the southern and eastern regions of Serbia and on the territory of Kosovo and Metohija (Gavrilović et al., 2017). The serpentine mountains of Central Serbia along the river Ibar represent a relatively large core of ophiolithic flora in the Central Balkans. It is the centre of distribution of old trans-regional endemics such as: *Halacsya sendtneri, Haplophyllum boisserianum, Potentilla visianii* and *Eryngium serbicum*. Local endemics include *Tulipa serbica* (Stevanović et al., 2003).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72897322

Out of the total taxon number in the investigated area, 73 (8.27%) belong to group of endemic, sub-endemic, relict and endomorelic taxa. There are 40 of endemic and sub-endemic species (*Eryngium serbicum, Helleborus multifidus* subsp. *serbicus, Tulipa serbica, Odontarrhena bertolonii* subsp. *scutarina (syn. Alyssum janchenii), Alyssum markgrafii, Galatella albanica, Dianthus pinifolius, Euphorbia glabriflora, Fumana bonapartei, Halacsya sendtneri, Haplophyllum boissierianum, Hieracium bauhini* subsp. *pseudosparsum, Hypericum rumeliacum, Lamium bifidum* subsp. *balcanicum, Potentilla visianii, Ranunculus psilostachys, Scabiosa fumaroides, Scrophularia canina* subsp. *tristis, Sedum album* (syn. *S. serpentini), Stachys scardica, Linum flavum, Trifolium trichopterum, Rorippa lippizensis, Salvia amplexicaulis, Digitalis laevigata, Melampyrum heracleoticum, Eryngium palmatum, Achillea coarctata, Alyssum montanum* subsp. *serbicum, Campanula lingulata, Cytisus austriacus* subsp. *heuffelii, Galium pseudoaristatum, Iris reichenbachii, Lamium garganicum* L. subsp. *garganicum, Lamium garganicum* L. subsp. *glabratum, Lathyrus hallersteinii, Petrorhagia illyrica* subsp. *haynaldiana, Poa perconcinna, Ranunculus serbicus, Rhinanthus rumelicus, Trifolium pignantii*).

Based on the distributional range of obligate serpentine endemics, Stevanović et al. (2003) presented the following general classification: (1) trans-Balkan or trans-regional Balkan endemics (taxa distributed in the greater part of serpentine areas in the Balkans); (2) regional endemics (taxa restricted to a single floristic subregion or province); and (3) local or steno-endemics (taxa distributed in a single floristic district or narrow geographical area such as a single mountain or island).

On the investigated terrains in the middle course of the Ibar river valley, 11 taxa from obligate serpentine endemics are in the trans-regional endemic (TRE) category : *Alyssum markgrafii*, *Sedum album* (syn. *S. serpentini*), *Potentilla visianii, Potentilla heptaphylla subsp. australis, Euphorbia glabriflora, Haplophyllum boissierianum, Fumana bonapartei, Eryngium serbicum, Halacsya sendtneri, Stachys recta* subsp. *baldacii* and *Scrophularia canina* subsp. *tristis.*

4 taxa are obligate serpentine endemics from the regional endemics (RE) category: *Helleborus multifidus* subsp. *serbicus, Alyssum montanum* subsp. *serbicum, Galatella albanica* and *Tulipa serbica* (stenoendemic according to Millaku et al., 2018). It was right here, on the Ibar Valley serpentines, Beli Laz locality (locus classicus), that this endemic *Tulip* was identified (Tatić and Krivošej, 1997). Unfortunately, in the last three years, due to the regional dumping site development, the primary habitat has been devastated, without any possibility to be protected.

Out of the total taxon number, 31 taxa belong to a group of internationally significant vascular plants (IUCN, Stojanović et al., 2015). Out of that, 14 taxa have been protected by CITES Convention. These are the followings: *Anacamptis pyramidalis, Cephalanthera rubra, Epipactis helleborine, Epipactis microphylla, Galanthus nivalis, Limodorum abortivum, Neottia nidus-avis, Orchis mascula, Orchis morio*, *Orchis papilionaceae, Orchis purpurea, Orchis tridentata, Ophrys apifera* and *Platanthera bifolia.*

Comparative floristic analysis

In order to gain a better insight into the flora diversity in these habitats, as well as the level of floristic closeness, a comparative analysis of the flora from Studena mountain, near the city of Kraljevo, has been done by Tatić (1969) in his multi-year research as well as with flora of Goleš mountain, researched by Krasniqi et al. (2019).

DOI: http://dx.doi.org/10.15666/aeer/1805_72897322

The Ibar serpentine massive with the valley in the lower course of the Ibar river traverses though central Serbia and extend west from the mountain Studena (Lukić et al., 2015) where it covers the largest space on Studena mountain; the river itself flows 17.1 km along the mountain. In his studies Tatić reported 390 taxa, the largest number of which belonged to *Compositae, Poaceae, Leguminosae, Caryophyllaceae, Rosaceae* and *Lamiaceae* families, which is similar to the spectrum of the most numerous families of flora in the Kosovo part of the Ibar serpentine range. The number of two mutual taxa in two compared areas is 196, so the index of similarity by Sørensen is 30.66%, which is unexpectedly low since Studena mountain represents the continuation of the Ibar serpentine massive that starts in the middle course of the river in Kosovo.

An assumption of floristic dissimilarities in the Kosovo part of the Ibar valley and Studena mountain, has been based on the differences between the altitudes of these two areas (the Ibar gorge 500-900 ma, Studena mountain above 1000 ma, with the highest peak of Kavgalija 1356). Furthermore, the composition of the geological background has probably influenced floral development. The geological background of Studena mountain exclusively consists of serpentinite; in the Kosovo part of the Ibar valley apart from serpentinite, there are also peridotite and unmodified ultramaphyte rocks. While Tatić emphasized phytocenologic research studies on Studena mountain, our attention was turned to purely floristic research projects in the Kosovo's part of the Ibar valley (which may be corroborated by a total number of 882 identified taxa), taking also into account the size of the investigated area. Since the serpentine is considered as a vulnerable habitat, it is important to emphasize that no Studena mountain species recorded by Tatić has been classified as extinct in Serbian flora. Our assumption is that the described species can be found there nowadays, but we also recommend future field research to prove this assumption.

Mountain Goleš, in the central part of Kosovo and Metohija, represents the beginning of the serpentine-peridotite massif, which covers the left bank of the Sitnica river, goes towards the Čičavica Mountain, enters the valley of the upper stream of the Ibar river in Ibarski Kolašin, and continues along the middle Ibar river course. Krasniqi et al. (2019) recorded 295 taxa on this mountain (with a surface area of 22.2 km^2) over a three-year study (2015-2019). Considering the size of the mountain range covered by the conducted survey, a larger number of taxa would be expected. However, such floristic "poverty" confirmed the fact that serpentinite habitats are floristically poorer than habitats with other types of geological substrates. The number of two mutual taxa in the two compared areas is 218, so the index of similarity by Sørensen is 37.04%. It should be noted that this value is not large, although the number of common species is as high as 2/3 of all taxa found on Goleš Mountain. The reason could certainly be a disproportion to the number of identified species and the size of territories explored.

Families with the highest number of taxa on Goleš mountain were *Compositae* (34), *Leguminosae* (25), *Rosaceae* (25), *Poaceae* (18), and *Caryophyllaceae* (18). In taxonomic spectrum in the Ibar river valley, *Compositae* (105) and *Leguminosae* (86) are also dominant, followed with *Poaceae* (66), *Lamiaceae* (51), *Brassicaceae* (50), *Caryophyllaceae* (49). *Rosaceae* family in taxonomic spectrum of most dominant plant families in the Ibar river valley occupies eight position. Significant involment of the *Lamiaceae* and *Caryophyllaceae* families indicate the expression of stronger Mediterranean floristic influences, as well as a greater presence of bare rocky habitats.

Krasniqi et al. (2019) on Goleš Mountain state that out of the total number of identified taxa, 8 of them are endemic, of which 5 endemic species occur on the Ibar

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_72897322

valley serpentinite (*Galatella albanica, Halacsya sendtneri, Linum flavum, Potentilla visianii* and *Haplophyllum boissierianum*). Various floristic elements meet and overlap in mountain ranges in the central part of Kosovo, dominated by European floral element, followed by Euro-Asiatic and Sub-Mediterranean, Balcan, Mediterranean and Pontic elements similar to the interim holarctic- Mediterranean character of flora in the Ibar river valley.

Due to the background characteristics, the serpentine areas of the Ibar valley and their flora have not been exposed to negative anthropogenic influences so far. Yet, in the previous 3-4 years, the negative human influences have been detected in the areas along the highway. We consider that establishing a better connection between scientific and professional public and the people who are in charge of planning and infrastructural construction along the Ibar valley could contribute to the preservation of the habitats of some significant and endangered species, which unfortunately was not the case with locus classicus of the *Tulipa serbica* species.

Conclusion

The presence of 882 taxa grouped into 83 families and 386 genera has been identified in the course of the research of serpentinite flora performed in the middle stream Ibar river valley, for the period of 16 years. Taxonomic spectrum of families is dominated by *Compositae* (105), followed by *Leguminosae* (86), *Poaceae* (66), *Lamiaceae* (51), *Brassicaceae* (50), *Caryophyllaceae* (49), *Apiaceae* (43) etc. The greatest number of genera belong to families *Compositae* (51), followed by *Poaceae* (38), *Apiaceae* (26), *Brassicaceae* (24), *Leguminosae* (24), *Lamiaceae* (22). Among the genera the most species rich are *Trifolium* (17) followed by *Carex* (16), *Euphorbia* (14), *Veronica* (14), *Vicia* (13), *Lathyrus* (12), *Hieracium* (11), *Centaurea* (8), *Medicago* (8), *Rosa* (7) etc. An analysis of life forms showed that the investigated area has hemicryptophyte characters, with significant participation of therophytes (21.99%). The chorological spectrum is dominated by Holarctic species (41.83%). The presence of 73 taxa from a group of endemic, sub-endemic, relict and endomorelic taxa was determined. Out of the total taxon number, 31 taxa belong to a group of internationally significant vascular plants. Out of that, 14 taxa have been protected by CITES Convention. A comparative analysis of the serpentinite flora in the Ibar river valley and the Studena mountain as well as in the Goleš mountain showed a relatively small floristic similarity, which was unexpected, since these two mountains represent the beginning and continuation of the Ibar serpentine massive that starts in the middle course of the river in Kosovo. Only a good knowledge of floristic diversity may initiate the procedures that may lead to preserving and protecting rare and endangered and internationally important species in these areas. Since serpentinite habitat is considered as vulnerable we are proposing continual habitat monitoring as well as monitoring of all endangered and rare species in the Ibar river valley in future research projects. For some species seed collecting for a seed bank could be one of the conservation measures.

Acknowledgements. The authors are grateful to dr Marjan Niketić, from the Natural History Museum in Belgrade, for his help in the determination of genus *Hieracium* and *Cerastium*.

EFFECTS OF NITROGEN FERTILIZATION ON CORIANDER (*CORIANDRUM SATIVUM* L.): YIELD AND QUALITY CHARACTERISTICS

IZGI, M. N.

Kiziltepe Technical Vocational School of Higher Education, Mardin Artuklu University, Mardin, Turkey
e-mail: necatizgi@hotmail.com; phone: +90-532-655-3083; ORCID: 0000-0003-1657-1169

(Received 21st May 2020; accepted 16th Sep 2020)

Abstract. Coriander (*Coriandrum sativum* L.) is a spice plant belonging to the Apiaceae family. In this study, the aim was to specify the effects of different nitrogen doses on the yield and quality properties of coriander. In this research; plant height, number of branches, number of umbels, thousand seed weight, seed yield, oil content, fatty acid composition, essential oil rate and essential oil composition were examined. The essential oil contents in coriander fruits was determined by Clevenger apparatus. Fatty oil was isolated by cold press. Essential oil and fatty oil compositions were determined by Gas chromatography–mass spectrometry (GC/MS-QP2020) device. While nitrogen doses did not positively affect fruit yield, they had a significantly positive effect on the herbal characteristics of coriander (plant height, number of umbels and thousand fruit weight). It was revealed that nitrogen doses had positive significant effect essential oil rate. Increasing nitrogen doses affected rate of linalool. Nitrogen doses had a significant effect only on butyric acid, and for fatty oil rate and other major fatty acids their effect was not significant. It has been determined that high fruit yields are obtained at 60 and 80 kg ha^{-1} nitrogen applications and that the rate of essential oil and linalool is the highest at 100 kg ha^{-1} nitrogen doses especially in the second year.
Keywords: *Coriandrum sativum, essential oil, fatty oil, linalool, nitrogen doses*

Introduction

Coriandrum sativum L. is a medicinal and spice plant belonging to the Apiaceae family. It is named as “kişniş” in Turkish and “coriander" in English and is one of the oldest spices in the world. Its matured fruits and fresh leaves are used as spices and traditional medicine. Matured fruits contain between 0.03-2.7% of essential oil. The major component of the oil is linalool, accounts for about two-thirds of the oil (Shahwar et al., 2012). Essential oil of coriander is used in cosmetic industry because of the valuable components such as linalool.

The variation of essential oil content and composition in essential oil plant depends on their genetic structure, climatic conditions and agronomic applications (Telci et al., 2006a,b, 2010). The commercial value of coriander fruit is determined by its physical properties, chemical composition and bioactive effects (Furan and Geboloğlu, 2017). The essential oil and main component linalool are important raw materials in the perfume, cosmetic and pharmaceutical industries. It is also used in food and preventive medicine due to its bactericidal and fungicidal effects.

As in other medicinal and spice plants, in coriander, quality is as important as yield. The effects of cultural practices and environmental factors on these plants are more common than all other cultivated plants. Nitrogen is a plant nutrient that is effective not only in terms of growth and yield, but also in terms of seed quality, it plays an important role in the synthesis of plant components with the effect of different enzymes (Jr. Jones et al., 1991; Marschner, 2011). Nitrogen fertilization increases plant growth, essential oil, fixed oil and total carbohydrate and soluble sugar. Nitrogen is involved in photosynthesis, respiration and protein synthesis. It gives the leaves their dark green color, promotes hard vegetative

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73237336

growth and leads to more efficient use of existing inputs and ultimately to higher productivity (Pawar et al., 2007). Khalid (2013) stated that in the nitrogen dose applications, the values obtained were significantly higher than those of the control group and that they found significant results in plant growth characteristics.

Coriander production has been increasing day by day in Mardin province, as in different regions of Turkey. However, in the region where the experiment is carried out, there are not enough studies related to coriander cultivation, especially the need for nitrogen and the relationship between nitrogen and yield and quality. The yield of coriander is low in Mardin and its vicinity compared to the actual yield potential due to unsuitable fertilization and agricultural practices. For this reason, the research was carried out in order to evaluate the nitrogen demand of the registered Gamze cultivar in Mardin region of Turkey under the plain conditions of Mardin province and to find the effect of different nitrogen levels on yield and quality.

Material and Methods

Coriander (*Coriandrum sativum* L.) is a spice plant belonging to the Apiaceae family, which is used. As plant material; Gamze variety, which adapts to the plain conditions of Mardin province and is preferred by farmers, was used. This study was carried out for two years under plain conditions of Mardin Province in Turkey during the 2014-2015 and 2015-2016 vegetation periods.

Experiment area has a hot and dry weather in summers and rainy and warm in winters. *Table 1* shows the climatic data for the application area. While the total rainfall data of January in the first year that the study was conducted and of April in the second year, were low compared to the average of long years, the total amount of precipitation in the other months was parallel to the average of long years. In the first and second years, monthly average temperature and humidity values were similar to the temperature average values of long years.

Table 1. *Some meteorological data for long years (2004-2016) * and 2014-2015-2016 growing periods in Mardin province* **

**Sources: Turkish State Meteorological Service

The soil has a clay-loam structure and is poor in organic matter (1.18%). It is slightly alkaline (pH = 8.05), lime content is very high (36.65%), and no salinity problems (0.010%). Phosphorus (31.50 kg), potassium (104.16 mg kg^{-1}) is sufficient for soil uptake.

The experiment was set up according to the Randomized Blocks Experiment Design with three replications. In the trial area, 5 different doses (0, 40, 60, 80 and 100 kg ha^{-1}) of nitrogen (Ammonium sulphate) were applied on the soil. The plot area has an area of totally 4.5 m^2 as 5 rows on each plot with 3 m length, 1.5 m width and 30 cm planting distance. In the plantation, 1 m distance between plots and 2 m between blocks were arranged. The number of plants in the study was arranged as 66000 plant ha^{-1}. Sowings were performed manually on 15 October 2014 in the first year and 16 October 2015 in the second year. After the sowing, weeding was performed three times and irrigation was made 5 times in the summer months. On June 22, the harvest performed manually; calculations were made on the current area by removing 25 cm as edge effect from the row tops and one row on the sides.

Essential oil and fatty oil analysis

Volumetric method was used to determine the extraction and quantity of essential oils for distillation in ripe fruits; Coriander fruits are ground and exposed to distillation with Clevenger apparatus for 2.5 hours (Clevenger, 1928). The essential oil samples obtained were kept in the refrigerator at 4 ℃ until analysis.

In the fatty oil extraction method, fatty acids were converted to methyl ester derivatives, 0.1 g oil was taken in a 15 ml plastic centrifuge with a lid and 10 ml n-hexane was added. It was strongly shaken after closing its lid and 2N KOH solution with methanol (0.5 ml) was appended. It was strongly shaken again after closing its lid and left

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73237336

in a dark environment for 2 hours until the supernate clarified. For analysis, the supernate was exposed to GC method and after that the sample was prepared for the analysis.

Fatty acids were dissolved in 40 mg of oil n-heptane for methylation prior to analysis. The tube was rinsed off with 2 M KOH (2 mL) and then for phase formation was waited. The supernatant containing the fatty acids was taken in vials and diluted in n-hexane. Fatty oil and essential oil component analysis performed with the GC/MS-QP2020. GC/MS conditions were given in *Table 3*.

Table 3. *GC/MS conditions*

Data analysis

Agronomic characteristics of the study were analyzed by using the JMP 5.0.1 statistical program (SAS Institute Inc., 2002), and the differences between means of nitrogen doses were compared using Student's t-test at the 0.05 probability level (Gosset, 1908).

For essential oil and fatty oil, the analysis was applied using the IBM SPSS Statistics for Windows (IBM Corp., 2017). The significance of year differences of essential oil and fatty acids between fruit samples was tested by analysis of variance (ANOVA) and represented by critical value from an F-test (F) and statistical significance (p). Essential oil means, fatty oil means, major components of essential oil and fatty acids with significant variation were compared by using Duncan Multiple Range Test (Duncan, 1955). Year difference significances were compared by T-test.

Results and Discussion

For coriander (*Coriandrum sativum* L.), data on the effect of different nitrogen doses on plant characteristics were given in *Table 4* and on quality characteristics were given in *Table 5, Table 6, Table 7* and *Table 8*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73237336

Agronomic characteristics and yield

Plant height (cm)

When the different nitrogen doses in coriander were examined in terms of plant height, the difference between years was insignificant and the difference between nitrogen doses was statistically significant ($p<0.05$) and interaction factor was insignificant. Regarding the average value of two years, the highest value was found to be 62.8 cm in 60 kg ha^{-1} nitrogen application group and the lowest value was found to be 39.2 cm in the control group. After the application of 60 kg of nitrogen per hectare, decreases were observed in plant height (61.6 and 57.0 cm) (*Table 4*). Nitrogen fertilization was found to have a negative effect on plant height when the optimum dose given to the plant was exceeded.

Table 4. *Some agronomical characteristics of different nitrogen dose applications in coriander (Coriandrum sativum L.)* *

Nitrogen Doses (kg ha^{-1})	Plant Height (cm)			Number of Branches (piece $plant^{-1}$)			Number of umbels (piece $plant^{-1}$)			1000 fruit weight (g)			Fruit yield (kg ha^{-1})

* Different letters after the same column data indicate significant difference at the 0.05 level or similar

In his study about effect of different fertilizers effect on coriander, Kan (2007) found effect of DAP (include 18% nitrogen) fertilizer on plant height as insignificant. Erdoğdu and Esendal (2018), in their study about cultivar and nitrogen doses, specified significant ($p<0.01$) positive relation between nitrogen doses and plant height. They determined that plant height varies between 90.20- 109.40 cm regarding to mean data of doses. According to Okut and Yıldırım (2005) effect of nitrogen doses on plant height is insignificant. However, Karadoğan et al. (1997) and Kırıcı et al. (1997) stated a positive significant relation between nitrogen doses and plant height.

Number of branches per plant

The difference between the number of branches by years, the difference between average of years in terms of fertilizer doses and interaction factors were found to be insignificant. The mean number of branches was found to be 4.8 in the first year and 6.0 in the second year. Regarding the average of two years, the highest number of branches was obtained in the control group (6.2 piece $plant^{-1}$), and the lowest number of branches (4.7 piece $plant^{-1}$) was obtained with 60 kg ha^{-1} nitrogen application. It was observed that increased nitrogen doses did not affect the number of branches in the plant (*Table 4*).

Kan (2007) found effect of DAP fertilization and year interaction on number of branches as significant ($p<0.05$) and according to mean data, he obtained that number of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73237336

branches varies between 3.76- 5.09 with DAP fertilization and year interaction. Khalid (2013) obtained significant relation of number of branches and nitrogen doses and measured values between 2.8- 7.1 cm for coriander. In literature statistically significant increase was observed parallel to increasing nitrogen doses (Karadoğan et al., 1997; Kırıcı et al., 1997; Nayak et al., 2009).

Number of umbels per plant

The difference in the number of umbels by years was found to be insignificant and the difference between nitrogen dose applications was found to be significant ($p<0.05$). It was calculated that there were 12.2 umbels per plant in 2015 and 13.4 umbels in 2016. It was found that the highest number of umbels by the average of years is 100 kg ha^{-1} in nitrogen application and the lowest number of umbels is (10.1 plants) in 60 kg ha^{-1} nitrogen application (*Table 4*). Applications over 60 kg of nitrogen per hectare resulted in a decrease in the number of umbels in the plant. In different nitrogen dose applications (up to 60 kg ha^{-1}), the number of umbels decreased as the plant height increased. The values obtained regarding the number of umbels: Some researchers do not find any significant effect of nitrogen doses on number of umbels per plant (Karadoğan et al., 1997; Okut and Yıldırım, 2005; Erdoğdu and Esendal, 2018). However, Kırıcı et al. (1997) stated that nitrogen application has positive significant effect on number of umbels per plant and found values between 13.15-16.80 umbels per plant.

1000 fruit weight (g)

Regarding thousand fruit weight, difference by years was insignificant and the difference between nitrogen dose averages was significant ($p<0.05$). In the first year a thousand fruit weight was found to be 12.9 g and in the second year it was found to be 12.5 g. The highest average value (13.4 g) was obtained in 100 kg ha^{-1} nitrogen application, and the lowest value (12.0 g) was obtained in the control group (*Table 4*).

In previous studies conducted on 1000 seeds, Kan (2007) did not find any significant effect of nitrogen doses on thousand seed weight, Kandemir (2010); Karadoğan et al. (1997) and Okut and Yıldırım (2005) obtained significant positive effect of nitrogen doses on thousand seed weight and they found values between; 7.01g - 8.25g; 9.74 g - 11.06 g and 8.01 g - 8.77 g, respectively.

The highest weight of 1000 fruits at the highest nitrogen dose (100 kg ha^{-1}) indicates that nitrogen increases protein accumulation in fruits (Pawar et al., 2007). It can be said that the differences in thousand fruit weight in coriander stem from different agricultural practices as well as environmental differences as in other herbal characteristics.

Fruit yield (kg ha^{-1})

The effect of different nitrogen dose applications on seed yield and the difference between the year averages were found to be insignificant. Yield per hectare in the first year was determined as 1950 kg in the first year and as 2413 kg in the second year. Regarding the different nitrogen doses average, the highest value (2374 kg ha^{-1}) was obtained in the 80 kg ha^{-1} nitrogen application and the lowest value (1976 kg ha^{-1}) was obtained from the control group (*Table 4*).

Kan (2007) and Reddy and Rolston (1997) did not found any significant effect for nitrogen application on fruit yield, Patel et al. (2013) found significant relation and obtained 1203 kg from the application of 80 kg of nitrogen per hectare. Karadoğan et al.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73237336

(1997) and Okut and Yıldırım (2005) stated that increasing nitrogen doses cause an increase in seed yield. Kırıcı et al. (1997) found significant effect and measured highest value as 1780 kg ha^{-1} at 60 kg ha^{-1} nitrogen application. Erdoğdu and Esendal (2018) found significant positive effect and obtained values between 982.0 - 1467.0 kg ha^{-1} in coriander. Akbarinia et al. (2007), in their nitrogen amount experiment, found that there was a significant increase in seed yield at 60 kg ha^{-1} nitrogen application.

In fruit yield, genetic control was found to be more dominant than nitrogen fertilization.

Quality characteristics

Essential oil rate

Variation in essential oil rate was given in *Tables 5 and 6*. Variation of mean data of years in essential oil content was not significant statistically and means are the same for both years as 0.18%. While main factor of year was not significant, doses and interaction factors were significant ($p<0.01$). Regarding to mean data of doses, statistically ($p<0.05$) highest value was obtained at 80 kg nitrogen per hectare application as 0.20%; statistically ($p<0.05$) lowest value was obtained at control group as 0.17% (*Table 6*). While the same value was obtained in both years at 80 kg ha^{-1} nitrogen application, relatively higher value was obtained at 40 and 60 kg ha^{-1} nitrogen application in second year, at control group and 100 ha^{-1} nitrogen application in first year.

Essential Oil		0.18±0.02	0.18±0.02

In the study about coriander, İzgi et al. (2017) stated that essential oil content of coriander varied from 0.2% to 0.6%. Erdoğdu (2012), Kan (2007), Khalid, (2013) and Kırıcı et al. (1997) reported that the effect of nitrogen dose on the proportion of essential

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73237336

oil is statistically insignificant. However, in another study, Khalid (2015) found effect of fertilizer (nitrogen and phosphorus) on essential oil rate as positively significant ($p<0.05$) and values between 0.2% - 0.3%. Patel et al. (2013) found significant positive relation and values between 0.41 - 0.51%. In study about response of coriander to nitrogen treatment, Lenardis et al. (2000) found that essential oil rate was increasing statistically with increasing nitrogen doses in coriander. Gil et al. (2002) stated that fertilizer (nitrogen) factor was not significant for essential oil, but year factor is significant for European coriander and interaction (year x fertilizer) factor is significant for Argentinean coriander ($p<0.05$). In their study about nitrogen doses and density effect on coriander quality, Moosavi et al. (2013) found that nitrogen doses have positive significant effect on essential oil rate of coriander and obtained values between 0.15 - 0.33% and tested highest value from 120 kg ha^{-1} nitrogen application. Akbarinia et al. (2007) found that the highest essential oil rate was obtained with 90 kg N per hectare application.

*:$p<0.05$; **:$p<0.01$; NS: not significant; [1]: Different letters after the same column data indicate significant difference at the 0.05 level or similar

Results in the study is suitable with Gil et al. (2002), Lenardis et al. (2000), Moosavi et al. (2013) and Patel et al. (2013). However, values are lower. It can be caused from difference of essential oil between cultivars. According to these results, it can be said that,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73237336

ecological conditions, cultural applications and cultivars can cause differences for nitrogen effect on essential oil rate.

Essential oil composition

In the study where the effect of different doses of nitrogen in the coriander on essential oil components was determined, 18 components in total were detected (*Table 5*). The major components of coriander were found to be linalool, γ-terpinene, α-pinene, geranyl acetate and camphor. It was observed significant ($p<0.05$) differences between main factor years for linalool and geranyl acetate. Mean data between nitrogen doses were statistically significant for linalool ($p<0.05$), γ-terpinene, α-pinene, geranyl acetate and camphor ($p<0.01$). Significant interaction was tested for linalool ($p<0.05$), γ-terpinene, α-pinene, geranyl acetate and camphor ($p<0.01$). Highest mean value for linalool was obtained at 100 kg ha^{-1} nitrogen application (66.71%). Lowest value was measured at control group (57.35%). Linalool rate was increased by increasing nitrogen doses. Highest value (8.67%) for γ-terpinene was obtained at 60 kg ha^{-1} nitrogen application and lowest value (5.84%) was obtained at control group. Highest value (7.03%) for α-pinene was measured at 60 kg ha^{-1} nitrogen application and lowest value (5.80%) was obtained at control group. For geranyl acetate, highest value (6.15%) was obtained at 40 kg ha^{-1} nitrogen application and lowest value (3.68%) was obtained at control group. For camphor, highest value (4.78%) was obtained at 40 kg ha^{-1} nitrogen application and lowest value (3.08%) was obtained at 100 kg ha^{-1} nitrogen application. Regarding to components of essential oil, linalool was increase with increasing nitrogen doses, γ-terpinene was increase until 60 kg ha^{-1} nitrogen application; α-pinene, geranyl acetate and camphor were increase until 40 kg ha^{-1} nitrogen application.

In their study about cultivar and location, İzgi et al. (2017) found 12 total components and 4 major components in Gamze cultivar as linalool (74.7% - 82.2%), α-pinene (0.3% - 4.1%), neryl acetate (3.6% - 6.5%) and γ-terpinene (1.9% - 4.2%). In his study of nitrogen treatment effect on essential oil composition of coriander, Khalid (2014) obtained 15 different contents of essential oil, and found linalool (75.5% - 76.9%), limonene (6.8% - 7.4%) and camphor (3.7% - 3.9%) as major components of coriander and stated that values of major component differ from control group significantly. In another study about effect of micro and macro nutrients on essential oil of coriander, Khalid (2015), found that major components of essential oil in coriander (linalool, limonene and camphor) increase with increasing fertilizer (NP) doses but effect is not significant statistically. However, he found that α-pinene increase significantly ($p<0.05$) with fertilizer application.

The results that obtained from this study was lower than literature, but effect of fertilizer factor was suitable with literature. It can be caused from different ecological conditions, cultivars and cultural applications.

Fatty oil content (%)

Variation in fatty oil content was given in *Tables 7 and 8*. While fatty oil content was higher at second year, year differences were not statistically significant. Although highest value (23.64%) was obtained at 80 kg ha^{-1} nitrogen application and lowest value (23.14%) at 40 kg ha^{-1} nitrogen application, differences between doses were not statistically significant.

In their study about cultivar effect on coriander, Gökduman and Telci (2018) reported that mean fatty oil rate is 18.64% for Gamze cultivar. Keskin and Baydar (2016)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73237336

determined the mean fatty oil rate of the Gamze type as 24.62% under the ecological conditions of Isparta. Khalid (2012) found significant effect of fertilizer (NP) on fatty oil rate and values between 2.5% - 6.8%. Regarding to mean data of fatty oil, Khalid (2013) found difference of nitrogen doses significant ($p<0.05$) and values between 5.5% - 8.2% in coriander. Values found in this study is higher than Khalid (2012, 2013)'s findings and same with Keskin and Baydar (2016) and Gökduman and Telci (2018).

*: $p<0.05$; **:$p<0.01$; NS: not significant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73237336

It has been found that the effect of genetic control on the fatty oil rate in the coriander is stronger than nitrogen fertilization.

Fatty acids composition (%)

A total of 12 fatty acids were determined in the fatty oil samples obtained from different nitrogen applications in coriander. The components of the major fatty acids were found as petroselinic acid, butyric acid and linolenic acid. Doses and interaction factor were not statistically significant for petroselinic acid and linolenic acid. Year differences were not statistically significant for major components of fatty acids. Regarding to dose differences, while highest mean value (62.18%) for petroselinic acid was observed at 100 kg ha^{-1} nitrogen application, mean differences between dose groups were not statistically significant. For linolenic acid, highest value (10.33) was obtained at 60 kg ha^{-1} nitrogen application; however dose differences were not statistically significant. Doses and interaction factor were statistically significant ($p<0.05$) for butyric acid, but year factor was not significant. Statistically ($p<0.05$) highest value of butyric acid (26.35%) was observed at 60 kg ha^{-1} nitrogen application and lowest value was observed at 100 kg ha^{-1} nitrogen application.

Information on the fatty acid content of coriander in order to nitrogen application in literature is very limited. Akbarinia et al. (2007) measured that highest fatty acid compositions were obtained with 90 kg per hectare nitrogen application. Keskin and Baydar (2016) found petroselinic acid, major component of fatty oil in coriander, at level of 79.16%. Msaada et al. (2010), in their studies, where they examined the fatty oil content of coriander in different maturation periods determined 12 components, and among them, identified petroselinic (80.36 ± 8.45), linoleic (14.12 ± 1.35), palmitic (4.09 ± 0.42) and stearic (0.66 ± 0.05) acid as the major components. Ramadan and Mörsel (2002) found 12 components and reported that the main oil components and rates in coriander fruit were petroselinic acid (65.7%) and linoleic acid (16.7%). In the study of oil rate in different part of Tunisian coriander, Sriti et al. (2009) obtained 9 components and found petroselinic acid (74.07%), linoleic acid (13.41%) and oleic acid (5.91%) as major components in fatty acids of fruit. In their study of salinity effect on coriander, Neffati and Marzouk (2008) obtained 9 different components of fatty acids and found α-linolenic acid (24.14%) as a major component.

