Abstract. Inappropriate use of antibiotics causes the emergence of multidrug resistant bacteria. Therefore, this study investigated the rate of beta- lactamase resistance genes and drug resistance pattern of 87 *E. coli* isolated from feces of different hosts. The rate of resistance to amoxicillin, cefotaxim, ceftriaxone, and meropenem were the highest in *E. coli* of humans compared to other hosts. 18 (20.6%) isolates were positive with *bla*CTX-M and *bla*TEM and 17 (19.5%) of them were found in heavy antibiotic users, but only one *bla*CTX-M gene (1.1%) was discovered in the low antibiotic user group of pigeons. The rate of *bla*CTX-M gene was the highest in *E. coli* isolated from the feces of humans, 13.7%, whereas the highest rate of *bla*TEM was found in *E. coli* of poultry, 3.4%. The highest rate of *bla*CTX-M and *bla*TEM genes were recorded in phylogenetic groups B2 and D at the rate of 61.5% and 60%, respectively. There were sequence similarities between local and foreign beta-lactamase genes, but single nucleotide polymorphism was found in comparison to CTX-M3 isolated in Poland. We conclude that *E. coli* isolated from humans were more resistant to antibiotics compared to other hosts and the rate of CTX-M gene was more common in human hosts.
Keywords: *ESBLs, antibiotic resistance, human, animal and birds*

Introduction

The emergence and spread of multidrug resistant bacteria is on the rise and becoming a real threat to the global public health. Failure of treatment increases morbidity and mortality due to development of resistance to previously effective drug by bacteria (Garcia, 2014). The indiscriminate use of antibiotics is the main reason leading to the increased resistance in bacteria and this has been seen in both humans and animals (Collignon et al., 2013; Chantziaras et al., 2014). Domestic animals, including poultry, have been used as a source of food by humans from ancient times, but it has been considered as one of the potential sources of delivering bacteria carrying beta lactamase resistance genes to humans. This leads to colonization of bacteria in the gut of humans after consuming contaminated meat or gaining bacteria by direct or indirect contact with animals and eventually causing severe infections (Lazarus et al., 2015).

Escherichia coli (E. coli) is a gram negative facultative anaerobic bacteria and belongs to the family of Enterobacteriaceae (Sorum and Sunde, 2001). These bacteria are mostly found in intestinal tract of humans and animals as part of the normal flora. *E. coli* strains cause different diseases in humans including gastrointestinal infection, urinary tract infection and neonatal meningitis (Todar, 2007). *E. coli* causes food poisoning in humans after consumption of contaminated food by producing lethal toxins that could lead to gastroenteritis. Pathogenic *E. coli* stains are classified into different types based on their virulence properties and serological characteristics (Todar, 2007; Martinez-Medina and Garcia-Gil, 2014). Enteropathogenic *E. coli* (EPEC) is a strain of *E. coli* found in both humans and some other types of animals like dogs, cats, rabbits, and horses. It causes watery diarrhea after producing an adhesion toxin (intimin) which has the ability to bind intestinal cells leading to cell deformities. This variant type of *E. coli* is moderately invasive and stimulates an inflammatory response. Enterotoxigenic *E. coli* (ETEC) strain is found to be implicated in the watery diarrhea in humans especially children in the developing countries and in animals such as sheep, goats, pigs, dogs, cattle, and horses. This strain is not invasive and lodges locally in the lumen of the intestine (Croxen et al., 2013). Enteroinvasive *E. coli* (EIEC) is a variant causing diarrhea only in humans. The patients characteristically have a profuse diarrhea with or without blood and high fever. Enterohemorrhagic *E. coli* (EHEC) strain results in bloody diarrhea with the ability to infect urinary tract and causes acute kidney failure: hemolytic uremic syndrome. It is moderately invasive and produces Shiga toxin that can cause severe inflammatory response. This strain was discovered in both humans and animals (cattle and goats) (Rendón et al., 2007). Enteroaggresive *E. coli* (EAEC) is a noninvasive variant of *E. coli* that can cause watery diarrhea only in humans and has the ability to produce heat-stable enterotoxins (ST) and hemolysin, pore forming toxins. Adherent-Invasive *E. coli* (AIEC) is an invasive strain causing disease in humans and its more common in patients who have Crohn's disease. The strain is able to multiplicate intracellularly after invading intestinal epithelial cells (Martinez-Medina and Garcia-Gil, 2014).

E. coli strains are found to live in the gastrointestinal tract where they develop resistance against antimicrobial agents and able to acquire resistance genes faster than other natural microorganisms because of the selection pressure due to heavy usage of antibiotics (Van Den Bogaard and Stobberingh, 2000; EFSA, 2010). It was recently revealed that propagation of extended spectrum β-lactamases (ESBL) is very rapid with *bla*CTX, one of the common ESBLs, now discovered in different parts of the world. In addition to humans and domestic animals, this resistance gene has been recovered in wild animals and birds in the last few years (Livermore et al., 2007; Coque et al., 2008; Guenther et al., 2010; Pinto et al., 2010; Veldman et al., 2013). Proliferation of this resistance gene in wildlife creates global public health threat at an alarming level. Wild birds attract the attention of the researchers because of their potential roles in transmitting diseases and becoming carriers of bacteria to humans. In addition, wild birds harboring *E. coli* in their intestinal tracts can become a source of dissemination of resistant bacteria (Benskin et al., 2009; Wasiński et al., 2013).

In Iraq, many studies have been conducted to isolate bacteria with resistance genes from human patients, but there are scarce studies on wildlife and free animals including birds. This study focused on a comparative study to investigate and compare the rates of antibiotic-resistant *E. coli* with beta lactamase resistance genes in three classes of antibiotic users. First group was categorized as heavy antibiotic consumers: humans and chicken of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60256040

the poultry houses because of their chronic exposures to antibiotics. Second group was categorized as intermediate antibiotic consumers: free pastured domestic animals and free ranging chickens because of their limited access to antibiotics and the last group was categorized as non-antibiotic users; such as free living birds including sparrows, singing birds, pigeons, and wild animals like turtles, wild rabbits and hedgehogs.

Materials and methods

Sample collection and bacterial isolation

A total of 87 *E. coli* strains were isolated from fresh stool of humans, animals and birds as follows: Humans (healthy) 10 (E1-E10), human patients (diarrhea and UTI) 12 (E11-E22), chicken of poultry houses 11 (E23-E33), free pastured domestic animals 10 (E34-E43), free ranging poultry 14 (E44-E57), wild animals (rabbit, hedgehog, and turtle) 10 (E58-E67), sparrows 8 (E68-E75), pigeons 12 (E76-87) (*Table 1* and *Table 2*). The sample collection was carried out between August and September 2019 in Sulaimani province. One gram of every sample was homogenized with 500 µl of normal saline in a clean container and the mixture was swabbed on selective media, MacCkonkey agar, and incubated at 37 ºC for 20 hours. A typical colony was isolated and streaked again on eosin methylene blue agar (EMB) for further purification and identification of *E. coli*. At the end, the colonies with metallic sheen green characteristic were chosen for the final confirmation by molecular biology technique using polymerase chain reaction (PCR).

Antibiotic susceptibility testing

The antimicrobial susceptibility testing of *E. coli* isolates to six classes of beta lactam antibiotics were carried out using Kirby Bauer disc diffusion method following the protocols and guidelines recommended by the Clinical and Laboratory Standards Institute (Clinical and Laboratory Standards Institute, 2012). The antibiotics tested in this study were: amoxicillin (AX 25 µg), amoxicillin-clavulanic acid (AMC 30 µg), oxacillin (OX 1 µg), meropenem (MEM 10 µg), ceftriaxone (CRO 30 µg) and cefotaxime (CTX 30 µg) (Bioanalyse, Ankara, Turkey).

Molecular biological methods

DNA extraction

Total DNA of *E. coli* was extracted by boiling fresh colonies grown on nutrient media. The boiling was carried out by dissolving one single colony in 150 µl sterilized distilled water in a micro tube and then the mixture was heated at 99.9 °C on a heating block for 15 minutes (Dashti et al., 2009). The mixture was allowed to precipitate at room temperature and the supernatant containing DNA was used for PCR.

E. coli confirmation and phylogenetic grouping

Beta-glucuronidase (*uidA*) gene was used to confirm *E. coli* via PCR amplification of its flanking region. If no *E. coli* isolate harbor (*uidA*) gene, an attempt was made to amplify a second specific *E. coli* marker gene, the universal stress protein (*uspA*). This PCR identification confirmation of *E. coli* was carried out according to Chen and Griffiths, 1998; Heijnen and Medema, 2006; Godambe et al., 2017).

This study used the protocol according to Bonacorsi et al. (2000) to determine a phylogenetic grouping of *E. coli* with some modifications in PCR reactions. The grouping depends on finding and amplifying three genes: the chuA, yjaA and DNA fragment TSPE4.C2. Two of the genes, the chuA and yjaA, were amplified using duplex conventional PCR, but DNA fragment TSPE4.C2 was amplified via singleplex PCR.

Polymerase chain reaction of blaCTX-M and blaTEM-1

Two common extended spectrum beta lactamase resistance genes (ESBLs), *bla*CTX-M (550 bp) and *bla*TEM-1 (1080 bp) (Bradford, 2001) were amplified. Duplex PCR was used to amplify both genes. The primers and protocols used were according to Ahmed et al. (2007, 2009).

PCR condition and Gel electrophoresis

All PCR reactions in this study including multiplex and singleplex were carried out in PCR tubes composed of 20 µl volume of reaction mixture. The volume was prepared by adding 2 µl of DNA template of each isolate into a mixture containing 10 µl of 2X premix *RedTaq* DNA polymerase (SBS Genetech, Beijing, China), each primer with a concentration of 0.25 µM and the final volume attained with distilled water. The following conditions were used to run PCR using applied biosystem thermo cycler (Applied biosystem 2720, California, USA): The run started with 94 °C for 5 min, the run continued with 35 cycles of three different temperatures (94 °C 30 sec, 55 °C 30 sec, 72 °C 30 sec), and finally the PCR reaction was ended with last temperature condition of 72 °C for 7 minutes.

Gel electrophoresis was carried out through running PCR products on DNA agarose gels (2% for phylogenetic grouping genes and 1% for the other genes) at 100 V for 30 minutes. The resolved genes and DNA ladders were visualized under blue light using SmartDoc 2.0 Imaging System (Accuris, NJ, USA) after staining with fluorescent dye, GoodView (SBS Genetech, Beijing, China).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60256040

Sequence analysis

The PCR products of CTX-M genes were gel recovered and purified using gel extraction purification kit (SBS Genetech, Beijing, China). The purified Products were sequenced using Sanger sequencing on ABI 3730XL capillary machine (CHU de Québec-Université Laval, Québec city, Canada). All sequences of this study were submitted to the GenBank National Center for Biotechnology Information (NCBI) via Bankit (Benson et al., 2015) and obtained accession numbers (MN597105-MN597117).

The obtained sequences were aligned to available sequences of CTX-M gene in Genbank using NCBI BLASTn search tool (http://www.ncbi.nlm.nih.gov/). The multi-sequence alignment of the sequences of this current study and those sequences available in the GenBank was carried out using ClustalW multi alignment tool. Phylogenic tree was drawn for all our sequences and retrieved sequences of the GenBank using the neighbor-joining (NJ) method (Phylogeny.fr) (Dereeper et al., 2010).

Results

Isolation and phylogenetic grouping

Eighty-seven (87) *E. coli* isolates were recovered from the different categories of antibiotic users in order to compare the drug resistance pattern to the antibiotics and the rate of the resistance genes. The *E. coli* isolates were recovered using conventional culture method and genetically confirmed using molecular biology techniques. *E. coli* gene marker, beta-glucuronidase (*uidA* 201 bp) was used for the final confirmation. The flanking region of the gene (201 bp) was amplified using *E. coli* specific primers (*Figure 1*). Out of 87 isolates, 83 (95.4%) isolates were positive for *uidA* marker gene. Four isolates remained questionable to be *E. coli*, so the second *E. coli* marker gene, *uspA* was used to identify the isolates. PCR amplification of the universal stress protein (*uspA* 800 bp) was carried out using specific primers for *E. coli uspA* gene. The Four (4.5%) remaining isolates were positive for *uspA* gene therefore all the isolates were confirmed to be *E. coli*.

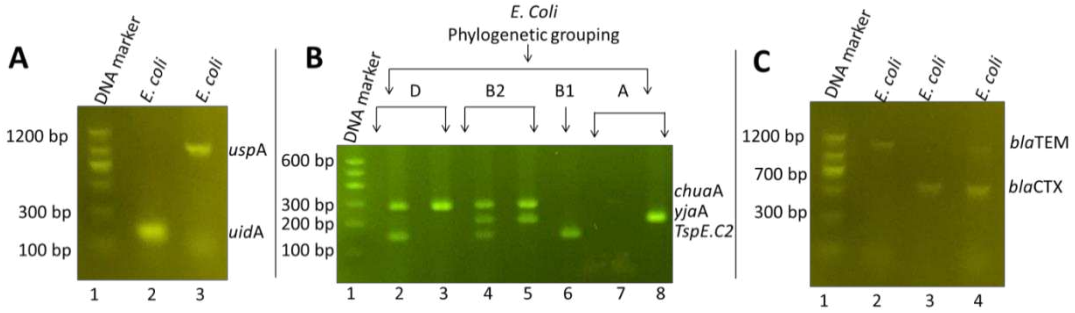

Figure 1. *PCR amplification of different genes of E. coli. (A) PCR amplification of uidA and uspA genes used for the confirmation of E. coli. (B) Phylogenetic grouping* based on the different combinations of chuaA, yjaA, and TspE.C2 (Bonacorsi et al., 2000). (C) PCR amplification of beta lactamase resistance genes, blaTEM, and blaCTX. * The phylogenetic grouping was carried out in two PCR reactions, but two PCR reactions were mixed to clarify and show the combination of different genes of the groups, lane 2 and 3*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60256040

There are four main phylogenetic grouping of *E. coli* strains: A, B1, B2 and D. Commensal strains of *E. coli* belong to group A and B1 (Saralaya et al., 2015). *E. coli* strains in group B2 and to lesser extent group D are virulent extra-intestinal strains (Bonacorsi et al., 2000). All the 87 *E. coli* isolates were subjected to the phylogenetic grouping of *E. coli* based on different combinations of *yja*A, *chu*A, and *TSPE4.C2* genes. Out of the 87 *E. coli* isolates, group B1 was the dominant group with 55 isolates (63.2%) followed by group B2 with 16 isolates (18.3%) and then group A with 10 isolates (11.4%). Group D was the least with just 6 isolates (6.8%) (*Table 1*). Out of 22 isolates recovered from humans, the highest rate 10 (45.4%) were under group B2 while the lowest rate 9% (2 isolates) was in group A. The rate of group B1 in all animals and birds was the highest at 73.8% (48 out of 65), but group D recorded the lowest rate at 4.6% (3 out of 65).

Antibiotic susceptibility testing

E. coli isolates were investigated to determine their antibiotic resistance phenotype against different classes of beta lactam antimicrobials (*Figure 2*). The highest resistance pattern revealed in this study was to oxacillin (1 µg) 54.5%, and the lowest resistance rate was against meropenem (10 µg) 1%. The resistance rate of the other antibiotics was as follows: amoxicillin (25 µg) 19.3%, amoxicillin-clavulanic acid (30 µg) 50.3%, cefotaxime (30 µg) 16.7%., and ceftriaxone (30 µg) 13%. The resistance score of each *E. coli* isolates are shown in *Table 2*.

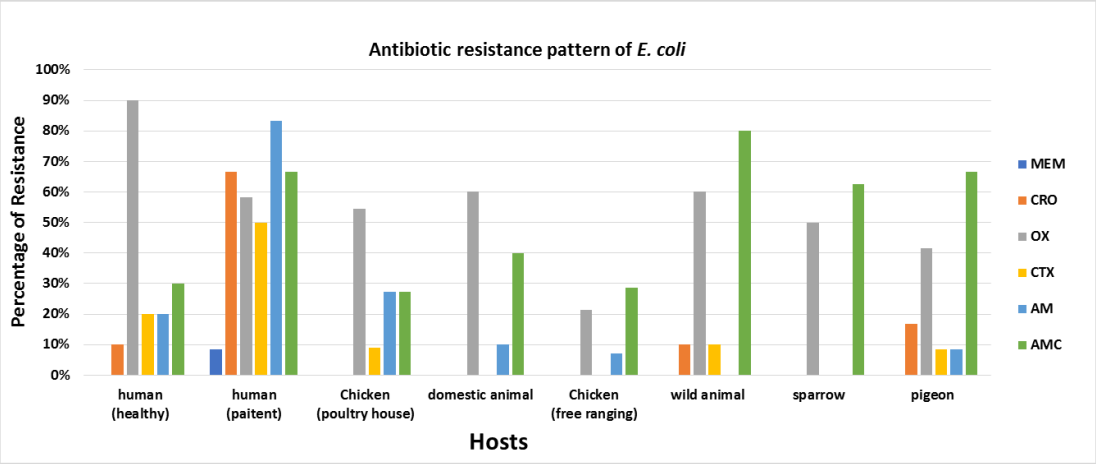

Figure 2. *Antibiotic resistance pattern of E. coli isolates in different hosts*

Antibiotic resistance pattern of E. coli in different hosts

Resistance rate to Oxacillin (1 µg) was high in all different hosts compared to other antibiotics. Resistance rate was the highest in healthy humans (90%) followed by human patients (58%) and chicken of poultry houses (55%), but the lowest rate was in free ranging chickens (21%) (*Figure 2*). *E. coli* isolated from wild animals had the highest rate of resistance to amoxillin-clavulanic acid (30 µg) (80%) among all the hosts followed by human patients (67%) and the lowest rate was in poultry housing chicken (27%). In human patients, the resistance rates of *E. coli* isolates to amoxicillin, ceftriaxone (30 µg), cefotaxim (30 µg), and meropenem (MEM 10 µg) were the highest in human patients

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60256040

compared to other hosts at the rates of 83%, 67%, 50%, and 8% for the antibiotics respectively.

The rate of resistance genes, blaCTX-M and blaTEM-1 genes in E. coli isolated from different hosts

CTX-M is a class A beta-lactamase enzyme with a great activity against cefotaxime. It is believed to have evolved from two beta-lactamase enzymes, TEM and SHV after several mutations. More than 172 types of this enzyme have been found (Antonopoulos et al., 2018; Ramadan et al., 2019) and some of these enzymes are active against both ceftazidime and cefotaxime (Boyd et al., 2004; Paterson and Bonomo, 2005). This class of beta-lactamase is mostly found in *E. coli* and *Salmonella enterica*, but they are also present in other members of Enterobacteriaceae (Woodford et al., 2004; Hudson et al., 2014). In this study, a set of primers was used to amplify and sequence *bla*CTX-M gene in order to identify, to family level, the type of CTX-M in the area.

The amplicons of *bla*CTX-M (550 bp) and *bla*TEM-1 (1080 bp) were amplified using gene specific universal primers to determine the rate of the beta lactams resistance genes in the area of the study (*Figure 2*). Out of 87 samples, 18 (20.6%) were positive for the beta lactamase resistance genes, *bla*CTX-M and *bla*TEM-1 (*Table 1*). The rate of *bla*CTX-M was remarkably higher, 13 (14.9%) compared to *bla*TEM 5 (5.7%) isolates (*Table 1*). The highest number of *bla*CTX resistance gene, 10 (11.1%) was discovered in human patients, but the highest rate of *bla*TEM, 3 (3.4%) was found in chickens of poultry houses. In total, 12 (13.7%) *bla*CTX resistance genes were recovered in *E. coli* of heavy antibiotic user hosts (all in human), whereas only one resistance gene (1.1%) was found in none antibiotic consumer hosts and none of the resistance genes were recovered from the intermediate antibiotic users.

Most of the beta lactamase genes, *bla*CTX-M and *bla*TEM were recorded in phylogenetic group B2 and D at the rate of 61.5% and 60%, respectively. The highest rate of *bla*CTX was found in phylogenetic groups B2 and B1 at the rate of 38.4% and 30.7%, followed by group D (23%) and A (7.6%). However, most of the *bla*TEM were located into group D and B1 at equal rate of 40% followed by group B2 (20%) and none of them was recorded in group A (*Figure 3*).

Sequence analysis of blaCTX-M

*bla*CTX-M genes isolated in this study were sequenced using sanger sequencing. The results from the sequencing of CTX-M genes recovered from *E. coli* isolates in different hosts were aligned together (*Figure 4*). The results showed that all the sequences were similar to one another with no mutation observed.

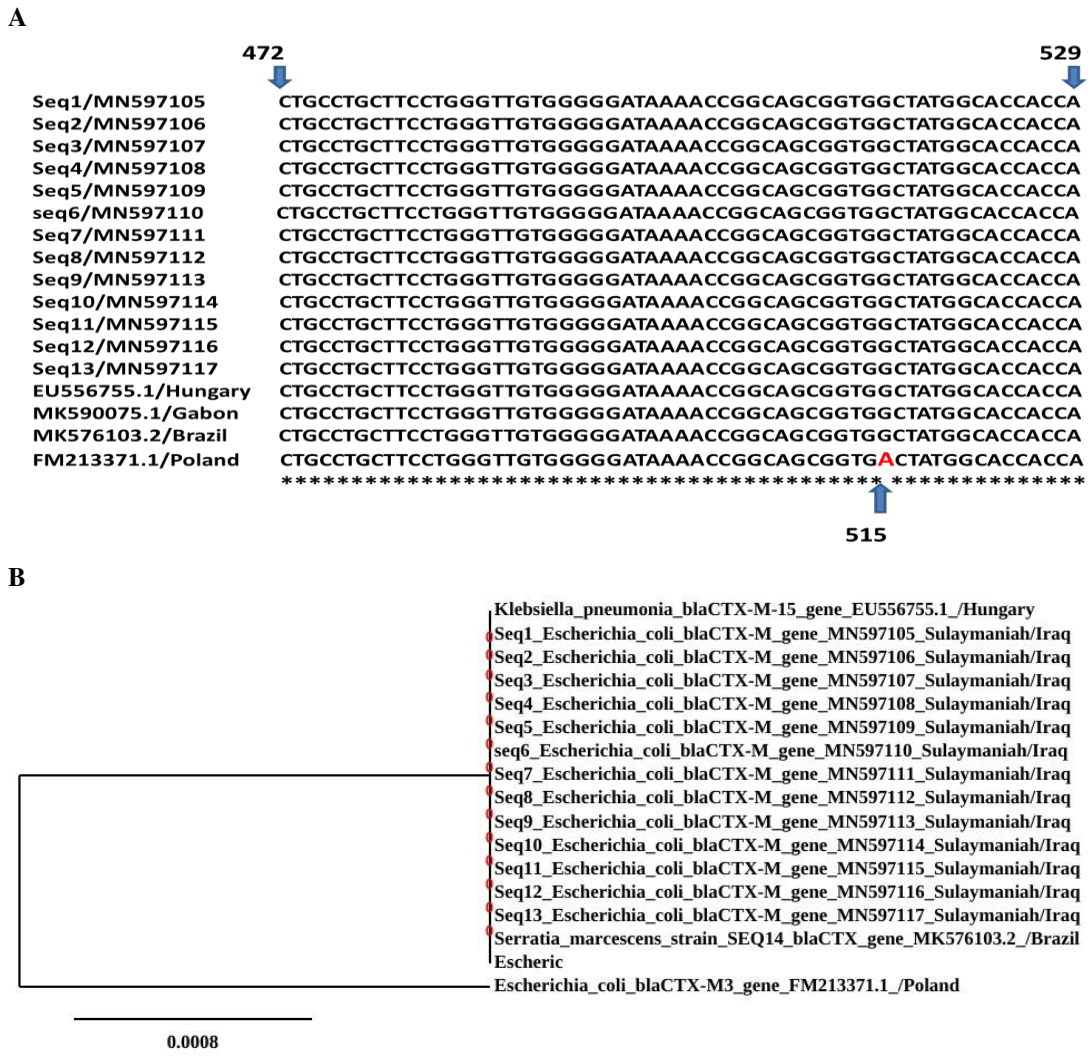

Figure 4. *Multiple sequence alignment and phylogenic tree of blaCTX-M genes recovered from E. coli and some other species. (A) CTX-M gene in E. coli strains isolated from Sulaimaniyah in comparison with published CTX-M genes of E. coli, Klebsiella pneumonia, and Serratia marcescens strains from GenBank. (B) Phylogenetic CTX-M gene in E. coli strains isolated from Sulaimaniyah in comparison with homologous published CTX-M genes in GenBank*

The CTX-M gene sequences of *E. coli* were also compared to available sequences on GenBank using BLAST search. The sequence is completely similar to available sequences deposited in the database from other countries. But interestingly one single nucleotide difference (single nucleotide polymorphism, SNP) was revealed when CTX-M3 gene from our study was compared to that published in Poland, FM213371.1 (*Figure 4*). The single nucleotide polymorphism position was indicated in nucleotide number 515 as indicated in *Figure 4*. The phylogenetic tree showed the degree of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60256040

similarity between local strains with that from Brazilian, Hungarian and Gabon and the SNP observed with the strain from Poland.

Discussion

To our knowledge, this is the first comparative study in Iraq to report the presence of ESBL producing *E. coli* in different antibiotic consumers, heavy antibiotic consumers, intermediate antibiotic consumers, and low antibiotic users. This study was conducted in summer 2019 between September and October. Humans and poultry houses were considered as heavy antibiotic users because they consume large amount of antibiotic for treatment and prophylaxis purposes in the area of the study due to easy access to buy antibiotic over the counter without any drug prescription. Intermediate antibiotic user was used in this study to denote those animals and birds consuming antibiotic in very rare events. Domestic animals and birds are being reared by villagers and are not using antibiotics to rear them except in very necessary cases such as in debilitating diseases. Non-antibiotic user refers to those animals and birds which are not domesticated. They live freely and they are not exposed to antibiotic because they don't have close contact with humans. In this group are wild animals (hedgehog, turtle and rabbit), sparrows and wild pigeons.

The result of this study showed a high percentage of fecal *E. coli* bearing *bla*CTX and *bla*TEM, 20.6% of 87 *E. coli* isolates isolated from feces of humans, animals and birds. Out of 18 beta lactam resistance genes, 13 (14.9%) were *bla*CTX and five (5.7%) were *bla*TEM. The highest rate of *bla*CTX genes 13.7% (12 isolates) were recovered from humans. Most of the resistance genes were found in heavy antimicrobial users, 17 out of 18 resistance genes in 87 isolates (19.5%). The rate of resistance genes was higher in human patients (11.1%) than in healthy humans. There were no beta lactamase resistance genes, *bla*CTX, and *bla*TEM, recorded in intermediate antibiotic users (live stocks and free living poultry) in this study. The high percentage of *E. coli* producing *bla*CTX in human feces is comparable with studies in different countries. This study is totally in agreement with the study of many countries that the rate of *bla*CTX is significantly high (Valentin et al., 2014). The rate of *bla*CTX is 0% in *E. coli* isolated from feces of poultry in the current study and this result is similar to the finding in many countries of Asia and Europe. In The Netherlands *E. coli* harboring *bla*CTX was recorded 0%. In addition, it is comparable with the study in other countries of Europe where the prevalence of *bla*CTX is very low such as in Belgium (2%), and the United Kingdom (12%) (Smet et al., 2008; Randall et al., 2011; Huijbers et al., 2014). Same low record was investigated in Asian countries, Japan and China with low percentage of 0-2%, whereas the finding is different from different studies carried out in Africa. It is concluded in many studies that the rate of *bla*CTX is significantly high and it is one of the most prevalent genes in live stocks and poultry (reviewed in: Alonso et al., 2017). This is however at variance to the finding in Ghana where they recorded high rate of *bla*CTX in poultry, 96% (Falgenhauer et al., 2019). So the geographical distribution of *bla*CTX in this study area is more similar to Asia and Europe and it is the opposite to that of Africa.

For non-antibiotic consumers (wild animals, pigeon, and sparrow) also the lowest prevalence rate of beta lactamase resistance genes was recorded. From the *E. coli* isolated from feces of 30 animals and birds, only one (1.1%) *E coli* isolate producing *bla*CTX gene was recovered in pigeon and there was not any *bla*TEM recorded in this

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60256040

category of animals. Comparative study of *E. coli* bearing ESBL in wild birds is not similar in different countries on the same continent. In Europe, the prevalence is very high in some countries while it is very low in others. The rate of *bla*CTX is 0% and 0.7% in Denmark and Poland, respectively, which is more similar to our results. Similar studies showed that prevalence rate was relatively higher in African, Tunisia (10.8%), and in some other countries of Europe (Guenther et al., 2012; Veldman et al., 2013; Alcalá et al., 2016; Ben Yahia et al., 2018). But the rate is much higher in some countries of Europe, in The Netherland (37.8%) and in Spain 74.8% (Stedt et al., 2015).

Sequence analysis of CTX-M revealed that all CTX-M gene sequences recovered in *E. coli* isolates in this study from different hosts were similar depending on multiple sequence alignment and phylogeny tree. Among all the hosts except for humans, only one CTX-gene was discovered in *E. coli* of pigeon (MN597117) and it had 100% sequence similarity with CTX genes of *E. coli* isolated from humans (MN597105-MN597116) (*Figure 4*). The local sequences were then compared to published CTX-M genes of the same strain and other species of bacteria found in the GenBank. The local sequences showed 100% sequence similarities with sequences found in Brazil (MK576103.2), Hungary (EU556755.1), and Gabon (MK590075.1), but there was one nucleotide change in the CTX-M3 found in Poland (FM213371.1) and this difference can be seen in phylogenic tree and multiple sequence alignment in *Figure 4*.

Distribution of *E. coli* phylogenetic groups on different categories of antibiotic consumers carried out in this study. The result showed that the highest rate of heavy antibiotic users was categorized under phylogenetic group B1, 13.7% and B2, 12.6%, while the lowest rate was in group A, 6.8%. Both groups of intermediate and low antibiotic users recorded high rate categorization under group B1 with the rate of 49.4%. Most of the beta lactamase genes, *bla*CTX-M and *bla*TEM were recorded in phylogenetic group B2 and D at the rate of 61.5% and 60%, respectively, and the highest rate of *bla*CTX was found under phylogenetic group of B2, 38.4%. This result is comparable with published conclusion that most pathogenic *E. coli* belong to phylogenetic groups B2 and D and these two groups were prevalent in those human patients who are heavy antibiotic users (Bingen et al., 1998).

Antibiotics have been hitherto effective antibacterial agents used to treat bacterial infection in the field of human and veterinary medicine. Ability of bacteria to produce resistance against antibiotics impedes or delays the treatment which results in economic losses and even morbidity (Grover et al., 2013). In addition, wild birds can become a source of spreading resistant bacteria from one area to another especially to humans (Peirano et al., 2011). Therefore, this comparative study investigated the drug resistance pattern differences between high to low antibiotic users. The multidrug resistance and drug resistance pattern of these tested antibiotics in *E. coli* is significantly important because beta-lactam antibiotics (cephalosporins) especially meropenem (new generation) are known as the frontline antibiotics for the treatment of bacterial infection (Bradford, 2001). Furthermore, bacteria harboring *bla*CTX and *bla*TEM resistance genes become resistant against different classes of beta-lactam antibiotics (Boyd et al., 2004; Paterson and Bonomo, 2005). Therefore, six beta-lactam antibiotics were chosen to investigate the resistance phenotype of *E. coli* in this study, amoxicillin (25 μg), amoxicillin-clavulanic acid (30 μg), oxacillin (1 μg), meropenem (10 μg), ceftriaxone (30 μg) and cefotaxime (30 μg).

The rate of antibiotic resistance was higher in *E. coli* isolated from heavy antibiotic users than in other groups in this study against amoxicillin (25 μg), amoxicillin-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60256040

clavulanic acid (30 μg), oxacillin (1 μg), meropenem (10 μg), ceftriaxone (30 μg) and cefotaxime (30 μg) (*Figure 2*) and followed by wild animals against oxacillin and amoxicillin-clavulanic acid which showed relatively high resistance. In total, the resistance percentage to oxacillin was the highest and the sensitivity against meropenem was remarkably high in all *E. coli* isolates in this study. 29 (33.3%) out of 87 isolates showed multidrug resistance to different antibiotics especially against different antibiotics and the highest rate of multidrug resistance was in heavy antibiotic user group, 15 (17.2%). This multidrug resistance were comparable in different studies in different countries (Forward et al., 2004; Yan et al., 2004; Sunde, 2005; Ahmed et al., 2009; Hansen et al., 2013). *E. coli* isolates bearing *bla*CTX showed resistance to extended spectrum antibiotic, cefotaxim. This finding is consistent with some studies in different countries, Ghana, (Hackman et al., 2014), Ethiopia (Zeynudin et al., 2018) and India (Upadhyay et al., 2015) that most bacteria harboring CTX-M resistance genes are resistant to third generation of cephalosporin.

Conclusion

This study revealed a remarkably high rate of *bla*CTX in *E. coli* isolated from different hosts and it is obviously more predominant in heavy antibiotic user hosts (humans) in Sulaimani region/Iraq. *bla*CTX and *bla*TEM were mostly found in phylogenetic groups B2 and D. Pathogenic *E. coli* isolated from human patients showed higher degree of resistance to antibiotics compared to other hosts. Meropenem (10 μg) antibiotics remains the most active against *E. coli* in all hosts. So *E. coli* living in the intestinal tract of domestic animal, free living poultry, free living flying birds and wild lives are less resistant to antibiotics and less often carry beta lactam resistance genes compared to human. Therefore, those animals and birds do not pose a big threat and risk to human public health in this study area.

Acknowledgements. We acknowledge the president of Sulaimani Polytechnic University and especially Assistant Professor Dr. Alan Faraydoon Ali for his great help and academic support to perform this research. Also, we would like to appreciate Mam Humanitarian Foundation for their financial and logistic support.

FOLIAR APPLICATION OF DIANELLA ENSATA, AMBROSIA DUMOSA AND MORINGA OLEIFERA IMPROVED BARLEY GROWTH AND YIELD TRAITS UNDER DROUGHT STRESS

ALGHABARI, F.

Department of Arid Land Agriculture, Faculty of Meteorology, Environment & Arid Land Agriculture, King Abdulaziz University, P.O. Box 80208, Jeddah 21589, Saudi Arabia (e-mail: falghabari@hotmail.com; phone: +96-655-827-7766)

(Received 26th Feb 2020; accepted 7th Jul 2020)

Abstract. Barley (*Hordeum vulgare* L.) is one of the major cereal crops cultivated in Saudi Arabia. A pot experiment was performed to estimate the effect of drought stress on barley crop while natural plants extract were used as a management strategy. The experiment was laid out in a completely randomized design with three repetitions. Pots grown barley were thinned to three plants per pot and allowed to grow undisturbed until the start of reproductive stage. Aqueous extract of flax liliy; *Dianella ensata,* burro-weed; *Ambrosia dumosa* and drumstick tree; *Moringa oleifera* were used along with the control. Drought stress treatments were 40%, 60% and 100% field capacity. The application of *Dianella ensata* and *Moringa oleifera* produced double number of productive tillers and 30-38% recovery for number of spikelets per spike. Severe drought stress reported a substantial decrease (-31%) in number of grains per spike and 1000 grain weight while the application of *Moringa oleifera* has achieved 28% higher number of grains per spike and 24% higher 1000 grain weight. The application of *Moringa oleifera* also reported an increase of 28-35% in leaf area and chlorophyll content. On contrary to other traits, a positive correlation exists between the drought stress and root length.
Keywords: *drought stress, cereal crop, drought mitigation, field capacity, Hordeum vulgare*

Introduction

The global population is continuously increasing and the growth may reach up to 9.7 billion by 2050, so global agriculture is supposed to produce 70% more food in future. In addition, there are other fields for world agriculture to fight, to try to eliminate increasing poverty and hunger, and to restore the diminishing natural agricultural resources as was called for by the food and agriculture organization (FAO, 2009; Bourne, 2009). Crop production is not coping with the increasing demands for food, and this is due to many stressing factors (Alghabari et al., 2015; Fahad et al., 2017, 2018). Scarce rainfall in arid regions is considered the main reason for low crop production, so efforts are needed to manage this problem. Policies should be directed toward planting of drought resistant salt tolerant crops, and crops with short duration together with the application of growth promoting substances (Ihsan et al., 2016a). Naeem et al. (2018) reported a positive role of calcium in drought stress management in maize crop. Daur et al. (2018) studied the positive role of rhizobacteria isolated from the roots of various plants of Saudi Arabia on alfalfa growth and yield.

The annual grain crop barley (*Hordeum vulgare* L.) is one of the cereal crops famous for cultivation in arid and saline regions (Alghabari and Ihsan, 2018). It contains high percentages of carbohydrates, and rich in minerals and vitamins. Barley is considered one of the valuable food resources, and can be used as whole grain as an animal feed for goats, sheeps or processed and making different food products and infant foods. Barley can succeed in arid areas with limited water suuply. Plant growth and yield decreased under drought stress (Fenta et al., 2014), and this reduction in growth and yield is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60416052

attributed to changes in the physiological and phnological parameters of the plant due to the scarcity of water (Ihsan et al., 2016b). There is a continuous reduction in soil water supplies throughout the world, and this is suggested to cause losses in plant production all over the world up to 30% by 2025, compared to the current yields (Zhang, 2011). When planting crops under arid land conditions they face water deficit stress throughout their growth cycle especially at anthesis (Ihsan et al., 2016b; Fahad et al., 2017).

On the other hand climatic conditions are continuously changing, and these changes had negative impact on crop growth and yield due to escalation in drought, salinity and heat stresses intensity. Of these stresses drought can be considered the most devastating abiotic stress (Alghabari et al., 2015; Alghabari and Ihsan, 2018). Drought stress problem increased tremendously in field crops due to climate change, anthropogenic activities, bad crop choice, improper use of land and low irrigation efficiency. Production of new genetically bred drought tolerant crop varieties will help in solving problem of agriculture in arid regions. Plant growth promoting extracts of natural plants would be another suitable option due to their safety and low prices.

In nature there are many drought stress tolerant wild plants with many potentialities that can be used with crop plants (Abbasi et al., 2009), for they represent sources of number of biochemicals which have growth stimulatory characters. There is a limited work on the use of wild plant species as drought stress ameliorators in field crops. Saudi desert is rich in wild flora and efforts should be exerted to discover their growth promoting potential in detail. Drought stress arises from diminish in fresh water resources, reduction in annual rainfall, and inability in storing rain water and generally features of aridity of the region. Drought stress causes a serious damage to field crops particularly at germination and flowering stages. Planting of barley is preferred in arid regions because it is considered a short duration crop and its water requirement is very low, and in spite of that barley crop growth faces severe drought cycles resulting in minimum seed germinaion and final grain yield.

The current study was performed to estimate the impact of drought stress on barley growth, yield and root characteristics. The wild desert plant species water extract was used as a drought stress management strategy. The wild desert plants; *Dianella ensata, Ambrosia dumosa, Moringa oleifera* Lam were compared for drought stress regulation in pot sown barley crop.

Materials and Methods

Layout of the experiment

A model pot experiment was conducted to evluate the response of barley (*Hordeum vulgare*) crop against drought stress and its management through foliar application of natural plants extract (NPE). The experiment was performed at the Hada Al-Sham Agricultural Research Station of King Abdulaziz University Jeddah, Kingdom of Saudi Arabia during 2018. Three NPEs (Flax liliy; *Dianella ensata,* burro-weed; *Ambrosia dumosa,* drumstick tree; *Moringa oleifera*) were used along with the control. These plants were selected based on their adaptibility to arid environment of Saudi Arabia and their properties to withstand drought stress. Drought stress treatments were applied as 40%, 60% and 100% of field capacity (FC) at the onset of reproductiove stage. The experiment was layed out in a completely randomised design with a factorial arrangements. There were three repetitions for each treatment, and a total number of 36

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60416052

experimental units were used in this experiment. The used NPE, FC and sequence of treatments are presented in *Table 1*.

Table 1. *Tabulated presentation of treatments; natural plant extract (NPE) and field capacity (FC)*

Sr. No	Treatments	Common name	Botanical name
	Natural Plants Extract (NPE)		
1	NPE1	Control	Water
2	NPE2	Flax lily	*Dianella ensata*
3	NPE3	burro-weed	*Ambrosia dumosa*
4	NPE4	drumstick tree	*Moringa oleifera* Lam
	Drought stress (FC)		
1	FC1	100%	No stress
2	FC2	60%	Moderate stress
3	FC3	40%	Severe stress

Pots preparation

Soil collected from the agriculture fields of Hada Al-Sham research station was mixed with farmyard manure (2:1 ratio) to improve the soil physio-chemical and biological properties of the growing medium. Soil field capacity was determined by using gravimetric method. The irrigation water ratios were 40% FC extreme drought stress, 60% FC moderate drought stress and 100% FC no drought stress were considered as control (non-stressed). The pots were 30 cm tall and 22 cm wide. Each pot was filled with three kg of growth medium. Sowing of barley seeds was carried out on second week of February. At least ten healthy seed (variety; Sanober-96) were sown in each pot.

Treatments application

After 15 days of germination, the number of plants were thinned to three plants per pot and excessive plants were removed. The chemical fertilizer NPK was applied at a rate of 4 g : 2 g : 2 g per pot dissolved with irrigation water. Fertilizers were applied in two split doses at 30 days time interval starting from tillering. Field capacity level of each treatment was adjusted and the exact amount of water was added to each pot under each stress treatment. The soil FC was determined according to the gravimetric method (Alghabari and Ihsan, 2018). The pots were weighted at three days interval and manually irrigated to maintain the required FCs.

Preparation of wild plants extract

Three wild plants (*Dianella ensata, Ambrosia dumosa, Moringa oleifera* Lam) were used to study their response against drought stress in a pot experiment. Two kg air dried biomass of each plant was ground to fine powder and soaked in 5 liters of water for 80 minutes. The mixture was boiled for 3 hours at 100 °C to obtain the concentrate solution, which was then cooled and saved in plastic bottles for further use (Yasmeen et al., 2012).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60416052

Application of wild plants extract

Drought stress was started at the onset of reproductive stage (initiation of spike) and continued untill the maturity stage. The NPEs were exogenously sprayed after diluting the extract 10 times. The NPEs were applied at three times before start of drought stress -10 and after drought stress 20 and 40 days of drought stress application. Plants were harvested at maturity and the following parameters were measured.

Data collection

Data were collected from each pot separately at the time of the harvest of the experiment. Data collection included different growth, yield and root characteristics. Plant height (cm) was measured from the base of the plant to the tip of the spike through a measuring scale. The number of spikes per plant were manually calculated through counting the number of productive tillers. The plant weight was measured from each plant excluding the root biomass and presented in grams. Single spike weight was measured from the spike of the primary tiller. The spike length were measured by following the procedure adoted for the measurement of the plant height. The number of spikelets per spike and number of grains per spike were manually counted from each spike. The 1000 grain weight was recorded by weighting the 100 grains and multiplying it with 10 for each treatment. The flag leaf area was measured through leaf scanner and chlorophyll content through chlorophyll meter. Both characters were measured before the harvest of the plants but after completing the application of treatments. The root dynamics were measured as root length, root fresh and dry biomass accumulation. A measuring scale was used to measure the root length from the base of the stem to the tip of the root. Root fresh weight was taken with the help of digital balance. For the measurement of root dry weight, the fresh root samples were transferred to hot air oven for 72 hours. The temperature was set at 70 °C. The root dry weight was measured after uniform drying of all the root samples.

Statistical analysis

It was a two factor experiment; 1) drought stress and 2) natural plants extract. Drought stress consisted of three levels while plant extracts have four levels. The total number of treatments were twelve. The experiment was run in a completely randomised design with three repetitions. Data were statistically analyzed by using analysis of variance under SAS software, and least significant difference (LSD) test was used to determine and compare treatment means to estimate their significance. Figures are drawn by using MS excel software. Verticle lines on the figures represent the standard error bars.

Results

Growth traits

Table 2 represents the data for the barley growth characteristics. The effect of natural plants extract was highly significant ($p \leq 0.01$) for barley plant height, number of spikes per plant and single plant weight. The effect of drought stress was significant ($p \leq 0.05$) for plant height and plant weight while non-significant ($p \geq 0.05$) for number of spikes per plant. The interaction of natural plants extract and drought stress were highly significnt ($p \leq 0.01$) for plant height and number of spikes per plant while significant ($p \leq 0.05$) for single plant weight.

Drought stress displayed a negative effect on plant growth characteristics and the severity of the negative effect increases with the increase in the level of drought stress. On contrary, the application of natural plants extract has ammeliorated the negtive effects of drought stress and improved plant growth characteristics. The maximum plant height was recorded under normal growth conditions with the application of *Moringa oleifera* leaf extract. Similarly, this treatment reported the maximum plant height at moderate and severe drought stress as compared to control and other natural plants extract treatments. The foliar application of *Moringa oleifera* leaf extract reported 11% increase in plant height under normal condition and 15% at 40% field capacity as compared to control. Number of spike per plant were less affected by the application of natural plants effect and field capacity for 100% FC and 60% FC while the effect was more significant at 40% FC. The foliar application of *Dianella ensata* and *Moringa oleifera* leaf extracts produced a double number of productive tillers as compared to control at 40% FC. The plant weight has sharply decreased with the increase in drought stress levels. The 40% FC exhibited a 44% decrease in plant weight as compared to 100% FC. The application of *Moringa oleifera* leaf extract presented a 26% recovery in plant weight at severe drought stress (40% FC) when compared to control.

Spike characteristics

Spike related characters such as single spike weight, spike length and number of spikelets per spike were presented in *Table 3*. The effect of natural plants extract was highly significant (p≤0.01) for single spike weight and spike length while significant (p≤0.05) for number of spikelets per spike. The effect of drought stress was highly significant (p≤0.01) for single spike weight while significant (p≤0.05) for spike length and number of spikelets per spike. The interaction of natural plants extract and drought stress was highly significant (p≤0.01) for single spike weight and number of spikelets per spike while non-significant (p≥0.05) for the spike length.

*; figures differing in letters are statistically significant at p≤0.05, **; significant at p≤0.01, ns; non-significant, LSD; least significant difference. NPE 1; Water, NPE 2; *Dianella ensata*, NPE 3; *Ambrosia dumosa*, NPE 4; *Moringa oleifera* Lam

The application of *Moringa oleifera* leaf extract procured the maximum spike weight and that was statistically non-significant to other three natural plants extract treatments at 100% FC. Spike weight, spike length and number of spikelets per spike were gradually decreased with the application of drought stress irrespective of the application of natural plants extract. At moderate drought stress the application of *Moringa oleifera* leaf extract reported 96% improvement in spike weight as compared to control. The application of *Moringa oleifera* leaf extract displayed 7% and 21% recovery in spike length at moderate and severe drought stress levels as compared to the control. The 40% FC confirmed 39% decrease in number of spikelets per spike as compared to 100% FC. The application of *Dianella ensata* and *Moringa oleifera* plant extracts demonstrated 30% and 38% recovery for number of spikelets per spike as compared to control at severe drought stress respectively.

Grain attributes

Table 4 presented the data of number of grains per spike and 1000 grain weight. Both traits are exeedingly important and directly contribute in final yield. The main effects of natural plant extracts and drought stress were significant (p≤0.05) for number of grains per spike and 1000 grain weight while their interaction was highly significant (p≤0.01). The application of moderate drought stress at 60% FC level presented a slighter decrease (12-14%) while the severe drought stress level at 40% FC reproted a substantial decrease (28-31%) in number of grains per spike and 1000 grain weight, respectively. *Moringa oleifera* reported the maximum number of grains per spike and 1000 grain weight and it was followed by the *Dianella ensata* that was the 2nd best treatment for the mitigation of drought stress on barley grain attributes. Under severe drought stress the application of *Moringa oleifera* leaf extract achieved 28% higher number of grains per spike and 24% higher 1000 grain weight as compared to control.

Flag leaf area and chlorophyll content

Flag leaf attributes are presented in *Figure 1*. Flag leaf area and chlorophyll content play an important role in active photosynthesis and carbon assimilation. Effect of natural plants extract, drought stress and their interaction was significant (p≤0.05) for both flag leaf area and chlorophyll content. The flag leaf area ranged from 25-30 cm^2 for unstressed pots to 17-22 cm^2 for severe drought stressed pots. The values of leaf chlorophyll content ranged from 7-8.9% for unstressed pots to 4.6-6.2% for severe drought stressed pots. The application of *Moringa oleifera* reported an increase of 28-35% in leaf area and chlorophyll content at severe drought stress as compared to control, respectively.

Root dynamics

Root characteristics such as root length, root fresh and dry weight are measured at plant harvest and data is presented in *Figure 2*. The effect of natural plants extract, drought stress and their interaction was significant ($p \leq 0.05$) for root characteristics. Drought stessed displayed a negative effect on root fresh and dry weight while it improved the root length. The effect of natural plant extract was also positive for root length and fresh and dry biomass accumulation. The 40% FC ensured the maximum root length with an increase of 45% as compared to 100% FC. At sever drought, the application of natural plants extract reported an increase of 71-62% in root fresh and dry weight as compared to control. Moringa oleifera and Dianella ensata contributed significantly for the mitigation of drought stress and improvement in root characteristics.

Discussion

Drought is the most intimidating abiotic stress that affects growth and yield of field crops. Drought causes many damaging effects on crop morphological and physiological

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60416052

characteristics. It causes alteration in leaf morphology and gives rise to morpho-physiological changes that leads to impaired plant growth and grain development thus reducing plant yield (Alghabari and Ihsan, 2018). Because of drought stress the crop plants face disturbance in their osmotic balance, reduction in stomatal conductance, reduction in photosynthetic activities, lowering rate of membrane electron transport and also rate of evapotranspiration and loss of water from plants increases, and all these processes ultimately lead to reduction of growth and development thus reducing the final crop yield (Srivalli et al., 2003; Allahmoradi et al., 2011; Alghabari et al., 2014, 2015; Hussain et al., 2018). Crop plants under arid land conditions are subjected to water deficit stress especially at reproductive stage.

Barely growth and yield components were significantly affected by the extracts of the three natural plants (*Dianella ensata, Ambrosia dumosa, Moringa oleifera* Lam). These plants may have been containing growth stimulating molecules that may be present in any part of these plants; leaves, roots, stem, flower or fruit. Their presence in the root rhizosphere was demonstrated by many researchers (Bertin et al., 2003; Stock et al., 2019). Ihsan et al. (2015) reported growth inhibitory effects of different plants extract while Alghabari (2018) documented growth stimulatory effects of desert plants extract in mungbean crop. Application of plant based growth regulators is now considered a new agricultural field after its proven positive role in abiotic stress relief, economically viable and environment friendly. The role of the wild and natural plant extracts in reducing effects of drought impact on barley plant growth and yield may be due to their positive role in regulation of moisture supplies to crop plants, and in making nutrients more available to crop plants and enhancing the rate of photosynthesis.

Dianella ensifolia is an evergreen, perennial herb with grass-like leaves growing from a branched, gradually spreading rhizome. It can grow up to 1.5 metres tall, spreading at the roots to form quite large clumps. The plant is sometimes gathered from the wild for use as a medicine, pesticide and dye. *Ambrosia dumosa* is a highly branched shrub 20 to 90 cm in height. It is present in desert areas of the world. It becomes dormant during drought stress, losing all of its leaves to prevent water loss by transpiration. *Moringa oleifera* is a fast-growing, drought-resistant tree native to the Indian subcontinent. It is well adapted to arid lands of Saudi Arabia. A deciduous tree that can reaches a height of 10–12 m.

Many researchers have reported the growth stimulatory effects of different plants in field crops. Cowpea growth, yield and protein content were stimulated by the aqueous extract of *Malva parviflora* and *Artemisia ludia* (Lashin et al., 2013). Application of moringa leaf extract at two weeks interval after emergence has imporved maize plant height, fresh and dry weight, number of grains per cob and 100 grain weight (Biswas et al., 2016). Application of different plants extract controlled wheat leaf rust caused by *Puccinia triticina* and improved grain yield components such as 1000 grain weight (Shabana et al., 2017). The improvement in crops growth and yield by the foliar application of moringa plant aqueous extract suggested that it activated the antioxidants mechanism in plants to enable them to alleviate the oxidative damage caused by drought stress. It may have improved the physiological and molecular attributes in stressed plants that helped them to combat the adverse conditions of environmental stresses. *Moringa oleifera* is rich in amino acids, ascorbate, minerals and zeatin compounds known for their growth promoting potential (Latif and Mohamed, 2016). Chemical analysis of moringa leaf extract showed that GA4 is most likely in crosstalk with auxin is the major growth enhancer (Brockman et al., 2020).

DOI: http://dx.doi.org/10.15666/aeer/1805_60416052

The ability of plants to resist drought stress and to improve their growth under drought through application of plant growth regulators is because of these extracts act as osmoregulators regulating osmosis in plant species, working as signaling agents, and hence reduces reactive oxygen species production and photorespiration. Overall, improvement in photosynthesis and in nutrient uptake enabled plants to resist and tolerate drought stress. The improvement of barley plants growth and yield under drought stress by application of *Dianella ensata* and *Moringa oleifera* Lam water extracts is due to the stimulatorry role of these extracts through increasing leaf osmotic process, plant water uptake, photo-assimilation and improvement of the plant antioxidant defense system. In future, studies are needed to identify wild plant species that have growth stimulatory effect under drought stress which can be used in field crops to tolerate and resist drought stresses. Reseach is also needed to identify and isolate the compounds that play an active role in drought stress mitigation.

Conclusion

Drought stress significantly affected barley growth and yield. The adversity of the drought stress increased with the decrease in field capacity. Application of wild plants (*Dianella ensata, Ambrosia dumosa, Moringa oleifera* Lam) aqueous extracts improved growth and yield of barley crop. The foliar applied extracts alleviated the negative effects of drought stress through improving crop growth and grain contributing traits that enabled the barley to effeciently absorb water and nutrients. The *Moringa oleifera* was the most promising wild plant extracts. It is recommended to screen and quantify the biomolecultes that have growth promoting effects through chromatographical processes and be produced as commercial commodities for utilization in plant drought tolerance and growth promotion under stressful environment.

(Received 2nd Mar 2020; accepted 10th Jul 2020)

Abstract. Mt. Tianmu is one of the most important refugia of Tertiary relict plant taxa in Eastern China. We analyzed the habitat characteristics, community structure, demographic structure, and production methods of Tertiary relict deciduous forests at 1,100 m on Mt Tianmu (1,506 m), Zhejiang province, China. *Emmenopterys henryi* mostly occurred in unstable habitats with gap-formation or landslides, and these populations showed a sporadic regeneration pattern. *E. henryi* colonized and established at unstable sites by abundant wind-dispersed seeds. After colonization, *E. henryi* persisted for a long time and dominated in the canopy layer and even reached emergent layer due to its long lifespan and vegetative reproduction capability. It could thus be regarded as an undifferentiated climax pioneering species with an 'r-selected' life history that produced abundant minute seeds and experienced intermittent recruitment and often became pioneer species of secondary succession after moderate disturbance. Here, we discussed conservation strategies for Tertiary relict deciduous trees as climax pioneering species that accounted for the peculiarity of their habitat and population structure in broad-leaved forests.
Keywords: *habitat instability, root sucker, population structure, reproduction methods, regeneration strategy*

Introduction

Tertiary relict floras contain survivors from plant communities that were distributed throughout a large part of the Northern Hemisphere during much of the Tertiary (i.e. 65-15 million years ago (Ma)) (Milne and Abbott, 2002). They are now mainly restricted to warm humid areas (refugia) in southeastern and western North America, East Asia and southwest Eurasia (Milne and Abbott, 2002; Hampe and Arroyo, 2002). A number of deciduous broad-leaved ancient genera, considered to be Tertiary relicts, are found today in subtropical broad-leaved forests of China, such as *Davidia involucrate*, *Tetracentron sinense*, *Cercidiphyllum japonicum* var. *sinense*, *Euptelea pleiospermum*, *Ginkgo biloba, Cyclocrya paliurus*, *Emmenopterys henryi*, *Tapiscia sinensis*, *Fortunearia sinensis* etc. (Del Tredici, 1992; López-pujol et al., 2006; Gong et al., 2008; Wei et al., 2010; Wu et al., 2018). The current populations of these trees are very small and they usually coexist with other evergreen, deciduous and coniferous trees at relatively restricted ranges (Gong et al., 2008; Wu et al., 2018). During the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60536067

Quaternary glaciations, these ancient species experience severely reduced regeneration and survived while most other members of their group were wiped out (Tzedakis et al., 2002; Shen et al., 2002; Tang et al., 2011; Qian et al., 2016). A majority of these species are globally threatened now (López-Pujol et al., 2006). How these relict species survive and persist under current climate conditions or those of rapid climate change and frequent human activities became an important topic for rare and endangered species conservation (Calleja et al., 2009).

Emmenopterys henryi Oliv, belonging to the Rubiaceae family, is an endangered deciduous tree endemic to China (Zhang, 2016). It is characterized by a long lifespan, intermittent flowering with 2-4 year intervals, production of abundant wind-dispersed minute seeds (0.3-0.6 g per 1000 grains) and reduce competitive ability with other deciduous pioneer tree species and evergreen tree species during the juvenile stage (Wang et al., 2002). It is of ancient origin, a relic of the paleotropical flora of the Cretaceous Period, Mesozoic Era, and is considered valuable both for its unique position in the flora of China and in the systematic evolution of the Rubiaceae. *E. henryi* primarily occurs in ravines and mountain valleys at altitudes of 400-1400 m in southwestern China and the Yangtze River Valley. Populations of *E. henryi* have been affected by habitat destruction and over-exploitation in the wild. It has been listed as a threatened species within China due to its lower regeneration. Previous researches mainly focused on chemical components, seed physiology, community structure and genetic structure (Ma and He, 1989; Zhang et al., 2007; Li and Jin, 2008; Guo et al., 2017a,b; Ma et al., 2019). Kang et al. (2007), Guo et al. (2017a) and Ma et al. (2019) also reported that *E. henryi* regenerates through both sexual and asexual modes, but scientific analysis of its regeneration mechanism along the topographic gradients, has not been described. Further studies may be necessary to evaluate potential adaptation of populations to local environmental conditions.

Therefore, this paper focuses on: (1) community structure, distribution pattern and demographic structure of main trees, and (2) the production methods of *E. henryi* population along the topographic gradients, to reveal that how they persisted as related to habitat. The inhabiting habitats, production methods and regeneration strategy of other similar relict trees have been compared to determine whether these relict trees have similar peculiarity for persistence at relatively restricted ranges.

Materials and Methods

Study site

The study was conducted at the Mt. Tianmu Nature Reserve (30°18’30’’ ~ 30°21’37’’N, 119°24’11’’ ~ 119°27’11’’E, Zhejiang Province, P. R. China), which is one of the most famous protected areas in China and throughout the world due to its remarkable number of large, rare and endangered plants. The foothill region is located at 300-350 m a.s.l., which gradually rises to 1,056 m a.s.l. Mt. Tianmu is characterized by a subtropical humid climate (Qian et al., 2002). According to records from weather stations at Chanyuan Temple (350 m a.s.l.) near the base and Xianrending (1,506 m a.s.l.) near the summit of Mt. Tianmu from 1987 to 1996, the average annual temperature is 14.5 ^{o}C and 9.0 ^{o}C, and the average annual precipitation is 1,739 mm and 1,751 mm for Chanyuan Temple and Xianrending, respectively (Da et al., 2009). Because the stratum was affected by tectonic movements and volcanic activity, the study area is made up of steep slopes and irregular terrain, especially many complex

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60536067

landscape structures between 900 m and 1,100 m a.s.l. 90% of this area is covered with volcanic rock, and the zonal soils are comprised of red soils (below 600 m a.s.l.), yellow soils (600-1,200 m a.s.l.) and brown yellow soils (above 1,200 m a.s.l.) (Xia, 2004).

Data collection

The population size and distribution region of *E. henryi* on Mt. Tianmu is small by our survey on July to August 2010, which mainly concentrated on the mid-altitude region from 900 m a.s.l. to 1,200 m a.s.l. They were mainly distributed at roadsides, and in valleys, gravel mounds, cliffs, etc. Besides, we also founded that a few of seedlings and saplings of *E. henryi* grow on fallen log of the gap-maker. We established plots by patch sampling in twelve locations representing three micro-topographies (*Table 1*). Plot 1-4 (total 1,600 m^2) was established in an old canopy gaps surrounded by old-growth *Cryptomeria fortunei*. These plots were located on hollow head with an average 20.0° incline. Plots 5-8 (total 1,600 m^2) were established in flood terrace with an average 16.0° incline. Plot 9-12 (total 1,400 m^2) was established in river bed on a seasonally active channel with a mean 23.8° incline. A more detailed description of these three microtopographies was shown in *Table 2* by surveyed.

Table 1. *The geological properties of 12 sampling plots*

Plot	GPS position	Microtopography	Sampling area (m^2)	Altitude (m)	Slope (°)	Aspect
1	30°20′18.4″,119°25′44.8″	Hollow head	400	1062	15	S30E
2	30°20′32.3″,119°26′06.8″	Hollow head	400	1113	10	S65W
3	30°19′52.0″,119°25′45.6″	Hollow head	400	1000	30	NE45

12	30°20′18.4″,119°25′47.8″	River bed	200	975	22	S74E

Table 2. *The characteristics of three different microtopographies*

Habitat	Hollow head	Flood terrace	River bed
Situation	Upper gentle slope	Lower gentle Slope	Middle gentle slope
Litter cover	High	Low-high	Low
Soil depth	Deep	Medium	Shallow
Soil humidity	Low	High	Low
Disturbance type	Soil erosion	Soil erosion	Soil erosion
Physical stability	Relatively stable	Moderately unstable	Unstable

Because the canopy layer forms at heights above 8 m in these plots, we expressed the strata of the forest as follows: tree layer, 8 m < height (H); subtree layer, 4 m ≤ H ≤ 8 m; shrub layer, 1.5 m ≤ H < 4 m; sapling, 0.5 m ≤ H < 1.5 m; seedlings, H < 0.5 m. In each whole plots, we recorded the species, measured the diameter at breast height (1.5 m above ground; DBH) and the height of trees ≥ 1.5 m. The quantities and heights of seedlings and saplings of *E. henryi* were also identified and measured.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60536067

The plantlets of *E. henryi* were classified into two types, true seedlings from seed-origin and root suckers from adventitious buds on lateral roots, identified by removing the litter and surface soil of lateral roots. Besides, individuals with own root systems in shrub or tree layer were also considered to be seed-orientated. Root suckers remained connected to parent tree for several years and could increase competitively and greater survival under adverse environmental conditions (Ky-Dembele et al., 2007; Beaudet and Messier, 2008).

Data analysis

The dominant species were identified by Ohsawa's dominance analysis method using the relative basal area (RBA) of each species. This analysis is based on the least deviation (*d*) between the share obtained by a given species, as a percentage of the total basal area (x_i), and its calculated share if all species were equally represented (x'):

$$d = 1/N\left\{\sum_{i\in T}(x_i - x')^2 + \sum_{j\in U} x_j{}^2\right\} \quad \text{(Eq.1)}$$

where T is the number of 'top species' in a given dominant-number-model, U is the number of remaining species, and N is the total number of species. For example, in a community dominated by single species, x'=100/T (where T=1), the top dominant's share is 100%. If, however, two species share dominance, the top two dominants share 50%, or if there are three co-dominants, 33.3%, and so on. Species diversity was expressed by Shannon-Wiener Index.

For determining whether these Tertiary relict trees have similar regeneration mechanisms, more or less complete information on the inhabiting habitat, seed mass per 1000 grains, dispersal agent and production methods was available from literatures (Shang et al., 2016). The types of vegetative reproduction were clarified into five types. Seedling sprout means a plantlet of seed origin that was affected by shoot dieback, but re-sprouted from the root collar of the seedling; root sucker means a plantlet arising vertically from superficial lateral root; coppice means a plantlet arising from stumps of cut mature tree in response to logging or non-logging disturbances and which root diameter exceeds 10 cm; water sprout means a plantlet developed from the base of alive mature tree; layer means a plantlet developed from low hanging lateral branch (Ky-Dembele et al., 2007).

Results

Floristic characteristics

Within a total of nearly 4,600 m^2 plots in all habitats, 69 woody species belonging to 54 genera and 37 families were recorded (*Appendix A*). The tree life-forms were deciduous broad-leaved, evergreen broad-leaved, deciduous coniferous and evergreen coniferous, but only 9 species were evergreen. Of the deciduous species, 3 genera (*Pseudolarix, Emmenopterys* and *Cyclocarya*) were endemic to China, 7 genera (*Kalopanax, Acanthopanax*, *Ehretia, Corylopsis, Deutzia, Dendrobenthamia* and *Stachyurus*) were endemic to East Asia. Of the evergreen trees, one genus (*Cunninghamia*) was endemic to China, 3 genera (*Cryptomeria*, *Lithocarpus* and *Orixa*) were endemic to East Asia. Northern temperate deciduous broad-leaved genera such as

DOI: http://dx.doi.org/10.15666/aeer/1805_60536067

Petrocarya, *Acer* and *Viburnum*, pantropic genera and old-world temperate genera were also appeared. Besides, many relict species such as *E. henryi*, *Cyclocarya paliurus*, *Magnolia cylindrical*, *Pseudolarix amabilis* were co-existed in the community. Hence, the ancient and complexity of community were remarkable that with so many plants of diverse geographic distributions as well as Tertiary relicts.

E. henryi could establish them on different microtopography along habitat instability and become a dominant. In the hollow head with relatively stable, was co-dominated by *P. amabilis*, *C. fortunei* and *E. henryi*; the relative dominance value of *E. henryi* was 15.2-67.6%. In the flood terrace with moderately unstable, *C. fortunei*, *E. henryi* and *P. amabilis* were co-dominant; the relative dominance value of *E. henryi* was 23.7-57.2%. In the river bed, *E. henryi* as the first dominant was co-dominated with *C. fortunei* and the relative dominance value reached to 41.9-97.0%.

Height-class distribution with increasing habitat instability

The height-class frequency distribution of all woody species is shown in *Fig. 1*. In the hollow head, the number of evergreen individuals was more than deciduous and the ratio of evergreen/deciduous was 1.16. Evergreen species such as *Cyclobalanopsis gracilis*, *Lithocarpus harlandii* and *C. fortune* were found in the shrub, subcanopy and canopy layers. Besides, deciduous trees *E. henryi* and *C. paliurus* were also found in all three layers, and the former even reaching the emergent layer (above the canopy, more than 20 m). In the flood terrace, the number of evergreen individuals was decreased, and the ratio of evergreen/deciduous reached to 0.48. They mainly appeared in shrub and subcanopy layer (below 10 m) while *E. henryi* were found in all layers. In the river bed, although *C. fortunei* could reach the emergent layer, evergreen individuals including *L. harlandii* and *C. fortunei* were rare and mainly confined to the shrub layers. The canopy, subcanopy and shrub layers of the forest were occupied by *E. henryi* and other deciduous trees such as *Alangium chinense* and *Bothrocaryum controversum*.

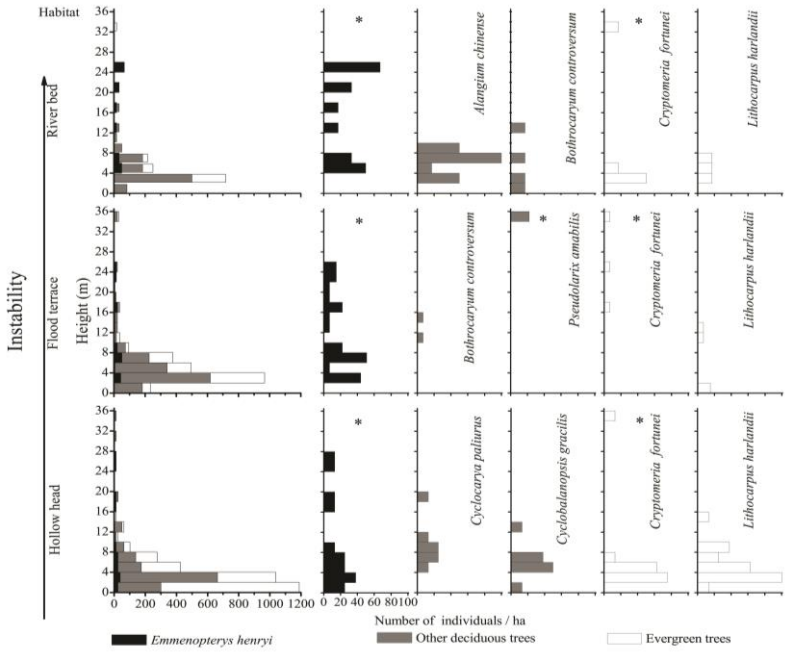

Figure 1. *Height-class frequency distribution of all individuals and main populations with increasing. Dominant species are indicted by an asterisk*

Population structure with increasing habitat instability

These communities include unimodal, sporadic and L types of size-class frequency distribution (*Fig. 2*). The unimodal type, with a single peak in the intermediate or large size-classes, and fewer if any individuals in small size-classes, suggests a weak regeneration pattern. Evergreen trees *L. harlandii*, *C. gracilis* and *Cunninghamia lanceolata* located on valley and *C. fortunei* appeared in all three habitats were of this type. The sporadic type, with more than one peak in the size-classes, indicates the possibility of good regeneration. *E. henryi* occurred in all three microtopography were of this sporadic type, but the number of populations decreased along habitat instability. Active regeneration is suggested by the L type having the highest frequency in small DBH classes. In hollow head and flood terrace habitats, evergreen trees *L. harlandii*, *C. gracilis* and *C. lanceolata* was of this type, indicating that these evergreen canopy species were suppressed by the dominant deciduous species but their populations could develop.

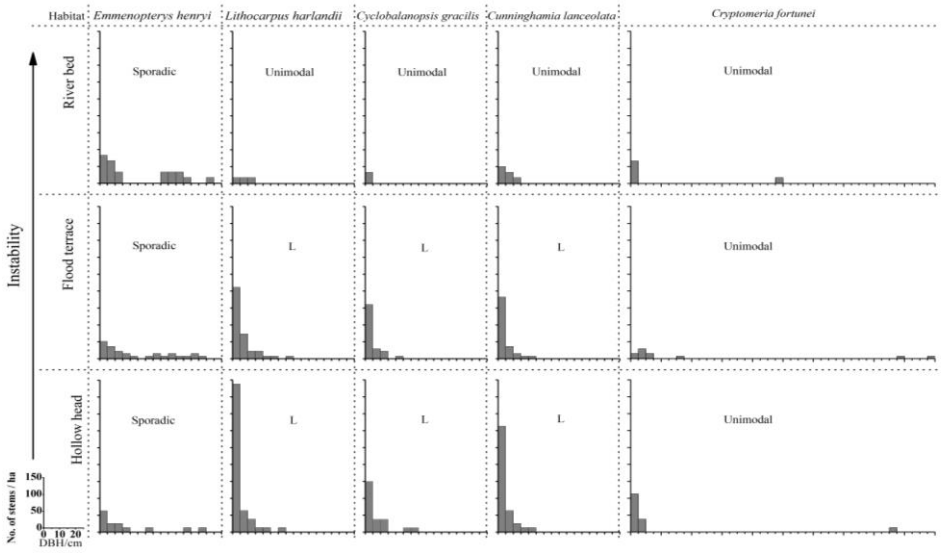

Figure 2. *Size-class frequency distribution for the E. henryi population and main evergreen tree with increasing habitat instability*

Sprouts ratio of E. henryi population at different habitat

Although the reproduction of *E. henryi* was by means of seeds at many habitats, such as gravel mound, canopy gap and fallen-log by our investigation, the resprouter by root sucker were also abundant at hollow head and river bed habitat (*Fig. 3*). In the hollow head, 23 stems (including 14 seedlings and 9 saplings) were found to regenerate successfully from root suckers and 9 individuals were true seedlings or assumable seed-orientated trees. And 2 of these individuals were located on fallen-log. In the river bed, 6 stems originated from root suckers and 6 individuals were true or assumable seed-orientated trees. The suckering stems accounted for 72% of all stems in the hollow head, while 50% in river bed.

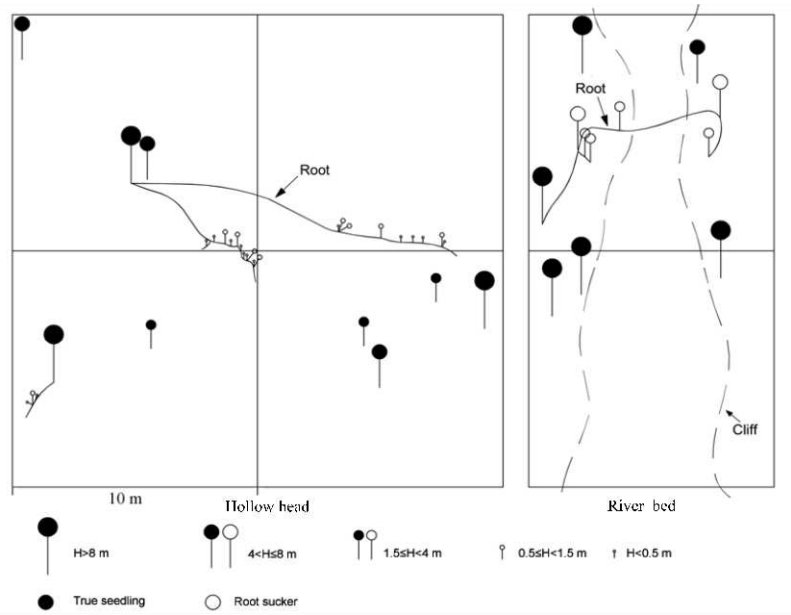

Figure 3. *Vegetative mode of E. henryi population in hollow head and river bed*

Discussion

Reproductive strategy and population persistence of E. henryi in relation to micro-topography

The distribution of *E. henryi* on Mt. Tianmu was primarily at unstable habitats, such as hollow head valleys, flood terrace, fallen logs and gravel-mounds. This was similar to other Tertiary relict species, such as *Euptelea polyandra* in warm-temperature forest of Japan (Sakai and Ohsawa, 1993), *Euptelea pleiospermum*, *Cercidiphyllum japonicum* and *Davidia involucrata* in subtropical evergreen broad-leaved forests of western China (Tang and Ohsawa, 2002; Wei et al., 2010; Wu et al., 2018), *Frangula alnus* subsp. *Baetica* and *Prunus lusitanica* in Iberian Peninsula of Spain (Hampe and Arroyo, 2002; Calleja et al., 2009; Pardo et al., 2018). All these trees seem to require very particular unstable habitats where competition from other trees is limited.

At those unstable habitats, the deciduous pioneer tree *E. henry*i could colonize firstly by mean of abundant minute seeds production (0.3-0.6 g per 1,000 grains) after moderate disturbance (Kang et al., 2007; Shang et al., 2016). Their populations experienced intermittent recruitment as shown by the sporadic type of stem-diameter class frequency distribution, while evergreen trees regenerated more weakly along habitat instability (*Fig. 2*). At hollow head and flood terrace habitat with lower unstable, *E. henryi* can dominate in the canopy layer and even reach the emergent layer due to its long life span (*Fig. 1*; *Appendix A*). When these habitats become more stable, the evergreen trees *L. harlandii*, *C. gracilis* and *C. lanceolata* may become dominants according to the regeneration pattern (*Fig. 2*). At river bed habitat with frequent landslide, *E. henryi* could recruit well due to the possibility of good regeneration while other evergreen trees were not (*Fig. 2*). Here, the *E. henryi* dominated forest in the river bed on Mt Tianmu could be regarded as a topographic climax phenomenon formed in an area of landslide disturbances.

The results of this investigation showed that asexual reproduction resprouted by long-distance root (root sucker) was the important mechanism of seedling recruitment of *E. henryi* population (*Fig 3*, Guo et al., 2017a). The suckering stems accounted for 72% of all plantlets in hollow head compared to 50% in river bed. This is because although *E. henryi* can colonize at different habitats by the active production of seeds, the seed germination and seedling establishment are influenced by environmental filtering (Zhang et al., 2007; Guo et al., 2017b). The seed germination and seedling recruitment of *E. henryi* at current conditions are hampered by the thick layer of leaf litter in gentle slope habitat except for fallen-log, which agrees with previous findings that seedlings produced by small seeds may be unable to emerge in sites with thicker litter layers (Carlton and Bazzaz, 1998; Castro et al., 1999). After the stage of seedling-establishments, a light-demanding deciduous pioneer tree, *E. henryi* can not compete with modern deciduous pioneer tree species and evergreen tree species due to its reduced competitive ability during the juvenile stage (Zhang et al., 2007; Pulido et al., 2008). On the other hand, resprouts arising from vegetative reproduction grow faster than newly established seedlings due to their well-established root system (Ky-Dembele et al., 2007), providing better resistance to stress in their first years (Deiller et al., 2003), and a stronger competitive advantage (Beaudet and Messier, 2008). It can be considered that root suckers probably contribute to the survival and maintenance of *E. henryi* population by reducing vulnerability to severe disturbance and recruitment failure (Guo et al., 2017a).

Ohsawa (1991) have suggested that most sporadic type species who experienced intermittent recruitment can be regarded as a kind of pioneers in the climax forests and called ‘undifferentiated canopy components’ that between a nomadic pioneer and a climax species. *E. henryi* populations have experienced intermittent recruitment in hollow head and flood terrace habitat with relatively stable (*Fig. 2*). Moreover, *E. henryi* is a deciduous pioneer tree that characterized by a long life span, intermittent flowering with 2-4 year intervals, and production of abundant wind-dispersed minute seeds (0.3-0.6 g per 1,000 grains). Thus we suggested that *E. henryi* can be regarded as an undifferentiated climax pioneering species with an ‘r-selected’ life history.

Persistence mechanism of Tertiary relict deciduous trees as climax pioneering species

A large number of deciduous broad-leaved trees of ancient genera, considered to be Tertiary relicts, occurred in the mid-altitude region of subtropical mountains (*Table 2*; Shang et al., 2016). The Tertiary relict trees seem to require very particular unstable habitats that mainly distributed on valley, forest edges, steep slopes and stream banks (*Table 3*). This is probably due to the importance of differential growth, differential survival and differential dispersal of species as well as its evolutionary factor (Pullio, 2008; Qian et al., 2016).

Since the Quaternary era, the distribution, population size and regeneration capacity of many Tertiary relict plant species has changed greatly (Tzedakis, 2002; Calleja et al., 2009; Zhang et al., 2016). Owing to their reduced competitive ability with modern floras and their ecophysiology (Pulido et al., 2008), these species need to colonize on ‘safe sites’ where competition from other species is limited (Tang and Ohsawa, 2002). The environmental stochasticity in unstable habitats could provide more opportunity for regeneration of seed-orientated species and decrease interspecific competition (García, 2003). Therefore, Tertiary relict trees would recruitment intermittent by abundant minute wind-dispersal seeds (*Table 2*; Zhang et al., 2007; Li et al., 2008).

Table 3. *Known distribution habitat, vegetation regeneration strategies, and dispersal agent of the main relict deciduous tree in China's subtropical forests*

Relict deciduous trees	Main habitats	Seed mass (g/1,000)	Dispersal agent	Vegetative mode
Annamocarya sinensis	Valley, stream bank	9000-13000	Mammals	Water sprout; Coppice
Bretschneidera sinensis	Humidity valley, stream bank	715-780	Wind	Coppice
Camptotheca acuminata	Stream bank, forest edge	34-45	Wind	Water sprout
Cercidiphyllum japonicum	Steep slope, valley, stream bank	0.75-0.9	Wind	Water sprout
Cyclocarya paliurus	Steep slope, creek valley, forest edge	200	Wind	Water sprout
Davida involucrata	Steep slope, ravine	3400-5500	Mammals	Water sprout; Coppice
Eucommia ulmoides	Valley,dry ravines	58-130	Wind	Root sucker; Coppice
Halesia macgregorii	Steep slope	125-220	Birds	Water sprout
Liquidambar formosana	Valley, stream bank	4.3-6.4	Wind	Water sprout
Liriodendron chinense	Valley	22-35	Wind	Coppice
Nyssa sinensis	Valley, stream,steep slope	125-240	Birds	Water sprout
Pteroceltis tatarinowii	Foothill, forest edge, river bed	21-28	Wind	Water sprout
Tetracentron sinensis	Valley, hillside, rocky ravine	0.1-0.15	Wind	Coppice

Note: Sources: Shang et al., 2016

On the other hand, Tertiary relict trees could sprout new shoots in subtropical area of China, including water sprouts, coppices, and root suckers (*Table 2*). It seems to allow the population to recruitment quickly after disturbance. This supplemental mechanism for population persistence is similar to that of *E. henryi* in our study, *E. polyandra* in Japan and *Rhododendron ponticum* in Mediterranean, which allocate more resources to sprouts than to reproduction by seeds (Sakai et al., 1995; Mejías et al., 2002).

These characteristics are coincident with the general tendency that the Tertiary relict deciduous trees survive and persist well in the unstable scree slopes where competition is not severe, but are unable to thrive in the stable habitats where competition is more rigorous (Tang and Ohsawa, 2002). Consequently, minute easily-dispersed seeds and seedling recruitment supplemented with vegetative reproduction seem to be most important reasons why Tertiary relict deciduous trees have been able to persist at a given site after frequent disturbance (Milne and Abbott, 2002).

Conclusion

Many of Tertiary relict deciduous trees regarded as an undifferentiated climax pioneering species with an 'r-selected' life history has very few individuals remaining. They are of high conservation concern due to their rarity and their phylogenetic uniqueness, and are therefore very important to China and the world. Responsible conservation efforts should aim to maintain present populations of these species and expand their distribution by creating new habitat. Firstly, restoration efforts should focus both on preserving habitats by protecting valley bottoms, stream habitats, and hollows, and also on preserving or restoring the natural disturbance regime. Secondly, we should prohibit salvage logging or clearing of fallen trees so that this wood can

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60536067

provide opportunities for the recruitment of seedlings. Thirdly, in order to maintain sufficient genetic variation in a small area, it is important to increase the population of true seedlings (i.e. not resprouts) through protection of seedlings and/or increasing the sowing density. Moreover, plantations could function as starting points for the natural restoration of extirpated populations in unstable habitats. These measures, together with effective legal protections against human disturbance, might help to improve the long-term persistence of Tertiary relict trees in subtropical area of China during future changes in climate.

Abstract. Soybean may undergo growth disorder due to destructive plant organisms. One of these organisms threatening the productivity of soybean is *Bemisia tabaci* Genn. This research aims to study the response of soybean lines suffering from *B. tabaci* fertilized with four different doses of potassium (K), K0= 0g/kg soil, K1= 0.02789 g/kg soil, K2= 0.055g/ kg soil, K3= 0.083 g/ kg soil. This research used a randomized complete block design with three replications. The genotype difference influenced pod width, pod thickness, number of unfilled pods, number of reproductive nodes, days to flowering, and days to maturity. The variation of dose influenced plant height, pod length, number of unfilled pods, the weight of 50 seeds, and days to maturity. Interaction (genotype x fertilizer) affected many aspects such as plant height, pod length, pod width, pod thickness, number of filled pods, total pods per plant, number of reproductive nodes, seed length, seed weight, and seed thickness, the weight of 50 seeds, days to flowering, and days to maturity. The research result of each genotype showed a different response to every dose.
Keywords: *agronomy, Bemisia tabaci, fertilizer, maturity, honeydew*

Introduction

Many kinds of plant destruction organisms disturb the growth of the soybean plant. Such organisms can be in the form of pests or weeds. *Bemisia tabaci* Genn. is one of the pests of soybean cultivation (Castillo et al., 2011; DEFRA, 2015). Plant destruction organisms attack some parts of the plant, such as leaf, stem, or root. *B. tabaci* is an insect sucking the liquid of leaves and spreads the*Cowpea Mild Mottle Virus* (CpMMV) (Brito et al., 2012; Putnam, 2016). This particular virus can damage the plant structure. Soybean plant infected by CpMMV undergoes leaves spotting, chlorosis, and malformation (Tavasoli et al., 2009; Salaudeen and Aguguom, 2014). The damage to plant structure influences the physiology and metabolism of the plant. The damage to the soybean leaf structure can change the leaf function and the quality, as well as the productivity of soybean Brito et al. (2012).

The efforts to minimize the CpMMV attack carried by *B. tabaci*Genn. have frequently been conducted. One of the efforts is repairing the plant variety. Nowadays, many soybean lines are resistant to CpMMV (Zubaidah et al., 2010). This effort should be continued by fertilizing so that the quality of the soybean line increases. The dose of fertilizer should be adequately applied to streamline the use of fertilizer and maximize productivity. One of the elements needed by the soybean plant in the significant amount

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60696085

is potassium (K) since its role is essential for plant growth (Hopkins, 2004; Sczerba et al., 2009).

Potassium (K) is a macromolecule contained in the soil. The high need for the plant to this element can be fulfilled by applying fertilizer containing K until this particular element can be used well by the plant. The use of K influences much to the plant. The role of K is, for example, increasing enzyme activation, reducing the loss of transpiration water through the set of stomata, increasing the production of ATP, helping assimilate translocation, increasing N absorption and protein synthesis, assisting in balancing carbohydrate and protein, increasing the efficiency of photosynthesis process (Marschner, 1995; Pettigrew, 2008), increasing the plant length and plant production (Hamouda et al., 2015), repairing the destructed tissue (Zain and Ismael, 2016), increasing the efficiency of the use of water (McKenzie and Pauly, 2013). K also has a role in strengthening the cell wall, and it is involved in the process of sclerenchyma tissue lignification so that it can enhance the plant resistance to a particular disease (Baiea et al., 2015).

The plant uses K in physiology and metabolism processes. The appropriateness of the use of K dose based on the plant need can streamline the plant's physiology process that will have a positive impact on plant productivity. K determines the resistance, quality, and productivity of the plant by noticing the dose based on the need (Magen, 2008; McKenzie and Pauly, 2013). Plant productivity is in the form of agronomical traits produced. Some agronomical characteristics can be observed such as plant height (Farhad et al., 2010), number of branches, number of total pods per plant, the weight of 50 seeds, number of filled pods, number of unfilled pods, total seeds per plant, the weight of seed per plant, days to flowering, and days to maturity (Magen, 2008; Hamouda et al., 2015), number of reproductive nodes and number of leaves (Baiea et al., 2015). This research was done by using the variation of K dose for soybean genotype attacked by *B. tabaci* so that the response to the plant's agronomica traits can be known.

Methodology

Place and Time of Study

The research was conducted in Kendalpayak Research Station, Indonesian Legume, and Tuber Crops Research Institute, Malang, Indonesia, in November 2016 until January 2017. The preparation was done by filling the soil into a polybag after the soil was dried, sieved, and mixed with manure. The soil used was Entisol soil type. Four seeds of soybean were planted in every polybag and treated based on the fertilizer dose that had been determined. The plant was grown in an open-air condition. The watering and weed cleaning was done once a week until the soybean plants were harvested. The soybean plant is ready to harvest if the pods become yellow or brownish.

Research Design

This research used a randomized complete block design with three replications to analyze the response of the soybean genotype attacked by *B. tabaci.* Soybean genotypes used were UM.4-1, UM.7-2, UM.2-4, UM.7-6, UM.6-2 genotypes, and two check varieties of Gumitir and Wilis. These lines were used as the first factor. The treatments of K dose were K0= 0 g/kg, K1= 0.0278 g/kg, K2= 0.0550 g/kg, and K3= 0.0830 g/kg was used as the second factor. The K was from KCl fertilizer. The basal fertilizing was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60696085

also conducted by using 0.0363 g of nitrogen (N)/kg and 0.0917 g of phosphate (P)/kg in order for the plant can grow optimally. The chemical properties of the soil before the treatments applied are presented in *Table 1*.

Table 1. *Soil chemical properties before treatment were applied*

Soil chemical properties	Value
N (%)	0.08
P_2O_5 (ppm)	188.00
K (Cmol/kg)	0.26
pH	6.70

Data Analysis

The observation was done to the agronomical traits of soybean plant including plant height, number of branches, pod length, pod width, pod thickness, number of filled pods, number of unfilled pods, number total pods, number of reproductive nodes per plant, seed length, seed width, seed thickness, seed weight per plant, the weight of 50 seeds, days to flowering and days to maturity. The digital screw micrometer was used to measure pod length, pod width, and pod thickness, as well as seed length, seed width, and seed thickness after soybean was harvested. The data were analyzed with ANOVA by using SPSS 7.0 program; if the result showed a significant relationship, the LSD test was then conducted.

Results and Discussion

Variations of K fertilizer doses have a different effect on the resistance to the honeydew. The honeydew attack was analyzed, and the results are presented in *Figure 1*. *Figure 1* shows that the K0 dose resulted in the lowest percentage value of the resistance compared to the other doses. This case means that by applying this dose, the soybean became the plant that was most resistant to the honeydew. Honeydew is a secondary metabolite produced by *B. tabaci*. The resistance of the soybean plant by K0 dose was not significantly different from the K2 dose condition. The other doses, such as K1 and K3 doses, resulted in the highest percentage value compared to the other doses; it means that the resistance level was lack (almost close to the slightly resistant category). However, the percentage value resulted was still categorized as resistant. This case shows that the K dose getting higher does not always affect the soybean plant resistance since it is influenced by the other factors as well.

The different response of soybean lines attacked by *B. tabaci* was indicated by the interaction between the soybean lines and variations of K dose affecting significantly to such 12 variables as the plant height, pod length, pod width, pod thickness, number of filled pods, total pods per plant, number of reproductive nodes, seed width, seed thickness, the weight of 50 seeds, days to flowering and days to maturity ($p>0.05$).

Agronomical traits of the plant determine the quality and productivity of the plant. The following sixteen aspects were observed to determine the response of the plant to the fertilizer. The different influence was shown in the use of genotype, fertilizer, and interaction of both of them to the agronomical traits observed. The analysis of variance is presented in *Table 2*.

UM.2-4 with K3 dose showed the longest days to flowering compared to the other doses. However, the K3 dose that with UM.7-2 and 7-6 lines showed the shortest days to flowering compared to the other doses to these lines. UM.4-1 and 6-2 lines flowered quickly after giving K1 dose. A variety of Gumitir flowered quickly by giving K0 dose. Meanwhile, a variety of Wilis flowered quickly after giving K2 dose (*Figure 2*). The speed of days to flowering of a plant is influenced by the plant's metabolism and biochemistry processes. K of a plant increases the plant growth parameter; one of them is flowering initiation (Awon et al., 2012).K can influence the optimum metabolism of the plant so that it can initiate the flowering (Hawkesford et al., 2011). The accuracy of the dose used is the critical factor that should be taken into account. Too much or too little dose can decelerate the flowering process of the plant (Manoj Kumar et al., 2013).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60696085

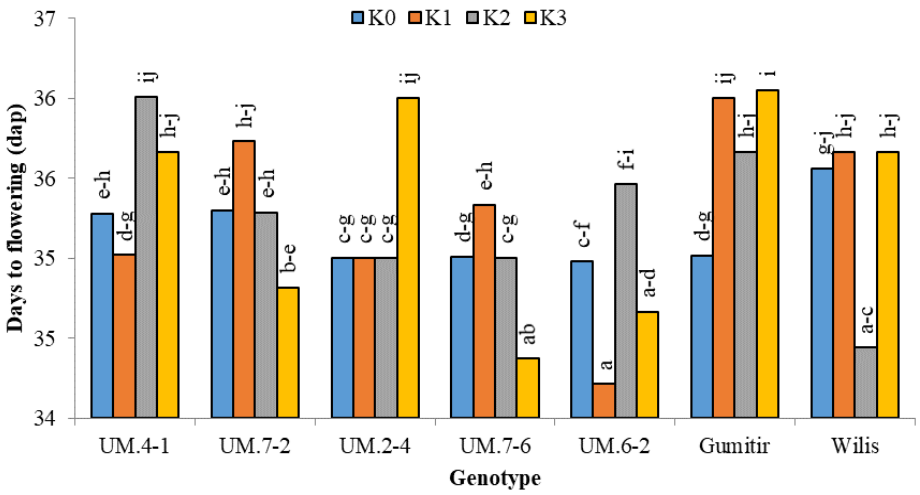

Figure 2. *Interaction of genotype × fertilizer to the days to flowering. Note: dap=day after planting*

The UM.7-2 line with K3 dose produced soybean with the quickest days to maturity compared to the other interactions. Days to maturity in the other interactions (besides UM.7-2 line with K3 dose) showed an insignificant difference (*Figure 3*). The plant growth process determines the speed of days to maturity of the plant. K determines the optimal metabolism performance to initiate the maturity/crop ripening (Hawkeford et al., 2011). If the plant can grow and develop well, absorb and utilize the nutrition optimally; it can do the metabolism process optimally, and the plant can grow and produce its product optimally. Days to maturity is determined by the character shown by the plant (Manoj Kumar et al., 2013). In soybean plants, if the pods become tawny, it means that the plant is ready to harvest.

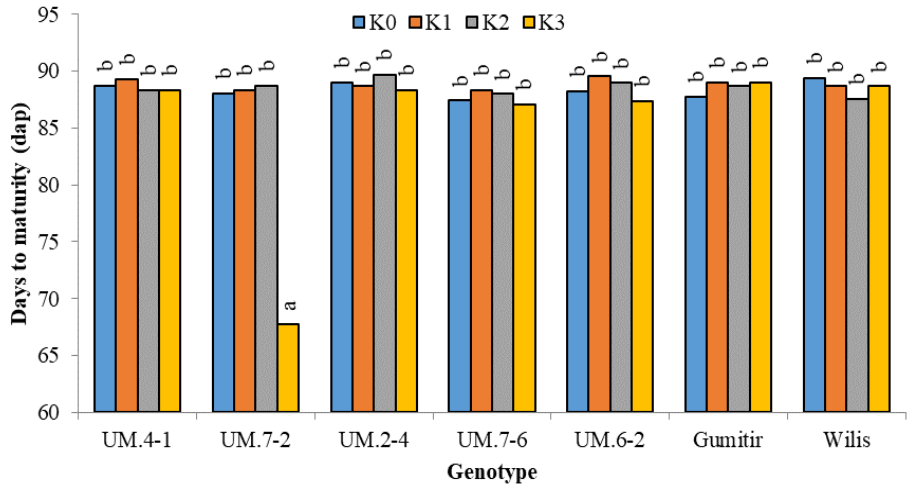

Figure 3. *Interaction of genotype × fertilizer to the days to maturity*

The result of the analysis of plant height showed that the UM.6-2 line with K0 dose produced the highest plant, but when it was K3 dose, it produced the shortest plant. On the contrary, the UM.4-1 line produced the highest plant when applied with K3 dose

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60696085

and produced the shortest plant when at K0 dose. Variety of Gumitir showed that the higher the K dose, the plant growth was getting higher as well. The highest plants were in UM.7-2 and 7-6 lines after they were applied K0 dose. Meanwhile, in the UM.2-4 line and the variety of Wilis, the highest plant was produced at the K3 dose (*Figure 4*). K dose and genotype influenced the soybean plant height. The optimum plant height can be reached by giving fertilizer based on the need for soybean genotype. The accuracy in determining the fertilizer dose supports the growth of maximum plant height (Farhat et al., 2010; Yaqoub et al., 2015). A plant needs fertilizer as the nutrition supply; besides, it gets the nutrition from the soil. One of the elements contained in the fertilizer in the treatment is K. K influences the growth and process as well as the metabolism of the plant (Marschner, 1995), including the increase of fission and cell lengthening (Pal et al., 2016). The plant that is growing with an optimum height is one of the direct effects of giving K (Manal et al., 2016). This case was caused by the fulfillment of nutrition needed by the plant by absorbing it from the soil (Xiang et al., 2012). The research results showed that K0 and K3 doses have contributed to influencing the soybean plant height in any genotypes and varieties used. Thereby, we can know that both doses were fitting to the need of some soybean genotypes in initiating the growth of plant height.

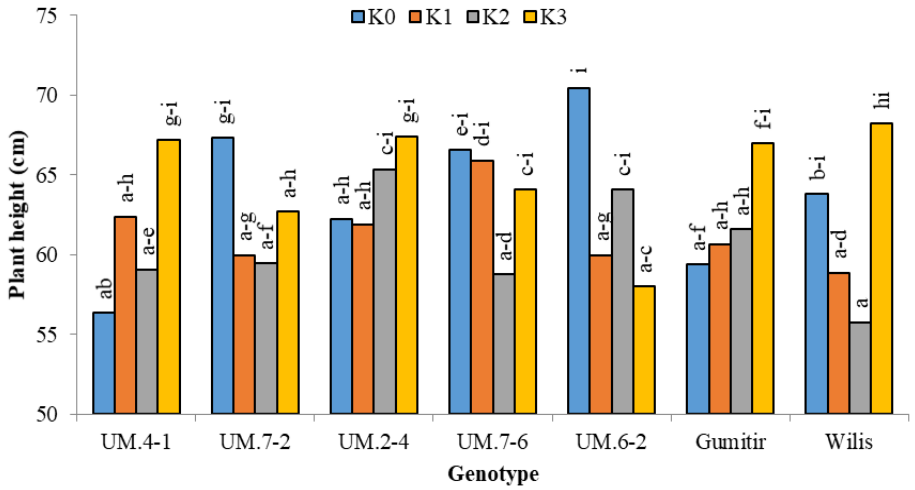

Figure 4. *Interaction of genotype × fertilizer to plant height*

The UM.2-4 line that was applied K1 dose produced soybean with the highest number of reproductive nodes compared to several reproductive nodes resulted from giving the other doses. Giving K1 dose to the UM.7-2 line also resulted in the highest number of reproductive nodes. However, Gumitir with K1 dose resulted in the smallest number of reproductive nodes instead since the highest number of reproductive nodes of this variety was produced in UM.4-1. Another dose like K0 on the UM.6-2 line and the variety of Wilis produced the most significant number of reproductive nodes. Meanwhile, if the K0 dose with UM.7-2, 2-4, and 7-6 lines, they produced the smallest number of reproductive nodes (*Figure 5*). A number of reproductive nodes of a particular plant are closely related to the plant height. Plant height has more areas that can initiate the growth of reproductive nodes rather than the short plant. Thereby, it can be said that higher the plant, the number of reproductive nodes produced will be higher

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60696085

as well (Sutrisno and Kuswantoro, 2016).In producing an optimum and high plant, a plant needs sufficient nutrition to facilitate the metabolism process and the growth of the plant. The same thing should be done in forming the reproductive nodes of the plant as well. Giving the right dose of K is related to the nutrition absorption process needed by the plant (Beg and Ahmad, 2012) so that it can support the optimum growth of the reproductive nodes. The fulfillment of K and nutrition required to do the metabolism process can result in the character related to plant productivity.

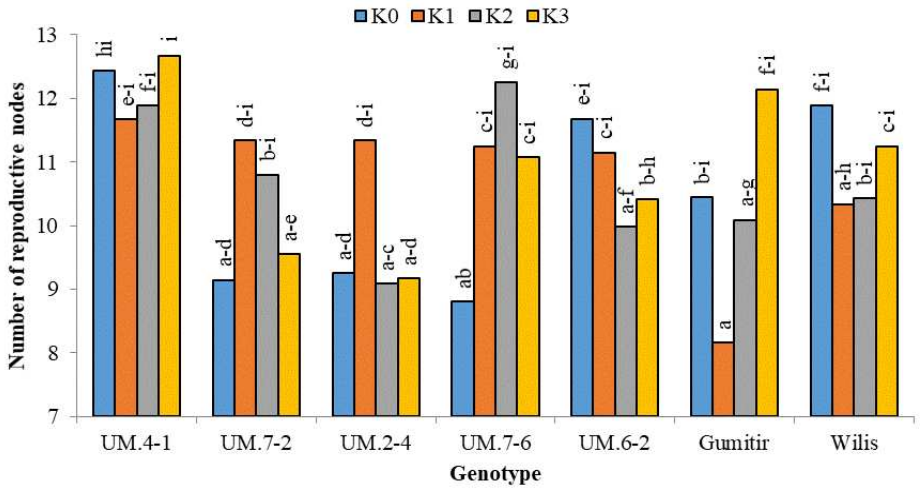

Figure 5. *Interaction of genotype × fertilizer to a number of reproductive nodes*

Figure 6 shows that the UM.2-4 line with K1 dose produced the highest total pods compared to the other treatments. A variety of Gumitir with K1 dose resulted in the smallest number of total pods per plant since the highest number of the total pods had resulted from the K3 dose. In the UM.6-2 line, K0 dose could produce the highest number of total pods per plant, and this condition was similar to the variety of Wilis and UM.4-1line. However, UM.7-2 and 7-6 lines with K0 dose produced the smallest total pods instead. *Figure 4* shows that UM.2-4 lines with K1 dose produced the highest total pods compared to the other doses.

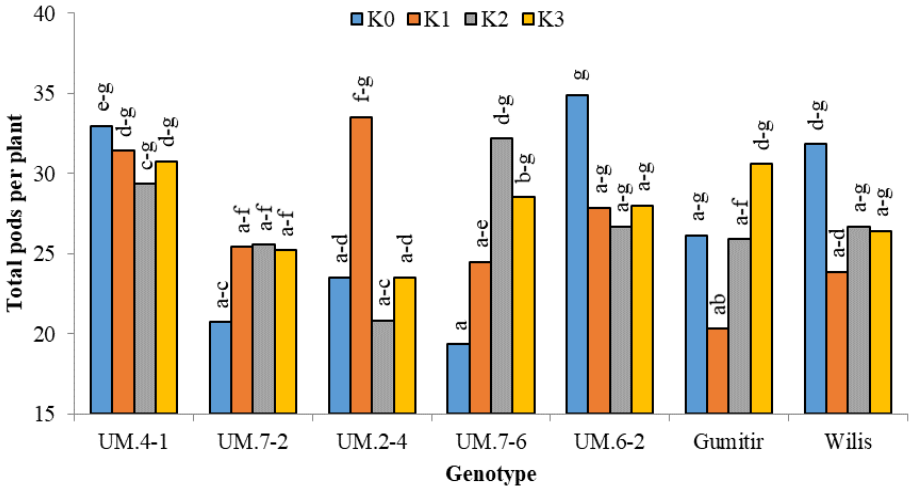

Figure 6. *Interaction of genotype × fertilizer total pods per plant*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60696085

Meanwhile, in the variety of Gumitir, K1 dose produced the lowest total pods per plant since the highest total was resulted after applying K3 dose. In the UM.6-2 line, K0 produced the biggest number of total pods per plant, and it was similar to the variety of Wilis and UM.4-1 lines. UM.7-2 and 7-6 with K0 dose produced the smallest total pods. K3 dose resulted in the biggest total pods only in UM.7-6 line (*Figure 6*). The total pods per plant are correlated to the number of reproductive nodes of a certain plant (Chakma et al., 2015). A large number of reproductive nodes of a certain plant can maximize the growth of pods of soybean plants. The pod is the product of assimilating the storage of the photosynthesis process. Total pods per plant are influenced by the maximum growth and metabolism of the plant. The optimum growth is realized in forming the pods produced by the plant (Xiang et al., 2012).In the growth process, the soybean plant needs nutrition, and it can get the nutrition from the soil or the fertilizer. Total pods will increase in the plant with K with the dose matched with the need for the plant (Chauhan et al., 2013). The appropriateness of K dose is related to the efficiency of its use in the metabolism and biochemistry processed in the plant. The dose that is needed in the various genotypes is based on the need of each soybean genotype.

K0 on to UM.6-2 line and the variety of Wilis, and these lines had the biggest number of filled pods compared to other doses. Meanwhile, UM.7-2 and 7-6 lines had the smallest number of filled pods if they were applied with K0 dose. Both lines resulted in the highest number of filled pods after giving the K2 dose. However, K2 dose caused the lowest number of filled pods in the UM.4-1 line. Meanwhile, UM.2-4 line with K1 had the highest number of filled pods compared to the other dose variations. This case contrasted with the variety of Gumitir with the lowest number of filled pods if applied with a K1 dose (*Figure 7*). A number of filled pods produced showed the plant productivity. Some pods filled seed (filled pod) and unfilled seed (unfilled pod). Soybean plant will be more productive if the number of filled pods is more than the number of unfilled pods. The effectiveness of photosynthesis and assimilate translocation processes in the plant influences number of filled pods (Liesche, 2016). The optimum process is supported by the maximum absorption of nutrition done by the plant (Chakma et al., 2015). K is one of the nutrition needed by the plant. The fulfillment of K within the plant can maximize the assimilate translocation process so that there are many filled pods produced. K as the fertilizer for a plant can increase plant productivity in creating the filled pods (Hussain et al., 2011).

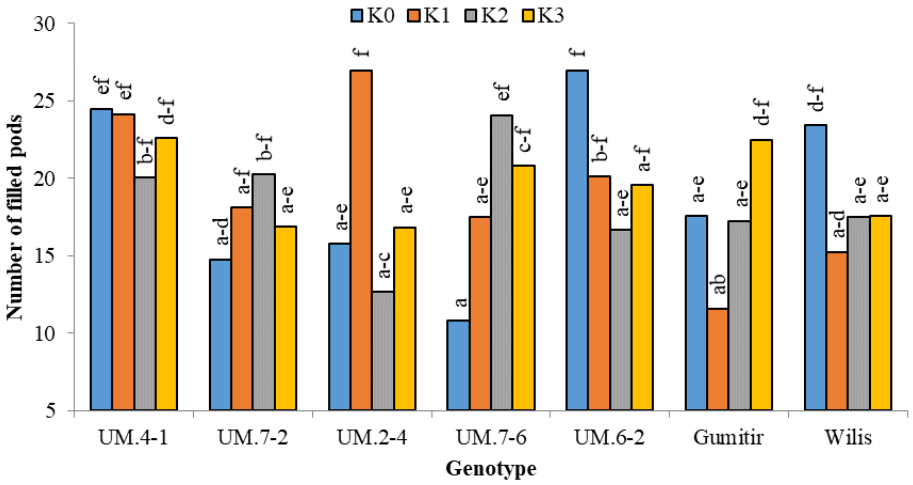

Figure 7. *Interaction of genotype × fertilizer to number of filled pods*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60696085

UM.7-6, 4-1, and 2-4 lines that were applied with K1 dose produced the longest soybean pod. However, K1 dose produced the shortest soybean pod on Gumitir and Wilis. In the UM.7-2 line, K0 dose produced the longest pod compared to the other doses. However, this particular dose produced the shortest pod in UM.7-6 and 6-2 lines (*Figure 8*). The soybean pod produced is one of the plant productivities. Productivity is the result of optimum growth since the need for nutrition can be well fulfilled. The optimum absorption of K supports the growth of the soybean plant so that it can result in the intended productivity (Abbasi et al., 2014). Seed size filled within the pod influences the pod length. This case is closely related to the process of pod filling, forming the filled pod, which is assimilating the translocation process. K helps to optimize the plant assimilate translocation.

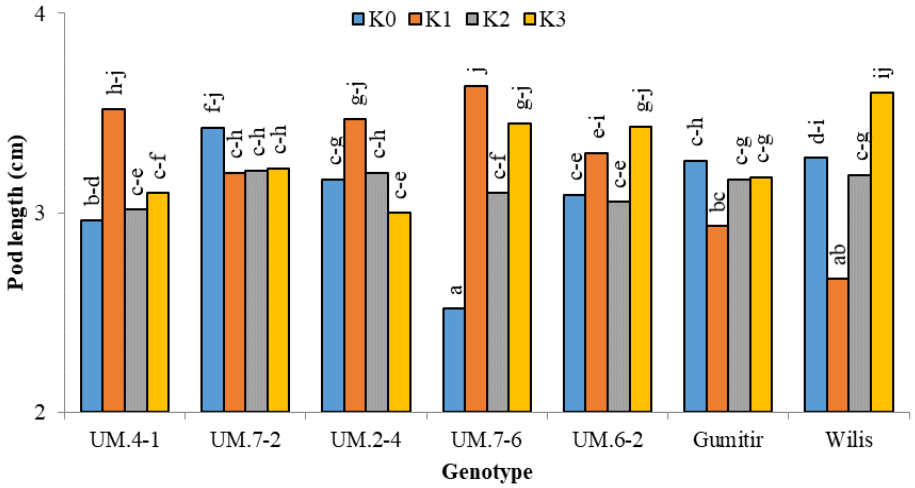

Figure 8. *Interaction of genotype × fertilizer to pod length*

The results showed that in UM.7-6 and 7-2 lines, K0 dose produced the widest soybean pod compared to the other doses. Meanwhile, in the variety of Gumitir, the widest pod was produced after givingK3dose. It was different from the UM.6-2 line, which produced the widest pod after giving K0 and K3 doses. In the other lines, like UM.4-1, 2-4, and variety of Wilis, the difference of pod width resulted did not show a significant difference (*Figure 9*). The soybean plant productivity, as indicated by the pod width, produced as well. The optimum growth is fully supported by the availability of nutrition needed in metabolism and photosynthesis processed. The proper K dose can optimize soybean plant growth (Chen et al., 2007). It was the same with the length and width of soybean pod; they were influenced by the seed size filled within the pod as well. Thereby, the optimum assimilate translocation process truly determines the pod produced with the maximum width. This process can be maximized by fulfilling the need for K in the plant, based on the need of each genotype.

The less the K dose, the pod produced would be thicker in the UM.2-4 line. UM.7-2 line and variety of Wilis with K0 dose also produced the thickest pod. However, in UM.4-1, 6-2, and variety of Gumitir, the thickest pod resulted from K3 dose. The lowest dose resulted in thin pods like those in UM.4-1, 7-6, and 6-2 lines. K1 dose produced the thickest pod in the UM.7-6line. However, this dose produced the thinnest pod in UM.7-2line, the variety of Gumitir and Wilis (*Figure 10*). The thickness of the pod

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60696085

produced is correlated to the seed-filled within the pod. The seed quality is obtained from the effectiveness of assimilating translocation from the photosynthesis result by fulfilling the K dose needed by the plant. The photosynthesis process's effectiveness supports the effectiveness of assimilating translocation influencing plant productivity (Yooyen et al., 2015).

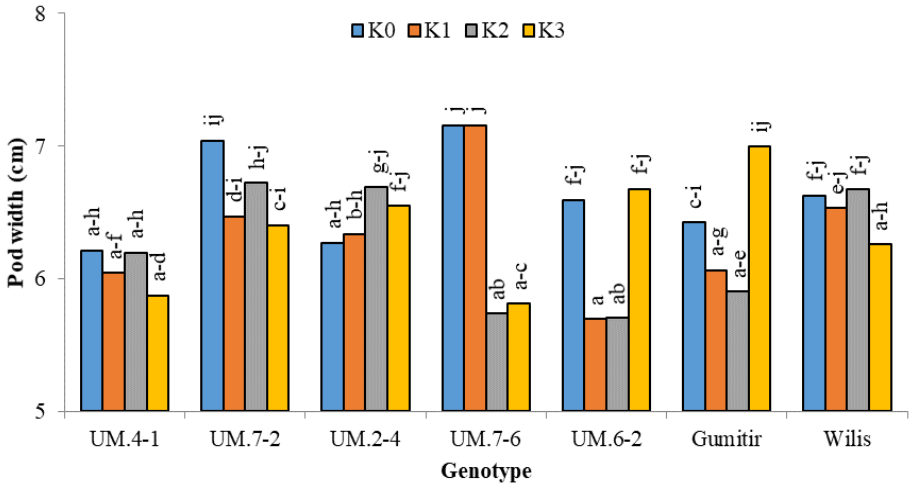

Figure 9. *Interaction of genotype x fertilizer to pod width*

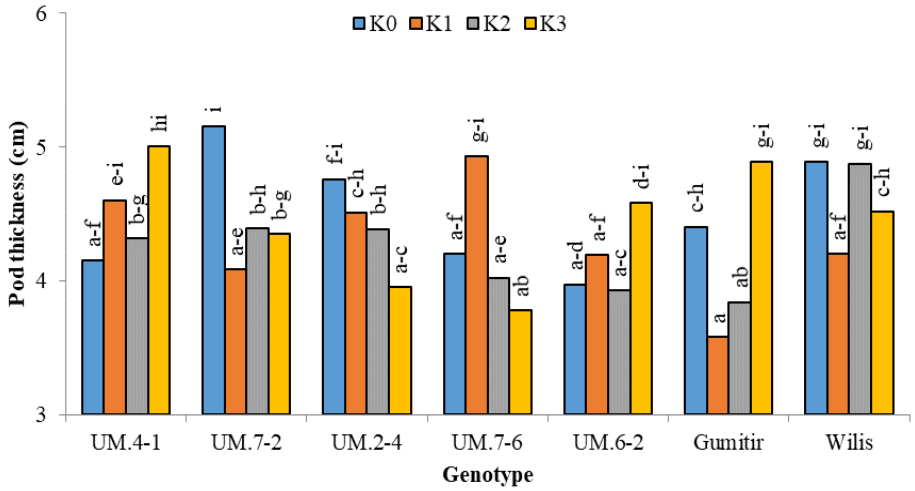

Figure 10. *Interaction of genotype × fertilizer to pod thickness*

The higher the K dose, the seed produced in the UM.2-4 line would be wider as well. K3 dose produced the widest seed in the variety of Gumitir. Meanwhile, in UM.4-1, 7-6, and 6-2 lines, the widest seed was produced after givingK1dose. Besides, the other doses like K0 dose produced the widest seed only in the variety of Wilis (*Figure 11*). The seed width influences plant quality and productivity. The seed is produced by the assimilate translocation as the result of photosynthesis (Ayub et al., 2012). The higher the dose, it will be in line with the productivity resulted (Chakma et al., 2015). Some factors influence the production of seed as the result of plant productivity; one of them is the use of fertilizer. Giving the various doses of K to the plant can initiate the forming

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60696085

of seed optimally (Khan et al., 2007; Hosinkhani et al., 2013). The optimum seed is indicated by the thick and wide seed to maximize the plant product and show the effectiveness of the plant productivity.

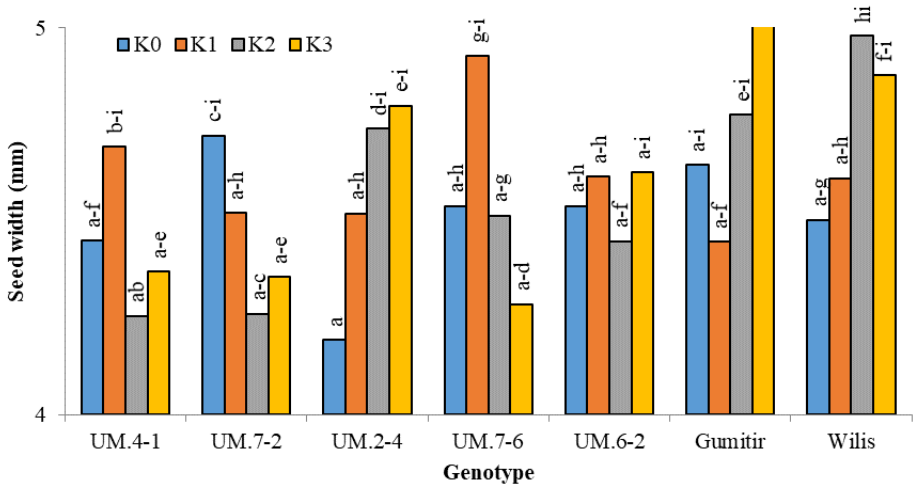

Figure 11. *Interaction of genotype × fertilizer to the seed width*

The UM.2-4 line showed that the higher the K dose, the seed produced would be thicker. UM.6-2line and variety of Gumitir with K3 dose produced the thickest soybean. However, UM.7-2line produced the thickest seed after giving K0 dose. Besides, the other doses, like K1 dose, gave optimum results in the form of thick seed in UM.4-1 and 7-6 lines while K2 dose was optimum in the variety of Wilis (*Figure 12*). The thick seed showed optimum plant productivity. The optimum productivity can be reached by considering the K (Mahadik and Chpde, 2015). The productivity is supported by the increase in photosynthesis and assimilate translocation (photosynthate) to produce the crop. K can increase seed productivity resulted from the soybean plant (Asri and Sonmez, 2010). The dose based on the need for the plant can maximize plant productivity. One of the productivity results is the optimum size of the soybean seed.

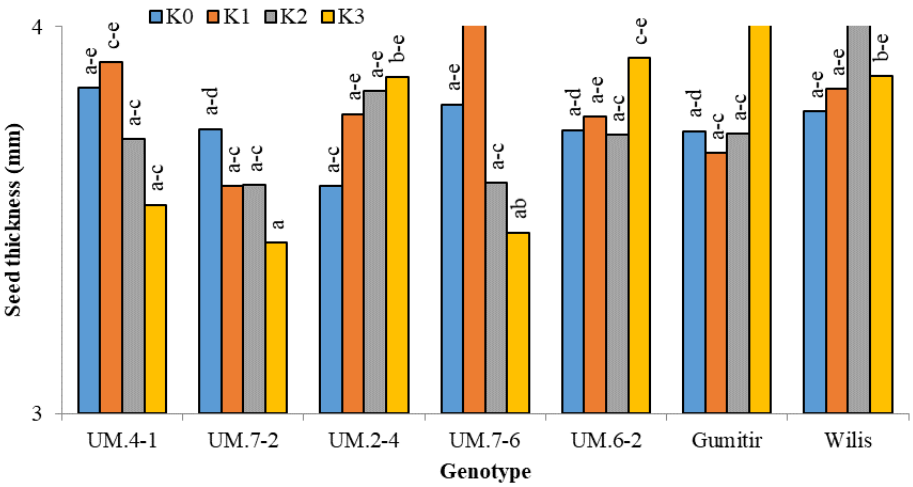

Figure 12. *Interaction of genotype × fertilizer to the seed thickness*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60696085

The results showed that a variety of Wilis, UM.7-2, and 6-2 lines with K0 dose produced the soybean with the heaviest weight of 50 seeds. However, the UM.2-4line that was applied with K0 produced the soybean with the lightest weight of 50 seeds. K2 dose with UM.4-1 line and variety of Gumitir caused the heaviest weight of 50 seeds. However, in a variety of Wilis, K2 dose produced the lightest weight. The UM.2-4 line produced the heaviest weight of 50 seeds when at K1 dose.

On the contrary, when this dose with UM.7-2, 7-6, and 6-2 lines, they produced the lightest seed (*Figure 13*). The maximum photosynthesis and assimilate translocation processes had produced the thick and wide seed with the highest weight of 50 seeds. If those processed were not optimal, the weight resulted would be low. The photosynthesis and assimilate translocation processes were influenced by K supporting the growth and metabolism processes (Weerahewa and David, 2015). Fertilizing by using K can increase the assimilate accumulation so that it increases the plant product as well (Calvante et al., 2015). The plant product was in the form of soybean seed. K is the most effective nutrient in maximizing photosynthesis and photosynthate translocation to increases the weight of the product (Yassen et al., 2010). The increase of plant products can be indicated by the quality of the product resulted. The weight of 50 seeds was influenced by seed thickness and seed width. The thick and wide seed is the result of the intended productivity with high quality. K, in the planting process, influences the quality of the plant product (Dawood et al., 2014; Zhao et al., 2015).

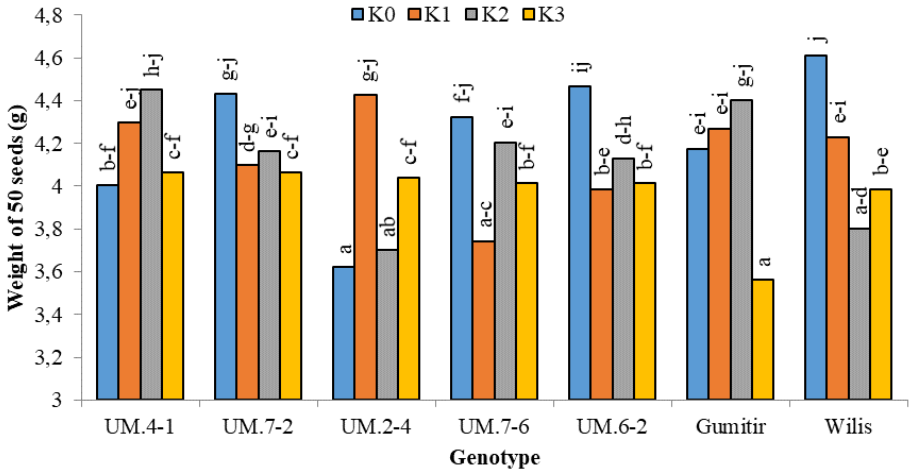

Figure 13. *Interaction of genotype × fertilizer to the weight of 50 seeds*

The responses shown were the effect of giving K to the soybean plant attacked by *B. tabaci*. Fulfilling the need for potassium (K) streamlines its use in influencing the metabolism process (Pettigrew, 2008), and maximizes the plant productivity (Hamouda et al., 2015). The soybean plant productivity was produced from the effectiveness of physiology and biochemistry processes. K is very significant for and needed by the plant. K is available within the soil naturally, and it can be provided by giving fertilizer. The plant absorbs the K within the soil through the transport mechanism of K related to and influences the other mechanisms like water transport (Sczerba et al., 2009) and maintains the cell turgidity that also maintains the leaf form. This case is closely related to the photosynthesis process. The turgid cell can produce the normal shape of the leaf

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60696085

so that it can maximize the photosynthesis process (Hopkins, 2004). Photosynthesis produces assimilation that should be translocated from the leaf to the other parts of the plant, such as root, stem, and it will be stored in the food storage. Assimilate translocation can occur optimally if the K dose is appropriate (Calavante et al., 2015; Al-Shaheen et al., 2016). The optimally assimilate translocation can maximize plant growth, influence plant height, the number of reproductive nodes, influencing total pods so that it is stored in the food storage like seed and pod. The quality of seed and pod is influenced very much by the optimally assimilate translocation. In this research, the assimilate translocation was optimal and able to produce long, wide, and thick pods, also thick and wide seed with some filled pods and total pods per plant as well as the weight of 50 seeds.

All research results of each line showed the different responses of every dose. This case was influenced by the genotype, environment (Thilakarathna and Raizada, 2015), the dose in a planting process (Hellal and Abdelhamdi, 2013), and the soil condition (McKenzie and Pauly, 2013). Therefore, a soil test should be done to optimize the use of potassium dose in every variety and reach the intended product (FAO, 2000). This case is because the appropriateness in determining the dose used will influence productivity (Kuswantoro, 2017).

The relationship among the agronomical traits is known by using correlation-regression analysis. The analysis results are presented in *Table 3*.

Table 3. *The Relationship among Agronomical traits*

DF= days to flowering, NUP = number of unfilled pods, DM = days to maturity, TPP = total pods per plant, PH = plant height, NRN = number of reproductive nodes, NBMS = number of branches of the main stem, SL = seed length, PL = pod length, SW = seed width, PW = pod width, ST = seed thickness, PT = pod thickness, W50 = weight of 50 seeds, NCP = number of filled pods, SWPP = seed weight per plant, SM = honeydew

The results showed that there was a significant correlation between some variables. A number of filled pods is related to total pods per plant with a value of 0.973, meaning that if the number of filled pods is getting higher, total pods per plant will be higher as well. The correlation test score between the number of filled pods and number of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60696085

reproductive nodes per plant was 0.845; so there was a significant correlation; if the number of total pods is getting higher, the number of reproductive nodes will increase as well. A large number of reproductive nodes can maximize the pod growth produced in a certain plant (Chakma et al., 2015). This case is influenced by many factors, such as the availability of water and the line of plant type planted (Kuswantoro, 2017).

The number of filled pods is also closely related to seed weight per plant with a score of 0.766. This phenomenon is because the number of filled pods is the form of productivity that resulted from a particular plant. If filled pods produced increase, seed weight per plant would increase as well (Xiang et al., 2012). A large number of filled pods should be continued by the increase in seed and pod size to produce seed weight per plant that significantly increases (Kuswantoro et al., 2014). This phenomenon is because a large amount of filled pods does not always produce seed weight per plant if the seeds produced have a small size.

Total pods per plant were closely related to a number of reproductive nodes with a score of 0.858. It means that the higher total pods per plant produced, the number of reproductive nodes is getting higher as well. The correlation test between total pods per plant and seed weight per plant revealed a score of 0.738. It showed a significant correlation meaning that the higher the total pods per plant, seed weight per plant is getting higher as well. This phenomenon is because the number and weight are in line due to the positive correlation. The number of reproductive nodes is significantly correlated to seed weight per plant with a score of 0.675, meaning that a higher number of reproductive nodes, seed weight per plant, is getting higher .

The three aspects, such as the number of reproductive nodes, number of total pods per plant, and seed weight per plant, showed a significant correlation. This case is because the reproductive nodes are the first spots of soybean pod revealing (Chakma et al., 2015). Reproductive nodes are commonly found in the stem and main branch (Kuswantoro, 2017). This thing determines a large number of pods per plant produced by soybean plants. The number of reproductive nodes is related to several filled pods produced by the soybean plant (Kuswantoro, 2017). Thereby, it will be able to influence seed weight per plant produced as well.

The results of the correlation test between seed length and seed width, seed length and seed thickness and seed width, and seed thickness were 0.754; 0.696; and 0.837, respectively. This case means that there was a significant correlation between seed length and seed width, seed length and seed thickness, and seed width and seed thickness. The longer seed produced, the seed will be wider and thicker as well. Seed length, seed width, and seed thickness influence the quality and productivity resulted (Ayub et al., 2012). The seed is a significant product of the effectiveness of assimilates translocation done by the plant. The seed size is an essential thing in influencing plant productivity. This case is because the seed size determines the seed weight per plant produced directly (Kuswantoro, 2015).

The result of the correlation test also showed a significant correlation between some other variables. Pod width is correlated to seed length and seed thickness with the scores of 0.521 and 0.505, respectively. Pod thickness is also correlated to seed length, which was 0.501. This case means that the wider pod, the seed within it will be longer and thicker as well. The long and thick seed produces the wide seed directly so that it is said that seed is optimally produced (Ayub et al., 2012). Thereby, the wide and thick pods are needed to cover the seeds resulted from the soybean plant.

DOI: http://dx.doi.org/10.15666/aeer/1805_60696085

Conclusions

Interaction (genotype x fertilizer) affected many aspects such as plant height, pod length, pod width, pod thickness, number of filled pods, total pods per plant, number of reproductive nodes, seed length, seed weight, and seed thickness, the weight of 50 seeds, days to flowering, and days to maturity. Optimal results were obtained if the dosage is given according to the needs of each soybean genotype. The potassium affected plant height and pod length. The increasing level of potassium leads the pest severity to increase.

Acknowledgments. We gratefully thank Kemenristek BRIN for the Higher Education Basic Research grant funding. We would also like to Bapak Udin (the laboratory staff at UM), Endrik Nur Rohman, Nur Lina Safitri, and Dyah Kusuma Wardhani Syabikhisma Arsy for their valuable contribution to the study.

Abstract. The objective of this study was to determine the effect of *Ecklonia maxima* extract on monosaccharide, structural and non-structural carbohydrate as well as lignin contents in two *Lolium perenne* cultivars against the background of a varied nitrogen fertilisation regime. A field experiment was arranged as a randomised sub-block design (split-split-plot) in Poland. The following factors were examined: biostimulant Kelpak SL applied at 2 $dm^3.ha^{-1}$ and a control (no biostimulant addition); nitrogen application rates of: 0, 50, 100 and 150 kg ha^{-1}; cultivars of *Lolium perenne:* Diament and Gagat. The research reported here demonstrated positive effect of *Ecklonia maxima* extract on *Lolium perenne* chemical composition. Its results showed that structural carbohydrate and lignin contents in grass biomass may be reduced whereas non-structural carbohydrate content may be increased by means of an application of sea alga extract, which results in an improved quality of feed produced from these grasses. The biostimulant applied in combination with each nitrogen rate significantly increased the concentration of monosaccharides and non-structural carbohydrates, and reduced the concentration of structural carbohydrates and lignin in *Lolium perenne* biomass. Increasing nitrogen rates significantly increased cellulose, hemicellulose and lignin contents but they reduced amounts of monosaccharides and non-structural carbohydrates in the test grasses.
Keywords: *Kelpak, biostimulant, fertilisation, grass, monosaccharides, cellulose, hemicellulose, non-structural carbohydrates*

Introduction

As the reliance of agriculture's on chemicals (mineral fertilisers, plant protection agents) may negatively affect both food quality and the natural environment, innovative solutions have been increasingly sought (Niewiadomska et al., 2020). Due to this, in order to reduce such reliance, an alternative solution in the form of natural preparations, which include biostimulants, used as fertilisers is gaining more and more popularity all over the world (Colla and Rouphael, 2015; Sosnowski et al., 2016; Kocira et al., 2018a). An application of natural growth regulators may become one of components of modern agricultural practice. Scientific literature claims that these preparations are environmentally friendly, beneficially affect yield quality and quantity (Godlewska and Ciepiela, 2016; Caruso et al., 2019), and frequently eliminate a large part of biotic and abiotic stress (Rathore et al., 2009; Haider et al., 2012; Sharma et al., 2014). Simultaneously, an application of biostimulants may prove to be economically viable (Rengasamy et al., 2015). Sea algae extracts (division of green, red and brown algae) are biostimulants which have become quite popular in crop plant production (Du Jardin, 2015). *Ecklonia maxima*, a brown alga, is harvested off the coast of South Africa and along the Atlantic coast of Africa. Large amounts of this seaweed are deposited on the seashore, which results in environmental pollution. When collected, the organic matter

DOI: http://dx.doi.org/10.15666/aeer/1805_60876097

may be utilised to produce the preparation called Kelpak which, in addition to plant hormones (cytokinins (0.03 mg/l) and auxins (11 mg/l), gibberellins, abscisic acid, brassinosteroids), contains polysaccharides (absent in terrestrial plants), amino acids, polyphenols as well as macro- and microelements (Strik et al., 2004; Papenfus et al., 2012; Rengasamy et al., 2015; Rauphael et al., 2017).

Although literature reports claim that sea algae extracts display a positive effect on many species of cultivated plants, the influencing process of those extracts have not be fully understood yet. The effect of biostimulants may, to a great extent, depend on the plant species and cultivar (Sultana et al., 2005; Battacharyya et al., 2015). There is still a paucity of information on an application of biostimulants to meadow plants.

The objective of this study was to determine the effect of *Ecklonia maxima* extract on monosaccharide, structural and non-structural carbohydrate as well as lignin contents in two *Lolium perenne* cultivars against the background of varied nitrogen fertilisation regime.

Materials and Methods

Experimental Design

A field experiment was arranged as a randomised sub-block design (split-split-plot) with three replicates at the Siedlce Experimental Unit of the University of Natural Sciences and Humanities in Poland (52.169° N, 22.280° E) in late April, 2009. The plot area was 10 m^2. The soil of the experimental site represents average soils, Hortic Anthrosol (WRB). Prior to the experiment set-up the characteristics of the soil were as follows: neutral pH (pH in 1n KCl = 7.2), high humus content (3.78%), high available phosphorus and magnesium contents (P_2O_5 - 900 $mg.kg^{-1}$, Mg - 84 $mg.kg^{-1}$) and average total nitrogen and available potassium contents (N - 1.8 $g.kg^{-1}$ DM, K_2O - 190 $mg \cdot kg^{-1}$). Soil chemical analysis was carried out at an accredited laboratory of the Chemical and Agricultural Research Laboratory in Warsaw (Poland). Available phosphorus and potassium in the soil were extracted by means of the Egner-Riehm method (Staugaitis and Rutkauskiene, 2012) and available magnesium - using the Schachtschabel method (Staugaitis and Rutkauskiene, 2012). Phosphorus was determined by the colorimetric method, total nitrogen by the Kjeldahl method and potassium and magnesium by the atomic absorption spectrophotometry AAS. The following factors were examined:

- biostimulant (sea bamboo extract) with the trade name Kelpak SL applied at 2 $dm^3.ha^{-1}$ and a control (no biostimulant addition);
- nitrogen application rate: 0, 50, 100 and 150 kg ha^{-1};
- cultivars of *Lolium perenne*: Diament and Gagat.

The growth stimulant applied in the experiment is an extract from the fastest growing seaweed (kelp) *Ecklonia maxima* harvested off the coast of South Africa. The extract contains, among others, the natural plant hormones auxins (11 mg $L^{-1}$and cytokinins (0.03 $mg.L^{-1}$). The commercial name of the stimulant is Kelpak SL, and it is manufactured by Kelp Products (Pty) Ltd. P.O. Box 325, Simon's Town, the Republic of South Africa.

The sowing amount of *Lolium perenne* L. variety Gagat and Dukat was calculated on the basis of standards developed by Research Centre for Cultivar Testing (COBORU, 2008). Standard cultivation methods were used in the experiment, and additionally the plants were fertilized with various doses of nitrogen and the Kalpak SL biostimulator.

DOI: http://dx.doi.org/10.15666/aeer/1805_60876097

The grass sowing rate was 38 kg ha^{-1} (TWG - thousand-grain weight – 3.2 g, 1187 kernels per square meter).

In the growing season, when the experiment was set up, neither the nitrogen regime nor the biostimulant were applied. The season was an introductory period when three weed-control cuttings were made. After the second cutting, mineral fertilisation was applied to all the plots at the rates of 30 kg ha N (ammonium nitrate) and 30 kg.ha K_2O (potash salt). Phosphorus was not applied as the soil was rich in available forms of this element. Over the study period (2010-2012), the cutting regime was three harvests per year. Ammonium nitrate was applied three times per year. The total nitrogen amount was split into three equal rates which were applied before each cutting. Phosphorus and potassium needs of the grass were calculated taking into account the expected dry matter yields, the appropriate (from the ruminant nutrition standpoint) mineral contents of hay as well as soil P and K availability.

Phosphorus and potassium fertilisation was applied to all the plots. Phosphorus was applied once as triple superphosphate at a rate of 40 kg ha P_2O_5 in spring. The amount of potassium (160 kg ha K_2O) was split into three equal rates and applied prior to each cutting as 60% potash salt. The biostimulant was sprayed as an aqueous solution; the rate was 2 dm^3 of biostimulant per hectare diluted in water to 400 dm^3. The spraying the rate 2 dm^3 of biostimulant was performed before each cutting: the first application was three weeks before the first cutting, the second one two weeks after the first harvest and the last cutting three weeks after the second harvest.

Weather Conditions

Weather conditions differed during the study period (*Table 1*). Average air temperatures and precipitation sums in all the growing seasons were higher than the long-term means and the precipitation was very unevenly distributed. In 2010 and 2011 rainfall was, respectively, by 115.3 and 80.5 mm higher than the long-term means. It is worth noticing that in July 2011 the precipitation was 4.5 times higher than the long-term mean for July, and it constituted 48% rainfall of the whole growing season. Also in June 2012 precipitation was by 50.5 mm higher compared with the long-term mean for this month. By contrast, high rainfall shortages were recorded in April 2010, September 2011 and 2012.

Chemical Analysis

During harvest of each cut, green matter from each plot (whole area, that is 10 m^2) was weighed to determine the yield, and 0.5 kg green matter samples of grass were taken to determine the drying-up coefficient and to carry out chemical analyses. The samples were left to dry in a ventilated room. Airy dry matter was weighed (to determine dry matter yield per plot) and was then shredded and ground. The obtained material was subjected to chemical analysis to determine dry matter, monosaccharides, cellulose, hemicellulose, lignin, total protein, crude ash and crude fat. The components were determined in powdered dry plant material placed on Petri dishes by near infrared spectroscopy (NIRS) using a NIRFlex N-500 spectrometer and ready-to-use INGOT® calibration applications. INGOT® is a set of Universal NIR calibrations (adapter to the NIRFlex N-500 data format) for the analysis of raw materials and finished products, e.g. grass. Non-structural carbohydrates were calculated following Virkajärvi et al. (2012):

$$\text{Non-structural carbohydrates} = 1000 - (\text{total protein} + \text{crude ash} + \text{crude fat} + \text{cellulose} + \text{hemicelluloses} + \text{lignin}) \quad \text{(Eq.1)}$$

Statistical Analysis

Means presented in tables 2-6 for each factor (biostimulant: N rate; cultivar; cut) and for interactions between these factors were calculated (for each characteristic studied) using all the data for individual experimental combinations obtained in replicates from each cut in all the study years. The data was processed by means of STATISTICA StatSoft, Inc. (2011) (data analysis software system), version 10 (www.statsoft.com). The program was used to conduct variance analysis (ANOVA/MANOVA). Significance of differences between means for the experimental factors was checked using Tukey's test at the significance level of $\alpha \leq 0.05$.

Results and Discussion

The concentration of monosaccharides, structural and non-structural carbohydrates as well as lignin is an important criterion of forage grass assessment. Monosaccharide content in both *Lolium perenne* cultivars (*Table 2*) depended on all the experimental factors. Regardless of the nitrogen fertilisation regime, cuts and cultivars, the sea alga extract significantly increased monosaccharide content in *Lolium perenne* biomass, which improved the forage quality. Kelpak application increased monosaccharide content by 31.8% in cv. Gagat biomass, and by 40.7% in cv. Diament biomass, which indicates that the effect of the biostimulants was cultivar-related. A positive effect of sea algae extracts on the concentration of the discussed compounds in the biomass of various plant species has been confirmed by Pacholczak et al. (2012), Sridhar and Rengasamy (2011) as well as El-Miniawy et al. (2014). The results of the study reported here indicated a significant interaction of the biostimulant with nitrogen rates. The highest increase in carbohydrate content following *Ecklonia maxima* extract application, amounting to as much as 44.3%, was recorded in the biomass of grasses cultivated in the plots without nitrogen fertiliser. In earlier studies, Godlewska and Ciepiela (2013) demonstrated that the biostimulant Kelpak applied to units without nitrogen fertiliser contributed to an average increase of 42.4% in the sugar content in the biomass of orchard grass and *Braun's festulolium.*

Different small letters within the same line indicate significant differences. Values in columns for individual factors indicated with different, capital letters differ significantly

Regardless of the remaining factors, increasing nitrogen rates significantly reduced sugar content in the biomass of the test plants, which has been confirmed by results reported by other authors (Godlewska and Ciepiela, 2018). The highest decline in the *Lolium perenne* content of monosaccharides (by 32.8%, on average) compared with the biomass harvested in the unit without nitrogen fertiliser was recorded at the rate of 150 kg N ha^{-1}.

Analysis of results obtained for successive cuts revealed that grasses harvested with the second and third cut contained significantly less monosaccharides compared with their contents determined in the first cut plants (average across years). It can be explained by the fact that plant respiration and utilisation of these compounds is higher at high temperatures.

Non-structural and structural carbohydrate contents as well as lignin content are species-related and exerts a substantial effect on the quality of produced feed. Both an excess and shortage of these compounds in feed fed to ruminants is not recommended. Kelpak application had the same extent of a positive effect on cellulose, hemicellulose and lignin contents in both *Lolium perenne* cultivars (*Tables 3, 4 and 5*), the contents being by, respectively, 6.64, 8.38 and 8.68% lower in the biomass of these grasses. The differences were statistically significant. The obtained results disagree with research by Kocira et al. (2018b) who applied a natural sea alga extract-based biostimulant and obtained a significant increase in the soybean seed content of lignin. The aforementioned discrepancy may result from the fact that the effect of natural biostimulants heavily depends on their concentration, application method and, first and foremost, crop plant species and cultivar (Sultana et al., 2005).

Different small letters within the same line indicate significant differences. Values in columns for individual factors indicated with different, capital letters differ significantly

An interaction of sea alga extract and nitrogen fertilisation was consistently in the direction of reducing the concentration of structural carbohydrates and lignin in both *Lolium perenne* cultivars treated with the biostimulant at each nitrogen fertiliser rate. The strongest interaction was recorded in the plots fertilised with 150 kg N ha^{-1} where Kelpak application contributed to a decline in the *Lolium perenne* content of cellulose, hemicellulose and lignin (respectively, by 7.79, 14.6 and 9.74%). Unfortunately, it is impossible to refer these results to other reports due to lack of literature on this issue.

Regardless of the remaining factors, nitrogen fertilisation contributed to a decline in the *Lolium perenne* content of the discussed compounds. Cellulose and hemicellulose contents in grass biomass declined as nitrogen rates increased, the differences being statistically significant. Similar tendencies were observed for lignin content but significant differences were found only between lignin content in plants harvested from plots without nitrogen fertiliser, and plants fertilised with the nitrogen rate of 150 kg^{-1} ha^{-1}. According to Szkutnik et al. (2012) as well as Ciepiela et al. (2016), high nitrogen rates contribute to a decline in the grass content of raw fibre, which is consistent with the study results reported here.

The concentration of cellulose and hemicellulose in grasses depended significantly on cuts, and differences in the contents of these compounds in the test grass biomass harvested with individual cuts were significant.

Lolium perenne cv. Diament contained less structural carbohydrates and lignin than cv. Gagat but the differences were statistically insignificant.

Non-structural carbohydrate content in both *Lolium perenne* cultivars as affected by the biostimulant, nitrogen fertilisation and cuts is shown in *Table 6*. Statistical analysis of the study results demonstrated a significant influence of all the experimental factors on non-structural carbohydrate content in the test plant material. The results indicate that there was a uniform positive effect of the biostimulant on the *Lolium perenne* content of the discussed compounds. Grasses treated with Kelpak contained by 9.79% more non-structural carbohydrates compared with their concentration in the biomass of plants which had not been treated with the biostimulant. As far as an interaction between *Ecklonia maxima* extract and nitrogen rates is concerned, there was found a significantly higher non-structural carbohydrate content in both grass species treated with the biostimulant and at each nitrogen rate. The lowest increase in the concentration of the compounds following Kelpak application, amounting to 8.15%, was found in the biomass of plants fertilised with the rate of 50 kg N ha^{-1}, it being the highest (11.9%) in the biomass of plants treated with the biostimulant and fertilised with nitrogen at the rate of 150 kg.ha^{1}.

Regardless of the remaining factors, increasing nitrogen rates reduced the concentration of non-structural carbohydrates in grass biomass, the majority of the differences being statistically significant. The only insignificant differences were recorded between *Lolium perenne* biomass contents of the discussed compounds determined in plots fertilised with the nitrogen rates of 50 and 100 kg ha^{-1}.

Seasonal changes in the concentration of non-structural carbohydrates in the biomass of the harvested plants were observed, the differences being statistically significant. The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60876097

lowest amounts of non-structural carbohydrates were determined in plants harvested with the second cut, them being the highest in the first cut, the differences being significant. Similar relationships were reported by Ciepiela and Godlewska (2015) for orchard grass and Braun's festulolium. As far as *Lolium perenne* cultivars are concerned, cv. Diament were found to contain by 6.28% more non-structural carbohydrates compared with their content determined in cv. Gagat, the difference being significant.

Conclusions

The research reported here demonstrated a positive effect of *Ecklonia maxima* extract on *Lolium perenne* chemical composition. Its results showed that structural carbohydrate and lignin contents in grass biomass were reduced whereas non-structural carbohydrate content increased by means of an application of sea alga extract, which results in an improved quality of feed produced from these grasses. The biostimulant applied in combination with each nitrogen rate significantly increased the concentration of monosaccharides and non-structural carbohydrates, and reduced the concentration of structural carbohydrates and lignin in *Lolium perenne* biomass. Increasing nitrogen rates significantly increased cellulose, hemicellulose and lignin contents but they reduced amounts of monosaccharides and non-structural carbohydrates in the test grasses. The concentration of the examined components in the biomass of *Lolium perenne* plants clearly varied during the growing season. Further studies are needed to develop more comprehensive results and evaluate the impact of different rates of biostimulants.

Acknowledgments. The results of the research carried out under the research theme No. 41/20/B were financed from the science grant granted by the Ministry of Science and Higher Education.

Abstract. This phytosociological study was carried out during 2016-2019 in Terich valley, Hindukush range, Chitral Pakistan. The objective of this study was to determine the vegetation dynamics along various ecological parameters. The quantitative data of vegetation were collected from five monitoring sites using the systematic-random sampling quadrate method. The size of quadrates was 10 m^2 for the trees, 6 m^2 for shrubs and 1.5 m^2 for herbaceous species. Three communities viz. *Elaeagnus-Prunus-Adiantum*, *Fraxinus-Rosa-Acanthophylum* and *Hippophae-Sophora-Poa* community structures were established at foot-hills. Mid-hills comprised *Ferula-Artemisia-Capparis*, *Prangos-Ribes-Berberis* and *Astragalus*-Astragalus-Eremurus* communities. Community structure was quite different at sub-alpine (*Artemisia-Rhodiola-Rosularia*, *Betula-Scutellaria-Taraxacum*) and alpine zones (*Anaphalis-Cousinia-Kobresia*, *Alajja-Oxyria-Oxytropis*). Soil samples were collected and analyzed to study soil properties. Soils were slightly acidic and had low content of organic matter. Vegetation was found to be under extreme biotic stress. Results also showed that vegetation at higher elevation showed lower species richness.

Keywords: *phytosociology, edaphic parameters, similarity index, species diversity, species richness, maturity index, dry temperate vegetation*

Introduction

Vegetation is an ecological expression of plants growing together in a specific area (Wahab et al., 2010). Vegetation structure depends upon the prevailing environmental conditions (Khan et al., 2011). Plant community is the collection of functional units of species both spatially and temporally. The changes in the community structure are due to seasonal variations and the sampling time (Forzieri et al., 2011; Ali et al., 2018; Hussain et al., 2019). Therefore, the community structure reflects seasonal aspects. The key environmental factors influencing the makeup of the community include over-grazing, deforestation, trampling, construction of buildings, soil erosion, chopping and other natural factors (Ali and Malik, 2010). Vegetation is also influenced by atmospheric humidity, soil moisture, aspect and grazing intensity (Ahmad, 2009; Shaheen and Qureshi, 2011). Vegetation plays a significant role in ecosystem composition and worldwide water balance (Kucharik et al., 2000). Soil is the main factor that determines the different features of vegetation species in particular area (Khan et al., 2010a). Physio-chemical properties of the soil also influence the plants distribution pattern on small scale (Bakkenes et al., 2002). Topography is also an important determinant of vegetation structuring as it alters other environmental factors like temperature, humidity etc. Difference in altitudes, slope and aspect also support different communities (Arora, 2002). The present study was conducted in Terich Valley Chitral of Hindukush range. Five monitoring sites were established viz. Shagrom, Warimon, Zondrangam, Rosh Gol

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60996119

and Ghari. On the basis of importance values (IV) 10 different plant communities were established at monitoring site. Different environmental factors such as temperature, soil type, topography and biotic factors influence the composition and the distribution of plant communities in the investigated area. A lot of quantitative phytosociological work has been published from various parts of Pakistan. Ahmed et al. (2006) surveyed different climatic regions of Himalaya and recorded 4 mono-specific forests for analyses of vegetation. Ali et al. (2007) described plants associations and other ecological characteristics of rangelands of Dir. Khan et al. (2010b) observed the physiognomy of *Monotheca buxifolia* forest in Lower Dir with altered elevations and established 6 species associations with *Monotheca buxifolia*. Rashid et al. (2011) recorded the communities structure of Malam Jabba, swat. Ahmed et al. (2011) investigated forests of *Cedrus deodara* in Himalayan and Hindukush mountainous range. Khan et al. (2012) documented the vegetation pattern of forested regions of Chitral. Khan (2012) explored the community structure of *Quercus* species in district Dir. Data were analyzed by Point Centered Quarter method, PC-Ord for cluster classification and Dentrended correspondence analysis for ordination of edaphic and environmental factors. While the major types of *Quercus* sp. vegetation associations were also assessed. Khan et al. (2010c) explored the vegetation-environment relationship of Chitral applying Point Centered Quadrate technique. Mohib Shah (2013) surveyed the phytodiversity and vegetation-environment relationship of Peer Taab graveyard (Swabi). Muhammad et al. (2015) worked on vegetation structure of *Acacia modesta* at various elevational values in Malakand division. Rahman et al. (2016) recorded vegetation composition of *Isodon rugosus* communitie of Khwaza khela, Swat. Khan et al. (2016) worked on pines' forests and their phytosociology in Indus-Kohistan. A total of six groups and four specific plots of *Cedrus deodara* were enlisted. Irshad et al. (2016) recorded the stress on environment about scattering pattern of different species of *Punica granatum* community in district Lower Dir. Ali et al. (2018) documented 15 plant communities, 5 for shrubs, 5 for herbs and 5 for trees of Hindukush Range Swat Pakistan. Ilyas et al. (2018) worked on Kabal Valley, Swat Pakistan to describe the vegetation structures of the sub- tropical range. Hussain et al. (2019) quantified different aspects of vegetation in Koh-e-Safaid Range, Upper Kurram, Pakistan, and summed up seven plant communities of trees, shrubs and herbs, and no studies have addressed the vegetation structure of Terich valley, Chitral a series in the famous Hindukush Mountain range in Pakistan. Being situated on "ecotone zone" this region exhibits special geological features and hence special sort of vegetation distribution. The present study in this region was therefore, aimed to document vegetation structure and characteristics species to inform future conservation strategies.

Materials and methods

Study area

Terich valley is a charming valley of Chitral, Pakistan which provides a wide range of habitat to wild flora. It is located 72º 07′ to 73º 97′ E longitude and 35º 20′ to 36º 55′ N latitude in Chitral. It is bounded on the North by Tajikistan, on the West by Badakhshan, on the South by Nuristan while on the East by District Ghizer of Gilgit-Baltistan (*Fig. 1*). Rugged and uneven terrain characterizes the valley. The climate is cold temperate type. Temperature ranges from -12 ºC in winter to 30 ºC in summer. Phytogeographically, Terich valley lies in the Irano-Turranian floristic region.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60996119

Floristically, the Irano-Turranian region is luxuriant occupied 45.6% of the flora of Pakistan. In Terich valley, Terich Mir (7685 m) the highest peak of the Hindukush range is followed by Saraghrar (7349 m), Shakawar (7116 m), Langar Peak (7100 m) and many other peaks with low altitudes.

