The native tree species in Turkish forests have lost many of their characteristics, especially in some regions, due to long years of irregular utilization and inappropriate interventions (Atmış et al., 2007). Besides raw wood materials, forests play an important role protecting biological diversity. Harmful insect species that lead to considerable economic losses in Turkish forests are controlled through various methods; the General Directorate of Forestry (GDF) spends a significant amount of money for that purpose. Therefore, this study evaluated the current status of biological control practices in Turkish forests and compared it with chemical controls method from the ecological-economical perspective.

Materials and methods

In this study, the insect control methods in Turkish forests were evaluated in general terms as a first step. Secondly, biological control methods and practices were examined. Finally, biological and chemical control methods were compared and analysed from an economical perspective. Data from 2004 to 2014 relating to these control methods, practices and economic expenditure in Turkey were evaluated. As it is difficult to express the benefits of sustainability of ecosystem services in insect control areas in economic and monetary terms, the costs of control methods were highlighted (Pak et al., 2010; Deniz and Ok, 2015).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_341353

Data were collected separately from 28 Regional Directorates of Forestry across Turkey in 2015 and 2016. The collected data included information about the size and cost of areas where chemical methods were applied, successful and failed cases for chemical and biological control methods and amounts of predatory species provided. Total and unit costs were estimated, and the amount of profit and loss was determined. Previous costs were converted to 2015 values using the Domestic Producer Price Index (D-PPI). Moreover, the Turkish Central Bank's data were used for international audiences and the unit costs were converted to USD. In general economic evaluations, all costs were taken into account, irrespective of the success status of insect control efforts in the relevant areas. However, the areas where the methods were successful or failed were taken into account when comparing the biological and chemical control methods; not only the economy of a method but also its success at the intended level is important. Therefore, biological and chemical control methods were evaluated from the perspective of cost minimization and cost saving regardless of their ecological impacts.

Results and discussion

Biological control practices in Turkish forests

The insect control methods that have been implemented in Turkey include chemical control with insecticides, biotechnical control with pheromone and pheromone traps, and mechanical control by way of collecting nest and egg batches of pine processionary moths (*Thaumetopoea wilkinsoni and T. pityocampa*) or trap trees for bark beetles (GDF, 2015). However, biological control methods appear to be preferred over these other control methods in recent years (*Fig. 1*); chemical control methods that cause harm to forests, organisms and people are largely abandoned.

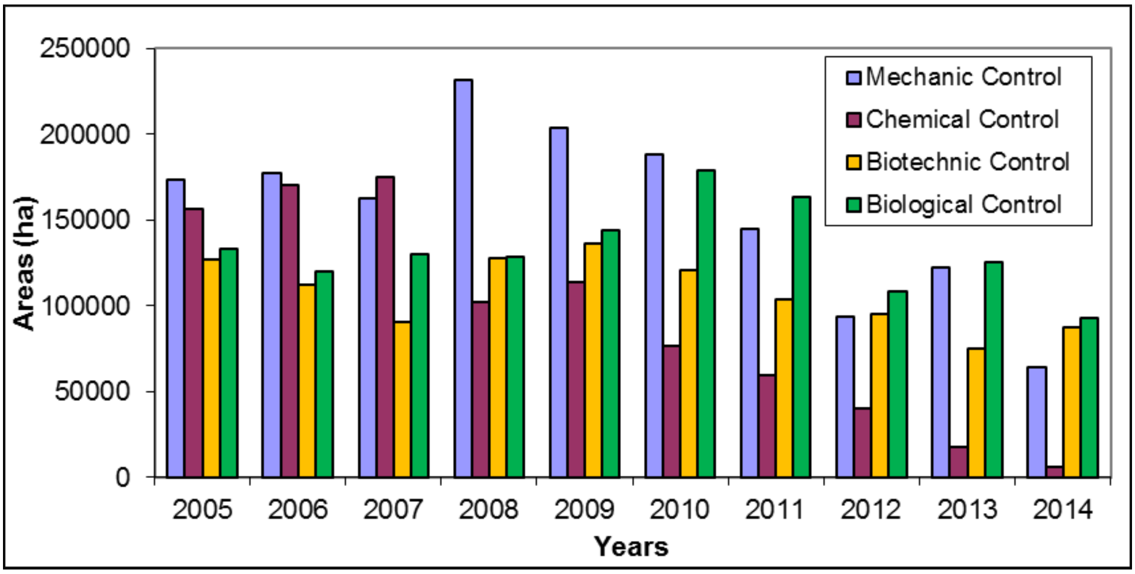

Figure 1. *Distribution of control methods by areas in Turkish forests (2005-2014)*

Formica rufa (Hymenoptera, Formicidae) is one of the important natural enemies used against the pest insects in Turkish forests. They can feed above and below the soil, and can reach the tops of the highest trees in an area with a radius of 25-100 m

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_341353

depending on the individual. It was found that a *F. rufa* colony can kill 100.000 insects within 24 hours (Avcı et al., 2000). Therefore, four proper nests can control an area of one hectare. For that reason, it is important to use *F. rufa* ants for biological control with a view to protecting the health of forests and ensuring the continuity of the ecological balance (Oğurlu, 2000; Avcı et al., 2000). *F. rufa* is naturally distributed intensively in the West Black Sea region located in the northwest of Turkey, most parts of the Black Sea region, some parts of the Marmara, Central Anatolia, and the Inner Aegean region in the west. The forest in Senirkent-Kapıdağ of Isparta province in the southwest of the country constitutes the southern boundary of the distribution area of the species. Their presence in Turkey was identified at an elevation of 950-2000 m and mainly in *Pinus sylvestris* forests (Avcı et al., 2000). The transplantation of *F. rufa* nests started in the 2000s, and increased significantly; successful practices were observed (*Fig. 2*).

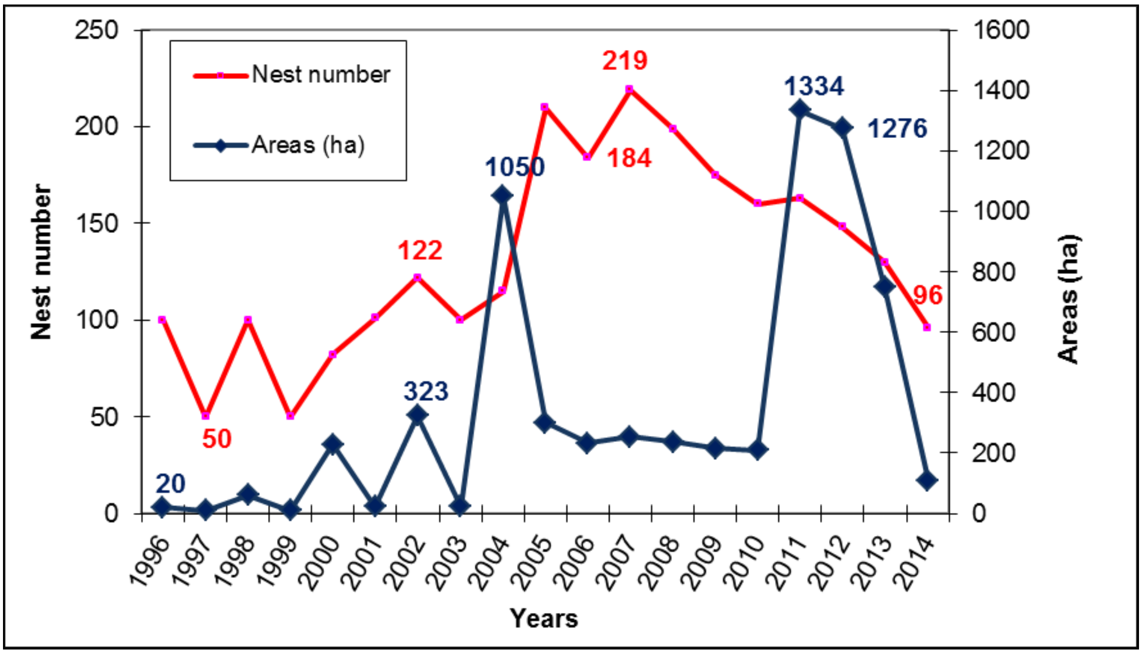

Figure 2. *Transplantation of Formica rufa nests (1996-2014)*

Calosoma sycophanta (L.) is on one of the most important predatory species for the forestry office in Turkey, produced in biological control laboratories established in different parts of the country and used against pine processionary moths (PPM). Mechanical control of PPM is expensive, while chemical control is known to have an adverse effect on the environment. In contrast, the adults and larvae of *C. sycophanta* that have a lifespan of 3–4 years affect the larvae and pupa of PPM *T. wilkinsoni*, which is very important for biological control. PPM causes physiological and primary damage on *Pinus brutia*, *P. sylvestris*, *P. pinea, P. halepensis* and *P.nigra* trees in Turkey. The adults of *C. sycophanta* can kill around 5-10 larvae per day. Considering that the adults can eat 7 PPM a day on average, an adult can kill 280 larvae a year on average, and around 900-1000 larvae on average throughout its life (Kanat et al., 2005; Anonymous, 2006). *C. sycophanta* is also a predator of *Lymantria dispar* and *Euproctis chrysorrhoea* that cause damage to beech, willow, linden and fruit trees. *C. sycophanta* feeds on the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_341353

larvae and pupa of the insects. GDF started rearing this species more intensively especially after 2004, in its biological control laboratories. The method of transplanting the larvae of *C. sycophanta* to the areas where PPM are distributed intensively has been very successful (*Fig. 3*).

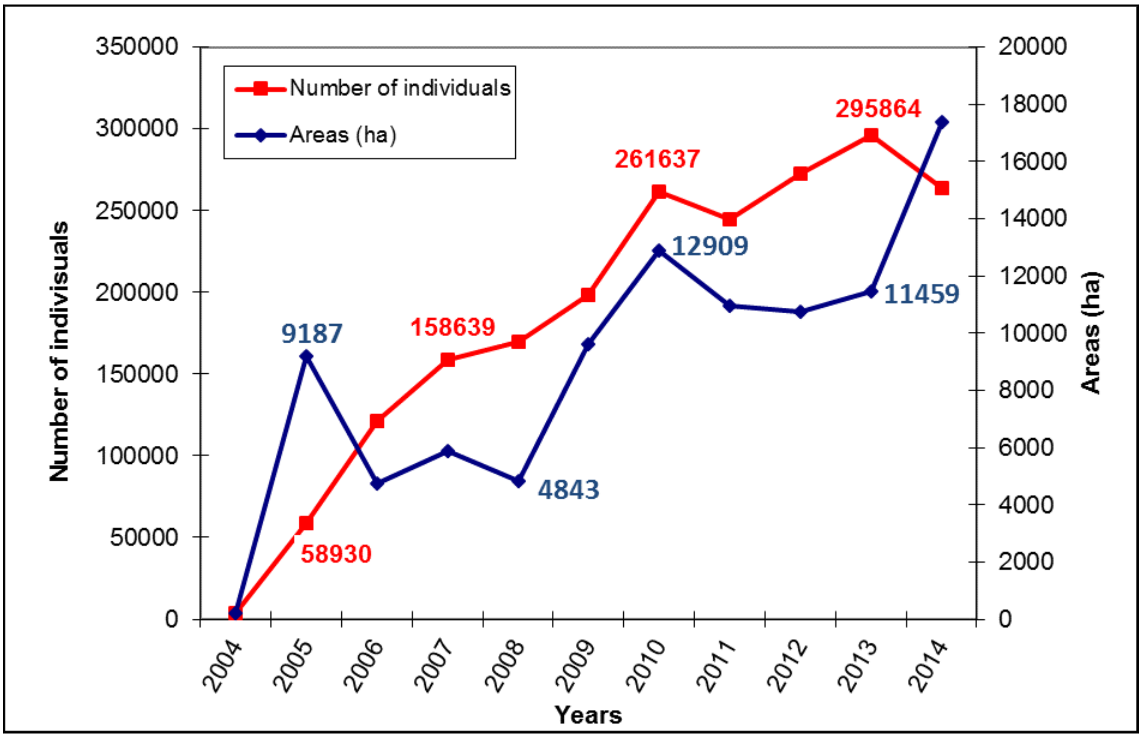

Figure 3. *Rearing and application areas of Calosoma sycophanta (2004-2014)*

One of the most important predators for bark beetle species in Turkey is *Thanasimus formicarius* (L.) (Coleoptera, Cleridae). This predator feeds on the adults, caterpillars and pupa of the bark beetles (*Ips typographus, Pityokteines curvidens, I. sexdentatus, Orthotomicus erosus* and *Tomicus minor* etc.) that cause damage to all coniferous forests (pine, fir, spruce) (Anonymous, 2006). *T. formicarius* is an important natural enemy, as it moves fast and thus can capture and kill the bark beetles. *T. formicarius* produces one generation per year in the East Black Sea region (180–1800 m) located in the northeast of Turkey and the Erzurum Sarıkamış location (2000-2400 m) in the east. The flying period of the insect is March-April at 180 m in the East Black Sea region, and extends from May to September at an elevation of 2000 m in Erzurum Sarıkamış. Studies show that *T. formicarius* can consume around 10 adult bark beetles per day and around 300 adult bark beetles throughout its lifespan (Akbulut et al., 2005). *T. formicarius* is a very important predator of *I. typographus* by feeding on its larvae, pupa and adults. *T. formicarius* is considered to be an important factor for the stabilization of *I. typographus* populations. Studies have reported that 81% of *I. typographus* in West Germany and 53% in Switzerland die in the logs where it coexists with *T. formicarius*. The number of *T. piniperda* also decreased by 92% in the environment where it coexists with *T. formicarius* (Yüksel et al., 2001). Akbulut et al. (2005) reported that *T. formicarius* had an effect on all bark beetles, though limited, and it had the most successful proliferation and attack on scotch pine (*Pinus sylvestris*) and oriental spruce

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_341353

(*Picea orientalis*) forests. *T. formicarius* is found intensively on the main galleries of *I. sexdentatus* in scotch pine forests, and prefers primarily *I. typographus* in the oriental spruce forests and then *I. sexdentatus*. It is determined that it prefers *P. curvidens* (%16.29) as a main target (Akbulut et al., 2005). *T. formicarius* is another important species farmed by GDF. This species is currently used in the field against bark beetles to a significant extent (*Fig. 4*).

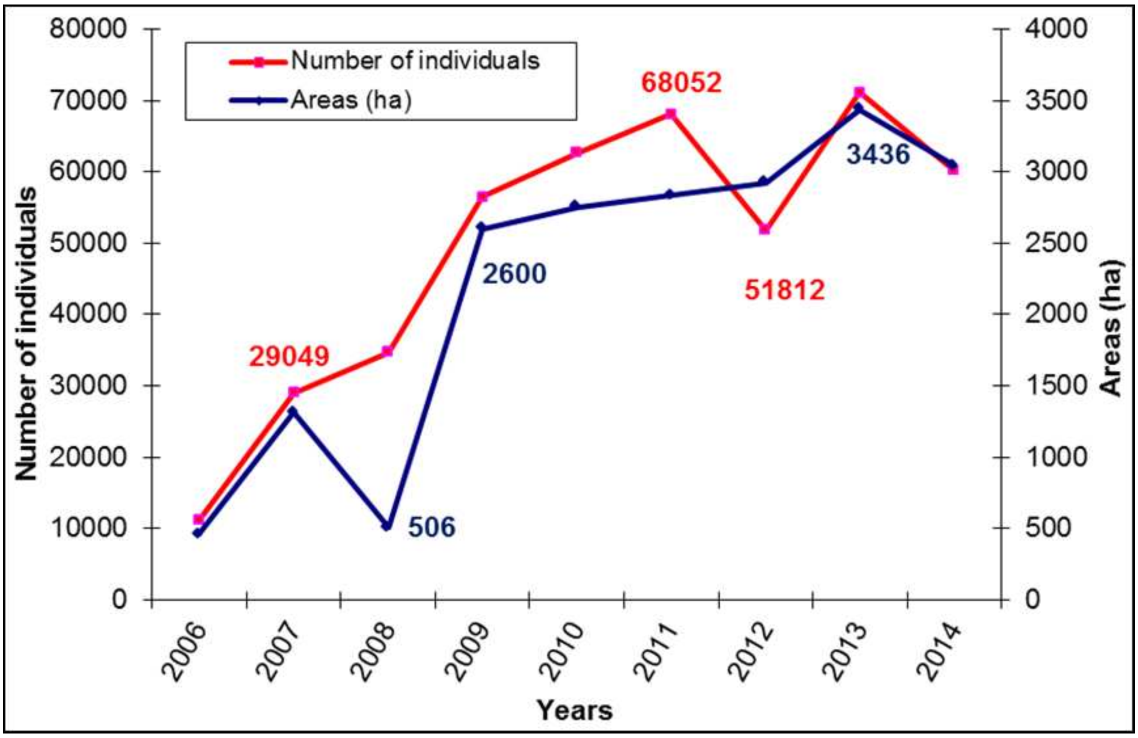

Figure 4. *Thanasimus formicarius rearing and application areas (2006-2014)*

Rhizophagus grandis Gyll. (Coleoptera, Rhizophagidae) is distributed in the Central and Northern European areas, Baltic countries and Siberia. In Turkey, *R. grandis* is an effective natural enemy of *Dendroctonus micans* Kug. which causes extensive damage to oriental spruce forests in an area of 75.000 hectares in Artvin and Posof located in the northeast. Bergmüller (1903) first reported that *R. grandis* was an important species in preventing the *D. micans* epidemics in Europe. Great achievements have been obtained with regard to the control of these insects in Turkey and many European countries. The epidemic of *D. micans* was mitigated with *R. grandis* by around 80–85% (Yüksel and Koçyiğit, 2001). Özcan et al. (2005) found that *R. grandis* could control *D. micans* by 78%.

R. grandis is being reared for the first time in Turkey, and has been used successfully for many years against *D. micans* that causes damage to oriental spruce (*Picea orientalis*) forests. In those treated areas, *D. micans* is no longer a significant threat and the natural balance has been restored in the spruce forests. As a consequence, the rearing of *R. grandis* has declined since 2009 (*Fig. 5*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_341353

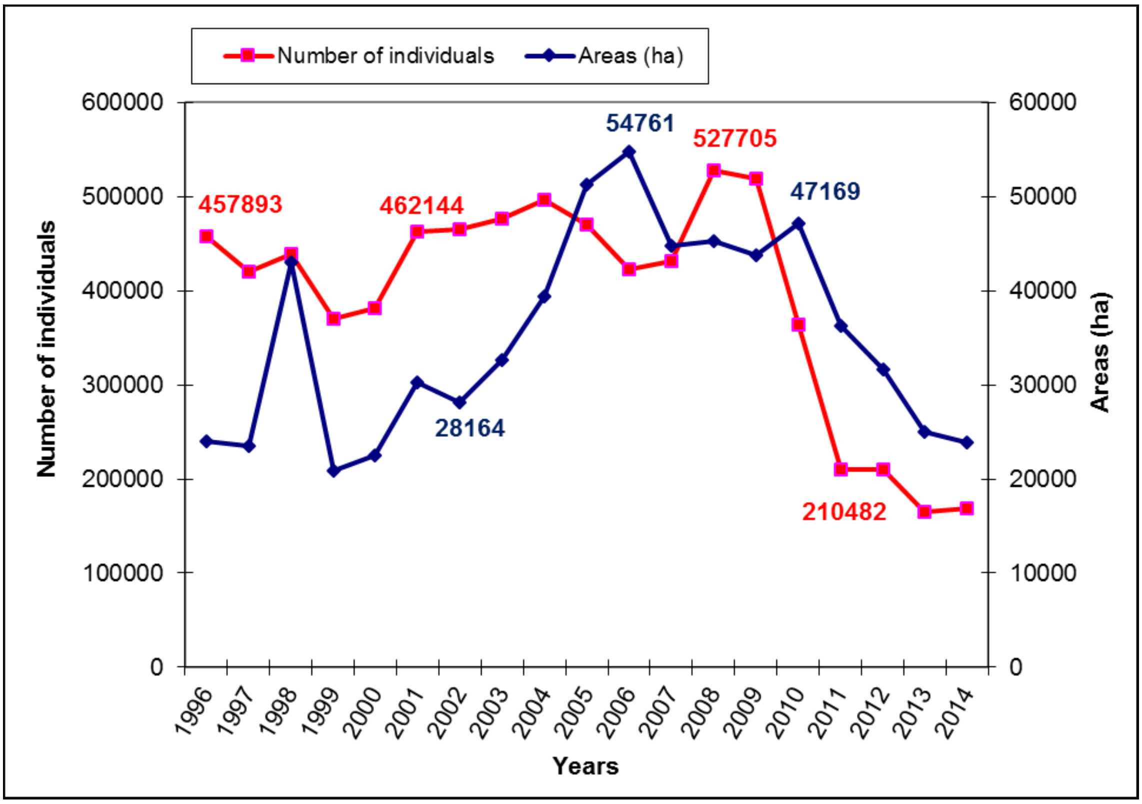

Figure 5. *Rhizophagus grandis rearing and application areas (1996-2014)*

Rhizophagus depressus (F.) (Coleoptera, Rhizophagidae) is another important predatory of bark beetles in Turkey. This species is distributed in the East Black Sea region at an elevation of 1000-2000 m, in Erzurum Sarıkamış at an elevation of 2000-2400 m., and in Bolu and Aladağ at an elevation of 1000-1700 m. with 2 generations per year. *R. depressus* attacks the nests of *I. sexdentatus* (58.43%), *I. acuminatus* (38.13%), *T.minör* (30.49%) and *T. piniperda* (29.52%) in *Pinus sylvestris* forests. The most important results of *R. depressus* were obtained against the insects that damaged *P. sylvestris* forests.

Particularly, *R. depressus* has been reported to have high efficacy on the populations of *I. sexdentatus* in Sarıkamış. The density of this predatory species in the nests of bark beetles in Sarıkamış is at minimum 31.89% and decreased the harmful population in *T. piniperda* nests by around 41%. The harmful insect species it prefers in the spruce forests are *Pityokteines spinidens*, *O. erosus*, and *I. typographus* (Yüksel et al., 2005). Meydan et al, (2005) reported that the density of *R. depressus* is 39% in the nests of *T. minor*, 33% in the nests of *T. piniperda*, 25% in the nests of *I. acuminatus* and 57% in the nests of *I. sexdentatus*. In the study, it was found to prefer mainly *I. sexdentatus*. While *R. depressus* was reared in the biological control labs of GDF and transplanted to nature in order to prevent the epidemics caused by this bark beetle in Turkey, a more effective species, *Thanasimus formicarius,* has been reared predominantly in recent years. Therefore, the quantity of *R. depressus* insects reared has declined significantly since 2013 (*Fig. 6*).

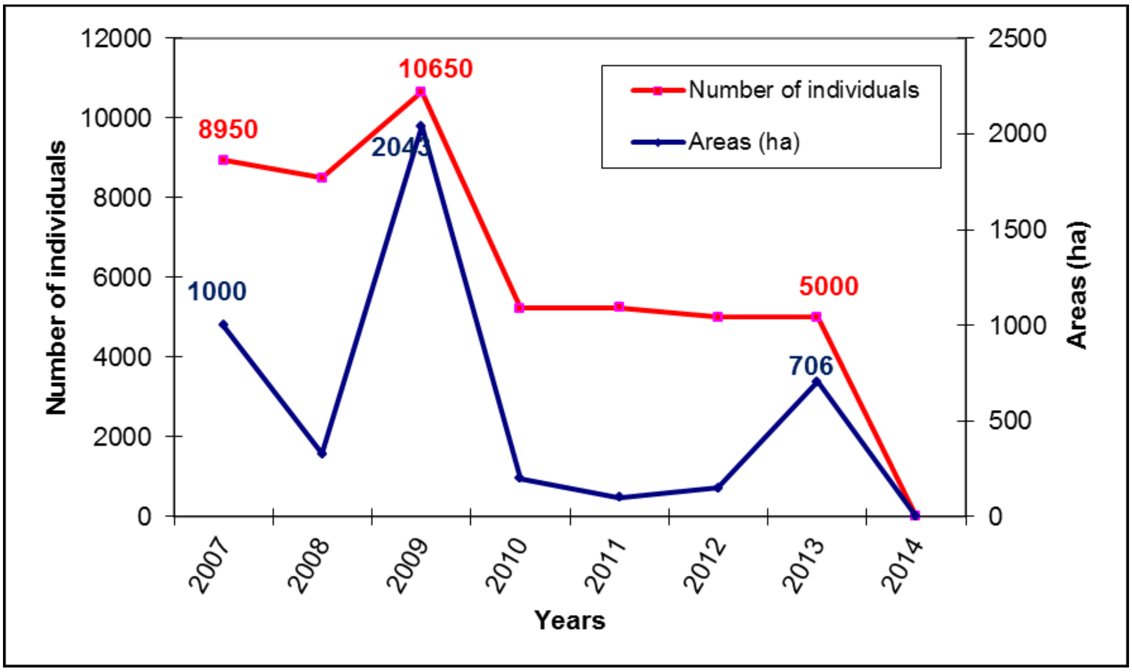

Figure 6. *Rhizophagus depressus rearing and application areas (2007-2014)*

Economic evaluation of biological and chemical control practices in Turkish forests

An analysis of the cost of insect control practices performed by the GDF reveals that mechanical control is one of the most expensive (*Fig. 7*).