According to this study, it can be concluded in literature that nitrogen fertilization has a positive effect on butyric acid in coriander fruits. The limited change in the nitrogen applications of the primary metabolite fatty acids can be explained by the fact that the control of the genetic structure in the plant is more dominant.

Conclusion

This research aims to determine the effect of nitrogen fertilization in coriander on fruit yield and quality in plain conditions of Mardin province. The results are given below as items.

1. It has been observed that nitrogen doses have an insignificant effect on fruit yield.
2. It has been tested that nitrogen doses have an insignificant effect on essential oil rate.
3. Linalool increased in parallel with increasing nitrogen doses.
4. Nitrogen fertilization did not affect fatty oil rate and other major components statistically.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73237336

5. Year differences were not statistically significant for essential oil and fatty oil rates.
6. In coriander seeds; It has been determined that genetic control is stronger in the fruit yield, fatty oil content and fatty acids composition compared to nitrogen dose applications.
7. Since nitrogen fertilization increases the linalool ratio in the fruit and thus the essential oil quality, the use of the appropriate dose will increase the market value of the coriander product.
8. At the end of the study; In addition to the application of nitrogen dosage, additional studies on quality relationships with some other important plant nutrients, sowing time and harvest time have emerged.

(Received 19th May 2020; accepted 17th Sep 2020)

Abstract. Indonesian durian (*Durio zibethinus* Murr.) germplasms cultivated on Nias Island were assessed for their genetic diversity and relationships using Random Amplified Polymorphic DNA (RAPD) markers. Fifty accessions were collected from five populations or zones in Nias Island, Indonesia. All RAPD fragments were polymorphic as revealed by the use of OPA-01, OPA-03, OPA-07, OPA-13, OPN-06, and RAPD-05 primers within and among the durian germplasms. Primer OPA-03 was evaluated as a highly informative marker. Similarity values (Jaccard) ranged from 0.216 to 0.423 between different populations and 0.00 to 0.89 within the populations. The genetic structure between populations ranged from 1.71 to 1.92 for mean number of alleles (n_a), and from 1.35 to 1.59 for effective number of alleles (ne). Shannon's diversity index (I) ranged from 0.34 to 0.51, and the Nei's gene diversity index (h) ranged from 0.21 to 0.34. Result of cluster analysis based on Unweighted Pair Group Method with Arithmetic Mean (UPGMA) grouped all germplasms into thirteen clusters, some were admixtures between different populations. Result of Principal Coordinate Analysis (PCoA) confirmed the UPGMA dendrogram with the results of five main clusters among durian accessions from Nias Island, Indonesia.
Keywords: *durian, germplasm, polymorphism, principal coordinate analysis, molecular diversity*

Introduction

Durian (*Durio zibethinus* Murr.) is one of the edible *Durio* species with an approximate number of 30 species dispersed throughout the world (Brown, 1997). This popular tropical fruit species has been cultivated mainly in Southeast Asia, including Malaysia, Thailand, and Indonesia as a potential export commodity. Indonesia's durian production is thought to increase following an average annual increment of 4.86% in 2013 which also coherently increased its selling price from year to year due to its popularity and high market demands (CDISA, 2014). The popularity basis of this fruit is due to its sweet and strong-pungent aroma with a fleshy texture of its edible pulps (Belgis et al., 2017). In addition, the fruits are rich in essential nutrients which may provide beneficial health properties to the consumers as well as supporting the local business of many durian farmers to improve their socio-economic life (Ho and Bhat, 2015).

There are currently two mostly known and favored durian species from Indonesia, namely durian (*D. zibethinus* Murr.) and lai (*D. kutejensis* Hassk. & Becc.), both were reported originate from and harvested mainly in Kalimantan (Borneo) (Reksodihardjo, 1962). Moreover, Borneo is described as one of the durian germplasm centers in the world with a total of 18 species, followed by Malaya (11 species), and Sumatra (7 species) while several Indonesian durian species has also been regarded as endemic germplasms (Kostermans, 1953; Nyffeler and Baum, 2000; Uji, 2005). Until 2015, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73377351

Government of Indonesia has listed 93 superior local durian cultivars compiled from three officially-commercialized durian species, the *D. zibethinus, D. kutejensis,* and *D. oxleyanus* with future possibilities on identifying other wild cultivars to be promoted and listed in Indonesian collection of indigenous durian cultivars (Santoso et al., 2016).

Information on the diverse local cultivars will also support the plant breeding sector, especially the crop breeder to produce progenies with adaptive and varying phenotypes or to select parental lines with improved productivity responding to future changes (Moreno and Trujillo, 2005). Among three durian species in Indonesia, *D. zibethinus* cultivars are mostly known and consumed especially in Sumatra and Java due to its abundance and availability regardless of harvesting period. Nias Island is one of the regions in North Sumatra, located in the eastern Indian Ocean, known for its intense trade of many local *D. zibethinus* cultivars compared to other provinces in Indonesia. The island is inhabited by local tribe or the Nias people who are practically cultivating *D. zibethinus* in many agricultural fields or harvesting the wild cultivar directly from the forest (Hannum et al., 2019). Moreover, Gunungsitoli as the central city of Nias Island, has been declared by the Government of Indonesia as an iconic city for durian tourism to increase the socio-economic life of the locals. However, there is no information and comprehensive study on their *D. zibethinus* germplasm originating from the island.

To date, studies on identifying or grouping the *D. zibethinus* populations (cultivars) based on their genetic characteristics using genetic markers have been reported. Genetic markers and polymerase chain reaction (PCR), produced a more informative result in characterizing the genetic diversity than morphological features, along with its advantages and limitations (Weising et al., 1995; Ibrahim et al., 2010). Genomic profiling using RAPD markers, has been reported as a preliminary investigation on the classification of durian cultivars in countries with abundant durian germplasms, including Indonesia (Ruwaida et al., 2009; Vanijajiva, 2011; Mursyidin and Daryono, 2016; Prihatini et al., 2016; Rosmaina et al., 2016). RAPD analysis was favored as the initial method in genetic fingerprinting due to its simplicity, low-cost, tiny amount of target DNA requirement, and non-requirement of target genetic sequences (Welsh and Mc-Clelland, 1990; Williams et al., 1990). Practicality of these markers increased their performance as attractive guidance in studying the overall genetic variation and population genetic structure (Lynch and Milligan, 1994). To our knowledge, RAPD-based profiling of local durian cultivars has been reported for some regions in Indonesia, but still no information for the cultivars originating from Nias Island in North Sumatra. In this study, six RAPD markers were utilized to evaluate the genetic variation among 50 durian accessions with an emphasize on the relationship between and within durian populations from Nias Island, Indonesia.

Methodology

Plant materials

Durian (*Durio zibethinus* Murr.) accessions from five different populations comprising Nias City, Central Nias, West Nias, North Nias, and South Nias were collected randomly from Nias Island in 2019 (*Fig. 1*). The list of 50 durian accessions and their vernacular names is listed in *Table 1*. The foliar parts were sampled and preserved in a dried zip-lock bag filled with silica beads prior experimentation in the laboratory (*Fig. 2*).

DNA isolation and PCR amplification

Extraction of DNA genomes was carried out from foliar parts of selected accessions following the principle of hexadecyltrimethylammonium bromide (CTAB) with modification on using 4% CTAB solution and additional 2 mg of polyvinylpyrrolidone (PVP) during extraction (Murray et al., 1980). The isolated DNA was quantified at $A_{260/280}$ using NanoPhotometer P-Class® (Implen, US) and was visually checked on 1% agarose. Six decamer RAPD primers namely OPA-01, OPA-03, OPA-07, OPA-13, OPN-06, RAPD-05 were screened for amplification of scorable and reproducible DNA fragments. PCR reaction of a 20 µL reaction mixture contains: 10 µL (0.5 unit) of DreamTaq Green PCR Master Mix (2×), 2 µL (100 ng) of DNA template, 1 µL (0.6 mM) of primer, and 7 µL nuclease-free water. Thermal cycler (SensoQuest GmbH, Germany) was used for PCR-RAPD reactions with specification as follows: 95 °C (30 s), 34 °C (30 s), 72 °C (1 min), and 72 °C (5 min). The reaction products (5 µL) were mixed thoroughly with 2 µL loading dye prior loading. Both PCR products and DNA ladder (1 kb) were separated in 1.5% agarose with 1× TAE buffer. The PCR products were resolved by running gel at 70 V for 45 min. The gels were stained in 1 L of distilled water added with 10 µL of ethidium bromide for 10 min. The gels were observed under UV light and documented inside of a gel imaging device (G:Box Syngene, India). PCR-RAPD was repeated twice to ensure the reproducibility of reactions.

Data analysis

DNA polymorphism was evaluated and scored manually based on the presence (1) and absence (0) for each scoreable DNA fragment to generate a binary data set. The number of alleles and polymorphic bands were calculated for each primer as the percentage of polymorphisms (%). Determination of the marker suitability was evaluated through three parameters:

The polymorphic information content (PIC) value of each primer was the average of all loci in a primer (Powell et al., 1996):

$$Polymorphic\ Information\ Content\ (PIC) = 2fi(1 - fi) \quad \text{(Eq.1)}$$

The marker index (MI) value which explains the usefulness of a marker to discriminate the polymorphism. The effective multiplex ration (EMR) was obtained from a multiplication of the number of loci polymorphic in the germplasm set of interest (Varshney et al., 2007):

$$Marker\ Index\ (MI) = EMR\ x\ PIC \quad \text{(Eq.2)}$$

The resolving power (RP) value shows the ability of the most informative primers to discriminate genotypes of interest, where i_b is the band informativeness (Prevost and Wilkinson, 1999):

$$Resolving\ Power\ (RP) = \sum i_b \quad \text{(Eq.3)}$$

Genetic diversity among populations was estimated by following parameters: the average number of alleles (n_a), effective number of alleles (n_e), heterozygosity (h) (Nei,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73377351

1973), Shannon's diversity index (*I*) (Shannon, 1949), and percentage of polymorphic loci (P%) using POPGENE ver. 1.32 (Yeh and Boyle, 1997). The binary data of each population and accession were calculated for the similarity values (Jaccard, 1908) using NTSYS-pc ver. 2.1 by applying Similarity for Qualitative Data, Simple Matching (SimQUAL-SM) feature (Rohlf, 2000). The genetic relatedness or cluster analysis among populations and within 50 durian accessions was visualized in a UPGMA dendrogram by applying the Sequential Agglomerative Hierarchical and Nested (SAHN) module in NTSYS-pc. In addition, a Principal Coordinate Analysis (PCoA) was used to plot the ordination matrices using EIGEN and PROJ features (NTSYS-pc).

Results

The assessment of genetic diversity among 50 durian germplasms used six RAPD primers to characterize their genetic information based on the presence/absence of polymorphic bands (*Fig. 3*). We observed that all primers produced legible and reproducible polymorphic patterns in two repetitions. Two factors in determining the genetic diversity using molecular markers are marker informativeness and marker performance with the results listed in *Table 2*. Each RAPD primer was evaluated for its informativeness based on the following parameters (*Table 2*). Sixty-six clear and reproducible RAPD fragments (200–2800 bp) was generated in this study. Interestingly, all RAPD bands showed a high level of polymorphism (100%) which also meant that no conserved pattern or monomorphic bands were observed. The average of polymorphic bands was eleven with the range from nine (OPA-01, RAPD-05) to fourteen (OPN-06) with an average of eleven. The polymorphic RAPD fragments were carefully scored and utilized for clustering and ordination analysis herein.

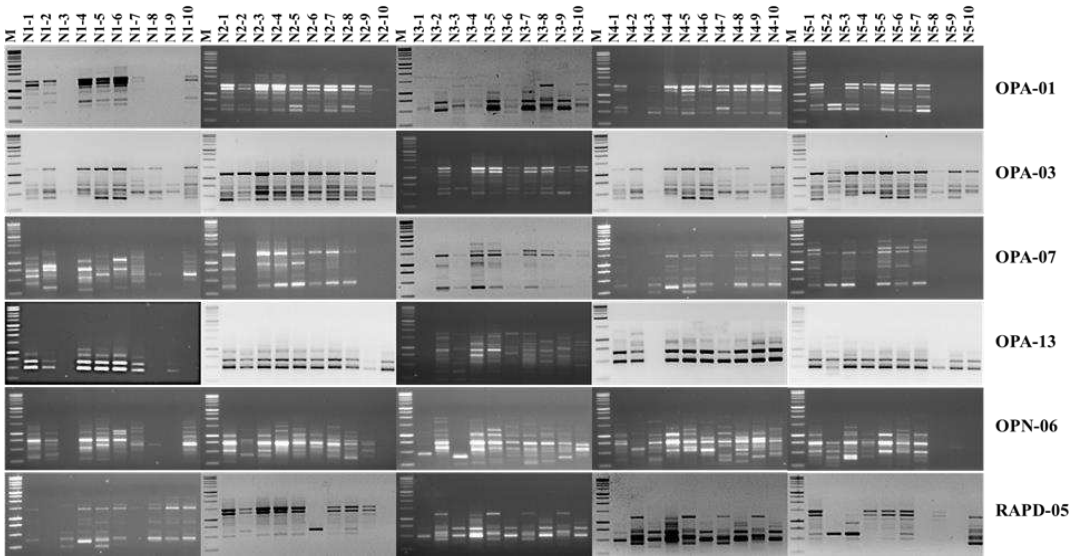

Figure 3. *Genetic profile of the 50 Durio zibethinus Murr. accessions (N1-1–N5-10) generated by five RAPD primers. Marker used was 1 kb (250-10,000 bp)*

Each accession was analyzed for the evaluation of its marker performance based on the following parameters (*Table 2*). The average PIC value was 0.42 for 66 polymorphic bands with the range between 0.29 to 0.48. Forty-three RAPD fragments were regarded

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73377351

as greatly informative (PIC ≥ 0.4), four fragments were low (0.0–0.2), while the remaining nineteen fragments were medium (0.2–0.4) (*Fig. 4*). OPA-01 was observed as with the highest PIC value (0.48) while the lowest (0.29) was obtained from RAPD-05. The highest EMR (7.36) was observed for primer OPA-03 with the mean per primer was 4.46 (*Table 2*). The overall performance from each RAPD marker was evaluated from its marker index (MI). The MI for the six primers ranged from 0.50 (RAPD-05) to 3.46 (OPA-03) with an average of 1.94. The resolving power (RP) of RAPD primers is a parameter which indicates a discriminatory properties, ranged from 3.48 (RAPD-05) to 10.24 (RAPD-03) with an average of 7.47. There were significant correlations for PIC–MI ($r = 0.85$, $P = 0.032$), EMR–MI ($r = 0.99$, $P = 0.000$), EMR–RP ($r = 0.94$, $P = 0.006$), and MI–RP ($r = 0.90$, $P = 0.015$) which showed that the parameters of marker performance resulted in our study were considerably related each other.

Table 2. *Polymorphism and marker characteristics of RAPD primers*

Primer name	Sequence (5′- 3′)	Number of fragments			% Polymorphism	PIC	EMR	Marker index	Resolving power

Genetic diversity of five durian populations from Nias Island was estimated based on the RAPD amplification results under following range of values: effective number of alleles (n_e) from 1.35 to 1.59, mean number of alleles (n_a) from 1.71 to 1.92, Nei's gene diversity index (h) from 0.21 to 0.34, and Shannon's diversity index (I) from 0.34 to 0.51 (*Table 3*). Based on the polymorphic loci (P%), West Nias and North Nias displayed the highest variation of durian cultivars with the percentage of 92.42 for both zones. According to the overall variation resulted from P%, the ranking among Nias durian population was West Nias/North Nias > South Nias > Central Nias > Nias City. Our findings then strongly suggested that the durian germplasms cultivated in five different regions were highly varying as evidenced effectively through RAPD genetic analysis.

Table 3. *Estimates of genetic diversity within five populations (zones) using RAPD markers*

Index	Nias City	Central Nias	West Nias	North Nias	South Nias	All
n_a	1.71	1.88	1.92	1.92	1.89	2.00
n_e	1.35	1.55	1.52	1.59	1.56	1.77
h	0.21	0.32	0.31	0.34	0.33	0.42
I	0.34	0.47	0.47	0.51	0.49	0.60
P%	71.21	87.88	92.42	92.42	89.39	100.0

n_a = Average number of alleles; n_e = Effective number of alleles; h = Heterozygosity; I = Shannon's diversity index; P% = Percentage of polymorphic loci

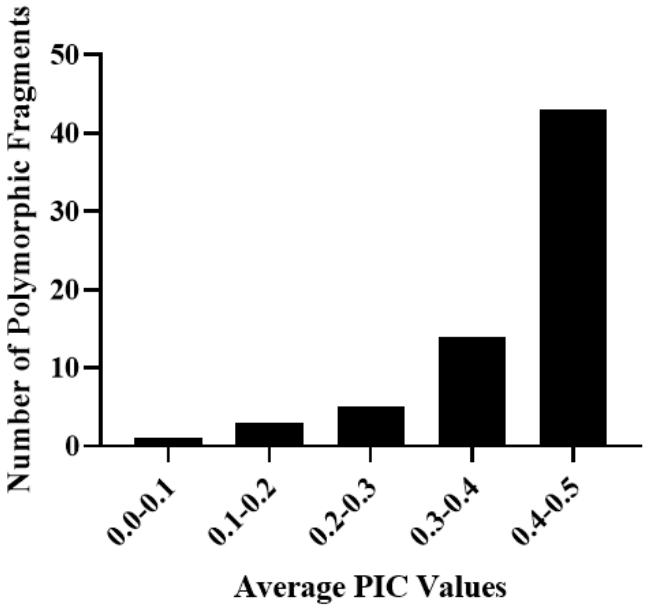

Figure 4. *Average PIC values for polymorphic bands generated by RAPD primers in 50 durian accessions*

The similarity values among populations were estimated using Jaccard's similarity matrices retrieved from RAPD binary data. The similarity values ranged from 0.216 to 0.423 with an average of 0.31 (*Table 4*). A UPGMA dendrogram was constructed to depict the populations grouping (*Fig. 5*). The result showed the ingrouping of Nias City, West Nias, and North/South Nias populations with Central Nias being an outlier. In addition, results showed that populations of North Nias and South Nias were more similar (42%) than others while the population of North Nias was separated indicating its high genetic dissimilarity.

Table 4. *Similarity matrix based on Jaccard's coefficient from five populations (zones)*

Index	Nias City	Central Nias	West Nias	North Nias	South Nias
Nias City	1.000	-	-	-	-
Central Nias	0.263	1.000	-	-	-
West Nias	0.333	0.294	1.000	-	-
North Nias	0.216	0.233	0.367	1.000	-
South Nias	0.410	0.175	0.342	0.423	1.000

Genetic diversity among 50 durian individuals or accessions were based on the Jaccard's similarity values. The similarity value of overall accessions ranged from 0.00 to 0.89 with an average of 0.44 (data not shown) indicating a close genetic relationship within the accessions. A UPGMA dendrogram revealed the eight main clusters and four outliers (cluster 6,7,8,10), with cluster (1) comprises the largest members with fourteen germplasms (*Fig. 6*). In order to visualize a better degree of differentiation among accessions, the spatial analysis using PCoA was utilized to represent the relative genetic similarities among individuals. The result was plotted into a two-dimensional plot generated from PCoA based on the calculated eigenvalues and eigenvectors.

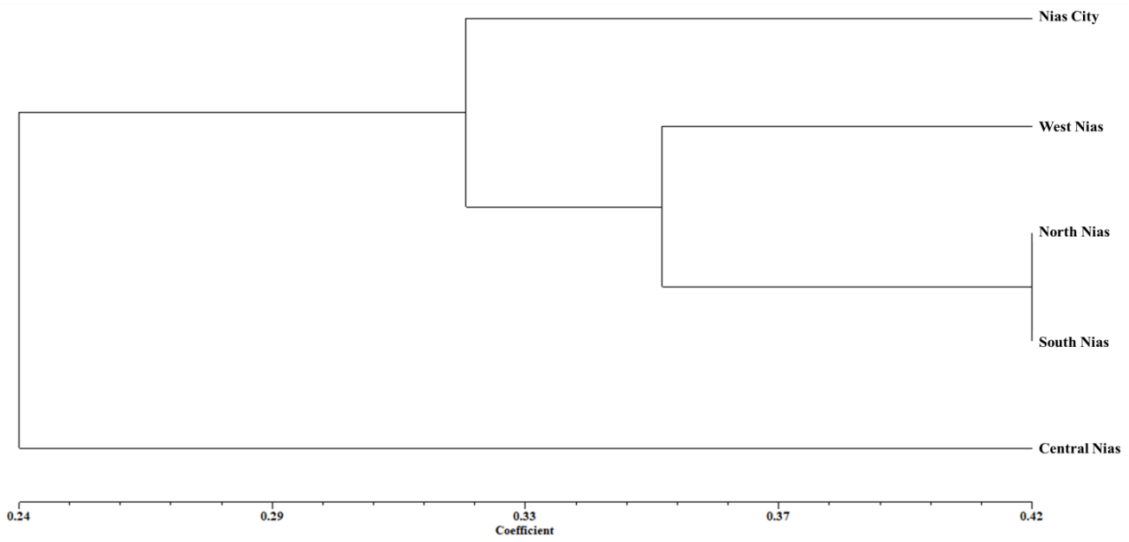

Figure 5. *A UPGMA dendrogram among five populations (zones) based on Jaccard's similarity coefficient calculated from RAPD data set*

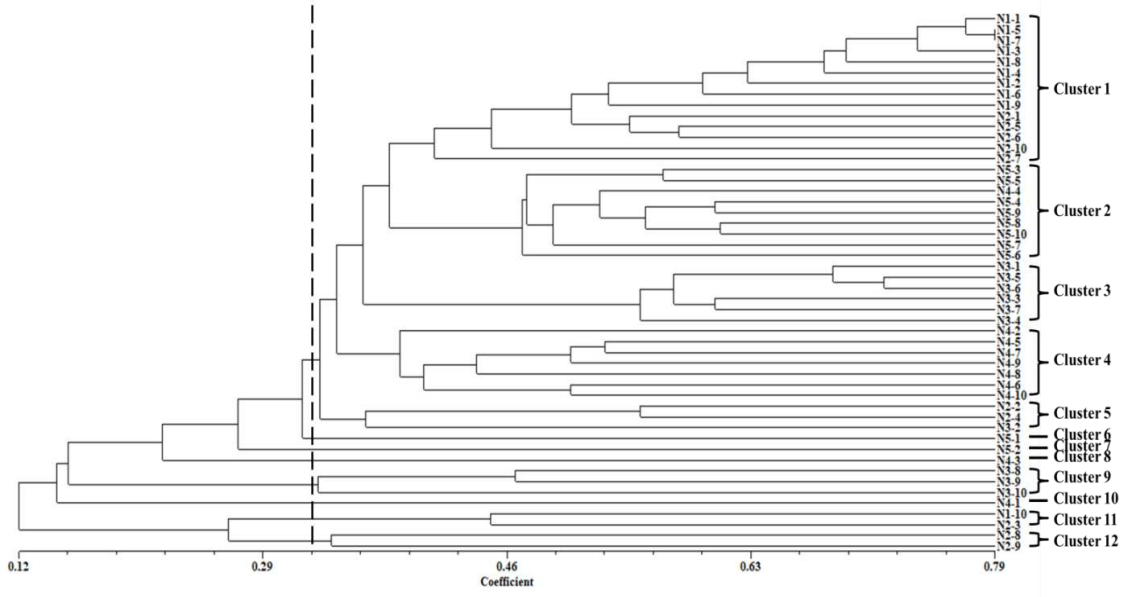

Figure 6. *A UPGMA dendrogram among 50 durian cultivars (N1-1–N5-10) based on Jaccard's similarity coefficient calculated from RAPD data set*

Results showed that the first two principal coordinates contributed for 53.9% of the total variation, with lesser contribution of other coordinates (<4%) each (*Fig. 7*). The accessions were later grouped into five clusters based on their coordinates; cluster (1) comprises four germplasms, cluster (2) with one germplasm, N4-1, cluster (3) with three germplasms, cluster (4) with sixteen germplasms, and cluster (5) with twenty-six germplasms. Moreover, the three-dimensional plot was generated and confirmed the coordinative trend with the 2D plot indicating a clear distinction among the 50 accessions (*Fig. 8*).

Discussion

Identification of new crop germplasms by using DNA fingerprint is important prior the release and introduction of new varieties/cultivars to the agricultural fields and the differentiation of wild accessions bearing beneficial phenotypic traits. Genetic diversity and structure among 50 durian (*D. zibethinus* Murr.) accessions cultivated in different zones (regions) of Nias Island, Indonesia were analyzed using RAPD markers in this study. The PCR-RAPD has been utilized to employ the genetic characterization and profiling among germplasms for the major reason of its simplicity and ease of application. However, RAPD technique had some limitations, such as dominant type of inheritance, poor reproducibility, and co-migration issue (Munthali et al., 1992; Lowe et al., 1996). In this study, we optimized the reaction conditions and found out that during two repetitions, good and scorable DNA fragments were generated and they were consistent hereafter. Six RAPD primers (OPA-01, OPA-3, OPA-07, OPA-13, OPN-06, RAPD-05) produced an absolute polymorphism percentage (100%) among 50 accessions based on the absence/presence or binary data of DNA fragments. Therefore, the six RAPD markers used in this study were regarded as equally effective in determining polymorphisms as revealed from its PIC value in the level from moderate to high informative (Hildebrand et al., 1992).

RAPD primer with high PIC value also indicated the more usefulness of its utilization among primers, following other parameters such as EMR, MI, and RP in determining the genetic distance within a population (Kalinowski, 2002). Variety of RAPD primers have been reported to determine the genetic diversity of other local durian cultivars. Ruwaida et al. (2009) also employed six RAPD primers (OPA-01, OPA-02, OPA-07, OPA-16, OPA-18, OPA-19) in assessing the diversity of five durian cultivars from Java, Indonesia and reported them to be sufficient in separating between cultivars. Mursyidin and Daryono (2016) utilized five RAPD primers (OPA-01, OPA-07, OPA-16, OPA-18, OPA-19) to differentiate 11 durian accessions from South Kalimantan, Indonesia. Li and Midmore (1999) suggested that the use of few primers will be satisfactory in differentiating genotypes with high variations.

The high level of diversity in durian cultivars may due to the existence of wild hybrids within populations since durian is known as open pollinating plants in which pollination being facilitated by mostly fruit or nectarivorous bats (Bumrungsri et al., 2009). In addition, utilization of different DNA markers and other profilling techniques may produce different results in estimating the durian genetic diversity. Rosmaina et al. (2016) reported the high variation among five durian cultivars from Indonesian germplasm with a low genetic relationship or Nei and Li's genetic distance (0.27 to 0.47) based on RAPD analysis. Prihatini et al. (2016) reported a high variation among 32 durian F_1 hybrids from Indonesia based on RAPD analysis (0.14 to 0.77). Vanijajiva (2012) applied the inter simple sequence repeat (ISSR) markers to detect genetic variation among 14 durian accessions from Thailand and reported the less genetic relationship (0.63 to 1.00). Sundari et al. (2017) reported a medium to high level of genetic diversity (0.41 to 0.93) 15 durian cultivars from Ternate Island, Indonesia based on RAPD analysis. Nurlaila et al. (2019) reported the medium level of variation among 18 local durian varieties from South Sulawesi, Indonesia by using the morphological traits (0.08 to 0.50).

Based on our results, the fifty durian accessions collected from five different zones or populations in Nias Island were highly diverse (0.21 to 0.42) among populations. Hence, the result again supported the fact that the genetic diversity of Nias cultivars

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73377351

were slightly higher than previous reports and worth investigated. Based on the cluster analysis, the dendrogram showed a close relationship between North and South durian populations, while Central Nias and Nias City were different despites its adjacent location. Furthermore, the dendrogram among 50 accessions showed that some accessions with different geographical origins or zones were clustered together in the same group. We assumed that the phenomenon may due to the mobility of local farmers from the Central Nias/Nias city or any initial geographical points to other regions cultivating the durian seeds in the new agricultural locations. The similar finding was also reported from sesame (*Sesamum indicum* L.) populations in West Bengal, India as revealed from the RAPD analysis (Saha et al., 2019). Human factor may then be responsible for the geographical detachment of associated cultivars in some cases (Stankiewicz et al., 2001).

Deeper analysis among accessions was done by plotting the converted binary data into eigenvalues and projected using principal coordinate analysis (PCoA). Based on the 2D plot, we assigned five clusters out of the thirteen durian clusters constructed previously from UPGMA dendrogram analysis, with some admixtures among populations. Confirmatory analysis using the 3D plot projection using three coordinates supported our grouping although some accessions between cluster (4) and (5) were indiscriminative to some coordinates. N4-1 was the only cultivar discriminated and far distantly from other accessions hence grouped into own cluster (2). The existence of N4-1 cultivar in Nias Island revealed its unique genetic identity which may be explored thoroughly for any beneficial and tolerant traits to environmental changes.

In practical term, N4-1 may divert even more further than its members in the long term which can later be categorized as a new species or sub-species. Further investigations are needed to uncover this phenomenon since no comprehensive study on the botanical backgrounds or information of durian cultivars from Nias Island so far. The PCoA method has been used to discriminate many crop cultivars based on the RAPD database, such as Brazilian coffee plants (Sera et al., 2003), Indian coconut accessions (Upadhypay et al., 2004), Turkish marijuana accessions (Pinarkara et al., 2009), Thailand durian populations (Vanijajiva, 2011), durian populations from Indonesia (Santoso et al., 2016), and our study. Interestingly, Santoso et al. (2016) found that the Sumatra and Kalimantan durian cultivars were closely related based on the PCoA projection through the use of microsatellites as molecular markers. However, the study only used the accessions from the mainland of North Sumatra and still not incorporated the accessions from Nias Island. We assumed that more distinctive genotypes may be observed by studying the durian cultivars from Nias Island as evidenced from RAPD analysis in this study, but this will need a more comparative studies in the future.

Conclusion

Based on the genetic similarity and population genetic structure analysis, the study concluded that the local durian cultivars originating from Nias Island were highly diverse. The result of clustering analysis produced thirteen clusters with some admixtures between different geographical populations. Under population level, the North Nias and South Nias were closely related revealing a possible human factor in durian diversification in the level of varieties or cultivars. Based on PCoA projection, we further grouped the durian populations into five clusters with major accessions

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73377351

grouped into cluster (4) and (5). Moreover, N4-1 is the only cultivar placed in its own cluster (2) indicated a distinct genetic identity among cultivars. As a recommendation related to this study, we suggest that N4-1 may be possibly harnessed and studied for its beneficial genotypic and phenotypic agricultural traits such as its fruit quality and productivity with other characteristics in agronomical aspect. Therefore, a correlation study between agro-morphological and genetical traits from each cultivar must be assessed for a rapid identification of cultivars under practical terms in the future.

SPATIAL STAND STRUCTURE ANALYSIS OF ULUDAĞ FIR FORESTS IN THE NORTHWEST OF TURKEY

ÇOBAN, S.

Department of Silviculture, Faculty of Forestry, Istanbul University-Cerrahpasa, Bahcekoy-Sarıyer, 34473 Istanbul, Turkey
(e-mail: scoban@istanbul.edu.tr; phone: +90-212-338-2400; fax: +90-212-338-2424)

(Received 22nd May 2020; accepted 14th Sep 2020)

Abstract. Forest structural characteristics, which are one of the key determinants of species and habitat diversity, have also been used as a constitutive factor in sustainable forest management. This study aimed to analyse the spatial structure (Clark-Evans, segregation and species mingling) of pure fir (7 plots, 1000-1600 m a.s.l.), fir dominated (5 plots, 1000-1400 m a.s.l.) and fir-beech co-dominated (7 plots, 1000-1300 m a.s.l.) stands at the center and edge distribution of *Abies nordmanniana* ssp. *bornmuelleriana* in Sub-euxine zone of Euro-Siberian region of Turkey. The Shannon diversity of tree species was found significantly ($P < 0.01$) lower in the edge distribution (Bolu-Aladağ) (0.418 ± 0.081) compared to Yenice (0.824 ± 066). *Fagus orientalis* showed a clumped distribution in fir dominated stands where it is not competitive compared to *Abies nordmanniana* ssp. *bornmuelleriana* but it had a spatial association with other species in co-dominated stands. Light demanding deciduous trees such as *Quercus hartwissiana*, *Carpinus betulus* and *Populus tremula* were observed in pure groups, whereas *Pinus sylvestris* and *Pinus nigra* did not show a tendency towards clumping and had a spatial association with other species since they were located in upper stand layer. As shown in this study, spatial data in stand profiles provide new opportunities for understanding ecosystem structure and silvicultural treatments.
Keywords: *Euro-Siberian, mingling, aggregation index, beech, species segregation index, stand profile*

Introduction

Forest tree composition is shaped by competitive interactions among individuals in natural forests which determine the size and position of individual trees. These interactions among species are reflected in complex stand structures and highly diverse mixture of species (Hui et al., 2018). Specific structures generate particular processes of growth and regeneration, thus tree growth and the interactions between trees depend, to a large degree, on the structure of the forest (Forrester, 2019; Bastias et al., 2020). On the other hand, forest structure is not only the outcome of natural processes but is also determined to a considerable extent by silvicultural interventions (Gadow et al., 2012). Aguirre et al. (2003) define stand structure as the spatial distribution of the tree positions, the spatial mingling of the different tree species and the spatial arrangement of the tree dimensions. Spatial stand structure, which is an important facet of habitat diversity, is associated with ecological stability and species diversity (Neumann and Starlinger, 2001; Pommerening, 2002; Kint et al., 2003; Szmyt, 2012; Gao et al., 2014; Bastias et al., 2020). Therefore, forest ecosystem diversity does not only refer to species richness but to a range of phenomena that determine the heterogeneity within a community of trees, including the diversity of tree sizes and tree locations (Ni et al., 2014).