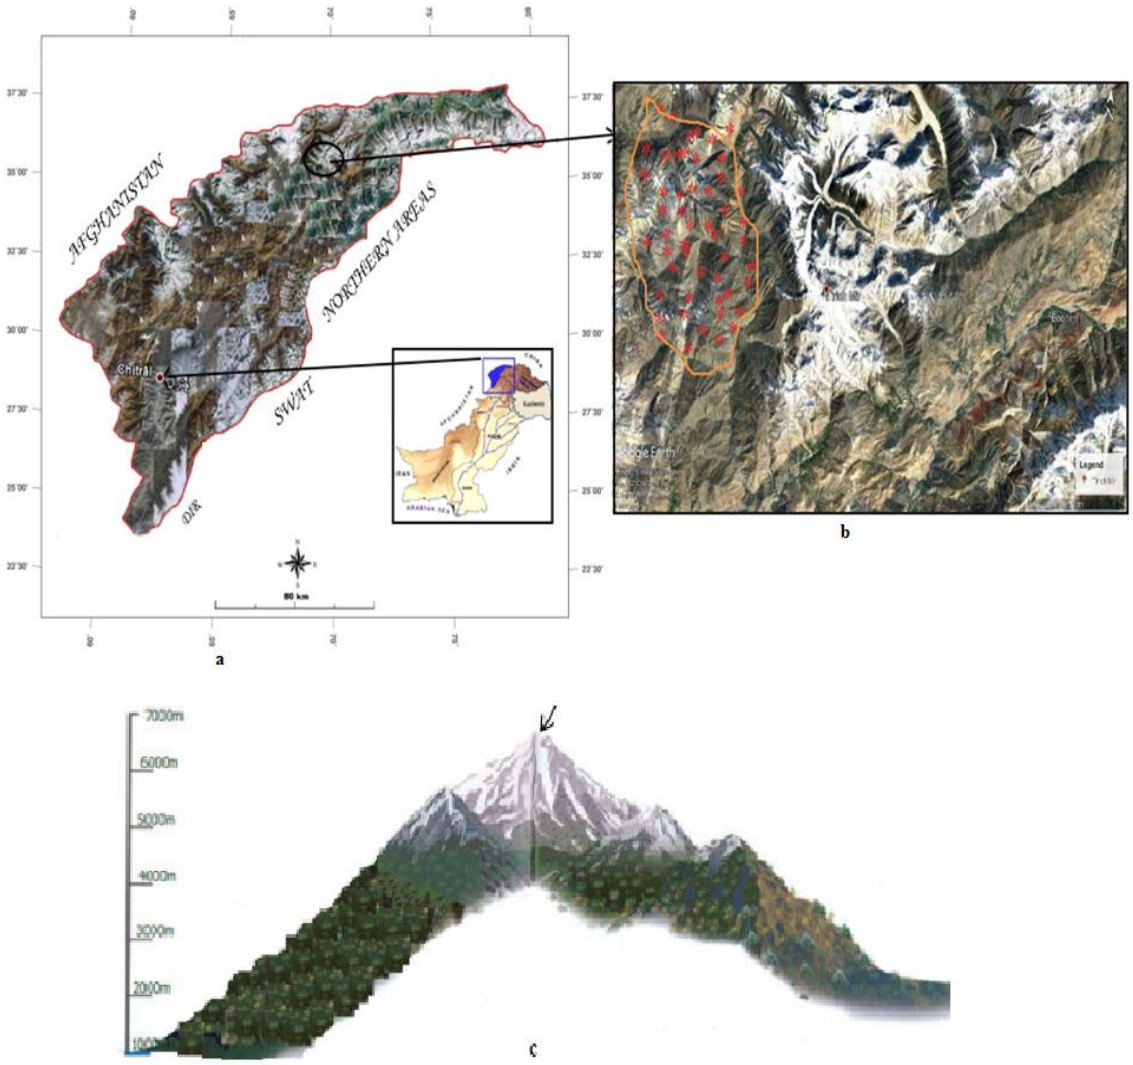

Figure 1. *a) Geo-reference Map of Chitral, b) The study area showing the sampling sites, c) View of Research area along Terich Mir*

Phytosociology

Phytosociological studies were conducted in 5 monitoring sites (*Table 1*). These sites were selected based on altitude, topography, species composition and physiognomic features. Vegetation was evaluated by using 15 (1.5 m^2) quadrats for herbs, 10 (5 m^2) quadrats for shrubs, 5 (10 m^2) quadrats for trees at each monitoring site. Phytosociological attributes viz. Density, cover and frequency of each species was measured and values were changed to relative values to calculate IV (Importance value). The plant communities were established based on highest importance values following (Hussain, 1989; Ahmad and Shaukat, 2012).

DOI: http://dx.doi.org/10.15666/aeer/1805_60996119

Table 1. *Locations, geographical and ecological characteristics of the sampling sites*

Main Location	Altitude (m)	Slope (°)	Aspect	Soil type	GPS Coordinates	Vegetation
Shagrom	1000-2500	12 17	Foot & Mid-hills	Sandy loam	71.41 35.54	Herbaceous
Warimon	1600-2420	25 29	Foot & Mid-hills		71.46 35.53	Scrubby
Zondrangam	1760-2350	15 32	Foot & Mid-hills		71.05 35.45	Scrubby
Rosh Gol	3440-3650	16 33	North facing & South facing		71.41 35.53	Sub-alpine
Ghari	2950-4200	27 22	North facing & South facing		71.41 35.41	Alpine

Species diversity

Species diversity was obtained by Hussain (1989) method.

$$\text{Diversity Index (D)} = \frac{\sum n(n-1)}{N(N-1)} \quad \text{(Eq.1)}$$

where,
D= Simpson index,
N= Number of individuals of all species,
n= Number of individuals of a species.

The obtained value was subtracted from 1 to obtained Diversity Index.

Species richness

Species richness was calculated after Menhinick (1964) using the following formula.

$$d = \frac{S}{\sqrt{N}} \quad \text{(Eq.2)}$$

where,
d= Species richness,
S= Total number of species in a stand,
N= Total number of individuals in a stands.

Similarity index

Similarity index was calculated by using Sorensen's index (Sorensen, 1948) as modified by Motyka et al. (1950).

$$Is_{mo} = \frac{2W}{A+B} x100 \quad \text{(Eq.3)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60996119

where,
Is= index of similarity of Motyka,
W= Sum of the lowest quantitative value of species common to both stands A and B,
A= Sum of the quantitative value of all species in stands/community A,
B= Sum of the quantitative value of all species in stand/community B.

Maturity index

Community maturity index was obtained by Pichi-Sermolli (1948) method.

$$\text{Degree of maturity index} = \frac{Ft}{N} \quad \text{(Eq.4)}$$

where,
Ft= Frequency values of all species in a stand,
N= Total number of species in a stand.

Importance value index (IVI)

The ecological importance of a species in relation to the community structure was obtained by adding the relative values of density, frequency and cover.

The equation used for the calculation of IVI is given as under:

$$\text{Importance value index (IVI)} = \frac{\text{D3} + \text{C3} + \text{F3}}{3} \quad \text{(Eq.5)}$$

Soil analysis

About 1 kg soil sample (upto a depth of 15 cm) was taken from each five localities of Terich valley. The collected samples were then mixed to get a composite sample, kept in polythene bags and taged appropriately for analyses in the research laboratory. The soil samples analyses were carried out at Pakistan Tobacco Board, Mardan for determination of physio-chemical properties. Soil Texture triangle was used for the identification of texture classes (Bouyoucos, 1936; Brady, 1990). Soil pH was noted by using 1:5 soil water suspensions (Black, 1965). For quantification of organic matter in soil followed Walkley (1947). Lime % ($CaCO_3$) was determined by acid base nutrilization following Rayan et al. (1997). Nitrogen concentration was estimated with Kjeldahl methodology (1983) and Na Concentration was examined by using flame photometery. Potassium and Phosphorus contents were quantified following Olsen and Sommers (1982).

Results

Present study was conducted in Terich valley, Chitral Hindukush range Northern Pakistan during 2016-19. Five selected sites viz. Shagrom, Warimon, Zondrangam, Rosh Gol and Ghari were established. The study area shows a distinctive floristic composition and vegetation pattern. A total of 195 species were documented in five sampling sites. Based on importance value (IV) at Shagrom, Warimon, Zondrangam, Rosh Gol and Ghari from each monitoring sites two communities each were recorded (*Table 2*). The vegetation of the area was mostly scrubby, characterized by herbaceous, shrubby plants and rarely trees.

A. Community structure of foothills vegetation

Shagrom (Site-I)

Elaeganus-Prunus-Adiantum community (EPA)

This plant community was established at Shagrom at an elevation of 1000 m-1550 m having 21 species. *Elaeganus angustifolia* (IV. 24.31), *Prunus jacquemontii* (IV. 19.99), and *Adiantum venustum* (IV. 19.66) were the dominant plant species. Co-dominant species were the *Berberis lyceum*, *Capsella bursa-pestoris*, *Brassica campestris*, *Conyza aegyptiaca*, *Cynodon dactylon* and *Mentha longifolia* (*Table 2*). Soil of this site was basic in nature having pH 8.5 and electrical conductivity 0.4 dsm^{-1}. Similarly soil texture has been reported with 2.6% clay, 38.0% silt and 58.86% sand, respectively. Organic matter was 2.05% followed by calcium carbonate 13%. The nitrogen content 0.1035%, phosphorus 15.28 mg/kg and potassium 114.33 mg/kg was recorded respectively (*Table 3*).

Table 3. *Edaphic variables, mineral content and plant communities at 5 monitoring sites*

Warimon (Site-II)

Fraxinus-Rosa-Acanthophyllum community (FRA)

This community was established at an altitude of 1200 m-1600 m comprised of 30 species. Dominant species of this community includes *Fraxinus xanthxyloides* (IV. 19.63), *Rosa webbiana* (IV. 17.93) and *Acanthophyllum laxiflorum* (IV. 17.92). Co-dominant shrub species include *Crataegus songarica*, *Tamaricaria elegans*, *Rhamnus prostrata*, *Clematis alpina*, and *Cotoneaster affinis* who grew around this community (*Table 2*). Soil pH was 6.6 and electrical conductivity 0.06 dsm^{-1}. The soil consisted of 4.56% clay, 30.66% silt and 62.86% sand, textured with sandy loam. Soil contained 2.16% organic matter and 16.25% calcium carbonate. Nitrogen content was 0.114% which was better than Shagrom community. Phosphorus content was 5.87

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60996119

mg/kg and potassium 96.33 mg/kg was also estimated which has a normal range required for the plant growth (*Table 3*).

Zondrangam (Site-III)

Hippophae-Sophora-Poa community (HSP)

This community was established at altitude of 1320 m-1760 m having 32 species. The dominant species of this community was *Hippophae rhamnoides* (IV. 17.36), *Sophora mollis* (IV. 13.86) and *Poa pratensis* (IV. 13.62). The co-dominant species were *Carex stenocarpa*, *Cirsium willichi*, *Cardaria draba*, *Coriandrum sativum*, *Lolium temulentum*, and *Tamaricaria elegans* (*Table 2*). Soil was sandy loam of this site with 20.61% clay, 38.01% silt, and 39.501% sand. The pH was 8.1 and 0.291 dsm^{-1} electrical conductivity was also calculated. Similarly, organic matter 2.28% and calcium carbonate was estimated 8.4%. Nitrogen content was recorded 0.117% followed by phosphorus 12.16 mg/kg and potassium 187 mg/kg, respectively (*Table 3*).

B. Community structure of midhills vegetation

Shagrom (Site-I)

Ferula-Artemisia-Capparis community (FAC)

This community was composed of 26 species located at an altitude of 2250 m-2500 m. *Ferula narthex* (IV. 19.55), *Artemisia sieveriana* (IV. 17.11), and *Capparis spinosa* (IV. 15.33) were the dominant species. The co-dominant species of this community were *Cotoneaster racemiflorus*, *Juniperus communis*, *Cichorium intybus*, *Acantholimon stocksii*, and *Astragalus imitensis* (*Table 2*). The soil pH was 6.6 and electrical conductivity 0.129 dsm^{-1} which represents acidic nature of soil. The soil texture was sandy loam and composed of clay 5.67%, silt 42.0% and sand 51.39%. Organic matter was estimated 2.1% and calcium carbonate 5.01%. The concentration of nitrogen was calculated 0.104%, phosphorus 20.391 mg/kg and 116 mg/kg potassium, respectively (*Table 3*).

Warimon (Site-II)

Prangos-Ribes-Berberis-community (PRB)

Along 2320 m-2420 m altitude *Prangos-Ribes-Berberis*-community was recorded having 22 species. *Prangos pabularia* (IV. 24.82), *Ribes orientale* (IV. 21.79) and *Berberis calliobotrys* (IV. 20.74) were dominant species. The co-dominant species of this community includes *Tetrapogon villosus, Trisetaria loeflingiana, Thlaspi perfoliatum* and *Cirsium arvensis* (*Table 2*). The texture of the soil recorded sandy loamy which contains clay 0.681%, silt 18.01% and sand 76.41%. The pH of the soil was 6.3 and electrical conductivity 0.201 dsm^{-1}. Chemical analysis revealed 1.87% organic matter and 5.49% calcium carbonate. The nitrogen concentration was estimated 0.087% followed by 55.67 mg/kg phosphorus and 238 mg/kg potassium (*Table 3*).

Zondrangam (Site-III)

Astragalus-Astragalus-Eremurus community (AAE)*

This community consisted of 20 species which was reported along 2260 m-2350 m altitude. The dominant species were *Astragalus affghanus* (IV. 23.43), *Astragalus edelbergianus* (IV. 21.64) and *Eremurus stenophyllus* (IV. 21.04). *Juniperus excelsa,*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60996119

Astragalus amberstianus, Acantholimon longiscapum, and *Ephedera gerardiana* were co-dominants (*Table 2*). Chemical analysis of soil revealed 1.551% organic matter, 11.49% calcium carbonate, 0.081% nitrogen, 12.24 mg/kg phosphorus, 132 mg/kg potassium, pH 8.1 and 0.021 dsm^{-1} electrical conductivity. The soil texture represents sandy loam contributed clay 11.67%, silt 15.0% and sand 70.41% (*Table 3*).

C. Community structure of sub-alpine and alpine vegetation

Rosh Gol (Site-IV)

Northern slope

Artemisia-Rhodiola-Rosularia community (ARR)

Artemisia-Rhodiola-Rosularia community was recorded from Rosh Gol along (South facing) of sub-alpine region at an altitude of 3125 m-3440 m. This community was consisted of at had 23 species. The dominant species were *Artemisia parviflora* (IV. 22.76), *Rhodiola wallichiana* (IV. 22.03) and *Rosularia alpestris* (IV. 22.06). *Seriphidium brevifolium, Rosa ecae, Pseudognaphalium luteo-album, Artemisia persica,* and *poa bulbosa* were co-dominants (*Table 2*). Texture of the soil was sandy loam with clay 6.51%, silt 24.99% and sand 72.21%. The soil of this site had 0.81% organic matter and 0.51% calcium carbonate. Amount of nitrogen 0.12%, phosphorus 14.01 mg/kg and potassium 183.8 mg/kg was estimated. The pH was calculated 6.6 and electrical conductivity 0.489 dsm^{-1} (*Table 3*).

Southern slope

Betula-Scutularia-Taraxicum community (BST)

This community consisted of 21 species at Rosh Gol along (North facing) of the sub-alpine region at an altitude of 3320 m-3650 m. The dominant species were *Betula chitralica* (IV. 27.21), *Scutellaria multicaulis* (IV. 20.79) and *Taraxacum tricolor* (IV. 15.88). The co-dominant species were *Tricholepis toppinii, Taraxacum brevirostre, Seriphidium chitralensis,* and *Arnebia hispidisma* (*Table 2*). The pH of soil was 6.6 and electrical conductivity 0.48 dsm^{-1}. The soil was sandy loam with clay 6.3%, silt 25.94% and sand 70.2%. Chemical properties of the soil showed organic matter 0.84% and calcium carbonate 0.51%, respectively. The nitrogen concentration 0.141%, phosphorus 15.99 mg/kg and potassium 186.8 mg/kg was investigated (*Table 3*).

Ghari (Site-V)

Northern slope

Anaphalis-Cousina-Kobresia community (ACK)

This community had 19 species at Ghari site of the alpine zone (South facing) located at an elevation of 2870 m-2950 m. *Anaphalis stantonii* (IV. 29.48), *Cousinia pycnoloba* (IV. 25.74) and *Kobresia laxa* (IV. 22.25) were dominants; while *Puccinellia minuta*, *Psychrogeton chitralicus, Cystopteris fragilis, Ferula hindukushhensis, Koelpinia linearis,* and *Asplenium septentrionale* were co-dominants (*Table 2*). Soil of this site had sandy loam texture with clay 2.79%, silt 34.2% and sand 61.2%. The pH was calculated 7.89 and electrical conductivity 0.2679 dsm^{-1}. Similarly, organic matter 0.75% and calcium carbonates 2.7%. Nitrogen concentration was recorded 0.12%, followed by phosphorus 12 mg/kg and potassium 84.2 mg/kg (*Table 3*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60996119

Southern slope

Alajja-Oxyria-Oxytropis community (AOO)

Ghari alpine zone (North facing) located at an altitude of 3620 m-4200 m. The community of this site had 23 species. The dominant species of this community included *Allaja rhomboidea* (IV. 24.63), *Oxyria digyna* (IV. 21.35) and *Oxytropis chitralensis* (IV. 20.96). *Tanacetum grifthii, Alotis smithii, Astragalus coluteocarpus,* and *Betula utilis* were co-dominants (*Table 2*). Soil of this site was sandy loam in texture with 2.91% clay, 30.201% silt and 61.2% sand particles. Soil pH was 7.5 and organic matter content was estimated 0.78%. Calcium carbonate was found to be 2.49%. Similarly, concentration of nitrogen 0.15%, phosphorus 15.99 mg/kg and potassium 88.2 mg/kg was also estimated (*Table 3*).

Similarity index

According to Motyka's index of similarity (Motyka et al., 1950), FRA community was found to be 46.1% similar to HSP community. The similarity between PRB community and A*AE community was to be found 28.5%. The analysis showed that similarity between EPA community and that of FRA community was 23.52%. Similarly, index of FAC and PRB communities was 8.33%. EPA community was 7.54% similar to HSP community. Only 5.12% similarity was observed between A*AE community and ACK community. Similarity between ACK, EPA communities and ACK, BST communities was recorded 5% each; followed by similarity of A*AE, EPA communities and ACK, PRB communities 4.87% each. Similarity index was observed for EPA, ARR, EPA, BST, ACK, ARR and ACK, AOO 4.76% each respectively. EPA community showed minimum similarity with PRB community i.e. 4.65%, while the remaining communities had less than 4% similarity index among themselves (*Table 4*). Seasonal variation was the main cause of similarity index between communities. The high similarity index between the communities is due to characteristics such as similarity in composition of nutrients, the proximity of stands to each other that had almost similar habitat conditions in terms of N, P, K, pH and soil from clay loam to sandy loam. The high similarity index among some plant communities during the monsoon and spring seasons might be due to the occurrence of the same shrubs, trees, evergreen perennial herbs and geophytes while most of plant communities dominated by annuals showed least similarity among themselves.

Simpson diversity index

Species diversity was obtained by Hussain (1989) method. Species diversity is affected by various biotic and abiotic factors including elevation, climatic conditions, edaphic characteristics, grazing, browsing, and anthropogenic activities. Species diversity is the main attribute of vegetation dynamics, which reflects the composition and productivity of vegetation. Species diversity calculates the complexity and function within the community. At Site-I Simpson's diversity was found to be 0.1149 followed by Site-II and Site-III with diversity values of 0.159 and 0.1069, respectively. At Site-IV diversity was 0.1004 followed by Site-V with a value of 0.111, Site-VI 0.118, Site-VII 0.127, Site-VIII 0.110 and Site- X had diversity value of 0.174. The lowest value was recorded for Site-IX i.e. 0.106 (*Table 5, Fig. 2*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60996119

Species richness

Species richness was calculated after Menhinick (1964). The species richness of a specific region is the result of various environmental factors such as geography, topography, species pool, area productivity and species competition. In the present study the maximum species richness was recorded 0.132 at Rosh Gol North slope followed by 0.104 at Shagrom Midhills, 0.18 at Ghari south slope and 0.16 at Warimon. The high species richness is directly linked with favorable environmental conditions and soil factors. The low species richness 0.12 was recorded in the foothills of Shagrom. Similarly, midhills of Warimon and the north slope of Ghari contributed 0.11 species richness, followed by foothills 0.10 species richness of Zondrangam and south slope of Rosh Gol respectively (*Table 6, Fig. 3*). Variation in altitude and physicochemical properties of soil may also have profound influence on species richness. The species richness was high during spring but decreased during the monsoon season. This is due to dominance of annuals and geophytes during spring which disappear at the onset of the monsoon season. The low species richness was due to lack of water, high temperature, overgrazing and deforestation. However, in contrast to this, the species richness follows the interpolated richness pattern.

Table 6. *Species richness and maturity index among different communities*

Sites	Communities	SR	MI

Maturity index

Maturity index was calculated according to Pichi-Sermolli (1948). This is a new index for appraising the vegetation pattern of an area affected by environmental and edaphic conditions. During the present study, index of maturity of communities ranged from 27.0 to 37.69. The highest value of maturity index 37.69 was recorded in the communities of Shagrom. Similarly, maturity index of the communities of south slope Rosh Gol 37.14, followed by the midhills of Zondrangam 35.5. The maturity index of communities in North slope Ghari 35.26 and North slope Rosh Gol was 32.60. Maturity index of the communities of foothills Shagrom was 31.42, while in the midhills communities of Warimon was 31.36. The lowest maturity index 27.18 was reported in south slope communities of Ghari and foothills communities of Warimon 27.0 (*Table 6, Fig. 4*). All the stands were immature which might be due to lesser adaptation to the microclimate of the study sites. This was further enhanced due to high anthropogenic pressures which disturbed the natural balance of the plant communities and prevented them from attaining maturity. Low maturity reflects the heterogeneity within the plant communities as a result of poor adaptability to the ecological conditions of area.

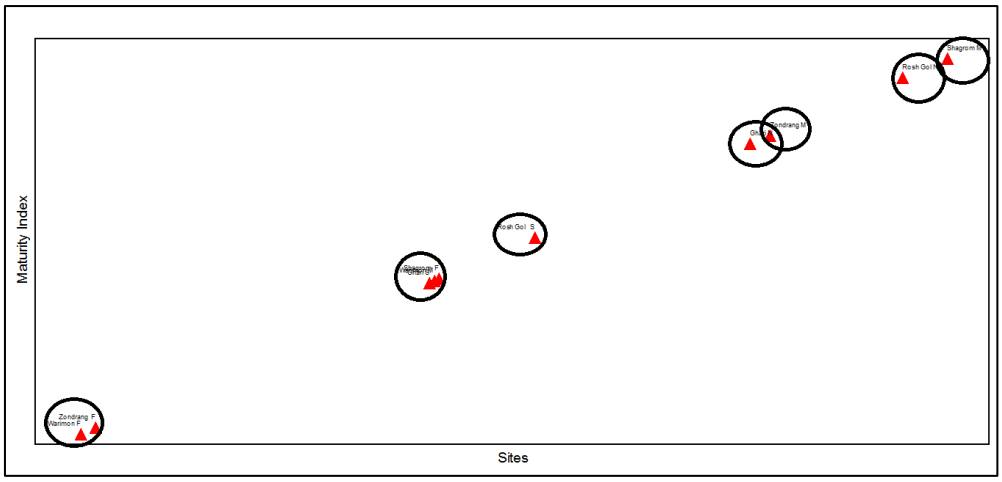

Figure 4. *Maturity index among communities through PC-Ord. Key to abbreviations used in Figs. 2, 3 & 4: Site-I: Shagrom (Foothills), Site-II: Warimon (Foothills), Site-III: Zondrangam (Foothills), Site-IV: Shagrom (Midhills), Site-V: Warimon (Midhills), Site-VI: Zondrangam (Midhills), Site-VII: Rosh Gol Northern slope, Site-VIII: Rosh Gol Southern slope, Site-IX: Ghari Northern slope, Site-X: Ghari Southern slope*

Discussion

During current study the vegetation of Terich valley, was classified into ten plant communities based on importance values (IVs) which is in line with the works of Hussain et al. (2010, 2019), Ali et al. (2018), Srivastava et al. (2016), Gandhi and Sundarapandian (2014), Altay et al. (2012), Zhang and Zhang (2011), Tsiourlis et al. (2009), Liu (2008), Hirst and Jackson (2007) and Oswalt et al. (2006). At Site-I foothills and midhills EPA-FCA communities were established. Distribution of trees was very rare due to lavish wood cutting in this site. Inadequate trees and relatively thick bushes spread close to the lower regions showed the disturbed nature of habitat which is under gigantic biotic pressure. Expanding population and development of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60996119

residential units is the main reason behind the species loss in this locality. Similar communities are reported from their respective study areas by Ali et al. (2018), Hussain et al. (2015), Mehmood et al. (2015), Ilyas et al. (2015) and Rashid et al. (2011). Site-II foothills and midhills had FRA-PRB communities. Species of Trees and shrubs showed a clumped dispersion pattern at these monitoring sites. Effects of soil disintegration were more visible at Site-I and Site-II where dissolved soils had herbaceous individuals like *Conyza aegyptiaca*, *Cynodon dactylon*, *Crataegus songarica*, *Tamaricaria elegans*, *Rhamnus prostrate* and *Verbascum thapsus* which are the indicator species of eroded soils. Similar communities but with different IV are reported by Hussain et al. (2019), Khan et al. (2016), Ummara et al. (2015), Forzieri et al. (2011) and Wahab et al. (2010). Site-III foothills and midhills exhibited HSP-AAE communities. This site had a uniformly spread thick scrubs of *Juniperus, Astragalus, Acantholimon,* and *Ephedera*. Deforestation was likewise not excessively disturbing when contrasted with that of foothills and midhills of Terich valley monitoring sites. At higher altitude the valley was practically undisturbed anyway the environment will confront biotic pressure, particularly the anthropogenic stresses from increasing population in the low laying villages in the next few years. These findings are backed by works of Hussain et al. (2015), Khan et al. (2016), Ali et al. (2015), Ilyas et al. (2015), Sharma et al. (2014), Ali and Malik, (2010) and Wahab et al. (2010). ARR-BST communities were found at north and south slopes of site-IV. This sub-alpine zone supported the richness of *Artemisia parviflora*, *Rhodiola wallichiana*, *Rosularia alpestris, Seriphidium brevifolium, Rosa ecae, Pseudognaphalium luteo-album, Artemisia persica,* and *poa bulbosa.* This is line with findings of Ali et al. (2018), Ilyas et al. (2015), Siddiqui et al. (2011), Ahmed et al. (2011) and Hussain et al. (2004). At north and south slopes of site-V, ACK-AOO communities were recorded from this alpine zone. Plants of this site was found healthy with the special case on Northern slants where deforestation was very clear because of fuel wood extraction by local people for *Betula utilis*. These results are in line with the works of Haq et al. (2015), Naveed (2014), Ilyas et al. (2012), Khan et al. (2010, 2011), and Ahmed et al. (2009).

Conclusion

This research shows vegetation dynamics based on 195 sampling units at 5 monitoring sites. Soil analyses cover 11 parameters with different properties at each site. Variations in edaphic variables, temperature, humidity and slope are due to spatial variations among plant communities at different monitoring sites. Vegetation is endangered in the study region and needs to be conserved until it's too late. The vegetation cover decreases anthropogenic factors, over grazing, natural calamities, and erosion. Extraction of Terich valley trees by local communities, particularly during harsh winters, not only reduces the density of the tree, but also increases the rate of soil erosion. Climate change has not spared vegetation in the Hindukush range and with each passing year, floral diversity is growing. Impacts of anthropogenic pressure for maturity index are evident from the low ratings. Highest similarity index was recorded for community FRA which was found to be 46.1% similar to HSP community. Highest maturity index value was recorded for communities FAC at Site-IV i.e. 37.69 followed by communities BST at Site-VIII i.e. 37.14. Species richness of community AOO was estimated high 0.18 at Site-X. At Site-X Simpson's diversity was found to be maximum for community AOO 0.17 followed by community FRA at Site-II with diversity values

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_60996119

of 0.15, respectively. Low maturity index values suggest the plant communities' inability to cope with anthropogenic, edaphic, and climatic stresses. Likewise, low values of index of similarity indicate the heterogeneity between plant communities. The structure of vegetation indicates local flora is fighting a war of its survival. Once covered under a thick blanket of vegetation, bare patches are now visible on mountain slopes. Proper management of the grazing should be ensured for understory plant regeneration. To check the erosion due to landsliding and flood, fast-growing plant species must be cultivated to rehabilitate the degraded and fragmented habitat. A comprehensive program must be designed through involving local masses, conservationists, Governmental and Non-Governmental Organizations to take useful measures for threatened plants and their conservation with special focus on endemic species to mitigate their extinction risk.

(Received 26th Mar 2020; accepted 9th Jul 2020)

Abstract. A factorial experiment was conducted in Kurdistan-Iraq to identify responses of European wheat varieties to vernalization treatments at 22ºC, 4ºC and -18ºC for two and four weeks in a Complete Randomized Block Design (CRBD) experiment with three replicates. Sabir-beg had the highest and most desired performance for most of the traits studied including grain yield. The highest spike and grain number were recorded for Hereford and Skalnige, respectively. Incubation temperatures had highly significant effects on most of the traits, including grain yield. Two weeks-vernalization at low temperature is satisfactory for vernalization of these wheat varieties. The interaction between varieties and incubation temperature produced varying effects. Grain number is mainly genotype-related. Sabir-beg×two weeks incubations had spent minimum days to flowering, followed by days to maturity. The varieties were persistent in their interaction with the incubation period. The interaction effect of 4ºC×four weeks incubation advanced flowering, extending flowering-maturation period to give a higher spike number. Harvest index, biomass, and grain yield were highly significant for both interactions of varieties×incubation temperature and varieties×incubation period. The three-factors interaction had a highly significant effect on most traits. The wheat varieties can be developed with more predictable responses to *in vitro* vernalization as an alternative to early sowing.
Keywords: *variety, in vitro, low temperature, VRN gene, grain yield*

Introduction

One of the critical stages in plant development is flowering, that affects crop production. The stage of crop vegetative/reproductive transition is a combination of plant responses to the environment including stresses (Kazan and Lyons, 2014). Optimal products can be obtained by the management of these stages. The time to flowering must coincide with favorable conditions to guarantee the species survival via producing viable seeds. Vernalization, a prolonged period of low temperature, is one of the environmental stimuli that is required to initiate flowering (Michaels, 2009; Dixon et al., 2019). Vernalization, as a plant cue, is required to transit the plant to reproductive stages, which means shifting from the vegetative growth to flowering and seed production (Trevaskis, 2010; Woods et al., 2019). This phenomenon is promoted by a chilling treatment (Chouard, 1960; Muterko and Salina, 2018). The effect of vernalization is to reduce the production period of leaf primordia (Griffiths et al., 1985), and consequently reduce the number of leaves and the tillers initiated on the main shoot (Gott et al., 1955; Levy and Peterson, 1972).

Winter cereals have a quantitative vernalization requirement for flowering (Woods et al., 2019). It has been identified that vernalized plants are more prone to flower earlier than non-vernalized (Robertson et al., 1996). Winter wheat genotypes grown under temperate regions can be vernalized at a seedling stage or even at full grain maturity, during the chilling period of winter (< 4°C) (Clay et al., 2012; Mureşan et al., 2019).

DOI: http://dx.doi.org/10.15666/aeer/1805_61216136

Bread wheat is one of the most cultivated grain crops occupying a wide range of lands worldwide, its winter varieties are planted in the autumn and they have adequate tolerance to survive freezing temperatures in winter. This adaptation occurs due to the reduction of moisture content and the accumulation of soluble carbohydrates in the crown area of the wheat plant, causing the reduction in growth rate at this stage, providing the plant resistance to frost temperature (Clay et al., 2012). Hence winter wheat varieties usually have higher yield potential than spring varieties planted later in the spring because of their longer growing period and vernalization explosion (Galiba et al., 2009; Li et al., 2013). Response to vernalization is one of the most important factors affecting environmental adaptation of wheat (Wang et al., 1995; Whittal et al., 2018). This action has been found to be under the effect of three genes of VRN1, VRN2, andVRN3, as a major gene for the vernalization in winter wheat. This was mapped using a population of recombinant inbred lines (RILs) generated from two winter wheat cultivars (Yan et al., 2006, 2015). After exposing the plants to non-freezing temperature for certain periods of time the cold-responsive genes are activated (Armonienė et al., 2013). Based on the exposing period of cold temperature to promote flowering on time, winter wheat has three categories; a weak winter type requires less than two weeks, a semi-winter type requires 2-4 weeks exposing of low temperature for flowering: while a strong type requires longer cold exposure (4 weeks and more) for timely flowering (Crofts, 1989). Flowering in wheat occurs after all main-stem leaves have appeared and are fully expanded. It is the consequence of the rate of leaf appearance which is controlled mostly by the temperature of the apical meristem and leaf expansion zones (McMaster and Wilhelm, 2003). *Triticum aestivum* L. (wheat, 2n = 6x = 42) is known to be cultivated across the most variable land area than any other grain crop (Rozbicki et al., 2019).

Vernalization requirement of winter wheat varies according to their genetic construction (Whittal et al., 2018). Varieties obtain sufficient vernalization when sown at an early time in autumn, while in case of late sowing with any reason, varieties will not start flowering on time (Mureşan et al., 2019), making the plant to have reduced flower or have late initiation, making the yield to be reduced quantitatively and qualitatively. The objective of this study was to identify the response of winter wheat varieties to different vernalization treatments in the control environment before planting, aiming at establishing the latest safe sowing date for winter wheat varieties, with a reasonable yield.

Materials and methods

A factorial experiment was conducted in the experimental field of the College of Agricultural Engineering Sciences, University of Sulaimani, Kurdistan of Iraq, located at Lat. 35˚ 34′ 307″; N, Long. 45˚ 21′ 992″; E, 765 m asl. CRBD experiment was conducted for five varieties, four European and one local variety (factor A), see *Table 1*.

Grains were treated with three different temperatures, namely at room temperature (22^{o}C), at laboratory condition, 4^{o}C (in a refrigerator) and at -18^{o}C, in a freezer (factor B), for two different periods of two and four weeks (factor C). The incubation started on 12th November 2018 for four weeks incubation and on 27th November 2018 for two weeks incubation, to be directly sown on 12th December after termination of the designated period, see metrological data in *Table 2*. All treatment combination were sown in three replicates. Each replicate was applied on an area of 0.60 m^2, planting was performed on lines of two-meter length, distanced 30 cm between the lines, and 50 cm between replications.

Total rainfall (mm)				1215.6

The land was tilled twice, smoothed, and plots were prepared before sowing. The varieties were sown on 12th December 2018 containing 30 treatment combinations in which they were homogenous experimental units. Grains size from all varieties was unified by sieving, to obtain persistent population density in the field. After incubation treatment for designated periods, the grains were planted within the lines for all replicates. Each replicate consisted of 3.5 g with uniform size.

The recommended doses of 80 kg N/ha and 80 kg P_2O_5/ha were applied for the experiment and all other agricultural practices were conducted as required. There was no chemical application (herbicide, herbicide, or pesticide) for the treatments, and the experiment was run under rainfed condition. Some physical and chemical properties of the experimental soil are given in *Table 3*.

Table 3. *Physical and chemical properties of the studied soil*

Soil properties	Soil texture (P.S.D)	Sand ($g.kg^{-1}$)	Silt ($g.kg^{-1}$)	Clay ($g.kg^{-1}$)	E.C. ($dS.m^{-1}$)	pH	O.M. ($g.kg^{-1}$)	$CaCO_3$ ($g.kg^{-1}$)	Total N ($mg.kg^{-1}$)	K^+ (L^{-1})
Values	Clay	41.0	430.50	528.50	0.61	7.32	21.6	107.0	1.07	0.12

Note: E.C.: electronic conductivity; O.M.: organic matter; $CaCO_3$: Calcium Carbonate; K^+: potassium ion

The measurements of agro-morphological traits for growth characteristics, yield, and its components were recorded. Measured traits were:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61216136

- Plant Height: recorded at physiological maturity, height was recorded as the length in centimeters from the soil surface to the tip of spike excluding awns.
- Days to flowering: recorded as the number of days required from sowing till flower initiation.
- Days to maturity: recorded as the number of days required from sowing till physiological maturity.
- Spike number/m^2: calculated as a number of spikes per unit area (m^2).
- Grains/spike: counted as an average of the number of grains per spike for 5 selected spikes randomly per each plot.
- 1000- Kernel weight (g): one thousand grain weight (g) were taken at random from a bulk grain yield of each replicate.
- Biomass yield (ton/ha): recorded as the weight of all biological products of the plant above the soil surface per unit area.
- Harvest index (HI): Counted as a percentage of grain weight to biomass, according to the following equation (Shewry, 1998).

$$H.I. = \frac{\text{Grain yield}}{\text{biomass yield}} \quad \text{(Eq.1)}$$

- Grain yield (ton/ha): calculated as a yield of grains of unit area, converted to ton per hectare.

Data were recorded for the agronomic traits, yield, and its components, and analyzed using XLSTAT 2016 software. The source of variance and comparison between the genotypes were determined. The comparisons of trait means were made using Duncan's multiple range test at 5% level of probability.

Results and Discussion

Studying phenological alteration such as vernalization is essential in winter wheat (*Triticum aestivum* L.), to cope with the adverse effects of global warming on crop production, especially under arid and semi-arid conditions (Shourbalal et al., 2019). It has been indicated that each degree increase in temperature results in the reduction of wheat production by 6% (Asseng et al., 2015). Advancing the process of flowering, through partial phenological alteration in winter wheat, is an important step to reduce the effect of drought (Searle and Coupland, 2004). To induce yield production of winter wheat in mild and dried condition, a period of vernalization is required to initiate reproductive stage following vegetative growth (Heide and Sønsteby, 2015).

The analyzed results indicated a significant variance of the genotypes and their interaction treatments with variable incubation temperature and the exposure period to the incubated temperature (*Table 4*). Vernalization determines flowering and heading times, giving a significant influence on the adaptability of wheat plants to different environmental conditions, that mainly contribute to establishing yield and yield components (Slafer, 2003; Chen et al., 2013). Varieties had a highly significant variance for all the studied traits. The levels of incubation temperature had highly significant effects on days to maturity, spike number/m^2, grain number/spike, 1000 kernel weight, harvest index, and grain yield, while they had a significant effect on days to flowering.

Period of incubation for different temperatures had no significant effect on the studied traits, except plant height and days to maturity. The interaction of varieties×incubation temperature had a highly significant effect on all traits except for biomass yield. Distribution of the bio-product between sink and source for the wheat varieties was not influenced by the period of incubation. Both interactions of varieties×incubation temperature and varieties× incubation period had similar effects on the studied traits, as harvest index, biomass yield, plant height, and grain yield, and 1000 kernel weight were highly significant for both interactions. A very close pattern was also stated for the interaction between the incubation temperature and the incubation period. The interaction of all three factors showed a highly significant effect on all traits except grain number/spike.

Wheat varieties had a considerable variable effect on the studied characteristics (*Table 5*). Plant height tends to be the highest in Sabir-beg variety (114.861 cm), while other varieties have a close range of height with each other (only 4 cm differences), their values are ranging from 73.8-78,833cm for Maribos and Ritraw, respectively. The local variety (Sabir-beg) spent shorter period to start flowering (101.94 days from sowing), it was earlier in flowering as well than Hereford with a total of 28 days. The same trend was obtained for days to maturity for Sabir-beg and Hereford, respectively. Maximum days required to maturity was referred to Mariboss, spending 179.7 days after sowing. Hereford had the highest number of spike per unit area (413.667 spike/m^2), while the least number of spikes was referred to Mariboss.

Table 5. *Effect of varieties on agronomic traits, yield and its components of wheat varieties*

Varieties	Plant height (cm)	Days to flowering	Days to maturity	Spike number/m^2	Grain number/ spike	1000 kernel weight (g)	Harvest index	Biomass yield (ton/ha)	Grain yield (ton/ha)
Mariboss	73.807 d	133.833 a	179.722 a	311.889 d	28.983 d	22.822 c	0.250 bc	11.701 c	2.905 c
Skalnige	76.370 c	130.778 bc	177.167 b	339.833 c	40.556 a	19.370 d	0.262 ab	10.069 d	2.738 d
Hereford	78.017 b	130.056 c	174.167 d	413.667 a	34.519 c	19.330 d	0.248 c	12.678 b	3.363 b
Ritraw	78.833 b	131.611 b	175.722 c	369.556 b	38.256 b	25.019 b	0.219 d	12.395 b	2.733 d
Sabirbeg	114.861 a	101.944 d	145.056 e	319.167 d	22.633 e	31.298 a	0.264 a	15.756 a	4.162 a

In terms of grain number/spike the highest number of 40.566 grain was recorded for Skalnige variety, followed by Ritraw, however the least number of grain (22.633) was recorded for Sabir-beg variety. A wide range of 1000 kernel weight was also observed for the varieties under study. The maximum of 31.298 g was recorded for Sabir-beg, while the lowest value of 1000 kernel weight was recorded for Hereford and Skalnige, respectively, with nearly 11 g less weight than Sabir-beg. Harvest Index was also significant for the varieties studied. Sabir-beg had the highest harvest index of 0.264, followed by Skalnige, while the lowest harvest index referred to Ritraw. Biomass was also indicated the variation between the varieties under study. Sabir-beg had indicated the highest biomass yield of 15.756 ton/ha, while the minimum of 10.069 ton/ha was recorded for Skalnige. The same pattern of superiority in the grain yield was recorded for Sabir-beg giving a total of 4.162 ton/ha grain yield. The superiority of local wheat varieties to most of the newly introduced genotypes in another study by Ali et al. (2018) compared to some European varieties for the yield and its component highly supports the current result. The genetic variations that drive a wide response of the genotype understudy could serve the development of a new cultivar with high resilience to future climate changes through the introgression of important traits.

DOI: http://dx.doi.org/10.15666/aeer/1805_61216136

The levels of temperature treatment had variable effects on the studied traits (*Table 6*). Plant height had no significant difference for different temperature levels. Days to flowering was affected with -18ºC incubation, however the incubation at 4ºC had no significant effect on flowering day. Vernalization sensitivity of some of the wheat varieties could be the reason for delaying flowering in certain environmental conditions (Ortiz-Ferrara et al., 1995), making the temperature level of 4ºC to be with less effect to flowering compared to the normal ambient temperature of 22ºC. The same pattern was also observed for days to maturity, spending less days to maturity (166.333 days) for -18ºC incubation. A positive effect of vernalization on days to flowering has been confirmed by other researchers (Sharma et al., 2012). This trend indicates the effect of low-temperature incubation on the vernalization of the varieties under study, giving the desired signal to vegetation period for some days, allowing plants to shift to flowering and maturity period earlier. Hence, in case of impossibility of sowing in the normal sowing times in autumn or at the beginning of winter, the requirement of vernalization could be afforded *in vitro* as a substitute to early sowing. In terms of the spike number per unit area, the low temperature of 4ºC had a significant effect on the spike number (364.233 spike/m^2).

Table 6. *Effect of incubation temperature on agronomic traits, yield and its components of wheat varieties*

Temperature	Plant height	Days to flowering	Days to maturity	Spike number/m^2	Grain number/ spike	1000 kernel weight (g)	Harvest index	Biomass yield (ton/ha)	Grain yield (ton/ha)
22 ˚C	84.266 a	125.300 a	170.833 a	345.533 b	35.297 a	23.701b	0.268 a	12.669 a	3.475 a
4 ˚C	84.839 a	125.400 a	170.933 a	364.233 a	32.383 b	22.707 c	0.256 b	12.376 a	3.232 b
-18 ˚C	84.029 a	122.233 b	166.333 b	342.700 b	31.288 b	24.295 a	0.221 c	12.514 a	2.835 c

A reverse effect was recorded for the vernalization temperatures on the number of grains per spike, as the increased chilling temperature has negatively reduced the grain number/spike. There were also significant differences in the levels of incubation temperature for 1000 kernel weight. Decreasing the temperature to 4ºC had a negative effect on the weight of kernels, while a further reduction in the incubation temperature to -18ºC had increased the weight of 1000 kernels (24.295 g). Harvest index was negatively affected due to the reduced temperature. Total biomass was not affected by different incubation levels. The accumulation of bio-product is more genetically controlled (Kumar et al., 2016; Brinton et al., 2017), while tracking the product to be accumulated to different parts of the plant is a matter of environmental effect in addition to genetic structure. Grain yield was identified to be reduced by decreasing the incubation temperature.

The incubation period for the wheat varieties seems to have a high effect on plant height and days to maturity (*Table 7*). Plant height had a few increases with the extended incubation period, while days to maturity has decreased with the same trends of incubation extension. No significant increase in grain weight was realized by increasing the period of incubation from two to four weeks duration. This result indicates the satisfaction period of two weeks incubation at low temperature for the wheat varieties under study. The varieties under study might be weak winter genotypes and the 2 weeks duration could be satisfactory for vernalization as extending to four weeks duration of a cold explosion being non-necessary for the current genotypes.

The interaction of varieties×incubation temperature for the grain of wheat varieties had different effects on the studied characteristics (*Table 8*). The interaction between Sabir-beg and 4ºC gave the maximum plant height of 115.583 cm, while the minimum plant height of 72.078 cm was referred to as the interaction between Mariboss and 22ºC incubation. Same interaction effect of Sabir-beg×4ºC was recorded for minimum days required to flowering (101.667 days). The interaction of Sabir-beg variety to other incubation temperatures had the same effect on the days to flowering. The maximum number of days required to start flowering (131.5 days) was recorded for the interaction between Mariboss and 22ºC incubation. Like days to flowering the minimum days to maturity was referred to Sabir-beg interaction with different incubation temperatures, requiring 145 days to maturity, however, the maximum days spent to maturity was recorded for Mariboss with the incubation of 22ºC×4ºC. The maximum spike number of 442 spike/m^2 was identified for the interaction of Hereford×22ºC incubation, followed by the interaction of the same variety with -18ºC. The minimum number of spikes/m^2 was recorded for Mariboss interacted with 22ºC incubation. Grain number is one of the yield component traits that was recorded as a maximum of 49.667 grains/spike for the interaction of Skalnige variety with 22ºC incubation.

The minimum grain number/spike referred to the interaction of Sabir-beg with all incubation treatments. From this result, it seems that the grain number trait is mainly genotype-related (Guo et al., 2015), as the incubation treatment has no significant effect on the improvement of this trait. The interaction of Sabir-beg with the 4°C and -18°C incubations showed the maximum weight of 1000 kernel (32.185 g and 31.233 g, respectively). Skalnige interacting with 4°C incubation had the minimum of 1000 kernel weight (17.1333 g). The interaction of Sabir-beg with the 4°C had the maximum record for harvest index, biomass yield and grain yield, while the minimum record refer to Ritraw interacting with -18°C incubation for both traits of harvest index and grain yield. It is clear that Sabir-beg is the most adapted variety to the local environment, requiring less vernalization, which makes the interaction of this variety with low incubation temperatures to give less effect. In terms of biomass yield the minim value (however not significant) referred to the interaction of Skalnige with all incubation temperatures. Less vernalization effect on the European varieties characteristics in this study could refer to the presence of allelic variation (VRN) at vernalization (Whittal et al., 2018). Presence of another allele (VRN4) or recessive VRN allele to VRNI gene could drive the transcription of this gene without severe needs for vernalization period (Goncharov, 2004; Kippes et al., 2015), or they might be semi-winter cultivars that require less period of low incubation temperature for full vernalization, and capable of switching to generative development under local environmental conditions (Goncharov, 2004; Li et al., 2013). Another possibility is that, planting the current varieties by mid of December did not allow the germinated plant to catch enough short day exposure, as a short day phototropism combined with low temperatures is required to permit VRN1 expression for floral transition of the meristem at an earlier period (Hemming et al., 2008; Li and Dubcovsky, 2008; Whittal et al., 2018), as a result no realized differences between the treated vernalization and controlled wheat grains were recorded.

The interaction between varieties and incubation periods had different effects on the studied characteristics (*Table 9*). Plant height had the maximum value of 115.722 cm for the interaction between Sabir-beg and four weeks incubation, followed by the interaction Sabir-beg×two weeks incubations. A minimum plant height was referred to as Mariboss interacted with four weeks incubations. The same interaction of Sabir-beg×2 weeks incubation had spent the minimum days to start flowering (101.778). Regarding plant height, the maximum days required to start flowering was recorded for Mariboss interacting with two and four weeks incubations. The same pattern was also realized for days to maturity. Spike number was identified to be at the maximum rate (423.00 spike/m^2) for Hereford interacting with two weeks incubation, while the least value was recorded for the interaction of Mariboss×2 weeks incubation, giving 296.444 spike/m^2.

A maximum number of 40.978 and 40.133 grain/spike was identified for Skalnige interacting with two and four weeks incubations, while the least number of 22.39 grains/spike referred to Sabir-beg interacting with two weeks interaction. The highest 1000 kernel weight was 31.488 g and 31.109 g for Sabir-beg interacting with two and four weeks incubations, respectively. While the interaction of Hereford with four weeks incubation had the lowest weight of 18.506 g for 1000 grain of wheat. Harvest index was identified to be at a maximum rate of 0.289 for Mariboss interacting with four weeks of incubation. Biomass yield had the maximum value of 15.773 and 15.739 ton/ha for Sabir-beg variety interacting with two and four weeks of incubation, respectively. A minimum value of 9.231 ton/ha was recorded for Skalnige interacting with two weeks incubation. Grain yield also had the same pattern as biomass yield, giving the maximum

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61216136

yield of 4.197 and 4.127 ton/ha for the interaction of Sabir-beg with two and four weeks of incubation, respectively. The minimum grain yield was recorded for Mariboss interacting with 2 weeks incubation. The results here indicated the superiority of Sabir-beg interacting with both incubation periods, which surpassed other varieties in the majority of traits. The persistence of the genotypes is a major insight for this experiment, as the incubation of four weeks period had no significant change compared to the two weeks incubation.

Table 9. *Effect of varieties and period of storage interaction on agronomic traits, yield and its components of wheat varieties*

Varieties × Incubation period	Plant height (cm)	Days to flowering	Days to maturity	Spike number/m^2	Grain number/ spike	1000 kernel weight (g)	Harvest index	Biomass yield (ton/ha)	Grain yield (ton/ha)

The effect of different vernalization temperatures and the period of incubation is clarified in *Table 10*. The interaction between incubation temperature and the period of incubation was not significant however the highest plant height of 85.44 cm was recorded for 4^{o}C×4 weeks incubation. The same interaction was significant for days to flowering, recording the least days spent to flowering, while it had the highest and most significant number of days to maturity. It seems from this result that the interaction effect of 4^{o}C incubation with four weeks period had allowed the flowering to be advanced, allowing the plant to stay longer in the flowering stage giving a higher number of spike per unit area with reasonable biomass. Proper management of the flowering period results in higher productivity, however, the highest yield of 3.584 has resulted from the interaction of 4^{o}C×2 weeks incubation. Significant effect of vernalization in wheat has been investigated previously at the temperature below 10^{o}C (Robertson et al., 1996).

Same interaction of 4^{o}C×4 weeks incubation showed the highest potential of 365.333 spikes per square meter, however it is not statistically significant. Grain number/spike was also not significant for the interaction between the incubation temperature and the period of incubation, while the maximum value of 35.43 grain/spike was recorded for the interaction between 22^{o}C×2 weeks incubation. The interaction

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61216136

of -18°C×4 weeks incubation showed the highest value of 26.182 g for 1000 kernel weight. The interaction of 4°C×2 weeks incubation gave the highest harvest index of 0.281, while the lowest value referred to the interaction of -18°C×2 weeks incubation. Biomass yield recorded the maximum value of 13.007 followed by 12.931 ton/ha for the interaction of -18°C×4 weeks incubation and 22°C×2 weeks incubation, respectively. Grain yield was identified to reach a maximum of 3.584 ton/ha for the interaction of 4°C×2 weeks incubation, the lowest grain yield of 2.515 ton/ha has been identified for the interaction between -18°C and 2 weeks incubation. This combination treatment between different incubation temperatures and their periods could explore the efficiency of 4°C with two weeks incubation could be satisfactory to induce the vernalization in the wheat varieties under study, as any further extension in the duration of cold treatment would not affect a reduction in the flowering period (Kim et al., 2009).

Table 10. *Effect of temperature and period of storage interaction on vegetative growth, yield and its components of wheat varieties*

There are variable effects on all the traits with the triple interaction effect of varieties×temperature×incubation period (*Table 11*). Sabir-beg interacting with the other two factors showed the best records for the traits plant height, days to flowering, days to maturity, 1000 kernel weight, biomass and grain yield. The reason for surpassing Sabir-beg by the other genotypes either individually or interacting with other factors could refer to the genetic architecture of these genotypes to validate VRN1 alleles to reduce or eliminating the vernalization requirement and able to manage the vernalization stage in a few days at a suitable temperature ranged from 5-20°C (Mureşan et al., 2019). Hereford×4°C×two weeks incubation had a reasonable grain yield after Sabir-beg, recoding 4.546 ton/ha, also the maximum harvest index of 0.327 was recorded for it.

Despite the above results for the interaction of genotypes, incubation temperature, and its period, many other genotypic and environmental factors could be involved in this highly complex biological process. It is identified that mechanisms of vernalization are not just genetically controlled, they are also categorized based on their interactions with the environment (Griffiths et al., 2009). Despite the complexity of genetic and environmental interaction in vernalization operation, other genes are also involved in relation to vernalization, such as VER2 (Yong et al., 2003), which encourage de-vernalization in wheat by silencing the activity of VRN1 gene.

Conclusion

The wheat varieties had a highly significant variance for all the studied traits. Sabir-beg had the highest and most desired performance for most of the traits including grain yield, while Hereford had the highest spike number per unit area, and Skalnige showed the highest grain number/spike. The incubation temperatures had a highly significant effect on most of the traits including grain yield. Days to flowering was reduced with -18^{o}C incubation. The same pattern was also indicated for days to maturity, spending less days to maturity when vernalized at -18^{o}C treatment.

Period of incubation for different temperatures had a significant effect on plant height, days to maturity, and 1000 kernel weight. This result indicates the satisfaction period of two weeks incubation at low temperature for the wheat varieties. Sabir-beg is a local variety that is mostly adapted to the local environment, requiring less vernalization, as the interaction effect of this variety at low incubation temperature had less effect on the studied traits.

The interaction of varieties×incubation temperature had a highly significant effect on all traits except biomass yield. The interaction of 4^{o}C with different wheat varieties had superiority to direct some of the important traits. It also seems that grain number is mainly genotype-related as the incubation treatment has no significant effect on the improvement of this trait. This result assured the necessity of involving the European varieties in field trials to be used directly or in a breeding program to improve the grain number/spike as an important trait related to yield. The high number of 40.566 grain/spike for Skalnige variety compared to 22.633 grain/spike of local variety is a big support for the importance of involving the European variety in the improvement program of wheat in the Kurdistan region of Iraq. The varieties persistency is also an outcome of their interaction with the incubation period, as the incubation of four weeks period had no recognized change on the traits compared to the two weeks incubation. The interaction effect of 4^{o}C×four weeks period had allowed the flowering to be advanced, allowing the plant to stay longer in the flowering and maturation period giving a higher number of spike per unit area, which indicates the effect of low incubation temperature on the varieties under local environmental conditions.

Both interactions of varieties×incubation temperature and varieties×incubation period had a similar effect on the traits studied, as harvest index, biomass yield, and grain yield were highly significant for both interactions, but with less effect on improving the yield. This could refer to the availability of different alleles for VRNI gene, reducing the necessity of vernalization period or reversing its effect. Cold treatment (vernalization) can not alone regulate the flowering initiation, coordinating the responsive interaction of the plant with its environment, it is also necessary to express floral activation. The interaction of all three factors showed a highly significant effect on all the traits. Cultivation of the European varieties under study under local environmental conditions is recommended to boost the increase of grain yield in wheat. *In vitro* vernalization for the grains is a substitute solution for completing the required vernalization period, that might be raised by delaying sowing or unsatisfied cold period during planting and growing season to vernalize such varieties. Further filed trial is suggested in the future, involving more variable wheat genotypes to evaluate the yield resiliency and homeostasis of broad and diverse alleles under local environmental conditions.

Abstract. Lake Tortum is a natural deep and landslide-set lake located in the northeast of Erzurum in the Eastern Anatolia Region of Turkey. The lake is under the influence of anthropogenic activity and pollution from agriculture. This paper, it was aimed to estimate the trophic level of Lake Tortum together with biological and some physicochemical parameters, as well as the external phosphorus load of this lake. The Lake was determined to be mesotrophic according to Secchi depth, total phosphorus concentration and chlorophyll-a tests. External phosphorus load was calculated above the critical phosphorus value determined for lakes. The lake has been shown in the eutrophication phase due to the nutrient inflow results exceeding the lake's loading capacity, the presence of some eutrophic species in the phytoplankton composition, and the periodic increase in blue-green algae. A total of 51 phytoplankton species were identified in the study period, belonging to 12 functional groups. The seasonal succession of dominant functional group is code LM (*Ceratium hirundinella*). The mean value of Q index in Tortum Lake was estimated as 1.88 which pointed out the tolerable ecological quality status.
Keywords: *external phosphorus load, phytoplankton composition, Q index, eutrophication*

Introduction

Global warming and discrepancies in seasonal transitions diminish the freshwater resources each day. In addition to that, available freshwater resources face pollution threats with industrialization and increases in urban population. Determination of the nutrient status of a lake and uncovering the factors affecting it are very important in protecting the present water resources.

Lentic systems are impacted by the rock structure and climate of the catchment, or drainage basin, in which they are located, and each lake has its own dynamics (Wetzel, 2001). Lentic systems have a tendency to transform into ponds and swamps. That process takes a few hundred years in large lakes, but it can happen faster in their smaller counterparts (Tanyolac, 2009). Humanity has an impact on the evolution process of lakes as well. The main pollution sources for lake systems are urban, industrial, and agricultural activities (Metcalf and Eddy, 2002). In addition to those, nuclear power plants and poorly planned hydroelectric power plants are pollution sources. Organic and inorganic pollutants not only disrupt the physicochemical composition of lakes, but they also alter the biological structure (Coban, 2007). Pollutants and climate change have led to increases in eutrophication, fish deaths in some period (expecialy summer months), increasing of invasive species in lakes, carbon dioxide emission from lakes, and methane emission from sediments, as well as an increase in aquatic plants. Besides, excessive water diverted from lakes drops the water level of those lakes (Jessepsen et al., 2009).

In addition to physicochemical parameters such as N, P, Si, Ca, and Mg content, phytoplankton communities and other aquatic organisms, such as fishes and macrophytes, are used as bioindicators in the determination of the trophic levels of lakes. Various studies have been conducted to determine the trophic levels of lakes by using phytoplankton communities and benthic algae (Thunmark, 1945; Nygaard, 1949; Lepistö and Rosenström, 1998). Those methods were not accepted by other researchers, however, because the phytoplankton communities exist as different species in different regions, and it was not understood whether pollution has any observable effect at all on the species distribution (Padisák et al., 2006). On the other hand, recent studies have illustrated that phytoplankton, macrophytes, benthic organisms, and fishes can be considered as biological parameters in the process of lake trophic level determination.

Reducing the nutrient level in lakes can improve water quality by controlling eutrophication. In addition to the restriction of external nutrients, the nutrients accumulated in the sediments—and especially phosphorus—should be removed in the process of nutrient reduction in lakes, because high nutrient accumulation can alter the biological structure. The most significant step in remediating a lake successfully and permanently is the determination of the corresponding nutrient load of the lake beforehand (Van Damme et al., 2007).

The aims of the study were to determine the trophic level of Lake Tortum, located in the Eastern Anatolian region of Turkey, and the effect of agricultural and other anthropogenic pollutants on the water quality and phytoplankton composition of the lake.

Materials and Methods

Research area

Lake Tortum, a natural landslide-barricaded lake, is situated in northeastern Erzurum. It is between 40° 35′ and 40° 39′ north latitude and at 41° 38′ east longitude, at an altitude of 1012 m and 95 km from the city of Erzurum. It is about 8 km in length and 0.7 km in width, and the average depth is 100 m. The lake has been utilized for touristic and fishing activities. The main water flow to the lake comes from Tortum Stream. The stream, which is approximately 50 km in length, starts in the Mescit, Yıldızdağ, and Ereğli Mountains and collects all the water from a 1900 km^2 catchment in the Tortum District and enters the lake. After its exit, it creates a large waterfall at the shoreline. Later, it merges with the Çoruh River (Kıvrak, 2006; Kıvrak and Gurbuz, 2010).

Research on identification of trophic level on the lake are limited. The first study was carried out in the lake in 1982 for determination of phytoplankton species and some physico-cemical water quality parameters. Another study has been performed on the lake between 2005-2006. In this study, it was investigated if there was changed in plankton species, and finally, in the 2012-2013 period, the structure of the lake's phytoplankton communities and the changes in some water quality parameters were investigated (Altuner, 1982; Kıvrak, 2006; Fakıoglu et al., 2014, 2018). With its 6.45 km^2 lake area, Lake Tortum is a significant lake in Tortum Stream catchment (1653 km^2). The average depth of the lake is 100 m, and its volume is assumed to be 57.6 hm^3. The hydrological and morphometric measurements related to the lake are provided in *Table 1*. Some of the values in the table were provided from DSI (The General Directorate of State Hydraulic Works, Tur, Ministry of Agriculture and Forestry).

* Standard Deviation, ** The different capital letters in the same column show the differences between months ($p<0.05$)

Fieldwork and sampling

Between February 2017 and January 2018, monthly water and plankton samples were taken in Lake Tortum (Erzurum). A total of 5 stations have been identified through the lake (3 stations) and Tortum Stream (2 stations) (*Fig. 1*). Three stations in the lake and in 5 different depths at each station (surface, 5 m, 10 m, 30 m, and 40 m depth) samples were collected by Ruttner type sampler. Simultaneously, one station at the entrance of Tortum Stream to the lake and one station at its exit were taken water samples for investigation of extarnal phosphorus loading. Phytoplankton samples were taken with the plankton nets for identification of phytoplankton in the lake. To determine the number of phytoplankton, water samples with Lugol solution added, which were taken from both stations and depths of the lake, were brought to the laboratory with polyethylene containers. In order to determine the atmospheric phosphorus loading, presipitations coming to the location of the lake were collected in a sterile container every month and then transferred to the polyester sample bottles of 2 L.

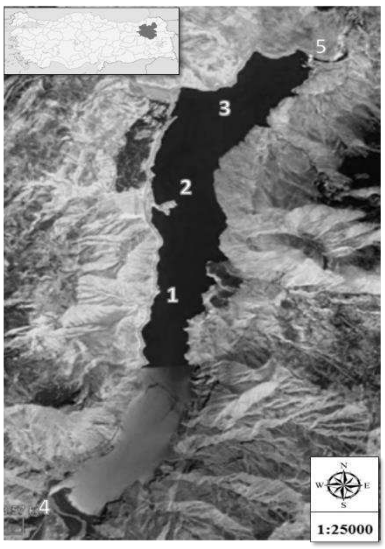

Figure 1. *Location of Lake Tortum and stations*

DOI: http://dx.doi.org/10.15666/aeer/1805_61376162

Identification and calculation of phytoplankton

Phytoplankton species were identified under a binocular microscope with 100x and 400x magnification using a literature (Hustedt, 1930; Huber-Pestalozzi, 1938, 1942, 1950; Starmach, 1966; Prescott, 1973; Lind and Brook, 1980; Popovski and Pfiester, 1990; Cox, 1996; Komarek and Anagnostidis, 1999; John et al., 2002). The detected species have been checked on www.algaebase.com. Diatoms were investigated after precipitating the water samples with Lugol's solution addition; then nitric and sulfuric acids in equal volumes were utilized for boiling and acid-washing to remove the organics and expose the diatoms' silica skeletons (Round, 1953). For the enumeration of phytoplankton, water samples were first put into 10 mL graduated cylinders, and Lugol's solution was added and left overnight. After that, 3 mL of that solution was conveyed to phytoplankton enumeration rings, and the enumeration was done via an inverted microscope (Utermohl, 1958; Anonymous, 2003).

The Q phytoplankton assemblage index was estimated following Padisák et al. (2006), and ranged from 0 to 5 on a scale according to the WFD (World Framework Drictive) requirements. According to WFD's five grade evaluation system can be evaluated at 0-1: bad; between 1 and 2 as tolerable; 2-3: medium; between 3 and 4 as good, and 4-5: excellent quality (Padisák et al., 2006). For Lake Tortum, the factor numbers described for the Hungarian lake type 1 were used (Padisák et al., 2006). Phytoplankton species constituted more than 5% of total biomass were classified into functional groups according to Reynolds et al. (2002) and Padisák et al. (2009). The Water Framework Directive was adopted by the European Union in 2005. Turkey is a country in the process of integration into the European Union. Therefore, the rules have brought this directive has been implemented in Turkey. In this context, watershed-based study has been conducted in Turkey. In these studies, it was stated that the values developed for Hungarian lake type can be adapted in the use of Q index for in the evaluation of phytoplankton communities in Turkey, as well (Selek and Karaaslan, 2019).

Water quality analyses and chlorophyll-a

Water temperature, dissolved oxygen, pH, conductivity (with YSI Multiparameter), and Secchi depth (with Secchi Disk, 20Ø) were measured in situ. Total hardness analyse in water samples were conducted according to Anonymous (1995). In TP (total phosphorus) analyses, the first part (digestion) was done by using the persulfate decomposition technique. Consequently, free orthophosphate phosphorus (PO_4-P) was analyzed by the ascorbic acid method. Ammonia-nitrogen (NH_3-N) was detected by the Nesslerization method. Nitrite-nitrogen (NO_2-N) was detected by making use of the color formed with diazotization of sulfanilic acid (by nitrite) and the addition of the product to N-1-naphthylethylenediamine dihydrochloride. Its absorbance was then measured via 523 nm wavelength light. Nitrate-nitrogen (NO_3-N) concentration in water samples was determined by the yellow color formed after the nitrate's reaction with brucine sulfate; then the solution's absorbance was measured via 410 nm light (Anonymous, 1995). For chlorophyll *a* detection, 1-L water samples were collected, and the combined water filtration system filtered them through a Whatman GF/C filter. The filtrate was left for 3 to 4 hours and decomposed. After that, it was left in 10 mL of %90 acetone solution, and the centrifuged extract's optical density was monitored in a spectrophotometer in wavelength of 630, 645, and 665 nm light (Strickland and Parsons, 1972).

External phosphorus loading

The TP loading reaching the lake from the land (TPL, land loading) is equal to the multiplication of the entering waters' phosphorus export coefficients and the catchment area. The phosphorus export coefficient (Ep) is calculated from the TP carried by the streams in a year—flow rate x TP concentration ($kg.yr^{-1}$) divided by the area of the stream in the catchment calculated through planimeter from a standard topographic map (1:50.000) (Kirchner and Dillon, 1975).

$$LL = \sum As\ xEp \quad \text{(Eq.1)}$$

LL: Land loading ($kg.yr^{-1}$),
As: Stream catchment area (km^2),
Ep: Phosphorus export coefficient ($kg.km^{-2}.yr^{-1}$).

The atmospheric phosphorus loding (AL) was calculated according to Dillon and Rigler (1975).

$$AL = P \times TPp \times Ao \quad \text{(Eq.2)}$$

AL: Atmospheric loading ($kg.yr^{-1}$),
P: Annual precipitation ($mm.yr^{-1}$),
TPp: Average TP concentration in rainwater (mgL^{-1}),
Ao: Surface area of the lake (km^2).

$$NL = LL + Al \quad \text{(Eq.3)}$$

NL: Natural loading ($kg.yr^{-1}$),
LL: Land loading ($kg.yr^{-1}$),
AL: Atmospheric loading ($kg.yr^{-1}$).

In Turkey, the phosphorus load coming from domestic wastewater has been determined to be 3–4 g/d/capita, according to the İller Bankası General Specification of Wastewater Treatment Plant Process (Ozden, 2002). As a result, artificial or domestic load was calculated as (DL).

$$DL = N \times \frac{\frac{3.5g}{day}}{capita} \times 365\ days \quad \text{(Eq.4)}$$

DL: Domestic load ($kg.yr^{-1}$),
N: Basin population (individual).

The phosphorus load reaching the lake ($kg.yr^{-1}$) is equal to the sum of natural and domestic loads.

$$TPL = NL + DL \quad \text{(Eq.5)}$$

TPL: Total phosphorus load ($kg.yr^{-1}$),
NL: Natural load ($kg.yr^{-1}$),
DL: Domestic load ($kg.yr^{-1}$).

On the other hand, the total phosphorus loading factor is equal to the TP load divided by the lake's surface area.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61376162

$$Lp = TPL \div Ao \quad \text{(Eq.6)}$$

Lp: Total phosphorus loading factor ($kg.km^{-2}.yr^{-1}$),
TPL: Total phosphorus load ($kg.yr^{-1}$),
Ao: Surface area of the lake (km^2).

Vollenweider (1976), emphasized that water residence time is also important in the critical load formula. It was found that the critical phosphorus concentration should be between 10 mg/m^3 and 20 mg/m^3. According to that, the following formula is used to calculate critical phosphorus loading:

$$Lcritical = 10q\left(1 + \sqrt{tw}\right) \quad \text{(Eq.7)}$$

Lcritical: Critical phosphorus loading ($mg.m^{-2}.yr^{-1}$),
q: Flushing rate ($m.yr^{-1}$),
tw: Hydraulic retention time (year).

The permit water loading ($g.m^{-2}.yr^{-1}$) and the critical loading value ($g.m^{-2}.yr^{-1}$) was determined by the equations, used to be flushing rate (q, $m.yr^{-1}$), given below (Chapra and Tarapchak, 1976):

$$Lpermit = 0.011(q + 12.4) \quad \text{(Eq.8)}$$

$$Lcritical = 0.025(q + 12.4) \quad \text{(Eq.9)}$$

Critical phosphorus loading could also be calculated by using field phosphorus loading ($g.m^{-2}.yr^{-1}$), chlorophyll-a (mgL^{-1}) and flushing rate (q, $m.yr^{-1}$) (Chapra and Tarapchak, 1976):

$$Lcritical = 0.0055\ (chl\ a)^{0.69}\ (q + 12.4) \quad \text{(Eq.10)}$$

Statistics

The monthly, stationary, and depth-related changes in the data taken from the three selected stations' surface, 5 m, 10 m, 20 m, 30 m, and 40 m depths were examined with IBM SPSS 20 software. To understand the collective effect of the stations and seasons, water temperature, dissolved oxygen, pH, conductivity, Secchi disk, total hardness, NH_3-N, NO_2-N, NO_3-N, TP and PO_4-P were analyzed by the use of three-factorial Analysis of Variance (ANOVA). The Duncan test was employed to determine the intergroup differences. Canonical Correspondence Analysis was done with XLSTAT software.

Results

Physico-chemical parameters of Lake Tortum

The average depth of the Lake Tortum (100 m) was provided from DSI (The General Directorate of State Hydraulic Works, Tur, Ministry of Agriculture and Forestry). The depth of Secchi was determined between 3 m and 5 m throughout the year. The lowest value (2.15±0.74 m) of Secchi depth was measured in April and the highest value (7.80±1.51 m) in June during the clean water phase. The mean Secchi depth was 4.42 m.

Stationary and depth-related changes in water temperature, dissolved oxygen, pH, conductivity and total hardness values were statistically significant ($p < 0.05$). Water temperature, dissolved oxygen, pH, conductivity, and total hardness mean values in the lake were 10.64 ºC, 6.81 mgL^{-1}, 8.47, 0.289 $mS\ cm^{-1}$, and 166 mgL^{-1} $CaCO_3$, respectively (*Table 1*).

The catchment area of Lake Tortum, shows microclimate characteristics (Duman, 2009), so the lake not ice-covered in winter, and the mean water temperature in the winter months was measured as 6 °C. The thermal stratification in spring and autumn periods was weak, but a considerable stratification was observed in summer. Thus, Lake Tortum belongs to the warm monomictic lake class in Wetzel's (2001) classification of the lakes according to their stratification.

Detected lowest dissolved oxygen value was (5.6 mgL^{-1}) in September and the highest value (8.65 mgL^{-1}) in April. The dissolved oxygen value in the lake water supply and the drainage water of the lake was also higher than the lake and the average minimum and maximum values were found to be 5.06 mgL^{-1} and 11.03 mgL^{-1}, respectively (*Table 1*). The lowest water temperature value was detected at the 1st station (4.1 ºC) in February, at a depth of 5 and 10 m, and the highest water temperature value at the 1st station (25.4 ºC) on the surface in August. Depending on the depth of the Tortum Lake water temperature, a significant stratification was detected in the summer and autumn seasons. In spring, the water temperature value on the surface was measured at 10.26 ºC, and as the depth increased, a decrease of 1 ºC was observed in the water temperature value. During the winter period, the water temperature value ranged between 5.37 ºC and 5.8 ºC, respectively, at depths of 0-40 m. At the stations that feed the lake and discharge the lake water, the water temperature value was determined as the lowest 3.4 ºC and 4.8 ºC, the highest 24.1 ºC and 25.1 ºC, respectively.

The mean pH value was measured as 8.48 ± 0.12. According to Turkish Environmental Legislation Inland Water Resources Classification, the lake was identificated as first class waters quality (Anonymous, 2012). pH was measured in June at its lowest value in the 1st station (8.0) and the highest value in February at the depth of 10 m (8.9) in June. At the 2nd station, the lowest value (8.1) was found at the surface in July at the surface depth in July (8.79). The lowest value at the 3rd station (8.32) was determined at the depth of May 20 m, the highest value (8.7) at 0 m and at a depth of 5 m in July (*Table 1*).

The difference between TP, PO_4-P, NH_3-N, NO_2-N and NO_3-N concentration values between stations, months and depths was found to be statistically significant ($p < 0.05$). TP, PO_4-P, NH_3-N, NO_2-N, and NO_3-N (mean± SD) were 0.31 ± 0.03 mgL^{-1}, 41.05 ± 2.65 μgL^{-1}, 0.14 ± 0.02 mgL^{-1}, 0.55 ± 0.08 mgL^{-1}, and 1.10 ± 0.02 mgL^{-1}, respectively.

TP values were 0.33 ± 0.03 mgL^{-1}, 0.34 ± 0.04 mgL^{-1}, and 0.27 ± 0.03 mgL^{-1} in the first, second, and third stations, respectively. PO_4-P showed its lowest value (0.0 ± 0.0μgL^{-1}) at all stations except for the months of July, August, and January. The highest values in the first, second, and third stations were 77.84 ± 0.09 μgL^{-1}, 39.20 ± 0.01 μgL^{-1}, and 47.16 ± 0.02 μgL^{-1}, respectively (*Table 2, Table 3*).

For differences of NH_3-N at the stations, the lowest value at the first station was found in January in all depths; on the other hand, the highest value was 0.25 ± 0.01 mgL^{-1} at 10 m, 30 m, and 40 m depths in March. At the second station, the lowest value was 0.06 ± 0.01 mgL^{-1} on the surface in June, and the highest value was 0.43 ± 0.02 mgL^{-1} at 40 m depth in January. At the third station, the lowest value was 0.0 ± 0.0 mgL^{-1} at the surface in August, and the highest value 0.45 ± 0.02 mgL^{-1} was at 5 m depth in January (*Table 4*).

DOI: http://dx.doi.org/10.15666/aeer/1805_61376162

When the NO_3-N values were examined according to different months and stations, the lowest mean value at the first station was 0.02 ± 0.01 mgL^{-1} in January, while the highest value was 6.06 ± 0.05 mgL^{-1} in September. The lowest mean value at the second station was 0.01 ± 0.01 mgL^{-1} on January, while the highest value was 5.59 ± 0.02 mgL^{-1} in September. The lowest mean value at the third station was 0.0 ± 0.0 mgL^{-1} in August and January, while the highest value was 9.45 ± 0.05 mgL^{-1} in September. The mean values of NO_3-N at the first, second, and third stations were 1.05 ± 0.02 mgL^{-1}, 0.99 ± 0.05 mgL^{-1}, and 1.27 ± 0.03 mgL^{-1}, respectively (*Table 5*).

NO_2-N values were lowest in February, March, and January for all stations and were highest in December. In March, July, and January, the second and third stations NO_2-N values for all depths were 0.0 ± 0.0 mgL^{-1}. During the same period at the first station, a concentration of 0.38 ± 0.01 mgL^{-1} was measured, at the surface only. The largest NO_2-N values at the first, second, and third stations were detected as 4.38 ± 0.01 mgL^{-1}, 4.69 ± 0.01 mgL^{-1}, and 5.63 ± 0.01 mgL^{-1}, respectively (*Table 6*).

External phosphorus loading in Lake Tortum

The land phosphorus load was calculated by the multiplication of phosphorus export coefficient (kg yr^{-1}) and catchment area (km^2). Tortum Stream continuously supplies water to Lake Tortum from its catchment area of 16.534 km^2. The phosphorus export coefficient (Ep) was calculated to be 0.07934 kg km^{-2} according to Kirchner and Dillon (1975) methods. The morphometric and hydrological parameters of Lake Tortum have been supplyed from DSI (*Table 7*).

The land phosphorus load was found to be 1312 kg yr^{-1} (*Equation 1*), while the atmospheric loading (AL) is 31 kg yr^{-1} (*Equation 2*). The natural phosphorus load is 1343 kg yr^{-1} (*Equation 3*), whereas the domestic phosphorus load is 9707 kg yr^{-1} (*Equation 4*). The external TP loading to the Lake Tortum is 11050 kg yr^{-1}. The TP load coeficient was computed to be 1.71 $g.m^{-2}.yr^{-1}$ (*Equation 6*). According to the formulas developed by Chapra and Tarapchak (1976) and Vollenweider (1976) from the calculated phosphorus loadings of Lake Tortum measured in 2017.

$$\begin{aligned} L_{critical} &= 10 \text{ x } 74.42\ (1+0.34641) \\ &= 1002 \text{ mg.m}^{-2}.\text{yr}^{-1} \\ &\sim 1.002 \text{ g.m}^{-2}.\text{yr}^{-1} \end{aligned} \quad \text{(Eq.7)}$$

$$\begin{aligned} L_{permit} &= 0.011\ (74.42 + 12.4) \\ &= 0.96 \text{ g.m}^{-2}.\text{yr}^{-1} \end{aligned} \quad \text{(Eq.8)}$$

$$\begin{aligned} L_{critical} &= 0.025\ (74.42 + 12.4) \\ &= 2.17 \text{ g.m}^{-2}.\text{yr}^{-1} \end{aligned} \quad \text{(Eq.9)}$$

$$\begin{aligned} L_{critical} &= 0.0055\ (0.04)^{0.69}\ (74.42 + 12.4) \\ &= 0.05 \text{ g.m}^{-2}.\text{yr}^{-1} \end{aligned} \quad \text{(Eq.10)}$$

Chlorophyll-a

The changes in the value of chlorophyll-a in different months, stations, and depths were found to be statistically significant ($p < 0.05$). The mean chlorophyll-a value of the lake was 0.04 mgL^{-1}, and the lowest value was measured as 0.01 mgL^{-1} in the months of February 2017 and January 2018, whereas the highest value, 0.15 mgL^{-1}, was detected in April. When the changes according to the stations and depths are considered, the lowest value at the first station (0.0 ± 0.0 mgL^{-1}) was found at all depths in February and at all depths except the surface in January. The highest value, on the other hand, was 0.31 ± 0.01 mgL^{-1} in April at 10 m depth. At the second station, the lowest value (0.0 ± 0.0 mgL^{-1}) was found at all depths in January and February. The highest value, on the other hand, was 0.27 ± 0.02 mgL^{-1} in April at 5 m depth. At the third station, the lowest value (0.0 ± 0.0 mgL^{-1}) was observed in November and December, whereas the highest value (0.26 ± 0.01 mgL^{-1}) was in April and at the surface.

Strong correlations were found between chlorophyll-a and NH_3-N and PO_4-P. On the contrary, the correlation was weak with other parameters. Additionally, there was a negative correlation with TP and NO_3-N (*Table 8*).

Phytoplankton composition and biodiversity in Lake Tortum

In this study, 51 phytoplankton species in total were detected in Lake Tortum; they were Bacillariophyta (38), Charophyta (2), Chlorophyta (7), Cyanobacteria (3) and Pyrrophyta (1). Throughout the investigation period, the most detected species was *Ceratium hirundinella.* In addition to these, there was a specific increase in species *Microcystis aeruginosa* and *Oscillatoria limosa* (*Table 9*).

Pyrrophyta were detected throughout the study period at the first station. On the other hand, Cyanobacteria species showed an increase only in the autumn. At the second station, all species increased in number in April. A sharp decrease in the number of all species was observed in the summer months. Later, especially in October, the number of individuals from Bacillariophyta, Cyanobacteria, and Pyrrophyta increased. Charophyta had an increase in their number in January. At the third station, Bacillariophyta were observed throughout the study period. Bacillariophyta, Cyanobacteria, and Pyrrophyta were detected increase in the number of species in April, September and October. Additionally, Cyanobacteria were more frequently detected in February and March than were the other division (*Fig. 2*).

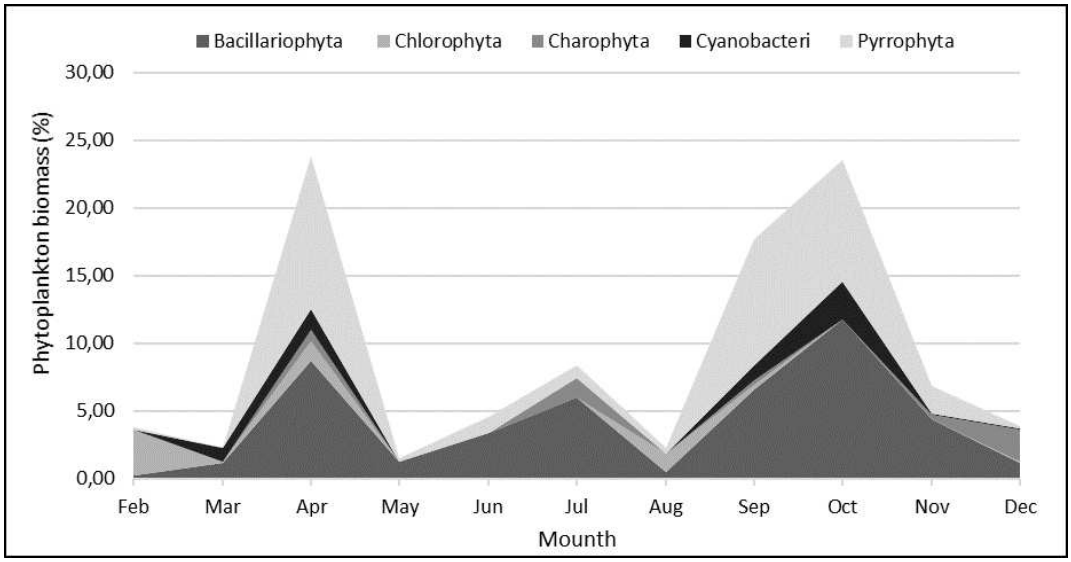

Figure 2. *Phytoplankton composition of Lake Tortum*

The dominant functional groups were both LM (*Ceratium hirundinella*) and MP (pennate diatoms) in the Lake Tortum in 2017-2018. *Ceratium hirundinella,* which is the only species found continuously during the research period, showed an increase in the autumn periods. *Cyclotella ocellata* (D) showed numerical increases in October and November. The Pennad diatoms, *Fragilaria capucina* (MP), were observed intensively in September. The other pennad diatoms *N. saprophila* and *N. palea* (MP) were idendificated in spring and early summer. In addition, *Microcystis aeruginosa* (LM) was found to be increasing in April, May and in October and *Oscillatoria limosa* (MP) was observed intensively in April (*Fig. 3*). the Q index indicated tolerable (mean 1.88) ecological conditions. The Q quality index based on stations (1, 2 and 3) were 1.79 (tolerable), 2.21 (medium) and 1.63 (tolerable), respectively (*Fig. 4*).

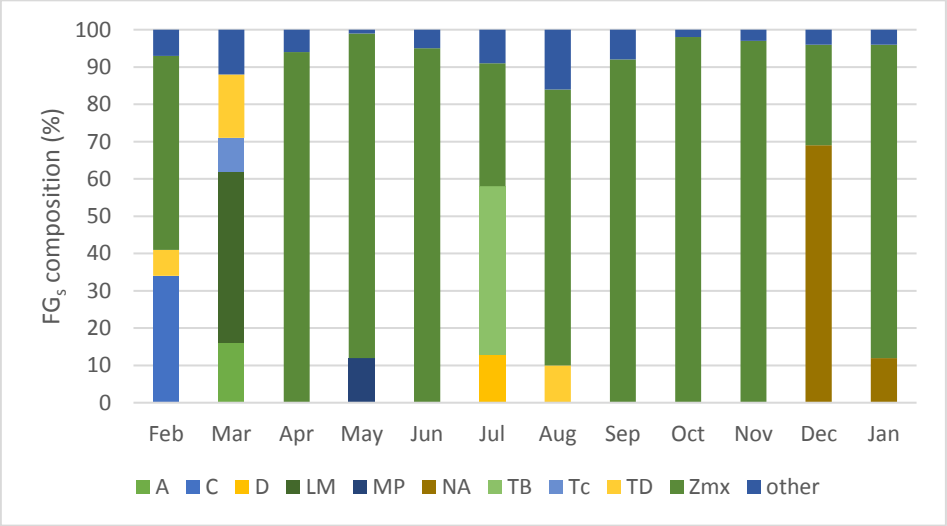

Figure 3. *Seasonal succession of phytoplankton functional groups (FGs) in in Lake Tortum. "Others" mean phytoplankton species that constituted less than 5% of the total biomass*

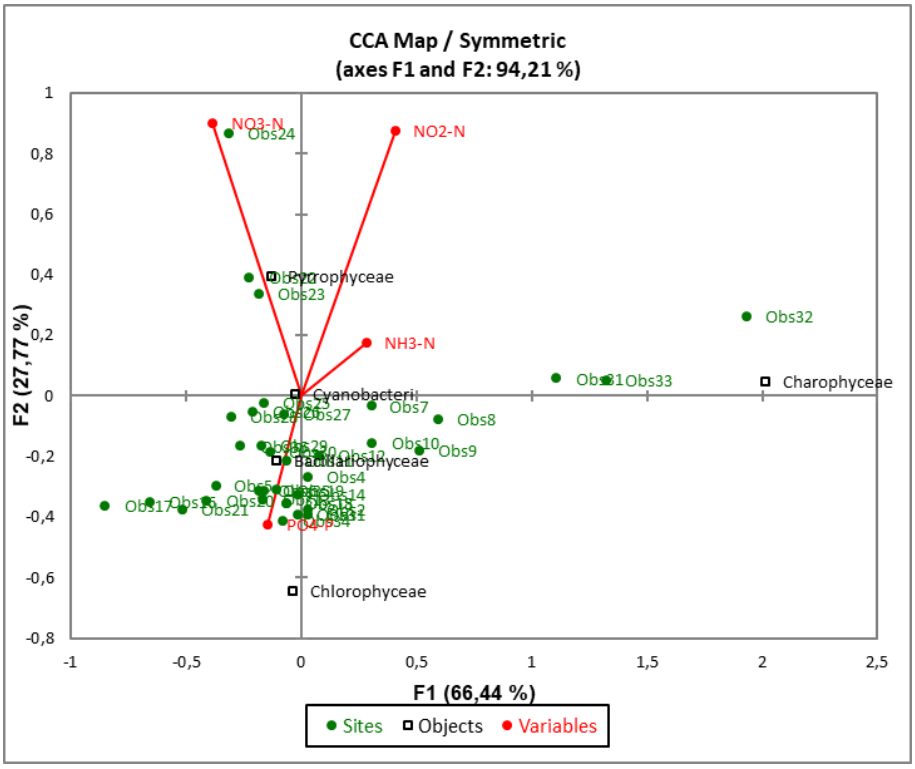

Figure 4. *Species-conditional triplot based on a canonical correspondence analysis of the example phytoplankton data displaying 27.77% of the inertia (= weighted variance) in the abundances and 94.21% of variance in the weighted averages and class totals of species with respect to the environmental variables*

Discussion

Lake Tortum is a landslide lake; moreover, it is a deep and open lake (Tanyolac, 2009). According to measurements of DSI, the mean depth of lake adopted as 100 m. Previous measurements of mean depth were 110 m in 1982 (Altuner, 1982), 100 m in 2003 (Kıvrak, 2006), and 80 m in 2013 (Fakıoglu et al., 2014). This lake is the major source for the Tortum Waterfall; for that reason, the regulator in the discharge region of the lake is opened during periods of drought to feed the waterfall. Thus, there may be temporary reductions in the water level. Nevertheless, the studies done in Lake Tortum indicate a 10 m reduction in depth since 1982.

In this study period, a weak thermal stratification in the lake has been observed. Even though mean water temperature value was measured 6.81 ± 1.00 ºC in this study, it was measured in 2003 and 2013 as 12.85 ± 5.75 ºC and 10.5 ºC, respectively (Kıvrak, 2006; Fakıoglu et al., 2014). Warm winters are especially critical to temperate in monomictic lakes, because the temperature affects the duration of the winter and its strength and, consequently, the thermal budget of the lake and the vertical distribution of nutrients and dissolved oxygen (Stratile et al., 2003).

The mean dissolved oxygen value in Tortum Lake was found as 6.81 ± 1.00 mgL^{-1} during the study. When there was mixing in the lake, an increase in dissolved oxygen concentration at the 40 m depth was observed. According to Turkish Environmental Legislation for Inland Water Resources Classification, the lake was identificated as II. class waters quality (Anonymous, 2012). The average dissolved oxygen value was found

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61376162

12.85 ± 5.75 mgL^{-1} in 2006 and 10.5 mgL^{-1} in 2013 (Kıvrak, 2006; Fakıoglu et al., 2013). Dissolved oxygen value has droped significantly since 2006. Increased organic load in the past years and subsequent organic degradation may have caused a decrease in dissolved oxygen value. However, fishing in the lake has been banned in the past 5 years, which has increased the fish population. In this case, it is thought that it will affect the decrease in oxygen value.

The lakes being in the easily melted area are hard-water lakes and forthis type of lakes the pH is close to 8.5 (Tanyolaç, 2009). Tortum Lake is located in the basin where landslide events are seen too much and the average pH value of lake was measured as 8.48. And, according to the total hardness classification of Lawson (1995) for lakes, water of Lake Tortum is in the hard water classification. Plant biomass is particularly high in moderately hard water bodies (Tanyolac, 2009). Therefore, biodiversity in the lake is very low, only two types of chlorophytes were observed in the littoral region, and only 51 phytoplankton species were identified in the lake.

The mean electrical conductivity was 0.289 ± 0.03 mS cm^{-1}. In another study in Lake Tortum in 2006, the electrical conductivity was found to be 0.308 mS cm^{-1} (Kıvrak, 2006). Natural lakes with discharge points typically have electrical conductivity values between 0.1 and 1 mS cm^{-1}. (Ozturk, 2014). It is possible to establish a connection between total dissolved solids concentration and electrical conductivity. The more ion and total dissolved solids concentrations in water, the higher electrical conductivity it has (Metcalf and Eddy, 2002). Tortum Stream carries almost 2.5 million m^3 of suspended sediment carries to the lake every year (Kopar and Sevindi, 2013).

In deep lakes, changes in depth and vertical stratification alter the water quality (Salmoso et al., 2002). In this study, according to the trophic status range of natural lakes reported by Wetzel (2001) and Anonymous (1982), Tortum Lake, Secchi depth (4.15 m), chlorophyll-a (0.04 ± 0.0005 mgL^{-1}) and total phosphorus concentration (0.31 ± 0.03 mgL^{-1}), was calculated as mesotrophic. In 1982, the lake was reported to be in an oligotrophic state (Altuner, 1982), and it was pointed to be oligo-mesotrophic in 2003, as well (Kıvrak, 2006). Unfortunately, the studies on this lake are very limited. In addition, not all physico-chemical parameters of the lake have been studied in these previous studies. However, these studies cover only certain periods, not every period. Although it makes it difficult for us to understand the change in the lake very clearly, collecting the data of the lake is important for the future of the lake.

In terms of TP values, the lake's trophic level changed from the oligotrophic to the mesotrophic level. In deep lakes, such trophic level changes are under the control of both climatologic and anthropologic variables (Salmoso et al., 2002). The highest TP value was seen on the surface at the first station. At the second and third stations, especially during the time when the mixing is strong (such as in summer months), the 40 m depth showed high TP values. Phosphorus has a tendency to precipitate on sediments in the particle state (Pulatsu and Topcu, 2012). Besides, the TP also depends on the geologic structure of the region and on organic matter entry into the water (Wetzel, 2001; Tanyolac, 2009). The mean orthophosphate concentration was found to be 0.1 ± 0.01 mgL^{-1} in this study. That value was 0.05 mg/L in a study done in 2003 in Lake Tortum (Kıvrak, 2006). According to Wetzel (2001), increased zooplankton numbers come from increased orthophosphate concentration, whereas Ozkundakçı (2014) claimed that they were affected by agricultural pollution. Zooplankton species and number were observed quite abundant over the study period. While a fraction of the phosphorus is expected to precipitate on sediments in deep and monomictic Lake Tortum, another part

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61376162

again returns to the water column according to the sedimentation, disintegration, and transformation ratios. Moreover, the concentrations of Fe, Al, Cd, and Pb elements were found to be low in heavy metal analyses conducted in Lake Tortum water, yet the potential ecological risk coming from those elements together has been determined to be moderate (Kaya et al., 2017). The increase in total phosphorus value in the lake, led to an increase in the number and variety of the primary producers of the lake. At the first station, where the lake is fed, the chlorophyll *a* value in summer months at the 40 m depth was found to be 0.03 ± 0.01 mgL^{-1}, while at other stations in the spring months and in the epilimnion stratum (the upper thermal layer of the lake), it was 0.13 ± 0.02 mgL^{-1}. Similar situations were also observed in other deep lakes, Lakes Gordo and Iseo; in both of them, when the temperature rose in the summer months, both the algae biomass and the level of nutrient salts increased (Salmaso, 2002).

In this study, the NH_3-N mean value was found to be 0.14 ± 0.07 mgL^{-1}. Fakıoglu et al. (2014) and Kıvrak (2006) were found that value to be 0.15 mgL^{-1} and 0.19 ± 0.01 mgL^{-1} in 2013 and 2006, respectively. The mean NO_2-N concentration and NO_3-N concentration were calculated 0.55 ± 0.08 mgL^{-1}, 1.10 ± 0.02 mgL^{-1}, respectively. An increase was observed for those values in comparison to NO_2-N (0.07 mgL^{-1}, 0.002 ± 0.0 mgL^{-1}) and NO_3-N (0.48 mgL^{-1}, 0.08 ± 0.01 mgL^{-1}) values found in 2013 and 2003. In this case, we can say that the amount of ammonia-nitrogen coming to the lake is decreased or the ammonia-nitrogen might be converted to nitrite-nitrogen by the nitrobacterias. Approximately 92% of the villages around the lake were built on the mountain slopes. The lands that have flatness are used as agricultural lands which contain rich alluvium material (Kopar and Sevindi, 2013). In addition, the increase in nitrite concentration is important as it is an indicator of pollution caused by organic or industrial waste (Pulatsu et al., 2014).

Reduction of the external phosphorus load to the lake is a very crucial step in eutrophication control. There are several studies illustrating the success of that process (Cole, 1983; Oenema, 1991). In Lake Tortum, phosphorus loading was calculated to be 11050 kg yr^{-1} (*Equation 5*). That value is much higher than the critical phosphorus loading value calculated by the formula of Vollenweider (1976). Two main factors on the external phosphorus loading are agricultural activities and the absence of sewer systems (Bronmark and Hansson, 2017). There have been intense reclamation and road expansion activities in recent years on Tortum Stream. Besides, sewer systems are absent in many regions in the vicinity of Tortum Stream and its tributaries. This study found the main component of the TP to be the artificial artifical phosphorus loading. The domestic load was calculated 9707 kg yr^{-1} (*Equation 4*). In the studies carried out in Mogan Lake, domestic phosphorus load was found 2998 kg yr^{-1} in 2002 (Pulatsü and Aydın, 1997). In another study conducted on the same lake, domestic phosphorus load was determinated 8084 kg yr^{-1} in 2004 (Fakıoglu and Pulatsu, 2004). Domestic phosphorus load value of the study was found to be higher than those values in Lake Mogan, which is a eutrophic lake status. While Lake Mogan is not only a shallow lake, but also under effect of agriculture and anthropogenic pollution, Tortum Lake is both deep and many of these effects are not seen on the shore of the lake. Nevertheless, the external phosphorus load calculated for Tortum Lake was found to be high. This is thought to be a threat to the lake. On the other hand, for the potential ecological risk evaluation of the lake, it was found to be under moderate risk threat; however, while the contamination load risk should be 0, it was found between 0 and 1 (Kaya et al., 2017).

The phosphorus export coefficient was calculated to be 1.71 g m^{-2} yr^{-1} (*Equation 6*) for Lake Tortum in this study. Even though that value is less than the critical load of 2.17 g m^{-2} yr^{-1} (*Equation 9*), it is still higher than the permissible phosphorus export coefficient (0.96 g m^{-2} yr^{-1}, *Equation 8*). Kirchner and Dillon (1975) considered a field with a phosphorus export coefficient between 1.41 and 14.88 g m^{-2} yr^{-1} to be a forest field and pasture. Lake Tortum is in that category. However, the lake was determinated as oligotrophic status according to the Dillon and Rigler (1975) classification. The phosphorus export coefficient was found to be lower than the critical value of Wetzel (2001) for agricultural and forestry fields.

The reaction of deep lakes to the reduction of external nutrient load has been reported to be faster than that of shallow lakes (Beklioğlu, 1999). Harper (1992) stated that permissible phosphorus loading is 0.4 g m^{-2} yr^{-1} and that hazardous phosphorus loading is 0.8 g m^{-2} yr^{-1} for 100 m deep lakes. Thus, Lake Tortum's phosphorus load is higher than the hazardous level. Even though the nutrient status of the lake was determined to be mesotrophic in terms of TP concentration, unless the necessary precautions are taken the lake might rapidly transform into a eutrophic state. In another deep lake, Lake Bolsena, it was stated that remediation of the lake will take a very long time due to the increase in the external phosphorus loading and the fact that the increase also raised algae production and mineralization in the hypolimnion, the lower thermal layer of the lake (Mosello et al., 2018).

Phytoplankton communities react to the changes in the lake environment rapidly, while they are also in a rivalry for seasonal succession, which is why alterations in the environmental conditions lead to huge compositional diversity (Scheffer et al., 2003). In this study, 51 phytoplankton were detected. Altuner (1982) investigated the phtoplankton in the lake in 1981, and 35 species in total were detected from Bacillariophyta, Chlorophyta, Cyanophyta, Dinophyta, and Crysophyta. Another researcher examined the phytoplankton community in the lake in 2006 and found only 12 species, mainly from Bacillariophyta (Kıvrak, 2006). Lake Salda and Lake Burdur are a deep and highly alkaline lakes of Turkey. These lakes were found at the oligotrophic level due to low nutrient and chlorophyll-a measurements. In both lakes, the taxa of phytoplankton were low (15 taxa in Lake Salda, 21 taxa in Lake Burdur) (Kazanci et al., 2004; Girgin et al., 2004).

The dominant phytoplankton species change according to the nutrient level of the lake. In Lake Tortum, species *Microcystis aeruginosa* shows an increase in number from time to time. Desmidiaceae and centric diatoms indicate that the lake is oligotrophic, and pennate diatoms and cyanobacteria, on the other hand, are an indicator of a eutrophic lake (Harper, 1992). Species from both groups have been observed in Lake Tortum. The phytoplankton and benthic algae compositions were detected in 1979–1981 as oligotrophic. The researchers observed a high number of *Cyclotella kützingenia,* a centric diatom, and, albeit in low numbers, *Ceratium hirundinella* and *Microcystis* spp. (Altuner, 1982). On the other hand, in a study done in 2002–2003, the dominant species were determined to be *Chlamydomonas microsphaerella*, *Cyclotella krammeri*, *C. glomerate*, and *Ceratium hirundinella*, while the rare species were *Stephanodiscus rotula*, *Fragilaria ulna*, *Cocconeis placentula*, *Cymbella affinis*, *Navicula salinarum*, *Carteria* spp., *Staurastrum vestitum*, *Trachelomonas volvocina*, and *Peridinium cinctum* (Kıvrak, 2006).

The most detected species in our study was *Ceratium hirundinella*. The second and third were *Cyclotella meneghiniana* and *Fragilaria capucina*. According to Reynolds et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61376162

al. (2002) Cyclotella spp. generally found in oligotrophic lakes, but Padisák et al. (2009) reported that this species has mesotrophic or eutrophic lakes. Although *Ceratium hirundinella* was reported as a species found in nutrient-rich oligotrophic and mesotrophic lakes in summer months (Reynolds et al., 2002), the highest number they reached in this study was seen in October. Some researchs were turn *C. hirundinella* considered as oligotrophic and mesotrophic lakes; while others were evaluated as eutrophic to hypertrophic, small to medium-sized lakes (Padisák et al., 2009; Aboim et al., 2020). However, Dinoflagellata taxa often have been found in eutrophic and mesotrophic lakes of Turkey (Gönülol and Obalı, 1986; Taş et al., 2002; Yerli et al., 2012). Moreover, the indicators of nutrient-rich turbid lakes, *Ulnaria ulna* and *Nitzschia* spp. (Padisák et al., 2006), were also detected in this study. Besides, *Anabaena elenkinii* (code: H1), *Microcystis aeruginosa* (code: LM), and *Oscillatoria limosa* (code: MP), belonging to Cyanobacteria, and *Chlamydomonas microsphaerella* and *Asterionella formosa* (code: C), belonging to Chlorophyta, were also observed. They are indicators of eutrophic water bodies (Kıvrak, 2006). Reynolds et al. (2002) indicate that *Asterionella formosa*, *Aulacoseira granulata* (code: P), and cyanobacteria are typical indicators of eutrophic lakes. In Lake Tortum, *Asterionella formosa, Aulacoseira granulata*, and *Microcystis aeruginosa* species were detected. In 2014, a yellow area was spotted in the lake, and, when it was investigated, a rapid increase in the numbers of *Asterionella formosa* was found.

When functional groups were examined on a month-by-month scale, dominant functional groups were found to be LM (*C. hirundinella,* Microcystis) in April, October and November, MP (Diatome, Navicula, Cymbella, Oscillatoria) in March, C (*Asterionella formo*sa) in Februvary, B (*Cyclotella meneghiniana*) in March and TB (Fragilaria, Nitzschia) in July. In Lake Mogan, the dominant phytoplankton functional groups of the study period were X2, H1, Y, LM, F, Lo, M, W1, C, P, X1, and S1 and the Q index was indicated a moderate ecological status for Lake Mogan (Demir et al., 2014). Lake Tortum was determined to be mesotrophic according to chemical parameter and chlorophyll-a. Hovewer, Q index was indicated tolerable ecological quality status. The reason for this is that *C. hirundinella*, which is located in Lake Tortum, is evaluated as a functional group in not only oligotrophic but also eutrophic lakes.

Q index has changed in bad ecology except in February and August (clean water phase) in 1th station due to seasonal change in stations. Similarly, it was observed in 3rd station, but this station was in excellent ecological condition in July. It is thought to be the reason that the high phosphorus loading to the lake affects the biodiversity in the 1st station, while filling the lake in 3rd station and the use of these areas as recreational areas. The 2nd station is in the moderate ecological state. Since Tortum Lake is in the deep lake class, it is thought that the ecological status of this station is better than the others. Water quality variables and phytoplankton were examined within the Jequitinhonha River lower course. Results indicated that chemical oxygen demand, dissolved aluminum, and turbidity were the main factors which influenced phytoplankton community structure and composition (Aboim et al., 2020).

In this study, the highest number of total phytoplankters by count was found in April whereas the lowest count was in January. In Lake Tortum, the TP load was found to be higher than the critical phosphorus load. In addition to that, NO_2-N and NO_3-N were also high in concentration. As a result, both the species biodiversity and their numbers increased. In the development of Charophyta was effected NO_3-N value and in Pyrrophyta were found to play a role NO_3-N and NH_3-N values. TP and PO_4-P were found to be a

DOI: http://dx.doi.org/10.15666/aeer/1805_61376162

limiting factor in species in Bacillariophyta and Chlorophyta. Cyanobacteria group algae were calculated as limiting both nitrogen and phosphorus fractions (*Fig. 5*). However, Pedators are known to be the main factor in the phytoplankton species diversity and numerical increase as well as nutrient salts. After the rapid increase in the number of phytoplankton in April, there was a sharp decline in May, which can be attributed to the grazing pressure coming from zooplankton at that time, which was also seen in October. It has been reported that, after the increase in phytoplankton and subsequent decrease in nutrients and the filtration of the zooplankton, a clear-water state can arise (Lampert and Sommer, 1997). On the other hand, after the increase in the TP load and, consequently, the increase in phytoplankton and suspended algae (and production) in the lake, there may be a shift in phytoplankton species to the toxic ones or the ones that have not been grazed efficiently by hunter species. That may result in an algal bloom. In addition to that, the increase in phosphorus loading causes an increase in production, biomass, and microalgae composition (Dogan-Saglamtimur and Saglamtimur, 2018).

Conclusion

It is important to protect and to continuously monitor inadequate freshwater resources and to control the changes that can occur in the lakes as well. Deep and meromictic lakes are especially problematic in regard to restoring their trophic states. It is reported that, in temperate climates where meromictic lakes are prevalent, global warming has a stronger and more steady impact on stratification and, consequently, on lake restoration (Lepori et al., 2018). The works done on Lake Tortum, such as island creation by adding earth and degradation of the shoreline, along with the destructions on Tortum Stream, have significantly damaged the lake ecosystem. Lake Tortum's contamination increases every day. For that reason, species composition in the lake has transformed with time, and more and more eutrophic species have started to appear and become dominant species. In conclusion, the detection of the mechanisms affecting the ecology, hydrology, and morphology of deep lakes is critical for protecting these aquatic systems.

In the future studies are recommend that comprehensive determination of carbon, nitrogen and phosphorous substance loads entering the lake from external point and spread sources, and the use of lake models (mathematical model), including bioprocesses (carbonaceous removal, nitrification, denitrification, photosynthesis) and other physical (sedimentation, resuspension) and chemical processes (adsorption, chemical precipitation) that have an impact on the consumption and production of the lake.

(Received 28th Aug 2019; accepted 14th Sep 2020)

Abstract. The objective of this study is to determine the stand structure and spatial distribution patterns in rare mixed stands of Oriental spruce (*Picea orientalis* L.), Scots pine (*Pinus sylvestris* L.) and Caucasian fir (*Abies nordmanniana* (Stev.) Spach. subsp. *nordmanniana*). The study was conducted in Ovacik Forests of Artvin, Turkey in 2016. To evaluate stand structure, the distribution of tree species was determined according to developmental stage (seedling- thicket stage; sapling- pole stage; small wood stage; medium - large wood stage) and vertical structure (overstory, middlestory and understory). Spatial distribution of trees was analyzed using Ripley's K function in ArcGIS. Results showed that all three species contributed to the mixed stand. Caucasian fir dominated in in all plots and plots had a layered structure. Spatial analyses revealed that all trees showed clumped distributions ($p<0.01$) at smaller scales. Scots pine and Caucasian fir mostly showed random distribution whereas Oriental spruce showed a clumped distribution at 0–7 m scales. Each of the tree species at the medium wood developmental stage showed random distributions at all scales. Clumped distribution was observed in the middle and understory while trees in the overstory layer were randomly distributed.
Keywords: *spatial pattern, layered structure, Scots pine, Oriental spruce, Caucasian fir*

Introduction

Spatial distribution can be described as the data set of points positioned in an almost planar area (Gabriel et al., 2013). It is possible to use spatial distribution to express how forest trees are distributed since they are obtained by the analysis of point data (Montes et al., 2008). In the context of forestry, spatial distribution can be described as the point distribution pattern of trees in a stand or forest area (Dale, 2000).

In spatial distributions that are grouped into two classes, as intra- and inter-species, points belonging to the same species represent intra-species (univariate) distributions and points belonging to different species represent inter-species (multivariate) distributions. Intra-species distributions are classified as random, clumped or regular while interspecies spatial distributions are classified as segregated or aggregated (Ripley, 2005).

Spatial distribution of trees is important in investigating forest regeneration methods, as it reflects the spatial distribution of seedlings (Paluch, 2006). In other words, the spatial distribution of trees reflects the element that triggers regeneration and the subsequent arrival of seedlings at the site. Therefore, it can be said that understanding the spatial distribution of forest trees is important in maintaining the continuity of silvicultural systems.

DOI: http://dx.doi.org/10.15666/aeer/1805_61636179

Spatial distribution of trees is important in defining stand structure (Gadow et al., 2012). The spatial patterns of trees in mixed stands determines their mixing patterns. Since the crowns are adjacent in single-layered mixtures, this mixing pattern is also called a horizontal mixture. In multi-layered mixtures, crowns of tree species in the mixture are overstory, understory or middle story, relative to each other and therefore this mixing pattern is also termed a vertical mixture (Genc et al., 2012). Random, clumped and regular distributions can be referred to as tree-wise, group-wise and row-wise mixtures, respectively, to characterize horizontal mixing patterns in mixed stands (Del Rio et al., 2015).

Tree species are located randomly in mixed stands in tree-wise mixtures while, in group-wise mixtures, tree species are scattered in clumps or groups within the stand. In row-wise mixtures, distribution is regular because there is a particular distance between trees and a regular row-wise mixture is usually observed in artificial regeneration sites (Genc et al., 2012).

Due to the mountainous and rough terrain in forests of the Artvin region, stand structures and mixing types change over even short distances. Such changes are observed especially with respect to tree species and mixing rates. Ovacik forests located in the Artvin region show good examples of such forests, which are also forests with the least human intervention. For these reasons, Ovacik forests have been the subject of this present study.

In this study, we tested changes in stand structure and the hypothesis that spatial patterns of trees will differ, depending on development stage and stand layer, in mixed stands which have different mixing ratios of Scots pine, Oriental spruce and Caucasian fir. Accordingly, mixing patterns were characterized in relation to the distribution patterns of the three tree species.

Materials and methods

Study area

The study was conducted in the Ovacik Forest Management Unit of the Ardanuc Forest Enterprise of Artvin Forest Regional Directorate, Turkey (*Fig. 1*) in 2016. The site is a natural mixed forest of Scots pine, Oriental spruce and Caucasian fir (*Fig. 2*). The characteristics of the study site are given in *Table 1*.

Data collection

Three 0.25-ha plots were randomly selected within the stand. The plots used in this study were square to accurately determine the spatial distribution of the trees. Plots were typically located on sites with 40–60% slopes. Since the plots would be regarded as 50 m × 50 m, the length of the plots perpendicular to the contour lines in sloped sites was determined by taking the cosine of the angle between stems (Q). Accordingly, the length of the plot sides was calculated using the following equation (*Eq. 1*).

$$Plot\ side\ length\ =\ 50\ m/Cos\ (Q) \qquad \text{(Eq.1)}$$

All trees, including cut, fallen and standing dead trees with DBH greater than 4 cm, were numbered. Measurements of DBH, tree height and distance-angle between stems were carried out in every plot to determine the coordinates of individual trees. The tree-to-tree distance-angle measurement method was used because of the convenience of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61636179

central tree selection and the practicality of the procedure (Ripley, 2005). All live, standing dead, fallen stems and stumps were considered for distance-angle measurements in each plot. Trees in each plot were classified into classes with a 3-cm range based on their DBH, and the height of three trees per species in each diameter class was measured by using the Blume-Leiss (Baumhöhenmesser-von-Bloeck) hypsometer (manufactured in Oranienburg, Brandenburg Germany), accurate to within 1 cm.

Data analysis

The mean DBH values, which are used to differentiate stand development stage diameter thresholds in forest management (Genc et al., 2012), were used to determine the number of Scots pine, Oriental spruce and Caucasian fir trees in the plots at each development stage (*Table 2*), namely seedling stage (a), sapling stage (b), small wood stage (c) and medium to large wood stage (d). The number of trees and basal area calculated for each plot were grouped according to development stage DBH intervals for each species, and their numbers and proportions were determined.

Table 2. *DBH ranges of development stages*

Development Stage*	Symbols	DBH Ranges
Seedling - thicket stage	a	$d_{1.3} < 8$ cm
Sapling - pole stage	b	$8.0 < d_{1.3} < 19.9$ cm
Small wood (tree) stage	c	$20.0 < d_{1.3} < 35.9$ cm
Medium - large wood stage	d	$36.0 \leq d_{1.3}$

* In the later parts of the article, symbols of the development stages have been used

The DBH and height values measured for each species were regressed against one another using the SPSS program (IBM, Armonk, NY, USA). The S regression model was considered to be the most appropriate model to estimate the height of trees which were not directly measured. The S model consists of the following equations (*Eqs. 2-3*).

$$y = e^{b_0 + b_1/x} \quad \text{(Eq.2)}$$

$$lny = b_0 + b_1/x \quad \text{(Eq.3)}$$

where y is the estimated height, e is the natural log (2.71), x is the measured DBH (i.e. the independent variable) and b_0 and b_1 are the coefficients of the regression equation.

There is a systematic error in the *Eq. 2* because the coefficients were calculated using logarithm-transformed data. The values obtained using these regression equations need to be multiplied by a correction factor to remove this systematic error. The correction factor used in this study (f) is calculated using the Baskerville (1972) equation (*Eq. 4*), below which "e" and "Syx" represent the natural log and the standard error of the equation, respectively.

$$f = e^{\frac{S_{y.x}^2}{2}} \quad \text{(Eq.4)}$$

The vertical arrangement of a stand is characterized by determining the layering of the canopy using physical data of tree height or vertical extent (Morsdorf el al., 2010). The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61636179

classification, based on the vertical status of a tree, was taken into account to calculate the proportions of the number of trees within each stand layer for determining the vertical mixture in the plots. According to this, trees with heights greater than two-thirds of the maximum height were classified as overstory (O) whereas trees whose heights fell between one-third and two-thirds of the maximum height were categorized as middlestory (M), with trees whose heights were less than one-third of the maximum height being grouped into the understory (U) class. Stand dominant height, determined as the mean height of the highest 100 trees per hectare, was calculated for each plot.

Analysis of spatial distributions

The coordinates of the trees were grouped according to species, developmental stage and stand layer difference in order to generate the spatial distribution maps. Point distribution data files and species distribution maps were generated in ArcGIS 10.2.1 software released by Environmental Systems Research Institute (ESRI), using these grouped coordinates.

Spatial distribution analyses were conducted using the multi-distance spatial cluster analysis method in ArcGIS software. ArcGIS software uses Ripley's K function (Ripley, 2005) in multi-distance spatial cluster analysis (Mitchell, 2005). The null hypothesis is that all trees at the site display random distribution. Confidence intervals were used to test the reliability of the observed and expected values and to determine significant deviations from the complete spatial randomness pattern. Confidence intervals was constructed at the 99% confidence level (99 simulations).

Spatial analysis was focused on developmental stages (a, b, c, and d) and stand layers (O, M, and U) for all trees (A) and individual tree species (Scots pine, Oriental spruce and Caucasian fir). In the tables and figures, spatial analysis results were labeled for each tree species according to their developmental stages and stand layers. For example, results of spatial analysis for all trees (A) at the seedling stage (a) were labeled as A(a) and the understory (U) for all trees were labeled as A(U).

Results and discussion

Stand structure

The number of trees in plots 1, 2 and 3 were 764, 1028 and 852 trees ha^{-1}, respectively, and the basal area in plots 1, 2 and 3 were 43.26, 46.9 and 44.35 m^2 ha^{-1}, respectively. All three species contributed to the mixture in all of the plots in terms of tree number and basal area. Even though Caucasian fir represented the main stand species in terms of number in each of the plots, Scots pine dominated only in plot 2 in terms of basal area (*Table 3*).

The greatest basal area occurred in stages c (small wood stage) and d (medium to large wood stage) in all of the plots. An examination of species presence by number and basal area in the plots showed that Oriental spruce and Caucasian fir were present at each development stage, while Scots pine was mainly concentrated at stages c and d, with few individuals at stage b and almost none in stage a. Similar to these results Gokturk and Demirci (2017) stated that in the majority of the mixed stands of the scots pine, oriental spruce and Caucasian fir there was little or no scots pine youths and thickets. This result showed that the number of seedlings was affected by the stand structure as reported by Kara and Topacoğlu (2018) and Paluch et al. (2019). Pretzsch et al. (2015) reported that

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61636179

the absence of Scots pine seedlings from stands where it contributes to the mixture is related to the amount of light. Scots pine seedlings needs minimum 35% light to achieve 50% of the growth that would be achieved in full light, while spruce and fir needs 20% and 15% light, respectively (Hale, 2004). The crown cover and branching, and the needle density of Oriental spruce and Caucasian fir were greater than for Scots pine. Therefore, the top canopy of Oriental spruce and Caucasian fir was opaque compared to the Scots pine canopy, resulting in light intensities less than required for growth of Scots pine seedlings in the lower canopy.

Table 3. *Mixing rates of trees by species and development stages (DS) in the plots*

Species	DS	Number of Trees (trees ha^{-1})			Number of Trees (%)			Basal Area (m^2 ha^{-1})			Basal Area (%)

*A emphasizes all tree species in the plots

It is clear that Scots pine seedlings cannot find an opportunity to become established because of insufficient light following the emergence of Oriental spruce and, in particular, Caucasian fir seedlings at the site. It is evident that the growth conditions are not favorable for Scots pine under Caucasian fir and Oriental spruce cover.

Caucasian fir dominated in terms of number of trees in plot 2, where mature Scots pines dominated in terms of basal area. This situation may lead to misleading assumptions when the continuity of the mixture is considered. For example, Scots pine, which dominates in terms of basal area, can be thought to have continuity in the mixture and that regeneration can occur without considering the risk of the species disappearing at the site. As a result of the reality of the situation, the continuity of the mixture may be disrupted.

The S regression model, which characterizes the relationship between the height and DBH of Caucasian fir, Oriental spruce and Scots pine trees, was significant at p<0.001 in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61636179

all plots across each species. The heights of the trees were predicted by using the coefficients estimated from the regression analyses (*Table 4*) in the S regression model.

Table 4. *Stand top heights and coefficients of the S model*

3	1.0147	Scots Pine	3.395	-12.512	0.889	0.17	105.375	0.000
	1.0065	Oriental spruce	3.396	-10.075	0.452	0.11	9.257	0.014
	1.0383	Caucasian fir	3.303	-9.102	0.454	0.27	14.298	0.002

When the distribution of tree number proportions in stands was evaluated, results showed that the proportion of tree numbers in each stand layer in all plots was greater than 10%. Caucasian fir dominated the overstory in plots 1 (32.46%) and 3 (22.54%) in terms of the number of trees whereas Scots pine and Oriental spruce dominated in plot 2 (15.12% for each species). In addition, Scots pine, Oriental spruce and Caucasian fir were largely located in the overstory in terms of tree numbers and basal area mixing ratios (*Table 5*).

Table 5. *Mixing ratios of species in the plots*

Sample Plot	Stand Layer	Number of Trees (%)				Basal Area (%)			
		Scots pine	Oriental spruce	Caucasian fir	*Total*	Scots pine	Oriental spruce	Caucasian fir	*Total*
1	Overstory	15.71	9.95	32.46	*58.12*	36.84	13.39	41.77	*92.00*

2	Overstory	15.12	15.12	14.73	*44.96*	41.60	20.25	26.71	*88.56*
	Middlestory	2.33	18.22	15.50	*36.05*	0.90	2.83	5.67	*9.39*
	Understory	0.39	1.16	17.44	*18.99*	0.05	0.05	1.95	*2.06*
	Total	17.83	34.50	47.67	*100.00*	42.55	23.13	34.33	*100.00*
3	Overstory	15.96	21.60	22.54	*60.09*	33.86	27.76	31.91	*93.52*
	Middlestory	0.94	13.15	15.49	*29.58*	0.37	2.27	3.15	*5.79*
	Understory	0.47	6.10	3.76	*10.33*	0.02	0.42	0.25	*0.69*
	Total	17.37	40.85	41.78	*100.00*	34.24	30.45	35.31	*100.00*

Each of the three species consisted of less than 10% in terms of basal area of the middle and understory layers across all plots. The dominant species in the overstory in terms of basal area were Caucasian fir (41.77%) in plot 1 and Scots pine (41.60 and 33.86%) in plots 2 and 3, respectively. Even though the proportion of Scots pine in the upper layer was very high, there was almost no Scots pine in the middle and understory layers. Oriental spruce and Caucasian fir dominated the middle layer and the understory in terms of basal area as well as in terms of the number of trees.

Spatial patterns of tree species at different developmental stages

When the three tree species in plot 1 were analyzed together, the pooled trees (labeled A) showed clumped distribution at scales 2–8 m (*Table 6, Figs. 2, 3*). Similarly, A(c) (i.e. trees of all species at small wood stage) showed a clumped distribution at scales 5–11 m, while A(a), A(b) and A(d) were randomly distributed at all scales. Oriental spruce was distributed at random over all scales while the distribution of Scots pine and Caucasian fir were clumped at scales 2–3 m and 4–11 m, respectively. When the tree species were analyzed at different developmental stages, Caucasian fir (c) showed clumped distribution at scales 4–12 m, while all three tree species at the other developmental stages showed random distribution (*Table 6, Figs. 3, 4*).

"A" symbolizes all three species, "r" random distributions, "c" clumped distributions. Blank rows indicate that spatial analysis are not performed due to insufficient number of stems. a, b, c, and d means seedling - thicket stage, sapling-pole stage, small wood (tree) stage and medium- large wood stage

The three tree species (A) in plot 3 displayed a clumped distribution at the 2–5 m scales as in the other sample plots, when the tree species were analyzed together. Scots pine and Caucasian fir showed random distribution at all scales, whereas Oriental spruce showed a clumped distribution at the 2–7 m scales. A (b) showed a clumped distribution at the 2-4 m scales, whereas trees (A) at other developmental stages showed random distributions at all scales. Clumped distributions were observed in Oriental spruce (a) and Caucasian fir (c) at scales of 2–5 m and 9–12 m, respectively, while random distributions were observed at other developmental stages for each of the three tree species (*Table 8, Figs. 3, 4*).

The spatial distribution of trees within mixed stands may differ according to the silvicultural characteristics of the species present in the mixture and their mixing rates. Therefore, the species found at the site, their developmental stages and their frequencies are the determining factors in assessing spatial distribution (Gokturk, 2013). The spatial patterns displayed by the species were similar even though the number and basal area values of the trees differed.

Kazempour Larsary et al. (2018) stated that identifying spatial patterns of trees according to development stages is a first step in understanding regeneration process. Seedlings mostly emerge in clusters (Mason et al., 2007; Pardos et al., 2007). Stem exclusion takes place in these clusters over time as a result of competition for nutrients

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61636179

and light. The subsequent decrease in the number of stems results in these clusters being replaced by a random distribution (Kazempour Larsary et al., 2018; Muhamed, 2019). Therefore, tree seedlings display a clumped distribution initially, which develops over time into a random distribution (Gu et al., 2019). In the present study, it has been determined that each tree species at the growth stage d showed a random distribution at all scales.

"A" symbolizes all three species, "r" random distributions, "c" clumped distributions. Blank rows indicate that spatial analysis are not performed due to insufficient number of stems. a, b, c, and d means seedling - thicket stage, sapling-pole stage, small wood (tree) stage and medium- large wood stage.

The random distribution observed in the plots of Scots pine, which is a typical shade-intolerant tree, can be attributed to the fact that most of the Scots pine trees at the sites are at the medium-wood stage, d. The findings of Pardos et al. (2007) and Gu et al. (2019) support the observed distribution of Scots pine at our site. Pardos et al. (2007) reported that Scots pine seedlings emerged at a site in clusters. In the current study, unfortunately, there were no pine seedlings in any of the sample plots. For this reason, spatial analysis could not be performed for developmental stage a in Scots pine.

Several studies have showed that Caucasian firs can occupy a site because their seedlings can grow under the canopy (Grassi et al., 2004; Nagel et al., 2006; Hofmeister et al., 2008). Based on this, the random distribution observed in Caucasian fir at our sites can be attributed to its ability to colonize a site.

Aldrich et al. (2003) reported that the tendency of tree species to clumped distribution increases as their shade tolerance increases. The clustering tendency observed in Oriental spruce in our study can be attributed to its shade tolerance. Even though the shade-tolerant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61636179

trees of Oriental spruce and Caucasian fir are treated as similar species in silvicultural applications in Turkey, Caucasian firs may display a distribution pattern different to that of Oriental spruces, because their seedlings exhibit a denser presence under the canopy compared to being restricted to gaps within the stand (Grassi et al., 2004). Despite the fact that Gokturk (2013) assigned the random distribution observed in Caucasian fir to its low stem number at a site, the dominance of Caucasian firs in terms of number of trees in all plots in the present study site supports the observation that Caucasian firs tend to display a random distribution.

Spatial patterns of tree species at different stand layers

Spatial analysis results showed that stem distribution patterns of trees at different stand layers differed among the species. When the tree species at different stand layers were analyzed together, A (O) showed random distribution at all scales, whereas a clumped distribution was observed at A (M) and A (U) in plot 1 (*Table 9*).

Table 9. *Spatial cluster analyses of tree species at stand layers for plot 1*

Stand Layer		Scale (m)													
		0	1	2	3	4	5	6	7	8	9	10	11	12	13<
A	O	r	r	r	r	r	r	r	r	r	r	r	r	r	r
	M	r	r	r	r	r	c	c	c	c	c	r	r	r	r
	U	r	r	c	c	c	c	c	r	r	r	r	r	r	r
Scots pine	O	r	r	r	r	r	r	r	r	r	r	r	r	r	r
	M														
	U														
Oriental spruce	O	r	r	r	r	r	r	r	r	r	r	r	r	r	r
	M	r	r	r	r	r	r	r	r	r	r	r	r	r	r
	U	r	r	r	r	r	r	r	r	r	r	r	r	r	r
Caucasian fir	O	r	r	r	r	r	r	r	c	c	c	c	c	c	r (c)
	M	r	r	r	r	r	r	r	r	r	r	r	r	r	r
	U														

"A" symbolizes all three species, "r" random distributions, "c" clumped distributions, while "r(c)" means more random points than clumped. Blank rows indicate that spatial analysis are not performed due to insufficient number of stems. O, M and U means overstory, middlestory and understory

Similar findings were reported by Sotiris and Alan (2005), who showed that the larger trees in a mixed stand showed a random distribution whereas the smaller trees showed a clumped distribution. Similarly, Hao et al. (2007) observed that the trees in the overstory and middle story layers showed a random distribution, while the trees in the understory layer exhibited a clumped distribution. Unlike the situation in plot 1, A (O) showed a clumped distribution at scales 7–13 m and 2–4 m in plots 2 and 3, respectively (*Tables 10, 11*).

In each of the plots, because of the absence of sufficient numbers of Scots pine in the middle story and understory layers (*Figure 5*), spatial analysis could not be carried out. Scots pine were substantially present in the overstory and showed random distribution at all scales (*Tables 9, 10 and 11*). Oriental spruce was randomly distributed in all stand layers and at all scales in plots 1 and 2, whereas a significantly clumped distribution was observed only for Oriental spruce (U) at the 3–7 m scales in plot 3. In the overstory layer,

DOI: http://dx.doi.org/10.15666/aeer/1805_61636179

a clumped distribution was observed only in Caucasian fir. Caucasian fir (O) showed a clumped distribution at 7–12 m scales in plot 1 and at 2–11 m scales in plot 3, whereas it showed random distribution at all scales in plot 2.

Table 10. *Spatial cluster analyses of tree species at stand layers for plot 2*

	U														

"A" symbolizes all three species, "r" random distributions, "c" clumped distributions, while "c(r)" means more clumped points than random points. Blank rows indicate that spatial analysis are not performed due to insufficient number of stems. O, M and U means overstory, middlestory and understory

The results of spatial analysis of the tree species at different stand layers showed that clumped distribution was observed in the middle and understory layers, whereas trees at the overstory layer were randomly distributed. Gokturk (2013) also reported that a clumped distribution of the trees was observed in the middlestory and understory,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61636179

whereas, toward the overstory, the random nature of the tree distribution increased. The findings of Hanewinkel (2004) and Hao et al. (2007) support these findings. Hanewinkel (2004) found that the trees in the overstory were distributed randomly whereas the trees in the middlestory or understory layers were distributed in a clumped manner. In the present study, a clumped distribution was more commonly seen when all tree species were analyzed together rather than when the species were analyzed individually.

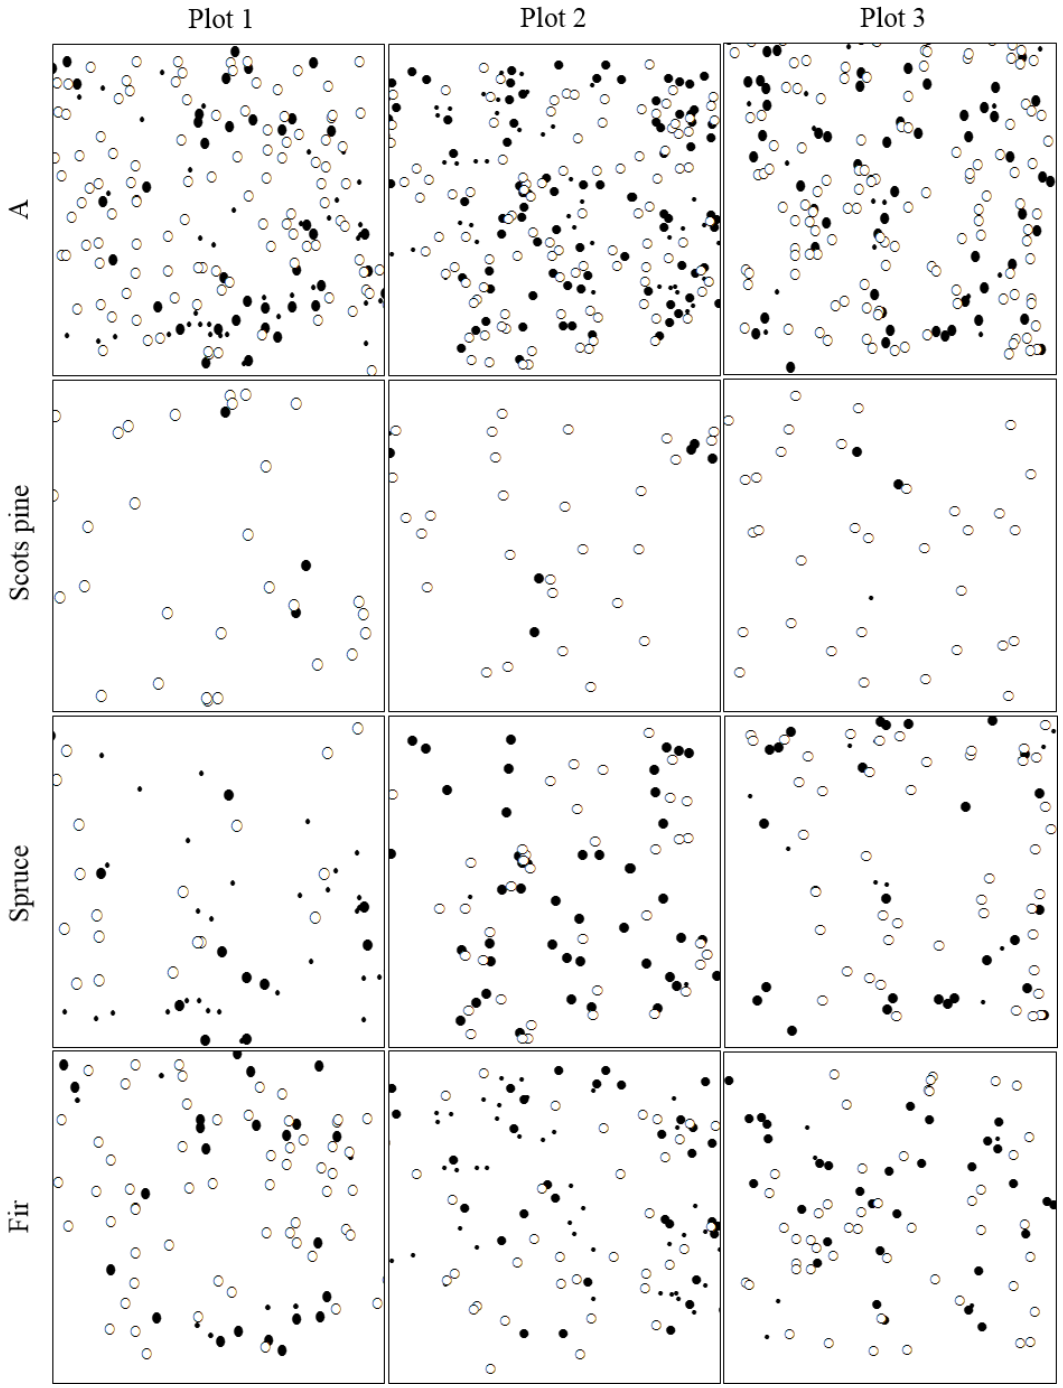

Figure 5. *Distribution maps of tree species at stand layers (circle: overstory, closed circle: middlestory, small closed circles: Understory, A symbolizes all scots pine, Oriental spruce and Caucasian fir trees)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61636179

Martens et al. (2000) stated that, with the increase in the height of the trees, the amount of light reaching the ground under the stand decreased. Based on this statement, it can be said that light plays an important role in the reduction of clumped distributions in the sample areas. Although clumped distributions would be expected to decrease in the lower layers due to a lack of light, clustering continues because the species colonizing these layers are shade-tolerant Oriental spruce and Caucasian fir. The number of individuals at the seedling-thicket and sapling-pole stages in the lower layers is an important factor determining the clumped distribution.

Conclusions

In the present study, the spatial distribution patterns of trees, based on development stages and on stand layers, were determined in Scots pine, Oriental spruce and Caucasian fir in a mixed stand. Because the quantity of trees affects the spatial distributions, the number of trees and the stand structures were identified prior to the spatial analyses. Caucasian fir dominated in terms of tree numbers in all plots. Findings showed that Oriental spruce and Caucasian fir were present at every developmental stage whereas Scots pines were mainly concentrated at the c and d development stages and in the upper layer. There was almost no Scots pine in the middle and understory layers. In the middle story and the understory, Oriental spruce and Caucasian fir dominated in terms of both basal area and number of trees. These results shows that the scots pine gradually disappears from mixtures. In order to maintain the continuity of the mixtures, scots pines must be preserved in silvicultural cuttings in these mix stands.

The stands in all plots had layered canopies, resulting in both horizontal and vertical mixing. Spatial distribution analyses revealed that Caucasian firs displayed only random distribution, and Scots pines exhibited mostly random distribution whereas Oriental spruces tended toward a clumped distribution. Random distributions were observed at all scales in the medium wood development stages of all three species, whereas clumped distributions were generally seen at other development stages. Trees in the middlestory and understory layers showed clumped distribution while trees in the overstory layer were randomly distributed. It could be determined, on the basis of these distributions, that Scots pine and Caucasian fir had a tree-wise mixture whereas Oriental spruce displayed a group-mixing pattern. Studies about species interactions with the increasing sampling size and number in spruce-fir-scots pine mixed stands should be done for to be able to discuss the underlying factors behind the reported results.

The spatial distributions of trees in the mixed stands of Scots pine, Oriental spruce and Caucasian fir can be retained or they can be altered, based on the needs of the individual species, by silvicultural interventions. Changed spatial distributions also imply changes in mixing patterns. Therefore, it is important to identify the target mixing pattern and then to adjust intervention intensity accordingly, by means of silvicultural practices. Before the silvicultural cuttings, it is necessary to conduct studies for determination of spatial and mixing patterns based on spatial analysis and the results of these studies should be taken into consideration for to ensure sustainability of these stands.

Abstract. To deal with lead (Pb^{2+}) contamination, four engineered biochar materials: NaOH modification of biochar (BC_{Na}), $KMnO_4$ impregnation of biochar (BC_{Mn}), hydroxyapatite modified biochar (BC_{HA}), and chitosan modification of biochar (BC_C), were compared for their adsorption and desorption capabilities. Steam exploded oil-rape straw was selected as the biomass material. Scanning Electron Microscopy-Energy Dispersive Spectroscopy (SEM-EDS) examination of biochars revealed that the modified adsorbents surface was covered by the respective modifying mineral. Adsorption and desorption studies were executed to examine the properties of adsorbents and the focal adsorption/desorption mechanism. The findings revealed that Mn oxides and hydroxyapetite nano-particles were conceded well within the biochar structure and formed inner sphere complexes perhaps with oxygen bearing functional groups. The extra adsorption sites formed by the impregnated respective minerals play the crucial roles in Pb^{2+} adsorption in an aqueous solution. Pb^{2+} adsorption isotherm experiments by BC_{Mn} was well determined by the Langmuir model with the highest adsorption capacity of BC_{Mn} being 70.92 mg g^{-1} followed by the BC_{HA} (49.26 mg g^{-1}). While, the adsorption kinetics of Pb^{2+} by all adsorbents were well determined by pseudo-second-order kinetics with the highest adsorption capacity of BC_{Mn} being 22.61 g (mg h)$^{-1}$. $KMnO_4$ and hydroxyapatite modified biochars exhibited very promising physicochemical and adsorptive properties for adsorbing divalent metal Pb^{2+} and might thus have high potential as a soil amendment and an alternative adsorbent for environmental remediation.
Keywords: *biochar, modification, heavy metals, kinetics, isotherms*

Introduction

Lead (Pb^{2+}) is considered as one of the most deleterious environmental pollutants because of its persistence and non-degradability nature in the terrestrial ecosystem (Wang et al., 2015a). Pb^{2+} contamination of soil and water is reputed all over the world as one of the key substantial problem in our ecosystem (Arshadi, 2015). Heavy metals including Pb^{2+} in aquatic system has also been revealed in Russia (Snakin and Prisyazhnaya, 2000), the USA (Triantafyllidou et al., 2014), India (CPCB, 2008), France (Ayrault et al., 2012), China (Li et al., 2012), Argentina (Kohn et al., 2001), Korea (Lee et al., 2005) and numerous other countries. A huge amount of Pb-contained waste-water is inescapably discharged from mining-related industries annually in China, as it is one of the key producer and consumer of Pb^{2+} in the world (Zhang et al., 2012). Pb^{2+} also can be espoused and concerted in organisms (Mohan et al., 2014a) and proposes deleterious effects on living organisms (Lu et al., 2012). Furthermore, Pb toxicity has serious implication on human health including damage of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61816197

the reproductive and central nervous system, hypertensive toxicity which ultimately leads towards fatality (Zhang et al., 2019).

Numerous conservative and modern practices have been passed on for Pb^{2+} removal, for instance; ion exchange, electrocoagulation, membrane filtration, precipitation and adsorption (Malamis et al., 2010). Adsorption has been identified to be an influential, meek and efficient methodology for Pb^{2+} removal (Inyang et al., 2012). There is still a crucial requirement for designing an environment friendly and low-cost adsorbent for reducing Pb^{2+} pollution in terrestrial environment. Biochar as one of the biosorbents has recently gained increasing attention in removal and bioavailability decrement of heavy metals in soil and water medium as well (Wang et al., 2015b; Rechberger et al., 2017). Bundles of novel measures have been established for improving biochar adsorption capacity for heavy metals through improving surface characteristics (Mejias Carpio et al., 2014), effective functional groups (Becidan et al., 2017), hydrophobic/hydrophilic characters (Chen et al., 2014) and surface charges etc. (Samsuri et al., 2013). In addition, the use of diverse engineering approaches in biochar production, such as treatment of biomass or modification of biochar surface has ensued in numerous great proficiencies and efficient novel modified biochars with adsorption capacities equivalent to or even better than that of a few commercially available activated carbons.

The pristine biochar can be significantly modified with impregnation approaches; metal salts/oxides of minerals can be mixed with biochars (BCs) to expedite physical/chemical bonding of metal ions in the porous structure of biochars. To further improve the metal adsorption/sorption proficiency of biochars, these biosorbents have been pretreated or modified prior to pyrolysis process. The distinct improvement of divergent biochar materials has been revealed in previous studies (Rajapaksha et al., 2016; Sizmur et al., 2017), where improvement of metal adsorption has been analytically proved. To further improve the adsorption of biomass-derived biochars, biomass pretreatment is led to increase porosity because biomass fractionation process is beneficial for the succeeding activation process (Harun and Danquah, 2011; Rizwan et al., 2020).

In the current years, several technical innovations and applications of steam explosion were reported (Jia et al., 2013; Chen and Peng, 2014; Liu et al., 2014; Huang et al., 2015; Chen et al., 2019a). Steam explosion consequences in the hemicelluloses being hydrolyzed, the cellulose and lignin is marginally depolymerised, which aid in binding particles collectively during the densification process. Our previous group study (Chen et al., 2019a) revealed that steam explosion could remarkably change the physicochemical properties of typical agricultural feedstocks such as oil-rape, wheat, rice, maize and cotton straws and their derived biochars. In the current study, the most effective feedstock of oil-rape straw was selected for further mineral impregnation and biochar modification as well. It was hypothesized that chemical modification following steam explosion would fabricate the novel biochar with satisfactory adsorption and desorption properties. Apparently, this is the first study on modification of biochar/biomass following steam explosion of oil-rape straw. The particular objectives of the present study were thus (1) to quantify the adsorption and desorption characteristics of the engineered biochars for Pb^{2+}, (2) and then to recommend a measure for preparing the novel engineered biochar.

Materials and methods

Oil-rape straw pretreatment and biochar production

Oil-rape straw residues were collected from Shang Zhuang experimental station, China Agricultural University, Beijing (40.14°N, 116.18°E). The details of the steam explosion (SE) pretreatment and biochar synthesis were described previously in Chen et al. (2019a). Briefly, oil-rape straw was steam-exploded for 2 min at 210°C and 2.5 MPa using a QB-200 platform, in Hebei Heavy-Duty Mechanical Factory. The steam exploded straw was distributed into two bulks. One bulk of steam exploded oil-rape straw was kept in a stainless steel reactor and heated in a muffle furnace at 500℃ for 2 h under N_2 flow (10 psi). The solid residues in the reactor were obtained and denoted as BC.

Synthesis of engineered biochars

The above described prepared biochar (BC) was further modified with chitosan and NaOH. The detailed protocol for the preparation of engineered biochars was described in our previous study (Chen et al., 2019b). Briefly, three g of chitosan was initially dissolved in 180 mL acetic acid (2%) solution, and further mixed with 3 g BC while stirring for 30 min at a rotatary shaker. The obtained suspension was then drop-wise added into a 900 mL NaOH (1.2%) solution and further retained for 12 hours. The obtained biochar material (named as BC_C) was further washed with deionized water to eliminate the surplus sodium hydroxide till the pH value became neutral and afterwards the obtained product was oven dried at 70℃ for 24 h (Zhou et al., 2013).

The NaOH-modified biochar (BC_{Na}) was synthesized according to Li et al. (2017). Briefly, 10 of the BC were mixed with 100 mL of 2 M NaOH solution with vigorous stirring for 12 h at 100℃. The biochar was oven-dried as described above followed by washing 3 times with 0.01 M $NaHCO_3$ solution to remove impurities and further 3 times washing with deionized water until the pH value reached pH 7.

Second bulk of steam exploded oil-rape straw was used for further modification. A nano-hydroxyapatite suspension solution was prepared by adding two grams of nano-hydroxyapatite mineral powder to 500 mL deionized water followed by the ultra-sonication of the mixture for 30 minutes. Ten grams of steam exploded oil-rape straw were agitated with the nano-hydroxyapatite suspension for 1 h, then oven dried at 60℃ for 24 hours. The hydroxyapatite-pretreated straw was kept in a quartz tube and then slowly pyrolized as described above (Yao et al., 2014; Yang et al., 2016). The solid residue was denoted as BC_{HA}.

One hundred grams of the SE oil-rape straw were vigorously agitated with 1000 ml 2% $KMnO_4$ solution at 80℃ for 3 h and then ultra-sonicated for 20 min, then oven-dried at 105℃ for overnight. The straw was slowly pyrolized as described above. The collected biochar (denoted as BC_{Mn}) was rinsed 3 times with 0.01 M $NaHCO_3$ solution and further 3 times with deionized water (Li et al., 2017). The details and study circumstances of studied biochars are given in *Table 1*.

Adsorption kinetics and isotherm studies

Adsorption isotherms were determined for Pb^{2+} by using the identical protocol as described in a previous study (Wang et al., 2015a), with minor modifications. A range of Pb^{2+} (25 mL, 1–250 mg L^{-1}) sorbate concentrations of solution and 24 hours contact time period was set in the adsorption isotherms study. Nitrate salts were used for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61816197

preparing all solutions. Concisely, 0.1 g of biochar in a 25 mL Pb^{2+}, three drops of phenol were added in each sample to prevent microbial growth. Hence, the sorbent concentrations were 2.5 g L^{-1} for all treatments. In addition, to prevent metal precipitation, the initial pH values of the Pb^{2+} solutions were adjusted to 5 in all cases, by using 0.01 M HCl and 0.01 M NaOH solutions. In a former study (Li et al., 2017) it was revealed that the highest adsorption capacities were obtained at pH 5.0, hence this pH was used in the current study. The isotherms and kinetics tests were executed in triplicates and mean values were used for further data analysis.

Table 1. *Tested biochars and study circumstances are given as:*

Tested Biochar	Abbreviation	Study circumstances
Pristine Oil-rape straw biochar	BC	Oil-rape straw was pyrolyzed at 500℃ for 2 h under N_2 flow (10 psi).
Steam Exploded-Pretreated	BC_{SE}	Oil-rape straw was steam-exploded for 2 min at 210°C and 2.5 MPa.
$KMnO_4$-Impregnated	BC_{Mn}	Hundred grams of steam exploded rape straw was mixed with 1000 ml 2% $KMnO_4$ solution prior to biochar production.
NaOH-Modified	BC_{Na}	Ten grams of biochar was mixed with 100 ml of 2M NaOH solution, stirred vigorously at 100℃ for 12 h.
Hydroxyapatite-Modified	BC_{HA}	Two grams of hydroxyapatite powder was dissolved in 500 ml deionized (DI) in ultrasonic condition. Ten grams of steam exploded oil-rape straw were agitated with the nano-hydroxyapatite suspension for 1 h (prior to biochar production).
Chitosan-Modified	BC_C	Three grams of chitosan was first dissolved in 180 ml of acetic acid (2%), and 3 g of the as-is biochar was added to this solution.

Investigation of Pb^{2+} (50 mg L^{-1}) adsorption kinetics by biochars was carried out following the methods described above. Batch adsorption tests were conducted in triplicates using 50 ml centrifuge tubes on a rotatory shaker at 180 rpm. At each sampling time (0-24 h), the suspensions were collected and promptly filtered by using 0.22 ml pore size nylon membrane filters (GE cellulose nylon membrane). The Pb^{2+} ions concentrations in the resulting supernatant were determined by using inductively coupled ICP-OES (Optima 2300, Perkin-Elmer SCIEX, USA).

Desorption study

Desorption experiments were executed to examine, if biochar adsorption of Pb^{2+} was reversible and the Pb^{2+} immobilization aptitude of biochar was assessed. For desorption experiment, all Pb^{2+} loaded biochar samples were shaken for 24 h with 0.01 M HNO_3 (background electrolyte at pH = 5.00); (Trakal et al., 2014b), 0.01 M $CaCl_2$ (solution simulating ‘‘bioavailable form’’ of metal; Houba et al., 1996); and finally 0.01 $NaNO_3$ (solution exhibiting ‘‘geochemically active form’’ of metals; Tipping et al., 2003) to assess potential metal desorption. The aqueous solution phase was then separated from the sorbent using a centrifuge and promptly filtered by using 0.22 ml pore size nylon membrane filters. The residual concentrations of Pb^{2+} ions in the resulting supernatant were then determined using ICP-OES.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)

Calculations

The adsorption amount (q_t) was determined according to the equation given below:

$$q_t = \frac{(C_0 - C_t)\,V}{m} \quad \text{(Eq.1)}$$

Here, q_t denotes the maximum adsorption quantity of metal ions at a specific time t (mg/g), m represents the mass of biochar used (g), V denotes the volume of solution used (dm^3), and C_0 and C_e represents the initial and equilibrium concentration of the Pb^{2+} ions (mol/dm^3), respectively. The Langmuir model is expressed as (Langmuir, 1916; Aksu and Isoglu, 2005):

$$q_e = \frac{q_0 K_L C_e}{1 + K_L C_e} \quad \text{(Eq.2)}$$

Here, q_e denotes the maximum adsorption capacity at equilibrium stage (mg/g), and C_e represents the concentration of Pb^{2+} ions at equilibrium (mg/dm^3). While, q_0 (mg/g) and K_L are constant of the Langmuir equation (dm^3/mg) and both these constants can be calculated from its linear form. The Freundlich model can be expressed as below (Freundlich, 1906; Zhang et al., 2011):

$$q_e = K_F C_e^{1/n} \quad \text{(Eq.3)}$$

Pseudo second order model can be given as the following equation (Blanchard et al., 1984; Ho and McKay, 1998).

$$\frac{t}{q_t} = \frac{1}{K_2 q_e^2} - \frac{t}{q_e} \quad \text{(Eq.4)}$$

Pseudo first order kinetic model equation can be expressed as:

$$log(q_e - q_t) = log(q_e) - \frac{k_1 t}{2.303} \quad \text{(Eq.5)}$$

Here, q_e and q_t represent quantities of Pb^{2+} ions adsorbed at equilibrium stage and at specific time t, respectively. k_1 and k_2 are the pseudo-first and second-order rate constants for the adsorption process.