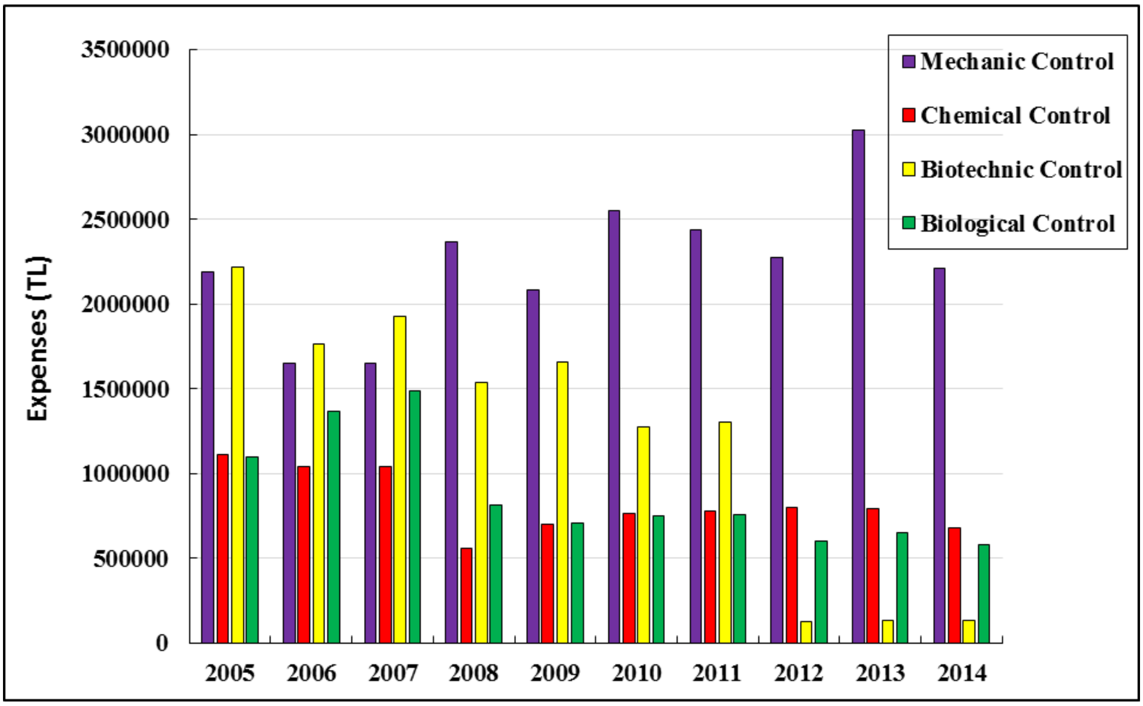

Figure 7. *Distribution of the costs of control methods used in Turkish forests (2005-2014)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_341353

This is followed by biotechnic control methods. *Fig. 7* shows that the expenditures have declined in recent years thanks to the success of biotechnical control. As for chemical control, the expenditures of GDF fluctuated from 2005 to 2014; overall it had a declining trend. However, as shown by *Table 1*, although the surface area where the GDF applied chemical control decreased from around 150 thousand ha to 10 thousand ha, it is noteworthy that the expenditures incurred for chemical control did not decline at the same rate. On the other hand, the cost of chemical control declined significantly from 1.113.000 TRY in 2005 to 680.125 TRY in 2014 (*Table 1*). In other words, although the area where chemical control was applied decreased by 15 times, the money spent for it decreased by only 1.6 times. One of the most important factors leading to that result was that almost all pesticides used for chemical control were imported and the TRY-USD exchange rate was high. Another factor is the need to reapply pesticides in the areas where chemical control failed.

Table 1. *Area-cost chart for biological and chemical control practices (2005-2014)*

Years	Chemical control			Biological control		
	Areas (ha)	Control costs (TRY)	Adjusted to 2015 (TRY)*	Areas (ha)	Control costs (TRY)	Adjusted to 2015 (TRY)*
2005	156.103	1.113.000	2.290.658,05	133.430	1.100.000	2.263.902,83
2006	170.379	1.038.499	1.915.544,61	120.153	1.366.706	2.520.932,92
2007	174.741	1.039.411	1.809.675,40	130.099	1.489.248	2.592.867.95
2008	102.415	557.000	897.047,74	128.475	814.000	1.310.945,90

2013	17.257	790.562	888.856,37	125.670	651.235	732.206,18
2014	5.729	680.125	718.970,33	120.751	576.956	609.908,84
Total	**915.780**	**8.262.902**	**12.575.492,31**	**1.353.504**	**8.822.551**	**13.821.194,13**

**Domestic Producer Price Index (D-PPI) was used for conversion (TUIK, 2017).*

Regarding biological control, the expenditures increased from 2005 to 2007, while decreasing in subsequent years (*Fig. 7*). This is because the GDF increased biological control practices by increasing the rearing of *C. sycophanta* in 2005, *T. formicarius* in 2006, and *R. depressus* in 2007. The decrease in the cost of biological control starting from 2008 was associated with the effectiveness and success of the control efforts (*Table 1*). Another point is that the average size of the areas where biological control methods were applied also varied significantly over the years. The average size of these areas decreased over the past years, while the reduction in the costs was more remarkable. This shows that the cost of biological control decreased as the natural balance was restored over the years (*Table 1*). As *Table 1* indicates, the costs in different years were converted to 2015 values for a more robust and accurate interpretation of the total costs of biological and chemical control over a period of years. At that stage, the unit costs were also calculated in order to determine the estimated amount of savings when biological control was preferred over chemical control (*Table 2*). To calculate the estimated amount of savings, it was assumed that biological control

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_341353

was preferred to chemical control. Thus, it was presumed that chemical control method was abandoned in the areas where biological control was applied, and the opportunity cost derived was retained by the GDF as savings. Accordingly, the estimated amount of savings in 2015 when the GDF preferred biological control to chemical control was around 1.75 million USD. Furthermore, in addition to this economic profit, the GDF also improved the effectiveness and success of control efforts from 2005 to 2014 on a continuous basis.

Table 2. *Unit costs of chemical and biological control and total savings*

Control Method	**Total Control Cost (TCC)** *TRY*	**Total Area (TA)** *ha*	**Control Unit Cost[1] (CUC)** *TRY/ha*	**Control Unit Cost[*] (CUC)** *USD/ha*	**Total Savings[2] (TS)** *USD*
Chemical Control	12.575.492,31	915.780	13,73	5,05	
Biological Control	13.821.194,13	1.353.504	10,21	3,75	1.751.840,23

*[1]CUC = TCC / TA, [2]TS = TBCA * (CCUC-BCUC)*
TBCA: Total Biological Control Area, CCUC: Chemical Control Unit Cost, BCUC: Biological Control Unit Cost
[*]Central Bank of Turkey average TRY-USD exchange rate of 2015 (1 USD = 2.72 TRY)

The economic analyses on biological and chemical control show that the cost of biological control is 3.75 USD per ha, compared to about 5.05 USD per ha for chemical control. These findings indicate that chemical control is 1.4 times more expensive than biological control in Turkey. An evaluation reveals that one of the most important factors affecting this difference is that the pesticides used for chemical control are imported and expensive. Moreover, harmful insects became resistant to the insecticides, requiring supply of new chemical compounds. This factor increases the cost of every new insecticide. For chemical control to succeed, pesticides have to be applied to the area until results are seen, which is another reason for the increased cost. Furthermore, special protective clothing, equipment and tools are needed to apply the pesticides in the field during chemical control. Annual periodical maintenance also increases the cost of chemical control. The cost of biological control is high initially, but decreases as the balance of the ecosystem is restored over time. The predators left in the area reproduce on their own and reduce the pest insect population below the economic loss threshold. Typically, it is not necessary to transplant the predators to the site every year. In other words, repetition is either not needed or very limited, which decreases the overall cost significantly. Another point related to cost is that the GDF employs its own laboratories and technical staff for the rearing of predators. Contrary to chemical control, they are not imported; therefore, the cost of rearing predators is low. Moreover, there is no need to use special clothing and equipment during the field application of biological control, which also decreases the cost.

Conclusions

In this study, the current status of biological control practices addressing pest insects in Turkish forests was analysed and compared with chemical control methods from an economic perspective. The first biological control was applied in Turkish forests in 1967, when *Formica rufa* was transplanted. However, the efforts regarding biological

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_341353

control were not that extensive until the 2000s. Turkish forestry organizations needed to take action because: the pesticides used with chemical control were harmful for the forests and human health, the chemical compounds used for the preparation of these pesticides were expensive, and the insects developed resistance against the pesticides. As a result, biological control efforts were increased especially after 2000 in Turkish forests, while the chemical control practices were eventually abandoned. This indicates the importance that the Turkish forestry organization attaches to the biological control method especially in recent years.

In particular, *C. sycophanta* since 2004, *T. formicarius* since 2006 and *R. depressus* since 2007 have been predominantly reared and extensively used during biological control operations. The quantity of these species and the areas where they are used have increased over the years and significant achievements were obtained. It is important from the ecological perspective that natural balance is restored gradually in these areas where biological control is applied. However, the economic aspects of insect control efforts are as important as the ecological aspects. From this perspective, an important finding of this study was that significant economic savings were obtained in addition to the ecological benefits as the chemical control was abandoned. The successful results including cost savings obtained by biological control practices add to point to the fact that the ecological balance in Turkish forests is gradually being restored.

The economic analyses revealed that the cost of biological control was around 3.75 USD per ha as compared to around 5.05 USD per ha for chemical control. Thus, when the ratio of the unit costs are calculated, it was found that the chemical control method was around 1.4 times more expensive than the biological control method. It is estimated that the economic savings will further increase as the areas where biological control is applied are extended, and the areas where chemical control is applied are reduced. Indeed, as the ecosystem gains back its natural balance in time through biological control, the cost of biological control per unit area will decrease; therefore, it is estimated that the economic savings will further increase. Thus, biological control is the most economic method for Turkish forests. The analyses revealed that the economic saving derived by abandoning chemical control methods is estimated at around 1.75 million USD in 2004-2014.

In conclusion, the primary benefit of biological control is that it restores ecological balance and thus ensures continuity of the ecosystem services. Its secondary benefit is the cost savings it brings. Therefore, the use of biological control methods to address pest insects in Turkey's forest ecosystems contributes remarkably to ecological and economic sustainability.

Abstract. *Acacia ehrenbergiana* Hayne and *Acacia seyal* Del. are two desert trees of the Algerian Sahara that for a long time were confused. These two species present high potentials for desert areas rehabilitation therefore for successful seed germination and establishment three pre-germination treatments (manual scarification, boiling water and concentrated sulphuric acid) were used to overcome seeds dormancy. Once the optimal conditions are determined, we examined the effects of two abiotic stresses (salinity and water deficiency) on their seeds germination using eight levels of salinity (0, 50, 100, 150, 200, 250, 300 and 350mM of NaCl) and six concentrations of PEG_{6000} (0, -2, -4, -6, -8 and -10 bars) on *Acacia ehrenbergiana* Hayne and *Acacia seyal* Del. Germination rate and mean germination time were calculated and data were subjected to analysis of variance (ANOVA) followed by Newman-Keuls test. Our results show that manual scarification and sulphuric acid had significant effects on the seeds germination of *Acacia ehrenbergiana* Hayne meanwhile, only sulphuric acid enhanced *Acacia seyal* Del. seeds germination. Under salt and water stresses, the germination rate and mean germination time of *Acacia ehrenbergiana* Hayne were less affected than those of *Acacia seyal* Del. Therefore manual scarification and sulphuric acid treatments could be applied and adopted at laboratory level or even at nurseries to raise plants germination and plantations establishment for desert areas rehabilitation. Thus, *Acacia ehrenbergiana* Hayne seems to be more suitable for massive propagation as it demonstrates resilience when facing harsh abiotic stresses (salt and water stresses).
Keywords: *Acacia trees, seeds, germination, coat dormancy, abiotic stress, desert*

Introduction

Native acacia trees are frequent, widespread and emblematic species that grow in Algerian desert areas which cover 2/3 of the country surface. They are represented by six species; five of them were recently transferred from the genus *Acacia* to the genus *Vachellia*: *Acacia tortilis* (Forssk.) Hayne subsp. *raddiana* (Savi) Brenan., *Acacia nilotica* subsp. *adstringens* (Schumach. & Thonn.) Roberty, *Acacia nilotica* subsp. *tomentosa* (Benth.) Brenan, *Acacia ehrenbergiana* Hayne, *Acacia seyal* Del. and one species: *Acacia laeta* R.Br. ex Benth. was transferred to the genus *Senegalia* (Ross, 1979; Kyalangalilwa, 2013).

These species play fundamental roles in desert areas, allowing sand's fixation, helping the water infiltration and improving the redistribution of nutritive elements in the soil. Moreover, their ability to develop dual symbiosis with *Rhizobia* and endomycorrhizal fungi contribute to the improvement of soil fertility (Grouzis and Le Floc'h, 2003; Noureddine et al., 2010). These prominent, wide range ecological services

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_355368

providers are well adapted to the main constraints of arid and semi-arid areas (drought, high temperatures, salinity and extreme light…) therefore, they are valuable trees and good candidates to combat desertification and to integrate any restoration, rehabilitation and reforestation programs in Algeria. Indeed, they have been already included as elite species in the Great Green Wall project, a project of plantation initiated by sahelian countries to fight the desertification progress (Dia and Niang, 2010; Ba, 2010; Hannani and Chehma, 2012).

The propagation and the distribution of these species require higher germination and establishment rates. One of the obstacles of acacias seed germination is the impermeable teguments to water and oxygen causing a physical dormancy (Holmes et al., 1987). In this case, it is necessary to apply pre-germination treatments to overcome the coat dormancy. Several artificial methods have been used to break the dormancy of these seeds, including physical (manual scarification, boiling water and cold water) and chemical pre-germination treatments (sulphuric acid and organic solvents) (Hanna, 1984; Cavanagh, 1987; Côme, 1970; Mousavi et al., 2011; Aref et al., 2011).

In addition, studies of the effects of most frequent environmental stresses encountered in these areas such as salt and water stresses on germination stage are of outmost importance for regeneration and consequently successful establishment of plantations (Aref et al., 2004; Jaouadi et al., 2010).

Studies have been carried out in order to determine the effects of pre-germination treatments, salt and water stresses on acacias seed germination (Teketay, 1996; Al-Mudaris et al., 1999; Ndour et Danthu, 1999; Jaouadi et al., 2004; Aref et al., 2004; Jaouadi et al., 2010; Kassa et al., 2010; Abari et al., 2011).

In Algeria, few published articles focused on these species including the works of Kebbas et al. (2015) and Hannani et al. (2016) on the effects of pre-germination treatments on *A. tortilis* (Forssk.) Hayne subsp. *raddiana* (Savi) Brenan. and the studies of Karoune et al. (2013) and Kebbas et al. (2013) on the characteristics of germination under salt stress of *A. albida* (Del.) A. Chev. and water stress on *A. tortilis* (Forssk.) Hayne subsp. *raddiana* (Savi) Brenan. respectively. Recently, Kheloufi et al., 2016 investigated the germination behaviour and compare the levels of tolerance to salinity in three *Acacia* species (*Acacia delbata* Link., *Acacia ehrenbergiana* Hayne and *Acacia tortilis* (Forssk.) Hayne var. *raddiana.*

A. ehrenbergiana Hayne which is found in the North Sahel, the Southern and Central Sahara, the Arabian Peninsula and East Africa resembles the *A. seyal* Del. Sudano-Sahelian species (Benchelah et al., 2006; Contu, 2012). *A. ehrenbergiana* Hayne grows in dry semi-desert areas where it represents one of the most drought-tolerant species among the common African acacias occurring in the rainfall belts 50-400 mm. In Algeria, this species can be found in Ahaggar, Tassili n'Ajjer and Tinghert Hamada while *A. seyal* Del. stands are rarely found in Ahaggar (Sahki and Sahki, 2004; Contu, 2012). Moreover, *A. ehrenbergiana* Hayne has not been mentioned in the flora dedicated to the Sahara; in Ozenda (1958) and Quezel and Santa (1962-1963); a raison of its confusion with *A. seyal* Del. (Celles and Maniere, 1980; Sahki and Sahki, 2004; Benchelah et al., 2006).

So, this study aims to describe seeds morphological characteristics of *A. ehrenbergiana* Hayne and *A. seyal* Del., two native species of the south of Algeria (Tamanrasset). Furthermore, we determined the effects of pre-germination treatments, salt and water stresses on their germination.

Material and methods

Seeds of *A. ehrenbergiana* Hayne and *A. seyal* Del. were collected from mature pods of healthy trees in 2013 from Tamanrasset (22° 47' 13" North and 5° 31' 38" East) which is located in the south part of Algeria, about 2000 km far from the capital Algiers.
Seeds of *A. ehrenbergiana* Hayne were collected from Amlawlawen area about 15 Km far from Tamanrasset city while *A. seyal* Del. seeds were collected from Taghemout area approximately 50 km far from Tamanrasset city.

In the laboratory of soil biology in 2014, the seeds were removed from their pods, damaged and insect infected seeds were discarded and the empty ones were eliminated using the floating method (Ahmadloo et al., 2011). The seeds were stored at laboratory conditions at 2-5 °C and 80% of humidity.

Seeds were evaluated with both a light microscope (ZEISS Primo Star) and a scanning electron microscope (Jeol JSM 6360LV). Their morphological characteristics: colour, shape, texture, areole shape and position, shape of the hilo-micropylar region, spermoderm brightness, seed weight refers the weight of 1,000 seeds according to ISTA (the average of 10 replicates of 100 seeds weight multiply by 10), size, volume, surface, viability and water content were evaluated (Baldwin, 1942; Justice, 1972; ISTA, 1993).

Effects of pre-germination treatments on acacias seeds germination

Seeds dormancy of acacias species is associated with seed coat impermeability to water and oxygen which constitutes in one hand an adaptive factor for their survival but in the other hand, it is an obstacle for germination even when conditions are optimal. So, in order to overcome the seeds dormancy, we performed three pre-germinations treatment, we applied Manual Scarification (MS) which consists of careful nicking or filing seed coat by hand with a nail clipper on the opposite side of the seed embryo to allow water to inter into seeds. We used Boiling Water (BW) which involves soaking the seeds in boiling water for one hour in order to soften the seed coat. And finally, soaking seeds in concentrated Sulphuric Acid (SA) H_2SO_4 96% during one hour to weaken seed coat is conducted (Danthu et al., 1992; Ndour, 1997).
In order to minimize any fungal infection of the seeds during the incubation period, seeds were washed with distilled water then their surface were sterilized by immersion in ethanol 70° for 30 seconds and in sodium hypochlorite solution 0.58% for one minute followed by three washes in sterilized distilled water. All these steps where done in a sterile hood.

Five replicates per treatment, with 20 seeds placed in plastic Petri dishes on filter paper were incubated in the darkness because of the seeds light insensitivity (Danthu et al., 2003) at 25°C (primarily experiments) and under a relative humidity of 80%.

Effects of salt and water stresses on acacias seeds germination

From the results of the pre-germination treatments, optimal conditions were determined and used for further experiments. After applying the sterilization and germination protocols, salt stress effects on seeds germination at different levels of NaCl (0, 50, 100, 150, 200, 250, 300 and 350 mM) were evaluated and different solutions of PEG_{6000} (0, -2, -4, -6, -8 and -10 bars) were used to induce osmotic stress (Michel and Kaufmann, 1973).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_355368

The seeds were humidified with NaCl and PEG_{6000} solutions every 48 h under sterile conditions and counting the germinated seeds which was defined as the emergence of the radical was done.

Determination of germination parameter

The Germination Rate (GR) and Mean Germination Time (MGT) were determined according to Côme (1970).

$$GR = n/N * 100 \qquad \text{(Eq.1)}$$

Where N is the total number of seeds and n is the number of germinated seeds.

$$MGT = N_1T_1 + N_2T_2 + \ldots + N_iT_i / N_1 + N_2 + \ldots N_i \qquad \text{(Eq.2)}$$

Where N_1 is the number of germinated seeds in T_1 and N_2 the number of seeds that germinated between T_1 and T_2.

Statistical analysis

The data was represented as mean ± standard deviation (SD). The experiment was made as a completely randomized design with five replicates (n=5) of twenty seeds of each replicate. The data were statistically treated by one-way analysis of variance (ANOVA) and the mean values were compared using Newman-Keuls test at P< 0,05 to establish the significant differences between each treatment and control.

Results

Seeds characteristics of A. ehrenbergiana **Hayne** *and A. seyal* **Del.**

The morphological characteristics of the two acacias species studied represented in (*Table 1*) and (*Fig. 1*) show some similarities in seeds shape, texture, areole shape and position. *A. ehrenbergiana* Hayne have a light brown colour while *A. seyal* Del. have a greenish brown colour. Morphology of the seeds varied significantly (P < 0,05) in length, width, volume, surface and weight of 1000 seeds. The seeds showed a high viability of 90 and 95% for *A. ehrenbergiana* Hayne and *A. seyal* Del. respectively.

Effects of pre-germination treatments on acacias seeds germination

In this work, we investigated the effects of three pre-germination treatments to overcome the seeds dormancy of *A. ehrenbergiana* Hayne and *A. seyal* Del. All pre-germination treatments improved the GR and MGT for both species while the control group presented very low GR (13% for *A. ehrenbergiana* Hayne and 18% for *A. seyal* Del.) and we noticed an increase in the MGT of both species (7,79 days for *A. ehrenbergiana* Hayne and 6,78 days for *A. seyal* Del.).

Using sulphuric acid and manual scarification presented high significant difference (P<0,001) compared to the control group with the same and the best effects on *A. ehrenbergiana* Hayne seeds germination while sulphuric acid seems to be the best pre-germination treatment improving GR and MGT of *A. seyal* Del. Moreover, boiling water treatment came in the last position for both species giving a GR three times higher than the untreated seeds and two times lower than sulphuric acid and manual scarification (*Fig. 2*).

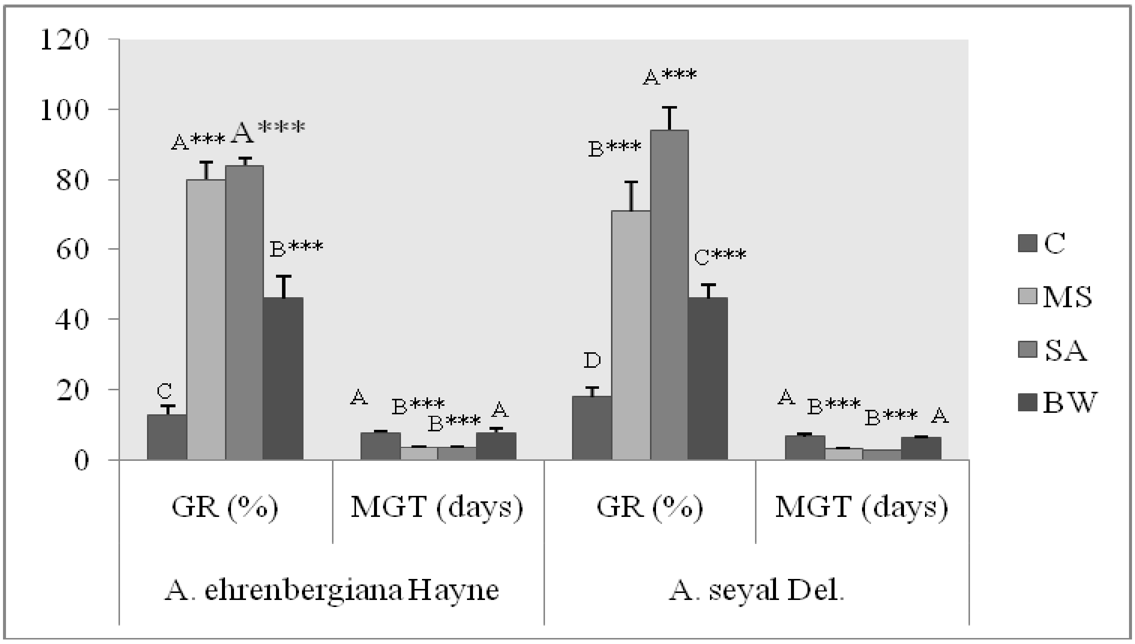

Figure 2. *Effects of manual scarification, sulphuric acid and boiling water on A. ehrenbergiana* Hayne *and A. seyal* Del. *seeds germination*

*Germination rate (GR), Mean Germination Time (MGT), Control (C), Mechanical Scarification (MS), Sulphuric Acid (SA), Boiling Water (BW), n=5, *** Very high significant difference with the control (P<0,001), A, B and C statistical similarity between treatments, Means followed by the same letter are not significantly different at P <0.05 using the Newman-Keuls test.*

Effects of salt and water stresses on acacias seeds germination

In our study, the germination behaviours under different environmental limiting conditions of salt and water stresses on germination of *A. ehrenbergiana* Hayne and *A. seyal* Del. were investigated.

Our results show that the highest GR and the shortest MGT occurred in the control group and we noticed an inverse correlation between GR and NaCl concentrations. Indeed, increasing salinity levels decreased GR and increased MGT presenting a very high significant difference (P<0,001) compared to control group for both species. Moreover, *A. seyal* Del. seems to be more sensitive than *A. ehrenbergiana* Hayne which germinated even at high levels of salt (at 350 mM) (*Table 2*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_355368

Table 2. *Effects of salt stress on GR and MGT of A. ehrenbergiana* Hayne *and A. seyal* Del. *seeds germination*

Species		***A. ehrenbergiana* Hayne**		***A. seyal* Del.**	
		GR (%)	**MGT (days)**	**GR (%)**	**MGT (days)**

	300	16±2,23***	9,63±0,24***	12±2,73***	9,76±0,22***
	350	11±2,23***	10±0,00***	0±0,00***	0±0,00***

Mean ± standard deviation, Germination rate (GR), Mean Germination Time (MGT), Control (C), n=5, *** Very high significant difference with the control (P<0,001), ** high significant difference with the control (P<0,01) using the Newman-Keuls test

Germination assessment of *A. ehrenbergiana* Hayne and *A. seyal* Del. seeds under water stress was investigated using different concentrations of PEG $_{6000}$. The different water stress levels significantly affected their seeds germination. A reduction in GR and an increased MGT were observed with very high significant difference (P<0,001) when compared with the control group. Thus, seeds of *A. ehrenbergiana* Hayne seems to tolerate high levels of water stress (-10 bars) with a GR of 21% and an MGT of 8,92 days compared to *A. seyal* Del. which could not germinate at -10 bars (*Table 3*).

Discussion

Acacia ehrenbergiana Hayne and *Acacia seyal* Del. are two native species to Algeria that have diverse economic and ecological significance. However, their seeds dormancy that causes low germination percentage seems to be problematic for their usage in afforestation or restoration programs.

Seeds characteristics of A. ehrenbergiana **Hayne** *and A. seyal* **Del.**

The seeds of *A. ehrenbergiana* Hayne and *A. seyal* Del. that were examined by both a light microscope and a scanning electron microscope presented some morphological similarities in seeds shape and texture, areole shape and position, shape of the hilo-micropylar region and spermoderm brightness and some differences in colour, size, volume, surface and 1000 seeds weight.

We noticed that *A. ehrenbergiana* Hayne seeds are smaller than *A. seyal* Del. seeds while Al-Gohary and Mohamed (2007) found that seeds of *A. seyal* Del. were smaller than those of *A. ehrenbergiana* Hayne. Furthermore, in contrast of our study where we observed a light brown colour of *A. ehrenbergiana* Hayne seeds and a greenish brown colour of *A. seyal* Del. seeds, Waly (2012) reported the dark brown colour of *A. ehrenbergiana* Hayne while Al-Gohary and Mohamed (2007) reported the brown colour of *A. ehrenbergiana* Hayne and the yellowish brown of *A. seyal* Del. seeds

In our study, seeds of both species have an oblong shape while Al-Gohary and Mohamed (2007) mentioned an obovate shape for *A. seyal* Del. and an oblong shape for *A. ehrenbergiana* Hayne seeds. Due to environmental impact, genetic variations and strategies of adaptation to different environmental conditions and soil types, differences in colour and size were reported by different studies (Al-Gohary and Mohamed, 2007; Waly, 2012; Elmagboul et al., 2014).

The present investigation revealed a significant difference in 1000 seeds weight between the two studied species. In addition, similar results of 1000 seeds weight have been noticed when compared with standard Kew database for both species (26 g for *A. ehrenbergiana* Hayne and 42 g for *A. seyal* Del.).