Forest stand structure is essential inputs for understanding ecosystem structure and functioning, and hence for sustainable forest management (Kint et al., 2003; Schall et al., 2018). For this reason, forest structural characteristics have been a key determinant in silvicultural methods (i.e. thinning methods). Therefore, the description of stand structural characteristics has been commonly undertaken in silvicultural researches.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73537367

Forest stand structural characteristics have been traditionally illustrated using hand-drawn profiles based on actual measurements which show the horizontal and vertical projection of the stand (hereafter stand profile) (Çoban et al., 2016, 2018). Stand profiles, which are a depiction of a section through the forest, offer good opportunities for illustrating and analyzing horizontal and spatial forest structures (Nielsen and Nielsen, 2005). In Turkey, the earliest use of stand profiles in silvicultural researches dated back to 1970's (Aksoy, 1978; Bozkuş, 1986; Yönelli, 1986; Özalp, 1989; Ertaş, 1996; Çoban, 2013). Especially, stand profile measurements were carried out in phytosociological studies. These profiles were used to characterize vertical stand structure and tree size distributions. However, the spatial pattern of trees recorded and marked in the horizontal profile has not been evaluated so far. This spatial data provide a comprehensive description of the spatial structure of a forest using indices which have been developed in the past few decades in order to quantify neighborhood competition (Aguirre et al., 2003; Hui et al., 2018). In addition, determination of the spatial pattern of tree species in mixed stands is important in gaining a better understanding of the underlying ecological processes which will provide critical information about community structure and species coexistence (Ni et al., 2014).

In this study, it was aimed to determine spatial patterns of pure and mixed stands of fir in different site conditions. It was hypothesized that (1) tree species diversity of fir forests do not differ in the center and edge distributions in Sub-euxine zone of Euro-Siberian phytogeographic region (2) *Abies nordmanniana* (Stev.) Spach. subsp. *bornmuelleriana* (Mattf.) Coode & Cullen and *Fagus orientalis* Lipsky., which have similar shade tolerance, will have the same spatial pattern in all stand types.

Materials and methods

Site description

The study area is located in the northwest of Turkey, which is the main distribution area of *Abies nordmanniana* (Stev.) Spach. subsp. *bornmuelleriana*, hereafter will be referred as *Abies bornmuelleriana*. Stand profiles were selected from Karabük-Yenice (Çitdere) (Özalp, 1989) and Bolu-Aladağ forests (Aksoy et al., 2012) representing both center and edge distributions in Sub-euxine zone of Euro-Siberian phytogeographic region. Çitdere (6091 ha) is located in Yenice district of Karabük province which is in the western part of the Blacksea Region. It lies between 41°00'14" and 41°05'06"northern latitudes and 32°21'06" and 32°27'45" eastern longitudes. The altitude of the region ranges from 640 m a.s.l. to 1810 m a.s.l. Aladağ mountain (4502 ha) is situated between 31°33′30″ - 31°38′00″ eastern longitudes and 40°37′30″ - 40°41′30″ northern latitudes in the southern part of the Bolu province. The altitude of the mountain ranges from 750 m a.s.l. to 1840 m a.s.l. (*Fig. 1*).

The meteorological stations representing climate of the study areas are Karabük-Büyükdüz (1962-1970) and Bolu Şerif Yüksel Research Forests (Aladağ Mt.) (1975-1995). Mean annual precipitation and temperature were measured as 1371 mm and 6.2 °C at Büyükdüz station (1560 m), 882 mm and 5.7 °C at Bolu-Aladağ (1550 m).

Vegetation

The Euro-Siberian phytogeographical region was subdivided into Euxine, Sub-euxine and Xero-euxine zones from north to south (Zohary, 1973) since mountain

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73537367

ranges create varied climate characteristics. The Euxine zone is characterized by deciduous and mixed forests from the colline to submontane zone and various mixture combinations of *Abies bornmülleriana-Fagus orientalis* forest in the montane zone. The Sub-euxine zone is characterized by mixed *Carpinus-Quercus* and *Pinus nigra* forests and pure coniferous forest consist of *A. bornmülleriana* on northern slopes and *Pinus sylvestris* on southern slopes in the montane belt (above 1200/1300 m) (Akman, 1995; Mayer and Aksoy, 1998). The Xero-euxine zone surrounds Central Anatolia and characterized by forest-steppe vegetation with *Quercus pubescens* as the main tree (Zohary, 1973; Mayer and Aksoy, 1998; Kurt et al., 2006).

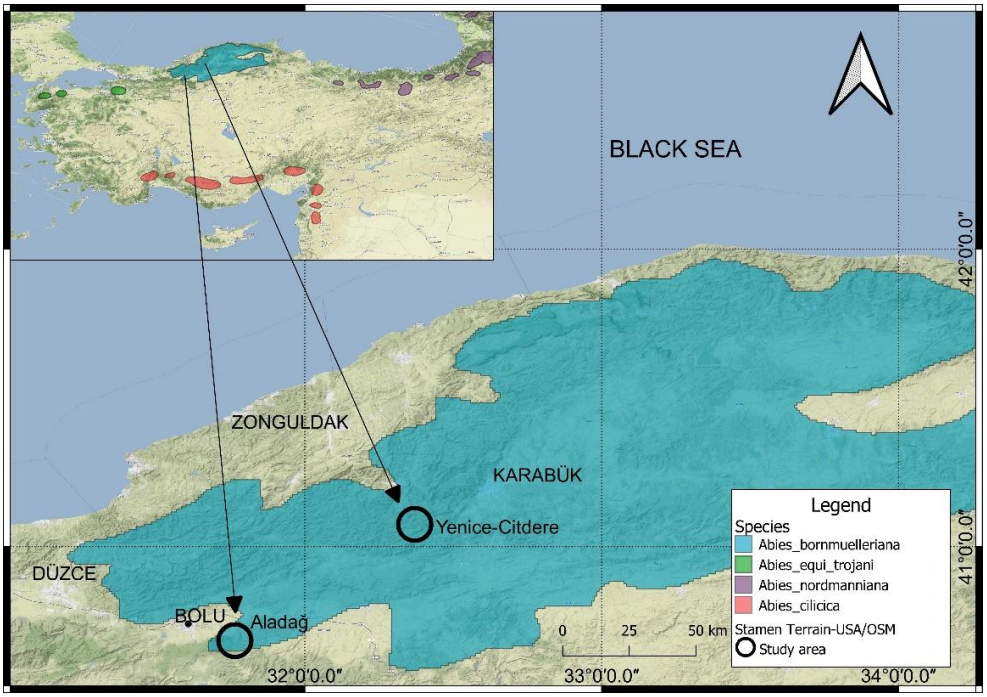

Figure 1. *Location of the study area (species distributions were taken from Alizoti et al., 2011)*

According to Çoban and Willner (2019), *Abies bornmuelleriana* dominated forests were classified under the alliance of *Lonicero caucasicae-Piceion orientalis* Çoban et Willner 2009, the order *Abieti nordmannianae-Piceetalia orientalis* Çoban et Willner 2019 and the class *Vaccinio-Piceetea* Br.-Bl. in Br.-Bl. et al. 1939. Mesic beech and fir-beech forests under the alliance *Fagion orientalis* Soó 1964, the order *Rhododendro pontici-Fagetalia orientalis* Passarge 1981 and the class *Carpino-Fagetea sylvaticae* Jakucs ex Passarge 1968.

Data preparation

Tree spatial data was taken from the original stand profiles of Özalp (1989) and Aksoy et al. (2012) which were used to characterize the stand structure of forest communities. Field sampling of the latter study was carried out in 1978 and vegetation data was published in 2012. Stand profiles are based on actual measurements of the positions, heights, heights of the lowest branches, and the diameters at breast height of trees over 5 m (Aksoy, 1978). In each diagram, tree positions, which were shown on millimeter papers at scale 1:200 for the whole plot, were measured with respect to a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73537367

Cartesian coordinate system. Stand profiles where Abies bornmuelleriana had a relative species per hectare (SPH) of at least 20% were included in the analysis. As a result, 19 stand profiles were obtained which were further grouped into pure fir (>85% fir), fir dominated (70-85% fir) and fir-beech co-dominated (20-70% fir) stands. The classification of the available data resulted in 7 stand profiles in both pure fir and fir-beech co-dominated stands and 5 stand profiles in fir dominated stands (*Table 1*).

Table 1. *Details of sample plots and their classification (species less than 10% of relative species per hectar (SPH) in any of the plots were not shown)*

Pure forests occurred between 1000 and 1600 m a.s.l., fir dominated forests 1000-1400 m a.s.l. and fir beech co-dominated forest between 1000 and 1300 m a.s.l. Pure forests were also found on steeper slopes compared to other units (*Fig. 2*).

Computed indices

In order to analysis spatial structure of the stands, following distance-dependent indices, also known as spatially explicit indices were used.

Species mingling (M_i)

Mingling (M_i) is defined as the proportion of neighbours which do not belong to the same species as the reference tree (Gadow, 1993; Füldner, 1995). The distribution of the M_i values, in conjunction with the species proportions within a given tree population, allows a detailed study of the spatial diversity within a forest. With four neighbours, indices have five possible values: 0.00, 0.25, 0.50, 0.75 and 1.00. While higher values show different species intermingled, small values indicate pure groups. For instance, a value of Mi = 0 is obtained if the neighbouring species belong to the same species, whereas Mi = 1 when all neighbouring trees are different than reference tree (*Eq. 1*).

$$M_i = \frac{1}{n}\sum_{j=1}^{n} v_{ij} \qquad \text{(Eq.1)}$$

where n is the number of the nearest neighbours, $v_{ij} = 1$ if the $species_j \neq species_i$ and $v_{ij} = 0$ otherwise.

Aggregation index of Clark-Evans (CE)

Clark-Evans index (CE) expresses the extent to which a forest deviates from the stands with a complete randomised spatial distribution of trees (*Eq. 2*). It uses distances between nearest neighbours and it is measured for all individuals located on the plot (Clark and Evans, 1954). The values are restricted to the range between 0 and 2.15 and values lower than 1 indicate clumped distribution, while regularity is assumed if the values are over 1. While complete regular hexagonal distribution results in the highest index of 2.15, random distribution equals to 1 (Neumann and Starlinger, 2001).

$$CE = \frac{1}{n}\sum_{i}^{n} r_i 2\sqrt{p} \qquad \text{(Eq.2)}$$

where r_i is the distance from one tree to his next neighbour and r is density of tree per square meter.

Species segregation index (S)

The Pielou Index (S) (Pielou, 1977) compares the observed number of mixed pairs with the one expected under random conditions, independently of their spatial pattern (*Eq. 3*). Values of the S index vary between −1 and 1. If $0 < S < 1$ indicates that the nearest neighbours are always same species (spatial separation or segregation of species) and if $-1 < S < 0$, spatial association between two species is observed (Kint et al., 2003). In the plots more than two species, segregation index is calculated by comparing one species against all others.

$$S = 1 - \frac{N.(b+c)}{m.s+n.r} \qquad \text{(Eq.3)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73537367

N is the numbers of all pairs of trees, m and n are the number of individuals of A and B respectively, r and s are the number of times species A and B are found as the nearest neighbours of a reference tree (Pommerening, 2002).

Species related Shannon index

The Shannon index (Shannon and Weaver, 1949) which describes species diversity was calculated based on SPH. The Shannon index takes the relative abundance of different species into account rather than simply expressing species richness. The Shannon index is affected by both the number of species and their evenness.

$$H = -\sum_{j=1}^{n} p_j . \ln\left(p_j\right) \qquad \text{(Eq.4)}$$

where p_j is relative frequency of tree species and n is number of tree species.

All of the values mentioned above were calculated using CRANCOD 1.4 (Pommerening, 2012) and stand profile figures were produced using the package ggplot2 (Wickham, 2009). Statistical significiance of groups in terms of measured parameters was tested using Systat SigmaPlot (SigmaPlot 14 trial version, www.systatsoftware.com). When the Shapiro-Wilk test showed the homogeneity and Brown-Forsythe test Equal Variances ($p > 0.05$), Student's t-test was applied to the data. Pearson Product Moment Correlation was used to measure the strength of association between pairs of variables.

Results

Tree species diversity

Fir and beech mixed forests of Yenice were found to have significantly ($P < 0.01$) higher diversity of tree species (0.824 ± 066) compared to Aladağ (0.418 ± 0.081). There was not a statistically significant difference between fir dominated (0.702 ± 0.103) and fir-beech co-dominated stands (0.798 ± 0.065). *Fagus orientalis* was the most common tree species in the mixture in both regions. Species such as *Carpinus betulus, Pinus sylvestris, Pinus nigra, Taxus baccata, Sorbus torminalis, Populus tremula* and *Quercus hartwissiana* had a scattering occurrence in the mixtures (less than 10% relative SPH). *Quercus hartwissiana* joined stand mixture only in Yenice region. Also, tree species diversity decreased with the ratio of fir ($r(18) = -0.69$, $p < 0.01$) (*Table 2*).

Spatial structure of stands

Mean distance to the first neighbour of all trees was 2.06 ± 0.16, 1.88 ± 0.19 and 2.07 ± 0.16 for pure fir, fir dominated and fir-beech co-dominated stands. When segregation of species was compared among stand types, there was a segregation ($S > 0$) between accompanying species in fir dominated stands (*Fig. 4c*). This means low numbers of mix pairs of the nearest neighbours. On the other hand, low spatial associations both on plot and species level were found in the co-dominated and pure stands except for plots C3 and C9 (*Figs. 3* and *4b, d*). Unlikely, *Abies bornmuelleriana* spatially associated with other species whereas *Fagus orientalis* segregated in the plot C2 (*Fig. 4a*) where *Carpinus betulus* and *Quercus hartwissiana* admix. In that plot,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73537367

Fagus orientalis form pure groups. In general, light demanding coniferous trees (*Pinus nigra* and *Pinus sylvestris*) had spatial association with other species, whereas light demanding deciduous trees (*Quercus hartwissiana*, *Carpinus betulus* and *Populus tremula*) highly segregated and clumped. A positive correlation was found between altitude and segregation index ($r(19) = 0.58$, $p < 0.01$) means that a spatial association and low mixtures occur among different species at higher altitudes.

Clark-Evans Aggregation index at plot level showed a regular distribution (CE > 1) of trees except for plots A8, C2 and C9 (*Figs. 3* and *4a, d, e*) which have a low clumping trend. However, when species were evaluated separately, all of the species showed a clumping distribution except *Abies bornmuelleriana.* It had a low clumping only in fir-beech co-dominated stands where *Fagus orientalis* had also similar pattern. Other trees were much more clumped compared to main dominant species. Increasing fir ratio caused a regular distribution for *Abies bornmuelleriana* and a strong clumping distribution of *Fagus orientalis* in fir dominated stands except for plot A10 (located on a steep slope at 1400 m) where *Abies bornmuelleriana* also had a low clumping degree (*Fig. 3*). A negative correlation was found between fir ratio and CE index of Beech ($r(15) = -0.70$, $p < 0.01$) showing clumping distribution pattern in fir dominated stand. Besides, increasing altitude caused a significant decrease in beech CE index ($r(15) = -0.52$, $p < 0.05$).

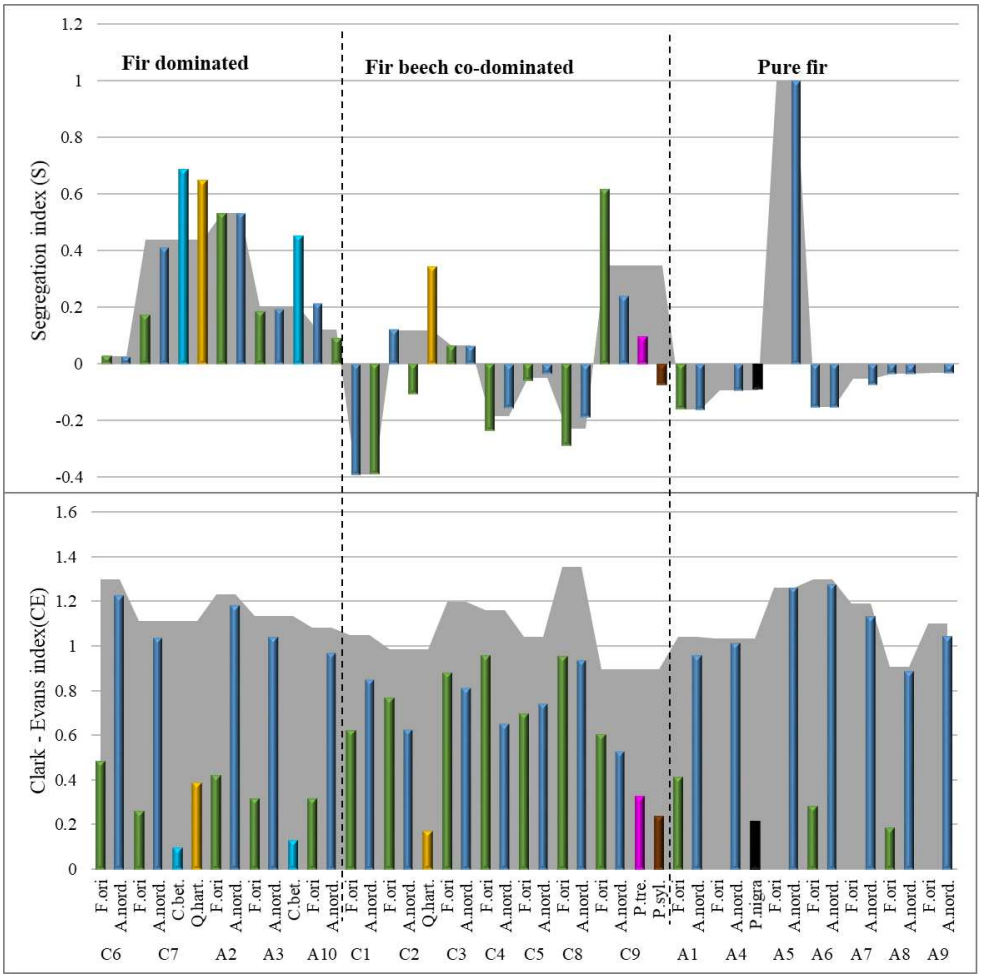

Figure 3. *Species segregation (S) and Clark-Evans aggregation (CE) index in plots (gray area represent plot mean; F.ori: Fagus orientalis, A.nord.: Abies bornmuelleriana, C.bet.: Carpinus betulus, Q.hart: Quercus hartwissiana, P.trem.: Populus tremula, P.syl: Pinus sylvestris)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73537367

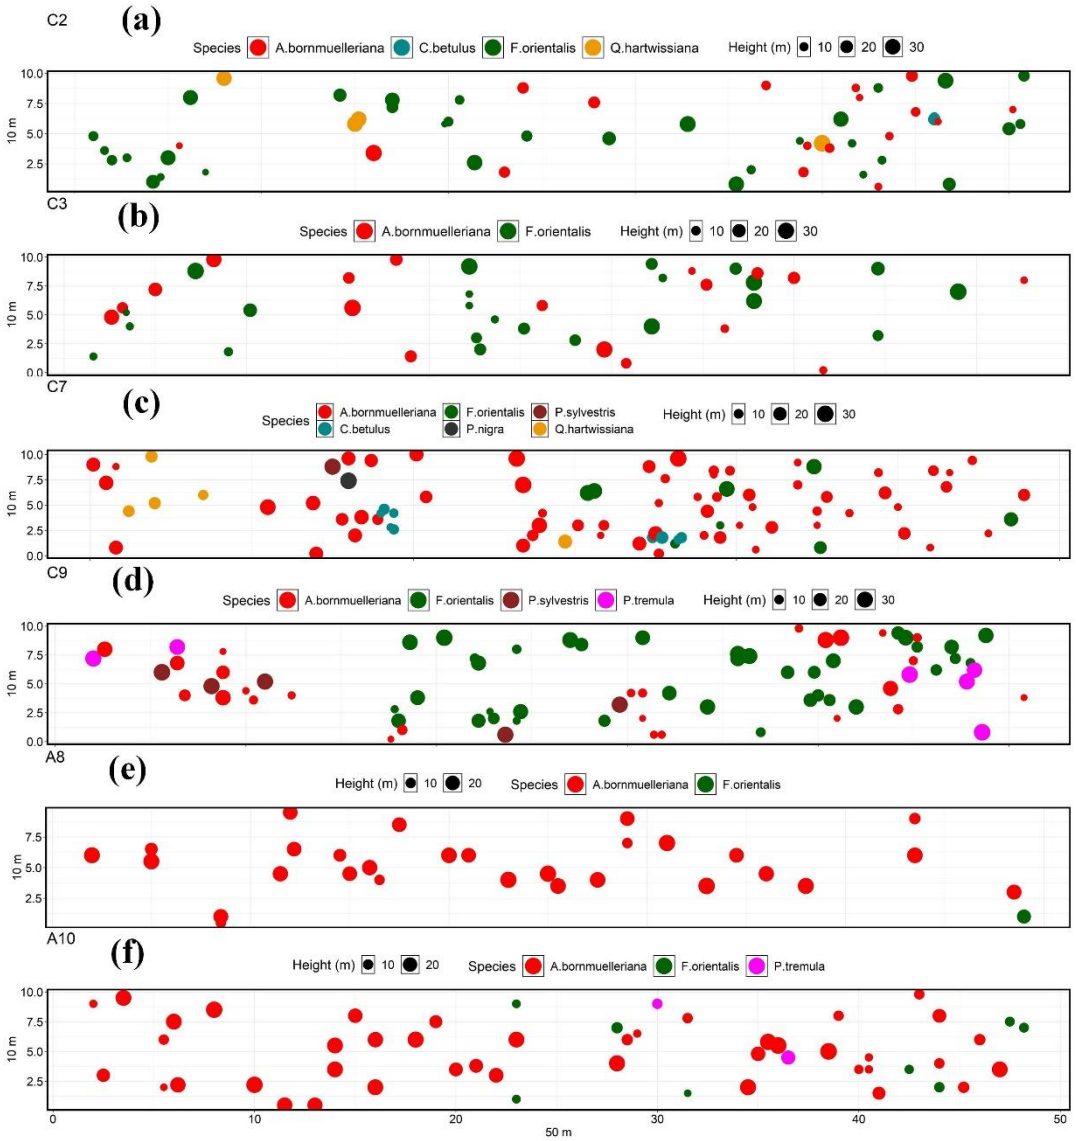

Figure 4. *Some of the horizontal stand profiles mentioned in the text (sizes of the circles represent tree heights)*

The Mi distribution clearly reveals that *Abies bornmuelleriana* and *Fagus orientalis* have an opposite behaviour in fir dominated and co-dominated stands. *Abies bornmuelleriana* does not form pure groups in fir-beech co-dominated stands where it occurs from low to complete mixtures, but *Fagus orientalis* can also occur in pure groups (17-40 %) (*Figs. 4a, b, d* and *5*). On the other hand, *Abies bornmuelleriana* predominantly occurs either in pure groups (20-60%) or low to medium mixtures in fir dominated stands. Here, *Fagus orientalis* occurs from medium to complete mixtures with other deciduous trees but not in pure groups (*Figs. 4c, f* and *5*). In addition, correlation analysis showed a negative correlation between fir ratio and species Mi ($r(18) = -0.80$, $p < 0.001$) and Shannon diversity ($r(18) = -0.69$, $p < 0.01$) which means that abundant fir ratio decrease mixture and tree species diversity (*Table 2*). However, increasing beech ratio causes a regular distribution of beech ($r(15) = 0.69$, $p < 0.01$) and high mingling of species ($r(15) = 0.66$, $p < 0.01$) in the stand.

Pinus sylvestris is surrounded by mostly different species in line with CE and S indexes. Since small clusters or individuals of species (i.e. *Carpinus betulus* and *Quercus hartwissiana*) were always surrounded by different species, Mi index does not reveal pure groups of species, instead a low mingling value (*Figs. 4c* and *5*). However, using CE, S and Mi indexes give detailed information about the spatial distribution of all species.

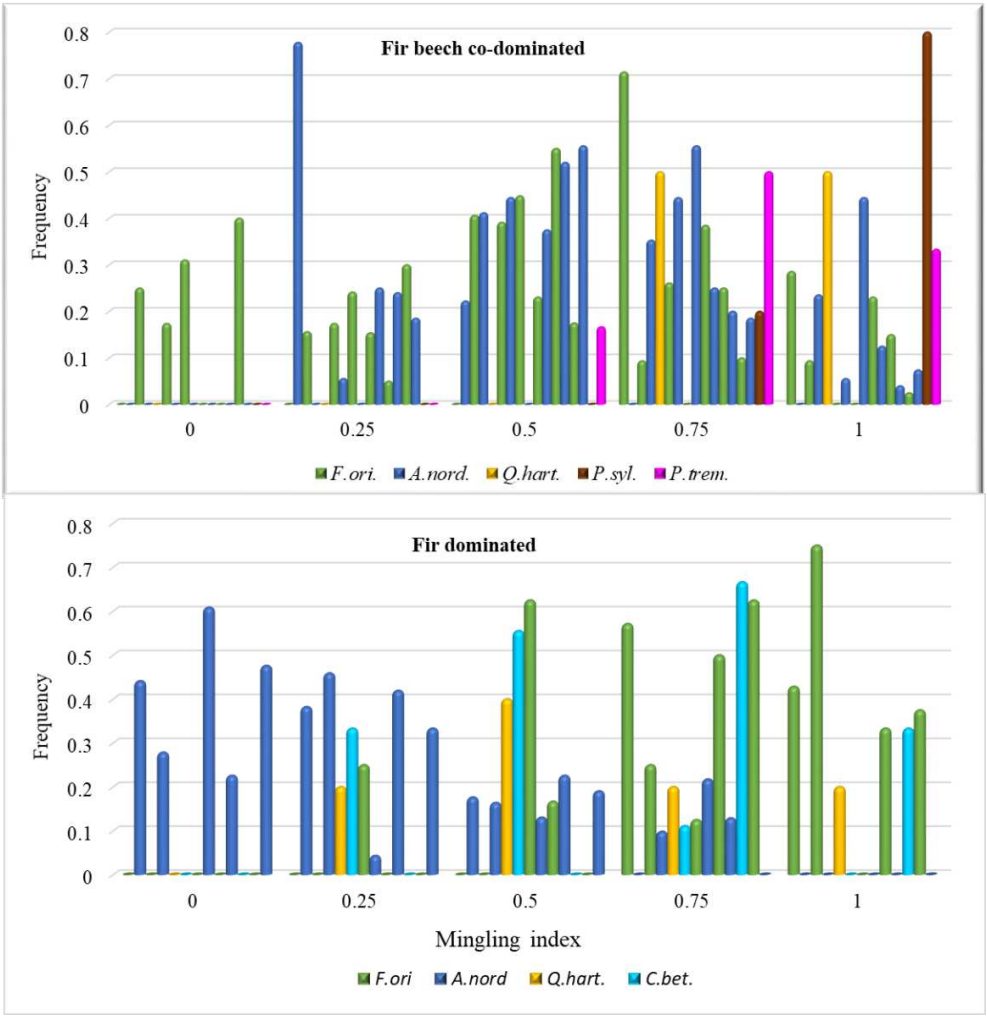

Figure 5. *Species mingling (Mi) index of species in fir beech co-dominated and fir dominated stands (F.ori: Fagus orientalis, A.nord.: Abies bornmuelleriana, P.syl: Pinus sylvestris, P.trem.: Populus tremula, Q.hart: Quercus hartwissiana, C.bet.: Carpinus betulus)*

Discussion and conclusions

Northern Anatolia exhibits a great variety of forest types composed of many tree species owing to differing edaphic, climatic and topographical factors (Çoban and Willner, 2019). Mountain ranges extending east-west direction cause both altitudinal and horizontal differences in forest communities. For instance, the isolation effect of high mountains increases continental effect which is reflected in the dominance of coniferous forest at the expense of deciduous trees towards inland (e.g. Aladağ Mountain). For this reason, deciduous mixed forests are mostly replaced by pure or fir dominated montane coniferous forests on north facing slopes, while southern slopes are dominated by *Pinus sylvestris* dominated forests in Sub-euxine zone (Aydın et al., 2008). The current study showed a significantly lower tree species richness in fir and beech forests of Aladağ mountain (0.418 ± 0.081) compared to Yenice (0.824 ± 066). Accordingly, tree species richness of Yenice forest was given as 24 containing 20 deciduous trees (Özalp, 1989) and 15 containing 12 deciduous trees on Aladağ (Aksoy et al., 2012). This reveals a decrease in the numbers of tree species in forest composition from north to south due to decreasing annual temperature and precipitation. Thus, the first hypothesis was not supported by the results of this study since tree species diversity was significantly lower in fir stands of Aladağ mountain located in the edge of sub-euxine zone. However, species richness is only one component of forest biodiversity which comprises genetic and ecosystem diversity (Simberloff, 1999). According to Pommerening (2002), spatial stand structure, which is an important factor in determining habitat and species diversity, is linked to the ecological stability of forests. For this reason, determination of forest structural attributes are suggested for an effective forest management (Latham et al., 1998; Ehbrecht et al., 2017; Vilà-Cabrera et al., 2018; Põldveer et al., 2020).

Spatial pattern is a matter of concern within silviculture since regular distribution provides maximal space and optimal growing conditions, while a clustered distibution causes increment loss (Pretzsch, 1995; Neumann and Starlinger, 2001; Del Río et al., 2016). Spatial distribution of tree species in mixed forest is determined by many factors related to habitat heterogeneity and environmental requirements of species. Besides, species with differing tolerances to environmental factors are confined to their own niche which causes clumped distribution (Pielou, 1961). Segregation between two species occurs when one species is more likely to be found near its own species. According to Pielou (1961), if both species are aggregated it does not necessarily follow that they will be segregated from each other. Thus, one of the species may have clumped pattern whereas other has regular pattern also means segregated distribution. Therefore, segregated distribution reveals that at least one of the species has been effected from habitat patchiness or familial clumping. Segregated and aggregated stands present group mixture of two species (Pielou, 1961). This situation was revealed with the comparison of CE and S indexes in the fir dominated forest where clumped pattern of *Fagus orientalis* (Beech $CE < 1$) and regular pattern of *Abies bornmuelleriana* (Fir $CE > 1$) revealed a segregated pattern between two species (*Figs. 3* and *4f*). Similarly, *Quercus hartwissiana, Populus tremula* and *Carpinus betulus* had clumping pattern with segregated and clumping distribution ($S > 1$, $CE < 1$). On the other hand, clumped and unsegregated distribution of both species in fir-beech co-dominated forest means more or less single mixtures of both species. According to Neumann and Starlinger (2001), both CE and S are describing microstructure by focusing on the distances between single trees or sample points to trees, respectively. Besides, mingling index

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73537367

describes mutual positioning of different species or intermingling (Szmyt, 2012; Põldveer et al., 2020). In this study, differing spatial patterns were determined among species. *Fagus orientalis*, which is the most common tree species co-occuring with *Abies bornmuelleriana*, had both regular and clumping distribution depending on the stand type. In contrast, a regular distribution of *Abies bornmuelleriana* was found in pure fir and fir dominated stands which were also supported with the correlation between fir ratio and fir CE ($r(18) = 0.63$, $p < 0.01$). Such variations might be caused by both habitat heterogeneity and silvicultural characteristics of the species. Petritan et al. (2015) explained the regular distribution of fir overstorey trees by their smaller crown radii compared to beech and the different crown shape, which allow them to grow closer together. On the other hand, *Abies bornmuelleriana* and *Fagus orientalis* are characterised as shade-tolerant species and can thrive under sheltered conditions for a long time. However, fir has a lower assimilation capacity which reflects its greater shade tolerance and ability to grow assimilation tissue under lower lights conditions than beech. For this reason, beech reacts much faster to changes in light intensity and adapts better in gap openings (Čater and Levanič, 2013). Besides, the behaviour is not totally fixed and shade tolerance within species may be affected by site quality (Carter and Klinka, 1992). Shade tolerance of both dominant species provided a high degree of spatial mingling in fir-beech co-dominated forest. *Fagus orientalis* showed segregation and low mingling values in fir dominated forest but the spatial association with other species in fir-beech co-dominated stands. This might be caused by habitat heterogeneity or beech are not so competitive in fir dominated sites where it can only thrive in groups. Özel and Ertekin (2012) indicate that the mixture rates of fir increase depending on altitude in NW Anatolia. Hence, *Fagus orientalis* is confined to the most suitable niches as determined by the correlation between altitude with CE of beech ($r(15) = -0.52$, $p < 0.05$) and with S ($r(19) = 0.58$, $p < 0.01$) which indicate increasing clumping pattern at higher altitudes. Bulušek et al. (2016) indicated that clumped spatial pattern of beech was positively influenced by increasing altitude, extreme conditions of the site as well as by stand density in European beech (*Fagus sylvatica* L.) stands. Thus, the second hypothesis was not supported by the results of this study since the spatial pattern of *Fagus orientalis* does not solely depend on shade tolerance but site condition or stand type which effect its competition capacity.