Data analysis

All the tests were carried out in triplicates and the mean data was reported to plot adsorption kinetics and isotherms. The obtained data was examined statistically by using Statistics 8.1 software. The variability in the data was determined as the standard deviation and threshold of significance was $p < 0.05$.

Results

Morphological characteristics of the studied biochar

To investigate the surface morphology characteristics of the studied biochars, SEM-EDS images of the pristine and numerous engineered biochars used in this study were obtained (*Figs. 1, 2 and 3*). The results displayed that porous structure exists on the biochar that sustains the disordered pattern of the pristine oil-rape straw cell morphology. As it is evident from the SEM images there is deposition of Mn, Na and Ca/ P on BC_{Mn}, BC_{Na} and BC_{HA} respectively. On the other hand, there is no obvious deposition on pristine and SE biochars (*Fig. 1a,b*). Furthermore, pristine biochar structure was disturbed, fragmented, and even shattered after SE pretreatment, which had a substantial impact on the structure of the corresponding biochars.

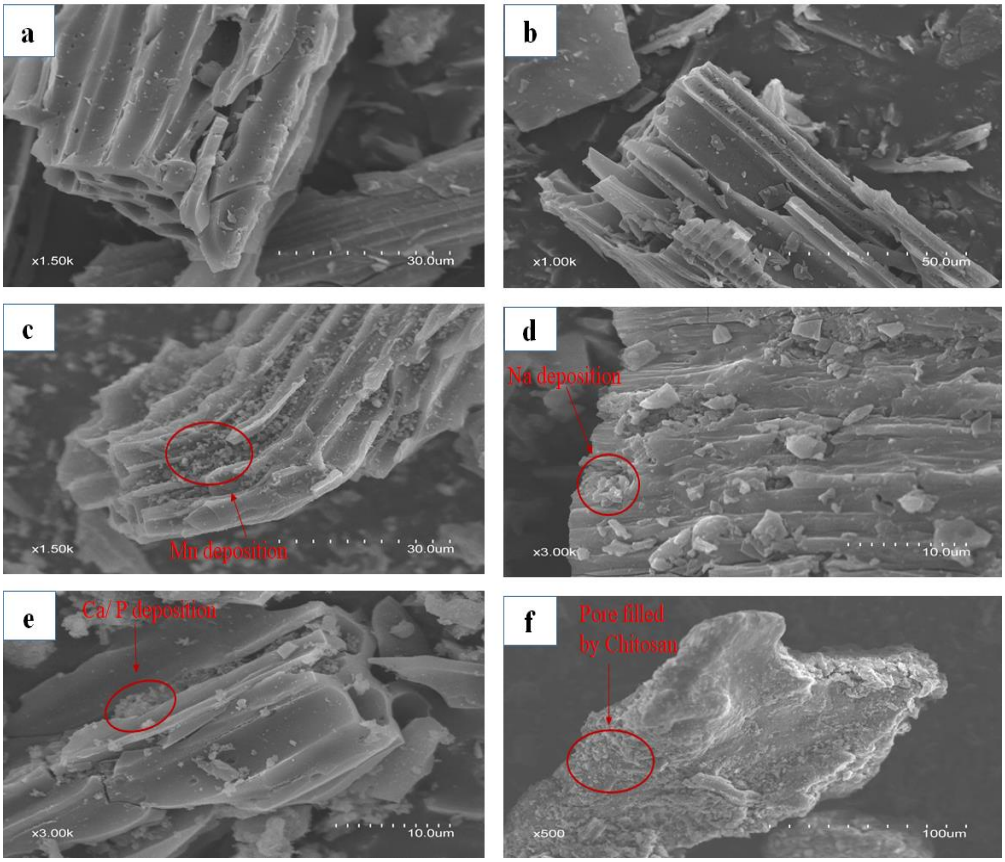

Figure 1. *SEM analysis of the biochars derived from pristine (BC) (a), SE pretreated (BC_{SE}) (b), $KMnO_4$-impregnated (BC_{Mn}) (c), NaOH- (BC_{Na}) (d), hydroxyapatite (BC_{HA}) (e), and chitosan (BC_C) (f)*

Additionally, the findings of surface elemental examination by using the EDS spectra obviously confirmed the higher concentration of respective various mineral contents in terms of weight and atomic percentages (*Figs. 2 and 3*). After modification, the higher concentration of these minerals depicts that these minerals were successfully impregnated on the respective biochar surface. Moreover, EDS elemental composition analysis of biochars further affirmed that biochars not just have greater amounts of oxygen and carbon, yet they additionally contain substantial amounts of slag

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61816197

components such as P, Cl, P and K amongst others (*Figs. 2 and 3*). The accumulation of Mn oxides on the BC_{Mn} surface, which was further confirmed by SEM-EDS analysis and these could provide more adsorption sites for Pb^{2+}. SEM-EDS analysis of studied BCs also confirmed the significant concentration of potassium and chlorine in the respective biochar. The SEM images of BC_{HA} is identical to that of BC, with the exemption that the amounts of P and Ca elements enhanced on the surface of biochar.

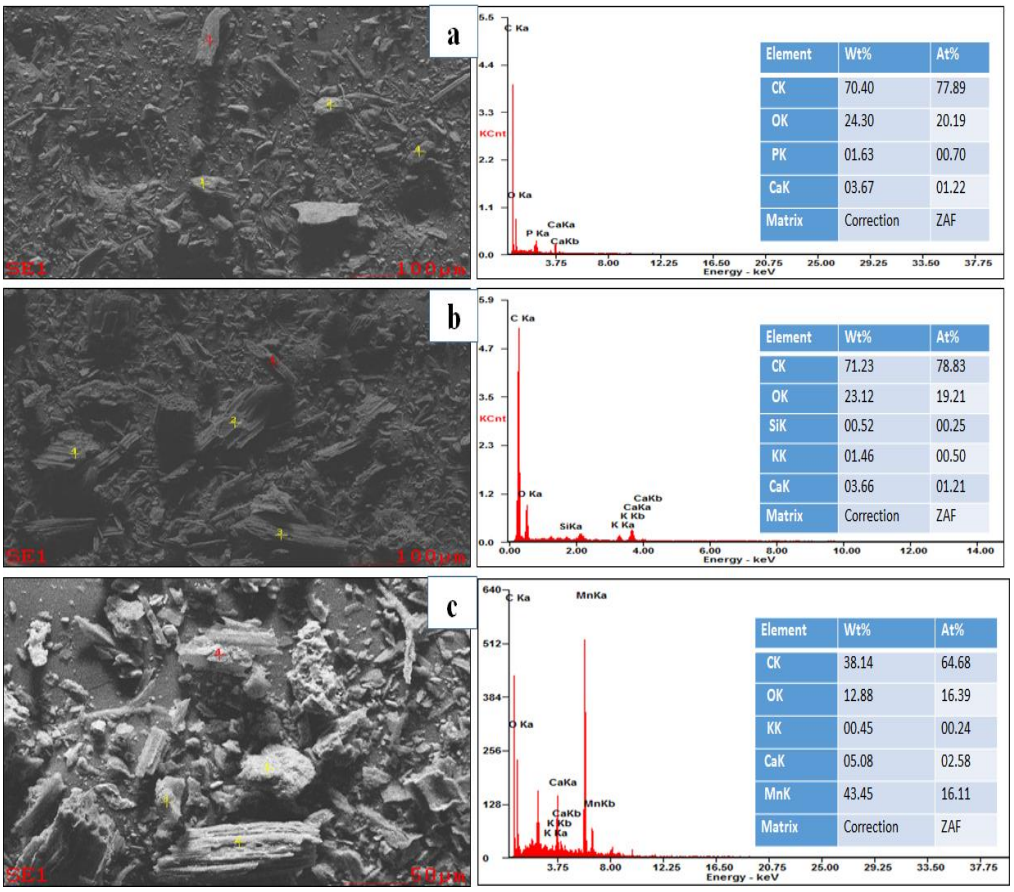

Figure 2. *EDS analysis of the biochars derived from pristine (BC) (a), SE pretreated (BC_{SE}) (b), and $KMnO_4$-impregnated (BC_{Mn}) (c), and their corresponding EDS spectra with atomic elemental ratio*

Adsorption isotherms

In order to check the distribution of the adsorbate molecules between the liquid and the solid phases in equilibrium state, the adsorption equilibrium isotherm is necessary (Almeida et al., 2009). We performed Pb^{2+} batch adsorption experiment and the obtained experimental data was fitted in Langmuir and Freundlich models. In the present study linear forms of isotherm models were being employed instead of non linear forms as 95 % of liquid-phase adsorption studies used non linear forms (*Fig. 4, Table 2*). The data obtained from isotherm models was well fitted by using Langmuir models and 0.99 R^2 value was obtained for approximately all samples (*Table 2*). The Pb^{2+} adsorption hiked dramatically when the equilibrium solution concentration of Pb^{2+} was less than 30 mg L^{-1}.

DOI: http://dx.doi.org/10.15666/aeer/1805_61816197

Table 2. *The isothermal parameters calculated from both Langmuir and Freundlich equations for Pb^{2+} adsorption by pristine (BC), $KMnO_4$- (BC_{Mn}), hydroxyapatite- (BC_{HA}), NaOH- (BC_{Na}) and chitosan-modified- (BC_C) biochars*

Biochars	Langmuir			Freundlich		
	Q_{max}	K_L	R^2	1/n	K_F	R^2
BC	18.32	0.05	0.99	0.56	1.11	0.98
BC_{Mn}	70.92	0.24	0.98	0.71	9.92	0.89
BC_{Na}	37.04	0.04	0.99	0.67	1.6	0.98
BC_{HA}	49.26	0.18	0.99	0.49	6.37	0.75
BC_C	32.89	0.07	0.99	0.65	1.94	0.96

Q_{max} is the maximum adsorption capacity (mg g^{-1}). K_L is the Langmuir constant related to the sorption energy (L mg g^{-1}). 1/n is the Freundlich constant associated to surface heterogeneity. K_F is the Freundlich constant associated to sorption capacity ($mg^{(1-n)} L^n g^{-1}$)

In contrast the Pb^{2+} adsorption inclined to plateau when equilibrium concentration of Pb^{2+} was more than 30 mg L^{-1}. Adsorption capacities (q_e, mg g^{-1}) of the engineered biochars were raised significantly, as compared with the pristine biochar at this concentration. The results are consistent with a previous study (Foo and Hameed, 2010). The adsorption capacity of BC_{Mn}, BC_{HA}, BC_{Na} and BC_C is 287.12%, 168.89%, 102.18%, and 79.53%, respectively, much higher than BC. The maximum adsorption capacities of the biochars were observed in the following order: $BC_{Mn} > BC_{HA} > BC_{Na} > BC_C > BC$.

Table 2 shows the correlation coefficient, Langmuir and Freundlich models parameters. It is obvious that marginally better fits were attained by the use of the Langmuir model as compared to those attained from the Freundlich model, proposing that Pb^{2+} adsorption on these biochar was more constant with the Langmuir model rather than with the Freundlich model. Consequently, it was presumed that the adsorption happened mainly in monolayers, or occurred through fixed number of equal and energetically corresponding sites on the surface of biochar. In particular, Mn-modified biochar (BC_{Mn}) revealed the highest potential for Pb^{2+} adsorption, in which Q_{max} and K_L values were 3.87 times and 4.8 times (respectively) as high as those of virgin biochar.

Adsorption kinetics

Kinetic models were used to access the effect of contact time on the quantity of adsorbed Pb^{2+} on biochar and all the parameters of kinetic equations are given in *Table 3.* In the initial hours, the adsorption rate was very high. The rate of adsorption subsequently declined with the loom in equilibrium concentrations. Twenty-four hours were considered enough to confirm that the adsorption has reached equilibrium stage. Pseudo first order and pseudo second order models were used to evaluate the adsorption mechanism, (*Table 3*). The obtained regression coefficients (R^2) after using pseudo first order were 0.79-0.96 and the fitted model perceived a poor fit in the experimental data (*Table 3*). The pseudo second order equation fitted the kinetics data well and the regression coefficient of most samples was more significant (*Table 3*). The calculated q_e accorded the experimental data well, specifying the Pb^{2+} adsorption on engineered biochars follows the pseudo second order model which presumes chemisorption mechanism.

DOI: http://dx.doi.org/10.15666/aeer/1805_61816197

Table 3. *Fitting parameters for the kinetic equations that describe Pb^{+2} adsorption on pristine (BC), $KMnO_4$- (BC_{Mn}), hydroxyapatite- (BC_{HA}), NaOH- (BC_{Na}) and chitosan-modified (BC_C) biochars*

Biochars	Pseudo-first-order model			Pseudo-second-order model		
	q_e	K_1	R^2	qe	K_2	R^2
BC	8.32	0.037	0.91	11.78	0.03	0.95
BC_{Mn}	18.93	1.24	0.79	22.61	0.78	0.96
BC_{Na}	11.04	0.42	0.89	13.67	0.36	0.91
BC_{HA}	14.26	0.18	0.81	16.49	0.37	0.96
BC_C	10.89	0.08	0.90	12.65	0.05	0.92

Where, q_e is calculated data, (mg g^{-1}). K_1 is the rate constant for pseudo-first-order adsorption (L h^{-1}). While, K_2 is the rate constant for pseudo-second-order (g (mg h)$^{-1}$)

The Pseudo second-order equation determined the adsorption of Pb^{2+} on the surfaces of BC, BC_{Mn}, BC_{HA}, BC_{Na} and BC_C as well (*Table 3*). Adsorption rate constant (K) for various chars was in the following orders: BC_{Mn} > BC_{HA}> BC_{Na} > BC_C > BC. The rate constant is higher for BC_{Mn} (0.78 g (mg h^{-1}) than for BC (0.03 g (mg h^{-1}), suggesting the rapid adsorption of Pb^{2+} to BC_{Mn} (*Table 3*).

Desorption capacity

A post desorption test was piloted to examine the stability of the adsorbed metals onto/into these adsorbents (closely related with variable adsorption mechanism of each biochar). In the beginning, all the loaded Pb^{2+} was desorbed from every examined biochar and most of the adsorbed Pb^{2+} was detached from BC_{Mn}, BC_{HA}, BC_{Na}, BC_C and BC using the 0.1 M HNO_3. The desorption aptitude of all the biochars was much higher with HNO_3 extractant (*Fig. 5*). As 98.31%, 89.42%, 91.56%, 93.98% and 95.71% of metal desorption occurred in BC, BC_{Mn}, BC_{HA}, BC_{Na}, and BC_C, respectively. While, 9-11% of pre-loaded Pb^{2+} in BC_{Mn}/ BC_{HA} could be fixed in the studied biochars after desorption is anticipated to expose the ‘‘geochemically active form’’ of metals (Tipping et al., 2003).

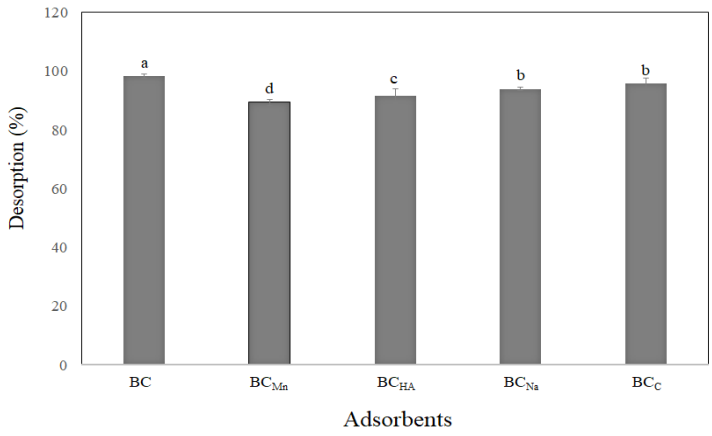

Figure 5. *Pb^{2+} desorption capacity by pristine (BC), $KMnO_4$- (BC_{Mn}), hydroxyapatite- (BC_{HA}), NaOH- (BC_{Na}) and chitosan-modified (BC_C) biochars by using 0.1 N HNO_3 solution. Experimental conditions: pH 5.0, initial concentration 50 mg/L, agitation rate 180 rpm, temperature 25°C, contact time 24 h*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61816197

Next, metal desorption was carried out using 0.01 M $CaC1_2$ for the assessment of bioavailable metal forms (Houba et al., 1996), and desorption is variable for all the studied biochars (*Fig. 6*). Pb^{2+} was desorbed at lower rate (2.67%-4.34%) in all types of biochars. Obviously, BC has much desorption capacity (4.34%) and BC_{Mn} has the lowest one (2.67%). Finally, background electrolyte of 0.1 M $NaNO_3$ having pH 5.00 was used for desorption of Pb^{2+} from biochars (*Fig. 6*). Results exhibited that Pb-desorption was trivial in all cases (<1.83%), which was caused by the contrasting behaviour of Pb^{2+} (higher stability and affinity to organic matter in Pb^{2+} at a specific pH) and by variable metal adsorption mechanisms.

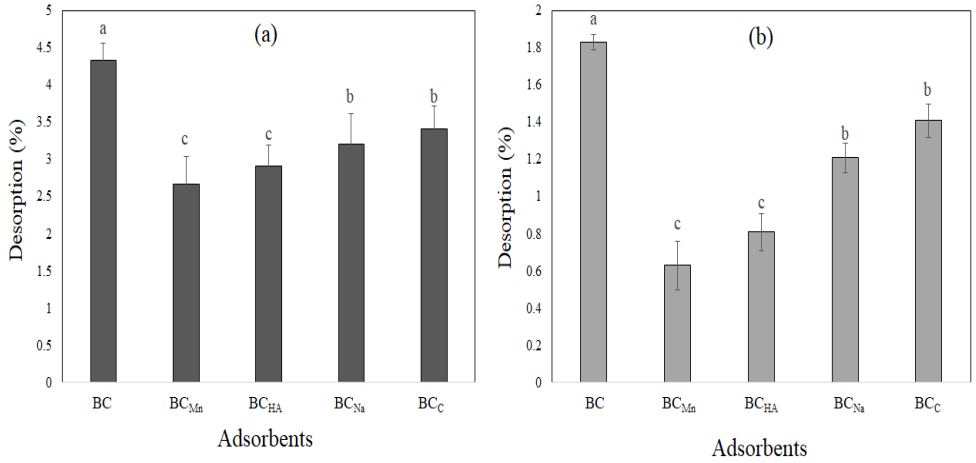

Figure 6. *Pb^{2+} desorption capacity by pristine (BC), $KMnO_4$- (BC_{Mn}), hydroxyapatite- (BC_{HA}), NaOH- (BC_{Na}) and chitosan-modified (BC_C) biochars by using 0.1 N $CaCl_2$ (a) and 0.1 M $NaNO_3$ (b). Experimental conditions: pH 5.0, initial concentration 50 mg/L, agitation rate 180 rpm, temperature 25°C, contact time 24 h*

Discussion

Our results revealed that the surface of biochars derived from SE-treated feedstock became coarser, compared to the smooth surface, clear anatomy, and distinctive pore structure in the biochars derived from the pristine feedstock. Our results are consistent with a previous study (Chen et al., 2019a). The accumulation of small particles on the BC_{Mn} surface is very obvious in SEM-EDS images, and is probably due to potassium permanganate. Due to Mn oxides formation, the porous structure was obstructed by these Mn oxide particles that are formed during pyrolysis (Petit et al., 2010). Various compounds of Mn oxides with various phases like β-MnO_2, δ-MnO_2, and MnO_2- coated sand have been reported to have strong affinity for various divalent metal cations (Tripathy and Kanungo, 2005). This might enhance the surface area of respective biochar and expose additional adsorption sites for Pb^{2+} (Chia et al., 2015).

All the four modified biochars had significantly greater maximum adsorption capacities (Q_{max}) and K_L values than the pristine biochar, which could direct that both feedstock pretreatment and biochar modification significantly increase the adsorption capacity of Pb^{2+}. The Langmuir model, presumes that the adsorptions of metal happened on a homogenous surface by monolayer adsorption deprived of any interaction between the adsorbed ions and has been used efficiently in many monolayer adsorption processes. Whereas, the Freundlich model presumes that the adsorption of metal ions

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61816197

took place on heterogeneous surfaces and sorption was multilayer. As evident from *Table 2* the adsorption isotherms are well described by the Langmuir model, suggesting that adsorption could be mono-molecular. As cited earlier, the adsorption/sorption efficiency differed not merely amongst tested metals, but usually differed among all the studied biochars. This might be because of the diverse adsorption mechanisms of respective metals on the studied biochars. As it is reported ion exchange, complexation and physical adsorption are liable for adsorption and sorption of metal on the surface of biochar (Sohi et al., 2010; Lu et al., 2012; Ahmad et al., 2014). However, these metal ions adsorption mechanisms are different for different kinds of biochars.

The adsorption proficiency of Pb^{2+} by these five adsorbents enhanced with time and then plateaued when equilibrium was attained. In the early stages adsorption capacity of Pb^{2+} by the pristine and modified biochars was much faster, probably because adsorption mainly took place on the external surfaces of biochars (Li et al., 2017). Pb^{2+} diffused into the carbon pores with the passage of time and further reacted with interior active sites of the carbon skeleton, where the adsorption process is comparatively slow (Babel and Kurniawan, 2003). BC_{Mn} and BC_{HA} adsorbed Pb^{2+} faster than BC and reached the equilibrium stage within only four hours. On the other hand, BC, BC_{Na} or BC_C needed eight hours to attain adsorption equilibrium. The aptitude of BC_{Mn} to grasp fast and proficient adsorption equilibrium which is extensively employed for the treatment of heavy metals contaminated water particularly in emergency conditions. Results of our investigation are in accordance with those of Ofomaja et al. (2010) who indicated that the sorption kinetics of heavy metals is considerably dependent on the physiochemical properties of biochar.

Solute-uptake rate is determined by adsorption kinetics which in turn governs the time of adsorption process (Ofomaja et al., 2010; Betts et al., 2013). Validation of the sorption kinetics model and the potential rate controlling steps was checked by pseudo first (Lagergren, 1898) and pseudo second order models (Ho and McKay, 2000). These parameters are beneficial for the selection of the optimal operating conditions. Furthermore, the adsorption capacities attained from pseudo-second-order model fitting are reconcilable with the experimental data, along with a chemisorption rate-controlling mechanism, where the limiting step is a physicochemical sorption or adsorption process including valence forces through the sharing or exchange of electrons between the sorbent and the sorbate (Vijayaraghavan and Yun, 2008). Findings of the current study are also in line with the observation of Li et al. (2017). Thus, this study speculated that these modified biochars may have higher potential for adsorption of pollutants as compared to pristine biochar. In addition, oil-rape straw might be suitable to SE pretreatment for preparing novel biochar for waste-water treatment and other environmental applications.

Following the results of an earlier study (Anastopoulos et al., 2015), 0.1 N HNO_3 was perceived as the best desorbing solution among numerous solutions. This proposes a dominant role for exchange sites in determining the adsorption properties of the various adsorbents. It is presumed that higher concentration of protons (H^+) of 0.1 N HNO_3 solution triggered intense competition of the H^+ between the metal ions for the adsorbent's exchange sites throughout the ion exchange process, and to the resultant desorption of Pb^{2+} ions adsorbed on exchange sites of the adsorbents surface (Anastopoulos et al., 2015). Obtained results of desorption study are most probably because of the predominant weak Pb π-bindings with poly-organic chains, e.g. physical adsorption and, in contrast, due to the stronger fixing of metals into the engineered

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61816197

biochar structures caused mostly by the cation release (particularly for BC_{Mn}). These results support the findings about the very strong fixation of Pb^{2+} to the structure of BC_{Mn}, BC_{HA}, BC_{Na} and BC_C (ion exchange adsorption mechanism). This partial desorption of adsorbed Pb^{2+} in the biochar after all extractions might be described by surface complexation reactions (Namgay et al., 2010). The current study, recommends that this often perceived partial extraction using $NaNO_3$ and $CaCl_2$ might be the result of strong bonds to biochar surfaces that would make adsorbed Pb^{2+} unavailable. So our study recommends that Pb^{2+} adsorption is not entirely reversible using $CaCl_2$ and $NaNO_3$ regardless of modifying agents, in contrast, it can be accomplished with HNO_3 as an extractant. Our findings are in accordance with previous studies (Trakal et al., 2014; Anastopoulos et al., 2015). Thus the current study, may reveal that the adsorbed Pb^{2+} was much more stable on the modified biochar with a lower desorption rate, as compared to the pristine biochar.

Conclusion

To summarize, $KMnO_4$ and nano-hydroxyapatite modification significantly improved the adsorption capacities of biochar for Pb^{2+}. The highest adsorption capacity for Pb^{2+} was exhibited by Mn and nano-hydroxyapatite modified biochars (70.92 and 49.26 mg g^{-1}, respectively), as compared to pristine biochar. Additional adsorption sites on engineered biochars appeared to play more significant role in Pb^{2+} adsorption instead of specific surface area of biochars. It can be concluded that cation-π bonding and cation exchange are the key mechanisms responsible for the highest adsorption capacities of studied biochars. Surface precipitation, surface electrostatic attraction and surface complexation are responsible for higher adsorption capacity in BC_{Na}. Conversely, BC_C exhibiting lower adsorption capacity might be caused by plenty of protons that obstructed the approach of Pb^{2+} ions, prompting to the decreased adsorption of Pb^{2+}. Thus, the manganese oxide impregnated biochar might provide an efficient way to elevate Pb^{2+} removal from aqueous medium. Although, various metal removal mechanisms are involved in the current study, but ion exchange mechanism is a crucial one among others. Furthermore, ion exchange mechanism revealed solid binding of adsorbed metal as affirmed by the post desorption of fully metal loaded biochars. To conclude, these biochars showed much promising adsorptive properties for divalent metals and might thus have a high potential as a soil amendment and an alternative adsorbent for environmental remediation. Further competitive adsorption and desorption studies are necessary in order to accurately estimate the heavy metal adsorption/desorption capabilities of biochar in natural environments.

Abstract. Cold severely affects plant growth and metabolism. The analysis of the characteristics of metabolite variations in seedlings under cold stress can help understand the physiological mechanism of *Anabasis aphylla* when responding to stress. In this study, gas chromatography-mass spectrometry technology was used to systematically analyze the changing characteristics of the metabolite profiles of *A. aphylla* under cold stress. A total of 116 types of differential metabolites were stably detected, of which 41 were up-regulated, while 75 were down-regulated. The metabolites of carbohydrates, amino acids, and organic acids formed the majority. The results showed that cold stress had a significant impact on the differential metabolites of *A. aphylla* seedlings. Via enrichment of metabolites such as γ- aminobutyric acid, α- ketoglutaric acid, and 1-kestose, *A. aphylla* could reduce the extent of damage caused by cold stress. The results of this study provide a basis for further analysis of the molecular and physiological mechanisms of the cold stress response of *A. aphylla*.
Keywords: *desert plant, differential metabolite, low temperature, carbohydrate, amino acids, organic acids*

Introduction

Cold is one of the most important abiotic stress factors to affect plant growth, plant development, geographical distribution, and crop yield. For cold-sensitive plants, cold stress from 1 to 10 °C can cause disorders in physiological processes such as water condition, mineral nutrition, photosynthesis, respiration, and metabolism, resulting in severe damage and even death of the plants (Wu et al., 2015). However, after a long evolutionary process, many plants that grow in a relatively low-temperature environment developed a well-established defense mechanism adapting to adverse environmental conditions. Studies have shown that the adaptation of plants to cold is related to the regulation of several metabolic pathways, particularly in the regulation of carbon metabolism, photosynthesis, and membrane lipids (Li, 2015). In Junggar basin of China, some desert plants have low temperature germination feature during snow-melting during the snow-melting period of early spring, these desert plants include *H. ammodendron*, *Haloxylon Persicum*, *Anabasis elatior*, *Lepidium apetalum* and *Anabasis aphylla* (Huang et al., 2003; Han et al., 2011; Peng et al., 2018). In the field, we found that germination speed of *Anabasis aphylla* was higher than other species, while its seedling regeneration probability is very low. Therefore, study on regeneration disorder mechanism of *A. aphylla* seedling is necessary for desert vegetation protection.

Anabasis aphylla is a semi shrub belonging to the Chenopodiaceae family. It is an important type of plant community for windbreak, sand fixation, and for the protection of the local ecological environment as well as surrounding land resources (Wang et al., 2017). The snow-melting period at Junggar basin happens within a 10-day period in March. During this time, the average daytime temperature is above 0 °C and the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61996215

maximum temperature is maintained at 7-14 °C, while the night-time minimum temperature drops below 0 °C (Zhou et al., 2009). Consequently, the ground surface is in a repeated freeze-thaw state during the snow melting period (Gornish et al., 2015). During field observations, we discovered that a large quantity of *A. aphylla* seedlings had already germinated under the snow at the snow-melting period, which indicates that *A. aphylla* has already adapted to the cold. In recent years, comparative transcriptomics, proteomics, and metabolomics studies combined with mutation analysis of cold resistance have significantly increased our understanding of the complex network of signaling pathways of the cold training process and the necessary molecular changes (Janda et al., 2014). Via proteomics studies, we found that the adaption of *A. aphylla* to cold was primarily achieved through changes in the energy metabolism. The proteins associated with the energy metabolism could be identified, such as the fructose-bisphosphate proteins, malate dehydrogenase proteins, citrate synthase proteins, oxygen-evolving enhancer protein, and photosynthetic proteins. However, the proteomic study mainly focused on the classification and identification of the associated proteins as well as on the analysis of the interaction between proteins and the function of the proteins, it cannot intuitively describe the physiological state of the plants under stress, while a plant metabolomics study is conducive to the overall study of the response of a biological system to changes in genes or the environment. The overall changes of the metabolites can directly reflect the physiological and pathological states of the organism and help to uncover complex plant stress response mechanisms (Teng et al., 2011). At present, metabolomics studies of plants under stress have been widely applied in species such as *Arabidopsis thaliana*, rice, potatoes, and *Festuca arundinacea* (Tarryn et al., 2016; Lin et al., 2017; Aliferis and Jabaji, 2012; Li et al., 2016). Studies have shown that under environmental conditions such as drought, salinity, or extreme temperature, the plant amino acid content increased significantly (Lanzinger et al., 2015; Annick et al., 2016), while the contents of several carbohydrates such as sucrose, lactose, and trehalose were also significantly increased induced by stress (Min et al., 2014; Wingler and Roitsch, 2008). Further studies have revealed that under adverse conditions, the contents of organic acids involved in the tricarboxylic acid (TCA) cycle showed increasing characteristics of metabolite changes at an early stage, while decreasing characteristics at a later stage (Widodo et al., 2009). However, a metabolomics study of *A. aphylla* seedlings under cold stress has not been reported yet. In this study, metabolomics technology was utilized for an analysis of the differential metabolites of *A. aphylla* seedlings under cold stress, thus providing a theoretical basis to explore the complex metabolic processes as well as their products and the secondary metabolic network structure.

Materials and methods

Plant materials and stress treatments

In the northwestern of China, it is mainly distributed around the piedmont alluvial fan, the Gobi Desert, and sand dune gravels areas (*Fig. 1*). *A. aphylla* seeds were obtained from the southern edge of the Gurbantünggüt Desert (E84°49′-85°23′, N45°21′-45°40′) in Xinjiang, China. All collected *A. aphylla* seeds were sterilized by soaking them in 10% H_2O_2 for 30 min, after which they were rinsed with distilled water. For the control treatment, the sterilized seeds were germinated on filter paper discs soaked with distilled water in Petri dishes at room temperature and a 16-h light/8-h dark

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61996215

photoperiod until seedlings were approximately 3 cm in length. For the cold treatment, 3-cm-long seedlings were kept in a -3 °C growth chamber for 12 h each day for one week. For each treatment, 3-g seedlings were selected as samples and quickly frozen in liquid nitrogen individually and stored at -80 °C for metabonomics analyses. Both treatments had eight biological replicates.

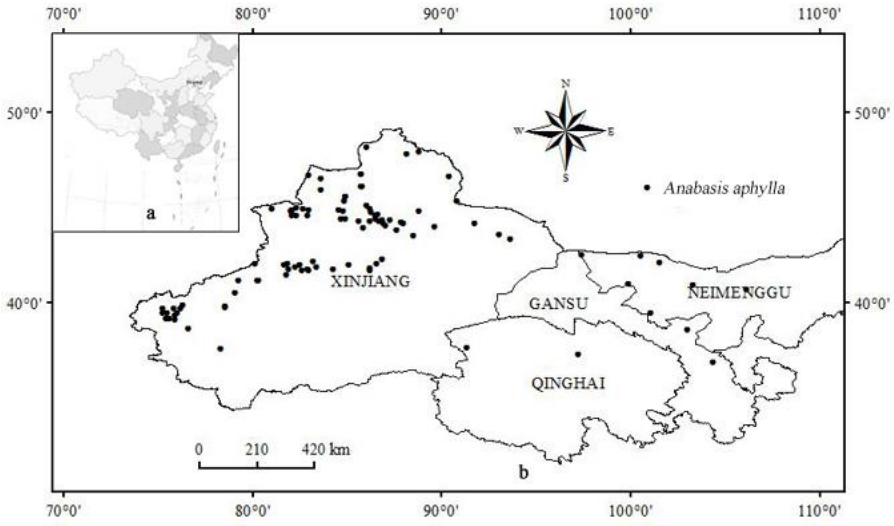

Figure 1. *Distribution of A. aphylla in northwestern China. (a) Map of China; (b) distribution of A. aphylla in northwestern China*

Sample pretreatment

Precision weighed 60 mg *A. aphylla* samples into 1.5 mL centrifugal tube, after adding 360 μL cold methanol and 40 μL internal standard (L-2-chlorine-phenylalanine, 0.3 mg mL^{-1}, methanol configuration) and homogenate (ground in Tissuelyser-48 (60 Hz, 2 min)). Then extracted by homogenate ultrasound at 30 min and sequentially added 200 μL chloroform and 400 μL water, again 30 min extracted by ultrasound and centrifuged for 10 min (14000 rpm, 4 ℃) at cold. Thereafter, collected 500 μL supernatant placed into glass derivative bottle, then dried with rapid centrifugal concentrator and added 80 μL methoxy pyridine hydrochloride solution (15 mg. mL^{-1}), after 2 min vorticity shock later, carried on oximation reaction 90 min in 37 ℃ shock incubator, then removed and 80 μL of N,O-bis trifluoroacetamide (BSTFA) containing 1% trimethylsilyl chloride (TMCS) derivative reagent and 20 μL n-hexane were added, after 2 min of vortex oscillation, reaction 60 min at 70 ℃. Later the samples were taken and placed at room temperature for 30 min for gas chromatography-mass spectrometry (GC/MS) metabolomics analysis (Lin et al., 2017).

GC/MS analysis

Each 1 μL aliquot of the derivatized solution was injected in split less mode into the Agilent 7890A-5975C GC-MS system (Agilent, USA). Separation was carried out on a non-polar DB-5 capillary column (30 m × 250 μm I.D., J&W Scientific, Folsom, CA), with high purity helium as the carrier gas at a constant flow rate of 1.0 mL min^{-1}. The GC temperature programming began at 60 °C, followed by 8 °C min^{-1} oven temperature

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61996215

ramps to 125 °C, 4 °C min^{-1} to 210 °C, 5 °C min^{-1} to 270 °C, and 10 °C min^{-1} to 305 °C, and a final 3 min maintenance at 305 °C. The electron impact (EI) ion source was held at 260 °C with a filament bias of -70 V. Full scan mode (m/z 50−600) was used, with an acquisition rate of 20 spectrum/second in the MS setting.

Quality control (QC) sample

QC sample was prepared by mixing aliquots of the all samples to be a pooled sample, and then analyzed using the same method with the analytic samples. The QCs were injected at regular intervals (every eight samples) throughout the analytical run to provide a set of data from which repeatability can be assessed.

Data analysis

The acquired MS data from GC-MS were analyzed by ChromaTOF software (v 4.34, LECO, St Joseph, MI). Briefly, after alignment with Statistic Compare component, the CSV file was obtained with three-dimension data sets including sample information, retention time-m/z and peak intensities, and the internal standard was used for data quality control (reproducibility). After internal standards and any known pseudo positive peaks, such as peaks caused by noise, column bleed and BSTFA derivatization procedure, were removed from the data set, and the peaks from the same metabolite were combined, the detectable metabolites of samples in GC-MS were 293 in total. The data set was normalized using the sum intensity of the peaks in each sample.

The data sets resulting from GC-MS were separately imported into SIMCA-P + 14.0 software package (Umetrics, Umeå, Sweden). Principle component analysis (PCA) and (orthogonal) partial least-squares-discriminant analysis (PLS-DA) were carried out to visualize the metabolic alterations among experimental groups, after mean centering and unit variance scaling. Variable importance in the projection (VIP) ranks the overall contribution of each variable to the (PLS-DA) model, and those variables with VIP > 1.0 are considered relevant for group discrimination.

In this study, the default 7-round cross-validation was applied with 1/seventh of the samples being excluded from the mathematical model in each round, in order to guard against overfitting.

Metabolite identification

All of the differentially expressed compounds in treated group were selected by comparing the compounds in the treated group with the control using the multivariate statistical method and Wilcoxon-Mann-Whitney test. Metabolites with both multivariate and univariate statistical significance (VIP > 1.0 and $p < 0.05$) were annotated with the aid of available reference standards in our lab and the NIST 11 standard mass spectral databases and the Feinh databases linked to ChromaTOF software. The similarity of more than 70% can be considered as reference standards.

Results

Chromatograms of cold stress and control treatment

Figure 2 shows the result of overlapping GC-MS total ion current (TIC) of the quality control samples (QC). This was a preliminary study of the reproducibility of the method.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61996215

Figure 2 shows that the reproducibility of the retention time and the corresponding intensity of *A. aphylla* QC sample mass peaks were very good, indicating the whole analysis method to be stable and reliable, making it useful for subsequent analysis. The typical TIC diagram of each set of sample is also presented (*Figs. 3* and *4*).

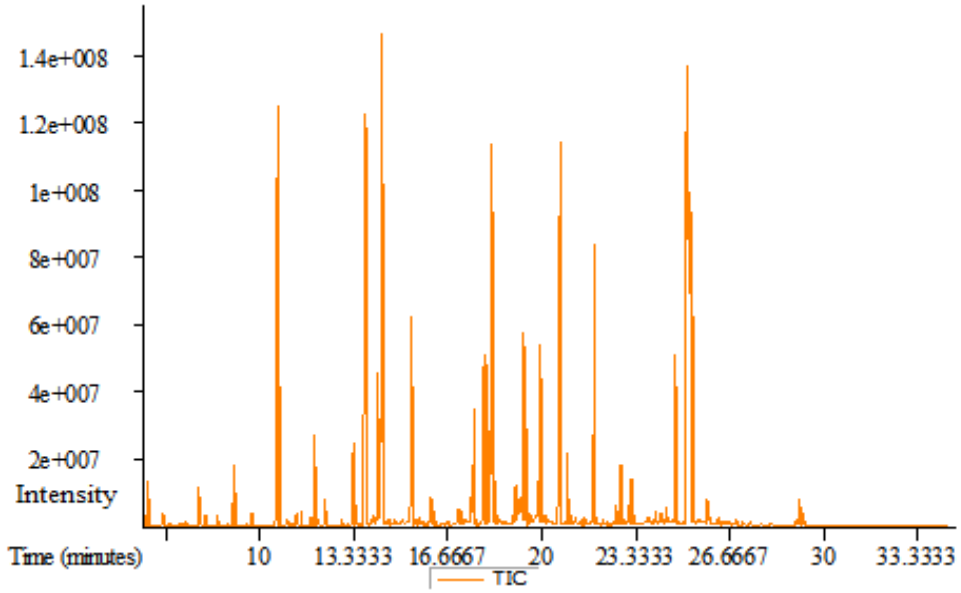

Figure 4. *Total ion chromatography (TIC) of A. aphylla from control treatment samples*

PCA, PLS-DA, and OPLS-DA analysis of A. aphylla seedlings under cold stress

PCA, PLS-DA, and OPLS-DA analyses were conducted on the *A. aphylla* samples in both the cold treated group and the normal temperature control group, and the scores of the two groups are shown in *Figures 5, 6,* and *7*. The PCA score diagram shows that the results of the eight duplicates from the cold treated group and the control group were well divided into two groups and were clustered together respectively, indicating that the error of the pretreatment method and the instrument analysis system were relatively small and that the reliability of the data was high, indicating that the method can be used for subsequent analysis. Using PLS-DA and OPLS-DA for further analysis of the GC-MS data from the control group and the treatment group, the results showed that the cold treated *A. aphylla* seedlings were clearly separated from the control group. Both the fitting degree and the predictive value of each model indicated good reliability of the models and the metabolites of the *A. aphylla* seedlings under cold stress showed significant changes compared to the control group.

Differential metabolite analysis under cold stress

293 metabolites were detected from the samples of the treated group and the control group, of which 116 metabolites with VIP > 1, $p < 0.05$ were screened out as differential metabolites. Among these, 41 were up-regulated, while 75 were down-regulated. The mass-to-charge ratio and the abundance of the characteristic fragmentation pattern of each chemical compound were compared to the standard fragmentation pattern in the NIST database and the Feihn metabolomics database to obtain the name of metabolites. The detected metabolites mainly included organic acids, amino acids, carbohydrates, alkaloids, phytohormones, organic bases, quinones, flavonoids, and other substances. Among these, the most abundant identified materials were amino acids, organic acids, and carbohydrates, including 21, 15, and 8 different types of substances in each category, respectively (*Table 1*); therefore, the materials in the three categories were the main focus for subsequent discussion and analysis. The metabolites in the focused discussion are listed in *Figure 8*. Some of these metabolites are associated with the ornithine cycle and the TCA cycle, and these identified metabolites are labeled in green in the diagram (*Figs. 9* and *10*).

Discussion

During growth and development, plants are often subjected to stresses such as environmental stress (temperature and moisture), biological stress (diseases, pests, and weeds), and nutritional deficiency stress (nitrogen, phosphorus, and potassium) (Hans et al., 2006). Plants can defend themselves against biotic and abiotic stress factors by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61996215

regulating their metabolic network to induce the production of a series of specific metabolites as response (Teng et al., 2011). Metabolomics can qualitatively and quantitatively analyze all metabolites within a specified biological sample under given conditions (Oliver et al., 2000). Therefore, using metabolomics to analyze changes of metabolites to study the metabolic regulation of plants under stress has gained increasing attention (Vicent et al., 2013).

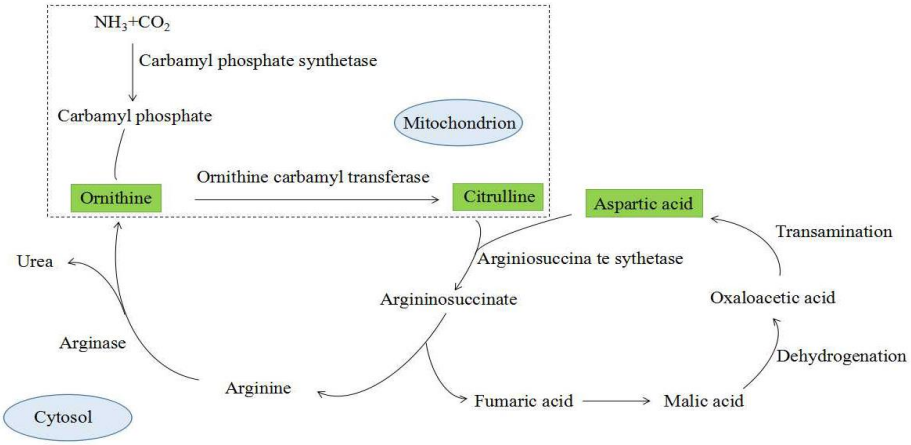

Figure 9. *Identified three amino acid metabolites are involved in the ornithine cycle*

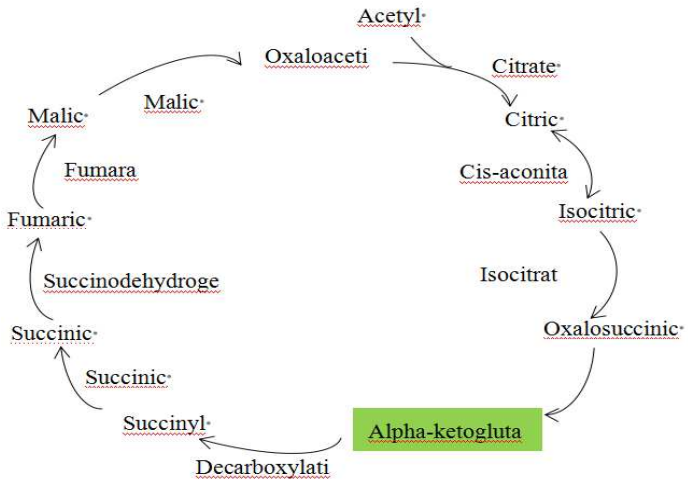

Figure 10. *Identified organic acid metabolites are involved in the TCA cycle*

Effects of cold on carbohydrate metabolites of A. aphylla seedlings

Carbohydrates play an important role in the life process, and it is the main source of energy required for all life to maintain alive. Our study on differential metabolites of *A. aphylla* seedlings under cold stress showed that carbohydrates played very important roles in the response of *A. aphylla* seedlings to cold stress. Among these, tagatose, D-talose, ribose, and 1- kestose accumulated in the seedlings under cold stress, while melezitose, cellobiose, trehalose, and sedoheptulose showed a trend of down-regulation. D- talose is an aldohexose, tagatose is a sweetening agent, often used in food and drug

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61996215

industry, and cellobiose is the hydrolysis product of cellulose, which also forms the basic structural unit of cellulose. Many studies have focused on cellobiohydrolase; however, the significance of cellobiose in plants has been rarely reported (Fan et al., 2018). Melezitose has been identified from the nectar secretion of plants such as the North American pinon pine, the Douglas fir, leguminous plants, and the poplar (Aderkas et al., 2012; Tian et al., 2018). Some researchers have also indicated that melezitose was once isolated from the leave secretion of the Yunnan pine. It is mostly used in the food industry (Mu and Lu, 1984). Therefore, only sedoheptulose, trehalose, and 1-kestose, which play important roles in plants, were discussed here. Sedoheptulose belongs to the heptoses and is an important primary and secondary metabolite in the pentose phosphate cycle, photosynthesis, other carbohydrates synthesis, and the biosynthesis of shikimic acid and aromatic ammonia (Xie, 2009). Studies reported that as the primary product of plant photosynthesis, sedoheptulose may be converted from 1,7-diphosphate sedoheptulose produced from carbon source through the Calvin cycle and the aldolase reaction at the end. This is not only the main storage form of carbon in plants, it also plays a key role in the carbon balance of plant. Sedoheptulose in plant mainly exists in the forms of 7-phosphate sedoheptulose and 1,7-diphosphate sedoheptulose and is involved in plant photosynthesis (Keith, 2017). Lee et al. have described sedoheptulose in the leaves of *Cornus oficinalis* of Comaceae, and it was also found in *Sedum spectabile* of Crassulaceae (Lee et al., 1989; Tolbert and Zill, 1954). Trehalose is a non-reducing disaccharide, widely distributed in organisms. Genome sequencing results showed that trehalose biosynthesis genes are widespread in plants (Lunn et al., 2014). In most plants however, the content of trehalose is very low, indicating that trehalose may not directly participate in the plant metabolism, but may be involved in signal regulation, metabolic regulation, and gene expression regulation processes (Paul et al., 2008). The synthesis, decomposition, and regulation of trehalose are important components of the plant sugar signal transduction pathway (Chen et al., 2014a). Studies have found that trehalose has a significant effect on the protection of *Volvariella volvacea* under cold. Furthermore, a large number of studies have shown that in stress conditions such as freezing and refrigeration, trehalose can prevent protein denaturation and protect cells from damage (Wang et al., 2008). However, Veluthambi et al. suggested that too much trehalose can severely inhibit the growth of plants. This would be because the excessive amount of trehalose impairs sugar utilization and reduces phloem transport processes (Veluthambi et al., 1982). In this study, in the seedlings of *A. aphylla*, trehalose was found to be down-regulated under cold stress, which is similar to the results of previous studies (Maria et al., 2013). 1-kestose is a linear inulin-type fructan and fructan is the most widely distributed biopolymer in nature. The fructan metabolism is an important means for regulating environmental stress in plants and the accumulation of fructan in plants can enhance their stress resistance (Wu et al., 2011). Studies have shown that fructan is mainly distributed in plant cell vacuoles. Under cold or cold conditions, fructan in the vacuoles is de-polymerized and releases large amounts of free fructose, which can reduce the water freezing point in plant tissues, thus acting as a vacuole osmotic buffer and cold protective agent in plants (Wang, 2000). Scholars have reported that the winter wheat varieties with strong cold resistance have higher fructan contents; after the introduction of the levansucrase gene that synthesizes fructan into sugar beet and tomato, the obtained transgenic plants not only exhibited cold resistance, but also expressed functions of drought resistance, salt tolerance, and improved fruit quality (Tognetti et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61996215

al., 1989; Sevenier et al., 1998; Wang et al., 2004). The contents of the metabolites sedoheptulose and trehalose detected in this study under cold conditions were 0.66 times and 0.80 times that of the contents under normal temperature, respectively. However, under cold, the content of 1-kestose was 3.32 times that of the content under normal temperature, indicating that cold stress inhibits the photosynthesis and carbohydrate metabolism in *A. aphylla* seedlings but does not affect the normal growth of plants. *A. aphylla* may adapt to a cold environment by accumulating 1-kestose or other carbohydrate metabolites.

Effects of cold on amino acid metabolites of A. aphylla seedlings

During the metabolic regulation process of responding to abiotic stress, the synthesis and decomposition of metabolites in plants are in a delicate dynamic state of equilibrium in order to swiftly respond to the changes of the external environment and to maintain the normal metabolism of the plant (Zhou et al., 2017). In addition to carbohydrate substances, the contents of amino acids in *A. aphylla* under cold stress also differed. As the basic components of the biological functional macromolecule proteins and the important nitrogen metabolites in plants, amino acids play important roles in the nitrogen metabolism and in plant stress resistance (Song et al., 2012). By comparing *A. aphylla* seedlings under cold treatment to the control under normal temperature, a large number of amino acids and amino acid metabolic intermediates revealed to be produced under cold stress. Among these, only few amino acids were up-regulated such as isoleucine, γ-aminobutyric acid, proline, cycloleucine, phenylalanine, and β- glutamic acid, while asparagines, L-homoserine, O-acetyl serine, methionine, 4-hydroxybutyrate, cysteic acid, threonine, aspartic acid, ornithine, histidine, citrulline, alanine, sarcosine, and intermediate metabolites of tryptophan, kynurenine, and xanthurenic acid were down-regulated.

γ-aminobutyric acid (GABA) is a non-protein amino acid found in many organisms and it is an important component of the free amino acid pool, which is widespread in every part of the plant (Yang et al., 2014). Under normal growth conditions, the GABA content is relatively low in plant tissue; however, under conditions of environment stress, physiological stress, or insect pest and other adverse conditions, the concentration of GABA will sharply increase. This reduces the damage of adverse conditions to plants, while enhancing plant resistance under stress through the stabilization of the cell membrane structure, reduction of activity oxygen damage, and regulation of biological macromolecule synthesis (Fait et al., 2008). Two major ways exist to synthesize and transform GABA in plants: glutamic acid decarboxylation and polyamine degradation. Glutamic acid metabolism plays an important role in plant growth, while GABA, as a glutamic acid enzymatic product, also plays an integral role in the life cycle of plants (Francisco et al., 2014). A study by Shelp et al. (2006) reported that plant endogenous GABA could stabilize and protect the thylakoid membrane against freeze damage *in vitro*, while exogenous GABA treatment could reduce the occurrence of cold damage and reduce the damage to plants. Proline is one of the components of plant proteins and it is widely distributed in plants in a free state. When the ambient temperature is lowered, the accumulation of proline plays an important role for protecting the stability of the cytoplasmic membrane of plants and for scavenging free radical damage (Matysik et al., 2002). Therefore, many researchers regard the content of proline in plants as one of the indexes to determine the cold hardiness of plants. It is generally assumed that the accumulation of proline under stress

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61996215

may be a great help for plants to recover after stress relief since proline can be used as both carbon source and nitrogen source, and it can also provide a large amount of energy for cell recovery (Sun et al., 2017). Many studies have shown that under cold, proline contents in plants such as *Festuca arundinacea*, tea tree, *Cinnamomum camphora*, and *Hibiscus syriacusplants* showed a significant increase compared to control groups, indicating that plants can adjust their proline content in response to adverse environmental conditions of cold (Li et al., 2016; Yang et al., 2004; Wen, 2017; Li and Zou, 2016).

The ornithine cycle in plants plays an important role in their adaptation to cold stress. Except for a few free amino acids that are increased during the accumulation, the majority of the amino acids were down-regulated under cold stress. Aspartic acid is the precursor of the biosynthesis of amino acids such as threonine, isoleucine, and methionine, as well as purine and pyrimidine. Ornithine, citrulline, and aspartic acid participate in the *in vivo* biosynthesis process of ornithine in plants. During this process, arginine is hydrolyzed into ornithine and urea via arginase; the carbamoyl group on the carbamyl phosphate is transferred onto ornithine, thus forming citrulline by ornithine transcarbamylase. Citrulline is then transported from the mitochondria to the cytoplasm and is condensed with aspartic acid to form argininosuccinic acid. Argininosuccinic acid is decomposed into arginine via argininosuccinase, releasing fumaric acid. The fumaric acid that is generated from the ornithine cycle not only connects the ornithine cycle and the citric acid cycle, it can also be decomposed by urease to produce ammonia, which can be used in the synthesis of other nitrogen-containing compounds such as nucleic acids, hormones, chloroplast, heme, amine, and alkaloids (He et al., 2014). The results of this study showed that cold stress significantly affected the amino acid metabolism, and weakened the ornithine cycle process, while differential metabolites such as isoleucine, β-glutamic acid, phenylalanine, cycloleucine, γ-aminobutyric acid, and proline were significantly up-regulated, indicating that *A. aphylla* seedlings had adapted to the cold environment via accumulation of these amino acids. The reason for the decreases in the contents of the majority of amino acids might be due to an inhibition of the metabolism under cold, resulting in amino acid decomposition.

Effects of cold on organic acid metabolites of A. aphylla seedlings

Cold stress induced the accumulation of a large quantity of organic acids in *A. aphylla* seedlings. The content of organic acids directly reflects plant growth and metabolic activity (Zhao et al., 2013). Malonic acid, also known as maleic acid, is a succinic acid analogue that can be used as a competitive inhibitor of succinate dehydrogenase, thus inhibiting the corresponding respiratory process (Ye et al., 2012). In our study, the content of malonic acid in *A. aphylla* seedlings under cold stress was increased by 2.35 times compared to the control group. This indicates that the respiration of *A. aphylla* seedlings was decreased and the metabolic activity was reduced. Some studies have also reported that plant respiration was inhibited under the treatment of high concentration of malonic acid. At the same time, the consumption of soluble solids was decreased, enabling plants to slow their growth under stress to survive the hazards caused by an adverse environment (Guo et al., 2016).

Abiotic stress induces the production of large quantities of reactive oxygen species in plants, which may activate proteases and induce excessive production of NH_4^+ in cells. To avoid surplus of NH_4^+, plants usually convert excessive NH_4^+ into glutamic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_61996215

acid/glutamine via transamination or convert it into α-ketoglutaric acid via glutamate dehydrogenase, entering the TCA cycle (Dai et al., 2010). Our results indicate that compared to the control group, the content of α-ketoglutaric acid was significantly increased under cold stress in the TCA cycle metabolism, indicating that the cold does not inhibit the TCA cycle, and that the energy metabolism was not compromised. Since the TCA cycle is the hub of communication among the metabolisms of carbohydrates, lipids, and amino acids, cold stress cannot only affect carbohydrate, lipid, and protein metabolisms, but can also directly affect the synthesis of several amino acids. Among the identified 15 organic acids, the relationships between many of these organic acids and plant stress resistance remain unknown. Tartaric acid is a dicarboxylic acid, and it exists in plants such as grapes, bananas, and tamarind, and is commonly used as antioxidant synergist, retarder, and chelating agent. Some studies suggest that tartaric acid is a good antidote, which is important for the germination and growth of plant seeds under heavy metal stress (Chen et al., 2014b). Some of the organic acids such as 4-hydroxybutyrate, mucic acid, glutaric acid, gallic acid, and 3-hydroxypropionic acid are also commonly used for chemical production, medicine and health care, food processing, and in research of separation and extraction technologies. The applications and significances of these organic acids in plants still require further exploration.

Conclusion

Gas chromatography-mass spectrometry technology was used in this study to analyze the metabonomic changes in *A. aphylla* seedlings under cold stress. A total of 116 differential metabolites were identified, including organic acids, amino acids, carbohydrates, alkaloids, auxins, organic bases, quinone compounds, flavonoid compounds, and other substances. In this study, most of the differential metabolites found in *A. aphylla* seedlings under cold stress showed a down-regulated trend. Through the analysis of carbohydrates such as sedoheptulose and trehalose, various amino acids, and the organic acid malonic acid, it was found that photosynthesis, respiration, carbohydrate metabolism and ornithine cycle of *A. aphylla* seedlings were all inhibited under cold stress; however, at the same time, *A. aphylla* seedlings were able to lower the extent of damage caused by adversity via accumulation of metabolites such as γ-aminobutyric acid, α-ketoglutaric acid, and 1-kestose. The results of this study provide a foundation for further analysis of the molecular and physiological mechanisms of the response of *A. aphylla* to cold stress.

Abstract. Maize, the third most important cereal crop around the globe, is hampered by devastating abiotic factors including salt stress. Calcium is known to increase plant tolerance to biotic and abiotic stresses by influencing physiological processes. The current study was carried out to investigate the genetic variation of maize hybrids against salt stress in combination with exogenous application of calcium (Ca^{2+}) in a hydroponic culture. Three levels of salinity, each with NaCl (0 mM, 75 mM, and 150 mM) and Ca^{2+} (0 mM, 2.5 mM, 5 mM) were applied to maize hybrids in three replications and data were recorded for key morpho-physiological traits. The results showed that all concentrations of NaCl significantly affect the maize hybrids with Sarhad White Azad Jammu Kashmir (SWAJ 6,7) and Syngenta 8441 being the least affected by both 75 mM and 150 mM NaCl concentrations. The exogenous application of 2.5 mM Ca^{2+} with 75 mM salt concentration showed significant effects on all morpho-physiological traits of maize hybrids. Better growth performance, maintenance of nutrient contents, lower accumulation of toxic sodium ions and lower Na^+/ K^+ in SWAJ6,7 and Syngenta 8441 indicate that these maize hybrids are more tolerant to salinity stress than the others under study.
Keywords: *hydroponic, ion contents, Zea mays* L.), *NaCl, proline*

Introduction

Soil salinity is one of the key environmental constraints that limit the production of crop throughout the world (Jiang et al., 2018). In arid and semiarid regions, the soil salinity more severely affects crop production due to global climate changes and as consequences of irrigation practices (Farooq et al., 2015). In Pakistan around 6.8 million hectares of land is affected by salinity. Therefore, major agricultural area remains uncultivated (Chaudhary et al., 2017). Saline soils have high pH and electrical conductivity (EC > 4.0 dS/m) and are usually rich in sodium, chloride and sulfate ions, with high absorption rate of sodium (Flowers and Flowers, 2005). In the rhizosphere, osmotic pressure due to high saline condition reduces mineral and water uptake by the plant, which ultimately affect primary and secondary metabolism of the plant (Hendawy and Khalid, 2005). The cumulative response of meristematic and expanding cells to salt stress is the inhibition of shoot growth which is observed primarily under salinity stress (Shoresh et al., 2011). Salt stress causes various morphological and metabolic modifications in plants by creating osmotic stress and ionic imbalance thus disrupts the vital cellular functions (Taylor et al., 2004; Yildirim et al., 2006). Osmotic stress leads to the reduced water absorption by roots and increase water loss from leaves. This

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62176232

mechanism is called hyperosmotic stress and it leads to various physiological modifications in plants such as nutrient imbalance, decreased photosynthetic activity, decreased stomatal apertures, membranes interruptions, modifications in antioxidant enzymes and failure to detoxify reactive oxygen species (ROS) (Soliman and El-Shaieny, 2014). The formation of ROS due to salt stress interrupts vital cellular functions by causing damage to various cell components such as DNA, protein and lipids (Gupta and Huang, 2014). Plant tissues exposed to saline soil accumulate more Na^+ and Cl^- which is one of the most detrimental effect as it causes severe ionic imbalance in plants by decreasing uptake of important mineral ions which are essential for the growth and development of plant (James et al., 2011). Reduced water permeability and aquaporin abundance of membrane under salinity stress is restored by calcium treatment (Martínez-Ballesta et al., 2008).

Calcium, an essential plant nutrient is responsible for the maintenance of structure and functions of plant membranes. It also increases the stability of cell wall structures, selectivity and transport of ions and improves the metabolic activities in plants. Calcium as second messenger plays a crucial role in signal transduction in response to developmental and environmental signals (Guo et al., 2019). Almost half of the cellular Ca^{2+} is bound mainly to carboxyl groups of pectins in the cell wall (Cramer, 2002). Previous studies indicated that salt induced inhibition of growth is improved by high content of Ca^{2+} bound to pectin on cell wall (Madea et al., 2005). Increased Na^+ ions due salinity stress reduces calcium availability and its transport to growing regions of the plant (Shoresh et al., 2011). The reduction of Ca^{2+} concentration in salinized plants severely effects the physiological function. The addition of supplemental Ca^{2+} provide protection by stabilizing on the cell-wall components (Tuna et al., 2007).

Maize (*Zea mays* L.), an important cereal crop is grown under wide range of soil and climatic conditions. It is an important C4 plant belongs to the grass family Poaceae (Farooq et al., 2015). About 21% of the total maize grain produced is consumed as food throughout the world (Chaudhary et al., 2017). The larger producer of maize is the United States with annual yield of about 4096190 thousand million tons. In Pakistan average yield of maize is 4268 kg/ha (Economic Survey of Pakistan, 2012-13). Various biotic and abiotic stresses extremely affect the yield potential of maize crop. Among abiotic stresses, salinity reduces the maize yields by causing numerous biochemical and physiological changes in plants (Zafar-ul-Hye et al., 2014). Maize is found to be moderately sensitive to salt stress. However, extensive genetic variation exists intra-specifically in maize for salt resistance (Mansour et al., 2005). The current study was aimed to explore the genetic variation of five different maize hybrids against salt stress in combination with exogenous application of Ca^{2+}.

Materials and Methods

In order to investigate the influence of exogenously applied $CaSO_4$ as calcium source on five maize hybrids under salt stress, an experiment was conducted in 2018 under hydroponic conditions in the greenhouse of COMSATS University Islamabad, Abbottabad Campus, Pakistan. Maize hybrids used in current study were:
COMSATS Random Mating 8 (CTRM 8), Pirsabak Experimental Variety 2 (PSEV 2), Sarhad White Azad Jammu Kashmir 6, 7 (SWAJ 6, 7) and Syngenta 8441.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62176232

Plant growth and experimental treatments

The seeds of five maize hybrids (CTRM 8, PSEV 2, SWAJ 6-7, Syngenta 8441 and XPW3) were sterilized with 1% HOCl for 10 minutes and rinsed with distilled water, the process being repeated 3 times. The seeds were germinated on moist thin sheets of foam at 25°C in an incubator. After germination, uniform sized seedlings were transferred in constantly aerated pots containing 1/3rd strength Hoagland's solution. Plants were adapted to full strength nutrient solution in 25% increments every second day in similar way as described by Richter et al. (2015). The experiment was carried out in a completely randomized design (CRD). Plants were subjected to different concentrations of NaCl along with application of Ca^{2+} as foliar at four leaf stage. Seven different treatment combinations with three replicates per treatment were used. Treatment combinations were as follow:

T1: Control (Hoagland solution alone); T2: Salt Stress (75 mM NaCl); T3: Salt stress and foliar (75 mM NaCl + 2.5 mM Ca^{2+}); T4: Salt stress and foliar (75 mM NaCl + 5 mM Ca^{2+}); T5: Salt Stress (150 mM NaCl); T6: Salt stress and foliar (150 mM NaCl + 2.5 mM Ca^{2+}); T7: Salt stress and foliar (150 mM NaCl + 5 mM Ca^{2+}).

Growth parameters

Growth parameters were scored at seventh day of treatments application by measuring leaf number, leaf area, shoot length and maximum root length. Fresh weights of plants were taken immediately after harvesting. For dry weight, plant organs were placed in an incubator at 75℃ for 72 hrs (Sun et al., 2018). Leaf area was calculated according to *Equation 1*:

$$A = LL * W * K \quad \text{(Eq.1)}$$

where,
LL represents leaf length,
W is the maximum width and
K is a shape factor with value 0.75.

Chlorophyll content

Chlorophyll extraction was done by grinding 0.1 g of fresh leaves in 15 ml of acetone (80%). This mixture was then subjected to centrifugation at 5000 rpm for 10 minutes at 4°C. Supernatant from each sample was collected until the residue was turned into colorless mixture. The chlorophyll content was measured using spectrophotometer at wavelength of 645 nm and 663 nm (Nayyar et al., 2005).

Relative water content

Relative Water content (RWC) was determined according to *Equation 2* as described by Loutfy et al. (2012).

$$RWC(\%) = [(FW - DW)/(TW - DW)] * 100 \quad \text{(Eq.2)}$$

where,
FW represents fresh weight,
TW is Turgid weight and
DW is Dry weight.

DOI: http://dx.doi.org/10.15666/aeer/1805_62176232

Electrolyte leakage

For determination of electrolyte leakage (EL), 10 leaf discs of about 10 mm diameter from expanded leaves of all maize hybrids were taken and rinsed with distilled water to get rid of electrolytes adhered to the surface. These leaf discs were incubated at 10°C after placing them in glass tubes filled with 10 ml of distilled water for 24 hr. The initial electrical conductivity (EC1) of the solution was measured using conductometer. To release all electrolytes, these tubes were heated at 95°C in water bath for 20 min followed by cooling at room temperature. After that final electrical conductivity (EC2) was determined.

EL was calculated using *Equation 3* (Yildirim et al., 2009).

$$EL = \left(\frac{EC1}{EC2}\right) * 100 \quad \text{(Eq.3)}$$

Plant mineral ion contents

For determination of mineral ions, 100 mg of dried plant samples (roots and leaves) were heated for about 5 hrs in furnace at 520°C for ash formation. The ash of each plant sample was then solubilized in nitric-perchloric acid mixture (5:1) and volume was raised to 15 ml using distilled water. Afterwards filtered suspensions were used to determine the concentrations of Na^+, K^+, Ca^{+2} and Mg^{+2} using atomic absorption spectrometry. For standard curves, different concentrations of Ca^{+2}, K^+, Na^+ and Mg^{+2} were prepared by diluting stock solution of $CaSO_4$, KCl, NaCl and $MgSO_4$. The standard curve was used to determine the content of each element in the plant organs (roots and leaf) and expressed in mg g^{-1} dw (Qadir, 2016).

Proline contents

Leaf proline content was extracted and analyzed by the method of Bates et al. (1973). 0.1 g of fresh leaf of all maize hybrids were ground using liquid nitrogen in a mortar. 1 ml of sulfosalicylic acid (3% w/v) was added to the resulted homogenate powder of leaves and then filtered. The filtrate was reacted with 1 ml of glacial acetic acid (GAA) and 1 ml of ninhydrin reagent (1.25 mg Ninhydrin in 30 ml of GAA and 20 ml 6 M H_3PO_4) and placed in an incubater for 1 hr at 95°C. To terminate the reaction, reaction mixture containing tubes were kept in ice bath for 5 min followed by vigorous mixing with 2 ml toluene. After warming at 25°C, the chromophore was measured at 520 nm. L-proline was used as a standard.

Statistical analysis

For statistical analysis, results of all experiments were expressed as mean ±standard deviation (SD) of three replicates. Data were subjected to one-way analysis of variance (ANOVA) and LSD multiple comparison test ($P < 0.05$) using the SPSS statistical package. Significant differences are indicated by alphabets in figures and tables.

Results

Growth parameters of maize under salt stress and Ca^{2+} treatments

The growth parameters of maize seedlings were evaluated by measuring leaf area, root length and shoot length of plants under salt stress. Effect of salt stress and calcium on

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62176232

growth parameters of five maize hybrids (CTRM8, PSEV2, SWAJ 6, 7, Syngenta 8441 and XPW3) are listed in *Table 1*. Under salt stress all five Maize hybrids react differently. Salt addition showed significant effect on growth parameters like leaf area, root length and shoot length of plants. The maximum decrease in these parameters was observed in CTRM 8 and XPW 3 whereas maximum shoot length, maximum root length and leaf area was exhibited by SWAJ 6, 7 and Syngenta 8441 which showed improved growth traits. However, effects of salinity were significantly alleviated in all five maize hybrids by foliar application of 2.5 mM Ca^{2+}. Although application of 5 mM Ca^{2+} also improved plant growth but the effect was not significant as compare to 2.5 mM Ca^{2+} (*Table 1*).

Leaf chlorophyll content in maize under salt stress and Ca^{2+} treatments

Salt stress showed significant effect on total leaf chlorophyll contents of maize hybrids. Increase in salt stress resulted decrease in chlorophyll contents of maize leaves. It is found from the results that the high levels of salinity (150 mM NaCl) induced reduction in the total chlorophyll contents of leaves significantly in comparison to leaves of control plants. However, Ca^{2+} application on plants under salt stress increased the leaf chlorophyll contents (*Table 2*). Importantly, 2.5 mM Ca^{2+} treatments showed significantly higher total chlorophyll contents compared to that of 5 mM Ca^{2+} treatments.

RWC of maize under salt stress and Ca^{2+} treatments

Salt stress significantly reduced RWC in all maize hybrids with more prominent effect in CTRM8 and XPW3 in comparison with the control conditions. Salt-induced water imbalance resulted in decrease RWC. However, foliar application of 2.5 mM and 5 mM Ca^{2+} on salt-stressed maize plants increased RWC significantly in comparison to plants under salt stress only (*Table 2*).

Electrolyte leakage under salt stress and Ca^{2+} treatments

The increasing salt concentrations enhanced EL value of all maize hybrids (*Table 2*). The highest EL was observed in CTRM 8 and XPW3 in comparison to SWAJ 6, 7 and Syngenta 8441 under all stress conditions. However, supplemented Ca^{2+} reduced MP of salt stressed plants compared to plants without Ca^{2+} under salt stress. The application of Ca^{2+} significantly improved MP by decreasing the electrolyte leakage under salt stress.

Na, K^+, Ca and Mg contents of leaves and roots under salt stress and Ca^{2+} treatments

Salinity has very clear effects on ionic composition of maize. Maize genotype SWAJ 6, 7 and Syngenta 8441 showed better chemical attributes at all levels of salt stress. In all five maize hybrids, Na^+ accumulation in leaves and roots was proportional to the NaCl concentration in the medium applied exogenously. Significant increase of Na^+ levels was found in roots and leaves of all maize hybrids under treatments. This increase was more obvious in the leaves of XPW 3 than that in SWAJ 6, 7 and Syngenta 8441 hybrids (*Fig. 1a*). The highest concentration of Na^+ were observed in the roots of SWAJ 6, 7 and Syngenta 8441 at 150 mM NaCl treatment in combination with 2.5 and 5 mM foliar Ca^{2+} applications (*Fig. 1b*). Sodium accumulation in roots and leaves of maize hybrids under combined treatment of NaCl + Ca^{2+} was found less than sodium in plants under treatment of NaCl alone. Ca^{2+} application thus alleviates the hyperaccumulation of Na^+ ions in plants under salt stress (*Fig. 1a,b*).

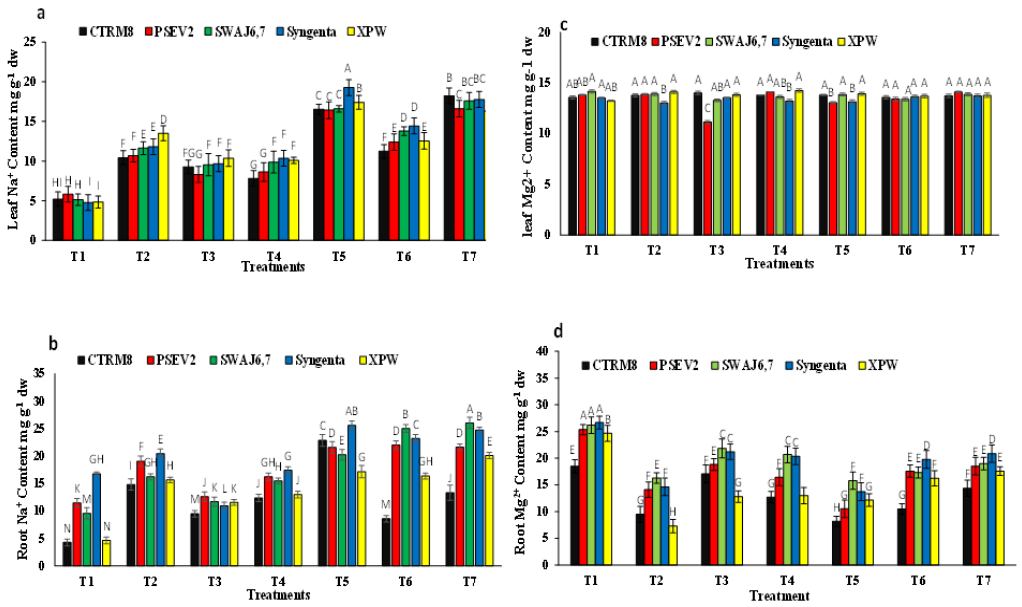

Figure 1. *The Na concentration of leaf (a) and root (b) Mg concentration of leaf (c) and root (d) of five maize hybrids (CTRM8, PSEV2, SWAJ 6, 7, Syngenta 8441, XPE3) in response to salinity and Ca^{2+} supplement. Values are means ± SE of three replicates*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62176232

Mg^{2+} content of leaf showed no significant effect under salt stress and foliar application of Ca^{2+} under salinity did not change the Mg^{2+} contents in leaf (*Fig. 1c*). However, salinity showed negative effect on root Mg^{2+} contents. Foliar Ca^{2+} application enhanced concentration of Mg in roots of all maize hybrids under salt stress (*Fig. 1d*).

Salt stress had induced noticeable variations in Ca^{2+} and K^+ contents in leaves and roots of all maize hybrids. In comparison to that of control plants, all five maize hybrids showed decline in K^+ and Ca^{2+} contents of roots and leaves under salt stress. This decrease in K^+ and Ca^{2+} was more pronounced in CTRM8 and XPW3 as compared to SWAJ 6, 7 and Syngenta 8441 maize hybrids. Supplemental Ca^{2+} enhanced the K^+ and Ca^{2+} concentrations of leaves and roots of maize plants under salt stress. At all salinity levels, maintenance of high level of K^+ was better in SWAJ 6, 7 and Syngenta 8441 in comparison to CTRM8 and XPW3 (*Fig. 2*).

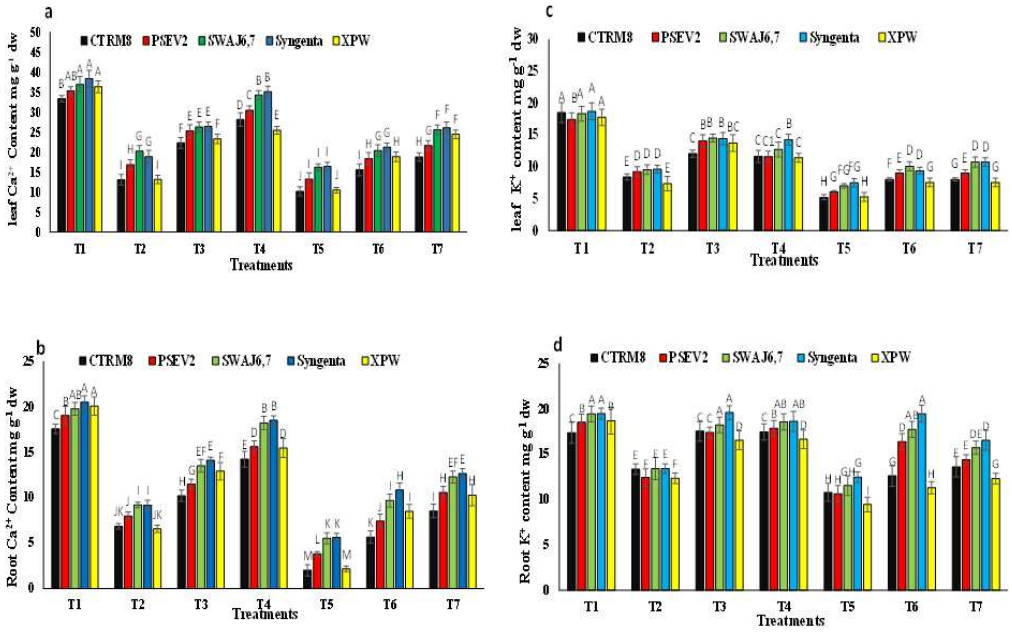

Figure 2. *The Ca concentration of leaf (a) and root (b) K concentration of leaf (c) and root (d) of five maize hybrids (CTRM8, PSEV2, SWAJ 6, 7, Syngenta 8441, XPE3) in response to salinity and Ca^{2+} supplement. Values are means ± SE of three replicates*

For all five maize hybrids, Na^+/K^+ ratio increased dramatically under salt stress with more notable effect in leaves of CTRM8 and XPW3 (*Fig. 3*). Supplemental Ca^{2+} resulted significant decline in Na^+/K^+ ratio of maize leaves under salt stress.

Proline contents of maize leaves under salt stress and Ca^{2+} treatments

Analysis of proline contents of maize leaves indicated that application of salt resulted in increased proline contents in all maize hybrids with more pronounced effect in CTRM8 and XPW3 as compare to SWAJ 6, 7 and Syngenta 8441. Under salt stress, proline contents in maize enhanced significantly (*Fig. 4*). However, proline concentration was markedly decreased in plants with exogenous application of 2.5 mM and 5mM concentrations of Ca^{2+} under salt stress. The less proline contents were found in plants treated with 2.5 mM Ca^{2+}.

Discussion

The current study was carried out to investigate the genetic variation of five maize hybrids against salt stress in combination with exogenous application of calcium (Ca^{2+}). The decrease in plant growth parameters such as shoot length, root length, leaf area, plant weight (fresh and dry) due to salt stress, confirming many prior findings (Mulholland, 2002; Yurtseven et al., 2003; Agong et al., 2004; Ahmad, 2012). Excessive Na^+ accumulation in presence of NaCl resulted in nutritional and metabolic imbalances due

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62176232

to ion toxicity which led to reduction in growth parameters of maize hybrids. It was reported that higher accumulation of Na^+ ions is the main cause of decreased plant growth and metabolism (Zhu, 2002). The genotypes with less concentration of Na^+ produced more biomass as confirmed by Munns and James (2003).

Ca^{2+} ion shows ameliorating effect on growth parameters of plants under salt stress may be by competing with Na^+ ion for binding with membranes. Ca^{2+} application minimized the harmful effects of NaCl and enhanced plant growth of all five maize hybrids. Previous studies also reported that exogenous Ca^{2+} application increased plant growth and tolerance to salt stress in *Cassia angustifolia* (Senna) (Arshi et al., 2005), *Eleusine coracana* (finger millet), *Thinopyrum ponticum* (wheatgrass) and *Lolium perenne* (ryegrass) (Sima et al., 2009), *Cakile maritime* (Sea Rocket) (Amor et al., 2010), *Zea mays* (Maize) (Shoresh et al., 2011), *Cunninghamia Lanceolata* (Chinese fir) (Liu et al., 2014), *Lycopersicon esculentum* (Tomato) (Parvin et al., 2015) and *Calligonum mongolicum* (Xu et al., 2017). Ameliorative effect of calcium by enhancing the vegetative growth and total dry weight of plants under salt stress has also been confirmed by Manivannan et al. (2007). Improved growth performance of SWAJ 6, 7 and Syngenta 8441 under salt stress indicate that these maize hybrids are more tolerant to salinity stress than CTRM8, PSEV2 and XPW3.

Salt stress showed significant effect on total leaf chlorophyll contents of maize hybrids. Increase in salt stress resulted decrease in chlorophyll contents of maize leaves. It is found from the results that the high levels of salinity (150 mM NaCl) induced reduction in the total chlorophyll contents of leaves significantly in comparison to leaves of control plants. Netondo et al. (2004), Amini and Ehsanpour (2006) and Naher (2014) also reported similar findings. Moreover, chlorophyll contents were less affected in SWAJ 6, 7 and Syngenta 8441 than CTRM8 and XPW3 indicated that they were able to maintain photosynthetic capacity under salt stress. However, Ca^{2+} application on plants under salt stress increased the leaf chlorophyll contents (*Table 2*). A range of plant species responses from positive to negative effects to supplemental Ca^{2+} have been described in previous studies (Cramer, 2002; Cabot et al., 2009). Nevertheless, total leaf chlorophyll significantly increased by supplemental Ca^{2+} under salt stress (*Table 2*). Similar responses were found in other plants such as *Cucumis sativus* L. (Cucumber), *Fragaria ananassa* (strawberry) and *Vigna radiate* (Mung bean) (Kaya and Higgs, 2002; Kaya et al., 2002; Manivannan et al., 2007). Importantly, 2.5 mM Ca^{2+} treatments showed significantly higher total chlorophyll contents compared to that of 5 mM Ca^{2+} treatments.

Reduction in RWC in salt stressed plant is a common phenomenon. In present study all five maize hybrids showed decreased RWC under salt stress with less significant effect under mild stress of 75 mM NaCl in Syngenta 8441 and SWAJ 6, 7. Similar water shortage induced by salt was observed in *Oryza sativa* and *Zea mays* affected with salt (Cicek and Cakirlar, 2002; Tuna et al., 2008). Plants supplemented with Ca^{2+} showed improved RWC may be due to water retention under salt stress. Similar results were reported by Tahjib-Ul-Arif et al., (2018).

Membrane permeability (MP) can be determined by measuring electrolyte leakage (EL). Plasma membranes are primarily affected by ion-specific salt injury (Mansour et al., 2005). Hence, for the identification of salt tolerant plants, determination of electrolyte leakage from plasma membranes is an important criterion (Ashraf and Ali, 2008). In present study, all maize hybrids showed increase in EL under salt stress which is an indication of membrane dysfunction. The increased permeability of cellular membranes for electrolytes and ions is the clear indication of membrane dysfunction caused by salt

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62176232

stress and it can be measured by the electrolytes and efflux (Qadir, 2016). The highest EL was observed in CTRM 8 and XPW3 in comparison to SWAJ 6, 7 and Syngenta 8441. Demidchik et al. (2014) stated that efflux of K^+ is mainly related to electrolyte leakage. However, supplemented Ca^{2+} reduced MP of salt stressed plants compared to plants without Ca^{2+} under salt stress. The application of Ca^{2+} significantly improved MP by decreasing the electrolyte leakage under salt stress.

Salinity has very clear effects on ionic composition of maize. Significant increase of Na^+ levels was found in roots and leaves of all maize hybrids under treatments. This increase was more obvious in the leaves of XPW 3 than that in SWAJ 6, 7 and Syngenta 8441 hybrids (*Fig. 1a*). The highest concentration of Na^+ were observed in the roots of SWAJ 6, 7 and Syngenta 8441 at 150 mM NaCl treatment (*Fig. 1b*). Similar response was also reported in other plants such as Malus species, *Myrtus Communis* L. (Myrtle), Citrus and *Pistacia vera* (Pistachio) (Liu et al., 2012; Acosta-Motos et al., 2015; Martínez-Alcántara et al., 2015; Rahneshan et al., 2018).

Salt stress had induced noticeable variations in Ca^{2+} and K^+ contents in leaves and roots of all maize hybrids. In comparison to that of control plants, all five maize hybrids showed decline in K^+ and Ca^{2+} contents of roots and leaves under salt stress. This decrease in K^+ and Ca^{2+} was more pronounced in CTRM8 and XPW3 as compared to SWAJ 6, 7 and Syngenta 8441 maize hybrids. Supplemental Ca^{2+} enhanced the K^+ and Ca^{2+} concentrations of leaves and roots of maize plants under salt stress, similar to findings in other plant species (Tuna et al., 2007; Nedjimi and Daoud, 2009; Cabot et al., 2009; Kwon et al., 2009). At all salinity levels, maintenance of high level of K^+ was better in SWAJ 6, 7 and Syngenta 8441 in comparison to CTRM8 and XPW3 (*Figure 2*).

Increase in salinity levels lead to increased uptake of Na^+ which dramatically increased Na^+/K^+ ratio in roots and leaves of all maize hybrids. For all five maize hybrids, Na^+/K^+ ratio increased dramatically under salt stress with more notable effect in leaves of CTRM8 and XPW3 (*Fig. 3*). Supplemental Ca^{2+} resulted significant decline in Na^+/K^+ ratio of maize leaves under salt stress. It is documented that in salt-stressed plants, Ca^{2+} sustains K^+/ Na^+ selectivity and K^+ transport at the plasma membrane. Exogenous Ca^{2+} can reduce K^+ loss and enhance its uptake in plants under salt stress by affecting different channels as demonstrated by several previous studies (Shabala and Newman, 2000; Maathuis and Sanders, 2001; Shabala et al., 2003, 2005, 2006). This indicates that Ca^{2+} amelioration of salt stress is a critical process in K^+ transport regulation that may induce growth in plants. Better chemical attributes of SWAJ 6, 7 and Syngenta 8441 at all levels of salt stress could be the reason of their tolerance to salt stress.

Proline is considered as a source of nitrogen and carbon for rapid recovery of plants under salt stress. It acts as free radical scavenger and not only adjust the osmotic pressure of plant but also found to involve in stabilization of membranes and some macromolecules in plant cells. Less accumulation of proline contents in salt stressed maize seedlings treated with calcium shows protective role of calcium in plants by reducing osmotic pressure caused by salt stress (Hoque et al., 2007). Therefore, plants accumulated less proline contents under salt stress with application of calcium. Accumulation of proline is the primary defense response in many plants under salt stress to adjust the osmotic potential as reported in various salt sensitive/ tolerant cultivars such as *Zea mays* (Maize), *Vigna radiate* (Mung bean), *Sesamum indicum* (sesame), *Setaria italica* L. (foxtail millet) and *Pistacia vera* (Pistachio) (Mansour et al., 2005; Misra and Gupta, 2005; Koca et al., 2007; Veeranagamallaiah et al., 2007; Chelli-Chaabouni et al., 2010). Some studies showed that under salt stress, tolerant

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62176232

cultivars accumulate more proline than the salt sensitive cultivars (Misra and Gupta, 2005; Rahneshan et al., 2018). However, proline accumulation is also controversial with reference to tolerance and osmotic adjustment in plants exposed to undesirable environmental conditions (Ghars et al., 2008) as indicated by some studies where more proline accumulated in salt sensitive cultivars than the salt tolerant cultivar (Claussen, 2005). In current study proline accumulation was significantly higher in maize hybrids evaluated as salt sensitive (CTRM8 and XPW3) than in salt tolerant (SWAJ 6, 7 and Syngenta 8441). These results suggest that loss of cell homeostasis is responsible for excessive proline accumulation in salt sensitive hybrids. Similar results have been reported in previous studies where salt sensitive genotype of *Sorghum bicolor* L. (Sorghum kaya) (Wheat Arta) (Akbari et al., 2016) accumualted more proline under salt stress. These findings indicate that more proline accumulation is due to loss of cell homoeostasis. Moreover, these results suggest that salt tolerance is not fully reflected by proline accumulation itself in plants; however, proline accumulation could be an indicator of stress.

Conclusion

The overall results indicate that the growth parameters of all five maize hybrids were affected significantly by different salt stresses. However, better growth performance, maintenance of nutrient contents, less accumulation of toxic sodium ions and lower Na^+/K^+ in SWAJ 6, 7 and Syngenta 8441 indicate that these maize hybrids are more tolerant to salinity stress than all others. It is also concluded that the foliar application of Ca^{2+} against salt stresses improved the growth parametrs of hybrids. Therefore, it can be concluded that the salt stress can be mitigated by the exogenous application of Ca^{2+} in crop plants. Further, the experiment might be repeated in different locations with different maize hybrids for making concrete recommendations.

Abstract. Objective: Pomegranate extract gallic acid inhibits the proliferation of prostate cancer PC-3 cells by promoting IGFBP7 expression. Methods: PC-3 cells were divided into six groups: control group (NC), blank control group (BL), IGFBP7 overexpression group (IGFBP7), Pomegranate extract gallic acid group (5.0 μmol/L, 10.0 μmol/L, 20.0 μmol/L). Cell proliferation was detected by MTT assay; apoptosis of each group was analyzed by flow cytometry; the expression levels of IGFBP7, AKT and mTOR were assessed by Western blot. Results: The proliferative plural of PC-3 cells in IGFBP7 group and pomegranate gallic acid group were significantly lower than those in NC and BL groups ($P < 0.05$). The pomegranate gallic acid group showed dose- dependence. The results of Western blot analysis showed that IGFBP7 group and The levels of IGFBP7 in the pomegranate extract gallic acid group were significantly higher than those in the NC and BL groups ($P < 0.05$), while the levels of AKT and mTOR plural were significantly lower than those in the NC and BL groups ($P < 0.05$). Pomegranate extract gallic acid showed dose-effect further elaborated within each group. Conclusion: Pomegranate extract gallic acid can inhibit the expression level of AKT/mTOR protein by enhancing the expression level of IGFBP7, thereby inhibiting the AKT/mTOR signaling pathway, the result is an inhibitory effect on the proliferation of prostate cancer PC-3 cells.
Keywords: *pomegranate extract gallic acid, IGFBP7 protein, AKT/mTOR protein, PC-3 cell, prostate cancer*

Introduction

Pomegranates (*Punica granatum* L.) are widely distributed and are cultivated in large quantities in China, India and Asia, Africa, Europe along the Mediterranean Sea, and California, USA. Among them, the key production areas of Chinese pomegranates are mainly fruit production, including Lintong, Ganxian, and Sanyuan in Shanxi Province, Zaozhuang in Shandong Province, Suzhou, Nanjing, Xuzhou, Pi xian in Jiangsu Province, Mengzi, Qiaojia, Jianshui, Chenggong in Yunnan Province, Yecheng Pomegranate in Xinjiang, Huili in Sichuan, Huaiyuan in Anhui Province, Xiaoxian, Suixi, Chaoxian (now Chaohu area of Hefei City), etc., as a common fruit, has many biological uses in areas like edible, medicine and health care, especially against cancer, cardiovascular and cerebrovascular diseases, liver disease and inflammatory infection certain treatment and prevention effects. The effective components of pomegranate are mainly the polyphenols in its fruit, and the pomegranate extract gallic acid is one of the main phenolic substances. It had many biological activities such as antibacterial, anti-inflammatory, anti-oxidation, liver function protection and anti-tumor. Function (Feng,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62336241

2014; Lee, 2017; Pang, 2017; Rasool, 2010). Recent studies have shown that polyphenols have a positive significance in inhibiting the proliferation and migration of tumor cells (Panth, 2017; Momtaz, 2017). At present, prostate cancer is the primary factor that endangers male health in the world. The incidence of males is the second in the world, and the incidence of developed countries is the first. It ranks among the highest rates of male genitourinary malignant tumors (Wang, 2019). In this study, the mechanism of action of pomegranate extract gallic acid on prostate cancer tumor cells was explored. Different concentrations of pomegranate extract gallic acid were used to treat prostate cancer PC-3 cells. This provides a theoretical basis for the development and application of pomegranate extract gallic acid.

Materials and methods

Cell line

The prostate cancer PC-3 cell line was purchased from the Shanghai Cell Bank of the Chinese Academy of Sciences.

Experimental drugs and related reagents

Pomegranate extract gallic acid (GA) was purchased from Nanjing Surang Pharmaceutical Technology Development Co., Ltd., with a mass fraction of 99%(China); fetal bovine serum, DMEM high glucose medium, and trypsin were purchased from Sigma (USA); rabbit anti-human IGFBP7 was purchased from Abcam (UK); Annexin V/PE Apoptosis Detection Kit, MTT Cell Proliferation and Cytotoxicity Assay Kit from Shanghai Biyuntian Biotechnology Co., Ltd (China).

Experimental methods

PC-3 cells were divided into six groups: control group (NC), blank control group (BL), IGFBP7 overexpression group (IGFBP7), 5.0 μmol/L pomegranate extract gallic acid group (5.0 μmol/L GA), 10.0 μmol/L pomegranate extract gallic acid group (10.0 μmol/L GA), and 20.0 μmol/L pomegranate extract gallic acid group (20.0 μmol/L GA). The NC group was cultured in DMEM high-glucose medium; the BL group was transfected with blank plasmid in PC-3 cells and cultured in DMEM high glucose medium (Johnson, 2018; Zephania, 2019); IGFBP7 overexpression group was transfected with IGFBP7 plasmid on PC-3 cells. The cells were cultured in DMEM high glucose medium. The pomegranate extract gallic acid group was not transfected with PC-3 cells. The concentration of pomegranate extract gallic acid in the medium was 5.0 μmol/L, 10.0 μmol/L and 20.0 μmol/L, respectively. The culture medium of each group was incubated for 24 h in an incubator with 5.0% CO_2 and a temperature of 37 °C.

IGFBP7 transfected cells (Hu, 2017)

PC-3 cells were inoculated into 24-well plates, and the cells were observed to be in good condition after 48 h, that is, adherent growth, when the cell fusion rate reached 60% to 80%, prepared for transfection. Lipofectamine TM 2000 transfection kit (Invitrogen, USA), IGFBP7 and internal reference primers were designed and synthesized by Shanghai Shenggong Biotech Co., Ltd. to transfect PC-3 cells and stably express IGFBP7 gene.

DOI: http://dx.doi.org/10.15666/aeer/1805_62336241

MTT assay to detect cell proliferation (Maleki, 2020)

Six groups of cells were taken, trypsinized, and inoculated into a 96-well plate to adjust the cell density to 1.5×10^4/well, and continue to incubate. The cultures were stopped at 12, 24 and 48 h, and 20 μL of MTT was added. The culture was continued for 4 h. 150 μL of dimethyl sulfoxide was added and shaken for 10 min. The OD value of each well was measured by a microplate reader at 570 nm.

Apoptosis detection apoptosis rate (Guo, 2016)

PC-3 cells in logarithmic growth phase were inoculated into 96-well plates for 24 h. The NC group, the BL group and the IGFBP7 transfection group were cultured in DMEM medium, and the treatment group was added with 5.0 μmol/L, 10.0 μmol/L and 20.0 μmol/L pomegranate gallic acid for 24 h, and the Annexin V/PE apoptosis detection kit was used. The cells were prepared in strict accordance with the instructions and the apoptosis rate of the above six groups of prostate cancer PC-3 cells was analyzed by BD FACSCanto II flow cytometry.

Western blot detection of total protein extracted from each group of cells (Wei, 2016)

The protein concentration was determined by the BCA method. After treatment with different concentrations of pomegranate gallic acid for 24 h, PC-3 cells were collected and washed twice with cold PBS. The resulting cells were then lysed on ice for 10 min. After centrifugation at 12000 × g for 10 min at 4 °C, the supernatant was transferred to a fresh tube and stored at -70 °C. The protein concentration was determined by using a BCA test kit, and 50 μg of each well was loaded, and the sample was separated by SDS-PAGE at a concentration of 12%, transferred, blocked, and added with a primary antibody at 4 °C overnight. Wash the membrane, add the secondary antibody, incubate for 1 h at room temperature, and wash the membrane with TBST. The band gradation value was determined by adding the illuminant using ImageJ software.

Statistical processing and analysis (Guo, 2016)

The results were processed and statistically analyzed using the SPSS19.0 statistical software package. The mean ± standard deviation ($\overline{X} \pm s$) was used. The pairwise comparison was performed by LSD-t test; the count data was expressed by the rate value. The comparison was performed using the χ 2 test. $P < 0.05$ indicates that the difference was statistically significant.

Results

PC-3 cell inhibition results

The results of six groups of cells after different treatments inhibited PC-3 cells. The IGFBP7 overexpression group and the three GA groups (5.0 μmol/L group, 10.0 μmol/L group and 20.0 μmol/L group) were significantly higher than the BL and NC group; and compared with the BL and NC groups, there are statistical differences between the three GA groups ($P < 0.05$), IGFBP7 overexpression group and the three GA groups showed obvious time-effect relationship and dose-effect relationship (see *Table 1*).

Table 1. *Inhibition of PC-3 cells in six groups after different treatments ($\bar{x} \pm s$)*

Groups	Number of samples	12 h	24 h	48 h
		OD value	OD value	OD value
NC group	5	0.45 ± 0.02	0.56 ± 0.03	0.87 ± 0.03
BL group	5	0.46 ± 0.02	0.57 ± 0.03	0.85 ± 0.04
IGFBP7 transfection group	5	0.21 ± 0.03a,b	0.25 ± 0.08a,b	0.33 ± 0.08a,b
5.0 μmol/L group	5	0.54 ± 0.03a,b	0.59 ± 0.08a,b	0.69 ± 0.08a,b
10.0 μmol/L group	5	0.39 ± 0.02a,b,aa	0.45 ± 0.08a,b,aa	0.48 ± 0.08a,b,aa
20.0 μmol/L group	5	0.26 ± 0.04a,b,aaa	0.30 ± 0.05a,b,aaa	0.46 ± 0.05a,b,aaa

a: $P < 0.05$, the difference from the NC group was statistically significant
b: $P < 0.05$, the difference from the BL groups was statistically significant
aa: $P < 0.05$, the difference was statistically significant compared with the 5.0 μmol/L GA group
aaa: $P < 0.05$, the difference was statistically significant compared with the 10.0 μmol/L GA group

Apoptosis detection

Compared with the NC group (4.84 ± 0.45) and the BL group (5.16 ± 0.38), the apoptosis rates of PC-3 cells in the IGFBP7 overexpression group and the three GA groups (40.52 ± 1.76, 15.98 ± 1.89, 30.36 ± 1.7 and 39.04 ± 1.43) increased significantly. Compared with NC group and BL group, the difference between IGFBP7 overexpression group and the three GA treatment group was statistically significant ($P < 0.05$), and there was a significant dose-effect relationship between with the three GA groups. The result is shown in *Figure 1*.

Comparison of six groups of IGFBP7 protein levels

Western blot method was used to detect the effect of different treatments on the expression of IGFBP7 protein in PC-3 cells. Compared with NC and BL groups, the results showed that the expression levels of IGFBP7 protein by IGFBP7 overexpression group and the three GA groups (5.0 μmol/L group, 10.0 μmol/L group and 20.0 μmol/L group) was significantly increased; and compared with BL and NC groups, the three GA groups are statistical differences between groups ($P < 0.05$). The result is shown in *Figure 2*.

Comparison of six groups of AKT protein levels

Western blot method was used to detect the effect of different treatments on the expression of AKT protein in PC-3 cells. Compared with NC and BL groups, the results showed that the expression levels of AKT protein by IGFBP7 overexpression group and the three GA groups (5.0 μmol/L group, 10.0 μmol/L group and 20.0 μmol/L group) were significantly reduced. And compared with the BL and NC groups, the three GA groups are statistical differences between groups ($P < 0.05$). The result is shown in *Figure 3*.

Comparison of six groups of mTOR protein levels

Western blot method was used to detect the effect of different treatments on the expression of mTOR protein in PC-3 cells. Compared with NC and BL groups, the results showed that the expression levels of mTOR protein by IGFBP7 overexpression group and the three GA groups (5.0 μmol/L group, 10.0 μmol/L group and 20.0 μmol/L group) were significantly reduced. And compared with the BL and NC groups, the three GA groups are statistical differences between groups ($P < 0.05$). The result is shown in *Figure 4*.

Discussion

IGFBP7, as a member of the IGFBP superfamily, plays an extremely important role in metabolic processes such as cell differentiation, proliferation and growth. A large number of studies have confirmed that the expression of IGFBP7 is related to the occurrence of various cancers (Wei, 2016; Chen, 2017; Kim, 2018; Akiel, 2017; Benassi, 2015), which is Many tumor suppressor factors. The data shows that IGF can bind to PI3K to produce protein kinase phosphorylation, activate the Akt/mTOR signaling pathway, and thereby promote cell proliferation, while IGFBP7 is an IGF binding protein 7 factor, which inactivates PI3K protein, inhibits Akt/mTOR signaling

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62336241

pathway, and produces cell inhibition role (Zhao, 2017; Xu, 2013). The results of this study suggest that the level of expression of IGFBP7 protein in prostate cancer PC-3 cells after treatment with different concentrations of pomegranate extract gallic acid group (5.0 μmol/L group, 10.0 μmol/L group and 20.0 μmol/L group) and IGFBP7 overexpression group was significantly higher than the untreated group, but the corresponding AKT protein and mTOR protein expression levels were significantly lower than the untreated group. This result confirmed that the mechanism of pomegranate extract gallic acid inhibiting the proliferation of prostate cancer PC-3 cells may firstly enhance the expression of IGFBP7 protein, and then weaken the expression levels of AKT protein and mTOR protein, causing negative feedback of AKT/mTOR signaling pathway. It is related to regulation and eventually produces the inhibitory effect of tumor cells. However, whether the regulation of AKT/mTOR signaling pathway by gallic acid from pomegranate extract also blocks PI3K protein expression still needs further verification.

In the process of cell proliferation, differentiation, apoptosis and invasion, the AKT/mTOR signaling pathway plays a key role, and is an important signaling pathway in the process of tumor development (Wang, 2019; Zhao, 2019; Gasparri, 2018; Li, 2019). Data show that in the signal pathway of P13K/Akt/mTOR, the upstream pathway of mTOR, P13K is phosphorylated by AKT protein to activate mTOR gene expression and promote tumor cell apoptosis (Gao, 2016; Johnson, 2018). The results suggest that the apoptosis rate of PC-3 cells treated with IGFBP7 protein expression group and pomegranate extract gallic acid group (40.52 ± 1.76, 15.98 ± 1.89, 30.36 ± 1.76, 39.04 ± 1.43) was significantly higher than the untreated NC and BL groups (4.48 ± 0.45, 5.16 ± 0.38), this result indicates that PC-3 cell apoptosis is related to AKT/mTOR signaling pathway. In addition, the inhibitory effect on prostate cancer PC-3 cells has a significant dose-effect and time-effect relationship with the concentration and action time of pomegranate extract gallic acid. There were also some defects in this paper. Considering that pomegranate gallic acid also has certain toxicity to cells, the concentration is relatively low, and whether 20 μmol/L was its maximum effective concentration remains to be further discussed.

Conclusion

The study found that naturally-derived polyphenolic compounds play an important role in inhibiting the proliferation and migration of tumor cells, but there are certain differences in the reports of their mechanism of action (Wang, 2017; Estrela, 2017; Amani, 2017). This experiment used different concentrations of pomegranate extract gallic acid to treat prostate cancer PC-3 cells. It was found that pomegranate extract gallic acid can inhibit the expression level of AKT/mTOR protein by stimulating the expression of IGFBP7 and inhibit the AKT/mTOR signaling pathway Therefore, it has the effect of inhibiting the proliferation ability of PC-3 cells, and there is a significant dose-effect and time-effect relationship between this action trend and its concentration and action time. Studies have shown that compared with the NC and BL groups, the proliferation of PC-3 cells in the IGFBP7 transfection group and the three groups of pomegranate extract gallic acid was significantly reduced. The proliferative capacity of cells, as for the molecular mechanism of this result needs to be further explored.

(Received 28th Jan 2020; accepted 22nd May 2020)

Abstract. Maintaining population growth and competitiveness of arable lands is forcing plant scientist to develop novel ways to enhance grain yield per plant. Several studies on wheat have demonstrated the manipulation of the number (supernumerary spikelet) and arrangement (spike branching) of spikelets. Several genes (*FZP, ndsu, mrs1*, *qTS2A-1, bh, Ppd-1, bh^t*, *bh^m, sb1, sb2, TFL*) controlling supernumerary spikelet and spike branching trait have been reported. Different supernumerary spikelet and branched head wheat germplasm sources (Fen 33, SG203, R107, 166 Schakheli, AUS15910, Kalyan Sona, SWP-BSW1, BS-33, Yupi branching, WCB617 etc.) are also available in the world. However, little is known about the genetic underpinnings, mechanism, plant signaling and physiological aspects of these traits in wheat. Further, these traits are negatively correlated with grain weight and number of tillers per plant and are highly influenced by environmental factors, even tetraploid and hexaploid wheats with reported tendencies of ear branching show different expressions in different environments. In this review, which is a first review report to our knowledge, we have reported the possibilities to exploit these traits to double the number of grains per spike through the use of available supernumerary and branched head germplasm resources and how plant scientists can overcome the negative correlations to develop a sustainable phenotype.
Keywords: *branched head, environmental factors, food security, germplasm sources, grain yield, spike architecture*

Introduction

World food security is challenged by climate changes and loss of arable land due to urbanization and ever increasing population (Godfray et al., 2010). Therefore, an increase in cereal grain production is required to feed the growing population which is anticipated to rise up to 9 billion by 2050. Bread wheat (*Trticum aestivum* L.) is one of the most needed food crop in the world. Its yield in terms of grain production/plant mainly depends on the structural design of the inflorescence. Wheat scientists consider that managing spike architecture is one possible way to increase per plant yield. Dobrovolskaya et al. (2015) reported that genetic determinism of inflorescence development may permit new spike architecture to be designed, with the aim of improving grain production. New spike morphology may lead towards increase in the number of spikelets in the spike i.e. making selections for wheat forms with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62436258

supernumerary spikelet and branched spike. These traits are natural variation in wheat inflorescence and holds great potential for boosting bread wheat yield by doubling the number of grains per spike (Li and Zhao, 2000). However, spike branching is negatively correlated with kernel weight and number of tillers per plant. Wheat breeders observed that low kernel weight/size is very problematic and hard to overcome in the branched or supernumeric spikes (Yen et al., 1993). Furthermore, stability of the lines to express spike branching trait is influenced by environmental dynamics such as vernalization, temperature, time of sowing, nutrients availability and photoperiod (Swaminathan et al., 1966; Pennell and Halloran, 1984a). Fortunately, some wheat germplasm is available that show stable expression of branching trait which can be exploited to create desired variation in the architecture of wheat inflorescence and to boost the grain yield. Studies have shown that it is practical to utilize genes underlying spike branching character to develop stable cultivars with more kernel weight and tillering capacity (Poursarebani et al., 2015). The objectives of this review are to: (1) highlight the importance of supernumerary spikelet and spike branching trait and their potential utilization in improving wheat crop productivity, (2) describe the detailed genetic basis including underlying genes, evolution and mechanism of supernumerary spikelets and spike branching trait development in wheat, (3) understand the genetic basis, morpho-physiological, biochemical and molecular aspects, (4) provide knowledge regarding expression of these characters, some stable materials and isogenic lines developed for pyramiding different underlying genes, (5) in the end, environmental factors affecting the expression of supernumerary spikelet and spike branching traits and prospects are highlighted.

Genetics of Supernumerary Spikelet and Spike Branching

The branching appearance in wheat inflorescence is due to a spontaneous mutation that has been recognized since prehistoric times (Tschermak, 1914; Sharman, 1944). A mutant with adventitious branching in the ears was found in nature in *T. turgidum* var. mirabile Korn (2n = 28). In 1957, a mutant with ear branching was isolated from M_2 progeny of *T. aestivum* var. N. P. 797 (2n = 42) treated with 10 μC. per seed of S^{35}. Swaminathan (1966) observed that this mutant had about 15% pollen sterility and 30% seed sterility and gave rise to both normal and branched ears when seeds were sown from open pollinated heads. The proportion of branched ears was found 9 to 54% in different years. Later on, spike branching and supernumerary spikelets has been witnessed in diploid (*T. monococcum*, bh^m locus; chromosome $2A^mS$; Amagai et al., 2014), tetraploid (*T. turgidum*, bh^t locus; chromosome 2AS; Klindworth et al., 1997; Poursarebani et al., 2015) and hexaploid wheat (*T. aestivum*, *bh* genes; chromosome 2AS, 2BS, 2D, 4A, 4B, 5A; Peng et al., 1998; Dobrovolskaya et al., 2015). The loci maintaining the branchless inflorescence are located in syntenic chromosome positions in all the respective genomes. This shows that branch repression in wheat is controlled by major orthologous genes and defects in these genes are responsible for the formation of lateral branching (Poursarebani et al., 2015). These branched heads are distinct in phenotype from the supernumerary spikelets having additional spikelets per node of rachis (Pennell and Halloran, 1983). Fundamental genetic factors for supernumerary spikelet phenotype found to be assorted and exemplified for paired spikelet phenotype (Boden et al., 2015) or multi–rowed spike (*mrs*) locus (Dobrovolskaya et al., 2009). Echeverry-Solarte et al. (2014) reported seven QTLs controlling supernumerary spikelet development located on 2D, 5B, 6A, 6B and 7B chromosome. All the reported genetic factors for supernumerary spikelet and spike branching trait in different wheat germplasm are summarized in *Table 1*. Despite of

enduring efforts of scientific community, the phenomenon of laterally formed branches has always remained elusive in wheat.

Evolution & Domestication

Modern form of cultivated wheat is one of the oldest cereal crops opted by the early farmers for domestication and improvement (Gross and Olsen, 2010). This domestication represents the course of selection and adaptation of wild relatives based on their versatile genetic background to meet the human needs like taste, yield, cultivation and harvest methods (Gepts, 2004; Lenser and Theiben, 2013). Archeological evidences show that the domestication of wheat started 10000 to 12000 years ago (Doebley et al., 2006) in the Fertile Crescent (Glemin and Bataillon, 2009). The set of traits altered during this process is commonly known as domestication syndrome included alteration in architecture of plant, depletion of toxin compounds, compact growth habit, early maturity and other yield related traits (Konopatskaia et al., 2016). Besides grain yield, shape, and color spike morphological characteristics like spike shape, presence or absence of awns, spike branching and supernumerary spikelets per spike were the key factors which remained the subject of interest for early farmers and breeders.

No literature is reported about the evolution and domestication of branched spike or supernumerary spikelets per spike. The possible reason is the low yield as compared to branchless wheat and that's why early farmers and breeder were reluctant to select branched wheat. However, many scientists reported the presence of branched wheat

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62436258

spike as abnormality in spike morphology which appeared rarely in *Triticum* species (Dobrovolskaya et al., 2017). Pliny the Elder has mentioned the presence of branched spike in *T. trugidum* 2000 years ago (23-79 AD) under the name of Ramosum and Centigranum (de Candolle, 1883). Some other names like "Miracle wheat", "Mummy", "Egyptian", "Jerusalem wheat", and "Seven-headed" has also been reported in the literature to describe the branching pattern of this tetraploid wheat (Dahlgren, 1922; Dorofeev and Korovina, 1979). This branching pattern in tetraploid wheat is due to the natural mutation which has been known since ancient times (Poursarebani et al., 2015). The character of branched spike is usually exhibited by the tetraploid wheats, that's why all the members of tetraploid wheat having branched spike are classified in a separate group named as *T. turgidum convar. compositum* (L.f) A. Filat. It is noteworthy that the members of this group possess unique spike morphology which is characterized by the development of additional spikelets on rachis nodes or spikelets appear on the extended rachilla in the form of branching especially in the lower portion of the spike (Dobrovolskaya et al., 2009). This type of branching is known as turgidum type of branching (Dobrovolskaya et al., 2017). The other species of genus *Triticum* in which branched spikes have been observed are *T. dicoccum, T. polonicum*, *T. spelta* and *T. vulgare* (Masubuchi, 1974; Wang et al., 2016).

Wheat Germplasm Sources with Supernumerary Spikelet and Spike Branching Trait

Researchers emphasized that current performance of wheat is generally supposed to be sink regulated (Miralles and Slafer, 2007; Lawlor and Paul, 2014). Therefore, spike branching is important for increasing sink capacity and improving the yield potential. Many researchers in the world have developed and maintained germplasm sources/varieties with supernumerary spikelet and spike branching traits. These lines differ in giving stable expression in all kind of favorable and unfavorable environments. However, some stable lines are also present in the world. The detail of such germplasm is presented in *Table 2* and pictorial view of supernumerary spikelet and branched head wheat along with normal spike wheat is given in *Figure 1*.

Role of Phytohormones and Growth Regulators in the Development of Supernumerary Spikelets

In hetero branching spike the supernumerary spikelet attribute was influenced by light intensity, varied temperature, nutrients balance (Koric, 1975; Peanell and Halloran, 1983) and plant hormones (McSteen and Leyser, 2005). Plant growth and development regulated by natural and synthetic plant growth regulators are being implemented as potential investigation tool to elucidate plant responses on physiological basis or to explore the mechanisms of biochemical control. Among many plant hormones, auxin plays a cardinal role to promote polar growth of floral meristems and all other organ primordia (Cheng and Zhao, 2007; Benjamins and Scheres, 2008; Delker et al., 2008). Localized auxin biosynthesis is resulted from activation of YUC (YUCCA flavinmonooxygenase) genes which indicates that auxin biosynthesis is also necessary for initiation of floral meristem (Zhao, 2008). It is well documented that the role of auxin transport and biosynthesis in axillary meristem initiation is found in monocots (Poursarebani et al., 2015).

Figure 1. *Pictorial view of normal spike along with supernumerary spikelet and branched spike wheat*

Plant architecture and reproduction is dependent on axillary meristems that developed in axils of plant leaves. In reproductive growth, flowering branches or flowers produced from axillary meristems, thus during development of grass inflorescence, axillary meristems give rise to branches and spikelets before they give rise to flowers (McSteen et al., 2000; Bommert et al., 2005). Plant hormones and transcription factors controlled the uniqueness and determinacy of various kind of meristem (Bortiri and Hake, 2007; Thompson and Hake, 2009; McSteen, 2009). Hormones play a significantly important role to regulate the branching of shoot and inflorescence (McSteen and Leyser, 2005; Beveridge, 2006; Barazesh and McSteen, 2008; Ongaro and Leyser, 2008). Axillary meristem initiation required auxin for both vegetative and inflorescence development while cytokinin controlled the volume of meristem and consequently affects branching indirectly (Shani et al., 2006; Kyozuka, 2007).

Findings of Tetsuka (2001) provided important information regarding the function of chemical metabolism associated to the genetic aspects and photoperiodism in stimulating the supernumerary spikelet differentiation, by showing overproduction of endogenous concentration of gibberellic acid, nucleic acids and phosphatide in wheat mutant Norin52. Likewise, exogenous application of gibberellic acid and nucleic acids had positively affected the supernumerary spikelets differentiation indicating their role on spikelet developmental phase by influencing chemical metabolism while phosphoric substances and their derivative nucleic-like compound might show their efficacy on differentiation of supernumerary spikelets and rachis branch development. In autumn sowing, exogenously applied uracil and thymine had significantly promoted supernumerary spikelets formation, hence uracil induced the differentiation of the side-type supernumerary spikelets and the thymine stimulated the double-type supernumerary spikelets. Pearce et al. (2013) reported that wheat genotypes expressing *VRN1* has positively responded to exogenous application of gibberellins in terms of accelerated spike development. The *VRN1* and gibberellic acid's simultaneous existence leads toward up-regulation of floral meristems identity genes '*LEAFY and SUPPRESSOR OF OVEREXPRESSION OF CONSTANS1-1'*.

It is well documented that character of branched rachis was effectively modulated by exogenous auxin which induced interratic branched rachis. Foliage application of Indole-3-Acetic Acid (IAA) and Indole-3-Butyric Acid (IBA) (0.1 mM) after two ridge stage of shoot apex, induced maximum increase in quantity of branched rachis by 82.6 and 78.3% respectively while 2,4-D and Naphthalene acetic acid (NAA) applied at concentration of 1

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62436258

mM produced 57.6 and 46.7% more branched rachis in comparison with untreated plants. Likewise, whole spike subjected to 1 mM NAA and 2,4-D illustrates improvement in the number of spikelet 57.2% and 53.4%, correspondingly over non-sprayed plants. Moreover, application of auxins stimulated the expression of *TFL* gene during the occurrence of branched rachises that designates the central role to auxins in directing the branched spike development and *TFL* might be correlated with this development of branched rachises in wheat. The newly developed young spike had high level of Indole acetic acid in genotypes having branched spike as compared to normal spike wheat lines. It might be attributed to higher relative expression of *TaIAR3*, an auxin synthesis related gene, in wheat line having branched spike as compared to normal spike lines (Wang et al., 2017). Therefore, it can be speculated that higher IAA contents might be involved in the development and growth of branched spike in wheat. Floral identity in newly formed floral primordial was stimulated by floral meristem identity genes *LFY* and APETALA1 (AP1) in terms of establishment and maintenance of floral identity (Simon et al., 1996). Thus, polar transport of auxin and *LFY* coordinately alter flower development by regulating genes needed for growth of the floral organs and might be contributed to branched spike (Yamaguchi et al., 2014). It is also reported that higher level of endogenous IAA positively influenced the expression of *FLO/LFY* in juvenile vegetative shoot apices and leaf primordia (Wang et al., 2017). It might play a key role in development of inflorescence architecture and regulation of floral meristems initiation in several plant species (Kyozuka et al., 1998; Bomblies et al., 2003).

Molecular Characterization

Efforts were started in the last century to get the better understanding of genetics of supernumerary or branched spike in tetraploid wheat. The study revealed that trait is regulated by one recessive gene designated as *bh*, *branched head* (Percival, 1921; Sharman, 1944). Later on same type of gene action was observed in diploid (*T. monococcum*) and hexaploid wheat. The gene(s) controlling this trait is resided on the homeologous group 2 which is also affected by other environmental factors (Penell and Halloran, 1983; Klindworth et al., 1990, 1997). Further study in hexaploid wheat elucidated that branching spike is controlled by three different genes names as *Normalizator* (*Nr*), *Ramifera* (*Rm*) and *Tetrastichon* (*Ts*). Among these genes, *Rm* and *Ts* complement each other to produce the branched spike phenotype while the *Nr* acts as dominant repressor of branched spike (Koric, 1973). Further studies also supported that spike branching in hexaploid wheat is regulated by three different genes (Penelle and Halloran, 1983; Dencic, 1988). Recently, Dobrovolskaya et al. (2015) showed that the formation of supernumerary spikelets or spike branching in bread wheat is under the control of *WHEAT FRIZZY PANNICLE* (*WFZP*) resided on the short arm of homeologous group 2. The molecular characterization of orthologue genes of *WFZP* in other members of Poaceae family (maize, rice, barley, and sorghum) suggest that this gene belongs to *ERF* (ethylene-responsive element-binding factor) family of *AP2* transcription factors (Chuck et al., 2002) which are meant to function as repressor to the formation of lateral branching of meristem (Komatsu et al., 2003; Zhang et al., 2017). Detailed structural and functional analysis of wheat *WFZP* genes revealed the presence of mutations in two homeologous genes i.e. *TaWFZR-2A* and *TaWFZR-2D* which are responsible for the formation of branched spike in hexaploid wheat (Dobrovolskaya et al., 2015). Another study in tetraploid wheat (*T. trugidum*) found a mutant allele of *WFZP-A* designated as *TtBH-A1* having an amino acid substitution in the DNA binding domain to produce branched spike (Poursarebani et al., 2015). In tetraploid wheat, two types of spike branching phenotypes are found which are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62436258

named as "true spike ramification" and "false-true spike ramification" which have some resemblances in their phenotypes. *TtBh-A1* is mainly responsible for the true spike ramification phenotype while false-true spike ramification is under the regulation of another recessive allele designated as *SHAM RAMIFICATION 2 (SHR2)* and both are located at chromosome 2AL (Amagi et al., 2014). However, the information regarding structural and functional pathway of *SHR2* is still lacking (Dobrovolskaya et al., 2017). Recently, Dixon et al. (2018) elaborated the genetic factors controlling the formation of paired spikelets, a form of branched spike in hexaploid wheat. The study shows that *TEOSINTE BRANCHED1* (*TB1*) an ortholog of maize domestication gene locus interacts with *FLOWERING LOCUS T1* (*FT1*) to regulate the inflorescence architecture in bread wheat.

Although several studies have elaborated the inheritance and genetics of branched spike or supernumerary spike in wheat but a very few studies elaborated the molecular markers linked to these traits (Echeverry-Solarte et al., 2014). Dobrovolskaya et al. (2009) reported the mapping of a major locus controlling multi-row spike (*mrs*) in wheat on chromosome 2D which is linked to microsatellite locus *Xwmc453*. Similarly, a QTL flanking two SSR markers (*Xgwm275* and *Xgwm122*) was mapped on chromosome 2A in Tibetan wheat (Li et al., 2011). In *T. durum* Desf. var. ramosoobscurum Jakubz. "Vetvistokoloskaya" R-107 three F_2 mapping populations were used to map the branched head spike. The results depicted that the trait of branched head was located on chromosome 2A flanked proximally by the molecular marker *Xgwm425* (Haque et al., 2012). In *T. monococcum* the locus of branched head *(bh^m)* was mapped on chromosome $2A^m$ along with co-segregating marker *Xgwn122* present at the distal end of the gene (Amagi et al., 2014). The detailed mechanism of supernumerary and spike branching trait development in wheat based on above discussion is presented in *Figure 2*.

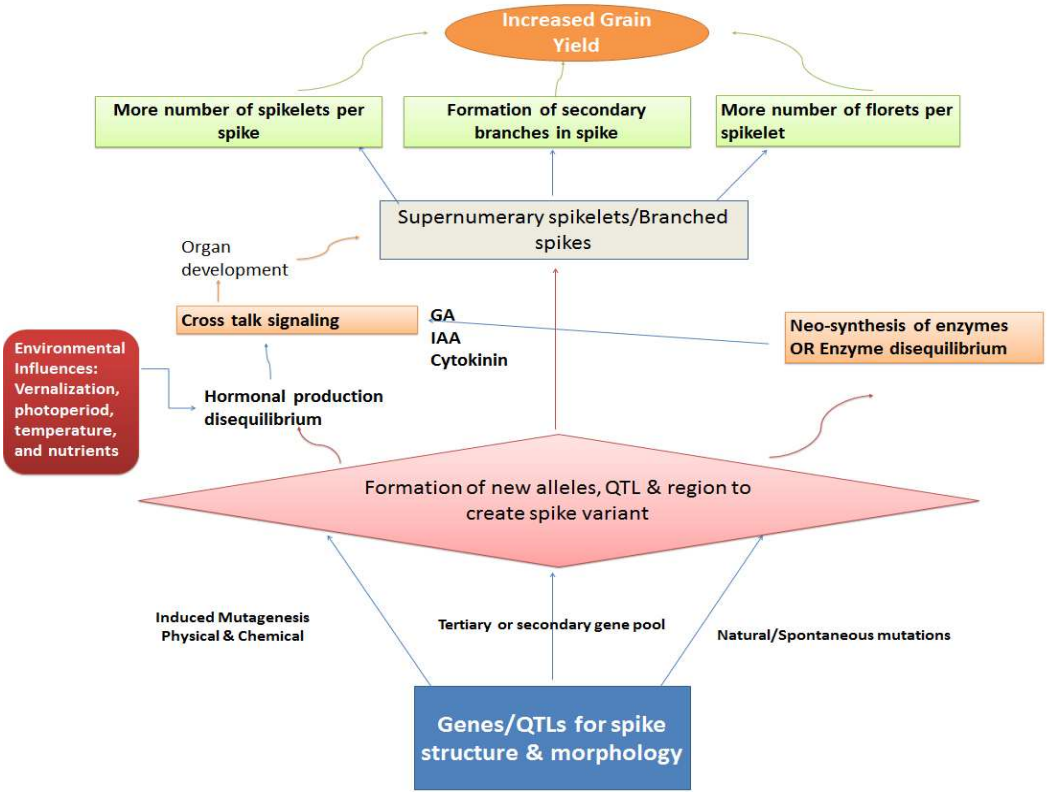

Figure 2. *Mechanism of Supernumerary Spikelet and Branched Spike Development*

Grain Yield and Quality of Normal vs. Supernumerary Spikelet and Branched Spike

The impact of supernumerary spikelet on other agronomically important yield contributing traits is not clearly mentioned in literature; however, some studies have found that branched head genotypes are negatively correlated with yield contributing traits including reduced tillering, low grain weight, some sterile florets, delayed heading and maturity (Hucl and Fowler, 1992) and ultimately less grain yield (Zhang et al., 2012). However, some branched genotypes defy these generalizations (Martinek and Bednar, 1998). For example, some lines in Tibetan Triple-Spikelet wheat have good grain production with more than 120 seeds per spike and appropriate thousand grain weight (Yang et al., 2005). Miracle wheat, a highly stable phenotype with branched spikes has a higher yield potential as compared to unbranched tetraploid wheats (Poursarebani et al., 2015). Further, it has also been observed that grain yield of such genotypes can be enhanced by improving the fertility of sterile florets (Pennell and Halloran, 1984a,b).

Quality of supernumerary grains is extremely important for the end users. Traits like; starch (amylose and amylopectin), proteins and gluten protein contents are important to focus. Limited information is available about the quality of these grains. Few of the recent studies of genome wide association (GWA) revealed that gluten protein contents were positively correlated with supernumerary spikes (Echeverry-Solarte et al., 2015). Singh et al. (2018) pointed out that next generation sequencing coupled with haplotype-based approaches can be helpful to detect the real changes in multiple environments. These results are encouraging for the plant scientists; however, further studies are required to explain the quality of grains and their products.

Influence of Environmental Conditions

The degree of supernumerary spikelet and ear branching appearance in wheat is strongly associated to environmental effects. Tendency of both tetraploid and hexaploid wheats towards branched headings differs under different vernalization, photoperiod, temperature, moisture and nutrient regimes (Sharman, 1967; Pennell and Halloran, 1984a,b).

Vernalization

Ups and downs in the required vernalization of wheat affect the potential seed number per head. Similarly, the branched spike and supernumerary spikelet expression is influenced by vernalization. Pennell and Halloran (1984a) studied two tetraploid and six hexaploid wheats with branched spike tendency and found that the expression differed in lines with strong vernalization response. They also indicated high stability in the expression of supernumerary spikelet in certain genotypes especially under different environments and their potential to incorporate this character in breeding material or commercial wheat varieties to increase grain number per head.

Photoperiod

Day length is also crucial to express the potential of supernumerary spikelets into grain yield. Pennell and Halloran (1984b) reported that wheats with tendency of branched heads develop more supernumerary spikelets in short photoperiod

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62436258

environment (9-14 h) with weak vernalization. The expression of this character was high in long photoperiod environment (24 h) lines having strong vernalization response. Sharman (1967) also reported significant expression under short photoperiods whereas Rawson and Ruwali (1972b) found that the initiation of supernumerary spikelet takes longer photoperiod than in normal wheat. Fedorov (1955) also indicated length of the day as main conducive factor.

Temperature/Time of Sowing

The variations in spike morphology especially spike branching is strongly associated with time of sowing and mean minimum and maximum temperature at the time of heading. Sharman (1967) reported that the branching in wheat is caused by a recessive gene and appear only in normal or low temperature conditions and inhibited at longer day length or high temperature. Pennell and Halloran (1984b) also endorsed these findings. Meena et al. (2008) reported the occurrence of hetero-branching spike in bread wheat at different temperature and sowing times. The mean minimum and maximum temperatures at heading stage during early sown crop were 6.90^{o}C and 22.79^{o}C while the corresponding figures under late sown conditions were 8.39^{o}C and 24.09^{o}C. They characterized the most striking morphotypes having two fully developed spikes on a single culm. Such morphotypes were expressed only in early sown F_2 generation. There was no such type of segregation observed in F_2 material sown late in December. It may be due to low heritability of the character and threshold controlled by one or more recessive genes at various temperatures.

Nutrients

Appearance of branched spike is not limited to environmental conditions and is hereditary (Masubuchi, 1974). This trait is strongly influenced by nutritional conditions. Vigolov's (1954) reported that branched spikes can be obtained from fertile soils. Ryzei (1950) also produced branched wheat after removing the majority of the spikelets and gave abundant nutrition to the remaining spikelets. Ryzei (1950), Muhin (1952) and Vigolov (1954) observed nutritional conditions as main influencing factors on the plant to produce branched heads. Reduced grain weight or size in branched spike might be the result of other factors like less nutrition, or compact grain in a spike (Koric, 1975).

Future Prospects

Genome Wide Association Mapping

Spike length, grain number and size have extensively been studied in the recent to identify the genomic regions associated with these traits (Singh et al. 2018; Rehman-Arif et al. 2020; Shokat et al. 2020). Studies investigated the underlying QTLs/genes in branched genotypes and studied the association of agronomically important traits (AIT) in these genotypes on the basis of phenotypic analysis. Some molecular marker studies also identified genetic regions controlling the spike branching trait (Li et al., 2011; Echeverry-Solarte et al., 2014), but to date only one study investigated the association of these genetic regions with AIT using genome wide association mapping (GWAS). Echeverry-Solarte et al. (2015) evaluated several recombinant inbred lines from a cross between WCB414×WCB617, a normal and branched spike phenotype, respectively.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62436258

They identified QTLs associated with nine spike related traits and 10 AIT, and found chromosome 2DS rich for these characters. Therefore, GWAS can be used to detect QTLs for spike branching, supernumerary spikelet and AIT of bread wheat. It can also identify common genomic regions with QTL for spike related and AIT and also to explore novel alleles with possible use in breeding wheat improvement programs.

Next Generation Sequencing

In comparison to 1950s, a massive increase in our information about the biological basis of plant productivity has opened new prospects for novel breeding strategies. The large and complex genome of bread wheat represents a big challenge, but at the same time offers a large reservoir of genes that can be targeted to breed for desired traits (Nadolska-Orczyk et al., 2017). Detailed description and an analysis of the reference sequence of the hexaploid wheat genome by International Wheat Genome Sequencing Consortium (IWGSC), paved the way for the development of wheat varieties resilient to climate changes, endowed with higher yields, improved nutritional quality and sustainability (Appels et al., 2018). Now, genes involved in supernumeric wheat can be easily exploited following reference sequence. Next generation sequencing (NGS) can be used to sequence these genes and to understand the mechanism of supernumerary spikelet development at genetic level. This technique can also pave the way for expression analysis of these genes in the source material or otherwise their transformation in the elite bread wheat germplasm.

Gene Pyramiding

Pyramiding of elite alleles for dynamic development of spike branching in bread wheat can be rewarding. Even researchers have combined different spike branching genes to develop near isogenic lines in wheat (Zhang et al., 2012). However, very little research has been focused on the effects of pyramiding spike branching genes on AIT in bread wheat. This is due to lack of suitable materials and unfavorable environmental influences (Zhao et al., 2012). These results are encouraging for the plant scientists; however, further studies are required to explain the effects of combining spike branching genes on agronomically important traits in bread wheat.

Speed Breeding

Recent advances in generation advancement in plant breeding research i.e. “Speed Breeding” by Watson et al. (2018) can be potentially utilized to understand the optimum environment required for the expression of supernumerary or spike branching trait in wheat. Speed breeding protocols can be used for modeling the ideal photoperiod, temperature and nutrient conditions that favor the expression of these traits. Hence, genetic control of spike branching in relation with environmental influences can be exploited and rationalized.

Conclusion

Supernumerary spikelet and branched spikes holds enormous potential for boosting number of grains/spike and ultimately wheat yield. These are genetically controlled and can be exploited in future breeding programs. Although some negative correlations among other yield components and environments put hindrance to use these traits for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62436258

the development of commercial high yielding wheat cultivars. However, possibilities are there to break these strong linkages through plant improvement approaches and by modeling the ideal photoperiod, temperature and nutrient conditions that favor the expression of these traits. Recent approaches of next generation sequencing can be helpful to investigate these traits more precisely. Likewise, certain physiological aspects, along with plant signaling are yet to be covered. Additionally, workload management from source to sink is also not been studied yet. Despite of all missing information, still these traits can be exploited and their maintained germplasm sources can be utilized to improve yield potential in this globally important crop.

(Received 3rd Feb 2020; accepted 9th Jul 2020)

Abstract. Six cultivars of durum wheat (*Triticum durum* L.), namely Iraq-7, Acsad-65, Cham-1, Ovanto, Crezo and Simeto, were evaluated the five different environments (seasons) in Sulaimani region-Iraq from (2014-2015 until 2018-2019) using Completely Randomized Block Design (CRBD) with three replications in order to study correlations, path analysis, stability and genotypic resultant for all studied traits which were grain yield and its components. The results of combined analysis across the five seasons as summarized below: the mean squares due to cultivars and the interaction between cultivars × seasons were highly significant for all characteristics. The Simeto cultivar showed the best value for grain yield and most its important components. The correlation between grain yield and spike weight m^{-2} and harvest index was positive and highly significant, while it was positive and significant with grain weight $spike^{-1}$ as the average of all seasons. Maximum positive direct effect for grain yield was recorded to be spike weight m^{-2}, while maximum positive indirect effect was recorded by spike weight m^{-2} via harvest index as the average of all seasons. The highest stability and genotypic resultant value among all traits recorded by biological yield via Crezo cultivar reached 0.829 and 0.951 respectively.
Keywords: *grain yield, correlation, path analysis, stability, genotypic resultant*

Introduction

Wheat (*Triticum durum* L.), is grown in all regions of Iraq, mostly under rain fed conditions including Kurdistan regions. Therefore, annual production is affected to large extent by the annual and seasonal distribution of precipitation, environmental states and crop managements like sowing time, soil fertility, etc. Like to the other crops, increasing the potential of yield is an important target of durum wheat improvement programs production. However, durum wheat yields in most production regions seem to be no more than the potential yields of the cultivars and far below the theoretical maximum yields (Rharrabti et al., 2003). For the production of high-quality durum wheat, dry environments are necessary, with warm days and cold nights during the growing season so that large grains are obtained with yellow color, vitreous kernels (more than 95%), hard texture and high test weight (about 82 kg hL^{-1}), alongside high protein content (greater than 10%) and strong gluten (greater than 30% wet gluten), which gives elasticity to dough for industrial use (Acevedo and Silva, 2007). As Borlaug and Dowswell (1997) observed, "The only way for agriculture to keep pace with population and alleviate world hunger is to increase the intensity of production in those ecosystems that lend themselves to sustainable intensification, while decreasing intensity of production in the more fragile ecosystems." By 2020, "The world's farmers will have to produce 40% more grain... most of which will have to come from yield increases" (Pinstrup-Andersen et al., 1999). Production increases can originate from

various sources: (1) genetic gains in GYP; (2) genetic gains in tolerance to a biotic and biotic stresses; (3) gains through improved and novel CMR production techniques and technological gains related to optimizing permanent and variable factors of the environment; and (4) synergistic effects among these factors. Of these, GYP and GYP improvement occupy center stage in research (Pfeiffer et al., 2000). The improved genotypes are evaluated in multi-environment trials to test their performance across different environmental conditions. In most trials, crop yield fluctuates due to suitability of genotypes to different conditions which is known as genotype × environment interaction (G×E) (Kang, 1998). Yield and other quantitative traits of crop plants, are among the most important in studying genotypes grown in multi-environments. In this kind of studies, it is important to differentiate the best genotype in term of performance and stability across environments (El-Sahookie and Al-Rawi, 2011). The various phenotypic homeostasis measures were used to evaluate the echo of genotypes when grown in different environments. Summarized genotype-by-environment interaction through homeostasis and genotypic resultant (El-Sahookie and Al-Rawi, 2011). Statistically concept according to Estimates of (H%) and (GR) according to (El-Sahookie, 1990), who mentioned if the value of homeostasis is less than 85%, it means that the cultivar was unstable across environments, and if the value of genetic resultant was high and close to unity, it means that the cultivar has a good performance under varying environments. The development of high-yielding cultivars requires a thorough knowledge of the existing genetic variation for yield and its components (Shukla et al., 2006).

The objective of the study is to estimate the inheritance between cultivars and environment and finding stability for selecting a cultivar suits the environmental conditions prevailing in the region.

Materials and methods

Six durum wheat cultivars were used as plant material in this study (Iraq-7, Acsad-65, Cham-1, Ovanto, Crezo and Simeto). The traits were conducted during the winter season of 2014-2015 until 2018-2019 at University of Sulaimani, Sulaimani-Iraq. (Latitude: 35° 33' N; Longitude 45° 27' Est. altitude of approximately 830 m). At each experimental season all cultivars were sown according to Completely Randomized Block Design with three replications, according to the following linear modeling (Al-Mohammad and Al- Yonis, 2000). Wheat was sown in autumn at sowing density of 450 plants m^{-2}. Each experimental plot was consisted of 6 rows, 5 m in length with 0.25 cm apart rows. The experiments were sown at (November 15 2014, December 10 2015, November 12 2016, November 16 2017 and December 5 2018) respectively. The recommended doses of fertilizer was used which was 40×40 kg nitrogen and P_2O_5/ha respectively. All phosphorus fertilizer and half of nitrogen fertilizer were applied at the Zadoks growth stage 25. Recorded data were subjected to the analysis of variance ANOVA using MSTATC software. Relative magnitude of year, genotypes and their interactions attributed to total sum of squares were calculated as percentage (Akcura et al., 2006). Stability analysis and genotypic resultant were performed for each trait studied. The correlation and path analysis were conducted. The experiments were harvested at (June 6 2015, June 9 2016, June 5 2017, June 8 2018 and June 10 2019) respectively.

DOI: http://dx.doi.org/10.15666/aeer/1805_62596279

Studied traits: Spikes number m^2, Spike weight m^2 (g), Average spike weight (g), Spike length (cm), Grains number $spike^{-1}$, 1000-grain weight (g), Grain yield t h^{-1}, Biological yield t h^{-1} and Harvest index.

From each plot at each block ten individual plants were chosen randomly to study these traits from the guarded rows.

Climate conditions of Sulaimani region

The climate of Sulaimani governorate is semi-arid environment: wet and cold in winter dry and hot in summer; During July and August, the average temperature is between 39-43 °C, and overwhelmingly amount to nearly 50 °C. Autumn means high temperatures are 20-30 °C in October, cooling slightly in November. Precipitation is limited to winter and spring months, and the overall average annual rainfall of 550-700 mm was at Sulaimani city. An overview of experimental conditions is given in *Table 1*.

Table 1. *Metrological data for experimental location during five winter seasons*

Months	2014-2015	2015-2016	2016-2017	2017-2018	2018-2019

Results

Data represented in *Table 2* illustrate the mean squares for variance sources of all characters. It was observed that the differences among cultivars were highly significant for all characters at the first and the second season 2014-2015 and 2015-2016.

Concerning to the third season 2016-2017 the differences among cultivars were highly significant for all characters except weight of $spike^{-1}$ and biological yield which were significant only.

Data recorded for the fourth season 2017-2018 represent in the same table confirmed that the differences among cultivars were highly significant for spikes number m^{-2}, spikes weight m^{-2}, spike length and 1000-grain weight, while it was significant for average spike weight, grains number $spike^{-1}$, grains weight $spike^{-1}$, grain yield and biological yield, whilst the differences among cultivars were not significant for harvest index.

Regarding to the last season 2018-2019 as represent in the same table it was observed that the differences between cultivars were significant for all characters except spike length and grain yield which recorded highly significant differences among cultivars and the differences were not significant for harvest index.

Data due to combine analysis for the average of all seasons represent in *Table 1,* confirming that the effect of seasons were highly significant on all characters except harvest index which responded significantly to seasonal effect. The mean squares due to cultivars and the interaction between cultivars were highly significant for all characters as combine analysis. From the same table it was noticed that the interaction between cultivars and seasons were highly significant for all characters, the analysis of genotype by environment interactions is of the primary importance for most crops (Ceccarelli, 1996; Annicchaiarico, 2002; Voltas et al., 2002 and Rodriguez et al., 2008).

Data in *Table 3* illustrate the means of grain yield and its related components for all seasons and their averages. Concerning to the first season 2014-2015, the Smeto cultivar produced the highest value for spike wt. m^2, average spike wt., spike length, grains wt. $spike^{-1}$, 1000-grain wt, grain yield and harvest index reached 736.000 g, 1.920 g, 10.833 cm, 1.613 g, 30.517 g, 4.110 t h^{-1} and 0.439 respectively, while Crezo cultivar exhibited the highest value for spikes number m^{-2} and grains number $spike^{-1}$ reached 424.000 spikes and 52.000 grains. The highest value for biological yield was 9.867 t h^{-1} produced by Cham-1 cultivar. The lowest value for almost all characters exhibited by Ovanto cultivar with the exception of harvest index which was showed by Cham-1 cultivar.

Concerning to the second season 2015-2016, the Iraq-7 cultivar produced the maximum values for spikes number m^{-2}, spikes weight m^{-2}, grains number $spike^{-1}$, grain yield and harvest index reached 312.000 spikes, 621.333 g, 46.667 grains, 4.990 t h^{-1} and 0.335 respectively, while the highest value for biological yield was 16.077 t h^{-1} produced by Acsad-65. The Simeto cultivar gave the highest value for average spike weight, spike length, grains weight $spike^{-1}$ and 1000-grain weight reached 2.453 g, 7.333 cm, 1.790 g and 47.280 g, respectively. The lowest values for most characters produced by Crezo cultivar.

Regarding to the third season 2016-2017, the means of the characters represent in the same table confirmed that the highest value for most characters such as spike weight m^{-2}, average spike weight, grains number $spike^{-1}$, grain weight $spike^{-1}$, grain yield, biological yield and harvest index produced by Crezo cultivar reached 1060.690, 2.975, 50.100, 2.096, 6.004, 11.200 and 0.547 respectively, while the highest value for spikes number m^{-2} and spike length recorded by Iraq-7 reached 463.333 spikes and 7.583 cm respectively, but Smeto produced the highest weight of 1000-grain reached 47.773 g. Cham-1 cultivar recorded the lowest value for most characters.

Data represent in the same table respect to the fourth season 2017-2018, ratified that Iraq-7 recorded the highest value for spike number m^{-2}, spike weight m^{-2}, spike length, grain yield and biological yield reached 437.222 spikes, 694.939 g, 7.773 cm, 4.437 t h^{-1} and 12.206 t h^{-1} respectively. While Crezo cultivar recorded the highest value for average spike weight, grains number $spike^{-1}$, grains weight $spike^{-1}$ and 1000-grain weight reached 2.250 g, 49.667 grains, 2.064 g and 41.330 g respectively, whilst the highest value for harvest index was 0.408 recorded by Simeto cultivar. The lowest value for most characters produced by Acsad-65 and Simeto cultivars.

Concerning to the fifth season 2018-2019, it was illustrate that Iraq-7 showed maximum value for spike number m^{-2}, spike length and harvest index reached 474.815 spike, 8.177 cm and 0.496 respectively, while the highest grains number $spike^{-1}$ was 56.633 recorded by Ovanto cultivar and for 1000-grain weight and biological yield the highest values were 53.752 g and 22.478 t h^{-1} recorded by Crezo cultivar respectively. The Smeto cultivar recorded the highest value for spike weight m^{-2}, average spike weight, grains weight $spike^{-1}$ and grain yield reached 1007.759 g, 3.933 g, 2.978 g and 7.633 t h^{-1} respectively. Acsad-65 and Cham-1 cultivars recorded the lowest value for most characters.

Data recorded for the average of all seasons represent in the same table, confirming that the Simeto cultivar recorded the highest value for most characters including spike weight m^{-2}, average spike weight, grains weight $spike^{-1}$, 1000-grain weight, grain yield and harvest index reached 738.913 g, 2.621 g, 2.072 g, 43.902 g, 5.086 t h^{-1} and 0.414 respectively, while Iraq-7 showed the highest value for spikes number m^{-2} reached 421.407 spikes, while for spike length the highest value was 7.925 cm recorded by Ovanto cultivar and for both grains number $spike^{-1}$ and biological yield the highest values were 49.893 grains and 13.651 t h^{-1} respectively. The lowest value for most characters recorded by Cham-1 cultivar as the average of all locations.

Data in *Table 4* explain the effect of seasons on grain yield and its components of durum wheat cultivars, signifying that the highest values for most characters recorded at the fifth season 2018-2019 including spike weight m^{-2}, average spike weight, grains number $spike^{-1}$, grains weight $spike^{-1}$, 1000-grain weight, grain yield and biological yield reached 928.585 spikes, 3.230 g, 50.372 spikes, 2.508 g, 50.294 g, 7.048 t h^{-1} and 17.073 respectively. While the lowest value for most characters exhibited by the first season 2014-2015.

Data represented in *Table 5* illustrate stability and genotypic resultant across all seasons for all studied characters. Highly significant interaction due to cultivars and seasons for all studied characters were recorded from this table variant values of stability and genetic resultant for all characters were represented. Iraq-7 cultivar recorded the highest stability for spike number m^{-2} reached 0.643, while the highest genotypic resultant was o.637 recorded by Cham-1 for the same trait. The Simeto cultivar exhibited the highest value for stability and genotypic resultant due to traits spike weight m^{-2}, average spike weight, grain weight $spike^{-1}$, 1000-grain weight, grain yield and harvest index reached 0.690 and 0.750, 0.574 and 0.690, 0.523 and 0.649, 0.633 and 0.748, 0.638 and 0.729, 0.634 and 0.714 respectively. Ovanto cultivar showed the highest value for stability and genotypic resultant due to spike length reached o.801 and 0.824 respectively. The highest value for stability and genotypic resultant for both grains number $spike^{-1}$ and biological yield recorded by Crezo cultivar reached 0.739, 0.838 and 0.829, 0.951 respectively.

Simple correlation coefficients among characters were representing in *Table 6* for all seasons. Regarding to the first season 2014-2015 (in *Table 6a*) which illustrate the correlation among characters and the path analysis to determine the direct and indirect effect of yield components on grain yield. Grain yield recorded highly significant and positive correlation with all its components except biological yield. Highly significant and positive correlations were recorded between spikes number m^{-2} with all characters except

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62596279

average spike weight, grain weight spike^{-1} and biological yield which were not significant. Spike weight m^{-2} recorded highly significant and positive correlation with all characters except biological yield, which was not significant. Average spike weight produced highly significant and positive correlation with all characters except spike number m^{-2} and biological yield which were not significant. Highly significant and positive correlations were recorded between spike length and the other characters. Grains number spike^{-1} recorded highly significant and positive correlation with all characters except spike number m^{-2} which was only significant and biological yield which was not significant. Grain weight spike^{-1} showed highly significant and positive correlation with all characters except biological yield which was only significant and spikes number m^{-2} which was not significant. 1000-grain weight recorded highly significant and positive correlation with all characters except biological yield which was not significant.

Table 6a. *Simple correlation coefficient among each pairs of traits at 2014-2015*

From the same table the path coefficient analysis for the direct and indirect effect of yield components on grain yield represent in the same table due to the first season. Maximum positive direct effect in grain yield was 0.924 recorded by harvest index and followed by spike length with 0.287. Maximum indirect effect in grain yield 0.815 recorded by harvest index via 1000-grain weight and followed by 0.781 for also harvest index via spike weight m^{-2}.

At the second season (*Table 6b*) highly significant and positive correlation were recorded between grain yield and spike weight m^{-2}, average spike weight, grain weight $spike^{-1}$ and harvest index, while the correlation was significant and positive between grain yield with spike number m^{-2} and 1000-grain weight. Spike number m^{-2} recorded highly significant and positive correlation with spike weight m^{-2}, while significant and positive correlation was recorded between spike number m^{-2} with spike length and harvest index.

Table 6b. *Simple correlation coefficient among each pairs of traits at 2015-2016*

DOI: http://dx.doi.org/10.15666/aeer/1805_62596279

Spike weight m^{-2} showed highly significant and positive correlation with average grain weight $spike^{-1}$ and harvest index. Average spike weight recorded highly significant and positive correlation with grain weight $spike^{-1}$, 1000-grain weight and harvest index. Spike length showed highly significant and positive correlation with 1000-grain weight. Grain number $spike^{-1}$ produced highly significant and positive correlation with 1000-grain weight and biological yield. Highly significant and positive correlation was recorded between grain weight $spike^{-1}$ with 1000-grain weight and harvest index. 1000-grain weight showed highly significant and positive correlation with biological yield.

From the same table and the second season the path analysis confirmed that the maximum direct effect in grain yield recorded by grain weight $spike^{-1}$ with 0.912 and followed by biological yield 0.443, while maximum positive indirect effect was 0.827 recorded by grain weight $spike^{-1}$ via average spike weight and followed by 0.780 for also grain weight $spike^{-1}$ via harvest index.