The water content is a critical factor that influences seed life span and viability; thus, from the results of the water content of *A. ehrenbergiana* Hayne (4,45%) and *A. seyal* Del. (5,37%) we could classify these species as true orthodox seeds implying successful long term storage (Chin et al., 1989).

In the other hand, the viability of the two species was assessed by the tetrazolium test which consists on the measurement of how many seeds in a lot are alive and could develop into plants. This test show high percentages of 95% and 90% of viable seeds of *A. ehrenbergiana* Hayne and *A. seyal* Del. respectively indicating their good conservation. In contrast, the tetrazolium viability test conducted by Al-Hammad and Al-Ammari, 2017 revealed that most non-germinated seeds of *A. ehrenbergiana* (80%) were dead.

Effects of pre-germination treatments on acacias seeds germination

Acacia seeds have a coat dormancy that acts primarily as mechanical barrier limiting water and oxygen entrance. In natural conditions, hard seed coats are broken by fire, extreme temperatures, and digestive acids in animals stomachs or by the abrasion of blowing sand (Luna et al., 2009). In laboratory and nursery conditions, artificial methods are used. According to many authors, manual scarification, sulphuric acid, hot

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_355368

water and dry heat treatments can break down the coat inhibition (Sadhu and Kaul, 1989; Danthu et al., 1992; Al-Mudaris et al. 1999; Grouzis and Le floc'h, 2003; Abari et al., 2012; Karoune et al., 2013; Rasebeka et al., 2014).

In this study, we tested three methods to overcome seed dormancy in *A. ehrenbergiana* Hayne and *A. seyal* Del. We revealed that manual scarification and sulphuric acid treatments are the best pre-germination treatments for *A. ehrenbergiana* Hayne while sulphuric acid treatment enhanced the GR of *A. seyal* Del. In addition, boiling water presented low germination rates for both species.

The study of Teketay (1996) revealed that manual scarification had the best effect on *A. seyal* Del. seeds where the germination percentage reached 100%. In the other hand, Aref et al. (2011) indicated that manual scarification was the best pre-germination treatments for *A. ehrenbergiana* Hayne seeds where the germination percentage was 96 %, followed by sulphuric acid and boiling water with the germination percentages of 94% and 69 % respectively. In contrast of our findings, the work of Aref et al. (2000) show that boiling water had positive effect on *A. seyal* Del. germination percentage (34.25%) while it has less effect on *A. ehrenbergiana* Hayne germination with a germination percentage of 9.35%.

Effects of salt and water stresses on acacias seeds germination

Seeds germination is a complex process depending on the genetic and environmental factors. Abiotic factors, such as salt and water stresses limit plant germination and growth during early seedling stages (Mansour, 2000). Salt and water stresses affect plants in a similar way. The osmotic effect causes a deficient in water absorption that limits seed imbibition leading to a series of metabolic changes such as the reduction in seed reserves hydrolysis and their use. Salt and water stresses can completely inhibit germination and cause a reduction in plant growth (Ahmad and Bano, 1992).

The effect of salt stress on acacias seeds germination was described by several authors (Ndour and Danthu, 1999; Aref et al., 2004; Abari et al., 2011; Karoune et al., 2013) which showed that increasing salt concentrations decreased the GR of the studied acacias species. However, in all cases, the acacias species were considered as salt tolerant species and Marcar et al. (1991) indicated that acacias species differed in their salt tolerance.

Our results of germination behaviour of *A. ehrenbergiana* Hayne and *A. seyal* Del. show that both species germinated at low concentrations of NaCl (50 mM and 100 mM) with at least 50% GR, while the GR at high concentration (350mM) was decreased to 11% for *A. ehrenbergiana* Hayne seeds and it presented a total inhibition in *A. seyal* Del. seeds. This might be due to the inhibition of the radical emergence as a response to water deficit and their toxic effects on the embryo (Mazher et al., 2007). Jaouadi et al. (2010) suggested that *Acacia tortilis* (Forsk.) Hayne ssp. *raddiana* (Savi) Brenan. is significantly affected by 9 g L^{-1} of NaCl giving a germination rate of 60%, furthermore, this species continues to germinate even at high concentrations of NaCl reaching 18 g L^{-1} with a germination rate of 50%. In our case, *A. ehrenbergiana* Hayne could germinate even at high level of NaCl (350 mM = 17g L^{-1}) however it gave a GR of 11%. Also, the study conducted by Kheloufi et al. (2016) revealed that the seeds of *A. ehrenbergiana* Hayne collected in Oued Tin Amezzegin (Tamanrasset, Southern of Algeria) gave a final GR of 100% for the first three seawater treatments (0, 10, and 30 %) and 78 % in the presence of 50% of seawater.

DOI: http://dx.doi.org/10.15666/aeer/1504_355368

The results of the effect of water stress on *A. ehrenbergiana* Hayne and *A. seyal* Del. seeds showed that GR of both species were significantly affected particularly, *A. seyal* Del. seeds which presented an inhibition at high level of water stress (-10 Bars). Kassa et al. (2010), reported that this species can germinate even at high level of water stress (-12 MPa) and asserted that it is classified as tolerant species to water stress. In addition, Ndour and Danthu (1999) reported that *A. ehrenbergiana* Hayne is more tolerant than *A. seyal* Del. to water stress and both species are considered as tolerate species to water stress because they germinated even at -2,1 MPa.

Our research was lead by the lack of studies on the biology and characteristics of seeds of highly tolerant and beneficial trees in arid areas of Algeria. The present study show some important elements to distinguish between *A. ehrenbergiana* Hayne and *A. seyal* Del regarding their seeds morphological characteristics. In addition, because of their seed coat dormancy, we applied chemical and physical treatments in order to obtain rapid and synchronous germination essential for ensuring seedling establishment. We described the optimal germination conditions of these two species and established their germination behaviour under salt and water stresses two of the most frequent environmental stresses that prevail in arid areas of Algeria. These results are of a significant important as *A. ehrenbergiana* Hayne and *A. seyal* Del. two native species that present a good choice and could be suitable for land rehabilitation, restoration and afforestation programs in these areas.

Acknowledgements. The authors would like to extend their sincere appreciation for all the team of National institute of Forest Research - Station of Tamanrassat- Algeria for their help in providing the seeds of *A. ehrenbergiana* Hayne and *A. seyal* Del.

Abstract. In organic farming the use of mineral fertilizers is highly restricted; hence biofertilizers are often used. The aim of the research was to investigate the effects of different fertilizers on soil microbial communities and enzymatic activity after conventional production. A field with potato cultivation under conversion to an organic system was established. The nitrogen organic fertilizer Bioilsa and two microbial biofertilizers – UGmax and EM – were used. The highest values of dehydrogenase activity (DHA) were observed in the soil where UGmax was used alone. Application of biofertilizers also caused an increase of DHA in variants with Bioilsa fertilizer. The differences in activity of phosphatase in relation to application of different biofertilizers were observed, but it was higher than in variants with Bioilsa. Application of Bioilsa had a positive effect on activity of acid and alkaline phosphatases, but probiotic EM reduced this positive effect. The total number of bacteria and actinobacteria was the highest in EM variants, not fertilized with Bioilsa. In the case of the fungal population no correlation with fertilization was noted. We conclude that biofertilizers can activate the microbial and enzymatic activity of the soil after intensive agriculture production and can neutralize the negative impact on these parameters of nitrogen fertilizer.
Keywords: *biofertilizers, nitrogen organic fertilizer, soil microbiology, dehydrogenase activity, phosphomonoesterases*

Introduction

Organic farming avoids application of synthetic fertilizers and pesticides, uses organic inputs, promotes recycling for nutrient supply and emphasizes cropping system design and biological processes for pest management (Le Guillou and Scharpé, 2001; Araújo et al., 2009). In the European Union, organic production of agricultural products is certified and regulated by Council Regulation 834/2007 (2007). During conversion to organic production there are in force restrictions on the use of mineral fertilizers and plant protection products that are subsequently maintained. The soil fertility can be improved only by establishing a rotation with legumes or large amounts of manure. This paper hypothesized that biofertilizers are helpful to restore microbial balance in the soil after intensive agriculture production. The aim of the study was to investigate the

DOI: http://dx.doi.org/10.15666/aeer/1504_369383

impact of biofertilizers and nitrogen organic fertilizer on soil microbial communities and soil chemical properties in a farm under conversion to organic production.

Review of Literature

The soil microbial community plays an important role in maintaining soil fertility in an organic agriculture system. The microbial fertilization is beneficial especially for organic farming under the condition that microorganisms are not genetically modified. Biofertilization (e.g. using microbial fertilizers) is now a very important method of providing plants with their nutritional requirements without having an undesirable impact on the environment (Yassin, 2002; Abd El-Malek, 2005; Abou El-Yazied and Sellim, 2007). This method of fertilization is one of the many factors which play an important role in activating the enzymatic and microbial properties of the soil. It is particularly important in the system of organic farming because healthy soil is a crucial factor for both healthy plants and high yield.

In an organic system production of some crops is problematic in regard to nutrients, particularly enzymatic nitrogen. One of them is potato cultivation, the fourth most important food crop of the world. Potatoes are the most common crop in the world and are grown all over the world, production in Europe accounting for approximately 40% of world production. However, potato production is steadily decreasing. In Poland organic potato production covers 4% of the area of total organic farmland. The use of microbiological bio-agents (also referred as ‘biofertilizers’) can enhance tuber yielding and chemical composition of the soil; it has been studied for some years (Trawczyński and Bogdanowicz, 2007). Many different biofertilizers are available on the market for agricultural use. The products are claimed to enhance plant growth and yields and to improve soil fertility, but often their microbial composition is not specified in detail, making it difficult for the users to evaluate the product and for scientists to prove its effectiveness (Schenck zu Schweinsberg-Mickan and Müller, 2009).

One from many available biofertilizers is UGmax and probiotic Effective Microorganisms (EM). EM are microbial inoculants promoting stimulation of plant growth and soil fertility in agriculture. It is not clear whether EM contain microorganisms that can act as plant growth-promoting microorganisms (PGPM) (Meyer et al., 2010). UGmax is a microbiological preparation composed of yeasts, lactic acid bacteria, photosynthetic bacteria, *Azotobacter*, *Pseudomonas* and *Actinobacteria*, as well as potassium. UGmax aims at improving physiochemical soil properties. It accelerates the decomposition of post-harvest residue and organic fertilizers, activates nutrients from minerals or insoluble compounds and improves water relations (Długosz et al., 2010). Thus, crops can use elements from mineral fertilizers more efficiently, which in turn allows farmers to lower mineral fertilization doses, consequently limiting the emission of harmful substances to surface waters. The positive effect on potato tuber yield volumes is also well known after biofertilizers (Zarzecka et al., 2011).

The use of microorganisms is a source of controversy. There is evidence in the literature of both their usefulness in agriculture (Sangakkara et al., 2011) and a lack of evidence (Mayer et al., 2008; Mayer et al., 2010; Martyniuk and Księżak, 2011; Martyniuk, 2011). These preparations contribute to the improvement of the biological activity of the soil, increasing the binding of free nitrogen from the air, reducing the erosion and loss of nutrients.

Unlike organic farming, conventional agriculture is largely dependent on intensive chemical inputs and has an important role in improving food productivity. However,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_369383

organic farming is a sector which is able to secure the food needs for the growing number of consumers. It grew from $3.2 billion in 2008 to $5.5 billion in 2014, demonstrating increased demand for organic products and opportunities for growth (http://www.ofrf.org/organic-faqs). Many studies from around the world have compared organic and conventional farming systems in terms of soil properties. According to them microbial activity and nitrogen mineralization rates were higher under organic production than under conventional production (Workneh and van Bruggen, 1994). Enhanced soil fertility and higher biodiversity found in organic plots may render these systems less dependent on external input (Mäder et al., 2002). Organic farming with compost amendment showed the best results in terms of microbial biomass carbon, nitrogen and phosphorus (CNP) (Amaral and Abelho, 2016). Organic farming has been shown to favor soil biota in comparison with intensive farming (Kallenbach and Grandy, 2011; Santos et al., 2012). Field soils in organic farms were also more productive than conventional fields, probably due to the beneficial effects on soil properties of long-term organic amendments. The soil under the organic agricultural system presents higher microbial activity and biomass and lower bulk density than the conventional agricultural system (Araújo et al., 2009). In this context the changes taking place in the soil during the conversion period and after microbial fertilizers treatments applied to speed up the restoration to homeostasis are very interesting. The reality of contemporary agriculture necessitates the search for products improving the development and yield of crops, which are distinguished by a strong consequential impact in the entire crop rotation. When diagnosing the influence of different agrotechnical and chemical factors, including fertilizers, on the state of soil, enzymatic and microbial activity are considered to be good indicators of the soil environment quality because of their high sensitivity and rapid reaction. Monitoring the pedosphere by means of methods based on enzymatic tests enables complex assessment of changes taking place in the soil environment as a result of fertilization (Niewiadomska et al., 2010; Notrcliff, 2002; Tian et al., 2009).

Material and Methods

Study location and experimental designs

In 2014-2015 in the Experimental Station of the Institute of Plant Protection – NRI (western part of Poland, Wielkopolska region) in Winna Góra (52.2N; 17.4E) the experiment was established with potato cultivation under the first (2014) and the second year (2015) of conversion to an organic system (*Fig. 1*). On each experimental field wheat was cultivated as a forecrop. The experiment was carried out on plots (size plot 100 m^2 with randomized distribution) within the one big area. Due to the necessary rotation, experimental plots were changed in subsequent years, although they were located side by side and within the one big area under conversion to organic production. Type soil was classified as clay soil with classification III b. One potato cultivar was cultivated – Ditta. No manure fertilizer was used. During the experiments the weather conditions were noted (*Table 1*).

In the experiment organic nitrogen fertilization delivered by Bioilsa was used as the first research variant. The second research variant consisted of two biofertilizers, approved for organic plant production, probiotic EM (ProBiotics Polska) and UGmax (PPHU "Bogdan"), applied at a dose of 40 l and 1 l ha^{-1}, respectively. Effective microorganisms (EM) were a mixed culture of beneficial microorganisms including a predominant population of lactic acid bacteria (*Lactobacillus* sp.) and yeast (S*accharomyces* sp.), and a small proportion of photosynthetic bacteria (*Rhodopseudomonas* sp.), actinomycetes and fermenting fungi. No macro- or microelements are contained. UGmax contains lactic acid bacteria, photosynthetic bacteria, *Azotobacter*, *Pseudomonas*, yeasts, actinomycetes and some macro- and microelements (mg dm^{-3}), N–1200, P-220, K-2905, Mg-100, Na-200, Mn-0.3 (Sosnowski and Jankowski, 2013) These biofertilizers were applied in different methods, as soil and foliar application, due to the potential of biofertilizers to stimulate the natural defenses of potato plants. Before planting directly to the soil and during vegetation four foliar sprays, separately for each microbial product, were used at a 10-day interval. Thus, e.g. the first spraying was performed before row closure, and the third treatment was applied in full blossom. The experimental plots with biofertilizer treatments were divided into two separate parts in regard of Bioilsa application – applied or not. This fertilizer contains 12.5% organic nitrogen and 42% organic carbon, gradually releasing nitrogen and approved for organic farming (NPK 12:0:2). It was applied in the spring, 3 weeks before potato planting on selected plots at a dose of 300 kg/ha. This dose was chosen because it is mean between recommended doses, used as a standard in our tests and it was established on the basis of our experience. Three repetitions were made for each combination within one big experimental area and in each year.

Determination of carbon, nitrogen and phosphates in the soil

Soil samples for chemical analysis were collected at 30 cm depth (between rows of potatoes) from the experimental plots three times during each season, at the beginning of potato vegetation, at the beginning of plant drying and after harvest. The collected soil was dried in the open air and sieved through 2 mm-thick screens, then packed in a plastic bag. Unless specified otherwise, all reagents used in this study were analytical grade. The term “water” implies de-ionized water and was used for all sample extraction, soil sample preparation and standard solutions.

The standard phosphate solutions were prepared by measuring off the appropriate volume of the 100 $mg \cdot cm^{-3}$ o-PO_4^{3-}, prepared from KH_2PO_4 (Merck, Germany) standard solution into 100 cm^3 volumetric flasks and filling up to the mark with water. Serial dilutions were made to obtain the standard concentrations; 0.1; 0.2; 1.0; 2.0; 5.0; 10.0 and 20.0 $mg \cdot cm^{-3}$ phosphate-P. The extraction of phosphate-P was carried out according to the Egner-Riehm method. 0.04 M calcium lactate buffer (being acidified by hydrochloric acid up to pH 3.5 – 3.7) was used as an extracting agent. 200 cm^3 of the lactate buffer was added to the air-dried soil sample (approx. 5.000 g) placed in a screw-capped 500 cm^3 bottle. Activated carbon (approx. 0.20 g) was added and the bottle tightly screw-capped. The mixture was then shaken for 90 min on a Heidolph REAX 20-12 shaker (15 rpm). The phosphate-P in soil extract was measured photometrically via phosphomolybdate and reduction to molybdenum blue according to PN-EN ISO 15681-1:2006. The extracted samples were analyzed using a MLE FIA-System flow injection analyzer. All pH measurements were carried out using Elmetron CP-501 pH meter. The pH meter was standardized with use of standard buffers (Merck). A Heidolph shaker model REAX 20-12 was used for shaking all samples while extraction of phosphate-N was carried out.

In order to determine total content of nitrogen (N) and carbon (C) in the soil Vario MAX CNS Element Analyzer apparatus was used. The samples were dried at 105°C for 60 min and after that sample material was weighed in an amount of 1200 mg to reusable cups made of ceramic. The mineral soil program with max 4% content of C in a sample was used. Oxygen was dosed for 120 s in the amount of 100 ml/min with the threshold of O_2 15‰. Sandy soil was used as a certified reference material (Soil Standard Sandy OAS Cat No. B2180 – Batch no. 133506, Elemental Microanalysis Ltd) with content N=0.7 g kg^{-1} and C= 8.3 g kg^{-1}. Obtained results were N=0.68 g kg^{-1} with recovery 97.14%, and C=8.31 g kg^{-1} with recovery 100.12%. In determination of N and C we used the so-called daily factor for N=1.0036, for C=0.9884, which resulted from the signs of L-glutamic acid.

Microbial analysis

In order to determine the microbial community total numbers of bacteria, actinobacteria and fungi were evaluated. The enzymatic soil activity was assessed by content of dehydrogenases, acid and alkaline phosphatase. Sampling was performed in this same way as for chemical analysis. After that each soil sample was transported to the laboratory in PCV bags, in the fridge but not frozen.

Enumeration of selected microorganisms

The plate method was applied to determine the populations of microorganisms in soil samples collected from under the plants, at a depth of 0-20 cm. Soil microorganisms were counted on adequate agar substrate (in five replications) and expressed in colony-forming units (cfu) g^{-1} dry weight (DW) of soil. The total number of bacteria was determined on Merck Standard agar after 72 hours (3 days) of incubation at 25°C; fungi were determined on a Martin (1950) medium after 5 days of incubation at 24°C; actinobacteria were assessed on a Pochon medium after 5-7 days of incubation at 25°C (Grabińska-Łoniewska, 1999).

Soil enzymatic activity

The analyses of the enzymatic activity of soil in different experimental variants were based on the colorimetric method applied to measure the dehydrogenase activity (DHA), where 1% TTC (triphenyl tetrazolium chloride) was used as a substrate. The measurement took place after 24-hour incubation at a temperature of 30ºC and a wavelength of 485 nm and it was expressed in μmol TPF $(24h)^{-1}$ g^{-1} DM of soil (Thalmann, 1968). The biochemical analyses of soil involved the determination of activities of acid (EC3.1.3.1) and alkaline (EC 3.1.3.2) phosphomonoesterases (PAC and PAL) by the method of Tabatabai and Bremner (1969). The activities were determined using as substrate disodium p-nitrophenyl phosphate tetrahydrate, after 1 hour incubation at 37°C at wavelength of 400 nm. Results were converted into μmol p-nitrophenol PNP h^{-1} g^{-1} DM of soil.

Statistics

The changes in the microbial composition of soil and enzymatic activity were analyzed statistically. Analyzed and computed data are the means of 3 samplings per year. The results were averaged because similar changes were observed after the use of the formulations throughout the experiment. The results (mean of 2014 and 2015) were subjected to analysis of variance by means of the Statistica 9.1 program. A one-way ANOVA was carried out to determine the effects of the cultivation methods. For the F-test showing significant differences, Tukey's test (HSD) at the probability level $p = 0.05$ was additionally performed to compare mean values.

Results

Dehydrogenases and phosphatases (acid and alkaline) are the most frequently investigated soil enzymes, because they exhibit noticeable reactions to stress factors (Bielińska and Mocek – Płóciniak, 2012). The analysis of variation in selected groups of soil microorganisms, such as total bacterial count, and the count of fungi and actinobacteria, is an adequate measure of soil bioactivity. The influence of different soil

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_369383

fertilizers on the microbiological state of soil was researched in the experiment. The following question arose: is the active ingredient included in the Bioilsa fertilizer strong enough to optimize the conditions of existence of bacteria improving soil properties and to acquire nutrients for agricultural production by potatoes, or is it better to apply the active ingredient with other commercially available biofertilizers, such as UGmax or soil probiotics in the form of EM. The univariate analysis of variance proved a highly significant influence (α=0.001) of the used fertilizers on the biochemical activity of soil under potato cultivation (*Table 2*).

Table 2. *F test statistics and significance levels of one-way analysis of variance for the activity of enzymes and number of selected groups of microorganisms associated with fertilizers regardless of type of trade product*

Soil parameter	F test statistic
Dehydrogenases	10.1619^{***}
Acid phosphatase	6.770^{***}
Alkaline phosphatase	3.8382^{***}
Total number bacteria	4.3473^{***}
Actinobacteria	4.5623^{***}
Fungi	2.1431^{ns}

Note: Standard deviation value was determined from five measurements.
**Statistically significant difference from control on significance level α = 0.05.*
***Statistically significant difference from control on significance level α = 0.01.*
****Statistically significant difference from control on significance level α = 0.001.*
DHA – dehydrogenases activity; PAC acid phosphatase activity; PAL - Alkaline phosphatase activity

The results show that the highest values of dehydrogenase activity (DHA) under the potato cultivation were observed in the variant with UGmax alone. They were much (157%) greater than in the control variant, where no fertilizer was applied (*Fig. 2*).

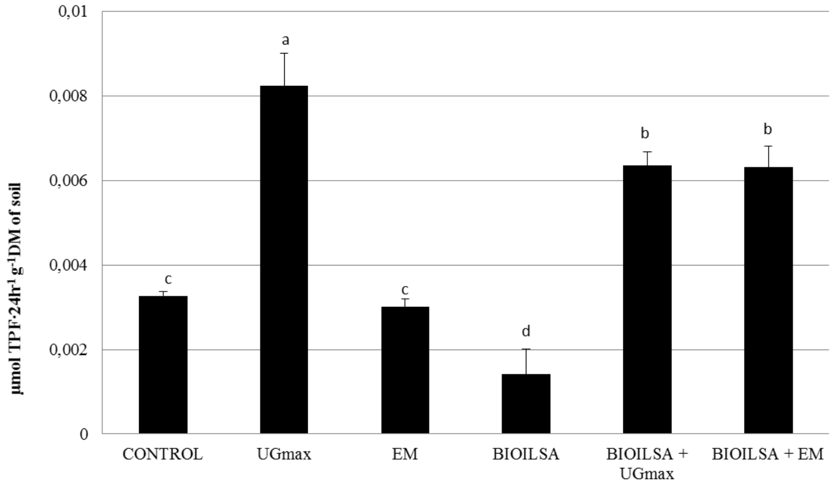

Figure 2. *The effect of different of fertilizers on the dehydrogenases activity*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_369383

The lowest dehydrogenase activity was observed in the variant with the Bioilsa fertilizer; it was 43% lower than in the control combination, where the activity of this enzyme was similar as in the combination with the probiotic formulation EM (*Fig. 2*).

The next indicator, acid and alkaline phosphatases activity, was statistically significantly higher (p=0.001) in the non-fertilized (control) variant compared with the other combinations. No differences in activity of phosphatase in relation to sole application of UGmax or probiotic EM were observed and it was higher than in variants with Bioilsa fertilizer. On the other hand, in the variant where Bioilsa and UGmax fertilizers had been applied simultaneously the lowest value of acid and alkaline phosphatase activity was observed (*Fig. 3* and *4*).

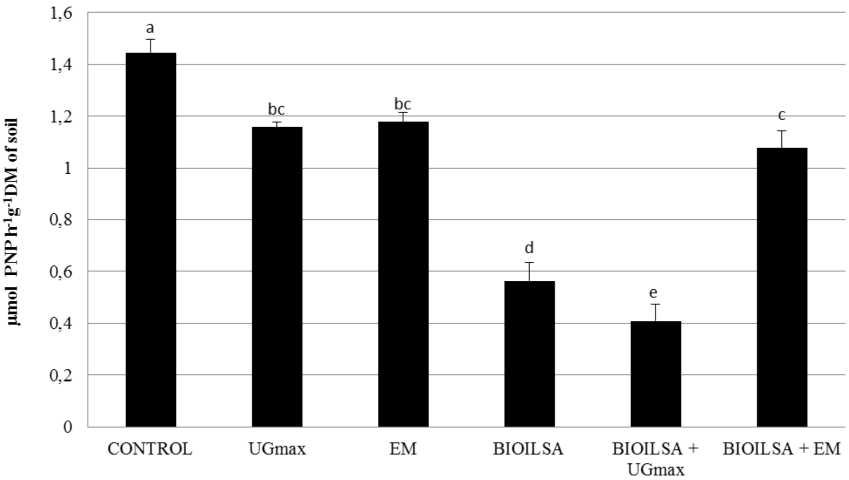

Figure 3. *The effect of different of fertilizers on the acid phosphatase activity*

Note: data are represented as means of five replications. Values after means are standard deviations ±; Means values ± standard errors; a, b, c, d, e – homogenous groups according to Tuckey's test; different letters denote statistical differences at level α=0.05; n=5

Generally, in variants with application of Bioilsa higher values of nitrogen, carbon and phosphorus were noted compared to variants without this organic fertilizer. The highest value (0.750 g kg^{-1}) of nitrogen was observed in variants with Bioilsa and without biofertilizers, but in combination without Bioilsa addition the biofertilizers can increase the content of nitrogen in the soil. However, it was not statistically confirmed (*Table 3*).