The main differences in the spatial pattern were determined between light demanding deciduous trees and shade tolerant species. In stands dominated by both shade tolerant species, light demanding deciduous trees such as *Quercus hartwissiana*, *Carpinus betulus* and *Populus tremula* were observed in pure groups. This finding was also supported by Petritan et al. (2012) who highlighted that oak in beech dominated stand has a greater chance of survival when co-occuring in groups. In contrast, light demanding *Pinus sylvestris* and *Pinus nigra* did not show a tendency towards clumping and had a spatial association with other species. Because, these species always situated within the overstorey layer and excluded from suppress of shade tolerant species such as *Abies bornmuelleriana* and *Fagus orientalis*. Indeed, *Pinus sylvestris* and *Pinus nigra* situated in the upper stand layer in all stand types (Özalp, 1989). In addition, pioneer characters of these species allowed early establishment in the successional stage. As a result, light demanding coniferous trees which showed a random distribution and spatial association with other species. Whereas other light demanding deciduous trees showed segregated and clumped distribution.

In conclusion, the diversity of spatial patterns in pure and mixed stands arise as a result of the species identity of dominant species (Petritan et al., 2015) and habitat heterogeneity. However, species with identical characteristics can create varied patterns depending on the dominated species and site quality. In this respect, spatial and structural patterns of diverse forests must be determined for developing appropriate silvicultural methods. Stand profiles, which are based on actual field measurement, are useful tools for analysing both structural and spatial characteristics of the forest using spatial and structural indices. Especially, if the sizes (diameter and height) of each tree were given in the profile, competition between tree species can be calculated with different indices. Thus, as indicated by Kint et al. (2003), the impact of management and/or competition on stand structure can be evaluated detaily. Stand profiles, which were sampled from different forest types, provide new opportunities using spatial pattern analysis. According to Yılmaz et al. (2019), analysing the spatial structure of forests reveals competition relationships among trees which make valuable contributions to silvicultural treatments. Especially, detection of tree spatial patterns and structural attributes in a forest stand can provide critical information on occurring dynamics, and steer management decisions (Carrer et al., 2018). Therefore, old or new stand profiles can be used to develop appropriate silvicultural methods for various stand types using spatial pattern analysis. At this point, terrestrial laser scanner technology, which provides many individual tree attributes with high accuracy, can be used to obtain stand profile data (Yurtseven et al., 2019).

Abstract. Fish gut microbiota can be affected by factors such as diet, habitat, and genotype. However, whether the foregut and hindgut microbiota respond similarly to these factors is still ambiguous. Given the fact that foregut has more communication with fish habitat and food intake, we hypothesized that the foregut microbiota is possibly more affected by external factors (e.g., habitat), while the hindgut microbiota tends to be mainly influenced by the host itself (e.g., genotype). To test our hypothesis, the V4 region of the gut bacterial 16S rRNA gene was amplified and sequenced by the MiSeq platform. A total of 1,139,703 high-quality sequences and 7,698 OTUs (without singlets) were obtained. Results indicated that the major factors that affect the fish gut microbiota patterns were the gut sections and habitats, rather than fish species. The foregut microbiota was indeed more similar to the water microbiota than hindgut microbiota, whereas the hindgut microbiota between fish species showed relatively more differences than that of foregut microbiota. Therefore, foregut and hindgut microbiota exhibited different response patterns to the habitat environments and host genotypes. This finding extended our understanding of the maintenance mechanism of fish gut microbial biodiversity.
Keywords: *freshwater lake, gut microbiome, high-throughput sequencing, silver carp, bighead carp*

Introduction

Gut microbiota not only assist their host in digesting food, but also help host to resist the invasion of pathogens (Stevens and Hume, 1998; Mountfort et al., 2002; Saha et al., 2006; Nicholson et al., 2005, 2012; Mardinoglu et al., 2015; Macpherson et al., 2018; Martens et al., 2018). Increasing evidence indicated that different gut positions were colonized by different microbiota (Eckburg et al., 2005; Ni et al., 2014a). Although it has been confirmed that many factors, such as diet, genotype, geography, lifestyle, and development of host (Ni et al., 2014b; Lloyd-Price et al., 2016; Yadav et al., 2016; Yan et al., 2016; Li et al., 2017; Ding et al., 2018), cast the composition and metabolism of gut microbiota, the influence degrees of these factors on gut microbiota at different gut positions are still ambiguous. Considering gut dysbiosis closely relates to host diseases

DOI: http://dx.doi.org/10.15666/aeer/1805_73697378

(Martin et al., 2009; Nicholson et al., 2012; Lloyd-Price et al., 2016; Xiang et al., 2018; Huang et al., 2018; Ni et al., 2019), elucidating the influence of external and internal factors on the composition of gut microbiota will promote artificial regulation to the composition of gut microbiota and also can help the host to prevent some diseases.

Silver carp (*Hypophthalmichthys molitrix*, M.) and bighead carp (*Hypophthalmichthys nobilis*, N.) are important players in the biological network of freshwater ecosystems (Ni and Jiang, 1954; Xie, 2003). They are also major targets of aquaculture and are key protein resources in China. Previous studies showed that these species have different feeding preferences, i.e., silver carp and bighead carp are prefer to filter-feeding the phytoplankton and zooplankton, respectively (Ni and Jiang, 1954; Chen, 1982). In addition, comparing with hindgut, the foregut has more connection with the water environment, and foregut microbiota are more likely to be influenced by habitat.

Therefore, we hypothesized that the fish foregut microbiota was more possibly affected by external factors such as host habitats and diets, while the hindgut microbiota tend to be mainly influenced by host genotypes. To test the hypothesis, 16S rRNA genes of the foregut and hindgut microbiota of silver carp and bighead carp collected from different habitats (lake and pond) were analyzed using high-throughput sequencing. The finding of the present study would extended our understanding of the maintenance mechanism of fish gut microbial biodiversity.

Materials and methods

Experimental design and sampling procedures

Silver carp and bighead carp were collected from three freshwater lakes, i.e., Shangshe Lake (S, 30°7′-30°9′ N, 114°11.5′-114°16.5′ E), Wuhu Lake (W, 30°47′-30°50′ N, 114°28′-114°33′ E), and Niushan Lake (N, 30°16′-30°22′ N, 114°27′-114°38′ E), and two freshwater ponds in China under different environmental conditions (*Fig. 1*). The experimental lakes are all shallow-water freshwater lakes in the middle reaches of the Yangtze River, with complex freshwater biological communities and high biological productivity. The lake is less polluted, and the utilization method is mainly fishery development. Niushan Lake belongs to the Liangzi Lake water system, with a water area of 40 km^2. The existing area of Shangshe Lake and Wuhu Lake is 11.9 km^2 and 21.2 km^2, respectively. The two ponds are artificially stocked and managed aquaculture water bodies which located on the south bank of Liangzi Lake (30°04'-30°20' N, 114°31'-114°42' E). Sampling was performed in May 2013. Three individuals of each species were randomly selected in each site with the exception of Niushan Lake, in which only one silver carp and three bighead carp were catched, and then immediately transported to the laboratory with in situ water. The fish body was cleaned with 70% alcohol and anatomized according to a previously described method (Ni et al., 2014b). About 0.5 g of the gut contents from the foregut and hindgut were aseptically extracted and then stored at -20 °C for downstream DNA extraction. Water samples from the three lakes and two ponds (i.e., Shangshe Lake-SW, Wuhu Lake-WW, Niushan Lake-NW, Pond I-PIW, and Pond II-PIIW) were also collected for environmental microbiota analysis. About 500 mL of each water was first filtered with a 1.2-μm glass-fiber (GF/C) filter and then with a 0.22-μm filter to collect microbes for DNA extraction.

All experiments involving animals were performed under the protocols approved by the Institutional Animal Care and Use Committee of Institute of Hydrobiology, Chinese Academy of Sciences (Approval ID: keshuizhuan 08529).

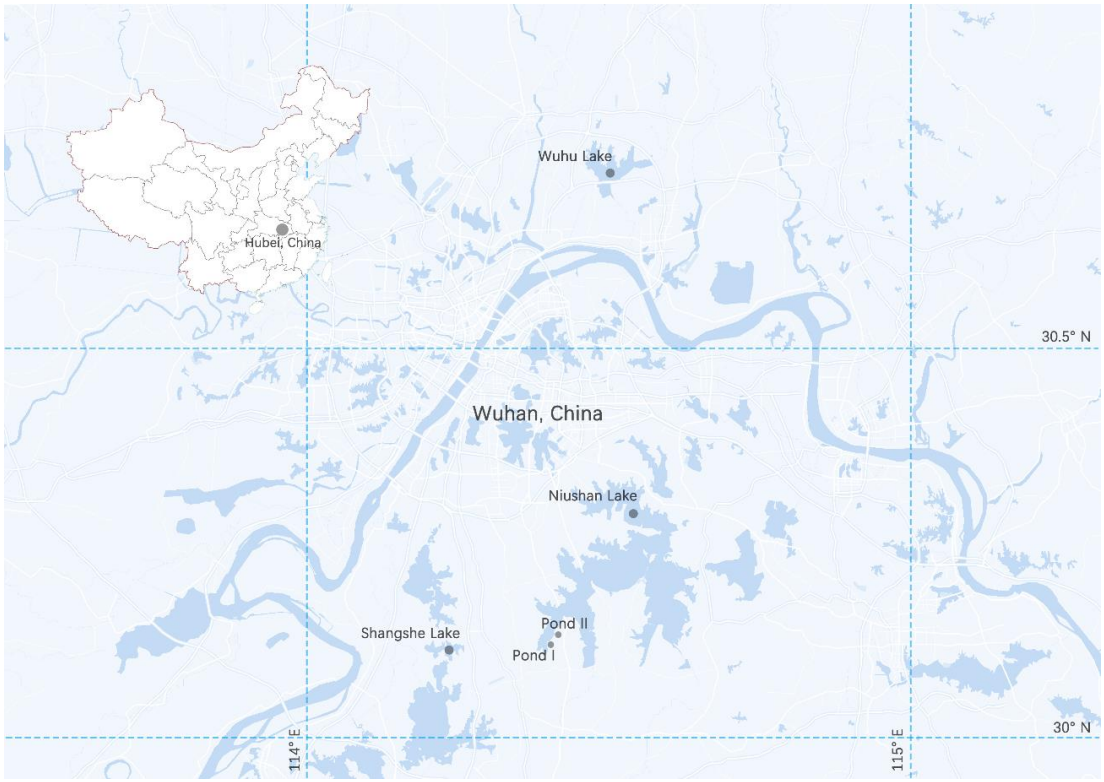

Figure 1. *Map shows the locations of sampling lakes and ponds*

DNA extraction and high-throughput sequencing

Genomic DNA of the gut microbiota was extracted from approximately 0.5 g of gut contents using a PowerFecal® DNA isolation kit (MoBio, CA, USA) according to the manufacturer's instructions. Genomic DNA of the habitat water microbiota was extracted from the filter membranes using the PowerFecal ® DNA isolation kit (MoBio, CA, USA) too. DNA concentration was determined by a NanoDrop ND-1000 and then diluted to the same concentration (2 ng/μL) for subsequent PCR amplification. The V4 region of the bacterial 16S rRNA gene was amplified using 515F and 806R primers to compare the gut microbiota as our previous description (Yan et al., 2016). The PCR products were visualized using 1% agarose gels stained with ethidium bromide. The successfully amplified PCR products were quantified using a PicoGreen dsDNA assay kit (Invitrogen, CA, USA). The products of each sample were equally combined and then subjected to gel purification. The purified DNA was re-quantified using the PicoGreen dsDNA assay kit, and the DNA library was applied for sequencing on the MiSeq platform according to the manufacturer's instructions.

The MiSeq reads were qualitatively filtered and processed with the Galaxy pipeline (http://zhoulab5.rccc.ou.edu:8080/root). After trimming the primer and deleting the sequences that contain N, the sequences with lengths of 245-260 bp were retained for subsequent analysis. The OTUs were generated by UCLUST clustering method with 97% sequence similarity. Then singlets were removed from further analysis. To exclude the interference of sequencing depth on the absolute abundance of each OTU, the relative abundance of each OTU was used in further analysis.

Data analysis

The UPGMA clustering was performed using the software XLSTAT 7.5.2. Redundancy analysis (RDA), principal component analysis (PCA), and non-parametric multivariate analysis of variance (PERMANOVA) were conducted using vegan package (Dixon, 2003) in R version 3.0.1 (R Core Team, 2017).

Results

A total of 1,139,703 (18684 ± 3720, mean ± S.E.) high-quality sequences and 7,698 OTUs (619 ± 360) without singlets were obtained from the foregut and hindgut samples of silver carp and bighead carp, and the habitat water. Excepting a small part (2.86 ± 3.29%) of sequences could not be classified into any phylum, a total of 7,667 bacteria OTUs were categorized into 23 phyla, whereas 9 OTUs were attributed to archaea (Euryarchaeota or Crenarchaeota). Bacteroidetes primarily appeared in hindgut microbiota of lake fishes. Cyanobacteria primarily appeared in the foregut microbiota of lake fishes and freshwater. Fusobacteria primarily appeared in gut microbiota of pond fishes and hindgut microbiota of lake fishes (*Fig. 2*). UPGMA clustering showed that freshwater microbiota embedded the branch of foregut microbiota (*Fig. 2*). This result showed that the freshwater microbiota were more similar with foregut microbiota of the fishes.

DOI: http://dx.doi.org/10.15666/aeer/1805_73697378

At OTU level, the result of RDA revealed that the gut microbiota clustered according to gut sections (i.e., foregut or hindgut) and habitats (i.e. lake or pond) rather than fish species (*Fig. 3A*). Although neither foregut nor hindgut microbiota of fishes were separated according to the fish species (MNAOVA, p = 0.24 for foregut; and p = 0.09 for hindgut), both foregut microbiota (MNAOVA, p = 0.005) and hindgut microbiota (MNAOVA, p = 0.005) were separated from each lake and each pond (*Fig. 3B,C*). Excluding the influence of habitat, only the foregut microbiota of Pond II fishes (MNAOVA, p = 0.005) and the hindgut microbiota of Shangshe Lake fishes (MNAOVA, p = 0.005) were significantly separated from silver carp and bighead carp. In addition, the hindgut microbiota of Wuhu Lake (MNAOVA, p = 0.06) and Pond I fishes (MNAOVA, p = 0.08) were significant differences between silver carp and bighead carp. These results implied that the hindgut microbiota easier separated according to fish species. For the fishes living in the lakes, their foregut tend to cluster together, whereas their hindgut tend to separated according to the fish species and lake (*Fig. 3D*). However, those trends was not true in the gut microbiota from pond fishes (*Fig. 3E*).

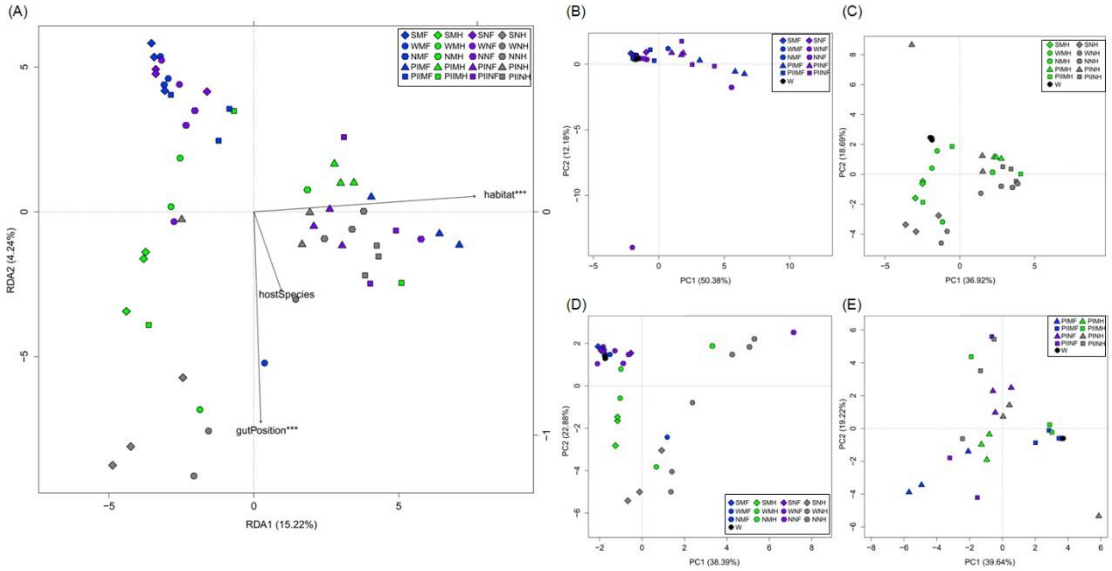

Figure 3. *RDA profiles of microbiota from fish guts and freshwater. SM: the gut microbiota of silver carp sample from Shangshe Lake; SN: the gut microbiota of bighead carp sample from Shangshe Lake; WM: the gut microbiota of silver carp sample from Wuhu Lake; WN: the gut microbiota of bighead carp sample from Wuhu Lake; NM: the gut microbiota of silver carp sample from Niushan Lake; NN: the gut microbiota of bighead carp sample from Niushan Lake. PIM: the gut microbiota of silver carp sampled from pond I; PIN: the gut microbiota of bighead carp sampled from pond I; PIIM: the gut microbiota of silver carp sampled from pond II; PIIN: the gut microbiota of bighead carp sampled from pond II. W: the water microbiota of lakes and ponds. * $p < 0.05$, ** $p < 0.01$, and *** $p < 0.001$*

Heatmap and clustering based on the dominant OTUs compositions of microbiota revealed that almost all of the gut microbiota of pond fishes were clustered into a clade. However, the foregut microbiota of lake fishes were separated from hindgut microbiota, only with individual outliers (*Fig. 4*). This indicated that the gut microbiota differentiation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73697378

of silver carp and bighead carp was decreased under artificial pond culturing condition. Similar to the UPGMA clustering based on the dominant phyla of the microbiota, water microbiota embedded the branch of foregut microbiota (*Fig. 4*). An OTU of Cetobacterium was enriched in the gut microbiota of pond fishes. However, other OTUs of Cetobacterium was enriched in the hindgut microbiota of lake fishes (*Fig. 4*).

Discussion

Fish gut microbiota is significantly affected by various factors, such as gut position (Eckburg et al., 2005; Ni et al., 2014a), diet (Ley et al., 2008; Muegge et al., 2011), and habitat (Ni et al., 2014b). In the present study, we found the gut positions (foregut or hindgut) and host habitats (lake or pond) significantly affected the gut microbiota of silver carp and bighead carp (*Fig. 3A*). This indicated that microbiota formed independent communities in the foregut and hindgut of silver carp and bighead carp, it is consistent with previous studies (Eckburg et al., 2005; Ni et al., 2014a). The differences of microbiota at different gut positions probably caused by the differences of external and internal environments at different gut positions. The foregut is closer to fish mouth and its microbiota was probably easier impacted by external environmental factors of host, such as diet compositions, habitat environments, and some other unexpected factors. Simultaneously, the foregut microbiota would more similarly with habitat water microbiota, as shown in the present study (*Fig. 2* and *Fig. 4*). However, the hindgut is far from fish mouth and its microbiota was probably affected by internal factors, such as host health, and host genotype. Therefore, the hindgut microbiota was generally separated according to the fish species as showed in the present study (*Fig. 3B,C*).

Geographic isolation is the major factor that restricts the spread of microorganisms and causes the distance-decay relationship (Green et al., 2004; Green and Bohannan, 2006; Ni et al., 2014a). Geographic differences in gut microbiota were reported in human (Escobar et al., 2014; Shin et al., 2016; He et al., 2018) and fish (Ni et al., 2014b). Our results showed that the gut microbiota of the fishes differed from their living habitats. This result indicated that the effect of geographic isolation not only affect the freshwater microbiota, but also showed important impacts on the gut microbiota of fishes living in the freshwater.

Previous studies that used classical morphological methods to identify food contents indicated silver carp mainly feeds on phytoplankton, and bighead carp prefer to the zooplankton (Ni and Jiang, 1954; Chen, 1982). Host diet is an important factor that affects the compositions of gut microbiota (Heavey and Rowland, 1999; Savas et al., 2005; Ley et al., 2008; Ward et al., 2009; Muegge et al., 2011; Tims et al., 2011; Walker et al., 2011). Wu et al. (2012) found that the core bacteria of the herbivorous grass carp include Proteobacteria, Firmicutes, and Actinobacteria. Wu et al. (2010) indicated that the dominant phyla of the carnivorous yellow carp are Proteobacteria, Fusobacteria, and Bacteroidetes. Li et al. (2012) reported that the dominant phyla of omnivorous common carp are Proteobacteria and Fusobacteria. These studies implied that the dominant microbiota phyla are affected by host diet. However, the present study did not show feeding habit resulted in different hindgut microbiota between silver carp and bighead carp. This inconsistency may be caused by one or more factors, such as substantial overlapping of their feeding, and disturbance of other unexpected factors on gut microbiota.

Conclusion

In conclusion, gut sections (i.e., foregut or hindgut) and habitats (i.e., lake or pond) rather than fish species were the major factors that can significantly affeced the gut microbitoa of silver carp and bighead carp. The foregut microbiota would more similarly with habitat water microbiota, and the hindgut microbiota was easer separated according to the fish species than foregut microbiota. Therefore, there have different response

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73697378

patterns of foregut and hindgut microbiota to habitat environments and host genotypes. Although the finding extended our understanding of the maintenance mechanism of fish gut microbial diversity, the function of the microbial diversity and the function and inflencing factors of each component of the gut microbiota still need to further study.

(Received 30th May 2020; accepted 20th Aug 2020)

Abstract. Inflammatory bowel disease (IBD) is a set of multifactorial gut inflammatory conditions. The most common types of IBD are ulcerative colitis (UC) and Crohn's disease (CD), which are attributed to a deregulated immune response to an imbalance in the gut microbiome. The occurrence of IBD is increasing worldwide, with over one million people in the USA and 2.5 million in Europe estimated to have one form of the disease. Furthermore, an increase in IBD has recently been reported in industrialized countries in Asia, South America, Africa and the Middle East, which suggests that it has developed into a global disease with rising prevalence in each continent that may incur substantial healthcare costs in the future. Studying the gut microbiome of patients with IBD can provide a deeper understanding of the role that gut microbiota plays in the development of disease. This will further help in therapeutic microbiome manipulation of patients with IBD.
Keywords: *ulcerative colitis, Crohn's disease, immune response, intestinal microbiota, dysbiosis*

Introduction

Bacteria, viruses, fungi, protozoa, and many other microorganisms can live together as a community, but can also live in close association with humans, plants, and other complex organisms. This is possible through relationships of parasitism, commensalism, and mutualism between microorganisms and their hosts (Lederberg and McCray, 2001). The interacting community of microorganisms within or in proximity to multicellular organisms is referred to as a microbiome. The microbiome forms an ecological community of pathogenic, commensal, and symbiotic microorganisms in a biological environment, such as the human body. There is a strong mutual relationship between microbes and humans as the human body can benefit from microbe's ability to support the conditions necessary for human healthy life, while microbes benefit from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73797392

obtaining needed resources of the human body. The nasal, skin, oral, urogenital, and gastrointestinal linings of an individual comprise unique and varying microbial communities. The human microbiome is a significant contributor to balanced immunogenicity through symbiosis. Alteration of the microbiome can result in the emergence of diseases. Thus, the condition of microbiomes is an essential effector on human health. Understanding the microbial compositions of healthy individuals is key to determining the influence of the microbiome on the occurrence of human disease.

Inflammatory bowel disease (IBD) and a number of other diseases have exhibited differences in the function and structure of gut microbiota. This can be observed in healthy humans, where changes in gut microbiota can result in a disturbance of the immune system. Over one million Americans and two million Europeans have been reported to suffer from relapsing-remitting forms of IBD (Kaplan, 2015). The data suggests an increase in IBD globally, but with the highest incidence and prevalence reported in Western countries. Nonetheless, the newly industrializing countries of Asia, South America, Africa, and the Middle East, have reported a rapid increase in IBD (Kaplan, 2015).

Lozupone et al. (2012) have characterized the pathophysiology of IBD as a reluctance to regulate immune response to imbalance in the gut microbiome. Therefore, compared to healthy individuals, patients with IBD have lower numbers of bacteria with anti-inflammatory capability and an increased number of bacteria with pro-inflammatory capability. Dysbiosis is currently considered the most appealing target for scientific research on IBD as it gives the opportunity for clinicians to intervene and alter the natural course of the disease. Given the large variation in gut microbiota across populations, the complex task of mapping the microbiota of healthy populations must be carried out. The microbiota of the diseased population was recently mapped though the Human Microbiome Project (HMP) run by NIH.

The Human Gut Microbiome

There are about a hundred trillion microbial organisms that comprise the human gut microbiota (Lozupone et al., 2012). These diverse organisms include viruses, protozoa, fungi and bacteria, which comprise more than 1000 different types of bacterial species (Honda and Littman, 2012) (*Fig. 1*). These bacterial species are made up of more than three million non-redundant microbial genes (Qin et al., 2010). A number of factors, including diet (Collado et al., 2010; Goldsmith and Sartor, 2014), age (Hopkins et al., 2001), gender, genetic composition (Khachatryan et al., 2008), geographic location (Sonnenburg et al., 2004), and health or disease status (Collado et al., 2010) of the individual influence the gut microbiota after birth. Four phyla (e.g., Bacteroidetes, Actinobacteria, Proteobacteria, Firmicutes) were found to dominate over 99% of human intestinal bacteria (Ley et al., 2008), of which two phyla (Firmicutes and Bacteroidetes) are most common in the intestinal bacteriome of healthy adults (Andoh, 2016). These microbes are densely populated in the colon and the distal ileum (Eckburg et al., 2005). The human gut hosts a large microbial community whose genetic content is described as a metagenome. The colonizers consist of a metagenome made up of 100 times the population of genes in the human genome. Dominguez-Bello et al. (2010) indicated that this metagenome is usually investigated by targeted sequencing of marker genes, including 16S ribosomal RNA.

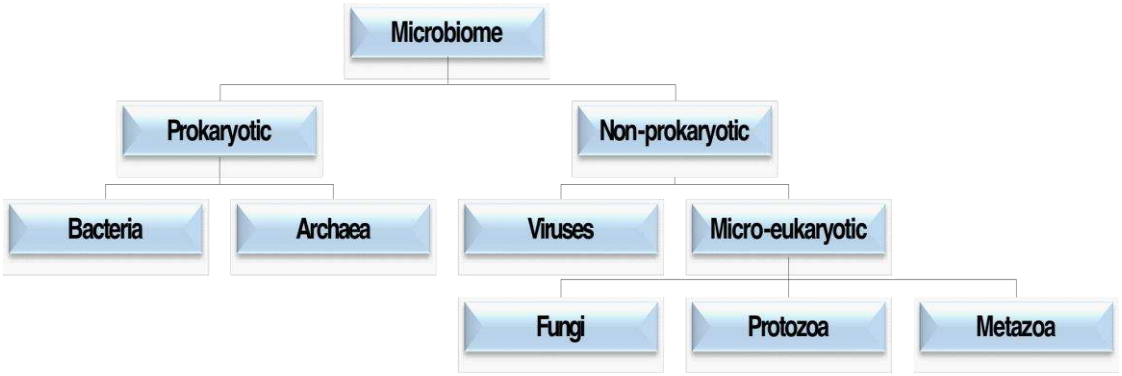

Figure 1. *Microorganisms of the human gut microbiome*

Development Process of the Human Microbiota

As a person ages, the microbiota varies in stability and diversity. Interactions between the gut microbiome and the host begin from birth and continue throughout life. In the early years of an individual, the density and stability of the microbiome are usually low (Claesson et al., 2011). By early adulthood, the microbiome begins to demonstrate significant diversity and stability (Lozupone et al., 2012), while the microbiome reaches maximum complexity and remains relatively stable throughout most of an adult's life. However, in later years and in the elderly, Biagi et al. (2010) note that the stability and diversity of the microbiome decreases.

The mode of birth highly determines the microbiota of an infant. In the case of vaginal birth, the microbiota of the infant takes after that of the mother. In a Caesarian birth, as Dominguez-Bello et al. (2010) pointed out that the microbiota in the skin of the newborn takes the characteristics of the mother. Feeding methods also affect the establishment of the microbiome; the microbiota of formula- and breast-fed newborns differ both in diversity and structure (Guaraldi and Salvatori, 2012). While the microbiota of breast-fed babies basically comprises Bifidobacteria, Penders et al. (2006) noted that microbiota of bottle-fed with formula babies basically consists of *Clostridium difficile, lactobacilli predominate, Bacteroides fragilis, and Escherichia coli*. At the age of three, a child's microbiome resembles that of an adult, and stabilizes with time. At this age, the number of species approximates 100, although this continues to increase and may exceed 1000 in adulthood. The ecological system of the gut also stabilizes and becomes more complex in adult life owing to the predominant composition of Firmicutes and Bacteroidetes (*Fig. 2*). However, old age causes a reduction in the stability of the ecosystem. Notably, the dominating phyla at this stage shifts from Firmicutes to Bacteroides, and the number of Bifidobacteria reduces while that of Proteobacteria rises. As an individual reaches old age, the microbiota shifts towards a *Clostridium*- dominated community, and the population of Bacteroidetes rises. This explains the significant difference between the microbiota of a young adult and that of an older person (Penders et al., 2006). Pregnancy enhances the development of Proteobacteria and Actinobacteria, as well as enhancing diversity. However, the gut microbiota gradually regains its original formulation after delivery.

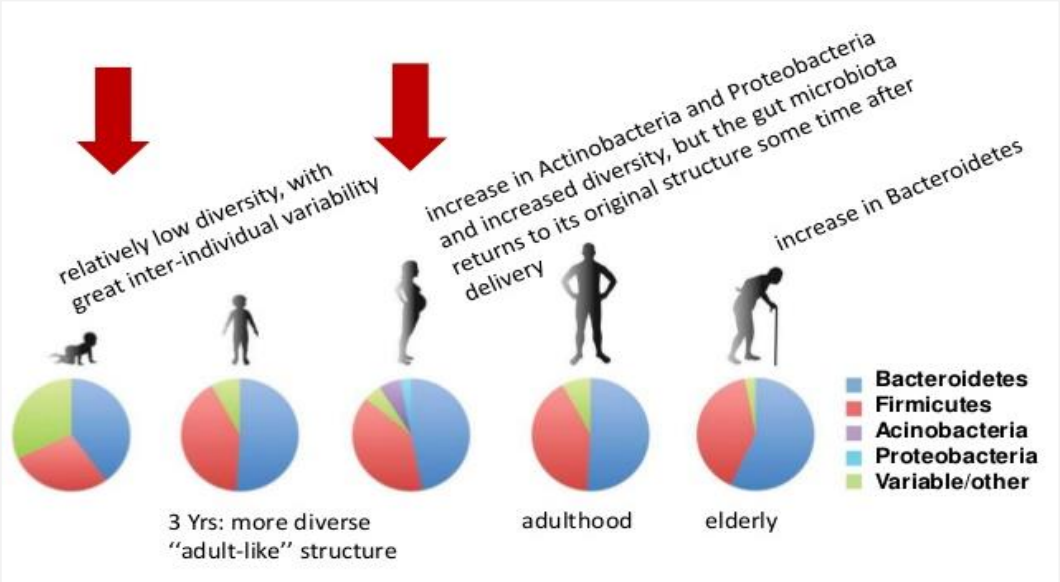

Figure 2. *The structure of the human intestinal microbiota across the life cycle. Modified from Kostic et al. (2013)*

Effects of Geology on Gut Microbial Assorted Variety and Stability

A geographical region can be associated with various ways of life that correspond with a variety of dietary practices (including such factors as country, city, countryside, religion, etc.). In the microbiota creation in volunteers from Venezuela, Malawi, and the US (0-70 years old), it was found that regardless of age, the microbiota structure could be categorized by country (Yatsunenko et al., 2012). The least microbially diverse group in that investigation was grown-up Americans of which the bacteria *Prevotella*, in particular, was underrepresented in this group. When comparing African and European children, De Filippo et al. (2010) discovered a greater number of *Prevotella* in African children. The fecal microbiota of African children is rich in Actinobacteria and Bacteroidetes, but has lower quantities of Firmicutes; European children have microbiota that are rich in Proteobacteria and over double the normal quantity of Firmicutes compared to Bacteroidetes. Moreover, Ou et al. (2013) noted a greater quantity of *Prevotella* in Africans in contrast to African Americans. A comparative study was carried out between the Tanzanian Hadza hunter-gatherers, and Italians (Schnorr et al., 2014). In a few African populaces in this examination, high levels of *Succinivibrio* and *Treponema* exist. These two microscopic organisms have a high fiber-debasing potential. This high potential may be predictable owing to a vigorously plant-based diet. Additionally, the Hadza gut microbial environment has relatively low levels of *Bifidobacterium.* This is thought to be the effect of the absence of dairy foods in the diet and lack of contact with domesticated animals.