Concerning to the third season 2016-2017 (*Table 6c*) the grain yield recorded highly significant and positive correlation with all characters except spike number m^{-2} and spike length which were significant only. Spike number m^{-2} recorded highly significant and negative correlation with average spike weight, grain weight $spike^{-1}$, 1000-grain weight and biological yield, but it correlated significantly and negatively with spike weight m^{-2} and grain number $spike^{-1}$. Spike weight m^{-2} produced highly significant and positive correlation with average spike weight, grain number and weight $spike^{-1}$, 1000-grain weight, biological yield and harvest index, while it correlated significantly and positively with spike length. Average spike weight showed highly significant and positive correlation with grain number and weight $spike^{-1}$, 1000-grain weight, biological weight and harvest index. Spike length correlated significantly and positively with grain number $spike^{-1}$ and harvest index. There are highly significant and positive correlations between grain number $spike^{-1}$ with each of grain weight $spike^{-1}$, 1000-grain weight, biological yield and harvest index. Grain weight $spike^{-1}$ recorded highly significant and positive correlation with 1000-grain weight, biological yield and harvest index. 1000-grain weight showed highly significant and positive correlation with biological yield. Biological yield gave highly significant and positive correlation with harvest index.

From the same table, it was noticed that harvest index produced maximum direct effect value in grain yield reached 0.638 and followed by 0.491 for biological yield. The highest indirect effect value on grain yield recorded by harvest index via grain number $spike^{-1}$ reached 0.592 and followed by 0.513 for harvest index also via spike weight m^{-2}.

Concerning to the fourth season 2017-2018 (*Table 6d*), the correlation between each pairs of characters represent in the same table. Grain yield recorded highly significant and positive association with spike number and weight m^{-2} and biological yield, while it correlated significantly and positively with spike length and harvest index, but it correlated significantly and negatively with 1000-grain weight. Spike number m^{-2} produced highly significant and negative association with average spike weight, grain weight $spike^{-1}$ and 1000-grain weight, and correlated high significantly and positively with spike weight m^{-2} and biological yield. Spike weight m^{-2} recorded highly significant and positive correlation with spike length and biological yield, but it correlated high significantly and negatively with grain weight $spike^{-1}$ and 1000-grain weight, and also recorded significant correlation and negative correlation significant with average spike weight. Average spike weight produced highly significant and positive correlation with grain number and weight $spike^{-1}$ and 1000-grain weight, while it correlated high significantly and negatively with biological yield, whilst the correlation between

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62596279

average spike weight and harvest index was significant and positive. Highly significant and positive correlation was recorded between grain number spike^{-1} and each of grain weight spike^{-1}, 1000-grain weight and harvest index. Grain weight spike^{-1} showed highly significant and positive correlation with 1000-grain weight, while it correlated high significantly and negatively with biological yield and also correlated significantly and positively with harvest index. 1000-grain weight recorded highly significant and negative correlation with biological yield.

From the same table the path analysis indicated that the harvest index recorded the highest direct effect in grain yield reached 1.024 and followed by 0.973 for spike weight m^{-2}. The highest indirect effect value on grain yield was 0.896 recorded by spike weight m^{-2} via biological yield and followed by 0.703 for harvest index via grain number spike^{-1}.

Spike number m^{-2} showed highly significant and negative correlation with each of average spike weight, grain weight $spike^{-1}$ and 1000-grain weight. Spike weight m^{-2} produced highly significant and positive correlation with average spike weight, grain number and weight $spike^{-1}$, 1000-grain weight and harvest index, whilst with biological yield and positive correlation was recorded. There are highly significant and positive correlation between average spike weight and each of grain number and weight $spike^{-1}$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62596279

and 1000-grain weight, while significant and positive correlation was recorded between average spike weight and harvest index. Spike length recorded significant and negative correlation with biological yield. Highly significant and positive correlation was recorded between grain number spike^{-1} with each of grain weight spike^{-1} and 1000-grain weight, but it correlated significantly and positively with each of biological yield and harvest index. Grain weight spike^{-1} showed highly significant and positive correlation with each of 1000-grain weight and harvest index. Finally, 1000-grain weight recorded significant and positive correlation with harvest index.

The path analysis for the studied characters as the average of all seasons was illustrated in the same table, confirming that the spike weight m^{-2} recorded maximum positive direct effect in grain yield reached 2.129, while maximum negative direct effect was -1.347 recorded by grain number spike^{-1}. Maximum positive indirect effect in grain yield was 1.912 recorded by spike weight m^{-2} via harvest index and followed by 1.655 for also spike weight m^{-2} via grain number spike^{-1}. Maximum negative indirect effect in grain yield was -1.116 produced by grain number spike^{-1} via average spike weight and followed by -1.114 for also grain number spike^{-1} via grain weight spike^{-1}.

Discussion

The results of variance analysis for spikes number m^{-2}, spike length, grains number spike^{-1}, spike weight, 1000-grain weight and grain yield are given. Effects of locations and years on investigated traits were statistically significant ($P < 0.01$), except for year effects on spike weight. Differences among the genotypes were significant for all investigated traits. Genotypes × environment interactions were found to be significant for all investigated traits except for spikes number m^{-2}. The results of the combined analysis of variance showed a strong influence of the locations on spikes number m^{-2}, grains number spike^{-1}, spike weight, 1000-grain weight and grain yield. Genotypic effects were mainly observed for spike length. Gradual changes in yield and yield components were determined by the genotype and also by the environment (Moragues et al., 2006).

Two years averaged values of yield components and grain yield. The reason of upper grain yield at Sivas-Ulas could be also short period of dry matter production and nutrition conditions (Rharrabti et al., 2003). Negative effects on spikes m^{-2} were minor and 1000-grain weight could be maintained. The simultaneous increase in both spikes m^{-2} and grains spike^{-1} produced the highest increase in grains m^{-2}, grain yield plant^{-1}, and biomass (Pfeiffer et al., 2000). For instance, in durum wheat growing in Mediterranean environments, grain weight was superior in modern cultivars in Turkey (Koç et al., 2003), but remained unchanged in Italian and Spanish cultivars from the 20th century (Royo et al., 2007). In bread wheat, grain weight has been reduced (Trethowan et al., 2007; Matus et al., 2012; Guarda et al., 2012) or has not changed (Zhou et al., 2007) with genetic improvement. The increase in grain yield was a consequence of a greater grains number m^{-2} and higher grain weight in the more modern cultivars. The test weight was lower in the 1960s and increased curvilinear with year of cultivar release. The yield progress of a set of advanced lines evaluated between 2006 and 2015 was very high, due to genetic progress, but this was also due to management improvements, particularly adjustment of fertilization practices conducted during the first three years. Unlike other Mediterranean agro environments, a longer growing cycle together with taller plants seems to be related to the increase in the grain yield of durum

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62596279

wheat during recent decades (Alejandro et al., 2019). Hence, future crop improvement has to emphasize grain yield potential (grain yield plant^{-1}), yield stability, and user preferences in concerted, interdisciplinary approaches. Issues of environmental sustainability must be an integral part of the research agenda. To achieve these goals, crop breeding at CIMMYT aims to protect high genetic yield potential as a prerequisite of broad adaptation through incorporating resistance to a biotic and biotic stresses.

This strategy capitalizes on newer empirical methods. The analysis revealed that improvements in grain yield plant^{-1} (Pfeiffer et al., 2000). Grain yield growth rates must match future demands for food. To achieve projected production levels, breeding for realized grain yield should emphasize enhancement of yield per se and grain yield stabilization through integrated, interdisciplinary approaches that take into account environmental sustainability. This challenge requires concerted, complementary efforts to gather a critical mass of scientists and achieve essential operational sizes; sound hypotheses and strategies, translated into breeding objectives; free exchange of Germplasm and information; and dynamic cooperation among the global community of scientists. Each one of these requirements must be met if we are to accomplish our common mission: the alleviation of poverty in developing countries (Pfeiffer et al., 2000). Higher grain yields are associated with higher grain weight (v4), which resulted from early flowering (v1), and so more emphasis should be given to these traits for the improvement of yield potential in durum wheat under highland rain fed conditions. Positive correlation of stability variance (σ^2) with v4 component indicated that the grain weight is the main contributor towards GE interaction for grain yield in rain fed durum wheat (Mohammadi et al., 2016).

In modern durum wheat resulted from higher biomass, primarily through an increased grains number m^{-2} via an augmented spikes number m^{-2} and/or grains spike^{-1}. Spike weight and grain biomass production rate per day increased, while 1000-grain weight decreased (Pfeiffer et al., 2000). Earlier efforts to increase biomass focused on manipulating spikes m^{-2} and later by augmenting the grains number spike^{-1}, both of which are suitable traits in phenotypic selection. The avenue of selecting for grains m^{-2} via a higher grains number spike^{-1} proved superior in raising grain yield plant^{-1}. The balance in yield components may have approached a near optimal constellation, as results from crop comparison suggest. With limited scope for increasing the partitioning of assimilates to the grain, future progress has to be based on increased biomass (Pfeiffer et al., 2000). The maximum values of harvest index (0.53) found in the current work were higher than those reported by Royo et al. (2007). The correlation matrix among the agronomic traits of the 10 cultivars evaluated during three growing seasons indicated that grain yield showed a positive and significant correlation with grain m^{-2} ($p < 0.05$) and 1000-grain weight ($p < 0.001$). Plant height showed a negative and highly significant ($p < 0.001$) correlation with 1000-grain weight and harvest index. Spike m^{-2} had a positive correlation with grain m^{-2} but a negative correlation with grain spike^{-1}. There was a positive relationship between grain yield and spikes number m^{-2} together, whereas spike lengths were negatively correlated to grain yield.

The results of this study also imply that Line-5 and cultivar Gidara among genotypes were the most stable cultivars and can be used as breeding materials. The spikes number m^{-2} and spike length could be adequate to introduce the differences among genotypes (Sakin et al., 2011). The stability parameters showed a wide range of variation between cultivars for grain yield. By simultaneous selection for yield and stability the cultivars Crezo and Iraq-7 had the best values according to most parameters of stability; hence, it

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62596279

has a wide adaptability over a range of environments of rainfall conditions in Sulaimani, Kurdistan-Iraq (Aziz et al., 2015). The old cultivar Rash gull was characterized by a minimal responsiveness to improved environmental conditions, showing an almost stable grain yield in agreement with the concept of stability. Crezo and Iraq-7 cultivars had the best values according to the most parameters of stability (bi, S_2di, Pi, DFM, EV and mean); hence, it has a wide adaptability over a range of environments and may be considered as a future wheat cultivar for wide range cultivation under varying of rainfall conditions in Iraq (Aziz et al., 2015).

Improved yield stability, as evidenced by the correlation of grain weight and plant height with stability variance of yield. This indicates that the key strategies for yield stability improvement are most likely to be the grain weight and plant height under rain fed conditions. High yielding breeding lines at warm and moderate cold locations had good tolerance ability throughout the whole stress season especially to terminal drought and heat stresses. The cold stress was more dominant than drought stress at cold locations, as none of the breeding lines did not surpass the bread wheat old variety (beard wheat) cultivar with good tolerance to cold stress and widely adapted to highland rain fed regions indicating no genetic gain for cold tolerance in breeding lines compared to this popular cultivar. Mean yield of five top yielding breeding lines at warm location was 2469 kg ha^{-1} and at moderate location was 1930 kg ha^{-1} and top old variety (G25) at warm and moderate cold locations produced 1884 and 1624 kg ha^{-1}, respectively. These results indicated yield improvements equal to 40 and 18% for first five top yielding breeding. The results also clearly indicated that higher grain yields are associated with higher grain weight (v4), so more emphasis should be given to these traits for the improvement of yield in durum wheat under rain fed conditions. Selection for high value grain weight resulting from yield stability in breeding lines which is a major step towards facilitating the increasing a biotic stress expected from the predicted climate change. In conclusion, path analysis provided a useful picture for understanding GE interaction and grain yield components compensation in rain fed durum wheat, and hence these traits may be taken as indices of selection purposes. The responses of the individual genotypes did not reveal a common structure that would explain genotypic differences in tolerance to environmental stresses. However, the determination of genotypic strategies that maximize tolerance to environmental stresses deserves further research (Mohammadi et al., 2016).

The results of combined analysis of variance showed a strong influence of the locations on plant height, spikes number m^{-2}, grains number $spike^{-1}$, spike weight, 1000-grain weight and grain yield. Genotypic effects were mainly observed for spike length (Sakin et al., 2011). Strong influence of environmental conditions on spikes number m^{-2}, grains number $spike^{-1}$, spike weight, 1000-grain weight and grain yield. Genotypic effects were mainly observed for spike length. Diyarbakir location which had higher average rains and temperatures in the experimental years resulted better ecological conditions for durum wheat cultivation when compared with that of Tokat and Sivas locations. The highest grain yield was obtained from Line 299, whereas the lowest grain yield was obtained from Line-Gdem-2-1. Line-4 and cultivar Gidara can be considered as judged by their *bi* values and adaptation classifications, whereas genotype line 5 can only be considered stable by the *S2 d* value. Line 5 and cultivar Gidara were both stable in yield ability and also appeared in the stable group based on the cluster analysis. In the first principal component spikes number m^{-2} and spike length were the most important traits contributing to variation that obtained about 44.3%. There was a positive

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62596279

relationship between grain yield and spikes number m^{-2} together, whereas spike length was negatively correlated to grain yield. The results of this study also imply that Line 5 and cultivar Gidara among genotypes were the most stable cultivars and can be used as breeding materials. The spikes number m^{-2} and spike length could be adequate to introduce the differences among genotypes. (Sakin et al., 2011).

Environmental variations seemed to be of importance in determining performance, and therefore, evaluation based on several years and locations is a necessary strategy to be pursued in the breeding program (Yue et al., 1997). Year to- year climatic variation has a great impact on the degree of stress experienced by crops, hence the use of testing environments to represent stressed target environments. Since each environment consists of a combination of various factors, in other words, cold and drought stresses that influence adaptation and stability performance, it is difficult to specify all the differences between environments in relation to these factors (Chapman et al., 1997). High yield of durum wheat under fluctuation environments requires not only high yield in a unique environment, but also the stability of relatively high yield across varied environments (Mohammadi et al., 2016). The main purpose of multi-environment experiments in durum wheat is to identify superior varieties based on multiple traits and mega environments. Given the unpredictable environmental factors in the GE interaction studies, different models (GE, GE interaction, and AMMI), were developed to elucidate the effect of genotype, environment, or interaction; they are still used in breeding studies (Kendal, 2019; Kendal and Sayar, 2016).

In addition, the GT biplot technique has been used for a long time by many researchers to understand the effect of genotype and environment on the relationships between agronomic, physiological and quality characters, and yield (Yan and Tinker, 2006; Kendal and Dogan, 2015; Akcura et al., 2016; Oral et al., 2018). The GT biplot is used to compare varieties based on multiple traits and to define them based on these traits. This technique does not suffice to determine the effect of combining all the traits on yield under multiple environmental conditions, while the relationship between each trait and yield can be determined. Therefore, the GYT biplot technique has been developed to determine the effect of combining all traits with yield under multiple environmental conditions. However, publications based on multiple traits combined with grain yield (GYT) in different environments to evaluate the varieties are limited (Yan and Frégeau-Reid, 2018). Genotype×environmental interaction (GEI) is an important consideration in plant breeding programs because it reduces the progress from selection in any one environment (Hill, 1975). Significant GEI results from the changes in the magnitude of differences between genotypes in different environments or changes in the relative ranking of the genotypes. Consistent performances across different sites and/or years are referred to as stability. Partitioning GEI into stability statistics assignable to each genotype evaluated across a range of environments is useful in selecting stable genotypes. Different stability estimates are proposed to measure the stability of genotypes tested under a wide range of environments (Fernandez et al., 1989; Hill, 1975; Pritts and Luby, 1990).

Conclusion

It was observed clearly that the performance of each cultivar was differed from location to other depending on the climatic condition, referring to positive response of this cultivar to favorable environmental factors of that location. The presence of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62596279

genotype × environment interaction was indicated by changes in relative rankings over environments. The stability pattern revealed by the analysis indicated that the tested wheat genotypes are narrowly adapted, and no genotype was found to have high grain yield plant^{-1} performances in all environments. The development of high-yielding cultivars requires a thorough knowledge of the existing genetic variation for yield and its components for our cultivars under the study. The best stability and genotypic resultant recorded by Crezo cultivar due to the biological yield character at different environments, indicating this genotype had high performance at different environments and should be not disregarded in future studies. The Simeto cultivars, exhibited the best results for yield and most its components across all environments, could be used in future breeding programs to increase yield ability under normal and drought stress conditions, respectively. The stability parameters showed a wide range of variation between cultivars for grain yield. By simultaneous selection for yield and stability the cultivars Crezo and Iraq-7 had the best values according to most parameters of stability; hence, it has a wide adaptability over a range of environments of rainfall conditions in Sulaimani, Kurdistan-Iraq. In the view of present results it was concluded that environment plays an important role in correlation among characteristics.

Recommendation

Carrying out more investigations for cultivars with survival potentials in the prevailing climate conditions in the region, and under different environmental conditions to ensure their yield stability and to estimate their performances under different cultural practices. For more understanding of the environment, it is recommended to increase some locations under different planting dates to insure the stability and genotypic resultant of more cultivars.

GENETIC ANALYSIS FOR SEVEN PEA CULTIVARS (*PISUM SATIVUM* L.) USING LINE × TESTER METHOD FOR SEED YIELD AND ITS COMPONENTS IN F_5 GENERATION UNDER SULAIMANI CONDITIONS

HAMA-AMIN, T. N.

Biotechnology and Crop Science Department, College of Agricultural Engineering Sciences, Sulaimani, Iraq
(e-mail: taban.najmaddin@univsul.edu.iq, tabantaby@yahoo.com)

(Received 3rd Feb 2020; accepted 9th Jul 2020)

Abstract. Seven pea cultivars (*Pisum sativum* L.) were crossed in a line × tester mating design. The 12 F_5 generation and their parents were evaluated using a completely randomized block design with three replications in Kurdistan Reign, Iraq at Qlyasan Agricultural Research Station, University of Sulaimani, during the winter season of 2015-2016. Heritability in a broad sense was high for all treats except number and seed weight pod^{-1} which were low, while in narrow sense it was low for all treats except average pod weight and 100-seed weight which were high. Highly significant and positive correlation was found between seed weight plant^{-1} with pod number plant^{-1}, while highly significant and negative correlation was recorded between seed weight plant^{-1} with pod length and seed weight pod^{-1}. Seed number pod^{-1} recorded maximum direct effect in seed weight plant^{-1}, while maximum positive indirect effect in seed weight plant^{-1} recorded by pod length via pod number plant^{-1}. The present study was conducted to find out the relative importance of various yield traits for seed yield and to evaluate promising genotypes by mean of correlation and to find genetically diverse genotypes which can be used further in a various breeding program in developing wide yielding varieties.
Keywords: *gene action, heterosis, heritability, combining ability, correlation and path analysis*

Introduction

Pea (*Pisum sativum* L.) is a self-pollinated, diploid crop with 14 chromosomes (2n = 14). Pea originates from Near East and Mediterranean regions. It is one of the world's oldest crops cultivated as early as 9,000 years ago for human consumption and animals feed (Askander et al., 2018). Peas is one of the four of the most important cultivated legume and largest world's legume crop in the production after soybean, peanuts and dry beans (Yoshida et al., 2007 and Smykal et al., 2012).

Pea (*Pisum sativum* L.) is an important legume grown as a garden and field crop throughout the temperate regions of the world. Pea is valued primarily for the nutritional quality of its seeds. Pea protein is low in sulfur containing amino acids i.e. cysteine and methionine, but rich in lysine and other essential amino acids (Ceyhan and Avci, 2005). It is the source of protein having essential amino acids that have high nutritional values for resource poor households (Nawab et al., 2008). Moreover, some important minerals such as calcium, phosphorus and iron are also present in abundant quantities in pea which are lacking in cereals (Haque et al., 2014). Pea contains 20-25% starch, 4-10% sugar, 0.6-1.5% fat and 2-4% minerals (Makasheva, 1983). The present nutritional situation is a matter of great concern because most of the people are suffering from malnutrition (Mahbub et al., 2016).

The line × tester analysis method is used to breed both self and cross-pollinated plants and to estimates favorable parents and crosses, and their general and specific combining abilities (Kempthorne, 1957). Combining ability analysis is an important

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62816294

tool for the selection of desirable parents together with the information regarding nature and magnitude of gene effects controlling quantitative traits (Basbag et al., 2007). General combining ability and specific combining ability which identify the hybrids with high yield are the most important criteria in breeding programs (Ceyhan, 2003).

The knowledge of combining ability and nature of gene action is necessary for the selection of best parents for hybridization in order to improve the existing cultivars. It is also necessary to know the performance of a cross combination in comparison to the parents involved in the hybrids (Tampha et al., 2018).

The objective of this study was to measure the phenotypic variability of these traits, to obtain the general and specific combining ability, and to estimate heritability, heterosis, correlation and path analysis assess their potential use in breeding for winter season that suits the environmental conditions prevailing in the region.

Materials and methods

The present investigation was conducted at Qlyasan locations, in Kurdistan Region-Iraq, Agricultural Research Station, College of Agricultural Engineering Sciences-University of Sulaimani located (Lat 35° 34′ 307″; N, Long 45° 21′ 992″; E, 765 masl) 2 km North West of Sulaimani City, during (2015-2016). The experimental material comprises seven pea cultivars (*Pisum sativum* L.). Three cultivars (1/Avolla, 2/America, 3/Jeza) implemented as females, hereafter designated as lines, and four cultivars (4/Joneor, 5/Packland, 6/Arvena, 7/Samara) were used as males, fixed as testers (*Table 1*). All parental cultivars were crossed to produce 12 F_1 crosses according to the line × tester mating design assessed by Kempthorne (1957). F_1 seeds were sown in the field, along with their parents, in Complete Randomize Block Design with three replication. Each plot comprised one row of 2 m length with space of 40 cm between rows and seeds were placed 20 cm apart. Five competitive plants (excluding border plants) were chosen and data were recorded for: Pods number plant^{-1}, pods weight plant^{-1}, pod length, average pod weight, seeds number pod^{-1}, seeds weight pod^{-1}, 100-seed weight, biological weight plant^{-1} and seeds weight plant^{-1}.

Table 1. *Studied breeding materials*

Line parent	Tester parent			
	4- Joneor	**5- Packland**	**6- Arvena**	**7- Samara**
1-Avolla	1 × 4 Avolla × Joneor	1 × 5 Avolla × Packland	1 × 6 Avolla × Arvena	1 × 7 Avolla × Samara
2-America	2 × 4 America × Joneor	2 × 5 America × Packland	2 × 6 America × Arvena	2 × 7 America × Samara
3-Jeza	3 × 4 Jeza × Joneor	3 × 5 Jeza × Packland	3 × 6 Jeza × Arvena	3 × 7 Jeza × Samara

Genetic parameters: general combining ability (gca) and effects, specific combining ability (sca) and effects, heterosis percentage as the F_1s deviation from average parental values, heritability in broad sense, heritability in narrow sense, average degree of dominance (ā), correlation and path coefficient analysis. The collected data were submitted to analysis of variance as proposed by Al-Mohammad and Al-Yonis (2000) to estimate significant differences among cultivars. Combining ability effects are very

Results

Data in (*Table 3*) illustrate the significance of ANOVA table components due to studied characters. The mean squares due to genotypes and parents were highly significant for all characters, while the mean squares due to parent's × crosses were highly significant for only pod weight plant^{-1}, pod length, biological yield plant^{-1} and seed weight plant^{-1}. The mean squares due to crosses were highly significant for all characters except seed number pod^{-1} which was significant only. The mean squares due to lines, there were highly significant mean squares for all characters except seed number and weight pod^{-1} which were only significant. The mean squares estimated for testers were highly significant for all characters except pod length which was significant only, but the characters seed number pod^{-1} and 100-seed weight were not significant. The mean squares due to line × tester were highly significant for all characters except average pod weight^{-1}, seed number pod^{-1}, seed weight pod^{-1} and 100-seed weight which were not significant.

Data in (*Table 4*) explain the average of studied characters for parents and their F_5 crosses. Maximum value for pod number plant^{-1} produced by the cross 1 × 6 with 35.256, while for pod weight plant^{-1} it was produced by the cross 2 x 4 with 35.125 g, whist for average pod weight produced by the cross 2 x 5 with 1.493 g. Maximum value for pod length, seed weight pod^{-1} and biological weight plant^{-1} produced by the cross 2 × 6 with 8.000 cm, 1.281 g and 40.375 g respectively. The cross 2 × 7 showed maximum value for 100-seed weight with 23.392 g. The cross 3 × 6 accepted the highest value for pod length and seed number pod^{-1} with 8.000 cm and 6.033. Maximum value for see weight plant^{-1} produced by the cross 1 × 4 with 17.338 g. The same table illustrates the average of characters due to the parents, parent 2 produced the highest value for pod length and 100-seed weight with 8.000 cm and 28.253 g. Parent 3 exhibited the highest value for seed number pod^{-1} and seed weight pod^{-1} with 6.833 and 1.277 g. The highest value due to pod number plant^{-1}, biological weight plant^{-1} and seed weight plant^{-1} produced by parent 6 with 36.929, 44.195 g and 20.268 g. Parent 7 gave the highest value for pod weight plant^{-1} and average pod weight with 30.389 g and 1.577 g. The lowest value due to almost most characters produced by parent 5 and 6.

Table 5 explains the heterosis values estimated as the percentage of F_5s deviated from mid parental values. Maximum positive heterosis values for pod number plant^{-1}, average pod weight and seed number pod^{-1} were 20.115, 7.207 and 2.719% respectively produced by the cross 2 × 5, while the cross 2 × 6 produced maximum positive value for seed weight pod^{-1} and 100-seed weight with 5.031 and 3.932%. The cross 3 × 5 gave the highest positive heterosis value for pod weight plant^{-1} and biological weight plant^{-1} with 22.989 and 23.703%. The highest heterosis positive value for pod length was 11.364% produced by the cross 3 × 6, while for seed weight plant^{-1} it was 4.401% produced by the cross 1 × 4. The cross 3 × 7 showed maximum negative heterosis values for most characters. The positive value due to heterosis ratify the over dominance gene effect for the parent with high value, while the negative heterosis value signify the partial dominance gene effect for the parent with low value.

Table 6 illustrates the estimation of gca effect for parents due to studied characters. Maximum positive gca effect for pod number plant^{-1} was 5.747 produced by tester parent 4, while for pod weight plant^{-1} and 100-seed weight were 3.164 and 5.261 respectively produced by line parent 2. Maximum positive gca effect value for pod length and biological weight plant^{-1} were 0.750 and 3.187 respectively produced by tester parent 6. The tester parent 5 showed maximum positive gca effect value for average pod weight with 0.140. The line parent 3 exhibited the highest positive gca

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62816294

effect for seed number pod^{-1} with 0.387. The tester parent 5 showed maximum gca effect value for seed weight pod^{-1} with 0.058, while for seed weight plant^{-1} was 1.120 produced by tester parent 4. Maximum negative gca effect value for pod number plant^{-1} was -4.902 and for pod weight plant^{-1} was -3.883 produced by tester parent 3, while for 100-seed weight and biological weight plant^{-1} was -2.802 and -5.522 produced by line parent 1 and tester parent 4 respectively. The positive value of gca indicated to the tendency of these parents to increase the value of this character, while the negative gca value indicate to the ability of these parents to reduce the value of this character.

Table 6. *Estimation of general combining ability (gca) effect for the parents of the studied characters*

Parents	Pods no. plant^{-1}	Pods weight plant^{-1} (g)	Pod length (cm)	Average pod weight (g)	Seeds no. pod^{-1}	Seeds weight pod^{-1} (g)	100-seed weight (g)	Biological weight plant^{-1} (g)	Seeds weight plant^{-1}(g)

The estimation of the sca effect of crosses represent in (*Table 7*). The highest positive effect for seed number pod^{-1} produced by the cross 1 × 4 with 0.314, while the cross 1 × 5 showed maximum positive sca effect for pod length and seed weight pod^{-1} with 0.944 and 0.071 respectively, but for average pod weight it was 0.058 produced by the cross 2 × 4 and for biological weight plant^{-1} it was 5.145 produced by the cross 2 × 7. The cross 3 × 5 produced maximum sca effect value for pod number plant^{-1}, pod weight plant^{-1}, 100-seed weight and seed weight plant^{-1} with 8.657, 6.530, 1.189 and 1.795 respectively. Maximum negative sca effect value for pod number plant^{-1} and seed weight plant^{-1} was -6.748 and -1.871 produced by the cross 1 × 5, while for pod length and seed weight pod^{-1} it was -1.167 and -0.082 produced by the cross 1 × 6. The cross 2 × 4 showed maximum negative sca effect for biological weight plant^{-1} with -7.581 and for pod weight plant^{-1} it was -7.150 produced by the cross 2 × 5, while for average pod weight it was -0.048 produced by the cross 2 × 6, but for both seed number plant^{-1} and 100-seed weight it was -0.356 and -1.086 respectively produced by the cross 3 × 7.

The estimation of some genetic parameters for the studied characters represent in (*Table 8*). The ratio of $\sigma^2_{gca}/\sigma^2_{sca}$ for all characters was less than unity except average pod weight and 100-seed weight which were more than unity. The average degree of dominance was more than unity for all characters except average pod weight and 100-seed weight, this indicate to the over dominance gene effect in controlling the inheritance of most characters. Heritability in broad sense was found to be high for most characters except the characters seed number pod^{-1} and seed weight pod^{-1} in which they found to be low. The estimation of heritability in narrow sense was low for all characters except the characters average pod weight and 100-seed weights which were recorded high estimation.

Data in (*Table 9*) explain the simple correlation coefficient among all characters. The character pod number plant-1 correlated high significantly and positively with pod weight plant-1 and seed weight plant-1 r = 0.597 and 0.690 respectively, while there were significant and negative correlation between pod number plant-1 with pod length and seed weight pod-1 r = -0.512 and -0.485 respectively. The character pod length exhibited highly significant and positive correlation with seed weight pod-1 r = 0.743, but it correlated high significantly and positively with seed weight plant-1 r = -0.702. The character average pod weight recorded significant and positive correlation with seed weight pod^{-1} r = 0.519. Seed weight pod^{-1} produced significant and positive correlation with 100-seed weight r = 0.493, but it recorded highly significant and negative correlation with seed weight plant^{-1} r = -0.666.

Data in (*Table 10*) explain the path coefficient analysis indicated to the direct and indirect effect of the character seed weight plant^{-1}. The character seed number pod^{-1} recorded maximum positive direct effect in seed weight plant^{-1} with 0.428 and followed by biological weight plant^{-1} with 0.322. Maximum negative direct effect in seed weight plant^{-1} recorded by pod length with -1.002 and followed by average pod weight with -

0.240. Maximum positive indirect effect in seed weight plant^{-1} recorded by pod length via pod number plant^{-1} with 0.513 and followed by pod weight plant^{-1} via pod number plant^{-1} with 0.184. Maximum negative indirect effect was -0.744 recorded by pod length via seed weight pod^{-1} and followed by -0.439 recorded by pod length via seed number pod^{-1}.

Discussion

Analysis of variance for the mean sum of square due to parents and crosses showed significant differences for all the characters studied indicating the presence of variability among parents and crosses. The mean sum of square due to progenies was significant for all the characters studied. There were no significant different among the lines. There were significant differences among the testers for seed yield plant^{-1}, 100-seed weight and harvest index. The line × tester interaction gave significant differences for all the characters studied indicating the diversity among crosses and the prevalence of non-

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62816294

additive variance. Parents versus crosses also showed significant differences for all the characters. The present findings were quite similar with that of Ceyhan et al. (2008), Kumar et al. (2009) and Kumar et al. (2016).

Al-Hamdany (2014) reported that the General Combining Ability was significant for seed yield, 100-seed weight and pods weight but non-significant for seeds pod^{-1}, while sca for most characters was significant in pea. Tawfiq and Abdulla (2014) carried out genetic analysis between seven pea in a half diallel crosses and showed that the variance due to specific combining ability was larger than that of general combining ability for some studied characters, while the gca/sca variance ratio to be more than one in most studied traits, indicate the importance of additive gene effect in the inheritance of all characters.

Singh and Mishra (2002) derived information on combining ability in 10 × 10 diallel set. The mean sum of squares due to gca and sca variances were highly significant for all the characters except seeds pod^{-1}. Pandey et al. (2006) reported that combining ability analysis showed significant difference for gca and sca variance for all the characters. Parent Lincoln appeared to be one of the best combiners for all the traits. The mean squares for general combining ability were observed higher than those of specific combining ability in all the characters (Singh et al., 2007).

Significant means squares due to line, crosses, half diallel, parents Vs crosses observed for yield its contributing traits. The gca/sca variance ratio were less than unity for seeds pod^{-1}, yield plant^{-1}, 100-seed weight, indicating predominance of additive gene effects for these character, therefore, it is suggested that selection in F_1 generation may be either following progeny or simple recurrent selection (Suman et al., 2017).

All the morphological traits showed highly significant variations among the genotypes and the variations could be used in plant improvement program. Pod length, 100-seed weight, pods plant^{-1}, seeds plant^{-1} and seed yield plant^{-1} were controlled by additive gene action and selection for the improvement of these traits could be effective. Furthermore, among studied traits, four traits *viz,* 100-seed weight, seeds pod^{-1} and seeds plant^{-1} showed highly positive correlation and positive direct effect on seed yield. Therefore, emphasis should be given on these traits during selection in breeding program in order to increase seed yield (Khan et al., 2017).

F_1 crosses had more seed yield, more plant height, more pods plant^{-1}, more seeds pod^{-1}, a greater pod yield and more 100-seeds weight than the average of their parents. Heterosis was found to be significant for seed yield and its components. The values reported in this study are in agreement with the values of heterosis obtained by Lejeune-Henaut et al. (1992), Mishra et al. (1993), Sarawat et al. (1994) and Ceyhan (2003) which is attributable to non-additive gene effects rather than over dominant ones.

It was found that the magnitude of sca variance (σ^2_s) was higher than gca variance (σ^2_g) for all the characters under studied. Hence, the ratio of σ^2_g/σ^2_s was less than unity for all the characters indicating the predominant role of non-additive gene action for all the characters understudied. Similar results were also reported by Ceyhan (2006), Bora et al. (2009), Esposito et al. (2013) and Suman et al. (2017). The combining ability analysis has been the most important and efficient tool in choosing the desirable parents for hybridization programs. This technique makes it possible to classify the parental lines in terms of superiority in cross combinations and the gene action involved in the inheritance of different characters. Therefore, analysis of combining ability has been the most important and efficient tool in selecting the desirable parents for a hybridization program (Sharma et al., 2013). Singh et al. (2010) observed higher values of variance

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62816294

due to gca for pod length, and green pod yield plant^{-1} showed presence of additive gene action while it was non additive for pods number plant^{-1} based on both the generations.

The sca variance component was predominant indicating the importance of non-additive gene effects for all the characters except for peas pod^{-1} and pod yield which were influenced by additive gene action, suggesting their improvement through pure line selection (Kalia and Sood, 2009). Genes are the functional units that govern the development of various characters of an individual. Gene action refers to the behavior or mode of expression of genes in a genetic population. Genes control synthesis of proteins which in turn control expression of various traits of organisms. Knowledge of gene action in plant breeding helps in the selection of parents for use in the hybridization programs and also in the choice of appropriate breeding procedure for the genetics improvement of various quantitative characters (Sharma et al., 2013).

The knowledge of gene action is very useful to a plant breeder in the selection of parents for hybridization, the estimation of some other genetic parameters and choice of breeding procedures for the genetic improvement of various quantitative characters. In an autogamous crop exploitation of non-additive genetic variance as such would be impractical. Since, the research investigation exhibited that earliness and yield attributing traits were predominantly controlled by additive gene effects, simple selection procedure like single seed descent would be effective for isolating short duration progenies in advanced generations. Simple progeny selection may be followed for selecting transgressive segregate in later generations for developing genotypes having long pods. The cross combinations involving poor × poor, good × good and poor × good general combining parents with highest significant sca effects may be obtained for different horticultural traits. Crosses having both the parents as poor general combiners may involve dominance × dominance or epistatic interaction. Such crosses may not give good transgressive segregate in later generation. The crosses involving good × good general combiners and showing high sca effects could be utilized for the purpose of developing high yielding genotypes and obtaining transgressive segregate in F_2 generation (Sharma et al., 2013).

Dhillon et al. (2006) reported additive and non-additive gene effects governed the inheritance of all the studied characters. The additive gene effects were more pronounced for pods number plant^{-1} and pod length, whereas the non-additive gene effects were more pronounced for seeds number pod^{-1}, pod yield plant^{-1}. Sharma and Sharma (2012) observed the prevalence of over dominance for most of the traits. Low estimates of narrow sense heritability indicated the presence of non-additive gene action for most traits. These characters also exhibited medium to high level of heritability and the selections in segregating generation could be effective for evolving early maturing types.

Sharma and Bora (2013) reported higher values of heritability in broad sense and genetic gain indicating that the additive gene actions are important in determining the characters *viz*. 100 green pod weights and pod yield revealed. Therefore, selection program based on these characters would be more effective in improving yield parameters of garden pea. Combining ability analysis for six physiological characters in pea revealed in some traits by additive gene action, while both additive and non-additive gene actions were important for controlling some studied traits as found by Sirohi and Singh (2013).

Seed yield plant^{-1} exhibited highly significant and positive correlation with 100-seed weight (0.3775), pods number plant^{-1} (0.3524), harvest index (0.3270), seeds number pod^{-1} (0.3262) and biological yield (g) (0.2828). The occurrence of negative as well as positive indirect effects on yield by one or another character presents a complex

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62816294

situation where a compromise balance is required to attain proper balance of different yield components, for determining the ideotype of seed yield in field pea. The highest positive direct effect on seed yield plant^{-1} was exerted by harvest index (0.7902) followed by biological yield (g) (0.7820), 100-seed weight (0.3406), seeds number pod^{-1} (0.2788) and pods number plant^{-1} (0.2622) (Srivastava et al., 2018).

The genotypic correlation coefficient between different characters was generally similar in sign and nature to the corresponding phenotypic correlation coefficients in the experiment as found by Tyagi et al. (2012) and Pooja et al. (2015) also. However, in general, genotypic correlation coefficients were higher in magnitude from the corresponding phenotypic correlation coefficient values. Similar, results have been reported by Mahant et al. (2001), Arya et al. (2004) and Kumar et al. (2003). High positive direct contribution to seed yield plant^{-1} was exhibited by harvest index and biological yield plant^{-1}. However, 100-seed weight exhibited positive considerable direct effect on seed yield plant^{-1}. Patel et al. (2006) also reported positive correlation between seed yield plant^{-1} with pods number plant^{-1} and pod length at genotypic and phenotypic level. Ghobary (2010) also obtained results that revealed; important yield components effect directly like biological yield, harvest index and 100-seed weight. The simple correlation Coefficient among characters and path analysis between seeds weight plant^{-1} and other characters. It was observed that the character seeds weight plant^{-1} correlated positively and highly significantly with the character pods number plant^{-1}, pods weight plant^{-1}, biological weight plant^{-1} and harvest index recording (0.857, 0.839, 0.694 and 0.505) respectively. The character biological weight plant^{-1} and harvest index exhibited maximum positive direct effect in seeds weight plant^{-1} recording (0.630 and 0.456) respectively, the character pods number plant^{-1} showed the highest positive indirect effect in seeds weight plant^{-1} via harvest index recording (0.191) (Tofiq et al., 2015).

All the characters showed moderate to low phenotypic and genotypic coefficient of variation. Genotypic coefficient of variation was the highest for 100-seed weight (37.24) followed by seeds plant^{-1} (15.27). 100-seed weight had the highest heritability (95.97). Pod length, 100-seed weight, pods plant^{-1} and seeds plant^{-1} showed significant positive genotypic and phenotypic correlation with seed yield. In path analysis, 100-seed weight, seeds number pod^{-1} and seeds plant^{-1} showed positive direct effect on yield. Considering genetic variability, correlation and path analysis, emphasis should be given on pod length, seeds pod^{-1}, seeds plant^{-1} and 100-seed weight during breeding program to improve seed yield of pea (Khan et al., 2017).

Conclusion

The preponderance of non-additive type of gene action clearly indicated that selection of superior plants should be postponed to later generation. It could be clear that non-additive genetic variance is considered to be the major source of the total genetic variance responsible for the inheritance of most of the studied characters except average pod weight and 100-seed weight. The crosses involving (good × good) general combiners and showing high sca effects could be utilized for the purpose of developing high yielding genotypes and obtaining transgressive segregation in F generation. The high values of average degree of dominance for almost all of the studied characters which were more than unity confirm the superiority of non-additive gene effect in the inheritance of the studied characters which make the hybridization to be the method to improve these characters.

Recommendation

Continuous breeding programs are required to reveals pea cultivars for high yielding crosses like Avolla × Joneor. Further works is recommended to fix the desirable genes respect both forage and seed yield. More investigation were required to evaluate more pea cultivars at autumn and spring seasons which survival potential to the climatically conditions prevailing in Sulaimani region.

(Received 18th Feb 2020; accepted 9th Jul 2020)

Abstract. Compatible segmented taper and volume equations were developed for Dahurian larch, Korean spruce, Manchurian fir, planted Dahurian larch and Mongolian pine in northeast China. The model form developed by Max and Burkhart (1976) was fitted to the data of 720 sample trees. The data was randomly split into two sets for each species: 80% of total data was used for model fitting, and 20% of total data was reserved for model validation. The proposed equation provided good results for the whole tree and different stem sections. Mean prediction errors for diameter and volume were less than 1.9 cm and 0.005 m^3, respectively. The recommended model provided adequate diameter and merchantable volume estimates against ten relative height classes, examined for each species. Additionally, the model's estimates were superior to the existing volume tables for these commercial species, particularly for Korean spruce, Manchurian fir, and planted Dahurian larch.
Keywords: *segmented models, taper and volume, Dahurian larch, Korean spruce, Manchurian fir, Mongolian pine*

Introduction

China has assigned a strategic position to forestry development and ecological improvement, being pivotal factors in the sustainable development of the society and economy. A significant increase of 8.94% has been achieved in the total forest cover during the past forty years. However, sustainable forestry development remains a rigorous challenge to bridge supply and demand conflicts and meet other national and international commitments (Jia and Qu, 2011; Zeng et al., 2015). At the same time, plenty of room for improvement is available in terms of multiple products and services of the forests. Therefore, sustainable forest management is declared as a core objective of the forestry research for which accurate predictions of the standing volume are a prerequisite.

Distributed over an area of 32.71 million hectares with 28.18 billion m^3 of standing volume, northeast China is the largest forested area in the country (Zeng et al., 2015). It is recognized as a national base of wood products and a region of ecological significance. This region covers 30% of the total area, and almost half of the national ecosystem carbon is stored in these forests (Zhang et al., 2018).

Natural and planted Dahurian larch (*Larix gmelinii*), Korean spruce (*Picea koraiensis*), Manchurian fir (*Abies nephrolepis*), and planted Mongolian pine (*Pinus sylvestris*) are dominant commercial tree species in NE China. The forests of *Larix gmelinii*, *Picea koraiensis*, and *Abies nephrolepis*, and plantations of *Larix gmelinii* and *Pinus sylvestris* occupy 10.6 million ha, 4.3 million ha, 3.1 million ha, 2.8 million ha, and 0.2 million ha area, respectively. The corresponding standing volume of these species is 955.2 million m^3, 1001.6 million m^3,1135.6 million m^3, 163.9 million m^3, and 13.5 million m^3 (Chinese Ministry of Forestry, 2009). *Larix gmelinii* is the dominant tree

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62956308

species of Larix forests and covers 55% of the total area, 75% of total volume (Zhou et al., 2002). *Picea koraiensis* is the leading species of Picea forests with *Abies nephrolepis* as a major associate in NE China.

China has the largest forest plantations in the world; over an area of 79 million ha, that amounts to 25% of the world's total (FAO, 2015; Payn et al., 2015). Dahurian larch is generally planted after fire incidents and logging due to its fast growth and cold tolerance. The growth rate of these plantations is an important indicator to assess the forest recovery process and carbon sequestration potential (Jia and Zhou, 2018). Mongolian pine (*Pinus sylvestris* L. var. *mongolica* Litv.), a geographical variety of Scots pine (*Pinus sylvestris* L.) is highly tolerant to cold, drought, and soil infertility. It has been widely planted in the Three-North (north, northeast, northwest) project of China for timber production, windbreaks, and soil and water conservation (Zhang et al., 2019). Measurement tools are required for the sustainable management of these species that should allow for the industrial and ecological advances in Chinese forestry.

As a measurement tool, taper models are an essential component in prevailing forest management and planning systems (Heidarsson and Pukkala, 2011). Generally, taper models use the diameter at breast height, total height, and height above ground as independent variables, since these measurements can be easily recorded during routine forest inventories (Brooks et al., 2008). Such models can estimate (i) diameter at any height; (ii) total volume; (iii) merchantable volume and merchantable height; (iv) and volume of a log from any section of the stem (Kozak, 2004). Additionally, taper models are utilized in timber quality studies, decisions support systems, assessing the impact of silvicultural treatment on stem taper, and in the modelling of carbon allocation in different stem sections (Deleuze and Houllier, 2002; Ikonen et al., 2003; Younger et al., 2008).

Taper models have been a topic of interest in forest mensuration and management studies for over a century (Fang and Bailey, 1999). Newnham (1988) has described two reasons that bring taper models into topicality. Firstly, no single theory can satisfactorily explain all types of stem forms. Secondly, taper models are flexible tools for total and merchantable volume estimates that can comply with the changes in market trends and product classification. Practically, this flexibility of taper models keeps them under perpetual studies.

Numerous taper models of different forms have been developed over the years. A detailed discussion is available in the literature regarding the types, evolution, and comparison of these models (Rojo et al., 2005; Diéguez-Aranda et al., 2006; Sakici et al., 2008; Crecente-Campo et al., 2009; Özcelik and Crecente-Campo, 2016; Burkhart et al., 2019). The approaches of variable form taper equations and segmented taper equations have substantiated their superiority in different studies, e.g. (Barrio Anta et al., 2007; Li and Weiskittel, 2010; Schröder et al., 2014; Lumbres et al., 2016; Özcelik and Dirican, 2017; Sakici and Ozdemir, 2018). Generally, variable form taper functions provide the lowest range of local bias and maximum precision. However, they are unable to calculate total stem volume or log volume and merchantable height. Numerical integration and iteration procedure is required to calculate these variables. Alternatively, segmented taper functions can be integrated to calculate volume, and merchantable heights can be obtained directly from the equation (Kozak and Smith, 1993).

The integration of a taper equation can provide volume estimates to any merchantability limit, as well as to the total tree height. Taper and volume equations are compatible when total volume calculated by the integration of a taper equation is identical to the results of the volume equation (Demaerschalk, 1972). The primary benefit of a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62956308

compatible taper volume system is to achieve consistent results from both taper and volume equations (Burkhart and Tomé, 2012; Özcelik and Göceri, 2015).

There are some references to taper and volume studies of *Pinus sylvestris* (natural forests) in Europe, the USA, and Turkey (e.g., Laasasenaho, 1982; Westfall and Scott, 2010; Özcelik and Brooks, 2012). In China, *Larix gmelinii*, *Picea koraiensis*, *Abies nephrolepis*, and *Pinus sylvestris* L. var. *mongolica* have been studied, but the investigations were focussed on biomass and climate change (Zhou et al., 2002; Wang et al., 2012, 2018; Dong et al., 2014; Ma et al., 2014). A segmented taper equation was also presented for planted *Larix gmelinii* in NE China (Jiang and Liu, 2011). However, compatible taper and volume equations are yet to be developed for these dominant tree species in NE China.

At present, volume estimation is based on the volume tables, which were developed more than three decades ago (Heilongjiang Forest Bureau, 1981). The species under analysis provide timber for building logs, railway sleepers, construction, shipbuilding, and plywood and veneer. Other uses include soundboards in the musical instrument, boxes, and raw materials for the pulp industry. The versatility in their uses requires accurate estimates of the diameters and volumes to different merchantability limits. The conventional volume tables are no longer adequate for volume estimation in fluctuating market trends and product specifications.

The objective of this study was to develop a volume equation that can correctly estimate the tree volume to any merchantable size. A widely recognized and flexible taper equation presented by Max and Burkhart (1976) was evaluated for five commercial tree species of NE China. The total volume estimates, obtained from the proposed equation, were also compared with the prevailing volume tables.

Material and methods

Study area

This study was conducted at Lilin forest farm (129°15′-129°30′ E, 48°74′-49°9′ N) covering an area of covering an area of 8128 hm^2 and Jinsha forest farm (130°06′-131°58′E, 45°16′-46°37′ N), with an area of 6651 hm^2 located in Wuying forest bureau and Qitaihe City, respectively in Heilongjiang province, NE China. The sample trees of Dahurian larch, Korean spruce, and Manchurian fir were selected from the natural stands in the Lilin forest farm. It falls in the cold temperate forest with a continental monsoon climate. The mean annual precipitation fluctuates from 550 to 600 mm, and the mean annual temperature ranges from 0°C to 2°C. The predominant forest types are *Larix gmelinii*, *Picea koraiensis*, *Abies nephrolepis*, and deciduous broadleaf mixed forest (Tan et al., 2007).

The sample trees of planted Dahurian larch and Mongolian pine were selected from the Jinsha forest farm (*Figure 1*). This area is located in the middle temperate humid climate zone, with four distinct seasons and uneven distribution of precipitation in each season. The mean annual precipitation is 549 mm, and the mean annual temperature is 4.0℃. The typical soil type of the study area is mainly dark brown soil (Burger and Shidong, 1988).

A sample of 770 trees was collected from natural stands and plantations, covering the existing range of stand densities, conditions, and sites. Diameter at breast height (D) was measured to the nearest 0.1 cm. Later, the trees were felled to measure the total height (H) to the nearest 0.1 m. The diameter outside bark (d) was measured at the heights (h) of 0.3,

DOI: http://dx.doi.org/10.15666/aeer/1805_62956308

0.6, 1, 1.3, 2, 3 m, and then at an interval of 1 m for the rest of the stem. The data were randomly split into two sets for each species: 80% of total data (617 sample trees) for model fitting and 20% of total data (153 sample trees) for model validation. Descriptive statistics for both data sets are shown in *Tables 1 and 2*. The overlapping bolts method was used to calculate the actual volume of each bolt and tree (Bailey, 1995).

Data analysis

The segmented model of Max and Burkhart (1976) was selected for this analysis based on its good results for many tree species. For example: Appalachian hardwood species in Virginia (Martin, 1981); *Pinus taeda* in East Texas (Coble and Hilpp, 2006); important conifer species in Turkey (Brooks et al., 2008); *Larix kaempferi* in South Korea (Doyog et al., 2017); and *Betula alnoides* in South China (Tang et al., 2017). This model contains three sub-functions, combined in a single equation to represent the top, middle, and bottom stem sections as a cone, paraboloid, and neiloid frustums. The equation is of the form:

$$\frac{d^2}{D^2} = b_1(Z-1) + b_2(Z^2-1) + b_3(a_1 - Z)^2 I_1 + b_4(a_2 - Z)^2 I_2 \qquad \text{(Eq.1)}$$

where:

$$I_i = \begin{cases} 1 & Z \le a_i \\ 0 & Z > a_i \end{cases} \quad i = 1,2$$

$Z = h/H$, h = height above the ground to the measurement point (m), H = total tree height (m), D = diameter over bark at breast height (cm), d = diameter over bark (cm) to the measurement point at height h, a_i = joining points to be estimated from the data, and b_i are regression coefficients (i = 1,2,3,4).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62956308

The volume equation derived through the integration of Max and Burkhart (1976) taper equation is:

$$V = KD^2H\begin{Bmatrix} b_2/3(Z_u{}^3 - Z_l{}^3) + b_1/2(Z_u{}^2 - Z_l{}^2) - (b_1 + b_2)(Z_u - Z_l) \\ -b_3/3[(a_1 - Z_u)^3 J_1 - (a_1 - Z_l)^3 K_1] \\ -b_4/3[(a_2 - Z_u)^3 J_2 - (a_2 - Z_l)^3 K_2] \end{Bmatrix} \quad \text{(Eq.2)}$$

where:

$$J_i = \begin{cases} 1 & Z_u \le a_i \\ 0 & Z_u > a_i \end{cases} \qquad K_i = \begin{cases} 1 & Z_l \le a_i \\ 0 & Z_l > a_i \end{cases}$$

$K = 0.0000785$, $Z_l = h_l/H$, $Z_u = h_u/H$, h_l = lower height of interest, and h_u = upper height of interest. All other variables, as previously defined.

Simultaneous fitting of taper and volume equations was carried out to minimize the diameter and volume prediction errors at the same time. The parameters used in taper and volume equations were the same. Both equations were fitted independently for all species using SAS PROC MODEL (SAS Institute Inc., 2008). Correlated error structure of the data was not considered in the SAS MODEL procedure. Prediction accuracy is slightly influenced even if the error structure is accounted for during the fitting procedure (Kozak, 1997).

Data evaluation

Three goodness-of-fit statistics, mean absolute bias (MAB), the standard error of the estimate (SEE), and fit index (FI) were tested. The notations for these statistics is as under:

$$MAB = \frac{\sum_{i=1}^{n} |y_i - \hat{y}_i|}{n} \quad \text{(Eq.3)}$$

$$SEE = \sqrt{\frac{\sum_{i=1}^{n} (y_i - \hat{y}_i)^2}{n-k}} \quad \text{(Eq.4)}$$

$$FI = 1 - \left[\frac{\sum_{i=1}^{n} (y_i - \hat{y}_i)^2}{\sum_{i=1}^{n} (y_i - \bar{y}_i)^2} \right] \quad \text{(Eq.5)}$$

where: y_i , $\hat{y}_i$ stand for the measured and predicted values of the i^{th} observation, $\bar{y}_i$ is the mean of $\hat{y}_i$, n symbolize the total number of observations, and k is the number of model parameters.

Comparison of taper equations among species

The method of the non-linear extra sum of squares was used to observe whether different taper functions would be needed for different species (Neter et al., 1990). In this method, fitting of full and reduced models (*Eq. 6*) is required. It has been implemented to assess the need for separate models for different species (Rivas et al., 2004; Brooks et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_62956308

2008; Özcelik et al., 2016). The full model constitutes a separate set of parameters for each species, while the reduced model involves the same set of parameters for all species. The full model is attained by expanding all global parameters with a dummy variable and an associated parameter to distinguish the species. The significance of the comparison between full and reduced model is based on *F*-test of the formula:

$$F = \frac{(SSE_R - SSE_F)/(df_R - df_F)}{SSE_F/df_F} \quad \text{(Eq.6)}$$

where: SSE_R, SSE_F, df_R, and df_F are the error sum of squares and degrees of freedom for reduced and full models, respectively. The non-linear extra sum of squares follows an *F*-distribution.

Generally, *F*-test (*Eq. 6*) is believed to be significant, if the *P*-value is below 0.05. In this case, taper equations are not the same across species, and more tests are required to evaluate the differences. Since any possible combination of the species can produce these differences, the *F*-test of full and reduced models (*Eq. 6*) was carried out for all possible pairs of species.

Results and Discussion

Taper equations

Simultaneous fitting was performed to obtain the parameter estimates of taper and volume equations for each species. All parameters were significant at $P<0.0001$. *Table 3* highlights the values of MAB, SEE, and FI for the diameters of each species. Above 95% of the total variation was explained for the prediction of diameter. The estimated SEEs were less than 1.9 cm for all species. The plots of residuals against the predicted diameters are shown in *Fig. 1*. Most of the residuals were clustered near the centre of the data points. There was no apparent increase in the error variance with the increase of tree size.

Table 3. *Fit statistics for compatible taper and volume equation system for five species*

Species	Taper (cm)			Volume (m^3)		
	MAB	SEE	FI	MAB	SEE	FI
Dahurian larch	1.1317	1.4083	0.9703	0.0003	0.0025	0.9602
Korean spruce	0.1755	1.6977	0.9685	0.0004	0.0042	0.9715
Manchurian fir	0.1646	1.8650	0.9552	0.0004	0.0043	0.9500
Planted Dahurian larch	0.0430	1.1502	0.9749	0.0001	0.0023	0.9681
Planted Mongolian pine	0.0047	1.1392	0.9833	0.0001	0.0027	0.9767

Note: MAB, Mean absolute bias; SEE, Standard error of the estimate; FI, Fit index

The performance of the Max and Burkhart equation was also evaluated for different stem sections by using ten relative height (*h/H*) classes for all species. The statistics of MAB and SEE were calculated for diameter and volume prediction (*Tables 4, 5*). The SEE values were relatively smaller for Dahurian larch, planted Dahurian larch, and Mongolian pine for larger (>10%) relative height classes (*Table 4*). However, the values of MAB and SEE were higher for Dahurian larch, Korean spruce, and Manchurian fir near the ground.

As a whole, the standard errors of the estimates were higher for 0-10% and above 60% relative heights in all species. These specific relative heights are connected with the butt swell and the point corresponding to the base of the live crown for the sampled trees (Jiang et al., 2005). Previously, this trend was also noticed for other species (Özcelik and Brooks, 2012; Özcelik and Crecente-Campo, 2016).

Volume equations

The values of MAB, SEE, and FI for total stem volume are given in *Table 3*. Above 96% of the total variance of the volume was explained in all species except Manchurian fir, where 95% of the total variance was indicated. The value of SEE was less than 0.005 m^3 for all species. The proposed equation was also examined for volume estimation of different stem sections (*Table 5*). The range of SEE was 0.0005 m^3 to 0.0072 m^3 depending upon the species and relative height classes. As compared to Korean spruce and Manchurian fir, the average error was lower and almost the same for Dahurian larch and planted species. Most of the residuals were accumulated around zero, showing that the predictions were not biased (*Fig. 1*).

The average errors (SEE) in diameter and volume predictions correspond to the previous evaluations of the Max and Burkhart equation. Brooks et al. (2008) and Özcelik and Brooks (2012) reported the maximum SEE of 2.83 cm and 2.53 cm, respectively, in diameter prediction by relative heights for major commercial trees in Turkey. In our case, the SEE was 2.86 cm for this variable. However, the standard errors were lower for the estimates of total stem diameter, total volume, and sectional volume in this study. Doyog et al. (2017) recorded the SEE in diameter predictions of Japanese larch as 1.74 cm for total stem and 2.38 cm for different sections, lower than this study. Conversely, the values for volume estimates were higher compared with our results. Interestingly, the analysis by Jiang et al. (2005) showed a similar tendency for yellow poplar in West Virginia.

A comparison was also carried out between total volume estimates by the proposed model and existing volume tables for the species analysed (*Table 6*). Total volume predictions based on the validation data were better than the estimates of volume tables in terms of the MAB and SEE for all species. Particularly for Korean spruce, Manchurian fir, and planted Dahurian larch, the SEE was 30%, 33%, and 24% less than the volume tables. The plots of total volume residuals for the proposed equation and the prevailing volume tables exhibited higher prediction errors in volume tables for all species (*Fig. 2*). In general, the predictions were larger for bigger trees. This model not only provides a better prediction of total volume but can also predict volumes to any specific height. The available volume tables are devoid of this useful characteristic. Finally, the suggested taper and volume equations were refitted to the combined data (fitting and validation datasets). Species wise parameter estimates are depicted in *Table 7*.

Fitting results with the combined data for full and reduced models based on the proposed *equation (6)* are shown in *Table 8*. The *F*-statistic computed by *equation (6)* was 241.51, which indicates a probability of Type I error of less than 0.0001. Thus, taper equations were not the same for different species. *F*-tests were exercised for each possible pair of the species to detect the differences. All of the ten possible paired comparisons produced significant *F*-values, indicating the nonconformity of one equation for different species. Therefore, separate parameter estimates by species and stand origins (planted vs. natural) were developed.

The Max and Burkhart equation has delivered reliable results in many studies (Martin, 1981; Coble and Hilpp, 2006; Brooks et al., 2008; Özcelik and Brooks, 2012; Doyog et

DOI: http://dx.doi.org/10.15666/aeer/1805_62956308

al., 2017; Tang et al., 2017). Among five equations, this model provided the most consistent results in predicting the diameter, height, and volume of Appalachian tree species in Virginia (Martin, 1981). Coble and Hilpp (2006) recommended it for diameter and volume estimation of loblolly pine in East Texas. Out of 28 taper equations, the Max and Burkhart equation was the best-segmented model for *Betula alnoides* in South China (Tang et al., 2017). It was recommended for major commercial tree species of Turkey and Japanese larch in South Korea (Brooks et al., 2008; Doyog et al., 2017).

Conclusions

This study presents an initial attempt to develop compatible taper and volume equations for Dahurian larch, Korean spruce, Manchurian Fir, and planted Dahurian larch and Mongolian pine in NE China. Fitting of the taper and volume equations was performed simultaneously to confirm the numeric consistency. The model of Max and Burkhart behaved consistently in terms of fit statistics, sectional performance, and graphical interpretation for diameter and volume estimates. The prediction of total stem volume by the proposed equation was superior to volume tables in vogue for the species under study. As an additional attribute, this model can also be applied in the field for the estimation of stem volume to any specific height.

Abstract. Enclosure age induces technical difficulties related to establishing recovery measures for degraded rangeland biomass. The long-term and continuous enclosure of a degraded rangeland may provide strong theoretical support for this practice. In this study, enclosure measures were established to monitor the plant communities in the long-term grazing rangelands of Xilamuren in the Inner Mongolian Plateau, China, for 11 years. This study found that the number of species decreased in the enclosure rangeland every year, especially the number of perennial forbs. Grazing reduced the interannual fluctuation in the plant community biomass, and enclosure increased the biomass of perennial bunchgrasses and perennial rhizomatous grasses. In the enclosure treatment, community biomass began to decrease in 2014 (an extreme drought year), and there was no significant difference in biomass between the enclosure and grazing treatments in the 11th year. Our results indicate that grazing maintains grassland species and reduces the interannual fluctuations of biomass, and enclosure increases the risks of plant communities coping with extreme drought climates.
Keywords: *species, plant functional groups, community, precipitation, Inner Mongolian Plateau*

Introduction

Grassland ecosystems are one of the largest ecosystems in the world (White et al., 2000). Pasture-based grazing not only provides human beings with products of direct economic value, such as meat, milk, skin, and wool, but also has the extremely important service functions of maintaining the relative constancy of atmospheric components, improving climate, maintaining the biological gene bank, and fixing CO_2, soil and water conservation (Steffens et al., 2008; Reszkowska et al., 2011), among others (Sala and Paruelo, 1997; White et al., 2000). China has the third largest area of grasslands and rangelands in the world (3.9×10^8 ha, occupying 41% of the total land area of China). However, over the past half century, the sharp increase in the number of livestock and human activities have been the most important factors in reducing grassland vegetation coverage, biomass and biodiversity (White et al., 2000; Schönbach et al., 2011). Therefore, it is necessary to study the restoration and rational utilization of degraded rangelands (Nan, 2005).

Existing theory suggests that excessive livestock carrying capacity is an important cause of rangeland degradation. Therefore, the comprehensive interference of feeding, trampling and defecation of livestock can be reduced or eliminated by reducing the stocking rate of grazing livestock or encircling animal husbandry. The original degraded rangeland plant community can recuperate and promote seedling

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63096320

germination and growth to improve rangeland productivity. In theory, it should be an ideal measure for rangeland restoration. However, Ruiz-Jaen (2005) stated that most grassland recovery programs rarely last for more than 5 yr. Conversely, long-term grassland observations may be established by replacing time with space (historical background). Although this method can adequately solve the problem regarding time, there are certain hidden dangers; that is, the rangelands can vary in microenvironment, terrain, heterogeneity, climate and other factors. Thus, long-term continuous research in the same study area (grazed vs. enclosed) is needed to statistically evaluate potential differences.

Rangeland plants are also vulnerable to climatic factors, especially extreme climatic variation. Previous research has shown that the climatic characteristics from January to July were primary factors driving plant community changes (Bai et al., 2004). Westoby (1989) noted that the transition of community succession required particular rainfall events (such as rare heavy rain) to drive a change in community composition. This finding is of great interest to us, and we wondered whether extreme drought will also change the characteristics of a community during a long-term enclosure experiment. As the direct manager of rangeland plant community composition and diversity, the quantitative change of herbivores will lead to a series of cascading effects (Bai et al., 2004) of multispecies, plant functional groups and intercommunity feedback regulation in rangeland ecosystems. This has piqued our interest, and we propose that rangeland plant communities facing extreme drought will also have a significant impact, and grazing and enclosure plant communities will show different responses.

In our study, the research determine site was a severely degraded grazed rangeland. Annual dynamic changes in plant communities in long-term (11-yr) enclosed areas of the rangeland were studied to 1) frequency dynamic changes in species and plant functional groups under grazing and no grazing; (2) dynamic changes in plant functional group biomass and community biomass due to grazing and no grazing; and (3) potential factors that drive changes in community biomass.

Materials and methods

Study area

The research site was located in the Xilamuren rangeland (111°12′E, 41°21′N) (desert steppe.) in Darhan Muminggan United Banner, Baotou, Inner Mongolia, China (*Fig. 1*). This region has a gentle topography with a mean elevation of 1468 m. The soil type was chestnut soil with a soil organic matter layer of 5-10 cm. From 2007 to 2017, the mean annual precipitation was 273 mm (*Table 1*). Between 60 and 80% of precipitation occurred during the plant growth season (May to October). The annual evaporation was 2526 mm. The mean temperature by month remained similar from 2007 to 2017. The mean temperature was 4.2 ℃ (maximum 38.0 ℃; minimum -39.4 ℃) (*Table 1*). The coverage of plant communities ranged from 39% to 68%. The dominant species was Stipa krylovii (Roshev.), and the codominant species were Leymus chinensis (Trin.) and Agropyron cristatum (Linn.). Historically, rangelands were mainly used by nomads. Since the implementation of the grassland contract system in 1988, local herdsmen have changed from traditional nomadic life to long-term settled grazing. No utilization was performed between 1988 and 2006, and the enclosure experiment was initiated in 2007.

Study site setting

For the enclosure treatment, three 40 ha enclosures were established in the rangeland in early May 2007. No livestock entered these enclosures during the 11-yr period. Sites were selected for similarity of natural habitat factors, including slope and slope aspect. For the grazed treatment, three sites were closed to the enclosure treatments, and each site area was 40 ha. For the grazed treatment, three 40-ha sites were selected close to the enclosure treatments. Grazing was by sheep only, and the stocking rate of each site was 0.30 sheep ha^{-1} $month^{-1}$, resulting in a 50 to 55% grass utilization rate (Wang et al., 2014). Sites were similar in topography and landforms to the enclosure sites. Grazing took place from May to October every year. In the evening, the flock was allowed in the site, with no supplementary feeding.

Sampling method

Changes in vegetation were determined in August, which is the peak biomass in desert rangelands. To determine the biomass of each plant species present, ten 1 m^2 quadrats were regularly placed along the transect in a Z-shaped orientation. The transect lines were 200 m long and laid 5 m away from the boundary enclosure to avoid edge effects. Along each transect, 1 m^2 quadrats were laid at intervals of 20 m. For each quadrat, live and dead aboveground biomass was clipped at the ground level, and dead parts were removed (Bai et al., 2012). Plants were clipped by species in each quadrat and numbered. The fresh materials were brought back to the laboratory and put in an oven at 105 ℃ for 10 min. Then, samples were dried to constant weight in a drying cabinet at 65 ℃, and finally, the dry sample was weighed. A total of 60 quadrats were investigated each year. The data for this study were collected from 2007 to 2017, with 660 quadrats in total.

Plant functional groups

According to the existing literature and the plant types in the experimental fields, plants were divided into five functional groups (Bai et al., 2004): perennial bunchgrasses, perennial rhizomatous grasses, perennial forbs, shrubs and subshrubs, and annual or biennial herbs (*Table 2*).

Statistical analysis

Independent sample t-tests were used to examine and compare the plant community biomass, biomass of each functional group and biological differences in dominant species in the enclosure and grazing rangelands in the same year. Analysis was completed in SAS 9.0 (SAS Institute Inc., Cary NC, USA).

A regression equation was constructed between community biomass and grazing treatment, annual precipitation, perennial bunchgrasses, perennial rhizomatous grasses, perennial forbs, shrubs and subshrubs, and annual or biennial herbs by using partial

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63096320

least squares. According to the obtained regression equation, variables important in prediction (*VIP*) can be identified.

$$VIP_j = \sqrt{\frac{q\sum_{h=1}^{m} r^2(Y,t_h)w_{hj}^2}{\sum_{h=1}^{m} r^2(Y,t_h)}} \quad \text{(Eq.1)}$$

In *Equation1, q* is the number of independent variables, $r(Y,t_h)$ is the covariance of two observational variables, and w_{hj} is component *j* of axis w_h.

The larger the *VIP* of the independent variable is, the stronger the effect of the independent variable on the community biomass. If the *VIP* of the independent variable is > 1, the independent variable is considered an important index that affects the community biomass, and if the *VIP* of the independent variable is < 0.5, the independent variable is considered an unimportant index that does not affect the community biomass (Li et al., 2015). The above statistical analysis was completed in SAS 9.0 (SAS Institute Inc., Cary NC, USA).

To further analyze factors driving biomass changes in rangeland plant communities, we selected variables with *VIP* > 1 and defined these variables as observable variables, and we defined plant functional groups as potential variables. A structural equation model was constructed for statistical analysis with the maximum likelihood as the estimation method (Bansal et al., 2014). The above statistical analysis was completed in Amos 20 (IBM, SPSS, Armonk, NY, USA).

Results

Frequencies of species and functional groups

Fifty-nine plant species were found in the 11 years of field observation, among which the frequencies of *Stipa krylovii*, *Cleistogenes squarrosa*, *Agropyron cristatum* and *Convolvulus ammannii* were always higher than 0.1 (*Fig. 2*). First, compared with grazed rangeland, frequencies of *Artemisia frigida*, *Heteropappus altaicus* and *Allium mongolicum Regel* in the enclosure treatment decreased year by year, which is contrary to patterns observed for *Koeleria cristata var. poaeformis* and *Salsola collina*. Second, the total numbers of plant species decreased every year under the grazing treatment (*Fig. 2*), while the numbers of plant species remained stable at approximately 10 species under the grazing treatment. From the perspective of plant functional groups, the frequencies of perennial bunchgrasses were always higher than 0.8 in the 11 years. Compared with the enclosure treatment, interannual changes in the frequency of perennial rhizomatous grasses were relatively higher under the grazing treatment than under the enclosure treatment. This is opposite to patterns observed for annual and biennial herbs.

Biomass of common species, plant functional groups and communities

Over the 11 years, *Stipa krylovii*, *Cleistogenes squarrosa*, *Agropyron cristatum* and *Convolvulus ammannii* were all found in both grazed and enclosed treatments. The biomass of *Stipa krylovii* was higher under the enclosure treatment than under the grazed treatment ($P < 0.01$), which reached a maximum value in 2012 (*Fig. 3*). The

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63096320

range of fluctuation in interannual biomass of the common species under the grazed treatment was lower than when enclosure was allowed. Additionally, *Stipa krylovii*, *Cleistogenes squarrosa*, and *Agropyron cristatum* are perennial bunchgrasses. The results of the plant functional groups showed that the biomass of perennial bunchgrasses and perennial rhizomatous grasses significantly increased in the enclosure treatment. However, the biomass of perennial forbs decreased (*Fig. 4*). Community biomass results showed that ranges of interannual fluctuations of community biomass were similar under the grazing and enclosure treatments. The community biomass maximum value in 2012 was over 600% higher than that in 2017 (minimum value), where enclosure occurred, but the community biomass under grazing was relatively low. However, the range of interannual fluctuation in community biomass under grazed treatment was relatively lower than when enclosure occurred. In the first 10 yrs, community biomass under the enclosure treatment was significantly higher than that under the grazed treatment ($P < 0.01$), but there was no significant difference between the two treatments in the 11th year; however, community biomass in the enclosure treatment began to decrease in 2014.

Biomass of plant functional groups and communities between 2007 and 2017

The results of the independent sample t test showed that over the 11 years, the community biomass under enclosure decreased 41.17% ($P < 0.05$). The difference was mainly reflected in the perennial bunchgrasses and perennial rhizome grasses. Compared with the perennial bunchgrasses and perennial rhizome grasses in 2007, the perennial bunchgrasses and perennial rhizome grasses decreased 26.61% and 49.56% ($P < 0.05$) in 2017. However, under the grazing treatment, there was no significant difference between the biomass of communities and functional groups in 2007 and 2017 (*Fig. 5*).

Driving factors for biomass

Regression equations were constructed between community biomass and five plant functional groups, annual precipitation and grazing treatment by using partial least squares, which were used to calculate the VIP value for each factor that drives the changes in community biomass. The results showed that perennial bunchgrasses, perennial rhizomatous grasses, precipitation and grazing were important indexes (VIP > 1) that affected changes in community biomass (*Fig. 6A*). The selected indexes were used to construct the structural equation model in this study as indicated by nonsignificant P values (*Fig. 6*). The results of this model showed that grazing had a negative effect on the biomass of the plant functional groups and indirectly affected the community biomass ($R^2 = 0.90$) (*Fig. 6B*). However, precipitation had a positive effect on the biomass of the plant functional groups and indirectly affected the community biomass.

Discussion

Compared with the grazed rangeland, the numbers of species in the enclosure plant communities decreased every year, which is in contrast to the results of other studies (Loeser et al., 2007; Liu et al., 2016, 2017). These differences may be caused by the following factors: a) Dominant species: the competitive advantages of the dominant species significantly increased when grazing was excluded, which increased the biomass of perennial bunchgrasses and perennial rhizomatous grasses, especially bunchgrasses (e.g., *S. krylovii*, *C. squarrosa* and *L. chinensis*). Moreover, when this

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63096320

rangeland is supplied limited resources, increases in dominant species inevitably lead to decreases in survival chances of other species (e.g., *A. frigida*, *H. altaicus* and *A. mongolicum Regel*). In addition, in the grazing treatment, the biomass of perennial bunch grasses was always at a low level, which may be related to the selective feeding of herbivores and the palatability of the plants themselves. Koerner et al. (2018) suggests that when herbivores reduce the abundance (biomass, coverage) of dominant species (for example, because dominant plants are delicious), additional resources can be used to support new species, thereby increasing biodiversity. b) Habitat homogenization: Livestock disturbance causes rangeland to produce a variety of habitat patches to ensure that plant species in different successional stages will coexist; however, large livestock disturbances were removed from the enclosed rangeland, which resulted in habitat homogenization, resulting in a decrease in the number of species. c) Species migration: Under grazed treatment, plant seeds can spread effectively with the help of anemophily (wind), insects and large herbivores, increasing the chances of survival of the species, which in turn increases the number of species. Under enclosure treatment, the spread of plant seeds can occur only through anemophily or insects, which greatly limits the spread of species. In this study, the biomass of *S. krylovii* under the grazing treatment was 3496% higher than that under the enclosure treatment. The spatial distribution data are not presented in this study, but in the 1 m^2 quadrat, the biomass of *S. krylovii* reached 296.19 ± 36.00 g in 2012, and limited spatial dispersion (small-scale diffusion) could have caused strong spatial aggregation of the population. The aggregation of plants caused by limited spatial transmission can make the population appear to have a patchy distribution (Webb and Peart, 2000). However, the occurrence of small-scale plant aggregations in relatively harsh habitats may lead to competition and self-thinning of plants (Javier, 2012) and may even lead to the death of young plants, leading to a decrease in the number of species in the enclosure communities every year.

Enclosure increased community biomass, which was mainly because disturbance by foraging, trampling and defecation of livestock was eliminated by enclosing the rangeland. Thus, dominant species in the community that were previously strongly impacted by livestock could quickly exert their competitive advantages to change the species composition of the community. Related results have shown that fencing enclosures increased the biomass of grassland plant communities (Han et al., 2015; Kohyani et al., 2011; Lu et al., 2015). However, in our study, we found that the range of fluctuation in the interannual biomass of plant communities under grazing was relatively lower than that of plant communities in the enclosure treatment because livestock disturbance may stimulate supercompensation effects in plants that drive them to conduct an effective carbon assimilation process. In addition, during long-term livestock disturbance, plant communities may be in the “intermediate disturbance” stage, which reduces competition effects of specific plants in the plant communities, enables nondominant species to utilize growth space (Altesor et al., 2005), and increases community biomass, which is consistent with the results of this study. From the perspective of plant functional groups, the structural equation model also shows that grazing livestock can indirectly regulate the biomass of plant communities by affecting plant functional groups, such as perennial bunchgrasses and perennial rhizomatous grasses, thus releasing competition among different plant functional groups. It makes it in a relatively stable state for a long time, which verifies the hypothesis of a compensation effect between functional groups in the community (Bai et al., 2004).

By screening the important indexes that affect community biomass, we found that grazing affected community biomass. However, we also found that biomass fluctuations always increased and decreased with changes in annual precipitation, and excluding grazing increased the effect of annual precipitation on rangeland plants (Wang et al., 2014). Further analysis showed that the community biomass where grazing was excluded was higher than that under the grazed treatment from 2007 to 2016, and there was no difference between the two treatments in 2017. However, the community biomass in enclosure areas began to decrease in 2014. These data are similar to the research results of Bai et al. (2004). The biomass of rangeland plants decreases during extreme drought years and cannot be effectively increased in the following several years except after extreme precipitation (Westoby, 1989). This impact may be because in the Inner Mongolian desert grassland where there are four distinct seasons, the aboveground branches of perennial bunchgrasses usually survive only one growing season, while underground organs can survive for many years (Li et al., 2012). These underground vegetative organs (bud banks) play a decisive role in the reproduction and survival of plant populations (Hartnett et al., 2006). However, extreme droughts can cause devastating damage to underground organs. In addition, under such drought conditions, the quantity of microorganisms decreases, their activity weakens, and the mineralization rate and fluxes of carbon and nitrogen in the soil decrease significantly (Bloor and Bardgett, 2012). This in turn affects the growth, development, and reproduction of rangeland plants so that they cannot be restored for a long time. This result provides a warning that long-term exclusion of livestock seems to increase vulnerability when extreme drought occurs, and if these rangelands face successive years of drought or long-term drought, plant communities that have remained enclosed for long periods of time will be more vulnerable than those in grazed rangelands, which may result in more severe degeneration. That is, excluding grazing may increase the risks of plant communities coping with global changes.

Conclusion

Based on the analysis of the plant community biomass in grazed and enclosed rangelands for 11 consecutive years in Inner Mongolia, it is concluded that grazing

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63096320

reduces plant community biomass and the range of interannual fluctuation in biomass, while enclosure increases the biomass of perennial bunchgrasses and perennial rhizomatous grasses, and the difference was mainly reflected in the perennial bunchgrasses and perennial rhizome grasses. Therefore, it is of great significance for the ecology and management of desert grassland to set a reasonable enclosure. In addition, precipitation had a positive effect on the biomass of the plant functional groups and indirectly affected the community biomass. Our results also indicated that in the face of extreme climate, enclosure increases the impact of extreme precipitation on plant communities and increases risks associated with extreme drought conditions. This indicated that in the face of future climate change, especially precipitation and seasonal changes, long-term enclosure is not an appropriate measure for rangeland restoration.

Abstract. *Eurycoma longifolia* Jack is traditionally used as an aphrodisiac and health supplement for various diseases. Due to its potential commercial value as a plantation crop as well as to conserve its germplasm, it is necessary to establish a suitable protocol of propagation as a better alternative for mass production. Hence, this study describes an efficient and reproducible *in vitro* regeneration system of *E. longifolia.* Cotyledonary node explants were excised from 2-week-old *in vitro* seedlings and cultured on Murashige and Skoog (MS) medium supplemented with different concentrations of 6-benzyl aminopurine (BAP), kinetin (KIN) and thidiazuron (TDZ). In addition, various concentrations of indole-3-butyric acid (IBA) and α- naphthaleneacetic acid (NAA) were tested for *in vitro* rooting of shoots. From the results, it was observed that 1.0 mgL^{-1} of BAP induced the highest percentage of shoot formation (76.7%) from cotyledonary node explants. The best rooting response was observed on half-strength MS medium containing 0.5 mgL^{-1} IBA with an average of 3.2 roots per shoot. Regenerated plantlets were successfully acclimatized to *ex vitro* conditions with an 85% survival rate. Overall, this *in vitro* regeneration protocol provides a rapid technique that can be utilized for commercial propagation and genetic transformation of this medicinal plant.
Keywords: *seed germination, shoot multiplication, in vitro rooting, acclimatization, cytokinin and auxins*

Introduction

Medicinal plants have been an essential part of the ethnobotanical aspect of the people around the world since ancient times. Today, the majority of people are still relying on traditional remedies to meet their primary health care needs (Parveen et al., 2010; Uprety et al., 2012; Alsarhan et al., 2014; Jamshidi-Kia et al., 2018). *Eurycoma longifolia* Jack or Tongkat Ali as locally known in Malaysia is an important medicinal plant belonging to the family Simaroubaceae. Due to its diverse medicinal values, every part of the plant is used as medicine, especially the roots (Rahmawati and Esyanti, 2014; Yahya et al., 2015). The traditional use of the Tongkat Ali root extracts as anti-inflammatory and analgesic remedies is well established. Studies have revealed that the root extracts of Tongkat Ali have antimalarial, cytotoxic, aphrodisiac, antioxidant, anti-tumor, anti-inflammatory, anti-pyretic, and anti-amoebic properties, and also it has been applied in the treatment of diverse conditions such as fatigue, impotence, loss of sexual desire, high blood pressure and fever (Bhat and Karim, 2010; Rehman et al., 2016). Conventional propagation of Tongkat Ali via seed germination is considered as the most common method for the plant propagation, but as a woody plant, it is difficult for several reasons

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63216333

such as low rate of seed germination and poor flowering (Keng et al., 2002; Rahmawati and Esyanti, 2014; Thu et al., 2016).

Being a recalcitrant plant, the seeds took a long time to germinate and have the lowest percentage of germination due to immaturation of the zygotic embryo (Ayoba et al., 2013; Zeng et al., 2014). Furthermore, Tongkat Ali roots were harvested after 4-7 years of cultivation, so the production of the roots is time-consuming, and fluctuated depending on the seasons (Chua et al., 2011). Therefore, the tissue culture technique was an urgent need for rapid propagation on a commercial scale to meet the pharmaceutical industry demand (Lulu et al., 2015). Previously, efforts have been conducted on Tongkat Ali regeneration using different explants such as shoot tips, roots, stems, leaves, and cotyledons (Hussein et al., 2005, 2012; Mahmood et al., 2010; Rodziah and Madihah, 2015). However, regeneration protocols on Tongkat Ali are not well developed; mainly due to the recalcitrant nature of plants. Direct shoot regeneration through the organogenesis provides a better solution for propagation within a short period of time and less soma clonal variability (Juturu et al., 2015).

Development of suitable *in vitro* regeneration protocols is one of the major prerequisites for improvement of genetic characters of plants using biotechnological methods (Venkatachalam and Kavipriya, 2012; Singh et al., 2015). Although *in vitro* propagation was an alternative method for mass production and conservation, studies had shown that shoot induction of recalcitrant species still rare due to its woody nature (Hussein et al., 2012; Isah, 2016). As an important plant in folk medicinal practices, an efficient propagation protocol is urgently needed to fulfil the market demand for Tongkat Ali. *In vitro* micropropagation provides an alternative solution for obstacles faced by the conventional method of propagation. It can also be applied as a strategy for conservation and utilization of genetic resources (Groach and Singh, 2015; Singh, 2018). Thus, the current study reported a rapid micropropagation system of *E. longifolia* through cotyledonary node explants by using different concentrations of various plant growth regulators.

Material and methods

Plant material and seed germination

The plant material used in this study was provided by Institute of Bioscience, University Putra Malaysia. All experimental procedures were carried out at Plant Biochemistry and Biotechnology Laboratory of Biochemistry Department at University Putra Malaysia. Matured ripe dark-red fruits of Tongkat Ali were washed with detergent and rinsed under running tap water for 30 minutes. Then the epicarp and mesocarp of the fruits were manually removed (*Fig. 1B*). Surface-sterilization of seeds was carried out in laminar-flow hood according to procedure described by Mahmood et al. (2010) as follows: seeds soaked for 5 minutes in 70% (v/v) ethanol; and then submersed for 20 minutes in 20% (v/v) Clorox® plus two drops of Tween-20; after that the seeds were rinsed with sterile distilled water five times. *In vitro* seed germination was carried out to ensure aseptic growth conditions of seedlings that would be used as a source of explants (cotyledonary nodes). After sterilization, the seed coat was removed to accelerate the rate of germination and help to avoid any phenolic compounds that naturally released in culture media from seed coats (*Fig. 1C,D*). Embryos were inoculated into 15 × 2.5 cm vials containing 20 mL of full-strength Murashige and Skoog (1962) (MS) medium without plant growth regulators (PGRs) (*Fig. 1E,F*).

Culture medium and conditions

All experiments were conducted using MS medium with the addition of 3% sucrose, and various concentrations of PGRs. A medium without any PGRs was included as a control. Culture medium solidified with 0.25% Gelrite, and the pH of culture medium was set to 5.8 using HCl or 1N NaOH prior autoclaving for 20 minutes at 121ºC and 1.06 kg cm^{-2} pressure. All cultures were initially maintained in the growth room in the dark at 25 ± 2°C for 1 week, then transferred to 8 h dark and 16 h light photoperiod supplied by cool white fluorescent bulbs (35 µmol m^{-2} s^{-1} photon flux density). Relative humidity was maintained at 60%.

Shoot induction from cotyledonary node explants

Cotyledons nodes were excised from 14-day-old *in vitro* raised seedlings (*Fig. 2C*) under sterile conditions and used as explants. The cotyledonary node explants with intact embryonic axis were cultured on MS medium supplemented with different concentrations (0.2, 0.5, 1.0, 2.0 and 3.0 mgL^{-1}) of 6-benzylaminopurine (BAP) and kinetin (KIN) as well as thidiazuron (TDZ) at concentrations (0.1, 0.2, 0.5, 1.0 and 2.0 mgL^{-1}). Data on shoot regeneration percentage, number of shoots per explant and shoot length were frequently recorded every week of culture. For shoots proliferation, the shoots were regularly sub-cultured at six-week intervals onto the fresh MS medium containing the same cytokinin composition. After harvesting the multiple shoots, the original cotyledonary nodes were recultured on a fresh medium for further shoot multiplication.

In vitro rooting and acclimatization

In order to obtain a complete plantlet, regenerated shoots (2.5 - 4.5 cm in length) were aseptically excised and transferred to rooting medium comprising of half-strength MS medium without auxins or with auxins such as indole-3-butyric acid (IBA) or naphthaleneacetic acid (NAA) at different concentrations (0.2, 0.5, 1.0 and 2.0 mgL^{-1}). The observations on root induction percentage, root number and root length were recorded weekly. Acclimatization was initially carried out in the laboratory as follows: plantlets that have vigorous shoots with a well-developed root system were gently

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63216333

removed from the culture medium and washed carefully with autoclaved distilled water to remove the traces of nutrient medium from the roots. Then the plantlets potted in 7.5 cm plastic pots containing an autoclaved jiffy-7 medium. Plantlets were watered and immediately covered with transparent polyethylene bags to maintain high humidity around the plantlets. The plantlets were maintained in the growth room at 25 ± 2ºC in 16 h light and 8 h dark photoperiod (35 µmol m^{-2} s^{-1} photon flux density supplied by cool white fluorescent bulbs). After two weeks the humidity around the plantlets was gradually reduced by puncturing the polyethylene bags with small holes. Finally, the polyethylene bags were removed and plantlets were shifted to big plastic 18cm-pots containing garden soil. These plantlets were then kept under natural day light conditions (12/12-h of light/ dark photoperiod) at the greenhouse for normal growth.

Statistical analysis

All experiments were designed as a complete randomized design (CRD) with 10 replicates and repeated three times. The percentage of seed germination was calculated with the following *Equation 1* (Keng et al., 2002).

$$\frac{n}{N} x\ 100\% \qquad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63216333

In *Equation 1,* n is the number of seeds germinated and N is the total number of seeds used in each germination treatment. The observations on the treatments were recorded weekly. Finally, the data obtained were subjected to ANOVA (one-way analysis of variance) to examine whether they were statistically significantly different from each other or not using Minitab software. Means were subjected to Tukey's test ($p \leq 0.05$) and the results were expressed as means ± standard errors (SE).

Results

Effects of plant growth regulators on shoot bud induction

Types of plant growth regulators (PGRs) and their concentrations have been reported to influence organogenesis in plants, as evidenced in this study with the multiplication of shoots from cotyledonary node explants. As shown in *Table 1*, frequency, number and length of multiple shoots formed varied significantly with PGRs supplementations. Variance analysis revealed that shoot proliferation rates differed significantly ($P \leq 0.05$) based on concentrations and type of cytokinin used. The three cytokinins, namely BAP, KIN and TDZ at different concentrations were tested for their ability to induce multiple shoots. Multiple shoots were initially formed from cotyledonary node explants within 15 to 20 days in the presence of cytokinins (*Fig. 2D*). These multiple shoots were induced by supplementing the media with 0.2 - 3.0 mgL^{-1} BAP, KIN or 0.1 - 2.0 mgL^{-1} TDZ. Cotyledonary node explants cultured on MS medium without the PGRs (as a negative control) did not give response to shoot buds formation. Among different cytokinins tested, BAP at a concentration of 1.0 mgL^{-1} showed the highest frequency of multiple shoots induction (76.7%) with the maximum shoot number (4.87±0.70) shoot per explant compared to other concentrations of KIN or TDZ (*Table 1, Fig. 2E*). For shoot proliferation, cotyledonary nodes were regularly subcultured onto fresh medium of the same composition of PGRs.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63216333

Based on the current study, BAP was more efficient cytokinin in *E. longifolia's* multiple shoot induction and proliferation, where the number of shoots per explant was significantly higher at 1.0 mgL^{-1} BAP treatment as compared to KIN and TDZ. In general, increased concentrations of plant growth regulators over the optimum concentration resulted in reducing the frequency of shoot induction and the number of shoots per explant (Rahimi et al., 2013; Khan et al., 2015; Kazeroonian et al., 2018). Our study also shows that the TDZ was less effective than BAP or KIN and the shoots formed from the TDZ-containing MS, were stunted and failed to elongate even when the shoots were subcultured on PGR-free MS medium. Moreover, a small amount of callus was observed on some explant cultured on the TDZ-containing medium. Low concentrations of TDZ also inhibited shoot elongation as compared to the BAP treatments; hence shoot induction and elongation with BAP treatment was preferred.

Rooting of the shoot and plantlets acclimatization

Different concentrations of IBA and NAA were added to half-strength MS medium to induce rooting in *E. longifolia*. In this study, regenerated shoots with 2.5 - 4.5 cm in length were excised from the cotyledonary nodes and transferred to the half-strength MS medium supplemented with different concentrations of IBA and NAA or without any auxins (*Table 2*). Initiation of root was observed even from the shoot cultured on half-strength MS medium without auxins with an average number of 0.26 ± 0.15 roots per shoot after three weeks. Although the root formation was observed in MS medium without auxins, the presence of auxins was required to induce a higher number of roots. *Table 2* shows that, out of the four concentrations of IBA tested, 0.5 mgL^{-1} of IBA has proven to be the best concentration for rooting, which represents the highest value of rooting (3.20 ± 0.50). Moreover, the root length was the longest (3.66 ± 0.52 cm) and developed relatively normal in the same concentration of IBA (*Fig.2F,G*).

Table 2. *Effect of different concentrations of IBA and NAA in ½ MS medium on root induction from in vitro shoot of Eurycoma longifolia*

*Means within a column that do not share a letter are significantly different at $p \leq 0.05$ using Tukey's test

In the current study, it was observed that no callus was induced around the shoot's bases, whereas the roots were initiated directly from the shoot (*Fig. 2H*). Increasing the level of IBA had caused a steady decline in the root formation compared to the medium without auxin (control), which emphasized the fact that a high concentration of auxin in tissue culture conditions could affect root development. It was observed that the platelets

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63216333

which had developed root systems before being transferred to soil, seemed to be well-established in the acclimatization stage. In this study, the acclimatization of *in vitro* plantlets with *ex vitro* condition was successfully carried out. Initially the plantlets were transferred to the plastic pots (7.5 cm diameter) containing an autoclaved jiffy-7 medium and covered with transparent polyethylene bags to maintain high humidity and kept in the growth room for the first 2 weeks. The data has shown that 85% of plantlets survived and developed into grown plants when transferred into the soil. No variation in leaf morphology was recorded when they were compared to *in vivo* plants (*Fig. 2I*).

Discussion

Direct shoot regeneration protocol provides a potential rapid technique that can be utilized in genetic transformation. In this study, multiple shoots formation was induced from cotyledonary node explants. It has been reported that cotyledonary nodes were the optimal *in vitro* explants for shoot production in other plants such as *Cassia sophera* (Parveen and Shahzad, 2010), *Sassurealappa Clarke* (Groach and Singh, 2015) and *Cucumis sativus* L. (Venkatachalam et al., 2018). In this study cytokinins such as; BAP, KIN and TDZ were tested for their *in vitro* effects and showed different responses of shoot formation. BAP at low concentration of 0.2 mgL^{-1} BAP showed only 20% shoot induction with an average of 0.83 shoots number. However, BAP at 1.0 mgL^{-1} produced the highest shoot induction (76.7%), with 4.87 number of shoots. Nayak et al. (2013) reported that in *Withania somnifera* the best result was recorded with 1.0 mgL^{-1} BAP and 100% of the cotyledonary nodes exhibited shoot initiation within 12 days. In addition, Kumar and Chandre (2009) reported that among the three cytokinins (BAP, KIN and TDZ) used, BAP was the best cytokinin for inducing the maximum number of shoots from the apical meristem of *Stylosanthes seabrana*. Their result also showed that 1.0 mgL^{1} KIN induced 63.3% multiple shoots with a lower number of shoots (2.40 shoot per explant) on average.

Shoot induction decreased (36.7%) with an average of shoot number 1.13±0.39 at a higher concentration of BAP concentration (*Table 1*). Venkatachalam and Kavipriya (2012) reported a similar result of the frequency of shoot regeneration from the cotyledonary node of *Arachis hypogaea* L. using two cytokinins BAP and KIN with different concentrations. KIN induced the lower percentage of the shoot. Similar observations on the effectiveness of BAP at lower concentration detected in several plant species such as *Ricinus communis* (Alam et al., 2010); *Lens culinaris* (Bermejoa et al., 2012); *Psoralea corylifolia* (Pandey et al., 2013) and *Vitex negundo* (Groach et al., 2014).

Formation of stunted shoots was a common problem with MS medium containing TDZ, as have been reported for several plant species, such as *Cassia siamea* (Parveen et al., 2010); *Withania somnifera* (Nayak et al., 2013); *Elaeocarpus blascoi* (Siva et al., 2015) and *Platanus acerifolia* (Bao et al., 2017). However, prolonged exposure of regenerated shoots to medium supplemented with high concentrations of TDZ resulted in distortion in the shoots. Similar observations have also been reported in other studies (Parveen and Shahzad, 2010; Ahmed and Anis, 2012; Dewir et al., 2018). The proliferation of multiple shoots could be stimulated by adding cytokinins to the regeneration medium, but it can inhibit their further growth and elongation. Therefore, elongation of the shoot could be consistently inhibited by TDZ due to its high cytokinin activity (Kumar and Reddy, 2012; Siddique et al., 2015). Similarly, in several studies on other plant species such as *Cassia sophera* (Parveen and Shahzad, 2010), *Curculigo*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63216333

latifolia (Babaei et al., 2014) and *Jatropha curcas* (Aishwariya et al., 2015) it has been reported that the higher concentrations of TDZ resulted in stunted shoot and callus production.

It has been reported that with an increase in concentrations of cytokinins, the responding frequency of explants and the number of shoot regeneration was increased up to certain limits and then reduced markedly (Naing et al., 2015; Seo et al., 2017; Kumari and Harsh, 2018). Cotyledonary nodes as an explant have been also reported to be an efficient starting material to induce multiple shoots in many of other plant species such as *Sterculia urens Roxb* (Devi et al., 2011), *Citrullus colycynthis* (Meena et al., 2014) and *Mucuna bracteata* DC. (Aziz et al., 2018). These nodes had a better regeneration response compared to the other parts of the plant due to its regenerative axillary meristem cells (Hsieh et al., 2017).

Rooting of *in vitro* regenerated shoots is an important step for successful *in vitro* regeneration of whole plantlets (Toppo et al., 2012; Shekhawat et al., 2015). It produces the whole plant that can survive in *ex vitro* conditions. Roots could be only induced from the shoots which are not succulent or fragile. Development of roots should be directly from the base of the shoot and no callus should be formed to provide a good vascular connection between shoot and root (Anwar et al., 2010). In general, auxins are used for root induction, but they might prevent the continued growth of roots if they remain on the same rooting medium (Harahap et al., 2014). IBA is an auxin that is widely used for root induction in *in vitro* cultures (Baque et al., 2010; Patel et al., 2014). A study conducted by Hussein et al. (2005) on shoot regeneration from shoot tip explants of *Eurycoma longifolia* found out that, out of different concentrations of IBA tested only 0.4 and 0.5 mgL^{-1} were able to induce roots from the *in vitro* plantlets. This is in agreement with our study, which shows that 0.5 mgL^{-1} of IBA is the best concentration for root induction of *E. longifolia*. IBA at 0.5 mgL^{-1} produced the highest percentage of roots (80%) with an average 3.20 root per shoot (*Table 2*). Kumar and Nand (2015) reported a similar observation with the same concentration of auxin (IBA 0.5 mgL^{-1}) in half-strength MS medium for root induction from *Asteracantha longifolia*. However, NAA is more potent than IBA and IAA for the induction of adventitious roots from leaf explants of *E. longifolia* (Hussein et al., 2012).

The superiority of IBA over the other auxins in the induction of root has been previously reported in other studies (Parveen and Shahzad, 2010; Hussein et al., 2012; Agarwal et al., 2015; Bohra et al., 2016). A previous study by Hussein et al. (2005) on *E. longifolia* reported that MS medium supplemented with NAA or IAA, tended to form callus at shoot's bases. Whereas, only IBA showed a sign of direct root formation. These observations could be due to the fact that IBA is more resistant to chemical degradation than other auxins during the autoclaving of culture media, or it might be due to the location of auxin receptors of the plant tissues, where different types of auxin react differently based on the position of its receptor (Nissen and Sutter, 1990; Zhao et al., 2014; Andujar et al., 2019).

Micropropagated plantlets, which are developed in a controlled microenvironment might desiccate and die if they were directly placed at a low level of humidity or higher light level that is stressful as compared to *in vitro* conditions. Moreover, during the acclimatization process the plantlets have poor photosynthetic capability and the leaves act as a source of carbohydrates for the newly developing leaves. This poor photosynthetic capability could cause the deaths of some of the micropropagated plantlets (Chaari-Rkhis et al., 2015). Syafiqah et al. (2017) suggested that the usage of 100% jiffy

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63216333

was the suitable potting medium for the acclimatization of *Labisia pumila* plantlets. Yahya et al. (2015) reported that jiffy-7 was the best potting media for Tongkat Ali acclimatization. Their results showed that 100% of plantlets survival was obtained with jiffy-7 medium.

Conclusion

In conclusion, the present study described a rapid and simple protocol for mass propagation. The result showed that the high frequency of multiple shoot induction was possible from the cotyledonary node explants of *E. longifolia* plant. The complete regeneration system described here can be achieved within 12 weeks; a much shorter period as compared to the germination in forest sandy soils in nature which normally takes eight months to grow up to the same height of the *in vitro* propagated plants. This protocol would be beneficial for large-scale propagation that could meet the increasing demand of the pharmaceutical industry. However, it can be used to perform further experiments to obtain transgenic plants or other biotechnological approaches.

Acknowledgements. The authors would like to thank the Biodiversity Unit at Institute of Bioscience, University Putra Malaysia for providing the plant material for this research.

Abstract. A meta-analysis was conducted to investigate the effect of returning farmlands to forests or pastures on soil animal diversity and its regional differentiation characteristics in China. Overall, based on the Shannon-Wiener index and Simpson index values, we found that returning farmland to forest (pasture) had an important effect on soil animal diversity. Forests and pastures might have a higher species richness and lower species evenness of soil animals than farmland. The effect of returning farmland to forest on soil animal diversity was greater than the effect of a return to pasture, although the effects varied between different land use/cover changes. The Shannon-Wiener index and Simpson index values showed different regional characteristics of soil animals when returning farmland to forest (pasture) in North China, South China, Northwest China and Qinghai-Tibet China. Returning farmland to forest (pasture) should be more conducive to increasing soil animal species richness in high-temperature regions and increasing soil animal species evenness in low-temperature regions. Furthermore, in low-temperature regions, returning farmland to forest affected the soil animal diversity more than returning farmland to pasture. Returning farmland to forest was more conducive in improving soil animal diversity synthetically in dry regions, and the changes in soil animal diversity due to the effect of returning farmland to pasture were not evident between dry and rainy regions in China.
Keywords: *soil fauna, Shannon-Wiener index, Simpson index, land use, land cover, species richness, species evenness, meta-analysis*

Introduction

Currently, with global attention focused on biodiversity and its protection, soil animal diversity and its ecological service functions have attracted widespread international and local attention from scholars (Bardgett and Cook, 1998; Shao et al., 2015). Soil animals are an integral component of soil ecosystems and play the role of consumers and decomposers in ecosystems (Albers et al., 2006). These animals have important effects on soil formation, soil structure, fertility conservation and energy flow (Bardgett and Wardle, 2010). Environmental changes and external disturbances could affect the composition and distribution of the soil animal community (Ponge et al., 2013; Baretta et al., 2014).

Land use/cover changes affect the input of litter, leading to changes in soil physicochemical properties, and change the characteristics of the soil animal

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63356353

community (Jangid et al., 2011; Liu et al., 2011). Many related studies have shown that vegetation type, soil organic matter, and soil physicochemical properties have important effects on soil animal community structure. For example, changes in land use patterns from forest to farmland radically change vegetation types, resulting in changes in a number of environmental factors, such as soil organic matter, soil temperature and water, and thus changing the structure and composition of the soil animal community (Tan et al., 2008; Yin et al., 2010). Some researchers suggested the richness and diversity of soil animals were influenced by a wide range of agricultural and other land use practices (Baker, 1998), and land-use intensification strongly influenced biodiversity by altering habitat heterogeneity, the distribution of habitat types and their expanse (Eggleton et al., 2005). The richness of different soil animal groups showed contrasting relationships with location and land-use type (Birkhofer et al., 2012).

Returning farmland to forest (pasture) is a China's governmental environmental program that converts arable land to forestry plantation or permanent pasture in order to protect and improve the ecological environment with the principle of sustainable development. Returning farmland to forest (pasture) is a major ecological restoration policy for controlling soil erosion and desertification in China. The process prevents soil erosion by ending land cultivation operations, planting trees and grass, restoring vegetation and controlling soil erosion (Li et al., 2008). The implementation of this policy can cause large-scale and transformative changes in surface cover, but due to the difference of surface vegetation between forest and pasture, the distribution of litter and underground organic matter shows obvious differences, which has a significant different effect on the regional ecological environment, and subsequently affects differently the habitat conditions and diversity of soil animals (Yang, 2004; Liu and Men, 2009). Land use changes across China demonstrated significantly temporal and spatial differences during the last two decades (1990–2010). The area of farmland decreased in the South China and increased in North China. Forest decreased first, and then increased. Pasture continued decreasing (Sun et al., 2018). Thus, increasing interests focused on the effect of land use changes on soil animal diversity in China. Chinese scholars have conducted a series of studies on the changes in soil animal diversity under different land use/cover changes, such as changes between farmland, forest and pasture (Liu et al., 2011; Zhang et al., 2014; Wei et al., 2014). However, due to the complexity of the underground soil ecosystem, previous studies have failed to draw comprehensive conclusions regarding the effect of land use/cover changes on soil animal diversity or to clarify soil animal diversity after the implementation of the policy of returning farmland to forest (pasture) in China. Therefore, correctly and scientifically evaluating the effect of land use/cover change on soil animal diversity has great significance for the scientific management of land, the protection of soil animal diversity and the maintenance of soil ecological function. In addition, China's four geographic regions are North China, South China, Northwest China and Qinghai-Tibet China. The regional characteristics are significant, which include topography, climate and vegetation types, etc. The above factors have important effects on soil animal diversity. So here, regional differentiation characteristics of the effect on soil animal diversity under the policy of returning farmland to forest (pasture) in China is investigated. A meta-analysis is a comprehensive statistical analysis of different studies based on the same research topic (Sun et al., 2015). Meta-analyses have been applied in ecological studies in China (Tian et al., 2014; Zhang et al., 2015; Zhao et al., 2017).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63356353

However, there have been no reports of meta-analyses on the effect of returning farmland to forest (pasture) on soil animal diversity. Based on a meta-analysis, the effect and regional differentiation characteristics of land use/cover change on soil animal diversity caused by the policy of returning farmland to forest (pasture) in China were comprehensively analysed.

Materials and methods

Data collection and selection criteria

We collected data on the effect of returning farmland to forest (pasture) on soil animal diversity in Chinese farmland from peer-reviewed articles published in both Chinese and English language journals from 1999 to 2018. The keywords used for the search included the following: returning farmland to forest, returning farmland to pasture, land use, land cover, vegetation types, soil animal, soil fauna, diversity, farmland, forest, and pasture. The articles in Chinese were collected from the China National Knowledge Infrastructure (CNKI) database, and those in English were from ISI-Web of Science and Google Scholar. Articles were only included if they met the following criteria: 1) the study area needed a detailed geographical location; 2) there was at least one land use change that included returning farmland to forest, returning farmland to pasture or converting forest to pasture; 3) there was at least one detailed chart or description of the soil animal diversity index (Shannon-Wiener or Simpson) before and after the land use change; 4) the soil animal sampling methods, determination methods, and diversity analysis and calculation methods were identical; 5) the means and sample sizes had to be reported; and 6) returning farmland to forest (pasture) could be represented by two different land use types as long as they were located in adjacent sites. The process was conducted following the flowchart diagram presented in *Fig. 1* (Moher et al., 2009), and a total of 60 peer-reviewed articles were selected for our analysis (*Appendix*). Then in those 60 articles, the data of soil animal group number and density was collected for meta-analysis to investigate the change before and after land use change.

Data grouping

To investigate the regional differentiation characteristics of the effect of returning farmland to forest (pasture) on soil animal diversity, the selected data were grouped. For China, according to the comprehensive characteristics of geographical location, physical geography and human geography, the data were divided into four groups: North China, South China, Northwest China and Qinghai-Tibet China, which the boundary between North China and South China is Qinling and Huaihe, the boundary between North China and Northwest China is the Greater Khingan Mountains and the Great Wall, and the boundary between Northwest China and Qinghai-Tibet China is Kunlun Mountains and Qilian Mountains (Chi et al., 2015). In order to further investigate the regional differentiation characteristics, we divided the regions according to annual average temperature (< 12ºC and > 12ºC) and annual rainfall (< 200 mm, 200-400 mm, 400-800 mm and > 800 mm) because of the annual average temperature of study regions and the division base of semi-arid, semi-humid and humid region in China.

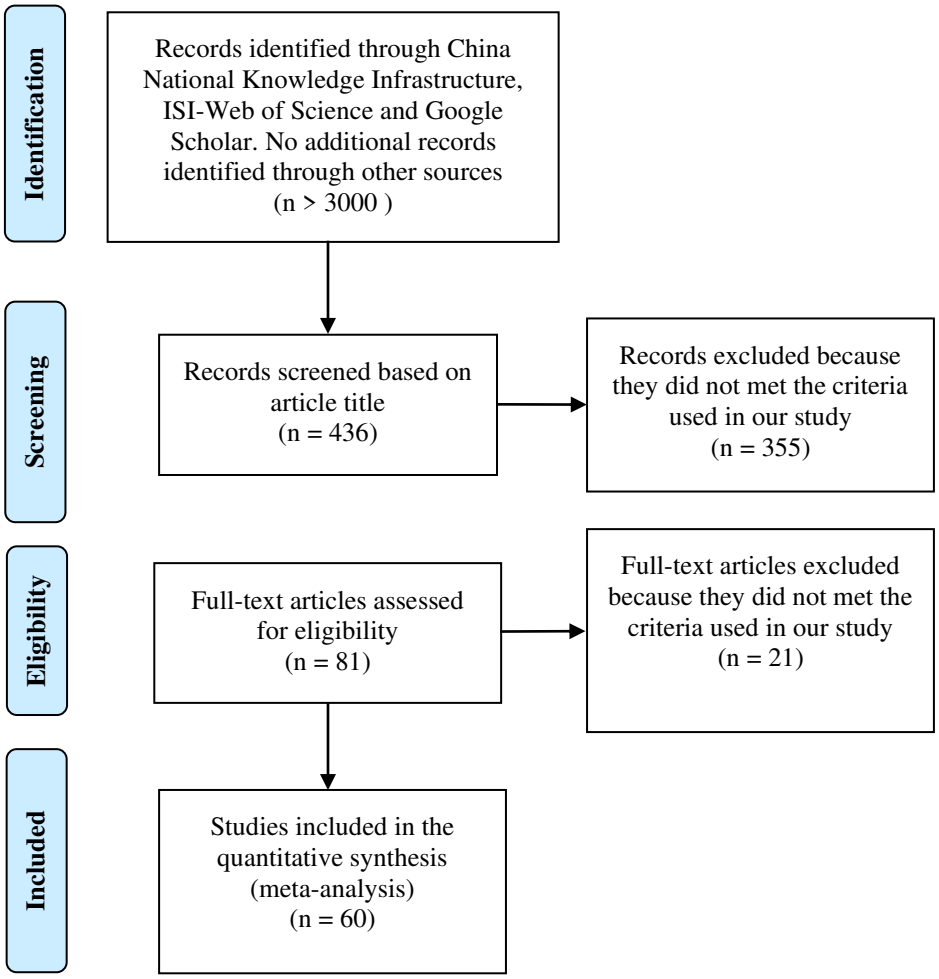

Figure 1. *Flowchart diagram of the process used to obtain the literature data to build the database in our study*

Data analysis

The Shannon index (Shannon, 1948) and Simpson index (Simpson, 1949) were selected as our soil animal diversity metrics because they are often used for analyzing soil animal alpha diversity in soil ecology (Bardgett and Cook, 1998; Wang et al., 2018). Although the Shannon index and Simpson index consider both species richness and species evenness, the Simpson index is more sensitive to community species evenness (Magurran, 1988; Xu et al., 2011). A large Simpson index value indicates that soil animals are unevenly distributed and the ecological functions of dominant species are prominent. The simultaneous increase in the Shannon index and decrease in the Simpson index indicate an increase in soil animal diversity. However, it is possible that the Shannon index and Simpson index increase simultaneously under the same treatment, which generally indicates potential species evenness loss. The Shannon index and Simpson index are calculated using the following *equations*:

$$\text{Shannon index} = -\sum_{i=1}^{S} p_i \ln p_i \qquad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63356353

$$\text{Simpson index} = \sum_{i=1}^{S} {p_i}^2 \quad \text{(Eq.2)}$$

where p_i is the proportion of individuals of category "i " to the total number of individuals in the community and S is the number of groups.

The variance in each index and the sample sizes of the corresponding research were included in our study. Web Plot Digitize software 3.12 (Rohatgi, 2012) was used to extract the data from the articles that provided only graphics. The variances were obtained by contacting the authors of the articles when the variance data were missing. If the variance data could not be obtained in some articles, the proportion of the variance to the average value of the existing data was used as the standard for calculating the variance based on previous studies (Skinner et al., 2014).

In ecological studies, the meta-analysis effect size was generally shown by the natural logarithm of the response ratio (R), and the objective regulations reflected in selected research data were obtained by using weighted integral method (Hedges, 1999). In this study, the ratio of the average index (X_t, X_c) of soil animal diversity before and after returning farmland to forest (pasture) was taken as the response ratio, and the natural logarithm (ln$R$) was taken as the effect size.

$$\ln R = \ln \frac{X_t}{X_c} = \ln X_t - \ln X_c \quad \text{(Eq.3)}$$

where R is the response ratio, ln$R$ is the effect size, X_t is the mean value of each index before returning farmland to forest (pasture) and X_c is the mean value of each index after returning farmland to forest (pasture). The effect size of each data pair was obtained by meta-analysis, and the weighted mean effect size, lnR_{++}, and its 95% confidence intervals were obtained by calculating the weight based on the standard deviation.

The effect of returning farmland to forest (pasture) on soil animal diversity was significant ($P < 0.05$) if all confidence intervals were greater than 0. Conversely, there was a significant negative effect ($P < 0.05$) if the confidence intervals were all less than 0. If 0 was within the confidence interval, returning farmland to forest (pasture) had a nonsignificant effect on soil animal diversity. We also used the percentage transformed from the mean effect size to explain the response of soil animal diversity on returning farmland to forest (pasture):

$$\left(e^{\ln R_{++}} - 1\right) \times 100\% = \left(R_{++} - 1\right) \times 100\% \quad \text{(Eq.4)}$$

Publication bias was quantified by rank-correlation methods, which included Kendall's tau and Spearman's rank-order method; a $P < 0.05$ indicates the existence of publication bias (Begg and Mazumdar, 1994). Rosenthal's fail-safe method (Rosenthal, 1979) was used to evaluate the publication bias results (*Table 1*). When the fail-safe number is considerably larger than $5k + 10$ (where k is the original number of studies), the result is not affected by publication bias and the meta-analysis result is reliable (Hoeve et al., 2012). In this study, Metawin 2.1 software (Rosenberg et al., 2000) was used for the meta-analysis, and Origin 8.5 software was used for generating the figures.

Results

Effect of returning farmland to forest (pasture) on soil animal diversity

Across all studies, the Shannon-Wiener index and Simpson index showed different responses by soil animals to returning farmland to forest (pasture) (*Fig. 2*). The Shannon-Wiener index results showing the effect of returning farmland to forest (pasture) on soil animals are shown in *Fig. 2a*. On average, the Shannon-Wiener index value for forest was 18.35% higher than that of farmland, which was significant; however, compared with farmland, the mean effect size of the Shannon-Wiener index value for pasture was positive, but the effect was nonsignificant. In addition, the Shannon-Wiener index value significantly decreased by 9.71% from forest to pasture. The effect of returning farmland to forest (pasture) on soil animals by the Simpson index is shown in *Fig. 2b*. According to *Fig. 2b*, the Simpson index changed significantly with the conversion of land use types, which was caused by returning farmland to forest (pasture). On average, the Simpson index significantly increased by 2.14% and 3.38% in changing farmland to forest and pasture, respectively. In addition, the Simpson index value for forest was 4.32% lower than that of pasture. According to *Fig. 3*, the group number and density of soil animals significantly increased by 9.31% and 46.69%, 3.86% and 62.24% when returning farmland to forest and pasture, respectively.

Regional differentiation characteristics of the effect of returning farmland to forest (pasture) on soil animal diversity

The Shannon-Wiener index and Simpson index values showed different regional characteristics of returning farmland to forest (pasture) on soil animals in China (*Fig. 4*). According to *Fig. 4a*, in North and South China, the Shannon-Wiener index value for forest was 34.21% and 17.75% higher than that of farmland, respectively, which was significant. However, compared with farmland, the mean effect size of the Shannon-Wiener index value for forest was negative, and the effect was nonsignificant in Northwest China. The Simpson index value significantly increased by 5.68% and 3.37% when returning farmland to forest in North and South China, respectively, but significantly decreased by 10.64% in Northwest China. According to *Fig. 4b*, in North and Qinghai-Tibet China, the Shannon-Wiener index value for pasture was 50.92% and 25.59% higher than that for farmland, respectively. In Northwest China, the Shannon-Wiener index value for pasture significantly decreased by 21.05%, and the effect was nonsignificant despite the negative mean effect size in South China. When

DOI: http://dx.doi.org/10.15666/aeer/1805_63356353

returning farmland to pasture, the Simpson index value significantly decreased by 9.36% and 9.62% in North and South China, respectively. In Qinghai-Tibet China, the Simpson index value for pasture significantly increased by 63.57%, and the mean effect size was positive. However, the effect was nonsignificant in Northwest China. According to *Fig. 4c*, in the conversion from forest to pasture, the mean effect size of the Shannon-Wiener index was negative, and the effects were nonsignificant in North and South China. The Shannon-Wiener index value for pasture was 14.52% lower than that for forest in Northwest China. The Simpson index value for pasture significantly decreased by 1.93% in South China and significantly increased by 23.06% in Northwest China. In addition, the effect was nonsignificant in North China.

According to *Fig. 5*, in North China, returning farmland to forest had significant positive effects on the group number and density of soil animals, 29.62% and 124.13%, respectively. Moreover, returning farmland to pasture had significant positive effects on group number and density, with percentages of 65.68% and 164.86%, respectively. In South China, returning farmland to forest had significant positive effects on the group number and density of soil animals, with percentages of 23.59% and 56.85%, respectively. Moreover, the group number of pastures was 10.97% higher than that of farmland, which was significant. However, the effect of density was nonsignificant compared with the effect of farmland. In Northwest China, returning farmland to forest decreased the group number and density significantly by 13.84% and 11.44%, respectively, and returning farmland to pasture changed the percentages of the group number and density were -11.88% and 16.78%, respectively. In Qinghai-Tibet China, returning farmland to pasture changed the percentages of the group number and density were 7.88% and 84.81%, respectively.

Regional differentiation characteristics caused by temperature and rainfall

When the average temperature was < 12ºC and > 12ºC, returning farmland to forest significantly increased the Shannon index value by 18.60% and 17.72%, respectively (*Fig. 6a*). Moreover, the Simpson index value significantly decreased by 10.13% when the average temperature was < 12ºC, and then significantly increased by 41.30% (*Fig. 6d*). In addition, the group number and density changed by -3.79% and 11.28% when the average temperature was < 12ºC, and increased by 26.23% and 56.87% when the average temperature was > 12ºC (*Fig. 7a* and *7d*). Returning farmland to pasture

significantly increased the Shannon index value by 12.73% and significantly decreased the Simpson index by 7.50% when the average temperature was < 12ºC. Moreover, the return significantly increased the Simpson index by 31.48% and had a nonsignificant effect on the Shannon index when the average temperature was > 12ºC (*Fig. 6b* and *6e*). In addition, the group number and density changed by -9.49% and 43.21% when the average temperature was < 12ºC, and they increased by 19.50% and 91.08% when the average temperature was > 12ºC (*Fig. 7b* and *7e*).

With an increase in annual rainfall, returning farmland to forest significantly increased the Shannon index by 34.94%, 83.5%, and 14.24%, except for the nonsignificant effect at 400-800 mm (*Fig. 6a*). The Simpson index significantly decreased by 66.91% and 14.45%, at amounts < 200 mm and 400-800 mm and then increased significantly by 9.67% at amounts > 800 mm, but there was a nonsignificant effect at amounts from 200-400 mm (*Fig. 6d*). In addition, the group number changed by 118.17%, 49.68%, -7.98% and 18.3%, and the density changed by 364.80%, 341.57%, 3.51% and 55.22% when the amount was < 200 mm to > 800 mm (*Fig. 7a* and *7d*). Returning farmland to pasture significantly increased the Shannon index by 128.71% at amounts from 200-400 mm but had a nonsignificant effect in other regions (*Fig. 6b*). The Simpson index decreased significantly by 4.59% at amounts between 400-800 mm and then increased significantly at amounts > 800 mm, but there was a nonsignificant effect in other regions (*Fig. 6e*). In addition, the group number changed by 46.89%, -29.25% and 26.92% at amounts from 200-400 mm to > 800 mm, and the density changed by 98.97%, 81.92%, -24.72% and 119.71% at amounts from < 200 mm to > 800 mm. Returning farmland to pasture had a nonsignificant effect on the group number at amounts < 200 mm (*Fig. 7b* and *7e*).

Discussions

Returning farmland to forest

Under China's governmental environmental program of returning farmland to forest, a large amount of farmland has been converted to forest (Wang et al., 2011). The conversion of land use types has changed the cycling of soil organic matter (Detwiler, 1986; Zhao et al., 2014), the soil physicochemical properties (Adejuwon and Ekanade, 1988; Toohey et al., 2018) and the soil animal habitat (Eggleton et al., 2005). As a result, there have been important effects on soil animal diversity. The results of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63356353

present study confirm that returning farmland to forest has an important effect on soil animal diversity, as indicated by the Shannon-Wiener index and Simpson index values, and indicate that returning farmland to forest increases soil animal richness. However, returning farmland to forest might have decreased the soil animal evenness and increased the proportion of dominant species. This result was consistent with previous studies regarding the effects of changes from farmland to forest on soil animal diversity. Bartz et al. (2014) found that forest provided better soil conditions for the development of a higher diversity of soil animal compared to farmland. Okwakol (2010) also reported that forest had a higher soil animal diversity compared with farmland.

Returning farmland to pasture

Returning farmland to pasture had an important effect on soil animal diversity, but its effect on the Shannon index and Simpson index values were inconsistent (*Fig. 2*). The Simpson index value significantly increased by 3.38%, which indicated that soil animal evenness decreased and the proportion of dominant species increased. The above results show that the nonsignificant effect on the Shannon index might have been caused by the comprehensive results of an increase in species richness and a decrease in species evenness, which was suggested by the results of our study (*Fig. 2*). Similar results were reported by Cluzeau et al. (2012), who demonstrated most of the soil animal groups exhibited lower values of abundance and community richness in farmland than in pasture. In addition, regarding the conversion from forest to pasture, the Shannon index value decreased and the Simpson index value increased, indicating a decrease in soil animal diversity (-9.71%, 4.32%). This was consistent with the results obtained by Callaham et al. (2006). The group number and density of soil animals significantly decreased, which might have been caused by the lower soil animal richness and soil animal evenness of pastures compared with forests because the distribution patterns of the soil animal community changed with the change in surface vegetation cover (Vohland and Schroth, 1999; Yin et al., 2017).

Regional differentiation characteristics

There were significant differences in topography, climate, soil properties and vegetation types in North China, South China, Northwest China and Qinghai-Tibet China, which had important effects on soil animal diversity. So the effect on soil animal diversity showed different regional characteristics when returning farmland to forest (pasture). In North China, returning farmland to forest increases soil animal species richness, and soil animal species evenness might decrease. While returning farmland to pasture increased both the species richness and species evenness of soil animals, returning farmland to pasture significantly increased the soil animal diversity. The effect on soil animal diversity was nonsignificant because the changes in the Shannon index and Simpson index values were nonsignificant in the change from forest to pasture even though the species richness increased. In South China, returning farmland to forest has an important effect on soil animal diversity, which might have been caused by the increase in species richness and the decrease in species evenness of soil animals. Returning farmland to pasture increased soil animal diversity, which might be caused by the highly significant increases in species richness and species evenness even though the effect indicated by the Shannon index was nonsignificant. In addition, the changes in soil animal diversity might have been caused by both a decrease in species richness and an increase in species evenness from the conversion of forest to pasture. In

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63356353

Northwest China, the increase in soil animal diversity might have been caused mainly by the increase in species evenness when returning farmland to forest. Returning farmland to pasture can decrease soil animal diversity largely due to a decrease in species richness. With the conversion from forest to pasture, the change percentages of the group number and density were -12.77% and -41.75%, respectively (*Fig. 5*). The Shannon index value decreased significantly, and the Simpson index increased significantly, which might have been caused by the significant decrease in species richness and species evenness. In Qinghai-Tibet China, returning farmland to pasture has an effect on soil animal diversity, which was possibly caused by the increase in species richness and decrease in species evenness. The above regional differentiation characteristics were supported by some studies of land use change affecting soil animal diversity in other countries and regions, which indicated that the effect of land use change on soil animal diversity showed different regional differences with the change of geographical environment (Rossi and Blanchart, 2005; Karanja et al., 2009; Begum et al., 2013; Steinwandter et al., 2017).

Effect of temperature and rainfall

In China, the effect on soil animal diversity showed different regional characteristics when returning farmland to forest (pasture) because of differing regional natural conditions. The regional climate conditions mainly include temperature and rainfall, which have important effects on the cycling of soil organic matter and soil physicochemical properties (Kirschbaum, 1995; Mani et al., 2018). Therefore, to further discuss the regional differentiation characteristics, we divided the regions according to the annual average temperature and annual rainfall in China.

Returning farmland to forest (pasture) should be more conducive to increasing soil animal species richness in high-temperature regions and increasing soil animal species evenness in low-temperature regions. The improvement of plant community coverage and vegetation height after converting farmland greatly improved the survival conditions of soil animals and attract more soil animals to inhabit the land and survive (Mathieu et al., 2004). Additionally, the conversion was very beneficial for the concentration of dominant species. This benefit was proved by our study results, i.e., the proportion of dominant species increased in high-temperature regions. Returning farmland to pasture had a nonsignificant effect on the Shannon index when the average temperature was > 12ºC, which might be caused by the comprehensive effect of both the increase in species richness and the decrease in species evenness. Furthermore, in low-temperature regions, returning farmland to forest affected soil animal diversity more than a return to pasture because the mean effect size of the Shannon index decreased and the Simpson index increased from forest to pasture when the annual average temperature was < 12ºC.

With an increase in annual rainfall, the effect of returning farmland to forest on species richness and evenness gradually decreased and was conducive to the concentration of dominant species. Our study found that arid regions were more conducive to improving soil animal diversity when returning farmland to forest because soil animals are more sensitive to vegetation changes under drought conditions (Schlaghamerský et al., 2014). Alternatively, the result might be because of the lower amount of data in the meta-analysis. While the regional differentiation characteristics of the effect of returning farmland to pasture on soil animal diversity were not evident with the increase in annual rainfall, returning farmland to forest can increase soil animal

DOI: http://dx.doi.org/10.15666/aeer/1805_63356353

diversity better the conversion to than pasture at amounts < 200 mm. The Simpson index value increased significantly at amounts of 200-400 mm, which could be interpreted by the increase in dominant species. At amounts > 800 mm, the Shannon index value decreased, which can be interpreted by the complicated comprehensive effect of both the increase in species richness and the decrease in species evenness. In particular, at amounts of 400-800 mm, returning farmland to forest (pasture) decreased the species richness but improved the species evenness. The specific reasons require further study.

Conclusions

Based on the results of our meta-analysis, the effects of returning farmland to forest (pasture) on soil animal diversity and its regional differentiation characteristics are complicated. The conclusions are as follows: (1) Overall, returning farmland to forest (pasture) had an important effect on soil animal diversity, which included the increase in species richness and the decrease in species evenness, and forests had a higher soil animal diversity than pastures; (2) In China, the effect of soil animal diversity showed different regional characteristics that largely depended on the specific geographic region and climate conditions, mainly temperature and rainfall, when returning farmland to forest (pasture).

In our study, a meta-analysis was used to investigate the effect of returning farmland to forest (pasture) on soil animal diversity, but in an actual underground ecosystem, many factors have different and comprehensive effects on soil animal diversity. Therefore, the analysis of regional differentiation characteristics and mechanisms requires further study. In addition, the reliability of some results may be reduced because effective data could not be obtained or the amount of data was relatively small, and therefore, future studies of these topics require further improvement.

Acknowledgments. We thank the library of the Northeast Institute of Geography and Agroecology of the Chinese Academy of Sciences for their support. We thank Michael S. Rosenberg for his help supplying the meta-analysis software. The present study was supported by the National Basic Research Program of China (No. 41430857).

(Received 21st Mar 2020; accepted 11th Aug 2020)

Abstract. The selection of suitable reference evapotranspiration (ETo) models in case of climatic data scarcity is a challenging task as it plays a pivotal role in agriculture and water resource management. Therefore, the research work deals with selecting the appropriate mass transfer reference evapotranspiration model using multi criteria decision technique (MCDM) in a semi-arid region of the southern part of Kingdom of Saudi Arabia i.e., Abha. The ten mass transfer methods with ten criteria (statistical indices) using available weather parameters from 1980 to 2018 have been illustrated in this study. Models were calibrated (1980-2006) and validated for the period (2007-2018). The objective weight was computed by criteria importance through inter criteria correlation (CRITIC) method and performance score by weighted sum model (WSM), weighted product model (WPM), weighted aggregates sum product assessment (WASPAS) and evaluation based on distance from average solution (EDAS) methods which in turn rank the evapotranspiration method. The rankings obtained from MCDM techniques were validated with ranking by GPI method using spearman ranking coefficient. The result from MCDM shows that Saif model is the best model and that also GPI yielded same result. The methodology applied in this study can be adopted in any other region which in turns proved to be beneficial for crop cultivators, crop advisors, researchers, and water resource management.
Keywords: *water management, CRITIC, WSM, WPM, WASPAS, EDAS*

Introduction

The reliable estimation of reference evapotranspiration (ETo) is a crucial part of regional water resources planning, net irrigation requirement, agriculture water requirements and to model the climate change effect (Pandey et al., 2016). The ETo can be measured directly by lysimeter, but the procedure is time consuming and expensive (Mehdizadeh, 2018). The ETo could be indirectly calculated using a site-specific energy balance or empirical models that typically includes meteorological data, altitude, and latitude. Of the indirect methods, FAO56-PM is the most effective method for the precise estimation of ETo (Allen et al., 1998; Berti et al., 2014). However, it demands high and reliable data quality which is difficult to achieve (Valiantzas, 2013). The precise quantification of the ETo forecasts is dependent on meteorological input data (Allen, 2008). The lack of climate data leads to the need for a simple empirical equation requiring less climate parameters, such as mass transfer, radiation and temperature methods (Sentelhas et al., 2010). Researchers in different regions such as India, Bosnia, Africa, China and Saudi Arabia have developed and applied many empirical equations (Pandey and Pandey, 2018; Cadro et al., 2017; Djaman et al., 2017; Lang et al., 2017;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63556375

Alblewi et al., 2015) as an alternative to lysimeter or standard FAO56-PM. However, mass transfer-based models involving lesser climatic parameters are among the most commonly used (Valipour, 2017). Such empirical equation should be assessed and validated against lysimetric or standard FAO56-PM technique due to regional constraints (Bogawski and Bednorz, 2014). In previous research, mass transfer methods typically only include evaluation of the studied model. Few research conducted evaluation calibration as well as validation of mass transfer equation (Djaman et al., 2016). In addition, rankings using performance assessment of different models are rarely studied against Standard FAO56-PM (Almorox et al., 2015). Alternatively, previous studies adopt few questionable statistical indices for performance evaluation of reference evapotranspiration, such as RMSE or MBE (Muhammad et al., 2019). Therefore, multiple statistical indices must be used to assess the performance of the mass transfer equation in order to obtain a realistic result. However, it is a challenging task for decision-makers (DMs) to find optimum decision. Therefore, powerful tool is desired for the final selection. Recently, researchers applied multi-criteria decision making (MCDM) techniques in the field of water resource management (Minatour et al., 2015; Makropoulos et al., 2008). To date, different MCDM methods have been developed for ranking purpose (Mardani et al., 2016) such as Water reservoirs (Srdjevic et al., 2004), urban water management (Zarghami et al., 2008), groundwater management (Pietersen, 2006), water conservation (Janssen et al., 2005), and irrigation planning (Gupta et al., 2000). Senent-Aparicio et al. (2017) assesses the effects of climate change in the Segura river basin (SE Spain) using SWAT and Fuzzy TOPSIS. Many studies have been carried out in the Kingdom of Saudi Arabia to estimate various ETo models against the FAO-56 Penman Monteith models (Abo-Ghobar and Mohammad, 1995; Al-Omran et al., 2004; ElNesr et al., 2010; Islam et al., 2019 a, b; Islam et al., 2020). In the study region, the ranking of mass transfer-based equation was rarely studied using MCDM. The goal of this study is to estimate (evaluate) ETo using ten mass transfer equations for the period between 1980-2018 and to further improve its efficiency, it is calibrated for the period between 1980-2006 and validated against standard FAO56-PM for the period between 2007-2018 and finally ranked by MCDM technique. The suggested methodology in the present study could be used in future for selecting best reference evapotranspiration model as a substitute to standard FAO56-PM in any region around the world. Also, the calibration improves the preciseness of ETo estimation. Moreover, the best selected model for estimating ETo could be used by agriculturist, hydrologist, policy and decision makers for the strategic planning of water resource management in the future.

Materials and methods

The present research was conducted to evaluate the performance of mass transfer-based ETo under limited climatic condition against standard FAO56-PM during evaluation (1980-2018), calibration (1980-2006) and validation (2007-2018) under semi-arid scenario Abha, KSA. The weather data is taken from Abha meteorological department at GPS location 18°14’N, 42°39’E. Such partitioning of calibration and validation period is attributed to the need for more data to train the algorithms, as suggested by Valipour (2015). The performance of these equations has been based on ten statistical criteria. The model ranking was based on MCDM techniques, where weightage is obtained by CRITIC method, while ranking by WSM, WPM, WASPAS

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63556375

and EDAS method. The ranking results from MCDM were compared with the outcome of GPI. The spearman ranking correlation was used to check the accuracy of the MCDM ranking. The fundamental objective of this study work is to choose the best model in the study region to replace the FAO56-PM model since this model required several climatic parameters that were sometimes difficult to achieve in the mountainous Abha region due to signal connectivity problems. Moreover, to select FAO56-PM as a standard against mass transfer models. The first important step is to validate its accuracy with respect to experimentally measured data.

The stepwise methodology adopted in the study is described by the flowchart in *Figure 1*.

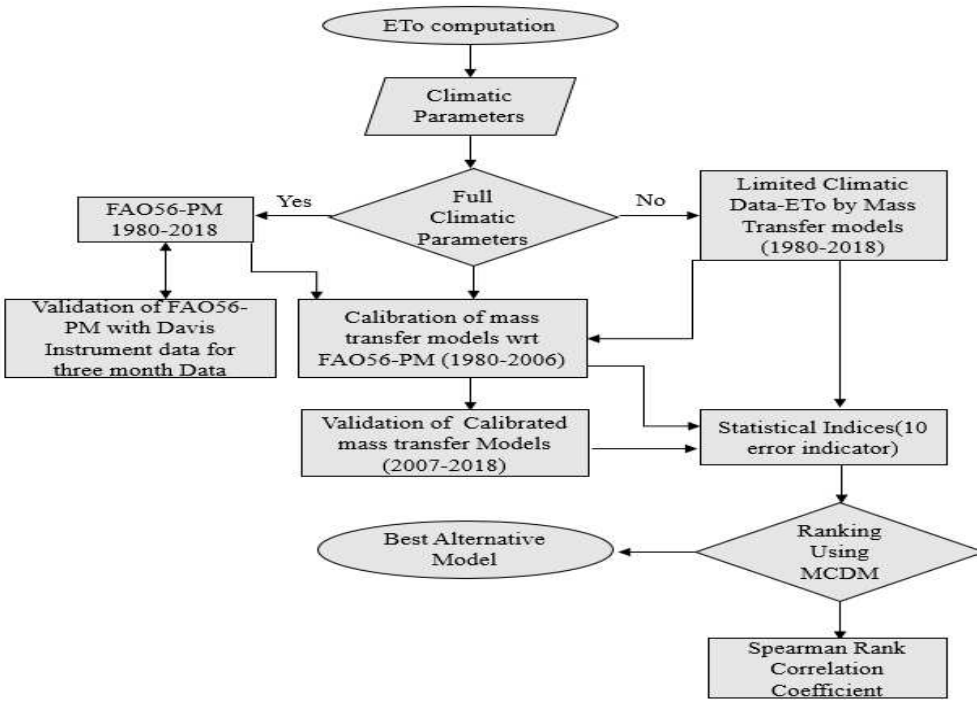

Figure 1. *Methodology (stepwise computation)*

Experimental setup

For the validation of the FAO56-PM model The measurement of the Davis Vantage Pro2 weather station at GPS location 18°15'06"N, 42°33'27"E was taken for a period of three months, i.e. from February to April, 2019. The schematic diagram for the weather station is given in *Figure 2*. The integrated instrument includes all sensors – anemometer, rain collector, temperature, humidity and solar irradiance – for measuring all required climatic parameters as well as measured evapotranspiration. The specific aim of reading from the Davis instrument is to verify the result from estimates of FAO56-PM using climatic data obtained from measurement of sensors against measured ETo from the weather station so that it can be used as a reference for other mass transfer model, as the FAO56-PM model is used in this analysis for evaluation, calibration and validation purposes. The outcome of plots of estimated FAO56-PM against measured ETo from Davis instrument reading (*Fig. 3*) indicates that there is a strong association between two readings with a very small error as indicated from the figure.

FAO56-PM and mass transfer model description

The estimation of reference evapotranspiration was done using well-recognized model i.e., FAO56-PM as given by *Equation 1* as well as ten mass transfer equation as given by *Equations 2-11* under data limitation in the study region between 1980-2018. Models selected for the study region are largely accepted under similar climatic conditions. Models are mentioned below.

Standard model (FAO 56-PM) (Allen et al., 1998)

$$ETo = \frac{0.408\times\Delta\times(Rn-G)+\gamma\times\left(\frac{900}{T+273}\right)\times u_2\times(e_s-e_a)}{\Delta+\gamma\times(1+0.34u_2)} \quad \text{(Eq.1)}$$

Empirical models (mass transfer)

Dalton (1802)

$$ETo = (0.3648 + 0.07223u_2) \times (e_s - e_a) \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63556375

Trabert (1896)

$$ETo = 0.408 \times 0.3075 \times \sqrt{u_2} \times (e_s - e_a) \quad \text{(Eq.3)}$$

Meyer (1926)

$$ETo = (0.375 + 0.05026u_2) \times (e_s - e_a) \quad \text{(Eq.4)}$$

Rohwer (1931)

$$ETo = 0.44(1 + 0.27u_2) \times (e_s - e_a) \quad \text{(Eq.5)}$$

Penman (1948)

$$ETo = 0.35 \times (1 + 0.24u_2) \times (e_s - e_a) \quad \text{(Eq.6)}$$

Albrecht (1950)

$$ETo = (0.1005 + 0.297u_2) \times (e_s - e_a) \quad \text{(Eq.7)}$$

Brockamp (1963)

$$ETo = (0.543u_2^{0.456}) \times (e_s - e_a) \quad \text{(Eq.8)}$$

WMO (1966)

$$ETo = (0.1298 + 0.0934u_2) \times (e_s - e_a) \quad \text{(Eq.9)}$$

Mahringer (1970)

$$ETo = 0.15072 \times \sqrt{3.6u_2} \times (e_s - e_a) \quad \text{(Eq.10)}$$

Saif (2019b)

$$ETo = (0.37 + 0.72u_2) \times (e_s - e_a) \quad \text{(Eq.11)}$$

where ETo is in mm day^{-1}. Rn and G represent net radiation and heat flux density of soil (MJm^{-2} day^{-1}) respectively. u_2 represent the velocity of wind at 2 m height (m s^{-1}). T represents mean temperature at height of 2 m (°C). (e_s–e_a) (kPa) represent vapour pressure deficit. Δ and γ denoted vapor pressure curve (slope) and psychrometric constant (kPa °C^{-1}) respectively. RH_{mean} = Mean Relative Humidity (%).

Calibration and validation of ET_O equations

To calibrate Mass Transfer Models. The graph between mass transfer equation and standard FAO56-PM equation was plotted and regression analysis was performed (Allen et al., 1998). The calibration technique adopted was defined by *Equation 12:*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63556375

$$ET_{FA056-PM} = a.ET_{EMP} + b \quad \text{(Eq.12)}$$

where $ET_{FAO56\ PM}$ denotes estimated result by FAO56-PM model while ET_{EMP} denotes the various empirical equation using in the present study (10-mass transfer equations). The constant a (slope) and b (intercept) called as calibrated empirical coefficients. The calibrated equations must have slope (a) close to unity while intersept (b) should be near to zero for best result. In order to estimate calibrated coefficient a (slope) multiply the slope of a regression line by inversing the slope in order to make the slope of equation closer to unity. Also to get b (intercept) closer to zero opposite sign value of intercept was added for new regression equation (Xu et al., 2013).

Evaluation criteria and global performance index (GPI)

For the GPI computation (*Eq. 13*), various statistical indices (error indictor) as described by *Equations 14-23* is required prior to the estimation of GPI. (Ali et al., 2019). The ideal value of all indices equals zero except for R^2 it is taken as 1. Despotovic et al. (2015) used the concept of GPI by normalizing the errors between the scale of 0 to 1 and further subtracting it from the equivalent medians then adding up the differences so obtained using the weight factors. The expression for GPI for the i^{th} model is as follows:

$$GPI_i = \sum_{j=1}^{10} \alpha_j \left(\tilde{y}_j - \tilde{y}_{ij}\right) \quad \text{(Eq.13)}$$

where α_j depends on statistical values (+1 value for recommended value 0 and -1 for recommended value 1 (e.g. R^2). $\tilde{y}_j$ and $\tilde{y}_{ij}$ are the median and scaled values, respectively.

Willmott and Matsuura (2005) applied MAE in their study as given by *Equation 14*.

Mean absolute error (MAE)

$$MAE = \frac{1}{n}\sum_{i=1}^{n}\left|ET_{O,Mi} - ET_{o,FAO56-PM}\right| \quad \text{(Eq.14)}$$

Root mean square error

$$RMSE = \left[\frac{1}{n}\sum_{i=1}^{n}\left(ET_{O,Mi} - ET_{o,FAO56-PM}\right)^2\right]^{\frac{1}{2}} \quad \text{(Eq.15)}$$

Mean absolute relative error (MARE)

$$MARE = \frac{1}{n}\sum_{i=1}^{n}\left|\frac{ET_{O,Mi} - ET_{o,FAO56-PM}}{ET_{O,Mi}}\right| \quad \text{(Eq.16)}$$

In the modelling of solar radiations, Behar et al. (2015) and Gueymard (2014) used U_{95} as given by *Equation 17:*

Uncertainty at 95%

$$U_{95} = 1.96(SD^2 + RMSE^2)^{\frac{1}{2}} \quad \text{(Eq.17)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63556375

Root mean squared relative error

$$RMSRE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(\frac{ET_{O,Mi}-ET_{o,FAO56-PM}}{ET_{O,Mi}}\right)^2} \quad \text{(Eq.18)}$$

Also in the modelling of global solar radiation, Li et al. (2013) applied RRMSE as given by *Equation 19:*

Relative root mean square error

$$RRMSE = 100 \times \frac{\sqrt{\frac{1}{n}\sum_{i=1}^{n}\left(ET_{O,Mi} - ET_{o,FAO56-PM}\right)^2}}{\sum_{i=1}^{n} ET_{O,Mi}} \quad \text{(Eq.19)}$$

Mean bias error

$$MBE = \frac{1}{n}\sum_{i=1}^{n}\left(ET_{O,Mi} - ET_{o,FAO56-PM}\right) \quad \text{(Eq.20)}$$

Correlation coefficient

$$R^2 = 1 - \frac{\sum_{i=1}^{n}\left(ET_{O,Mi} - ET_{o,FAO56-PM}\right)^2}{\sum_{i=1}^{n}\left(ET_{O,Mi} - ET_{O,Mi_{av}}\right)^2} \quad \text{(Eq.21)}$$

Maximum absolute relative error

$$erMAX = max\left(\left|\frac{ET_{O,Mi} - ET_{o,FAO56-PM}}{ET_{O,Mi}}\right|\right) \quad \text{(Eq.22)}$$

Moreover, Stone (1993) and Mulaudzi et al. (2015) applied t-statistics in the evaluation of solar radiation as shown by *Equation 23:*

$$t = \left[\frac{(n-1)MBE^2}{RMSE^2 - MBE^2}\right]^{\frac{1}{2}} \quad \text{(Eq.23)}$$

Multi criteria decision technique

For the implementation of MCDM techniques the weightages were computed using CRITIC method and for measuring the performance score of various empirical equations (alternatives), the models i.e., WSM, WPM, WASPAS and EDAS were used using the same statistical indices as implemented in GPI (criteria). Of all the criteria, the R^2 criteria is referred to as beneficial criteria and the other nine are non-beneficial criteria. The performance values (the higher the value the better the model will be) of the different ETo models will determine the promising model in the Abha region, which is one of the novelty in this research work. The adopted technique is as defined by *Figure 4*.

Objective weight

The objective weight is computed by criteria importance through inter criteria correlation (CRITIC) method. The method is first proposed by Diakoulaki et al. (1995)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63556375

and it is objective weighting methods. In order to find the contrast between criteria correlation analysis are done (Adalı and Işık, 2017). There is m feasible alternatives, A_i (i = 1, 2, …, m) and n evaluation criteria C_j (j = 1, 2, …, n) in the problem. The stepwise methodology is described below:

Step 1 To establish decision matrix X showing alternatives performance as compared to various criteria.

Step 2 The normalization of decision matrix is done using *Equation 24:*

$$r_{ij} = \frac{x_{ij-x_j^{min}}}{x_j^{max} - x_j^{min}} \quad \text{(Eq.24)}$$

where r_{ij} represent performance value of normalized decision matrix of i^{th} alternative on j^{th} criterion.

Step 3 The weight of the j^{th} criterion (w_j) is obtained as by *Equation 25,* where C_j is given by *Equation 26*:

$$w_j = \frac{c_j}{\sum_{i=1}^{m} c_j} \quad \text{(Eq.25)}$$

where

$$C_j = \sigma_j \sum_{i=1}^{m} (1 - r_{ij}) \quad \text{(Eq.26)}$$

C_j is the quantity of information contained in j^{th} criterion, σ_j is standard deviation of the j^{th} criterion and r_{jj}' is the correlation coefcient between j^{th} and j'^{th} criteria.

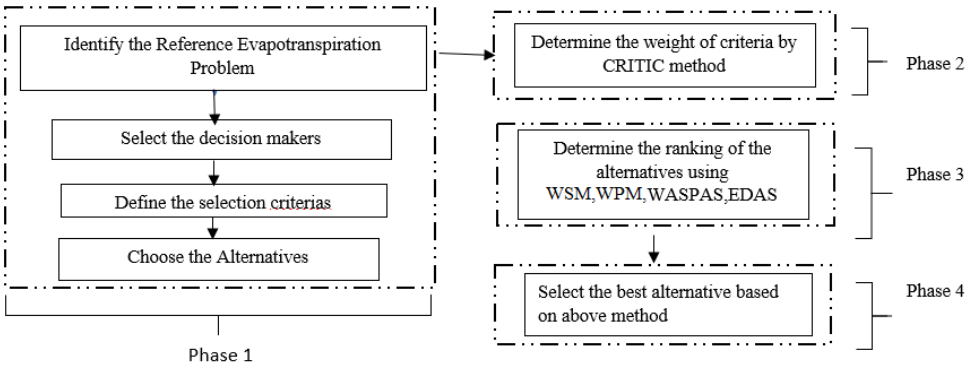

Figure 4. *Application of MCDM in selecting best ETo model*

Performance score

Weighted sum model (WSM) (Mann and Evangelos, 1989): The importance of i^{th} alternative by WSM technique is computed using *Equation 27:*

$$Q_i^{(1)} = \sum_{j=1}^{n} \bar{x}_{ij} w_j \quad \text{(Eq.27)}$$

Weighted Product Model (WPM) (Mann and Evangelos, 1989): The importance of i^{th} alternative by WPM technique is computed using *Equation 28:*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63556375

$$Q_i^{(2)} = \prod_{j=1}^{n} (\bar{x}_{ij})^{w_j} \quad \text{(Eq.28)}$$

Weighted Aggregates Sum Product Assessment (WASPAS) method: A joint generalized criterion of weighted aggregation of additive and multiplicative method is then proposed as given by *Equation 29* (Šaparauskas et al., 2011).

$$Q_i = 0.5Q_i^{(1)} + 0.5Q_i^{(2)} = 0.5 \sum_{j=1}^{n} \bar{x}_{ij}\, w_j + 0.5 \prod_{j=1}^{n} (\bar{x}_{ij})^{w_j} \quad \text{(Eq.29)}$$

Evaluation based on Distance from Average Solution (EDAS) method:

The methodology is adopted as studied by Keshavarz et al. (2015). The stepwise computation by EDAS method is described below:

Step 1. Criteria and alternatives are decided based on need of problem.

Step 2. Decision matrix of X based on selected criteria and alternatives are established as given by *Equation 30:*

$$X = |X_{ij}|_{n\times m} = \begin{bmatrix} x_{11} & x_{12} \dots & x_{1m} \\ \vdots & \vdots & \vdots \\ x_{n1} & x_{n2} \dots & x_{nm} \end{bmatrix} \quad \text{(Eq.30)}$$

where x_{ij} represents the value of i^{th} alternative with respect to j^{th} criterion based on performance.

Step 3. AV based on all criteria are determined using *Equations 31-32:*

$$AV = [AV_j]_{1\times m}, \qquad j = 1, \dots\dots, m. \quad \text{(Eq.31)}$$

$$AV_j = \frac{\sum_{i=1}^{n} X_{ij}}{n}, j = 1, \dots\dots, m. \quad \text{(Eq.32)}$$

Step 4. The PDA and NDA matrices are calculated based on the type of Criteria as given by *Equations 33-38:*

$$PDA = [PDA_{ij}]_{n\times m} \quad \text{(Eq.33)}$$

$$NDA = [NDA_{ij}]_{n\times m} \quad \text{(Eq.34)}$$

If criterion j is benefit criteria,

$$PDA_{ij} = \frac{max\left(0, (x_{ij} - AV_j)\right)}{AV_j} \quad \text{(Eq.35)}$$

$$NDA_{ij} = \frac{max\left(0, (AV_j - x_{ij})\right)}{AV_j} \quad \text{(Eq.36)}$$

If criterion j is non beneficial criterion,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63556375

$$PDA_{ij} = \frac{max\left(0, \left(AV_j - x_{ij}\right)\right)}{AV_j} \quad \text{(Eq.37)}$$

$$NDA_{ij} = \frac{max\left(0, \left(x_{ij} - AV_j\right)\right)}{AV_j} \quad \text{(Eq.38)}$$

Here, PDA_{ij} and NDA_{ij} indicate the positive and negative distances of i^{th} alternative from AV in terms of jth criterion, respectively.