Table 3. *The content of the nitrogen, the carbon and phosphorus in the soil*

Plots with different type of fertilizers	**Total content/whole season, average value**		
	Nitrogen (N) g kg^{-1}	**Phosphorus P_2O_5 mg $(100g)^{-1}$ a.d.m**	**Carbon (C) kg^{-1}**
Bioilsa. non - biofertilizer	0.750	28	7.195
Bioilsa. with UG max	0.693	28.6	6.601
Bioilsa. with EM	0.696	45.7	6.550
Average for plots with Bioilsa	**0.721**	**34.1**	**6.782**
Non Bioilsa. with UGmax	0.721	30.8	6.703

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_369383

Non Bioilsa. with EM	0.713	28.2	6.593
Non Bioilsa. non – biofertlizer	0.705	25.5	6.770
Average for plots without Bioilsa	**0.713**	**28.16**	**6.688**

Note. a.d.m - air dried mass, – only indicative values are noted, with no statistical tests, samplings were taken three times within whole season

After application of the nitrogen organic fertilizer (Bioilsa) the average content of the nitrogen was higher (0.721 g kg^{-1}) compared to plots not fertilized with Bioilsa (0.713 g kg^{-1}); the content of the carbon was 6.78 g kg^{-1} in relation to plot not fertilized with Bioilsa (6.68 g kg^{-1}). The value of the last evaluated element, phosphorus, was 34.1 mg compared to non-fertilized 28.1 mg. Fertilization with Bioilsa in various modes influenced the parameters of chemical properties (*Table 3*).
The phosphorus content was higher in the soil after Bioilsa application; it may have caused that activity of phosphatases was lower compared to results obtained for samples collected from non-Bioilsa plots (*Fig. 3* and *4*). There were analogical observations about alkaline phosphatase (*Fig. 4*).

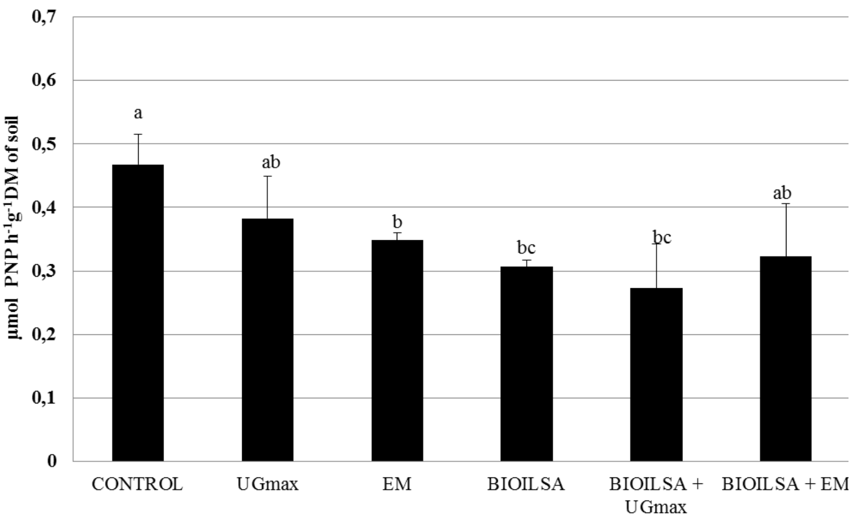

Figure 4. *The effect of different of fertilizers on the alkaline phosphatase activity*

Note: data are represented as means of five replications. Values after means are standard deviations ±; Means values ± standard errors; a, b, c – homogenous groups according to Tuckey's test; different letters denote statistical differences at level α=0.05; n=5

The results of the influence of all used fertilizers applied to the soil under potatoes on the number of selected groups of soil microorganisms point to a highly significant influence (α=0.001) on the changes in the number of total bacteria and actinobacteria in soil. This effect was confirmed by statistical tests (*Table 2*). This correlation was not observed in fungi (*Table 2*). The total number of bacteria and actinobacteria was the highest in EM variants not fertilized with Bioilsa. In variants with Bioilsa application the microbial products had an impact on increase of the population of these microorganisms (*Fig. 5* and *6*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_369383

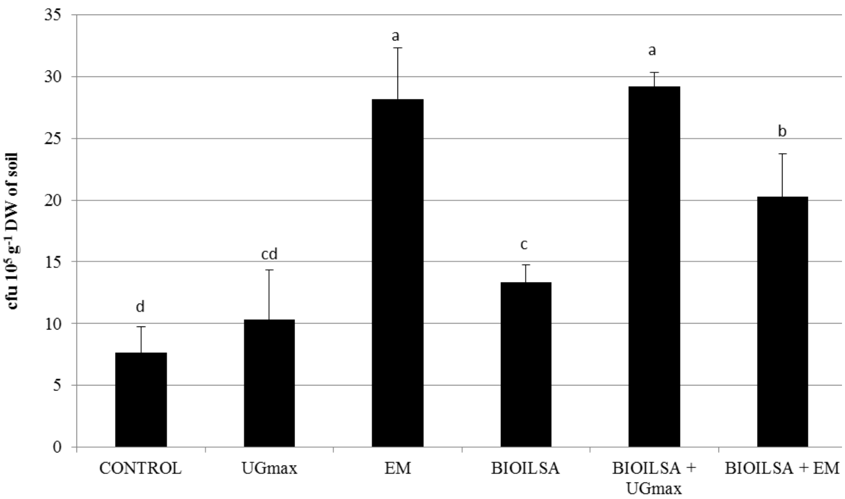

Figure 5. *The effect of different of fertilizers on the total number bacteria*

Note: data are represented as means of five replications. Values after means are standard deviations ±; Means values ± standard errors; a, b, c, d – homogenous groups according to Tuckey's test; different letters denote statistical differences at level α=0.05; n=5

According to Szember (2001), the latter group belongs to a so-called ecological group of microorganisms, which indicates soil fertility. It is noteworthy that the formulations applied to the soil contained certain amounts of macroelements (UGmax, Bioilsa), which may have increased the count of this group of microorganisms. There were similar results in the study by Swędrzyńska et al. (2011), who reported that there was a large increase in the count of actinobacteria when microbial formulations were applied to soil under perennial ryegrass. It is noteworthy that in our study the greatest increase in the count of these microorganisms was observed when probiotic EM had been applied (*Fig. 5* and *6*).

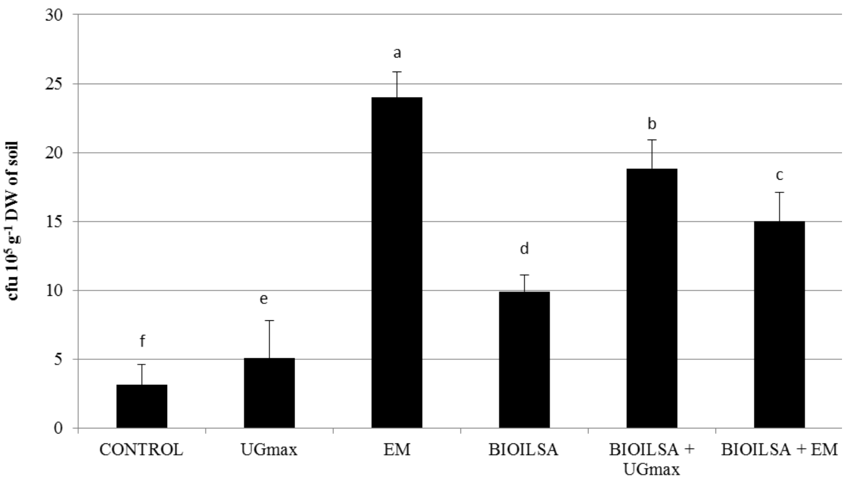

Figure 6. *The effect of different of fertilizers on the Actinobacteria*

Note: data are represented as means of five replications. Values after means are standard deviations ±; Means values ± standard errors; a, b, c, d, e, f – homogenous groups according to Tuckey's test; different letters denote statistical differences at level α=0.05; n=5

The increase in the total count of bacteria and actinobacteria in these variants can be explained in two ways. The microorganisms supplied in the formulations may have been a perfect source of carbon for autochthonous bacteria colonizing the soil environment. On the other hand, the fertilizing formulation with macro-, microelements and microorganisms may have promoted the availability of nutrients and in consequence increased the count of these groups of microorganisms. There were similar correlations observed in fungi, but they were not statistically significant (*Fig. 7*).

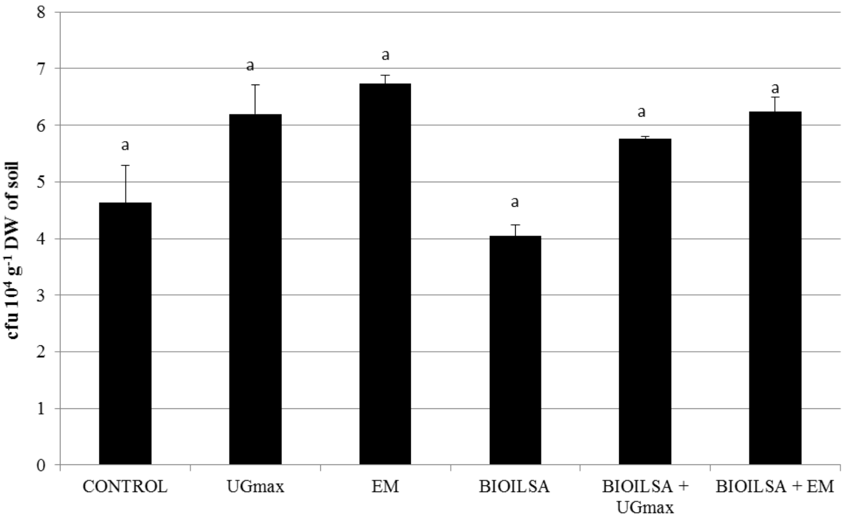

Figure 7. *The effect of different of fertilizers on molds (the fungi)*

Note: data are represented as means of five replications. Values after means are standard deviations ±; Means values ± standard errors; a – homogenous groups according to Tuckey's test; the same letter denote not statistical differences at level α=0.05; n=5

Discussion

According to Brzezińska and Włodarczyk (2005), DHA in the soil is an indicator of the intensity of respiratory metabolism of microorganisms, especially eubacteria and actinobacteria. The analysis of the activity of these enzymes provides information about the content of organic matter or fertility of the substrate. We can conclude that increased dehydrogenase activity in the variant where UGmax was applied to the soil was primarily caused by additional microorganisms included in this product as well as macro- and microelements contained in this fertilizer.

When measuring acid phosphatase activity it is necessary to remember that the amount of this enzyme in the soil environment is strongly influenced by plants, whose roots secrete considerable amounts of it, especially if they do not receive a sufficient supply of phosphorus (Burns, 1985; Dahm et al*.,* 1986; Żebrowska and Ciereszko, 2009). The high concentration of acid phosphatase in the control combination (where fertilization had not been applied) may have been the plants' response to a lesser supply of phosphorus in the soil environment. Many authors mention the fact that if there is a deficit of absorbable phosphorus in soil, plants' roots secrete higher amounts of phosphatase catalyzing hydrolysis of the C-O-P bond in organic phosphorus compounds (Schneider et al., 2001).

It is known that if phosphorus content is low, the activity of these enzymes is higher. According to Bielińska and Mocek-Płóciniak (2012), their long-term observations

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_369383

proved that the acid phosphatase enzyme was strictly correlated with the physiochemical properties of soil. We noted statistically significantly low activity of acid phosphatase in the variants where the nitrogen organic fertilizing formulation had been applied. This indicates that microbial formulations provide plants adequate amounts of phosphorus. Tarafdar and Rao (1990) reported a correlation between the uptake of phosphorus by plants, yield and acid phosphatase activity.

Microorganisms are attributed a significant role in the functioning of the soil ecosystem (Ahemad et al., 2009). They play a key role in controlling the reactions which are necessary to maintain soil fertility and structure. The soil is also characterized by bioactivity, which is indirectly influenced by soil microorganisms and the enzymes they secrete (Kieliszewska-Rokicka, 2001). The existence of soil microorganisms is not only limited to providing access to mineral compounds. They cause favorable transformations in soil, optimizing the living environment, growth and yield of plants. Positive effects on yield and plant healthiness after application of the same formulations were presented in the paper of Kowalska (2016). Apart from that, they participate in transformation of soil organic matter and are decisive to soil structure and its pH. They produce numerous bioactive substances in soil. Soil microorganisms detoxify many chemical compounds which are harmful to other organisms living in this environment, and they eliminate pathogenic organisms (Niewiadomska, 2013).

Conclusion

The research has shown that the highest values of dehydrogenase activity under the potato cultivation were observed in the variants with UGmax. Application of all tested fertilizers stimulated the availability of phosphorus to plants in the soil, because measurements showed the lowest phosphatase activity in soils collected from plots fertilized with Bioilsa. The positive effect of the different fertilizers UGmax and probiotic EM applied in the experiment on potatoes was also observed in the groups of soil microorganisms under study. Their number was greater than in the variant not fertilized with Bioilsa. When Bioilsa formulation was applied, the microbial products had a stimulating effect on the enzymatic activity or number of microorganisms. Such correlations were not observed only for the acid phosphatase activity after the application of UGmax. From the microbiological point of view the research findings should be regarded as promising. Our research indicated that biofertilizers can activate the microbial and enzymatic activity of the soil after intensive agriculture production and can neutralize the negative impact on these parameters of nitrogen fertilizer. We recommend continuing studies to confirm their effectiveness and usefulness in sustainable agricultural production.

Acknowledgements. This study was financed by the Ministry of Agriculture and Rural Development of Poland within the funding of the research for organic farming. Authors thank also to Dr. Marcin Grobela and Dr. Rafał Motała for making of the chemical analyses of the soil sample.

(Received 26th Mar 2017; accepted 21st Jul 2017)

Abstract. The subtropical broadleaved humid forest of Meghalaya, northeast India are characterised by small remnant patches. The major threats to the existing patches are anthropogenic activities such as encroachment of forest area, mining, extraction of forest resources, grazing and forest fire. The present study was carried out at Jarain and adjoining areas of Jaintia Hills in Meghalaya, northeast India to identify the current human disturbances and assess the floristic composition and structure of subtropical broad leaved forest along a fragment size gradient. Floristic sampling was carried out by laying 24 plots (20mx100m) across 10 forest fragments covering a sampled area of 4.8 ha. A total of 160 woody species (≥5cm dbh) belonging to 105 genera and 54 families were enumerated from all the studied fragments. The species richness was 69 in Small, 75 in Medium, 76 in Very Large (VL) and 77 in Large (L) fragment classes. In this study, Pearson's correlation analysis was performed to analyse the relationship between area, disturbance and phytosociological attributes. The results showed that the stand density increased (r = 0.71, p=0.01), while basal area decreased with disturbance (r = -0.74, p= 0.01). The density was high in 5-15cm dbh class that gradually declined with the increase in diameter. The basal area was high in >66cm dbh class in Very Large fragments whereas in small patches, the values were higher in 16-25cm dbh classes. The forests fragments under study also have a number of rare, endemic and threatened species. Therefore, it is suggested that the entire landscape be brought under the protected area network due to high species diversity.
Keywords: *area, conservation*, *species diversity, density, Jarain*

Introduction

Fragmentation of large continuous tracts of forest into smaller patches leads to biodiversity loss, population shift, collapse of community assembly and ecosystem integrity (Mikkelson, 1993). The species richness in the fragments are determined by a number of attributes such as geographical location, topography, shape, management regimes, landuse history, internal disturbances (Ochoa- Guano et al., 2004) and the rate of colonisation and extinction of species over a period of time (Vellend et al., 2006). Though time scale is an indispensible variable in fragmentation studies particularly on plant community which are long lived and their response is slow, the debt of extinction due to fragmentation is inescapable (Vellend et al., 2006). There are two views regarding the effect of fragment size on biodiversity conservation. According to one of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_385407

the views (the theory of island biogeography), fragments of larger area are supposedly assumed to harbour more species than the smaller fragments (Mac Arthur and Wilson, 1967). Larger fragments provide opportunity for establishment of varied microhabitats, space and resources to support more species and individuals (Schoener, 2010). Contrary to this, there are studies that have established that network of several small fragments have the potential of conserving biodiversity of a region (Toledo-Aceves et al., 2014; Ziter et al., 2013). In smaller fragments there is a high species turnover (Arroyo-Rodriguez et al. 2008). The consequence of fragmentation on species diversity may not be a linear species-area curve but are reflected through its response to edge effect which can cause cascading effects on the ecosystem. Tree species may be impoverished due to the loss of disturbance sensitive species in the fragments (Tabarrelli et al., 2004).

The larger fragments have more interior and are expected to support more of shade tolerant species (Benchimol and Peres, 2015). Species are susceptible to edge effect due to alteration in physical processes such as increase insolation, windthrow (Murcia, 1995; Laurance et al., 2000) and invasion by early successional species (Tabarelli et al., 2004). Gradual development of edge, affect the plant community since the ecological traits of the species may not be compatible with the conditions prevalent in the remnant habitat. The proportions of evergreen species in the edges are often replaced by deciduous elements associated with traits more adaptable to disturbance by shedding off their leaves to reduce water loss (Orihuela et al., 2015). Creation of edge may favour establishment of lianas (Laurance et al., 1998; Chettri, 2010) and light tolerant species (Ochoa-Gaona et al., 2004). However, epiphytes and herbaceous community may be threatened due to death of old growth trees that serves as host for the former and filter excess solar radiation to the herbaceous community (Hofmeister et al., 2013; Kolk and Naaf, 2015). Further, the invasion by light demanding species may pose competition with native old growth species that may alter the composition and structure of the community affecting ecosystem functions (Zhu et al., 2004).

Fragmented patches are more exposed to anthropogenic disturbances and small patches are highly susceptible to resource extraction that could further degrade the remnants (Cayuela et al., 2006). Although large reserves are usually preferred over smaller ones for conservation purpose, the effectiveness of forest patches to retain habitat core condition (Hofmeister et al., 2013), large subsets of species diversity and forest structure is still controversial (Lindenmayer et al., 2008; Gardner et al., 2009). There are studies that have established that species diversity increases with fragment size (Turner, 1996; Laurance et al., 2002). Contrary to this, species diversity has been observed to be independent of fragment sizes (Arroyo-Rodriguez et al., 2008; Hernandez-Reudas et al., 2014). Remnant patches can be of special interest irrespective of size because they may represent some of the only habitat left for certain species which are susceptible to disturbances particularly fragmentation. They may also have similar species diversity, complimentary to larger habitat necessary for biodiversity conservation and ecosystem services (Godefroid and Koedem, 2003). The consequence of fragmentation is of serious concern especially for species that are endemic, threatened or having ecological and economic interest.

The state of Meghalaya in northeast India is a part of the Indo-Burma hotspot (Mittermeier et al., 2004) and is rich in biological wealth and endemism (Upadhaya et al., 2012). The state supports various forest types ranging from tropical- evergreen, -semi evergreen to subtropical- broad leaved and -pine. The subtropical broadleaved humid forest found in higher altitudes (≥ 900 m asl) of the state have been recognised

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_385407

for their high species diversity and endemism (Upadhaya et al., 2003; Pandey et al., 2005; Jamir et al., 2006; Upadhaya, 2015). However, they occur in the form of highly fragmented patches and are poorly represented in the protected area network of the state (Upadhaya et al., 2013). The remnant subtropical forests are exposed to various kinds of disturbances and most of them have been converted to Pine *(Pinus kesiya)* dominated forest (Sarma, 2005). Other human activities such as overexploitation, deforestation, shifting cultivation, mining and urbanization have further contributed to the loss of subtropical broad leaved forest. Therefore, the present study was carried out at Jarain and adjoining areas of Jaintia Hills in Meghalaya, northeast India to:

- identify the current human disturbances operating in the remnant patches
- assess the floristic composition and structure of the forests along a fragment size gradient.

Materials and Methods

Study Sites

For the present study, forest fragments of different sizes ranging from 3.79 to 105 ha were selected at Jarain (E 25°19'20.45" - 25°19'25.55" and N 92° 07'42.33" - 92° 09'23.09", altitudinal range 1000m-1200msl), in Jaintia Hills of Meghalaya, northeast India. These patches were located within 5 km radius and represents similar climatic and edaphic conditions (*Figure 1* and *2*). The vegetation in the study area represents subtropical broad leaved humid forest (Champion and Seth, 1968). It is dense with short stature and the height of the tree rarely exceeds 18 m. The trees are distributed in three distinct strata and species like *Castanopsis* spp., *Daphniphyllum himalayenses, Eleocarpus lanceifolius, Engelhardtia spicata, Lithocarpus fenestratus, Magnolia insignis, Myrica esculenta, Persea odoratissima, Quercus semiserrata, Sarcosperma griffithii* and *Schima wallichii* usually forms the canopy layer. The species such as *Litsea elongata, Rhus acuminata, Syzygium tetragonum, Helecia nilagirica, Ligustrum robustrum* and *Lithocarpus dealbatus* forms the subcanopy layer. The undercanopy layer is dominated by large shrub or small trees such as *Camellia caduca, C. caudata, Daphne involucrata, Erythroxylon kunthianum, Eurya acuminata, Myrsine semiserrata, Symplocos spicata, Syzygium cuminii* etc. (Jamir et al., 2006; Pao et al., 2016).

The climate of the area is monsoonic with a distinct wet and dry period. The wet period extends from April to October during which more than 80% of the total rainfall occurs. The dry period extends from November to March with a rainfall of <20 mm and are characterized by low temperature (8ºC). In spring (April-May), the temperature starts to rise and there are few showers of rain as shown in *Figure 3* (Pao et al., 2016).

The Jaintia Hills is a continuation of the Meghalaya Plateau formed from the remnants of Pre-cambrian Indian peninsular shield. The rocks are mostly of Precambrian origin with gneissic composition such as granites, schist, amphibolits and calc-silicate (Central Groundwater Board, 2013). Soil texture of the studied sites varied from loamy sand to sandy. Bulk density ranged from 0.95 to 1.26 g cm^{-3} whereas, the porosity varied from 46.53 to 64.02%. The soil was acidic in nature (pH 5.4).

Sampling Design

The 10 fragments of different sizes selected for the study were arbitrarily classified into four classes viz. Small (< 4 ha), Medium (>5and <15 ha), Large (>15 and <50 ha) and Very Large (105 ha) to study the phytosociological attributes along a fragment size gradient. Three replicate fragments were maintained for each fragment class. However, in the case of the Very Large, three replicated plots were maintained from a single large fragment due to lack of large continuous forests in the study area (Santos et al., 2007). These replicated sites were abbreviated as S (S1, S2, S3), M (M1, M2, M3), L (L1, L2, L3) and VL (VL1, VL2, VL3) respectively *(Table 1).* All the fragments were once a part of the same forest.

The disturbance index for each site was assessed following Mir et al. (2016). A score of 0 to 10 was assigned to each anthropogenic factor viz., extraction of -timber, -fuel wood, encroachment upon forest land for settlement, agriculture, mining and quarrying; road construction, NTFP's collection, construction of ponds, grazing and fire. A score of 0 was considered to be negligible, 1 as low, 5 as intermediate and 10 as high. The forest having all the disturbances at the highest intensity would have a total score of 110.

For vegetation sampling extensive field survey was carried out from 2013-2015. To capture the heterogeneity of structure and composition of the plant community, in each fragment, two transects of 20mx100m were laid, one along the edge of the forest while the other was laid at a distance of 50m from the first tree on the edge (Page et al., 2009). Each transect was further divided into 20 quadrats of 10mx10m size for inventorization of all woody species having a diameter at breast height (dbh) of ≥5cm. The specimens were collected and identified using regional floras and the Herbaria at Botanical Survey of India, Eastern Regional Circle, Shillong. The nomenclature of the species follows the regional flora.

Data Analysis

The vegetation data from the two transect for each sites were pooled together. Community parameters such as frequency, density, basal area and importance value index (IVI) were computed following Misra (1968) and Mueller-Dombois and Ellenberg (1974). Various diversity indices such as Shannon Wiener, Simpson and Pielou were calculated following Magurran (1998). Sorensen's index of similarity (Sorensen, 1948) was used for comparing the floristic similarity between the fragments. A check list of rare, endemic and threatened species occurring in the study area was prepared based on published literature (Pandey et al., 2005; Upadhaya et al., 2013) and the recent IUCN Red List (IUCN, 2016).

Pearson correlations analysis was performed to examine the effect of fragment size and anthropogenic disturbances on species richness, density, basal area and various diversity indices. The software SPSS statistical package (Version 20) was used for statistical analysis.

Results

Site Characteristics and Disturbances

The fragmented patches under study were scattered amidst degraded grassland and human habitation. The major threats to the existing remnant patches are anthropogenic disturbances. Encroachment of forest land for agriculture, settlement, mining of coal, construction of ponds around streams and sand mining are common sight around most of the patches. Timber and non-timber forest product extraction, browsing, rampant fire during winter are also threatening the very existence of these remnant patches (*Table 1*). The number of cut stumps was high in S2 (105 stems) followed by M3 (94) and L1 (90) as shown in *Table 2*. Forest fragments M3, L1, S1 and S3 were highly disturbed whereas, S2, M1, M2, L3 and VL3 were mildly disturbed. The remaining three forest fragments L2, VL1 and VL2 were least disturbed. The patches close to human habitation were more disturbed (*Table 1*).

Floristic Composition and Diversity

A total of 160 woody species (≥5cm dbh) belonging to 105 genera and 54 families were enumerated from all the studied fragments. The average species richness per patch was 75 ±2. The species richness in the fragments ranged from 60 species in S2 to 83 in M1, L2 and VL1 fragments. The mean number of species was 69 species in Small Fragment class(S), 75 in Medium (M), 76 in Very Large (VL) and 77 in Large (L) classes (*Table 2*). The species richness did not increase with the increase in patch area ($r = 0.16$, $p = 0.61$). The studied fragments had a number of rare, endemic and threatened species (*Appendix 1*). Overall, the family Rubiaceae had the highest number of genera (8) followed by Lauraceae (7) and Rutaceae (6). In terms of species richness, Fagaceae was the dominant family with 17 species, followed by Rubiaceae (13) and Lauraceae (11).

Diversity indices varied among different fragment classes. The mean Shannon Wiener's diversity index (H') values ranged from 3.54 in Small to 3.76 in Medium fragment, while Large and Very Large showed a value of 3.56 and 3.64 respectively. Based on the H' values the fragment classes can be arranged in the order of

DOI: http://dx.doi.org/10.15666/aeer/1504_385407

M>VL>L>S. The Simpson's dominance index (D) showed a reverse trend to that of H'values. Based on the dominance index the fragments can be arranged in the order of S=L>VL>M. The values ranged from 0.03 to 0.05. Pielou's eveness index (J) ranged from 0.82 to 0.87 in all the fragments (*Table 2*).

Similarity

The species composition of the fragments in the study sites showed high similarity index ranging from 52-77% (*Table 3*). The similarity percentage between L1 and VL3 was highest (77%) and the least between VL2, M2 and M3 (mean 52.5%). The mean percentage of similarity among the fragment classes are 67% for Small, 63% for Medium, 69% for Large and 65% for Very Large respectively (*Table 3*).