Inflammatory Bowel Disease (IBD)

IBD is defined as a chronic intestinal inflammatory condition caused by host-microbe interactions in genetically susceptible individuals. The most common types of IBD are ulcerative colitis (UC) and Crohn's disease (CD), and the basic distinctions between them are location and severity. CD can affect any part of the digestive tract, but

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73797392

UC develops only in the colon and rectum. Patients with IBD often suffer from ongoing symptoms of abdominal pain, diarrhea, gastrointestinal bleeding, and malnutrition. Persistent disease activity has been linked to repeated hospitalizations and development of complications, such as the need for bowel resection, colorectal cancer, and mortality (Fakhoury et al., 2014). Both exogenous factors (abnormal microbiota) and host factors (intestinal epithelial cell barrier function, and innate and adaptive immune function) cause a chronic state of dysregulated mucosal immunity.

Global Incidence and Prevalence of Inflammatory Bowel Disease

The occurrence of IBD is increasing worldwide in the 21st Century. The prevalence of IBD varies with geographical region. The highest reported prevalence rates of the IBD are in Europe (UC, 505 per 1,000,000 persons/year; CD, 322 per 1,000,000 persons/year) (Ng et al., 2017). Regions with the highest annual incidence of IBD burden are Europe (UC, 24.3 per 100,000 persons/year; CD, 12.7 per 100,000 persons/year) and North America (UC, 19.2 per 100,000 persons/year; CD, 20.2 per 100,000 persons/year). The regions with the lowest reported IBD incidence are Asia and the Middle East (UC, 6.3 per 100,000 persons/year; CD, 5.0 per 100,000 persons/year) (Ng et al., 2017).

Urban areas may show a higher prevalence of CD than rural areas, and CD may also be higher in areas of higher socio-economic classes (Soon et al., 2012). The incidence of the disease begins to increase mostly among economically stable individuals. However, the ailment becomes more complex with time. An individual who initially belongs to low-incidence populations and migrates to a developed country before adolescence may show an increased prevalence of IBD. This is often the case with the first generation setting in a nation with increased IBD prevalence.

The "hygiene hypothesis" aims to explain the variation in incidence levels between developing and developed countries. According to this theory, an individual less exposed to childhood infections loses potentially beneficial organisms that enhance the development of a regulatory T cell. Additionally, such a person may not develop a strong immune repertoire because he or she has not encountered the noxious organisms (Pugazhendhi et al., 2011; Sood et al., 2014). Thus, such an individual might be more likely to develop IBD and other chronic immune diseases. It is often surmised that the emergence of IBD in Third World nations is a result of adoption of a Western lifestyle, including diet and the reliance on Western approaches to vaccination and medication. The significance of such developments in early life may be of particular significance. Though UC has been documented to have emerged before CD, the prevalence of CD in developed nations has overtaken that of UC in the past 20 years. However, developing nations have recorded an increasing incidence level of UC. India, for example, has recorded a drop in UC/CD ratio from 10:1 to 8:1. One notable trend is that the prevalence of CD rises once the disease has been present in a population for some time. Hong Kong has observed a UC/CD ratio that has declined to 1:1 from 8:1 (Ng et al., 2015). In general, the incidence of CD reaches its optimum in early adulthood, and the incidence rate declines in the elderly. The incidence of UC remains stable from early adulthood to retirement age.

East Asia and other parts of Asia have reported a trend of rising prevalence and incidence of IBD. Despite this trend being more acute in developing nations, some developed countries, such as Japan, have been shown to be affected. Also, the CD incidence rate has been more pronounced in female adults over male adults, although

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73797392

the past decade has recorded a higher incidence of CD in boys than in girls in developing countries. Over time, it may transpire that an equal CD prevalence for both sexes is reached. For example, studies from East Asia are suggesting a male predominance of CD and an equal sex ratio of UC (Ng et al., 2016).

Alterations in Intestinal Microbiota Implicated in the Development of IBD

The gut microbiota is believed to play a central role in the pathogenesis of IBD. Many studies give corroborated evidence for gut microbiota dysbiosis in IBD patients compared to healthy individuals. The gut microbiota of healthy people is made principally of microorganisms from the phyla Bacteroidetes (for the most part *Bacteroides* or *Prevotella* species), which are gram-negative, or Firmicutes (for the most part *Clostridium* and *Lactobacillus* species), which are gram-positive. Actinobacteria (that incorporate *Bifidobacterium* sp.), Proteobacteria (including *Escherichia coli*), and Verrucomicrobia (including *Akkermansia mucinophila*) are commonly present in small numbers in the gut microbiota of healthy individuals. The creation of gut microbiota varies in people with respect to age and advancement of disease (Huttenhower et al., 2012) (*Table 1*).

Table 1. *Composition of intestinal microbiota in healthy humans*

Reference	Sample	Microbial signature
(King et al., 2019)	50 healthy samples sequenced at GWU and 49 healthy samples taken from The Human Microbiome Project	• 155 bacterial species were identified, Bacteroidetes (31 phylotypes), Actinobacteria (32 phylotypes) and Firmicutes (63 phylotypes) had the highest abundance. • More than half of Firmicutes sequences were members of the Clostridia (20%) class, which was the highest abundant class, followed by Bacteroidia (18.5%), Bifidobacteriales (16.6%), Enterobacterales (14%), and Lactobacillales (14%). • Clostridiales and Bacteroidales orders had the highest abundance. • There were 26 members of the Bifidobacteriaceae family, belonging to *Bifidobacterium longum*, which were the most abundant species.
(Gill et al., 2006)	2 healthy adult subjects	• 133 bacterial phylotypes were identified; Actinobacteria (10 phylotypes) and Firmicutes (62 phylotypes) had the highest abundance. • 60% of the Firmicute sequences were members of Clostridia class (including Clostridia cluster XIV and Faecalibacteria.).
(Eckburg et al., 2005)	3 healthy adult subjects	• 395 bacterial phylotypes were identified, Bacteroidetes (65 phylotypes) and Firmicutes (301 phylotypes) had the greatest quantities. • Most (95%) of the Firmicutes sequences were members of the Clostridia class. • Low abundance of Proteobacteria sequences (including *Escherichia coli*), Actinobacteria, Fusobacteria, and Verrucomicrobia phyla. • *Bacteroides thetaiotaomicron* were detected in each subject.

GWU = George Washington University

A change in microflora synthesis, as in IBD, can contribute to intestinal damage. A few examinations have exhibited the Firmicutes phylum were less well represented in BD patients compared to healthy controls (Huttenhower et al., 2012; Rajilić-Stojanović et al., 2013), whereas members of Gammaproteobacteria were relatively light (Rajilić-Stojanović et al., 2013; Sokol et al., 2017) (*Table 2*). In CD patients, the Clostridia cluster IV group, in particular *Faecalibacterium* sp., has been shown to relatively low

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73797392

(Gill et al., 2006). Members of the Clostridia group XIVa, belonging to the *Roseburia* genus, also seem to be low in IBD patients (Rajilić-Stojanović et al., 2013). Data on Bacteroidetes report a general decrease in biodiversity in IBD patients (Mar et al., 2016; Sokol et al., 2017), also, significantly lower levels of putative beneficial OTUs; including *Prevotella copri* and the butyrate-producing bacterium *Faecalibacterium prauznitzii* (Willing et al., 2010).

Table 2. *Changes in gut bacteriome composition in IBD patients*

The Physiological Functions of the Gut Microbiota

The physiological benefits that gut microbiota have on the host are: 1) to supply of nutrients and energy (sustenance), 2) improvement of the immune system, and 3) functioning as host gatekeeper (*Fig. 3*) (Nishida et al., 2018). Details of these benefits are the following.

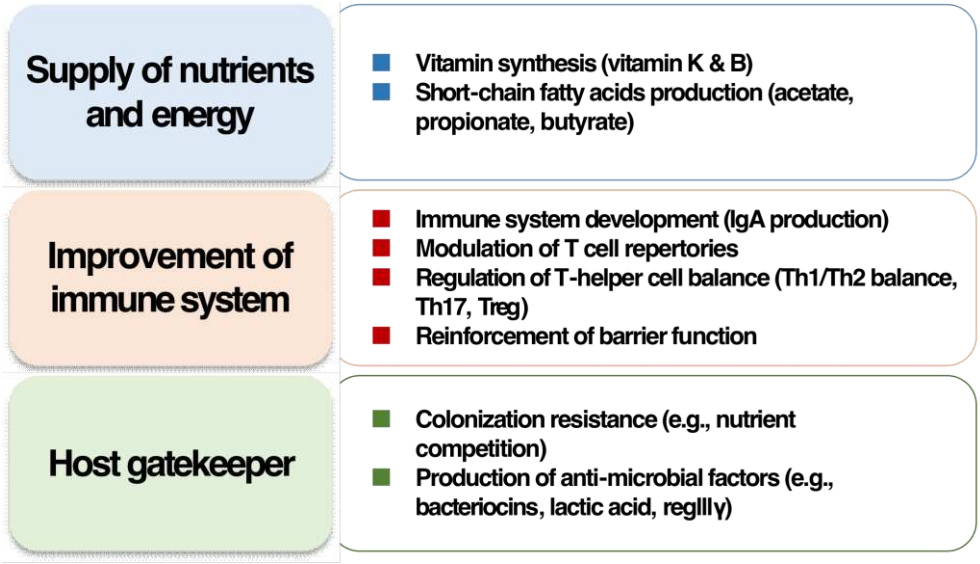

Figure 3. *Physiological functions of gut microbiota. Modified from Nishida et al. (2018)*

Supply of Nutrients and Energy

The gut microbiota supply energy and nutrients to the host (O'Hara and Shanahan, 2006). Commensal microorganisms in humans, for instance Bifidobacterium, can coordinate and provide supplements including water-dissolvable B vitamins and vitamin K (LeBlanc et al., 2011). In addition, intestinal bacteria provide short-chain fatty acids (SCFAs; C2-C6) by fermenting resistant starch or indigestible carbohydrates (dietary fiber). The Bacteroidetes and Firmicutes produce SCFAs from indigestible carbohydrates via participation together with species that have some ability to ferment oligosaccharide (e.g., Bifidobacterial). Anions in the colon are SCFAs, overwhelmingly, acetate, butyrate, and propionate (Marchesi et al., 2016). The latter are vital for a number of aspects of the host's physiology. For example, they are important for supplementing procurement, immune capacity, cell signaling, expansion control, and pathogen protection. SCFA levels are important for their anti-inflammatory effects and imperative for the upkeep of the mucosal barrier; for example, butyrate positively affects cell multiplication, separation, and development after epithelial damage (Lopetuso et al., 2016). The levels of SCFAs are significantly decreased in IBD, which may be a key factor in the degeneration of intestinal and immune homeostasis. The SCFA-producing bacteria are decreased in IBD patients, which include *Faecalibacterium* (Frank et al., 2007), Odoribacter, Leuconostocaceae, *Phascolarctobacterium*, and *Roseburia* (Ahuja, 2015).

Immune System Improvement

Microbiota that live in the intestinal tract play a vital role in the improvement of the host immune system. The host immune system, in turn, shapes the structure and function of gut microbiota (Kamada and Núñez, 2014). Germ-free (GF) mice (insufficient in the gut microbiota) show impaired immune development, which is distinguished by immature lymphoid tissues (Bouskra et al., 2008), reduced amounts of intestinal lymphocytes, and diminished elements of antimicrobial peptides (Cash et al., 2006) and immunoglobulin A (IgA) (Hapfelmeier et al., 2010). Reconstitution of the gut microbiota of mice is sufficient to restore these abnormalities of the immune system (Umesaki et al., 1995). One of these microorganisms is *Candidatus Arthromitis*, known as a segmented filamentous bacteria (SFB). The colonization of SFB alone advances the improvement of the mucosal immune system (Ivanov et al., 2009). The improvement of the host immune system is dependent on host-unequivocal microbiota, as the immune system becomes underdeveloped in GF mice colonized with human microbiota. The gut microbiota, furthermore, regulates T-cell repertoires and controls the T helper (Th) cell profile (Shanahan, 2002). Authoritative white platelets (in like manner called Tregs) are CD4+ lymphocytes, which coordinate or smother distinctive cells in the immune system (Littman and Rudensky, 2010). It has been shown that SCFA-producing strain in *Clostridium* clusters IV, XIVa, and XVIII from a sound human fecal precedent started the partition and improvement of colonic Tregs through butyrate production (Atarashi et al., 2013). This result supports part of the clinical data. The degree of *Clostridium* bunches XIVa and IV in the fecal models is lower in IBD patients compared to healthy individuals (Frank et al., 2007). The low number of *Faecalibacterium prausnitzii*, which belong to *Clostridium* cluster IV, is related to a high risk of recurrence of CD after surgery (Walker et al., 2011). The headway of Th17 cells, which are a subpopulation of effector T cells, is defined by their production of interleukin (IL)-17A, IL-17F, IL-21, and IL-22 (Littman and Rudensky, 2010), that are modulated by the gut microbiota. In GF or antibiotic-treated mice, the abundance of Th17 cells in the intestinal mucosa is decreased. One study has shown that the gut microbiota plays a part in the improvement of Th17 cells (Wu et al., 2016). A past report has demonstrated that microbes with adhesive properties to intestinal epithelial cells, for instance, *Citrobacter rodentium* and *Escherichia coli* (EHEC) O157, advance the enrollment of Th17 cells (Atarashi et al., 2015).

Host Gatekeeper

The gut microbiota also combats pathogens. Animals in GF condition are powerless to sullying by intestinal pathogens. An anomaly in the mucosal immune system may add to this lack of protection. Another instrument against pathogens that deform the physical and dietary of the gastrointestinal tract is the colonization of commensal microbiota, which neutralizes the colonization of pathogens (O'Hara and Shanahan, 2006; Sekirov et al., 2010). This framework that actively hinders the interruption of pathogens by commensal microorganisms is called a 'colonization obstacle' (Buffie and Pamer, 2013). The gut microbiota improves colonization assurance from intestinal pathogens by direct and indirect mechanisms of action. Some commensal microorganisms truly stifle intestinal pathogens by competing for nutrients or by starting the production of inhibitory substances. *Bacteroides thetaiotaomicron*, which is an abundant colonic anaerobe, utilizes starch used by *Citrobacter rodentium*, which

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73797392

adds to the dismissal of pathogens from the intestinal lumen (Kamada et al., 2012). *B. thuringiensis* secretes bacteriocins that target spore-molding *Bacilli* and *Clostridia*, for instance, *Clostridium difficile* (Huang et al., 2016).

Commensal microbiota and microbial products protect against pathogens indirectly by activating immune responses. For instance, lipopolysaccharides and flagellin derived from the gut microbiota enhance the expression of antimicrobial peptide and RegIIIγ, from epithelial cells by stimulating Toll-like receptor 4^+ stromal cells and $TLR5^+CD103^+$ dendritic cells (Brandl et al., 2008; Kinnebrew et al., 2010). Segmented filamentous bacteria (SFB) promote the secretion of IgA from B cells, the production of antimicrobial peptides, and the development of Th17 cells in the intestinal mucosa (Talham et al., 1999; Ivanov et al., 2009). The gut microbiota plays a central role in the pathogenesis of IBD. A number of studies provide varied evidence for gut microbiota dysbiosis in IBD patients diverging from healthy controls (Sartor and Wu, 2017; Nishino et al., 2018).

Conclusion

The population of useful bacteria is reduced in IBD, while the population of pathogenetic bacteria appear to grow. While microbiota differ at the phylogenetic level, the presence of inflammation is considered the major engine for microbiome changes in such diseases. Studies provide the platform for investigating microbiome diversity perturbations in diseases with varying etiology as well as plan for therapeutic microbiome manipulation, in populations which are unique, displaying a variable number of enteric infections and gut autoimmune diseases.

Abstract. For the improving regeneration and conservation of medicinal *B. polystachya*, stem cuttings were obtained from trees in Aseer area, Saudi Arabia, and two experiments were conducted to investigate factors affecting rooting (season and auxin type and concentration) and assessing growth performance of rooted cuttings. To test rooting factors, cuttings were collected during autumn, winter, and spring and treated with 500, 1000, and 2000 ppm indole-3-acetic acid (IAA), indole-3-butyric acid (IBA), and naphthyl acetic acid (NAA) during each season. Following the evaluation of rooting, the second experiment was conducted using the best rooted cuttings, to test growth performance of seedlings under the effect of different auxins and four types of growth media. Cuttings collected during spring and treated with IBA had the highest rooting percentage (91%–98%), number of roots (23–29 roots cutting $^{-1}$), and root length (26–39 cm). Regarding seedling growth, planting cuttings in growth substrate containing clay, sand, and peat moss (1:1:1 v/v) resulted in highest quality seedlings in terms of leaf number, stem height and relative growth rate. We concluded that spring cuttings collection treatment with 1000 ppm IBA, and transplantation to fertile growth media can be a useful technique for mass production of *B. polystachya*
Keywords: *propagation, auxins, cuttings, growth media, season*

Introduction

The development of vegetative propagation methods is a useful tool for the conservation of genetic resources, domestication of tree species, and national and international forest conservation plans. Hence, vegetative techniques are used as an essential tool for the mass multiplication of superior phenotypes/genotypes and production of true to type uniform plants (Thakur et al., 2008). Rooting of stem cuttings is a simple and economically feasible method of vegetative propagation usually utilized for many tree species (Mewar and Naithani, 2016). Several factors affect rooting such as the mother plant age, season, and application of root exogenous promoting hormones. Therefore, it is essential to understand the critical factors influencing rooting (Shekhawat and Manokari, 2016; Siddiqui and Hussain, 2007).

Roots development of cuttings differs from species to species. A variety of pre-treatments are performed to facilitate the successful rooting of cuttings such as, application of auxins which is the most common pretreatment in the vegetative propagation of plants. Many studies suggested that auxins a play detrimental role in rooting capacity by facilitating the earlier production of rooted cuttings that will necessary for vegetative propagation (Fogaca and Fett-Neto, 2005; Topacoglu et al., 2016). Adekola and Akpan (2012) and Sardoei et al. (2013) concluded that these auxins

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73937405

included indole-3-acetic acid (IAA), indole-3-butyric acid (IBA), and naphthyl acetic acid (NAA). The rooting period of plants following auxin application varies from species to species. In addition to other factors, auxins play a vital role in controlling plant growth and development influence the production of primary, secondary, and adventitious roots; they are the most frequently used plant growth hormones for rooting of cuttings in nursery practice. The commonly used auxin is IBA is synthetic auxin commonly used as an effective hormone to promote adventitious roots initiation compared to natural IAA (Pop et al., 2011). Successful propagation with the use of cuttings needs to select the right time cuttings collection, and this is intimately related to the natural phytohormones contents (Cristofori et al., 2010). In general, the growth medium is the most important factor determining seedling quality in the nursery (Baiyerin and Mbah, 2006).

Buddleja is a genus of flowering plants comprising approximately 100 species native to the tropics in America, Asia, and Africa (Corte's et al., 2006; El-Sayed et al., 2008). *B. polystachya* Fresen. is a multi-branched shrub that grow up to five meters; however, it may irregularly reached twelve meters height under favorable environment. This tree is widespread in the semi-arid highlands near the Red Sea coastal and distributed naturally in some countries like Eritrea, Ethiopia, Saudi Arabia, and Yemen where grown around forest, usually beside watercourse, at elevations 2200-3600 m above sea level (Chaudhary, 2001; Mohamedkassm et al., 2013). Several *Buddleja* species have been used in traditional medicine in many parts of the world, and the roots, leaves, and flowers of various Buddleja species have been used in folk medicine (Corte's et al., 2006; El-Sayed et al., 2008; Mohammed et al., 2016) reported that crude extracts of *B. polystachya* leaves contain certain chemical constituents that could possibly lead to antimalarial drug development and further more Al Ati et al. (2015) isolated and evaluated fifteen compounds from *B. polystachya* growing wild in Asir, one of these compound ethyl acetate fraction showed the most significant anti-inflammatory activity. Unfortunately, this valuable species is now present in a list of seriously endangered species according to International Union for Conservation of Nature and Natural Resources (IUCN, 2016).

This research work represented step to develop efficient and easy methods for the rehabilitation and conservation of *B. polystachya*, an ecologically and medicinally valuable species, by identifying the appropriate season for collection of cuttings and determining the types and concentrations of auxins for vegetative propagation and factors improving seedling growth such as growth media and auxin types.

Material and methods

First experiment

Site and seasons of cuttings collection: Healthy and uniform woody stem cuttings (average length 15 ± 3.5 cm) were collected during specific months of each season, autumn (September), winter (December), and spring (March), from stock trees of *B. polystachya* growing wild as scattered trees among others tree species in the Aseer region (18°12′63″ N, 42°31′01″ E; 2093.4 m above sea level), in the southwest of Saudi Arabia. This region is characterized by an average annual rainfall of 373.4 mm; monthly mean, minimum, and maximum temperature of 19.2 °C, 7.56 °C, and 31.0 °C, respectively; and relative humidity between 14.5% to 91.6%. All stem cuttings were collected in the early dawn (07:00 am) and kept in a plastic sealed ice container to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73937405

minimize drying. This experiment was designed to test the interaction effects of auxin type, their concentrations, and season of collecting cuttings on vegetative propagation of *B. polystachya* using stem cuttings. This experiment was repeated thrice during autumn, winter, and spring.

Experimental site

The study was conducted in a greenhouse at the College of Food and Agricultural Science, King Saud University, Saudi Arabia under controlled temperature (25 ± 1 °C) conditions with 12/12 h of light/darkness, and irrigated whenever needed during the period of the experiment. The vegetative propagation unit inside the greenhouse was covered using transparent plastic and equipped with a mist device.

Description and application of treatments

Three phases of the first experiment were conducted using three auxin types and concentrations, during autumn (September, October and November 2017), winter (December 2017, January and February 2018), and spring (March, April and May 2018) in order to test major factors affecting rooting ability of this species. Thirty treatments were applied, comprising three growth auxins, three concentrations of each auxin, and three seasons of cuttings collection (3 auxins×3 concentrations ×3 seasons + 3 controls) (*Table 1*). The plant growth auxins (IAA, IBA, and NAA) were imported from Sigma. Stock solutions of the three auxins were prepared at concentrations of 500, 1000, and 2000 ppm by weighing the respective fresh weight (g) of each auxin and dissolving in distilled water. Cuttings were immersed in each auxin concentration for 5 min before planting in nursery beds (3×0.5×2 m) with sand rooting media and cuttings were inserted 5–6 cm deep using a wooden stick.

Measurements

After 12 weeks, the assessment of rooting success was performed by harvesting five replicates from each treatment to evaluate the root formation of stem cuttings collected for the period of the first collection season (autumn) by manually counting the number of rooted cuttings (for rooting percentage computation) and number of roots per cutting, whereas root length was measured from the point of emergence to the tip using a linear meter. The evaluation of rooting was performed in the same way for the remaining two seasons (winter and spring).

Second experiment

Following screening for the factors improving rooting from the results of the first experiment, the second experiment was performed to test the effect of auxin type and seedling growth media on the growth of seedlings. Results of the first experiment showed approximately higher rooting percentage, number of roots and root length occurring in cuttings treated with 1000 ppm of the three auxins and collected during spring than in those of the other treatments and seasons. Therefore, three replicates of cuttings from each treatment of 1000 ppm of IAA, IBA, and NAA were transplanted into four growth media (clay, sand, combination of clay + sand (1:1 v/v), and clay + sand + peat moss (1:1:1 v/v). *Table 2* showed the growth media properties, such as soil organic carbon percentage (OC %) was obtained as described by Nelson and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73937405

Sommers (1982), soil texture was determined using the micropipette method (Miller and Miller, 1987), and water-holding capacity of soil was determined by the pressure plate method as described by Topp et al. (1993). After 12 weeks, for the evaluation of seedling growth, number of leaves per cutting were counted manually and relative growth rate of seedling height RGR(H) was estimated according to *Equation1* (Ostos et al., 2008).

$$RGR(H) = (LnH2 – LnH1) / t2 – t1 \quad \text{(Eq.1)}$$

where: RGR(H) = seedling height relative growth rate; H1 and H2 = initial and final seedling height, respectively; t2 and t1 = initial time and final time in month respectively.

Sand + clay + peat moss (1:1:1)	0.90-0.14	125-181	20.50

Experimental design

For the first experiment a factorial experiment (3 × 3 × 3) was set up using three different factors (three plant growth auxins, three concentrations of each auxin, and three seasons of cutting collection). The experiment was laid out in a completely randomized manner with five replicates per treatment. Then, the second experiment was designed as a factorial (3 × 4) of three auxins and four growth media.

Statistical analysis

The following statistical analyses were used: ANOVA was used to test the effect of treatments, the least significant difference multiple range-tests were used to identify differences between means, and the general linear model was used to test the interaction between the three tested factors (auxins, concentrations, and seasons of collecting cuttings). All statistical analyses were achieved by using SAS version 9.3.

Results

Rooting percentage

The interaction of auxin types, auxin concentrations, and time of collection of cuttings had highly significant ($p < 0.05$) effects on rooting percentage. All cuttings treated with the different concentrations of auxins showed a high mean rooting percentage (72%) regardless of collection season. However, although there is no significant difference between means of 1000, 2000 and 500 ppm IBA treatments, but the highest rooting percentages (98, 95% and 91%) were obtained in cuttings collected in spring when treated with the three levels of IBA (1000, 2000 and 500 ppm receptively), followed by cuttings treated with 2000 ppm of IAA and NAA (89.5%, and 86.4%) The minimum rooting percentages (59%, 63%, and 65%) were obtained in the control cuttings collected during the three season's autumn, winter and spring, respectively (*Fig. 1.*)

Number of roots per cutting

The interaction among auxin types, auxin concentrations, and collection season of cuttings on number of roots per cutting was highly significant. However, the combination of IBA, its concentration, and collection season resulted in differences in the mean number of roots per cutting, and cuttings collected during spring and treated with 500 or 1000 ppm of IBA, had the maximum roots per cutting (28.6 and 26.4 roots, respectively), followed by treatment with 2000 ppm IAA (24.6 roots) in comparison to the other treatments. In contrast, the minimum number of roots per cutting (1.0–2.8 roots) was recorded in the control cuttings during all seasons (*Fig. 2*).

DOI: http://dx.doi.org/10.15666/aeer/1805_73937405

Root length (cm)

The interaction effects of factors significantly improved root length in cuttings. The longest roots were 39.8, 27.5, 26.3, and 24.9 cm, recorded in cuttings collected during spring and treated with 500, 1000, and 2000 ppm of IBA and 2000 ppm of IAA, respectively. In addition, some cuttings collected during autumn had longer roots, especially under treatments with 1000 and 2000 ppm IBA. All control cuttings had the least root lengths (*Fig. 3*).

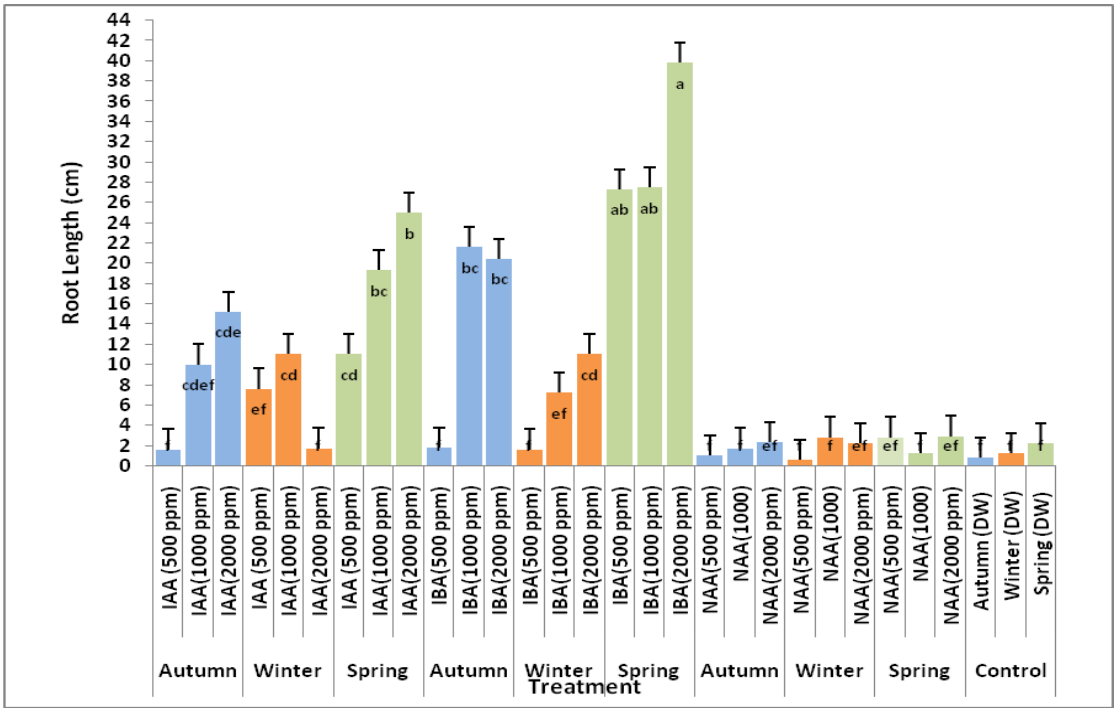

Figure 3. *Effect of treatment (three concentrations of IAA, IBA, and NAA and three seasons of cuttings collection) on root length of B. polystachya after 120 days. Columns with different letters indicate least significant differences ($P < 0.05$). DW = Distilled water*

Factors enhancing seedlings growth

Type of auxins and growth media significantly increased leaves per seedling. However, cuttings treated with IAA, IBA, and NAA grown in a mixture comprising peat moss with clay and sand (1:1:1 v/v) had the highest number of leaves (number of leaves increased by 144, 135, and 130%, respectively) compared to that in the control cuttings grown in the same media. In addition, cuttings treated with IBA grown in clay + sand (1:1v/v) had a higher percentage (115%) of number of leaves per cutting than the control seedlings grown in the same media. RGR(H) had the same trend as number of leaves per seedling, i.e., seedlings grown in media comprising a mixture of clay, sand, and peat moss had the highest rate of growth, followed by those grown in clay + sand media (*Table 3*).

Discussion

This study found that vegetative propagation of *B. polystachya* is considerably easy with the use of stem cuttings. However, for mass vegetative propagation aimed at

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73937405

obtaining a higher rooting percentage and vigorous seedlings with the highest number of long roots within the shortest time, the best time for collection of cuttings is spring and 1000 ppm IBA and 2000 ppm IAA and NAA are the best concentrations for treatment with auxins. The vegetative propagation of *B. polystachya* from stem cuttings is to some extent easy with or without the application of auxins, but cuttings treated with auxins had significantly higher number of roots and root length, especially the treatment with IBA. All three auxins promoted adventitious roots formation in the stem cuttings (*Fig. 4*), which is necessary for the vegetative propagation of many plant species (Druege et al., 2019). Auxins or plant growth hormones were used effectively in many plant species to promote the rooting of cuttings (Soundy et al., 2008; Singh et al., 2011; Sağlam et al., 2014).

Figure 4. *Root density of stem cuttings collected during spring and treated with 1000 ppm of (a) IAA, (b) IBA, (c) NAA and (d) control*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73937405

Various studies investigated the effects of different auxins on vegetative propagation via cuttings rooting and plant growth. Sevik and Guney (2013) study the effects of IAA, IBA, NAA, and gibberallic acid (GA3) in *Melissa officinalis*; Stefancic et al. (2005) investigated the effects of IAA and IBA in *Prunus spp*.; and Chhun et al. (2003) study the effects of IAA, IBA, and NAA in *Oryza sat*iva. These studies generally confirmed that the auxins or hormones have a significant effect on rooting, and consistent with these findings, the present study confirms that auxins can be a useful substance for increasing rooting in cuttings (Salmi and Hesami, 2016). The results revealed that increasing the level of the IAA, IBA, and NAA enhanced rooting percentage, number of roots per cutting, and root length. The role of increasing levels of auxin is well documented. An increased auxin concentration in the stem cutting produced by active auxin transferred from the leaves activated adventitious root creation from the cambium (Justamante et al., 2019). We found that the appropriate time for *B. polystachy*a cuttings collection is spring, and our results further confirmed that the season of cuttings collection is a critical factor for successful rooting. Our results confirmed the findings of other studies, the time of cuttings collection to be a major factor influence propagation of plant (Klein et al., 2000; Swamy et al., 2002; Haile et al., 2011). Ling and Zhong (2012) reported enhancing in rooting percentage of the Tetraploid Locust during May. Seasonal differences in successful rooting are common in woody plants, and the optimal season for rooting must be established independently for each species (Hussain et al., 2014). The rooting medium considered as proper atmosphere for rooting of cuttings (Tchinda et al., 2013), we used sand as the rooting medium in the first experiment, following Adugna et al. (2015) who used fine sand as rooting medium for *V. planifolia* stem cuttings and obtained 99.3% percentage of rooting. Although all seedlings were treated with the same concentrations of auxins and collected in the same season (spring), the interaction between IBA and combination of clay, sand, and peat moss was found to be more effective compared to that of the other two auxins and media (*Table 3* and *Fig. 5*).