Step 5. Weighted sum of PDA and NDA for all alternatives are determined by using *Equations 39-40:*

$$SP_i = \sum_{j=1}^{m} w_j \, PDA_{ij} \quad \text{(Eq.39)}$$

$$SN_i = \sum_{j=1}^{m} w_j \, NDA_{ij} \quad \text{(Eq.40)}$$

Here W_j indicates the weight of j^{th} criterion.

Step 6. For all alternatives, SP and SN values are normalised by using *Equations 41-42*):

$$NSP_i = \frac{SP_i}{\max\left(SP_i\right)} \quad \text{(Eq.41)}$$

$$NSN_i = 1 - \frac{SN_i}{\max\left(SN_i\right)} \quad \text{(Eq.42)}$$

Step 7. Appraisal score (AS) for all alternatives are calculated as:

$$AS_i = \frac{1}{2}\left(NSP_i + NSN_i\right) \quad \text{(Eq.43)}$$

where $0 \leq AS_i \leq 1$.

Step 8. According to the obtained AS, alternatives are ranked in descending order. The alternative with the highest AS is the best one among the other alternatives.

Results and discussion

This study presents a comparison (evaluation 1980-2018, calibration 1980-2006 and validation 2007-2018) of the selected ten mass transfer reference equations (alternatives) to the standard FAO56-PM. The models of mass transfer based were chosen in the study because of their rigor and comprehensiveness as defined by various researchers in the field of water resource management (e.g. Ali and Shui, 2009; Tabari et al., 2013). Average Monthly ETo per day (mm/day) during evaluation, calibration and validation period is given in *Tables 1-3* while the seasonal variation as shown by *Table 4*. The performance of different mass transfer equations was evaluated through

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63556375

ten statistical indices (criteria) as described in the methodology. The criterion weight of the different indices was determined using the CRITIC method, whereas four MCDM techniques i.e., WSM WPM, WASPAS and EDAS were used to rank the mass transfer method. In addition, the GPI ranking has been computed to validate the result using MCDM techniques. The rank correlation coefficient for Spearman was determined between MCDM and GPI technique to check the accuracy of MCDM technique. When comparing the reference evapotranspiration by selected mass transfer model with standard FAO56-PM in terms of correlation coefficient and error indices (*Fig. 5*) during the evaluation process, it was observed that all selected equations bears a strong correlation (R^2 ranges 0.89 to 0.96) with FAO56-PM with the highest correlation observed in the Saif model and lower by Trabert model. In addition, when evaluating the output of the same equations in terms of the error indicator, Saif model achieved the highest precision. The results assessed from 1980-2018 showed that some of the method of mass transfer performed better without calibration like Albrecht and Saif model, which is in agreement with Islam et al. (2019b). Similar findings were previously obtained after evaluating six ETo equations for the Senegal River Delta (Djaman et al., 2016). The results are in accordance with the analysis done by Djaman et al. (2015) under Sahelian conditions in the Senegal river valley. These models use the temperature and wind speed observation to estimate the ETo values (Shiri, 2018). Though in certain regions such models may provide accurate results (Xu and Singh, 2002; Tabari et al., 2013). The accuracy of the results of these models as described in Kiafar et al. (2017) may be reduced by low aerodynamic effects. Moreover, wind speed and air temperature were determined at different altitudes resulting in a significant number of related or equivalent equations. Therefore, it will be difficult to apply data from one location and/or height to another and apply a model developed in a specified region at another location with certainty (Shiri, 2018). Like the other ETo models, local calibration is a big drawback of such models. To overcome such problems, the comparison was made again with regard to correlation coefficients and error indicators while calibrating the whole equation against standard FAO56-PM (*Fig. 6*), All chosen equations were shown to have a high correlation (R^2 ranges 0.91 to 0.98) with the FAO56-PM with the highest correlation detected in the Saif model and lower in the Meyer and Trabert model. The Saif model also achieved the highest accuracy while observing the performance of the same equations in terms of the error indicator. The models are calibrated similar to the studies of Irmak et al. (2003) and Xu and Singh (2001). It has been found from the inspection of the output during calibration that the model calibration significantly enhanced the efficiency of all equations. Also same result noticed while validating the calibrated equations (*Fig. 7*) with (R^2 ranges from 0.872 to 0.921). The high correlation observed by Saif model and lower by Trabert model. Which is similar to result obtained by Bogawski and Bednorz, 2014 in study in Poland. Conversely Meyer equation perform better in north-western Ontario, Canada (Singh and Xu, 2002) Also while observing the performance of same equations in terms of error indicator the highest accuracy was achieved by Saif model. The result obtained is in agreement with Islam et al. (2019b). Additionally, the findings of the research are in agreement with Kisi and Zounemat Kermani (2014). From the study it has been confirmed that in some region overestimated the ETo by Mass transfer (Valipour, 2015; Winter et al., 1995) while other underestimated (Tabari et al., 2013; Djaman et al., 2015). Azhar and Perera (2011) and Zhai et al. (2010) calibrated ETo models and concluded that calibration can be used to modify ETo with multi-station data to improve its accuracy. Bormann (2011)

DOI: http://dx.doi.org/10.15666/aeer/1805_63556375

examined various models of mass transfer to examine climate change in Germany and noticed a substantial difference in the performance of all models. Therefore, MCDM technique was applied to rank different model based on performance.

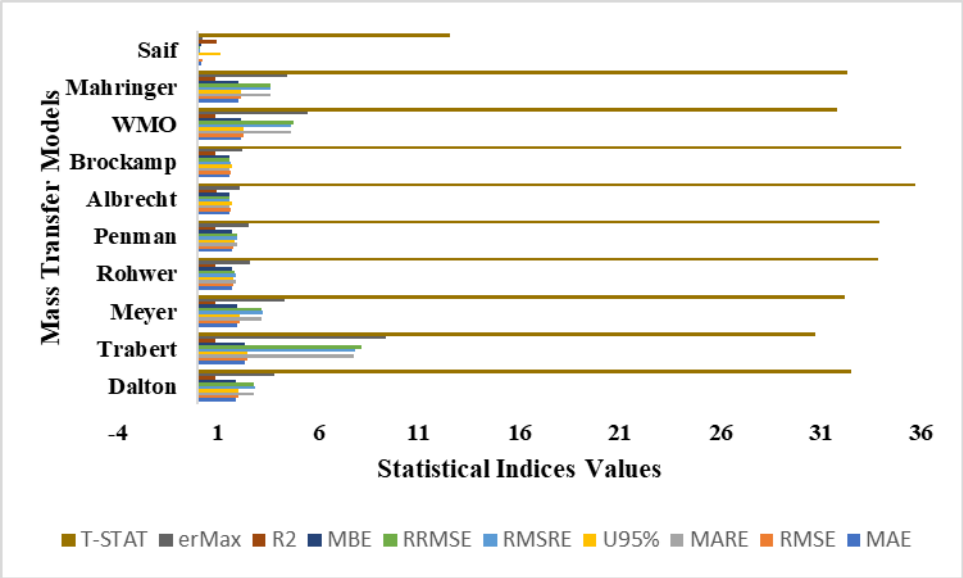

Figure 7. *Error indices of all model during validation*

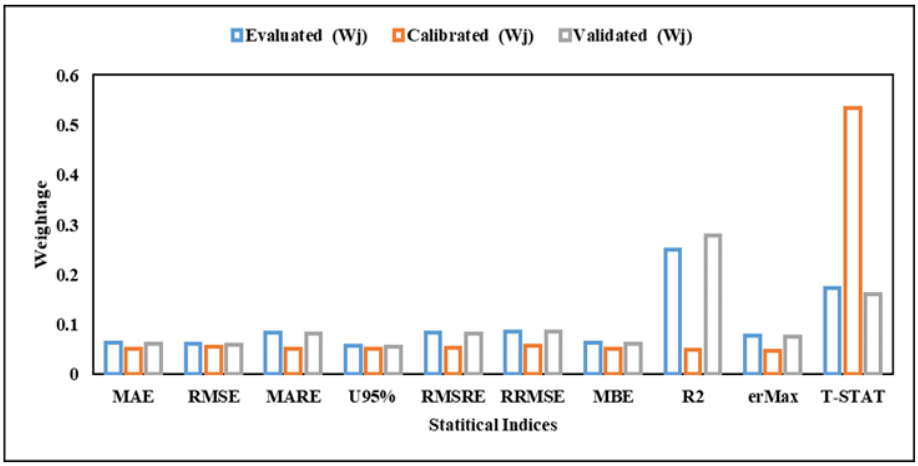

Figure 8. *Weightage by CRITIC method*

The performance score obtained by WSM, WPM, WASPAS, EDAS Models during evaluation calibration and validation. Furthermore, the performance score for validation as described in *Figures 9-11* is computed by GPI. The findings clearly show that the Saif model is the one that better fits the study region. The ranking of the MCDM technique shows that Saif model is the best model in the study area. In addition, GPA validates the same result as indicated (*Fig. 12*). Trabert model showed equally worst performance during evaluation, calibration and validation respectively. Also, spearman's ranking correlation is estimated between MCDM and GPI as shown in *Table 5*. This study finds strong concordance among the results of three different MCDM methods. Although the low-ranked alternatives were not always positioned alike, the best and second-best choices were the same for all three results. Similarly, the least preferred alternative was also the same. The important fact to note here is, despite the variety of data synthesis procedures and level of intricacy involved with these methods, the suggestions were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63556375

similar for the preferred alternatives. Since most of the water supply related problems seek to find the best suitable alternatives (Hajkowicz and Higgins, 2008; Sikder et al., 2015; Tirth et al., 2020), it could be inferred from the findings of the study that both simple and comprehensive MCDM methods yield the same output.

Conclusions

This study was conducted to evaluate (period: 1980-2018), calibrate (period: 1980-2006) and further validate (period: 2007-2018) ten reference evapotranspiration models against standard FAO56 PM model in southern region (Abha) of Saudi Arabia. The performance scores (ranking) of aforementioned alternative models were computed based on ten statistical indices. The overall effect of these ten statistical indices were

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63556375

computed by multicriteria decision technique such as CRITIC (weightage of statistical indices), WSM, WPM, WASPAS and EDAS (ranking of alternative models). The ranking by MCDM technique were compared by GPI ranking using spearman ranking coefficient. The following inference can be made after achieving aforementioned objectives:

1. This work provides an integrated decision support tool for evaluating water resource management strategies

2. The calibrated equation performs better and hence provide consistent result.

3. The ranking by MCDM techniques (WSM, WPM, WASPAS and EDAS) shows that Saif model gives best performance while estimating reference evapotranspiration also GPI confirms the same.

4. MCDM models proved to be a versatile technique for selecting the most promising model in the study region.

5. The results are likely to help minimize the error in estimating reference evapotranspiration, and in addition the approach implemented in this study can be used in regions around the world with similar topography and climatic conditions.

6. Further research are required to assess the impact of using a reduced data set for daily ETo estimation hourly. In addition, in future the seasonal shifts in ETo must also be examined. Additionally, similar problem can be ranked by other available MCDM methods in the future.

(Received 24th Mar 2020; accepted 20th Aug 2020)

Abstract. The present study was evaluated the application of humic acid (HA), which possess multifaceted biological action, and plant growth promoting rhizobacteria (PGPR) inoculation to improve the morphologic performance, yield and seed quality of safflower under different water regimes in the Eastern Anatolia region of Turkey. In a 2-year field trial, the two humic acid level (200 and 400 kg ha^{-1}) and the two rhizobacterial strains (*Bacillus megatorium* M3 and *Bacillus subtilis* OSU142) in together with control treatments were evaluated under irrigated and rainfed conditions using randomized complete block design with a split-split plot arrangement. Bacterial strains and humic acid levels highly increased plant growth, seed and oil yields, and seed nutrient contents under irrigated and rainfed conditions. However, the combined application of the OSU142 strain with 400 kg HA ha^{-1} resulted in the greatest enhancement of safflower growth and yield under irrigated conditions, and seed and oil yields increased by 101.8 and 127.6% with treatment of 400 HA + OSU14 respectively. Moreover, the integrated use of humic acids and PGPR inoculation relatively showed additive effect in the growth and yields of safflower under rainfed conditions, and increased by 186.5 with treatment of 400 HA + OSU142 and 257.1% with treatment of 400 HA + M respectively.
Keywords: *safflower, PGPR, humic acids, energy crop, agricultural sustainability, crop performance*

Introduction

Safflower (*Carthamus tinctorius* L.) is a dryland oilseed crop with a very long cultivation history. It is widely grown for food, medicinal, cosmetic and biofuel purposes over a wide range of geographical areas from Far East to American continent (Ekin, 2005). Nowadays, scientific interest in this species has gained importance as a result of mainly their utilization increase in human nutrition and non-food production due to their high-quality vegetable oil. In safflower oil, the major fatty acids are linoleic and oleic acids and their relative proportions determine the safflower oil's functional properties and nutritional value (Cao et al., 2013; Rapson et al., 2015). On the basis of the nutritional value of safflower oil, oil quality, in fact, shows similarity to that of olive oil and is valued for human health reasons since the high unsaturated fatty acids (linoleic and oleic acids) contents leads to significant reduction in blood cholesterol levels (Dajue and Mündel, 1996; La Bella et al., 2019). In this regard, safflower would seem to be more favorable when compared to those of the oils of major oilseed crops such as sunflower, rapeseed, maize and soy commonly used for food and non-food sector in the semi-arid and marginal croplands of the world and central-eastern Turkey (Ekin, 2005; Kizil et al., 2008; Ozturk et al., 2008). In general, oilseed crops for application in the non-food sector, especially regarding biofuel research and development projects, have attract intensive attention in recent years in Turkey. In this regard, safflower appears to be more suitable as a dryland oilseed crop that can adapt

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63776403

highly to chancing climate and soil conditions for the agriculture and biofuels industry among other widely cultivated crops (Nosheen et al., 2018). However, it is characterized by spiny nature and low seed yield which have devitalized farmers from taking on its cultivation in the many countries including Turkey in dryland farming (Ekin, 2005; La Bella et al., 2019).

To maintain high yielding potential in safflower cultivation is firstly required water stress and soil fertility management in semi-arid and highland regions typically characterized by variable and unpredictable inadequate rainfall, poor moisture storing capacity of soils, large diurnal ranges in temperature and frequent strong winds (Ozturk et al., 2008). Due to readily deterioration of soil, water and other environmental resources in those regions compared to agriculture areas in different regions of the world, future food and energy demand and its created pressures are likely to further exacerbate the damaged soil health and effects of drought (Somerville and Briscoe, 2001). Therefore, it is imperative to protect soil health and productivity and to enhance the water stress tolerance of crops under the changing environmental conditions. In particular, drought tolerance will likely become increasingly significant for producing steady yields in all oilseed crops under global climate change (Comas et al., 2013). Although the safflower is well adapted to dryland cropping system, its agronomic performance and seed quality is particularly dependent upon climatic factors such as temperature and rainfall in flowering and seed maturation stages, and is largely affected by water stress conditions in these periods (Weiss, 1983; Kumar et al., 2016; La Bella et al., 2019). There are yet no economically current technological vehicles to facilitate plant production under drought. But the introduction of novel techniques to increase water stress tolerance is crucial for increasing safflower oil-based food and biofuel production. In this context, the role of beneficial rhizosphere microorganisms is gaining premium importance in the development of climate change resilient agriculture and stress management.

The rhizosphere of plants, the interface between plant roots and soil, is widely colonized by soil microorganisms (e.g. plant growth promoting rhizobacteria, PGPR). After inoculated on seed, PGPR can successfully colonize plant roots and improve plant growth directly by either releasing of plant growth stimulating compounds (e.g. phytohormones such as cytokines or auxins) or improving in nutrient uptakes (e.g. N_2 fixing, P-solubilizing or siderophore release increasing nitrogen, phosphorus and iron availability, respectively) or indirectly by decreasing the harmful effects of pathogens via synthesis of antibiotics. Thus, the plant-bacteria symbioses could stimulate plant growth and yield by reducing dependency on traditional fertilizers, enhance the plant tolerance to both biotic and abiotic stresses, and serve to keep soil productivity and environmental health. However, the density and structure of the rhizosphere bacteria in the soil are dictated by soil pH, organic matter content, water and nutrient availability throughout the root surface (Bossio et al., 1998; Drenovsky et al., 2004; Garcia-Pausas and Paterson, 2011; Backer et al., 2018). On the other hand, biogeographical patterns including topographic and climatic variations have also the powerful impacts on density of bacterial community (Kristin and Miranda, 2013). In the world, several PGPR species (*Azotobacter, Azosprillum, Bacillus, Serratia, Enterobacter, Pseudomonas, Klebsiella* and *Variovorax*) as rhizosphere-colonizing microorganisms were the subject of intense study in the field or laboratory in various areas of the many countries in recent years. In this context, it was generated valuable information on the various field crops, such as sugar beet and barley (Cakmakci et al., 200 2006), sugarcane (Silva et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63776403

2017), sunflower (Shadid et al., 2012), wheat (Rosas et al., 2009; Hungria et al., 2010; Rana et al., 2012; Chandra et al., 2019), rice (Lucas et al., 2009), bean (Hoyos-Carvajal et al., 2009), canola (El-Howeity and Asfour, 2012), maize (Thonar et al., 2017) and soy (Cassán et al., 2009). However, each plant's responses to rhizobacteria cannot be expressed by admitted valid comprehension and this actually presents both an opportunity and a challenge. The capability of soil bacteria to reveal favorable effects on plant growth can be impaired under field conditions since other exterior factors come into play (Nelson, 2004; Backer et al., 2018; Chandra et al., 2019). Therefore, it has recently been demonstrated that the integrated use of humic substances and PGPR in agricultural practices could be envisaged as environmental-friendly technology to promote crop yield and quality. In addition, this sustainable agricultural approach can be a good means to enhance vegetable oil and biofuel production in water-deficit regions.

Humic substances, consisting of soil organic matter decomposition, are of crucial important for plant physiology and environmental protection by improving structure and fertility of soils and their resistance to erosion. However, they are a valuable complementary of soil microbiota, since they have natural hormone-like structure and exhibit biological activities. In addition, humic substances are show capacity to regulate the uptake and transport of nutrients to plants, improve crop yield and plant resistance to stress and effect root hair formation and lateral root development. Due to humic substances have a complex structure, which explains their versatile biological activity, the studies have majored on their interactions and structure with plants and associated rhizosphere microorganisms such as PGPR in controlled laboratory experiments. However, critical assessments of such interactions under real field conditions are necessary to quantify the current benefits on productivity, in view of improving practical modern technologies for advanced and sustainable agricultural systems purposed in enhancing crop yield and quality. Some authors (Canellas et al., 2013; Esringu et al., 2016; Schoebitz et al., 2016; Silva et al., 2017) suggested that co-application of humic substances and PGPR inoculation in several crop species grown under field conditions can increase significantly macro- and micro nutrient uptakes and root growth, which in turn led to the increase crop yield. Moreover, these authors reported that stimulation of biological activity by humic acid can further enhance nutrient cycling through the action of microorganisms. Another reason given for increased crop yield, was also attributed to be highly adaptation of plant to several stress conditions by integrated use of humic substance and PGPR (Nardi et al., 2009; Dobbss et al., 2010; Busato et al., 2012; Puglisi et al., 2013; Canellas and Olivares, 2014; Olivares et al., 2015). Previous studies also reported that inoculation of specific plant growth promoting bacteria species like N_2-fixing *Bacillus subtilis* and phosphorus solubilizing *Bacillus megatorium* instead of chemical fertilizers can serve as an environmental friendly alternative application and improve plant nutrition by increasing N and P uptake by plants (Cakmakci et al., 2001; Esitken et al., 2003). But, up till now no data are present in respect of the use of this *Bacillus* strains in safflower plants. However, only limited data are available with respect to the use of *Pseudomonas, Azosprillum* and *Azotobacter* spp., which were used to increase nitrogen uptake (Mirzakhani et al., 2009; Soleymanifard and Sidat, 2011; Sharifi et al., 2017; Nosheen et al., 2018), root morphology (Nosheen et al., 2011), and protein quantity and quality of seeds (Nosheen et al., 2016) in safflower.

Safflower is an important oilseed plant that grows optimally in dry conditions, but is negatively affected by drought in the phenological periods (i.e. germination, stem elongation and branching, flowering), which are the most critical periods in terms of plant moisture requirement (Dajue and Mündel, 1996; Ekin, 2005). Thus, the combined use of humic acids and PGPR inoculation was explored as a possibility for improving agronomic performance of the safflower under irrigated and rainfed conditions in arid and semi-arid regions.

Materials and methods

Site characterization

The safflower (Carthamus tinctorius L.) variety Remzibey-05 was investigated for its response to plant growth promoting rhizobacteria inoculation and humic acid application under irrigated and rainfed field conditions. The field experiment was carried out at the research farm located in Ahlat district (38° 46' N and 42°30' E with an altitude of 1722 m) in the Eastern Anatolia region of Turkey during the cropping seasons 2010 and 2011. The climate of experimental area is continental with 562.6 mm total rainfall in long-term average (1958-2017), concentrated in winter. Annual mean air temperature and relative humidity values are 9.3 °C and 63.8%, respectively. Maximum temperature is 22.8 °C in August and minimum temperature is -2.5 °C in January. The weather data were collected from weather station close to the fields (*Table 1*). In 2010 and 2011 years, mean temperature values were 16.5 °C and 16.0 °C and amounts of rainfall were 291.0 mm and 269.4 mm, respectively. The soil of experiment site was a silt-clay-loam, including 1.60% organic matter and pH 7. total N 0.15 g/kg, 6.8% CaCO 1.16 dS/m electrical conductivity (EC), 0.15 g kg^{-1} total N, 7.95 mg kg^{-1} available P, 3.30 mg kg^{-1} available Mn, 196 mg kg^{-1} available K, 5.85 mg kg^{-1} available Fe, 1.44 mg kg^{-1} available Zn and 0.59 mg kg^{-1} available Cu.

Plant material and experimental design

Safflower seeds were obtained from the Transitional Zone Agricultural Research Institute, Republic of Turkey Ministry of Agriculture and Forestry. The Remzibey-05 is an early-maturing safflower variety with Turkey of origin, drought-tolerant, spiny, open-pollinated, yellow flower color, white seed color, 32-35% oil content, high-oleic oil type and approximately 1.00 t ha^{-1} dryland seed yield. The field experiments lay out was split-split plot design in randomized complete block with three replicates, with water regimes (irrigated and rainfed) as the main plot, humic acid (Control: without the addition of humic acid, 200 kg ha^{-1} and 400 kg ha^{-1}) as the sub plots, and PGPR strains (Uninoculated control, *Bacillus megatorium* M3 and *Bacillus subtilis* OSU-142) as the sub-subplots. The humic acid doses were prepared by Agro-Lig™ (commercial products - 75% total organic matter, 65% total humic acid derived from leonardite, 22% max moisture, pH 3.5-5.5) in granule form.

Bacterial strains, culture media and seed bacterization

Gram-positive, non-pathogenic *Bacillus subtilis* OSU-142 and *Bacillus megatorium* M3 strains were kindly obtained from Atatürk University-Turkey. In the previous studies, strains used in this study were determined that they showed capacity to grow in N-free conditions, for hormones (IAA, GA_3),1-aminocyclopropane-1carboxylate (ACC)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63776403

deaminase and siderophore production, and to solubilize phosphate and to N_2-fixing (Cakmakci et al., 2001; Orhan et al., 2006). For the inoculation of safflower seeds, bacterial cultures were grown on nutrient agar for routine use. Subsequently, single colony was transferred to 500 mL flasks containing nutrient broth. The cultures were incubated on a rotating shaker (150 rpm) overnight at 28 °C aerobically, and then bacterial suspensions were diluted to final concentration at cell density of 1 x 10^9 colony forming unit ml^{-1} by sterilized and distilled water (sdH_2O). Safflower seed surface was disinfected by dipping first in 3% (v/v) sodium hypochlorite for 3 min and then 95% ethanol for 1 min. After surface disinfection, the seeds were washed 3–4 times with sdH_2O. Approximately, 5 g sugar (50 mg mL^{-1}) was added to each Erlenmeyer flasks, and the surface-sterilized seeds were soaked separately in this suspension. The seeds were treated with the bacteria in the flasks by shaking at 80 rpm for 2 h. For the uninoculated control, seeds were treated with sterile nutrient broth supplemented with sugar. After shaking, the seeds were taken out and air-dried on sterile Whatman filter paper sheets overnight.

Main cultivation practices and measurement of morphologic and yield data

The field experiment was carried out under rainfed and irrigated conditions. After soil was ploughed and harrowed, safflower seeds were sown at 40 cm row spacing on early April in both years. Overall, plant density was 40 viable seeds m^{-2} and sub-subplots area was 16 m^2. At the start of the field experiment, a basal dose of N (urea) and P (Triple Super Phosphate), at rates of 300 and 150 kg ha^{-} which might support root morphology and plant growth improvements in safflower (Nosheen et al., 2011), were applied to the plants. Humic acids were applied in the soil according to layout at sowing time and then mixed well in the soil. In the study, irrigation was applied based on the phenological periods (stem elongation and flowering), which are the most critical periods in terms of plant moisture requirement in safflower. This application called as supplemental irrigation, as a notion, refers to providing significant increases in yield by applying irrigation water in support of rainfall in plants grown under rainfall conditions as the most accurate approach in irrigation water management in the arid and semi-arid regions. In the study, the soil moisture has been allowed to fluctuate only at field capacity range, so soil water potential was controlled in the range between -10 and -20 kPa as indicated by Tensiometer at a depth of 15 cm below the soil surface in the irrigated treatment. Water was applied uniformly across all irrigated plots. Each of irrigations applied in the stem elongation (June) and flowering (July) growth periods represented a total of approximately 48 mm and 80 mm in 201 and 56 and 85 mm rainfall equivalent, respectively. Therefore, the total quantity of water received in irrigation conditions was 419.0 mm and 410.4 mm in the five-month cycle in 2010 and 2011 years, respectively. Weeds were controlled by hand. Safflower plants were harvested at the physiological maturity in mid-August in both years. Seed moisture content was also below 8.00%.

Morphologic and yield characterization were performed following the guide of International Plant Genetic Resources Institute for safflower. Each treatment was evaluated for 5 pre-harvest and 17 post-harvest traits. The pre-harvest traits were stem diameter (mm), plant height (cm), number (no.) of primary branches per plant, capitilum diameter (cm) and number (no.) of capitula per plant. Data was recorded for twenty healthy plants in each of 54 experimental plots. The post-harvest traits were number (no.) of seeds per capitulum, fertile and sterile seed percentage (%),1000-seed weight (g), seed oil and protein contents (%), seed, oil and protein yields (t ha^{-1}) and mineral composition of safflower seeds (mg/kg). Plant height was measured as main shoot length from soil surface to the uppermost capitulum of the plant. Diameters of stem and capitilum were measured by digital caliper. The total number of capitula and branches was recorded as number of capitilum and primary branches per plant. Thousand seed weight was measured as seed weight of 1000 achenes from each of plants in grams. Seed yield was recorded at the harvest area of 7.2 m^2 after removing the two rows border plants all around. Seed oil, protein and nutrient contents were analyzed in three replicates. Oil content was measured by Soxhalet extraction method using hexane as solvent. Protein content in seed samples was calculated from nitrogen using the conversional factor of 6.25 and determined by the Kjeldahl method for nitrogen content measurement in safflower. Magnesium (Mg), potassium (K), calcium (Ca), phosphorus (P), zinc (Zn), manganese (Mn), copper (Cu) and iron (Fe) contents in seed samples were determined by wet-digesting the ground seeds using HNO_3:$HClO_4$ (6:2 v/v) by Advanced Microwave Digestion System. Subsequently, mineral nutrients composition was evaluated by Inductively Coupled Plasma Optical Emission Spectrometry (iCAP 6000 SERIES, ICP Spectrometer) as per manufacturer's instructions.

Statistical analysis

In order to reveal if data are suitable for normal distribution and homogeneity, the Kolmogorov-Smirnov normality and Bartlett homogeneity tests were used. Afterwards, analysis of variance (ANOVA) was used to compare the effects of water regimes, humic acids and PGPR treatments interactions for 2 years using PROC GLM of SAS 9. Mean comparisons were conducted using Duncan multiple comparison test (DMRT). All the experiments were performed in three replicates and data were presented as descriptive statistics (means; n = 3). Since there were no significant year x treatment interactions for the tested most traits ($p < 0.05$), 2-year data were combined and used for the mean comparisons.

Results

Analysis of pre-harvest morphologic traits

The analysis of combined ANOVA showed significant differences by the tested factors (humic acids and PGPR inoculation) under both irrigated and rainfed conditions, as pointed by variations in multiple biometric characteristics of safflower growth (*Table 2*). Results from analysis of pre-harvest morphologic traits indicated that plant height significantly differed between soil moisture conditions. On average, the highest plant height was recorded in irrigated conditions. Plant height significantly ($P < 0.01$) increased with increasing doses of humic acid. Likewise, inoculations of OSU142 and M3 significantly ($P < 0.01$) increased plant height by 26.20 and 15.57%, over that of the uninoculated control, respectively. Significantly ($P < 0.01$) interactions were observed for W x HA, W x P, HA x P and W x HA x P (*Table 2*).

The mean values for the W x P and W x HA interactions (*Table 3*) revealed that, for both irrigated and rainfed conditions, the OSU142 strain and the 400 kg HA ha^{-1} treatment had the highest values for plant height, over their respective control treatments. Similarly, the interaction of HA x P (*Table 4*) indicated that humic acid and rhizobacterial inoculation increased the plant height, with 400 kg HA ha^{-1} and the OSU142 strain being the most effective. Moreover, there was significant ($P < 0.01$) W x HA x P interaction (*Fig. 1*) for plant height, and the highest plant height was recorded for plants treated with 400 HA + OSU142 in irrigated condition maintaining an increase of 47.8%, compared to their respective non-HA uninoculated control.

Significant differences ($P < 0.01$) in the stem diameter and number of primary branches per plant of safflower were observed for water regimes, HA, and PGPR inoculation (*Table 2*). Irrigation and HA applications considerably increased the both stem diameter and number of primary branches per plant of safflower, with the highest values noted for the 400 HA ha^{-1} treatment. PGPR inoculation also significantly increased stem diameter and number of primary branches, with higher values noted for OSU142 (*Bacillus subtilis*) than for M3 (*Bacillus megatorium*) and the uninoculated control. In addition, there were significant ($P < 0.01$) W x P and HA x P interactions for the stem diameter of safflower (*Table 2*). Mean values for the W x P interaction (*Table 3*) suggested that the highest stem diameter (7.97 mm) was for the OSU142 strain under irrigated conditions maintaining an increase of 22.7%, over their respective control treatment. The interaction of HA x P (*Table 4*) revealed that, for the 200 or 400 HA + OSU142 and the 400 HA + M3 treatments had the highest values for stem diameter (7.5 7.39 and 7.50 mm, respectively).

Number of capitula per plant and capitilum diameter for safflower were severely decreased by rainfed condition, whereas it increased with the application of HA and PGPR inoculation (*Table 2*). Furthermore, significant ($P < 0.01$) interactions were observed for W x HA, W x P and HA x P for these parameters. The W x HA and W x P interactions (*Table 3*) revealed that the highest number of capitula per plant and capitilum diameter for safflower was for the 400 kg HA ha^{-1} treatment and the OSU142 inoculation under the irrigated conditions, whereas the lowest values were observed for the without HA control and the uninoculated control under rainfed conditions. Likewise, the HA x P interaction showed that OSU142 significantly enhanced number of capitula per plant and capitilum diameter in the 400 kg HA ha^{-1} treatment by 104.6% and 22.2% over that of without HA and the uninoculated control, respectively. Mean values for the

DOI: http://dx.doi.org/10.15666/aeer/1805_63776403

W x HA x P interaction (*Fig. 2*) suggested that the highest number of capitula per plant was recorded for plants treated with 400 HA + OSU142 under irrigated conditions maintaining an increase of 63.6%, whereas the plants submitted to rainfed condition showed considerably increase rate of 181.4% in number of capitula per plant in the 400 HA + OSU142 treatment, over their respective control treatments.

Analysis of post-harvest seed traits

The post-harvest seed traits of safflower (number of seeds per capitulum, thousand seed weight, and fertile and sterile seed percentage) were significantly ($P < 0.01$) affected by all the treatments (*Table 5*). Irrigation application considerably increased the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63776403

number of seeds per capitulum, thousand seed weight, and fertile seed percentage, whereas the highest sterile seed percentage was noted for the rainfed condition. HA and rhizobacterial inoculation increased all the seed traits of safflower, except for sterile seed percentage. *Table 5* shows the significant ($P < 0.01$) interactions of W x HA, W x P, HA x P and W x HA x P for number of seeds per capitulum.

The W x HA interaction (*Table 3*) revealed the highest number of seeds per capitulum for the 200 kg HA ha^{-1} treatment under irrigated condition, from that of the non-HA treatment. Conversely, it was also noted increased with increasing humic acid under rainfed condition. The W x P interactions means (*Table 3*) indicated the highest number of seeds per capitulum of safflower was noted for all the bacterial inoculations under irrigated conditions, whereas the plants inoculated with the OSU142 strain increased the number of seeds per capitulum under both irrigated and rainfed conditions by 12.2 and 18.8%, respectively, over their respective control treatments. Similarly, HA x P interactions means (*Table 4*) revealed that all the bacterial inoculations significantly increased the number of seeds per capitulum in all levels of HA treatment, from that of the control. In addition, mean values for the W x HA x P interaction (*Fig. 3*) revealed

DOI: http://dx.doi.org/10.15666/aeer/1805_63776403

that the applications of 200 HA + M3 and 200 HA + OSU142 under irrigated conditions resulted in the highest number of seeds per capitulum by increases of 41.4% and 36.5%, whereas the plants submitted to rainfed condition showed considerably increase rates of 28.7% and 27.0% in number of capitula per plant in the 400 HA + M3 and 400 HA + OSU142 treatments, over their respective control treatments.

conditions. On the other hand, all HA and PGPR treatments enhanced the 1000 seed weight by 8.6 and 6.3%, respectively, over that of control (no HA or uninoculated). Similarly, fertile seed percentage significantly increased with increasing doses of HA and all the PGPR inoculations, whereas it considerably reduced the sterile seed percentage of safflower. The interactions between HA and PGPR were not significant for these parameters, but W x HA interaction was significant ($P < 0.05$) for 1000 seed weight only (*Table 5*). The highest values for 1000 seed weight were noted for all the HA doses under irrigated condition, maintaining an increase from 8.7 to 11.0%, compared to the control (*Table 3*).

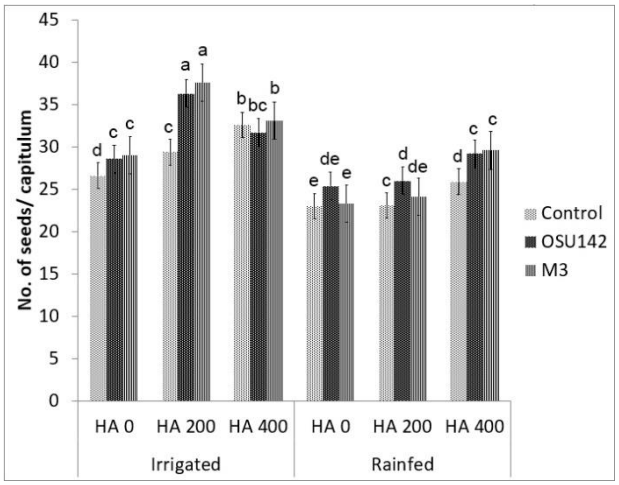

Figure 3. *The interactive effect of water regimes, humic acids and PGPR on the number of seeds per capitulum of safflower. Different letters along with water regimes, humic acids and PGPR treatments indicate significant differences in access treatment means from three replications tested at $P \leq 0.05$ according to DMRT*

Analysis of seed quality and yield traits

Seed oil and protein contents were significantly affected by all the treatments (*Table 6*). Irrigation significantly ($P < 0.01$ and $P < 0.05$) increased the seed oil and protein contents, respectively. Seed oil content significantly ($P < 0.01$) increased with increasing HA doses, while the highest seed protein contents noted for both HA doses compared to control plants. Rhizobacteria inoculation significantly ($P < 0.01$) increased seed oil and protein contents, with the highest oil content noted for M3 and with a higher protein content noted for OSU142 than for M3 and the uninoculated control.

Seed yield of safflower was significantly ($P < 0.01$) affected by water regimes, HA, and rhizobacterial strains (*Table 6*). For different water regimes, irrigation treatment induced a marked increase in the seed yield, with the lowest value noted for the rainfed conditions. Likewise, increasing doses of HA and PGPR inoculation (OSU142 > M3) increased seed yield (*Table 6*). Moreover, W x HA, W x P, HA x P and W x HA x P ($P < 0.01$) interactions were significant. The W x HA interaction (*Table 3*) revealed that the highest seed yield (3.04 t ha^{-1}) was recorded for 400 kg HA ha^{-1} under irrigated condition, and the lowest yield (1.02 t ha^{-1}) was recorded for the non-HA control under rainfed condition. The 400 kg HA ha^{-1} treatment significantly enhanced the seed yield by 60.8% and 83.3% under irrigated and rainfed condition, respectively, over that of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63776403

their respective non-HA control. The W x P interaction (*Table 3*) revealed that OSU142 was a potential strain for improving seed yield under both irrigated and rainfed conditions, with highest yield (2.92 t ha^{-1}) noted for the irrigation treatment. Similarly, the HA x P interaction (*Table 4*) showed that OSU142 in all the HA rates considerably increased seed yield by 105.8 and 119.8%, respectively, over that of the non-HA and uninoculated control. Moreover, the W x HA x P interaction (*Fig. 4*) revealed that the highest seed yield (3.37 t ha^{-1}) was recorded for 400 HA + OSU142 treatment under irrigated conditions, with increase of 101.8% and followed by 400 HA + M3 (89.8%) treatment, compared to their respective control. However, the treatments of 400 HA + OSU14 200 HA + OSU142 and 400 HA + M3 were resulted for the higher seed yields (2.1 1.95 and 1.91 t ha^{1}) under rainfed conditions, with increases of 186. 163.5 and 158.1%, respectively, compared to their respective control.

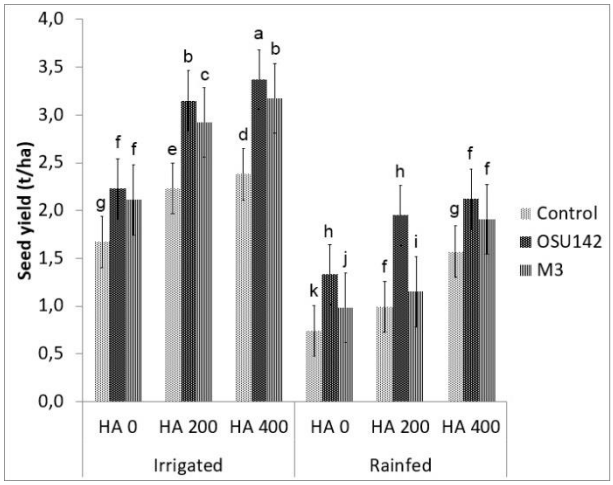

Figure 4. *The interactive effect of water regimes, humic acids and PGPR on the seed yield (t ha^{-1}) of safflower. Different letters along with water regimes, humic acids and PGPR treatments indicate significant differences in access treatment means from three replications tested at P ≤ 0.05 according to DMRT*

Results for the oil and protein yields showed trends similar to that seen for seed yield. Significant differences ($P < 0.01$) in the oil and protein yields of safflower were observed for water regimes, HA, and bacterial inoculation (*Table 6*). For different water regimes, the highest oil and protein yields were recorded for irrigated condition with 0.89 and 0.36 t ha^{-} respectively. The increasing doses of HA (400 HA > 200 HA) and PGPR inoculation (OSU142 > M3) significantly ($P < 0.01$) improved oil and protein yields (*Table 6*). Furthermore, significant ($P < 0.01$) interactions were observed in W x HA, W x P, HA x P and W x HA x P for oil yield. The W x HA interaction (*Table 3*) showed that the highest oil yield (1.10 t ha^{-1}) was recorded for 400 kg HA ha^{-1} under irrigated condition, and the lowest yield (0.29 t ha^{-1}) was recorded for the non-HA control under rainfed condition. Likewise, the W x P interaction (*Table 3*) revealed that OSU142 and M3 strains enhanced oil yield under both irrigated and rainfed conditions, with highest yield (1.01 and 0.98 t ha^{-} respectively) noted for the irrigation treatment. Furthermore, the HA x P interaction (*Table 4*) showed that the highest oil yield was observed for 400 HA + OSU142 treatment. Moreover, the W x HA x P interaction (*Fig. 5*) revealed that the highest oil yields were recorded for 400 HA + OSU14 400 HA + M3 and 200 HA + OSU142 treatments under irrigated conditions, with increases of 127. 119.1 and 108.4%, compared to their respective control, whereas the treatments of 400 HA + M3 and 400 HA + OSU142 were resulted in the higher seed yields under rainfed conditions, with increases of 257.1 and 226.5%, respectively, compared to their respective control.

Elemental analysis of safflower seeds

Macro- and micronutrients contents (P, K, Ca, Mg, Fe, Zn, Cu and Mn) of safflower seeds were significantly ($P < 0.01$) affected by water regimes, HA, and PGPR strains (*Table 7*). A higher P, K, Ca, Fe, Cu and Mn contents were noted for the irrigation treatment than for the rainfed condition, whereas rainfed condition induced a marked increase in Mg and Zn contents, with the lowest value noted for the irrigation treatment.

DOI: http://dx.doi.org/10.15666/aeer/1805_63776403

However, the seeds in both HA and PGPR treated plants generally had higher macro- and micronutrient contents compared to the control (no HA or uninoculated) plants.

The means were obtained from combined analysis of variance. ns, *, and ** represent nonsignificant and significant at $P \leq 0.05$ and $P \leq 0.01$ according to DMRT, respectively. CV: coefficient of variations

For macronutrient contents (P, K, Ca and Mg), the individual effects of all treatments were significant ($P < 0.0$ *Table 7*). All macronutrient contents increased with increasing doses of HA (400 HA > 200 HA), whereas the M3 inoculation noted for the highest P content, and the OSU142 inoculation noted for the highest K, Ca and Mg contents. For these parameters, significant interactions were observed in W x HA ($P < 0.01$) for Mg content, W x P ($P < 0.01$) for Ca and Mg contents, HA x P ($P < 0.01$ and $P < 0.05$) for all the macronutrients, and W x HA x P ($P < 0.01$) for P and Mg contents (*Table 7*). The W x HA interaction (*Table 8*) showed that the highest Mg content (1750.60 mg kg^{-1}) was recorded for 200 kg HA ha^{-1} under rainfed condition, and the lowest value (1272.78 mg kg^{-1}) was recorded for the non-HA control under irrigated condition.

Means having different letters are significantly different at $P \leq 0.05$ according to DMRT

Likewise, the W x P interaction (*Table 8*) revealed that OSU142 strains enhanced Ca content of seeds under both irrigated and rainfed conditions, with highest value (2811.25 mg kg^{-1}) noted for the irrigation treatment, whereas the highest Mg content of seeds (1843.75 mg kg^{-1}) noted for OSU142 inoculation under rainfed conditions. Furthermore, the HA x P interaction (*Table 9*) showed that the highest K, Ca and Mg contents were observed for 400 HA + OSU142 treatment, whereas the highest P content noted for 400 HA + M3 treatment.

Moreover, the W x HA x P interactions revealed that the highest phosphorus content was recorded for 400 HA + M3 under irrigated conditions, with increase of 56.3%, whereas the highest Mg content was recorded for 400 HA + OSU142 under rainfed conditions, with increase of 96.6%, compared to their respective control (*Fig. 6a* and *b*).

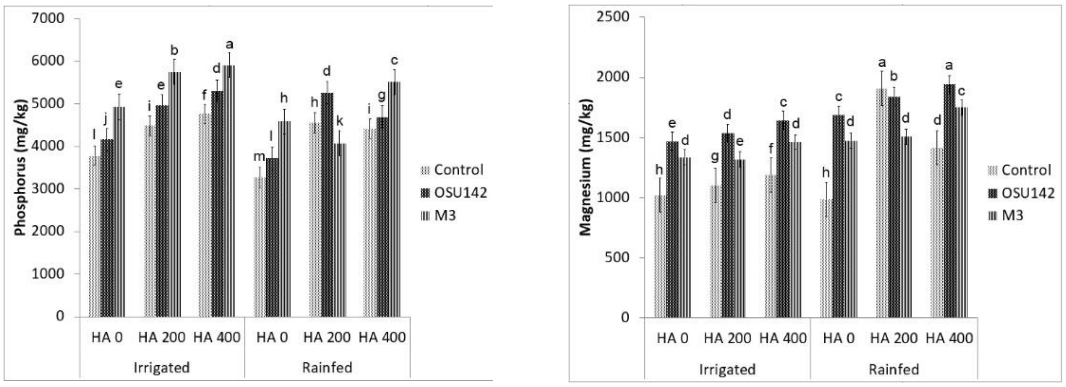
Means having different letters are significantly different at P ≤ 0.05 according to DMRT



(a) (b)

Figure 6. *Phosphorus content (mg kg^{-1}) (a) and magnesium content (mg kg^{-1}) (b) in seed at humic acid treatments and rhizobacterial inoculation and their interaction under the irrigated and rainfed conditions. Different letters along with water regimes, humic acids and PGPR treatments indicate significant differences in access treatment means from three replications tested at P ≤ 0.05 according to DMRT*

For micronutrient contents (iron, zinc, copper and manganese), the individual effects of all treatments were significant (P < 0.0 *Table 7*). Iron and manganese contents increased with increasing doses of HA (400 HA > 200 HA), whereas the highest zinc and copper contents noted for 200 kg HA ha^{-1} and non-HA control, respectively. The OSU142 and M3 inoculations significantly (P < 0.01) increased contents of iron, zinc and manganese, whereas it marked decline in copper content with the highest value noted for the uninoculated control. For these parameters, significant (P < 0.01) interactions were observed in W x HA for iron and copper contents, W x P for iron and zinc contents, HA x P for iron, zinc and manganese contents, W x HA x P for iron, zinc and manganese contents (*Table 7*). The W x HA interaction (*Table 8*) showed that the highest iron (60.68 mg kg^{-1}) and the lowest copper (13.82 mg kg^{-1}) contents were recorded for 400 kg HA ha^{-1} under irrigated condition, whereas the highest copper content (17.06 mg kg^{-1}) was recorded for the non-HA control under irrigated condition.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63776403

Likewise, the W x P interaction (*Table 8*) revealed that OSU142 strains improved iron content of seeds under both irrigated and rainfed conditions, with highest value (66.74 mg kg^{-1}) noted for the irrigation treatment, whereas the highest zinc content of seeds (46.55 mg kg^{-1}) noted for M3 inoculation under rainfed conditions. Furthermore, the HA x P interaction (*Table 9*) indicated that the highest iron and manganese contents were observed for 400 HA + OSU142 treatment, whereas the highest zinc content noted for 200 HA + M3 treatment. Similarly, the W x HA x P interactions (*Fig. 7a, b* and *c*) revealed that the highest zinc content was recorded for 200 HA + OSU142 under rainfed condition, whereas the highest iron and manganese contents were recorded for 400 HA + OSU142 under irrigated conditions, with increases of 51.3 and 41.9%, respectively, compared to their respective controls.

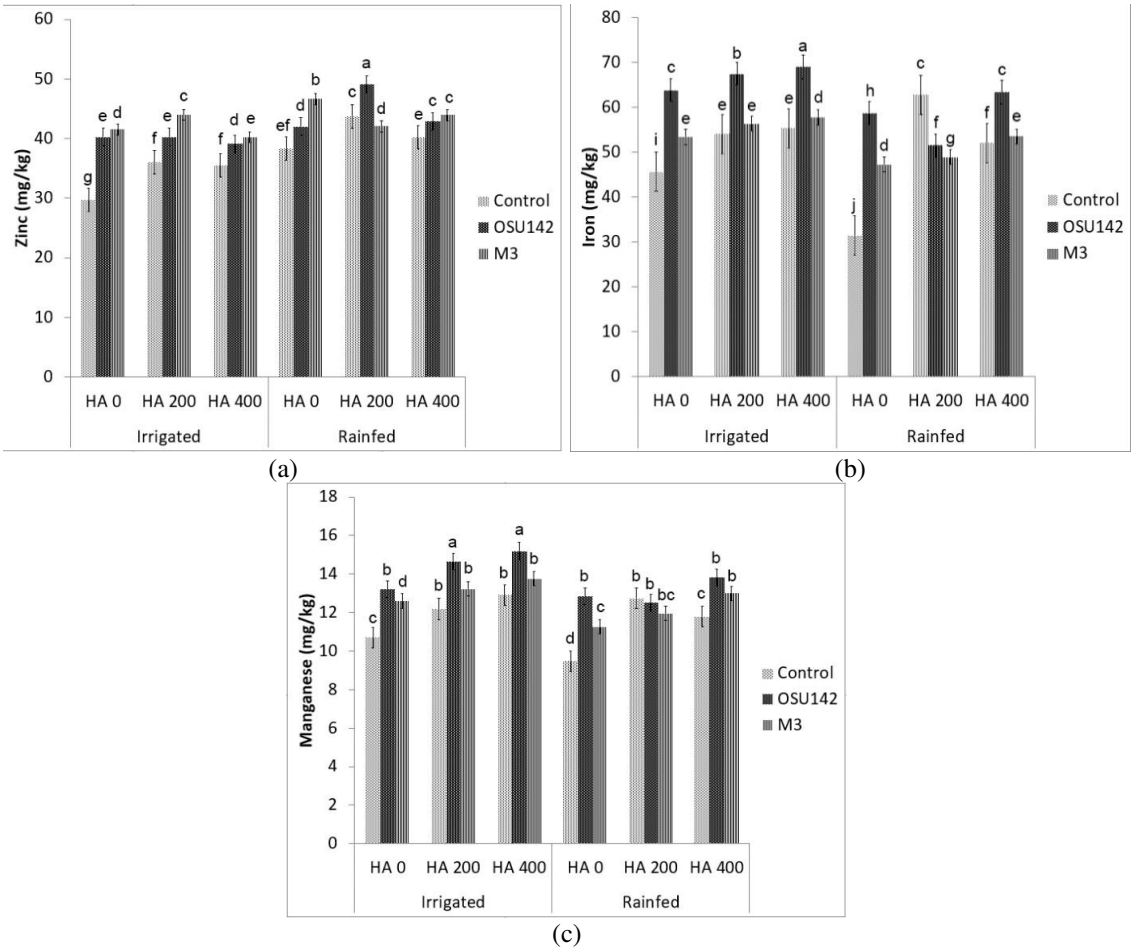


Figure 7. *Zinc content (mg kg^{-1}) (a), iron content (mg kg^{-1}) (b), manganese content (mg kg^{-1}) (c) in seed at humic acid treatments and rhizobacterial inoculation and their interaction under the irrigated and rainfed conditions. Different letters along with water regimes, humic acids and PGPR treatments indicate significant differences in access treatment means from three replications tested at $P \leq 0.05$ according to DMRT*

Discussion

In this two-year field study, humic acid (200 and 400 kg ha^{-1}) and two rhizobacterial strains (*Bacillus megatorium* M3 and *Bacillus subtilis* OSU-142) were evaluated for

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63776403

their effect on the growth, yield and quality of safflower under irrigated and rainfed conditions. The results indicated that humic acid and rhizobacterial inoculation under irrigated conditions significantly increased the growth and yield of safflower. However, the combined application of rhizobacterial strains and humic acid alleviated the negative effects of water deficit on growth and yield of safflower under rainfed conditions, thereby presented an improved strategy for the remediation of water stress in the safflower production in arid and semi-arid regions.

Nowadays, worldwide studies are intensively maintained to isolate and characterize the PGPR strains for improving crop production in sustainable agriculture and several stress conditions. Many PGPR species, including *Azotobacter, Azosprillum, Bacillus, Serratia, Enterobacter, Pseudomonas, Klebsiella* and *Variovorax* etc., improve plant growth by releasing of plant growth stimulating compounds (e.g. phytohormones such as IAA, cytokines or auxins) or improving in nutrient uptakes (e.g. N_2 fixing, P-solubilizing or siderophore production) or enhancing in plant tolerance to both biotic and abiotic stresses (Glick, 1995; Nelson, 2004; Kristin and Miranda, 2013; Backer et al., 2018). In the present study, OSU-142 (*Bacillus subtilis)* and M3 (*Bacillus megatorium*) strains, having properties of which were mentioned above, were tested for agronomic performance of safflower in the field conditions. Between the tested two bacteria, the N_2-fixing OSU-142 strain was determined the most effective in growth promotion (esp. plant height, stem and capitilum diameters, and number of capitula), and yields of seed, oil and protein in safflower. It was observed no difference between bacteria in terms of seed characteristics (e.g. number of seeds, 1000 seed weight, and fertile and sterile seed ratios) of safflower, whereas P-solubilizing M3 strain was showed the greatest performance in oil content improvement of seeds. Both of these strains have IAA and ACC deaminase production (Cakmakci et al., 200 2006), and these properties might be the cause of the noted plant growth promotion (Arshad et al., 2008; Glick, 2014; Vejan et al., 2016; Chandra et al., 2019). This potential relationship is supported by Belimov et al. (2009) and Chandra et al. (2019) who observed that inoculations of pea and wheat with *Variovorax* sp., possessing IAA, ACC deaminase, and N_2-fixing and P-solubilizing activities, significantly increased the shoot biomass of pea and yield characteristics of wheat. Similar effects of PGPR inoculation on plant growth promotion have been observed in the several studies in sugar beet and barley (Cakmakci et al., 200 2006), sugarcane (Silva et al., 2017), sunflower (Shadid et al., 2012), wheat (Rosas et al., 2009; Hungria et al., 2010; Rana et al., 2012; Chandra et al., 2019), rice (Lucas et al., 2009), bean (Hoyos-Carvajal et al., 2009), canola (El-Howeity and Asfour, 2012), maize (Thonar et al., 2017) and soy (Cassán et al., 2009). Moreover, the superior performance of OSU14 compared to that of M could be due to its N_2-fixing ability converting atmospheric nitrogen (N_2) into ammonia (NH_3) or related nitrogenous compounds in soil, which helps the plant in nitrogen acquisition (Cakmakci et al., 200 2006). Additionally, biological nitrogen fixation is considered to be an essential to plants because fixed inorganic nitrogen compounds are required for the biosynthesis of all nitrogen-containing organic compounds, such as amino acids and proteins, nucleoside triphosphates and nucleic acids. Hence, the greater nitrogen uptake by plants directly affects plant growth. In the study, the effect of M3 strain showing the higher performance in increasing oil contents of safflower seed could be due to its phosphate solubilizing ability, which one of the most important traits associated with plant phosphate nutrition. The previous studies also indicated that enhanced phosphate acquisition by phosphate solubilizing microorganisms positively affect seed oil

DOI: http://dx.doi.org/10.15666/aeer/1805_63776403

concentration of oilseed crops (Mirzakhani et al., 2009; Shahid et al., 2012; Sharifi et al., 2017; Nosheen et al., 2018; Chandra et al., 2019).

In the current study, the humic acid and bacterial inoculation considerably increased the morphologic, seed and yield characteristics of safflower in the field conditions. The results revealed that morphologic characteristics, such as plant height, stem diameter, numbers of branches and capitula, and capitulum diameter, and yields of seed, oil and protein were significantly affected by both humic acid and bacterial inoculation, thus their highest values obtained from 400 kg HA ha^{-1} and OSU142 strain, respectively. Similarly, the seed characteristics and seed protein concentration of safflower treated by humic acid and bacterial inoculation significantly increased compared to control, but showed no difference between HA doses or PGPR strains. Overall, the enhanced safflower growth due to humic acids and PGPR might be attributed to their beneficial effects on the plant growth, which affects because of promotion of root morphology, nutrient uptake, and soil biological activity etc. (Schmidt et al., 2007; Puglisi et al., 2013; Canellas and Olivares, 2014). The plants treated with 400 kg HA ha^{-1} exhibited considerably increased morphologic characteristics of safflower, which probably directly affected the root growth, especially lateral root emergence (Nardi et al., 2009), and indirectly improved photosynthetic rate, leading to increased growth and yield of safflower (Puglisi et al., 2013; Canellas and Olivares, 2014). This proposed explanation is supported by those of Canellas et al. (2013), who noted significantly enhanced the rate of net photosynthesis in maize in response to the increase of the humate concentration under greenhouse condition. Similarly, different endophytic rhizobacteria species have been also reported that increased the photosynthetic rate, stomatal conductance, transpiration velocity, water utilization efficiency in rice, which might support plant growth improvement (Chi et al., 2005). More recently, Schoebitz et al. (2016), Esringu et al. (2016) and Olivares et al. (2015) have reported significant growth and yield improvements in blueberry, Hungarian vetch and tomato, respectively, due to humates and PGPR inoculation under field conditions.

Although the studies recently reviewed basic mechanisms and synergistic effects produced by integrated use of humic substances and PGPR on nutrient uptake, growth and yield of various crops under different stress conditions (Baldatto et al., 2010; Glick, 2014; Esringu et al., 2016; Schoebitz et al., 2016; Silva et al., 2017; Olivares et al., 2017), their effects has not been previously reported in safflower under different water regimes. In the study, the enhanced growth and yield of safflower might be due to similar synergistic effects of humic acids and PGPR under irrigated and rainfed conditions. Similar to the present results, humic substances widely reported to having potential as enhancer of PGPR efficiency (Esringu et al., 2016; Schoebitz et al., 2016; Silva et al., 2017). Cakmakci et al. (2006) observed a positive correlation among soil organic matter content, PGPR strains and growing stage, and reported that the effect of PGPR was greater in the high soil organic matter content, and at early plant growth stages than at the later. In the previous studies, it has also been notified that the combined use of PGPR and humic substances increased productions of maize grains by 65%, tomato fruits by 87.1% and potato tubers by 140% under field conditions (Canellas et al., 2013; Olivares et al., 2015; Ekin, 2019).

Safflower is an extensively branching oilseed plant, and dry matter accumulation in connection with seed yield depends not only on plant height but also on numbers of branch and capitula, and some morphological characteristics sensitive to water deficit stress (Dajue and Mündel, 1996). In the current study, the plant height, number of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63776403

capitula per plant and number of seeds per capitulum were the highest for safflower plants treated with integrated use of humic acids and PGPR under irrigated conditions. However, their effects noted for relatively higher for safflower yield characteristics than for irrigated plants under rainfed conditions. Under rainfed conditions, the combined use of humic acid and PGPR helped the safflower plants acclimatize to water-deficit (rainfed) conditions by improving a variety of morphologic and yield characteristics, including plant height, stem diameter, number of capitula, capitilum diameter, number of seeds, 1000 seed weight and fertile seed percentage, which cause for enhancing seed and oil yields. The improved safflower growth and yield by bacterial inoculation and humic acids under rainfed conditions might be correlated with the enhancement in plant tolerance to drought by increasing their water content, which can be attributed to the enhancement of root growth by humic substances and PGPR inoculation. In addition, it has also been reported that PGPR could enhance the plant growth under stress conditions by biosynthesis of phytohormones (IAA, GA, and cytokines), producing the enzyme ACC deaminase, fixing asymbiotic nitrogen, and solubilizing of phosphates and other nutrient elements (Glick, 2014). This proposed explanation is consistent with the results of Sahin et al. (2015), who stated N_2-fixing, P-solubilization, and producing of IAA, GA and SA of PGPR has been basic factors improving nutrient uptake and growth of lettuce. They also reported that PGPR inoculation significantly increased growth and yield of lettuce plants under lower and well-watered conditions, and alleviated the harmful effects of lower irrigation conditions. Similar results were noted by Rubin et al. (2017) and Mutumba et al. (2018), who reported that plants were highly responsive to bacterial inoculation under well-watered conditions, but the effect was relatively higher under drought conditions. Other previous studies have also reported improving effects of PGPR inoculation on the yield and growth of different crops grown under drought stress (Vivas et al., 2003; Arkhipova et al., 2007; Marulanda et al., 2009; Sandhya et al., 2010).

In the current study, the interactive effect of humic acids and PGPR inoculation on nutrient contents of safflower seeds was studied in the natural field conditions. In general, the nutrient uptake of safflower plants except for Mg and Zn contents was lower in rainfed conditions, compared to the irrigated conditions. However, humic acids and PGPR inoculation considerable improved macro and micro nutrient contents of seeds except copper under both irrigated and rainfed conditions. In addition, K, Ca, Mg, Fe and Mn concentrations of the seeds noted for the highest for plants treated with OSU142 strain, whereas P and Zn concentrations in the M3 strain. In the study, the specialty of M3 strain highly responded to enhancing especially phosphorus and zinc uptake could be attributed to its P-solubilizing ability and affecting root growth and lateral root formation by producing plant hormones such as IAA in the rhizosphere (Cakmakci et al., 2001; Chandra et al., 2019). Likewise, N_2- fixing ability and phytohormone production of OSU142 strain also might have been one of the main factors improving growth and mineral nutrient uptake of safflower. Moreover, the combined use of humic acids and PGPR also alleviated the harmful effects of water deficit conditions on the mineral nutrient uptake. Under rainfed conditions, the reduction in nutrient uptake may be due to a notable decrease in root cation exchange capacity of the plants, which can accumulate some ions, organic and amino acids to avoid harmful effects of abiotic stress conditions in dry environments (Sahin, 2015). Similarly, the reduction in copper content may be attributed to strongly retain in the soil after the application of humic acids (Rong et al., 2020). Nowadays, the applications of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_63776403

humic acid and PGPR have been widely used to improve soil functions, to mobilize or immobilize cations and metal ions in soil, leading to increased nutrient uptake from soils (Rubin et al., 2017; Rong et al., 2020). In the study, the improvement in the nutrient concentrations of safflower seeds may be due to more effective mobilizing mineral nutrients from the soil because of enhanced excretion of organic acids through rhizosphere bacteria (Glick, 1995; Biswas et al., 2000; Chandra et al., 2019). Another possible reason for the improved nutrients from the PGPR is the roots enhancement by producing phytohormones, resulting in a larger root surface, and therefore, has positive effects on plant acquisition of nutrients and water (Vardharajula et al., 2011; Wang et al., 2012). In addition, an increase in zinc uptake because of root-induced changes (i.e. enhanced root growth, surface area and activity) in the rhizosphere after the application of PGPR has also been reported in lettuce (Sahin et al., 2015). More recently, many studies have reported that the integrated use of humic acids and bacterial inoculation would be provide the higher nutrient uptake and plant performance in the various stress conditions, and ultimately result in vigorous, well-established and healthy plants (Esringu et al., 2016; Silva et al., 2017; Olivares et al., 2017). Similarly, Baldatto et al. (2010) and Schoebitz et al. (2016) also reported that inoculation of PGPR in combination with humic substances increased root and shoot biomass of pineapple and blueberry plants, and nutrient contents increased by 80% K, 131% P and 132% N in pineapple, and 55% N and 56% K in blueberry, compared to uninoculated control.

Conclusions

In conclusion, the current study comprehensively evaluated the effect of humic acids (200 and 400 kg ha^{-1}) and two promising *Bacillus* spp. strain on the growth, yield and quality of safflower under rainfed and irrigated field conditions. The study revealed that 400 kg humic acid ha^{-1} with the *Bacillus subtilis* OSU142 strain was the most effective combination for growth, seed and oil yields, and seed quality of safflower under irrigated conditions. Moreover, the integrated use of humic acids and PGPR alleviated the unfavorable effects of water deficit under rainfed conditions, and presented an improving strategy for the remediation of water stress in the safflower production in arid and semi-arid regions. The present results suggest that the combined use of humic acids and PGPR can be used as a biotechnological intervention for the alleviation of water deficit stress in safflower production in the arid and semiarid regions.

(Received 3rd Apr 2020; accepted 29th Jul 2020)

Abstract. Field experiments were conducted to evaluate the impact of various chemical ripeners (Ethephon, Glyphosate, Sulfometuron-methyl) on sugarcane cultivars (HSF-242, NSG-311, HSF-240, NSG-555). Each chemical ripener (200 ppm) was applied as a foliar spray 15, 30 and 45 days before cane harvesting for planted crops and ratoons were collected. Chemical ripeners significantly enhanced the quality and sugar yielding traits including harvest index, juice extraction and purity, sugar recovery % cane and total sugar yield for planted crop especially when treatment was applied 45 days before cane harvesting. Changes in antioxidant activities indicated the influence of various chemical ripeners on the planted crop. Chemical ripeners were imperative to create short-term changes for early cane maturity and sugar yielding abilities. Performance of ratooning crop was normal concerning growth, yield and antioxidant activities according to its existing genetic makeup showing non-significant effect of chemical ripeners. It was concluded that chemical ripeners can be suitable to boost up sugar yielding characteristics by inducing early cane maturity for a short duration before cane harvesting and it will have no effect on lateral life cycle span and its ratooning abilities.
Keywords: *glyphosate, ethephon, sulfometuron-methyl, sugar production*

Introduction

Sugarcane (*Saccharum officinarum* L.) is considered as an industrial crop for the production of sugar (Neliana et al., 2019). Sugarcane is one of the world's major food-producing crops, providing about 75% of sugar in the world for human consumption (De Souza, 2008). Sugarcane is rich in sucrose which is accumulated in stalk internodes and is used to manufacture many industrial goods such as furfural, alcohol, dextrans etc. and some other natural pharmaceutical products (Ma et al., 2005).

Chemical ripeners (Ethephon, ethyl-trinexapac, glyphosate and sulfometurom methyl) are classified as growth retardants and growth inhibitors as described by Leite et al. (2011). Chemical ripening of sugarcane is an important component to profitable sugar production throughout the world. Harvesting of sugarcane often begins before the sugarcane reaches the desirable maturity level (Dalley and Richard-Junior, 2010). The main advantage of chemical ripeners is that they can suppress stalk and leaf growth much more rapidly and consistently than natural processes such as reduced temperatures or limiting soil moisture (Van Heerden et al., 2015). Ethephon, an ethylene releasing compound, was the first growth regulator in the early 1960s used for crop management and post-harvest quality in a wide range of agricultural, horticultural and forestry. The application of Ethephon in sugarcane has accelerated ripening, increased the overall sugar yield, and inhibited flowering (De Almeida and Caputo, 2012).

Glyphosate, an amino acid synthesis inhibitor, applied at sub-lethal doses has been widely used to increase sucrose levels in sugarcane (Solomon and Li, 2004). Glyphosate

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64056423

(N-phosphonomethyl glycine, $C_3H_8NO_5P$) is the analogue of glycine. It is a highly used herbicide throughout the world because it is an efficient killer of weeds, less toxic and available at low cost (Goscinny and Hanot, 2012). Leite et al. (2009) noted that ripener application for early harvest sugarcane led to an increase in technological quality, although sugar yield had been significantly affected, which positively contributed to the profit per unit area. El-Hamd et al. (2013) found that glyphosate application increased total soluble solids in cane juice but other quality parameters viz. sucrose content also increased proportionately. The introduction of sulfometuron-methyl, which overcomes some of the disadvantages of other ripeners, is therefore timely. Sulfometuron-methyl is a grass herbicide that showed promise as a chemical at low rates of application (Almendares et al., 2013). Many studies reported that sulfometuron-methyl regarding its potential ripening effect in sugarcane varieties, causes no damage to sugarcane production (t ha^{-1}) or the agronomic characteristics of the culture (Silva et al., 2007; Leite et al., 2010).

There is a lack of information about the use of chemical ripeners in Pakistan for sugarcane. There are different studies in few countries about the effective use of chemical ripeners for early cane ripening with higher sugar yield but there is no information and use of chemical ripeners in Pakistan. Secondly, residual effects of chemical ripeners has not been evaluated on sugarcane ratooning abilities. This study was conducted first time in Pakistan to find the efficacy of chemical ripeners on sugar yielding attribute on planted crop as well as its impact on the ratooning abilities.

Materials and methods

Experiments were carried out at Shakarganj Sugar Research Institute (SSRI) Jhang and University of Gujrat, Pakistan during 2018-19. Sowing of four sugarcane cultivars i.e. HSF-242, NSG-311, HSF-240 and NSG-555 was done in two sowing seasons i.e. spring and autumn during 2018 and 2019. Experimental design was RCBD (Plot size 30 × 30 feet beds) with four replicates. A seed rate of 75000 double-bedded setts per hectares was used with 2.5 feet row spacing. Seed was treated with hot water at 52 °C for 30 min and fungicide for better germination and to control sugarcane diseases. Soil insecticide was also applied in the soil to control termites. Double-cut setts were placed end to end in furrows at a depth of about 10 cm and covered with 5 cm soil. Immediate irrigation was applied after planting. Each chemical ripener was sprayed at cane formation and elongation phase. These concentrations have not been studied for sugarcane crop in previous research and with the treatment intervals of 15, 30 and 45 before cane harvesting. Researcher used less or more than 200 ppm concentrations of different chemical ripeners in sugarcane and used single dose application that is why this interval of treatments was applied.

The following treatments were applied on planted crop:

T0 = Control
T1 = 200 ppm Ethephon spray (15 days before harvesting)
T2 = 200 ppm Ethephon spray (30 days before harvesting)
T3 = 200 ppmEthephon spray (45 days before harvesting)
T4 = 200 ppm Glyphosate spray (15 days before harvesting)
T5 = 200 ppm Glyphosate spray (30 days before harvesting)
T6 = 200 ppm Glyphosate spray (45 days before harvesting)
T7 = 200 ppm Sulfometuron-methyl spray (15 days before harvesting)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64056423

T8 = 200 ppm Sulfometuron-methyl spray (30 days before harvesting)
T9 = 200 ppm Sulfometuron-methyl spray (45 days before harvesting)

The following quality, sugar yielding and antioxidant activities were determined for planted crop in January-February, 2019:

1. Harvest Index (%)
2. Juice Extraction (%)
3. Juice purity (%)
4. Sugar recovery % cane
5. Sugar yield (t ha^{-1})
6. Antioxidant activities (CAT, POD and SOD)

After the cane harvesting, ratoon was kept from the planted crop at which chemical ripeners were sprayed and the following parameters were studied in January-February, 2020:

1. Ratoon Sprouting (%)
2. Number of tillers per plant
3. Mill-able canes (t ha^{-1})
4. Juice Extraction (%)
5. Juice purity (%)
6. Sugar recovery % cane
7. Sugar yield (t ha^{-1})
8. Total cane yield (t ha^{-1})
9. Antioxidant activities (CAT, POD and SOD)

Harvest index (HI) was calculated for planted crop using this formula:

$$HI\ (\%) = \text{Stripped cane yield/Unstripped cane yield} \times 100$$

Juice extraction % was calculated both for planted and ratooning crop by this formula:

$$\text{Juice extraction } (\%) = \text{Juice weight (g) / Filter cake weight (g)} \times 100$$

Sugar recovery % of cane for planted and ratooning crop was calculated by using the formula as follows:

$$\text{Sugar recovery percentage} = [S - 0.4\ (B - S)] \times 0.73$$

where: B = Brix percentage, S = sucrose percentage, 0.4 and 0.73 constant factors.

Total sugar yield (t ha^{-1}) was calculated for each treatment by the following method:

$$\text{Total sugar (t ha}^{-1}\text{)} = \text{Sugar recovery} \times \text{Stripped-cane yield}/100$$

Estimation of CAT, POD and SOD activities were determined by the procedure of Chance and Maehly (1955).

Data were analyzed statistically using analysis of variance (ANOVA) technique using Ministate-C software and significant mean separation was done at $P \leq 0.05$ using Tukey's test.

Results

The following results were obtained by the applications of chemical ripeners in planted and ratooning crop.

Harvest index (HI) % for planted crop

Effect of chemical ripeners was highly significant in sugarcane for harvest index (*Table 1*). There were significant variations among sugarcane cultivars for HI and its interaction between ripeners and cultivars. Higher HI value was noted in cultivar HSF-240 with the treatment of Ethephon and Sulfometuron-methyl that was applied 45 days before cane harvesting. Cultivar NSG-555 showed the lowest HI values for all the treatments of ripeners (*Fig. 1A*). Overall, all the treatments that were applied 45 days before harvesting had the highest values for HI as compared to other treatments (*Table 2*). HI increased because chemical ripeners helped to produce maximum number of stripped cane.

Juice purity (%) in planted crop

It was noted from the results that the effect of chemical ripeners was highly significant for juice purity % of sugarcane. Variations among cultivars were significant while the interaction between ripeners x cultivar was highly significant (*Table 1*). Higher juice purity % was calculated in NSG-555 and the lowest juice purity was present in HSF-242 (*Table 2*). Applications of 200 ppm of Glyphosate and Ethephon that were applied 45 days before harvesting showed better results for juice purity (%). All the chemical ripeners applied 45 days before harvesting increased juice purity % (*Fig. 1C*).

Sugar recovery % of cane in planted crop

Sugar recovery % of cane significantly increased with the applications of chemical ripeners. There were highly significant results for sugar recovery % of cane among cultivars as well as in interactions of ripeners x cultivar (*Table 1*). The changes in sugar recovery % of cane was due to the changes created by chemical ripeners in juice extraction and purity %. Higher sugar recovery % of cane was obtained in NSG-555 by the applications of 200 ppm Glyphosate that were applied 45 days before cane harvesting. HSF-242 produced the lowest sugar recovery % of cane (*Fig. 2A*). All the chemical ripeners increased the sugar recovery % of cane but the treatments applied before 45 days were the best sugar recovery % of cane (*Table 2*).

Juice extraction (%) from planted crop

Data presented for juice extraction showed that chemical ripeners had highly significant juice extraction % (*Table 1*). Interaction of ripeners x cultivar were also highly significant. Cultivars had also highly significant response to chemical ripeners. Juice extraction % was increased by the treatments of chemical ripeners (*Fig. 1B*). Higher juice was extracted from HSF-240 with the applications of 200 ppm Ethephon that was applied 45 days before harvesting. Overall, NSG-555 cultivar had the highest juice extraction while the lowest juice quantity was extracted from HSF-242. From the results it was apparent that chemical ripeners produced early maturity and increased the production of juice in sugarcane (*Table 2*). All the chemicals applied 45 days before

Sugar yield (t ha^{-1}) of planted crop

Sugar yield was highly significantly affected by the applications of chemical ripeners. Sugar yield increased in all the cultivars by the treatments of chemical ripeners. Effect of chemical ripeners for cultivars and their interactions (ripeners x cultivar) also yielded highly significant results (*Table 1*). Higher sugar yield was obtained from NSG-555 and the lowest sugar yield was calculated in HSF-242. Higher sugar yield was noted by the applications of 200 ppm Sulfometuron-methyl and Glyphosate that was applied 45 days before cane harvesting. All the chemical ripeners applied 45 days before cane harvesting were the best for the production of sugar as compared to other treatments (*Fig. 2B*). As the chemical ripeners affected the juice extraction, juice purity and sugar recovery % of cane that resulted higher production of sugar (*Table 2*).

Antioxidant activities in planted crop

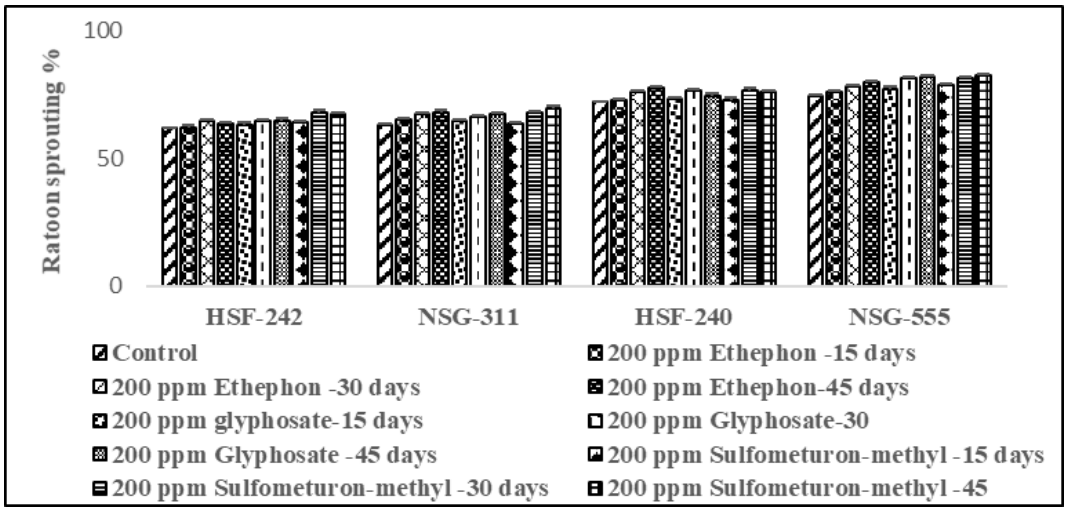
Antioxidant activities i.e. peroxidase (POD), catalases (CAT) and superoxide dismutase (SOD) were determined by evaluating the effects of Ethephon, Glyphosate and Sulfometuron-methyl. Effect of chemical ripeners was significant on POD activities in sugarcane (*Table 1*). Higher POD activities were noted in cultivar HSF-242 and the lowest was noted in HSF-240 (*Fig. 3A*). Maximum changes in POD was noted by the applications of Ethephon that were applied 30 and 45 days before cane harvesting. Cultivar HSF-240 had higher POD activities for Sulfometuron-methyl applications. There was a non-significant effect of chemical ripeners for CAT activities, however there were significant variations among cultivars (*Table 1*). Higher values of CAT were noted in HSF-240 and the lowest in cultivar HSF-242 (*Fig. 3B*). SOD activities were significantly changed by Chemical ripeners (*Table 2*). Maximum variations were noted in HSF-240 and the lowest values were noted in HSF-242 (*Fig. 3C*). Maximum value of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64056423

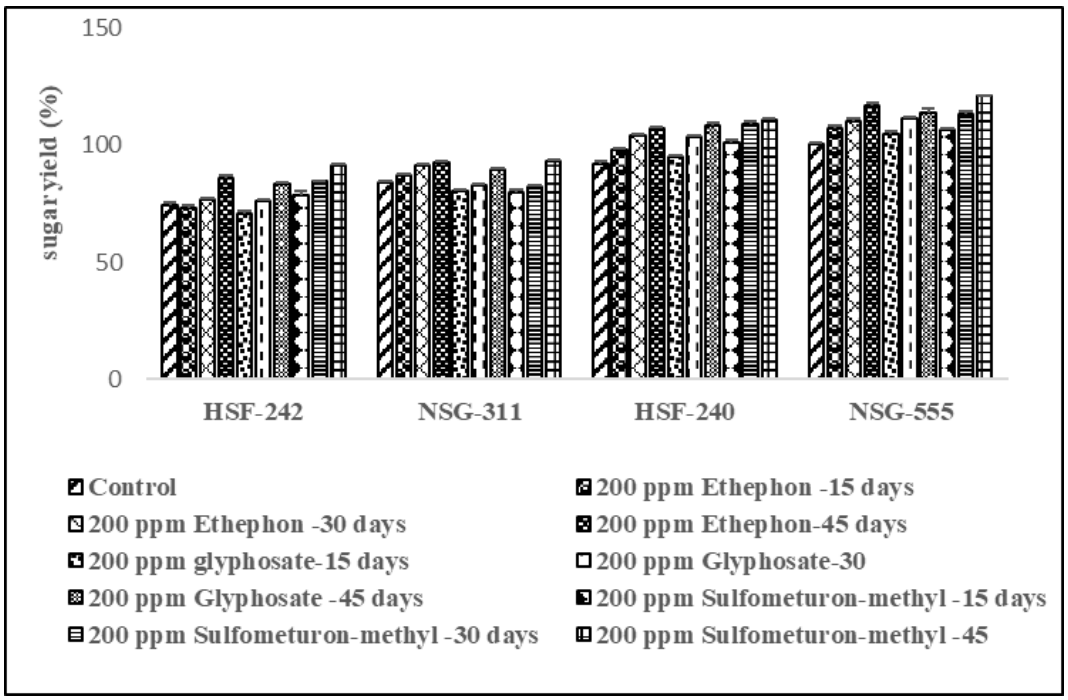
SOD was noted by the treatment of Glyphosate that was applied 45 days before cane harvesting.

Ratoon sprouting (%)

Data for ratoon sprouting of sugarcane crop is given in *Table 3*. Effect of chemical ripeners was non-significant on ratoon sprouting, however there was significant variations among cultivars. High sprouting % was noted in NSG-555 and the lowest in HSF-242 (*Fig. 4A*). Ethephon treatment applied 45 days before cane harvesting were the best as compared to other treatments.



A: Sugar recovery % of cane



B: Sugar yield

Figure 2. *Effect of different chemical ripeners on sugar yielding attributes of sugarcane cultivars in planted crop*

No. of tillers/plant of ratooning

Effect of chemical ripeners was non-significant on number of tillers/plant in ratooning crop, however there was significant variations among sugarcane cultivars (*Table 3*). Higher number of tillers was noted in NSG-555 cultivar and the lowest number of tillers was counted in HSF-242 (*Fig. 4B*).

Number of millable canes of ratooning

There was a non-significant effect of chemical ripeners on millable canes counted in ratooning crop (*Table 3*). Higher number of millable canes were counted in cultivar HSF-240 and the lowest number of millable cane was present in NSG-555 (*Fig. 4C*). Sulfometuron-methyl showed better results for millable canes in HSF-242.

D: Cane yield

Figure 4. *Effect of different chemical ripeners on ratooning growth and yield of sugarcane cultivars*

Cane yield (t ha^{-1}) of ratooning

Data for ratoon cane yield is given in *Table 3*. Effect of chemical ripeners was non-significant on cane yield, however there was significant variations among cultivars. Higher cane yield was calculated in NSG-555 and the lowest in HSF-240 (*Fig. 4D*). Chemical ripeners had non-significant effects on ratoon sprouting, number of tillers and millable canes due to that cane yield was also not affected.

Juice extraction (%) from ratooning

Table 4 showed that there were non-significant results for juice extraction % for ratooning crop. It was apparent that chemical ripeners did not affect the growth and quality attributes. It only affected the quality attributes during the maturity of planted crop by the applications of chemical ripeners. HSF-240 cultivar was the best in juice extraction during ratooning harvest (*Fig. 5A*).

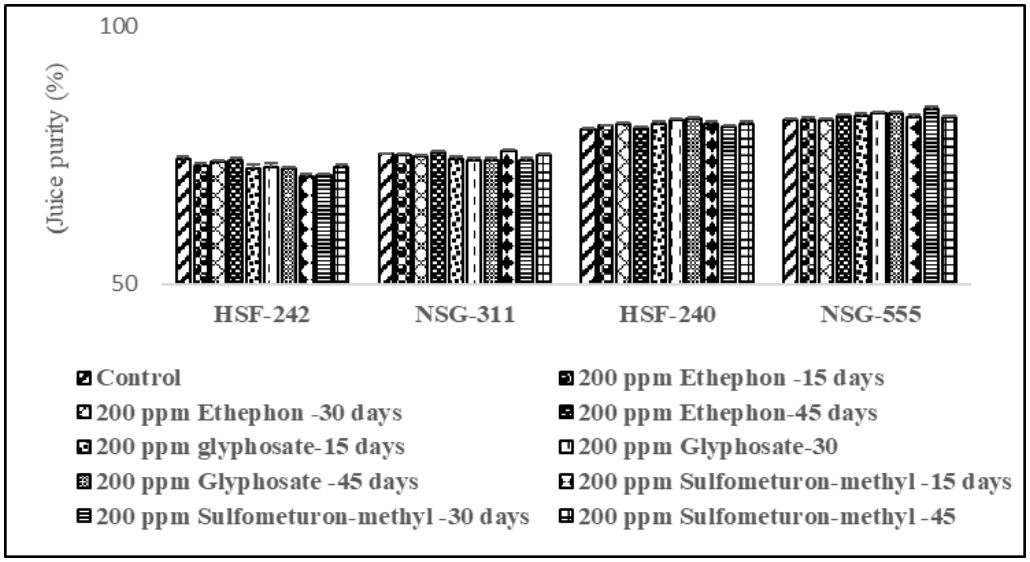
A: Juice extraction



B: Juice purity

Figure 5. *Effect of different chemical ripeners on juice extraction and purity of sugarcane cultivars in ratooning crop*

Juice purity (%) in ratooning

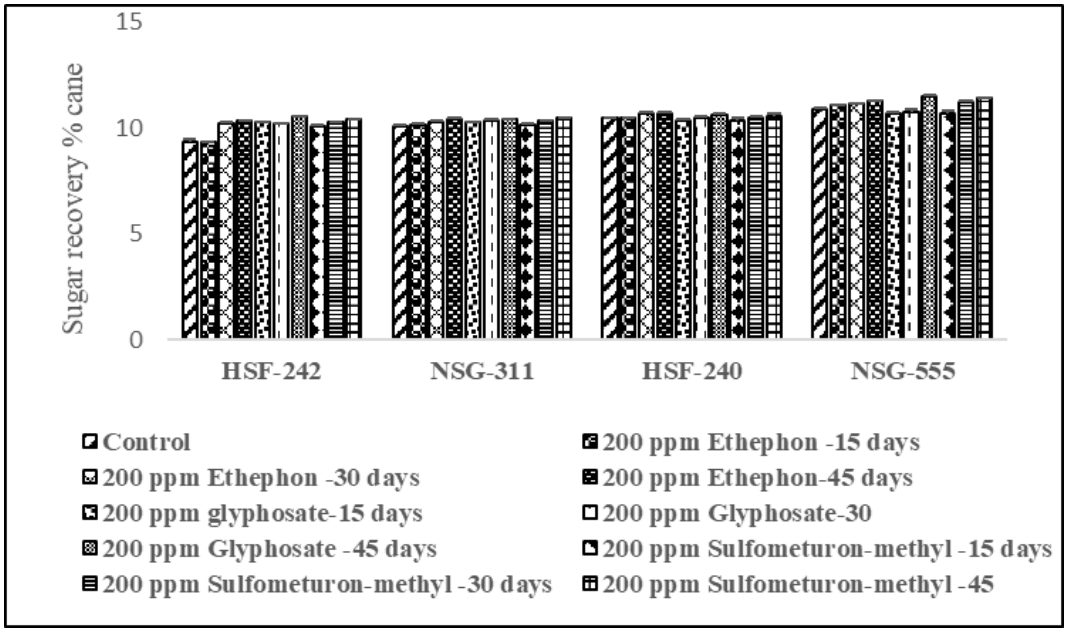
Effect of chemical ripeners was significant on juice purity % for sugarcane (*Table 4*). HSF-242 showed the maximum variations for juice purity in response to chemical ripeners especially Ethephon applied 45 days before harvesting. There were also significant variations among cultivars in response to chemical ripeners. The highest juice purity % was noted in NSG-555 and the lowest in HSF-242 (*Fig. 5B*).

Sugar recovery % of cane in ratooning

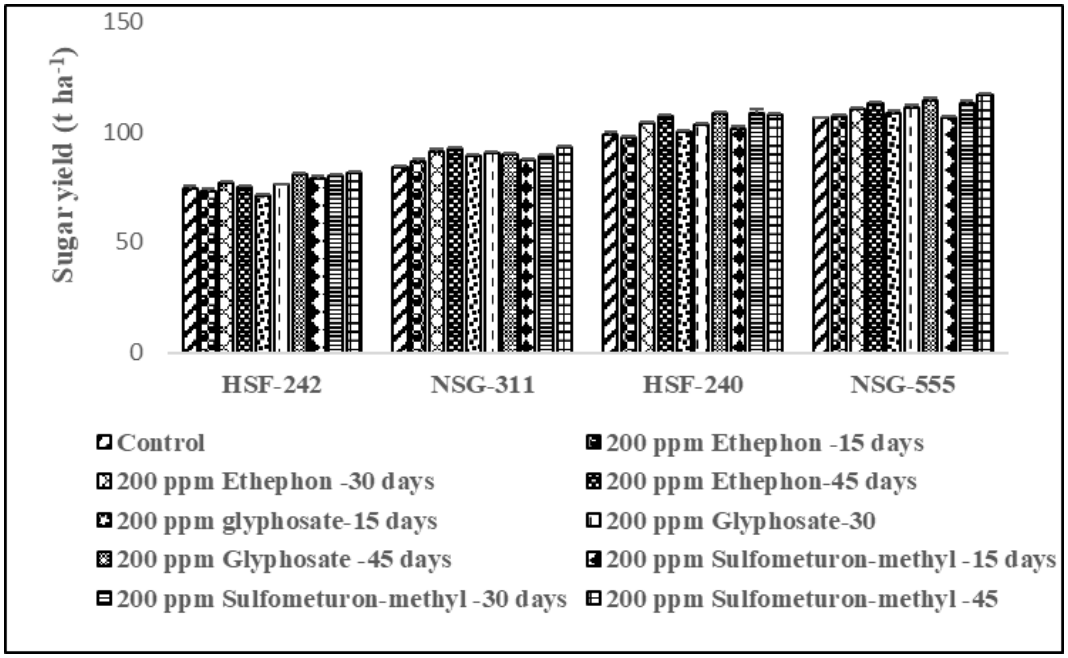
There was a non-significant effect of chemical ripeners on sugar recovery % of cane (*Table 4*). Higher sugar recovery % of cane were calculated in cultivar NSG-555 and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64056423

the lowest in HSF-242 (*Fig. 6A*). Results for sugar recovery % of cane was non-significant as other quality related parameters were also non-significant that also resulted no change in sugar recovery % of cane.



A: Sugar recovery % of cane



B: Sugar yield

Figure 6. *Effect of different chemical ripeners on sugar yielding attributes of sugarcane cultivars in ratooning crop*

Total sugar yield (t ha^{-1}) of ratooning

Results for total sugar yield for ratooning crop was similar as in the case of sugar recovery % of cane. There were non-significant results for total sugar yield (*Table 4*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64056423

Higher total sugar yield was calculated in cultivar NSG-555 and the lowest in HSF-242 (*Fig. 6B*). All the quality parameters had non-significant results for chemical ripeners that also resulted non-significant effects for total sugar yield.

Antioxidant activities in ratooning

There were non-significant effects for antioxidant activities i.e. peroxidase (POD), catalases (CAT) and superoxide dismutase (SOD). As on ratooning crop there was not any influence of chemical ripeners for growth, yield and quality that also affected antioxidant activities (*Table 4*). These results showed there was no change in ratooning crop towards any stimulant, its growth was normal depending upon the genetic makeup of sugarcane cultivars. Data related to antioxidant activities of POD, CAT and SOD is presented in *Figure 7*.

Discussion

Results have shown that chemical ripeners increased the harvest index (HI) of sugarcane. It might be due to the conversion of cane formation and elongation phase into ripening phase by Ethephon and Sulfometuron-methyl. Kapur et al. (2013) found the variations for HI in sugarcane between 66-81% among different cultivars with the applications of chemical ripeners. HI is a useful parameter to assess the suitability of different sugarcane cultivars for various products in the industry that can vary under the influence of different chemicals and stresses (Naidu and Venkataramana, 1989). It was noted that all the quality and sugar yielding attributes including juice extraction and purity, sugar recovery and yield was increased by the applications of different chemical ripeners. Chemical ripeners or herbicides can affect the production of ethylene that can induce early maturity. Lee and Dumas (1982) found the changes in ethylene production in tobacco with the applications of Glyphosate. Glyphosate beneficially increased the sucrose contents in sugarcane (McDonald and Jackson, 2001). Changes in ethylene level directly or indirectly regulate the lifespan of plants. Ethylene is tightly correlated with the biosynthesis of volatile organic compounds to create early ripening (Iqbal et al., 2017).

Karmollachaab et al. (2016) observed a beneficial increase in juice pole and brix value in sugarcane by applying Glyphosate and Ethephon for 40 and 65 days respectively. Most of the studies have shown that chemical ripeners inhibited the growth and enhanced the early cane ripening process in various crops including sugarcane. Ethephon inhibited the growth but it also enhanced the tillering and emergence of ratoon with rapid maturity. Different cultivars of sugarcane respond in different ways to Ethephon when it is used as a ripener (Castro et al., 2001; Silva et al., 2007). By applying sulfometuron-methyl, a reduction in pith process (50 to 60%) was noted with increased sugar yield (Castro et al., 1996). Studies have claimed that sulfometuron-methyl, as a ripener showed consistent improvement in sugarcane brix, pol and reduced pith process (Caputo et al., 2008). Li et al. (2004) compound ripener in sugarcane had an effect on stick's digestion, development and sugar accumulation. It was noted that sulfometuron-methyl did not affect the sugarcane crop yield (t ha^{-1}) and the agronomic features of the crop but was useful for early ripening (Silva et al., 2007; Leite et al., 2010). Different factors can affect the role of chemical ripeners as Solomon and Li (2004) found that cultivar of sugarcane, functional stage of crop at the time of application of ripeners, application rate of chemical, type or combination of ripener and the conditions of growth prior to or after application affected the response of sugarcane to ethephon and glyphosate.

DOI: http://dx.doi.org/10.15666/aeer/1805_64056423

During this study the change in antioxidant activities were also noted. Activities of enzymes (CAT, POD and SOD) are a significant index to foretell the plant responses to the changing environments and chemicals (Sen and Mukherji, 2009). In plants, antioxidants activities may act like a defense line for many troublesome conditions and induce early ripening (Lohrmann et al., 2004). Moreira et al. (2020) noted that the Glyphosate (0.15 L ha^{-1}) and ethephon (0.33 L ha^{-1}) provided the highest CAT and POD activities without affecting SOD activities of sugarcane. Gill and Tuteja (2010) found that glyphosate increased the CAT activities in sugarcane varieties SP80-1842 and SP80-3280.

In the present studies, it was noted that chemical ripeners had only positive increasing effects for quality and sugar yield for planted crop. It showed non-significant effect on the ratooning abilities, its yield and quality attribute. Ethephon anticipated harvesting stage by minimum 21 days and its residual effect lasted for 60 to 90 days after it had been applied (Caputo et al., 2008). It is well known that chemical ripeners are useful for early cane ripening as well as to enhance the sugar contents and yield in sugarcane but there are some reports showing the negative effect on ratooning abilities. Didier et al. (2017) noted that the applications of glyphosate reduced the sprouting and growth of ratooning crop of sugarcane. Chemical ripener interacted with the production of ethylene for early cane maturity at planted crop but its residual effect was not sustained in ratooning. It was noted that glyphosate negatively affected ratoon and number of stalk. The number and height of cane stalks per unit surface area was reduced (Dalley and Richard-Junior, 2010). Caputo et al. (2008) reported that ethephon showed non-significant effects on sprouting of sugarcane ratoon. Different research studies have reported that non-significant response to sulfometuron-methyl for ratoon of sugarcane. Silva et al. (2007) noted an enhancing effect on the tillering abilities of sugarcane under applications of various chemical ripeners.

Conclusion

It was concluded that chemical ripeners can be suitable to boost up the sugar yielding characteristics by creating early cane maturity for short term duration before cane harvesting of the crop and it will have no effect on lateral life cycle span and ratooning abilities of the crop.

Recommendations

It is recommended that chemical ripeners should be utilized to induce early cane maturity in order to achieve higher sugar production from sugarcane.

Abstract. Biogas production can support waste management efficiently – such an integrated system may reflect the approaches of a circular economic strategy. Our purpose was to assist in this task through the quantification of the methane potential of several substrates in Hungary, and by an investigation of the correlation between methane potential values and other biological-chemical parameters. The experimental substrates (n=10) were wastes and agricultural byproducts. Mesophilic anaerobic fermentation tests were carried out with the instrument AMPTS II in three parallel runs. Substrate from municipal solid waste was excluded, thus the number of parallel tests was nine. In addition, the following properties were assessed (n=3): organic matter, total solid content, volatile solid content (calculated), pH, C/N ratio, and respiration intensity. The methane potential values of the investigated substrates confirmed that Hungary has considerable potential for biogas production. Significant correlation was detected between methane potential (an anaerobic process) and respiration intensity (an aerobic process): the correlation was linear at R^2=0.9899. This phenomenon is very important and the finding is innovative although further research is required.
Keywords: *aerobic degradation, anaerobic degradation, biogas, manure, municipal solid waste*

Introduction

Environmental pollution, the uncertainty surrounding energy supplies, human and animal hygiene, and promoting the security of the food industry require complex and sustainable solutions that include treating and utilizing wastes and byproducts. Treating such materials using anaerobic fermentation has two main advantages: biogas is suitable for producing electricity and thermal power, and the composted digestate as a stable product has auspicious agronomic properties. Accordingly, the proportion of renewable energy that is produced and used can be increased, while the composted digestate is suitable for substituting synthetic fertilizers in agricultural practice, and the effective treatment of wastes and their byproducts is thereby supported.

Research on anaerobic fermentation technology is going through a revolution. The selection of suitable input materials, the preparation methods for substrates, the adjustment of circumstances during the sensitive process – all of these aspects require further scientific research before biogas plants can be operated effectively (Angelidaki

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64256441

and Ahring, 1992, 1993, 1994; Cheng and Zhong, 2014; Tabatabaei et al., 2018). In this paper the results of methane potential tests are presented. One of our purposes was to characterize the potential substrates in Hungary for biogas production and contribute to the establishment of a scientific database related to the Hungarian conditions. It is important to know the properties of the substrates found in Hungary, because the country possess's significant unutilized potential in biogas production. An additional purpose was to identify the correlation between methane potential (MP) and respiration intensity (AT_4) value of a substrate. The goal of it was to find a faster method for determination of suitability of potential substrate materials for biogas production. Carbon-to-Nitrogen ratio (C/N) is not proper in all of the cases (for example in the case of heterogeneous materials). Traditional MP tests need one month, however respiration intensity tests can be performed in 4-5 days.

Present results of methane potential tests

In the last few years, a number of studies about biomethane potential (BMP) tests have been carried out to demonstrate biodigestability, methane yield, reaction-rate kinetics, the extent of anaerobic activity, the influence of pretreatment, and the effects of mixing different viscosities (André et al., 2016; Wang et al., 2017a; Passos et al., 2017; Raj Paudel et al., 2017; Siddique et al., 2018). Many types of substrates, such as solid household waste, pulp and paper mill sludge, wastewater sludge, commercial foodwaste, livestock materials (manures) and agricultural byproducts, and plant residues have been investigated (Wang et al., 2012; Wei et al., 2015; Hidalgo and Martín-Marroquín, 2015; Pecorini et al., 2016; Ebner et al., 2016; Neshat et al., 2017). Pecorini and his colleagues (2016) also reported that BMP tests can contribute to characterizing and evaluating the optimal performance of a full-scale anaerobic digestion (AD) process.

Li et al. (2015) reported the laboratory scale methane potential (MP) tests of pig-, dairy-, cattle-, and rabbit manure. Based on the volatile solid (VS) (referred to dry matter; d.m.) and pH values of the substrates, these samples may be suitable for biogas production, although their C/N ratio and cellulose and lignin contents were not found to be adequate. Their analysis confirms that manures from different types of livestock may have very different properties, leading to variable performance in biogas production. During BMP tests different organic loading rates (OLR) were also investigated: 8, 16, 32, and 64 g VS/l. Results show that the maximum point of the methane potential curve was reported increasingly later in time, and cumulative methane potential decreased due to the increasing OLR. A further important result is the observation of a decrease in the degradation of organic material while OLR increases. De la Rubia et al. (2009) explained this phenomenon by claiming that high substrate concentration can lead to the inhibitory effects of ammonium-nitrogen. Another possible reason is the decrease in inoculum-to-substrate ratio. Dairy manure produced the lowest amount of methane because of its fibre content. Research by Wu et al. (2017) confirmed the results of Li and his colleagues: swine manure contains cellulose and hemicellulose in high proportions, which compounds have a low hydrolysis rate, therefore their biodegradability is also low. Thermal pretreatment of carbohydrates increases methane production: without pretreatment the MP of swine manure is 201.9 ml CH_4/gVS; however, three-day thermal treatment may increase MP by 39.5%.

Hardly biodegradable carbohydrates are present in significant proportions also in the organic fraction of municipal solid waste (OFMSW). OFMSW investigated by Ventorino et al. (2018) contained 30% cellulose, 21% hemicellulose, 15% starch, 12%

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64256441

pectin and 20% lignin. Ventorino performed medium-scale BMP tests (digesters were 100 l in capacity). According to their results, mechanical pretreatment efficiently increases biogas production. Krause et al. (2018) sorted an OFMSW fraction into its components and analyzed them separately, creating opposing results: in the case of certain carbohydrates, decreasing the size of pieces did not have a significant effect on MP. An important difference between the two types of examination is the method: Ventorino (2018) used dry fermentation, while Krause (2018) used wet fermentation. Dry fermentation is recommended if the dry matter content of the substrate is over 15% (Li et al., 2011; Ge et al., 2016; Chiumenti et al., 2018). However, this technology is not in practice routinely used. Riya et al. (2018) performed dry fermentation tests using 20 l volume and a semi-batch run. He found that the operation of the reactor can be stable if total solid (TS) content is between 18-27%.

However, it should be mentioned that the determination of methane potential is lacking with regard to the standardization of protocols (André et al., 2018). The values obtained by different laboratory procedures represent the methane potential stated in the literature that is used to dimension the units, thus sometimes resulting in under- or over-sizing. An interlaboratory assay in France involving eleven laboratories showed that interlaboratory reproducibility had a coefficient of variation (CV) of 20% and an interlaboratory repeatability with a CV of 10% for a given substrate, although different protocols were used in the laboratories (Cresson et al., 2015). For any given protocol and substrates, interlaboratory reproducibility had a CV of 17%, and a CV of 5% for intralaboratory reproducibility. In addition, anaerobic fermentation is an extremely complex process which is influenced significantly by biological-chemical factors, living and non-living agents, and the interactions between these (Ebner et al., 2016; Tsapekos et al., 2017). The more influential physical-chemical parameters are temperature, pH, C/N ratio, OLR, alkalinity, and the concentration of volatile fatty acids (VFAs) (Tufaner and Avsar, 2016; Koch et al., 2017; Ventorino et al., 2018). Nevertheless, a new European interlaboratory assay is taking place and should soon provide new conclusions in this aspect (Holliger et al., 2016).

Alternative parameters for characterization instead of BMP

Although BMP tests can be carried out very simply by using AMPTSII (Automatic Methane Potential Test System), this process takes at least 3-4 weeks, thus it would be practical and useful to be able to characterize potential substrates with analytical methods which take less time. Moreover, if such an analysis can be standardized, the reproducibility and reliability of results could be improved.

According to Wang et al. (2017b), the determination of the available carbon to nitrogen ratio (AC/N) may be an alternative way to appraise the suitability of potential substrates for biogas production. This procedure is particularly efficient in the case of substrates which contain slowly biodegradable compounds. However, all types of manure and MSW contain such components to some degree.

NIR spectroscopy (Near Infrared Reflectance Spectroscopy) can also be suitable for determining MP quickly and precisely (Triolo et al., 2014). NIRS is a non-destructive, real-time measurement which has also been used in biofuel technology over the last decade. In addition, there are a few studies regarding the application of NIRS in the estimation of methane potential – these are based on the following substrates: MSW; MSW mixed with agroindustrial wastes; and meadow grass (Lesteur et al., 2011; Raju et al., 2011; Doublet et al., 2013), respectively. The goal of Triolo and his colleagues was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64256441

to set up a robust model for predicting BMP based on NIR spectra. Their study is satisfactory and the related model can be used for the estimation of BMP. However, it should be mentioned that NIRS requires specific user knowledge, and a reference spectra database must be set up for calibration.

Standardized respiration intensity can be a further alternative for appraising MP. One suitable piece of equipment for performing such measurement is the so-called OxiTop®. Its scope is limited to determining the biodegradable organic content of mechanically-biologically treated wastes (there are a lot of cases when traditional analytical methods – total organic carbon, dissolved organic carbon, loss on ignition – are not suitable for determining this).

Tests using OxiTop®

Standardized German and Austrian methods for determining respiration activity (AT_4) are based on equipment made by Sapromat®. This technology is associated with several advantages (fluctuations in atmospheric pressure do not affect the measurements; oxygen is not a limiting factor; a great amount of data can be fixed; its operation is flexible), although the use of OxiTop® has become increasingly frequent over the last few years. The reason for this is the fact that OxiTop® is rather user-friendly and cheaper. It is, however, necessary to execute comparison tests in order to confirm the hypothesis that the two methods are equivalent. Binner et al. (2012) studied wastes (n=169) using both methods to the determine statistical relationship between them. Results showed that the correlation was good: R^2=0.987. The coefficient of determination was also appropriate in the case of low reaction wastes (AT_4 < 20 mg O_2/g d.m.): R^2 = 0.983. This research confirms that Sapromat® can be substituted by OxiTop®.

This is important for us, because our purpose was to find an appropriate method to prise the suitability of substrates for biogas production. C/N ratio is not proper in all of the cases (for example in the case of heterogeneous materials). Traditional MP tests need one month, however respiration intensity tests can be carried out in 5 days. Further purpose was to characterize substrate materials in Hungary.

Materials and methods

Experimental materials

Substrates

The samples were different manures and wastes; their abbreviations are listed in *Table 1*.

Table 1. *Abbreviations of the substrates*

Name of the samples	Abbreviation
Cattle manure with litter 1	CMwL 1
Cattle manure with litter 2	CMwL 2
Liquid cattle manure with straw	LCMwS
Swine manure	SM
Spent mushroom compost	SMC
Cattle manure fresh-compost	CMC
Liquid cattle manure with shredded straw	LCMwSS
Liquid swine manure with straw	LSMwS
Separately collected green waste	GW

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64256441

CMwL1 and CMwL2 are littered manures, while LCMwS and LCMwSS are liquid cattle manures. The difference between them is the method of pretreatment. We mixed these liquid manure samples with straw, but in the case of LCMwSS the straw was shredded into pieces of 2 cm size. SMC refers to spent mushroom. CMC is fresh cattle manure compost. SM is swine manure, while LSMwS is liquid swine manure with straw. Municipal solid waste (MSW) was treated using mechanical-biological methods. We investigated the fraction which is smaller than 25 mm. Green waste (GW) was supplied by a regional waste collection company. In the case of liquid manures, tests were executed after mixing them with straw in proportions of 1:1 by weight. The biodegradability of straw was not increased in advance (for example, using aerobic methods) to enhance hydrolysis. Straw was only shredded in the case of LCMwSS.

Inoculum

We obtained the inoculum from the mesophilic reactor of an operating plant in Hungary. The substrates of this plant are agricultural materials (animal manure and plant residue) and industrial food byproducts.

Experimental methods

BMP tests with AMPTSII

The anaerobic digestion study was carried out in AMPTS II, produced by Bioprocess Control AB. Comparison tests were performed using AMPTS II for determining BMP. Results confirmed the reliability of the method (Kleinheinz and Hernandez, 2016).

Before the tests, BMP reactors were purged with high purity nitrogen for three minutes to remove oxygen from the reactor head-space. The exact weight of substrates and inoculum was calculated by software based on the volatile solid content (VS) and the inoculum-to-substrate ratio (I/S). The latter was always 2:1. The total volume of substrate and inoculum in the reactors was always 400 ml, therefore the volume of the gas that was produced was 200 ml.

Blanks and positive blanks (references) were measured in every sequence in parallels of 3-3, thus we could measure only three different substrates (also arrayed in 3-3 parallels) in one sequence. In the case of blank measuring, only inoculum was entered into the reactors after weighing. In the case of positive blanks, we used microcrystalline cellulose, a product made by Molar Chemicals Kft. The positive blank was used as a reference with regard to identifying the biologically activity of the inoculum.

The length of time for one sequence was 20-30 days. Tests were stopped if the volume of methane produced in one day was less than 20 ml.

Further measurements

Before starting the tests it was necessary to determine the total solid (TS) and the organic matter (OM) content of the substrates and the inoculum; furthermore, to calculate VS content. The calculation of VS was accomplished according to *Eq.1*.

$$VS(\%) = (m_{dried} - m_{burned}) / m_{wet} \quad \text{(Eq.1)}$$

These data were necessary for determining the exact weight of the substrates and the inoculum to be put into the reactors. Total solid measurement was done based on the standard MSZ EN 13040:2008. Measurements of organic matter were based on the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64256441

method of loss on ignition (LOI) (MSZ EN 15935:2013). Further analytical measurements were carried out: C/N ratio, respiration intensity, and pH. Measurements of carbon and nitrogen content were performed using Elementar Vario Macro, the standard for which was MSZ EN ISO 16948:2015. Respiration intensity values were determined by using OXITOP®. Originally, the procedure was standardized to measure the biological stability of wastes, although it has been confirmed that OXITOP® can be efficiently and reliably used for another purposes (Binner et al., 2012; Malinska, 2016). The temperature at which measurement was taken was 20°C, and the duration of the tests was seven days (accordingly, the abbreviation for this measurement in the following parts of the paper is AT_7). pH was measured according to the standard MSZ EN 13037:2012. Every analytical measurement was carried out in three replications.

Statistical methods

The statistical analyses were performed using PAST3 statistical program version 1.0.0.0. Three independent replicates were used for each measurement. One exception is the BMP measurements of municipal solid waste (n=9). We did polynomial regression calculation on BMP curves. We accomplished normality tests and Levene's tests on methane potential, respiration intensity, carbon-to-nitrogen ratio and organic matter data. Valid normality and homogeneity of variance are minimum assumptions to doing ANOVA analysis on data. ANOVA analysis could not be used because of the violation of the assumptions, therefore non-parametric Kruskal-Wallis tests were accomplished on data.

Relationship between the four mentioned parameters (MP, AT_7, C/N, OM) was checked by cluster analysis.

Results

TS, VS, OM, C/N ratio, pH and respiration intensity results for the substrates can be seen in *Table 2*. The values represented are the averages of three replicate measurements in every case. VS is a calculated parameter (*Eq.1*). Relative deviation values (SD%) are represented in parenthesis for every substrate and every measurement. Relative deviation value of LSMwS in the case of TS measurements is outstanding. Probably the reason of that is the mistake of sample weighing (differences in the straw content). Relative deviation value of MSW in case of the pH measurements is also higher by an order of magnitude than the other pH values. The reason is the characteristic of MSW sample – MSW is very heterogenous so the number of replicates was not enough in this case.

From the perspective of anaerobic digestion, the pH values for substrates of agricultural origin were neutral or weakly alkaline, therefore adjustment of pH was not necessary. In the case of MSW, pH was low (5.44; SD%=10.4%), but we did not add sodium-hydroxide because Na^+ ions in high concentration may inhibit the process of anaerobic fermentation. The C/N ratio was outside the acceptable range (20-30) in the case of four substrates: SMC and CMC had a slightly lower value (13.9 and 11.6, respectively), while LCMwS and LCMwSS substrates had a higher C/N ratio than optimal (34.1 and 73.2, respectively). BMP and respiration intensity (AT_7) values can be seen in *Table 3*. The number of parallel measurements was also three. In the case of BMP measurements of MSW the number of replicates was 9 because of its heterogenity.

MSW	325.71 (16.7%. n=9)	19	137 (3.7%. n=3)

AMPTS II equipment saves data in continuously cumulated form, although separately, on a daily basis. Accordingly, we can characterize every single day according to the amount of methane that was produced and the differences in the three parallel measurements. The standard deviation of the blank measurements were between 1.3 – 14.87% in every measuring sequence. Positive blank measurements also confirmed the microbiological activity of the inoculum in every measuring sequence (0.2 – 10.6%).

DOI: http://dx.doi.org/10.15666/aeer/1805_64256441

Based on the results concerning respiration intensity, SMC and GW substrates contained biologically degradable organic matter in low amounts (9 and 7 mg O_2/g d.m., respectively), and their average BMP values are in line with this finding. LCMwS is outstanding from the point of view of respiration intensity (159 mg O_2/g d.m.); however, MSW and LCMwSS also showed high activity (137 and 98 mg O_2/g d.m., respectively). CMC and CMwL2 substrates (which contained nutrients hardly available to microorganisms in anaerobic digestion processes based on the shape of BMP curves (*Fig. 1*), standardized curves (*Fig. 2*), and gradient values (*Table 4*)) showed medium respiration intensity (40 mg O_2/g d.m. (22.1%) and 41 mg O_2/g d.m. (9.9%), respectively). Further results concerning the respiration intensity of all of the substrates and their standard deviations can be seen in *Table 3*. Relative deviations of CMC in the case of BMP and AT_7 measurements (30.2% and 22.1% respectively) are outstanding. CMC sample was a fresh compost, so the reason probably is the heterogenity.

The average methane potential curves of the substrates can be seen in *Fig. 1*.

Table 4. *Gradiation values of the initial phase (first 5 days) of MP curves*

	y	R^2
CMwL1	23.661	0.9299
CMwL2	9.7244	0.9754
LCMwS	41.018	0.9650
SM	15.386	0.9997
SMC	6.0845	0.9778
CMC	5.6638	0.0983
LCMwSS	31.116	0.9983
LSMwS	21.942	0.9940
GW	10.984	0.9997
MSW	51.306	0.9865

The shape of the BMP curve for substrate CMwL1 refers to the right conditions for anaerobic digestion. Based on the shape of the BMP curve of substrate CMwL2 (it has a moderate gradient), it is clear that the organic matter content is hardly available to microorganisms. Considering the results of the previous analytical measurements, there is significant difference between the two substrates in terms of AT_7. These seven-day and aerobic tests also showed the low availability of nutrients for microorganisms in the substrate-inoculum mixes (*Table 3*). In the case of LCMwSS, the high C/N value (73.2) indicated in forward inhibitor processes during AD, which assumption is confirmed by the shape of the BMP curve. The results for the CMC substrate are also expressed in average values, which is misleading: BMP (*Table 3*), respiration intensity (*Table 3*) and OM content (*Table 2*) results for CMC are associated with a notable standard deviation. In the case of MP tests, two measurements of the three replications showed the following: gas production started on the fifth day, and at the end of the test the final and cumulated methane yields showed more than 30% standard deviation relative to each other. Results of previous measurements of SMC substrate (low OM content (53.5%), C/N ratio (13.9) and respiration intensity (40 mg O_2 /g d.w.)) also indicated inhibition of microbial gas production. MSW is a strongly heterogeneous substrate, although the actual results also confirm its significant biodegradable material content. The average BMP of the nine MSW measurements (325.71 Nml/gVS, SD=16.7%, n=9) is in line with finding in the literature (Jokela et al., 2005; Liu et al., 2008; Pecorini et al., 2016; Krause et al., 2018; Ventorino et al., 2018).

Standardized curves were made from the standardized BMP values (calculation was based on the average values), and shown in *Figure 2*. In this way, the quality of degradation processes in the single reactors can be compared easily.

It can also be seen that CMC and CMwL2 substrates contained only weakly available nutrients (*Fig. 2*). The initial gradient of the curves (*Table 4*) indicates the previous phenomenon in numbers. Based on the standardization, there was no significant difference in the quality of microbial degradation processes between the nine parallel measurements of MSW (*Fig. 3*). Final and cumulated methane production varied between 228.86 – 385.57 Nml/gVS (SD%=16.7%) because of the quantity of added OM; however, biochemical processes continued very similarly, despite the heterogeneity of the MSW substrate.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64256441

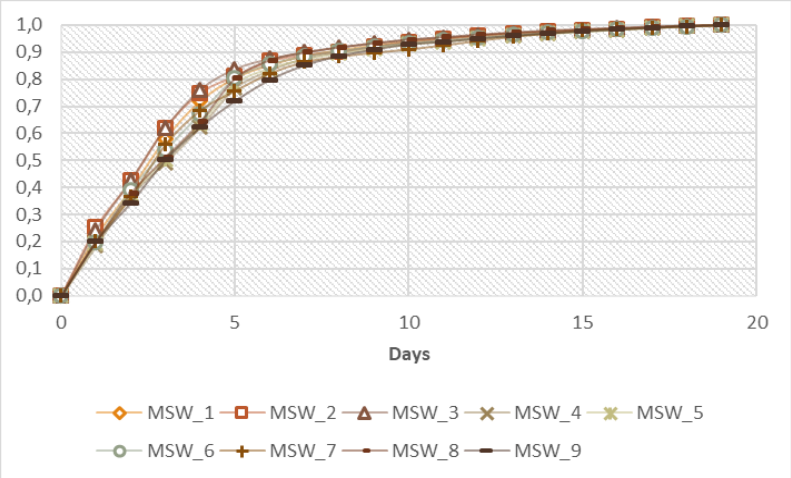

Figure 3. *Standardized curves of the nine parallel measurements of MSW*

The gradients of the initial five days of methane potential curves, and also the accuracy values for linear trend-lines can be seen in *Table 4*. The initial intensity of methane production shows the availability of organic matter in the substrate. Based on this conception, the OM content of CMC and SMC substrates was hardly available, although in case of CMC, after the first step of AD (hydrolysis), aerobic and anaerobic degradation also occurred (AT_7 40 mg O_2/g d.m., BMP 135.9 Nml/gVS). Degradation tests for SMC showed (AT_7 9 mg O_2/g d.m., BMP 48.39 Nml/gVS) that its biologically degradable organic matter content was minimal. Total organic matter content was measured with the 'loss on ignition' method; the result was also low: 53.5%.

Very important experience during our experiments is the correlation between BMP and AT_7 measurement. Respiration intensity measurement is based on aerobic biochemical processes, so the composition of the microbial consortium is different than under anaerobic conditions. However, data from these measurements (*Table 3*) showed strong correlation with BMP results from anaerobic digestion tests (*Table 3*). The correlation between the two kinds of data can be seen in *Fig. 4*. The quality markers of the linear correlation between the two parameters are: r=0.9955, R^2=0.9911, t=29.81, p=1.7372E-09, permutation p=0.0001. The results of these tests confirm our hypothesis: previous respiration intensity tests of potential substrate materials indicate their suitability for biogas production. This is very useful in practice because BMP tests are very time consuming. Performing respiration intensity tests is more time-efficient.

Statistical analyses

The first step of the statistical analysis involved doing polynomial regression fittings (second, third and fourth order) on BMP curves. According to the qualitative parameters different orders were fitted for the certain curves. Second-order regression was applied in the following three cases (*Table 5*): CMwL2, SMC, and CMC. Third-order regression was applied in the case of SM, LSMwS, and GW, and fourth-order in the case of CMwL1, LCMwS, LCMwSS, and MSW.

Normality tests were carried out on BMP, respiration intensity, C/N ratio, and OM content results (*Tables 6 and 7*). Data of AT_7 and C/N ratio measurements were well-modeled by normal distribution in case of all substrates.

In the case of BMP results, data of three substrates were not well-modeled by normal distribution: SM, LCMwS and CMC. The non-compliance of the results of BMP for SM and CMC substrates may originate from the low number of parallel measurements. The CMC substrate was heterogeneous, as represented in the values for standard deviation.

In terms of OM content, another two substrates were not well-modeled by normal distribution: CMwL2, and LCMwS. This non-compliance may also be due to their heterogeneity and the low number of parallel measurements.

However homogeneity of variance is also an assumption of the ANOVA analysis, therefore we applied Levene's test to test the null-hypothesis that the variance is equal across groups. Both of normality and homogeneity of variance need to be valid on data for applying ANOVA analsyis. Calculations of Levene's tests were done from means and also from medians. (p) values calculated from means are the following: BMP 0.001029, AT_7 0.02819, C/N 0.0001289 and OM 3.24E-04. (p) values calculated from medians are the following: BMP 0.3207, AT_7 0.194, C/N 0.5165 and OM 0.3059. These results of Levene's tests mean a violation for the whole amount of data, therefore one-way ANOVA could not be applied for analyzing.

Calculated parameters of Kruskal-Wallis tests on measurement data are the following. For BMP: H(chi2)=25.9, Hc(tie corrected)=25.9, p=0.002119. For AT_7: H(chi2)=27.51, Hc(tie corrected)=27.51, p=0.00115. For C/N: H(chi2)=26.79, Hc(tie corrected)=26.79, p=0.001516. For OM: H(chi2)=25.84, Hc(tie corrected)=25.87, p=0.002145. These result mean that there was a significant difference between sample medians in all of the measurements (BMP, AT_7, C/N, OM).

Based on cluster analysis, there is direct correspondence between BMP and respiration intensity: the correlation is 0.9986 (*Fig. 5*).

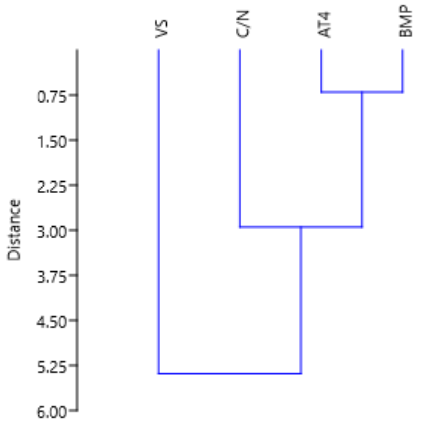

Figure 5. *Cluster analysis between the investigated parameters*

Discussion

Our results are in accordance with the results published in 2015 by Li et al. In these investigations, some substrates had an overly high or low C/N ratio. In such cases, it is expedient to mix the substrate with material which has other chemical characteristics in order to meet the criteria for biochemical processes and effective reactor operating (for example straw). The liquid manure substrates represented in this study were mixed with straw or shredded straw (LCMwS, LCMwSS, LSMwS). The BMP value of liquid manure mixed with previously shredded straw was lower than the same liquid manure mixed with straw (without shredding) (*Table 3*). However this result are in contrast with general findings in the literature (Neshat et al., 2017; Raj Paudel et al., 2017) concerning the effects of mechanical pretreatment. Probably the degree of shredding was small in the case of our experiment.

Fiber-characterised compounds (cellulose, lignin, hemi-cellulose) are hardly biodegradable (especially in terms of anaerobic degradation). This is the reason for the low BMP values of substrates which contain fibre in significant amounts (SM). However, prior aerobic treatment may increase methane production, but this was not investigated in the present study. Among the substrates investigated in this study, only SM contains fibre in significant amounts. According to Wu et al. (2017), cellulose and hemi-cellulose are significant components of swine manure. We could not measure fibre content, although the values for BMP and AT_7 for SM were notably lower than the results for cattle manures.

Based on the research of Krause et al. (2018) and Ventorino et al. (2018), weakly biodegradable carbohydrates are also present in the organic fraction of MSW in notable amounts. However, it is very important to take into consideration that the composition of MSW can be very different in certain regions. Besides this, the organic fraction in MSW is high in most cases – indicating that we can create value and products during the aerobic and / or anaerobic treatment of MSW. Because of its complex composition and heterogeneity, at least mechanical pretreatment is necessary before loading the reactors. Regarding weakly biodegradable compounds (carbohydrates of big molecular

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64256441

weight), we suggest mechanical-biological treatment prior to anaerobic digestion. In terms of the methane potential of the MSW substrate investigated in this study (325.71 Nml/gVS, SD=16.7%), this type of waste is definitely suitable for biogas production. This experience is totally in line with literature (Liu et al., 2008; Pecorini et al., 2016; Ventorino et al., 2018). On the other hand, municipal solid waste may contain organic and inorganic pollutants, therefore digestate obviously cannot be used in agriculture, nor after composting. Digestate from municipal solid waste must be incinerated. However, nowadays this process can be clean and environmentally safe, moreover, heat power and electricity can be produced from it. The MP values of the investigated substrates are in accordance with literature (Wang et al., 2012, 2017a; Hidalgo and Martín-Marroquín, 2015; Wei et al., 2015; André et al., 2016; Pecorini et al., 2016; Passos et al., 2017; Raj Paudel et al., 2017; Neshat et al., 2017; Siddique et al., 2018).

Correlation – with a good correlation coefficient – between data for respiration intensity and methane potential was not evident and was not written in the literature earlier. A basic difference between the two processes is the presence of oxygen, and therefore the difference in the microbial consortium of the biochemical process, thus it appears that degradation of the biodegradable fraction of the substrates occurred in two different biochemical ways. Despite this, we found linear correlation between the results of the two different examinations. This is an important fact, since respiration intensity tests with OxiTop® take a shorter time (4-7 days) than methane potential tests (at least one month).

Conclusion

According to the results of our laboratory-scale methane potential tests, the investigated substrates may be suitable for biogas production in full-scale conditions (in some cases, co-digestion may be needed). Hungary does have a significant potential in biogas production which is unutilized presently. The results of this study are especially important with regard to the establishment of a Hungarian scientific database which contains information about the biodegradability and other biological-chemical-physical properties of potential substrate materials. Henceforward we improve and enrich the database with further measurement data of substrates. It is also important to investigate the affects of pretreatments and certain adjustments (pH, OLR, etc.).

Considering the results of our investigation into correlation, there is a linear relationship between data concerning the aerobic and anaerobic parameters of wastes and agricultural byproducts. This finding can contribute to further developmental endeavors. The aerobic respiration intensity measurements need much less time than biomethane potential tests. Prising the suitability of potential substrates for biogas production can be done more effectively using the linear relationship represented in this study. However further research on this correspondence with bigger number of investigated samples is important (and with more replicates), and also pilot scale experiments are necessary.

Nowadays law on environment and on waste management is getting more and more strict in the European Union, so the results displayed may play an important role to support Hungarian developments on these fields.

(Received 8th Apr 2020; accepted 13th Aug 2020)

Abstract. This study conducted in a rearing room (RR) (300-410 ppm) and in an open roof ventilation greenhouse system (ORVS) (800-950 ppm). No changes observed on *Carpophilus mutilatus* colouration after treatment in the ORVS. The survival rate increased from 61.59% in the F1 to 73.05% in the F2 generation reared in the RR. However, a sharp decline was observed from 27.05% in F1 to 1.5% in F2 in the ORVS. There was significant difference in number of individuals between RR and ORVS in F1 and F2 (F 12.76 p= 0.001< 0.05). The life span of F1 and F2 in the RR took about 46 days to complete; 7-21 days from adult to larvae stage, 5-15 days from the larval to pupal stage and 3-10 days from adult to pupal stage. Whereas in ORVS, F1 and F2 took about 30 and 22 days, respectively to complete their life cycles; that is 7-14, 7-14 days (adult to larval stage), 5-10, 0-5 days (larval to pupal stage) and 3-6, 0-3 days (pupal to adult stage), respectively. These data can be used to describe the changes in *C. mutilatus* due to global warming effects, as CO_2 could be one of the main factors affecting the growth and development.
Keywords: *morphology, biology, climate change, insects, global warming*

Introduction

The life cycle and life span of insects depend on a variety of factors including biotic and abiotic factors. Biological information regarding the life cycle, life span and mortality rates of important groups of insects, especially pests and natural enemies, are crucially important for the biological control program (Gurr et al., 2000; Khaliq et al., 2014). These parameters are usually studied under laboratory conditions where the insects are reared in cages closely representing their native habitat, with the advantage that the studied parameters and test animals are well controlled and the trials can be carried out more easily than in the field (Leppla, 2009). Insect rearing in the laboratory is important as the basis for developing a cost-effective large-scale mass-rearing in Integrated Pest Management (IPM) (Echegaray and Cloyd, 2013). Nitidulid beetles in the genus *Carpophilus* are important pests of dried fruit worldwide but have recently also become serious pests of ripening stone fruit in southern Australia (James and Vogele, 2000), as well as palms, including dates and oil palm fruits (Blumberg, 2008; Nor Atikah et al., 2019). Adult beetles damage fruit either by chewing through the skin, usually at the stem end, or entering from the sites of mechanical damage.

Taxonomists also implemented a rearing method as the first step for species identification, especially at the early stage. The insect larvae and pupae need to be reared into adult stage in order to identify the species correctly (Gibbs et al., 2015). However, insect rearing methods often require optimum conditions that correlate with their natural

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64436455

habitats so that the insects are healthy, free from disease and can reproduce for future generations. Therefore, factors such as environmental conditions, food sources and rearing chambers should be appropriate, simple and cost-effective (Cohen, 2018). The rearing of nitidulid beetles in the laboratory had been studied to determine their diets (Dowd, 1987; Peng and Williams, 1990; Dowd and Weber, 1991) and under different temperature conditions (De Guzman and Frake, 2007; Cuthbertson et al., 2008) to measure their survival, development and reproduction rates (Tsukada et al., 2005; Okada and Miyatake, 2007; Meikle and Patt, 2011).

Greenhouse gases such as carbon dioxide, ethane and nitrous oxide are often associated with global warming (Cox et al., 2000; Root et al., 2003; Ainsworth and Long, 2005; Meinshausen et al., 2009). CO_2 accounts for about 82% of greenhouse gas emissions compared to other gases (EPA's Greenhouse Gas Inventory 2017). The CO_2 gas that is trapped in the atmosphere captures heat and prevents it from being released, which can lead to global warming. This phenomenon affects biological changes in many organisms such as animals and plants (Hunter, 2001; Peñuelas et al., 2002; Mondor and Tremblay, 2010; DeLucia et al., 2012; Khaliq et al., 2014). Insects are expected to be more vulnerable and sensitive to environmental changes as they are ectothermic organisms and have a short lifespan (Bale et al., 2002). For example, long-term studies on Lepidoptera found that the life cycles of this insect group are shorter as a result of global temperature changes (Roy and Sparks, 2000; Peñuelas et al., 2002; Wallis de Vries and van Swaay, 2006). The distribution of the lepidopteran species from the family Geometridae was elevated by 67 meters of altitude over 42 years due to increasing annual temperatures (Chen et al., 2009).

Previous studies, mostly conducted between 1980-90, included reports on the interactions between herbivorous insects and plants exposed to high concentrations of CO_2 gas (Agrell et al., 2000; Chen et al., 2005; Dáder et al., 2016). The oviposition behaviour of *Cactoblastis cactorum* (Stange, 1997, 1999), the feeding behaviour of the larvae of *Diabrotica virgifera* and *Helicoverpa armigera* (Rasch and Rembold, 1994; Bernklau and Bjostad, 1998) and the host-searching behaviour of mosquitoes (Gillies, 1980; Eiras and Jepson, 1991), all were reportedly influenced by the concentration of CO_2 gas as one of the most important environmental parameters. Most of these studies have been conducted in specialized rooms, especially in greenhouses or closed rooms with specific controlled parameters (Kimball et al., 2002).

In most studies, the CO_2 concentration was usually raised to twice the ambient level, or monitored between 700-720 ppm (Hughes and Bazzaz, 2001; Veteli et al., 2002; Johns et al., 2003). Therefore, our objectives were to investigate the effect of increasing CO_2 levels on the colour changes, mortality rates, life cycle and life span of the oil palm pest, the nitidulid beetle *Carpophilus mutilatus* reared under two different conditions, i.e. within the Rearing Room (RR) and in the Open Roof Ventilation Greenhouse System (ORVS). The results are expected to be very useful in predicting the future changes in the population of nitidulid beetles, particularly the pest species of our oil palm crop (Blumberg, 2008; Nor Atikah et al., 2019).

Materials and Methods

Trap design

The nitidulid beetle trap in the field was designed using a 1.0 L transparent plastic container with a cover. A 10.2 cm x 5.1 cm window was cut 5 cm from the top edge of the trap and then covered with a muslin cloth for air ventilation. The trap was filled with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64436455

dried soil up to 10 cm from its base. A rope was fastened to both sides of the trap to hang it onto a palm tree. Ripe bananas were used as food bait (*Figure 1*).

Figure 1. *Trap of C. mutilatus*

Cultural sampling of C. mutilatus

The sampling of *C. mutilatus* was conducted in September 2015 at an oil palm plantation in Felda Lui Muda, Negeri Sembilan, in the west coast of Peninsular Malaysia (GPS: latitude 3.013396 longitude 102.379504). The traps were used to obtain live samples of *C. mutilatus* for rearing process in the Rearing Room (RR). In the sampling area, only mature palm trees (aged 18 years and above) were selected for trapping. Three traps were hanged randomly 1 m above ground at 50 m apart from each other. The traps were inspected every three days and each trap was placed in a container containing ripe fruits and water. The trapped nitidulid beetles were taken to the Centre for Insect Systematics (CIS) laboratory, Universiti Kebangsaan Malaysia (UKM) for species identification. Only beetles from *C. mutilatus* species were selected for the rearing process in the rearing room.

Rearing process of C. mutilates in the Rearing Room (RR)

The rearing of *C. mutilatus* was conducted in the Rearing Room at the Biology Building, Faculty of Science and Technology, UKM following the method by Nur Hasyimah et al. (2018). The room temperature and humidity were controlled at 28-32 °C and 77-85%. A 19 x 14 x 12 cm transparent plastic container was used to rear the *C. mutilatus* specimen samples. The container was covered using a muslin cloth to prevent the beetles from escaping and a 3 cm depth of soil medium was placed inside each container to simulate the original natural habitat of *C. mutilatus* and to maintain moisture. In this study, the selected culture room was a closed system that was used exclusively for insect rearing and was also free from chemical contamination and other animals or insects. The room also had a good ventilation system to maintain the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64436455

temperatures at 28-32 °C and 77-85% humidity. Controlling temperature and humidity at appropriate levels is important to prevent fungus and other diseases that could affect the rearing process of the beetles (Singh, 1982).

A total of 200 test beetles were used for the experiment with 20 randomly selected individuals of *C. mutilatus* species placed in 10 different containers (replicates). In this study, only 20 adult beetles were placed in each culture container to prevent overpopulation, which could lead to a reduction in survival rates due to injury and lack of phosphorylation. The 3 cm depth of soil medium in the culture container was important for the pupal stage of the nitidulid beetles, which would also involve the process of fertilizing the soil during the developmental stages of their life cycle (Myers, 2001).

Once the larvae reach their optimum growth, they will excavate up to 2.5-7.5 cm depth in the soil to provide space for the pupal stage (Capinera, 2001). Water was sprayed every three days to maintain moisture in the container and ripe banana fruit was provided as a food source. The diet or food source provided is an important factor for optimal growth. In this study, mature palm fruit was given to the adult beetles as a food source. Palm fruit also provided a suitable medium for egg-laying and larval growth of the nitidulid beetles. The female would deposit its eggs in the mesocarp and in the early stage of development the larvae would eat and crawl within the fruit before exiting and searching for soil to continue with further pupal development (Glazer et al., 2007). Adult beetles would enter the palm fruit on the calcareous side and obtain food through the fibers (Blumberg, 2008).

The temperature and humidity parameters were monitored every three days using a Digital Hygrometer, i.e. a MEXTECH TM-2 model (Global Instruments, new Delhi, India) while CO_2 concentration was monitored using a CO_2 Meter, i.e a 8802-EN-00 version (BENETECH, China). The CO_2 concentration in the RR was between 300-410 ppm.

Rearing process of C. mutilatus in the Open Roof Ventilation Greenhouse (ORVS)

The same rearing process as above was used for *C. mutilatus* trial specimens placed in ORVS following the method by Nur Hasyimah et al. (2018). The temperature and humidity of the ORVS were controlled using a computerized system and ranged between 25-45 °C and 37-87%, respectively. Abiotic parameters such as temperature, air humidity and CO_2 concentration were monitored every three days through readings on the system's screen display. In ORVS, the CO_2 treatment was given daily from 9-11 am. Pure CO_2 spraying was continued for two hours at a concentration of 800–950 ppm. After two hours, the CO_2 levels inside the ORVS was almost equal to the CO_2 levels outside. The gas was supplied through a cylinder connected to the air-conditioning system for open-air chambers and vents. The CO_2 concentration was regulated by dilution with air produced by an air blower. CO_2 analysers were used to monitor CO_2 concentrations and the automatically controlled ORVS systems monitored by the Climate Change Institute (IPI), UKM.

Monitoring the life cycle and life span of C. mutilatus

The life cycle of *C. mutilatus* was monitored daily and the emergence of the first instar larvae was recorded. The larvae were promptly isolated into different containers containing the soil medium as described earlier. Larvae that had turned into pupae were removed from the soil and placed in different containers until they became adult beetles. Observations were conducted throughout the life cycle of the beetle up to the adult stage. The number of individuals at each stage (survival rates), lifespan and body colour changes

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64436455

were observed and judiciously recorded. In each stage, five individuals were selected and the colour changes were observed every two days under a microscope.

Data analysis

Two-ANOVA was used to determine any significant differences and variations between the test individuals observed between RR and in ORVS and in the F1 and F2 generations. The analysis was implemented by using Minitab17.

Results

Effect of the different CO_2 concentrations on the external morphology (body colour) of C. mutilatus in RR and ORVS

Life cycle was observed starting from the instar larval stage 1. No obvious change in body colour was observed in *C. mutilatus* reared in RR and in ORVS, even at elevated CO_2 levels. The short life cycle and morphology of *C. mutilatus* from the larval stage are as follows;

The larvae were milky-white colour on the first day of hatching and would turn into yellow when they reach the active stage and started searching for food (*Figures 2a-b*), while the pupae were white in the early stage, and would turn into brown upon reaching the final stage, and before emerging as adults (*Figures 2c-d*). Adult beetles of this species were dark brown or deep brown in colour (*Figures 2e-f*).

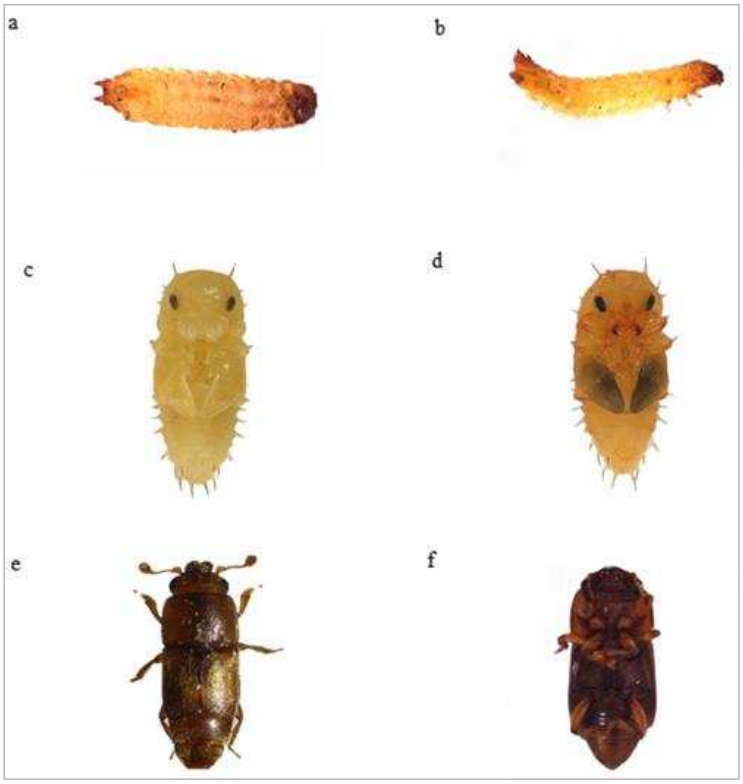

Figure 2. *External morphology of C. mutilatus a) Larval stage (ventral) b) Larval stage (c) Early stage d) Pupa stage e) Adult stage (dorsal) f) Adult stage (ventral), taken from the ORVS system*

Effect of different CO_2 concentrations on the number of individuals, life cycle and life span of C. mutilatus

The number of live *C. mutilatus* individuals at each developmental stage was recorded in the RR and ORVS systems. The CO_2 levels were between 300-410 ppm in the RR, and 800-950 ppm in the ORVS. In the RR, the average live individuals obtained for F1 was 2283 at the larval stage, 1727 at the pupal stage, and 1406 individuals that had successfully emerged into adults. For the F2 generation, from 1406 F1 adults, 5162 larvae, 4077 pupae and 3771 adults had successfully emerged (*Table 1*). In the ORVS, the average live individuals obtained for F1 generation was 244 larvae, 99 pupae and 66 adults. As for F2, 66 adults from F1 had produced 34 larvae and 13 pupae, while only one pupa had successfully emerged into the adult stage. In the RR, the species survival rate in the F1 generation was 61.59% and had increased to 73.05% in the F2 generation. The percentage of species survival rate in ORVS showed a sharp decline from 27.05% in F1 to 1.5% in the F2 generation. There was a significant difference in the number of individuals between RR and ORVS in the F1 and F2 generations ($F\ 12.76$, $p=0.001$, $p < 0.05$) (*Figure 3*).

Table 1. *Number of C. mutilatus individuals of F1 and F2 in the RR and ORVS systems*

Generation		1st Generation (F1)			2nd Generation (F2)		
Room	**CO_2 levels (ppm)**	**Larvae**	**Pupae**	**Adult**	**Larvae**	**Pupae**	**Adult**
RR	300-410 ppm	2283	1727	1406	5162	4077	3771
ORVS	800- 950 ppm	244	99	66	34	13	1

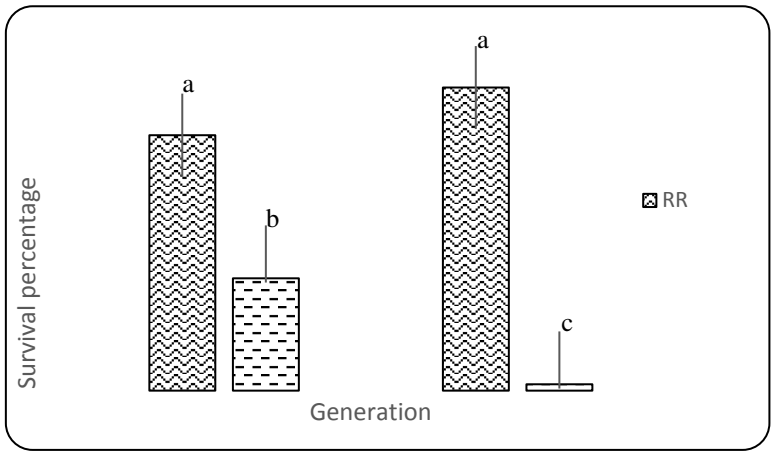

Figure 3. *Percentage of C. mutilatus F1 and F2 survival rates in RR and ORVS systems*

The life span of *C. mutilatus* F1 and F2 in RR took about 46 days to complete. In the RR, *C. mutilatus* took 7-21 days from adult to larval stage, 5-15 days from larval to pupal stage, and 3-10 days from pupal to adult stage. However, in ORVS, the F1 took about 30 days to complete its life cycle, i.e. 7-14 days from adult to larva, 5-10 days from larval to pupal stage, and 3-6 days from pupal to adult stage. However, in the F2 generation, *C. mutilatus* in ORVS had a shorter life cycle of 22 days, i.e. 7-14 days from adult to larval stage, 0-5 days from larval to pupal stage, and 0-3 days from pupal to adult stage (*Figure 4*).

DOI: http://dx.doi.org/10.15666/aeer/1805_64436455

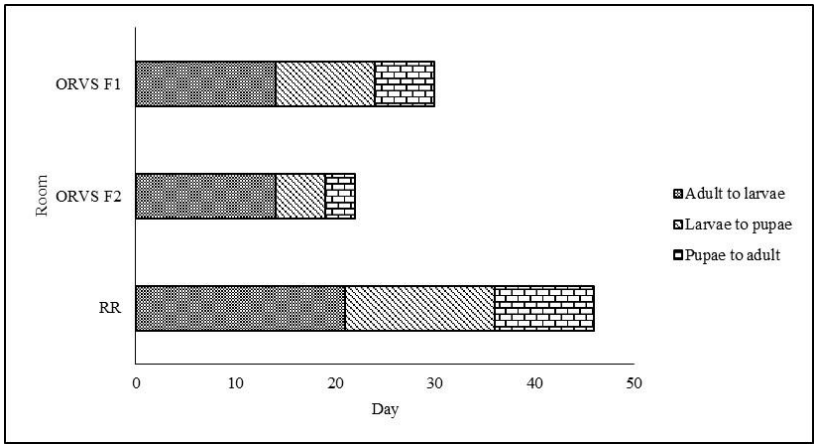

Figure 4. *The lifespan of C. mutilatus in RR and ORVS according the developmental stages*

According to *Table 2*, the number of individuals at each life stage in RR and ORVS also significantly differed. In RR, the adult to larva stage showed the highest number of individuals (1549 of F1 and 3147 of F2) compared to ORVS, recorded on day 8-14. In ORVS, the highest number of individuals recorded was 187 of F1 and 30 of F2, on days 0-7. The larval stage in RR was also recorded on days 6-10, with 994 and 2715 individuals of F1 and F2, respectively, while in ORVS the highest number of individuals was recorded on day 0-5, with 86 of F1 and 13 of F2, respectively. However, the pupal to adult stages in both RR and ORVS systems recorded the highest number of individuals on day 0–3, even though only one individual was recorded in F2 of ORVS.

Discussion

According to Hunter (2001), the Free-Air Carbon Dioxide Enrichment (FACE) and Open-Top Chamber (OTC), i.e. resembling ORVS, are two effective systems for studying long term interactions of plants and insects. In both systems, the CO_2 has been raised abnormally for the purpose of the ecological study, which is believed to have significant influence on the distribution, abundance and performance of insects that feed on plants (herbivorous insects). Furthermore, the elevated levels of CO_2 in the atmosphere could exert various effects on many insects either directly or indirectly, leading to marked changes in their life cycle, physiological and behavioural aspects (Lake and Wade, 2009; Yuan et al., 2009).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64436455

From this study, no colour change was detected after exposure of the test beetle individuals to high concentrations of CO_2 in the ORVS system. According to Zeuss et al. (2014), colour changes in butterflies would involve a change from lighter to darker coloured in cooler climate, and vice versa at warmer climates when exposed to higher CO_2 levels. In our study, despite the different CO_2 levels in the culture chambers, no changes were observed based on the morphology (body colour) of each stage of the life cycle. According to Roulin (2014), the increment of CO_2 led to a rise in temperature together with the UV radiation. However, the *C. mutilatus* has been categorised as a dark beetle species which is not affected by changes in CO_2 levels due to its resistance by the production of melanin. This pigment has become a useful indicator to study the adaptation of insects to climate change. The life cycle of the *C. mutilatus* species occurs mainly inside the ripe oil palm fruit to complete the larval stages before hibernating in the soil during the pupal stage (Nor Atikah et al., 2019).

Furthermore, previous study results indicated that increase in CO_2 could also reduce insect abundance by 22%, increase the nutritional rate and life span of certain insects by 17% and 4%, as well as lowering the growth rate and weight of pupae by 9% and 5% (Stiling and Cornelissen, 2007). In our study, significant differences in the number of individuals or abundance in the RR and ORVS systems indicate that high CO_2 concentrations could have induced changes in the hatching rate of the nitidulid beetle, *C. mutilatus*. This is proven by the differences in the survival rates of this species in both culture systems.

The survival rate of *C. mutilatus* in ORVS was lower than in RR, where the rate had also decreased in the F1 and F2 generations. However, the results of this study differ from studies on *C. dimidiatus* by Odeyemi et al. (2004) and *C. hemipterus* by Gbaye and Odeyemi (2005). Dáder et al. (2016) reported that the aphid, *Myzus persicae* showed lower survival rates from eggs to adulthood and shorter larval stages in ambient conditions, which was contradictory to our own findings. The egg stage of *C. dimidiatus* showed the highest level of tolerance to high levels of CO_2 compared to the other stages in its life cycle. The mortality rate of the eggs was 13.3% lower than that of the larvae and pupae at 50.0% and 33.3%, respectively, while 100% of the adult beetles died after exposure to high CO_2 levels for six hours (Odeyemi et al., 2004).

Carpophilus hemipterus also recorded the lowest egg mortality rate of 26.7% compared to 86.7%, 100.0% and 90.0% in larval, pupal and adult stages, respectively. However, in our study the egg stage was not successfully obtained from the emerged adults. Most insect eggs require less oxygen to survive compared to the larval, pupal and adult stages. The egg tolerance rate is due to an impermeable layer of egg coral structure that is not present at other stages (Chapman, 1971). In this study, the eggs stages were unsuccessfully collected and thus, not evaluated. However, the percentage of emergence in the pupal and adult stages were higher in larval, continued with pupal and then in adult stages in both conditions and in both generations.

Insects adapt differently when their habitat is changed. At higher CO_2 concentrations in ORVS, the life span of *C. mutilatus* was shorter than in the RR. The *C. mutilatus* F1 and F2 generations also survived, the second generation having a shorter life span than the first generation. The effect of increasing CO_2 concentration either in ambient conditions or in the system is usually associated with the interactions of plants and insects. This is because by increasing CO_2 the nitrogen cycle is affected and thus, resulting in a decrease in the C:N ratio in the plants (Ainsworth and Long, 2005; Oehme et al., 2013; Ryan et al., 2014). As a result of the changes, macronutrients such as calcium, magnesium

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64436455

and phosphorus would decrease due to the lack of water supply from the soil (Taub and Wang, 2008). Therefore, the lack of nutrients and plant quality due to the changes in CO_2 concentration would indirectly affect insects through their nutritional responses (Hughes and Bazzaz, 2001; Himanen et al., 2008; Stiling et al., 2013).

Our results showed that the life span of *C. mutilates* was shorter in ORVS compared to the RR, indicating that the life span of the beetles treated with elevated CO_2 above the ambient levels had been shortened, and this effect was not limited to F1 but was also observed in the F2 generation. However, this result was contradictory to those of previous studies, which reported that insects tended to reduce their growth rates and extend their life span in order to adapt to high CO_2 levels (Goverde and Erhardt, 2003). Insects from *Helicoverpa armigera* and *Orygia leucostigma* species also reportedly extended their lifespan when exposed to elevated CO_2 levels (Agrell et al., 2000; Chen et al., 2005).