Density and Basal Area

A total of 7711 individuals were enumerated in 4.8 ha sampled area. The stem density of woody individuals ranged from 501 individuals per 0.4 ha in L2 to 743 in M3 (*Table 2*). There was no significant increase in the stand density (r = -0.06, p= 0.86) with the increase in patch size (*Table 4*). However, the density increased significantly with the increase in disturbance (r = 0. 71, p= 0.01). The dominant species across the fragments in terms of density includes *Castanopsis purpurella, Helicia nilagirica, Persea odorratissima, Quercus semiserrata* and *Syzygium tetragonum* (*Annexure 1*).

The basal area showed a gradual increase with increase in patch size (r = 0.61, *p*= 0.01) but decreased with the increase in disturbance (r = -0.74, p= 0.01) (*Table 4*). The values were low (*Table 2*) in Medium (17.55 ± 0.90m^2/0.4ha) and Small (18.35 ± 0.91) as compared to Large (19.18 ± 1.70) and Very large (20.83 ± 0.46) patches. In terms of basal area, the dominant species in different fragments sizes are *Castanopsis purpurella*, *C. tribuloides*, *Helicia nilagirica*, *Quercus semiserrata* and *Syzygium tetragonum*.

* Significant at $p < 0.05$ and ** $p < 0.01$

Population Structure

The distribution of density in different diameter classes exhibits a reverse J-shaped curve. The number of individuals was concentrated in the lower diameter class (5-15 cm dbh) that gradually decline with the increase in diameter classes (*Figure 4*). The percentage contribution to total density by individuals in 5-15cm diameter-class ranged from 55-74% while the density in upper diameter-classes (>46 cm) contributed to about 1.35-13%. S1 contain the highest percentage (74%) of individuals in the lower diameter-class (5-15cm) followed by M3 (73%), L1 (72), VL1 and VL2 (71 each), M1 (67), S2 and L3 (65 each), S3 (64), VL2 (62), M2 (56) and minimum was observed in L2 (55). VL3 had the highest number of individuals in the higher diameter class (>66cm) with 12 stems per 0.4ha. The stem density in the lowest diameter class (5-

DOI: http://dx.doi.org/10.15666/aeer/1504_385407

15cm) was highest in the sites corresponding to fragments with maximum disturbance score viz., M3 (542 individuals), L1 (510) and S1 (496). There was a total absence of individuals in >66cm dbh class in L2 (*Figure 4*).

Basal area distribution exhibited a very irregular trend among the different diameter classes and fragment sizes. The basal area was high in 16-25cm diameter class in all the fragments that gradually decreased till 56-65cm dbh class followed by an increase in > 66cm dbh class in all the stands except in S2, M3 and L1 (*Figure 4*). The percentage contribution to the total basal area by the lower diameter class (5-15cm) was highest in M3 (26%) and lowest in VL1 and VL2 (12% each). Similarly, the contribution to basal area by >66cm dbh class was highest in larger fragment classes i.e., VL3 (39%), VL1 and VL2 (20% each).

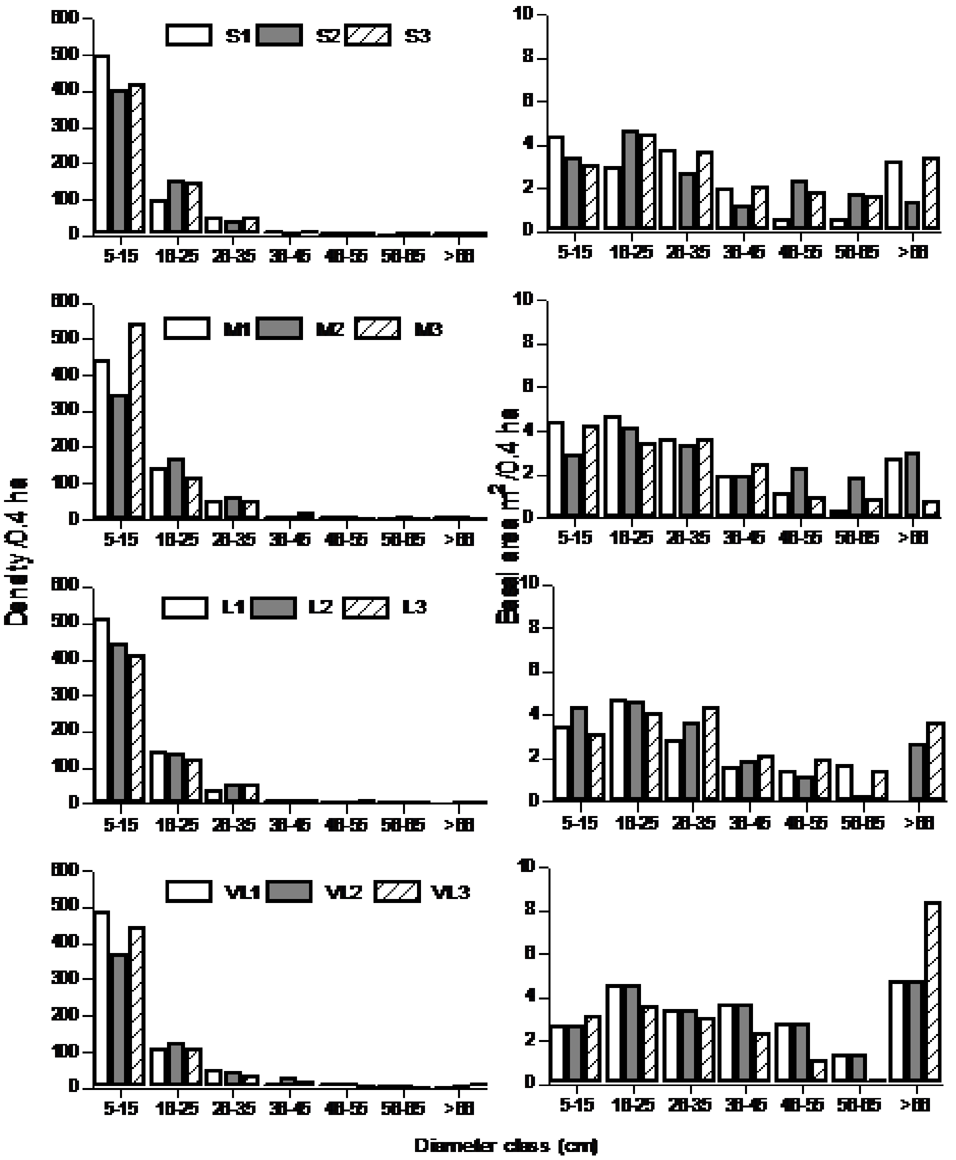

Figure 4. *Distribution of density and basal area in different diameter classes in the studied fragments*

Discussion

The site characteristics of the studied fragments have shown that they are exposed to one or the other form of human disturbances. Forest fragmentation and anthropogenic disturbance can cause synergistic detrimental effect on the composition and structure of a plant community. The presence of 160 woody species belonging to 105 genera and 54 families indicates a considerable level of plant diversity in the study area. It seems that the variation in species richness among the fragments is due to land use history, geographical proximity to human habitation, and anthropogenic disturbances (Echeverria et al., 2007). The species richness showed no linear relation with the increase in patch size. This finding is similar to that reported from temperate forest of Chile (Echeverria et al., 2007) and tropical highlands of Chiapas, Mexico (Cayuela et al., 2006; Ochoa-Gaona et al., 2004). Such observation could be attributed to spatial shape complexity, dispersal mechanism, establishment and maintenance requirements of the species (Lord and Norton, 1990; Bierregaard et al., 1992). Isolation could be another important determinant of tree diversity in the fragments. The presence of patches close to each other might have favoured the recruitment of species. Protection and management may be one of the reasons for fair presence of species as observed in small fragments (S1 and S2). However, these small fragments are under severe threat due to illegal extraction and other human disturbances. Edge effect as well as human disturbance favoured pioneer species like *Castanopsis purpurella*, *Helicia nilagirica*, *Quercus semiserrata*, etc. Such species constituted 66-89% of the total density and were dominant in all the fragments. Several studies have reported a preponderance of pioneer species after disturbance (Aguilar-Santaleiss and Castillo, 2013). The high similarity in species composition (52-77%) among the studied fragments could be the close proximity of the patches to each other. Trees are long lived species and hence time lag may delay the impact of fragmentation on species composition shift among the fragments (Tabarelli et al., 2004).

The studied forests harbour a number of rare (*Acer laevigatum*, *A. oblongum*, *Cinnamomum pauciflorum*, *Croton oblongus*, *Cyathea gigantea*, *Engelhardtia roxburghii*, *Litsea leata*, *Photonia integrifolia*, *Podocarpus neriifolia*) and endemic species (*Camellia cauduca*, *Citrus latipes*, *Ilex embeloides*, *I. venulosa*, *Schima khasiana*, *Viburnum simonsii*) of the region. These remnants patches are also the natural habitat to many of the species threatened at global level (*Eleocarpus prunifolius*, *Engelhardtia spicata*, *Ilex venulosa*, *Magnolia insignis*, *M. punduana*). Therefore, these patches are important from conservation point of view (*Appendix 1*).

Shannon Wiener's diversity index showed no significant increase with area, but was negatively related to dominance index. High dominance of certain species in response to disturbances may be responsible for this behavioural pattern of the community. The negative relation of evenness and dominance index with area indicate a more diverse plant community especially in the smaller fragments. Such findings reveals the potential role of small fragments in conserving plant diversity in fragmented landscape (Toeldo-Aceves et al., 2014; Hernandez-Ruedas et al., 2014).

Though stem density showed no linear relationship with the fragment size, it increased significantly with disturbance. Increase in density with disturbance, reflects the resilience of the fragments following past disturbance. Recruitment of individuals in gaps created due to selective extraction may lead to an increase in stem density as observed in tropical forests of Kenya (Fashing et al., 2004) and India (Bhuyan et al., 2003). According to Atkinson and Marin-Spotta (2015), disturbed forests have high

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_385407

density and low basal area and are a characteristic feature of early successsional forest. Further, due to edge effect, there is a preponderance of fast growing pioneer species that often have high ecological amplitude to survive and compete for resources in fragmented patches (Laurance et al., 2004). The physical factors at the edge are known to restructure the plant community (Tomimatsu et al., 2015). An increase in the number of cut stumps and stem density and a decrease of basal area in the smaller fragment categories indicates that such patches are not only vulnerable to edge effect alone but also to anthropogenic encroachment.

The density- diameter distribution showed reverse J-shaped curve and indicates that the studied stands are regenerating. Majority of the individuals (60-70%) were present in the lower diameter class (5-15cm dbh). The proportion of individuals in the lower diameter class (5-15cm dbh) was high in the disturbed sites. Recruitment of light tolerant species might have increased the stem density of the stand following disturbance (Majumdar et al., 2014). The low density in Very Large category may be due to thinning effect caused by larger trees as reported from the sholas of Western Ghats (Mohandass and Davidar, 2010). Extraction of trees for small timbers and poles were responsible for lower density in the middle diameter classes. Other causes could be the cultural disturbances in the form of selective felling during religious festivals and cremations (Jamir et al., 2006; Upadhaya et al., 2008).

There was a positive relation of basal area with patch size due to retention of some old growth large trees. Similar results have been reported from other subtropical forest of the region (Tripathi et al., 2010), tropical rainforest of Western Ghats (Bhat et al., 2000) and south eastern Madagascar (Ingram et al., 2005) and temperate forest of Southern Chile (Echeverria et al., 2007). Reduction of basal area in the smaller fragments represents a modification in the stand structure as the forest had returned to an earlier successional stage (Echeverria et al., 2007). Though the number of individuals was high in the lower diameter class (5-15cm) but their contribution to basal area was low. The irregular distribution of basal area in different diameter classes could be attributed to selective extraction by the villagers.

Conclusion

The forest patches under study are of high conservation value due to its geographical location being in the Indo-Burma biodiversity hotspot (Mittermeier et al., 2004). The area houses a rich plant wealth and has been identified as a high priority area for conservation that lies outside protected area network in Meghalaya (Upadhaya et al., 2013). The study also highlights the potential role of small patches in conserving plant diversity of the region. Thus a network of patches could serve as habitat for subset populations of the original habitat that can interact and exchange resources. They may also act as corridor for various ecological interaction, serves as source of propagules for regeneration and aid in the successional process of the surrounding non forested matrix. Therefore, it may be suggested that human disturbances operating in the area needs to be reduced and the entire landscape be covered under the protected area network. We also suggest that other life forms such as shrubs, herbs, epiphytes should also be considered to understand the overall effect of fragmentation on plant diversity at landscape level.

Acknowledgements. The authors are thankful to the Forest Department of Jaintia Hills Autonomous District Council for granting us necessary permission to work in the forest. The help and cooperation received from the local Raid Buam during the field survey is also acknowledged. The first author is thankful to UGC for financial support in the form of fellowship (Award No. F.15-6/December, 2011/2012 NET). The critical comments received from anyomous reviewers are acknowledged.

Conflict of Interest. We declare that there is no conflict of interest.

Abstract. It has been recognized and discussed in the literature that values associated with forest integrity, i.e., sustainability and diversity, are relevant to the three aspects of self-organisation: resilience, health, and evolvability. However, evolvability has not yet been studied and also there is still no relevant notion of forest health. This calls for a biodynamic approach to forests and clearly addresses questions relating to scaling and self-organisation since the different levels of detail must be compatible to ensure the consistency of sustainability and diversity assessments. To support the development of a biodynamic approach to forests we review the concepts of self-organisation, criticality and resilience, and their relationship to forest integrity in the light of fractal organisation theory. An exploration of fractal connectivity behind key bioindicators and biomonitors in the avoidance of a biodiversity threshold can be suggested thus far. Forest integrity refers to empirical scaling relationships that are emergent features of biodiversity. In a forest, species as different as fungi, plants, animals and insects, and processes as disparate as disturbance, dispersal, facilitation/competition and nutrient cycling, are related through ecological interaction networks; a 'fractal' is the 'collective phenomenon' of these networks.
Keywords: *biodynamic approach, forest integrity, fractal connectivity*

Introduction

Cyclic processes in the biosphere are self-organised and demonstrate sustainable development that inevitably involves change (Kazansky, 2010; Kimmins et al., 2007). The most important direct driver of change in forest biodiversity and ecosystems is habitat shifts and forest loss. Nearly half of the world's original forest cover has been lost, yet the economic potential of a large part of the global forest area is under-realized because of a lack of sustainable forest management (FAO, 2014). Even if forest loss were to end today, it would take hundreds of years for species numbers to reach a new, lower, equilibrium in response to the habitat shifts that took place in recent centuries (Millennium Ecosystem Assessment, 2005). This means that since large areas are required to conserve viable populations and that since nature reserves eventually become isolated islands in the landscape, the long-term fate of many forest-dependent organisms will depend on activities and conditions in the unreserved portions of forests (Lindenmayer and Franklin, 2002; Whittaker et al., 2001; Kemp, 1992). For this reason, the present understanding of sustainable forest management must include values associated with integrity. A significant change, compatible with economic realities, requires the intrusion of biological considerations and conservationist philosophy into modern methods of exploitation (Stern and Roche, 1974). This calls for a biodynamic approach to forests and clearly addresses questions relating to scaling and self-organisation since the different levels of detail must be compatible to ensure the consistency of sustainability and diversity assessments.

Values associated with integrity, i.e., sustainability and diversity, are in essence about maintaining the combined biospherical-societal system: humans, with their social, cultural, economic, and environmental needs, are an integral part of ecosystems. It means that the capacity to sustainably use forests rests on our understanding and interpretation of pattern and process at several scales, the recognition of thresholds, and the ability to translate knowledge into appropriate management actions in a reflexive manner (Garmestani and Benson, 2013; Thompson et al., 2009). However, there is no single underpinning model that fully meets all the requirements for evaluating the sustainability of multi-functional forest management (Rennolls et al., 2007). So, the focus of attention shifts from the value components of sustainable development projects, to the domain of existence, in that we can map and model single, or even multiple relationships, but not a total set of evolving interactions and feedbacks (Fernandez et al., 2014; Jiggins and Röling, 2002; Waldrop, 1992). Here the reflexivity makes possible to connect any aspects of reality, setting up feedback loops between them (Soros, 2010). This, in turn, makes fractal organisation theory, inspired by systems theory, fractal geometry, quantum mechanics, information dynamics, sociobiology, epigenetics, evolutionary biology and game theory, the central subject herein (Raye, 2012).

Fractal organisation theory could illuminate evolving interactions and feedbacks from the multiple perspectives of different types, so it is a means to support the development of underpinning models which are consistent, and scale appropriately across the levels of self-organisation and conceptual frameworks. Forest integrity is about three aspects of self-organisation: resilience, health, and evolvability (Freedman, 2012; Kay and Regier, 2000). Evolvability, however, has not yet been studied because it was presumed at the outset: empirical experiences with quantitative genetics and selective breeding produced a consensus that ‘phenotypic variation was effectively like a gas which could flow into any selective bottle’ (Luo, 2014; Altenberg, 2014). Also, there is still no relevant notion of forest health, as there is for humans: a set of properties that have been selected through evolution because they maximize fitness (De Leo and Levin, 1997). Resilience is ‘the capacity to change in order to maintain the same identity’ (Folke et al., 2010). Accordingly, to support the development of a biodynamic approach to forests we review the concepts of self-organisation, criticality and resilience, and their relationship to forest integrity in the light of fractal organisation theory.

Scaling laws

Pattern integrity or self-similarity – the retention of distorted copies of itself across scales – is a typical property of fractals, a concept introduced by Benoît Mandelbrot (1924-2010) and one of the fundamental mathematical results of the 20th century (Satija, 2016; Raye, 2012; Rozenfeld et al., 2009). Fractals are often considered the ‘fingerprints of chaos’: the term ‘fractal’ is based on the Latin *frāctus*, derived from *frangere* which signifies to break, to create irregular fragments (Mandelbrot, 1983). Also, a fractal is known as expanding symmetry or evolving symmetry (Kumar et al., 2017). Self-similarity is symmetry across scale. The manner, in which a fern leaf’s overall shape is replicated in each of its leaflets, and again in the subleaflets of each leaflet, is a familiar illustration of fractal relationship (Mosko, 2010). However, fractals are not extrapolated from a geometric logic based on units. Rather, we can think of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_409426

fractals as processes, possessing a self-replicating basis, which lead to a non-integer dimensionality (Fielder and King, 2014). Let's take, for example, the branching structures of resource distribution networks, such as the xylem that transport water through plants. According to West et al. (2009), 'the entire forest is, in a very real sense, a hierarchically branching resource supply network that can be described mathematically and behaves structurally and functionally like a scaled version of the branching network of the trees it contains': the analysis of the branching size distribution reveals an exponent which is essentially identical to the tree size distribution within a forest. So, a 'fractal' is what 'emerges' from these networks; it's the 'emergent property' of the network's memory. The analysis of fractality can provide a new strategy for studying cellular, organismal and community differentiation since fractal dimension is a good quantitative measure of the degree of morphological differentiation; it is also a useful measure for comparative studies across and among species, as they relate to cellular evolution (Smith and Behar, 1994). It should be noted, however, that the existence of changes in fractal dimension when shifting between scales implies that in place of true pattern integrity, we observe only partial self-similarity over a limited range of scales separated by transition zones. Fortunately, tests carried out using multifractals, which are objects that need a continuous spectrum of exponents to be described, may disclose the properties encoded in the data relating to the relationships on different scales; the basic graphic tools here are known as multifractal spectra or spectra of singularity (Drożdż and Oświęcimka, 2015). On the other hand, real fractals are, in fact, multifractals: the measure is not the same in every subset, and each of them has a different fractal dimension and a different associated diverging exponent (Solé and Manrubia, 1995). Several good introductions to multifractal methods applied to ecology can be found in Scheuring and Riedi (1994) and Borda-de-Água et al. (2007) (Saravia, 2014). Multifractals have been applied to vegetal communities (Scheuring and Riedi, 1994), tropical rainforest (Manrubia and Solé, 1996), and to the characterisation of species-area relationships (Laurie and Perrier, 2011; Yakimov et al., 2008; Borda-de-Água et al., 2002). Borda-de-Água et al. (2007) used the so-called multifractal approach to show that models which assume symmetric neutral dynamics and use realistic dispersal kernels predict scaling patterns of diversity and distribution very similar to those observed by Hubbell and Foster (1983) in the Barro Colorado Island rainforest, in Panama. Solé and Manrubia (1995) constructed a simple cellular automata model in order to simulate the gap dynamics of the Barro Colorado Island rainforest as well as the observed macroscopic spatial regularities. The observed and simulated fractal behaviour was shown to be related to self-similar dynamics of biomass.

'From a wildlife perspective, each organism scales the environment differently, and thus there is no absolute size for a landscape' (Sun and Southworth, 2013). As scale changes, new patterns and processes may emerge and controlling factors may shift even for the same phenomena (Wu and Li, 2006). Fortunately, the fractal hierarchy is a method which can be used to unify different scaling phenomena and rules in complex systems (Seuront, 2009). 'The hierarchy always follows a pair of exponential laws and a power law' (Chen, 2012). Power laws describe empirical scaling relationships that are emergent quantitative features of biodiversity (Brown et al., 2002). A power law is obtained when one observes a straight line in a plot of 'the number of events' versus 'how often they occur'; in other words, the probability $f(x)$ of an event of magnitude x occurring is inversely proportional to x: $f(x) \sim x^{-\alpha}$ (Rhodes and Anderson, 1996). $f(x) \sim$

x^{-1} – a critical dependence – is often associated with ‘self-organised criticality’ which provides a general mechanism for the emergence of scale-free networks with the characteristic power-law distribution of links (Graham, 2014; Nottale, 2013; Laurienti et al., 2011; Messier and Puettmann, 2011; Turcotte, 1999; Bak et al., 1989). ‘Scale-free model’ incorporates two generic mechanisms thought to be common to many real-world networks: growth of the network by addition of nodes and links at each time step and preferential attachment of new nodes to certain highly connected hubs – the existing nodes with a high number of links. In other words, ‘A scale-free topology automatically emerges whenever new species (nodes) add preferentially to pre-existing ones with a probability proportional to the number of pairwise interactions (links) of the target species’ (Jordano et al., 2003). However, most ecological interaction networks examined so far have cut-off numbers of pairwise interactions per species giving rise to a gradient of variation from scale-free to broad-scale and to single-scale distributions; these distributions depart in most cases from the power-law beyond cut-off values. Constraints in the addition of links such as morphological mismatching or phenological uncoupling between mutualistic partners restrict the number of plant-animal interactions established, causing deviations from scale invariance, which is solely described by a power-law function, $f(x) = kx^{\alpha}$, where the power-law exponent, α, is a measure of scale-invariance, and k is a constant (Katz, 2016). In food webs, the distribution of links changes from (partial) power-law to exponential to uniform as the level of connectance increases (Dunne et al., 2002).

Self-organised phenomena

Nothing happens directly in this indirectly ordered universe (Schauberger, 1936). Unlike the action of seasons and natural disasters, long-term change in the composition of communities is brought about by the activities of living organisms which themselves inhabit the environment. Over a period of time, the environment is modified by these organisms so it becomes suitable for colonization by another species and less suitable for those already there (Rose, 2005). For example, after a stand-replacing disturbance, shade-intolerant species colonize and grow into a dominant canopy, but due to their shade-intolerance they are unable to regenerate under their own canopy, so the understory (composed of shade-tolerant species) gradually replaces the canopy (Kotar, 1997). Thus, all elements of any developing living system co-determine each other, whether it is the coevolution of biological species, a behavioural act or an immune response (Kazansky, 2015). Any living organism has relatively autonomous organisation of metabolic processes and, at the same time, all living creatures are fundamentally dependent on each other via trophic, behavioural or sexual relationships, and also indirectly, via the environment (Levchenko et al., 2012). A forest exists by virtue of all the fungi, trees, other plants, insects, birds and other animals, and they are fully what they are by virtue of dwelling in that forest; neither can ‘exist’, at least not fully, without the other.

‘Self-organisation is basically the spontaneous creation of a globally coherent pattern out of the local interactions between initially independent components’ (Heylighen, 2001). ‘In the optic of biological research, the common meaning of self-organisation is defined by the global emergence of a particular behaviour or feature that cannot be reduced to the properties of individual system’s components such as molecules, agents and cells’ (Camazine et al., 2003 as cited in Di Marzo Serugendo et al., 2011).

DOI: http://dx.doi.org/10.15666/aeer/1504_409426

'Physiological interactions among molecules, cells, tissues, organs do not simply sum each other up: they are "entangled", "non-local", "non-separable" . . . they are "superposed"' (Longo and Montévil, 2011). Therefore, despite its intuitive simplicity as a concept, self-organisation has proven notoriously difficult to define and pin down formally or mathematically, and it is entirely possible that any precise definition might not include all the phenomena to which the label has been applied. One of the objectives of the present article was, therefore, to give prominence to the concepts of self-organised criticality and resilience because they are of relevance to forest integrity. As a result, forest integrity could be understood in terms of attractors as defined by conceptual inferences related to self-organised criticality and resilience (*Table 1*). The explanatory power of self-organised criticality stretches so far as to assume that a given scale-free phenomenon is caused by the system which organises its critical state by itself (Pruessner, 2012). This critical state acts as an attractor. The fractal patterns may be a fingerprint of a system close to a critical point (Manrubia and Solé, 1996). To substantiate such a viewpoint, Manrubia and Solé (1996) performed an extensive study of a real rainforest in Barro Colorado Island, Panama. They found the strong evidence of self-organised critical state in the power laws that the magnitudes of the system follow, both in space (fractality, correlation function, clearings and tree sizes distributions) and time (biomass fluctuations). Moreover, self-organised critical models of extinction have been used to explain power-law distributions of species' life span and extinction events in statistical evidence from the fossil record (Solé et al., 1997; Solé and Bascompte, 1996; Sneppen et al., 1995; Bak and Sneppen, 1993).