Figure 5. *Growth performance of seedlings under the effect of media (clay, sand, and peat moss (1:1:1 v/v) treated with 1000 ppm of (a) IAA, (b) IBA, (c) NAA, and (d) control*

The combination of clay, sand, and peat moss was the best growth medium in comparison to the other media. This interaction enhanced seedling growth in terms of increasing number of leaves and RGR(H). This can be due to the higher content of organic matter and water holding capacity of the medium. These results are previously conformed by findings of by Neelam et al. (2001) who reported that media with improved soil physical

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_73937405

and chemical traits and aeration leaded to superior plant growth and consistence with previously findings of Ahmed et al. (2017) who reported that media consisting of clay, sand and peat moss in equal ratios enhanced seedlings growth of *B. aegyptiaca*. Furthermore, there are several studies indicating the effect of organic matter on soil fertility (Martinez et al., 2003), survival and growth (Larchevêque et al., 2006), biomass (Moreno-Peñaranda et al., 2004), and seedling quality (Mañas et al., 2009).

Conclusions

This study developed an optimal method for the vegetative propagation of *B. polystachya* via woody stem cuttings. The results confirm that woody stem cuttings collected during the spring season and treated with 1000 ppm of IBA or 2000 ppm IAA or NAA had a high rooting percentage with high quality rooted cuttings, i.e., dense and longer roots. Rooted cuttings planted in a combination of clay, sand, and peat moss in equal proportion had dense, long roots. However, in general, seedlings resulting from stem cuttings treated with IBA were superior to seedlings from the other treatments in terms of shoot development (the highest number of leaves and stem height relative to the growth rate) after 6 months. Rooting of stem cuttings of *B. polystachya* is a feasible propagation method for producing high quality seedlings, which can be used as an adequate stock for rehabilitation, conservation, and future studies on the medicinal properties of this valuable tree species. Further research work should be needed to investigate mass propagation of this species using other methods of propagation as micro- propagation or crafting. More research will be needed to evaluate growth performance and or success of seedlings resulting from vegetative propagation under field or nursery conditions.

Acknowledgments. The authors would like to extend their sincere appreciation to the Deanship of Scientific Research at the King Saud University for its funding of this research through the Research Group Project No. RGP-VPP-226.

(Received 18th Jun 2020; accepted 16th Sep 2020)

Abstract. Pathogenic organisms such as viruses can infect multiple host species from different trophic levels. Honeybee, *A. mellifera* is naturally infected by many viruses. Understanding the mechanism underlying virus spread in honeybee colonies highly depends on the pathogenic ability of honeybee killing viruses in other insects such as ants, *Messor concolor* (Hymenoptera: Formicidae). The purpose of this study was to investigate the existence and prevalence of two significant viruses, deformed wing virus (DWV) and black queen cell virus (BQCV) of honeybees in ants from the nests around different honeybee apiaries in Southeast Turkey by using reverse transcription polymerase chain reaction (RT-PCR). Both viruses were present in two nests while the former existed in another hive. Some ant nests were uninfected. This study is the first to report the molecular detection of the honeybee infecting DWV and BQCV in ants. Further studies should be devoted to the mechanisms underlying virus spread between honeybee and other interacting insects especially the Hymenopterans.
Keywords: *honeybee virus, new host, foodborne transmission, Southeast Turkey*

Introduction

Insects are host to a wide range of viruses that have significant effects on their nature. Honeybee viruses are probably the best-known insect viruses due to important economic losses (Smith et al., 2013; McMenamin and Genersch, 2015). Presence of more than twenty different virus species infecting honeybee, most of which are single-stranded positive RNA viruses, have been reported so far (de Miranda et al., 2013). Understanding the transmission mechanism of honeybee viruses in a hive and apiary is necessary to reveal population dynamics of bee viruses as an important threat. The deformed wing virus (DWV) (Iflaviridae) and black queen cell virus (BQCV) (Dicistroviridae) are the most commonly found virus species (de Miranda et al., 2013).

Deformed wing virus (DWV) is probably the most commonly encountered virus species infecting honeybees (Bailey and Ball, 1991; Lanzi et al., 2006; Berényi et al., 2007). Deformed wing, shortened abdomens, discoloring, and a decrease in the life span of bees are the clinical indicators noticed under heavy DWV infection. Deformed wing virus infection mostly does not result in clear symptoms when transmitted by other vectors than the ectoparasitic mite, *Varroa destructor* (Mesostigmata: Varroidae) (de Miranda and Genersch, 2010). DWV transmits both vertically and horizontally and also isolated from all cast (Queen, Drone, Worker) and life stage (egg, larva, pupae, and adult) of honeybee. Commercial and wild bumble bees can be infected by DWV. *Bombus terrestris* and *Bombus pascorum* shows wing deformities, (Genersch et al., 2006), and serology in *Apis cerana* and *Apis florea* (Allen and Ball, 1996; Ellis and Munn, 2005). DWV was also recorded in other insects such as small hive beetle, *Aethina tumida* (Coleoptera;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_74077415

Nitidulidae) and the wax moth, *Galleria mellonella* (Lepidoptera: Pyralidae) which are in interaction with honeybee (Eyer et al., 2009; Traiyasut et al., 2016).

BQCV, one of the most common honeybee virus, multiplies in adult bees, particularly when ingested with the microsporidian parasite spores *Nosema apis* (Bailey et al., 1983; Tapaszti et al., 2009). The infection ability of these viruses is not restricted to *A. mellifera*. Previous reports indicated that wild species of bees, *Apis dorsata* and *A. florea* (Zhang et al., 2012), and *B. terrestris* (Choi et al., 2015) were also infected by DWV and BQCV. Understanding and monitoring the global dispersal of DWV and BQCV are crucial for predicting their epidemy and successfully controlling the aforementioned viruses (Freiberg et al., 2012). Previous studies revealed presence of some honeybee viruses infecting other Arthropoda and, especially, ant species. For example, the earliest bee virus detected in an ant species (*Camponotus vagus*) is the chronic bee paralysis virus (CBPV) which is both viral and replicative (Celle et al., 2008). In another study, beside BQCV and DWV, some other viruses such that Israeli acute paralysis virus (IAPV), Kashmir bee virus (KBV), and sacbrood virus (SBV) were detected in the species of 11 non-Apis hymenoptera and pollen pellets of forager bees (Singh et al., 2010). Further research approved the existence of honeybee viruses in some ant species such as Camponotus sp. and *Tetramorium caespitum* (Levitt et al., 2013). In addition, the Argentine ant (*Linepithema humile*) was also reported being infected by DWV, BQCV, and KBV (Gruber et al., 2017). Moreover, Lake Sinai viruses (LSVs) were detected in *Messor concolor*, *M. capitatus* and *M. barbarous* (Bigot et al., 2017). Caged ants (*Myrmica rubra*) fed with infected *A. mellifera* pupae can be infected by DWV (Schläppi et al., 2019). In total, 57 samples belonging to 13 different ant genera collected in apiaries were analyzed and 51 (89%) of the samples were found infected at least by one of the following honeybee viruses; DWV, BQCV, IAPV, SBV, KBV, and Acute bee paralysis virus (ABPV) (Payne et al., 2020).

During routine surveys, I found that infected honeybee individuals were taken by ants to their nests which could be a possible route of transmission for honeybee infecting viruses from bees to ants. Thus, the aim of this study was first to demonstrate whether two important honeybee infecting viruses, BQCV and DWV exist in *M. concolor*. Further, the genome variability of a partial sequence of DWV and BQCV were evaluated.

Material and Methods

Survey

Samples from 7 ant nests were collected from Southeast Turkey (Hakkari and Şırnak provinces), in June 2016 (*Figure 1*). From each nest, four ant samples were collected. This samples were placed in a freezer at -80 ºC till the laboratory analysis. The collected samples were transported to the laboratory for diagnostic studies and RNA isolations. Samples were stored in 70% ethyl alcohol for diagnosis at -80 for RNA isolation.

RNA extraction

For preparing homogenates from ant samples, liquid nitrogen was used in a sterile mortar. All homogenized ant samples were placed into the sterile Eppendorf tubes. The RNA was prepared using a modified silica-capture method (Foissac et al., 2001). Four ants (*M. concolor*) were extracted for each ant nest. Total RNA was resuspended in free RNases and DNases water and kept at 20 ºC temperature. Total RNAs were placed in a freezer at –20 ºC till for laboratory analysis.

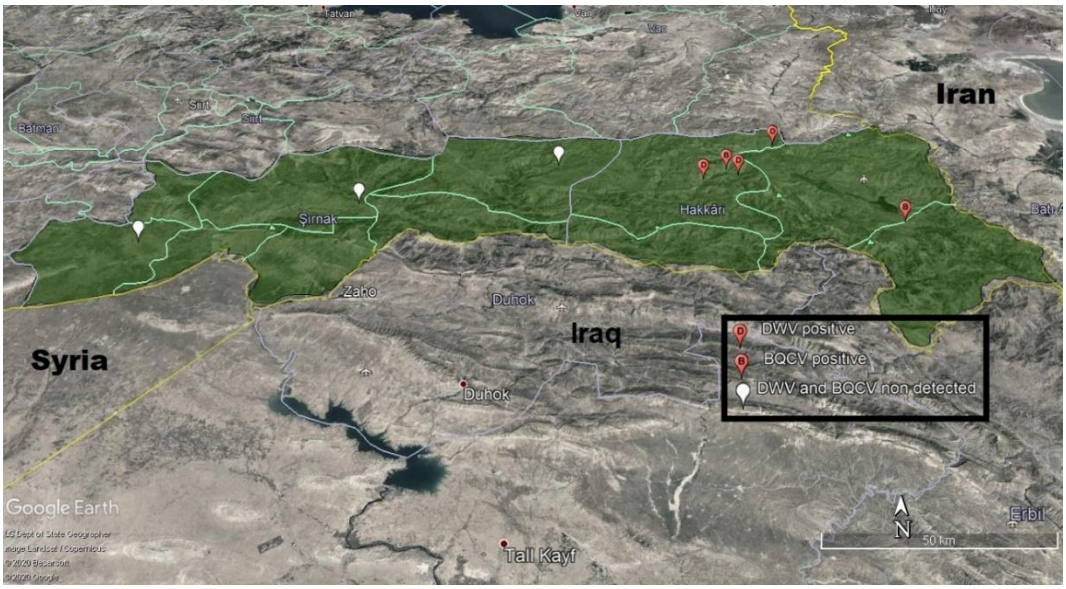

Figure 1. *The map of the collected ant sample is the green area. Each symbol shows the initial letter of the virus isolated from the collected ant sample*

RT-PCR of CP and RdRp genes

The DWV and BQCV viruses were detected using the procedure described in Rüstemoğlu and Sipahioğlu (2019). Genome-specific primers amplifying the 488 bp and 567 bp fragments of RNA depended RNA polymerase (RdRp) and partial coat protein (CP) genes were characterized by molecular cloning and sequencing for DWV and BQCV, respectively. The reverse transcription polymerase chain reaction was performed using a purified RNA from the RevertAid First Strand cDNA kit in accordance with the instruction of the producer company (Vilnius, Thermo-Fermentas Lithuania). The final volume was completed to 25 µl for PCR reaction. The solution comprised of 2.5 µl of 10 × reaction buffer (200 mM Tris–HCl pH of 8.4 and 500 mM KCl), 1 µl of cDNA, 0.5 µl of dNTPs (20 mM each), 1.5 µl of $MgCl_2$ (25 mM), 0.5 µL of each primer (100 pmol), 0.2 µL of Taq DNA polymerase and 18.3 µl of nuclease free water. Following, the partial CP and RdRp gene were amplified using thermal cycling diagram in a RT-PCR. The thermal cycle diagram was as follow; 2 minutes 35 cycles in a minute at 94 ºC temperature, 30 seconds at 57 ºC temperature, 45 seconds at 72 ºC temperature and finally incubated for 10 minutes at 72 ºC temperature. The amplified products at the end of the thermal cycling were separated using 1.5% agarose gel and stained with ethidium bromide to visualize (Sambrook et al., 1989).

Molecular cloning and sequencing

The virus isolates identified were cloned and sequenced separately. The isolation of amplified pieces was carried out in 1% agarose gel and recovered by using a GeneJET Gel Extraction Kit based on the prescription provided by the producer company (Thermo Scientific). The pGEM®-T Easy vector (Promega) was used to purify the DNA fragments. The plasmid was employed to turn competent cells of Escherichia coli JM 109 to ampicillin resistance using electroporation (BioRad, USA). Blue-white selection on X-gal medium plate was used to choose the transformants harboring the DNA of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_74077415

DWV-Ant-1 and BQCV-Ant-1 isolate and a colony PCR was employed to screen as positive clones. One clone, named DNA of DWV-Ant-1 and BQCV-Ant-1 was selected for the sequencing of DNA. Automated DNA sequences of Refgen Research and Biotechnology Company (İstanbul, Turkey) was used in sequencing the clones of cDNA.

Phylogenetic analysis

The sequences of DWV and BQCV used in comparisons were procured from the database of Genbank. The unreleased isolates for Turkish sequences of DWV and BQCV isolates were also used in the phylogenetic analysis. Multiple sequence alignments and phylogenetic reconstructions were performed for sequence similarity and phylogenetic analysis using the software of CLC Main Workbench and MEGA-X (Kumar et al., 2018). The stability of phylogenies was deduced by 1000 bootstrap replication using the method of maximum likelihood described in Tamura and Nei (1993).

Results

PCR results indicated that DWV (3/7) and BQCV (2/7) were found in the *M. concolor* nests (*Figure 2*). All positive samples were detected within the borders of Hakkari province (*Figure 1*). The sequence of DWV (GenBank Accession No. MT831948) isolates obtained from surveys had %99-95 similarity when compared with other DWV isolate records from different countries. The DWV sequence obtained from this study shows the most nucleotide similarity with KX373900.1 (France) (99.02%), MH267695.1 (Sweden), KT215905.1 (United Kingdom), KF840795.1 (Lithuania), HM067438.1 (United Kingdom) (98.77%) and KP835214.1 (Turkey), KF840794.1 (Lithuania), (98.53%) isolates, respectively. The BQCV sequence (GenBank Accession No. MT338252) obtained indicated the highest similarity to four isolates MK431882.1 (99.78%), MK431880.1 (99.10%), MK431881.1 (98.65%) and KP835213.1 (98.24%), respectively. These four BQCV isolates were obtained from *A. mellifera* in Turkey (Hakkari and Muğla). Besides these four isolates in the phylogenetic tree, BQCV (*M. concolor*) was clustered in a common branch with South Korean isolates JQ434132.1 (Ac), KP835213.1 (Am) and JQ434135.1 (Am). Phylogenetic trees were used to illustrate the relationships between the sequences. The phylogenetic trees were constructed with the confidence values for each node based on 1000 bootstrap replicates (*Figure 3* and *Figure 4*).

Discussion

This study clearly revealed that the isolates of both viruses, BQCV and DWV extracted from same hosts do not cluster (*Figures 3 and 4*). This may indicate that these two honeybee viruses have not undergone any specific changes to their hosts. The DWV and BQCV sequences obtained from *M. concolor* were mostly identical with nucleotide sequences found *A. mellifera* from same geographic origin.

The earliest bee viruses identified in ants (*Camponotus vagus* and *Formica rufa*) was the Chronic bee paralysis virus (CBPV) (Celle et al., 2008), followed by BQCV, DWV, IAPV, and SBV (Levitt et al., 2013). The DWV, BQCV, and KBV were detected in in Argentine ant (*Linepithema humile*) (Gruber et al., 2017). Lake Sinai viruses (LSV) as a honeybee virus detected in *Messor concolor*, *M. capitatus* and *M. barbarous* (Bigot et al., 2017). ABPV and DWV were detected from the ants (*Lasius platythorax*) collected from the apiary (Schläppi et al., 2020). Further the efforts on honeybee virus in ants revealed the presence of at least one of the DWV, BQCV, IAPV, ABPV, KBV, and SBV in Brachymyrmex, Forelius, Linepithema, Solenopsis, Nylanderia, Pheidole, Camponotus, Aphaenogaster, Crematogaster, Pogonomyrmex, and Pseudomyrmex ant genera (Payne et al., 2020). BQCV and DWV can infect other Apis species (*Apis florea* and *Apis dorsata*) (Zhang et al., 2012), some of bumble bee species *(Bombus terrestris, B. pascuorum, B. huntii, B. impatiens, B. vagans*, *B. ternarius*) (Genersch et al., 2006; Singh et al., 2010; Li et al., 2011; Peng et al., 2011), and isolated from the eastern carpenter bee (*Xylocopa virginica*), mining bees (*Andrena* sp.), yellow jackets (*Vespula vulgaris*), and sand wasp (*Bembix* sp.), pollen pellets from forager bees (Singh et al., 2010). Herein, the existence of DWV and BQCV in *M. concolor*, a carnivore ant species is reported for the first time.

The phylogenetic analysis showed that viruses isolated from the different host can cluster each other, for both BQCV and DWV, the sequences isolated from the ants clustered together with previous sequences from the *A. mellifera*. According to the phylogenetic tree, the hosts from the same geographical origin likely cluster each other, and besides during this the survey, it was observed that ants attack the honeybees, especially which have disabilities and cannot enter the hive because of wing deformations. These results suggest that BQCV and DWV might have transmitted from *A. mellifera* to *M. concolor*. *Messor concolor* could be another vector of these viruses as a possible spread route. In apiaries, any virus infected organism could pose a danger for honeybee populations especially, the hymenopteran insects sharing same sources with honeybees. On the other hand, since the infected honeybee individuals are dismissed from the hives and preyed by ants, the virus density in hives may reduce. Otherwise, infected honeybee individuals could be a greater threat for hives via conataminating healthy individuals by topical contact (Amiri et al., 2014, 2019; Coulon et al., 2018). Further, the genome variability of a partial sequence of DWV and BQCV were evaluated and it does not appear to be separated by the host, but rather moving between species.

Conclusion

In summary, this study reports the presence of two significant honeybee infecting virus species, DWV and BQCV from *M. concolor*, which is carnivore ant species, under natural conditions. These findings suggest that other trophic levels could be involved in spread of honeybee viruses. However, it is not clear how such an involvement could affect honeybee population dynamics. The presence of the honeybee infecting viruses should

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_74077415

be checked across other arthropod communities around apiaries which could help a better understanding of virus transmission routes.

Acknowledgements. I would like to appreciate the kind help of Dr. Sándor Csősz (California Academy of Sciences, San Francisco, USA) for the identification of ant specimens. This study was financially supported by Şırnak University Research Foundation (Project no: 2017.04.02.01).

Abstract. The paper aimed at identifying wheat genotypes tolerant to drought stress. The study repeated in three consecutive years was done on the alluvial soil of the Southern Morava river valley in South Serbia. The average wheat grain yield was higher by 124.5% under irrigation conditions than without irrigation. Over the experimental period, the average water consumed on wheat evapotranspiration under irrigation conditions was higher by 38.9% than without irrigation. Based on correlation statistical results and principal component analysis (PCA), in the case of stress resistant wheat genotypes, stress susceptibility index (SSI), tolerance index (TOL), mean productivity (MP), geometric mean productivity (GMP), stress tolerance index (STI), yield index (YI), yield stability index (YSI) as well as the LSD test was proved to be invariably efficient for determining the stress-tolerant genotypes. The result of tolerance index concerning drought and LSD test denoted that the Pobeda variety had a superior tolerance to stress due to drought than the other genotypes. Considering a comparatively low percentage of irrigated wheat fields in Serbia, it seemed to be outstandingly significant to identify the wheat genotypes tolerant to drought stress so that stable yields could be obtained.
Keywords: *winter wheat, drought stress, irrigation, water utilization efficiency, evapotranspiration*

Introduction

Crop production has been exposed to stress recently due to climate changes which have brought about extremely high temperatures with rather long dry periods. Drought stress takes place when soil and atmospheric humidity is low and the ambient air temperature is high. This condition is the result of an imbalance between the evapotranspiration flux and water intake from the soil (Lipiec et al., 2013). Namely, the stress caused by drought has a significantly negative effect on the crop yields. Implementation of crop management practices can potentially alleviate the harmful effects of drought and heat stresses and includes: soil management and culture practices, irrigation, crop residues and mulching and selection of more appropriate crop varieties (Lamaoui et al., 2018).

Wheat (*Triticum aestivum* L.) is said to be the most important crop in human nutrition with 728.1 million tons produced worldwide (FAO, 2018). However, Lizumi et al. (2018) found out that climate changes from 1981 to 2010 had decreased the wheat grain yield globally by 1.8%. In their research, Liu et al. (2016) foresaw that the wheat yield would

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_74177430

fall by 4-6% per each degree of temperature rise. Having analysed the temperatures and rainfalls in Europe over the last three decades, Moore and Lobell (2015) established the wheat yield to have dropped by 2.5%.

Thus, the extreme drought in Spain and Portugal in 2005 led to a lower yield by 50-60% (Isendahl and Schmidt, 2006) while in Serbia, according to Dragović and Maksimović (2000), it caused yield to drop even by 81%. Jovanović et al. (2013) also reported decreased crop yield by 10-50% depending on the intensity of drought.

Further, Hall (1993) defined drought as a relative yield of a genotype when compared to that under stress conditions. Thus, researchers had to select the genotypes prone to stress in order to use genetic variation for improving stress-tolerant varieties (Clarke et al., 1984). The authors who suggested the indices for establishing stress-tolerant genotypes, were numerous (Fischer and Maurer, 1978; Rosielle and Hamblin, 1981; Bouslama and Schapaugh Jr, 1984; Fernandez, 1992; Gavuzzi et al., 1997). In contrast, the wheat varieties of a high genetic potential for grain yield selected under optimal growing conditions were reported as non-resistant to drought (Blum, 1979; Ceccarelli and Grando, 1991). Richards (1996) also stressed that wheat selection should be made under stress and optimal growing conditions.

The research aimed to determine drought stress resistant wheat varieties grown in Serbia, based on the effect of drought stress on their grain yield, in order to provide information on which varieties are less susceptible to climate change.

Materials and methods

Experimental location

The study lasted for three years in the experimental field, in Batušinac (43º15´24″ N and 21º49´13″ E, altitude: 201 m asl), municipality of Merošina, not far from the city of Niš in South Serbia (*Fig. 1*). The study location is approximately 240 km away from Belgrade.

Experimental design

The trials were set up in a random block system in three repetitions. Drought tolerance of the seven varieties Pobeda, Zvezdana, Rapsodija, Renesansa, Evropa 90, Simonida and NS Rana 5, created at the Institute of Field and Vegetable Crops in Novi Sad (the National Institute of the Republic of Serbia) and that of the two varieties (KG 56 and Takovčanka), selected at the Institute for Small Grains – Kragujevac, were studied. In the experimental field, winter wheat sowing was carried out from the 10^{th} to 25^{th} October. Seeding rate was 500 germinative seeds per m^2. The areas of elementary plots were 6 m^2 and, during vegetation, usual agrotechnical measures for wheat were used. The total amount of nutrients deposited to soil was: N - 130 kg ha^{-1}, P_2O_5 - 85 kg ha^{-1}, K_2O - 110 kg ha^{-1}. Irrigation was done by drip irrigation method and its term was determined by observing dynamics of soil moisture down to 60 cm of depth, pre-irrigation soil moisture amounted to 70% of the field water capacity (FWC). Soil moisture content was measured by thermogravimetric analysis in the oven at 105-110ºC.

Rainfall was measured at the experimental field by rain gauge. The mean monthly air temperatures and monthly amount of rainfall for the study period and multi-annual average for the city of Niš (*Table 1*) were taken from the website of RHS (2019).

Winter wheat evapotranspiration (ET) was calculated using the water balance method (*Eq. 1a, b, c*; Simsek et al., 2005):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_74177430

$$ETm = R + I \pm \Delta S - D - Ro \quad \text{(Eq.1a)}$$

$$ETa = R \pm \Delta S - D - Ro \quad \text{(Eq.1b)}$$

$$\pm \Delta S = R + I - D - Ro - ET \text{ , (ETm or ETa)} \quad \text{(Eq.1c)}$$

where:
ETm = evapotranspiration determined in irrigation treatment for the growing season;
ETa = evapotranspiration determined in treatment without irrigation for the growing season;
±ΔS = change in root zone water storage over a given time interval;
R = rainfall;
I = irrigation water applied;
D = drainage water (percolation);
Ro = surface runoff which was set to zero.

Water utilization efficiency of winter wheat (WUE) has been calculated as the observed wheat grain yield divided by water consumption for evapotranspiration (*Eq. 2*):

$$WUE = \frac{GY}{ET} \quad \text{(Eq.2)}$$

where:
WUE = water utilization efficiency (kg ha^{-1} mm^{-1});
GY = wheat grain yield (kg ha^{-1});
ET = evapotranspiration (mm).

Drought resistance indices were calculated as below:

- Stress Susceptibility Index (*Eq. 3*; Fischer and Maurer, 1978):

$$SSI = \frac{1 - \left(\frac{Y_s}{Y_p}\right)}{1 - \left(\frac{\overline{Y_s}}{\overline{Y_p}}\right)} \quad \text{(Eq.3)}$$

- Tolerance Index (*Eq. 4*; Rosielle and Hamblin, 1981):

$$TOL = Y_p - Y_s \quad \text{(Eq.4)}$$

- Mean Productivity (*Eq. 5*; Rosielle and Hamblin, 1981):

$$MP = \frac{(Y_s + Y_p)}{2} \quad \text{(Eq.5)}$$

- Geometric Mean Productivity (*Eq. 6*; Fernandez, 1992):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_74177430

$$GMP = \sqrt{Y_p \times Y_s} \quad \text{(Eq.6)}$$

- Stress Tolerance Index (*Eq. 7*; Fernandez, 1992):

$$STI = \frac{(Y_s + Y_p)}{(\overline{Y_p})^2} \quad \text{(Eq.7)}$$

- Yield Index (*Eq. 8*; Gavuzzi et al., 1997):

$$YI = \frac{Y_s}{\overline{Y_s}} \quad \text{(Eq.8)}$$

- Yield Stability Index (*Eq. 9*; Bouslama and Schapaugh Jr, 1984):

$$YSI = \frac{Y_s}{Y_p} \quad \text{(Eq.9)}$$

where:
Y_s - yield of cultivar under stress condition;
Y_p - yield of cultivar under irrigation condition;
$\bar{Y}_s$ - total yield mean under stress condition;
$\bar{Y}_p$ - total yield mean under irrigation condition.

Statistical analysis

Data reported for the wheat yield were assessed by the analyses of variance (ANOVA) and Fisher's LSD test was used for all the significant differences at the $P < 0.05$ levels between the means. The relationship between crop yield and water used by evapotranspiration was evaluated using regression analysis. All the statistical analyses were made using software package JMP 15, Copyright SAS Institute Inc.

Results and discussion

The average wheat grain yield was higher by 124.5% with irrigation than without it (*Table 2*). Similarly, the effect of yield increased by 118.3% was established by Dutta et al. (2017) for the approximate values calculated for wheat ET. The highest irrigation during the season of 2014/15 exerted yield increase by 133.3%. The highest percentage of yield increase over the production year probably resulted from the rainfall deficiency in the period from April to July (134 mm) with longer dry periods.

The water used for wheat evapotranspiration with irrigation over the three years of the experiment amounted to 356.9 mm whereas ET amounted to 256.8 mm, being lower by 38.9% under stress conditions. The highest ET value (377.7 mm) with irrigation was recorded in 2015/16 when the highest mean monthly temperature of 19.2ºC was reported for the period from April to July (*Table 1*). The lowest ET value (227.4 mm) was recorded in the production year of 2014/15, during which the lowest amount of 134.7 mm rain fell.

Table 2. *Grain yield, evapotranspiration and WUE of winter wheat under stress and irrigation conditions*

Year	Conditions	Soil water supplies (mm)	Rainfall (mm)	Irrigation (mm)	Grain yield (t ha^{-1})	ET (mm)	WUE (kg ha^{-1} mm^{-1})
2014/15	Irrigation	63.6	134.7	150	5.89	348.3	16.9
	Stress	92.7	134.7	-	2.68	227.4	11.8
2015/16	Irrigation	59.4	198.3	120	6.25	377.7	16.5
	Stress	77.9	198.3	-	2.85	276.2	10.3
2016/17	Irrigation	69.4	185.2	90	6.37	344.6	18.5
	Stress	81.8	185.2	-	2.73	267.0	10.2
Average	Irrigation	64.2	172.7	120	6.17	356.9	17.3
	Stress	84.1	172.7	-	2.75	256.8	10.8

Note: ET - evapotranspiration, WUE - water utilization efficiency

The ET values calculated for wheat throughout the research with irrigation (344.6-377.7 mm) were similar to those cited by Vučić (1976) and Bošnjak (1999) in the environmental conditions of South Serbia. The ET value determined with irrigation was similar to those from 345 to 385 mm evidenced by Luchiari et al. (1997). In addition, Balwinder-Singh et al. (2011) reported the plant requirements for water to range from 345 to 404 mm. Cui et al. (2018) reported wheat ET to be 402 mm at the invariable value of 70% of FWC being the same as that in the current research. Different ET values of wheat were due to differences in wheat varieties, irrigation regime and pedo-climatic conditions pertained to the area studied.

The WUE of winter wheat irrigation along with optimal soil humidity averaged 17.3 kg ha^{-1} mm^{-1} whereas it averaged 10.8 kg ha^{-1} mm^{-1} without irrigation (*Table 2*). The rational irrigation regime used resulted in significantly higher WUE values, complying with results of numerous authors (Kang et al., 2002; Huang et al., 2005; Sun et al., 2006; Mahamed et al., 2011; M'hamed et al., 2015).

The inter-relation of the linear regression of wheat yield with water consumption on ET (*Fig. 2*) was determined with a positive high significant correlation (r = 0.95**) displayed between the yield and the total water consumption on ET over the three years of the experiment.

All the nine wheat genotypes showed considerably lower mean values (86.6-204.7%) under stress conditions than when irrigated (*Table 3*). Thus, the average wheat yield with irrigation proved to be the highest with Renesansa (6.55 t ha^{-1}) and the lowest with Simonida (5.75 t ha^{-1}). The genotype Pobeda achieved the highest (3.95 t ha^{-1}) and NS Rana 5 the lowest yield (1.92 t ha^{-1}) under stress conditions without irrigation.

Further, the linear regression (*Fig. 3*) confirmed a high percentage of variation between Yp and Ys whereas the correlation coefficient between the wheat yield with irrigation and stress was insignificant (r = 0.61).

The variance analysis showed a noticeable difference in wheat yield as an interaction between the genotype and agroecological conditions with or without irrigation. LSD test also revealed a significant difference in the yield between the genotypes with irrigation conditions (*Table 4*). However, no significant difference in yield could be reported between the following genotypes: Pobeda - Zvezdana, Rapsodija - Renesansa, Renesansa - Evropa 90, KG 56 - Evropa 90, Takovčanka - Simonida and Simonida - NS Rana 5, respectively (*Table 4*).

The variety Pobeda exposed to stress achieved a positive significant difference in its yield compared to the remaining varieties, meaning its best tolerance to stress due to water deficit (*Table 5*). In addition to Pobeda, Zvezdana and Evropa 90 also exhibited a significant tolerance to stress with no significant variations found in yield between the following wheat genotypes: Zvezdana - Rapsodija, Rapsodija - Renesansa, Renesansa - Evropa 90, KG 56 - Takovčanka, Takovčanka - Simonida, Simonida - NS Rana 5.

Note: *significantly different at LSD 0.05

The lower values of SSI and TOL showed susceptibility and tolerance of the genotypes affected by stress. Based on the values calculated for SSI (0.67) and TOL (2.35), Pobeda expressed a more superior tolerance to stress than the other genotypes did (*Table 6*). It is worth mentioning that Zvezdana (SSI-0.84; TOL-2.85), Rapsodija (SSI-0.94; TOL-3.44) and Evropa 90 (SSI-0.95; TOL-3.28) expressed a better tolerance to drought than the remaining wheat genotypes did (Clarke et al., 1992; Golabadi et al., 2006; Talebi et al., 2009; Ilker et al., 2011). Guttieri et al. (2001) stressed that when the SSI values were higher than one, wheat varieties were manifested as extremely susceptible to stress caused by drought.