The rise of CO_2 levels as a greenhouse gas (GHG) would affect the atmospheric temperature, and both abiotic factors could significantly affect the growth and development of many insect species (Agrell et al., 2000; Goverde and Erhardt, 2003; Mondor and Tremblay, 2010). Although some species are not affected by CO_2 changes, but as exothermic organisms, most insects are more sensitive and respond quickly to changes in temperature that affect their life cycles and growth rates (Bale et al., 2002). Insects also respond to rising temperatures by increasing their rates of growth, reproduction and mortality (DeLucia et al., 2012).

The development of nitidulid beetle species, namely *C. humeralis*, *C. hemipterus* and *C. mutilatus* at different temperatures had been studied by James and Vogele (2000), who reported that the lifespan of these three species were shorter at higher temperatures, i.e. 14-18 days at 32.5 °C compared to 47-65 days at 20 °C. These findings, however, contradictory to our results that in RR under ambient conditions (28-32 °C), the total lifespan of *C. mutilatus* was 46 days, whereas for ORVS it was 30 days. The mortality rate for each species was the lowest at temperature between 25-30 °C. The life span of *C. hemipterus* also exhibited similar effects when exposed to different temperature ranges where the growth rates for eggs, larvae and pupae were longer at low temperatures (18 °C) than at high temperatures, (30 °C). However, the mortality rate has increased with increasing temperature (Tsukada et al., 2008). At low temperatures of -10 °C to -8 °C, the mortality rates of *C. mutilatus* and *C. hemipterus* were higher with 100% mortality (Donahaye et al., 1991).

Conclusion

The nitidulid beetle *C. mutilates,* was selected as a model species to evaluate the colour changes, survival rate and life span of *C. mutilatus* (Coleoptera: Nitidulidae) in different concentrations of carbon dioxide (CO_2). This species is interesting because its life cycle from the egg to larval stages is spent inside the oil palm fruit. From this study, no significant changes were observed in the coloration of the larval to adult stages of *C. mutilatus* after exposure to treatment with high ambient CO_2 levels. In the RR, the species survival rate in the F1 generation was 61.59% and had increased up to 73.05% in the F2 generation. However, the survival rate in ORVS showed a sharp decline from 27.05% in F1 to 1.5% in F2 generation. Two-ways ANOVA shows there was significant difference in number of individuals between RR and ORVS in F1 and F2 (F 12.76, $p=0.001$, $p < 0.05$). The life span of F1 and F2 of *C. mutilatus* in RR took about 46 days to complete; i.e. 7-21 days from adult to larval stage, 5-15 days from larval to pupal stage, and 3-10

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64436455

days from adult to pupal stage. However, in ORVS, the F1 and F2 generations of *C. mutilatus* took about 30 and 22 days, respectively, to complete their life cycles; i.e. 7-14, 7-14 days from adult to larval stage, 5-10, 0-5 days from larval to pupal stage, and 3-6, 0-3 days from pupal to adult stage, respectively. This data can be used to describe the changes in *C. mutilatus* caused by global warming effects, as CO_2 could be one of the main factors affecting the species development. Further ecological study in the field (oil palm plantation) is suggested to relate the growth and development of the nitidulid beetles with other abiotic factors such as temperature, humidity, light intensity and also the most important parameter, i.e. CO_2 concentration in order to validate the effects on and biological responses of *C. mutilatus* to climate changes in the natural environment.

(Received 8th Apr 2020; accepted 29th Jul 2020)

Abstract. This study aimed to assess the sewage sludge (SS) amendments to agricultural soil on the biochemical composition of four plants (faba bean, wheat, spinach and cucumber). The applied SS rates were 0, 10, 20, 30, 40 and 50 g/kg soil. Plant leaves 45 days after SS treatments were used in biochemical parameter analyses. Starch decreased in spinach from 179.34 to 41.38 mg/g DW with SS treatments and increased in faba bean, wheat and cucumber at 10, 20, 30 and 40 g/kg rates. Water soluble carbohydrates and total non-structural carbohydrates declined in the four plants with SS treatments. Total lipids increased in faba bean and spinach up to 41.94 and 7.89 mg/g FW, respectively, at the SS amendment of 50 g/kg, while in wheat and cucumber the increase was detected only at 40 and 50 g/kg rates. In spinach, the accumulation of proline started at SS treatment of 10 g/kg, while, for wheat and cucumber the increase of proline was started at 20 g/kg SS. The highest proline accumulation was 0.96 mg/g FW in spinach at 50 g/kg SS rate. SS did not affect phenol content in faba bean and spinach with any treatment, whereas, the phenol declined in wheat and cucumber.
Keywords: *carbohydrates, economic plants, environmental pollution, phenol, proline*

Introduction

Application of sewage sludge (SS) in the agricultural sector as soil fertilizers is in several countries (Singh and Agrawal, 2008 and 2010). The municipal SS is a source of macro- and micro-nutrients for crops cultivated in SS amended agricultural soil (Ahmed et al., 2010; Abdul Khaliq et al., 2017). Soil amendment with SS at different rates has improved the growth and yield of several crops including faba bean (*Faba sativa* Bernh.), wheat (*Triticum aestivum* L.), spinach (*Spinacia oleracea* L.) and cucumber (*Cucumis sativus* L.) (Eid et al., 2017a, b, 2018, 2019). Bioaccumulation and translocation of certain heavy metals in tissues of crops cultivated in soil amended with sewage sludge were analyzed in several plants (Kabata-Pendias, 2011; Bourioug et al., 2014; Eid et al., 2020a, b).

Chemical constituents of plants grown in soils amended with SS play a vital role in plant physiology as biochemical responses to abiotic stresses (Sharma et al., 2018). Carbohydrates are major components in plant tissues since they are related to the primary metabolism. Carbohydrates content has been monitored in several crops when cultivated in SS amended soils (Han et al., 2004). Elevation of nitrogen, phosphorus and potassium content and other macro-nutrients in plants grown in agricultural soil supplemented with SS has been reported in several studies (Hue, 1988; Bourioug et al., 2014; Kępka et al., 2016). Proline content has been investigated wildly as protectant to environmental toxicity stress in many crops (Boudjabi et al., 2015). Phenolic compounds in plants such as *Beta vulgaris* and *Albizia lebbek* were reported in response irrigation with municipal waste water and heavy metal toxicity (Tripathi and Tripathi, 1999; Singh and Agrawal, 2010). Biochemical composition analyses of the four economic plants under investigation is essential since leaves of spinach, seeds of faba bean, grains of wheat and fruits of cucumber are used for human consumption and the hay produced from wheat and faba bean is used for animal feeding.

The objective of the current investigation is to determine the effect of SS application to agricultural soils on the content of starch, water soluble carbohydrates (WSC), total non-structural carbohydrates (TNC), total lipids, proline and phenol in leaves of faba bean, wheat, spinach and cucumber plants.

Materials and methods

Soil-sewage sludge treatments

Four plant species, namely, faba bean (*Faba sativa*), wheat (*Triticum aestivum*), spinach (*Spinacia oleracea*) and cucumber (*Cucumis sativus*) were used to assess the effects of soil amendments with SS on biochemical composition of leaves of the tested crops. The rates of soil-sewage sludge amendments were zero (control), 10, 20, 30, 40, and 50 g SS/kg soil. The detailed analysis the physic-chemical properties of the applied SS used in the current study was previously performed; salinity 2.07; pH 6.38; organic matter 65.1%; the heavy metals concentrations were Cd (1.17 mg/kg), Co (27.9 mg/kg), Cr (179.1 mg/kg), Cu (162.6 mg/kg), Fe (25.4 mg/g), Mn (595.7 mg/kg), Ni (138.7 mg/kg), Pb (671.2 mg/kg) and Zn (667.6 mg/kg) (Eid et al., 2017a, b, 2018, 2019).

Plant materials and growth conditions

The broad bean, wheat, spinach (Superdane 7 Star, F1 Hybrid, Denmark) and cucumber seeds were obtained from local markets in Abha City. The seeds were planted

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64576467

in plastic pots filled with 4 kg of each respective SS-soil mixture. Three biological replicates were used. The broad bean and wheat were grown for 80 days, while, spinach and cucumber were grown for 50 days. *Figure 1* shows the experimental setup of the four plants grown in pots represent the rates of sewage sludge-soil amendment rates. The greenhouse conditions were natural day/night regime and the plants were watered when needed (Eid et al., 2017a, b, 2018, 2019).

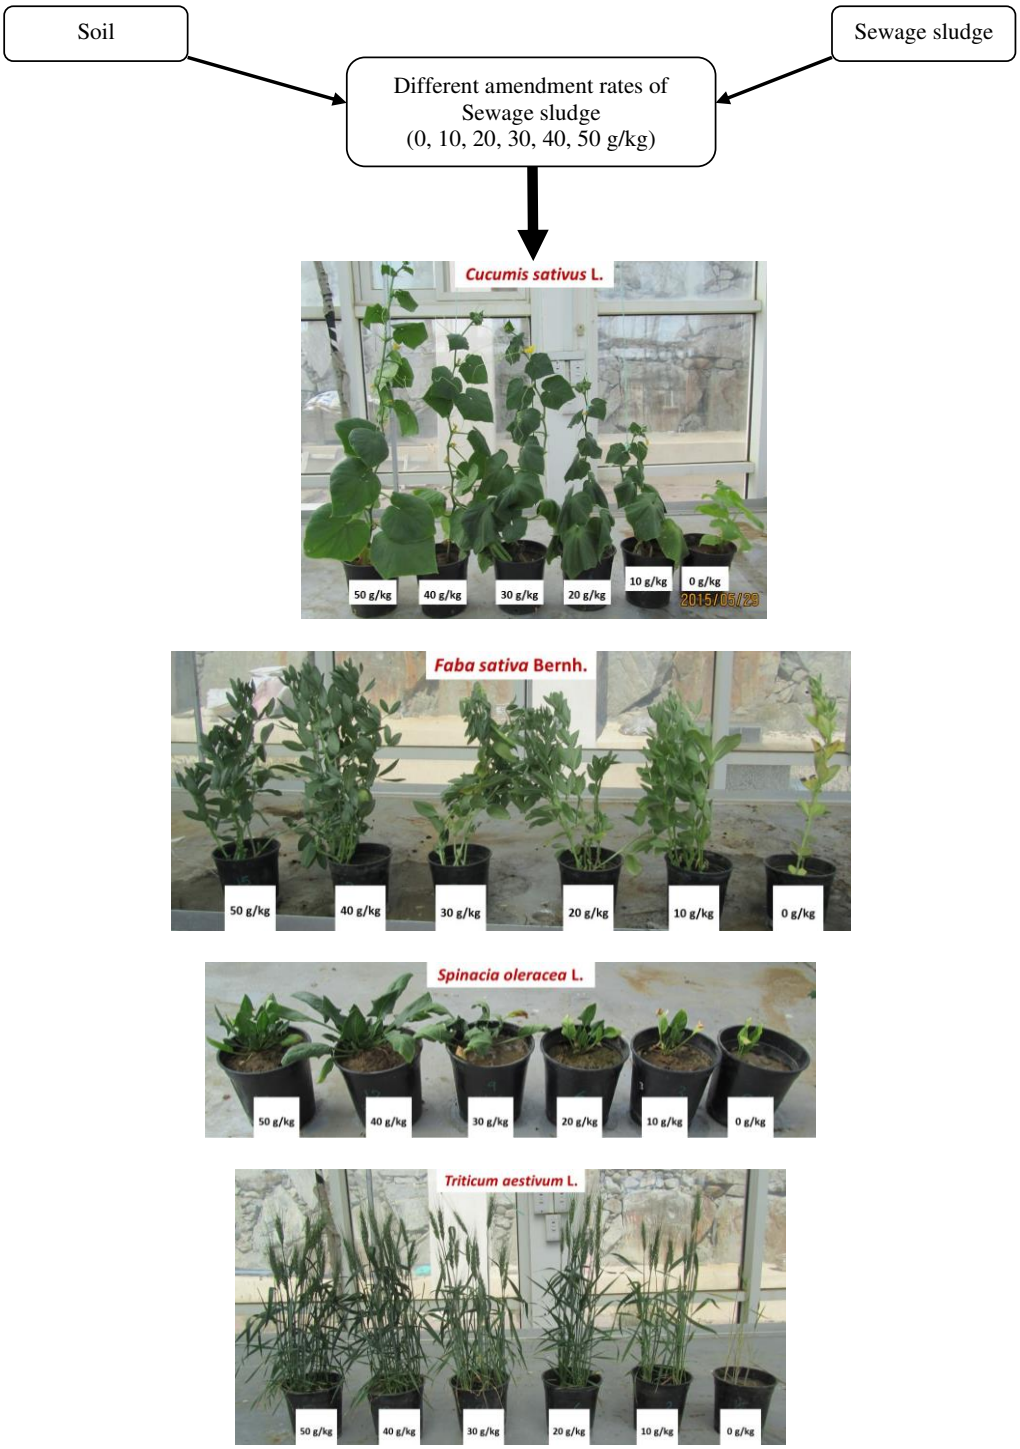

Figure 1. *A demonstration of the experiment steps with the four plants in pots represents the treatments of sewage sludge-soil amendment rates*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64576467

Biochemical analyses

Fully expanded fresh leaves from all the replicates for four species were sampled manually at 45 days, first washed under the running water and some kept in freezer at −20 °C for further estimation of total lipids, proline and phenol. Some leaves were dried in the oven at a temperature of 60 °C. Dried leaf materials were ground using a metal-free plastic mill into particles less than 0.4 mm for carbohydrate analysis. Total lipids concentration was measured following the method of Byreddy et al. (2016). Proline concentration was measured by the method of Bates et al. (1973). Total phenol concentration was measured following the method of Bray and Thorpe (1954). Water-soluble carbohydrates (WSCs) were extracted from 0.25 g of ground material with hot distilled water, while total non-structural carbohydrates (TNCs) were extracted from another 0.25 g of ground material using diluted H_2SO_4 following the method of Smith et al. (1964). WSC and TNC concentrations (mg/g DW) in the extracted solutions were measured by spectrophotometry using the phenol-H_2SO_4 colorimetric method as described in Granéli et al. (1992), where the standard was glucose. The starch concentration was calculated according to *Equation 1:*

$$\text{Starch (mg/g DW)} = 0.9 \times (\text{TNC conc. (mg/g DW)} - \text{WSC conc. (mg/g DW)}) \quad \text{(Eq.1)}$$

where TNC is the total non-structural carbohydrates and WSC is the water-soluble carbohydrates

Data analyses

Because absorption, accumulation and tolerance to heavy metals vary between different crops and at different levels of SS amendments (see Eid et al., 2017b) and hence heavy metal effects on the concentrations of total lipids, proline, phenol, WSC, TNC, and starch concentrations may vary between these different crops. Therefore, significant differences in the total lipids, proline, phenol, WSC, TNC, and starch concentrations between the spinach, cucumber, faba bean and wheat plants grown in soils amended with different rates of SS were evaluated using a two-way analysis of variance (ANOVA). The data were examined for their homogeneity of variance and normality of distribution, and when necessary, the data were log-transformed before a two-way ANOVA was performed. Significant difference between means among the five SS treatments were identified using the Tukey's HSD test at $p < 0.05$. Statistica 7.1 was used to process all of the statistical analyses (Statsoft, 2007).

Results and discussion

Application of sewage sludge to the agricultural soil has been reported to increase the growth and biomass of several crops. The growth of the four plants used in the current study was promoted when grown in soil amended with SS (Eid et al., 2017a, b, 2018, 2019). The biochemical parameters of leaves from the treated plants were determined. *Figure 2* illustrates the effect of SS treatments on starch content (mg/g DW) in faba bean, wheat, spinach and cucumber leaves. Spinach showed the highest content of starch as compared to faba bean, wheat and cucumber, however, the treatment with SS decreased the starch concentration significantly in spinach leaves with all SS amendment treatments from179.34 to 41.38 mg/g DW. For faba bean there

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64576467

was an increase in starch concentration at all SS treatments with obvious significant increase at amendments rates of 10 and 20 g/kg with concentrations of 73.07 and 89.56 mg/g DW, respectively. Starch concentration in leaves of wheat and cucumber increased at treatment rates of 10, 20, 30 and 40 g/kg with the highest concentrations at SS treatment of 20 g/kg with 100.42 mg/g DW of wheat and 95.86 mg/g DW of cucumber then starch concentrations were declined significantly at the highest SS treatment rate of 50 g/kg. Stimulation of carbohydrates as response to SS application has been reported in bean (Zeid and Abou El Ghate, 2007). The enhancement of starch synthesis in plants treated with sewage sludge could be a result of increasing photosynthetic pigments, i.e. chlorophyll, with the organic matter, macro- and micro-nutrients in SS which result in increasing of the starch biosynthesis (El-Maghraby and Gomaa, 1992).

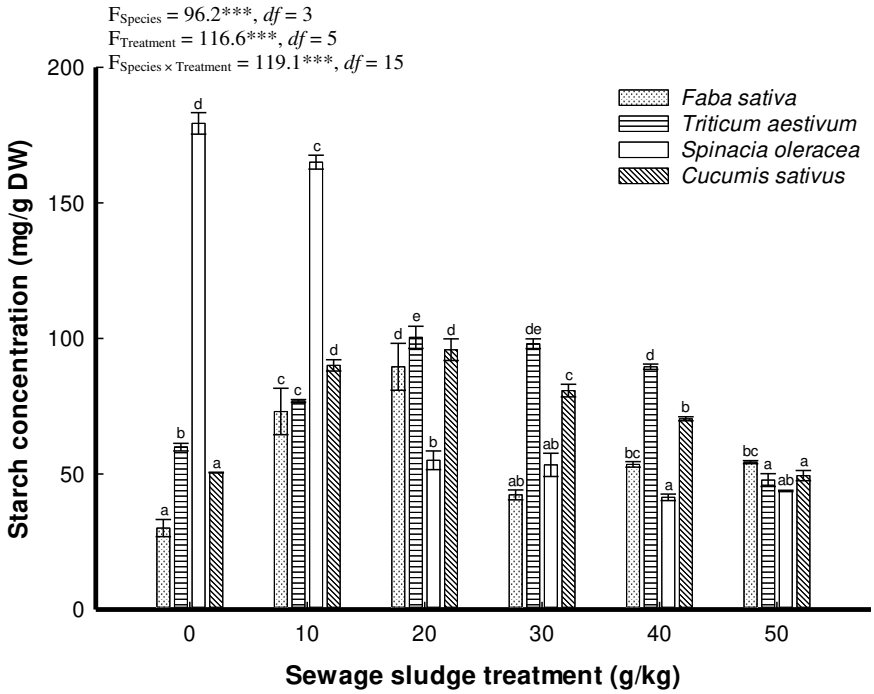

Figure 2. *Starch concentration (mean ± standard error) in leaves of the four plant species Faba sativa, Triticum aestivum, Spinacia oleracea and Cucumis sativus grown in soil amended with different sewage sludge treatment rates. Means (for each plant species) with different letters are significantly different at $p < 0.05$ according to Tukey's HSD test. ***: $p < 0.001$, df: degrees of freedom*

The concentrations of water soluble carbohydrates (*Fig. 3*) and total non-structural carbohydrates (*Fig. 4*) were inhibited in the four plant leaves due to soil amendment with SS at all treatment rates. It has been reported that total organic carbon was increased in response to SS treatments (Abdul Khaliq et al., 2017). Soluble sugar contents in sunflower plant grown in SS amended soil were increased significantly and suggested to play role in defense mechanisms that triggered by heavy metals in the SS (Belhaj et al., 2016). In maize plants, sugars content, proline and antioxidant enzymes activity were increased when the plant irrigated with sewage water (Abdel Latef and Sallam, 2015).

Total lipids concentrations in leaves of the four analysed plants are demonstrated in *Figure 5*. In both faba bean and spinach, the increase of total lipids was gradual and the significant levels were detected on SS treatment rates of 20 g/kg and above. For the wheat and cucumber, the significant increase of total lipids content in leaves was observed only at high SS treatment rates of 40 and 50 g/kg. Increasing of lipid peroxidation and proline content has been detected in tomato seedling grown in soil amended with SS (Elloumi et al., 2016). Several studies reported detoxification processes after exposure to SS which indicated using lipid peroxide assays in plant tissues and associate that with uptake of heavy metals from SS (Wyrwicka and Urbaniak, 2016).

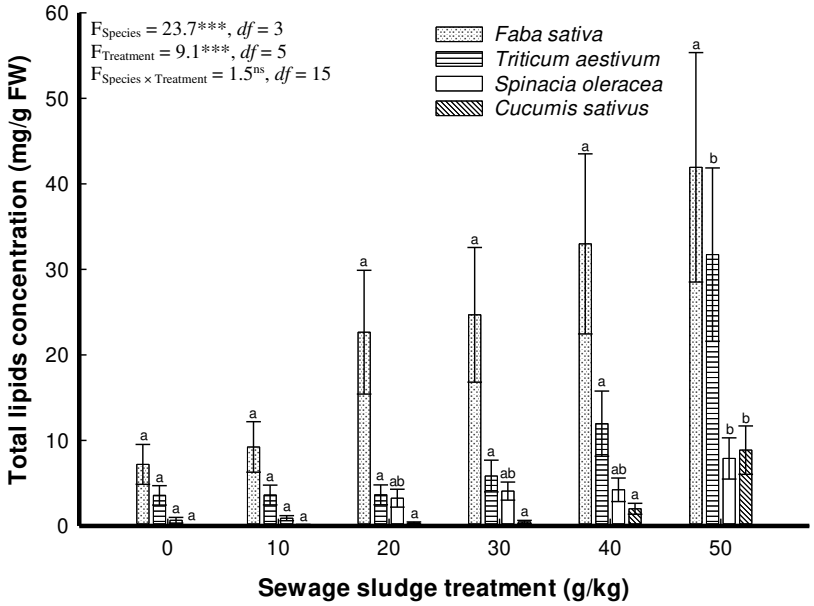

Figure 5. *Total lipids concentration (mean ± standard error) in leaves of the four plant species Faba sativa, Triticum aestivum, Spinacia oleracea and Cucumis sativus grown in soil amended with different sewage sludge treatment rates. Means (for each plant species) with different letters are significantly different at $p < 0.05$ according to Tukey's HSD test. ***: $p < 0.001$, ns: not significant (i.e., $p > 0.05$), df: degrees of freedom*

The amino acid proline is known to be accumulated in plant tissues as response of abiotic stresses on several crops (John et al., 2009). Proline concentration in leaves of the four plants was assessed (*Fig. 6)*. The proline concentration was in the same level in control plants. In faba bean, the increase of proline was slight at all SS treatment rates. The application of SS amendment rates stimulated the biosynthesis and accumulation of proline in leaves of wheat, spinach and cucumber plants. In spinach, the significant increase level of proline started at SS treatment of 10 g/kg with concentration of 0.39 mg/g FW to 0.96 mg/g FW at SS treatment 50 g/kg, while, in case of wheat and cucumber the significant increase of proline was detected at 20, 30, 40 and 50 g/kg SS treatment rates. It has been reported that proline may play a role in protection of enzymes, cellular organelles and adjust the osmotic pressure of plant cells under environmental stress conditions (Dhir et al., 2004; Tantrey and Agnihotri, 2010). The stress-protective role of proline was documented in wheat plants treated with cadmium (Asgharipour et al., 2011). Proline was accumulated in wheat plants cultivated in desert reclaimed soil amended with SS (Mazen et al., 2010).

Figure 7 presents the relationship between SS treatment rates and phenol concentrations in leaves of faba bean, wheat, spinach and cucumber. SS amendment did not affect the phenol content in faba bean and spinach at all treatment rates. On the other hand, phenol concentration in leaves of wheat and cucumber was declined with SS treatment. The decline was at rates of 40 and 50 g/kg in wheat and was at all SS treatment rates in case of cucumber plant.

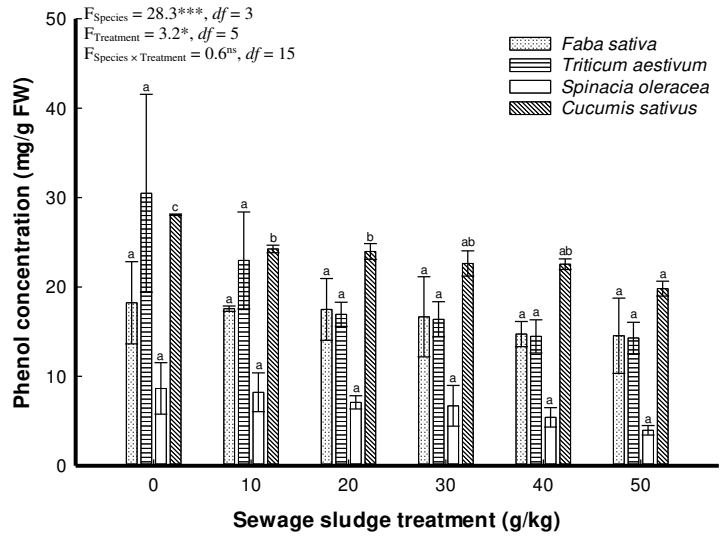

Figure 7. *Phenol concentration (mean ± standard error) in leaves of the four plant species Faba sativa, Triticum aestivum, Spinacia oleracea and Cucumis sativus grown in soil amended with different sewage sludge treatment rates. Means (for each plant species) with different letters are significantly different at p < 0.05 according to Tukey's HSD test. ***: p < 0.001, *: p < 0.05, ns: not significant (i.e., p > 0.05), df: degrees of freedom*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64576467

Phenolic compounds have been known in plant defense mechanisms against abiotic stresses such as heavy metal toxicity and to biotic stresses such as phytopathogenic fungi and bacteria in several plants (Singh and Agrawal, 2010; Daayf et al., 2012; El-Bebany et al., 2013). Thus, diminishing phenol content in plants grown in soil amended with SS may inhibit their resistance to pathogens.

Conclusions

The current investigation assessed the biochemical parameters in four crops (faba bean, wheat, spinach and cucumber) cultivated in agriculture soil amended with SS. The results revealed that the response at the biochemical level is differing according to the plant species and SS application rate. In spinach, starch was decreased significantly with SS treatments, whereas, increased in faba bean, wheat and cucumber at 10, 20, 30 and 40 g/kg SS amendment rates. The concentrations of water soluble carbohydrates and total non-structural carbohydrates were declined in all the tested plants as response to SS amendments. Total lipids were increased in all plants depend on the SS application rates. The increase of total lipids started at 20 g/kg SS treatment in faba bean and spinach, whereas, at 40 and 50 g/kg SS amendments in wheat and cucumber. The amino acid proline accumulated significantly in spinach, wheat and cucumber at all SS treatment rates, while the changes were not significant in faba bean. There were no significant differences in phenol content in faba bean and spinach. The phenol content was decreased in wheat and cucumber leaves with SS treatment. Application of SS to agricultural soils alters the chemical composition of crops. The application of SS at low amendment rates from 10 to 40 g/kg could be useful, whereas, the highest amendment rate, i.e. 50 g/kg is not recommended because of the negative effects on the biochemical composition of the plant, in addition to the possible accumulation of heavy metals in plant materials that may be used for human food or animal feed. The SS amendments could be oriented according to the crop consuming purposes. Future experiments on successive applications of SS in agricultural sites are needed to explore the long-term effects of SS on crops.

Abstract. Short-term nitrogen (N) deposition has exhibited great impacts on plant internal nutrient cycling in forest, grassland and desert ecosystems. However, the responses of plant nutrient status to chronic N deposition are not well understood, especially in alpine grasslands limited by soil N availability. This study used an N addition experiment that had been implemented since 2009 in the Tianshan mountains, northwest China, to investigate the effects of N addition at five levels (0, 1, 3, 9 and 15 g N m^{-2} $year^{-1}$) on the leaf nutrient concentrations and stoichiometric ratios of dominant perennial grasses (*Leymus tianschanicus*, *Festuca ovina*, *Agropyron cristatum and Koeleria cristata*) and forbs *(Potentilla anserina* and *Potentilla bifurca)* at the species, functional group and community levels. The results showed that increasing N addition significantly enhanced soil available N concentrations and soil available N:P ratios but had no detectable impacts on soil available phosphorus (P) concentrations. Nitrogen addition significantly reduced forb relative biomass, ranging from 13% in control plots versus 2% in the highest N addition plots. Furthermore, N addition increased the foliar N concentrations and N:P ratios for all the species, decreased foliar P concentrations for grasses, and had no significant effects on P concentrations in forbs. Plant carbon (C) concentrations remained relatively stable, resulting in reduced C:N as N addition increased. In contrast, N addition consistently increased leaf N concentrations, C:P and N:P and decreased leaf P concentrations and C:N at the community level. Regression analysis showed that soil available N and N:P ratios, rather than soil available P, were key parameters controlling plant N and P concentrations and stoichiometric ratios. Foliar N and P concentrations showed divergent responses to long-term N addition at the species and community levels, which implied that plant N and P cycling decoupled under N deposition. Grasses were more sensitive to N addition than forbs, resulting in significantly altered plant community composition.

These findings are important for understanding plant nutrient allocation strategies and how plants adapt to environmental changes, such as N deposition in alpine ecosystems.
Keywords: *aboveground biomass, alpine grassland, community composition, ecological stoichiometry, nutrient cycling, nitrogen addition*

Introduction

Ecological stoichiometry has been used to study the balance of multiple elements in many ecological processes (Elser et al., 2007). Plant carbon (C): nitrogen (N): phosphorus (P) stoichiometric ratios are closely related to ecosystem processes, such as nutrient cycling (Sterner et al., 2002; Lü et al., 2013; Li et al., 2016), litter decay (Manzonl et al., 2010), plant community structure and stability (Yu et al., 2010), and microbial composition (Güsewell et al., 2009). Previous studies have reported that plants tend to show stoichiometric variability in response to environmental disturbance, for instance, N deposition and P deposition (Sistla et al., 2015), but this flexibility varies across different species (Sardans et al., 2015). Therefore, determining the sensitivity of plant ecological stoichiometry is critical to clarify ecosystem patterns, processes and functions to N deposition.

Unprecedented increases in atmospheric nitrogen (N) deposition have occurred in drylands of China from 1980 to 2010 and are predicted to double by 2050 (Gu et al., 2015). Nitrogen is one of the primary limiting nutrients in grasslands; N addition not only facilitates plant growth but also enhances primary productivity (Bai et al., 2010). Moreover, increasing N availability has significant effects on plant internal nutrient cycling (Burton et al., 2012). The increase in leaf N concentration due to N addition has been extensively examined in grasslands (Lü et al., 2013; Li et al., 2016), wetlands (Mao et al., 2012), deserts (Zheng et al., 2018; Li et al., 2019) and forest ecosystems (Huang et al., 2019). However, large uncertainties exist regarding the impacts of N addition on leaf P concentrations. The effects of N addition on leaf P concentrations have been shown to be positive (Menge and Field, 2007), neutral (Kozovits et al., 2007; Lü et al., 2012), or negative (Li et al., 2016). Furthermore, nutrient traits in plants and their response to nutrient addition vary greatly among different species (Han et al., 2014; Hou et al., 2017; Wang et al., 2018; Lü et al., 2018). Studies in alpine grassland ecosystems are relatively scarce, and limited data are available regarding how enhanced N inputs affect leaf nutrient status. For example, N deposition enhanced the leaf P concentrations of *Seriphidium rhodanthum* but did not have a significant effect on that of *Stipa capillata* in alpine grasslands (Li et al., 2016). In contrast, Peng et al. (2017) found that N addition consistently decreased leaf P concentrations in alpine grasslands across a two-year period. Therefore, the existence of the potential divergent responses of plant nutrient status at the species level to N addition can constrain our understanding regarding the effects of N addition on plant internal nutrient cycling. More empirical evidence is needed to determine the effects of chronic N deposition on the nutrient status of plants in alpine grasslands.

To date, N addition affecting the plant nutrient status at the species level has been extensively investigated (Li et al., 2016, 2020; Hou et al., 2017), but the responses at the functional group and community levels remain limited. It is well documented that N deposition has significant effects on plant community composition and that plant nutrient status at the species level does not accurately represent the community level nutrient status (Han et al., 2014; Wang et al., 2018). N addition has significantly increased N concentrations and the N:P ratio at the community level (Hou et al., 2017; Wang et al., 2018), yet Lü et al. (2018) reported that N addition had no impact on the leaf N:P ratio at

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64696484

the community level. Moreover, positive, negative and neutral responses of P concentrations to N addition have been shown (Hou et al., 2017; Wang et al., 2018). Considering these inconsistent results, more experimental evidence is needed to obtain a general conclusion of plant ecological stoichiometry at the community level in response to enhanced N deposition. Furthermore, the duration of N addition is relatively short, and plant ecological stoichiometry to long-term N addition is still unknown in alpine grassland ecosystems.

Plant N and P statuses are tightly coupled with soil nutrient availability (Ågren et al., 2012). A recent study reported that N addition led to the decoupling of plant internal N and P cycling in a meadow steppe (Feng et al., 2019). This occurred because N addition significantly enhanced soil N availability and then led to soil acidification affecting plant-soil stoichiometry. Previous studies showed that N addition consistently enhanced leaf N concentrations and decreased the C:N ratio, thus influencing litter decay (Manzonl et al., 2010). Leaf N:P ratios have been used to determine plant nutrient limitation (Güsewell et al., 2004; Zhan et al., 2017). Nitrogen addition significantly increased leaf N:P ratios and finally resulted in plant growth limited by soil P availability (Zheng et al., 2018; Huang et al., 2019). Compared with stoichiometric variability at the species level, that at the community level is more difficult to reach a general conclusion for the following reasons. On the one hand, the plant nutrient status response to N addition is greatly dependent on species identity (Lü et al., 2012). On the other hand, N addition changes plant community composition, and the relative aboveground biomass significantly impacts plant nutrient status at the community level (Wang et al., 2018). There was a new finding showing that N addition significantly enhanced leaf N concentrations for grasses and forbs at the functional group level and had non-significant effects on P concentrations. However, the responses of leaf N:P ratios to N addition presented positive effects for grasses and neutral effects for forbs (Zhang et al., 2018). Increased N concentrations and negligible effects on P concentrations showed divergent responses of foliar N and P to N addition. Furthermore, studies regarding how plant nutrient status adapts to environmental disturbance are relatively limited. Simultaneously, how stoichiometric flexibility responds to N addition is highly variable from species to community. Therefore, more experimental evidence of plant nutrient status responses to long-term N addition is necessary, especially in alpine grassland ecosystems.

The Tianshan Mountains have been regarded as one of the areas critical for global biodiversity protection in temperate arid regions. The current total N deposition has been estimated at 8 kg N ha^{-2} yr^{-1} (Li et al., 2015). Previous studies have shown that N addition has great consequences on plant and soil C and N cycling. For instance, N addition tends to increase soil N_2O emissions and decrease methane uptake (Li et al., 2012; Yue et al., 2016); such results have mainly emerged from enhanced soil N availability by N addition. In addition, N addition generally enhanced plant growth and significantly increased plant N uptake (Li et al., 2015) because plant growth could be limited by soil available N. Studies regarding the effect of altered plant community composition and increased aboveground biomass due to N addition on plant ecological stoichiometry at the functional group and community levels in alpine grassland ecosystems are limited.

Therefore, a field experiment was designed to examine the effect of various N addition levels on leaf C, N and P concentrations and their stoichiometric ratios at the species, functional group, and community levels by taking advantage of an 11-year experiment with various N addition levels (0, 1, 3, 9 and 15 g N m^{-2} $year^{-1}$) in an alpine grassland in northwest China. We tested the following hypotheses: (1) long-term N addition increased

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64696484

leaf N concentrations from species to community because of significantly enhancing soil N availability by N addition but (2) decreased P concentrations primarily because of the non-significant effects of N addition on soil P availability, and (3) N addition generally mitigates N limitation but exacerbates P limitation based on the enhanced leaf N:P ratio.

Materials and Methods

Study site and experimental set up

This field experiment was conducted at the Bayinbuluk Grassland Ecosystem Research Station (42°18′-43°34′ N, 82°27′-86°17′ E), located on the south slope of the middle section of Tianshan Mountain in northwestern China. The long-term average (1981–2012) is 282.3 mm, with 60% of precipitation occurring in the growing season from May to September, and the mean annual temperature is −4.8 °C (Li et al., 2015). Furthermore, this natural grassland has a mean altitude of 2,500 m and a total area of approximately 23,000 km^2, belonging to the typical alpine and dry grassland. The soil is a Camisole according to the Food and Agriculture Organization soil classification system, with a high organic matter and N content and a low P content. Due to disturbance from human activities, the current atmospheric nitrogen deposition is approximately 8 kg N ha^{-1} yr^{-1}. The dominant grass species in the ecosystem are *Leymus tianschanicus, Festuca ovina, Agropyron cristatum and Koeleria cristata*, contributing approximately 87% to the aboveground biomass (*Fig. 1*).

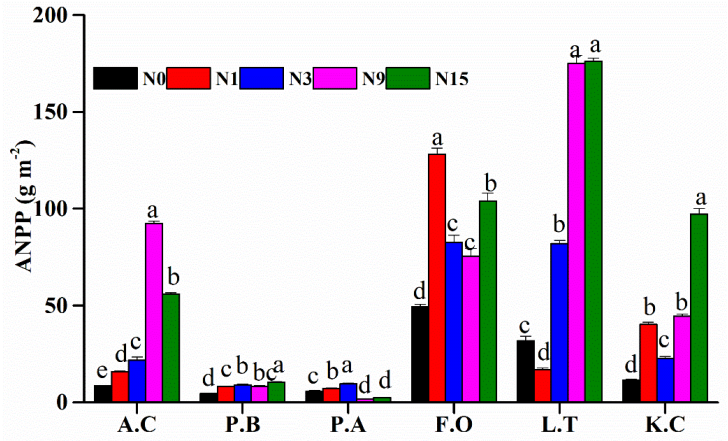

Figure 1. *Responses of plant aboveground biomass to N addition. Error bars + SE. Bars with different letters show significant differences (P <0.05) between the treatments. Leymus tianschanicus (L. T), Festuca ovina (F. O), Agropyron cristatum (A. C), Koeleria cristata (K. C), Potentilla anserina (P. A), and Potentilla bifurca (P.B)*

N addition experiments have been carried out since 2009. There were five treatments: control (N0), 10 (N1), 30 (N3), 90 (N9), and 150 (N15) kg N ha^{-1} yr^{-1}. Each treatment was established with four replicates, resulting in a total of 20 plots. Each 8 × 4 m plot was arranged in a randomized block design, and each plot was separated by a 1 m buffer. Nitrogen was added to the plots as purified NH_4NO_3 in two split doses applied in early May and June each year. A weighed amount of NH_4NO_3 was dissolved in 8 L water and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64696484

applied to each block using a sprayer to distribute the fertilizer evenly. The same amount of water was added to the control plots without N fertilizer.

Plant and soil sampling and chemical measurements

In mid-August 2019, aboveground biomass was sampled by clipping all plants in each plot using a 0.5 × 0.5 m quadrat at peak biomass time. The plant samples were harvested, sorted into species and then oven-dried at 65 °C for 48 h. The dry mass of all living plants in each quadrat was used to estimate the aboveground species biomass based on the four replicates for each treatment. Aboveground net primary production (ANPP) was estimated as the peak aboveground biomass during the growing season (Bai et al., 2010).

Leaf samples were collected from the dominant grass species *Leymus tianschanicus, Festuca ovina*, *Agropyron cristatum, and Koeleria cristata*, and perennial forbs of *Potentilla multifida* and *Potentilla bifurca* were also collected for chemical analysis. All plant species were divided into two plant functional groups: grasses and forbs. These species represented almost 95% of the total aboveground biomass. Similar leaves were randomly selected in the subplot (2 m × 2 m) from the center of each plot. The leaves were oven-dried at 65 °C to reach a constant weight, ground, and then mixed evenly for elemental analysis. Plant C and N contents were determined with an elemental analyzer (Vario micro, Hanau, Germany). The total P concentrations were measured by wet digestion with H_2SO_4+$HClO_4$. C, N and P concentrations were expressed as the nutrient content per unit mass (mg g^{-1}).

Soil samples (0–10 cm depth) were collected from each plot in August 2019. In the center of each plot at least 2 m away from the edge of the plot, five soil cores were collected using a 3 cm diameter soil auger and were mixed into a single composite sample. All soil samples were sieved through a 2 mm mesh to remove roots and litter. Soil available N was extracted with 50 ml of 2 M KCl solution. Then, the filtered soil extract was used to determine alkaline nitrogen concentrations with a Kjeldahl distillation system (VAP-45, Gerhaedf, German). Available soil P was measured by extracting soil with 0.5 M $NaHCO_3$ (pH = 8.5), followed by analysis with the molybdenum blue-ascorbic acid method (Olsen et al., 1954).

Calculation of data and statistical analysis

Plant nutrient concentrations at the functional group and community levels were estimated as species relative biomass as a weighting factor, and the C, N, and P concentrations and nutrient stoichiometric ratio were calculated for each species in every plot (Lü et al., 2018).

All statistical analyses were performed in SPSS version 23.0 (SPSS Inc. Chicago, IL, USA). Data were tested for normality using the Kolmogorov-Smirnov test and Levene's test for equality of error variance. One-way analysis of variance (ANOVA) was applied to test whether the N treatment influenced the plant nutrient concentrations and stoichiometric ratios of each species, with N treatment as a fixed factor. Differences among treatments were analyzed by Tukey's multiple comparison post hoc test. Linear regression analyses were conducted to determine the relationships between soil available nutrient concentrations, plant nutrient concentrations and stoichiometric ratios. All figures were constructed in Origin 9.0.

Results

Responses of soil available nutrients and ANPP

Nitrogen addition significantly enhanced the soil available N concentration, ranging from 189.62±10.1 mg kg^{-1} in the control plots (N0) to 267.40±4.0 mg kg^{-1} in the highest N addition plots (N15). However, N addition showed no significant effect on soil P availability, with a range from 7.52±0.56 to 8.62±0.9 mg kg^{-1} (*Fig. 2*). The soil available N:P ratio significantly increased across the N addition gradient (*Fig. 2*). N addition significantly enhanced ANPP for grass and decreased biomass for forb species, but the response of magnitude varied highly among species (*Fig. 1*).

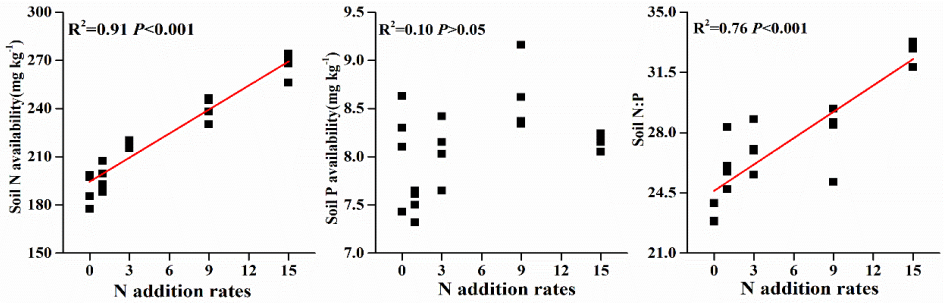

Figure 2. *Relationships between nitrogen (N) addition rates and soil available N and phosphorus (P) concentrations and available soil N:P ratios in the alpine grassland*

Responses of nutrient status at the species, plant functional group and community levels

The nitrogen addition rate and species identity had significant effects on leaf N and P concentrations and the N:P ratio (*Fig. 3*, *Table 1*). N addition significantly increased the leaf N concentrations of the six species (*Fig. 3*). In contrast, the P concentrations in the leaves of the four plant species significantly decreased and had no effects on P.A and P.B. Plant C concentrations remained relatively stable across N addition treatments (*Fig. 3*, *Table 1*). N addition significantly enhanced the N:P ratio but reduced the C:N ratio for all grass species (*Fig. 3*). The ratios of C to P were insignificantly affected by P.A and P.B but significantly increased for other species (*Table 1*).

Relationship between leaf nutrient status and soil available nutrients

For all species, the results showed that altered soil nutrient availability had non-significant effects on C concentrations. Leaf N concentrations and ratios of N to P were positively correlated with soil available N, while P concentrations and ratios of C to N were negatively correlated with soil available N concentrations (*Fig. 5*). Soil available N:P showed similar effects on leaf nutrient status with soil N availability. There was a

DOI: http://dx.doi.org/10.15666/aeer/1805_64696484

non-significant linear relationship between P concentrations in leaves and soil P availability, but a positive relationship was observed between N concentrations and soil P availability among 4 out of 6 species. However, soil available N:P significantly affected PTP and the plant nutrient stoichiometric ratio (*Fig. 5*).

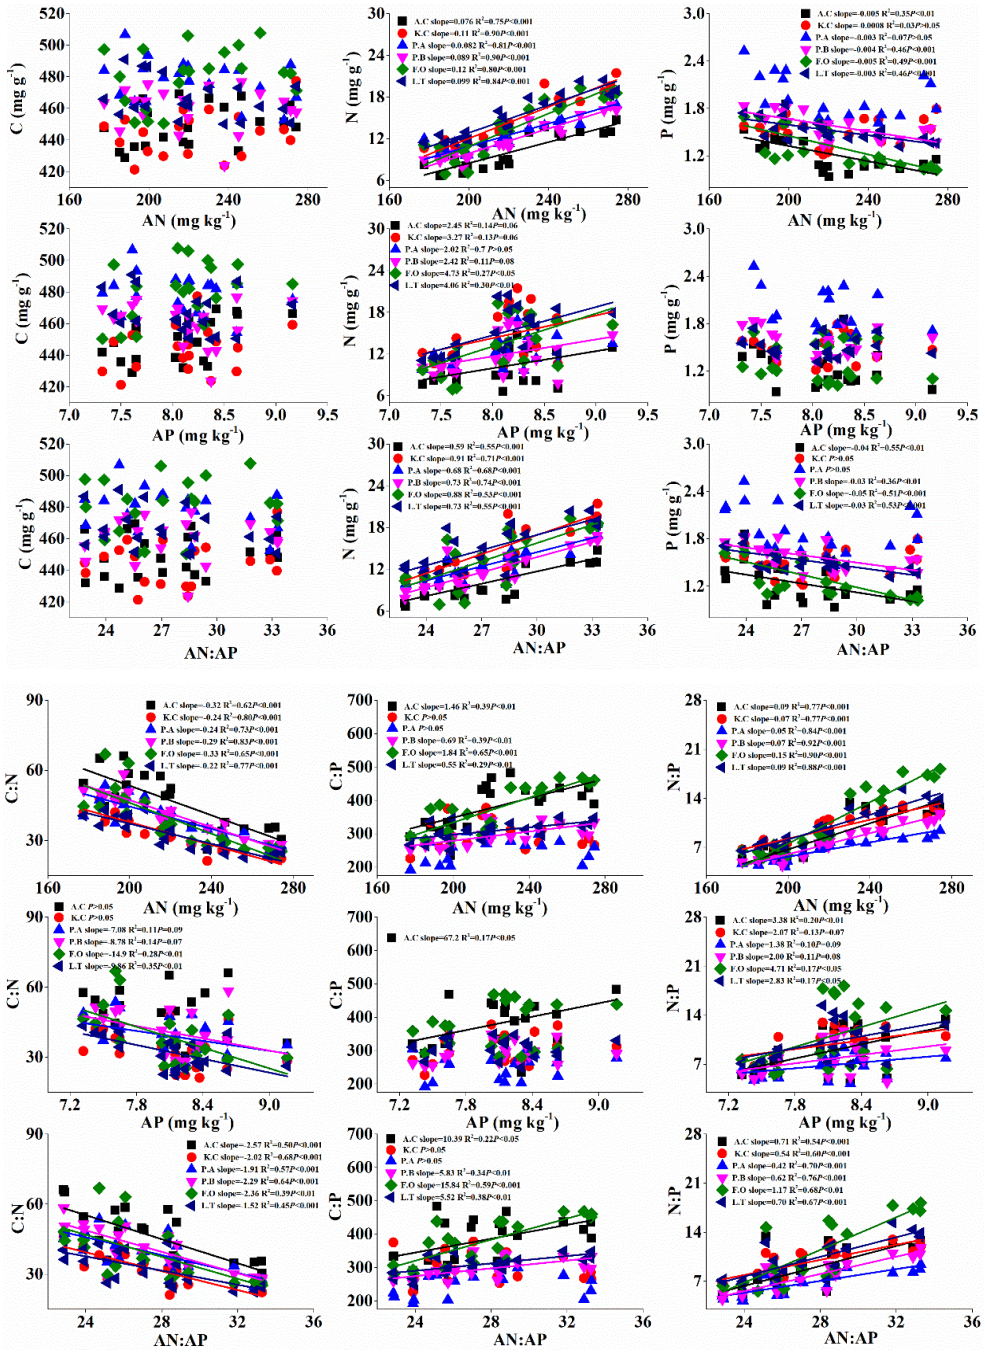

Figure 5. *Relationships between plant nutrient concentrations or stoichiometric ratio and soil available nutrients (AN, AP and AN:AP) at the species level. Leymus tianschanicus (L. At the community level, soil N availability had no impacts on C concentrations but increased N concentrations, C:P and N:P ratios; at the same time, it decreased the P concentrations and C:N ratio. Soil available P did not affect the C concentrations, P concentrations or C:P ratio (*Fig. 6*). The leaf N concentration and N:P ratio were positively correlated with the soil available P, and the C:N ratio was negatively correlated. The soil available N:P ratio revealed constant effects on the leaf nutrient status with soil N availability.

Discussion

Responses of species biomass to N addition

Nitrogen addition significantly increased soil N availability and had non-significant effects on soil available P, resulting in a higher soil AN:AP ratio. This is consistent with a study from alpine steppe (Peng et al., 2017). Altered soil available N significantly promoted grass species growth and enhanced plant biomass from 101.4±19.1 $g \cdot m^{-2}$ to 307.7±54.4 $g \cdot m^{-2}$ for the average of all N treatments. However, N addition had different effects on forb species biomass depending on species identity. Previous studies have reported that N addition significantly increased grass species biomass but had positive, negative and negligible impacts on forb species biomass (Han et al., 2014; Hou et al., 2017; Wang et al., 2018). These findings indicated that N is the limiting factor of plant growth in this grassland. The biomass responses of forb species against N addition indicated less sensitivity compared to grass species in our study. One possible reason could be that N addition might have increased the height of grass species, which would have restricted the availability of light in the lower layer of the forb species, resulting in limited plant growth (Bai et al., 2010; Zhou et al., 2018). In our study, N addition enhanced the biomass of dominant grass species and reduced the biomass of non-dominant forb species, which significantly affected the plant community composition and increased the risk of loss of forb species. Nitrogen deposition showed a positive impact

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64696484

by promoting plant growth and significantly improving plant aboveground biomass for forage supply, but its negative impact appeared in the form of alteration of plant community structure that resulted in loss of biodiversity (Bai et al., 2010; Wang et al., 2018).

Effects of N addition on the nutrient status of leaves and stoichiometric ratios at the species level

In the control plots, plant nutrient status revealed wide variation among species. In all species, the average concentrations of leaf C (463.11 mg g^{-1}), N (10.12 mg g^{-1}) and P (1.77 mg g^{-1}) were partly consistent with the results of previous studies on grasslands in China (He et al., 2006, 2008). In our study, plant N content was significantly lower compared to grassland in northern China, but our findings are supported by the results from alpine grasslands (Peng et al., 2017). Additionally, our results are also comparable with those of a previous study from alpine grasslands where multiple sites across the Tibetan Plateau have been tested (Zhou et al., 2020). It can be inferred that reduced nutrient accumulation in leaves could be the result of declined rates of plant absorption and utilization under drier and colder environments (Aerts et al., 1996). Moreover, the relatively low concentration of soil available N under conditions of less rainfall and low temperature would be the reason for the low plant N concentration in this alpine grassland (Tian et al., 2010). This can result not only from the rate of plant absorption and utilization slowing down in drier and colder environments and reducing leaf nutrient accumulation (Aerts et al., 1996) but also from the fact that the soil available N concentration is relatively low because of limited precipitation and low temperature (Tian et al., 2010), finally resulting in lower plant N concentrations in this alpine grassland.

N addition did not show any significant impact on plant C concentrations, but it increased plant biomass and led to more C sequestration in plants. Our results showed that N addition significantly increased leaf N concentrations. Increases in plant N concentrations following N addition have been well documented in many previous studies (Xia and Wan, 2008; Peng et al., 2017; Hou et al., 2017; Wang et al., 2018). It seems that soil available N significantly increased after N addition, which provided an adequate soil nutrient supply for plant growth. This also implies that plant growth is affected by N availability but that plants can exhibit luxury uptake when N is not a limiting factor (Sistla et al., 2015), hence carrying higher N concentrations. On the other hand, N addition significantly reduced the P concentration for grass species but did not show any effect on the P concentrations of forb species. In contrast, many previous studies indicated an increase in plant P concentration in response to N addition (Lü et al., 2013; Hou et al., 2017; Wang et al., 2018). Simultaneously, many studies also found that N addition significantly increased soil P availability in grassland ecosystems (Lü et al., 2013; Han et al., 2014; Li et al., 2016). This difference can be explained as follows. First, N addition significantly increased plant aboveground biomass for grass species in our study, which would have partly diluted the P content in plants (Hou et al., 2017). Second, N addition had an ignorable impact on the soil available P content and soil alkaline phosphatase activity, which would have direct effects on reducing the plant P concentrations. Hence, N addition had positive, negative and neutral effects on plant P concentrations (You et al., 2018), which partly supports our findings that N addition decreased or had no effect on plant P concentrations depending upon species identity. For instance, N fertilization decreased P concentrations in leaves of dominant grasses by 40% in an annual grassland

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64696484

(Menge and Field, 2007), while it had neutral effects on plant P concentrations for forb species in semiarid grasslands (Hou et al., 2017).

Our results clearly demonstrated that the N:P ratio in leaves was enhanced after N addition. These findings are in accordance with previous studies (Lü et al., 2013; Zhan et al., 2018), where they found that increased N deposition can induce a shift from N to P limitation or N-P colimitation. Furthermore, plant N and P concentrations showed opposite responses to each other, indicating nutrient decoupling in plants under N deposition. These outcomes are not consistent with previous reports that observed that plant N and P are tightly coupled in grassland ecosystems (Agren et al., 2012; Lü et al., 2013). It is possible that altered soil nutrient availability by N addition could have reduced the leaf C:N ratio, which would have promoted litter decomposition (Manzonl et al., 2010), because enhanced litter quality significantly promoted litter decomposition (Manzonl et al., 2010). Moreover, an increase in N inputs through fossil fuel combustion and cropland fertilization can greatly enhance the substrate nutrient availability for plants, which may also result in nutrient decoupling in plants, thus negatively influencing the plant community structures (Liu et al., 2015). For grass species, the responses of plant N and P concentrations and stoichiometric ratios following N addition could be controlled by soil N availability and soil available N:P, and the data suggest that the N:P ratio in plants and soils was strongly linked. Our results supported the idea that increasing N deposition not only induces changes in N concentrations directly but also leads to an indirect alteration in the soil available N:P ratio (Penuelas et al., 2012).

Effects of N addition on the nutrient status of leaves and stoichiometric ratios at the functional group and community levels

Our results indicated that leaf C remained relatively stable along the N addition levels at the functional group and community levels. However, N and P in leaves varied greatly among different plant functional groups. Nitrogen addition increased the N concentration and decreased the P concentration in leaves for the grass functional group; however, it showed a non-significant impact on N and P for the forb functional group. Nonetheless, N addition consistently increased the N concentration and decreased the P concentration at the community level. The responses of P concentration towards N addition were negative and neutral at functional group levels; thus, N addition did not enhance plant P uptake. These results are in line with the findings of (Hou et al., 2017; Wang et al., 2018), who described that N addition significantly increased the P concentration in grass species but had no impact on the P concentration of forb functional groups or community levels. This might have occurred because N addition did not affect soil phosphatase activity, leading to non-significant changes in soil P availability under long-term N addition. Furthermore, dominant grass species drove community-level N and P concentrations, which is also consistent with previous reports from typical steppe (Lü et al., 2018) and meadow steppe (Wang et al., 2018). The nutrient and stoichiometric responses of grass species to N addition are more sensitive than those of forb species, and the biomass of grass species was significantly enhanced, which could be a mechanism by which plants adapt to environmental changes, such as N deposition (Yu et al., 2010).

Nitrogen addition consistently decreased the C:N ratio and increased the N:P ratio in leaves at the functional group and community levels. Lower C:N ratios generally show fast decomposition (Hou et al., 2017). In our study, N addition significantly enhanced leaf quality and contributed to decomposition in this alpine grassland. N:P ratios have been used to determine relative nutrient limitation (Zhan et al., 2017) and regulate litter

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64696484

decomposition processes (Güsewell and Gessner, 2009). The enhancement of N:P ratios following N addition led to the decoupling of plant N and P, which agreed with many studies from diverse ecosystems, such as grasslands (Wang et al., 2018), wetlands (Mao et al., 2012) and desert ecosystems (Huang et al., 2018), indicating that N addition may alleviate N limitation and intensify P limitation. However, Han et al. (2014) found that N addition significantly increased P concentrations and C:P ratios at the species level, and this phenomenon was not observed at the community level. Furthermore, N addition significantly increased plant aboveground biomass, but only in one of the six species with the largest biomass was at the highest N addition, which implied that the growth of most species was not limited by N availability. If plant growth is limited by N, N addition will further promote plant growth. Considering the current high N deposition in China, plant growth may be limited by soil P availability in grassland ecosystems because the soil available P content was relatively lower than that in other regions (Han et al., 2005; Zhang et al., 2005). In brief, our results suggested that the N and P of plants from the species to community levels revealed divergent responses to long-term N addition in this alpine grassland, but the specific mechanism still needs to be explored further.

Soil available N and available N:P ratio as determining factors for plant nutrient concentrations and stoichiometric ratios

It has been well established that soil available N is a strong predictor of plant nutrient concentrations and stoichiometric ratios (Lü et al., 2013; Zheng et al., 2018). In our study, we confirmed that N addition directly affected plant N and P concentrations and stoichiometric ratios at the species and community levels by enhancing soil available N concentrations rather than through soil available P in this alpine grassland, which is in agreement with the results reported from alpine steppe ecosystems (Peng et al., 2017). Compared with soil available N concentrations, the effects of soil available P on plant nutrient concentrations and stoichiometric ratios could be considered minimal because long-term N addition did not cause significant changes in soil P availability among treatments.

Our results suggested that altered soil AN:AP ratio significantly affected plant nutrient status. For instance, plant N concentrations showed a significant positive relationship with the soil AN:AP ratio, but plant P concentrations had a significantly negative relationship with the soil AN:AP ratio at the species and community levels. This indicated that the responses of plant nutrient concentrations and stoichiometric ratios to N addition could be controlled by the soil available N:P ratio, and this N:P ratio in plants and soil is strongly coupled (Lü et al., 2013; Li et al., 2020). In desert grassland ecosystems, Zheng et al. (2018) found a positive linear correlation between the plant available N:P ratio and the leaf N:P ratio. In addition, Zhan et al. (2017) discovered that the leaf N:P ratio is positively correlated with the soil available N:P ratio across N addition treatments. These findings highlight the importance of the soil available N:P ratio in controlling plant nutrient status in alpine grassland ecosystems. This means that enhancing N deposition would change the plant community composition and plant internal nutrient cycling through direct alteration in soil N availability and by indirect changes in soil nutrient stoichiometry.

DOI: http://dx.doi.org/10.15666/aeer/1805_64696484

Conclusion

The divergent responses of plant N and P concentrations in leaves to long-term N addition at the species and community levels implied that plant N and P cycling decoupled under N deposition. Grasses were more sensitive to N addition than forbs, resulting in significantly altered plant community composition. Moreover, soil available N and the soil available N:P ratio, rather than soil available P, were the key environmental parameters that controlled the N and P concentrations and stoichiometric ratios in plants. These findings are important for understanding plant nutrient allocation strategies and how plants adapt to environmental changes in alpine ecosystems. Altered plant community composition of forb species by N addition has minor influences on leaf nutrient status. Briefly, these findings have important implications for understanding the influence of N deposition on grassland nutrient cycling. In the future, biogeochemical models should consider the divergent responses of plant nutrient cycling to nutrient changes.

Abstract. *Achnatherum inebrians* (drunken horse grass) is one of the main poisonous grasses in Chinese grasslands, and it is mainly distributed in the degenerated grassland in the northern pastoral area. Individual plants grown in desert, steppe and meadow ecosystems were collected from July to August in Xinjiang, China. The results showed that there was no significant difference in the inflorescences, stems and reproductive biomass in the desert, steppe and meadow ecosystems, while the leaf, above- and below-ground vegetative and total biomass in the desert was significantly lower than that in the steppe and meadow habitats. The allocation of the biomass into the leaf was the most and the inflorescences was the least in three habitats. The biomass of inflorescences/stems increased in all three habitats, but there was a certain fluctuation in the biomass of other components. The biomass of *A. inebrians* in steppe and meadow habitats distributed more resources into the above-ground part concerning the accumulation of total biomass, while the opposite trend was observed in the desert. In the process of growth, the resources in desert and grasslands decreased reproductive allocation and more resources were allocated into vegetative biomass. It can be seen that there are differences in growth characteristics, and biomass allocation of *Achnatherum inebrians* grown in different habitats, which shows the flexible growth and resource allocation strategies of *Achnatherum inebrians* in different habitats.
Keywords: *biomass; invasive plants, reproductive biomass allocation, vegetative biomass allocation, heterogeneous habitats*

Introduction

Growth and reproduction are two of the most fundamental life-history functions in plants (She et al., 2017). The pattern of resource allocation to sexual vs asexual growth is a core component of studies of plant life history (Bonser and Aarssen, 2009; Weiner et al., 2009). Plants can modify their biomass allocation patterns to adapt to different environments (Guo et al., 2012). Biomass is one of the basic biological and functional characteristics of plants and is the basic embodiment of material and energy accumulation (Hao et al., 2013). The pattern of the distribution of resources in plants to various organs is the main focus of studies of changes in plant growth patterns, while environmental changes will affect the distribution of biomass among various organs to varying degrees (Fan et al., 2017). Modular allocation in an organism refers to the proportion of assimilated resources used in roots, stems, leaves, inflorescences, fruits and other organs during plant growth and reproduction (Xiao et al., 2014). It reflects the ecological strategies of plants in different habitats (Weiner, 2004) and is the result of long-term adaptation to the environment (Poorter et al., 2012; Wang et al., 2017). As a functional index, the value representing plant modular allocation not only reflects the material circulation and energy flow in the ecosystem but also has very important

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64856497

significance in the composition of ecosystem structure (Bloom et al., 1985; Hovenden et al., 2014; Luo et al., 2017). Therefore, the measurement of the biomass of plant components is of great significance in ecosystem research (Wang et al., 2015).

Invasive plants represent a serious threat to the structure and function of invaded ecosystems (Si et al., 2013). Approximately 30-40% of the world's endangered plants are disturbed and affected by exotic species (Walker et al., 1997), and invasive plants change the direction of community succession by altering environmental conditions. Invasive plants undergo a series of interactions with the environment during the invasion process; these interactions play an important role in further expanding the scope of plant invasions (Alpert et al., 2000; Liu et al., 2010). To study the influence of the invaded environment on the spread and distribution of invasive plants is helpful to reveal the rules of successful invasion in a particular location (Zhu et al., 2018). The distribution of an invasive alien plant is not only related to the biological characteristics and origin of the species itself but is also closely related to the environment in the invaded area (Wu et al., 2006). Invasive plants can use different reproductive strategies to colonize new areas. Ramets, which are produced via asexual reproduction, have higher growth and survival rates than seedlings, which are produced as a result of sexual reproduction, but their dispersal is generally restricted to short distances (Holsinger, 2000; Barrett et al., 2008). Consequently, exotic species using both strategies (sexual reproduction and asexual reproduction) may show greater invasion success than others (Winkler and Fischer, 2002). Identifying the relative contributions of each reproductive mode to the propagation of an invasive species is crucial for devising efficient control strategies. Control methods based on the misunderstanding of dispersal mechanisms risk failure because such efforts do not target plant parts from which new populations arise (Albert et al., 2015). Invasive plants are divided into narrow expansion and broad expansion. Broad expansion includes the expansion of native species and the expansion of alien species. *Achnatherum. Inebrians* (drunken horse grass) belongs to grassland species, if it spreads in the grassland, it belongs to local expansion, and to deserts and meadows belongs to local invasion.

A. Inebrians is a perennial herb belonging to *Achnatherum* Beauv. in Gramineae. It is one of the main toxic weeds in the natural grassland in north-western China. It is mainly distributed in Gansu, Inner Mongolia, Qinghai, Tibet, Xinjiang and other areas in China and is toxic to sheep, cattle, horses and other domestic animals (Ren, 1954). As early as 1876, American scholars named the *A. inebrians* collected in Inner Mongolia *Stipa inebriants* (Hance, 1876). Keng (1959) changed the classification status from *Stipa* to *Achnatherum* and named the plant *A. inebrians*; this name is still in use today. Due to its strong stress resistance and toxicity, it is not eaten by local livestock and gradually spreads. The direct economic loss caused by the decrease in grass production alone exceeds US$15 million per year, and this species has become the main limiting factor for the healthy development of animal husbandry in the grassland (Li et al., 2018). In recent decades, with the aggravation of grassland degradation, the harm caused by *A. inebrians* to livestock has gradually gained people's attention (Ren, 1954). Scholars have conducted a great deal of research on its botanical characteristics, eco-biological characteristics (Wang et al., 1991; Ji, 2009), endophytic fungi (Li et al., 1996; Chen et al., 2016), control and utilization (Yang et al., 2015; Jin et al., 2017). *A. inebrians* is not distributed only in steppes and meadows, like *Aconitum leucostomum*, or only in deserts, like *Anabasis aphylla*. *A. inebrians* species is distributed in deserts, steppes and meadows. Therefore, this study aims to investigate the quantity and biomass

DOI: http://dx.doi.org/10.15666/aeer/1805_64856497

characteristics of components, vegetative growth and reproductive growth of *A. Inebrians*, as well as the changes of biomass allocation between the above-ground and the below-ground, and discusses the propagation characteristics and adaptation strategies of the plants in different habitats.

Materials and methods

Study site

The studied areas are located in Heijiagou and Xiejiagou of in Urumqi City, Xinjiang, China (*Fig. 1*). Among them: Heijiagou is located in the low hills of the shallow mountain belt in the middle of the northern slope of Tianshan Mountain. The annual average precipitation is 221.3 mm, the annual average evaporation is 1765.4 mm, the annual average temperature is 4.3 °C, the annual frost-free period is about 129 days, and the soil is mountain brown desert soil. Xiejiagou is located in the middle and low mountain zone of the northern slope of Tianshan Mountain, with an annual average precipitation of 388.7-535.9 mm, an annual average evaporation of 1141.7-1564.9 mm, an annual average temperature of 2.1-3.3 °C and a frost-free period of 100-113 days. The soil is mountain chestnut soil. In terms of utilization, it is the spring and autumn grazing grassland for local livestock and sheep.

Heijiagou and Xiejiagou in Urumqi county correspond to three grassland types of desert, steppe and meadow respectively, forming three different environmental sample areas. These areas are typical areas invaded by *A. inebrians*, where this species has become the dominant species in the community (*Table 1*).

Research methods

Samples were collected during the fruiting stage (July to August 2018) of *A. inebrians* in desert, steppe and meadow areas. Each habitat included 3 parallel transects with a spacing of more than 10 m. Each transect had 5 plants with relatively consistent plant height (*Table 2*) that were more than 5 m apart, i.e., 15 plants were taken from each habitat, for a total of 45 plants.

Different small letters and large letters mean significant difference at 0.05 and 0.01 level

After measuring the plant height and inflorescence length in the field, the below-ground system was excavated and the above-ground parts were removed. When sampling, care was taken to maintain the integrity of each branch. After the roots were washed clean, the whole plant was taken back to the laboratory for air drying. Then, the dry weight of the roots, stems, leaves and inflorescences were measured individually with a 1/10,000 electronic balance.

Data analyses

One-way analysis of variance (ANOVA) and Pos hoc-LSD was used to analyze data utilizing SPSS 22.0 statistical analysis software. Relationships between vegetative and reproductive, above-ground and below-ground biomass allocation and total biomass were evaluated using regression analysis. All the quantitative relations were carried out regression analysis of the linear function $y = a + bx$, the power function $y = ax^b$, and the exponential function $y = ae^{bx}$, The Duncan test at the 5% confidence level was used for comparisons. The most correlated one was used as its description model (Liu, 2004). The figure was drawn with Origin 8.0. Inflorescence, leaf, stem, root, above-ground,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64856497

reproductive, vegetative biomass allocation were calculated as follows (Liu et al., 2012; Tian et al., 2018):
Inflorescence biomass allocation (%) = (Inflorescence biomass/total biomass) ×100%
Leaf biomass allocation (%) = (leaf biomass/total biomass) ×100%
Stem biomass allocation (%) = (stem biomass/total biomass) ×100%
Root biomass allocation (%) = (root biomass/total biomass) ×100%
Above-ground biomass allocation (%) = (above-ground biomass/total biomass) ×100%
Reproductive biomass allocation (%) = (reproductive biomass/total biomass) ×100%
Vegetative biomass allocation (%) = (vegetative biomass/total biomass) ×100%

Results

Comparison of the biomass of different plant parts among three habitats

There was no significant difference in the inflorescences and stems biomass of *A. inebrians* in the three habitats ($P > 0.05$), but the leaves, roots and total biomass in the desert was significantly lower than that in the other two habitats ($P < 0.05$); there was no significant difference in the reproductive biomass in the three habitats ($P > 0.05$), but the vegetative biomass in the desert was significantly lower than that in the other two habitats ($P < 0.05$); the above and below-ground biomass showed significant difference in the desert, it was smaller than the other two habitats ($P < 0.05$) (*Fig. 2*).

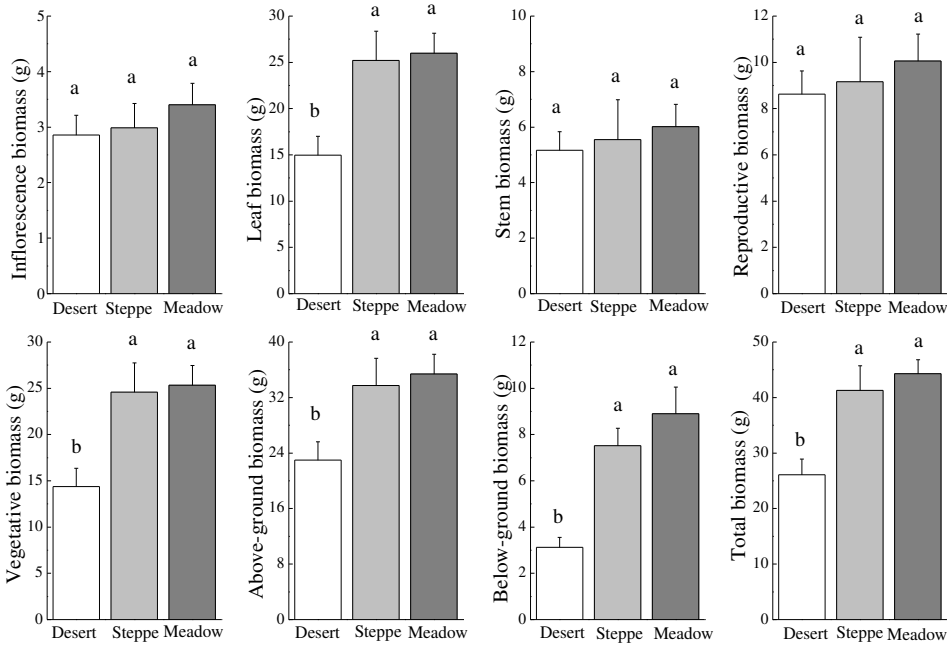

Figure 2. *Biomass of different parts of A. inebrians in three different habitats (g/plant). The error bars indicate standard error. Means not sharing a letter in common differ significantly at 5% probability level. N = 15*

The inflorescences, leaves, stems and roots biomass of *A. inebrians* in the desert represented 13.56%, 53.35%, 20.99%, and 12.11% of the total biomass of the plant, respectively, and biomass partitioning to the leaves and roots increased by approximately 5.67% and 8% of the total biomass in steppe and 8.55% and 5.47% of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64856497

the total biomass in meadow, respectively, while the biomass allocation to stems and inflorescences (approximately -7.45% and -6.24% in steppe, -7.18% and -6.84% in meadow, respectively) decreased accordingly, The average inflorescences, leaves, stems and roots biomass allocation in the three habitats were 9.23%, 57.68%, 15.73% and 17.36%, respectively (*Fig. 3*).

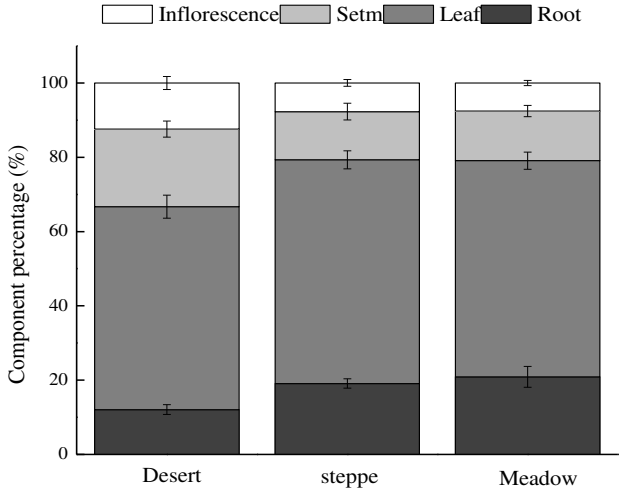

Figure 3. *Biomass percentages of different organs in relation to the total biomass of A. inebrians in three different habitats. The error bars indicate standard error. Means not sharing a letter in common differ significantly at 5% probability level. N = 15*

Changes of biomass of components in three habitats

Regression analysis of the root-leaf biomass, root-stem biomass, leaf-stem biomass, stem-inflorescence biomass and root-above-ground biomass correlations showed that there were similar positive linear correlations in desert and steppe, which reflected the structural and functional consistency and indivisibility of the individual plant organs. The coefficient of determination for the regressions including stem-inflorescence biomass showed a better fit across all three habitats than those involving the other organs, with R^2 values ranging from. The R^2 values of the root-leaf biomass, root-stem biomass, leaf-stem biomass, stem-inflorescence biomass, above-, root ground biomass and reproductive-vegetative biomass relationships fell within the ranges of 0.187-0.614, 0.001-0.231, 0.017-0.268, 0.347-0.636, 0.481-0.691 and 0.108-0.321, respectively, across all habitats, There are some differences in the biomass relationship of each component in the meadow habitat (*Fig. 4; Table 3*).

Relationship between the above- and below-ground biomass allocation and the total biomass of A. inebrians in three different habitats

The above-ground biomass allocation increased with the increase of the total biomass in steppe and meadow, while the above-ground biomass distribution decreased, indicating that more resources were allocated to the above-ground part with the accumulation of the total biomass of *A. inebrians*, while the change rule in desert habitat was just the opposite (*Fig. 5*). The determination coefficient R^2 of above-ground biomass allocation in each habitat was between 0.018 and 0.235, respectively. The coefficient R^2 of below-ground biomass allocation was between 0.011 and 0.235.

Relationship between the reproductive and vegetative biomass allocation and the total biomass of A. inebrians in three different habitats

Reproductive allocation decreased with the increase of total biomass in desert and meadow habitats, but increased in steppe habitats. With the increase of total biomass, the nutrient distribution of three habitats showed an increasing trend. The coefficient R^2 of reproductive biomass allocation was 0.089-0.326 for each habitat, and vegetative biomass allocation 0.262-0.835 for each habitat. It can be seen that in all three habitats, the reproductive allocation of *A. inebrians* decreased and more resources were allocated for vegetative growth (*Fig. 6*).

Discussion

Biomass is an important indicator that reflects the interaction between plants and the environment. It is the embodiment of plant adaptability to the environment and its growth and development trends. Individual and modular organism biomass, are also the embodiment of the ecosystem's ability to obtain energy (Yu et al., 2001). The comparison of the biomass of each component in different habitats showed that there was no significant difference between the biomass of inflorescence and stem in the three habitats ($P > 0.05$), but the total, biomass of leaf and root in the desert habitat were significantly lower than those in other two habitats ($P < 0.05$). The results showed that the difference in total biomass mainly came from leaves and roots, which were the above-ground photosynthetic organs and the below-ground nutrient absorbing organs. The difference of environment mainly affected the biomass of the two components. The biomass of vegetative was significantly lower than that of the other two habitats ($P < 0.05$), but the biomass of reproductive was not significantly different ($P > 0.05$). It can be seen that under the fragile environment, the growth of *A. inebrians* decreased. The above-ground biomass was significantly lower than those in the other two habitats

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64856497

($P < 0.05$), and the overall trend of above-ground components was that the above-ground components were smaller than those in the other two habitats ($P < 0.05$). The cumulative benefits of each component, especially the significant reduction of leaf biomass, led to the significant above-ground components biomass. It was lower than other habitats ($P < 0.05$); therefore, the total biomass showed the biomass of sacrificing leaves, vegetative branches and even roots, maintaining the growth of reproductive branches and inflorescences, and maintaining sexual reproduction.

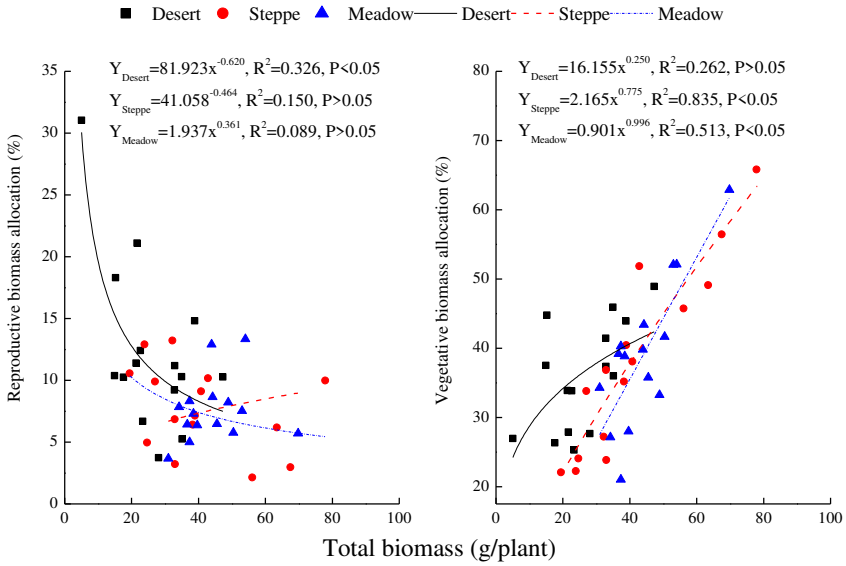

Figure 6. *Relationship between reproductive allocation, vegetative allocation and total biomass in A. inebrians. The error bars indicate standard error. Means not sharing a letter in common differ significantly at 5% probability level. N = 15*

The proportion of the biomass of various components to the total biomass represents the distribution ratio of assimilates to different organs and the coordinated relationships of various components during the growth process (Wang et al., 1995). In terms of biomass allocation, the biomass allocation into inflorescences and stems in the desert habitat was significantly higher than that in the steppe and meadow habitats, and the biomass allocation into the roots showed the opposite trends ($P < 0.05$). The proportion of leaf is the largest in biomass allocation of all habitats, Similar results have been obtained from previous studies (Yang et al., 2003). The mean value of the biomass allocation of each component in the three habitats indicated that leaf biomass allocation > root biomass allocation > stem biomass allocation > inflorescence biomass allocation; all of these differences were significant ($P < 0.05$) (*Fig. 3*). In terms of function, the leaves of plants are the production organs of nutrients, and the stems have multiple functions, such as nutrient transport and storage as well as supporting the leaves in expanding the growth space (Arenas et al., 2002). The distribution ratio to leaf biomass is the largest for all three habitats, and the distribution ratio to inflorescences biomass is the smallest. The pattern of biomass distribution in the three habitats is as follows: first to the leaves, then to the roots, and finally to the stem and inflorescences. This reflects that *A. inebrians* shows high ecological plasticity and strong adjustability. In response to different environments, *A. inebrians* uses different growth strategies to ensure its growth, development and reproduction.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64856497

The coefficient of determination for the regressions including stem- inflorescence biomass showed a better fit across all three habitats than those involving the other organs, with R^2 values ranging from 0.347 to 0.636. The differences in the species index and organ size may be due to the distribution of photosynthetic products, water and nutrients between the above-ground parts and roots (*Fig. 4; Table 3*).

It is generally believed that high root biomass allocation ratio is a common feature of plants responding to below-ground resource deficit in the process of desert succession (Gill et al., 2002). The above-ground biomass allocation increased with the increase of total biomass, but the below-ground biomass allocation showed the opposite trend. This reflects the growth law of the *A. inebrians*, with the accumulation of biomass, the *A. inebrians* in steppe and meadow habitat preferentially distributes more biomass into above-ground components by reducing the input of below-ground roots, which is an important way to ensure the sexual reproduction and population diffusion of plants (Li et al., 2009); In the desert environment, the above-ground biomass distribution decreases with the increase of total biomass, while the below-ground biomass distribution decreases with the total growth. The growth of root system is enhanced by the increase of biomass, so as to ensure the water and inorganic nutrition needed for growth and reproduction in arid environment. Similar results have been obtained from previous studies (Zhao et al., 2017; Zhou., 2015) (*Fig. 5*).

The biomass allocation of vegetative, reproductive allocation and total biomass allocation reflect the resource allocation strategies between sexual and asexual reproduction (Hong et al., 2007; Zhang et al., 2004). The results showed that the reproductive allocation of *A. inebrians* in desert and steppe decreased, while that of meadow increased. The biomass distribution of vegetative branches and the total biomass of three habitats increased. On the one hand, the spatial characteristics of desert, grassland and meadow were related to the environmental conditions. Compared with desert and steppe habitat, meadow habitat can provide enough space for the spread of the *A. inebrians*, and the light is sufficient. The most direct and effective growth strategy for the *A. inebrians* to rapidly occupy such a favorable space is asexual reproduction. On the other hand, after entering the invasion area and settling down, the population regeneration of *A. inebrians* is mainly carried out by vegetative reproduction; for the allocation of reproductive branches, *A. inebrians* is also kept at a medium average level, which shows that *A. inebrians* has strong sexual reproduction ability, which is similar to the previous research results (Hong et al., 2010). Therefore, this study further speculated that the local spread and diffusion of the *A. inebrians* in the invasion area, the population renewal mainly through nutrition reproduction, long-distance transmission, mainly through seeds, which need further study to investigate (*Fig. 6*).

Conclusion

There was no significant difference in the biomass of inflorescences, stems and reproductive branch of *A. inebrians* among the three different habitats of desert, steppe and meadow ($P > 0.05$), but the biomass of other components in the desert was significantly lower than those in the other two habitats ($P < 0.05$). The allocation of leaves biomass was the most and inflorescence was the least in three habitats, and the biomass of reproductive and vegetative, above-ground and below-ground biomass increased with the increase of total biomass. In the steppe and meadow habitats, more

energy is preferentially distributed to the above-ground components by reducing the input of below-ground biomass, but in the desert habitats, the opposite trend was observed.

In this paper, we only analyse the effect of different habitats on biomass and biomass allocation of *A. inebrians*. The allocation of biomass in the population of *A. inebrians* was neglected the influence of disturbance degree and genetic characteristics on them, and whether the difference of the relationship among the components of *A. inebrians* is related to their location Is it related to the level of phylogeny at present, certain regularity can be studied from these angles in the future Growth strategy of *A. inebrians* population.

Abstract. Groundwater pollution cause excessive levels of water quality parameters such as pH, Total Dissolved Solids (TDS), hardness etc, therefore, it is a severe problem for people. The present study describes the prediction of pH in groundwater using Artificial Neural Network (ANN) model and visual MODFLOW. It is observed that the pH level of study area is lower than the standard limit so that the water turns to acidic. The water is not suitable for drinking purposes thus a prediction model is needed to rectify this issue. A smart prediction modelfor pH was developed using ANN. Selected input variables were Hardness, Calcium (Ca), Magnesium (Mg), Sodium (Na), Potassium (K), Nitrite (NO_3), Chloride (Cl) and Sulphate (SO_4)and the best performance value was 0.025637. Also to simulate the groundwater of the study area, visual MODFLOW model was created.Using this model, pH is simulated for 365 days. From the calibration plot, it is known that the correlation coefficient of the observed and the simulated value is 0.92. From the simulation it is concluded that the pH level was almost the same for 365 days.
Keywords: *Mondaikadu, water quality, solute transport, simulation, prediction*

Introduction

Groundwater has been essential to sustain India's economy and to fulfill its domestic needs, and it also has agricultural and industrial use. Around 33% of the total population relies upon the utilization of groundwater for drinking (Nickson et al., 2005).Groundwater accounts for about 98% of all of the planet's available fresh water, and it is about 60 times more concentrated than the fresh water present in lakes and streams. India is the world's biggest groundwater user, with a yearly use of roughly 230 cubic kilometers for each annum (World Bank, 2012). The nation as a whole hasanet annual groundwater supply of 398 billion cubic meters (Water and Related Statistics, 2015). More than 60% of farming and 85% of drinking water supplies depending on it, groundwater is a basic asset for Indian rural zones.

Nowadays, groundwater pollution is considered as a world level issue. Many organizations are taking serious actions against this issue and creating regular monitoring programmes. A research studies on various features of groundwater, such as, storage potential, hydrogeology, water quality, vulnerability, and sustainability and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64996510

so on was conducted by many researchers (Chapagai et al., 2010; Pandeyet al., 2011, 2012). Particularly the quality of water is considered a key contributor to various diseases. In general, groundwater is less vulnerable to pollution as compared to surface water. Contamination of groundwater is due to the presence of certain pollutants in groundwater which exceed limits prescribed for drinking water. Arsenic, nitrate and carbon, which are of a geogenic origin, are the widely found pollutants. Many pollutants include bacteria, phosphates, and heavy metals that arise from human activities like domestic waste, agricultural practices, and industrial effluents. Groundwater quality may change from place to place as well as season to season. Weak environmental management schemes in factories contribute to water discharges of hazardous and agricultural wastes. This resulted in the contamination of those surface and groundwaters from which water is drawn for irrigation and household use (Pai and Mulye, 2016). Landuse pattern is one of the reasons for groundwater contaminations.

Many intelligent tools, such as linear and non-linear tools are successfully used to predict the water quality. Nowadays artificial neural networkis used to find a solution for many cases of water quality problems.Wagh et al.(2016) used the ANN model to predict sodium adsorption ratio (SAR) values, residual sodium carbonate, magnesium adsorption ratio, Kellys ratio and sodium percentage in Nanded tehsil ground water.It is found from the results that there is a strong agreement between the actual data and the ANN outputs for indices of irrigation suitability for training and testing datasets.Mohammadi et al. (2016) utilized ANN model to simulate concentrations of fluoride in groundwater resources in Khaf and surrounding villages based on the water's physical and chemical properties.The best results were observed by the MLP1 model with eight parameter inputs such as root mean square error (RMSE) and correlation coefficient of real and expected outputs.The simulation results from the MLP1 test stage as well as the high correlation between experimental and projected data suggested that this model can be used to predict fluoride concentrations in groundwater supplies with its high confidence coefficient.Kheradpisheh et al. (2015) developed the artificial neural network for Cl^-, EC, SO_4^{2-} and NO_3^- in order to assess the influence of the key input parameters, the test results were estimated and compared with the measured values.Palani et al. (2008) predicted the quantitative characteristics of the water bodiesusing ANN. The ANN model was developed at any location in the domain of interest for fast assessment and selected water quality variableswere forecasted. The input parameters measured at other locations serve as respective variables. Input variables include salinity, temperature, dissolved oxygen, and chlorophyll-alpha.The findings demonstrate the great potential of the ANN for simulating variables in water quality.

During the summer, winter and monsoon seasons, the level of pH in the study area is much less (5.4 to 6.2) when compared to the World Health Organization (pH 6.5-8.5) (WHO, 2008)and Indian Standards(pH 6.5-8.5) (BIS, 2009),therefore the water becomes acidic in nature and the quality of the water is degraded. The reason for low pH is due to the coconut retting zone of the study area (Jessy Mol and Baskaran, 2017). Since the level of pH is decreasing, modelling of pH is needed to find out the pH level in the future.The novel aspect of this study is the Visual MODFLOW combined with MT3DMS,it is used for the groundwater quality model, where the coconut retting zone of the study area is taken as the recharge zone for boundary conditions in MODFLOW. Therefore, the influence of the retting zone on the pH level can be predictedvery easily.

Materials and Methods

Study area

The area taken for study is in Mondaikadu Panchayat of Kanyakumari District, Tamil Nadu, India. It lies between $8^0$9'47" latitude and $77^0$16'48.09" longitude. The town averages 25 meters above Mean Sea Level (MSL). It is a coastal area of Kanyakumari District. The soil is usually red loam but in some areas there is also sandy loam soil. The average annual rainfall is 1456.8mmwith 79.7 rainy days. The precipitation is dispersed from April to December, and goes under three seasons, to be specific hot weather seasonal rainfall, South West monsoon and North East monsoon (ENVIS centre Tamil Nadu). The study area map is shown in *Fig. 1*.

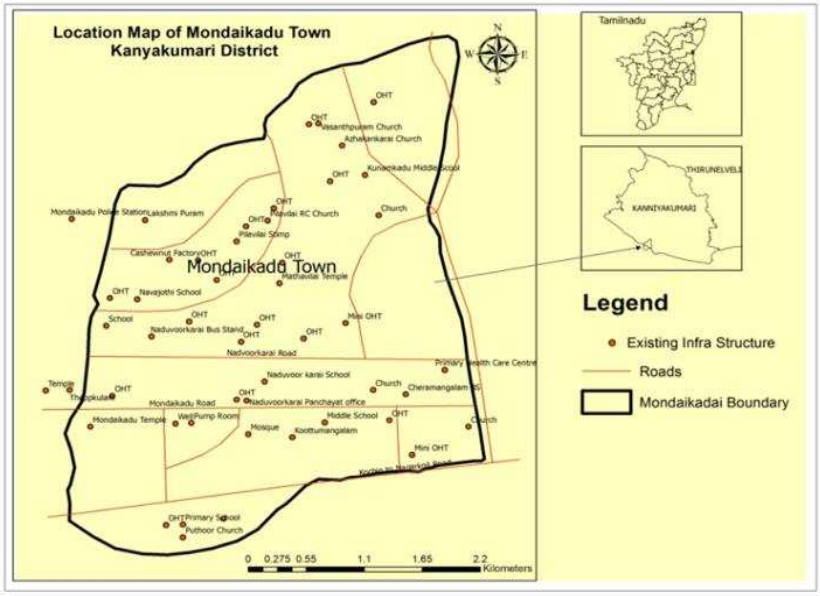

Figure 1. *Study area map*

Sample collection and analysis

Collection of samples is the key aspect of any type of scientific study. Twenty sampling points were chosen from the study area and samples for the three seasons were collected, namely winter (October to February), summer (March to May) and monsoon (June to September). For three years (2017-2019) the samples were collected from the study area, so that the total number of samples collected was 180. The approximate depth of the sampling was 50m. After 10 minutes of pump start, the samples were collected directly from the bore wells. The unstable parameters turbidity, pH and temperature were tested using digital meters at the sampling points. Other parameters were tested in a laboratory as per APHA (1998). Temperature, pH and turbidity were determined at the sampling site with a thermometer, systronics pH meter and Nephlometric turbidity meter respectively. Calcium and magnesium were determined titrimetrically using standard EDTA solution and total chloride by volumetric titration method. Sodium and Potassium were estimated using flamephotometry, Nitrite was determined using ion selective electrode.

Artificial neural network (ANN)

ANN is a tool for mathematical modelling. It works based on neural processing in the human brain. In the human brain, each neuron is connected as a network. In the same manner, in the neural network, the layout has a set of neurons and they are linked and organized. The information passes through a neural network, from the input to the output. The Network consists of interconnected node layers. These nodes are called neurons which function as elementary units of processing. From the various inputs each neuron receives the information and produces an output by the value. Its activation function happens when the weighted whole of its information is the statement (Kilicaslan et al., 2014).Every layer is related by its respective weights to the next layer (Nasr et al., 2012).*Eq.1* is used to calculate the weighted sum of the layer.

$$y_j = \sum_{i=1}^{n} W_{ij} x_i + \theta \quad \text{(Eq.1)}$$

where yj is the weighted sum of the jth neuron for the input data obtained from the n-neuron proceeding layer, Wij is the weight between the ith neuron and the jth neuron in the proceeding layer, xi is the contribution of the ith neuron in the proceeding layer and θ may be biased by the jth neuron. The input layer of the network is used to feed the data to the network; the hidden layer of the network is used to act as a collection of features detector, and the output layer is used to get out the result (Seyamand Mogheir, 2011).

In the forward direction, the input signal passes through the network from one to another layer. This process is named as Multi Layer Perception (MLP). Back Propagation Algorithm is used in MLP to solve the problems. This algorithm consists of Feed Forward and Feed Backward Network (Subbarayan, 2013).Feed Forward Back Propagation Network is mostly used in many water resources problems.The optimal weight is calculated by minimizing the Mean Square Error (MSE) of the training stage (Nasr et al, 2013). Mean Square Error is calculated by *Eq.2*.

$$MSE = \frac{1}{n} \sum_{1}^{n} (T_i - Out_i)^2 \quad \text{(Eq.2)}$$

where T_i and the out_i are the desired neural network target and output for the ith neuron respectively, n is the number of samples in the network. Neural networks have three stages; these are training stage, validation stage and testing stage. In the training stage, the network's weight and bias are computed. Learning functions are used at this stage to update weight and bias of the layer. Here, the trained network is validated. After that, the data set is used to examine the generalization of the network. This stage is the testing stage.

The network is classified as two types namely, supervised and unsupervised classification. Supervised classification means that the input and output data are given and the error is calculated for the predicted output and the output given to the network. Mostly used training function is trainlm function, Levenberg – Marquardt back propagation (trainlm) function locates the minimum of a multivariate equation it can be represented as the sum of the non-linear real-evaluated functions squares. It's an iterative technique that operates in such a way that every iteration of the algorithm is always reduced by output level. This component makes trainlm the quickest training algorithm for reasonably sized networks (Sharma and Venugopalan, 2014). This

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64996510

training function is often capable of getting lower mean square errors than the other training function (Kumar, 2010).

Visual MODFLOW model

Visual Modflow is used to simulate the Groundwater flow because of its most comprehensive and user-friendly modeling environment. MT3DMS is one of Visual Modflow's problem solving tool which is used to evaluate the simulation of contaminant transport. This model is completely incorporated, combining the strong analytical tools with a clear menu structure.In model creation or analysis of results, the model info parameters and results can be envisioned in 2D and 3D at any minute. The mathematical equation for groundwater model is given by *Eq.3*.

$$\frac{\partial}{\partial x}\left\{Kx\frac{\partial h}{\partial x}\right\}+\frac{\partial}{\partial y}\left\{Ky\frac{\partial h}{\partial y}\right\}+\frac{\partial}{\partial x}\left\{Kz\frac{\partial h}{\partial z}\right\}=Ss\frac{\partial h}{\partial t} \quad \text{(Eq.3)}$$

where, Kx, Ky are the Hydraulic conductivity of the x and y directions respectively, Kz is the Hydraulic conductivity of the z direction, x ,y, z are the Cartesian coordination, h is the Hydraulic head, Ss is the Specific storage of the porous material and t is the Time.

Transport equation

The equation represents motion of the solute mass transport through a volume of control. It indicates that the amount of masses absorbing or producing solute with the volume of control must be equal to a shift of solvent concentration with the volume of control. *Eq.4* gives the solute transport equation that is implanted in MT3D used for modeling.

$$\frac{\partial C}{\partial t}=\left[\frac{\partial}{\partial x_i}\left(D_{ij}\frac{\partial C}{\partial x_j}\right)\right]-\left[\frac{\partial}{\partial x_i}(V_i C)\right] \quad \text{(Eq.4)}$$

where,

V_i = Seepage velocities in x, y, z directions, m/s (LT^{-1}),
D_{ij} = Dispersion coefficients, m^2 /sec (L^2 T^1),
C = Solute concentration, mg/m^3 (ML^3),
t = Time.

Input data

The detailed hydrogeological description of the study area was collected to allocate the required modeling inputs. The data required to input the MODFLOW for groundwater modelling areelevation, quality data, observation well details, subsurface thickness, hydraulic head, contaminant concentration, conductivity, storage properties, dispersion coefficient, evapo-transpiration, recharge and Boundary conditions.

Simulation

A stress cycle is characterized as a time period during which all system stresses are constant. Design Visual Modflow was utilizing the data from the first time period of each given boundary condition for a steady state simulation. For transient simulations,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64996510

all of the data described in different time period for each boundary condition and well was automatically merged into the stress period format provided by Modflow.

Results and Discussion

ANN model for pH

A back-propagation Feed Forward Neural Network (FFNN) algorithm is used to compare the relationship between input and output. This model is performed using MatlabTool box for ANN (MATLABand StatisticsToolbox, 2012). Based on prior research by Sathyamurthy (2013), the ANN inputs for pH are identified. The selected output is pH and the input variables are Hardness, Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}, NO_3^{-},Cl^{-} and SO_4^{2-}. Several trials were conducted for each group to attain the suitable network structure until the appropriate training rate, the number of hidden layers and the number of neurons per hidden layer was reached. The best structure is the one that produces the minimum MSE in both the training and testing data (Nasr and Zahran,2014). The algorithm for back propagation minimizes the Mean Square Error in the output layer between the observed and the predicted output. The structure resulting in a minimal number of errors is the one selected as shown in figure. The network properties are as follows:

- Data Used: 160 for training 20 for testing.
- Network input: Hardness, Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}, NO_3^{-}, Cl^{-} and SO_4^{2-}.
- Network output: pH.
- Network type: feed-forward back –propagation.
- Training function: Levenberg–Marquardt algorithm (TRAINLM).
- Adaptation learning function: LEARNGDM.
- Performance function: MSE.
- Epochs: 1000.
- Number of neurons: 25, *Fig. 2* shows the neural network diagram of the model.

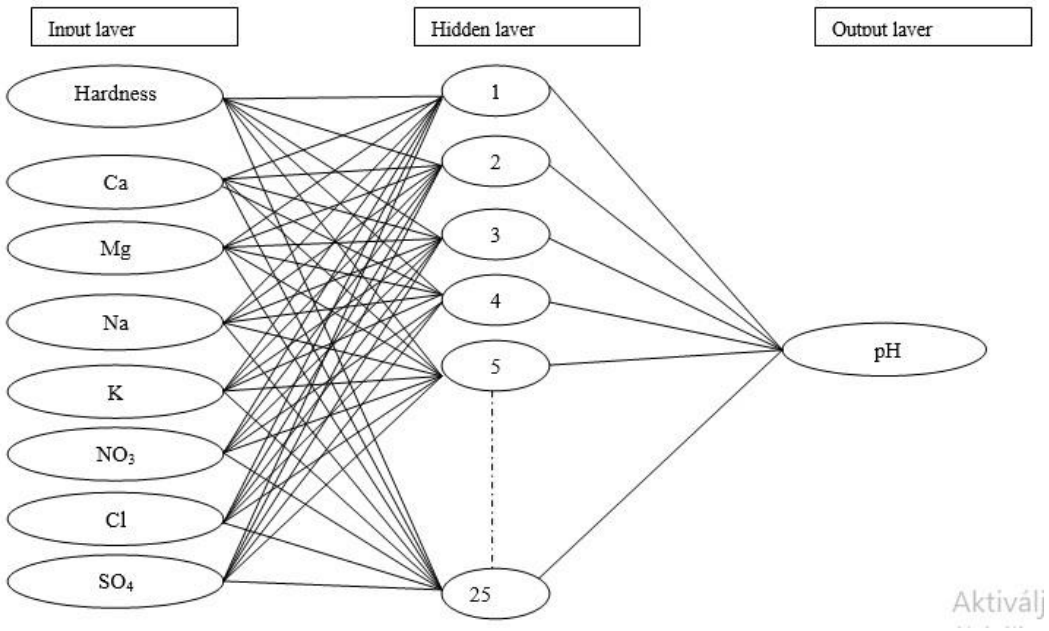

Figure 2. *Neural Network Diagram of pH*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64996510

To terminate the network training, the gradient's magnitude and the iterations of validation checks is used. The number of validity checks is 9,which is the right value to quit training. The output plot indicates the function's value as opposed to the iteration number in terms of preparation, evaluation, and test behaviors. Based on the MSE the best validation performance is 0.025637 at epoch 3 as shown in *Fig. 3*. Since the validation and test graphs are close, the training did not pose any major problems or over fit. During preparation, each layer neuron changes its weight vector toward the input vector group nearest to it.

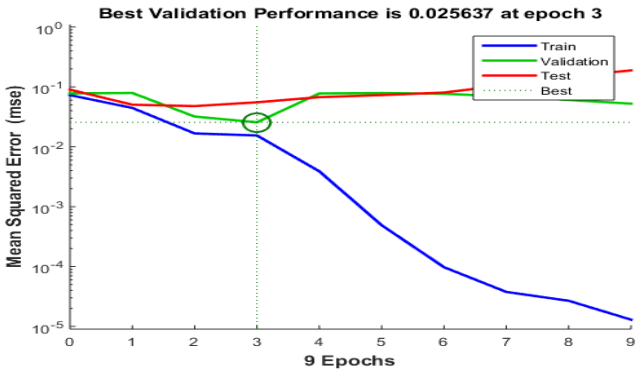

Figure 3. *Training performance graph*

As shown in *Fig. 4*, for training, validation, and testing, a linear regression analysis is performed to find out the correlation between the network outputs and goals. The dotted line represents the optimal outcome in each map, i.e. outputs = goals, while the dark line indicates the best linear regression that suits. The effects of regression (R-value), respectively, are 0.96, 0.99 and 0.98 for preparation, validation and research. Those results corresponded to a cumulative 0.96.

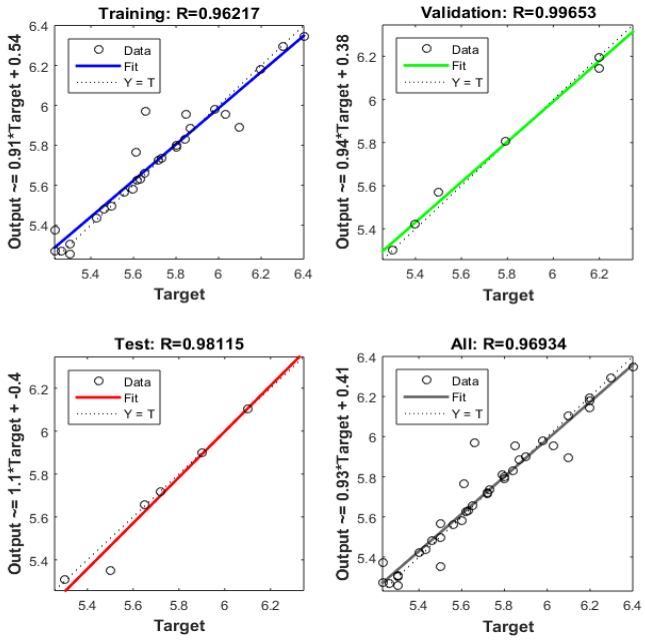

Figure 4. *Regression plot for training, validation and testing*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64996510

After training, validation and testing of the network, the created network can be used to predict the pH via the new input data. From *Fig. 5* it was found that the experimental pH analysis is similar to the expected data determined from the network and this confirms this model's validity. *Fig. 6* shows the linear relationship between the observed and predicted pH and it found R^2 0.927. From this, it is inferred that the model established is apt to predict groundwater pH.

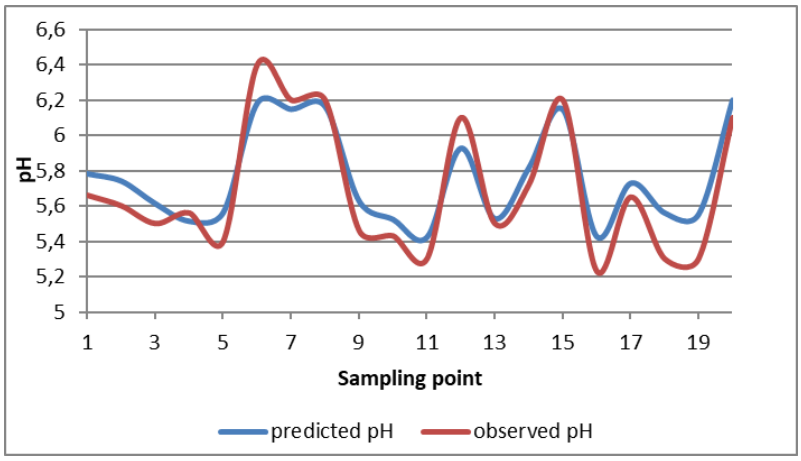

Figure 5. *Comparison of observed and predicted pH*

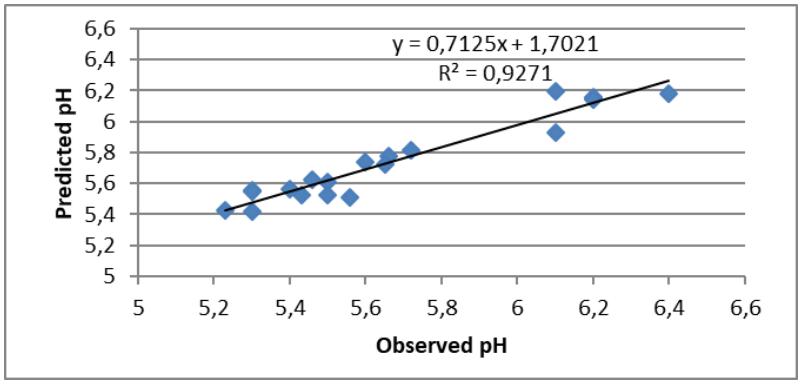

Figure 6. *Linear relation between observed and predicted EC*

MODFLOW model

Modeling of groundwater flow and transport is performed using Visual MODFLOW and MT3DMS tools (Harbaugh, 2005). The three Visual MODFLOW sections are Input, Run, and Output. The groundwater parameters and aquifer properties are given in the input section as input to the model. Based on the specifications, the correct engine and solver parameters are selected in the run portion, and the model is simulated.

Input of transport modeling

Hydro-geological characterization of the study area is performed to allocate the required modeling data. *Fig. 7* shows output obtained from the model, such as location of pumping wells and concentration wells and boundary conditions. The assigned

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64996510

boundary conditions of the study area are concentration and recharge boundary conditions. Since the pH level of the study area is less than the drinking water standards (WHO) the level of pH is given as the input to the concentration wells.

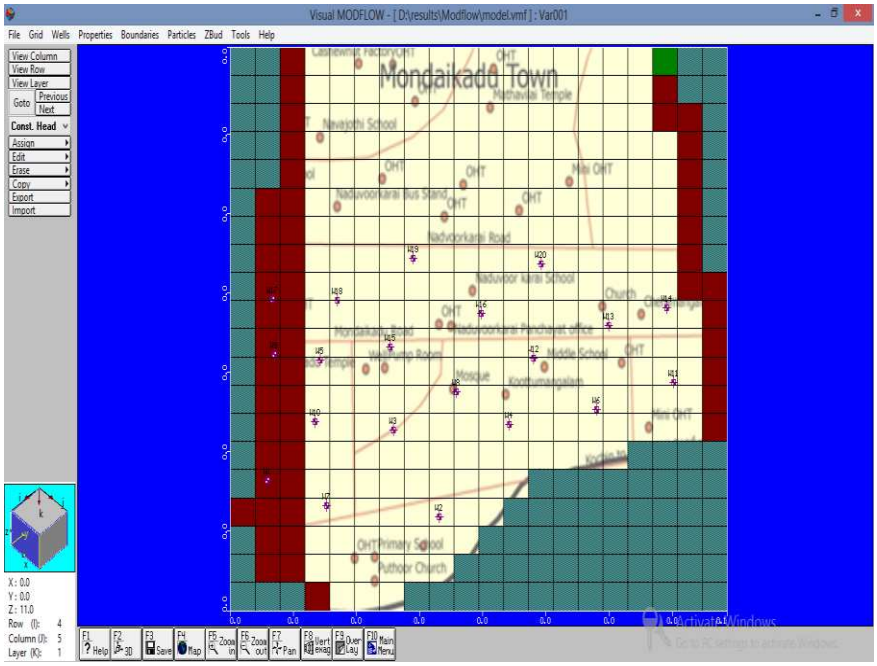

Figure 7. *Boundary conditions of study area*

Model simulation

The results of the transport contamination were simulated using the following assumptions.

Run Type	-	Transient flow
Time Steps	-	10 stress periods
Simulation Period	-	365 days
Solver	-	WHS solver
Layer	-	Single layer of unconfined aquifer

Model output

In *Fig. 8* the flow direction is initially from the south side towards the other three sides of the study area, because the south side is given as the recharge zone of the study area. The vectors of velocities represent the speed and direction of the particle of water as it travels through the field of flow.

Calibration of model

The pH is simulated and calibrated for 365 days; the calibration plot between the observed and the predicted pH is shown in *Fig. 9*. It shows the observed pH is 5.68 and the calculated pH is 5.35 same as the observed value of pH for another sample is 5.15 and observed value is 5.20. The correlation coefficient between the observed and the calculated value is 0.92; this value is nearer to 1, and therefore the model is calibrated in a correct manner.

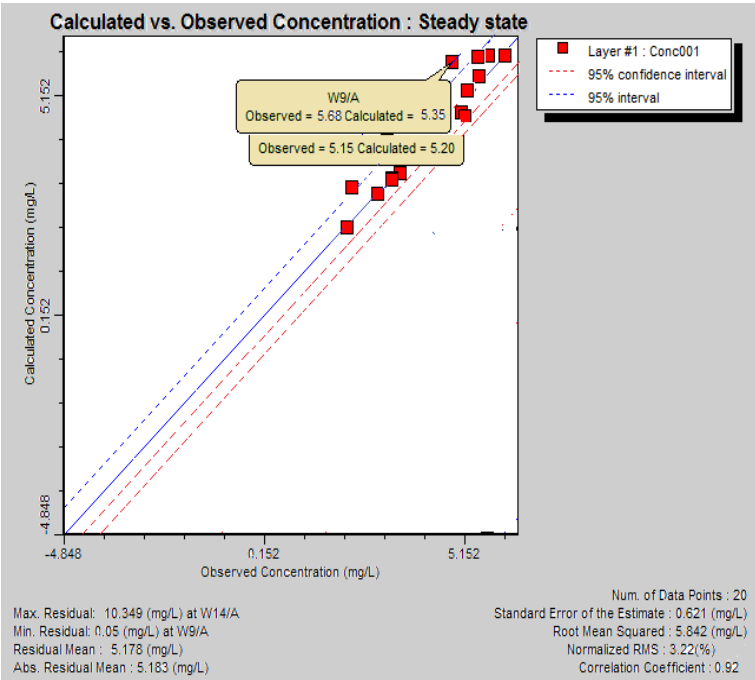

__Figure 9.__Model Calibration Chart

Conclusions

The pH was predicted by ANN model, using Hardness, Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}, NO_3^{-}, Cl^{-} and SO_4^{2-} as inputs. The best validation performance was 0.025637. Since the ANN model is based on the output data, the approach can be used for the other basins of study area, depending on the availability of data. To simulate the pH, Visual MODFLOW

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_64996510

model was used. The flow concentration was simulated for 365 days, and the correlation coefficient of the observed and the simulated value was 0.92. The decision makers and the groundwater managers associated with Mondaikadu will benefit if they use the findings of this paper as a decision support tool. It is recommended that the research can be done in the future by implementing various artificial recharge structures in the study area to enhance the groundwater quality.

Abstract. Straw is an important organic resource that could be recycled, however, few studies investigated the effects of straw decomposition on aggregate stability and organic carbon (OC) of different mineral soils. In this study, we conducted a constant temperature incubation experiment for 120 days in three different mineral soils consisting of two treatments: control soil and straw-amended soil. The results showed that straw addition promoted a significant increase of >2 mm water-stable macroaggregates as well as a significant decrease of microaggregates (<0.25 mm) compared with control soils (P<0.05). From day 15 to day 120, the three straw-amended soils significantly increased in mean weight diameter (MWD) and geometric mean diameter (GMD). The OC concentration of different particle-size aggregates in straw-amended soils increased significantly during the early 15 days of incubation, then gradually decreased during the later stages. After 120 days of incubation, the contribution of OC of macroaggregates to soil organic carbon in fluvo-aquic soil reached the highest (66.14%). Among them, the fluvo-aquic soil with 2:1 clay mineral showed better improvement of aggregate stability and OC concentration than red soil during straw decomposition. These results confirm the differences and benefits of straw application for soil structure and quality of different clay mineral types.
Keywords: *straw-amended soil, incubation, water-stable aggregates, aggregate stability, soil organic carbon*

Introduction

Soil aggregate is a special organic-inorganic-biological complex with multi-level structure or fractal characteristics. Its formation and stability process are extremely complex. As the basic unit of soil structure, it features complicated formation and stability process which is not only affected by the material composition of the soil itself, but also by human activities and other factors (Verchot et al., 2011; Zhang et al., 2014; Rabot et al., 2018). Quality soil aggregate plays an important role in regulating soil properties, as well as maintaining soil fertility and ecological environment function. It is not only conducive to the efficient use of water and fertilizer and crop growth, but also to improve soil erosion resistance and carbon sequestration. As its stability is closely related to many soil properties and the ecological environment, it

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65116528

plays a vital role in maintaining the sound and sustainable development of soil and the protection of ecological environment (Blanco-Canqui and Lal, 2004; Abiven et al., 2007; Bandyopadhyay and Lal, 2014; Wang et al., 2017). On the contrary, the decrease of soil structure stability will not only reduce the water and fertilizer utilization efficiency of the soil, but it also affects crop yield by increasing the risk of soil degradation and soil erosion, and destroying the sound and sustainable development of soil (Lal, 2008; Li et al., 2017; Vaezi et al., 2017). Therefore, the research on the structural stability and function of soil aggregates has always been one of the main focuses in the field of soil science.

Soil organic carbon (SOC) is the main factor of carbon balance in terrestrial ecosystems, and its small fluctuation may have a significant impact on greenhouse gas emissions and even carbon balance in terrestrial ecosystems (Vanhala et al., 2008; Lu et al., 2013). According to the research, there is a close relationship between SOC and aggregates, and the interaction between the formation of aggregates and the carbon sequestration is of great significance to promote soil carbon sequestration. As the main source of SOC, exogenous new carbon contains a variety of nutrient elements, whose direct addition can increase the number and activity of soil microorganisms, and promote the accumulation of SOC (Fonte et al., 2009; Blaud et al., 2012; Haydu-Houdeshell et al., 2018). The stability of soil aggregates mostly refers to the water stability of soil aggregates. The content and stability of water-stable aggregates play an important role in evaluating the stability of soil structure and soil anti-erosion ability. SOC is one of the most important factors that affect the structure of soil aggregates. As an important cementing substance in the formation of soil aggregates, it plays an important role in the formation of aggregates with different number and particle size distribution, promoting the aggregation of aggregates and the stability of water-stable aggregates (Chivenge et al., 2011; Ji et al., 2014; Zhu et al., 2017). At the same time, OC can be found mainly in aggregates, and soil aggregation can provide physical protection for SOC. Therefore, relevant scholars regard the stability of soil aggregates or the carbon sequestration capacity of soil as an important index to evaluate soil physical properties and SOC pool. They think that the improvement of the stability of soil aggregates, the quantity and quality of aggregates, as well as the content of SOC pool plays an important role in promoting the sound and sustainable development of agriculture and carbon cycle (Peth et al., 2008; Bimüller et al., 2016).

Straw is an important organic resource that can be recycled, at present, great importance has been attached to the sustainable development of agriculture by adopting the conservation tillage method with straw amendments or mulching as auxiliary measures. The application of straw can increase the concentration of SOC and promote the recycling of straw nutrients in the soil. The organic cement produced after straw decomposition can also promote the formation of soil aggregates, strengthen the cohesion between soil particles, and improve the structure of soil aggregates (Blanco-Canqui and Lal, 2004; Abiven et al., 2009; Blanco-Moure et al., 2012). For example, Gu et al. (2014) studied the effect of corn straw treatment on aggregate composition and OC concentration of aggregates in brown soil, which showed that the addition of corn straw significantly increased the content of >2000 μm water-stable aggregates, reduced the content of 250-2000 μm and <250 μm aggregates, and increased the stability of aggregates and OC concentration of aggregates. Tang et al. (2011) studied the effect of plant residue decomposition on the quantity and stability of red soil aggregates, which showed that straw treatment significantly promoted the formation of >2000 μm and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65116528

250-2000 μm water-stable aggregates, and improved the stability of aggregates. According to the above studies, straw addition has a great influence on the distribution, stability and OC concentration of soil aggregates. Soil aggregation processes were very complicated, different types of soil contain different clay minerals, which will affect the agglomeration of aggregates and the retention of OC, it is necessary to explore the agglomeration of aggregates and the retention of OC with the application of straw after the application of straw in different types of soil. However, there are few reports about the effect of straw decomposition on aggregates stability and aggregate-associated OC of different types of soil. It is difficult to distinguish the difference about straw decomposition on the distribution and stability of aggregates and aggregate associated OC of different types of soil, which requires further study. To this end, this paper studies the effect of straw application on the distribution and stability of water-stable aggregates in three different types of soil, and explores the distribution law of OC in different particle-size aggregates and the contribution rate of aggregate-associated OC during the process of rice straw decomposition with disturbance-free indoor incubation experiment. This study aims to provide theoretical support for the improvement of aggregate structure and OC in different types of soil.

Materials and Methods

Site description and experimental samples

The three typical soil samples were red soil (R Soil), fluvo-aquic soil (FA Soil) and lime concretion black soil (LCB Soil) in China, which were collected in their respective test stations in September 2014 with a sampling depth of 0-30 cm (*Fig. 1*). Five sampling points were evenly mixed and then quartered for sampling. Specifically, the sampling area of R soil is located in Yingtan R Soil Ecological Experimental Station of Chinese Academy of Sciences, Jiangxi Province, China (116°55′E, 28°15′N). The soil type is R soil developed from Quaternary red clay and the parent rock mineral types are mainly iron-aluminum oxides and 1:1 clay mineral, which is classified as Ultisol in the USDA soil taxonomy; the sampling area of FA soil is located in Fengqiu Ecological Experimental Station, Henan Province, China (114°24′E, 35°00′N). The soil type is FA soil developed from Yellow River sedimentation and the mineral type is mainly 2:1 clay mineral with high calcium carbonate content, which is classified as Inceptisol (USDA); the sampling area of the LCB soil (Vertisol) is located in Yangliu Experimental Site, Suixi, Anhui Province, China (116°46'E, 33°37'N), and the mineral type is mainly 2:1 clay mineral with montmorillonite as the main component (Lv and Li, 2006). After the coarse plant residues, large gravel and other impurities were removed from the collected soil, the soil was brought back to the laboratory for natural air drying in a cool and ventilated place, and then it was gently forced apart along the natural fragile zone so that it could pass through the 2 mm sieve. Special attention was paid to minimize the disturbance to the soil during the collection and transportation process to avoid the damage to the aggregates.

The basic properties of the three typical types of soil were shown in *Table 1*. The straw samples used in this experiment were rice straw cultivated in greenhouse. After 115 days of sowing, the above ground part of rice plants was obtained. After being dried at 60 ˚C, the collected rice plant residues were crushed and put into bags after 0.25 mm sieving. The C and N concentration of rice straw was 396.5 g kg^{-1} and 16.5 g kg^{-1}, C/N ratio was 24.03.

Experimental design

Self-designed experiment was conducted under three types of soil during different incubation periods. The experiment consisted of two treatments: no straw (control soil) and 1% straw (straw-amended soil). Each treatment was set with three repetitions. Specifically, three typical soil samples were sieved with a 2 mm sieve and 300 g were weighed into a 2 L plastic culture flask, 3 g of rice straw were added into the flasks, rice straw was evenly distributed in the test soil, then water was added to 70% of the maximum soil water capacity, and samples were incubated in a constant temperature incubator at 28°C. Meanwhile, the control treatment was also prepared. During the whole incubation period, the daily ventilation was ensured and the weight was measured every week to keep the constant soil moisture content. Then three repeated treatments of soil were carried out after 15, 60 and 120 days of incubation to determine the aggregate-associated OC, water-stable aggregates and other indicators.

Measurement indexes and methods

The aggregate-associated OC was measured by potassium dichromate oxidation-outer heating method; soil pH value was measured by potential method (soil water ratio 2.5:1); soil clay and silt content were measured by pipette method (Tiessen and Moir, 1993; Bao, 2000). Total carbon content of straw was measured by C/N element analyzer;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65116528

distribution and stability of soil aggregates were measured by wet sieving method, and water-stable aggregates with particle sizes of >2, 0.25-2, 0.053-0.25 and <0.053 mm were obtained (Nimmo et al., 2002; Six et al., 2004). The detailed calculation equations of stability index $R_{0.25}$ (>0.25 mm water-stable macroaggregates), geometric mean diameter (GMD), soil unstable aggregate exponent (E_{LT}), mean weight diameter (MWD), fractal dimension (D) and contribution rate of soil water-stable aggregate OC were extracted from relevant references and calculated as the following equations (Liu et al., 2012; An et al., 2016; Zhu et al., 2017; Xue et al., 2019).

$$\mathrm{MWD} = \frac{\sum_{i=1}^{n}(\overline{x_i}w_i)}{\sum_{i=1}^{n} w_i} \quad \text{(Eq.1)}$$

$$\mathrm{GMD} = \exp\left(\frac{\sum_{i=1}^{n} w_i \ln \overline{x_i}}{\sum_{i=1}^{n} w_i}\right) \quad \text{(Eq.2)}$$

$$E_{LT} = \frac{M_T - R_{0.25}}{M_T} \times 100\% \quad \text{(Eq.3)}$$

$$\frac{M(r < \overline{x_i})}{M_{\mathrm{T}}} = (\frac{\overline{x_i}}{x_{\max}})^{3-D} \quad \text{(Eq.4)}$$

where n denotes the number of aggregate size fractions, $\overline{x_i}$ is the mean diameter of aggregates retained in the ith sieve, W_i is the aggregate weight retained in the ith sieve, $M(r \leq x_i)$ is the weight of aggregates with a fraction diameter less than or equal to x_i, and M_{T} is the gross weight of aggregates.

Statistical analyses

The data were organized via Microsoft Excel 2013, the mapping was made by SigmaPlot10.0, the one-way analysis of variance of experimental data was conducted through SPSS22.0 and the least significant range (LSD) method was used for multiple comparison, with P<0.05 indicating significance level.

Results

Effects of rice straw addition on the distribution of soil water-stable aggregates in different mineral types

The addition of rice straw in the three types of soil showed a significant effect on the dynamic changes of water-stable aggregates during the whole incubation period in the three different mineral soils (*Fig. 2*), the water-stable macroaggregates (>0.25 mm) significantly increased, and the water-stable microaggregates (<0.25 mm) significantly reduced (P<0.05). The three types of control soil mainly contained water-stable microaggregates in the incubation process, and the proportion of >2 mm aggregates was very little, which was significantly different (P<0.05) from the other three particle-size aggregates; from day 15 to day 60, the number of macroaggregates showed no significant difference of the control treatment, after 120 days of incubation, for the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65116528

control soil, the proportion of water-stable macroaggregates increased slightly, but the water-stable microaggregates were still dominant.

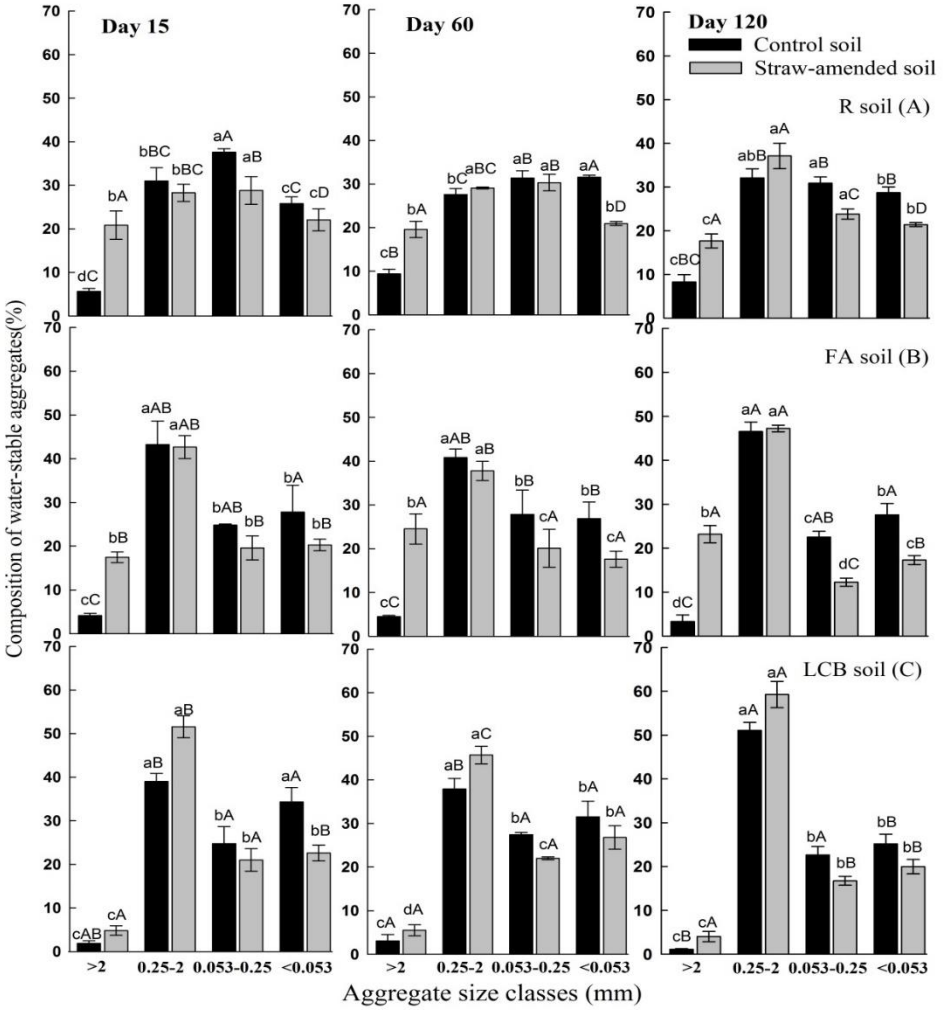

Figure 2. *Water-stable aggregate size distribution under different incubation periods (%). Different lowercase letters indicate significant differences among different particle-size aggregates under same treatments for the same incubation period (P<0.05). Different uppercase letters indicate significant differences among the same particle-size aggregates in the same soil type under different treatments for different incubation periods (P<0.05). $R_{0.25}$, >0.25 mm aggregates (water-stable macroaggregates). R Soil, red soil; LCB Soil, lime concretion black soil; FA Soil, fluvo-aquic soil*

Compared with the control soil, the three types of straw-amended soil showed a significant increase in >2 mm water-stable macroaggregates and remarkable decrease in 0.053-0.25 mm and <0.053 mm water-stable microaggregates during the early 15 days of incubation (*Fig. 2*). The proportion of macroaggregates ($R_{0.25}$) was increased by 270.3, 108.3 and 113.5% for the R soil (*Fig. 2A*), 598.2, 449.6 and 321.3% for the FA soil (*Fig. 2B*), and 157.2, 79.5 and 265.5% for the LCB soil after 15, 60, and 120 days of incubation (*Fig. 2C*), respectively, from day 15 to day 120 the amounts of newly formed >2 mm macroaggregates were significantly larger in the FA soil than in the R soil and in the LCB soil. With the increase of incubation time, the water-stable

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65116528

macroaggregates ($R_{0.25}$) of R soil and LCB soil increased more rapidly during the early incubation stage (within 15 days) than during the later stage (from day 15 to day 60). Among them, the water-stable macroaggregates of FA soil showed a continuous increase, and that of R soil and LCB soil showed a trend of increase first, then a slight decrease and then an increase during the whole incubation period. After 120 days of incubation, >2 mm water-stable aggregates in straw-amended R soil, LCB soil and FA soil were 113.5%, 298.0% and 595.8% higher than those in the control soil with the largest increase in FA soil. The 0.25-2 mm water-stable aggregates in straw-amended R soil, LCB soil and FA soil were 15.6%, 16.0% and 1.5% higher than that in the control soil with the largest increase in LCB soil. After 120 days of incubation, the order of water-stable macroaggregate in three types of soil was: FA soil > LCB soil > R soil, with a proportion of 70.4%, 63.3% and 54.8%, respectively, and the water-stable macroaggregates accounted for the majority in all straw-amended soil. The water-stable macroaggregate in R soil, LCB soil and FA soil increased by 35.6%, 22.0% and 41.1%, respectively after 120 days of incubation compared with the control soil, with the most obvious increase proportion in the FA soil.

Effects of rice straw addition on MWD, GMD, D and E_{LT} of three different mineral soils

Water-stable aggregate stability is an important indicator of soil structure, the addition of rice straw had a different positive effect on the stability of three types of soil aggregates during the incubation (*Table 2*). During the 120-days incubation period, MWD and GMD values of three types of straw-amended soils were significantly higher than those of the control soil, and E_{LT} and D values were significantly lower than those of the control soil (P<0.05). However, from day 0 to day 120, the differences of MWD, GMD, E_{LT} and D values of all control soils in different incubation periods were not very obvious. With the extension of incubation period, the MWD, GMD, E_{LT} and D values of the straw-amended soil at day 120 showed better changing trend than at day 15 and day 60, and the soil structural stability enjoyed continuous improvement. After 120 days of incubation, compared with the corresponding figures in the control treatment, the straw-amended FA soil's MWD and GMD increased by 59.4% and 90.3%, respectively, and its D and E_{LT} decreased by 8.1% and 40.7% respectively; the straw-amended R soil's MWD and GMD increased by 40.0% and 53.8% respectively, and its D and E_{LT} decreased by 3.8% and 24.2%; and the straw-amended LCB soil's MWD and GMD increased by 21.9% and 36.4%, respectively, and its D and E_{LT} decreased by 1.7% and 23.2%. Apparently, the FA soil showed the most prominent change of aggregate stability compared with R soil and LCB soil.

Effect of straw addition on the concentration of soil aggregate-associated organic carbon in different mineral types

Compared with the control treatment, the OC concentration of different particle-size aggregates in different types of straw-amended soil increased significantly (P<0.05), and the distribution of OC in different particle-size aggregates was significantly different (*Fig. 3*). During the whole incubation period, the OC concentration of the straw-amended soil aggregate was the highest after 15 days of incubation. During the later incubation stage (from day 15 to day 120), the OC concentration of the straw-amended soil aggregates decreased gradually. In general, the increase of OC concentration in microaggregates of three types of straw-amended soil was larger than that in macroaggregates, and the concentration of OC in water-stable microaggregates

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65116528

was higher than that in macroaggregates. In addition, with the extension of incubation period, these were few changes in the aggregate-associated OC concentration of the control treatment. The analysis results from aggregate-associated OC indicated that straw application had main effect on the improvement of aggregate-associated OC in different mineral soils, while incubation time and soil type had little effect on aggregate-associated OC in general (*Fig. 3*).

Different lowercase letters indicate significant differences among the same soil type under different treatments for different incubation periods (P<0.05). R Soil, red soil; LCB Soil, lime concretion black soil; FA Soil, fluvo-aquic soil

For the transport and distribution of OC in aggregates, compared with the control soil, when the straw-amended soil was incubated for 15 days, the concentration of OC in the >2, 0.25-2, 0.053-0.25 and <0.053 mm aggregates of FA soil increased by 42.7%, 11.2%, 123.6% and 60.3%, respectively (*Fig. 3A*); the concentration of organic carbon in the >2, 0.25-2, 0.053-0.25 and <0.053 mm aggregates of R soil increased by 41.5%, 8.1%, 21.5%, and 11.5%, respectively (*Fig. 3B*); the concentration of OC in the >2, 0.25-2, 0.053-0.25 and <0.053 mm aggregates of LCB soil increased by 21.4%, 25.4%, 34.7% and 50.0%, respectively, the aggregate-associated OC in FA soil increased the most (*Fig. 3C*). From day 15 to day 120, the aggregate-associated OC of all types of straw-amended soil decreased gradually, the OC decomposition rate in macroaggregates was faster than that of microaggregates. In the incubation period of day15 to day 120, it was found that for the three types of soil, the increase of OC in water-stable microaggregates was larger than that in macroaggregates, and the differences of OC concentration between macroaggregates and microaggregate showed a decreasing trend.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65116528

After 120 days of the incubation, except the <0.053 mm aggregate in LCB soil, the OC of other aggregates fraction in three types of soil was still significantly (P<0.05) higher than that in the control soil. The results showed that rice straw addition could improve the OC concentration of all aggregates in the three types of soil, and the increase of OC in microaggregates was significantly greater than that in the macroaggregates, but the increase degree of OC in aggregates of different types of soil was different during the 120 days of incubation period.

DOI: http://dx.doi.org/10.15666/aeer/1805_65116528

change in the contribution rate of OC in different particle-size aggregates to the SOC, which was mainly reflected in the contribution rate of water-stable microaggregate OC to SOC. Compared with the control soil, after 15 days of incubation, the three straw-amended soil types showed a significant increase in the contribution rate of >2 mm water-stable macroaggregates and significant decrease (P<0.05) in the contribution rate of 0.053-0.25 mm and <0.053 mm water-stable microaggregates. After 120 days of incubation, the contribution rate of OC in >2 mm aggregates of R soil, LCB soil and FA soil increased by 105.6%, 290.8% and 541.0%, respectively; the contribution rate of OC in >0.25 mm aggregates of R soil, LCB soil and FA soil increased by 18.6%, 20.7%, and 29.4%, respectively; and the contribution rate of water-stable macroaggregates in the three types of soil reached 51.98%, 59.07%, 66.14%, respectively; the highest contribution rate of water-stable macroaggregates to the SOC was found in the FA soil and the lowest of that was found in the R soil.

DOI: http://dx.doi.org/10.15666/aeer/1805_65116528

that the more the $R_{0.25}$, the larger the MWD value of soil aggregates, and the greater water stability of soil aggregates and the more stable of the soil structure. In general, as the addition of rice straw to three different types of soil could increase the proportion of macroaggregate and its water stability, it was an effective way to improve the physical and chemical properties of soil and enhanced the erosion resistance, but the improvement degree of aggregate stability of different mineral soils was different.

Discussions

Effect of rice straw addition on distribution and stability of water-stable aggregates in different types of soil

The results of this study showed that rice straw addition had a significant impact on the distribution and stability of three different types of soil aggregates. For the three types of straw-amended soil, the proportion of >2 mm and 0.25-2 mm water-stable macroaggregates increased significantly, and the proportion of 0.053-0.25 mm and <0.053 mm water-stable microaggregates decreased significantly during the incubation period of day 15 day 60 and day 120 compared to the control treatment (*Fig. 2*) (P<0.05). As a new exogenous carbon source, rice straw could increase the input of soil organic materials. The research showed that the increase of exogenous organic materials improved the activity of microorganisms and enzymes, and promoted the growth of microbial hyphae. With the growth of fungal mycelium and the decomposition of other microorganisms, the organic materials would be transformed to humus which was an important cement for the formation of aggregates. The humus can promote the combination of soil particles and minerals, with a stimulating effect on the formation of aggregates to promote microaggregates to be formed into macroaggregates (Verchot et al., 2011; Cui et al., 2011). The results of the experiment were similar to those of Sodhi

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65116528

et al. (2009), who found that rice straw compost could significantly increase the proportion of >0.25 mm water- stability macroaggregates in sandy loam. However, straw addition had different distribution and migration of three types of soil aggregates at different particle sizes, the amounts of newly formed >2 mm macroaggregates were significantly larger at the early incubation stage (within 15 days) than later incubation stage (from day 60 to day 120). After 120 days of incubation, the >2 mm water-stable aggregates in straw-amended R soil, LCB soil and FA soil were 113.5%, 298.0% and 595.8% higher than those in the control soil with the largest increase in FA soil and their concentrations were 17.68%, 4.02% and 23.18%, respectively. The order of the proportion of water-stable macroaggregate in the three types of soil was FA soil > LCB soil > R soil, and the increasing proportion of water-stable macroaggregate in FA soil was the most obvious from day 15 to day 120 (*Fig. 2*). On the one hand, the reason may be that the added rice straw was more finely crushed, and the finer the straw was, the easier it was to be used by microorganisms, and the closer it would be combined with the soil. After the straw was decomposed, it could provide rich carbon source for the microorganisms in the soil, stimulate the microbial activity, and lead to the increase of water-stable macroaggregates. On the other hand, the FA soil and LCB soil were 2:1-type clay minerals mainly composed of montmorillonite with high constant surface charge and large specific surface, but R soil was a highly weathered soil mainly composed of iron aluminum oxide and 1:1 clay mineral with large crystal particles and relatively small specific surface. ANOVA results of control soils from *Figure 2* showed that incubation time and soil types were not the major factors on the formation of aggregates, while according to ANOVA results of straw-amended soils, straw application was considered as the main effect on the formation of aggregates compared with control soils. According to the multilevel aggregate formation theory, 2:1 clay minerals (FA soil and LCB soil) had stronger adsorption capacity for organic matter than 1:1 clay minerals (R soil), and the organic binding agents play dominant roles in the formation and stabilization of soil aggregates with 2:1 clay minerals. Compared with R soil, FA soil and LCB soil would be more conducive to the formation of water-stable macroaggregates (Tisdall and Oades, 1982; Lugato et al., 2010).

MWD, GMD, D and E_{LT} of soil aggregates can better reflect the size distribution transformation, aggregation and erosion resistance of soil aggregates. The larger MWD and GMD values as well as the smaller D and E_{LT} values that indicate the higher average aggregation, the better structure and stability of the soil, and the stronger erosion resistance (Stoops, 2003; Wang et al., 2013; Tang et al., 2016). Compared with the control soil, the MWD and GMD values of water-stable aggregates in three types of straw-amended soil increased significantly and the D and E_{LT} values in them decreased significantly. The differences of MWD, GMD, E_{LT} and D values of three types of soil in different incubation periods (from day 0 to day 120) were not always significantly in the control soil, but the MWD, GMD, E_{LT} and D values of straw-amended soil showed continuous improvement during the 120 days of incubation period, and the change of aggregate stability of FA soil was the most obvious at 120-day compared with LCB soil and R soil (*Table 2*). There was a significant positive correlation between $R_{0.25}$ and MWD in three mineral soils, which indicated that as $R_{0.25}$ increased due to straw application, the MWD values also increased. Straw is an important resource of SOC, which promotes the aggregation and water stability of aggregates. The difference of determination coefficient in correlation analysis showed that the improvement effect on LCB soil and FA soil, which were mainly composed of 2:1 clay mineral, was better (*Fig.*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65116528

4). These results showed that with the addition of rice straw and the extension of incubation time, which improved the activity of microorganisms and enzymes, soil microorganisms can transform plant residues into organic binding agents, promoted the agglomeration of soil aggregates, and the degree of aggregation and stability of the three types of soil were significantly enhanced, and the soil structure was improved. Among them, the change of the stability of the FA soil was significant, which was consistent with the change of the macroaggregates, and the FA soil also enjoyed the best improvement of aggregate structural stability because FA soil was dominated by 2:1 clay mineral with high calcium carbonate contents, the content of silt and clay particles was greater than 77%, and the organic binding agents play dominant roles in the stabilization of soil aggregates. This was similar to the research results of Lu et al. (2014) and Sodhi et al. (2009). Sodhi et al. (2009), which concluded that straw composting treatment could significantly improve MWD and soil structural stability of sandy loam; Lu et al. (2014) found that rice husk biochar treatment could not only significantly improve the proportion of 2-5 mm and 0.25-0.5 mm macroaggregates of modified clay, but also reduce the proportion of <0.25 mm microaggregates, significantly improving MWD and GMD.

Effect of rice straw addition on distribution and contribution rate of organic carbon in different particle-size aggregates

The content of water-stable aggregates is an important indication to evaluate the stability of soil structure and erosion resistance, and relevant experimental studies had also revealed that the distribution of OC in different particle-size aggregates was different and the stability of OC in different particle-size aggregates was also different. The possible reason lies in that the distribution of exogenous new carbon in aggregates is different due to factors such as incubation conditions, soil types and types of exogenous materials (Tripathi et al., 2014; Zhang et al., 2016). The results of this study showed that the OC concentration of three types of straw-amended soil in four different particle-size aggregates was significantly (P<0.05) higher than that of the control soil during the 120 days of incubation periods, and there was a certain difference in the OC concentration of different particle-size aggregates (*Fig. 3*). For the transport and distribution of aggregate-associated OC, compared with the control soil, when the straw-amended soil was incubated for 120 days, the concentration of OC in the >2, 0.25-2, 0.053-0.25 and <0.053 mm aggregates of FA soil increased by 20.0%, 17.4%, 62.6% and 50.4%, respectively; the concentration of OC in the >2, 0.25-2, 0.053-0.25 and <0.053 mm aggregates of R soil increased by 14.7%, 0.2%, 41.9%, and 28.4%, respectively; the concentration of OC in the >2, 0.25-2, 0.053-0.25 and <0.053 mm aggregates of LCB soil increased by 19.9%, 14.1%, 32.0% and 8.4%, respectively (*Fig. 3*). The results showed that the lower the initial organic carbon concentration of soil aggregates was, the larger the increase range of the aggregate-associated OC was, the OC concentration increased rapidly during the early incubation stage (within 15 days) in all three amended soils, especially, the FA soil increased the most, and the OC concentration of the straw-amended soil aggregates decreased gradually from day 15 to day 120.

The increase range of the OC concentration of water-stable microaggregate was significantly larger than that of the macroaggregate, and the increase range of aggregate-associated OC in FA soil was the largest from day 15 to day 120, and the OC concentration in the water-stable microaggregates of the three types of soil was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65116528

generally higher than that of in the macroaggregates. This was similar to the results of Lee's study. Lee et al. (2009) studied the effect of different fertilization treatments on SOC and found that straw composting significantly increased the OC concentration of aggregates, and the OC concentration of water-stable microaggregates was higher than that of water-stable macroaggregates. The reason may be that the mineral types and clay content of the three types of soil were different, 2:1 clay minerals had stronger adsorption capacity for organic matter than 1:1 clay minerals. Due to the influence of biological, chemical and environmental factors, with the extension of incubation period, the aggregate-associated OC was gradually decomposing, OC available for microorganisms will decrease, and the straw crushing was relatively fine, which would have different effects on the increase and sequestration of OC of different particle-size aggregates. Moreover, the carbon sequestration by the microaggregates was not easy to decompose as it was protected physically and had biochemical resistance. Therefore, the OC of the microaggregates was more durable and stable in the soil. The FA soil and LCB soil contained higher silt and clay particles content with high constant surface charge and large specific surface, which would contribute to the increase and sequestration of the OC in the water-stable microaggregate. Therefore, the straw addition was of great significance to improve the soil structure and stability, increase OC concentration of soil aggregates, and improve carbon sequestration capacity (Six et al., 2000; Dimoyiannis, 2012; Song et al., 2019).

Compared with the control soil, after 15 days of incubation, all straw-amended soil types showed a significant increase in the contribution rate of water-stable macroaggregates and remarkable decrease (P<0.05) in the contribution rate of water-stable microaggregates. After 120 days of incubation, the contribution rate of OC in water-stable macroaggregates of R soil, LCB soil and FA soil was 51.98%, 59.07%, 66.14%, respectively. The FA soil enjoyed the largest contribution rate of OC in water-stable macroaggregates to SOC (*Table 3*). The reason for the decrease of the contribution rate of OC in water-stable microaggregates may be that the addition of rice straw promoted the activity of microorganisms and enzymes, increased the organic cementing substance, and helped the water-stable microaggregates to continuously bond and aggregate into water-stable macroaggregates, and the distribution proportion of >2 mm and 0.25-2 mm water-stable macroaggregates increased significantly. The increase extent of water-stable macroaggregates was larger than that of OC concentration in water-stable microaggregates, and the distribution proportion of water-stable microaggregates in the whole aggregates was relatively low.

Conclusions

Rice straw application resulted in significant effect on water-stable aggregates and aggregate-associated OC of the three typical types of soil during the whole incubation stage, which promoted the aggregation of water-stable microaggregates to macroaggregates. After 120 days of incubation, the proportion of water-stable macroaggregates in R soil, LCB soil and FA soil reached 54.8%, 63.3% and 70.4%, respectively, becoming the dominant aggregates, significantly improving the MWD and GMD of soil water-stable aggregates, and reducing the D and E_{LT} values (P<0.05). Furthermore, MWD and $R_{0.25}$ showed a significant positive correlation (P<0.001). These results suggest that the addition of straw enhanced the degree of aggregation of water-stable aggregates and improved soil aggregate stability, the increase degree of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65116528

aggregates content and stability was different, probably due to stronger adsorption capacity and high constant surface charge in 2:1 clay minerals than 1:1 clay minerals.

The straw addition also increased OC concentration in different particle-size aggregates of three types of amended soil, and the OC concentration increased rapidly during the early 15 days of incubation in the three amended soils, the contribution rate of organic carbon in >2 mm water-stable macroaggregates also significantly improved. Meanwhile, the increase of OC in water-stable microaggregates was larger than that in macroaggregates in all straw-amended soil. In conclusion, the addition of rice straw to three different types of soil was an effective way to increase the aggregates stability and aggregate-associated OC concentration, and the increase degree of aggregates stability and OC concentration of different types of soil was different, which could play a more important role in FA soil than in R soil and LCB soil.

This study analyzed the effects of straw addition on the distribution and stability of water-stable aggregates and aggregate associated OC in three different soil clay mineral types. Microbial processes related to decomposition of plant debris or root growth can greatly promote the formation of soil aggregates and nutrient decomposition. Therefore, the influence of straw addition on soil microbial biomass and microbial activity at different incubation stage should be further studied, and main factors affecting soil aggregates formation are also needed to be noticed. Additionally, the effect of straw addition on soil interparticle forces (electrostatic repulsive force, van der Waals attractive force and surface-hydration repulsive force) in different mineral types should be considered because they can reveal the relationship between the interparticle forces and soil structural stability. These further studies help to provide theoretical support for soil quality improvement in different mineral types.

Abstract. In this research study, leishmanicidal, antibacterial, antifungal, anticancer (MCF-7, 3T3 and HeLa cell lines) activities and GC-MS studies of *Perotis hordeiformis* extract and fractions were examined. Leishmanicidal bioassay, 96 Well Plate Method, Agar tube dilution method and MTT assay were the methods used for leishmanicidal, antibacterial, antifungal and anticancer activities. *Perotis hordeiformis* whole plant butanol fraction (PHWBF) exhibited leishmanicidal activity with IC_{50} 53.31 ± 0.59. *Perotis hordeiformis* whole plant hexane fraction (PHWHF) showed activity against bacteria such as *Staphylococcus aureus* having an inhibition percentage of 58.5%. *Perotis hordeiformis* whole plant methanol extract (PHWME) showed activity against fungi such as *Microsporum canis and Fusarium lini* having an inhibition percentage of 55% and 50%, respectively. *Perotis hordeiformis* whole plant hexane fraction (PHWHF) showed activity against *Aspergillus niger* having an inhibition percentage of 40% while *Perotis hordeiformis* whole plant aqueous fraction (PHWAF) showed activity against *Microsporum canis and Fusarium lini* having an inhibition percentage of 100% and 40%, respectively. *Perotis hordeiformis* whole plant butanol fraction (PHWBF) showed activity against cancer cell lines such as HeLa cell line and MCF-7 cell line with an inhibition percentage of 55% and 48%, respectively. Other extract and fractions were less active against cancer cell lines. GC-MS analysis showed 8 compounds in *Perotis hordeiformis* whole plant butanol fraction (PHWBF) which exhibited leishmanicidal and anticancer activities.

Introduction

Traditional plants are the main sources of phytochemicals, used for the preservation of human health and alleviating infectious diseases of mankind since prehistoric times. At present, the entire world has interest in green medicines and demands medicines originating from traditional plants rather than from a synthetic source. This is due to the fact that traditional drugs are safer than synthetic medicines which have toxicity and side effects. This stimulates the researchers to develop new medicines against microbes (Cordell et al., 2000; Nair et al., 2007). The drugs which are synthesized, are expensive, have side effects and the diseases are not properly treated. Hence, new antimicrobial agents are needed to be developed from traditional plant sources (Sieradzki et al., 1999; Dabur et al., 2007). According to the WHO, 80% of the population of the world use traditional medicines to cure infectious diseases (WHO, 1993). The compounds which are extracted from plant sources are more than 50% of current drugs (Baker et al., 1995). The medicinal plant, *Perotis hordeiformis* is a short lived perennial or annual and belongs to the Poaceae family. Sandy places are the main locations for the presence of this ethnomedicinal plant. This traditional plant is mainly distributed in Nepal, Thailand, Indonesia, India, Pakistan, Sri Lanka and Myanmer. This plant has significant antileishmanial, cytotoxic and antioxidant activities. *Perotis hordeiformis* has close resemblance with *Perotis indica* (Baloch et al., 2013). In this study, *Perotis hordeiformis* whole plant extract and fractions are used against leishmania major, six bacteria, five fungi and three cancer cell lines.