Table 1. *System integrity in terms of attractors by conceptual inferences related to self-organised criticality and resilience*

Concept	**Inference**	**Connection**
Self-organisation	'The basic mechanism underlying self-organisation is the variation which explores different regions in the system's state space until it enters an attractor' (Heylighen, 2001). 'Standard examples of attractors are stable equilibrium and stable limit cycle' (Fradkov and Chen, 2009). A limit cycle of infinite period is sometimes referred to as a chaotic state (Li and Yorke, 1975). An attractor – a region in state space that a system can enter but not leave – is a mathematical model of causal closure. 'Closure usually results from the nonlinear, feedback nature of interactions' (Heylighen, 2001). Therefore, it seems that reflexivity can act as an attractor when attempting to predict the outcome of a self-organising system at work (see Schiavello, 2013; Sandywell, 1996).	Reflexivity as an attractor
Criticality	'Dynamical criticality, a central property for the functioning of a living organism, naturally emerges as a consequence of evolution that favours evolvability' (Torres-Sosa et al., 2012). Also, it is a property of (classes of) dynamical systems that have a critical point as an attractor (Aschwanden, 2011; Bak and Creutz, 1994). Actually, many slowly driven open non-equilibrium systems self-organise to a critical point where everything can happen within well-defined statistical laws (Jensen, 1998; Bak, 1996; Bak et al., 1989). Moreover, as a system parameter changes through a critical value, a symmetry-broken attractor can be born (Lai, 1997). Lastly, when the symmetry is lost, it can be said that it is replaced by a collective mode.	Symmetry-broken attractor
Resilience	An ecosystem is resilient if it remains in the same domain of attraction and returns to the same state after a disturbance (Rietkerk and van de Koppel 2008). However, it may exist almost continuously in a transient state if there is frequent disturbance. So, it turns out that the final attractor toward which the system will converge (e.g., successional pattern, community type, etc.) usually depends on the initial conditions involving several attractors, leading to difficult issues related to the ability to predict which attractor a given trajectory will asymptote from (Freire et al., 2008; McDonald et al., 1985). Hypothetically, intransitivity, i.e., coexistence of attractors, is a peculiar characteristic of meta-communities without strict competitive hierarchies (Freire et al., 2008; Kerr et al., 2002).	Intransitivity of attraction

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_409426

The basic assumption of resilience thinking is that systems are most resilient in their natural (evolved) states (Hopkins, 2009). Over the long run resilience is needed to maintain organismal fitness, however, the dynamics of organismal fitness remain poorly understood over long time scales (Wiser et al., 2013). Although researchers such as Kauffman (1993) have started exploring the structure of fitness landscapes for various formally defined systems by computer simulation, examples of individual adaptation via plasticity by temporal variation of fitness-related traits observed during the lifetime of forest organisms are very seldom documented at this time (see Lindner et al., 2008; Heylighen, 2001; Durzan, 1993). This leads to a reconsideration of the traditional approach to forests focused on long-term dynamics in favour of biodynamic approach. 'The commonly accepted fact is that the cell/organism (any living organisation, in fact) is an open nonequilibrium system, which exists and functions only because of the incessant flow of energy/matter passing through it' (Kurakin, 2011). For that reason, one of the most fascinating and mould-breaking findings has been the discovery of self-organised spiral/loop patterns, occurring commonly in nonliving and living nature (Luo and Zhan, 2008; Hill, 2006; Heylighen, 2001; Bascompte and Solé, 1998; Jean, 1994). Spirals exist in formations such as weather patterns because the interplay between physical forces and matter tend towards that shape, while they also exist in formations such as forests. Fractal hierarchy underlies these formations in all growth processes (Hill, 2006; Selvam, 1998). For example, a positive feedback loop that results in periodic organ formation has been recently uncovered behind the spiral patterns of leaves on a stem by Bhatia et al. (2016). According to Selvam (1998), such patterns are the clearest examples of self-organised criticality in the plant kingdom.

Resilience, or the stabilizing effect of feedback loops, is defined as the ability of an adaptive system to absorb impacts before a threshold between attractors is reached where the system changes into a different state altogether (Messier and Puettmann, 2011; Thompson et al., 2009; Heylighen, 2001). Since the reaching of an attractor is an automatic process it can be viewed as a general model of self-organisation. Most modelled systems with just one stable attractor (e.g., successional pattern, community type, etc.) tend to return to this attractor when perturbed in their dynamics. When the dynamical system has more than one coexisting attractor, it often turns out that the fractal boundaries of the basins of attraction are leading to difficult issues related to the ability to predict which attractor will a given trajectory asymptote to (McDonald et al., 1985). 'An observer might see one kind of behaviour over a very long time, yet a completely different kind of behaviour could be just as natural for the system' (Gleick, 2008). This implies intransitivity – a major factor stimulating emergence of chaotic dynamics (Klimenko, 2015; Lorenz, 1990; Crutchfield et al., 1986). Stone and Ezrati (1996) argued that chaos theory may be particularly useful in modelling vegetation change, where nonequilibrium dynamics (e.g., disturbance, natural mosaic cycling, and habitat fragmentation) often prevail (Kenkel and Walker, 1996). Nevertheless, emphasis on a broader understanding of possible system behaviours and the effects of human intervention has contributed to a significant shift toward resilience thinking, away from the mathematics of chaos.

Self-organisation of a self-sustainable ecological community is a highly-ordered non-random process based on information written in the genomes of participating species. 'The genetic program of species constitutes the informational basis for the compensatory environmental processes initiated by the biota when challenged by an environmental change' (Gorshkov et al., 2004). In a forest, species as different as fungi,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_409426

plants, animals and insects, and processes as disparate as disturbance, dispersal, facilitation/competition and nutrient cycling, are related through ecological interaction networks; a 'fractal' is the 'collective phenomenon' of these networks. Not coincidentally, loss of fractal dimension by a system implies loss of collectivity, i.e., capability of the interconnected components to interact in a common mode (Waliszewski et al., 1999). Moreover, if fractal space, in which a dynamic process takes place, becomes a classic, i.e., Euclidean, space with integer dimension, this means that the process has left its strange attractor, and tends towards, or already is in, the state with a lower number of possible directions of further evolution (Devaney, 1986). To sum up, in the light of fractal organisation theory, forest integrity refers to empirical scaling relationships that are emergent features of biodiversity (see Messier et al., 2015; Simard et al., 2013; Chen, 2012; Marks-Tarlow, 2012; Raye, 2012; Willerslev and Pedersen, 2010; Gorshkov et al., 2004; Brown et al., 2002; Turcotte and Rundle, 2002; Kirilyuk, 2002; Sandywell, 1996).

General suggestions

What is sustainability in the context of forest integrity? It is maintaining scaling relationships inherent to self-organisation (see Graham, 2014; Simard et al., 2013; Rozenfeld et al., 2009; Rickles et al., 2007; Sandywell, 1996). In the presence of intransitivity, the forces driving self-organisation can be analysed with game theory (the analysis of group interaction). However, intransitivity implies that every alternative is dominated by another alternative, so no one pure strategy can be argued to be any better than another (see Ficici and Pollack, 2003; Cooter, 2000). Therefore, sustainable forest management guided by the principles of self-organisation is to be based on a collective of strategies (see Graham, 2014; Cornett and White, 2013; Schütz, 2011; Willerslev and Pedersen, 2010; Li and Bowerman, 2010; Rennolls et al., 2007; Rickles et al., 2007; Millennium Ecosystem Assessment, 2005; Ficici and Pollack, 2003; Lindenmayer and Franklin, 2002; Lorenz, 1990). The two principles of the self-organisation are nature automation, like self-regeneration of a forest, self-differentiation of a stand, self-structuration of a community, etc., and concentration on essential, such as on a protecting key response traits and ecosystem legacies that are critical in the avoidance of a biodiversity threshold, i.e., an abrupt decline in species richness, with habitat loss (see Mackey et al., 2015; Estavillo et al., 2013; Simard et al., 2013; Holt and Miller, 2011; Thompson et al., 2009; Rickles et al., 2007; Schütz, 2006; Diaci, 2006; Kotar, 2006; Kerr et al., 2002; Cody, 1985). In this context, 'A critical management target is conservation of genetic legacies for the system memory and adaptive capacity they provide' (Simard et al., 2013). Unfortunately, 'the vital requirements of clarity, simplicity and practicality do not appear to have been seriously considered in the formulation of many of the genetic criteria and indicators developed to date for the management and monitoring of forest resources' (Boshier and Amaral, 2004; *Table 2*).

How can geneticists help forest biodiversity adapt to changing ecoclimates? First, there should be an effort to complete vulnerability assessments and action plans for forest tree species. For example, in the U.S. Pacific Northwest and Southern Appalachian regions the Forest Tree Genetic Risk Assessment System (ForGRAS) was used to rank forest tree species for a number of primary risk factors: population structure, rarity, regeneration capacity, dispersal ability, habitat affinity, genetic variation, pest and pathogen threats, and climate change pressure (Erickson et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_409426

2012). Second, the conservation of biodiversity implies that the biotic verifiers, such as habitat shifts (*Table 2*), should necessarily be used by auditors and managers to derive an objective decision on the quality of the forest management under assessment. If wild organisms are extracted from their habitats and placed under artificial conditions never encountered in their natural environment, a decay of the genetic information will be manifested as an increase in genetic polymorphism of the populations and appearance of organisms with various defective properties not encountered in the wild type (Gorshkov and Makarieva, 1997; Gorshkov et al., 2004). Nevertheless, studies simulating the impact of forest exploitation, other silvicultural practices and forest fragmentation on genetic diversity are uncommon, and those that exist usually contain oversimplified representations of biological processes (Degen et al., 2004; Gorshkov et al., 2004).

An exploration of fractal connectivity behind key bioindicators and biomonitors in the avoidance of a biodiversity threshold can be suggested thus far. According to Holt and Miller (2011), bioindicators or biomonitors rely upon the complicated intricacies of ecosystems and use a representative or aggregated response to convey a dynamic picture of the condition of the environment. For instance, lichen diversity is commonly used as a general indicator of forest health and ‘ecological function’, as lichens are key primary producers with important linkages to nutrient cycling and forest food webs: high or low lichen diversity can result from certain types of air pollution, changes to forest management or stand structure, diversity of plant substrates available for colonization, favourability of forest climate, return interval of disturbances like fire, and so on (Jovan, 2008).

Abstract. Mowing measures are frequently used as a tool for species conservation. However, mowing intensity as well as ecological characteristics of different sites may have an influence on the respective species or assemblages. Based on a BACI study design we tested if the effect of mowing on carabid assemblages is more pronounced with a higher intensity of the mowing measures, and if the results are influenced by differences in environmental characteristics between individual study sites. Based on 2650 carabid individuals belonging to 43 species we demonstrated that an intensification of mowing intensity resulted in an increased effect on the carabid coenoses. While assemblages from study sites mown once in the year were located closer to those from unmown sites, assemblages from study sites mown twice in the year were clearly separated in ordination analysis. However, some environmental variables, as shown by plant indicator values, accounted for a comparatively high amount of the variance. The study confirms that in the context of using mowing as a measure for nature conservation the mowing intensity has to be taken into account, but also variation in environmental factors.
Keywords: *Carabidae, post agricultural land, mowing measures, biological diversity, BACI*

Introduction

Since long man has influenced his surrounding nature and environment. For example, with cutting of woodland in the middle ages agricultural landscapes became dominant in Europe. Changes in agricultural practices in the recent past lead to intensification of agriculture and change in land use, which are assessed to be main drivers of loss in biological diversity (e.g. Matson et al., 1997; Watt et al., 2007; Haźi et al., 2012). Thus, retransformation of agricultural production in order to contribute to ecosystem integrity is a key challenge of the twenty-first century (Scherr and McNeely, 2008). According to Gonthier et al. (2014) conservation strategies in agriculture require a multi-scale approach including reducing local management intensity and landscape-level approaches incorporating natural or semi-natural areas.

Traditional agricultural practices, as mowing in order to produce hay, should receive special attention. Mowing has also been proposed as a surrogate for grazing (Morris, 2000). Yet, diversity patterns depend on management intensity. For example, Kitahara et al. (2000) observed a highly significant decrease in butterfly species numbers with increasing mowing intensity. Likewise, Marini et al. (2000) detected reduced orthopteran and butterfly diversity with high fertilisation and cutting frequency. Carabid beetles are known to react to management practices in grassland habitats as well (Rainio and Niemelä, 2003) and are sensitive to human-altered abiotic conditions (Koivula, 2011). For example, regarding mowing of Swiss montane meadows Grandchamp et al. (2005) demonstrated a positive influence of fertilization intensity on species richness.

Number of cuts was positively related to the number of individuals. Mown sites in the central-eastern Alps had significantly more species than natural grasslands (Gobbi et al., 2015). Carabid beetles play an important role in agricultural systems, for example as biological control agents on agricultural pests (Humphreys and Mowat, 1994) or seed predators of weeds (Saska, 2008; Petit et al., 2014).

In 2013 a study was started following a "before-after-control-impact" (BACI) study design in order to analyse the effect of mowing measures on carabid beetles. A rather low management intensity in the second year of study (one-time mowing in the first week of July 2014) resulted in a rather weak effect of the mowing measures (Schwerk and Kitka, 2016). Hence, it remained an open question, if an intensification the mowing measures will lead to a more pronounced effect on the carabid assemblages. Moreover, differences in site characteristics independent from the mowing measures might have an additional influence on the formation of the carabid coenoses. Therefore, we increased the mowing intensity from one-time mowing to mowing twice in a third year of the study. In addition, we conducted phytosociological surveys on the study sites in order to specify site characteristics not related to the mowing measures.

The aim of the presented paper was to test (1) if the effect of mowing on carabid assemblages is more pronounced with a higher intensity of the mowing measures, and (2) if the results are influenced by differences in environmental characteristics between individual study sites.

Material and methods

Study sites and field methods

The study was carried out in 2013-2015 on post-agricultural fallow land abandoned from crop production for 21 years in 2013, located in the research area “Krzywda” in Western Poland (Dymitryszyn et al., 2013). Todays’ relief of the region is connected to the last phase of the Baltic glaciation with sand and loams covering almost the whole area. It is located in the zone of Atlantic climate with western wind dominating and a yearly rainfall of about 500-600 mm (Kucharski and Pawlaczyk, 1997; UMiG Tuczno, 2001). According to Matuszkiewicz et al. (1995) “Krzywda” is situated in the range of continental mesotrophic oak-pine mixed forest (Pino-Quercetum).

The study followed a "before-after-control-impact" (BACI) design with three treatment sites and three control sites. Thus, six study sites (B1 – B6) of 50 m x 50 m were established, three of which (B1, B4, B5) were mown with biomass removal on July, 5, in 2014 and on June, 26-27, and August, 17-18, in 2015. The remaining three study sites (B2, B3, B6) were left untreated in 2014 and 2015 (*Figure 1*).

Carabids were collected as described by Schwerk (2014a) using pitfall traps (Barber, 1931) from mid-May to mid-September. Three pitfall traps (distance 3 m) were installed in the center of each study site. The location of the traps was the same in each year of the study. Traps were glass jars topped with a funnel (upper diameter of about 10 cm) set flush with the soil surface. A roof was suspended a few cm above the funnel and ethylene glycol was used as a killing agent and preservative. In order to guarantee their proper functioning the traps were regularly controlled (about every two weeks). Determination and nomenclature of the individuals collected was carried out according to Freude et al. (2004).

At each study site an area of 6 m x 6 m was marked in order to elaborate a phytosociological survey. The surveys were elaborated in the second week of June 2015

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_427440

(before the first mowing on the treatment sites) by recording the species and describing their occurrence using the cover-abundance scale of Braun-Blanquet (1964).

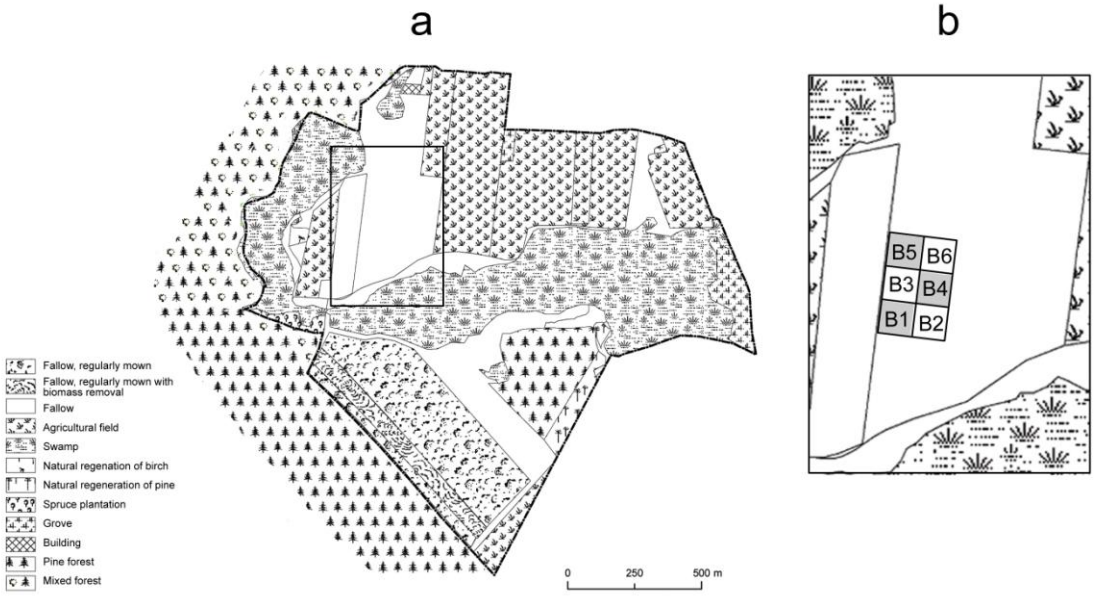

Figure 1. *Scheme of the research area "Krzywda" (a) with the location of study sites B1 – B6 (b). Study sites mown in 2014 and 2015 are indicated by grey colour (from Schwerk and Kitka, 2016)*

Statistical methods

The results of the three traps were pooled to one sample for each study site. For each species, the total number of individuals per study site and the dominance value (percentage share of the individuals of the respective species on the total number of individuals collected at the study site) were calculated.

For each phytosociological survey the values of coverage of the plant species were transformed to a value of mean percentage cover according to Braun-Blanquet (1964): + – 0.1%, 1 – 5%, 2 – 17,5%, 3 – 37,5%, 4 – 62,5%, and 5 – 87,5% (*Appendix 1*). Next, for each study site ecological indicator values of vascular plants were calculated according to Zarzycki et al. (2002). The ecological values according to Zarzycki are a modification of the method of ecological values of vascular plants according to Ellenberg (1974) adapted to the conditions of the Polish climate. Ecological indicator values for light, temperature, soil moisture, trophy (fertility), soil acidity (pH), soil granulometric composition, and organic matter content (humus) were calculated for each study site as a weighted average value of particular plant species cover values.

In order to analyse the similarities between the carabid coenoses a hierarchical cluster analysis was carried out using PAST v. 2.17c (Hammer et al., 2001; Hammer, 2012), with Euclidian distance as distance measure and agglomeration according to Ward. The dominance values of the species at the respective study sites were used. The strength of the nodes was tested by bootstrapping analysis (1999 resamplings). Bootstrap proportions (percentage of replicates where the node is still supported) of ≥70% correspond to a probability of ≥95% that the respective clade is correct (Hillis and Bull, 1993).

We carried out gradient analyses using the CANOCO for Windows version 4.53 (ter Braak, 1987; ter Braak and Šmilauer, 2002) with the aim to obtain information about the environmental basis determining the major pattern in variation (ter Braak and Prentice, 1988). DCA was first used to select the appropriate statistical model based on the longest gradient (ter Braak and Prentice, 1988) and then principal components analysis (PCA) was carried out. PCA was done using inter-sample distances without post-transformation of species scores. Because dominance values were used, the data were not transformed. CanoDraw for Windows version 4.14 was used to create a biplot with species fit range adjusted in such a manner that the 10 species with the highest fit into the ordination space were displayed (ter Braak and Šmilauer, 2002).

In order to test the significance of the individual environmental variables and the mowing treatment (defined as nominal variable) in 2015, we carried out a redundancy analysis (RDA) with Monte Carlo permutation tests (unrestricted, 1999 permutations) first for each variable separately and then using automatic forward selection of variables (reduced model) using CANOCO for Windows version 4.53 (ter Braak and Šmilauer, 2002).

Results

During the three years of study 2650 carabid individuals belonging to 43 species were collected. Total numbers of collected individuals declined constantly during the study, whereas total numbers of species increased from 2013 to 2014 but dropped from 2014 to 2015. A decline in numbers of species and individuals in 2015 is particularly evident for the control sites (*Appendix 2*).

The calculated plant indicator values exposed differences between the individual study sites (*Table 1*). High results for all indicator values were detected on study site B2, whereas study sites B5 and B6 exhibited comparatively low results for the majority of the indicator values. Thus, the values indicated a slight north-south gradient with respect to the site characteristics. Moreover, it is striking that the results for light values are particularly high on the control sites.

Table 1. *Plant indicator values recorded for the study sites in 2015 (L, light; T, temperature; M, moisture; Tr, trophy; A, acidity; GC, granulometric composition; H, humus)*

Study site / site type	L	T	M	Tr	A	GC	H
B1 / Treatment site	3.92	3.65	3.02	3.43	3.90	3.92	2.00
B2 / Control site	5.23	4.38	3.10	3.55	4.78	4.38	2.33
B3 / Control site	4.47	3.61	2.44	2.79	3.79	3.47	1.97
B4 / Treatment site	4.20	3.64	2.86	3.45	3.98	3.63	1.95
B5 / Treatment site	4.70	3.52	2.11	2.32	3.47	3.14	2.00
B6 / Control site	4.99	3.50	2.01	2.01	3.50	3.01	2.00

The cluster analysis separated the carabid coenoses into two basic clusters, strongly supported by a bootstrapping proportion of 100% (*Figure 2*). The first cluster contained all samples of study sites mown twice in 2015, two samples of study sites, which were mown once in 2014 (B4, B5) and the sample of the control site B6 from 2015. This cluster was divided into two clusters (bootstrapping proportion of 24%), resulting in a separation of study sites B1 and B4 from 2015 (two times mown) from the remaining

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_427440

sites. The second basic cluster contained all remaining samples from not mown sites (i.e. all remaining samples from control sites and the samples from B1, B4 and B5 from 2013) and also the sample from study site B1 from 2014, which was mown one time. Within this cluster the samples from study B6 of the years 2013 and 2014 were separated from the remaining samples (bootstrapping proportion of 15%).

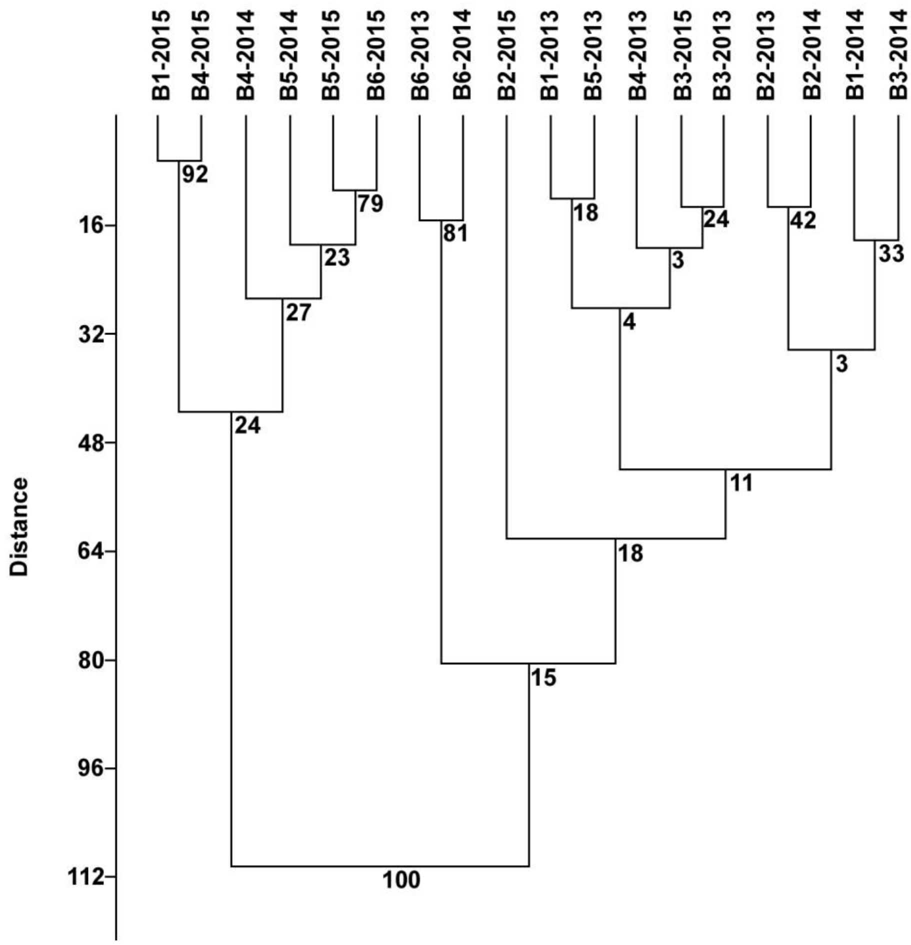

Figure 2. *Cluster analysis of the results based on Euclidian distance as distance measure and agglomeration according to Ward. Numbers indicate the percentage of replicates where each node is still supported (Hammer, 2012)*

The first and second ordination axis of the PCA (*Figure 3*) explained 39.4 % and 22.7 % of the variation in the dataset respectively. The study sites showed a distribution along the first ordination axis with respect to management intensity. Study sites two times mown in 2015 were located the most to the right side of the diagram. Two of the study sites being mown once in 2014 (B4, B5) were also somewhat shifted to the right side. However, the sample of study site B1 from 2014 (also mown one time) was located on the left side together with the majority of unmown sites, i.e. samples from treatment sites of the year 2013 and control sites. All three samples on study site B6 are located most on the upper site of the diagram along the second ordination axis. The sample of the year 2015 of this study site is also shifted quite far to the right side of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_427440

diagram. Among the species *Calathus fuscipes* was related to samples from study sites which were two times mown, whereas *Calathus erratus* took an intermediate position between samples from study sites two times mown and study site B6. *Amara aenea* was related to study site B6. Species related to samples from unmown study sites were *Harpalus luteicornis*, *Poecilus versicolor*, and *Pterostichus niger*.