Table 6. *Drought tolerance indices and mean yield of 9 wheat genotypes under stress and irrigation conditions*

Genotypes	Y_p	Y_s	SSI	TOL	MP	GMP	STI	YI	YSI

Takovčanka	6.32	2.24	1.16	4.08	4.28	3.76	0.37	0.81	0.35
Rapsodija	6.56	3.12	0.94	3.44	4.84	4.52	0.54	1.13	0.46

Note: Y_p - yield of cultivar under irrigation condition, Y_s - yield of cultivar under stress condition, SSI - stress susceptibility index, TOL - tolerance index, MP - mean productivity, GMP - geometric mean productivity, STI - stress tolerance index, YI - yield index, YSI - yield stability index

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_74177430

The values of indices MP-5.12, GMP-4.98, STI-0.65 calculated for Pobeda favoured stress-tolerance of this genotype along with the similar values found for the yield under irrigation and stress conditions of MP-4.84, GMP-4.52, STI-0.54 for Rapsodija, MP-4.75, GMP-4.49, STI-0.53 for Zvezdana and MP-4.75, GMP-4.40, STI-0.51 for Renesansa, respectively, thereby expressing their high tolerance to stress due to water deficit. Fernandez (1992) claimed STI index to have probably altered the genotypes having a high yield and withstanding stress due to drought. Numerous authors (Talebi et al., 2009; Dadbakhsh et al., 2011; Khodarahmpour et al., 2011; Mohammadi et al., 2011; Sareen et al., 2012) pointed out STI, GMP and MP efficiency with the stress-tolerant genotypes. Khayatnezhad et al. (2010) pointed out that none of these indices could distinctly determine high yielding genotypes under the optimal and stress conditions.

The analysis of calculated results YI (1.44) and YSI (0.63) denoted that Pobeda exhibited a higher stress tolerance than the remaining eight wheat genotypes did. In addition to Pobeda as stress-tolerant to drought, the values of YI and YSI reported for Zvezdana (1.20; 0.53), Rapsodija (1.13; 0.46), Renesansa (1.08; 0.46) and Evropa 90 (1.04; 0.47), respectively, also confirmed their good stress tolerance to drought.

In addition, wheat yield attained with irrigation showed no significant correlation with SSI and TOL indices but it did with MP, GMP and STI (*Table 7*). Thus, when irrigated, the wheat yield achieved a negative with SSI and TOL but a positive significant correlation with MP, GMP and STI. These results comply with those reached by: Fernandez (1992), Shafazadeh et al. (2004), Golabadi et al. (2006), Talebi et al. (2009), Boussen et al. (2010), Anwar et al. (2011), Sarren et al. (2012) and Abdolshahi et al. (2013).

Note: *significantly different at $p < 0.05$; Y_p - yield of cultivar under irrigation condition, Y_s - yield of cultivar under stress condition, SSI - stress susceptibility index, TOL - tolerance index, MP - mean productivity, GMP - geometric mean productivity, STI - stress tolerance index, YI - yield index, YSI - yield stability index

Based on PCA made for the three years of studies, the first two factors accounting for 93.9% data deviation were differentiated (*Table 8*). The first component accounted for 79.3% variation of the calculated indices. This component had a highly negative correlation with SSI and TOL, but a highly positive with Yp, Ys, MP, GMP, STI and YSI and a barely positive one with YI. The second component accounted for 14.6% index

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_74177430

deviation and was positively correlated with Yp, SSI, TOL and YI but barely correlated with the remaining indices embraced by the current studies.

Table 8. *Principal Component Analysis (PCA) - Correlations between variables and components*

Factor	Total	% of variance	Yp	Ys	SSI	TOL	MP	GMP	STI	YI	YSI
1	7.14	79.35	0.66	0.99	-0.97	-0.87	0.98	0.99	0.99	0.35	0.96
2	1.31	14.58	0.63	-0.08	0.21	0.44	0.14	0.06	0.03	0.77	-0.23

Note: Y_p - yield of cultivar under irrigation condition, Y_s - yield of cultivar under stress condition, SSI - stress susceptibility index, TOL - tolerance index, MP - mean productivity, GMP - geometric mean productivity, STI - stress tolerance index, YI - yield index, YSI - yield stability index

The biplot, resulting from the two basic factors for the genotypes and indices, is presented in *Fig. 4.* Fernandez (1992) denoted to the angles and directions of the vectors indicating the strength and correlation between either one of the two attributes. Thus, a significantly positive correlation was revealed between YI and Yp, Yp and MP, MP, GMP and STI. A significantly positive correlation was also noticed between STI and TOL but solely due to the impact of the second component whereas a significantly negative correlation resulted from that of the first component, which is in agreement with the correlation results outlined in *Table 7*. Therefore, in order to efficiently identify the stress-tolerant genotypes, STI, GMP and MP should be used, which is corroborated by the findings of Fernandez (1992), Talebi et al. (2009), Nouri et al. (2011) as well as by those of Mollasadeghi et al. (2011), Sareen et al. (2012).

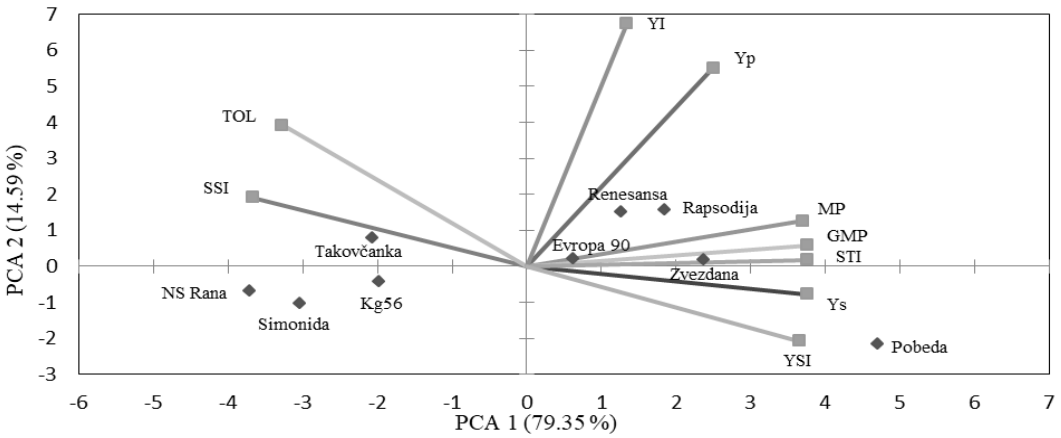

Figure 4. *PCA of drought tolerance indices*

Based on everything mentioned above as well as on the observations about the wheat genotypes within biplot, it may be inferred that Pobeda had a noticeably high tolerance to stress caused by drought along with Renesansa, Rapsodija, Evropa 90 and Zvezdana resisting the stress conditions quite satisfactorily, too.

Conclusion

Climate changes were the major reason for identifying stress-tolerant wheat genotypes, which would simultaneously lead to their stable yields. Drought led to a significant decrease in the average yield (124.5%). The average water used for wheat evapotranspiration under irrigation conditions over the study period amounted to 356.9 mm and that used for ET under stress conditions to 256.8 mm. The stress tolerance indices of STI, MP and GMP helped to differentiate adequately and efficiently the wheat genotypes of a high yield, both in optimal and in stress conditions. YSI, TOL and SSI values clearly indicated the stress-tolerant genotypes. As confirmed by Fisher's LSD test, the YSI, TOL and SSI proved to be invariably efficient for revealing the stress-tolerant wheat genotypes. The variety Pobeda exhibited a more superior tolerance to stress than it did with the remaining genotypes. Renesansa, Rapsodija, Evropa 90 and Zvezdana also displayed a considerably good tolerance to stress. The study results will, therefore, pave the way for high and stable wheat yields provided that modern farming techniques and adequate agroecological management are used.

Overall, climate changes will pose a grave threat to agricultural production in the future and that´s all the more reason to keep on making long-term experiments of the crop stress tolerance caused by climate extremes so that stable yields can be achieved.

Abstract. Thanks to archaeobotanical investigations, we can now treat it as a fact that the territory of Hungary is one of the longest inhabited parts of Europe. The Pannonian Basin plays a bridging role in the spread of plant cultivation knowledge along the path leading from the Middle East to the Balkans. The relationship between cultivated plants as well as weeds has been determined by the lifestyles of the populations that have lived in the Pannonian Basin and local climatic conditions. The cultivation of several species of plants is only associated with a specific archaeological era or a specific culture. The populations that have lived here have always brought and grown their own cultivated plants with them when they moved into the area. The archaeobotanical research in Hungary reaches back more than 140 years. During this long period of time 50 researchers were active in this topic and about 400 archaeological sites have been processed. Near 10 million seeds of 700 plant taxa (mostly species) were identified in the Pannonian Basin. Our catalogue of the weed remains from Hungarian excavations, indicates species and number of items, is classified on the basis of periods and sites, and ranges from the Neolithic to the Late Middle Ages.
Keywords: *excavation, archaeophyton, Carpathian Basin, ecology, plant cultivation*

Introduction

The study of prehistoric and historic weeds is an important topic of archaeobotany. Many attempts are made to match existing archaeobotanical data with the known agricultural systems of different archaeological eras. Küster (1985) was one of the forerunners who dealt with the distribution and origin of cereal weeds (Secalietea). Based on Rademacher (1968), and Willerding (1986) distinguished five different phases of weed flora development. Almost at the same time Knörzer (1984) described the prehistoric weed association of the North Rhein region under the botanical term *Bromo-Lapsanetum praehistoricum*. Recently, Frumin (2013, 2015, 2017) – partly based on Pysek's results (2002) – proposed an evaluation criterion for archaeobotanical weed records.

The ecological evaluation of weed species is based on the adaptation of ecological indicator values published in Raunkiaer's lifestyle system (1934). This was later re-introduced by Ellenberger et al. (1991). The so-called area classification evaluation system was developed by Ehrendorfer (1973) and further improved later on by Oberdorfer (1983).

The terms *thanatocoenology* and *thanatocoenosys* were created by Willerding (1983) based on the analysis of the ecological properties of weed remains recovered from

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_74317444

various excavations. Later on Jacomet et al. (1989) recommended a metric evaluation system of the possible habitats instead of attempting to reconstruct once existing plant associations. The so called *'comprehensive weed history method'* turned out to be an important and significant approach to understanding the agricultural development of archaeological cultures (Willerding, 1986; Jacomet et al., 1989; Kreuz et al., 2005; Kreuz and Schäfer, 2011).

In Hungary, the history of weed association development studies was written by herbologists and ecologist. Identification guides that were compiled in the last century also dealt with the dispersion of weed species. The works of Schermann (1966), Hunyadi (1988), Radics (1998), and Hunyadi et al. (2000) have to be mentioned among others. The ecological history and recent distribution of weeds within the Pannonian Basin has always been a significant issue and was dealt by numerous scholars such as Ubrizsy (1955), Ujvárosi (1957, 1973), Czimber (1987), Bartha (2000), Csontos (2001), Priszter (1997), Dancza (2011), and Lehoczky et al. (2013).

Weed associations were identified and described by Soó (1964-1985) and Borhidi et al. (2012). Based on the works of Ujvárosi (1952), Kárpáti et al. (1968), Soó (1973), Horváth et al. (1995), and Borhidi (1995) the so called life-form classification system and scale of Hungarian weed flora was also developed; a system aiming at the numerical and ecological analysis of weed associations.

The problems of apophytes (native species), archaeophytes (non-native, arriving before the 15th century) and neophytes (non-native, arriving after the 15th century) within the Pannonian Basin was first addressed by Terpó et al. (1999), Pinke and Pál (2005), Botta-Dukát and Balogh (2008), Balogh and Gyulai (2014) as well as by Henn et al. (2014) later on.

The study of invasive plants falls also within the issues of weed studies (Mihályi and Botta-Dukát, 2004). Processes of *synanthropisation* and anthropogenic effects influencing landscape changes were studied by Terpó (2000) and Pinke et al. (2011). Grouping of synanthropic plant species of different archaeological eras was done by Berzsényi (2000). Due to the effects of intensive agriculture many of the archaeophyton species are endangered by extinction in the Pannonian Basin today. For this reason, their examination also falls within the interest of historical agro-biodiversity research. A few of the adventive weeds are already on the list of protected and endangered plant species of Hungary (Udvardy, 2000).

In comparison to the above mentioned works, only very few studies dealt with the history, dispersion and development of weed species from an archaeobotanical perspective (Füzes, 1990; Gyulai et al., 1992; Berzsényi, 2000; Gyulai et al., 2013; Gyulai and Lakatos, 2013; Kenéz, 2014; Pósa et al., 2015). The basis of these is a catalogue of the weed finds sorted according to cultures and taxa, which was first compiled by Hartyányi et al. (1968, 1974), and later on improved by Gyulai (2010).

Materials and methods

The archaeobotanical record

Since the beginning of archaeological research (1860) in Hungary, nearly 50,000 sites were found. Out of these, 414 sites (1%) have been studied from an archaeobotanical aspect (*Fig. 1*). Most settlements are known to be from the Middle Neolithic (55 sites), the Roman Age (53 sites), and the Late Middle Ages (37 sites) (*Fig. 2*). Our research is based on the supplemented and updated archaeobotanical

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_74317444

dataset compiled by Gyulai (2010). This is a catalogue consisting of the seed, fruit, food and beverage remains from Hungarian excavations, indicating species and number of items, classified on the basis of periods and sites, ranging from the Neolithic to the Modern Ages, from the beginning of archaeobotanical research, up to the present, and in a chart form.

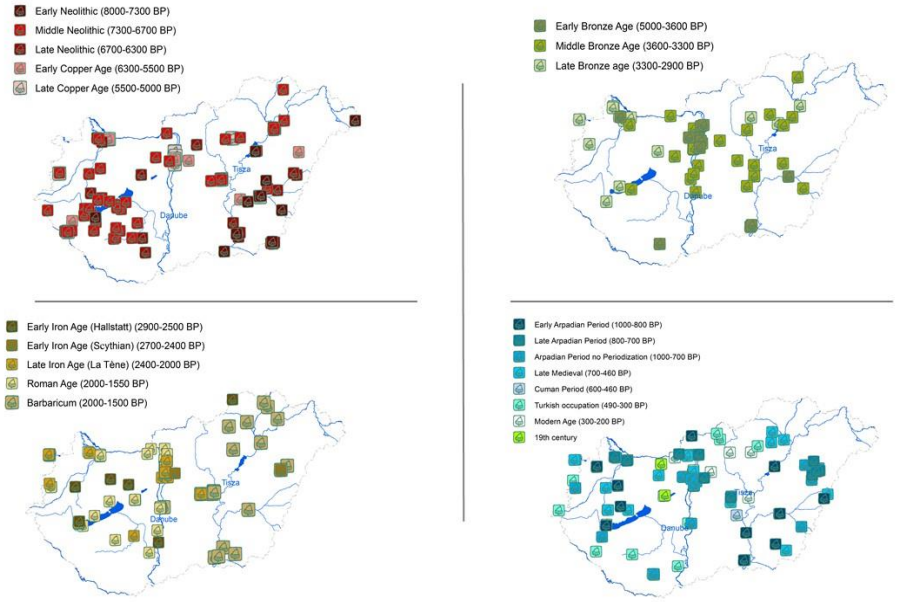

Figure 1. *Map of the archaeological sites in Hungary*

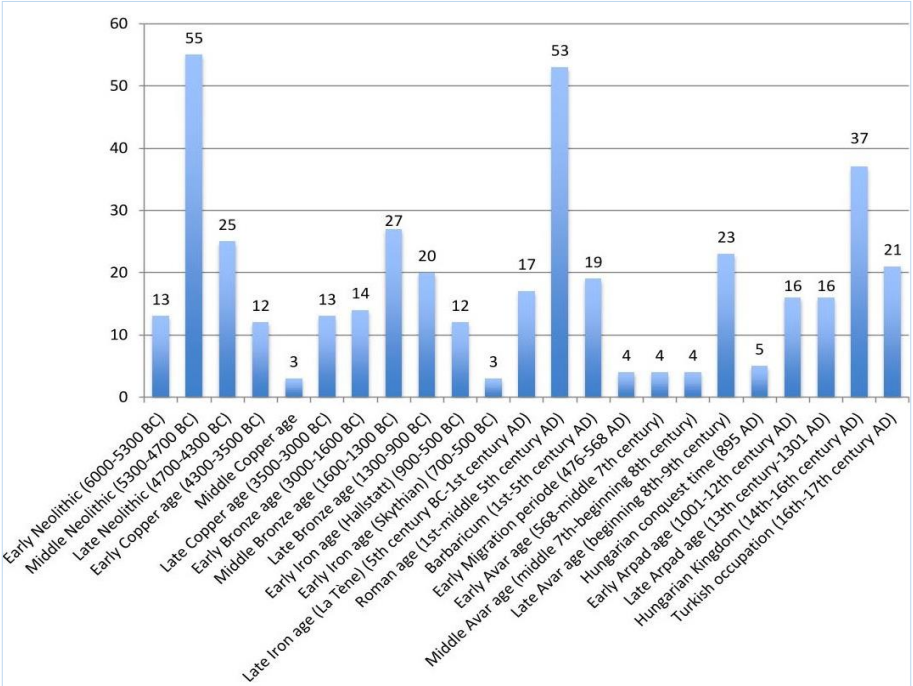

Figure 2. *Number of archaeological sites in every archaeological era, at which archaeobotanical analysis was carried out*

DOI: http://dx.doi.org/10.15666/aeer/1805_74317444

Methodological considerations

The research dataset was completed by the selection of weeds, based on the identification criteria published earlier by Jacomet et al. (1989). This resulted in the list of weed species according to archaeological periods. The weed species have been classified as follows: cereal weeds, root- or summer crop weeds and ruderal weeds. The database has been expanded with additional data: type of area, life-form, residence time status (apophyte, archaeophyte, neophyte) and height (low, medium, high). In the list of weed species, a value of '1' was assigned to species which were present in the archaeological period, whereas '0' means they weren't present. In case a weed was present in multiple periods, all instances were assigned a '1', since if we didn't, our results would've been deformed. Analysing the huge data set was conducted using the IBM SPSS Statistics 22.0 software. The statistical analysis encompassed the following:

- Relationship between cereals and cereal weeds.
- Fluctuation of cereal weed species.
- Distribution of cereal weed species, depending on if they are present in the latest age or not, regarding first appearance.
- Distribution of cereal weed species by plant height, first appearance.
- Distribution of cereal weed species by life form, first appearance.
- Distribution of cereal weed species by area.

Results

The distribution of the plant species broken down to the archaeological eras of the Pannonian Basin gives us an overview of when the number of weeds increased throughout the history of the geographical area. The periods of increase of weed species: Middle Neolithic, Middle Bronze age, Roman age, Late Middle Ages (*Fig. 3*).

It is interesting to note that the number of weed species of the settled nomadic cultures with steppe origins coming from the east (Middle Copper age, Scythians, Sarmatians, Avars, Hungarians) was always higher than in the previous period. Some segetal weeds (e.g. *Agrostemma githago*, *Bromus sp.*) arrived with Neolithic farmers from the south-east, who later migrated slowly towards the west accompanied by indigenous species of Central and Eastern Europe.

Distribution of cultivated and weed species

Together with the rising number of cultivated species the diversity of weeds grew as well (*Fig. 4*).

However, there is no significant difference in the proportion of cereal weed, root- or summer crop weed and ruderal weed species during the different periods. Although the typical process is growth, yet in some age to fall: Copper Age, Early Bronze Age, Migration Period. In our opinion, the separation of winter- and summer crop weeds was not realised in the Pannonian Basin; they arrived into this separated geographical area in with their original ecological 'faith'.

The increasing number of ruderal species may be closely related to the rising number of settlements in certain periods. At the beginning of the Neolithic era (e.g. Körös culture), new, foreign species associated with plant cultivation appeared in the landscape. At the beginning of cereal cultivation, einkorn wheat, emmer wheat and barley were the characteristic cereals with shorter growth-cycle common millet was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_74317444

added in the Bronze Age. Both cultivated and wild ones also arrived, primarily from Asia Minor and the Mediterranean, and to a lesser extent from Asia. These had lived in association with domesticated plants, often as wild relatives of domesticates in their places of origin. But, in a cultivated context, they were simply weeds. The first segetal associations of the Neolithic and the Bronze Age had relatively high number of species, much higher than expected. According to archaeological plant material, white goosefoot (*Chenopodium album*) was present in very large quantities, while *Avena fatua*, *Bromus arvensis*, *B. secalinus*, *Chenopodium hybridum*, *Fallopia convolvulus*, *Galium spurium*, *Vicia angustifolia* were also common. In the Roman age several new segetal species appeared: *Abutilon theophrasti*, *Anthemis cotula*, *Bifora radians*, *Centaurea cyanus*, *Cynodon dactilon*, *Diplotaxis muralis*, *Lathyrus hirsutus*, *Lepidium draba*, *Myagrum perfoliatum*, *Myosotis arvensis*, *Torilis arvensis*, *Vicia villosa*. In the Middle and in the early Modern Age the weed flora enriched with new species, in which grain trade also played a role: *Alopecurus myosuroides*, *Amaranthus retroflexus*, *Euphorbia exigua*, *Galeopsis tetrahit*, *Lepidium perfoliatum*, *Ranunculus sardous*, *Silene noctiflora*, *Vaccaria pyramidata*, *Valerianella carinata*.

Figure 4. *The most important data of the Hungarian Archaeobotanical Database*

Distribution of weed species by residence time status

There is no significant difference between the proportion of apophytes and archaeophytes during the different archaeological eras (*Fig. 5*).

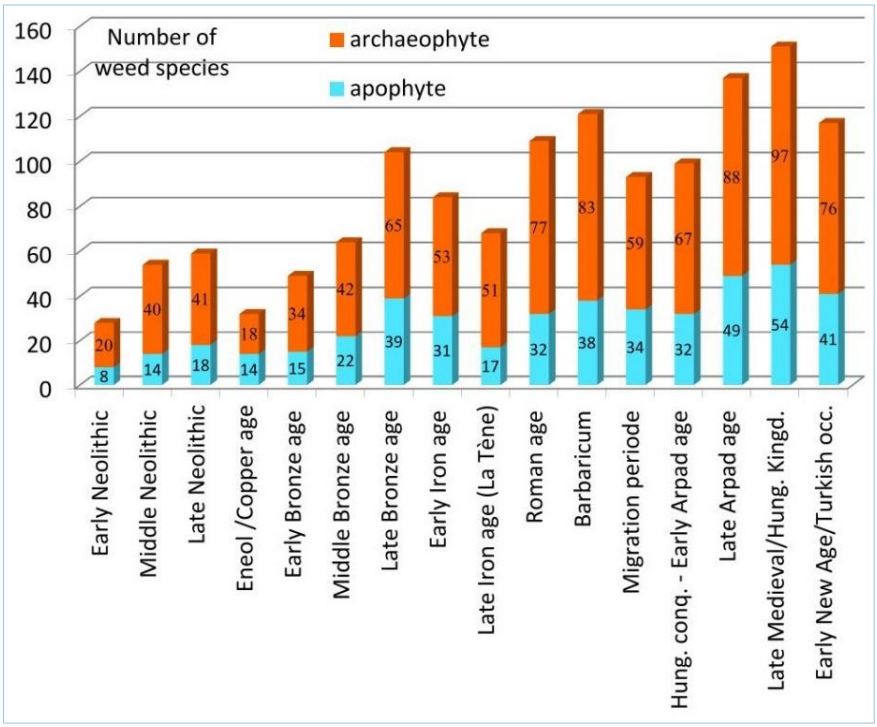

Figure 5. *The number of archaeophyte and apophyte weed species throughout the archaeological era of the Carpathian Basin*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_74317444

Until the Early Modern Age apophyte and archaeophyte species were dominant. However, there are terminological errors of their interpretation. When compared to western Europe, Bulgarian and Hungarian LBK species, five of them cannot be Hungarian apohytes because they also occurred in Bulgaria. So, the current division in other ages should also be reviewed. In addition to weeds introduced with sowing-seeds, elements of the previous flora were also present for some time. Domesticated species cultivated on arable land meant competition for the components of natural vegetation. Other plant species were less able to adapt to the changed conditions resulting from cultivation and subsequently disappeared. During the Middle and Late Neolithic period, a whole range of foreign weed species migrated to the central regions of Europe. Before AD 1500, the landscape was dominated by associations of archaeophytes and apophytes: archaeophytes: e.g. *Agrostemma githago*, *Centaurea cyanus*, *Echinocloa crus-galli*, *Papaver rhoeas*, *Setaria pumila*, *Sinapis arvensis*, *Stachys annua*, apophytes: *Artemisia vulgaris*, *Agropyron repens*, *Centaurea cyanus*, *Consolida regalis*, *Digitaria sanguinea*, *Portulaca oleracea*, *Raphanus raphanistrum*.

Relationship among cereals and cereal weeds

The number of cereal species in the Early Neolithic was higher than in later periods (*Fig. 6*). The existing cereal species were supplemented with new ones. In the latter two the high number of weeds may be related to manuring. In the beginning hulled wheats (einkorn wheat, emmer wheat) and naked barley, but later, after the Roman Age common wheat and rye were dominant. Until the Late Iron age, the number of cereal weed seeds were low compared to cereal grains. (Seed treatment was more effective perhaps?) The trend changed in the Roman Age. The number of cereal weed remains are many times higher than that of cereal grains. The number of weed species by winter cereals (einkorn wheat, emmer wheat, spelt, common wheat, dwarf wheat) and rye was proportionally higher than that of hulled wheat.

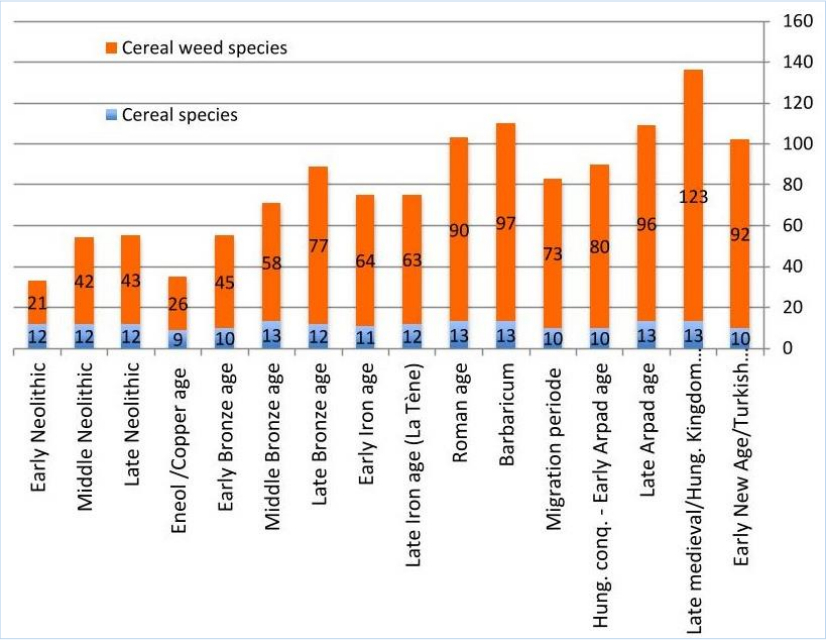

Figure 6. *The relation between cereal and cereal weed species throughout archaeological eras of the Carpathian Basin*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_74317444

The Neolithic, Bronze Age, Roman Age/Barbaricum and Late Middle Ages were the periods when most cereal weed species appeared (*Fig. 7*). Many cereal weed species disappeared in the Roman period (7) and even more in late Middle Ages (50!). In the Roman Age and late Medieval period, the weed flora changed thoroughly. Why? Both periods saw the use of ploughshare and manuring (*Fig. 8*).

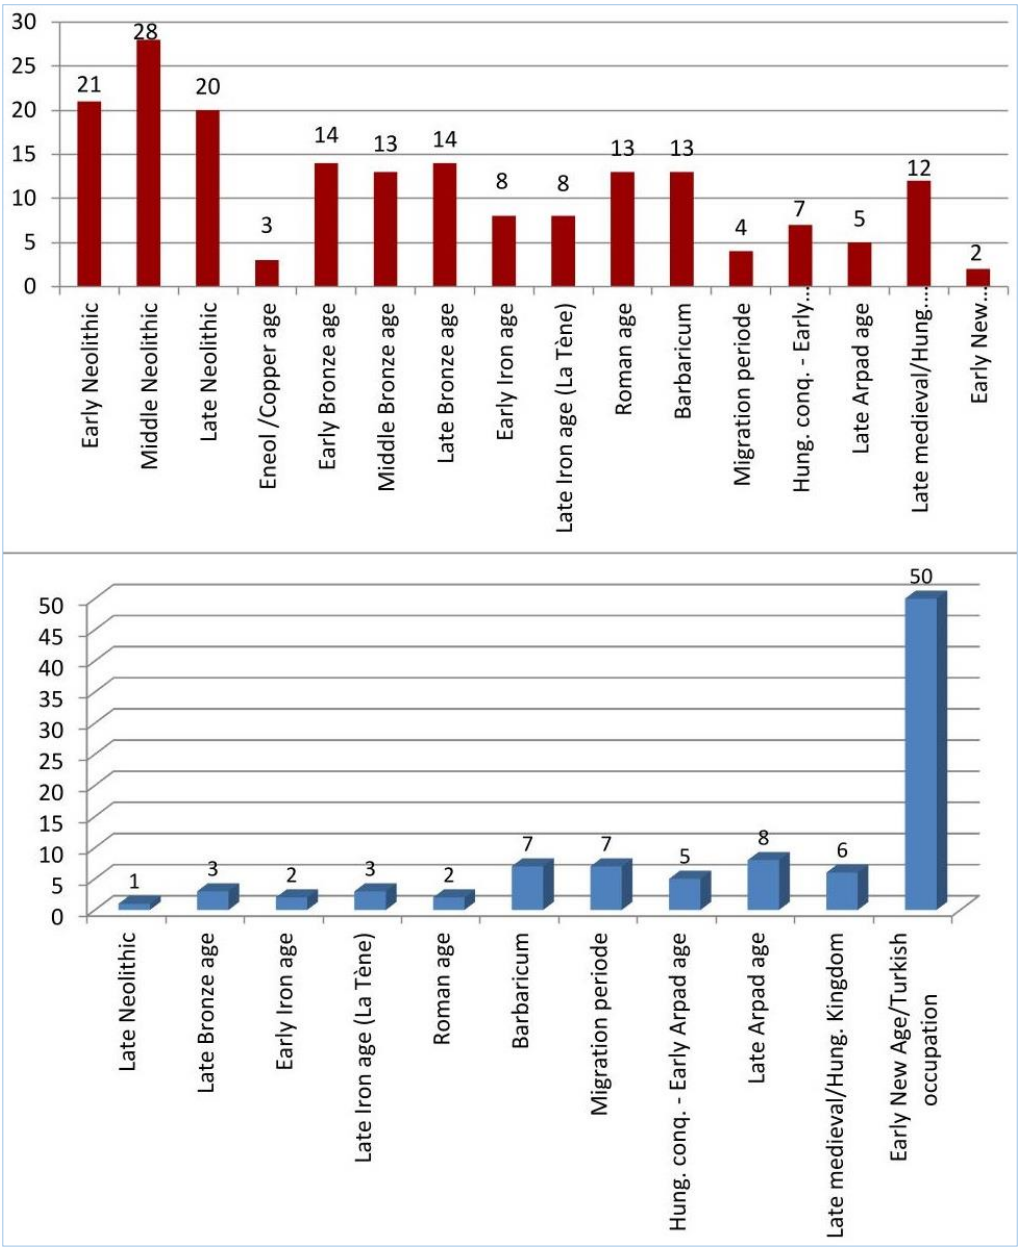

Figure 7. *The number of appearing (above) and disappearing (below) weed species within the archaeological eras of the Carpathian Basin*

Distribution of cereal weed species by plant height in first appearance

The presence of cereal weeds allows us to infer the time of sowing and the method of cultivation of cereals and the method of harvesting (high or low, with a sickle or with a scythe). Distribution of cereal weeds by height suggests that from the beginning until

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_74317444

Late Middle Ages the use of sickle for harvesting was common. Dominant are the medium, medium/high and high species (*Fig. 9*). They are mostly high weed plants, which indicates that cereals were harvested using a sickle, at about two-thirds of the height of stalks. In the Modern Age the new weeds are higher, therefore the harvesting method starts to change: from sickle to scythe. Of course, do not forget that the cereals were previously higher than they are today.

Discussion and conclusions

The up-to-date archaeobotanical database of Hungary contains the results of each known archaeological site, which was studied from an archaeobotanical point of view. Regardless of their publication the database contains all accessible data. This database, which provides an overview of the archaeobotanical results from 186 onwards was the basis of the present study, in which we analysed the development of weeds in the Pannonian Basin. Not only the list, but the changes in the appearance of apophyte and archaeophyte species was also compiled. The weed species were sorted according to height, by life form and by distribution area.

The appearance of weeds is connected to certain archaeological ears and phases: Early and Middle Neolithic, Middle Bronze age, Roman age, Late Medieval. This overlaps with the expansion of harvested species and a connection between the harvested and weed flora is emphasised.

The earliest dominant weed species in the Neolithic are: *Agrostemma githago, Avane fatua, Bromus arvensis, Bromus secalinus, Chenopodium album, Fallopia convolvulus, Galium spurium*. The most widespread and dominant seven weed species of the Pannonian Basin were studied.

The examination of the weeds according to their height shows that the ratio of medium and high species does not change from the beginning (Neolithic), which suggests that sickle was used until the Early Middle Ages to harvest cereals. Scythe was probably only used for harvesting later on.

No significant change can be detected in the ratio of the apophytes and the archaeophytes over time.

The fluctuation in the area-based distribution of the weed species is high. The strong Mediterranean effect in the Neolithic decrease by time and the number of Eurasian and Circumpolar species increases.