Materials and Methods

Plant material

Perotis hordeiformis whole plant was the plant material in this analysis.

Extraction

The medicinal plant *Perotis hordeiformis* was collected from Soorab, Balochistan, Pakistan and was authenticated by Prof. Dr. Rasool Bakhsh Tareen, Department of Botany, UoB, Quetta, Pakistan. *Perotis hordeiformis* was kept for one month under the shade and then powdered in a grinder. 1.5 kg powdered *Perotis hordeiformis* was macerated in 14 L of methanol for the period of seven days and then the mixture was filtered, and vaporized in a rotary evaporator. The crude extract of *Perotis hordeiformis* whole plant methanol extract (PHWME) was 24.52 g.

Fractionation of crude extract

The methanolic crude extract was fractionated with n-hexane and aqueous solvents in a separatory funnel and vaporized in a rotary evaporator to form *Perotis hordeiformis* whole plant hexane fraction (PHWHF) 8.1 g and *Perotis hordeiformis* whole plant aqueous fraction (PHWAF) 17.3 g. *Perotis hordeiformis* whole plant aqueous fraction (PHWAF) was fractionated with butanol to form *Perotis hordeiformis* whole plant butanol fraction (PHWBF) 4 g (Bakht et al., 2013; Achakzai et al., 2016, 2019).

Leishmanicidal bioassay

At 3000 rpm for 10 min, the leishmanial parasite such as promastigotes was sedimented. This parasite was counted by Neubaur chamber, diluted to a concentration

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65296537

of $1x10^6$ with fresh medium. In 96 well plate, 180 uL of parasite culture was added. The sample with the concentration of 20 uL was added and then serially diluted till final concentration of sample 1 ug/mL. $1x10^6$ cells/mL of parasite density was kept for negative control while for positive control, it varied. The 96 well plate including parasites, sample, positive and negative control was kept in an incubator between 21 to 22 ºC for the duration of 72 h. With the help of Neubaur chamber, parasites with IC_{50} values were counted (Atta-ur Rahman et al., 2001).

Antibacterial assay

96 well plate method

For the growth of bacterial strains, Muller Hinton medium was used. McFarland turbidity index with 0.5 was used for the adjustment of inoculums. In DMSO, extracts/fractions were added and from this stock solution were formed. In wells, media and samples were added while control wells were without extracts and fractions. Up to 200 uL, the wells were filled. $5x10^6$ cells were added in both control and test wells, which were then sealed with parafilm and kept in an incubator for 18-20 h. Alamar Blue Dye was added to all wells, which were then shaken for 2-3 h at 80 RPM. Blue to pink color change of dye indicated the growth of bacteria. Absorbance was recorded at 570 nm with ELISA reader (Pettit et al., 2005).

Antifungal assay

Agar tube dilution method

In this assay, in 1 mL of DMSO, 24 mg of sample was dissolved. SDA with the concentration of 32.5 g was dissolved in 0.5 L of Distilled water. With the help of steam, this growth medium was completely dissolved. This medium with 4 mL was poured in tubes with screw cap, autoclaved for 15 min at 121 ºC, cooled till 50 ºC. 66.6 uL of sample was loaded into non-solidified SDA. At room temperature, in a slanting position, tubes were solidified. Fungus was inoculated with 4 mm diameter into tubes. In other media, reference antifungal drug and DMSO were used as positive and negative control. Tubes were kept in an incubator for one week at 27-29 ºC, and examined twice in a week (Choudhary et al., 1995).

Calculating Inhibition % of fungal growth

$$Inhibition\% = 100 - \frac{linear\ growth\ in\ test\ (mm)}{linear\ growth\ in\ control\ (mm)} \times 100 \qquad \text{(Eq.1)}$$

MTT assay

In this study, cancer cell lines were cultured in Dulbecco's Eagle modified medium with 10% FBS, 2% antibiotics were used and then kept in 5% CO_2 in incubator at 37 °C. After the development of confluency, cell lines were harvested. In a 96 well flat, 5×10^4 cells/well were added and then after one day, sample with the concentration of 50 ug/mL was added, and kept for 48 hours in an incubator. The sample was removed after incubation. MTT with the concentration of 0.5 mg/mL was added, kept at 37 °C for hours in an incubator. Formazan crystals were formed when MTT was reduced. With the help of 100 ul DMSO, Formazan crystals were dissolved. Micro-plate reader was used for recording absorbance at 570 nm (Spectra Max plus, Molecular Devices,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65296537

CA, USA). In this assay, doxorubicin was used as a standard drug. The decrease in viable cells or percent inhibition was calculated with the help of the following formula:

$$\%\ Inhibition = 100 - \frac{mean\ of\ O.D.\ of\ test\ compound - mean\ of\ O.D.\ of\ negative\ control}{mean\ of\ O.D.\ of\ positive\ control - mean\ of\ O.D.\ of\ negative\ control} \times 100 \quad \text{(Eq.2)}$$

For the calculation of IC_{50} 20 mM stock solution of extracts/fractions were diluted into working solution with 50 uM and then in order to get less than 50 percent inhibition, working solution was further diluted in serial dilutions. With the help of EZ-fit5 software, IC50 was calculated (Scudiere et al., 1988).

Gas chromatography mass spectrometry (GC-MS) analysis triple quadrupole acquisition method MS parameters

For identification and quantification of *Perotis hordeiformis* compounds: 2 ul of *Perotis hordeiformis* extract or fraction was directly injected into the gas chromatograph mod.6890N Network GC System (Agilent Technologies Palo Alto, CA) together in the presence of mass spectrometer mod. 5973 Network Mass Selective Detector (Agilent Technologies Palo Alto, CA) and furnished in the presence of a column HP-5MS (30 m length, 0.25 mm interior diameter, 0.25 um film width Agilent Technologies, Palo Alto, CA). Helium gas was off. Injection was made into a split-splitless injector (split ratio 30:1) at 250 ºC. The oven program was the following: 70 ºC for 3 min then 6 ºC /min to 180 for 5 min, then 6 ºC /min to 280 ºC for 10 min, then 8 ºC /min to 290 ºC for 20 min. The MSD transfer line was set at a temperature of 250 ºC; MSD temperature quadrupole was of 150 ºC and ionization temperature was 230 ºC, Mass spectra were seventy electrovolts and scan achievement was accomplished in the series between thirty-five and 300 m/z. The identification of the components of the *Perotis hordeiformis* extract or fraction was assigned by matching their mass spectra with those available in the libraries NIST 02 and WILEY (El-Wakil et al., 2015).

Results and Discussion

Perotis hordeiformis whole plant butanol fraction (PHWBF) exhibited leishmanicidal activity with IC_{50} 53.31 ± 0.59. None of other *Perotis hordeiformis* extract and fractions exhibited leishmanicidal activity. Leishmanicidal activities of extract and fractions of *Perotis hordeiformis* are shown in *Table 1*.

Conclusion

In this research study, *Perotis hordeiformis* whole plant butanol fraction (PHWBF) exhibited leishmanicidal activity with IC_{50} 53.31 ± 0.59. None of other extract and fractions of *Perotis hordeiformis* exhibited leishmanicidal activity. *Perotis hordeiformis* whole plant hexane fraction (PHWHF) showed activity against bacteria such as *Staphylococcus aureus* having an inhibition percentage of 58.5%. *Perotis hordeiformis* whole plant methanol extract (PHWME), *Perotis hordeiformis* whole plant aqueous fraction (PHWAF) and *Perotis hordeiformis* whole plant butanol fraction (PHWBF) showed no antibacterial activity. *Perotis hordeiformis* whole plant methanol extract (PHWME) showed activity against fungi such as *Microsporum canis and Fusarium lini* having an inhibition percentage of 55% and 50%, respectively. *Perotis hordeiformis* whole plant hexane fraction (PHWHF) showed antifungal activity against *Aspergillus niger* having an inhibition percentage of 40% while *Perotis hordeiformis* whole plant aqueous fraction (PHWAF) showed antifungal activity against *Microsporum canis and Fusarium lini* having an inhibition percentage of 100% and 40%, respectively. *Perotis hordeiformis* whole plant butanol fraction (PHWBF) exhibited no antifungal activity. *Perotis hordeiformis* whole plant butanol fraction (PHWBF) showed anticancer activity against HeLa cell line and MCF-7 cell line with an inhibition percentage 55% and 48%, respectively. Other extract and fractions are less active against cancer cell lines. GC-MS analysis showed 8 compounds in *Perotis hordeiformis* whole plant butanol fraction (PHWBF) which exhibited leishmanicidal and anticancer activities. In the near future, in the Institute of Biochemistry, University of Balochistan, Quetta, Pakistan, the compounds present in the *Perotis hordeiformis* whole plant butanol fraction (PHWBF) will be isolated and tested against cancer cell lines and leishmaniasis and will lead to drug development with least toxicity and side effects.

Abstract. Snow cover greatly influences climate in Northeast China, and it is one of the most relevant parameters to analyze climate change. The Mollisol area of Northeast China is one of the three seasonal snow areas in the country. This study investigates the spatial distribution characteristics and variation trends of monthly snow depth over a 30-year period. Linear regression analysis was applied for each factor. The results indicated a non-significant decreasing trend of snow depth in the mountainous area. Snow depth in the plains increased by 0–0.4 cm/year. The spatial distribution of first, last, and cover days of snow, and the maximum depth of snow cover were consistent in their correlation with snow cover depth. The snow cover gradually decreased with increasing temperature, latitude, and change in topography (altitude) from northeast to southwest. In terms of snow cover days, the highest correlation was obtained for temperature during the snow accumulation and melting periods. In contrast, there was no correlation with precipitation. The volume of snowmelt water had a significant change every 10 years.
Keywords: *snow depth, snow cover days, climate change, snowmelt water volume, spatiotemporal distribution*

Introduction

Accumulated snow is an important source of freshwater in the Mollisol area of northeast China, where its average depth is 2–20 cm. Snowmelt provides water for industrial, agricultural, and domestic supplies in spring. Owing to approximately 100 years of intensive and uncontrolled development, utilization of water resources and soil erosion in this area are intensive. The combined effects of snowmelt runoff, freezing–thawing cycles, and incomplete thawed layer cause slope erosion and rill formation. With higher number of confluences, rills develop into ephemeral and young gullies (Xu et al., 2019). Therefore, it is important to analyze the spatiotemporal variation of snow depth in the Mollisol area of northeast China.

In recent decades, remote sensing has been effectively utilized to monitor snow dynamics at regional and global scales (Li et al., 2018). In April 1960, the Television Infrared Observation Satellite TIROS-1 was used to monitor snow cover in Canada for the first time. The optical sensor was mainly used for monitoring snow areas and albedos, but that was restricted by weather conditions. Quantitative remote sensing was then applied to solve the issue of cloud cover and achieve better accuracy of remotely sensed data (Basang et al., 2017; Chang et al., 2017). In recent years, passive microwave remote sensing with features of all-weather, multi-polarization, and limited penetration of the underlying surface of the earth has been widely used for snow monitoring. When compared with optical sensor satellites, microwave remote sensing satellites are more accurate and timelier in the acquisition of snow depth, snow–water

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65396554

equivalent, and snow cover. A common passive microwave sensor satellite includes a Scanning Multichannel Microwave Radiometer (SMMR), the Defense Meteorological Satellite Program (DMSP), and a series of special microwave imaging detectors such as the Special Sensor Microwave Imager (SSM/I) and Advanced Microwave Scanning Radiometer-EOS (AMSR-E) (Josberger et al., 2017; Tang et al., 2019).

Snow covers present high albedo and thermal insulation, and they are important for the global climate system and hydrological cycles (Brown et al., 2007; Li et al., 2019; Zhang, 2005). Snow affects the relationship between ground systems and climate, thereby influencing climate change (Scipión et al., 2013; Fassnacht et al., 2018; Tan et al., 2019). The accumulation of snow in arid and semiarid areas provides water for the ecosystem and human society. Snow depth is an easy parameter to measure and an important characteristic of snow cover (Liu et al., 2018), and it can be used to derive snow–water equivalent. In this calculation, the spatial variation of snow density is less significant than snow depth (Fassnacht et al., 2013; López-Moreno et al., 2013). Area and duration of snow cover and snow–water equivalent have decreased because of global warming (Kunkel et al., 2016). Foster et al. (1997) observed that the snow area in South America has decreased cyclically in the past 25 years using remote sensing technology. The period of snowmelt greatly influences the amount of water resources, climate change in surroundings, and downstream areas. Snow accumulation and ablation are diverse in different regions, and the estimation of snow–water equivalent can improve the accuracy of snow forecast (Kuraś et al., 2008; Dai et al., 2012). Therefore, the spatiotemporal distribution and variation of snow cover should be studied on a regional scale.

Precipitation and temperature are the main factors affecting the period of snow accumulation and ablation (Martinec and Rango, 1981; Waqas and Athar, 2019). Tachibana et al. (2007) made a preliminary estimation for Tokyo and nearby areas in Japan and discovered that snow cover did not significantly change with time. By analyzing the characteristics related to snow cover duration, Lethers and Luff (1997) observed that snow cover duration was highly correlated with precipitation and temperature. Schöner et al. (2019) reported that snow depth is mainly influenced by temperature at low altitudes and precipitation at high altitudes. They used snow–water equivalent data from 2002–2009 to interpret snow depth in northeast China by correlating snow cover with temperature and precipitation. The results showed that snow depth gradually decreased over time and temperature was the main influencing factor for snow cover change (Zhang, 2010). A study on the first and last days of snow cover over the past 42 years in the Greater Khingan Range indicated that the first day of snow cover was delayed, the last day was advanced, and the overall duration of snow cover was shorter (Chang, 2018). Snow cover is an important part of a climate system, and it serves as an indicator of climate change and overall climate. Accordingly, climate change also has an impact on the generation and maintenance of snow cover, and the changes in snow cover result from the combination of temperature, radiation, precipitation, altitude, and other climatic factors (Li et al., 2019; Orsolini et al., 2019). In this study, seasonal snow cover is classified into snow accumulation and snowmelt periods according to the variation and trend in the monthly snow depth over a 30-year period (Aizen et al., 1995). The main factors affecting snow cover duration are analyzed. The results lay a foundation to study the utilization of water resources based on snowmelt in the Mollisol areas of China under the prevalent climate change conditions, and provide data support for agricultural production and ecological environment monitoring.

Materials and methods

Study area

Mollisol areas are mainly distributed in the northeast plain of China. Shown in *Figure 1,* the study area is located between longitudes 119°01′ and 135°06′ and latitudes 30°48′ and 53°33′, and it covers 108.53×10^4 km^2 (Wang et al., 2020). Due to the large-scale cultivation in the Mollisol areas of northeast China, serious soil and water loss has occurred. Soil erosion in the study region has been detected in 27.5×10^4 km^2, which represents approximately 27% of the total area. The study area has an average altitude of 446.811 m, mean annual air temperature of -5–11 °C, and annual precipitation of approximately 300–1000 mm varying from the west to east. Considering the regionalization based on water and soil conservation, there are six secondary regions within the Mollisol area according to dominant landforms: the Greater and Lesser Khingan Range, mountainous and hilly region in the southeast of the Greater Khingan Range, mountainous and hilly part of the northeast, Hulun Buir hilly plain, Songliao plain sandy soil, and Changbai and Wanda mountain hilly (MWR, 2012).

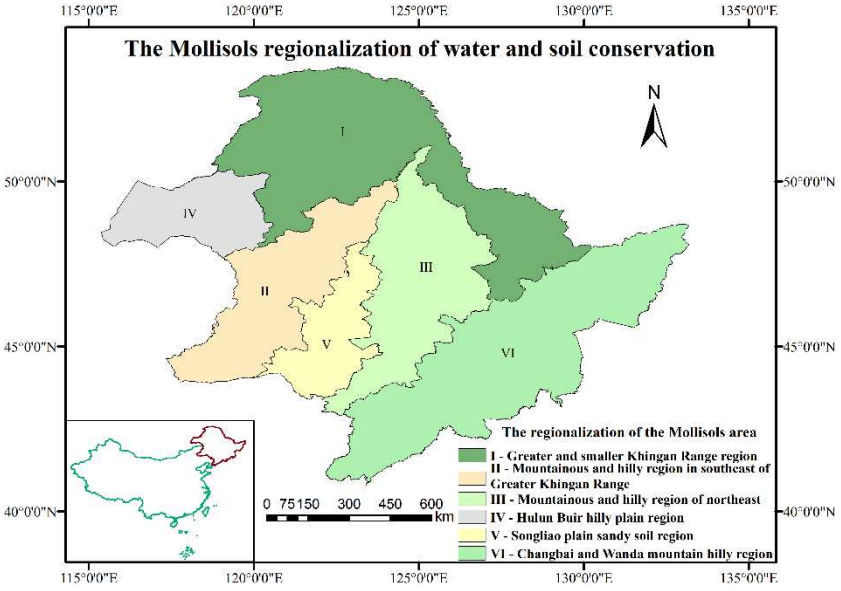

Figure 1. *Study area*

Data

A long-term series (1978–2016) of daily snow depth in China (http://westdc.westgis.ac.cn/) (Nie et al., 2019) was used for analyzing the snow cover (Dai and Che, 2014). Meteorological data was obtained from the national meteorological science center of China (http://data.cma.cn/). As shown in *Table 1,* the daily meteorological data was downloaded and collated from 71 meteorological stations, and it included precipitation, temperature, wind speed, and solar radiation from 1987 to 2016. Quality control was performed to evaluate the homogeneity of the series. This control involved detection of any breaks caused by changes in the location or in the instruments of the stations. In addition, any questionable values were removed, such as daily precipitation amounts lower than zero, until the series showed continuity for several years and gaps lower than <10% (Aguilar et al., 2005).

Average monthly snow depth (AMSD)

The average monthly snow depth (AMSD) was calculated as the ratio of monthly accumulated snow depth to the number of snow cover days. AMSD values from October of each year to May of the subsequent year were calculated (Baronetti et al., 2019). The average monthly variation rate (AMVR) was analyzed. The linear change

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65396554

tendency of each climate factor was analyzed using the linear regression analysis method with one variable. A confidence level of $p < 0.05$ was used to evaluate the significance of the trends (Shafiq et al., 2018; Yang et al., 2019). The linear regression equation is as follows:

$$b = \frac{n\sum_{i=1}^{n} x_i y_i - \sum_{i=1}^{n} x_i \sum_{i=1}^{n} y_i}{n\sum_{i=1}^{n} x_i^2 - (\sum_{i=1}^{n} x_i)^2} \quad \text{(Eq.1)}$$

where $y_i = b \times x_i + a$, $a = \bar{y} - b\bar{x}$, y_i is the AMSD data of the snow cover period of 1978–2016, x_i is the time series, a is the regression constant term, and b is the regression coefficient. In this study, b is used to quantitatively analyze the linear change tendency of climatic factors.

Duration and first and last days of snow cover

The first day of snow cover (SFD) is the 5th day of the first spell of a 5-day consecutive snow fall in autumn or winter, and the end day snow cover (SED) is the last day of the last 5-day consecutive snow fall in the spring of the subsequent year. The snow cover duration (SCD) is defined as the sum of days with a snow depth of more than 1 cm (Gusain et al., 2016; Mo et al., 2017; Orozco et al., 2019).

Snow cover duration and climate change

The correlation between snow cover duration and temperature, precipitation, radiation, altitude, and latitude were analyzed for 1987–2016 according to the methods provided by Liu and Chen (2000) and Buisan et al. (2015).

Periodic changes in snowmelt water volume

Data on snowmelt water volume was obtained from the maximum depth in the snow accumulation period during 1987–2016. The average snow density was 0.298 g/cm^3 (Ma, 2017). The Morlet wavelet method was used to analyze the multitemporal and spatial scale variation of snowmelt water volume. The continuous wavelet transform was as follows:

$$V_{volum} = \sum_{1}^{s} 0.298 \times area \times SD_{\max} \quad \text{(Eq.2)}$$

where V_{volum} is the volume of snowmelt water, *area* is a pixel area, and SD_{max} is the maximum snow depth.

$$W_f(a,b) = \frac{1}{\sqrt{a}} \Delta t \sum_{k=1}^{N} f(k\Delta t)\bar{\psi}(\frac{t-b}{a}) \quad \text{(Eq.3)}$$

where $W_f(a,b)$ can reflect the characteristics of time domain parameter b and frequency domain parameter a, Δt represents the sampling interval, and $f(k\Delta t)$ represents the output of the filter through the impulse response (Slavie et al., 2003).

Results and discussion

Temporal and spatial variation of snow depth

Based on the seasonal changes in northeast China, the hydrological year (HY) was defined as the period from December 1 to September 30 of the next year. The snow cover period in the Mollisol region begins in early October and ends in early May. The spatiotemporal distribution of AMSD is shown in *Figure 2*. Snow accumulation was lower in October and November. Snowfall first appeared in Mohe and Tulihe of the Greater Khingan Range, where the AMSD was 0–5 cm, and accumulation was rapid due to the influence of temperature. In February, the maximum value of AMSD was observed with an increasing trend from southwest to northeast. Owing to the influence of topography, AMSD in the Greater Khingan Range was 15–30 cm, and in the Changbai and Wanda mountain region it was 10–15 cm. However, the values were lower in the plain and low-altitude regions. From mid-March, snow depth began to decrease and the snow completely melted in early May. The AMSD value of the Mollisol region became below the effective snow depth within May and October.

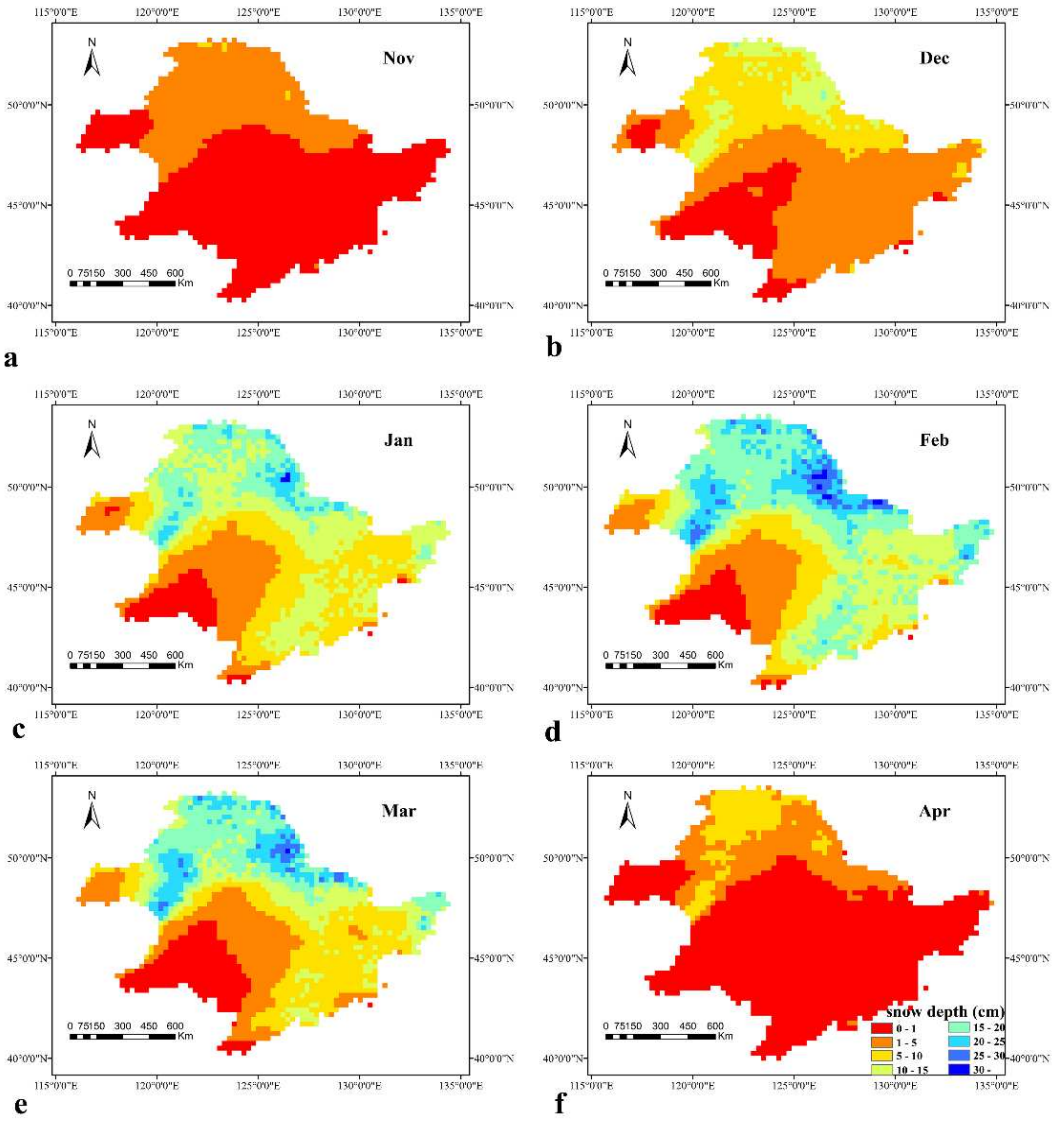

Figure 2. *Average monthly snow depth (AMSD) in the study area*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65396554

The AMVR values for the 30-year period considered in the study are shown in *Figure 3*, which was calculated by *Equation 1*. The AMVR in the Mollisol region increased by 0–0.1 cm/year in November with no significant variation throughout the area. Large areas with significant increase of above 0.2 cm/year occurred in the mountainous and hilly regions of northeast China in December. In January, the AMVR shows an insignificant increasing trend in snow depth for most areas, particularly in the mountainous and hilly region of northeast at 0–0.1 cm/year. In February and March, an insignificant decrease is evidenced in large areas of the Greater and Lesser Khingan Range, while a significant increase occurs in the mountainous and hilly region of northeast and the Sanjiang plain, with variations higher than 0.2 cm/year. In April, increasing and decreasing trends each occupied approximately half of the study area, in which the southern part of the Songliao plain's sandy soil region presented a significant decreasing trend.

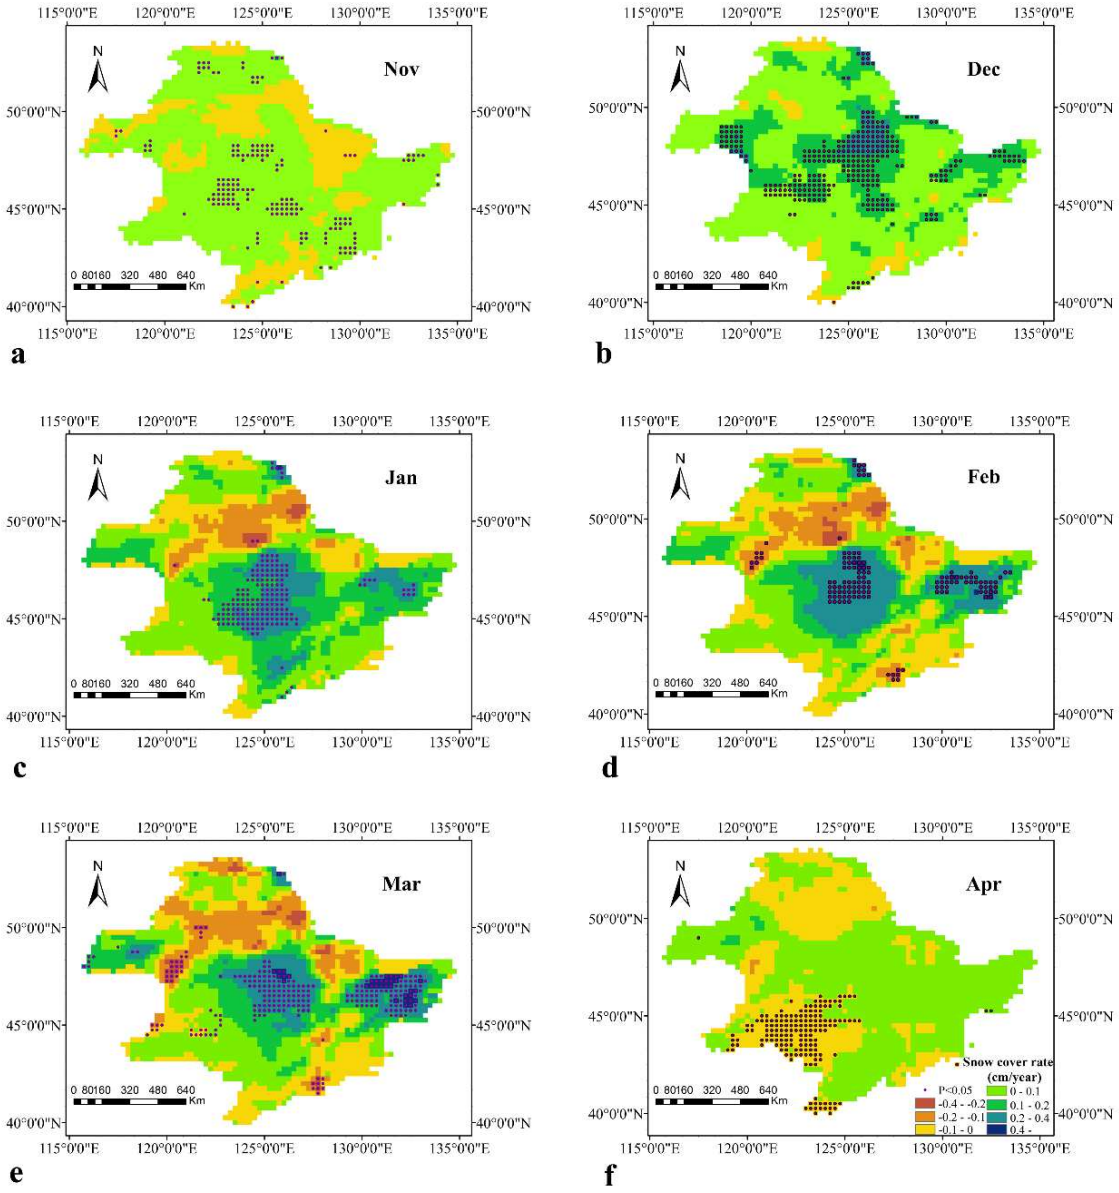

Figure 3. *Average monthly variation rate (AMVR) of snow depth in the study area*

DOI: http://dx.doi.org/10.15666/aeer/1805_65396554

Temporal and spatial variation of snow cover days

The variations of monthly average and maximum snow depths in the Mollisol region shown in *Figure 4* were consistent. The snow depth was shallow from October to November with a low rate of increase. From October to February, the snow depth increased at a fast rate and reached its maximum in February. Therefore, this period was defined as the snow accumulation period. From March to May, the depth of snow decreased continuously with a short duration of snowmelt. This period was defined as the snow ablation period.

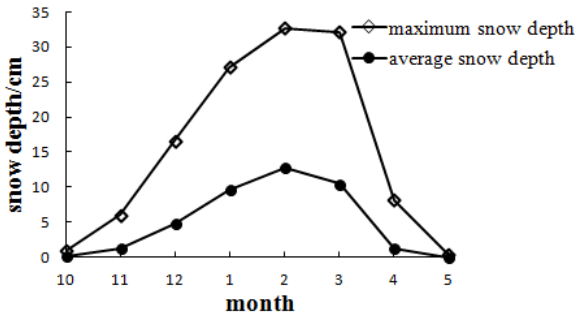

Figure 4. *30-year variation in monthly snow depth*

As shown in *Figure 5a*, during the 30-year period, the first day of snow appeared in the Greater Khingan Range of the Mollisol region from the 12th to 30th day, followed by the Lesser Khingan Range region from the 30th to 60th day. The first day of snow in the Changbai and Wanda mountain hilly region and mountainous and hilly region of northeast occurred between the 60th and 90th day. In the Songliao plain sandy soil region and mountainous and hilly region in the southeast of the Greater Khingan Range, the first day of snow occurred between the 60th and 90th day. It was delayed from north to south, and there was no snow in the south of the hilly region. The first day of snow in the Hulun Buir hilly plain region occurred between the 90th and 150th day. *Figure 5b* shows that the last day of snow was delayed the most in the Greater and Lesser Khingan Range, where it occurred between the 200th and 220th day. For the Changbai and Wanda mountain hilly region, mountainous and hilly region of northeast, and Hulun Buir hilly plain region, it occurred between the 180th and 200th day. The last day of snow for the Songliao plain sandy soil region and hilly region in the southeast of Greater Khingan Range occurred progressively from north to south.

As shown in *Figure 5c*, the snow cover plural for the northern part of the Greater Khingan Range, lesser Khingan Range and Changbai and Wanda mountain hilly region, and Hulun Buir hilly plain region were 180–200, 150–180, and 120–150 days, respectively. The snow cover duration in the mountainous and hilly region southeast of the Greater Khingan Range, Songliao plain sandy soil region, and mountainous and hilly region of northeast advanced from north to south (Whetton et al., 1996). The annual average of maximum snow depth in the Greater and Lesser Khingan Range, north region, Changbai and Wanda mountain hilly region, and mountainous and hilly region of northeast were 20–30, > 30, 10–20, and 5–10 cm, respectively. In addition, the annual average of maximum snow depth in the Songliao plain sandy soil region and mountainous and hilly region southeast of the Greater Khingan Range decreased from north to south.

Snow cover days and climate change

Linear regression analyses were performed to correlate average temperature, total precipitation, and latitude and altitude of meteorological stations with snow cover days and accumulation period, and the results are presented in *Figure 6*. Temperature presented a negative correlation with snow cover days during the snow accumulation period (*Fig. 6a*). No significant correlation was observed between total precipitation and snow cover days (*Fig. 6b*). The latitude (*Fig. 6c*) and altitude (*Fig. 6d*) of the meteorological stations were positively correlated with snow cover days during the accumulation period. Temperature was considered the main influencing factor for snow cover days during the accumulation period because its correlation value was the highest, at $R^2 = 0.55$. The correlation between environmental factors and number of snow cover days during the snow accumulation period were, in order of significance: average temperature > latitude of meteorological station > altitude of meteorological station > total precipitation.

Linear regression analyses were also performed to correlate average radiation, average temperature, and latitude and altitude of meteorological stations with snow cover days for the snow melt (ablation) period, and the results are presented in *Figure 7*. In the Mollisol region of northeast China, there was no correlation between total precipitation and snow cover days during the snow ablation period. However, there was a negative correlation between average temperature (*Fig. 7a*) and average radiation (*Fig. 7b*) with snow cover days. Altitude (*Fig. 7c*) and latitude (*Fig. 7d*) of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65396554

meteorological stations were positively correlated with snow cover days. The correlation with temperature during the snow ablation period was the highest, at $R^2 = 0.66$, which indicates that temperature presents the most influence on the number of snow cover days during the snow ablation period. The correlation with environmental factors were, in order of significance: average temperature > latitude of meteorological station > average solar radiation > altitude of meteorological station.

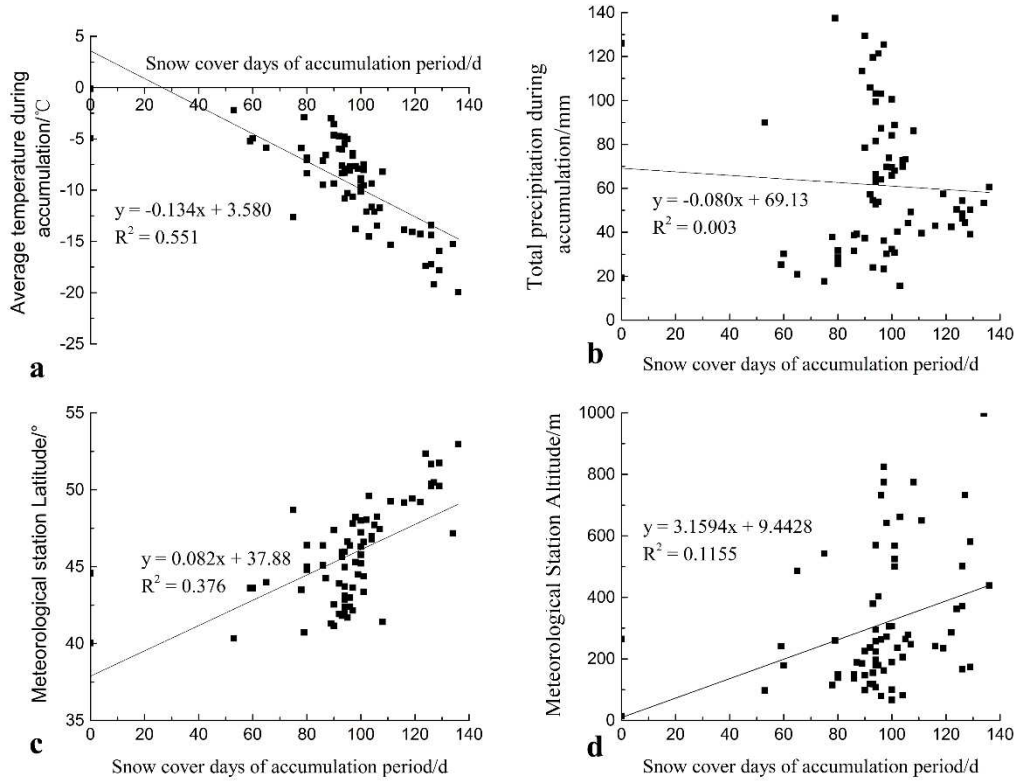

Figure 6. *Correlation between snow cover days and climatic factors in the snow accumulation period: (a) average temperature, (b) total precipitation, (c) latitude of meteorological station, and (d) altitude of meteorological station*

Time scale of snowmelt water volume

Figure 8a shows the volume diagram of the snowmelt water in the Mollisol region of northeast China, which is calculated by *Equation 2*. The annual volume of snowmelt water did not experience a continual increase or decrease, and the volume of snowmelt water varied by 2.764×10^9 m^3 every ten years. In the northeast China, the long-term variability of snow cover is marked by a stochastic oscillation superimposed on a small increasing trend over the past 30 years. No abrupt change was found in snow cover. In addition, the minimum and maximum snowmelt water volume occurred at 35.089×10^9 and 97.646×10^9 m^3 in 2008 and 2013, respectively. *Figure 8b* shows the wavelet analysis diagram of the snowmelt water volume in the studied region, which is calculated by *Equation 3,* and it indicates that the variation period was the most obvious in 3–5 years. Before 2005, the annual variation period of snowmelt water volume in 10 years was obvious. After 2005, snowmelt water volume showed a variation period of 5–7 years, and this period gradually decreased.

Trujillo and Molotch (2014) report that the snow–water equivalent curve can represent hydrological indexes in a HY (Egli and Jonas, 2009; De Gregorio et al., 2019; Yang et al., 2019). Accordingly, the snow accumulation and ablation periods varied in different regions. In this study, the spatiotemporal distribution showed that snow cover began to accumulate in mid-November, reached the maximum depth by the end of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65396554

February of the subsequent year, and completely melted in late March. The distribution pattern was consistent in terms of average maximum snow depth and number of snow cover days, and had the strong spatial heterogeneity in the whole area.

The results of this study contradict the trend of decreasing maximum snow cover in the Northern Hemisphere (Mote, 2003). The volume of snowmelt water in the Mollisol region of northeast China had no significant increase during the 30-year period. In terms of average snow depth under the global warming scenario, the Greater and Lesser Khingan Range and the Changbai and Wanda mountain hilly region showed a decrease, and the plain region showed an increase. The decrease in average snow depth at high attitudes is similar to those of previous studies conducted in the Alps and the Tianshan mountains (Li et al., 2019; Schöner et al., 2019). Meteorological data are mainly used to study the changes of snow depth, and the variation rate of snow depth is consistent with station observations (Tan et al., 2019). The results showed that the spatial variation of snow depth had no significant change.

Studies have shown that there is a strong correlation between spring temperatures and streamflow (Barnett et al., 2005; Niedzielski et al., 2019; Yang et al., 2020). Temperature and precipitation influence the duration of snow accumulation and ablation periods in high altitude mountains (Hantel et al., 2000). These studies reveal that average temperature and total precipitation can affect the entire snow season (Qin et al., 2006). However, in the present study, the results show that temperature was the main factor influencing snow accumulation and ablation periods. The difference may be due to the inconsistent length of time series, and the discrepancy in the selected sites and analytical methods. The findings also revealed that there was no correlation between precipitation and snow cover duration.

Conclusion

In the present study, the spatiotemporal distribution characteristics of snow cover during a 30-year period in the Mollisol region of northeast China were analyzed. Their correlation with climatic factors were also investigated. Data on the maximum snow cover depth was used to analyze the variation period of snowmelt water volume in the region. The main conclusions are as follows.

(1) The spatial distribution of snow depth was consistent with the secondary regionalization of the Mollisol region, and the maximum average monthly snow occurred in the Greater Khingan Range. Snow depth was largely affected by topographic factors, and it was relatively shallow in the plain region. The snow depth gradually increased from southwest to northeast, and the AMSD showed an increasing trend in most parts of the study region. However, the south region of the Greater and Lesser Khingan Range and the Changbai and Wanda mountain hilly region showed a decreasing trend of 0–0.4 cm/year. In contrast, the plain region showed an increasing trend of 0–0.4 cm/year.

(2) According to the variation pattern of monthly snow depth in the Mollisol region, the AMSD reached its maximum value in February. Therefore, the snow cover duration was divided into snow accumulation and ablation periods. Regarding correlation with snow cover days, temperature presented the highest positive value. The latitude and altitude of the meteorological stations also presented positive correlations with the number of snow cover days. In contrast, precipitation presented a non-significant correlation, and solar radiation presented a negative correlation.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65396554

(3) The first snow cover day appeared in the northern area of the Greater Khingan Range, and the duration of the snow cover was long. The onset of the first snow cover day occurred last in the mountainous and hilly region in the southeast of the Greater Khingan Range, where the duration of snow cover was short. The duration of snow cover and distribution of snow depth consistently increased from southwest to northeast within the study area.

(4) The amount of snowmelt water in the Mollisol region showed an overall increasing trend, and the 3–5-year variation period was the most significant, while the 5–10-year variation period was not significant, and the cycle gradually decreased. Additionally, the accurate start time of the snow ablation remains to be further studied in the follw-up study.

Abstract. The selection of appropriate fertilizers influences agricultural production, especially in water-limited conditions such as those on the Loess Plateau (China). In this study, we aimed to determine the optimum method for the fertilization of dryland crops. In a two-year split-plot experiment, we tested eight fertilization treatments with different combinations of organic and inorganic fertilizers and a no-fertilizer control. Crop yield, soil water storage, and soil water use efficiency (WUE) were assessed pre-sowing and post-harvest in 2017 and 2018. The results showed that soil water storage was decreased by fertilization, while the WUE and crop yield were both increased: compared to the control, WUE was 6–39% higher in 2017 and 8–39% higher in 2018, while crop yield was 3–21% higher in 2017 and 1–19% higher in 2018. The maximum effect on WUE and crop yield was achieved when a combination of organic fertilizer and either nitrogen or phosphate fertilizer was applied. Linear regression analysis revealed that soil water consumption (ET) was significantly positively correlated with crop yield. Our results provide a scientific basis for rational crop fertilization on the Loess Plateau and suggest that a combination of organic and inorganic fertilizers is the most appropriate.
Keywords: *inorganic fertilization, organic fertilization, agricultural production, soil water storage, rain-fed agricultural*

Introduction

In the world's typical traditional dry farming regions, scarce precipitation and insufficient water for irrigation have become the main factors limiting the improvement of agricultural productivity (Hamdy, 2003). Different soil water and fertilizer conditions are known to have important effects on crop growth, dry matter distribution, and crop yield (Yan, 2015). For instance, insufficient soil water affects the synthesis and transport of nutrients, reducing crop yield and quality, while inadequate fertility can affect soil water absorption and utilization (Zhang et al., 2007; Wu et al., 2019). The availability of soil water has complex interactions with soil microbial activities, soil physics and chemistry, and plant physiological and biochemical processes. In addition, soil water and fertilizers are important material resources in agricultural production. Therefore, the study of the relationship between fertilization and soil water is a key research area in crop yield and agricultural economic development (Huang, 2010).

Improving crop yield and soil water use efficiency (WUE) through rational fertilization strategies under water-limited conditions is a hot research topic (Guo et al., 2019). Many studies have shown that the effects of the addition of soil water and the application of fertilizer on crop yield are strongly dependent on the pre-existing soil water and fertility (Fan et al., 2005).

Some studies in the Loess Plateau have found that the effect of fertilization on crop yield is more significant when the soil's natural water level is low. With the improvement in soil fertility, soil water also increased, suggesting that soil water and fertilizer have a coupling effect on crop yield (Krbel et al., 2012; Tang et al., 2016). In another study, fertilizer application boosted soil WUE under all soil water conditions, but especially when soil water levels were already sufficient (Xue, 2009; De, 2013). Compared with the non-fertilization treatment, crop yield increased significantly when fertilized, but the yield difference was not obvious under drought conditions (Tahir, 2012). Soil water and fertilization have also been shown to have extremely significant effects on crop soil water consumption and soil WUE (Tang et al., 2016). Fertilization can significantly inhibit plant transpiration and soil water loss, increase the drought resistance and soil water consumption of crops, and increase soil WUE (Laxminarayana et al., 2011; Belay, 2002) Fertilization can also reduce the consumption of ineffective water in the soil, increase the water utilization rate, and boost the crop's ability to use the deep-layer soil water (Chen et al., 2016; Ren et al., 2019).

The Loess Plateau is a typical traditional dry farming region; it is located in a semi-arid/semi-humid climate zone and has undergone serious soil erosion. Due to the low precipitation level, its uneven seasonal distribution, and the low soil organic matter content, nutrients and moisture have become the key factors restricting agricultural production in the area. Precipitation is a natural event which determines the fluctuation in dryland crop yield. Careful fertilization that correctly influences the soil nutrient cycle can ensure high nutrient uptake of the crops and enhance soil fertility. Conversely, excessive fertilization has a limited effect on increasing yield and undermines the soil–crop system nutrient balance. Despite the importance of this issue in the Loess Plateau region, there are few reports that have directly looked at the relationship between fertilization and WUE in this area.

Our objective was to fill this gap in knowledge and to achieve a science-based recommendation for the fertilizer that is the most appropriate to the drylands on the Loess Plateau. In this study, we report the changes in crop yield and WUE under different fertilization scenarios in two consecutive years in which different crops were planted on the same study plots. We hypothesized that (1) fertilization would significantly increase soil water storage, WUE, and crop yield; and (2) the impact of an organic fertilizer would be higher than that of inorganic fertilizer.

Materials and methods

Basic geographic information and experimental soil conditions

The field experiment was conducted in 2017 and 2018 at a study site located in the middle of the Loess Plateau (36°51′N, 109°18′E). The site (*Fig. 1*) is located 1068 m above sea level; it has a mean annual temperature of 8.8 °C and an annual precipitation level of 500.0 mm in the last 10 years. The recorded annual precipitation was 557.6 mm in 2017 and 536.3 mm in 2018. The precipitation during the growth period (between March and September) was 443.1 mm in 2017, accounting for 79.47% of the total

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65556568

annual precipitation; the respective values were 503.1 mm and 93.8% in 2018. The climate details are shown in *Figure 2*. The soil type at the study site was loess soil; basic soil physical and chemical properties were measured at the depth of 0–40 cm before sowing in two years of experimentation (*Table 1*).

Fertilizer treatments

Organic and inorganic fertilizers were used. The nitrogen fertilizers (N) were urea and diammonium phosphate, the phosphate fertilizer (P) was diammonium phosphate, the potassium fertilizer (K) was potassium chloride, and the organic fertilizer (M) was sheep manure. Organic fertilizer treatments were the following: M, MN, MP, and MNP. Inorganic fertilizer treatments were NP, NK, PK, and NPK. In addition, a no-fertilizer treatment was used as the control CK. The fertilizers were spread evenly on the soil surface before sowing. Nine fertilization practices are shown in *Table 2*.

Table 2. *Experimental fertilization*

Treatment	Illustration
M	Sheep manure (0.75 kg/m^2)
MN	Sheep manure (0.75 kg/m^2) + Urea 0.021 kg/m^2
MP	Sheep manure (0.75 kg/m^2) + Diammonium phosphate (0.017 kg/m^2)
MNP	Sheep manure (0.75 kg/m^2) + Urea (0.021 kg/m^2) + Diammonium phosphate (0.017 kg/m^2)
NP	Urea 0.021 kg/m^2 + Diammonium phosphate (0.017 kg/m^2)
NK	Urea (0.021 kg/m^2) + Potassium sulfate (0.012 kg/m^2)
PK	Diammonium phosphate (0.017 kg/m^2) + Potassium sulfate (0.012 kg/m^2)
NPK	Diammonium phosphate (0.017 kg/m^2) + Urea (0.021 kg/m^2) + Potassium sulfate (0.012 kg/m^2)
CK	No fertilizer

Experiment design

Local heat and moisture conditions allow crops to only grow once a year. The planting mode used millet-soybean rotations, so millet was sowed on May 2 in 2017, and soybeans on May 4 in 2018. The millet cultivar was Hongyang 7. The soybean variety planted was Zhonghuang 35. Millet sowing in 2017 was quantitative sowing, planting density was 15 plants/m^2. The sowing method was drill, spraying 10% Monosulfuron 0.023 kg/m^2 on May 24 for chemical weeding in the experimental plot. In 2018, soybean planting density was 22 plants/m^2. At the end of May, when two compound leaves of soybean were grown after seedling emergence, 5% imazethapyr 0.0001 kg/m^2 was applied to soybean to remove weeds. Each of the 9 treatments was allocated 4 plots, yielding a total of 36 plots. Each plot was 3.5 m long and 8.57 m wide (plot area of 30 m^2). The plots were arranged in random blocks (*Fig. 3*). The soil fertility and environmental conditions in all plots were uniform. Organic, potash, and phosphate fertilizers were each applied once, while urea fertilizer was applied at a rate of 136 g per plot, and the remaining 500 g nitrogen fertilizer was applied during the flowering period. The millet was fertilized with urea on April 27th, 2017, and supplementary nitrogen fertilizer was added on July 3rd, 2017. Urea fertilizer was added to soybeans on April 28th, 2018, and supplementary nitrogen fertilizer was added on July 26th, 2018. The 9 fertilization treatments are shown in *Figure 3*.

Soil sampling and crop harvesting

Soil sample collection method: Taking each plot as a unit, the soil sampling point was more than 1 m of the boundary of the sample plot. Sampling points were randomly selected forming an S shape. Surface debris was then removed, and soil samples were collected. All soil samples from the same sampling point were combined and passed

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65556568

through a 2 mm sieve. Samples were stored and labelled after the relevant sampling information had been recorded. In all plots, the soil water level was measured every 10 cm up to the depth of 100 cm with a neutron moisture meter (Neutron moisture meter, Model CS830, Rurui Technology Company, Guangzhou, China). The weight water consumption was multiplied by the soil bulk density to obtain the volumetric water consumption (Wang et al., 2016). The soil water consumption was determined using the oven-drying method. The soil samples were brought back to the laboratory; plant roots and other impurities were removed, and the percentage of soil moisture in weight was measured (Lu et al., 2019). The soil bulk density was measured using a soil bulk sampler (Soil bulk sampler, Model JC-8028, Juchuang, Qingdao, China) for every soil sample. The soil pH was measured using a pH meter (pH meter, Model PHS-25, LEICI, Nanjing, China) for every soil sample.

At the end of the growing season, 3 quadrats (1 m × 1 m) were harvested in each plot by cutting at the soil surface level; the harvested plants were dried in an oven (75 °C, 24 h), weighed, and their value was converted to plot yield. Final crop yield was obtained by harvesting 4 replicates of each treatment. The 2017 millet was harvested on October 12th, and the 2018 soybean crop was harvested on October 4th. In 2017, soil moisture content before sowing was measured on April 26th, and post-harvest moisture was measured on October 13th. In 2018, soil moisture content before sowing was measured on April 20th, and post-harvest moisture was measured on October 5th.

Index calculations

The requisite indices were calculated according to the following formulae.

$$Sw = H_i \times D_i \times B \times 10 \quad \text{(Eq.1)}$$

where: Sw (mm) is the sum of soil water stored in different soil layers (Lu et al., 2019); D_i (g cm^{-3}) is the soil bulk density in different soil layers; H_i (cm) is the soil depth; and B (%) is the percentage of soil moisture in weight.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65556568

$$ET = W_1 - W_2 + P \quad \text{(Eq.2)}$$

where: ET (mm) is the water consumption during the crop-growing season (Xu et al., 2020a); W_1 (mm) is the water storage at a soil depth of 0–100 cm at sowing; W_2 (mm) is the water storage at a soil depth of 0–100 cm during harvest; P (mm) is the precipitation measured during the crop growth period.

$$\text{WUE} = {}^{Y}/_{ET} \quad \text{(Eq.3)}$$

where: WUE is water use efficiency (kg m^2 mm^{-1}) (Adimassu et al., 2017); Y (kg m^2) is the yield per unit plot.

Statistical analysis

One-way ANOVA analysis was used to examine the effects of fertilization treatment on soil water storage, soil WUE, and crop yield ($P < 0.05$). Before the analysis, we performed a normality and homogeneity test of the data. Linear regression analysis was used to show the relationship between crop yield and soil WUE. All statistical analyses were performed using the software package IBM SPSS Statistics (version 26.0). The differences between the treatments were calculated using the least significance difference test at a 0.05 probability level. Figures were prepared using Origin 9.0.

Results

Soil profile water content

In 2017, before sowing, the soil moisture water content in the 0–10 cm soil layer of the M, MN, MP, and NK plots was higher than that in the CK plots, while in the 10–100 cm soil layers the soil moisture water content of all the fertilization treatments was lower than that of the CK (*Fig. 4a*). The soil moisture water content of all fertilization treatments in the 0–10 cm soil layer was higher than that of CK after the crop harvest in 2017 and before sowing in 2018, and the soil moisture water content of all fertilization treatments in the 10–100 cm soil layers was lower than that of CK (*Fig. 4b, c*). Furthermore, after the crop harvest in 2018 the soil moisture water content of the M, MN, MP, and NPK treatments in the 0–10 cm soil layer was higher than that of the CK treatment, and in the 10–100 cm soil layers the soil moisture water content of all the fertilization treatments was lower than that of the CK treatment (*Fig. 4d*).

Soil water storage

In 2017, the soil water storage recorded in the CK plots exceeded that found in fertilized plots; it was 1.22–21.11 mm higher than that of all of the fertilization treatments, both before sowing and after harvest. Meanwhile, the soil water storage of the MN, MP, and MNP plots was higher than that of the other fertilization treatments, both before sowing and after harvest (*Fig. 5a*). In 2018, the soil water storage of the CK plots was greater than that of the fertilization treatments after harvest; meanwhile, the soil water storage in the MN, MP, MNP, and NPK plots was higher than in the other fertilization treatments, both before sowing and after harvest (*Fig. 5b*).

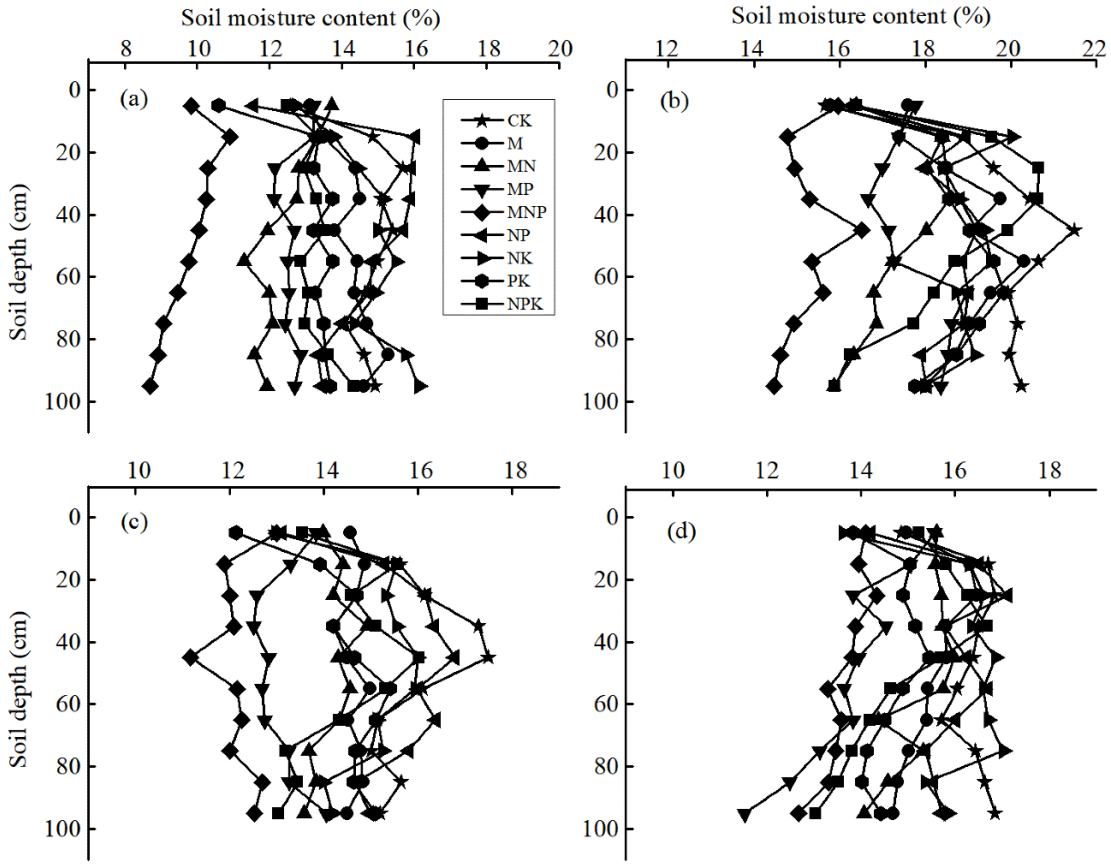

Figure 4. *Soil moisture water content (mean) in 2017 before sowing (a), 2017 after harvest (b), 2018 before sowing (c), and 2018 after harvest (d) in different fertilization treatments. Notes: M, organic fertilizer; MN, organic fertilizer combined with nitrogen fertilizer; MP, organic fertilizer combined with phosphate fertilizer; MNP, organic fertilizer combined with nitrogen and phosphate fertilizer; NP, nitrogen fertilizer combined with phosphate fertilizer; NK, nitrogen fertilizer combined with potassium fertilizer; PK, phosphorus combined with potassium fertilizer; NPK, nitrogen combined with phosphate and potassium fertilizer; CK, no-fertilizer control*

Crop yield and soil water consumption (ET)

Overall, higher crop yield was recorded after fertilization. In 2017, the crop yields of the M, MN, MP, MNP, NP, NK, and NPK plots were 15%, 11%, 8%, 21%,8%, 5%, and 11% greater, respectively, than that after CK treatment. In 2018, the crop yield of the M, MN, MP, MNP, NP, NK, and NPK plots was higher than that of the CK plots by 11%, 14%, 15%, 19%, 7%, 3%, and 11%, respectively (*Fig. 6*).

In 2017, the water consumption (ET) recorded in the CK plots lower than the other fertilized plots; approximately 12.83–47.73 mm lower than that of all fertilization treatments. Meanwhile, the soil water consumption of the MN, MP, and MNP plots was higher than that of other fertilization treatments, both before sowing and after harvest (*Fig. 7*). In 2018, the soil water consumption of the CK plots was lower than that of the fertilization treatments; meanwhile, the soil water storage in the MN, MP, MNP, and NPK plots was higher in other fertilization treatments (*Fig. 7*).

The linear regression showed that the ET was significantly positively correlated with crop yield ($R^2 = 0.846$, $P < 0.001$) (*Fig. 8*).

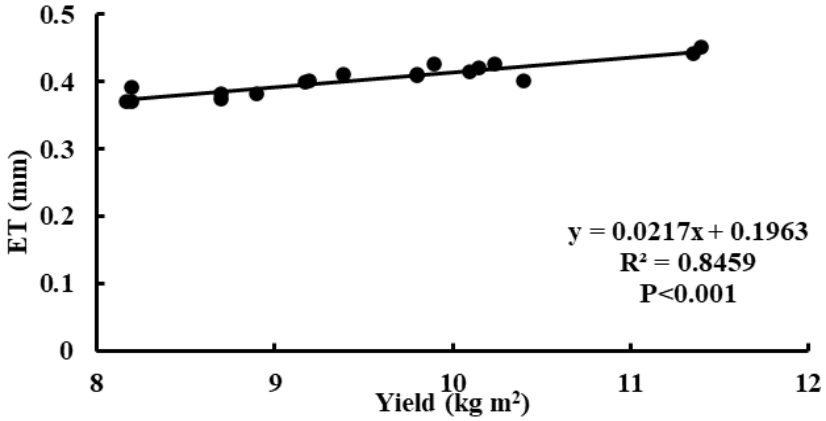

Figure 8. *The correlation between crop yield and soil water consumption (ET)*

Soil water use efficiency (WUE)

Overall, higher WUE was recorded after fertilization. In 2017, in comparison to the CK plot, the WUE of the M, MN, MP, MNP, NP, PK, and NPK plots was greater by 21%, 23%, 26%, 39%, 12%, 6% and 20%, respectively (*Fig. 9*). In 2018, the WUE of the M, MN, MP, MNP, NP, PK, and NPK plots was greater than that of the CK plots by 15%, 24%, 25%, 39%,12%, 8% and 20%, respectively (*Fig. 9*).

Discussion

Improving WUE is a major goal of agricultural development in arid and semi-arid areas. Appropriate fertilizer application can promote crop growth and development, encourage the growth of deep roots, and enhance crop use of deep soil water (Ameen et al., 2019; Tamaki, 1997). We tested whether the application of organic and inorganic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65556568

fertilizers will improve soil WUE and found that fertilization was closely linked to soil water storage and WUE (Samuelson, 2018; Zhang et al., 2019). In 2017 and 2018, soil WUE increased by 6–39%, and 8–39%, respectively, compared with the no-fertilization control, supporting Hypothesis 1. However, the soil water content and water storage showed an overall reduction compared with the no-fertilization treatment; this result is in line with those of the previous studies but contradicts Hypothesis 1.

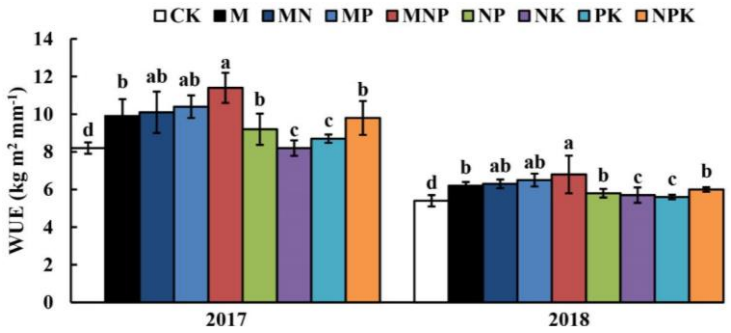

Figure 9. *Soil water use efficiency (WUE) (mean ± standard error) of the different fertilization treatments in 2017 and 2018. Values in the same column and year followed by different letters indicate significant differences (Duncan $P < 0.05$). M, organic fertilizer; MN, organic fertilizer combined with nitrogen fertilizer; MP, organic fertilizer combined with phosphate fertilizer; MNP, organic fertilizer combined with nitrogen and phosphate fertilizer; NP, nitrogen fertilizer combined with phosphate fertilizer; NK, nitrogen fertilizer combined with potassium fertilizer; PK, phosphorus combined with potassium fertilizer; NPK, nitrogen combined with phosphate and potassium fertilizer; CK, no-fertilizer control*

Multiple mechanisms and factors are at play in the effect of fertilization on crop water use. Previous studies have found that soil WUE follows the same changing characteristics as the leaf area index (De et al., 2013; Ibrahim et al., 2015; Krbel, 2012). Firstly, appropriate fertilization treatment can significantly increase the total amount of crop roots, enhance root vitality, and expand the space available to roots to absorb soil moisture and nutrients; it can also increase leaf area, boost the photosynthetic rate, reduce evaporation, and achieve maximum efficiency in the utilization of limited moisture in semi-arid areas (Wang, 2013; Liu et al., 2010). It is because fertilization promotes the vigorous growth of crops that the water consumption of ground evaporation is reduced (Sheoran et al., 2017). Therefore, after fertilization, the rapid growth of the crops increases soil water consumption and decreases soil water storage and content, while soil WUE increases. Secondly, the growth of the vegetation and the expansion of plant stems and leaves after fertilization results in a stronger plant cover on the ground surface, slowing down the water consumption in the form of surface evaporation, which also increases the plant water use. In addition, the abundant rainfall in the late filling stage (*Fig. 2*) is likely to have enabled the plants to fully exploit the available soil nutrients. This explains why the water consumption of the fertilized plots was significantly greater than that of the unfertilized control.

The ultimate goal of increasing crop WUE is an enhanced yield, which can be achieved when the right balance is struck between the source and sink conditions (Zhang et al., 2019; Amoah et al., 2012). Fertilization is an important agronomic measure for increasing source characteristics such as dry matter accumulation and sink characteristics such as crop yield (Chaab, 2011; Meng et al., 2012). Our results show

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65556568

that higher crop yield can be achieved by fertilization. In this study, the yield of plants treated with additional organic and inorganic fertilizers was significantly higher than that of the no-fertilization control. This is in line with the results of previous studies showing an overall increase in dry matter accumulation after fertilization.

Fertilization can enhance crop yield via a variety of pathways. It is known that low soil nutrient availability limit growth (Kurwakumire et al., 2014). Fertilization increases the amount of available nutrients in the soil, boosting the absorption and utilization of soil nutrients by plants. In addition, chlorophyll is essential for photosynthesis, and its content in leaves reflects the level of photosynthesis (Roland et al., 2012). Nutrients are required for chlorophyll production (Wang and Jin, 2007). Appropriate application of fertilizers can increase chlorophyll content in plant tissues, as demonstrated previously (Xu et al., 2020b); this promotes the growth of above-ground parts, thereby increasing biomass accumulation. Some studies have shown that fertilization can achieve higher yields through simultaneously improving cooperatively improving the indicators of crop dry matter accumulation, dry matter transport capacity of vegetative organs, and photosynthetic compound accumulation (Eisvand, 2018).

It is likely that both nutrient availability and water consumption are involved in the enhancement of crop yield observed after the application of fertilizers. This is consistent with our finding of a significant positive correlation between crop yield and soil ET, suggesting that the two occur synergistically after fertilization. Studies have shown that nutrients can increase water uptake, transport, and overall content in plants, thereby increasing yields (Tamaki, 1997). A 2006 study reported that the addition of organic and inorganic fertilizers increased the soil nutrient supply and the soil WUE during the crop growth period, benefitting plant growth and development, enhancing photosynthesis, and thus increasing plant biomass accumulation (Li et al., 2018). A positive feedback loop mechanism may be involved: it has been shown that increases in biomass promote transpiration, which indirectly promotes root growth and photosynthesis, thereby further increasing crop yields. Drought and nutrient deficiencies are typical characteristics of the Loess plateau and can have significant negative effects on crop yields (Amoah et al., 2012). Our study provided a preliminary look at the effect of different types of fertilization on crop production and WUE. There is scope for future studies to explore the complex mechanisms that drive the yield changes observed under different fertilization modes.

In recent years, owing to many countries' emphasis on the protection of the ecological environment and the quality and safety of agricultural products, more and more scientists have focused their research on the rational use of organic fertilizers (Sadeghzadeh and Rengel, 2011). We found that the use of organic fertilizers improved soil water efficiency and crop growth more than the use of inorganic fertilizers, which supported Hypothesis 2. One potential reason for this result is that organic fertilizers can improve the functional diversity of microbial communities in crop rhizosphere soils (Cheng et al., 2015; Wang, 2009) and are therefore superior to inorganic fertilizers in terms of their effect on plant nutrient absorption and transformation. For instance, Wang et al. (2012) found that the combined application of NPK fertilizers and organic fertilizer can make crops have improved yields and results in higher yields than NPK fertilizers alone. In addition, some studies have found that the nutrient release of organic fertilizer is slow and thus more helpful for subsequent improvement of soil fertility (Ren et al., 2019). Our results showed that the treatments that increased production and improved water use the most were the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65556568

combination of organic fertilizer with N and P fertilizer in 2017 and 2018. Further experiments are needed to quantify the economic benefits of organic fertilizer and elucidate its relative effects on different crop species. Additional factors such as ecological and environmental protection, sustainable soil use, and economic output benefits should be comprehensively considered when making definitive recommendations on the application of organic and inorganic fertilizers.

Conclusion

Our study sheds light onto the effect of organic and inorganic fertilizers on soil water use and agricultural production in rain-fed agricultural areas on the Loess Plateau (China). We examined the variations in soil WUE and crop yield under nine fertilization treatments. Our results revealed that fertilization increases soil WUE and crop yield but decreases soil water storage. The treatments combining organic fertilizer with N and P fertilizer had the strongest positive effect on soil WUE and crop yield. Based on our results, we therefore recommend the use of organic fertilizers in arid and semi-arid areas as a method for improving soil WUE and crop yield. Further studies should conduct similar analyses over a longer study period and with different crop species and attempt to elucidate the mechanisms at play in the effect of fertilization on crop yield.

Abstract. We investigated salt toxicity effects and related physiological as well as anatomical changes for adaptation in *Cynodon dactylon*. Eleven ecotypes from different areas of Pakistan were examined for their survival capacity in a controlled environment. The experiment was designed in a two factor Completely Randomized Design (ecotypes and 4 salt levels 0, 100, 200, 300 m*M* NaCl). Differently adaptive populations displayed specific structural and functional adaptations with respect to photosynthesis and photosynthetic pigments to withstand salinity. The ecotypes from saline and waterlogged areas exhibited higher Photosynthetic rate to same level of increase in salinity level. Transpiration rate of all ecotypes showed variations with different salinity levels and stomatal conductance increased in all ecotypes with increasing salinity. Similarly, all ecotypes responded significantly as far as chlorophyll contents were concerned. Most ecotypes consistently showed high leaf blade thickness and sclerenchyma thickness with elevated salinity except for plants collected from saline, waterlogged and salt affected wasteland. Different salt levels decreased the metaxylem cell area while phloem area increased in the ecotypes correspondingly. *Cynodon* ecotypes possessed low abaxial stomatal density at 300 m*M* salinity. Overall, physiological and anatomical adaptations to saline environments appeared very specific in grasses and supported life cycle under salt stress.

Introduction

Plants, as sessile organisms, are often subjected to various environmental stresses i.e. biotic and abiotic causing massive structural and functional changes (Khalid et al., 2020; Mickelbart et al., 2015; Pandey et al., 2017). Growth and all other plant activities depend on photosynthesis, photosynthetic pigments and photosynthetic machinery (Ashraf and Harris, 2013; Cardona et al., 2018). But these cellular systems are damaged by abiotic and biotic stresses (Gururani et al., 2015; Mohanty et al., 2006) especially the degradation of chlorophyll pigmentation due to alteration in gene expression (Dutta et al., 2009; Noman and Aqeel, 2017; Sharma et al., 2019) that limits photosynthesis but also reduce plant growth and yield (Ali and Ashraf, 2011; Arshad et al., 2016; Khalid et al., 2020, 2018; Thuynsma et al., 2016). The salinization of irrigated lands in arid/semi-arid areas is one of the major causes of low crop production in many parts of the world (Araus et al., 2010; Hussain et al., 2019).

Cynodon dactylon (L.) Pers. (Bermuda grass, locally known as Khabbal grass) is distributed abundantly in tropical and warm temperate areas (Shi et al., 2012) throughout the world between 45°N and 45°S (Ling et al., 2015). It tolerates high temperatures, drought, and salinity (Chen et al., 2015; Hu et al., 2015). It has C_4 photosynthesis pathway (Edwards et al., 2004) which is a complex adaptation evolved from C_3 photosynthesis (Carmo-Silva et al., 2008). The C_4 adaptation is extremely successful in the monocotyledonous families i.e., Poaceae and Cyperaceae (Besnard et al., 2009; Sage, 2004). Salinity tolerance, especially in grasses, depends on plant morpho-physiological features (Bahrani et al., 2010; Volkov and Beilby, 2017). In different *C. dactylon* ecotypes salinity ranges from 6 to 10 dS m^{-1}, and the different species are classified as semi-tolerant to tolerant to drought stress (Uddin et al., 2012).

Physiological adaptations are important criteria for salt tolerance selection (Ashraf, 2004; Gupta and Huang, 2014; Hernández, 2019), but anatomical modifications under high salinities are also crucial (Naz et al., 2014; Noman et al., 2017, 2012; Ye et al., 2015). Photosynthesis is affected by leaf anatomy and CO_2 exchange. Structural features of the leaf contributing to the maintenance of the high CO_2 concentration in the chloroplast stroma may have been selected during evolution (Terashima et al., 2011). Stomata and stomatal activities are much important for the photosynthetic activities and reduction in net photosynthetic rate, stomatal conductance, intercellular CO_2 concentration, quantum efficiency of PSII, and non-photochemical quenching in *C. dactylon* is directly linked to non-stomatal activities (Bhuiyan et al., 2015).

A typical respond to salt stress is the development of thick leaves due to the thickening of the cortex and mesophyll cells (Boughalleb et al., 2009; Geldner, 2013). The structural alterations in vascular bundles, the nature of lignified tissues are all thought to be very helpful in allowing the plant to fight against various environmental stresses (Noman et al., 2014; Qaderi et al., 2019; Zwieniecki et al., 2003). The emptying of the vacuoles of large bulliform cells induces leaf curling and the rolling of leaves that can be distinctively considered as an important adaptation against salinity-induced physiological drought stress for the water conservation and lowering the rate of transpiration (Alvarez et al., 2008; Balsamo et al., 2006; Hameed et al., 2013). Besides, the increased density and size of trichomes may also provide the additional benefit of enabling a plant to withstand environmental stresses like drought and salinity. Increasing the density of micro-hairs under conditions of increased salt may be one of the most effective mechanisms for salinity tolerance in Bermuda grass (Hu et al., 2015).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65696588

It was hypothesized that differently adaptive populations might have some specific structural and functional adaptations with respect to photosynthesis and photosynthetic pigment to withstand salt stress condition. The investigation was focused on the leaf anatomical changes as dermal tissues (epidermis, stomatal density and area, trichome length, and leaf hairiness), vascular tissues (large metaxylem vessels), and mechanical tissues (sclerenchyma) that influence photosynthesis and changes in chlorophyll pigments and gas exchange characteristics under salt stress conditions.

Materials and methods

Selected ecotypes of Cynodon dactylon

Various ecotypes of *C. dactylon* were selected from the Punjab, Pakistan from different ecological regions as reported by Tufail et al. (2017). The ecotypes (DF-SD) and (S-HS) were selected from saline arid regions. Ecotypes (KL-HS), (UL-HS), and (KKL-S) were collected from saline lakes in the Salt Range. Ecotypes (S-SW) and (T-SW) were from saline waterlogged areas. Two ecotypes were from salt-affected wasteland, (PA-HS) and (PA-RF). Two ecotypes were from non-saline well irrigated habitats, (MG-RB) and (BG-NS) (*Table 1; Fig. 1*).

Table 1. *Various ecotypes of Cynodon dactylon L. from the Punjab, Pakistan*

Sr. No.	Sampling sites	Ecotypes	Latitude (N)	Longitude (E)
1	Derawar Fort-Saline Desert	DF-SD	28° 75′	71° 33′

Cynodon dactylon culture and salt treatment

Naturally adapted populations of *C. dactylon* from several regions of the Punjab, Pakistan were established in the Botanic Garden, University of Agriculture, Faisalabad, in non-saline soil. The plants were kept under full sunlight and irrigated daily up to their establishment in Faisalabad environment. Randomly selected ramets from each ecotype of equal size (with two mature up tillers) were detached, fixed and grown in aerated hydroponics using half-strength Hoagland's nutrient solution (Hoagland and Arnon, 1950) for eight weeks. Air pumps were used for aeration of hydroponic culture system for about 12 h daily. Ten ramets from each population were selected for each replication and fixed in the pores of thermophores (mineral fiber) sheets for each experimental unit, which was placed on hydroponic culture solution.

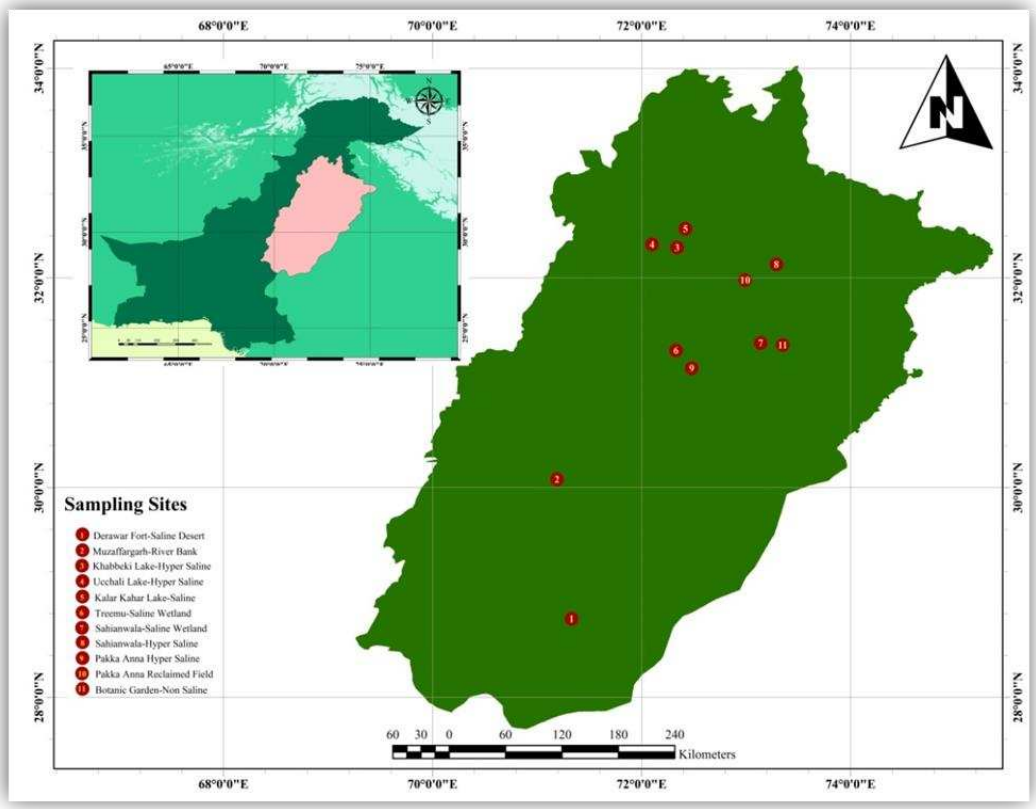

Figure 1. *Map of the Punjab, Pakistan showing ecotypes of Cynodon dactylon from different sampling sites*

Four salinity levels were maintained during the experiment viz. control (no salinity treatment), 100, 200 and 300 mM of NaCl salinity in solution culture up to flowering stage. After 8-weeks, plants were washed thoroughly and used for studying the various anatomical characteristics.

The ecotypes were subjected to salt stress after their establishment in the Faisalabad environment. The experiment for salt stress was arranged in two factor-factorial (ecotypes and salt levels) completely randomized design with ten replications and 0 (control), 100, 200, and 300 mM NaCl levels in aqueous culture media containing half-strength Hoagland's medium.

Leaf anatomical studies

Transvers sections of the newly grown leaves from three plants as replicates were made by the free hand sectioning by serial dehydrations in ethanol using double standard staining (Safranin and fast green) technique. Plant material was preserved in the Formalin Acetic Alcohol (FAA) fixative for 48 h and subsequently transferred to acetic alcohol (v/v acetic acid 25%, and ethanol 75%) solution for long term storage.

Photographs were taken by a camera-equipped light microscope (Meiji Techno: MT4300H USA). Parameters were recorded as: Leaf blade thickness (µm), Epidermal cell area (µm^2), Sclerenchymatous thickness (µm), Bulliform cell area (µm^2), Vascular Bundle area (µm^2), Metaxylem area (µm^2), Phloem area (µm^2), Trichome length (µm) and density, Stomatal area (µm^2) and density.

Photosynthetic parameters

Measurements of net CO_2 Assimilation Rate (*A*), Transpiration (*E*) and Stomatal Conductance, Sub Stomatal CO_2 concentration and Water Use Efficiency (calculated as WUE = A/E) were recorded by using LCA-4 ADC portable infrared gas analyzer (Analytical Development Company, Hoddesdon, England). The gas exchange measurements were performed *in situ* from 10:30 a.m. to 12:30 p.m. with specific specifications/adjustments as reported by Schiavon et al. (2016) and Tamayo et al. (2001).

Photosynthetic pigments

The chlorophyll a, b and carotenoids were determined according to the method of Arnon (1949).

Statistical analysis

The data were subjected using analysis of variance in completely randomized design. Redundancy analysis (RDA) was performed using Conoco 4.5 computer software.

Results

Photosynthetic attributes

Gas exchange attributes

The net CO_2 assimilation rate (*A*) decreased in the ecotypes of *C. dactylon* KL-HS, UL-HS, KKL-S, S-HS, PA-RF and BG-NS (*Table 1*) with increase in the concentration of salinity. The ecotypes from T-SW and S-SW responded the best to the maximum salinity level with higher net CO_2 assimilation rates (*Fig. 2*).

The transpiration rate (*E*) of ecotypes of *C. dactylon* from S-HS, PA-RF, and BG-NS decreased as the salt stress level increased (*Fig. 2*). Ecotypes from DF-SD, KKL-S, T-SW, S-SW showed slightly decreased transpiration rate at salinity levels (100 and 200 mM NaCl) but increased at 300 mM NaCl. The transpiration rate for the PA-HS ecotype peaked at 100 mM NaCl but decreased at higher levels of salt stress (*Fig. 2*).

The stomatal conductance of ecotypes from the DF-SD, M-RB, KL-HS, KKL-S, and BG-NS increased as the salinity level increased (*Fig. 2*). There was no significant variation in sub stomatal CO_2 concentration, for many of the experimental ecotypes, except from DF-SD, KL-HS, UL-HS and PA-RF exhibited reduced sub stomatal CO_2 concentrations at the highest experimental salinity level (300 mM NaCl) (*Fig. 2*).

Ecotypes from the DF-SD, M-RB, KL-HS, UL-HS, and BG-NS exhibited a quadratic response of water use efficiency to salinity. S-SW, S-HS, PA-HS exhibited quadratic responses and exhibited the highest levels of water use efficiency at 300 mM NaCl (*Fig. 2*).

Photosynthetic pigments

DF-SD, S-HS, and BG-NS exhibited slightly increased chlorophyll a levels at the 100 and 200 mM NaCl levels, and exhibited maximum reduction in the pigment at 300 mM NaCl (*Fig. 2*).

The chlorophyll b response was, for many of the experimental ecotypes, higher at the 100 or 200 mM NaCl levels. M-RB exhibited increasing chlorophyll b levels as salinity increased. KL-HS, UL-HS, and S-SW exhibited peak levels of chlorophyll b at 100 mM

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65696588

NaCl (*Fig. 2*). DF-SD, PA-RF. T-SW, S-HS, PA-HS, and BG-NS exhibited maxima at the 200 mM NaCl level (*Fig. 2*).

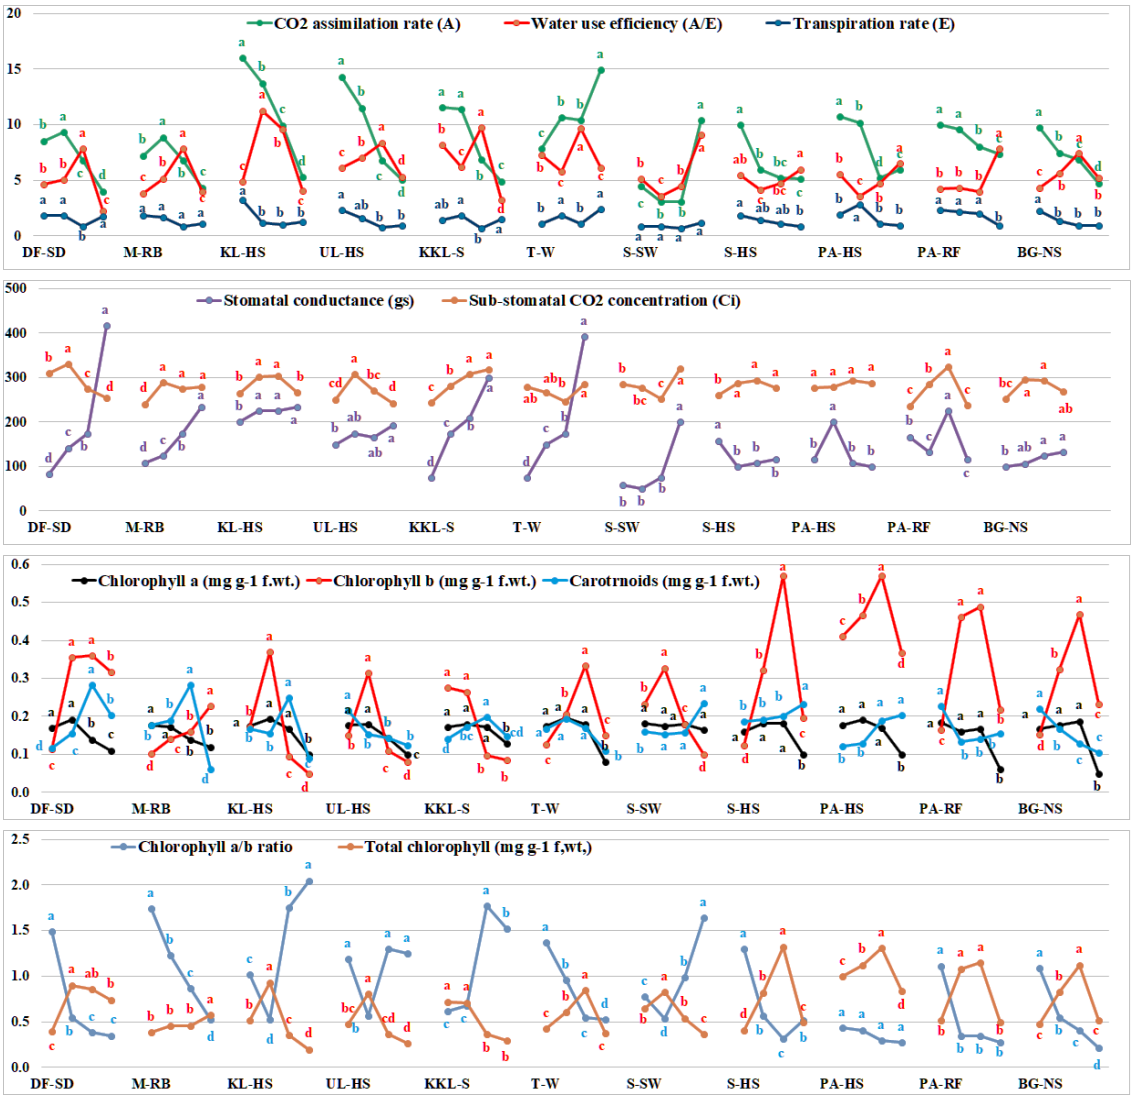

Figure 2. *Series plots of gas exchange characteristics and photosynthetic pigments under four salt levels (0, 100, 200, 300 mM) NaCl. DF-SD (Derawar Fort-Saline Desert), MG-RB (Muzaffargarh-River Bank), KL-HS (Khabbeki Lake-Hyper Saline), UL-HS (Ucchali Lake-Hyper Saline), KKL-S (Kalar Kahar Lake-Saline), T-SW (Treemu-Saline Wetland), S-SW (Sahianwala-Saline Wetland), S-HS (Sahianwala-Hyper Saline), PA-HS (Pakka Anna Hyper Saline), PA-RF (Pakka Anna Reclaimed Field) and BG-NS (Botanic Garden-Non Saline)*

The amount of leaf carotenoid pigments indicated different patterns of response in the experimental ecotypes at the experimental levels of salinity. While ecotypes from S-SW, S-HS and PA-HS exhibited increasing leaf carotenoid compounds due to salinity. DF-SD, M-RB, and KL-HS responded with higher amounts of carotenoids at 200 mM NaCl (*Fig. 2*).

Chlorophyll a and b ratio also decreased with increase in salinity level in ecotypes of *C. dactylon* from DF-SD, M-RB, T-SW, PA-HS, PA-RF and BG-NS (*Fig. 2*). Furthermore KL-HS, UL-HS and S-SW exhibited higher amounts of total chlorophyll at

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65696588

100 mM NaCl. Ecotypes from T-SW, S-HS, PA-HS, PA-RF and BG-NS exhibited higher amounts of total chlorophyll at 200 mM NaCl (*Fig. 2*).

Leaf anatomy

Many of the ecotypes of *C. dactylon* exhibited consistently increased leaf blade thickness with increased salt stress, except ecotypes from S-SW, S-HS, and PA-HS, which exhibited gradual increases of leaf blade thickness up to 200 mM NaCl stress but reduced leaf thickness at the maximum experimental salinity level. In the ecotypes from BG-NS, the maximum leaf blade thickness was observed at 100 mM NaCl, and increasing levels of salinity reduced leaf blade thickness (*Fig. 3*).

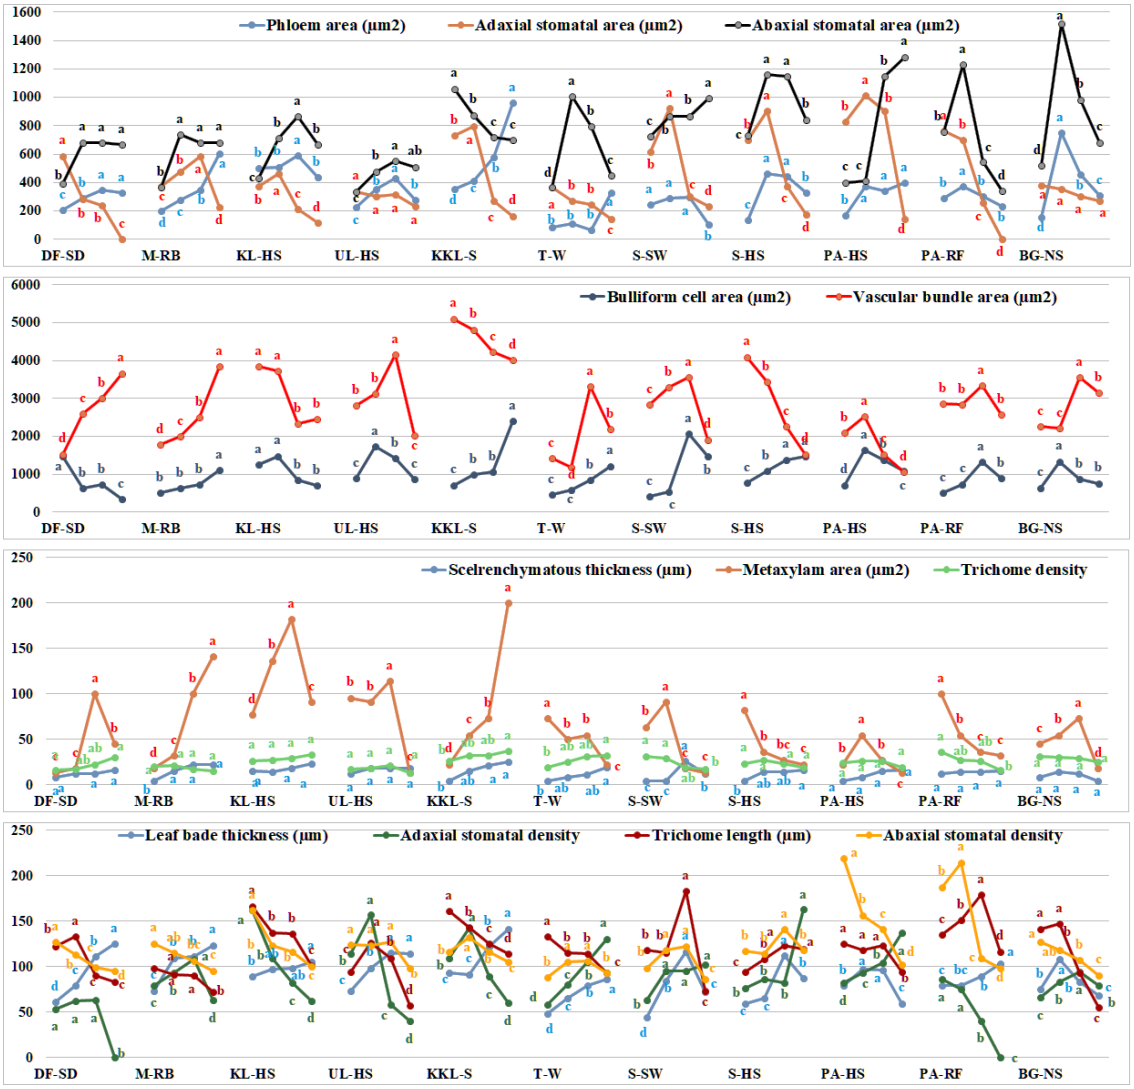

Figure 3. *Series plots of leaf anatomical attributes under four salt levels (0, 100, 200, 300 mM) NaCl. DF-SD (Derawar Fort-Saline Desert), MG-RB (Muzaffargarh-River Bank), KL-HS (Khabbeki Lake-Hyper Saline), UL-HS (Ucchali Lake-Hyper Saline), KKL-S (Kalar Kahar Lake-Saline), T-SW (Treemu-Saline Wetland), S-SW (Sahianwala-Saline Wetland), S-HS (Sahianwala-Hyper Saline), PA-HS (Pakka Anna Hyper Saline), PA-RF (Pakka Anna Reclaimed Field) and BG-NS (Botanic Garden-Non Saline)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65696588

Sclerenchyma thickness was consistently high where plants were subjected to 300 mM NaCl, except in the ecotypes from BG-NS, where the maximum sclerenchyma thickness was observed at 100 mM NaCl. With the increase of salinity a reduction of sclerenchyma thickness was observed, but S-SW exhibited a gradual increase of sclerenchyma thickness up to 200 mM NaCl stress, but reduced sclerenchyma thickness at 300 mM NaCl (*Fig. 3*).

The ecotypes of *C. dactylon* from M-RB, KKL-S, T-SW, and S-HS exhibited that bulliform cell area increased as salinity increased while bulliform cell area of DF-SD were described by a third order polynomial or sinusoid (*Fig. 3*). Ecotypes from KL-HS, UL-HS, PA-HS and BG-NS showed increased bulliform cell area at 100 mM NaCl stress, but above the 100 mM NaCl level, bulliform cell area decreased with increase in salinity. Furthermore, ecotypes from S-SW and PA-RF exhibited a quadratic response of bulliform cell area that peaked at 200 mM NaCl and decreased at the maximum experimental salinity level (*Fig. 3*).

Ecotypes from DF-SD and M-RB exhibited Vascular Bundle (VB) area that increased as salinity increased, while a negative linear component described the KL-HS, KKL-S and S-HS VB area in response to salinity. Ecotypes from UL-HS, T-SW, S-SW, PA-RF, and BG-NS exhibited marked induction of VB area at 200 mM NaCl stress, but reduced areas at 300 mM NaCl. Ecotypes from PA-HS exhibiteda quadratic response for VB area to salt stress that peaked at 100 mM NaCl (*Figs. 3, 4*).

Metaxylem cell area decreased in response to salinity, in the ecotypes from T-SW, S-HS and PA-RF, while M-RB and KKL-S exhibited increasing metaxylem area with the increasing salinity. The metaxylem area of ecotypes DF-SD, KL-HS, UL-HS, and BG-NS peaked at 200 mM NaCl stress. The metaxylem area of ecotypes from S-SW and PA-HS peaked at 100 mM NaCl (*Figs. 3, 4*).

Ecotypes from M-RB, KKL-S, T-SW, and PA-HS exhibited higher phloem areas at the highest experimental salinity level (300 mM NaCl). The phloem area of ecotypes from PA-RF and BG-NS peaked at 100 mM NaCl (*Figs. 3, 4).*

Most of the ecotypes of *C. dactylon* showed reduced stomatal density at the 300 mM NaCl level, (*Figs. 3, 5*). Stomatal cell area decreased in response to salinity in ecotypes from DF-SD, M-RB, KL-HS, and PA-HS. S-HS exhibited peak induction of stomatal density at 200 mM NaCl, and T-SW and PA-RF exhibited peak stomatal density at 100 mM NaCl stress (*Figs. 3, 5*).

Trichome length decreased in response to salinity in the ecotypes from M-RB, KL-HS, KKL-S, and T-SW (*Figs. 3, 6*). Trichome density increased in response to salinity in the ecotypes from DF-SD, KL-HS, KKL-S, and T-SW but decreased due to salinity in the ecotypes from M-RB, S-SW, PA-RF and BG-NS (*Figs. 3, 6*).

Redundancy (RDA) ordination

RDA ordination biplot for leaf anatomy

The RDA ordination biplot (*Fig. 7*) showed DF-SD showed the association with BCA at control and with Trichome Length (TRL), Abaxial Stomatal Density (ASD), Vascular Bundle Area (VBA), Trichome Density (TRD), Adaxial Stomatal Area (ADA), Sclerenchymatous Thickness (SCT), Leaf Blade Thickness (LBT), Adaxial Stomatal Density (ADD) and Metaxylem Area (MXA) at minimum salinity level 100 mM NaCl while from M-RB showed the same association up to maximum salinity level 300 mM NaCl and with Phloem area (PHA) at moderate salinity level

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65696588

200 mM. Ecotypes from KL-HS showed association with PHA up to maximum salinity level 300 mM, however from UL-HS showed association with TRL, LBT, SCT and TRD at moderate salinity level 200 mM and with VBA, MXA at maximum salinity level 300 mM. Ecotype from KKL-S showed association with VBA, MXA at 0, 200 mM, with TRL, ASD, VBA, TRD, ADA, SCT, LBT, ADD and MXA at minimum salinity level 100 mM. Ecotype from T-SW showed association with ADA at control (*Fig. 7*).

DOI: http://dx.doi.org/10.15666/aeer/1805_65696588

association with Chlorophyll-a (Chl-a), Chlorophyll-b (Chl-b), Caroteniod (CAR), Total Chlorophyll (Chl-T) and Transpiration rate (*E*) at control while the ecotypes from DF-SD and KL-HS with *gs* at moderate salinity level 200 mM. Ecotypes from M-RB and UL-HS showed no noticeable association along salinity gradient. Ecotypes from KKL-S showed association with *A* at 0 mM NaCl, with *gs* at minimum salinity level 100 mM however from T-SW showed association with *A/E* and *Ci* at control. Ecotypes from S-SW showed association with *A/E* at minimum 100 mM salinity level and with *A* and *Ci* at moderate salinity level 200 mM. However from S-HS showed association with *gs* at control 0 mM NaCl, with *A* and *Ci* at minimum salinity level 100 mM NaCl, with Chl-T, *E*, Chl-a and Chl-b at moderate salinity level 200 mM NaCl while at maximum salinity level 300 mM showed association with *A/E* (*Fig. 8*).

Ecotypes from PA-HS showed association with *A* at control 0 mM NaCl, with Chl-T, *E*, Chl-a and Chl-b at moderate salinity level 200 mM NaCl and with Chl-T, Chl-a Chl-b, CAR, *A, E* and chlorophyll a/b at maximum salinity level 300 mM NaCl, while PA-RF showed association with *A/E* at maximum salinity level 300 mM NaCl, however from BG-NS showed association with *Ci* at control 0 mM NaCl, with *A, Ci* at minimum salinity level 100 mM NaCl (*Fig. 8*).

Discussion

Across the world, increasing soil salinity is a serious threat for the plants (Habib et al., 2016) with respect to modifications in their physiological, biochemical and anatomical attributes. Ecotypes are the species that have long term genetic variations among their populations (Sridevi et al., 2012) and showed structural, functional and geographical variations that leads to genetic variance (Johnson, 2010; Phillips et al., 2015). Morphological, anatomical, physiological and biochemical adaptive markers are of prime importance to study the adaptive mechanism in differentially adapted ecotypes against abiotic and biotic stress (Hameed et al., 2011; Naz et al., 2009). Therefore, ecotypes of *Cynodon dactylon* were collected from various highly saline, moderately saline, marshy, waterlogged and non-saline areas to evaluate adaptation strength and extent of involvement of these adaptations in plant survival.

C. dactylon is also considered as halophytic grass due to strong resistance against salinity (Marcum et al., 2005; Pessarakli, 2015). In view of stresses *"escape"* or *"tolerance"* is the most prevailing phenomenon in adaptation (Sunkar, 2010; Witcombe et al., 2008). Salt tolerant grasses can minimize the detrimental effects of high salinity by showing a series of structural and functional modifications in anatomical and physiological characteristics of plants (Zhou et al., 2015) similar to our findings e.g. as lignification around the vascular region (Alam et al., 2015), increased thickness (succulence) of epidermis, midribs and cortical parenchyma (Vijayan et al., 2011), increased sclerenchyma in the leaves (Noor et al., 2015), reduced leaf area (Monteverdi et al., 2008), greater density of salt secreting glands and hairs on the leaf surface (Farooq et al., 2015), enlarged bulliform cells that help in leaf rolling to avoid water loss (Alvarez et al., 2008), increased stomatal density with decreased stomatal size (Hameed et al., 2013).

Our findings of adaptaive responses get advocacy from the subrized exodermis and endodermis, thick sclerenchymatous tissues around vascular bundle, large mesophyll cells and large cortical aerenchyma cells that are reportedly developed against stress (Noman et al., 2014; Noman et al., 2012; Yang et al., 2011). Tolerance level of *C. dactylon* to environmental stresses varies from highly sensitive to tolerant grass. Increased succulence

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65696588

for water conservation and toxic ion accumulation, excretory structures like micro-hairs for toxic ion exclusion (Colmer and Flowers, 2008), sclerification for desiccation tolerance and minimizing water loss, and wider metaxylem vessels for efficient water and nutrient conduction (Ali et al., 2009; Naz et al., 2014; Noman et al., 2017).

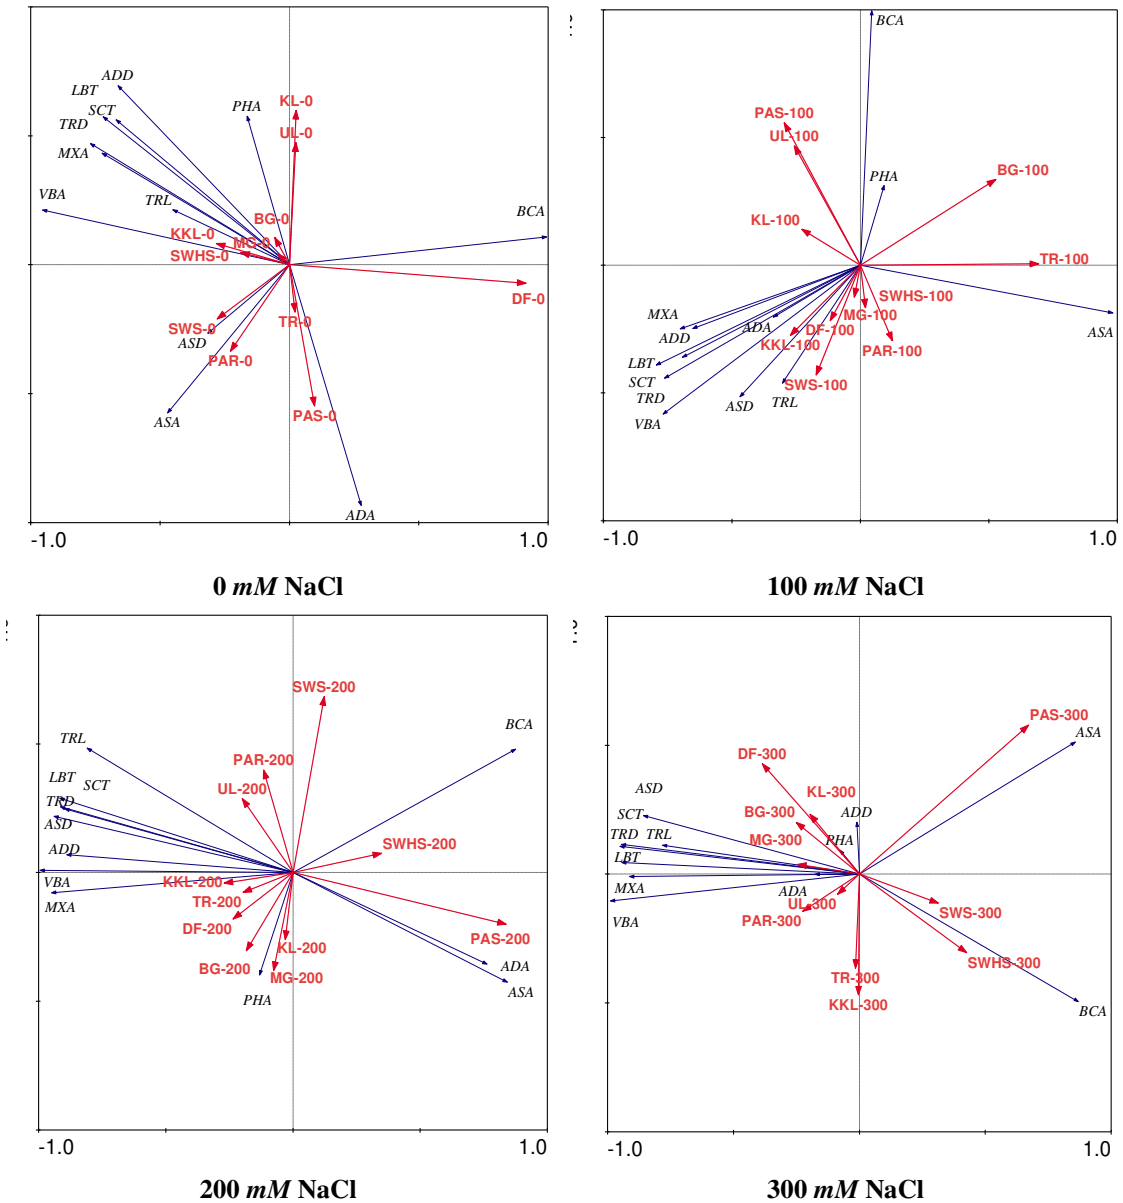

Figure 7. *RDA ordination biplot showing the effect of leaf anatomical characteristics on the ecotypes of Cynodon dactylon from various region of Punjab. DF (Derawar Fort), MG (Muzaffargarh), KL (Khabbeki Lake), UL (Ucchali Lake), KKL (Kalar Kahar Lake), T-SW (Treemu-Saline Wetland), SWS (Sahianwala-Saline Wetland), SWHS (Sahianwala-Hyper Saline), PAS (Pakka Anna Saline), PAR (Pakka Anna Reclaimed) and BG (Botanic Garden). Leaf anatomical characteristics are abbreviated as LBT: Leaf blade thickness, SCT: Sclerenchymatous thickness, BCA: Bulliform cell area, VBA: Vascular bundle area, MXA: Metaxylem area, PHA: Phloem area, TRL: Trichome length, TRD: Trichome density, ASA: Abaxial stomatal area, ASD: Abaxial stomatal density, ADA: Adaxial stomatal area and ADD: Adaxial stomatal density*

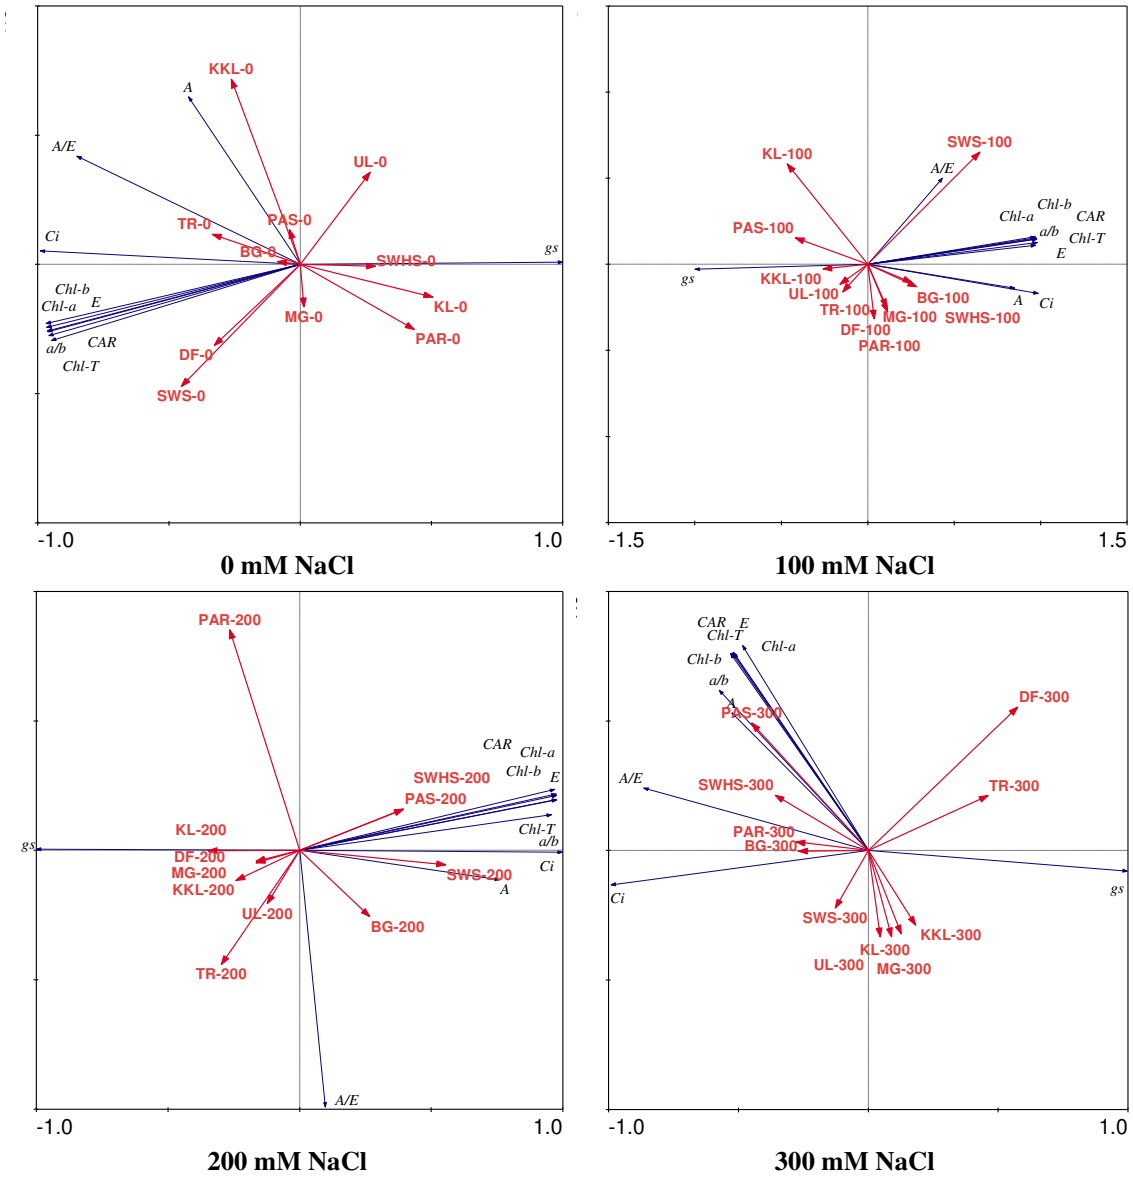

Figure 8. *RDA ordination biplot showing the effect of photosynthetic characteristics on the ecotypes of Cynodon dactylon from various region of Punjab. DF (Derawar Fort), MG (Muzaffargarh), KL (Khabbeki Lake), UL (Ucchali Lake), KKL (Kalar Kahar Lake), T-SW (Treemu-Saline Wetland), SWS (Sahianwala-Saline Wetland), SWHS (Sahianwala-Hyper Saline), PAS (Pakka Anna Saline), PAR (Pakka Anna Reclaimed) and BG (Botanic Garden). Photosynthetic characteristics are abbreviated as: A: Net-CO_2 assimilation rate, E: Transpiration rate, gs: Stomatal conductance, Ci: Sub-stomatal CO_2 concentration, A/E; Water use efficiency, Chl-a, Chlorophyll a, Chl-b, Chlorophyll b, a/b: Chlorophyll ratio a/b, Chl-T: Total Chlorophyll and CAR: Carotenoids*

Leaf blade thickness is a critical adaptation against harsh environment (Hameed et al., 2011). We noticed invariably increased in this characteristic among all ecotypes of *C. dactylon* under salt stress, mainly due to increased sclerification and bulliform cell area. Therefore, our finding is in accordance with the facts that sclerification is the immediate response of plants when exposed to moisture limiting environments. This process provides mechanical strength to soft and delicate tissue avoiding from collapse

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65696588

(Al-maskri et al., 2013; Leroux et al., 2015) and at the same time preventing undue water loss through leaf surface (Toon et al., 2015) and hence important for water conservation.

Additionally, we recorded increasing Metaxylem area with increased along with increased salinity levels, at least in more tolerant ecotypes of *C. dactylon.* This adaptive feature has earlier been reported for different plants facing salt stress, e.g., *Alternanthera bettzickiana* (Younis et al., 2013)*, Juncus* species (Al Hassan et al., 2015) and Cattail (Correa et al., 2015).

Increased density of micro-hairs with increasing salt level may be one of the most effective mechanism for salinity tolerance in this salt excretory halophyte (Hu et al., 2015). A substantial increase in trichome density and length was recorded in relatively more tolerant ecotypes of *C. dactylon,* which is regarded as an important ecological adaptation. The increased density and size of trichomes in this case provide additional benefit to a plant to cope with environmental stresses like drought and salinity. Stomatal area on abaxial leaf invariably increased under salinity in all cases except in ecotype from KKL-S but density decreased on both surfaces. In *C. dactylon,* abaxial leaf surface is directly exposed to sun and in that condition stomatal regulation is very important in controlling transpiration rate.

Photosynthetic parameters were severely affected in all grasses (Alam et al., 2015; Ali et al., 2015) and particularly in ecotypes collected from low and moderate salinities. Photosynthetic parameters, in particular net CO_2 assimilation rate, transpiration rate, water use efficiency decreased in most of ecotypes up to maximum salinity level 300 Mm except T-W. Stomatal conductance was observed higher in most of ecotypes with the increase of salinity except S-SW and some reports (Manuchehri and Salehi, 2015; Noman et al., 2018; Yu et al., 2013) have already mentioned these attributes supportive in halophytic or highly salt tolerant grasses.

Reduction in chlorophyll contents as a result of high salinity is well documented by many researchers (Amareh et al., 2015). However, stability in these parameters (chl a, chl b and carotenoids) in more tolerant ecotypes might have contributed to increased salt tolerance. Stimulated concentration of photosynthetic pigments chl b was observed in most of the ecotypes except UL-HS, KKL-S and S-SW and chlorophyll a and carotenoids showed reduction in most of ecotypes and showed increase Chl a pigment in sensitive ecotypes T-W and BG-NS and carotenoids in MG-RB at 200 mM NaCl indicates the better adaptation of these populations as also reported by (Takahashi and Badger, 2011)

Physiological mechanisms such as repression in transpiration loss, improved water-use efficiency, maintenance of turgor potential, deep root system, upregulation of antioxidants, stomatal regulation, and photosynthetic rate at low water potential, and synthesis of osmolytes/osmoregulation help plants to sustain growth and biomass production under stress condition as reported by Farooq et al. (2012), Khalid et al. (2019), Shafiq et al. (2014) and Zafar et al. (2016).

Conclusion

Cynodon dactylon is a widespread grass that has an excellent potential to inhabit a variety of habitats. Differently adapted ecotypes of this grass are independently evolved during the long evolutionary history and it is confirmed by their specific adaptive mechanism for salinity tolerance under similar controlled environments. The changes in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65696588

structural (Sclerenchyma bulliform cells, trichomes, broad metaxylem) and physiological (repression of transpiration, stability in chlorophyll contents) attributes confirms it's potential to thrive well in different conditions and laid the basis for future investigations. *Cynodon dactylon* being considered as best halophytes and have mechanistic ability to tolerance salinity, it is recommended for farmers to use it as an alternative fodder crop for salt effected areas/land.

EFFECT OF CHITOSAN PRETREATMENT ON SEEDLING GROWTH AND ANTIOXIDANT ENZYME ACTIVITY OF SAFFLOWER (*Carthamus tinctorius* L.) CULTIVARS UNDER SALINE CONDITIONS

GÜRSOY, M.

Guzelyurt Vocational School, Aksaray University, Aksaray, Turkey
e-mail: mehtapgrsoy@gmail.com; phone +90-532-404-4948

(Received 22nd Apr 2020; accepted 29th Jul 2020)

Abstract. Today, salinity has become a major problem in agricultural areas all over the world. However, plants develop a defense mechanism against stress by increasing various antioxidant enzyme activities in order to tolerate salt and other stress factors. In addition to this mechanism, the effects of stress are attempted to be reduced by various applications that increase enzyme activities. One of these applications is chitosan application. In this study, 4 different doses of chitosan pretreatment (0 (control) (Ch1), 0.2% (Ch2), 0.4% (Ch3), 0.6% (Ch4)) were applied to safflower cultivars (Balcı, Linas, Remzibey) for 4 hours under laboratory conditions. For each chitosan application, 50 seeds were germinated under saline conditions (0 (control) (S1), 50 mM (S2), 100 mM (S3), 150 mM (S4)) in petri dish. As a result of the study, it has been determined that chitosan applications provide increases in seedling length, root length, seedling wet weight, root wet weight, germination percentage, total chlorophyll, carotenoid, β-carotene and lycopene parameters. In the study, it was determined that the most effective chitosan application was Ch3 in terms of the properties examined in stress conditions. According to the research results, it was concluded that chitosan can be considered as a natural material that can positively affect in the defense mechanism of plants under stress conditions.
Keywords: *abiotic stress, environmental stress, damage, seed germination, seedling development*

Introduction

High soil salinity is an serious factor that limits agricultural production in many regions of the world (Yamaguchi and Blumwald, 2005). Salt soil conditions are also one of the most important environmental stress factors that damage plants significantly (Bulgari et al., 2019; Jafari and Garmdareh, 2019). In addition, stress factors that plants are exposed to divided into two types abiotic and biotic (Bulgari et al., 2019). Salinity, one of the abiotic stress factors, affects plants in two ways. Firstly it causes a decrease in soil water content through osmotic stress. In this way, the water intake of the plant is restricted. The second is that it causes excessive ion intake. In particular, it increases the uptake of Na^+ and Cl^- ions (Abogadallah, 2010). Various environmental stresses cause oxidative damage in plants, causing damage and even death of the plant's cells (Sharma et al., 2012). A variety of reactive oxygen species (ROS) are usually produced in plants under stress conditions. Plants develop molecular defense systems to avoid the effects of damage caused by ROS and limit ROS formation (Rejeb et al., 2014). To reduce oxidative damage in ROS cells, plants develop a defense system containing antioxidant enzymes as well as reduced glutathione, tocopherol, carotenoids and flavonoids such as non-enzymatic ascorbate (Nú˜nez et al., 2003; Azevedo-Neto et al., 2006).

Although germination of seed is one of the critical stages for seedling development and successful crop production, it is a complex process that is very sensitive to the negative effects of environmental conditions (Almansouri et al., 2001; Fan et al., 2013; Kataria et al., 2017). The negative effects of salt application on seed germination and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65896603

seedling development occur as physiological and biochemical changes such as osmotic stress, ion toxicity and oxidative damage (Yu et al., 2013; Alsaeedi et al., 2017; Fang et al., 2017). In plants, salt tolerance can be increased with some environmental applications as well as genetic mechanisms (Razzaq et al., 2020). Therefore, pretreatment applications to seed stimulate the metabolic processes of germination and increase the performance of the seed against various environmental conditions (Jisha et al., 2013; Kataria et al., 2017).

Recently, with the use of biostimulants, the resistance of plants to abiotic stress conditions has been increased and thus agricultural production and quality increase has been provided (Boehme et al., 2008; Mahdavi et al., 2011; Safikhan et al., 2018).

Biostimulators are defined as substances that stimulate the development of the plant obtained from various organic and inorganic substances and also play an important role in reducing the effects of abiotic stress (Boehme et al., 2008; Mahdavi et al., 2011; Du Jardin, 2015). Biostimulant application is one of the approaches to reduce abiotic stress and increase the yield and quality of the product in most plants (Safikhan et al., 2018). Today, one of the biostimulant applications is chitosan application. It is a natural, non-toxic biopolymer obtained by deacetylation of chitosan chitin (Katiyar et al., 2015; Younes and Rinaudo, 2015). In addition, the Crustacea family of the chitin is an important ingredient in crustaceans (crab, shrimp, crayfish, etc.) (No et al., 2002; Gürsoy et al., 2018). It is also stated by the researchers that the chitin is a natural aminopolysaccharide that is abundant in nature (Ravi Kumar, 2000). In addition to being biologically renewable, chitosan is biodegradable, biocompatible, antigenic and non-toxic, and biofunctional structure, and this polymer and the materials obtained using this polymer have been used in biomedical applications such as wound dressing material and drug delivery systems (Kim et al., 2007; Hosseinnejad and Jafari, 2016; Muxika et al., 2017).

In plants, it has been reported that antimicrobial activity, stimulating plant growth and development, inducing chitinase activity and increasing seed yield in the seed coating (Tay, 1993; Tham, 2001; Vasyukova, 2001; Devlieghere et al., 2004). Plant growth, seed germination, chlorophyll content and ion uptake can be increased with chitosan application (Ahmed et al., 2020).

Safflower (*Carthamus tinctorius* L.) is an annual medicinal and aromatic oilseed crop (Kumar and Kumari, 2005; Moghadam and Mohammadi, 2014; Golkar and Taghizadeh, 2018). In addition, it is an oil plant with flowers in yellow, red, orange, colors, with and without thorns, resistant to drought, with an average oil rate of 30-50% (Gürsoy, 2019).

In this study, it was aimed to determine the effect of chitosan pretreatment on the development of safflower cultivars, photosynthetic activity and antioxidant enzyme activities in saline conditions.

Materials and methods

Research material and growth conditions

Safflower cultivars (Balci, Linas, Remzibey) were obtained from the Central Field Crops Research Institute, Ankara, Turkey. The research was carried out at the Aksaray University Scientific and Technological Research Laboratory (ASÜBTAM). Before commencing the experiment, seeds of cultivars were kept in 5% sodium hypochlorite solution for 5 minutes for surface sterilization. Then washed with pure water and subjected to 4 hours priming with different concentrations of chitosan (Ch) solutions. Chitosan (Sigma-Aldrich, medium molecular weight, at 85% -acetylated, viscosity 270 cP, CAS: 9012-76-4) after dissolving in 0.1% acetic acid of commercially available

DOI: http://dx.doi.org/10.15666/aeer/1805_65896603

chitosan [0 (control) (Ch1), 0.2% (Ch2), 0.4% (Ch3), 0.6% (Ch4)]. For each Ch dose, 50 seeds were placed in sterile petri dishes on Whatman No:1 blotting papers and 10 mL of different doses of salt (0 (control) (S1), 50 mM (S2), 100mM (S3), 150mM (S4)) concentrations were added from solutions containing NaCl (Merck). Only water was added to the control petri dish. In order to prevent evaporation the petri dishes are wrapped with parafilm. The petri dishes were left to germinate at 24 ± 1^0C. The research randomized plots experimental desing were made with 3 replication according to the trial pattern. Measurements and observations were made on the 14th day of the study.

Germination percentage (%)

Germination percentage was calculated using the formula below.

$$\text{Germination\%} = (\text{number of germinated seeds} / \text{total number of seeds}) \times 100 \quad \text{(Eq.1)}$$

(Siddiqi et al., 2007)

Chlorophyll (mg/g)

The young leaf samples (0.25 g) from each safflower cultivar were filtered after homogenizing in 80% acetone (Merck) and the extracts were filtered with 25 ml with acetone. These samples were read at 663 nm and 645 nm wavelength (Beckman coulter DU 730 Life Sciences UV / VIS Spectrophotometer) followed by calculation of chlorophyll using the formula given below (Lichtenthaler, 1983; Amira and Qados, 2011; Kabay and Şensoy, 2016). Before each reading, the device was reset using blind reading.

$$\text{Chlorophyll a (mg/g)} = (12.7*663\text{ nm})-(2.69*645\text{ nm})*V/W*10000 \quad \text{(Eq.2)}$$

$$\text{Chlorophyll a (mg/g)} = (22.91*645\text{ nm})-(4.68*663\text{ nm})*V/W*10000 \quad \text{(Eq.3)}$$

$$\text{Total Chlorophyll} = \text{Chlorophyll a} + \text{Chlorophyll b} \quad \text{(Eq.4)}$$

Carotenoid (mg/g)

The carotenoid amount was determined according to the Jaspars formula by reading the extract used in determining the chlorophyll amount at 450 nm wavelength (Beckman Coulter DU 730 Life Sciences UV / VIS Spectrophotometer) (Turfan, 2017).

$$\text{Carotenoid} = (4.07\times A450-(0.0435\times\text{Chlorophyll a}+0.367\times\text{Chlorophyll b}) \quad \text{(Eq.5)}$$

β-Carotene (mg/g)

100 mg sample was homogenized for 1 minute in a mixture of 10 ml acetone-hexane (92:3) and filtered. The absorbance of the filtrate at 453, 505 and 663 nm was recorded. It is preferred in the calculation of carotene amount. (Turfan, 2017).

$$\text{mg β-Carotene/100 mg} = 0.0458 \text{ x } A663+0.372 \text{ x } A505-0.0806 \text{ x } A453 \quad \text{(Eq.6)}$$

Lycopene (mg/g)

100 mg sample was homogenized for 1 minute in a mixture of 10 ml acetone-hexane (92:3) and filtered. The absorbance at 453, 505 and 663 nm was recorded in the filtered

DOI: http://dx.doi.org/10.15666/aeer/1805_65896603

extract. The following formula was used to determine the amount of lycopene (Turfan, 2017).

$$\text{mg Lycopene/100 mg}=0.216xA663–0.304xA505+0.452xA453 \quad \text{(Eq.7)}$$

Statistical analysis

The experimental data obtained at the end of the research, was subjected to analysis of variance using MSTAT-C computer software. Duncan test was applied to determine the significance levels of the differences between means of applications.

Results

A statistically significant difference was determined at the level of $P < 0.01$ in Cultivars × Salt doses× Chitosan doses triple interaction (*Table 1*) in all the features studied.

When the seedling length feature is examined (*Table 2*), the longest seedling length was obtained from Balcı variety in S1 Ch3 application as 10.00 cm. The minimum seedling length was obtained in S4 Ch4 application and Balcı variety. Generally, the longest seedling length in all cultivars has been obtained in Ch3 application, and it is determined that chitosan is effective in eliminating the harmful effects of salt while increasing the salt doses. Chitosan application seems to inhibit the effects of salt stress, causing the seedling to grow higher. However, chitosan application had different effects on varieties. For example, in S1 and S4 applications in Balcı cultivar, it is seen that the seedling height is longest in Ch3. The same is true for the Linas variety. In Remzibey cultivar, Ch3 was found to be the longest seedling length only in S1 application, and in all other salt doses, the longest seedling length was detected in Ch1 application. In the Remzibey cultivar, a positive effect of chitosan applications against salt doses in terms of seedling length could not be determined. Cultivars × S doses × Chitosan doses interaction caused significant difference in seedling length feature at $p<0.01$ level. In this respect, when the study results were examined, it was determined that the harmful effects of salt doses were inhibited by interaction with chitosan. Similarly, salt doses interacted with varieties and showed different reactions in each variety.

Table 2. *Average values the effect of chitosan doses applied to safflower cultivars on saline length (cm) under saline conditions*

According to the Duncan test dissimilar letters in the column show different groups

In terms of root length (*Table 3*), the longest root length (3.80 cm) was detected in Remzibey variety and S1 Ch1 application. The shortest root length was determined as 2.59 cm in Remzibey cultivar and S4 Ch4 application. It is seen that root length increases with increasing Ch doses in all cultivars. However, this increase didn't occur only in the S1 dose, and it is the dose that does not apply salt since the S1 dose is a control application. In other words, with the application of salt, the effectiveness of chitosan has been revealed and it has been effective in lengthening the root length by inhibiting the negative effects of salt. Although this effect was determined in all varieties, the most effective chitosan application was determined as Ch3. Cultivars × S doses × Chitosan doses were determined statistically significant differences in root length characteristics in terms of $p<0.01$. With this interaction in all cultivars, root length feature was affected and increased due to salt doses and chitosan doses.

*According to the Duncan test dissimilar letters in the column show different groups

Seedling wet weight (*Table 4*) was determined as the most seedling wet weight of 0.45 g in Linas cultivar in S1 Ch3 application. The minimum seedling wet weight was determined as 0.28 g in S4 Ch1 application, that is, when S doses are highest but Ch dose is control, ie 0%. In all other applications, seedling wet weight increased with Ch application. Cultivars × S doses × Chitosan doses were determined statistically significant differences in seedling wet weight in terms of interaction with $p<0.01$. All cultivars were significantly affected by S and Ch doses. While the application of Ch3 in S2, S3 and S4 in the Balcı cultivar causes the formation of seedling wet weight the most, Ch3 application in all salt doses in Linas and in S2 and S3 in Remzibey were effective in obtaining the seedling wet weight the most. In S1 and S4, the dose of Ch3 was more effective.

In the root wet weight feature (*Table 5*), the maximum root wet weight was determined in Remzibey cultivar in Ch3 application in S1. Although S1 was a control dose, Ch affected root caused an increase in wet weight. However, in other S doses, the root wet weight increased with the increase of Ch. In terms of root wet weight, the most effective Ch doses were Ch2 and Ch3. Cultivars × S doses × Chitosan doses interaction showed statistically significant difference at $p<0.01$ in terms of root wet weight.

Table 5. *Average values of the effect of chitosan doses applied to safflower varieties under saline conditions on root wet weight (g)*

LSD%1	0.02351							

* According to the Duncan test dissimilar letters in the column show different groups

In germination percentage (*Table 6*), the highest germination rate was determined as 99.97% in Balcı cultivar in S2 Ch1 application. The least germination was detected in Linas cultivar and Ch4 application with 95.73%. Cultivars × S doses × Chitosan doses interaction showed statistically significant difference in $p<0.01$ level in terms of germination percentage. In all cultivars, the germination rate decreased with increasing salt doses. However, an increase in germination rate was determined in all cultivars and all S doses with Ch applications. For example, in the Remzibey cultivar, it is seen that the germination percentage is highest with the application of Ch3 at the dose of S4. Similarly, the most germination was determined in S3 and S4 in Ch3 in Balcı cultivar.

In terms of total chlorophyll (*Table 7*) Cultivars × S doses × Chitosan doses interaction showed statistically significant difference at $p<0.01$ level. Differences between varieties were determined with chitosan applications in applied salt doses. Although chlorophyll amount is expected to decrease with increasing salt doses, it has been determined that it increases with chitosan applications. Chitosan had a positive effect by eliminating the negative effect of salt by playing an encouraging role. The highest chlorophyll content was obtained in S1 and Ch1 and the lowest chlorophyll was determined in S4 Ch4 as 1.04 mg g^{-1}. However, the effects of S and Ch doses on varieties were in different ways. While S3, S3 and S4 increase Ch3 chlorophyll in the Balcı cultivar, it is determined that the application of Ch2 in S1 and S2 and Ch4 in S3 and S4 are more effective in linas cultivar. In Remzibey variety cultivar, Ch3 was determined as the most effective application dose in S2, S3 and S4.

When the amount of carotenoid is examined (*Table 8*), the most carotenoid amount is determined as S4 Ch3 as 4.09 mg g^{-1}. The minimum amount of carotenoids was determined as 1.59 mg g^{-1} in S1 Ch1. It was determined that as the S doses increased, the amount of carotenoids increased in all cultivars. However, it is seen that this increase is higher in Ch3. Cultivars × S doses × Chitosan doses interaction showed statistically significant difference at $p<0.01$ in terms of carotenoid amount. In all varieties, especially in S2, S3 and S4, the carotenoid decreased slightly in Ch2, but increased in Ch3.

When examined in terms of β-carotene (*Table 9*), the most β-carotene was found as S4 and Ch3 application in Balcı cultivar as 0.86 mg g^{-1}. It was determined as at least β-carotene 0.24 mg g^{-1} FW in S1 Ch1 application and Balcı variety. However, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65896603

interaction of Cultivars × S doses × Chitosan doses showed a statistically significant difference in $p<0.01$ level in terms of β-carotene. In terms of β-carotene, the effects of S and Ch doses on varieties were determined, and the highest β-carotene amount in Ch3 was determined in all S doses. Especially in S3, which has the highest salt dosage, the highest β-carotene was determined in all cultivars.

When the study results are examined in terms of lycopene (*Table 10*), the most lycopene was determined as 0.81 mg g^{-1} in Linas and Remzibey varieties in S4 and Ch3. The least lycopene was determined as 0.44 mg g^{-1} in S2 Ch1. Especially in S3 and S4 doses in which salt doses increased, the highest lycopene in Ch3 was determined. As in carotene, S4, which has a high salt dose in lycopene, has the highest lycopene content in all varieties in Ch3 application.

Discussion

In this study, in which different doses of salt were applied with different doses of chitosan pretreatment to the safflower varieties, although the results were evaluated, there was a decrease in some morphological features due to the increase of salt doses, and with the application of chitosan, the characteristics of seedling length, root length, root wet weight, seedling wet weight and germination rate an increase was observed. However, there are increases in biochemical properties with the effect of chitosan application in stress conditions. The most effective chitosan dose was determined as Ch3 in all the properties studied. Ma et al. (2012) reported that application of 0.0625% oligochitosan to the nutrient solution in which wheat seeds were grown reduces the negative effect of salt stress. Jabeen and Ahmad (2013), applied chitosan to sunflower and safflower varieties under salty conditions. As a result of the study, they reported that low concentration of chitosan application caused increase in germination parameters of both cultivars. In the study conducted by Sheikha and Al-Malki (2011), they reported that chitosan applications had an effect on the plant's growth parameters, such as seedling and root height, wet and dry weight. Al-Tawaha et al. (2018), 81.94 cm in plant height control application, 84.06 cm in 30 mg/L chitosan application, 84.38 cm in 60 mg/L chitosan application, 84.81 in 60 mg/L chitosan application, they reported that they had determined in cm. Salt stress affects chlorophyll metabolism and causes a significant decrease in chlorophyll production (Qin et al., 2019). Chlorophyll content is widely used in plants as an indicator of abiotic stress tolerance. In addition, chlorophyll decreases in plants exposed to stresses such as salinity, as a result of which growth is delayed (Safikhan et al., 2018). In recent studies, it has been reported by researchers that chitosan increases chlorophyll content in soybean and peanuts (Dzung, 2005). Yahyaabadi et al. (2016), applied chitosan to fenugreek plants under salt stress. As a result of the study, they reported that the application was effective in promoting plant growth by reducing salt stress on the water content of the leaf and photosynthetic pigment parameters. Turfan (2017), applied various abiotic stresses (salt, heavy metal, drought and lime) to the spinach plant. As a result of the study, it was reported that chlorophyll a, b, total chlorophyll and carotenoid,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_65896603

β-carotene and lycopene content increased in drought and lime stress applications. Stahl and Sies (2003), reported that carotenoids are pigments that play a very important role in the protection of plants against photooxidative processes in plants and are antioxidants that play an extremely active role in eliminating the harmful effects of free oxygen radicals. In addition to having antioxidant capacity, carotenoids also play a very important role in reacting to various stress conditions (Boba et al., 2011). In plants under stress, the amount of photosynthetic pigment consisting of chlorophyll a, chlorophyll b, total chlorophyll and carotenoid varies depending on factors such as species, type of stress, duration of stress, the period of the plant in the life cycle, and the intensity of stress (Turfan, 2017). Linic et al. (2019), it is suggested that carotenoids, which are specific metabolites, can play a positive role as natural substances in stress management in tolerant species. Rahman et al. (2018), reported that the application of chitosan to the strawberry plant in the form of a spray causes an increase in the carotenoid content of the plant. ß-carotene is an organic red-orange colored pigment that is abundant in plants (Pop et al., 2019). Falcinelli et al. (2017), reported that appropriate doses of salt cause increased phenolic compounds in rapeseed. He et al. (2020), reported that NaCl and $CaCl_2$ application can be used as a strategy that will increase the antioxidant activity through the accumulation of carotenoids as a result of their study in corn plant. In this study, it was determined that pre-application of chitosan to the seeds of safflower varieties against salt stress promotes the strengthening of the defense system by causing the enzyme activities of the varieties to increase.

Conclusion

In this study, besides the negative effects of salt doses, the positive effects of chitosan application, safflower varieties were affected at different levels. The most advantageous results were obtained from the Remzibey variety in terms of morphological (seedling length, root length, seedling wet weight, root wet weight, germination percentage) and biochemical (chlorophyll, carotenoid, β-carotene and lycopene) parameters. In addition, it has been determined that chitosan plays a role in promoting the increase of enzyme activities, which is the defense mechanism of plants under stress conditions. In this study, the third dose of chitosan (Ch3) caused the most advantageous results. As a result of the study, it was concluded that chitosan can be evaluated as a natural material that can be effective in the defense mechanism of plants under stress conditions. It has been concluded that with the pretreatment of chitosan in regions with salty soil conditions in the world, the germination and seedling development of plants can be increased accordingly it was concluded that yield and quality can be increased. However, applications should be made in other plants and under various stress conditions and their results should be evaluated.

Abstract. The analysis of spatiotemporal characteristics for groundwater depth can provide a theoretical basis for comprehensive management of groundwater and sustainable development of ecology and environment. The paper investigated the changing patterns of groundwater depth, and further explored the linear and nonlinear relationships between groundwater depth and four potential influencing factors using grey relational analysis and wavelet coherence during 2000-2017. The multiple linear regression and Random Forest (RF) models were proposed to predict the groundwater depth. Taking Xingtai city on the North China Plain as an example, the results indicate that: (1) The groundwater depth in a shallow aquifer has deepened significantly after 2006, and decreased from northwest to southeast. A clear upward trend was detected in the southeast region of the study area. (2) The change of groundwater depth is related to the consumption during agricultural irrigation period and the supply of heavy rainfall during flood season, and the deepest groundwater depth was detected in June. (3) The cross-correlation analysis demonstrated that main influencing factors of groundwater depth are precipitation and temperature. (4) The comparison between actual value and prediction value indicated that the RF model has better accuracy in predicting the groundwater depth than the multiple linear regression model.
Keywords: *groundwater comprehensive treatment, spatial and temporal variability, non-parametric Mann-Kendall test, grey relational analysis, wavelet coherence, random forest model*

Introduction

Groundwater is one of important sources of water for humans, especially in the arid and semi-arid areas (e.g., Algeria, Australia, China, Egypt, and Western United States) where water resources are insufficient, or the surface water is heavily polluted, due to serious ecological and environmental issues. Water for human life, agricultural irrigation and industrial activities mainly depends on the exploitation of groundwater resources (Alley et al., 2002; Oki et al., 2006; Wada et al., 2012). Globally, the groundwater accounts for 29.9% of all global freshwater resources (Shiklomanov, 2000; Li and Qian, 2018) and the shortages of water resource have become one of the most important challenges to humankind (Robertson and Sharp, 2013; Wang et al., 2016). Water resources problems are common throughout China (Jiang, 2009), especially, the North China Plain (NCP), which has serious groundwater problems including the overexploitation of groundwater or the groundwater pollution. The NCP is the biggest plain of China, and its aquifer system extends about 122,000 km^2, supporting over 11% of China's population and 14% of arable land (Pang et al., 2020). The groundwater has provided more than 70% of the NCP's total water supply, which can support

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66056622

agricultural irrigation, daily life, and economic development (Liu et al., 2011). However, the overexploitation of groundwater has accelerated since 1970s, and NCP has gradually become one of the most groundwater over-pumped zones around the world, with a long belt along the Beijing-Shijiazhuang-Xingtai area (Shah et al., 2003; Zhang and Li, 2013). The groundwater depth has declined more than 10-60 m in 40% of the entire NCP (Zheng et al., 2010). To avoid the problem of groundwater overexploitation, the government has already taken action to reduce groundwater consumption and adopt measures to adjust agricultural planting structure. For more scientific and effective management, it is important to analyze the changing patterns and causes of groundwater depth. The spatiotemporal evolution of groundwater systems is affected by many factors, including both natural and man-made factors, such as meteorological and hydrological conditions, geological environment, economic development, industrialization, and urbanization. Various measures have been taken to change the balance between groundwater consumption and supply. The analysis of the changes and causes of groundwater depth under the multiple influencing factors are thus of great significance for sustainable development of groundwater resources.

Many previous studies have focused on the changes of groundwater depth, to explore the ecological environment of groundwater resources, and to find a sustainable development path (Ebraheem et al., 2004). Generally, the studies on the spatial-temporal characteristics of groundwater depth have mainly combined with mathematical models. E.g., Manap et al. (2014) drew a map of groundwater potential in the Langat Basin, Malaysia based on probabilistic-based frequency ratio model (FR), and analyzed the spatial relationships between groundwater depth and various hydrological elements. The results indicated that FR model is a high precision way to validate the groundwater potential map (Manap et al., 2014). Naghibi et al. (2016) used the boosted regression tree (BRT), classification and regression tree (CART), and Random Forest (RF) models in conjunction with GIS to draw a groundwater potential mapping, and evaluated the simulation accuracy of the three models. The results showed that the BRT model produced the best prediction value in predicting locations of springs (Naghibi et al., 2016). With the development of urbanization, the impact of climate change and human life on groundwater continues to aggravate. Research scholars focus on the analysis of impact on groundwater changes from both natural factors and human activities. Green et al. (2011) proposed exploring the relationship between groundwater systems and climate change from two aspects: groundwater quality and groundwater volume (Green et al., 2011). Vidal et al. (2000) analyzed the spatiotemporal characteristics of groundwater chemical composition from the perspective of groundwater quality (Vidal et al., 2000). In addition, the groundwater system environment is complicated, and analyzing the potential influencing factors of groundwater is an important research direction. The RF model has been proved to be useful in discovering potential influence factors and predicting target value, and it can improve the prediction accuracy without a significant increased calculation. Iverson et al. (2008) used RF model to draw groundwater potential maps (GPMs), proving that the model is an effective method for drawing GPMs (Iverson et al., 2008).

The objectives of this study include: (1) To analyze the characteristics of groundwater depth from aspects of inter-annual, intra-annual, depth variation and spatial distribution. The non-parametric Mann-Kendall test is used to analyze the temporal and spatial trends and the catastrophe point of groundwater depth. (2) To further reveal the physical mechanism behind the changes of groundwater depth and its

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66056622

influencing factors, this paper explored the spatiotemporal characteristics of groundwater depth and relationships between several main influencing factors. The grey relational analysis and wavelet coherence are used to analyze the main influencing factors and their potential relationships. The multiple linear regression and RF models are used to predict the groundwater depth using the influencing factors as predictors, and the accuracy of two models are further compared. (3) To investigate the characteristics and causes of groundwater depth change, taking Xingtai city on the North China Plain as an example, which should be of great significance to coordinate the development of groundwater resources and maintain the stability of the water ecology.

Material and methods

Study area

The NCP is located in the middle part of the North China, and it refers to the region bordered to the north of the Yanshan Mountains, and west of the Taihang Mountains, to the south by the Yellow River, and to the northeast by the Bohai Gulf (Zhang et al., 2003). The NCP includes all the plains of the northern parts of Shandong and Henan Provinces, Beijing Municipality, Tianjin Municipality and Hebei province. Xingtai city is located at the central and southern part of Hebei province, and the surface water resources are scarce and groundwater is serious overexploited (Li et al., 2005; Sun et al., 2010). *Figure 1* shows the locations of the study area and spatial distribution of the groundwater monitoring stations.

Figure 1. *Study area and locations of groundwater monitoring stations in the shallow aquifer of Xingtai city, China*

Xingtai city is located between the longitude of 113°52′ - 115°49′ E and the latitude of 36°50′ - 37°47′ N. It has a total of 18 counties and cities with a total area of 12,456 km^2, of which the plain area is 8911 km^2 and the mountain area is 3545 km^2. Xingtai city has a temperate continental monsoon climate. The average temperature is about 13.1℃, and the precipitation is about 470 mm per year which rainfall is concentrated in summer. The types of groundwater mainly include confined water and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66056622

phreatic water. The confined water is generally below 100 m and is hard to mine. The groundwater in the shallow aquifer is the main source of agricultural and domestic water. This study mainly focuses on the groundwater in the shallow aquifer. Xingtai city is located in the transition zone from the mountain area to the plain area. The shallow groundwater monitoring stations are distributed in the eastern plain, including the water resources area of Luxi Plain, Heilonggang District, and Luxi District.

Data collection

The groundwater depth data were obtained from the Hydrological and Water Resources Survey Bureau of Xingtai city, Hebei province. The groundwater depth data from 41 monitoring stations in the plain area of Xingtai city during 2000-2017 were obtained to analyze the groundwater depth characteristics of the shallow aquifer. The Shapefile of the study area was downloaded from the Global Aviation Data Management (GADM) at https://gadm.org/download_country_v3.html to analyze the spatial distribution of groundwater depth using ArcGIS. The nature factors that might affect the groundwater depth such as precipitation, temperature, and evapotranspiration (ET) data from nine counties were used in the study. These data are obtained from Xingtai city meteorological bureau. The Gross Domestic Product (GDP) of Xingtai city was selected as the artificial factor affecting the depth of groundwater, which collected from the statistical yearbook of Xingtai city for the period of 2000-2017.

Research methodology

Non-parametric Mann-Kendall test

The trends of groundwater depth for 41 monitoring stations were analyzed using the non-parametric Mann-Kendall test method from 2000 to 2017. The Kendall's *S* is calculated using *Equation 1*.

$$S = \sum_{k=1}^{n-1} \sum_{j=k+1}^{n} \mathrm{sgn}(x_j - x_k) \qquad \mathrm{sgn}(x_j - x_k) = \begin{cases} 1, & if\,(x_j - x_k) > 0 \\ 0, & if\,(x_j - x_k) = 0 \\ -1, & if\,(x_j - x_k) < 0 \end{cases} \quad \text{(Eq.1)}$$

where *n* is the length of *X*, in this experiment, *n=18*.

The standardized *Z* statistic is provided in *Equation 2* (Shadmani et al., 2012; Jiang et al., 2015; Jiang et al.,2020).

$$Z = \begin{cases} \dfrac{S-1}{\sqrt{Var(S)}}, & if \quad S > 0 \\ 0, & if \quad S = 0 \\ \dfrac{S+1}{\sqrt{Var(S)}}, & if \quad S < 0 \end{cases} \quad \text{(Eq.2)}$$

The formula is normal distribution. *Var(S)* is the variance of statistic *S*. The positive values of *Z* indicate increasing trends of groundwater depth, negative values for decreasing trends, and *Z=0* is stationary. The null-hypothesis at α significance level

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66056622

will be rejected if $|Z| > Z_{1-\alpha/2}$, indicating statistically significant trends. Two significance levels of 10% and 5% are used in this paper to provide trends of groundwater depth, which corresponding the $|Z|$ is greater than 1.64 and 1.96.

Wavelet coherence

The wavelet analysis is used to reveal the nonlinear relationship between groundwater depth and its influencing factors. The wavelet coherence (WTC) is to detect regions with significant coherence (Jiang et al., 2018; Jiang et al., 2019b; Yan et al., 2020). The wavelet defines two time series X_n and Y_n as $W^{XY} = W^X W^{Y*}$, where $*$ is complex conjugate. The power spectrum P_k^X and P_k^Y of X_n and Y_n are defined as *Equation 3*.

$$D(\frac{\left|W_n^X(s)W_n^{Y*}(s)\right|}{\sigma X \sigma Y} < p) = \frac{Z_v(p)}{v}\sqrt{P_k^X P_k^Y} \quad \text{(Eq.3)}$$

where $Z_v(P)$ is the confidence degree of *P*, which is the square root of the wavelet spectrum.

The phase angle of the wavelet coherence is defined as *Equation 4*.

$$a_m = \arg(X, Y) = \arg\left[\sum_{i=1}^{n}\cos(a_i), \sum_{i=1}^{n}\sin(a_i)\right] \quad \text{(Eq.4)}$$

The standard deviation of the wavelet phase angle is defined as *Equation 5*.

$$s = \sqrt{-2\ln(R/n)} = \sqrt{-2\ln(\sqrt{X^2+Y^2}/n)} \quad \text{(Eq.5)}$$

The WTC $R_n^2(S)$ is the square of the of X_n and Y_n, and $R_n^2(S) \in [0,1]$, normalized by the smoothed wavelet power, where $[\cdot]$ smooth the wavelet spectrum in different time and scale, calculated using *Equation 6* (Jiang et al., 2014).

$$R_n^2(s) = \frac{\left|S\left[s^{-1}W_n^{XY}(s)\right]\right|^2}{S\left[s^{-1}\left|W_n^X(s)\right|^2\right] \bullet S\left[s^{-1}\left|W_n^Y(s)\right|^2\right]} \quad \text{(Eq.6)}$$

where $W_n^X(s)$ and $W_n^Y(s)$ are the wavelet transform of X_n and Y_n. The statistical significance level of the WTC is estimated using Monte Carlo methods. The smoothing operator S of $W_n^{XY}(s)$ in numerator and wavelet power spectrum (WPS) in denominator is given in *Equation 7* (Jevrejeva et al., 2003; Jiang et al., 2019a).

$$S(W) = S_{scale}\{S_{time}[W_n(s)]\} \quad \text{(Eq.7)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66056622

where S_{scale} and S_{time} are denoted smoothing along the wavelet scale axis and in time. S_{scale} and S_{time} are defined as *Equation 8* and *Equation 9*.

$$S_{scale}(W)\Big|_s = \left(W_n(s) * c_1 \frac{-t^2}{2s^2}\right)\Big|_s \quad \text{(Eq.8)}$$

$$S_{time}(W)\Big|_n = \left(W_n(s) * c_2 \Pi(0.6s)\right)\Big|_n \quad \text{(Eq.9)}$$

where c_1 and c_2 are the normalized constants, Π is the rectangle function, and 0.6 is the scale de-correlation length for the Morlet wavelet.