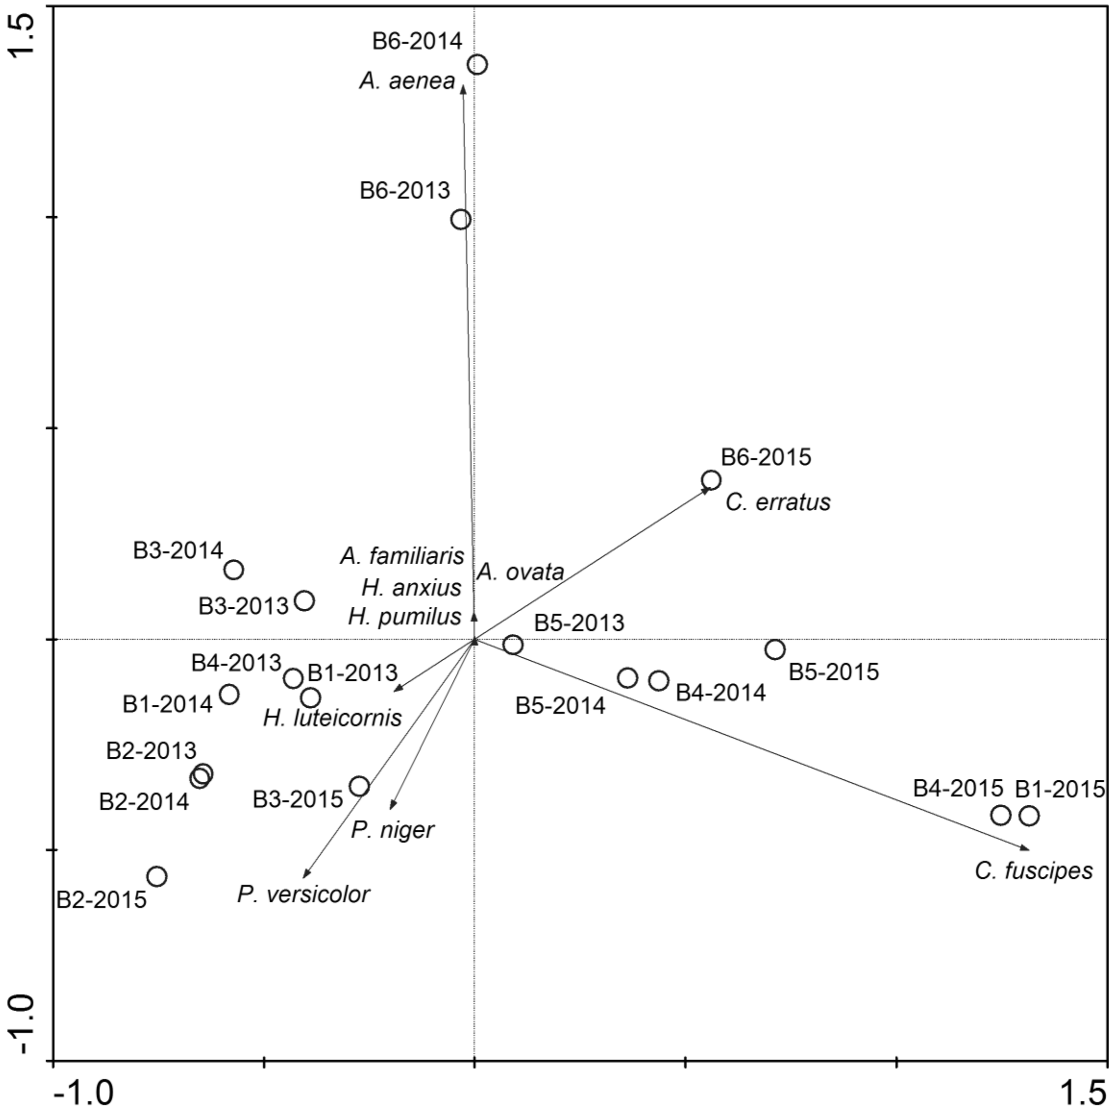

Figure 3. *Ordination plot based on principal components analysis (PCA) of the results for study sites (open circles) and species (arrows)*

Testing the environmental variables separately using Monte Carlo permutation tests revealed highest Lambda-1 values (above 40%) for humus content, temperature, light, and mowing (not mowing respectively), i.e. these variables accounted for most of the variance when considered singly (*Table 2*). However, none of them was statistically significant. When using forward selection Lambda-A values (additional variance the variable explained at the time it was included in the model) for temperature, light and the mowing measures are considerably reduced compared to the Lambda-1 values.

Discussion

Our results indicated that the management intensification from one-time mowing (in 2014) to mowing twice (in 2015) indeed resulted in an increased effect on the carabid coenoses. The cluster analysis resulted in a strong supported separation of almost all mown sites from the unmown sites and a weaker separation of two of the sites mown twice from the sites mown only once. However, the increased effect is particularly visible in the position of the carabid samples along the first ordination axis in the PCA. In Welsh peatland strong grazing by cattle and horses resulted in a strong influence on carabid assembages compared to an only little influence due to light sheep grazing (Holmes et al., 1993). Kaltsas et al. (2013), who investigated the response of carabid beetles to grazing in Cretan shrublands, described carabids as good indicators of grazing pressure at assemblage level, rather than species-specifically. Overgrazing resulted in lower species richness, and species richness and diversity were maximal under moderate to relatively high levels of grazing. Similarly, in a study by Mayr et al. (2007) carabid beetle diversity was the highest in grasslands with medium management intensity. In the study by Grandchamp et al. (2005) the number of cuts was positively related to the number of individuals. Since in our study a decline in numbers of species and individuals was visible particularly on the control sites, it seems that mowing at least counteracted trends of declining species and individual numbers.

Table 2. *Results of Monte Carlo permutation tests of the environmental variables tested separately and using automatic forward selection of variables (reduced model). During forward selection of variables "Temperature", "Light", "Unmown", and "Trophy" were not added to the model due to collinearity. Lambda-1 – variance explained by the environmental variables separately; Lambda-A – additional variance explained when included in the model using forward selection*

Variable	Tested separately			Forward selection		
	Lambda-1	F	*p*	Lambda-A	F	*p*
Humus	0.47	3.56	0.111	0.47	3.56	0.111
Temperature	0.46	3.42	0.109	-	-	-
Light	0.44	3.16	0.058	-	-	-
Mown	0.44	3.13	0.099	0.02	0.00	1.000
Unmown	0.44	3.13	0.104	-	-	-
pH	0.39	2.55	0.117	0.12	5.71	0.176
Gran. comp.	0.29	1.67	0.218	0.15	2.17	0.243
Moisture	0.22	1.12	0.372	0.24	2.41	0.108
Trophy	0.22	1.12	0.363	-	-	-

Among the carabid beetle species *Calathus fuscipes* showed the most distinct connection to the mowing treatment. *Calathus erratus* also benefitted from the mowing measures, but was also regularly frequent on study site B6. This result is in accordance with Schwerk and Szyszko (2009) and Schwerk (2014b), who detected highest abundances of these species on regularly mown fallow grounds. *Calathus fuscipes* seems to be particularly sensitive to management intensity, since it also showed higher numbers of individuals in agricultural fields subjected to conventional tillage with ploughing compared to fields with non-inversion tillage (Kosewska et al., 2014). The special position of study site B6 in the ordination diagram as well as the grouping of B6 from 2015 with the treatment sites in the cluster analysis points to special environmental

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_427440

characteristics specific for this study site. This aspect is supported by the differences in site characteristics revealed by the indicator values elaborated for 2015. The conclusion is possible that *Calathus erratus* reacts also on some characteristic not related to mowing. Accordingly, despite in average highest abundances on the treatment sites in 2014 (one time mown), Schwerk and Kitka (2016) could not demonstrate a statistically significant reaction of *Calathus erratus* on mowing. *Harpalus luteicornis*, *Pterostichus niger*, and *Poecilus versicolor* were closer related to not mown study sites. Former studies had already shown that *Poecilus versicolor* reacts much less on mowing measures than *Calathus fuscipes* and *Calathus erratus* (Schwerk and Szyszko, 2009; Schwerk, 2014b). *Pterostichus niger* is known as species preferring forest habitats, but was also detected regularly in different field margins (Asteraki et al., 1995). This species reacted significantly on a management intensity of one-time mowing on the study sites (Schwerk and Kitka, 2016).

A significant meaning has to be attributed also to differences in environmental characteristics between the sites, as for example the special position of study site B6 in the ordination diagram indicates. Several of the variables seem to be largely replaceable by each other, as indicated by the reduced Lambda-1 values when using forward selection. In our study particularly organic content (humus) accounted for a high amount of the variance in the assemblages. The significance of this parameter has been already described in literature. Gardner et al. (1997), studying the consequences of grazing pressure on carabids on heather moorlands in northeast Scotland, detected a strong influenced of soil organic content. In Welsh peatland biotopes the nutrient status and saturation of the substrate were most important with respect to carabid assemblages (Holmes et al., 1993). Sądej et al. (2012) showed a positive relation between soil organic matter and carabid species number in experimental agricultural fields in northern Poland.

According to Digweed et al. (1995) distances of 50 m should provide adequate statistical independence between traps. Yet, it cannot be excluded that the one-time mowing in 2014 on the treatment sites contributed to some degree to the more pronounced differences on these sites in 2015. However, since the effect of the mowing measures in 2014 was quite weak, we assess an influence on the results in 2015 as rather insignificant. It is reasonable to assume that the observed differences in 2015 were caused by the increased mowing intensity causing a more continuous effect on the carabids due to an earlier first mowing compared to 2014 and the additional later second mowing, which may have provoked some species to conduct linear direct walking behaviour in order to escape from unfavorable habitats (e.g. Baars, 1979; Riecken and Raths, 1996) and other species to enter the treatment sites.

Our study confirms that in the context of using mowing as a measure for nature conservation the mowing intensity has to be taken into account, since it appears that certain species can be facilitated by modifying mowing intensity. Additionally, the impact of environmental factors and their spatial variation has to be considered. In this regard attention should be paid to soil organic content. However, time of mowing is of importance too, for example delayed mowing may have a different effect on individual species or taxonomic groups (e.g. Humbert et al., 2012).

Acknowledgements. The authors like to thank Karsten Hannig for confirming the identification of some beetles and four anonymous referees for valuable comments on a former version of the manuscript. Abstract. Explosive boiling is a hyperactive boiling phenomenon, which is characterized by transient high heat flux. There are still few researches on the experimental comparative analysis on explosive boiling inducing by different cryogen liquid injection into water. In this paper, to advance our understanding of LNG (Liquefied Natural Gas), LN_2 (Liquefied Nitrogen) and LC_3H_8 (Liquefied Propane) injection into water process, a visualization experimental system is built. Visualized results show that LNG and LN_2 injection processes undergo a similar boiling, that is explosive boiling, which is characterized by bubbles cloud that strengthens heat transfer rate. LC_3H_8 injection into water triggers subcooled flow boiling. There is no significant breaking on the liquid cryogen column and without bubbles cloud. The maximum heat transferring flux can be over 1.9 MW/m^2 in the condition of LNG injection into unconfined water and under the pressure of 7 bars. In order to investigate the determinant factors for explosive boiling occurring, instability of Rayleigh-Taylor, Kelvin-Helmholtz, Weber number and Marangoni convection are analyzed and used to explain the differences of maximum pressure and its occurring time in different experimental conditions such as injection depth into water, injection pressure, water temperature and injecting fluid. As a result, it is reasonable to conclude that if the relative velocity between cryogen and surrounding fluid is high enough, the breaking of liquid column or droplets will be defined by the Kelvin-Helmholtz instability and Weber number. And in subcooling mixture or pure substance injection process, the periphery of the vapor film near the head of column is considerably stronger than other regions in the effect of Marangoni convection at the beginning of column floating upwards or the ending of column going downwards. All of these can be seen as the key factors to improve heat transfer capacity and trigger explosive boiling.
Keywords: c*ryogen; explosive boiling; experimental study; instability; Malangoni effect; bubble behaviors*

Introduction

Explosive boiling is a hyperactive boiling phenomenon, which is characterized by transient high heat flux. It is involved in many industry fields such as nuclear power, laser printing, microelectronic, fuel-coolant interactions (FCIs) and liquefied natural gas transportation. In liquefied natural gas transportation process, when discharging liquefied natural gas into water, direct contact heat exchange between liquefied natural gas and water with different temperatures about 180K would occur. Under some certain conditions, liquefied natural gas vaporization rate will rapidly increase and the heat flux is higher than the critical heat flux (CHF). However, such rapid heat and mass transfer process would not always take place. So far, the determinants of this phenomenon have not been clearly confirmed.

Some experimental studies on discharging cryogen on water have been reported since 1971. Nakanishi and Reid (1971) conducted a series experiments on four different phases liquefied natural gas discharging on water. Experiments showed superheating occurred until homogeneous nucleation arises or until heterogeneous nucleation takes place on

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_441456

small active impurities. If the substrate was chemically like the cryogen spilled and the interfacial liquid had a low freezing point, then the explosive boiling may occur. Garland and Atinson (1971) found a similar conclusion as Nakanishi and Reid. They thought the composition of liquefied natural gas was important in noticing explosive boiling and that the presence of a hydrocarbon film on water increased the probability of explosive boiling occurrences. Enger (1972) reported a series tests of Shell, which conducted experiments on different composition liquefied natural gas discharging on hot water. The experiments showed that in environmental temperature, when methane content in liquefied natural gas was not less than 40% along with a few mole present n-butane, the explosive boiling may occur. But from Koopman et al. (1982) and Goldwire et al. (1983) reports, the explosive boiling may occur when methane content in liquefied natural gas as high as 90%. Dahlsveen et al. (2001) conducted a process for liquefied natural gas injection. With changing composition of liquefied natural gas, experiments showed a much thicker vapor blanket and larger jet spreading angle (Dahlsveen et al., 2001; Khan and Noor, 2017)). Wen et al. (2006) conducted a series experiment of liquid nitrogen injection into water. With synchronized pressure and temperature measurement, heat transfer and pressurization rates had been establishing for application to a cryogenic engine. Pressurization rates of up to 5 bar/s were recorded, and heat transfer coefficients approximated for the latent heat transfer with assumed surface area were comparable to values found in other works on boiling heat transfer over very rough surfaces (Wen et al., 2006). Clarke et al. (2010) conducted a visualization study of liquid nitrogen injection into water with synchronized pressure and temperature measurement, to obtain insight into this phenomenon. It revealed a four-stage evolution of liquid nitrogen jet structure upon injection into water, with a thick vapor blanket forming around a liquid nitrogen core and break-up brought on predominantly through impact with the vessel wall. Maximum pressurization rate in excess of 350 bar/s were recorded and found to vary proportionally with injection pressure (Clarke et al., 2010; Anees et al., 2017).

Although previous studies have provided the experiences studies for explosive boiling, there are still few researches on the experimental comparative analysis on explosive boiling inducing by different cryogen liquid injection into water. In this paper, to advance our understanding of LNG (Liquefied Natural Gas), LN_2 (Liquefied Nitrogen) and LC_3H_8 (Liquefied Propane) injection into water process, a visualization experimental system is built. Pressure profiles are obtained and synchronized with images for obtaining the heat transferring flux. Base on the instability theories, the effect of the material properties of cryogen liquid, water temperature and injection depth into water are investigated, which is in attempt to find the key factors caused explosive boiling in the process. The bubble behaviors are also analyzed and found some characteristics to explain the extremely rapid heat transferring rate of explosive boiling (Deng et al., 2017).

Experimental apparatus

The experimental rig (*Fig. 1(a)-(b)*) consists of a condensation system, a mixer tank, an injector, a visualized pressure tank (*Fig. 1(c)*), and a data acquisition system (Zhang et al., 2015, 2016).

DOI: http://dx.doi.org/10.15666/aeer/1504_441456

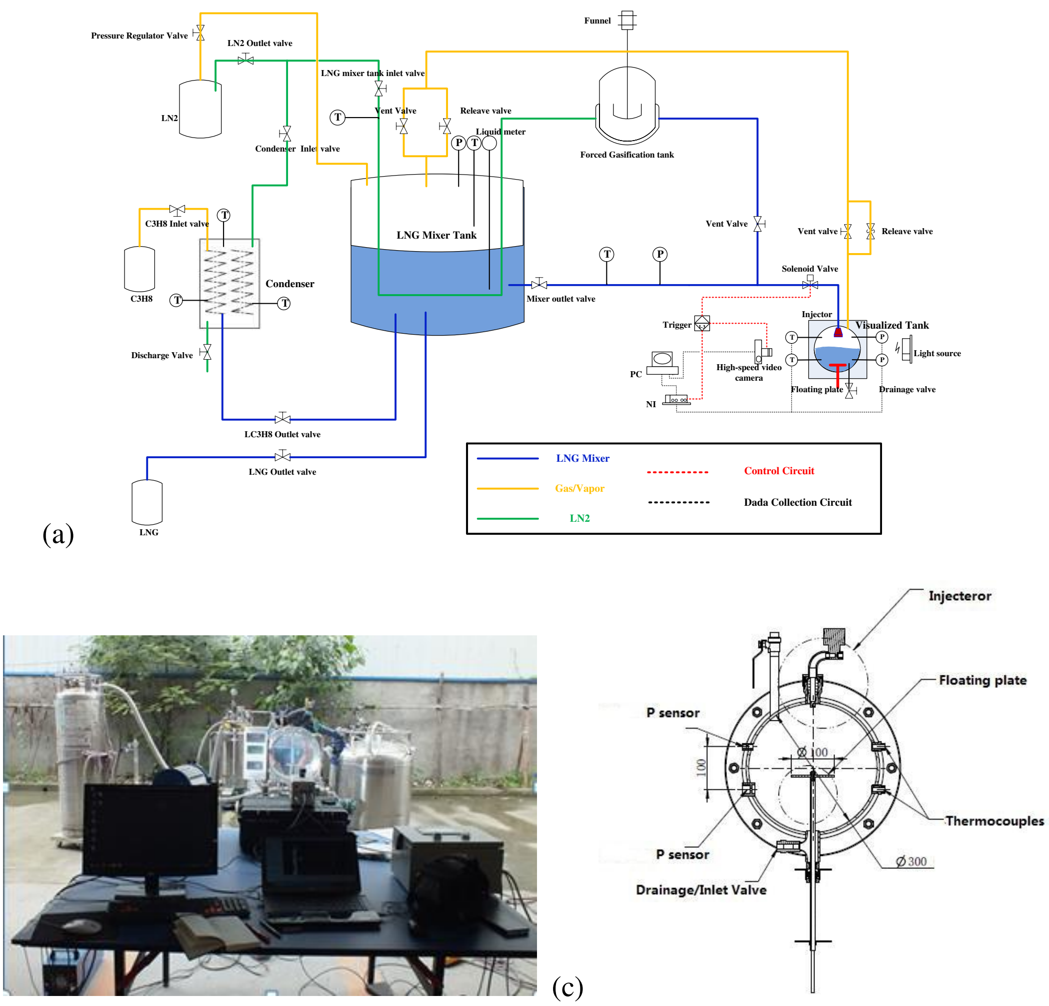

Figure 1. *LNG injection setup and apparatus: (a) schematic of experimental rig; (b) picture of apparatus; (c) positions of all sensors in tank.*

LN_2 and LNG are separately delivered through insulated pipe and outlet valve from a controllable pressure Dewar. Out of necessity, LNG injection must occur below its bubbling point, which can be conducted in the LNG mixer tank by LN_2. After the LN_2 delivered through LNG mixer tank, the temperature of LNG in mixer tank can be maintained at 100K(±5K) , that is ~10K below the LNG bubbling point. The pressure of LNG mixer tank equals to injection pressure, which is controlled by manually adjusting the pressure regular valve on LN_2 Dewar. Because the propane gas is storage in the gaseous phase, before injecting, it must be condensed into liquefied propane, which can be conducted in a similar way like LNG cooling process. In the LN_2 injection process, the system must be improved and the LN_2 Dewar outlet valve to be directly combined with the mixer outlet valve. Where after, the cryogen liquid is delivered to an ASCO intrinsically safe type cryogenic solenoid valve, which controls the opening of the injector. The injector is made of a 25mm length of steel pipe with an inside diameter of 5 mm. To prevent heat leakage, the all cryogenic liquid pipes are made of double insulated vacuum steel pipe, and before experiments, the pipes are precooled by LN_2 and the time is not less than 10 min.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_441456

The visualized pressure tank is a stainless cylinder of diameter 300 mm and depth 150mm with Perspex windows clamped onto each end. The safety valve and vent valve are fitted on the tank to prevent pressurization above 40 bars and can vent the vapor respectively. Two T-type sheathed thermocouples of 10mm in diameter, 140mm in length, with accuracy of 0.5% FS and two high frequency dynamic pressure sensors of 4mm in diameter, 10mm in length, with accuracy of 0.5% FS with minimum response time of 4μs are used to measure the temperatures and pressure within the tank. The positions of all sensors are illustrated in *Fig. 1(c)*.

The boiling process of LNG into water is recorded by a high-speed camera (Svsi Gigaview) with the frame rate of 532~17045 frames per second. In this series experiments, the frame rate is 1000 frames per second, and frame size is 640×480 pixels. A 575 W quartz metal halide light source is added to improve the qualities of the frames. The camera and the image acquisition software are triggered by the leading edge of a 5 V pulse generated within PLC (Programmable Logic Controller) hardware, programmed and controlled by the operator. The image acquisition software comes with the camera and can set the image acquisition rate, image pixel and exposure time. The same pulse triggers the National Instruments Data-Acquisition hardware and LabVIEW to acquire and store both pressure and temperature data, at a rate of 10,000 samples per second. Another 5V pulse is generated after 100 ms within the PLC, which is used to trigger the ASCO solenoid valve opening. The opening time is dependent on the trigger pulse width, which can be set manually within the PLC.

Experimental results

By controlling the LN_2 Dewar outlet pressure and outflow, the different injection pressures and thermodynamic states of cryogen can be adjusted. A number of cryogen injection experiments are conducted, of LNG, LN_2 and LC_3H_8, into water of different temperature and depth. The parameters for experiments are shown in *Table 1*. The LNG component concentration is provided by the LNG supplying company. By adjusting the location of floating plate under water, the cryogen injection into water depth can be controlled. Injecting during time can be controlled by the power time of ASCO solenoid valve.

Discussion

Heat transferring flux

As *Table 1* shown, the maximum pressure occurs in run 1, which injection pressure is one of the highest, water temperature is one of the lowest and floating plate location under water is bottommost. The pressure of the visualized pressure tank is shown in *Fig. 2(a)* over a 10 s timescale and additionally in *Fig. 2(b)* for the maximum pressure occurring time over 100 ms timescale (from 5400 ms to 5499 ms after injection). In *Fig. 2(a)*, the pressure data is recorded by the high frequency dynamic pressure sensors of 10 mm in length, before trigger activating 100 ms. In *Fig. 2(b)*, the pressurization is extremely rapid at ~300 bar/s. Using TNT equivalent model can simplify the process so that the heat transfer coefficient can be obtained. The following expressions relating the maximum pressure and the heat transfer flux (Zhang et al., 2015).

$$W_{TNT} = k\frac{aW_{LNG}Q_{LNG}}{Q_{TNT}} \quad \text{(Eq.1)}$$

$$\Delta P = P_0\left(3.9Z^{-1.82} + 0.5Z^{-1}\right) \quad \text{(Eq.2)}$$

$$Z = R\cdot W_{TNT}^{-1/3} \quad \text{(Eq.3)}$$

$$H_{RPT} = L_V\cdot W_{LNG}/\left(S\cdot t_d\right) \quad \text{(Eq.4)}$$

Where W_{TNT} is TNT equivalent, kg; W_{LNG} is LNG mass which is fragmented, kg; k is surface burst coefficient; a is equivalent coefficient; Q_{LNG} is bursting heat, J; Q_{TNT} is TNT bursting heat, J; ΔP is maximum pressure value, Pa; R is distance from pressure sensor, m; H_{RPT} is heat transfer flux, W/m^2; L_V is latent heat of LNG, J/kg; t_d is the duration time of pressure increasing, s. It is ~10 ms obtained from the *Fig. 2*. Combining Eqs. (1)-(4), the maximum heat transferring flux can be over 1.9 MW/m^2. It is ~7.8 times bigger than the theoretical limit of heat transferring flux of the pure liquefied methane nucleate boiling (0.244 MW/m^2) (Nail, 1999).

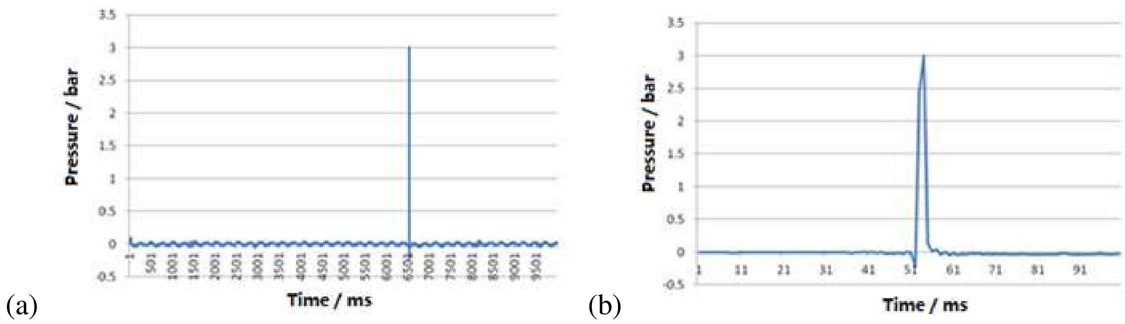

Figure 2. *Pressure curve correspondent to run 1 using the P sensor under water: (a) the time is from 0 ms to 10000 ms after injection; (b) the time is from 5400 ms to 5499 ms after injection).*

Theoretical analysis about instability

As cryogen injecting into water, the interface between cryogen and water would be with wave. If disturbances of all wavelengths are present, there will be some disturbances at small wave number and long wavelength that will amplify and cause the interface to be unstable. There are four main instability theories can be used to explain the explosive boiling mechanism of cryogen injection into water.

Rayleigh-Taylor instability (Van, 1992; Byoung et al., 2015; Awasthi, 2013)

It is the instability of an interface between two fluids of different densities which occurs when the lighter fluid is pushing the heavier fluid. If the energy of interface tension is higher than the sum of kinetic energy of fluctuations and potential energy, the interface will be with a stable vapor film. Otherwise, the interface will be unstable and the vapor film will be broken because of the Rayleigh-Taylor instability. It takes more effect on the leading end than the side of liquid column. The most dangerous wavelength is given by:

$$\lambda_D = 2\pi\sqrt{\frac{3\sigma}{|\rho_{cl} - \rho_w|g}} \quad \text{(Eq.5)}$$

Where λ_D is the most dangerous wavelength, m; ρ_{cl} is liquid cryogens density, kg/m^3; ρ_w is circumstance fluid density, kg/m^3; σ is the interfacial tension, N/m; g is the gravitational acceleration, m/s^2.

Kelvin-Helmholtz instability (Van, 1992; Awasthi et al., 2012; Hyun and Junseok 2015)

When there is a sufficiently large velocity difference across a small amplitude perturbed interface between two fluids, the interface is unstable. This interfacial instability is known as the Kelvin-Helmholtz instability. The instability occurs when the destabilizing effect of shear across the interface overcomes the stabilizing effect of gravity and/or surface tension. It takes obvious effect on the side of liquid column. If a specific disturbance wavelength is imposed on the system, the interface will be unstable for:

$$\left|\overline{u_{cl}} - \overline{u_w}\right| > u_c \quad \text{(Eq.6)}$$

$$u_c = \sqrt{\frac{2\pi\sigma(\rho_{cl} + \rho_w)}{\lambda_D \rho_{cl}\rho_w} + \frac{g\lambda_D(\rho_{cl} - \rho_w)(\rho_{cl} + \rho_w)}{2\pi\rho_{cl}\rho_w}} \quad \text{(Eq.7)}$$

If g is set to zero, we get the dispersion relation for a vertical interface, which implies that:

$$u_c = \sqrt{\frac{2\pi\sigma(\rho_{cl} + \rho_w)}{\lambda_D \rho_{cl}\rho_w}} \quad \text{(Eq.8)}$$

The most dangerous wavelength is given by:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_441456

$$\lambda_D = \frac{2\pi\sigma(\rho_{cl} + \rho_w)}{u_c^2 \rho_{cl} \rho_w} \quad \text{(Eq.9)}$$

Where u_c is critical velocity, m/s; u_{cl} is liquid cryogens velocity, m/s; u_w is circumstance fluid velocity, m/s.