The species composition and the change of the number of the cereal weeds is related to land management practices (e.g. use of plow), soil fertilising techniques (e.g. manuring) and with the increase of the level of arable crop production.

The weeds of autumn- and spring-sown cereals already separated at the beginning of the Neolithic. This ecological separation already appeared outside the Pannonian Basin. At the beginning the presence of winter crop weed species was higher, but with the appearance of the leguminous plants in the Bronze Age and the garden species in the Late Middle Ages, the significance of summer crop weeds or row crop weeds increased.

Abstract. *Laurus nobilis* L. a member of Lauraceae family, is a beautiful medicinal and aromatic, evergreen plant. In this study shortening of *in vitro* germination time and the appropriate sucrose and agar concentration for this approach were investigated. Excessive sucrose concentration negatively affected germination percentage, root length, shooting percentage and shoot length in Murashige and Skoog Medium (MS). Medium without sucrose (0 g/L sucrose) having the highest germination rate (96.3%), the highest root length per plant (3.84 cm), the highest shooting rate (96.3%) and the highest shoot length per plant (1.68 cm) in all concentrations of sucrose used (0, 10, 20 and 30 g/L) after 4 weeks of culturing. Although sucrose and agar interactions exerted effects on the germination percentage, additionally all concentrations of agar used (3, 6 and 9 g/L) showed that adding excessive amounts to the growth medium was not necessary to induce germination and shooting in general. 0 mg/L sucrose and 3 g/L agar found optimum composition of the media for both rooting and shooting in all used media. This protocol will be useful for rapid and economic large-scale *in vitro* cultivation of *Laurus nobilis* to obtain aseptic seedlings.
Keywords: *recalcitrant seed culture, tissue culture, organic additives, medium specification, rooting, shooting*

Introduction

Developing an efficient and rapid system for *in vitro* tissue and organ culture is highly dependent on plant genus, species, physical and chemical culture environment. The content of culture media for germination, shooting, rooting and multiplication has an enourmous efficacy on costs in large-scale commercial manufacturers producing ornamental plants, vegetable seedling, fruit sapling and secondary metabolites as well as governmental or private scientific research and development centers.

During the past decades different media have been developed for *in vitro* plant culture. One of the known important components are carbon sources such as sucrose. Sucrose is mostly used 2-4% to bring in the young explant ready to use carbon (Gamborg et al., 1976). Especially 3% concentration is choosen in lots of studies as known recommendation of (Murashige and Skoog, 1962). In some cases high level of sucrose can be caused decreasing *in vitro* germination or the other growth parameters (Jo et al., 2009; Huh et al., 2016). The second known components are gelling agents such as agar. Generally, if solid media is aimed to use, agar is added 0.6-0.8% ratio to increase media viscosity (Debergh, 1983). In some cases increasing ratio of the gelling agent led to a progressive decrease in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_74457455

adventitious shoot per explant (Owens and Wozniak, 1991; Casanova et al., 2008). On the contrary, decreasing ratio of the agent cause turning media solid to liquid is not suitable in some conditions such as germination, rooting or shoot multiplication in some plants. Because of inability of the explant to hold on the surface and subside to the bottom cause undesired physical condition as non-stability of the explant and oxygen deficiency for the plant parts. The model plants for the study, bay laurel (*Laurus nobilis* L.) belongs to the family Lauraceae family which include valuable genus (Werff and Richter, 1996; Judd et al., 1999; Marques, 2001). Bay laurel are dioecious, evergreen tree or shrub known as laurel, bay laurel or sweet bay (Marzouki et al., 2009). Nearly all plant parts have been used as medicinal-aromatic, ornamental, plant-animal health and environmental purpose for a long time (Patrakar et al., 2012; Chalal et al., 2017). Active chemicals of most of these usage obtained from traditionally grown or naturally existing plants. The high economic value of the species in Lauraceae family has caused these to be destroyed in the natural habitats over years as our long term observations. Optimized tissue culture techniques can provide protection of natural habitats. There are a few studies for different purposes given some information the *in vitro* propagation of *Laurus nobilis* L. (Rady et al., 1999; Souayah et al., 2002; Al-Gabbiesh et al., 2014; Nadarajan and Pritchard, 2014; Royandazagh, 2019). The objective of the present study was to evaluate the effect of sucrose and agar concentrations on *in vitro* germination, primary root and primary shoot growth of bay laurel (*L. nobilis*) in *in vitro* seedlings to achieve scientific and economic gain.

Materials and Methods

The research was carried out at Kocaeli University, Plant Tissue Culture and Biotechnology Laboratory during 2018-2019. The fruits of laurel were picked up from only one tree that have been observing for many years, at natural habitats of Kocaeli City in Turkey. As soon as the bay laurel fruits were collected at 2018 November, 24; they were brought to the laboratory and the fruit flesh was peeled with the help of paper towel. One day after this procedure, the seed coats were removed with fingernail to obtain naked seed. The naked seed (the average weight of 100 naked seeds was 0.574 g/seed) kept in refrigerator (8 ºC) until the next day to use. Seeds were washed with running tap water for 1 hour and soaked for 40 min. in 20% commercial bleach (Na-hypochloride 5≤) solution and rinsed in two changes of sterile distilled water. Seeds were cultured on MS medium (Murashige and Skoog, 1962) with full micro, macro elements and vitamins on four trade mark sucrose ($C_{12}H_{22}O_{11}$-MW:342.29) (0, 10, 20 and 30 g/L) and three trade mark agar-agar concentration (3, 6 and 9 g/L). The pH of the medium was adjusted to 5.6 with 1 M KOH or 1 M HCl prior to autoclaving for 15 min. at 121 ºC. The media were filled in sterile glass petri plates in 6 cm diameter subsequently sterile-naked seeds were placed on the surface of media and kept in culture room at 23 ºC under dark condition for four weeks. Each experimental treatment combination consisted of two factors; sucroseXagar (4X3). The experiment laid out in completely randomised design with 3 replications. In only one repeat which was carried out with 3 glass petri dishes each of which contained only one seed. Results were evaluated weekly after cultures along four weeks. The recorded parameters were germination percentages (%), root length (cm), shooting percentages (%) and shoot length (cm) of the newly germinating seeds. The data were subjected to analysis of variance and significant differences among the treatments were tested using two-way ANOVA and means were separated by Duncan Multiple Range Test at $P \leq 0.05$.

Results and Discussion

Germination started as of the first week and negative effect of high sucrose concentration observed and statistically detected by the time. There was no positive or negative effect of agar concentration on germination percentage along 4 weeks and at the end of study (*Tables 1, 2, 3, 4; Fig. 1*). The combination of sucrose and agar in used MS medium significantly affected *in vitro* seed germination percentage by the second week. At the same time root length was also statistically and negatively affected by high sucrose concentration at the end of the experiment.

Shooting started after two weeks of culture and similarly shooting percentage and shoot length statistically affected from high sucrose concentration negatively and sucroseXagar interaction after 4 weeks (*Tables 5, 6 7, 8; Fig. 2*). Similarly, there were no positive effect of agar concentrations on shooting percentage along 4 weeks of study. Agar doses showed effectiveness on shoot length in 2nd and 3rd week but at the end of the study the effect has disappeared and agar concentrations showed similarity in statistics.

Studies are available outlining the ineffectiveness of excessive agar or sucrose doses in *in vitro* cultures. For example; Rabaiolli et al. (2017) demonstrated better *in vitro* rhizogenesis was achieved when ½ WPM medium supplemented with 30 cm^3 vermiculite without agar than 3.5 g/L or 7 g/L used agar for primary and secondary root percentages in *in vitro* and survival rate and leaf number in *ex vitro* in *Handroanthus chrysotrichus*. Suthar et al. (2011), in their work on *Boswellia serrata* in *in vitro*, studied agar at the rate of 0.0; 0.2; 0.4; 0.6; 0.8% w/v in MS+0.5 mg/L BAP+0.05 mg/L NAA for shoot multiplication from shoot clusters and 0.0 to 1% (w/v) agar in rooting medium containing 0.5 mg/L IBA+ 0.25 mg/L NAA+ antioxidants solution from rooting from shoots. According to their results 0.2% agar concentration was the best in number of shoots and 0.0% agar gave the highest rate of shoot length, number of leaves, fresh and dry weight, chlorophyll a, b and total. Similarly, they found that 0.0 % agar gave the highest rooting percentage, number of roots, root length and shoot length. Casanova et al. (2008) studied on agar concentration (0, 2, 4, 6, 8, 10 and 12 g dm^3) and vessel closure for *Dianthus caryophyllus in vitro* culture. They emphasized that the highest organogenic response was obtained in MS medium solidified with 2 g dm^3 agar (17.7 shoots per petal) and the least response was obtained in MS medium with 12 g dm^3 (4.3 shoots per petal) after 30 days of culture. Cortés-Olmos et al. (2018) studied on different sucrose (20 and 30 gL^{-1}) and agar (8 and 10 gL^{-1}) in full and half strength MS medium for *Lophophora williamsii*. They found that neither agar and sugar concentrations nor MS strength changed seed germination percentage after 49 days. But seedling size and areoles per seedling found higher in lower sucrose (20 gL^{-1}) and lower agar (8 gL^{-1}) than higher ones (30 gL^{-1} sucrose and 10 gL^{-1} agar). In another study, Gürel and Gülşen (1998) studied on two cultivars of *Prunus amygdalus* shoot tip *in vitro* culture in MS media. Sucrose concentrations were 2, 3, 4, 5 and 6% at 0.7% agar and agar were examined at the rate of 0.5; 0.6; 0.7; 0.8 and 0.9% at 3% sucrose. They emphasized that not in initiation stage but both multiplication and transplantation stage highest and lowest sucrose levels negatively affected shoot production and growth rate of developing shoots. 3 and 4% sucrose level found better in this stages. In addition, they found that the increasing concentration of agar caused a decrease in the growth of shoot tip explants in initiation stage 0.5; 0.6 and 0.7% agar were found significantly better than 0.8 and 0.9 agar on shoot development. Schulze et al. (2017) studied on *in vitro* germination of *Prunus lusitanica*. They used MS media with or without GA_3 and with different BA with two sucrose level (30 and 60 gL^{-1}). Their findings showed that radical and shoot emergence were greater on media with 30 gL^{-1} sucrose than with 60 gL^{-1}. In *Hancornia speciosa* cultured *in vitro*, dos Santos et al. (2017) observed that increasing sucrose concentration up to 60 g L^{-1} reduced germination speed and seedling height when they use (15, 30, 45 and 60 g L^{-1} sucrose) after 60 days of *in vitro* culturing of the naked embryos.

Conclusion

In conclusion, the results of this study revealed that increasing sucrose concentration as carbon source negatively influence germination efficiency of *Laurus nobilis* from naked seeds derived from mature female tree (*Fig. 3*). Among all the treatments, all parameters recorded to evaluate seedling growth of *Laurus nobilis* showed better performance in 0 g/L of sucrose than 10, 20, and 30 g/L in MS medium. Higher concentration of sucrose caused lateness in germination and shooting with reduced germination and shooting rate, root and shoot length (*Figs. 4, 5, 6, 7*). When sucrose doses

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_74457455

are ignored and only agar doses are considered, there were no differencies in all parameters at the end of the experiment excepting middle stage of experiment. When sucrose and agar interaction were examined, 0 g/L sucrose with 3 g/L agar and 0 g/L sucrose with 6 g/L agar were found 100% in both germination and shooting percentage than 9 g/L agar. This results supports the hypothesis that agar as viscosity source and sucrose as carbon source reduces the availability of nutrients in media to the plants. Moreover, root and shoot length found the highest in 0 g/L sucrose with 3 g/L agar among all the treatments (0, 10, 20, and 30 g/L sucrose with 3, 6 and 9 g/L agar). The decreased germination and seedling capacity in seed explants may result from a decrease in the amount of water available in the medium that have high rate of sucrose and agar. In this perspective, it must be underlined sucrose and agar compositions should be experienced in all plant genus and explant types for commercially or academically valuable application to lower the cost and to achieve the right results from other tested treatments.

(Received 23rd Jul 2020; accepted 17th Sep 2020)

Abstract. In order to determine the spatial and temporal relationship between environmental factors and zooplankton functional groups in the Harbin section of the Songhua River, China, we collected water samples of zooplankton separately at 6 sampling sites in spring, summer and autumn in 2012. In this study, a total of 26 species of zooplankton were collected from Harbin section of the Songhua River, belonging to 6 functional groups. Both environmental factors and the biomass of zooplankton functional groups exhibited spatial and seasonal differences. Water temperature (WT), chemical oxygen demand (CODcr), total phosphorus (TP), nitrate (NO^{3-}) and dissolved iron (Fe^{3+}) were significantly higher in summer. On the contrary, pH, dissolved oxygen (DO) and 5 days' biochemical oxygen demand (BOD_5) were significantly lower in summer. The biomass of zooplankton functional groups was higher in spring and lower in summer. According to the results of Redundancy analysis (RDA): water temperature (WT), dissolved oxygen (DO), pH, chemical oxygen demand (CODcr), 5 days biochemical oxygen demand (BOD_5), total phosphorus (TP), N: P ratio (N:P) and dissolved iron (Fe^{3+}) were the major factors influencing zooplankton functions.

Introduction

Zooplankton functional groups play an important ecological role in aquatic environments, such as the energy and material flow links between phytoplankton from small primary producers and fish of larger secondary consumers. In the meantime, these aquatic organisms perform important functions in the biogeochemical cycle by participating in alternative food webs, such as consumers (e.g., microbial and detritus) (Leoni, 2016; Lira et al., 2018). Zooplankton has become increasingly important in biological monitoring projects because of their rapid response to natural and anthropogenic environmental changes (Vieira et al., 2011; Mano and Tanaka, 2016). Traditional systems divided zooplankton into different communities to reflect water quality condition and biodiversity, but it had trouble reflecting the ecological function of aquatic organisms (Hood et al., 2006). Therefore, in order to study the functional role of zooplankton in the ecosystem, ecologists proposed the concept of functional groups. The study of functional groups, is more directly reflected the interaction between environmental factors and aquatic communities, and is also helpful in understanding aquatic ecosystem and biodiversity (Hoeinghaus et al., 2007). The species characteristics of the functional groups were more closely related to the environment, which can better understand the indicative role of zooplankton in environmental changes (Le et al., 2005).

Functional traits are the characteristics of the interaction between an organisms and their ecosystem (Tilman, 2001; Petchey and Gaston, 2002). Including taxonomic and functional groups analysis may increase the evaluation of biological responses to environmental changes (Petchey and Gaston, 2006; Cianciaruso et al., 2009). In zooplankton communities, Litchman et al. (2013) pointed out that the functional groups of organisms may include three ecological functions of feeding, growth/reproduction and survival. According to Obertegger et al. (2011) and Rizo et al. (2017), zooplankton functional groups related to raptorial or microphage organisms in zooplankton feeding guilds association were used for assessment. At present, functional groups studies have been used more and more in many fields of ecology. For instance, ecological succession (Raevel et al., 2012), meta-community (Gianuca et al., 2018) and beta diversity (Pool et al., 2014).

The zooplankton was classified into different functional groups, which can effectively simplify the food webs, and simulate the ecological processes of zooplankton communities comprehensively and accurately. However, the designation and measurement of zooplankton functional groups is still a difficult task, especially for small organisms (Martiny et al., 2013). In order to study the plankton in Sanjiang plain in China's freshwater ecosystem, according to the size, feeding habits and nutrition level (Zhao, 2005; Benedetti et al., 2018), zooplankton was divided into ten functional groups: protozoa filter feeders (PF), protozoa carnivore (PC), rotifer filter feeders (RF), rotifer carnivore (RC), small copepods and cladocerans filter feeders (SCF), small copepods and cladocerans carnivore (SCC), middle copepods and cladocerans filter feeders (MCF), middle copepods and cladocerans carnivore (MCC), large copepods and cladocerans filter feeders (LCF) and large copepods and cladocerans carnivore (LCC).

Phytoplankton composition and structure have been researched by different scientists in the Songhua River in China (Bao et al., 1987; Wei, 2018). These authors have reported: (i) dominance of *Diatoms* and *Chlorophyta* and (ii) the most influential environmental parameters of pH, water temperature, specific conductance and total phosphorus in the Harbin section of the Songhua River, China. However, despite

DOI: http://dx.doi.org/10.15666/aeer/1805_74577471

phytoplankton and zooplankton forms essential component of aquatic foodweb, no studies about zooplankton community structure or functional groups has been conducted in the Songhua River, China. Songhua River is one of the seven major rivers in China, which is of great significance. The main objectives of this study are: (i) to assess the seasonal variation of zooplankton functional groups and their biomass and (ii) determine the environmental variables influencing the biomass of the seasonal variation of zooplankton functional groups in the Harbin section of the Songhua River. The results in this research are important for management of the Songhua River and other aquatic systems with similar characteristics in our nation.

Materials and methods

Research area

The study was conducted in the Harbin section of the Songhua River located at 45°N 126°W in Heilongjiang Province, Northeast China (*Fig. 1, Table 1*). Songhua River, is one of the seven major rivers in China. Harbin section of the Songhua River runs from Sanjiazi Village to Dadingzi Mountain with a total length of 66 km (Li et al., 2014). The annual precipitation was 300-1200 mm, and the overall trend was decreasing from southeast to northwest. The average annual runoff was 632.0×10^8 m^3 (1955-2010), and the average annual sediment transport was $1{,}259 \times 10^4$ t (1955-2010) (Songliao Water Resources Commission, 2012).

DOI: http://dx.doi.org/10.15666/aeer/1805_74577471

The survey of zooplankton groups was carried out in 6 sampling sites in spring (April 20, 2012), summer (July 10, 2012) and autumn (October 10, 2012), respectively. Each sampling site was sampled once on both sides of the Songhua River. Affected by monsoon climate, the surface water of the river was covered by ice from the end of November to the beginning of next April. The sampling sites of S1 and S2 located in the upstream, S3 and S4 located in the midstream and S5 and S6 located in the downstream.

Field sampling and analysis

Sampling collection and analysis

Water temperature (WT) was measured on field using water thermometer (Mercury-in-glass thermometer, Dezhou Runxin Experimental Instrument Co. LTD, China). PH, chemical oxygen demand (CODcr), permanganate index (COD_{Mn}), biological oxygen demand (BOD_5), total nitrogen (TN), total phosphorus (TP), dissolved oxygen (DO), ammonia-nitrogen (NH_4^+-N), nitrate (NO^{3-}) and ferric ion (Fe^{3+}) were determined using the standard methods on surface water (GB/T5750-2006) of the Chinese standard methods proposed by Ministry of Environmental Protection of People's Republic of China (MEP, 2006). We used a zooplankton net of 25 cm diameter on boat, 55 cm length and 65 μm mesh to zooplankton samples from subsurface (0.5-1 m depth) when flow velocity was under the range of 0.01-2.40 m/s, and then fixed in labelled bottles of 30 ml for further analysis. In the laboratory, zooplankton samples were identified using a microscope at 400×magnification (Motic BA210, Motic Inc., China). In this study, we considered copepod nauplii as a taxon (Wang, 1961; Crustacean Research Group, 1979; Jiang and Du, 1979; Han and Shu, 1995). The biomass of the zooplankton functional groups was evaluated using wet weight method of Zhang and Huang (1991).

Classification of zooplankton functional group

According to the researchers, the basic principle for classification of zooplankton functional groups is their size. The sampled zooplankton species in the Songhua River were classified into six functional groups according to their body size/length and mode of feeding (Zhao, 2005; Benedetti et al., 2018). The six functional groups are group PF (protozoa filter feeders), group PC (protozoa carnivore), group RF (rotifer filter feeders), group RC (rotifer carnivore), group SCF (small copepods and cladocerans filter feeders) and group MCF (middle copepods and cladocerans filter feeders). Group PF and RF are passive filter feeders feeding on phytoplankton, bacteria and organic detritus. Group RC and PC are active ambush feeders that target small motile prey or other zooplanktons. Functional group SCF consists of small copepods and cladocerans of body size less than 0.7 mm that mostly feed through filter-feeding on phytoplankton, bacteria, organic detritus and protozoa. Functional group MCF consists of those zooplankton species with body size in the range of 0.7-1.5 mm. MCF, is a filter-feeder feeding on phytoplankton, bacteria, organic detritus and protozoa, same as group SCF. Ecologically, MCF plays a major role as a food source for fish and also can control algal blooms (Meerhoff et al., 2007).

Data analysis

One-way analysis of variance (ANOVA), and Tukey's honestly were used in IBM SPSS STATISTICS 19.0 to determine significant difference between the seasonal changes of water environmental variables and zooplankton functional groups biomass

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_74577471

(Sharma et al., 2017). Water environmental factors (except pH) and biomass of zooplankton functional groups used log (x+1) transformation before conducting analysis in order to satisfy the normality and variance assumption. Relationship between the biomass of zooplankton functional groups and environmental factors was computed using CANOCO 4.5 software (Shen et al., 2014). We used Detrended Correspondence Analysis (DCA) before multivariate ordination analysis. This result of DCA showed that the largest gradient length of the axis was 1.584 less than 3. So the species data was linearly distributed and were more suitable for Redundancy analysis (RDA).

Results

Seasonal variations in environmental factors

The mean values of seasonal environmental variables recorded at the 6 sampling sites in the Harbin section of the Songhua River were presented in *Table 2* and *Fig. 2*. Most of the environmental factors presented statistical differences between seasons (One-way ANOVA and Tukey HSD test, $P< 0.05$). However, the mean values of COD_{Mn}, NH_4^+-N and TN did not vary significantly between seasons ($P> 0.05$). While WT, pH, DO, COD_{Cr}, BOD_5, TP, N:P, NO^{3-} and Fe^{3+}, were significantly different with seasonal variations ($P< 0.05$). The maximum mean values of WT, COD_{Cr}, TP, NO^{3-} and Fe^{3+} were observed in summer and their minimum mean values were observed in autumn, except TP and Fe^{3+}. On the contrary, the minimum mean values of pH, DO and BOD_5, were observed in summer and their maximum in spring, except DO. Unlike other significantly seasonal variations, the maximum mean value of N:P was observed in spring and its minimum mean value was observed in autumn.

Table 2. *One-way ANOVA and Tukey HSD methods were used to detect that the mean value (± standard error) of environmental factors varies with seasonal changes in this chart*

	Spring	Summer	Autumn	P-value
WT (℃)	20.33±1.51a	26.83±0.98b	11.5±0.84c	0.000
pH	8.66±0.46a	7.62±0.15b	8.02±0.15b	0.000
DO (mg/L)	8.67±2.56a	5.50±1.33b	10.13±0.27a	0.001
COD_{Mn} (mg/L)	6.60±1.81a	7.21±0.49a	5.49±0.99a	0.078
COD_{Cr} (mg/L)	21.67±5.5a	98.83±5.12b	14.00±1.79c	0.000

Seasonal and spatial variation of zooplankton functional groups

During the study period, 26 zooplankton species belonging to 20 genera were observed in spring, summer and autumn in 2012 in the Harbin section of the Songhua River, China (*Table 3*), where rotifers were composed of 17 species accounted about 65.38%, followed by protozoans with 6 (23.08%), cladocerans 2 (7.69%) and copepods 1 (3.85%). There were seasonal and spatial variation in biomass of zooplankton functional groups (*Figs. 3 and 4*). Our results showed that the largest number of zooplankton species was 17 in autumn, followed by 15 in spring and 14 in summer. The values of zooplankton functional group biomass were higher in spring at 0.48 mg/L, followed by 0.42 mg/L in autumn and 0.17 mg/L in summer. In spring and summer, RF functional group had the highest biomass contribution of about 41.10% and 49.52%, respectively. In autumn, approximately 62.58% of the total biomass contribution was of PF (*Fig. 3*). MCF was the second most contributors of the total biomass in summer, even if it was only collected in summer. The total biomass contribution of the PC was about 4.31%, and no PC was collected in spring and summer. Spatially, with exception of sampling sites S1 and S6 were dominated by SCF, all the sampling sites were dominated by group RF in spring. In summer, groups PF, RF and RC were presented in almost all sampling sites. However, MCF, only present in S2 and S3, and were dominated in S2 and S3. Group PF in all the sampling sites were dominated in autumn.

Redundancy analysis (RDA) of zooplankton functional groups with environmental factors variables

It was carried out to determine the relationship between the biomass of zooplankton functional groups and environmental factors variables in the RDA ordination in *Table 4*. The Monte Carlo test showed that the first axis and all typical axes were significant (F-ratio = 3.894, p-value = 0.0580; F-ratio = 3.974, p-value = 0.0040; 499 random permutations under simplified model). The first two of RDA eigenvalue axes together explained 75.3% (axis 1: 43.8%; axis 2: 31.5%) zooplankton functional group biomass and 83.2% (axis 1: 48.4%; axis 2: 34.8%) relationship of the zooplankton functional group biomass and environmental factors. The relationship between zooplankton

DOI: http://dx.doi.org/10.15666/aeer/1805_74577471

functional groups and environmental factors can be referred to arrow directions in *Fig. 5*. Axis 1 was mainly positive correlated with WT (r = 0.4939) and NH_4^+-N (r = 0.4442) and negatively related with TP (r = -0.3256). While Axis 2 was mainly positive correlated with WT (r = 0.7158) and COD_{Cr} (r = 0.7097) and negatively related with DO (r = -0.4201). Groups of PF and PC were positively related with DO, and negatively correlated with WT, COD_{Mn}, COD_{Cr} and NO^{3-}. Groups of RF, RC and SCF were positively correlated with pH, N:P and BOD_5, and negatively related with Fe^{3+} and TP. Conversely, Group MCF were positively correlated with Fe^{3+} and negatively correlated with pH.

Discussion

Seasonal variation of zooplankton functional groups biomass

Biomass is one of the most important variables to describe the spatial and temporal variation of zooplankton functional groups in aquatic ecosystems (Shi et al., 2015), which can reduce the disturbance of simulated ecosystem caused by large differences in zooplankton. The present study provided novel insights into the seasonal changes of the zooplankton biomass in the Harbin section of the Songhua River, China. Comparison with other waters of regions showed that the zooplankton biomass in the Harbin section of the Songhua River was significantly lower. In the recently published literature, the zooplankton biomass of Tuanjie Reservoir in Mudanjiang city (Sun et al., 2019) and Small Xingkai Wetland in Jixi City (Ma et al., 2019) showed were higher than thoese in the same province of the Songhua River in each quarter. The result of Shi et al. (2016) showed that the rivers with high velocity and sediment content were not suitable for the habitat and reproduction of zooplankton (Fang et al., 2012). The study of Mwagona et al. (2018) had also shown that zooplankton growth was affected when their nutrient levels were low, reducing their reproductive rate and prolonging their growth cycles. In this study, the biomass of zooplankton functional groups had significant differences between different seasons. Differences in functional groups and life history traits of the dominant species have to be taken into account to explain these seasonal biomass patterns. In spring and summer, the biomass of zooplankton was mainly RF, of which 86.79% was composed of *Brachionus quadridentatus* and 87.29% was composed of *ploesoma hudsoni*. In autumn, PF was dominant, mainly composed of *Strombidium viride* and *Vorticella microstoma*, which accounted about 46.50% and 46.61% of the total biomass, respectively. Studies have found a strong positive correlation between rotifer biomass and temperature (Galkovskaja, 1987). Therefore, when the water temperature turned cold, the RF who fed on bacteria, phytoplankton and organic matter gets less, and the PF which also fed on these things got less grazing pressure and became the dominant specie due to the decrease of RF. In spatial distribution, seasonal dominant functional groups changed most obviously in the sampling sites of S2 and S3: RF→MCF→PF. Summer temperature and nutrients provided the best conditions for MCF to be the dominant functional group. These factors greatly enrich the source of food resources for MCF. MCF which fed on bacteria, phytoplankton and organics inhibits the growth of RF by predation (An, 2016).

The driving factors of zooplankton functional groups in the Harbin section of Songhua Rive, China

The interaction between zooplankton functional groups and its relationship with water environmental factors, such as temperature, nutrients, bottom-up effect of phytoplankton, top-down effect of fish feeding, interspecies competition, were the main factors affecting the growth of zooplankton (Yang, 2006). At the same time, these physiological processes of zooplankton function groups showed a highly sensitive response to changes in the environment, and zooplankton function groups can amplify subtle changes in water environment and made it a very good indicator for freshwater ecosystems (Richardson, 2008). In temperate regions, water temperature and nutrients were the main environmental factors (Wen and Xie, 2013). In this study, RDA results indicated that water temperature was the main factor affecting zooplankton. The big difference in temperature of the Songhua River water along the year round considered

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_74577471

as a controlling factor related to range of tolerance of species. From the result of RDA, some function groups reacted positively to water temperature as group MCF, contrary to groups of PC and PF. We believe that the reproduction of these groups is related to temperature preference. Related researches showed that higher water temperature can promote the metabolism of zooplankton in the meanwhile they also increase the consumption of nutrients and proteins, and body mortality (Zheng, 1992). *Brachionus quadridentatus* quickly produced resting eggs at higher or lower temperatures (Xiang et al., 2018). However, MCF, which was composed of *Diaphanosoma*, was positively correlated with water temperature. Experiments had shown that *Diaphanosoma* often appeared in summer and prefer to live in warm water environment (Brendonck and Meester, 2003). The growth rate of *Diaphanosoma* was accelerated when water temperature rose, and the growth rate of *Diaphanosoma* was slower when water temperature was lower. In addition, RDA analysis indicated that group PF was positively related with DO and negatively related with NH_4^+-N and COD_{Cr}, and groups of RC and SCF were negatively correlated with TP. Similarly, with the research of Shen (1999) confirming that most protozoans were aerobic biological. The diversity of protozoans in the abundant water environment would be higher than that of the anaerobic environment. Lu et al. (2007) in the study of wastewater found that, although *Vorticella microstoma* was the indicator species of mesosaprobic zone. When increasing the DO in aeration activated sludge, the density of *Vorticella microstoma* in activated sludge was significantly higher than the control group. In the study of protozoans, it was found that the sessile ciliates diversity index (such as *Epistylisplicatilis*, *Vorticella convallaria*, *Pseudocarchesium aselli* and *Opercularia cylindrata*) and crawling ciliates (*Aspidisca costata* and *Aspidisca sulcate*) were negatively correlated with NH_4^+-N (Chen et al., 2003). In the study of zooplankton in Small Xingkai Lake Wetlands, it was found that COD was the main negative correlation factors affecting the functional groups of zooplankton (An, 2016). The author thought that the pollutants mainly came from agricultural wastewater around the river, which were directly affected the bottom-up effects of phytoplankton and indirectly affected the growth rate of zooplankton. In the study of Zhao and Yu (2019) of on zooplankton functional groups in Tai Lake, RDA results showed that zooplankton was positively related with COD_{Cr}. The results of Ma et al. (2019) revealed that TP were the main factors responsible of zooplankton functional groups biomass dynamics. The results of Meng et al. (2014) found that chlorophyta grew in phosphorus-restricted environments made thicker cell wall to makes less edible. The research of Siebielec et al. (2015), da Silva Cerozi and Fitzsimmons (2016) clearly proved that dissolved calcium ion should react with the phosphate in water forming insoluble calcium phosphate and other compounds that were not conducive to phytoplankton growth and propagation when the water environment was slight alkaline. In fact, Marzolf (1990) and Adamczuk et al. (2015) thought phytoplankton itself didn't meet all of the nutritional requirements of zooplankton. It further confirms that filter feeders of the protozoas and rotifera provided an important food supplement to carnivore functional groups under the condition of limited amounts of bacterial phytoplankton. So we should be undertaken to follow the changes in the ecosystem continuous monitoring of water characteristics and biota in the Harbin section of the Songhua River, China.

Conclusions

In this current study, a total of 26 species of zooplankton species were observed in 2012 in the Harbin section of the Songhua River, China. Zooplankton was divided into 6 functional groups: protozoa filter feeders (PF), protozoa carnivore (PC), rotifer filter feeders (RF), rotifer carnivore (RC), small copepods and cladocerans filter feeders (SCF) and middle copepods and cladocerans filter feeders (MCF). The biomass of zooplankton functional groups ranged from large to small in spring, autumn, and summer. One-way ANOVA and Redundancy analysis (RDA) showed that the environmental parameters as water temperature (WT), pH, dissolved oxygen (DO), chemical oxygen demand (COD_{cr}), 5 days biochemical oxygen demand (BOD_5), total phosphorus (TP), N: P ratio (N:P), nitrate (NO^{3-}) and dissolved iron (Fe^{3+}) influenced on the change of the biomass of zooplankton functional groups. Groups of PF and PC had strong relationships with dissolved oxygen (DO), water temperature (WT) and chemical oxygen demand (COD_{cr}) of environmental parameters. Groups of RF, RC and SCF had strong relationships with pH and total phosphorus (TP). Group MCF had strong relationships with dissolved iron (Fe^{3+}) and total phosphorus (TP). This study revealed that the zooplankton functional groups followed certain predictable pattern in the seasonal gradient. It could be useful for assessing and predicting the growth and development of zooplankton in the future. At present, functional-approach research studies for zooplankton communities in continental aquatic environments are scarce. Therefore, the scientific community must take into account the environmental and spatial dynamics of these organisms and conduct more research on the traits related to their different ecological functions.