Grey relational analysis

The grey relational analysis is used to analyze the degree of correlation between the influencing factors and groundwater depth, and to determine the main factors. The main evaluation model is determined in *Equation 10*.

$$R = Y \times W \quad \text{(Eq.10)}$$

where R is the comprehensive evaluation result vector of indicators, Y is the evaluation matrix of indicators, and W is the weight vector of indicators. The influencing factors selected in this study are rainfall, temperature, evapotranspiration, and GDP. The target value vector is determined in *Equation 11*.

$$F = \left[x_1^i, x_2^i, x_3^i, x_4^i\right] \quad \text{(Eq.11)}$$

where x_k^i is the original value of the index k in year i, and $(i = 1,2,\cdots 18), (k = 1,2,\cdots,4)$.

The physical meanings of the indicators are different, so the dimensions of the data are not the same. It is not easy to directly compare them, and it's necessary to perform the dimensionless processing of the data. The *Equation 12* is used for indicator normalization.

$$C_k^i = \frac{x_k^i - x_{k1}}{x_{k2} - x_k^i} \quad \text{(Eq.12)}$$

where x_{k1} is the minimum value of the k index, and x_{k2} is the maximum value of the k index.

The comprehensive evaluation is calculated by the correlation coefficient between each comparison column and the corresponding element in the reference column, which is determined as *Equation 13*.

$$\xi_i(k) = \frac{\min\limits_i \min\limits_k \left|C_k^* - C_k^i\right| + \rho \max\limits_i \max\limits_k \left|C_k^* - C_k^i\right|}{\left|C_k^* - C_k^i\right| + \rho \max\limits_i \max\limits_k \left|C_k^* - C_k^i\right|} \quad \text{(Eq.13)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66056622

where ρ is the resolution coefficient, and $0<\rho<1$. Normally, $\rho=0.5$.

The correlation degree refers to the average value of the correlation coefficient between each influencing element and the corresponding element in the reference column, which is determined as *Equation 14*.

$$r_i = \frac{1}{m}\sum_{k=1}^{m}\xi_i\ (k) \qquad \text{(Eq.14)}$$

According to r_i, factors related to the reference sequence are obtained. A larger r_i indicates that the factor is more closely related to the dependent variable.

Random forest (RF) model

The statistical model and artificial intelligence model are two common types of predictive models (Breiman et al., 2010). The statistical models take a long time to analyze the data of long-term series, and it is difficult to accurately predict the trend of the dependent variable. The artificial intelligence model has strong fitting ability and high intensive reading, so the random forest model is used to predict the groundwater depth in this study. Breiman et al. (2001) proposed the random forest model based on the regression tree model, which is widely used to explain the effect of multivariate on the dependent variable and to predict the dependent variable. The principle of RF model is to randomize the use of variables (columns) and data (rows), so that the classification trees can be generated, which can significantly improve the prediction accuracy (Van et al., 2014).

There are two key indicators in the RF model including the average reduction of standardity and Gini coefficient (Hong et al., 2017), indicating the number of trees (ntree) and the number of variables (mtry). The ntree changes according to dataset size, for datasets that are small, 50 trees may suffice. However, large datasets might require 100 or more trees. The ntree is often set to 100 in experiments (Bahareh et al., 2019). In this experiment, we randomly selected 70% of the dataset to calibrate the RF model. The remainder (30%) was used for accuracy testing. Variable importance is obtained from *Equation 15*.

$$VI_{mp}\left(Y_j\right) = \frac{1}{N}\sum_t errOOB_t^j - errOOB_t \qquad \text{(Eq.15)}$$

In *Equation 15*, N is the total number of trees. The function $VI_{mp}(Y_j)$ indicates the importance of the variable. The term $errOOB_t$ is the prediction error when all factors are considered, whereas $errOOB_t^j$ is the error after removing the j variable.

The RF model determines the importance of each variable based on the impact of the overall error on the model. By fitting the correlation between variables, it can be applied to different types of variables and missing values (Pourghasemi et al., 2013). The RF model can avoid over fitting and bias due to variable diversity (Rahmati et al., 2016). The Python is used for programming. The groundwater depth is used as independent variable, and the evolution factors such as precipitation, temperature, evapotranspiration, and GDP that affect the depth of groundwater are used as independent variables, to predict the groundwater depth for the period of 2000-2017.

Results and discussion

Spatial and temporal variability of groundwater depth

Temporal distribution of interannual variation of groundwater depth

Figure 2 shows the relationship between groundwater depth and precipitation in Xingtai city from 2000 to 2017, based on the average groundwater depth and precipitation data monitored at the observation wells in the study area. It can be seen that the fluctuation of groundwater depth is generally consistent with the change of annual precipitation, indicating that precipitation is one of the influencing factors of groundwater depth. From the trend line, it can be seen that the groundwater depth in Xingtai city has deepened, and the Person's correlation coefficient is 0.95 showed that the changes were statistically significant. The groundwater depth has dropped 5.56 m from 16.75 m in 2000 to 22.31 m in 2017. The decrease rate of groundwater depth is 0.7 m/a, and the descending rate is relatively large. The groundwater depth has been in a continuous downward trend from 2003 to 2012. The depth has slightly rebounded from 2015 to 2017, mainly because Hebei province unveiled effective engineering and non-engineering measures for groundwater overexploitation control in 2014.

The uneven distribution of water resources in Xingtai city, and the conditions of the groundwater depth also varied in counties. According to the counties of each monitoring station, the annual average groundwater depth in each county is calculated from 2000 to 2017, as shown in *Figure 3*. The groundwater depth in Heilonggang Plain including Julu county, Guangzong county, Nangong county and Wei county, is relatively shallow and the variations are within 5 m from 2000 to 2017. However, the depth is deep and changes more than 10m in the Luxi Plain including Nanhe, Longyao and Ren counties. The Longyao county has the maximum change of groundwater depth, and it has declined 1.97 m/yr.

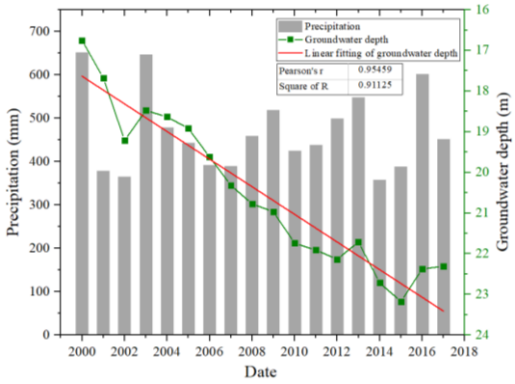

Figure 2. *Average groundwater depth and precipitation*

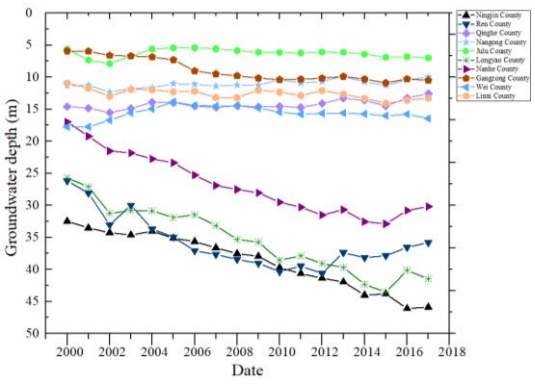

Figure 3. *Groundwater depth of counties*

Spatial distribution of interannual variation of groundwater depth

Figure 4 shows the spatial distribution of interannual changes in the groundwater depth in Xingtai city at 2000, 2005, 2010 and 2017 using Kriging interpolation method. It can be seen that the groundwater depth in the northwest of the study area is deeper than that in the southeast region. The annual average groundwater depth has increased from 18.25 m to 23.97 m, indicating an overall deepening trend. In 2000, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66056622

groundwater depth in northwestern areas of Ningjin county and Longyao county were deeper than in other counties, and the groundwater overexploitation was serious. However, it rebounded significantly in 2005. The overall groundwater depth of Julu County and Guangzong county was relatively shallow in 2000. As the overexploitation has increased, the groundwater depth has gradually deepened. The groundwater depth in the northwestern part of Nangong city was shallow in 2000, but the increase of overexploitation had decreased by 2015. It has rebounded under the implementation of overdraft control measures during 2015-2017. In the southeast of Wei County and the northwest of Linxi County, the groundwater depth dropped sharply in 2010.

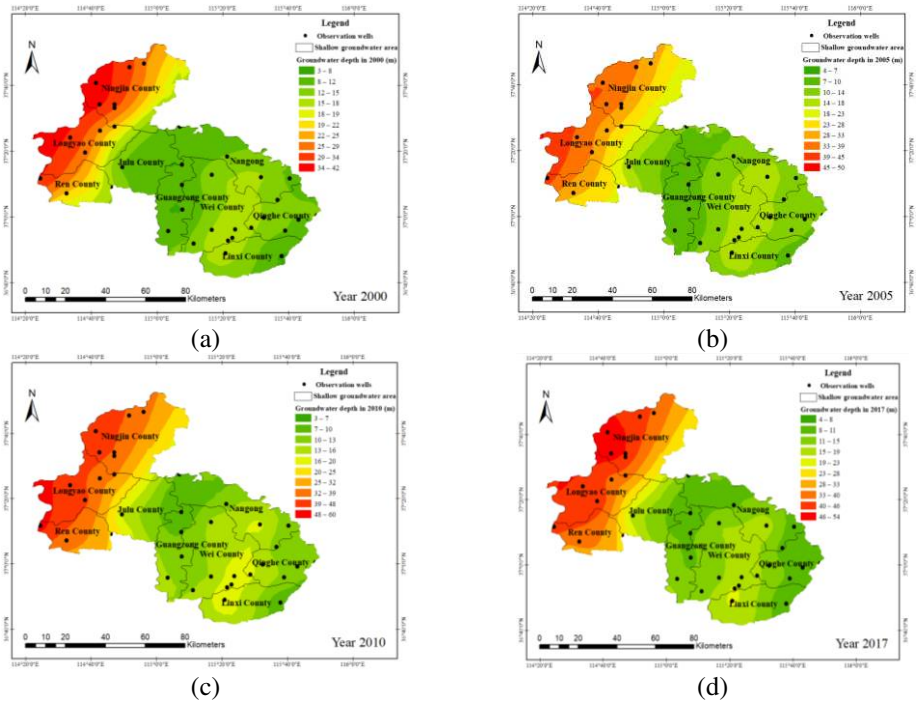

Figure 4. *Spatial distribution of interannual changes in groundwater depth (a) Groundwater depth in 2000; (b) Groundwater depth in 2005; (c) Groundwater depth in 2010; (d) Groundwater depth in 2017*

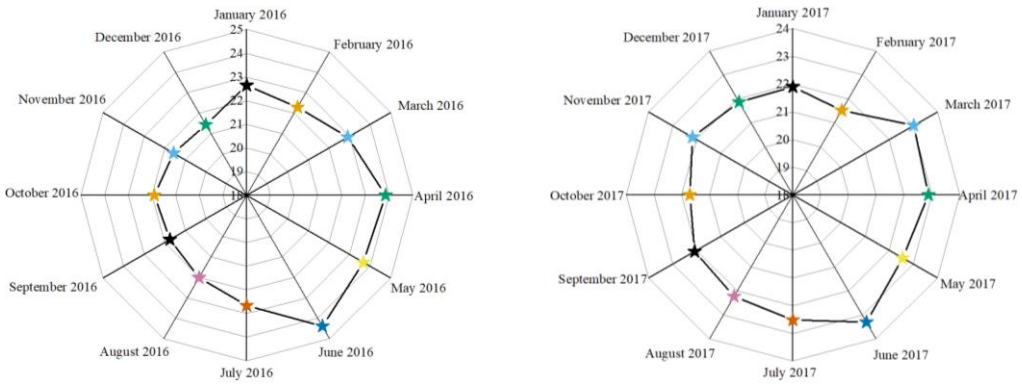
The results show that the groundwater depth in Xingtai city has deepened for the period of 2000-2017, and the rate of change has increased from 2000 to 2017, which is mainly consistent with previous results. For example, Li et al. (2014) found that the groundwater levels showed an overall decreasing trend over the past 50 years, and an increase in the groundwater depth at a rate of approximately 0.36 m/a.

Intraannual variability of groundwater depth

Figure 5 shows the trends of monthly groundwater depth in two typical years including 2016 and 2017, to analyze the intral-annual variations of groundwater depth in Xingtai city. The trends of groundwater depth in different years are similar, and June groundwater depth is the deepest. The annual spring irrigation period is from March to June, and agricultural irrigation is mainly from the exploitation of shallow groundwater, which made the groundwater depth deeper. With the increase of rainfall from July to September, the high permeability of the aquifer makes the groundwater recharged and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66056622

the groundwater depth rebounded. Crops like winter wheat are at the seedling stage from October to December, during which time the water demand is reduced, domestic water is stable, irrigation and replenishment are in a relatively balanced period, and thus the groundwater level is basically stable during this period. The trend throughout the year shows that the change of groundwater depth is related to the consumption during agricultural irrigation period and the replenishment of rainfall during flood season.



(a) (b)

Figure 5. *Trend of groundwater depth in typical years (a) Trend of monthly groundwater depth in 2016; (b) Trend of monthly groundwater depth in 2017*

The results showed that during the crops growing season from March to June, the groundwater depth is deep, which is mainly consistent with previous results. For example, Wang et al. (2009) found that the lowest water table was in the dry season with strong evaporation and less precipitation. Zheng et al. (2019) demonstrated that cultivation intensified water evaporation in the top soil layer (upper 10-20 cm), and the groundwater depth is reduced. The results showed that from July to September, the groundwater depth is recovered due to the increase of the rainfall, which is also mainly consistent with previous results. Wang et al. (2009) detected that the water table increases rapidly due to recharge by precipitation.

Spatial distribution of trends and abrupt change of groundwater depth

Figure 6 shows the spatial distributions of the trends of groundwater depth groundwater depth trends for 41 monitoring stations in the shallow aquifer of Xingtai city from 2000 to 2017 using the non-parametric Mann-Kendall test. The positive magnitude indicates the increasing trend of groundwater depth, and vice versa for decreasing trend. The results showed that eleven stations had downward trends in groundwater depth (the blue downward triangle), indicating that the groundwater depth has become shallower. All of them are distributed in the southeast of Xingtai city. Four stations that had significant decreasing trend at 10% significant level were located in the northern Guangzong county, central Nangong city, southern Wei county and northern Qinghe county, indicating clear rising trends of groundwater depth. However, there are six stations located in the middle of the shallow area have increasing trends. The stations located in the west and south of the shallow area shown significant upward trends (the purple upward triangle) at 5% significant level, indicating that the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66056622

groundwater depth will continue to decline, and the groundwater in these regions are overexploited which should be emphasized for governing.

Figure 7 shows the result of abrupt change of the groundwater depth using Mann-Kendall test. It can be seen that the groundwater depth in Xingtai city has increased since the 21st century (*UF*>0, *UB*>0), and it has significantly increased at significant level of 5% after 2005, indicating that the amount of groundwater exploitation has significantly increased since 2005. The results are mainly consistent with previous results. For example, Liu et al. (2017) found that the groundwater level continues to decline in the 21st century. At the same time, a sudden change in groundwater depth occurred in 2006, and the problem of groundwater overexploitation are beginning to be prominent.

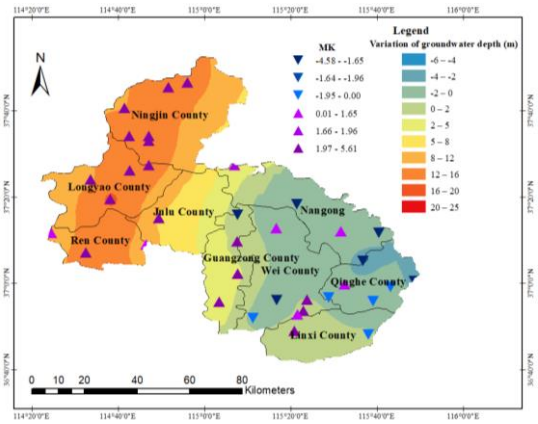


Figure 6. *Non-parametric Mann-Kendall test of groundwater depth in shallow aquifer*

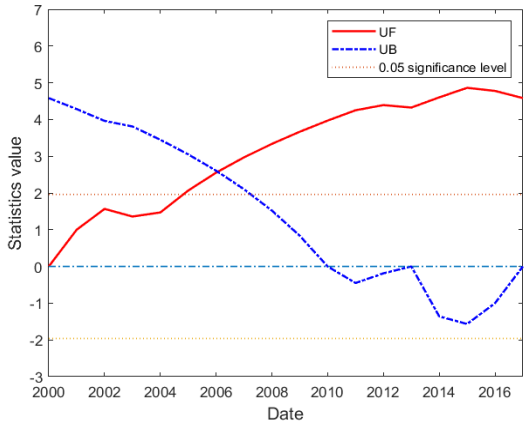

Figure 7. *Mann-Kendall abrupt change test of groundwater depth*

The influencing factors of groundwater depth and their relationships

Correlation and wavelet coherence analysis

The recharge of groundwater system in Xingtai city of Hebei province mainly originated from precipitation, river and irrigation infiltration. The excretion is mainly from groundwater exploitation and evapotranspiration of shallow aquifer groundwater. In addition, some potential factors also affect the change of groundwater depth. The annual average precipitation, evapotranspiration of shallow aquifer groundwater, annual average temperature, and GDP of Xingtai city are selected as influencing factors in this following analysis.

The importance of the influencing factors is obtained by using the gray relational analysis. From the correlation between the influencing factors and the groundwater depth, it can be obtained that the main influencing factor of the groundwater depth is the precipitation, followed by the temperature, and the correlation degrees are 0.9965 and 0.7193, respectively. It is indicated that increasing the amount of groundwater recharge is the first task to improve the groundwater overexploitation problems. The correlation degree between GDP of Xingtai city and the groundwater depth is 0.5652. The correlation coefficient between the evapotranspiration of shallow groundwater and the groundwater depth is 0.5192.

The wavelet coherence is further used to analyze the nonlinear relationships between groundwater depth and each influencing factor including rainfall, temperature (Tem),

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66056622

evapotranspiration, GDP, as shown in *Figure 8*. The results are compared with the importance scores obtained from the grey relational analysis. It can be seen that the groundwater depth is negatively correlated with the rainfall, and negatively correlated with the temperature. The groundwater depth is negatively correlated with GDP in Xingtai city for the period of 2000-2017.

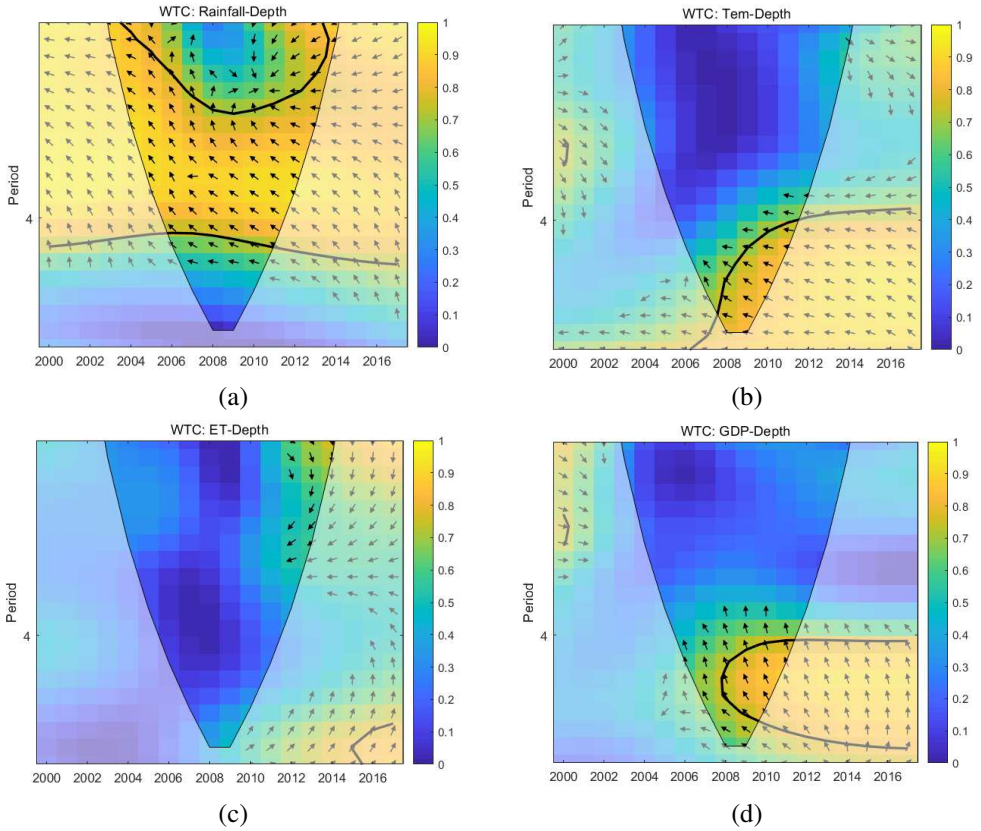

Figure 8. *The WTCs between groundwater depth and (a) Rainfall, (b) Temperature (Tem), (c) evapotranspiration, (d) GDP in Xingtai city for the period of 2000-2017*

The results revealed in *Figure 8* using wavelet coherence are generally consistent with the results using gray correlation analysis, indicating that the wavelet coherence method should be more feasible to investigate the nonlinear relationships between groundwater depth and influencing factors. The results indicated that precipitation is the mainly influencing factor of the groundwater depth, which is mainly consistent with previous results. For example, Liu et al. (2016) showed that large rainstorms can play an important role in regional shallow groundwater resources to recharge the groundwater. Meng et al. (2015) found that the precipitation infiltration recharge is closely related to the water table decrease. The results of the relationship between temperature and groundwater depth is mainly consistent with the previous results of Zhang et al. (2014), who detected that the average temperature of NCP had a close relationship with groundwater depth. The results showed that there is no significant correlation between evapotranspiration and groundwater depth, which is mainly concurred with Bai et al. (2017), who demonstrated that the total agriculture ET stayed relatively stable, in spite of the great adjustment of cropping pattern to reduce the exploitation of groundwater.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66056622

Tian et al. (2016) found that the factors such as the evaporation are less relevant to the groundwater depth variations, which concurred with our results.

Prediction of groundwater depth

The precipitation, temperature, evapotranspiration and GDP of Xingtai city are used as independent variables in multiple linear regression model, and the groundwater depth is dependent variable. The multiple linear regression is given in *Equation 16*, which can be obtained using Statistic Package for Social Science (SPSS) software.

$$y = -0.005x_1 - 1.703x_2 - 0.001x_3 + 0.003x_4 + 45.911 \quad \text{(Eq.16)}$$

where x_1 is the average annual precipitation, x_2 is the average annual temperature, x_3 is the evapotranspiration of shallow aquifer groundwater and x_4 is the GDP of Xingtai city for the period of 2000-2017.

The relative error is used to evaluate the simulation accuracy of the regression equation. *Figure 9a* shows the changes of the measured and predicted values of groundwater depth using multiple linear regression. It can be seen that the absolute value of the relative error of the groundwater depth during eighteen years is within 7%, and the relative error in 2000, 2001 and 2008 exceeded 5%. The correlation coefficient between prediction and actual values is 0.94. It shows that the predicted value obtained by the multiple linear regression model is consistent with the actual value, which should be an effective method for predicting the depth of groundwater.

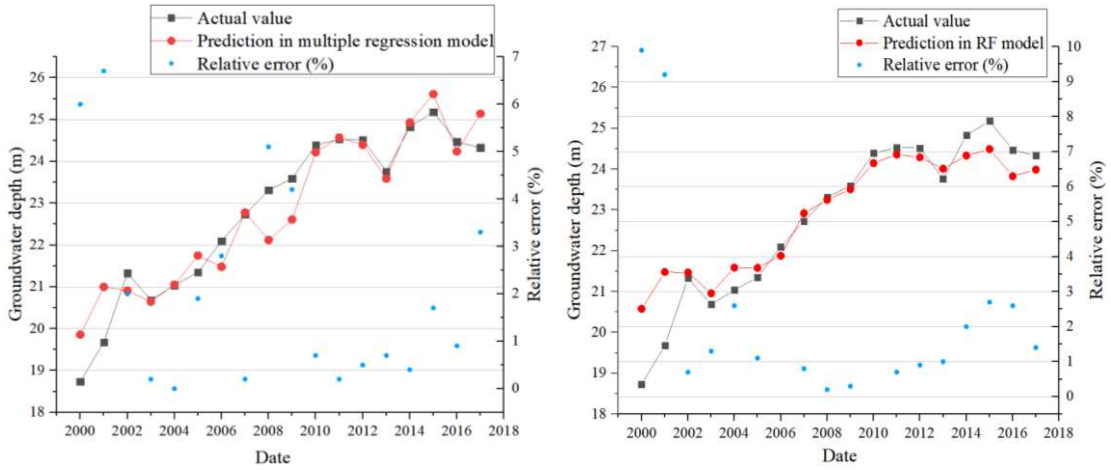

Figure 9. *The prediction and the actual value of groundwater depth by using (a) Multiple linear regression, and (b) RF model*

Similarly, the above four factors are used as independent variables to establish a RF model to predict the groundwater depth, as shown in *Figure 9b*, which showed that the prediction can better fit the actual value, and the correlation coefficient between the actual value and the prediction value is 0.97. Except for the relative error is 9% and the standard deviation is 1.2 in 2000 and 2001, the absolute relative errors of the prediction and actual values are less than 3%, and the standard deviation is less than 0.5 in other years. The prediction error and the standard residual value are small, indicating that the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66056622

RF model is more accurate in analyzing the changes of dependent variables under the influence of multiple factors and predicting the dependent variable.

After comparing the prediction values obtained by two models, it can be concluded that the multiple linear regression is an effective method to predict the groundwater depth using precipitation, temperature, evapotranspiration and GDP as predictors (*Figure 9a*). However, the random forest model has higher accuracy than that of multiple linear regression (*Figure 9b*), which is mainly concurred with Chen et al. (2019), who found that the prediction value of the RF model are ideal in the research of long time series.

Conclusions

The paper investigated the spatial and temporal characteristics of groundwater depth for the period of 2000-2017 in a typical city in NCP. The linear and nonlinear relationships between groundwater depth and influencing factors including precipitation, temperature, evapotranspiration and GDP were examined using gray correlation analysis and wavelet coherence. The multiple linear regression and random forest models were used to obtain the predictions of groundwater depth using the influencing factors as potential predictors. The main conclusions are summarized as follows:

(1) The groundwater depth in shallow aquifer of Xingtai city has generally deepened since the 21st century, and it has significantly increased after 2005. There has been a sudden change of groundwater depth in 2006. The problem of groundwater overexploitation has become prominent. The groundwater depth varied in different regions and different time. In the northwest, the groundwater depth was deep and still had a tendency to deepen. Therefore, it should be the key region for groundwater treatment. After unveiling the groundwater overdraft control measures in 2014 in Hebei province, the groundwater depth in shallow aquifer recovered from 2015 to 2017. In the eastern region, the groundwater depth has rebounded significantly.

(2) The change of groundwater depth is related to the consumption during agricultural irrigation period and the replenishment of rainfall during flood season. The deepest groundwater depth was detected in June. With the increase of precipitation, the groundwater depth rebounded from July to September. The irrigation water and groundwater recharge were in a relatively balanced at the seedling stage from October to December, during which time the groundwater depth was basically stable.

(3) The main factors that affected the depth of groundwater in shallow aquifer in Xingtai city were precipitation, temperature, GDP and evapotranspiration. The grey relational and wavelet coherence analysis showed that the temperature and precipitation had the most significant impacts on groundwater depth. There was a negative correlation between temperature and groundwater depth. The precipitation was negatively correlated with groundwater depth. There was a negative correlation between GDP and groundwater depth. However, there was no significant correlation between evapotranspiration and groundwater depth.

(4) The groundwater depth was predicted using two models including the multiple regression and RF model. The correlation coefficient between the predictive value and the actual value using the multiple linear regression model was 0.94, and 0.97 for RF model, indicating that the RF model should be more suitable to predict the groundwater depth than multiple regression, mainly because the nonlinear relationships between

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66056622

groundwater depth and its influencing factors, which were also revealed by the correlation analysis.

(5) In the process of excavating the influencing factors of groundwater depth, this paper mainly considered four factors including precipitation, temperature, GDP, and evapotranspiration. However, the change of groundwater is complicated, and it will be affected by other potential factors. Future studies are recommended to consider other influencing factors that might affect the groundwater depth. In addition, time series should be extended in future studies, in order to define cycles and analyze the relevance more accurately.

Abstract. Beer yeast powder was added to purple soil (PS) at a 1‰ mass ratio to prepare mixed soil samples (PS_B) to investigate the enhancement effect of fungus in the restoration of Cu^{2+}-polluted PS by sudangrass (*Sorghum sudanense* (Piper) Stapf.) and the intercropping of sudangrass and calliopsis (*Cosmos bipinnata* Cav.). Then, indoor potted experiments were performed to explore the physiological indices and Cu^{2+} accumulation in sudangrass and calliopsis in different Cu^{2+}-polluted PS and PS_B. Three key results were observed. (1) PS_B promoted the germination rate of sudangrass but inhibited that of calliopsis; the germination rates of sudangrass planted alone were higher than those of the intercropped ones under the same Cu^{2+} pollution concentration. Sudangrass grew well on PS_B, and its height was higher than that of calliopsis under intercropping conditions. (2) The aboveground and underground biomasses of sudangrass planted in PS_B by monoculture were higher than those by intercropping. The correlation of plant physiological indices in PS_B was higher than that in PS. (3) Cu^{2+} content in roots was higher than that in cormus. Soil polluted with 75 mg/kg Cu^{2+} was beneficial to the enrichment of plant, and the translocation coefficient was the largest in PS_B.
Keywords: *beer yeast powder, plant intercropping, phytoremediation, physiological characteristics, contamination accumulation*

Introduction

The discharge of livestock raising, industrial, and agricultural wastewater has caused serious heavy metal pollution of soil (Li et al., 2017; Barsova et al., 2019). The pollution control work became a difficult and important topic in the current research (Deng et al., 2020). Soil microbes can not only promote plant growth but also enhance the absorption of heavy metal ions by pollution-repairing plants (Liu et al., 2013). Therefore, adding microbes to the soil to improve the plants' remediation ability bears significance for the research of combined plant–microorganism remediation of soil pollution.

Phytoremediation has been the focus of studies and applied by many researchers due to its low cost and easy operation (Zheng and Yuan, 2017; Acosta et al., 2018). Seed germination rate and plant growth are promoted under low-concentration copper pollution (Li et al., 2018), but when Cu^{2+} levels in the soil exceeds a certain load, the growth of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66236635

plants will be seriously affected (Jin et al., 2012; Fu et al., 2016). *Elsholtzia splendens* Nakai and *Commelina communis* L. show high tolerance to Cu^{2+}-contaminated soil, whereas *Commelina communis* L. can normally grow in soil with a Cu^{2+} concentration of 500 mg/kg (Liu et al., 2006, 2014). In the phytoremediation of Cu^{2+}-contaminated soils, biomass directly determines the efficiency of restoration (Peng and Yang, 2005), whereas root exudates promote the root absorption of Cu^{2+} (Xu et al., 2017). Sudangrass (*Sorghum sudanense* (Piper) Stapf.) grows vigorously, has well-developed roots, and shows strong adaptability and resilience (Jia et al., 2014); thus, it is widely used in soil remediation and pollution control. The Cu^{2+} accumulation of sudangrass root reaches 673 mg kg^{-1} (Wang, 2014). Cropping patterns have observable effect on plant biomass and its adsorbability to heavy metals (An et al., 2011; Singh et al., 2012; Li et al., 2013; Wei et al., 2015), whereas intercropping can change the types and quantity of rhizospheric microorganisms (Nai et al., 2013), soil enzyme activity in the rhizosphere (Zhang et al., 2015), plant growth, and nutrient conditions and ultimately influence the absorption effect of heavy metals by plants (Su et al., 2010). Therefore, adjusting the planting pattern is one of the important ways to improve the effects of phytoremediation.

Microbial remediation technology has become an important topic in the treatment of heavy metal pollution (Xue et al., 2012; Jacob et al., 2018). Microorganisms present a good adsorption effect on heavy metal ions with the advantages of large specific surface area, rapid reproduction, and strong metabolic capacity (Cao et al., 2016), and their repair mechanisms mainly include biosorption and biotransformation (Xue et al., 2012). Cao and Cheng (2004) reported that at low Cu^{2+} concentration ($\leq$ 5 mg/L) in the soil environment, microorganisms exhibited a good repair performance for Cu^{2+} pollution, and the removal (consolidation) rate reached 25%–60%. Stanila et al. (2016) noted that beer yeast has a high adsorption capacity and adsorption rate for copper ions, and the adsorption equilibrium can be reached in 10 min. Studies demonstrated that the plant-microbial repair system is beneficial to the remediation of heavy-metal contaminants in soil (Li et al., 2015).

The phytoremediation, microbial remediation, and combined repair of Cu^{2+} in soil all achieve good outcomes. The advantage of intercropping can be further exploited if the combined microorganism–plant repair is optimized. The repair effect of Cu^{2+} can be improved to a great extent due to the no-increase repair cost. Minimal exploration was conducted in this area. In this paper, beer yeast was used to strengthen the intercropping of sudangrass and calliopsis (*Cosmos bipinnata* Cav.) for repairing different degrees of Cu^{2+} pollution of purple soil (PS). By measuring the changes in physiological characterization of sudangrass and calliopsis under different Cu^{2+} conditions and analyzing the combined repair effect of applying yeasract and interplant on Cu^{2+} pollution, this study can provide a reference for microorganism–plant intercropping to repair heavy metal-contaminated soil.

Materials and methods

Experimental materials

Potted soil (PS; a kind of soil formed on weathered materials of purple rock, and it maintains the physical and chemical properties of the parent material) was collected from the test field of China West Normal University. After multi-point sampling, the soil samples were mixed evenly, dried, and crushed, and the physicochemical properties of the soil samples were measured. *Table 1* shows the results.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66236635

Table 1. *Basic properties of the test soil*

Soil layer (cm)	pH value	CEC (mmol/kg)	TOC content (g/kg)	Cu^{2+} content (mg/kg)
0~30	8.08	288.46	16.66	18.60

The fungus powder was tested with beer yeast, which is a yellow-brown powder and granule with more than 60 million active bacteria per gram and less than 10% water content. The beer yeast was purchased from Guangzhou Pengxiang Agriculture Co., Ltd.

The test plants were sudangrass and calliopsis. The seeds with impurities, worm corrosion, and low maturity were discarded. A total of 960 full seeds of sudangrass and 120 full seeds of calliopsis were selected and soaked in 1% potassium permanganate solution for 15 min, rinsed with tap water, and three times by deionized water, and finally dried with a filter paper.

Copper pollution concentration was expressed as Cu^{2+}; the reagent was analytically pure $CuSO_4 \cdot 5H_2O$ and purchased from Xilong Chemical Industry Co., Ltd.

Experimental design

Beer yeast powder (B) was mixed with PS at a mass ratio of 1‰ to form the amended soil sample (PS_B). Three groups of indoor pot experiment of PS-S (single sudangrass planted on PS), PS_B-S (single sudangrass planted on PS_B), and PS_B-M (sudangrass and calliopsis intercropping planted on PS_B) were implemented. Among PS_B-M, PS_B-MS (sudangrass in sudangrass–calliopsis intercropping) and PS_B-MC (the calliopsis in sudangrass–calliopsis intercropping) were measured separately.

The Cu^{2+} content of soil in the pot experiments was set up for four treatments: 0, 75, 100 and 125 mg/kg soil. Each experiment was repeated thrice.

Plastic pots with a diameter of 43 cm, a width of 15.5 cm, and a height of 11 cm were loaded with 2.0 kg soil samples. Then, 500 mL Cu^{2+} solutions of different concentrations (0, 300, 400, and 500 mg/L) were added to the 36 pots in order. After the Cu^{2+} solution was permeated uniformly, 30 plant seeds (the number of sudangrass and calliopsis were 20 and 10 in the intercropping experiment, respectively) were sown uniformly at a depth of 2 cm below the soil surface of each pot. Then, the pots were watered at 100 mL volume per week after germination (four times in total). During the growth period, the germination rate and plant height of sudangrass and calliopsis were measured, and the biomasses of aboveground and underground parts were measured after harvest.

Experimental method

Determination of germination rate and plant height

The germination rates of sudangrass and calliopsis seeds and the number of seed germination was recorded every day. When the number of germinating seeds remained unchanged for two consecutive days, the germination was considered complete, and the germination rate was computed. The formula for germination rate is:

$$\text{Germination rate} = (\text{germination number of seeds} / \text{total number of seeds}) \times 100\% \quad \text{(Eq.1)}$$

The average plant height of sudangrass and calliopsis was measured every 3 days after germination (10 times in total). The plant height of all plants (sudangrass and calliopsis)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66236635

was measured separately. Then, the highest and lowest 10% scores were removed, and the average value of the remaining plants was calculated to obtain the average plant height.

Determination of biological indicator

All the plants were harvested after 30 days of growth. Then, the plant samples were divided into aerial (stems and leaves) and underground parts (roots). The soil and dirt that attached to the plant samples were thoroughly rinsed off with tap water, followed by rinsing with distilled water for three times. Then, the water was filtered out, and the fresh weight was determined. After weighing, the samples were individually loaded into a kraft bag and cured in an oven at 105 °C for 30 min and then dried to constant weight at 85 °C. The dry weight of the aerial parts and root parts was determined.

Determination of Cu^{2+} in plants

The leaves and root samples of the dried plant were grinded and passed through a 100-mesh nylon sieve. Cu^{2+} contents in plant samples were determined via Hitachi Z-5000 (Japan) flame atomic absorption spectrophotometry, and background absorption was corrected through Zeeman effect.

Data processing

SPSS 16.0 statistical analysis software was used to process the experimental data for variance and correlation analysis. SigmaPlot 10.0 software was adopted to improve data plotting. The data were expressed as the means with standard deviation, and different letters indicate significant differences among various amendments. Analysis of variance was performed to determine the effects of amendments, followed by Tukey's honestly significant difference test. Differences of $p < 0.05$ were considered significant.

Results and discussion

Effect of Cu^{2+} on the germination rate

Figure 1 shows the germination rate of plant seeds under different Cu^{2+}-contaminated soils. With the increase in Cu^{2+} concentration, the seed germination rates decreased in PS-S and PS_B-MC, whereas it increased first and then decreased in PS_B-S and PS_B-MS. When the concentration of Cu^{2+} was 0 mg/kg, the germination rate of PS-S was the highest (90%), that is, it was 1.13 times higher than that of other treatments. When the concentration of Cu^{2+} increased to 75 mg/kg, the seed germination rate of PS_B-S and PS_B-MS increased by 10.00% and 5.00% compared with 0 mg/kg, respectively. Meanwhile, the PS-S and PS_B-MC decreased by 20.00% and 10.00% compared with 0 mg/kg, respectively. When the concentration of Cu^{2+} was 100 mg/kg, the PS_B soil showed a strong promoting effect on the seed germination of sudangrass (PS_B-S and PS_B-MS), and the germination rate increased by 16.67% and 15.00% compared with that of 0 mg/kg. However, the germination rate decreased under the 125 mg/kg Cu^{2+} treatment.

Under the same Cu^{2+} concentration, the plant germination rate was expressed as PS_B-S > PS_B-MS > PS-S > PS_B-MC. When Cu^{2+} concentration was 0–125 mg/kg, the germination of sudangrass was promoted, but calliopsis was inhibited in PS_B. In general, PS_B soil samples had a promoting effect on the seed germination of sudangrass and inhibiting effect on calliopsis.

DOI: http://dx.doi.org/10.15666/aeer/1805_66236635

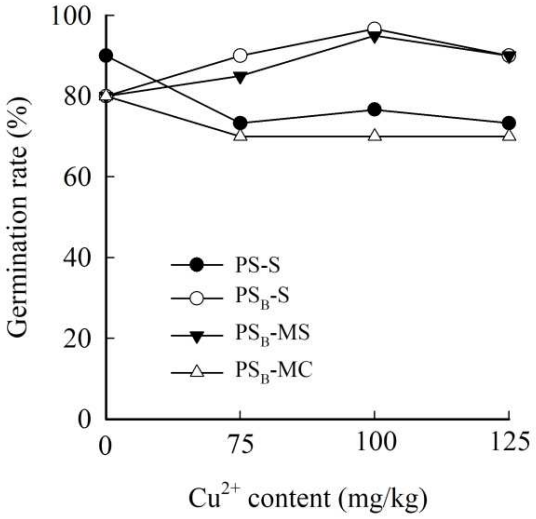

Figure 1. *Effect of Cu^{2+} content on the germination rate of the studied plants*

The germination of plant seeds is affected by pollution stress. Low concentration of pollution stress can improve the germination rate of plant seeds. With the increase in pollution concentration, the inhibiting effect of seed germination will gradually increase until germination cannot be achieved (Salian et al., 2018; Li et al., 2018). The addition of beer yeast can increase the microbial activity in soil, and at the same time, microorganisms can metabolize certain pollutants (Riaz-ul-Haq and Shakoori, 2000; Liu et al., 2013), thus reducing the inhibitory effect of pollutants on seed germination rate. Therefore, for PS-S treatment, 75 mg/kg Cu^{2+} treatment inhibited the germination rate of sudangrass, whereas for PS_B-S and PS_B-MS, the germination rate increased continuously with the Cu^{2+} content from 0 mg/kg to 100 mg/kg and reached the maximum under 100 mg/kg treatment, indicating that the addition of beer yeast played a role in promoting seed germination. Cu^{2+} inhibited the seed germination rate of calliopsis planted by intercropping, indicating the existence of inter-species survival competition (Sofo et al., 2013), which is consistent with the results of previous studies.

Effect of Cu^{2+} on plant height

Figure 2 shows that after germination (3 days later), the plant height gradually increased with prolonged growth period. The plant height of PS-S increased rapidly within 6 days after germination, with an average daily growth of 1.64 cm and a maximum of 1.98 cm. However, the growth rate was slow at 9–30 days and remained stable after the 15th day. The growth rate of PS_B-S increased the fastest with the increase in growth days and reached a maximum of 26.2 cm. For PS_B-M, the height of PS_B-MS was significantly higher than that of PS_B-MC. The plant height treatments were higher in 0 and 75 mg/kg Cu^{2+} than that in 100 and 125 mg/kg Cu^{2+}. At different concentrations of Cu^{2+}, sudangrass grew well on PS_B soil samples, and the height of calliopsis was lower than that of sudangrass under intercropping conditions, which indicates that bear yeast can promote the growth of sudangrass. The plant height and germination rate of the two plants had a similar relationship. After the addition of beer yeast to soil samples, the plant height of sudangrass significantly increased, but that of intercropping plants was inhibited.

DOI: http://dx.doi.org/10.15666/aeer/1805_66236635

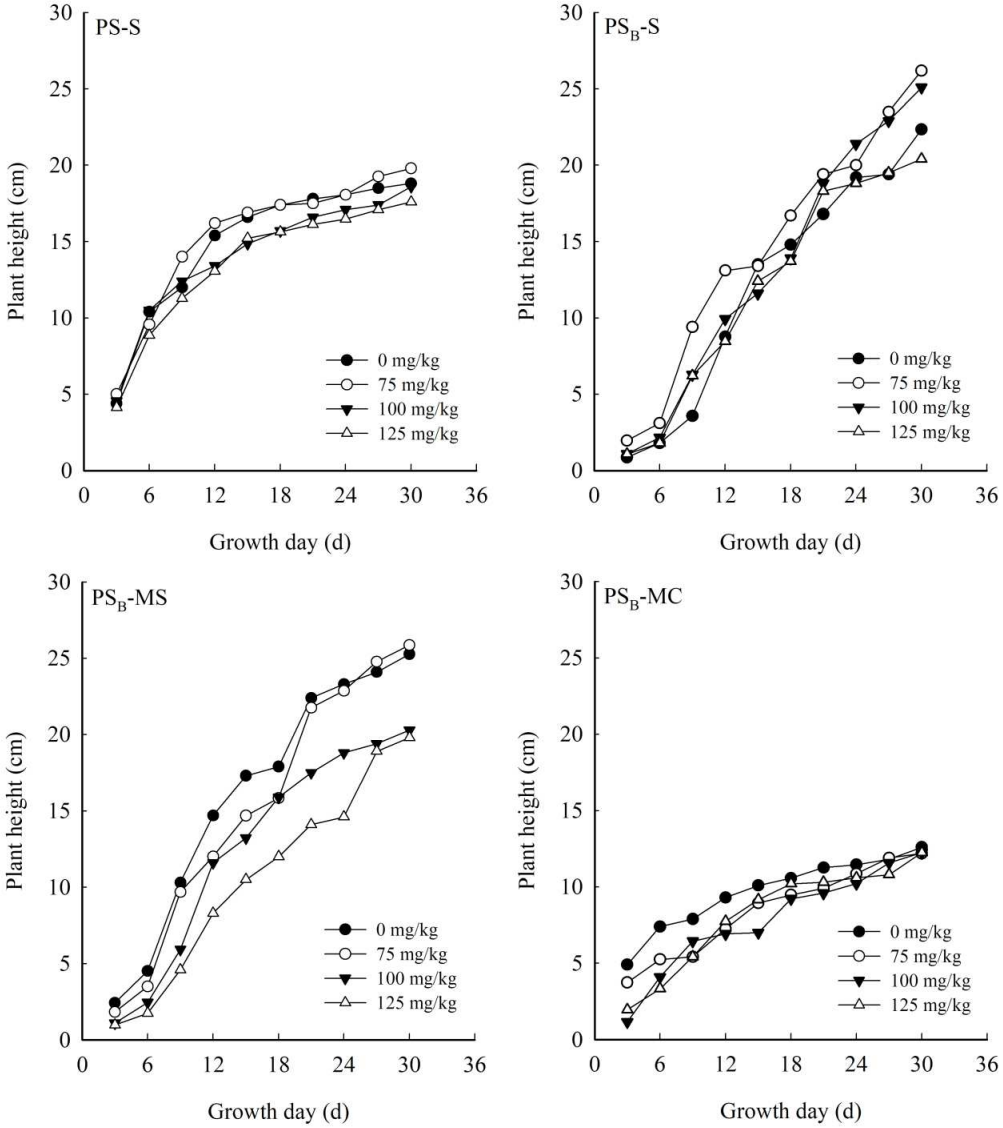

Figure 2. *Average plant height of sudangrass and calliopsis in 30 days*

Fresh and dry weights of aerial parts

The fresh and dry weights of PS-S, PS_B-MS and PS_B-MC increased first and then decreased with the increase in Cu^{2+} content of potted soil. The values reached the maximum at 75 mg/kg Cu^{2+} and 1.34–1.36 (PS-S), 1.43–1.58 (PS_B-MS), and 2.11–2.40 (PS_B-MC) times higher than that of 0 mg/kg Cu^{2+} (*Fig. 3*). The fresh and dry weights of PS_B-S showed a fluctuating trend with the increase in Cu^{2+} content. When the content of Cu^{2+} was 100 mg/kg, the fresh and dry weights of PS_B-S were the highest at 4.97 and 0.64 g, respectively, and significantly differed from those of other treatments ($p < 0.05$).

For the single-planting experiments, PS_B promoted the aboveground biomass growth of sudangrass, and the maximum biomass was reached at the Cu^{2+} content of 100 mg/kg. For the intercropping plants, the maximal promotion of the aboveground biomass was recorded at the Cu^{2+} content of 75 mg/kg. In summary, the aboveground biomass of sudangrass planted in PS_B by monoculture was higher than that planted by intercropping.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66236635

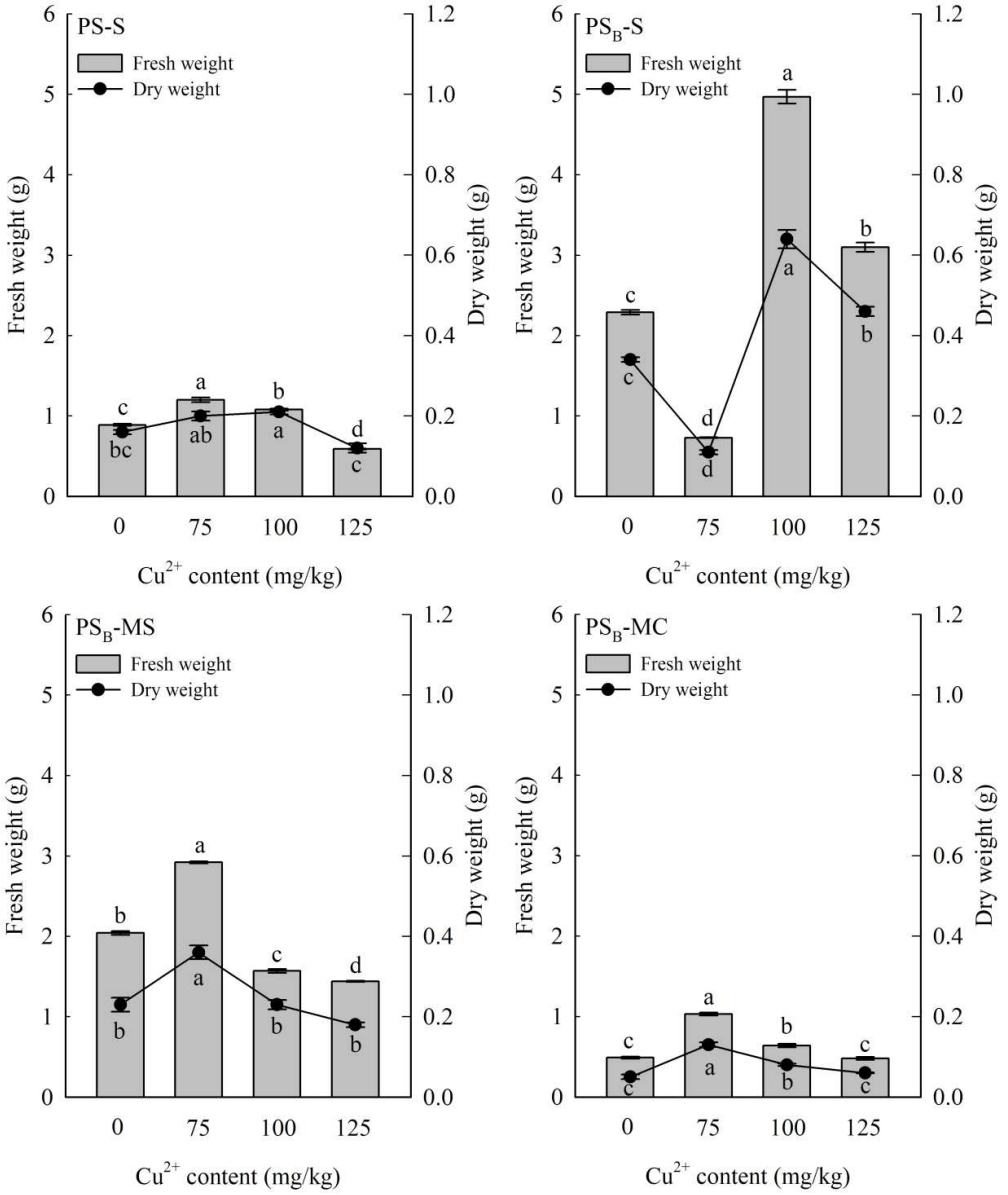

Figure 3. *Fresh and dry weights of aboveground parts of sudangrass and calliopsis. Note: Different lowercase letters indicate significant difference under various treatments at 0.05 levels (the same meaning of different lowercase letters in the following figures)*

Plant biomass is closely related to the overall growth status. Except for PS_B-S, the biomass of plants under 75 mg/kg treatment was high on the whole, indicating that low-concentration pollution stress is conducive to the accumulation of plant biomass. The biomass of PS_B-S was the lowest at 75 mg/kg Cu^{2+} and increased significantly at 100 mg/kg Cu^{2+}. This result is related to the tolerance of microorganisms to pollutants, and it is consistent with the research results by Boiko et al. (2020).

Fresh and dry weights of underground parts

With the increase in Cu^{2+} content, the root fresh and dry weights of PS-S and PS_B-S increased, reached the peak value at 100 mg/kg Cu^{2+}, and then decreased at 125 mg/kg

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66236635

Cu^{2+} (*Fig. 4*). The fresh and dry weights of roots of PS_B-MS and PS_B-MC were the highest under the 75 mg/kg Cu^{2+} treatment. A corresponding relationship was observed between the plant's root fresh and dry weights at different Cu^{2+} concentration treatments. The fresh and dry weights of intercropped sudangrass were significantly higher than those of calliopsis, indicating that sudangrass dominated the competition, and its root system had strong adaptability to Cu^{2+}-polluted PS. However, the plant roots grew poorly under Cu^{2+} concentration of 100–125 mg/kg, indicating that high concentrations of Cu^{2+} inhibited plant root growth. At 75 mg/kg Cu^{2+}, the intercropped plants showed better growth and stronger adaptability, but their underground biomass was still inhibited compared with the monoculture of sudangrass.

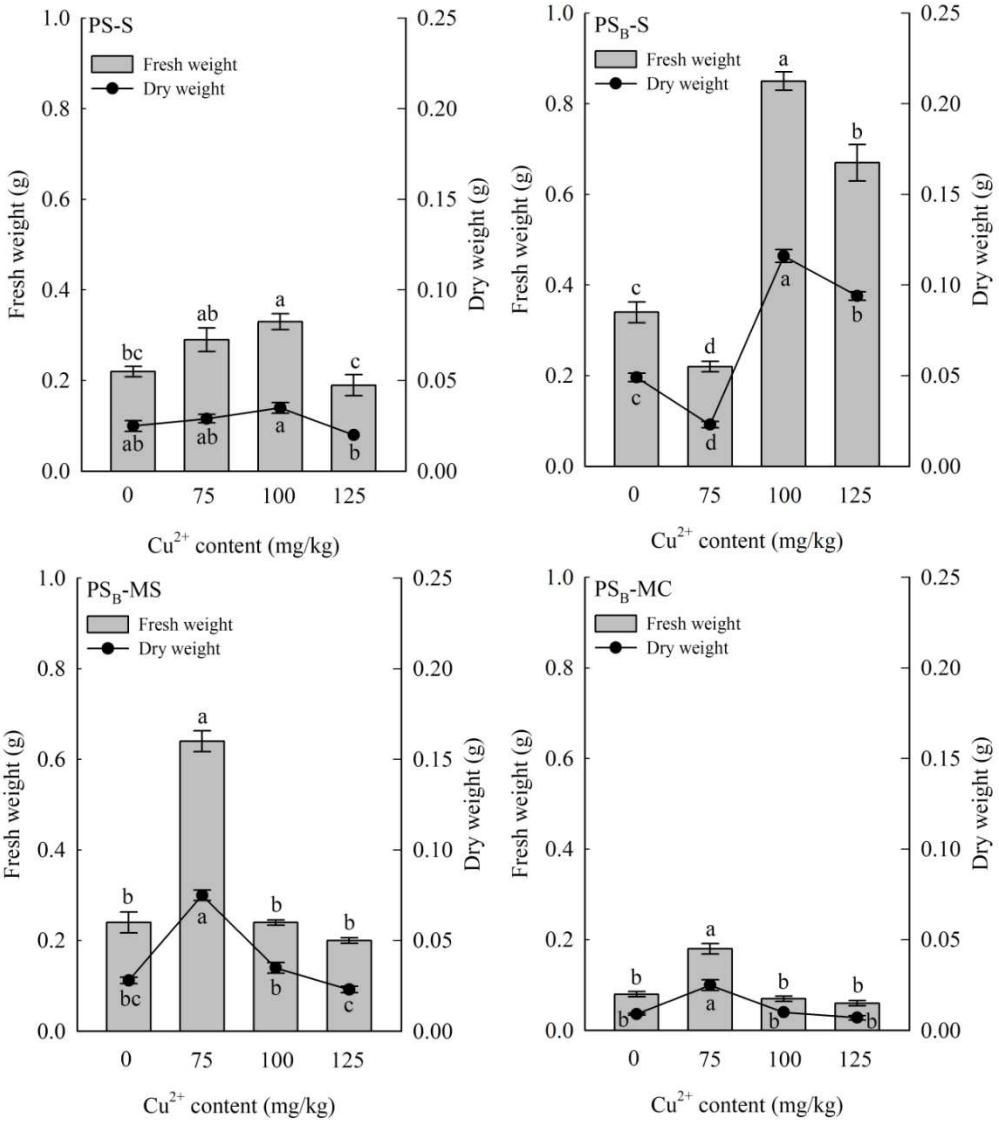

Figure 4. *Fresh and dry weights of roots of sudangrass and calliopsis*

Compared with the aboveground plant parts, plant roots are directly exposed to pollutants and have a higher tolerance to pollution. The root biomass was the largest under the treatment of 100 mg/kg Cu^{2+} for sudangrass monocultures. For the intercropped plants,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66236635

the two kinds of plant roots were influenced not only by pollution tolerance but also their competition relationship. The root biomass of intercropped plants was the largest under 100 mg/kg Cu^{2+} treatment.

Correlation analysis of physiological indices

Table 2 shows the positive correlation between various physiological indicators of sudangrass and calliopsis. No significant correlation was observed between plant height and other indicators, whereas a significant correlation was noted between dry and wet biomass. As for PS-S, the aboveground dry weight was significantly related to the root fresh and dry weights. For PS_B-S, PS_B-MS and PS_B-MC, a significant correlation existed between any two of the aboveground fresh weight, aboveground dry weight, root fresh weight, and root dry weight. An extremely significant correlation was recorded between the aboveground and root dry weights of PS_B-MS and between the aboveground fresh weight and root dry weight of PS_B-MC. The overall correlation of plant physiological indices in PS_B-S was higher than that in PS. For the same plant, the change in root and aboveground biomass was closely related to plant pollution tolerance. Therefore, compared with PS, PS_B showed a higher correlation between the aboveground and underground plant parts, which also indicates that microorganisms promoted the tolerance of plants to pollution.

Table 2. *Correlation analysis of physiological indexes of sudangrass and calliopsis*

Changes in Cu^{2+} Content of Plant Samples

Table 3 shows the content of Cu^{2+} in plant cormus (leaves and stems) and roots under different soil treatments. Cu^{2+} content in the cormus and roots of plants increased with the increase in soil Cu^{2+} concentration, with the maximum values reaching 8.82 (cormus in PS_B-MC) and 30.15 mg/kg (roots in PS_B-MC). Cu^{2+} content in the root was higher than that in the cormus, which indicates that the plant root system was more likely to enrich Cu^{2+}; this result was consistent with the findings of Wang et al. (2014). The enrichment coefficient of cormus and roots was the largest under the soil treatment of 75 mg/kg Cu^{2+}, indicating that the 60-day-grown plants were more capable of enriching low-concentration pollution. The enrichment coefficient showed the trend of PS_B-MC > PS_B-MS > PS_B-S > PS-S of cormus, whereas the trend was PS_B-MC > PS_B-S > PS_B-MS > PS-S for the roots. The largest translocation coefficient was observed on PS_B-MC, indicating that calliopsis was more capable of Cu^{2+} transport than sudangrass.

Table 3. *Remediation effect of Cu^{2+} on potted plants*

Treatmengts (mg/kg)		Overground part (cormus)		Underground part (roots)		Translocation coefficient (%)
		Cu^{2+} content (mg/kg)	Enrichment coefficient (%)	Cu^{2+} content (mg/kg)	enrichment coefficient (%)	
PS-S	75	2.60	3.47	14.82	19.76	17.54
	100	2.71	2.71	18.90	18.90	14.34
	125	2.76	2.21	19.69	15.75	14.02
PS_B-S	75	4.85	6.47	20.60	27.47	23.54
	100	5.05	5.05	21.81	21.81	18.57
	125	5.88	4.70	23.48	18.78	16.52
PS_B-MS	75	6.30	8.40	20.76	27.68	30.35
	100	6.56	6.56	24.74	24.74	24.09
	125	7.35	5.88	30.15	24.12	17.74
PS_B-MC	75	7.31	9.75	18.86	25.14	39.13
	100	8.07	8.07	23.68	23.68	34.12
	125	8.82	7.06	27.33	21.86	28.61

The above results were mainly due to the direct contact of root system to Cu^{2+}. Thus, the Cu^{2+} content of the root system was higher than that of the cormus. The enrichment and transport coefficients of intercropped plants were higher than that of monocultures and mainly caused by the competition between sudangrass and calliopsis. The competition involved the nutrients and pollution elements.

Conclusions

In this paper, the enhancement effect of fungus in the restoration of Cu^{2+}-polluted PS by sudangrass and the intercropping of sudangrass and calliopsis was studied by indoor potted experiments. The main conclusions are summarized as follows: PS_B promoted the germination rate of sudangrass, and the germination rates of sudangrass planted alone were higher than that of those planted by intercropping. Sudangrass grew well on PS_B, and the height of calliopsis was lower than that of sudangrass under intercropping conditions. The biomass of sudangrass planted in PS_B by monoculture was higher than

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66236635

that by intercropping. Cu^{2+} content in roots was higher than that in the cormus. The enrichment coefficient of cormus and roots was the largest under the soil treatment of 75 mg/kg Cu^{2+}.

The results of this study provide a reference for microorganism–plant intercropping to repair heavy metal-contaminated soil. Based on the conclusions obtained in this study, future research can be further discussed in the following aspects: (1) determination of optimum microbial dosage and its combination with plants; (2) collocation and selection of intercropped plants; (3) effects of microorganisms on plant rhizosphere and their combined effects on contaminants.

Abstract. Understanding how forest communities respond to environmental factors via intra- and interspecific variation in leaf functional traits is a fundamental challenge in forest ecology. Especially, little is known about the degree to which trees respond to environmental factors at the forest community level. To fill this gap, an experiment across 34 plots was conducted in a subtropical montane broad-leaved forest in western China. Based on 327 trees of 27 species, intra- and interspecific variations in leaf morphological and chemical traits were measured, and their relationship with environmental factors was determined. Canonical correlation analysis (CCA) was used to assess the relationships between the local environment and trait variation. Our results show that leaf morphological traits are related to chemical traits. The contribution of interspecific variability was dominant between species and communities, but intraspecific variability explained a large amount of variation (35.9%–56.2%) in chemical traits, despite the fact that high levels of species turnover were observed at the forest community level. Leaf traits showed responses to local environmental variables, with tree size being most strongly correlated. Our findings emphasize that leaf functional traits are correlated with environmental gradients. Therefore, to study the ecological process in subtropical forests using traits-based approaches, researchers need to account for their considerable intraspecific variability.
Keywords: *leaf morphological traits, leaf chemical traits, interspecific and intraspecific variability, tree size, soil properties, community ecology*

Introduction

Leaf functional traits including morphological traits, chemical traits, physiological traits, and symptoms, balance leaf construction costs against growth potential, reproduction and survival (Violle et al., 2007; Diaz et al., 2016). Foliar morphological traits reflect structural and physical characteristics, mainly including leaf mass, size, morphology and water status (Bussotti and Pollastrini, 2015). For instance, specific leaf area (SLA) is positively related to relative growth rates, leaf turnover rates, foliar nutrient concentrations and photosynthetic capacities in plant community assembly (Wright et al., 2004). Leaf dry matter content (LDMC) in particular has been regarded as an important component of the evolutionary history of species (Shipley et al., 2007; Messier et al., 2010). Foliar chemical traits, characterizing the mineral nutrition status, have been used as important parameters to recognize critical ecological processes of community assembly and species coexistence, and ecosystem structure and function (Aerts and Chapin, 2000; Wright et al., 2004). For example, leaf nitrogen content (LNC) is an extremely relevant ecological index, which is connected to photosynthesis, nutrient cycling, belowground diversity and water quality (Niinemets, 2010). By working with functional traits and their variation within and among communities,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66376661

researchers shed generalisable light on community assembly and ecosystem processes, one example is that three quarters of trait variation is captured in a two-dimensional global spectrum of plant form and function by analyzing variation in six major traits with the largest sample of global vascular plant species (Diaz et al., 2016). Traditionally, most previous studies operating on the mean values of species traits, focused on interspecific differences more between co-occurring species than within species (Wright et al., 2004; Mcgill et al., 2006; Cornwell et al., 2008). However, to date there is now growing evidence that intraspecific variability, can have significant effects on many ecological and evolutionary processes (Violle et al., 2012), moreover, sometimes the extent of intraspecific trait variation is similar to or greater than interspecific variation within and among plant communities. For example, many studies have demonstrated the importance of intraspecific variability for the maintenance of species coexistence, the dynamics of communities and the ecosystem properties in tropical forest, subtropical forest and grass ecosystems (Albert et al., 2010a; Messier et al., 2010; Bolnick et al., 2011). As such we need to consider that moving beyond the species mean approach by focusing on individual traits may improve our predictive ability of community ecology (Violle et al., 2012).

Trait-based community assembly rules have shed light on that environmental variation (or environmental filter) plays in shaping plant community functional trait composition (Albert et al., 2010a; Auger and Shipley, 2013). As the matter of fact, many studies have examined correlations in leaf traits with environmental variables like regional climate, local soil conditions and biotic interactions (Santiago and Wright, 2007; Atkin et al., 2008; Ordoñez et al., 2009), which can influences plant functional diversity and ecosystem function through primary production, carbon sequestration, trophic transfer and litter decomposition (Cornwell et al., 2008; Sedjo and Sohngen, 2012). To our knowledge, along environmental gradients the variation of many popular indices (e.g. aggregated trait averages) reflecting the functional characteristics of locally dominant species in ecological communities can be as a consequence of both species turnover and intraspecific trait variability (Lepš et al., 2011). In other words, not only can trait values among species vary in response to the environment (i.e., niche breadth) via phenotypic plasticity (Ashton et al., 2010), but intraspecific variability can also display different idiosyncratic responses (Albert et al., 2011). Especially, recent work also shows that an increasing interest in accounting for intraspecific functional trait variability on a regional to global scale, the response of functional, ecophysiological or demographic traits to environmental gradients (Mcgill et al., 2006; Hausch et al., 2018; Li et al., 2018). For instance, most studies dealing with intraspecific functional variability have focused on indirect gradients (e.g., altitude, latitude or longitude), which are unknown combinations of multiple direct environmental gradients that impact plant physiology (e.g., temperature, nutrient availability) (Cordell et al., 1998; Albert et al., 2015). Moreover, Violle et al. (2012) reported that the relative contribution of intraspecific trait variation to shifts in community-average trait values along environmental gradients reflects the importance of within-species trait responses to environmental stress. However, Lajoie and Vellend (2015) suggested that the relative contribution of intraspecific variation and species turnover to total trait variation along environmental gradients is poorly understood. For example, on account of the scale of environmental heterogeneity relative to the size of individual plants, the potential for individuals to express genetic and plastic trait differences across different environments, thus the relationship

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66376661

between spatial grain (plot or sampling unit size) and the relative extent of intraspecific trait variation within communities is more difficult to predict (Siefert et al., 2015). Therefore, how intraspecific variation is influenced by environmental gradients, this issue might be dependent on the functional traits measured, the spatial scale of observation, and the study habitat type (Luo et al., 2016).

Montane broad-leaved forests in the southwest Sichuan are known for their high biodiversity. Because of the complicated geomorphological features and climate conditions, they shape abundant tree species and large habitat heterogeneities. Moreover, these forest communities appear tremendously diverse ecological characteristics of their spatial structure, functions and dynamics, with wide ranges in growth rates and shade tolerance (Zhao et al., 2009). But to date little is known about the ecological processes of structural and functional features of these broad-leaved forests and their effects of large range of environmental factors in this region (Zhao et al., 2009). Therefore, this study centered on leaf functional traits and its responses to environmental gradients (especially local soil properties and stand structures) in forest communities. As we now know foliar morphology correspond to the fundamental tradeoff in leaf construction costs vs. light-intercepting surface area and foliar chemical compounds influence the nutrient cycling and photosynthetic machinery of forest ecosystems (Wright et al., 2004). Hence, in this study from two aspects of foliar morphology and foliar chemistry we discuss the following questions: (1) How variable are the leaf morphological and chemical traits across individuals and communities? (2) Whether the contribution of intraspecific variation is lower than that of interspecific variation, and whether these relative contributions would differ among traits? (3) Whether differences and relationships between leaf functional traits and environmental gradients had existed among communities, and how do leaf traits vary in response to environmental gradients (i.e., soil properties and stand structures)? To address these questions, we measured leaf functional traits, soil properties and stand structures of 34 plots collected from the montane broad-leaved forest in western China.

Materials and methods

Study site

This study was conducted in Shangli town of Ya'an City (30°11'N, 103°5'E, 900-1800 m a.s.l., *Fig. A1*), within the montane broad-leaved forest region. The area is a geomorphologic complex located in southwest Sichuan, western China. The study area is characterized by a subtropical humid monsoon climate. The mean annual temperature is 16.1 ℃ and the mean annual precipitation is 1772.2 mm (Zhao et al., 2009; Zhou et al., 2018). Annual average sunshine is 1019.9 h, with an average of 289 frost free days. The soils are derived from sandy mudstone and mudstone substrates and contain >5% organic matter and >2% nitrogen (N) content. Local conditions for plant growth are strongly P-limiting, with soil total phosphorus (P) and available P of 0.5 g/kg and 12.5 mg/kg, respectively. The dominant tree species in this region include *Machilus pingii*, *Machilus ichangensis*, *Phoebe zhennan*, *Castanopsis fargesii*, *Quercus serrata* and *Photinia beauverdiana*. Dominant shrub species include *Camellia oleifera*, *Dichroa febrifuga, Eurya groffii*, *Eurya glaberrima* and *Ficus heteromorpha*. Herbaceous species were represented by *Setaria plicata*, *Iris japonica*, *Hosta plantaginea*, *Pilea notate*, *Pteridium aquilinumvar* and *Latiusculum* (*Table A2*).

Field survey and leaf traits measurements

Data of forest communities were collected in forest plots from May to August 2017. According to the distributed characters of this study forest, 34 plots (20*20 m) were randomly sampled (*Fig. A1; Table A3*), with a minimum distance of 100 m from the outer forest margins, and a minimum distance of 250 m relative to one another. At each plot, each tree with a diameter at breast height (DBH) > 3 cm was recorded, overall, 2067 trees of 76 species were identified to the species level in total sampling areas. The procedure of leaf trait collection and measurements is described and explained below. One species was randomly selected in a plot with three mature and unshaded individuals based on DBH > 15 cm, of the 76 species in the survey data, sufficient trait data were collected for 327 trees of 27 species. In the field, leaves from these three individuals per species were assessed for chlorophyll content with a SPAD-502 meter (Konica Minolta, Tokyo, Japan), averaging five measurements taken on different parts of the leaf lamina. Next, we collected 10 in-tact leaves per individual tree for other trait measurements. In the laboratory, the fresh mass of each leaf was measured immediately with an SE202F electronic balance (Ohaus Corp., Parsippany, NJ, US). Leaves were scanned with a scanner (CanonScan LiDE 210, Canon Inc., Tokyo, Japan) and leaf area was calculated by using Image J (Pérez-Harguindeguy et al., 2013). An electronic digital caliper was used to measure leaf thickness (mm) at the center of the lamina by avoiding the major leaf veins. Leaves were dried to a constant weight at 70 ℃ for at least 3 days and then weighed. Specific leaf area (SLA), leaf dry matter content (LDMC), and leaf density (LD) were also calculated. Leaf N content (LCN) was determined with the Kjeldahl method and leaf P content (LCP) with spectrophotometry (Bao, 2000). Foliar N concentrations per unit leaf area (N_{area}) and foliar P concentrations per unit leaf area (P_{area}) were also obtained. All the leaf traits are described in *Tables A1* and *A2*.

Characterization of the stand structures and soil properties

The local environmental conditions of these 34 plots were focused on diameter at breast height (1.3 m, DBH), tree height, forest crown and stem density, and so on. In this study, we employed terms of forest stand structure to describe plot structures characteristics, which convey much information about the size distribution of trees, forest stand structure is the capital importance for understanding forest ecosystem structure and function. In each 20*20 m plot, censuses of all living trees with DBH > 3.0 cm were performed and the following parameters were recorded. DBH was measured using a caliper, height was measured with a vertex hypsometer; crown projection was inventoried in four cardinal directions. The basal area (BA), Shannon–Weaver's index of diversity (SHI) (Shannon and Weaver, 1949) and Pielou's evenness index (EVE) (Pielou, 1975) were computed for all sampled plots.

One soil sample per plot was taken using an auger, soil water content (here refers to actual water content, was calculated as (wet soil weight - dry soil weight)/dry soil weight) was quantified using the gravimetric method (Bao, 2000). An additional five profiles of the top 20 cm of depth were also collected in each plot and further mixed to make a combined soil sample per plot using this for chemical analysis. For each plot, soil samples were pooled, homogenized, air-dried and sieved (2 mm) for further analyses in the laboratory. Soil organic matter was determined by the Walkley and Black method and total N was determined by Kjeldahl digestion. Available P was estimated by the Olsen method; total K was extracted with 1 M ammonium acetate and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66376661

determined by atomic absorption spectrophotometry (Bao, 2000). The characters of stand structures and soil properties are described in *Tables A1* and *A3*.

Statistical analyses

Linear mixed models were used to analyze single-traits among individual species. Models were calibrated for each functional trait using individual trait measurements and included either no fixed effects (written as fixed ~1, m0) or a species fixed effect (fixed ~Species, m1) (Bolker et al., 2009; Albert et al., 2010b), to reflect interspecific, intraspecific variance, then we calculated a measure of explained variation based on the variances for the different models following (Xu, 2003): $R^2 = 1 - (\sigma m1)^2 / (\sigma m0)^2$, where σm1 and σm0 are the estimated error standard deviations under models m1 and m0 respectively. Variances were estimated by maximizing the restricted log-likelihood (REML).

According to Dodélec and Chessel (1991) and Albert's method (Albert et al., 2010a), we conducted the principal component analysis (PCA) to disentangle multidimensional structure within the leaf trait space at individual and community level. The relationships between leaf morphological traits and chemical traits were also explored by standardized major axis (SMA) regressions, a statistical tool highly recommended for allometric studies (Warton et al., 2006), using the PCA axis of morphological or chemical traits. There is an interest in knowing the slopes, which are fitted by minimizing the sums of squares of errors in X and Y dimensions, indicating the magnitude of the scaling between the variables. SMA regressions were performed using SMATR software (Falster et al., 2006).

To examine functional trait variations at the forest community level, all leaf traits were weighted by the relative abundance of each species to calculate the community weighted means (CWM) according to Lepš et al.'s (2011) method. We calculated three types of CWM parameters: (1) specific average trait values were calculated for each plot using the trait average of each species measured overall individuals of that species in that specific plot, which reflects the effect of both species' inter- and intraspecific trait variation; (2) fixed trait values were calculated for each plot using the single trait average of each species measured overall individuals of that species in the study, which changes in value among plots that are only due to interspecific trait variation; (3) intraspecific variability trait values were calculated from the differences between specific and fixed average traits and permit an estimation of the pure effects of the intraspecific variability. Specifically, to quantify how much intra- and interspecific variability, this can be employed three community parameters (fixed and specific averages and their difference) to run three parallel ANOVAs for each functional trait. Then, from outcomes of the preceding analyses, we partitioned inter- and intraspecific trait variability effects on plot-level traits values among plots, and used the method that the sum of squares of species trait variance for all plots ($SS_{specific}$) was decomposed into three different components which include fixed (SS_{fixed}) effects, intraspecific ($SS_{intraspecific}$) effects and covariation (SS_{cov}) effects, the equations as following: $SS_{cov} = SS_{specific} - SS_{fixed} - SS_{intraspecific}$ (Lepš et al., 2011). Where, $SS_{specific}$ was the 'total' variation of community trait averages originating from the specific averages. SS_{fixed} and $SS_{intraspecific}$ came from fixed averages, intraspecific trait variability above-mentioned ANOVAs respectively. SS_{cov} was Covariations of the species turnover (SS_{fixed}), intraspecific variability ($SS_{intraspecific}$) (more details in Lepš et al., 2011; Carlucci et al., 2015; Luo et al., 2016).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66376661

Finally, we used canonical correlation analysis (CCA) to quantify correlations between two sets of multidimensional variables (Tabachnick and Fidell, 2012). As leaf traits and environmental factors are multivariate in nature, an analytic approach that allows for multiple independent variables is thus preferred (Bajorski, 2012). The use of the canonical correlation for this study enabled a more in-depth analysis of the relationships between stand structure, soil factors, and leaf traits than would have been possible with univariate statistical procedures such as multiple regressions. Therefore, we can assume that two sets of random variables, X (leaf traits) with p variables and Y (environmental factors) with q variables, have means of zero. Let n be the number of observations, and let m be n-1. Then, we use two aggregate variables U and V to express X and Y in new linear combinations as U = aX, V = bY. Using PCA's idea, we will try to find the coefficient sets a and b, which lead to the maximum covariance of cov(U,V). The main steps includes (1) getting the covariance matrix cov(U,V), (2) employing Lagrange Multiply Method to maximize cov(U,V), and (3) getting U, V, a, b and their corresponding eigenvalues. From CCA, we can obtain the key values such as canonical correlation coefficients, explanation proportion, and significance testing value (Tabachnick and Fidell, 2012). Linear mixed analyses was conducted using the packages 'ape' (Paradis et al., 2004), the principal component analysis was performed using the packages 'FactoMinerR' (Lê et al., 2008) and the canonical correlation analysis was performed using the packages 'vegan' (Dixon, 2003) in the R (R 3.5.3 version).

Results

Leaf traits variations of the individuals of all species

Principal component analysis on individual data produced variation and structure of the leaf morphological and chemical trait space. Morphologic traits were positively correlated among themselves (*Table A4*). The data set was structured by a strong first axis (58.6% of the variance) that was primarily correlated with LDMC and SLA (*Fig. 1a*). The second axis explained 28.6% of the variance and to some extent was correlated weakly with the leaf area (LA) and LD (*Fig. 1a*). Multi-trait variation of chemical traits representing the first PCA component (43.2% of the variance) was mainly driven by leaf chlorophyll (LChl), and the second axis (36.5% of the variance) was driven by leaf N content (LCN), and they were both positively correlated among themselves (*Fig. 1c*).

The SMA regressions between morphological traits and chemical traits were largely significant relationships ($R^2 = 0.51$, $F = 284.3$, $P < 0.0001$, *Fig. 2a*). In addition, the morphological traits were significantly correlated with chemical traits such as LChl, LCN, leaf N content per area (N_{area}), and leaf P content per area (P_{area}) (*Fig. 3*). They were negatively related to leaf morphology, except for LCN. Similarly, the chemical traits were significantly correlated with the morphology related traits such as LA, SLA, LDMC, and LD (*Fig. 3*).

Leaf morphological and chemical traits led to similar results, with a partition around 80% vs. 20% for interspecific vs. intraspecific variability (*Fig. 4*). There were small differences between traits, with LD (up to 24.7%, *Fig. 4*) and P_{area} (up to 24.9%, *Fig. 4b*) showing relatively more intraspecific variability. Total variances are about 60% for leaf morphological and chemical traits, except for leaf thickness (LT) (up to 97.7%, *Fig. 1a*), LA (up to 79.7%, *Fig. 1a*) and LChl (up to 73.7%, *Fig. 4*).

See Table A1 for abbreviations of traits*

Leaf traits variations of the communities

At the community, PCAs of variation and structure of the leaf morphological and chemical trait were similar to PCA results at the species level. For the morphologic traits, PCAs results showed that the data set was structured by a strong first axis (72.0% of the variance) that was mainly explained by LDMC and SLA. A second axis (25.3% of the variance) was explained largely by LA and LD (*Fig. 1b*). Multi-trait variation of chemical traits represented the first PCA component (75.5% of the variance) and was mainly driven by LChl and LCN (*Fig. 1d*).

The SMA regressions indicated that morphology PCA2 was significantly correlated with chemistry PCA1 (*Fig. 2b*, R^2 was 0.89, $P < 0.0001$), and morphology PCA1 was significantly correlated with chemistry PCA2 (*Fig. 2d*, R^2 was 0.88, $P < 0.0001$). Chemistry PCA1 was significantly correlated with LDMC and LD, and chemistry PCA2 was significantly correlated with LT, LA, and SLA (*Fig. 5*, left column). Similarly, morphology PCA1 was significantly correlated with LChl and LCN, and morphology PCA2 was significantly correlated with LCN, N_{area}, LCP, and P_{area} (*Fig. 5*, right column).

Interspecific variability contributed to a greater proportion of explained variation to the functional shift than did intraspecific variability for leaf morphological and leaf chemical traits. For LT and LChl, the CWM trait variation was almost completely generated by interspecific variation, which accounted for 98.3% and 93.8% of the total variation, respectively. However, the contribution of intraspecific variation was greater than interspecific variation for LCN (56.2% vs. 21.0%), and there was a positive covariation between interspecific and intraspecific variation among the plots (*Table 1*). This, however, was not the case for LT (-2.3%) and LChl (-7.2%).

Intra- and inter-specific variability of CWM along different environmental axes

A canonical correlation analysis was conducted to evaluate the multivariate shared relationship between the leaf traits and the environmental groups, which yielded the first canonical variables with squared canonical correlations (Canonical R^2) and Wilks' Lambda values (*Table 2*). To total variability and interspecific variability, the full model across the first canonical variables was statistically significant except for leaf chemistry and soil properties. Meanwhile, for intraspecific variability, leaf morphology was

DOI: http://dx.doi.org/10.15666/aeer/1805_66376661

significantly correlated with soil properties (F = 5.29, $p < 0.0001$), and leaf chemistry were significantly correlated with stand structures (F = 1.63, $p = 0.02$).

Stand structures and soil properties significantly influenced leaf morphology and leaf chemistry (*Tables 3, 4, 5*). For instance, the total variation in LA, LDMC, and LCN were all significantly correlated with soil properties, which were mostly explained by soil water and soil P content (*Table A5*). Meanwhile, SLA, LD and all variables of leaf chemistry were significantly correlated with stand structures, which were mainly supported by tree sizes (e.g. H and DBH) (*Tables 3* and *A5*). Furthermore, soil properties explained 29.3% of the total variance in leaf morphology and stand structures explained 19.6% and 30.2% of the total variance in leaf morphology and chemistry (*Fig. 6*). In the same situation, the interspecific variation of LA and LCN were all

DOI: http://dx.doi.org/10.15666/aeer/1805_66376661

significantly correlated with soil properties, which were mainly supported by soil water and soil P content (*Table A6*). Specific leaf area, LChl, LCN, and LCP were significantly correlated with stand structures that mainly contributed by BA and DBH (*Tables 4* and *A6*). Soil properties explained 18.4% of the interspecific variance in leaf morphology, stand structure explained 26.89% and 31.7% of the interspecific variance in leaf morphology and chemistry (*Fig. 6*). For intraspecific variance, LA, LDMC, and LCN were all significantly correlated with soil properties, and SLA, LD, LCN, LCP, and Parea were significantly correlated with stand structures defined by stand tree height (*Tables 5* and *A7*). 40.7% of intraspecific variation of leaf morphology was explained by soil properties, and 20.9% of leaf chemistry was explained by stand structures (*Fig. 6*).

Discussion

Intra- and interspecific variability of leaf traits

Our findings indicate that leaf morphology traits of the between-species for two independent axes of trait covariation together accounted for approximately 87% of the variance. Likewise, at the communities, roughly 97% of the variance was explained in multidimensional trait space (*Fig. 1*). The first axis alone accounted for 58.6% of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66376661

variance at between-species and 75% of variance at the community, which depicted light capture dimension of the plant strategy spectrum and light availability (LDMC and SLA) (Wright et al., 2004; Lusk et al., 2008), and the second axis accounted for 28.6% of variance at between-species and 25.3% of variance at the community, which described investment physical attributes (LA and LD) (Chauvin et al., 2018).

For chemical trait spaces of the between-species and communities, the first axis reflected the chemical attributes, which is integral to the proteins of the photosynthetic machinery. The second axis represents an investment in foliar nutrition, which is essential to many of the chemical compounds involved in leaf structure and metabolism (Wright et al., 2004). Other results from The SMA regression analysis demonstrated that morphological traits were reciprocally correlated with chemical traits (*Figs. 2, 3, 5*). In fact, these traits are often found to be strongly correlated with each other across species and communities. For example, evergreen leaves are often sclerophyllous and associated with a lower SLA, lower leaf N content, and lower mass-based photosynthetic capacity (Curtis and Ackerly, 2010; Kröber et al., 2015). This trend is in line with the leaf economics spectrum (LES) that characterizes ecological strategies with quick to slow payback of investments of nutrients and dry mass (Wright et al., 2004; Osnas et al., 2013). At the leaf level, SLA, leaf dry matter content, and leaf N concentration has been employed to predict accurately the maximum photosynthetic rates of a wide range of species (Reich et al., 1997). At the plant level, all three traits have been found to be involved in a fundamental tradeoff between a rapid production of biomass and efficient conservation of nutrients (Poorter and Jong, 1999). And SLA (or related leaf traits) and LCN significantly impacted on primary productivity and nutrient cycling at the ecosystem level (Aerts and Chapin, 2000).

The importance of intraspecific variance has been neglected in community ecology for a long time (Bolnick et al., 2011). Recently, however, there has been greater attention paid to intraspecific variability, which has underlined the developments to integrate variation in both the intraspecific as well as interspecific levels in trait-based community ecology (Violle et al., 2012). Despite this increase in attention, understanding how intraspecific variation influences such functional shifts is not well understood in montane broad-leaved forests. Our results show that intraspecific variability of both leaf morphological and chemical traits account for roughly 20% of the variation, and interspecific variability explained 80% in functional turnover (*Fig. 4*). These findings illustrate that most of the variance in raw trait values was explained by differences between species. Intraspecific variance accounted for a smaller part of the total variance, resulting in either from genetic variation or phenotypic plasticity (Albert et al., 2011), in line with the growing consensus that intraspecific trait variation is not negligible (Albert et al., 2010b). This result could reflect the dissimilarity in high species turnover in montane broad-leaved forests (Luo et al., 2016).

Based on community-weighted mean traits values, the interspecific variation of leaf morphologic traits was the main contributor to functional trait change (*Table 2*). For chemical traits, intraspecific variability of LCN, N_{area}, LCP, P_{area} accounted for 56.2%, 42.8%, 36.2% and 35.9% variation, respectively. This was in accordance with previous results that intraspecific effects are often comparable to, and sometimes stronger than, species effects. These effects tend to be larger for direct ecological responses, whereas intraspecific effects and species effects tend to be similar for indirect responses; intraspecific effects are especially strong when indirect interactions alter community composition (Des Roches et al., 2018). Chemical functional traits are associated with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66376661

photosynthetic rate and nutrient cycling (Wright et al., 2004; Pérez-Harguindeguy et al., 2013), high variability in leaf chemical trait responses to stress or environmental gradients has been reported in previous studies (Auger and Shipley, 2013; Siefert et al., 2015). Finally, chemical traits are typically greater than leaf morphologic traits in broad-leaved forests, indicating that the relative contribution of intraspecific variation largely influences local functional composition, the maintenance of species coexistence, and the dynamics of communities (Lichstein et al., 2007; Bolnick et al., 2011; Courbaud et al., 2012; Violle et al., 2012; Luo et al., 2016).

Influence of environmental factors on intra- and interspecific trait variability

We found that soil properties significantly showed relationships with leaf morphology in total variance, interspecific variance, and intraspecific variance (*Table 2*), Soil properties accounted for 29.3%, 18.4% and 40.7% of the variation in these variables, respectively (*Fig. 6*). This result is interesting given that soil nutrient conditions (i.e., total soil N and total organic C) are the most important explanatory factors for SLA variation at both intra- and interspecific levels (He et al., 2018). In particular, LDMC of intraspecific variance was more significant than SLA with soil properties, and soil properties explained roughly 98% of variation intraspecific variance (*Fig. 6*). In other words, LDMC was a better predictor than SLA for describing the relationships between leaf morphologic traits and soil properties. Though LDMC and SLA were both correlate with nutrient availability, LDMC varied independently from leaf thickness and was also strongly correlated with resource availability and with relative growth rate (Garnier et al., 2004; Roche et al., 2004; Fortunel et al., 2009).

Leaf dry matter content has been recommended as a more reliable correlate of soil fertility in biomes not subject to severe water limitation (Vendramini et al., 2002). Another reason is that in montane broad-leaved forests, the shaded leaves have high SLA that results in the optimization of light capture rather than being associated with high soil fertility (Hodgson et al., 2011). Likewise, abundance-weighted LDMC, as opposed to SLA, was the superior predictor of aboveground net primary production (Smart et al., 2017). In addition, leaf area (LA) of inter- and intraspecific variance was related to soil attributes (*Tables 4, 5*), this indicated increasing in LA had greater access to light, leading to take advantage of increased soil resource availability, especially for tall species (Siefert and Ritchie, 2016), in line with the dominant plasticity mechanism, which predicts that competitive species have strong phenotypic plasticity to maximize resource capture and competitive ability (Ashton et al., 2010).

With regard to the relationships between leaf chemical traits and soil properties, our finding was that two categories showed inconspicuous relevance for the first canonical variable (*Table 2*). This result hints at the idea that soil properties had no systematic effect on foliar nutrient status, which might be because plants are able to constrain the flexibility of nutrient concentrations (Sistla et al., 2015). Namely, a change in soil nutrient availability did not necessarily imply a change in foliar nutrient status, especially when deficiencies were moderate (Luiro et al., 2009). Another explanation is that gradients of nutrient availability in soils were generally narrow, making investigations of the role of soil fertility in nutrient remobilization difficult (Achat et al., 2018). Additionally, their relationships were directly or indirectly affected by soil properties, soil types, parent materials, and climate gradients, even though their gradients were not very wide in our study sites (Augusto et al., 2017; Achat et al., 2018).

DOI: http://dx.doi.org/10.15666/aeer/1805_66376661

From a stand structural perspective, we suggest that leaf traits in interspecific and intraspecific variance were significantly correlated with stand characteristics. Previous studies on height and crown-related changed in leaf morphological, chemical and photosynthetic traits between and within species (Chmura and Tjoelker, 2008; Burgess and Dawson, 2010; Kenzo et al., 2016). For instance, mass- and area-based leaf N decreased, and specific leaf area (SLA) increased with increasing canopy depth, and SLA and leaf N -trait gradients showed variations between loblolly pine and slash pine (Kenzo et al., 2016). The intraspecific variance of leaf traits (e.g., LDMC, SLA) may also be related to aboveground biomass, which was potentially driven by the functional identity of tree height at different forest strata as well as at whole-community (Ali and Yan, 2018). In general, plant life history strategies suggest that taller species respond more strongly to leaf photosynthetic capacity (e.g. SLA, N and P content) because they potentially experience increasing light levels as they grow to the canopy. In contrast, small-statured species may remain in the shaded understory for their whole life cycle, and those results are supported by studies of the effect of light, nutrients and other environmental factors on plant leaf traits and their relationships (Santiago and Wright, 2007; Mao et al., 2017).

Our study showed that leaf N content per area (N_{area}) and leaf P content per area (P_{area}) (high values for acquisitive strategies) are strongly related to stand height and DBH in their intra- and inter-specific variance (*Tables A5, A6, A7*). Leaf density (LD) and dry matter content (LDMC) (high values for conservative strategies) are strongly in their interspecific variance responses to different stand height and DBH (*Tables A5, A6, A7*). Those findings that leaf traits consistently represent inter- and intraspecific variations in the studied forest have important implications in the individual plant strategies, community assembly and ecosystem function (Siefert et al., 2015). In addition, LDMC showed high contributions of interspecific variance to the changes along the stand structural gradient (*Fig. 6*). Those results hint at the fact that leaf traits and bivariate leaf trait relationships are modified by plant size, although their positive correlations generally remain invariant. However, a plant size effect on leaf traits relationships has scarcely been examined, although it may be critical to understanding plant life history strategies, especially for subtropical forests (Liu et al., 2010).

Conclusion

Our results revealed that the contribution of interspecific variability was dominant for leaf morphological and chemical traits at between-species and communities, despite the high level of intraspecific variability for leaf chemical traits (e.g. LCN, N_{area}, LCP, P_{area}) at communities in montane broad-leaved forest, which suggest that intraspecific functional variability should be a concern for ecologists. We also observed that intently relationships between leaf morphological and chemical traits presented by leaf assemblages at between-species and communities. Traits that are coordinated within plant strategies (leaf economics spectrum) showed that total, intra- and inter-specific variability responses to environmental gradients (stand structures and soil properties) when considered for the communities. Our findings highlight the structure of inter- and intraspecific variability in actual communities acts as a signature of community assembly processes, and alters with environmental gradients. In the future, we need more experiments to better understand the influence of sampling effort and design on the quantification of the absolute and relative amount of intraspecific trait variability

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66376661

within and among communities, and disentangle the extent and consequences of plastic and genetic trait variation at the community and ecosystem levels. Most importantly, the researchers should perform a more systematic evaluation of the effects of inter- and intraspecific variability on functional diversity indices and their relationships to environmental variables or other community properties on local scales.

Acknowledgments. This study was funded by the National Natural Science Foundation of China (Grant No. 31800352) and the National Major Protection Wild Plants Inventory Project (003Z0305), and was supported by Cooperative Innovation Center of Ecological Security in the Upper Reaches of the Yangtze River.

Author contribution. C. X. H. and X. J. R. performed the leaf morphological and soil measurements; Z. A. J. analyzed the data and wrote the article with substantial collaboration from all authors.

Conflict of interests. The authors declare that there is no conflict of interests.

Abstract. Rice weevil, *Sitophilus oryzae* is one of the most devastating primary pests of stored grains. Adults feed mainly on endosperm, while larvae feed on germ, resulting in reduced germination and nutritional value of kernels. The influence of a commodity condition on the food preferences of *S. oryzae* has been well documented, but the influence of previous feeding experience ("natal habitat preference induction" – NHPI theory) has not yet been confirmed. This research aims to test the NHPI theory, to study the behavioural responses of *S. oryzae* virgin males and females to different grains (maize, wheat and barley) depending on rearing substrate and feeding history and to test host, feeding and oviposition preference. In a "Choice test", the host preference was determined based on the adult distribution on specific grains, feeding preferences based on grain damage (%) and grain loss (%), and ovipositional preference based on the progeny production. The results indicate that host, feeding and ovipositional preference of *S. oryzae* was not dependent on the previous feeding experience. Maize was the most preferential grain, regardless on the rearing substrate, for both male and female weevils. Grain damage, weight loss and progeny production were higher on maize, regardless on the rearing history.
Keywords: *maize, grains, storage pest, food attractiveness, progeny*

Introduction

In general, annual grain losses in storages due to the presence of insect pests approach 15% (Joshi et al., 1991), while the maximum grain loss attributed to a single weevil species reached 19% in wheat and nearly 57% in rice (Banerjee and Nazimuddin, 1985).

Rice weevil, *Sitophilus oryzae* (Linnaeus, 1763), (Coleoptera: Curculionidae) is one of the most economically damaging primary pests of stored grains, primarily barley, maize, rice, and wheat (Atwal and Dhaliwal, 2002). This pest causes the highest damage to grains that are stored at 25 – 30 °C and at low relative humidity (Batta, 2004). Adult weevils feed mainly on endosperm, reducing the carbohydrate content while larvae feed preferentially on germ, resulting in reduced germination and nutritional value due to removal of a large percentage of the proteins and vitamins. Nonetheless, the kernel

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66636673

damage caused by *S. oryzae* enables other species, secondary pests (external feeders) to additionally damage the grain. Similarly, Zakladnoi and Ratanova (1987) reported that during the development, larvae consume about 50% of the total grain weight. Additionally, seed germination is reduced and infested grain is more susceptible to infestation by other associated pests and pathogens. Although polyphagous pests consume and develop on a wide range of hosts, their behaviour is influenced by several physical and chemical factors. The influence of a commodity condition on the food preferences of *S. oryzae* has been well documented, but available data on the influence of previous feeding experience (at a larval stage) on food preference are scarce (Trematerra et al., 2013). Some authors report that a previous experience on host plants can modify insects feeding behavior. Since the induction of insect's preference to host plants varies depending on both, plant and insect species, it is necessary to investigate each insect-host plant interaction to determine if this phenomenon occurs or not (Boica Junior et al., 2016).

The most comprehensive review on the storage insect-host plant interactions was published by Trematerra et al. (2013) who summarized theories on insect host preference. As mentioned by Trematerra et al. (2013), theories like Hopkins host selection principle (Dethier, 1954), neo-Hopkins principle (Jaenike, 1983) and "chemical legacy hypothesis" (Corbet, 1985) tend to explain how can host preferences be induced without being genetically fixed. The Hopkins host selection principle (Hopkins, 1917) assumes that a memory of the feeding substrate is formed during the larval stage, stored in the central nervous system and transferred across metamorphosis to the adult stage. This phenomenon is called "preimaginal conditioning" (Thorpe and Jones, 1937; van Hemden et al., 1996; Barron, 2001; Blackiston et al., 2008). The "neo-Hopkins principle" (Jaenike, 1983) postulates that the host preference is determined at the adult stage shortly after the emergence from pupa ("early adult experience") (Van Emden et al., 1996). To date, the most comprehensive theory on the induction of host plant preferences is the "chemical legacy hypothesis" (Corbet, 1985). Based on this theory, small amounts of molecules of environmental chemicals inside the insect body or on the body surface at larval or pupal stage are assumed to influence the adult's food preferences. In this case, induction might happen in any developmental stage by contact with traces of chemicals transferred from an earlier stage. In this theory, no "learning" and no "memory" transfer among stages is required.

Mentioned theories, that were based on the results from several studies, support the idea that the experience with plant chemical residuals at the larval and/or adult stage can influence adult preference. However, in most studies, it has been difficult to identify the specific factors by which larval experience has changed adult behaviour because several learning mechanisms are involved. As Dethier noted in 1982, the mechanisms by which natal experiences affect later preferences vary. Therefore, he endorsed the more general term to describe situations in which experience with particular stimuli (plant chemical) increases preferences for the same stimuli "preference induction" or "natal habitat preference induction" - NHPI (Davis and Stamps, 2004). Namely, NHPI is an umbrella concept that encompasses a few more specialized terms, such as the Hopkins host selection principle and the "chemical legacy".

According to the NHPI hypothesis, phytophagous insect females prefer to lay their eggs on the host species on which they developed as larvae (Schoonhoven et al., 1998). As mentioned by Davies (2004), at this point, NHPI in the strict sense has been observed in relatively few species, so additional studies of this phenomenon are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66636673

necessary. Even though there are numerous studies on the factors that affect the behaviour of *S. oryzae* in relation to previous experience at the adult stage, there is still inadequate information about the effect of natal exposure to specific nutrient medium. Food selection under natural conditions is influenced by various chemical and physical factors that affect insects' behaviour, ecological interactions and developmental or physiological status. Effects of feeding experience on food preference have been shown in various phytophagous insects, including stored-grain pests, as reported by Davis and Stamps (2004).

The relationship between preference of ovipositing females to certain plant species, growth, survival, and reproduction of offspring on those plants has been a central problem in the theory of insect-plant interactions. For *Sitophilus zeamais* (Motschulsky, 1855), it has been confirmed that females tend to lay eggs on maize kernels that are subjected to multiple visits, which emphasizes the significance of "already visited" kernels (Danho and Haubruge, 2003). However, for stored-product weevils, it is not clear what is the benefit from the oviposition on already-visited and infested kernels. Generally, it is considered that stored-product weevils differ significantly in food-mediated oviposition selection. As reported by Danho and Haubruge (2003), seed beetles like *S. zeamais,* can lay multiple eggs in a seed, increasing the competition among the larvae, while females of other species like bruchids, usually avoid competition during oviposition. As reported by Russell (1968), "kernel size" is a factor that also influences ovipositional preference of grain weevils and should not be overlooked.

As mentioned earlier, the influence of a specific commodity condition on *S. oryzae* development and preference depending on food quality has been well documented, but there are only a few available information for the nutritional preferences in relation to previous experience of food at larval stage. According to the NHPI hypothesis, phytophagous insect females prefer to lay eggs on the plant species on which they developed as larvae. This research aims to study the behavioral responses of virgin *S. oryzae* male and female adults to different grains on which they were not reared, and to test the NHPI hypothesis. Additionally, this work aimed to gain the information on host, feeding and oviposition preference of *S. oryzae*.

Material and methods

This work aimed to assess the feeding preference of *S. oryzae* weevils to different grains, in relation to previous feeding experience, as well as to test the NHPI hypothesis on this species. The influence of one factor- feeding experience at larval stage (i.e. rearing substrate) on host, feeding and oviposition preference of adults was assessed based on following indices: male and female distribution on different offered grains in a "Choice test", grain damage (%), remained grain weight (g), weight loss (g) and progeny production (male and female weevils).

Insect culture

S. oryzae weevils were reared for 10 generations on wheat kernels, variety Pobeda (wheat-reared weevils) and dent type maize kernels, hybrid NS640, (maize-reared weevils), in controlled conditions, at 27 ± 1 °C, 70 ± 5% RH and in continuous darkness (Trematerra et al., 2013).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66636673

Newly emerged, less than 12-h-old adults of *S. oryzae,* were collected from rearing jars containing wheat and maize. The weevils were sexed for the assay, individually according to the shape of the rostrum, which is distinctly longer, narrower and smoother in the females than in males (Halstead 1963) and pronotum characters (Nardon and Nardon, 2002). Weevils were starved 24 h before setting up the experiment.

Host and feeding preference

In a "Choice test", host and feeding preference parameters were determined.

The host preference was assessed based on the mean number of weevils in each Petry dish (males, females and males + females), attracted to different grains, after each exposure period. To determine the response of *S. oryzae* males and females to different grains, 20 sexed weevils were placed from the rearing substrate in the center of test arena, a plastic container with a lid (60×40×25 cm). Four treatments containing 100 g of wheat, maize and barley were offered in separate Petri dishes (Ø 9 cm). Three Petri dishes were placed in the test arena and the assay was carried out for 50 days, but the readings were made after 12, 36 and 60 h, and 7, 25 and 50 days.

Feeding preference parameters included: grain damage, remained grain weight and weight loss (expressed in %). Damaged grains were separated manually from undamaged grains using a magnifying glass and were weighed, separately. Percent of grain damage was calculated using the following formula:

$$\text{Grain damage } (\%) = \frac{\text{number of damaged grains}}{\text{total number of grains}} \text{ x } 100 \qquad \text{(Eq.1)}$$

Upon the conclusion of the experiment (50 days) and after the new generation emergence, weight loss was calculated based on the weight at the beginning of the experiment and weight of grains after the exposure of 50 days and the removal of insects. Experiment was replicated six times.

Ovipositional preference and progeny production

Ovipositional preference was assessed based on the progeny production. From each substrate, and replicate, after the termination of the feeding preference assay (25 days), the adults were removed and Petri dishes with grains were closed and maintained at the same temperature for an additional period, up to 50 days from the beginning of the experiment. After 50 days, dishes were opened, and live adult progeny was counted.

All experiments were performed at 27 ± 1 °C, 70 ± 5% RH, in continuous darkness, as the rearing of parenteral population. Experiments were set in six replications.

Statistical analysis

The differences between distribution percent of weevils on different grains, the amount of consumed food and difference in progeny production were tested using Bonferroni test and Students T test in statistical Software SPSS 17, for the confidence interval of 95%. To determine the strength of the differences between groups the effect size was calculated using Eta squared test (Cohen, 1992).

Results

Host and feeding preference

The number of weevils in different commodities significantly differed among recording periods. When provided with a choice of grains, wheat-reared males and females showed higher preference to maize and barley, compared to the wheat. In the first reading (after 12 h), the distribution of wheat-reared S. oryzae females in Petri dishes was 73% on maize, 22% on barley and 5% on wheat. This trend remained throughout the experiment. In the same period, males from wheat-reared population were distributed as follows: 67% of individuals on maize, 32% on barley and 1% on wheat (*Fig. 1*). The difference in distribution was statistically highly significant in both cases ($F = 466.7^{**}$, 740.3^{**}, $p < 0.01$, respectively). After 25 days, the total amount (100 g) of maize kernels was consumed in all replicates and both male and female weevils migrated mainly to barley (average 81% of individuals) and in smaller precent to wheat (19% of individuals). The difference was highly significant ($t = 387.8^{**}$, $p < 0.01$).

Maize-reared weevils were predominantly found on maize, followed by barley, while wheat kernels did not attract adults. Weevils already chose maize kernels in the first assessment, after 12 h (*Fig. 1*), and the number of both males and females on maize remained high during the entire observation period. However, slightly higher preference of males than females for maize kernels was recorded. After 12 h, the distribution of females was 93% on maize and 7% on barley, while males were distributed 89% on maize, 10% barley and 1% on wheat. The difference was highly significant ($t = 582.1^{**}$; $F = 962.5^{**}$, $p < 0.01$, respectively). This trend was more evident when pairs (the presence of male and female weevils simultaneously) were considered. Such distribution of individuals remained the same until the observation on the day 25. After 25 days, the entire amount of maize kernels was consumed and the weevils migrated mainly on barley (95% of weevils), and only 5% on wheat (in total, regardless on the sex). The difference was highly significant ($t = 744.1^{**}$, $p < 0.01$).

In the "Choice" test, after 50 days, in Petry dishes containing maize-reared weevils, the grain damage in maize (98.8%) was statistically higher compared to both barley (34.3%) and wheat (6.7%). The damages significantly differed from wheat-reared population ($F = 1481.0^{**}$, $p < 0.01$, Eta Squared 1.00) and the amount of consumed grains after 50 days is presented in *Table 1,* as well as the results on the remained grain weight and weight loss (%). The highest grain loss in wheat-reared case was evident in maize (84.3%), followed by barley (43.6%), while the lowest loss occurred in wheat (23.5%). The difference is statistically highly significant ($F = 167.4^{**}$, $p < 0.01$, Eta Squared 1.00).

Ovipositional preference and progeny production

Ovipositional preference was determined based on the progeny production. Significantly higher emergence of males and females from maize and barley grains, compared to the wheat, was recorded from maize-reared population (*Table 1*). On average, 18.62 males and 19.33 females emerged from maize, 12.71 males and 11.85 females emerged from barley, whereas 1.5 males and 2.0 females emerged from wheat. The differences between the number of emerged weevils from different substrates were significantly higher in maize-reared population, both for males ($F = 141.0^{**}$, Eta squared 1.00, $p < 0.01$) and females ($F = 530.0^{**}$, Eta squared 0.2, $p < 0.01$) as well as in a total number of emerged weevils ($F = 1377.6^{**}$, Eta squared 1.00, $p < 0.01$). However, the difference in sex emergence was not significant on certain grains.

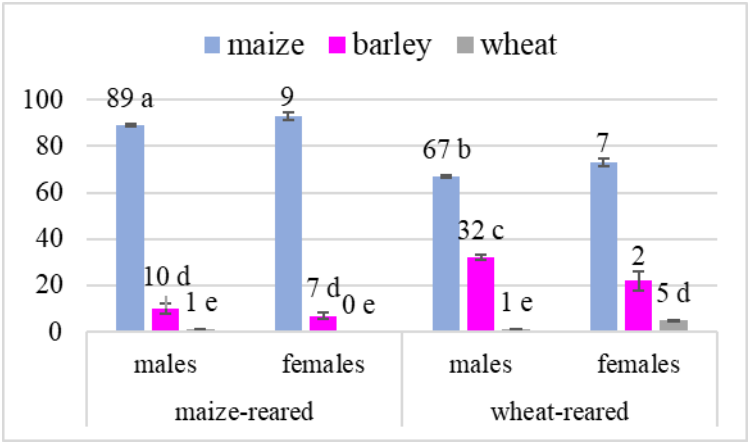

Figure 1. *Distribution of Sitophilus oryzae males and females after 12 h on different cereal grains*

From wheat-reared population, 9.8 males and 10.7 females emerged on maize, 7.6 males and 8.2 females on barley, while no progeny production was recorded on wheat (*Table 1*). The differences between sexes were not statistically significant, nor were the differences between maize and barley. However, the total differences, including wheat emerged progeny, were statistically highly significant for all, males (F = 1544.7**, Eta squared 0.94, $p < 0.01$), females (F = 5644.0**, Eta squared 0.63, $p < 0.01$) and total progeny (F = 3214.8**, Eta squared 1.00, $p < 0.01$).

Discussion

Cereal grains differ significantly in attractiveness to *S. oryzae*, but this effect depends on several factors (Baker, 1988). This study tended to determine the main factors influencing host, feeding and oviposition preference of *S. oryzae*, in relation to Natal habitat preference induction hypothesis (NHPI) and/or food attractiveness.

In phytophagous insects, the NHPI predicts that females prefer to lay their eggs on the same host species on which they developed as larvae. NHPI hypothesis is based on

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66636673

the fact that experience with a natal habitat, namely food they developed on, shapes the habitat preferences of adults. However, since scientists used different terms to describe this phenomenon (Immelmann, 1975; Jaenike, 1983; Barron, 2001) it is unclear how frequently NHPI occurs and what are the implications of its occurrence. Results from several studies suggest that experience with plant chemical compounds (residuals) at the larval and/or pupal stage can influence adult preference to specific food. However, in most studies, the specific factors by which larval or pupal experience has changed adult behaviour were not identified because several learning mechanisms are involved.

Results on the host preference determined in this study indicate that wheat-reared *S. oryzae* adults preferred maize (43% female and 39% male individuals), to barley (35% female and 32% male individuals) and wheat (22% female and 29% male individuals). Maize-reared individuals, both males and females, had higher preference for maize (89% males and 93% females), less for barley (10% males and 7% females), while wheat was of the least favourable choice (1% of males). These findings are in accordance with Trematerra et al. (2013) who reported that inequality of maize, rice, barley and wheat in experiments indicate the fact that the preference is also influenced by genetic predispositions and that there are several factors that determine the behavioral response of *S. oryzae* to specific semiochemicals from food that are not related with natal exposure. On the other hand, this inequality could also be caused by the fact that maize, rice, barley and wheat kernels release different concentrations of odour. Also, as suggested by Trematerra et al. (2013), males visited more different food sources than females, which can be attributed to males pronounced mobility compared to females when food is available. Also, repeated "visits" by males could have occurred which is probably related to an increased probability in finding a suitable mating partner (Campbell, 2005; Guedes et al., 2010).

Price et al. (2011) reported that polyphagous herbivores use multiple host-plants for feeding and/or oviposition which is considered an evolutionary adaptation that enabled these species to adapt to variable environments. Unfortunately, the mechanisms of host-plant choice are not always easily defined and many factors are of importance, larval physiology, natural enemies, reproductive behaviour etc. (Bernays, 2001; Forister and Wilson, 2013; Bernays and Grahm, 2013). Female should choose the most suitable host plant for oviposition and for her offspring to develop. However, as reported by Nanthagopal and Uthamasamy (1989), female may make host choice decisions based on factors influencing her survival, such as nutritional quality of the plant.

For phytophagous insects such as *S. oryzae*, oviposition and food choice decisions are essentially the same (Singer et al., 1992). There is some evidence that oviposition preference and performance of offsprings can be correlated with heritable variability for oviposition preference as reported by Singer et al. (1988) for phytophagous insects in general, and by Fox (1993) for bruchids.

Based on the results of our study, previous feeding experience on feeding behaviour of *S. oryzae* virgin males and males was only confirmed in the case of maize-reared populations. Trematera et al. (2013) concluded that larval experience does not affect host preference in *S. oryzae* adults and also, it is not determinative in food selection. However, it should be mentioned that presented results correspond the specific grain used in the experiment (i.e. varieties) and no generalization should be made, since the data obtained may not be transferable to other commodities. The higher preference of maize and barley compared to wheat might be also due to a release of different concentrations of volatile compounds from maize, rice, barley and wheat kernels. Plant-

DOI: http://dx.doi.org/10.15666/aeer/1805_66636673

borne volatiles play a role in food and host location, routing insect orientation and searching behaviour (Dicke and Baldwin, 2010). Germinara et al. (2008) indicate that for example, granary weevil adults can respond with different behavior to a wide range of cereal volatiles and that response may change depending on the concentration. Host finding behavior of weevils will depend on the balance of positive and negative volatile stimuli from grain as the relative concentrations of volatiles may change during storage. According to Visser (1986), phytophagous insects use volatiles from plant materials to locate suitable substrates and, as stated by Kanaujia and Levinson (1981) the presence of phagostimulatory compounds are considered crucial in the infestation process in storage pests. Additionally, Levinson and Kanaujia (1982) report that *S. granarius* male and female respond to various extracts from stored winter wheat. We can speculate that, since NHPI theory was not proven in our study, the food attractiveness, as a result of nutritive value and the presence of certain volatiles, was the factor influencing host, food and oviposition preference of *S. oryzae* to maize, primarily.

In our study, the feeding preference of *S. oryzae* towards wheat, maize, and barley was tested under "choice" conditions. Grain damage, grain weight loss and progeny production differed significantly among the various selected host grains. Grain weight loss was found to be the greatest in maize (98.8%) and the lowest in wheat (6.7%), for the population reared on maize. Subedi et al. (2009) also confirmed that, wheat was the least attractive host for *S. oryzae* compared to other cereals (rice, barley and maize). These authors reported that the greatest grain damage was observed in polished rice (18.75%) and less in wheat (16.25%) in a free-choice test. However, these findings are opposite to the results presented by Ansari (2003) where damages in wheat were the highest (67.78%), while in maize were significantly lower (40.97%). Subedi et al. (2009) reported that wheat was the most preferred host under no-choice conditions, however, when insects were offered a choice of polished rice and wheat, polished rice was the most preferred choice in "choice test". *S. oryzae* thus preferred polished rice under free-choice and wheat under no-choice.

Ovipostion and progeny production were higher on maize, regardless on the rearing history. In this study, the progeny production in maize-reared weevils was the highest on maize (37.9 in total), followed by barley (24.5 individuals; males + females) while the lowest on wheat (3.5 individuals). On wheat-reared population, the situation was similar, so in total (males + females) 20.5 weevils emerged from maize, 15.8 from wheat and none from barley. Our results also suggest that larger kernels, like maize are more desirable hosts for *S. oryzae*, comparing to small-kernel hosts, such as barley and wheat. Stejskal and Kucerova (1996) and Akhter et al. (2017) have demonstrated that *S. oryzae* prefers large kernels for oviposition than smaller, because they can contain more than one egg, comparing to smaller ones. Akhter et al. (2017) showed that *S. oryzae* adults preferred to lay larger number of eggs on pulse, which are considerably larger in size than other tested grains, rice and wheat. Russell (1968) also observed that weevil preferred to lay eggs in grains of larger size. Some other factors besides grains size also affect host and ovipositional preference. For example, seed with smooth surface are more preferred than rough and spiny ones (Salunkhe and Jadhav, 1982). Also, hardness of grain is very important factor which affects the oviposition rates (Teotia and Singh, 1968). Females accepted large kernels more quickly than small kernels and this contributed to increased oviposition in large kernels. The increase in the number of eggs per kernel appears to result from an increase in number of visits resulting in oviposition rather than an increase in the number of eggs laid during a visit (Campbell, 2002.)

Conclusion

This study tended to determine the main factors influencing host, feeding and oviposition preference of *S. oryzae*, in relation to NHPI and/or food attractiveness.

The results of this study reveal that host, feeding and ovipositional preference of rice weevil, *Sitophilus oryzae* was not depending on the previous feeding experience. Host preference, based on the distribution of females and males on different grains, grain damage, grain weight loss and progeny production differed significantly among selected host grains. Maize was the most preferential grain, in all aspects, regardless on the rearing substrate, for both male and female weevils. Grain damage, weight loss and progeny production were higher on maize, regardless of the rearing history, followed by barley. Oviposition and progeny production were the highest on maize, regardless of the rearing history. Since NHPI theory was not proven in our study, we can speculate that food attractiveness was most probably result of nutritive value and the presence of certain volatiles, and therefore was the main factor influencing host, food and oviposition preference of *S. oryzae* to maize. Additionally, we can speculate that kernel size plays very important role in host preference since in both wheat- and maize-reared population, adult weevils chose larger maize kernels before smaller wheat and barley kernels as the most preferable food source.

Future research should be directed towards identification of different volatiles in host-plants which influence the behavior of *S. oryzae* and conduct behavioral studies with identified volatiles. Also, population parameters of *S. oryzae* should be conducted on different hosts in a large number of generations in order to evaluate the adaptive response of *S. oryzae* to the change of host.

Abstract. Manipulation of heterotic potential is considered to be a vital approach for enhancing yield potential of wheat to overcome food security threats. Heterotic potential of ten F1 bread wheat hybrids was estimated for grain yield and contributing traits. Hybrids were developed by crossing five genetically diverse elite wheat lines/varieties with two local land races following line × tester mating fashion at the regional Agricultural Research Institute, Bahawalpur (Pakistan). The resultant hybrid progenies were grown along with parental genotypes during rabi season 2014-15. Highly significant genetic variability was present in the experimental material for the traits under study. Most of the crosses showed significant heterosis over mid, better and standard parents. Maximum significant commercial heterosis was observed in plant height (27.66%), followed by tillers per plant (16.67%), peduncle length (13.59%) and grain yield per plant (10.68%).The highest increase in grain yield per plant over the commercial variety was observed for the cross CB-35 × LR1 which may be considered for selection as hybrid or pure line wheat varieties for increasing grain yield.
Keywords: *food security, hybrids, crosses, genetic variation, heterosis*

Introduction

Wheat (*Tritium aestivum* L.), is the most important crop and among the major three cereal crops that provide staple nutrient source for 40% of world population (Giraldo et al., 2019) and 20 percent of the total energy requirement in human food (Shewry, 2009). Wheat belongs to the *poaceae* family, originating from the Levant region of the Near East and Ethiopian Highlands, but now cultivated worldwide (Belderok, 2000). Major cultivated species of wheat include: *Triticum aestivum*, which is a hexaploid species and is widely cultivated in the world; *Triticum durum*, the only tetraploid form of wheat widely used today, and the second most widely cultivated wheat; *Triticum monococcum*, a diploid species with wild and cultivated variants; *Triticum dicoccum*, a tetraploid species, cultivated in ancient times but no longer has widespread use; *Triticum spelta*, another hexaploid species, which is cultivated in limited quantities (Moon, 2008). It is used to make flour for leavened, flat and steamed breads and most of the baked foods (Hrivna et al., 2018) and for fermentation to make beer and alcohol (Tsenov et al., 2008).

In Pakistan, wheat is averagely used for about 60 percent of daily diet of common men with average per capita consumption of 125 kg (Khan et al., 2003). Pakistan is among top

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66756689

ten wheat producing countries of the world (Ihsanullah et al., 2002). The contribution of wheat to value addition in agriculture is 8.9 percent, while its contribution to GDP is 1.6 percent (GOP, 2019). Breeding efforts have resulted in various varieties of hexaploid wheat, having improved yield and grain characters. Varieties and advanced lines with different morphological and economic characteristics are now available as breeding stock.

To feed flourishing population of Pakistan; the genetic improvement of wheat genotypes for high yield potential is a dire need. For this purpose, the exploitation of maximum genetic potential from available genetic resources of wheat is a prerequisite. F_1 hybrid carrying heterotic effects, which are featured in all crop species, the yield gains are limited to the F_1 generation. Heterosis is considered as the superiority of the hybrids in comparisons to either of its parents. It is the allelic or non-allelic interaction of genes under the influence of specific environment. Heterosis has been estimated in a range of cultivated crops and has been the purpose of considerable importance to study as mean of increasing productivity of crop plant. It is now well established that heterosis does occur with proper combination of parents. Formerly, utilization of heterotic effects for grain yield was mainly ascribed to cross-pollinated crops. However, later it was reported in wheat as being predominantly self-pollinated for the first time by Freeman (1919), who well-versed the supremacies of F_1 crosses over their parents (Özgen, 1989). Briggle (1963) described existence of heterosis in substantial quantity for grain yield components in different F_1 wheat crosses. Keeping in view the above facts, the current research was designed to create genetic diversity and to estimate heterotic potential of crosses among elite lines/varieties with local races of wheat.

Materials and Methods

The plant materials for study consisted of 7 wheat (*Triticum aestivum*) genotypes including four strains (CB-35, CB-212, CB-214 and CB-219), one commercial variety (Mairaj-08) and two land races (LR-1 and LR-2) obtained from germplasm resources, Regional Agricultural Research Institute, Bahawalpur (Pakistan). All the genotypes were 99% pure and true breeding. The selection criteria of crossing lines (dwarf) was based on inducing semi dwarfness in next generation for enhanced yield. Sowing was done in *Rabi* (Winter crop growing months) season 2013-14, the seeds of each genotype was sown in two rows of 5 m length each separated by 30 cm. Recommended cultural practices (like fertilization, irrigation, weeding) were carried out during the whole experimental duration. At heading stage, crossing was made following line × tester fashion by keeping advance strains and commercial variety as lines (female parents) and land races as testers (male parents). Usual method for emasculation and pollination was adopted to prevent self pollination which a major limitation in hybrid production. 10-15 pairs of spikes were crossed to get optimum quantity of F_0 seed for each cross. At maturity, crossed spikes were cut, threshed manually, packed and labeled individually for each family.

Ten adjacent plants were tagged from the two central rows (5 plants from each row) prior to heading stage from each experimental plot. Data for various morpho-physiological traits including plant height, tillers per plant, days to heading, days to anthesis, days to maturity, grain filling period, peduncle length, spike length, grains per spike, grain weight per spike, 1000-grain weight and grain yield per plant were measured from tagged plants at appropriate stage.

DOI: http://dx.doi.org/10.15666/aeer/1805_66756689

Statistical Analysis

The analysis of variance was carried out following Steel and Torrie (1980). Significance of differences among genotypes for various plant variables was tested by least significant difference (LSD). Heterosis as compared to mid parent (MP Het.), better parent (BP Het.) and standard parent (SP Het.) as over the commercial variety i.e. Mairaj-08, was estimated using the formulae as

$$\text{Mid parent heterosis (MP Het.)} = (F_1 - \text{Mid parent})/\text{Mid parent}\rceil \times 100 \quad \text{(Eq.1)}$$
(Matzinger et al., 1962)

$$\text{Better parent heterosis (BP Het.)} = (F_1 - \text{Better parent})/\text{Better parent}\rceil \times 100 \quad \text{(Eq.2)}$$
(Fonseca and Patterson, 1968)

$$\text{Standard parent heterosis (MP Het.)} = (F_1 - \text{Standard parent})/\text{Standard parent}\rceil \times 100 \quad \text{(Eq.3)}$$
(Wynne et al., 1970)

The significance of heterosis was tested by applying t-test according to Wynne et al. (1970).

Results and Discussion

Analysis of variance revealed significant differences among all the genotypes for various traits under consideration. Variability due to genotypes was spliced into parents and hybrids, both the components also revealed significant variability with respect to all the characters. Parental genotypes were further split into lines and testers, both of which showed significant differences in performance for various morpho-physiological traits under study (*Table 1*). Mean performance of parents all the genotypes (parents and F_1 hybrids) and heterotic potential for various traits under consideration were as is as under.

Greater plant height is considered an undesirable character due to its positive correlation with lodging and negative relation with earliness. Thus taller plants tend to lodge more resulting in low grain yield (Mazurek and Sabat, 1984). Introduction of *Rht* dwarfing genes in tall stature wheat varieties resulted semi-dwarf varieties responsive to inputs which brought green revolution in 1960's. In present studies, parental genotypes which were used as females were short to semi dwarf statured ranging from 42 cm (CB-212) to 94 cm (Mairaj-08) as compared to males (LR-1 122.00 cm and LR-2 128.00 cm tall) (*Table 2*, *Fig. 1*).

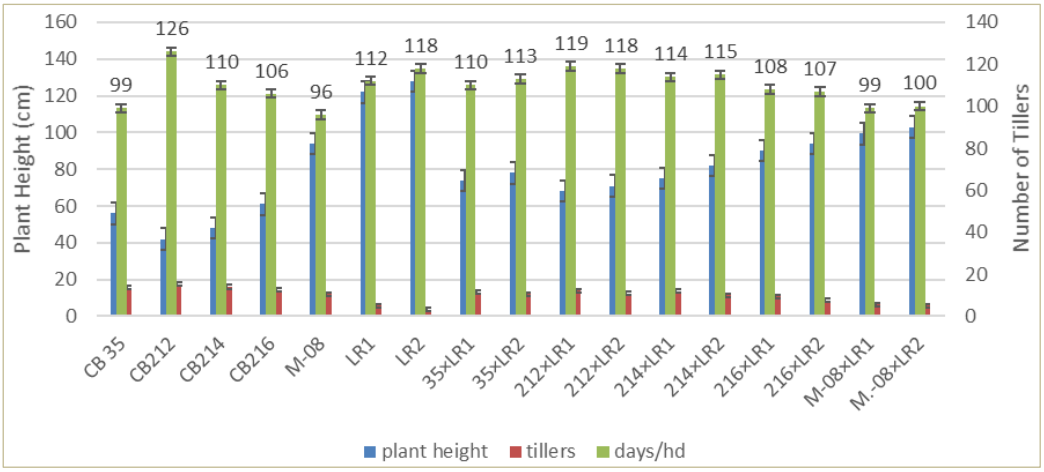

Figure 1. *Mean performance of parents and crosses for plant height, tiller per plant and days to heading*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66756689

All the F_1 crosses lied in between the range of parental genotypes with respect to plant height. CB-212 × LR-1, among F1 crosses, was at the lowest position regarding height while maximum height was recorded for the cross Mairaj-08 × LR-2 (103.00 cm) (*Table 2*, *Fig. 1*).

Lower value of number of days taken to 50% heading is directly related to earliness and vice versa. In present studies, parental genotypes which were used as females were ranging between 96.00 cm (Mairaj-08) to 126.00 (CB-212). While the male parents LR-1 and LR-2 were 112.00 cm and 118.00 cm, respectively (*Table 2* and *Fig. 1*).

All the F_1 crosses lied in between the range of parental genotypes with respect to number of days to 50% heading. Mairaj-08 × LR-1, among F_1 crosses, showed the minimum number of days for 50% heading (99) and hence was considered as the most favorable cross regarding earliness, closely followed by Mairaj-08 × LR-2 (100) (*Table 2*). While maximum days to heading were observed for the cross CB-212 × LR-1 (119.00) (*Table 2* and *Fig. 1*).

Days to anthesis are also a parameter related to short or long duration for maturity. It is also most affected by the environmental conditions. Maximum days to anthesis were taken by the line CB-212 i.e. 136 days while minimum days to anthesis were recorded for Mairaj-08 (110 days) (*Table 2*, *Fig. 2*). The results indicated Mairaj-08 as the favorable parent regarding earliness with respect to number of days taken for anthesis. Among male parents, LR-1 showed early anthesis (121 days) as compared to LR-2 which took 128 days (*Table 2* and *Fig. 2*).

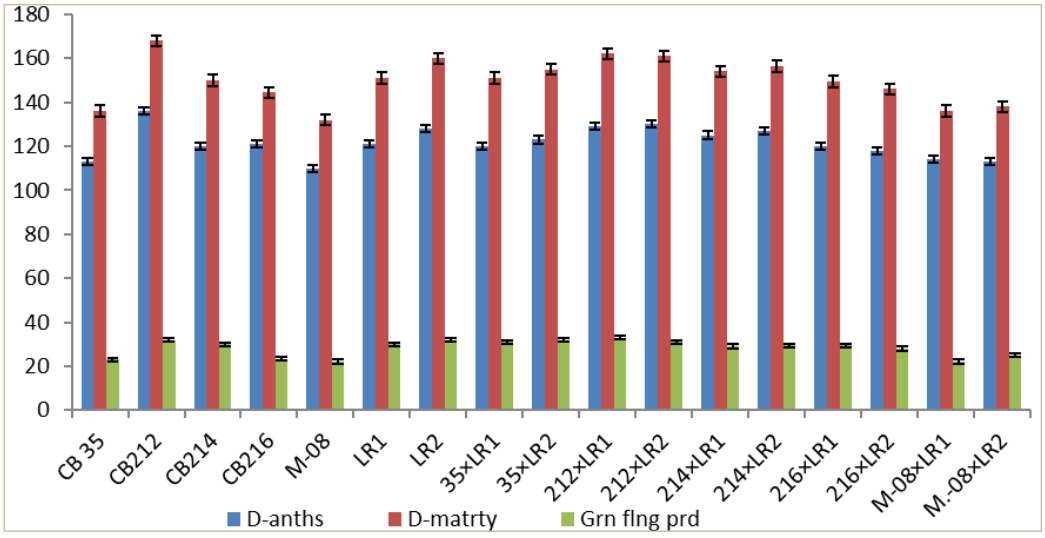

Figure 2. *Mean performance of parents and crosses for days to anthesis, days to maturity and grain filling period*

In some crosses where heterobeltiosis was observed over dominance might be involved and it may be concluded that effective selection of desirable recombinants from this material is possible. These results are in accordance with the previous findings (Sadeque et al., 1991; Ullah et al., 2006; Akbar et al., 2007) who also reported negative heterosis for plant height.

More tillers per plant results in more spikes per plant which increases the grain yield per plant. More tillering capacity was observed in lines ranging from 12.00 to 17.33 tillers

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66756689

as compared to testers (3.67 - 5.67 tillers per plant) (*Table 2*, *Fig. 1*). CB-212 produced the highest number of tillers per plant followed by CB-214 with 16.00 tillers while Mairaj-08 produced relatively lower number of tillers per plant (12.00) (*Table 2* and *Fig. 1*).

All the F_1 crosses lied in between the range of parental genotypes with respect to tillers per plant, Mairaj-08 × LR-2, among F_1 crosses, was at the lowest position regarding tillers per plant while maximum tillers per plant was recorded for the cross CB-214 × LR-1 (14.00) (*Table 2* and *Fig. 1*).

All the F_1 crosses lied in between the range of parental genotypes with respect to days to anthesis. Mairaj-08 × LR-2, took the lowest number of days regarding the trait (113.00), closely followed by Mairaj-08 × LR-1 (114.00 cm). CB-212 × LR-2 took the maximum number of days to anthesis (130 days), closely followed by CB-212 × LR-1 with 129 days to anthesis (*Table 2* and *Fig. 2*).

Days to maturity is the parameter directly related to crop duration whether early or late. A genotype taking more number of days to maturity is long duration and vice versa. Less number of days taken to maturity is desirable character. In current studies, among parental genotypes which were used as females, Mairaj-08 was the most early maturing with minimum days to maturity (132) followed by CB-35 which took 136 days to reach maturity (*Table 2*, *Fig. 2*). While CB-212 was recorded as the longest durational genotype taking 168 days to reach maturity (*Table 2*, *Fig. 2*). CB-214 and CB-219 took 150 and 144.33 days respectively, to reach their maturity stage (*Table 2*, *Fig. 2*). Among testers, LR-1 took 151 days while LR-2 took 160 days for maturity (*Table 2* and *Fig. 2*).

Range of F_1 crosses regarding number of days to maturity was recorded as 136 to 162 which are in between the two extremes of the parents for the concerned trait. Cross of Mairaj-08 with LR-1 and LR-2 were considered as the early maturing hybrids with 136 and 138 days taken to maturity, respectively (*Table 2* and *Fig. 2*). On the other hand, CB-212 × LR-1 took the maximum number of days to maturity with a value of 162 days, closely followed by CB-212 × LR-2 (161 days) (*Table 2* and *Fig. 2*).

Days taken for grain filling are also an important determinant of earliness or lateness of a variety or genotype. However it is also largely influenced by the environmental conditions. Minimum grain filling period was observed in Mairaj-08 (22 days), closely followed by CB-35 and CB-219 with values 23.0 and 23.33, respectively (*Table 2*, *Fig. 2*). CB-212 took the maximum days for grain filling i.e. 32 days, followed by CB-214 which required 30 days for filling of grains. While the testers LR-1 and LR-2 took 30 and 32 days period for grain filling (*Table 2* and *Fig. 2*).

In present studies, parental genotypes which were used as females were short statured for peduncle length ranging from 20 cm (CB-212) to 36 cm (Mairaj-08) as compared to males (LR-1 44 cm and LR-2 47 cm tall) (*Table 3* and *Fig. 3*).

All the F_1 crosses lied in between the range of parental genotypes with respect to peduncle length. CB-212 × LR-1, among F_1 crosses, was at the lowest position regarding peduncle length while maximum peduncle length was recorded for the cross Mairaj-08 × LR-1 (41.00) (*Table 3* and *Fig. 3*).

Almost half of the F1 hybrids showed increase in peduncle length over mid parental value but this increase was non-significant. All the crosses revealed heterobeltosis towards negative (lower) side, minimal decrease in peduncle length was recorded for the cross Mairaj-08 × LR-1 (*Table 4*). Above mentioned cross also gave the highest heterotic value of 13.89% for peduncle length over the standard parent (*Table 4*). These outcomes are in agreement with those of Farooque et al. (2005), Masood et al. (2005) and Ilker et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66756689

al. (2010) who advocated that long peduncle has positive direct effect on grain yield due to its photosynthetic activity.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66756689

Longer spike having more spikelets is usually, not always, considered associated with higher seed number per spike and ultimately the yield. The highest spike length, among lines, was observed in CB-212 (17.00 cm), followed by CB-35 with 16.33 cm average spike length (*Table 3*). Minimum spike length was recorded for the genotype CB-219 (9.33 cm) (*Table 3*). CB-214 and Mairaj-08 produced spikes of 11.67 and 11.00 cm length respectively. Both the testers, LR-1 and LR-2 produced shorter spikes with average length of 8.00 and 6.67, respectively (*Table 3* and *Fig. 3*).

Character of grains per spike is considered one of the major directly related yield components. Greater the number of grains per spike, greater will be the yield and vice versa. In present studies, parental genotypes which were used as females were showed a range of 42 to 49. Mairaj-08 gave the highest number of grains per spike followed by CB-219 (47). On the other hand CB-212 gave the least number of grains per spike (42). Among male parents LR-1 produced 36 grains per spike while LR-2 showed 33 grains per spike (*Table 3* and *Fig. 3*).

All the F_1 crosses lied in between the range of parental genotypes with respect to grains per spike. CB-214 × LR-1 was the most desirable cross as it produced the maximum grains per spike (46), followed by CB-214 × LR-2 (45) (*Table 3*, *Fig. 3*). While Mairaj-08 × LR-1 performed poor with respect to the character as it produced the lowest grains per spike (37), followed by Mairaj-08 × LR-2 and CB-212 × LR-1 which produced equal number of grains per spike (38) (*Table 3* and *Fig. 3*).

A range of 6.00 cm to 11.67 cm regarding spike length was recorded in F_1 population. CB-212 × LR-1 was considered the most favorable cross for higher spike length which produced spikes of 11.67 cm length (*Table 3*, *Fig. 3*). CB-212 × LR-2 and CB-35 × LR-1 produced spike of equal length of 10.00 cm. While the lowest spike length was observed in Mairaj-08 × LR-2 (6.00 cm), followed by CB-214 × LR-2 with 6.67 cm spike length (*Table 3*).

Maximum grain weight per spike was recorded for the line CB-35 (2.42 g), followed by CB-219 showed 2.40 g weight of grains per spike. While the lines Mairaj-08, CB-212 and CB-219 gave 2.36 g, 2.35 g and 2.26 g weight of grains per spike (*Table 3*, *Fig. 4*). While LR-1 and LR-2 produced 2.27 g and 2.13 g grain weight per spike (*Table 3* and *Fig. 4*).

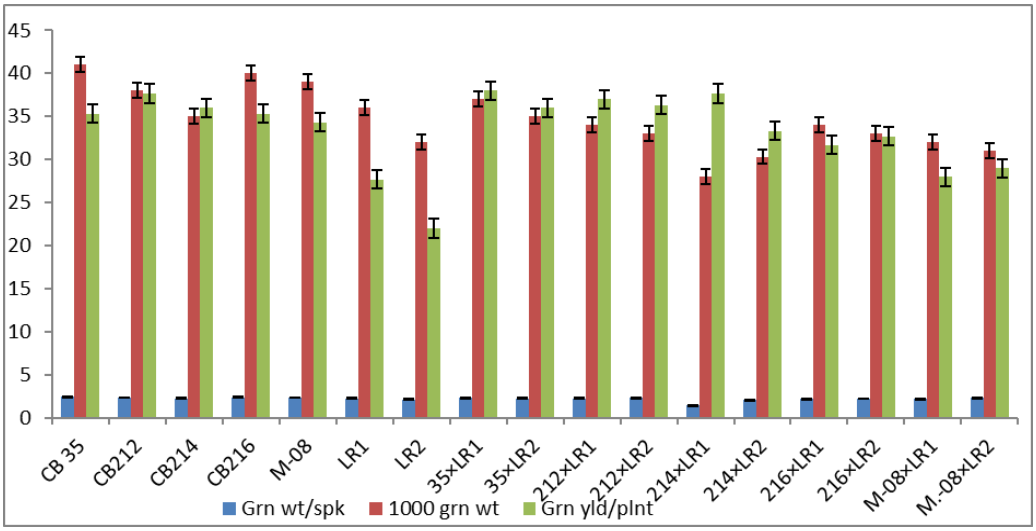

Figure 4. *Mean performance of parents and crosses for grain weight per spike, 1000 grain weight and grain yield per plant*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1805_66756689

Critical analysis of the data of mean performance of F_1 hybrids regarding grain weight per spike revealed that the cross Mairaj-08 × LR-2 produced the maximum grain weight per spike (2.32 g) (*Table 3*, *Fig. 3*). CB-35 × LR-1 and CB-212 × LR-2 showed equal value of 2.30 g for grain weight per spike. While CB-214 × LR-1 produced the lowest weight for grains per spike (1.46 g) (*Table 3* and *Fig. 3*).

All the F_1 crosses lied in between the range of parental genotypes with respect to 1000-grain weight. CB-214 × LR-1, among F_1 crosses, was at the lowest position regarding 1000-grain weight while maximum 1000-grain weight was recorded for the cross CB-35 × LR-1 (37.00) (*Table 3*, *Fig. 4*). All the crosses showed negative values for all three types of heterosis i.e. mid, better and standard parent. However CB-35 × LR-1 exhibited minimum decrease in 1000-grain weight in relation with mid (3.90%), better (9.76%) and standard parent (5.13%) (*Table 5*). Similar observations have been reported by Saleem and Hussain (1988), Abdullah et al. (2003), Hassan et al. (2007), Kumar et al. (2013) and Mahpara et al. (2015).

More tillers per plant results in more spikes per plant which increases the grain yield per plant. More grain yield per plant was observed in lines ranging from 37.67 to 34.33 as compared to testers (27.67 – 22.00). CB-212 produced the highest grain yield per plant followed by CB-214 with 36.00 grain yield per plant while Mairaj-08 produced relatively lower number of grain yield per plant (34.33) (*Table 3* and *Fig. 4*).

All the F_1 crosses lied in between the range of parental genotypes with respect grain yield per plant. Mairaj-08 × LR-1, among F_1 crosses, was at the lowest position regarding grain yield per plant while maximum grain yield per plant was recorded for the cross CB-214 × LR-1 (37.67) (*Table 3* and *Fig. 4*).

In present studies, parental genotypes which were used as females, having range of 35.00 (CB-214) to 41.00 (Mairaj-08) of 1000-grain weight as compared to males (LR-1, 36 and LR-2, 32 thousand grain weight) (*Table 3*, *Fig. 4*).

The negative estimates of heterosis and heterobeltiosis for plant height are preferred over their mid and better parent in wheat breeding because dwarfness is a desirable character (Budak and Yildirim, 1996). Almost all the hybrids showed reduction in plant height, most of which were significant too (*Table 6*). Maximum decrease in plant height as compared to mid parental value was observed in hybrid CB-35× LR-1 closely followed by CB-212 × LR-2, the later cross also showed the highest reduction in plant height over the better parent and standard parent (*Table 6*).

Maximum increase in tillers per plant over mid parent was observed in the cross CB-214 × LR-1 (26.15%), closely followed by Cb-35 × LR-2 (24.14%) (*Table 6*). While none of the crosses out yielded the better parent with respect to the higher parent. CB-212 × LR-1 showed 16.67% increase in tillers per plant as compared to the commercial parent (Mairaj-08), followed by CB-214 × LR-1 which showed 13.89% more tillers than the standard parent (*Table 6*). Heterosis in tiller plant per plant in wheat was also reported by many earlier researchers (Sadeque et al., 1991; Walia et al., 1993; Yu et al., 1997; Abdullah et al., 2002). So, these hybrids verified the earlier reviews.

Maximum decrease in days to heading over mid and better parent was observed in the cross Mairaj-08 × LR-2 (-6.54% and -15.25%, respectively) (*Table 6*). The above mentioned cross also showed minimum significant positive increase in days to heading (4.17%) over the standard parent (*Table 6*).

The outcome of the present study are in accordance with the results of Sadeque et al. (1991), Murai (1998), Wu et al. (2001) and Baric et al. (2004) who described that negative heterosis in days to heading may be an effective selection criteria for development of early maturing short durational cultivars in wheat.

The highest reduction in days to anthesis with respect to mid and better parent was recorded for the cross Mairaj-08 × LR-2 (*Table 6*). All the crosses showed increase in days to anthesis over the standard parent, while minimum increase was revealed from the above mentioned cross (*Table 6*). These findings are in accordance with previous reports by Chowdhry et al. (2005), Farooque et al. (2005), Ullah et al. (2006) and Boche (2013).

All the crosses showed negative heterosis over mid, better and standard parental value for spike length, however minimal decrease, also non-significant, in spike length as compared to mid and better parental value was recorded for the cross CB-219 × LR-1 (*Table 4*). While CB-212 × LR-1 showed minimum non-significant decrease in spike length as compared to the standard parent (*Table 4*). These significant outcomes are in agreement with those of Masood et al. (2005), Ilker et al. (2010) and Mahpara et al. (2015). Similar findings had been reported by researchers like, Walia et al. (1993), Li et al. (1997) and Hassan et al. (2007).

The genotypes produced as F_1 showed a range of 22 to 33 days for grain filling including Mairaj-08 × LR-1 at the lower extreme and CB-212 × LR-1 at the higher extreme (*Table 2* and *Fig. 2*). Grain filling period was considerably reduced as compared to mid and better parental value for the cross Mairaj-08 × LR-1 i.e. -15.38% and -26.67%, respectively (*Table 4*). While the same cross was at par the standard parent for the trait. These results were got supported by earlier reports of Murai (1998), Wu et al. (2001) and Baric et al. (2004), Ullah et al. (2006) and Beche et al. (2013).

The single cross Mairaj-08 × LR-2 was considered the most desirable genotype towards early maturity as it showed the highest heterotic effects over mid and better parent (-5.48% and -13.75%, respectively (*Table 4*). While none of the crosses showed reduction in maturity period as compared to standard parent, however the above mentioned cross showed minimum significant increase in maturity days over the commercial variety i.e. 4.55% (*Table 4*). These results of current study were supported by Farooque et al. (2005), Ullah et al. (2006), Hassan et al. (2007) and Boche (2013) who concluded that genotypes taking less number of days for maturity might possess the potential of yielding short durational pure lines.

The highest heterotic effects over mid parental value were observed for the cross CB-214 × LR-2 (13.92%), followed by CB-214 × LR-1 (12.20%) (*Table 5*). None of the crosses showed increase in grains per spike over better and standard parent, however the later mentioned cross exhibited minimum and non-significant decrease in grains per spike as compared to better parent and standard variety. Tiwari and Chakraborty (1992), Larik et al. (1999), and Hassan et al. (2007) observed similar results. These is agreement in earlier studies (Çifci and Yaðdi, 2007) but less than that of Fonseca and Patterson (1968) who found 100% heterobeltiosis in the crosses obtained from genetically different parents. On the other hand, Baric et al. (2004) found negative heterosis values in terms of number of grains spike in bread wheat crosses.

All the crosses exhibited negative values of heterosis over mid, better and standard parent except Mairaj-08 × LR-2 which presented positive yet non-significant heterosis over mid parental value (3.34%) (*Table 5*). The above mentioned cross also showed minimum and non-significant decrease as compared to better and standard parent with respect to grain weight per spike. These results were got supported by earlier reports of

Murai (1998), Wu et al. (2001), Abdullah et al. (2002), Farooque et al. (2005), Akbar et al. (2007), Ullah et al. (2006) and Boche, (2013).

Maximum significant increase in grain yield per plant, with respect to mid parental value, was recorded for the cross CB-35 × LR-2 (25.58%), followed by the cross CB-35 × LR-1 (20.63%) (*Table 5*). The later cross also showed maximum yet non-significant value for heterobeltiosis and the highest significant value (10.68%) for standard heterosis (*Table 5*). Results of heterosis in grain yield per plant were found in agreement with those of Wu et al. (2001), Abduulah et al. (2002), Faroque et al. (2005), Ullah et al. (2006), Akbar et al. (2007), Kumar et al. (2013) and Mahpara et al. (2015).

Conclusion and Recommendations

The research made use of semi dwarf lines to cross with land races in order to increase grain yield and to obtain noval germplasm resistant to lodging, which to good extent. It is recommended that since this research provides a baseline that could attract researchers to follow such and different crossing combinations with local land races to obtain improved varieties with significant yield for increased farmer premiums.

Abstract. Soil erosion is one of the major global environmental problems. Understanding the spatiotemporal changes in soil erosion is of great significance to its prevention and control of soil erosion and the optimization of ecological environments. Taking Central Yunnan Province (CYP), China as the study area, multitemporal remotely sensed images, GIS technology and the RUSLE model were used to estimate the amount of soil erosion in the CYP during 1980-2018. The results show the following: (1) During the study period, the soil erosion situation in the CYP showed a growing development trend. With 2005 as a turning point, the area of micro-erosion first decreased and then increased, and the area of soil erosion with mild and above intensity was effectively controlled. (2) Through the global spatial autocorrelation, the spatial distribution of soil erosion intensity in the CYP has significant aggregation, and the global Moran I index is between 0.48 and 0.66. The areas with moderate and above erosion intensity were mostly distributed in the mountains, northern valleys, and the northwestern and southwestern regions of the CYP. Through the analysis of local spatial autocorrelation, it is also proved that the distribution of intensity soil erosion is mostly related to regional topography.
Keywords: *soil erosion, RUSLE, temporal and spatial variation, spatial autocorrelation, Moran I index*

Introduction

Central Yunnan Province (CYP) is located on the western Yunnan-Guizhou Plateau and the eastern Yunnan Plateau. Nearly half of the mountainous plains (dams) in Yunnan Province are concentrated in the region, which has abundant soil and good water resources. According to the Bulletin on Soil and Water Conservation of the First National Water Conservancy Census, the type of soil erosion in Yunnan Province is hydraulic erosion. By the end of 2011, the total area of soil erosion was 109,588 km^2, accounting for approximately 7% of the total area of water erosion in China. The area of mild erosion is 44,876 km^2, accounting for 40.95% of the total area of hydraulic erosion; the area of moderate erosion is 3,476 km^2, accounting for 31.72%; the area of intense erosion is 15,860 km^2, accounting for 14.47%; the area of extremely strong erosion is 8,963 km^2, accounting for 8.18%; and the area of intense erosion is 515 km^2, accounting for 4.68%. As the core area of Yunnan Province, the soil erosion situation in central Yunnan is not optimistic; thus far, there is still insufficient research on soil erosion in the region. (Ministry of Water Resources of the People's Republic of China, 2013). With sustainable development in mind, soil erosion will lead to the destruction of soil resources, reductions

in arable land area, and decreases in soil fertility, all of which will affect productivity, deteriorate the ecological environment, destroy infrastructure, increase flood risk by silting up riverbeds, silt up rivers, lakes and reservoirs, and threaten urban and rural safety. Furthermore, soil erosion restricts the sustainability of agricultural production and seriously threatens the survival and development of human beings.

In the field of soil erosion research, the USLE (Universal Soil Loss Equation) model is the most widely used empirical model of soil erosion. According to their own soil erosion situation, many countries and regions have continued to improve and localize the USLE model. For example, the RUSLE (Revised Universal Soil Loss Equation) model was published in the United States in 1997 (Renard et al., 1997); the RUSLE2 model was obtained in 2002 (Gogichaishvili et al., 2014); and in 2008, Kirkby et al. (2010) considered soil infiltration and the impact of climate and climate drivers, and the PESERA (Pan European Soil Erosion Risk Assessment) model was improved by USLE; in 2015, Panagos et al. (2015) used European data for the estimation and scientific evaluation of the localized RUSLE model. From this attempt, the RUSLE2015 model was obtained. Additionally, the G2 model proposed in 2018 (Karydas et al., 2018) is based on the main principles and calculation formulas of the USLE and RUSLE models, and the monthly soil erosion rate model was constructed. The empirical model of soil erosion prediction has gradually been improved, and the localization research and treatment of relevant parameter factors of the model have also deepened; additionally, the obtained soil erosion simulation results are increasingly accurate.