Weber number (Van, 1992)

As cryogen injecting into water, the velocity difference between the two fluids will produce tangential stress on the interface. If the tangential stress is bigger than the surface tension, the cryogen column will be broken into liquid droplets. The minimum diameter of stable liquid droplets is dependent on the magnitude of shear stress, which will be increased with the velocity difference increasing. The minimum characteristic length of stable liquid column or droplets is given by:

$$L = \frac{We_c \sigma}{\rho_w \left(\overline{u_{cl}} - \overline{u_w}\right)^2} \quad \text{(Eq.10)}$$

$$We_c = \frac{8}{f} \quad \text{(Eq.11)}$$

Where L is minimum characteristic length of stable liquid column or droplets, m; We_c is critical Weber number; f is friction coefficient, f=0.44 when $500<Re<10^5$.

Marangoni effect (Tang, Zhu, and Sun, 2013)

Marangoni effect is caused by the heterogeneity of the surface tension near interface of two fluids with different temperature. In subcooled flow boiling, the surface tension gradient along two fluids contact interface is raised from the temperature difference in the vapor film around the liquid cryogen column, which leads to the tangential stresses of τ_{cl} and τ_{cv} on liquid cryogen side and vapor cryogen side at the interface respectively. Due to reaction of the stresses of τ_{cl} and τ_{cv}, the liquid and vapor phase of cryogen were accelerated and the Marangoni effect formed near the interface. *Fig. 3* shows a schematic diagram to describe the Marangoni effect near a smooth and stable vapor film caused by temperature gradient and the force balance in tangential direction on the cryogen surface. Under steady state condition, the balance of forces at the interface is:

$$\tau_{cl} + \tau_{cv} = \frac{d\sigma}{dT} \Delta T / \delta \quad \text{(Eq.12)}$$

Moreover, the shear stress on vapor side at the interface τ_{cv} can be neglected since the most gases viscosity is much smaller. Therefore, the simplification of (Eq.12) is:

$$\tau_{cl} = \frac{d\sigma}{dT} \Delta T / \delta \quad \text{(Eq.13)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_441456

Strength of Marangoni effect can be characterized by the Marangoni number

$$Ma = \left| \tau_{cl} \frac{\delta^2}{\alpha_{cl} \mu_{cl}} \right| \quad \text{(Eq.14)}$$

Where τ_{cl} is shear stress on liquid side, N/m^2; τ_{cv} is shear stress on vapor side, N/m^2; δ is the characteristic length of interface, m; α_{cl} is thermal diffusivity of cryogen liquid, m^2/s; μ_{cl} is the dynamic viscosity of cryogen liquid, kg/s•m.

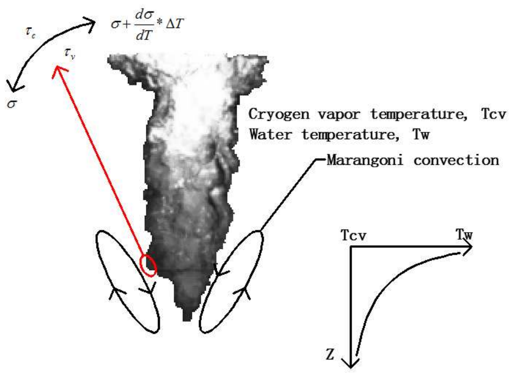

Figure 3. *Schematic diagram of Marangoni convection near the vapor film (The original image is 3d in Fig. 5)*

Effect of injection depth into water

Comparing run 1 and run 2, the maximum pressure of run 2 decreases ~46.5%, and the time of maximum pressure occurs ~270ms ahead. Besides the location of floating plate, the other parameters of experiments are similar. As a result of that, the mainly reason for the differences between the two runs is the depth of injection into water. According to the Kelvin-Helmholtz instability and critical Weber number theory, as (Eq.6) is satisfied, the interface between cryogen and water will become unstable and the liquid column of cryogen will be broken into small droplets, which diameter is equal to the λ_D or L is separately calculated by (Eq.9) and (Eq.10). The effective heat transferring area is remarkably increasing. But if the liquid column of cryogen impinges the floating plate, $\left|\overline{u_{cl}} - \overline{u_w}\right|$ will be reduced to zero, liquid column of cryogen stop breaking into droplets in the effect of instability. But the collision process will become complicated. The droplets of cryogen may be undergone two contradicting processes that are coalescence and breakup. The maximum pressure of run 2 is lower than run 1, it implies that the coalescence effect in the collision process has an obvious effect, that can decrease the heat transferring capacity and boiling rate. From another point of view, because the injection depth into water is unconfined, the breakup during time of liquid droplets or column in run 1 is longer than run 2 which induces the maximum pressure occurring time being aback.

As a result, as cryogen releasing or injecting into water, the maximum pressure or boiling rate will be reduced by confining the water depth, which can be used to limit explosive boiling occurring.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_441456

Effect of injection pressure

Comparing run 1 and run 3, the $\overline{u_{cl}}$ in run 3 is smaller than run 1, as a result, the maximum pressure of run 3 is ~45.5% smaller than run 1. It implies the heat transfer capacity and boiling rate of run 3 are both smaller than run 1. There are two main reasons for the difference of the maximum pressure. Firstly, in the effect of Kelvin-Helmholtz instability, as (Eq.6) is satisfied, the liquid column of cryogen will breakup into droplets, and the mean diameter of droplets is equal to the most dangerous wavelength λ_D, which will be reduced with $\left|\overline{u_{cl}} - \overline{u_w}\right|$ increasing. Secondly, basing on the Weber number theory, as $\left|\overline{u_{cl}} - \overline{u_w}\right|$ increasing, the tangential stress on the interface will increase, which will decrease the minimum characteristic length L that means the liquid droplets will break into much smaller droplets. The heat transferring area will dramatically increase, which implies both boiling rate and heat transferring capacity will substantial increase.

Furthermore, the occurring time of maximum pressure is ~1000ms earlier than run 1. It means the breakup duration time of liquid column and droplets of cryogen in run 3 is shorter than run 1. In an another word, the time of liquid column and droplets stopping breaking into smaller diameter droplets in run 3 is earlier than run 1.

In conclusion, the injection pressure is related to the boiling rate. As the injection pressure increasing, the maximum pressure will increase and its occurring time will be advanced, which will increase the probability of explosive boiling.

Effect of water temperature

Comparing run 2 and run 4, the water temperature of run 4 is higher than run 2, as a result of that the maximum pressure of run 4 is ~37.8% smaller than run 2. *Fig. 4a* shows the circumstance fluid is vapor film, whose temperature is equal to the water temperature of run 2. There is a hypothesis the water temperature is low enough that there is no evaporation occurring, so the circumstance fluid is water as the *Fig. 4b* showing. Both the most dangerous wavelengths in Rayleigh-Taylor instability in *Fig. 4a-b* are approximately equal. But the most dangerous wavelengths in Kelvin-Helmholtz instability and the minimum characteristic lengths in Weber Number theory in *Fig. 4a-b* varies greatly. It implies, as the concentration of vapor in the interface between cryogen and water decreasing, the most dangerous wavelengths in Kelvin-Helmholtz instability and the minimum characteristic lengths in Weber Number theory dramatically decreasing, which intensifies the cryogen column and droplets breaking up into much smaller droplets and promotes higher heat transferring rate and boiling intensity.

Furthermore, the maximum pressure occurring time of run 4 is a little bit later than run 2. That is because, as the water temperature increasing, the initial film boiling rate and vapor film thickness in run 4 are separately higher than run 2, which will decrease relative velocity and the instability effects of the interface, as a result of that it needs much more time to trigger cryogenic column breaking into droplets and dramatically decreasing heat transferring capacity.

(a) Circumstance fluid is vapor of cryogen *(b) Circumstance fluid is water*

Figure 4. *Most dangerous wavelength in Rayleigh-Taylor instability and Kelvin-Helmholtz instability, and minimum characteristic length in Weber Number Theory*

As a result, if the water temperature is increasing, the instability of Kelvin-Helmholtz and Weber number will be reduced. The diameter of droplets breaking from column will be increased. The effective area of heat transferring will be considerably decreased, which will reduce the heat transferring capacity and have less opportunity to trigger explosive boiling.

Base on the thermodynamics theory, if the temperature of water is higher than Leidenfrost temperature of cryogen (Van, 1992), there will be a film boiling. The Leidenfrost temperature for methane, ethane, propane and nitrogen are 161K, 249K, 312K and 126K, respectively. And only if the water temperature is equal or slightly greater than the superheat limit temperature of cryogen ($T_{superheat} < T_{water} < 1.1T_{superheat}$), the explosive boiling will be triggered (Luketa-hanlin, 2006; Ashraf et al., 2017). The superheat limit temperature for methane, ethane, propane and nitrogen are 168K, 269K, 326K and 110K, respectively. The superheat limit temperature of hydrocarbon mixtures is approximately the mole fraction average of the superheat limit temperatures of the components (Porteous and Blander, 1975). But the water temperature is not the only factor for triggering explosive boiling. Because, in run 1, run 2 and run 3, it has the same condition of water, the maximum pressures have great differences. There should be some other factors for triggering explosive boiling, such as injection pressure, injection depth into water and working substances (Zhang et al., 2016).

Effect of injecting cryogen

From *Table 1*, the run 1, 5 and 6 are separately used LNG, LC_3H_8 and LN_2. It shows that the maximum pressure of run 1 is ~18.9% bigger than run 6, and ~13 times of run 5. Furthermore, the maximum pressure occurring time of run 6 is earlier than run 1, and much earlier than run 5. There are three main reasons.

(1) LNG is mixture. In the process of LNG injecting, the LNG column will be heated by surrounding water and some of it will boil into vapor phase. As a result of that, liquid LNG components will change and bubble point changes correspondingly. On the effect of Marangoni effect, the surface tension gradient along two fluids contact interface is raised from the bubble point difference in the vapor film around the liquid cryogen column, which leads to the tangential stresses. If the tangential

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_441456

stress is bigger than the surface tension, the cryogen column will be broken into liquid droplets or big droplets further break into small ones. But LC_3H_8 and LN_2 are both pure substances whose boiling temperatures only relate to the pressure. So the surface tension gradient along two fluids contact interface is raised from the initial degree of subcooling. In run 6, the LN_2 is nearly saturation liquid, so there should be less Marangoni effect in this process. In run 5, the LC_3H_8 has ~120 degrees of subcooling, so there should be an obvious Marangoni effect. That can be seen from the *Fig. 5*. Comparing 1a~1f and 2a~2f, the pattern of LNG bubbles have a less value of L_c/D_c than LN_2 bubbles (L_c is the length of the bubbles pattern; D_c is the diameter of the bubbles pattern). It means LNG column suffers much more tangential stress than the LN_2, which makes more bubbles break up from side than the leading end. And from 3a~3f, the LC_3H_8 bubbles generate more from side than the leading end of liquid column. It means the Kelvin-Helmholtz instability and Marangoni convection occupies leading position on the process of column breaking into droplets.

(2) The degrees of subcooling of LC_3H_8 is much more than LNG and LN_2, as a result of that, it needs more time and heat to be saturated, and in turn, the maximum pressure occurring time of run 5 (LC_3H_8) is obviously later than the other runs of 1 (LNG) and 6 (LN_2). Furthermore, the maximum pressure occurring time of run 1 is a little later than run 6. On one side, the density of LNG is less than LN_2, which causes the relative velocity of LNG is slower than LN_2. On the effect of instabilities of Kelvin-Helmholtz and critical Weber number, the intensity of breaking of LNG is not as strong as LN_2. So the maximum pressure occurring time of LNG is not as early as LN_2. On the other side, the LNG is subcooling cryogen and the LN_2 is saturate substance. In the process of LNG injection, it needs some time to heat it to be saturated, though the time will be substantially short as the difference of temperatures of LNG and water being huge.

(3) From the above analysis, the Marangoni convection has an obvious effect on strengthen heat transferring rate. Base on the instabilities of Rayleigh-Taylor, Kelvin-Helmholtz and critical Weber number theory, the maximum pressure detected in LN_2 test (run 6) should be higher than LNG test (run 1). But the real results are just the opposite. The mainly reason is the effect of Marangoni effect. As the relative velocity becoming slower and slower, the Marangoni convection takes the leading position and the instability effects of Rayleigh-Taylor, Kelvin-Helmholtz and critical Weber number theory becomes weaker and weaker. Because of the effect of Marangoni convection prolonging the breaking time of droplets, the maximum pressure and the occurring time of maximum pressure in run 1 is separately higher and later than run 6.

Bubble behaviors analysis

From these images of 1a~1f and 2a~2f in *Fig. 5*, the structure and pattern of bubbles have a similar developing process in run 1 and run 6. It can be characterized in three main stages (Zhang et al., 2015; Clarke et al., 2010; Dahlsveen et al., 2001).

(1) Stable film boiling stage: from the images of 1a~1b and 2a~2b, it can be seen that liquid cryogen flashes as it impinges into water and forms a vapor void. Because the injection process is likely to continue for some time, the following liquid cryogen is injected into the void created by the former boiling cryogen. A velocity difference forms on the relatively stable vapor film between liquid cryogen and water, but the water outside vapor film is nearly static. So the liquid cryogen inside vapor film is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_441456

moving downwards under a high speed. There is no significant breaking on the liquid cryogen column, although formation of waves on the vapor film due to the instability of dynamics is observed.

(2) Bubbles cloud generation stage: as the liquid cryogen continuously moving downwards, on the effect of instabilities of Rayleigh-Taylor, Kelvin-Helmholtz and critical Weber number, the shearing stress is bigger than the surface tension, and then the ligaments and fragmentations take place. In the images of 1c~1d and 2c~2d, it shows the vapor film becomes thinner and lighter. There is a cloud of bubbles form on the head and the side of the column (Wen et al., 2006). The cloud of bubbles is extremely unstable; some of them will be coalescence and others will be continuously breaking up into smaller ones. The heat transferring rate will be dramatically increasing as a result of the bubbles growing up and breaking which enhances the heat convection between cryogen and water. On the effect of Marangoni convection, the images of 1c~1d show the bubbles cloud has a more unstable vapor film nearby the head of column than 2c~2d.

(3) Buoyancy taking over stage: in the images of 1e~1f and 2e~2f, it shows that, in the last stage of injections, the buoyancy force will take over. The bubbles cloud gradually disappears and forms much bigger bubbles that are so stable that they cannot be broken up again in the upwards moving process. Comparing the images of 1e~1f and 2e~2f, the bubbles cloud maintain longer in run1, because of the effect of Marangoni convection.

The images of 3a~3f in *Fig. 5* shows a different structure and pattern of bubbles. It can be characterized in two main stages.

(1) Stable flow boiling stage: in all images of run 5, the LC_3H_8 column has a relatively obvious shape and the boiling is not as violent as run 1 and 5. Most of it has no significant breaking except the periphery of the vapor film near the head of column in the image of 3d. There are three main reasons.

Firstly, the water temperature is ~303K, which is less than the superheat limit temperature of LC_3H_8. As a result of that, the explosive boiling would have less opportunity to take place and it undergoes a relatively stable boiling, that is subcooled flow boiling.

Secondly, because of the ~120 degrees of subcooling, after LC_3H_8 injecting into water, it needs much more time to be heated to the saturate temperature by surrounding water. As a result of that, it can maintain an obvious liquid column shape in a relative long time. Because the water temperature is less than the Leidenfrost temperature of LC_3H_8, the vapor film of run 6 is not as stable as run 1 and 5, and the surrounding fluid will be water. The relative velocity, which is related to density difference between LC_3H_8 and surrounding fluid, is less than run 1 and 6. Basing on the instability of Kelvin-Helmholtz and Weber number, as relative velocity decreasing, the most dangerous wavelength and minimum characteristic length will be considerably increasing. It implies the LC_3H_8 will become more and more stable and suffer less from the instability of Kelvin-Helmholtz and Weber number.

Finally, LC_3H_8 is ~120 degrees of subcooling. As a result, in subcooled flow boiling, the surface tension gradient along two fluids contact interface is raised from the temperature difference in the vapor film around the liquid cryogen column, which leads to the tangential stresses on liquid cryogen side and vapor cryogen side at the interface respectively. When the stresses accrete to higher than the surface tension, the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_441456

Marangoni effect will take place and some of the liquid column will breakup into small droplets, which can be seen in the image of 3d. From that image, we can also know that the periphery of the vapor film near the head of column is considerably stronger than other regions in the effect of Marangoni.

(2) Buoyancy taking over stage: in the images of 3e~3f, it shows that, in the last stage of injections, the buoyancy force will take over. The evaporating bubbles move upwards in a higher speed than the LC_3H_8 column and begin to separate from it. After that, the LC_3H_8 column still staying in the water is not broken again and some of it maintains liquid phase until floating on the water and forms liquid pool.

DOI: http://dx.doi.org/10.15666/aeer/1504_441456

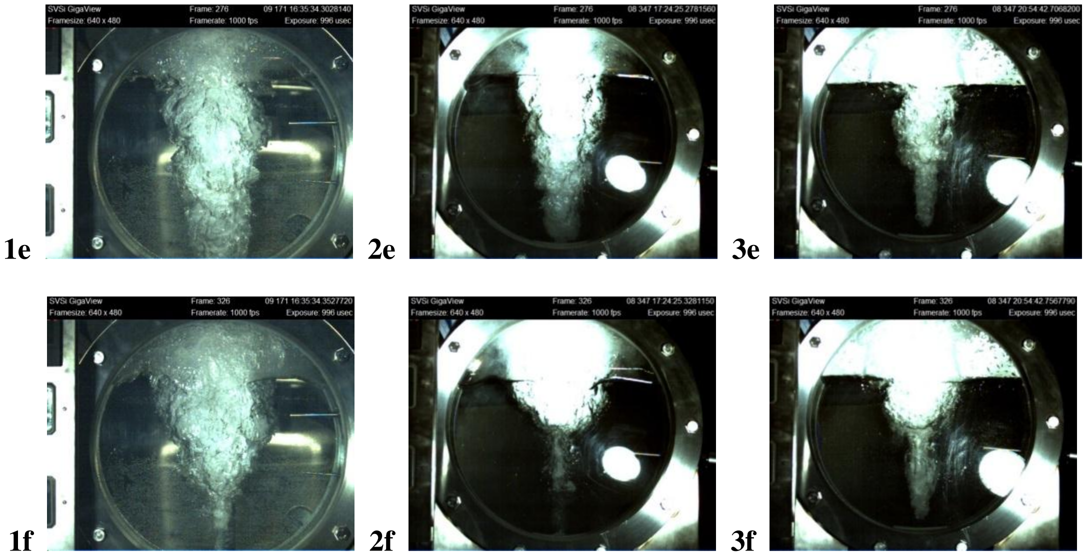

Figure 5. *Bubble behaviors of cryogen injection into water (1a~1f are images of run 1, 2a~2f are images of run 6, 3a~3f are images of run 5. The interval time between the adjacent two images is 50 ms).*

Conclusions

The process of cryogen injection into water was studied experimentally and theoretically. Main conclusions can be drawn as following:

(1) There are four main instability theories used in analyzing cryogen injection into water process. If the relative velocity between cryogen and surrounding fluid is high enough, the breaking of liquid column or droplets will be defined by the Kelvin-Helmholtz instability and Weber number theory. Furthermore, strong Marangoni effect on vapor film breaking can be obviously observed at the beginning of column floating upwards or the ending of column going downwards. And the periphery of the vapor film near the head of column is considerably stronger than other regions in the effect of Marangoni convection.

(2) When LNG is injected into unconfined water in the pressure of 7bar, the explosive boiling remarkably occurs with high heat transfer performance. The maximum heat transferring flux can be over 1.9 MW/m^2. It is ~7.8 times bigger than the theoretical limit of heat transferring flux of the pure liquefied methane nucleate boiling (0.244MW/m^2).

(3) Besides water temperature, both injection pressure and depth of injection into water influence explosive boiling occurring and its heat transfer performance.

(4) According to the images of bubble behaviors, LNG and LN_2 injection processes undergo a similar boiling, that is explosive boiling, which is characterized by bubbles cloud that strengthens heat transferring rate. LC_3H_8 injection into water triggers subcooled flow boiling. There is no significant breaking on the liquid cryogen column and without bubbles cloud.

Abstract. The purpose of this paper is to propose a new research method to solve the problem of reducing the "source" and "sink" measures in the implementation of low carbon governance, promote the development trend of "reducing sources and increasing exchange rate", and to achieve an ideal state of negative carbon emissions. This paper is based on the research of low carbon sustainable and carbon - water coupling in ecological environment management, and based on the social and economic demands, a carbon cycle system based on carbon emission and carbon capture characteristics and a water resource circulation system characterized by ecological water demand and water pollution are constructed, and the two structures are coupled to each other. The regional carbon and water symbiotic coupling system with the coupling relationship of carbon water circulation system is proposed. This paper analyzes the internal components of carbon-water coupling system and its influencing factors from the perspective of "low carbon", reveals its internal mechanism and establishes a multi-objective game decision model for water resources regulation in regional carbon-water symbiosis system. At the same time, this paper has optimized the water resources regulation and control in the pilot area. In this paper, by adjusting and perfecting the configuration of carbon and water coupling system in the regional water resources system, the "source - sink" integration in the carbon cycle is realized, which is the ideal mode of "reducing source and increasing exchange rate".
Keywords: *comprehensive evaluation model; sustainable development index; carbon-water coupling; low carbon mode; water resource rational allocation*

Introduction

Climate change has a profound impact on the supply and demand of water resources, leading to lower carbon capture capacity of ecosystems; In addition, socio-economic development leads to an increase in carbon emissions, carbon emissions increased and reduced carbon capture resulting in an integrated carbon-water system imbalance (Hannah et al., 2004; Hashem et al., 2016; Mi et al., 2014; Jiang et al., 2016; Petts et al., 2006). Although carbon emission reduction technology has been gradually promoted and applied (IPCC, 2007; Ge et al., 2015; Liu and Liu, 2010; Schramm, 2015), the ecological planning based on returning farmland to forest has also been implemented. But at present, the net carbon emissions are still in a high stage of increase, only from the past "increase sources, reduce sinks" model to "source reduction" model change, has not yet completely transition to the "source reduction and increase sinks" model. The reason is that the mitigation measures of climate change mitigation at the present stage will be separated from "reducing sources" and "increasing sinks" (China Water Resources Bulletin (1998-2007)), and lacking the comprehensive regulation and management system and methods of ecological and environmental systems of "reducing sources" and "increasing sinks". Water is a crucial environmental factor in the carbon capture and storage system of the ecological environment system. The "natural-artificial" dual water cycle changes

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_457465

the regional water conditions, affecting the formation, development and succession of ecosystems, and directly affects the carbon emissions and carbon capture processes of ecosystems, affecting the net carbon emissions of regional carbon (Feng et al., 2016; Zhang, 2016). According to *Figure 1* that the economic and social system is carbon source, the ecosystem is carbon sink. According to statistics, compared with 2000, China's carbon emissions and water consumption in 2012 respectively increased by 112.8% and 7.4% (Peng et al., 2015; National Development and Reform Commission, (2009)). Increased demand for water resources and increased demand for "fossil fuels" by socio-economic development has resulted in an increase in carbon "source" emissions and a reduction in carbon sinks. Therefore, the conceptual model of carbon-water symbiosis coupling based on carbon-water balance system is constructed, and the factors, structure and mechanism of regional carbon-water coupling system generalization model are discussed. Based on the identification of water resource, water user, carbon source and carbon sink, this paper reveals the relationship between water and water users, the relationship between carbon emission and carbon capture, and the mutual relationship between water cycle and carbon cycle, and to establish a theoretical and applied strategy for carbon-water balance to regulate and control water resources system under the effect of "low carbon".

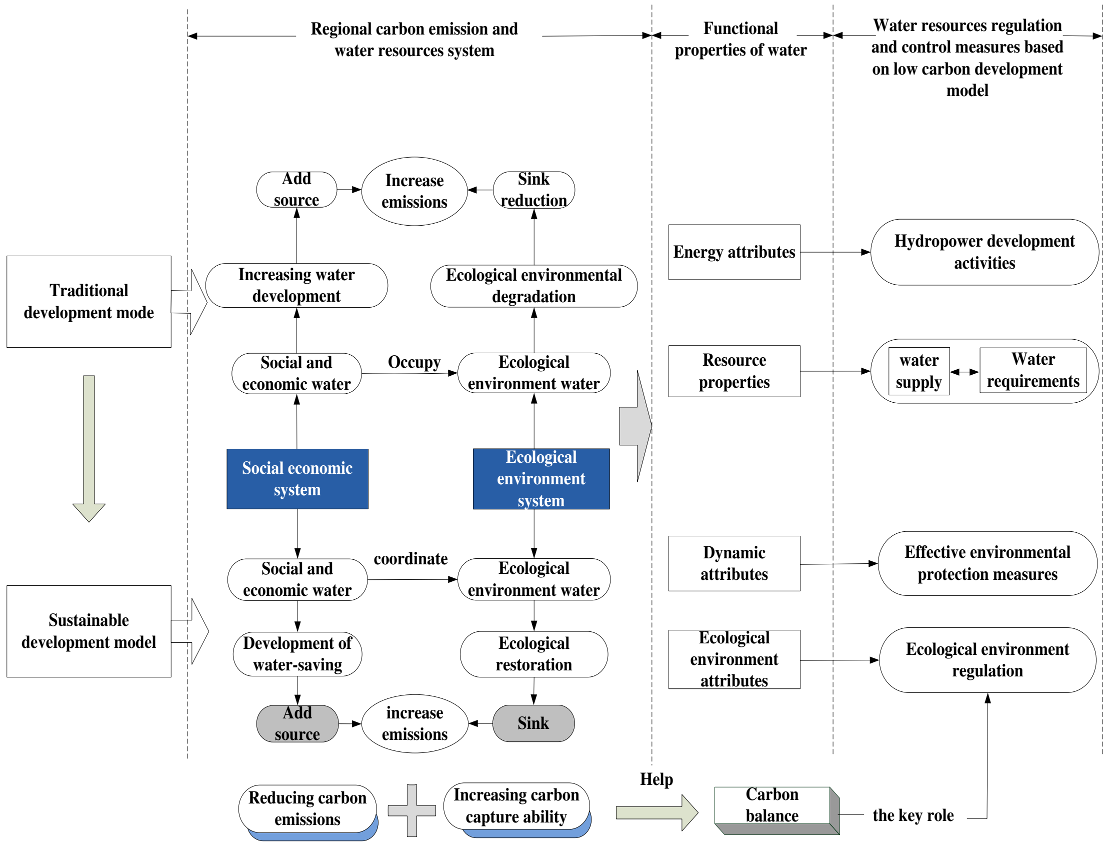

***Figure 1.** Water resources regulation and control of carbon balance mechanism diagram.*

Material and Methods

In this paper, the water quality and water quantity early warning model of regional carbon and water symbiosis mechanism is established by making use of system modeling,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_457465

data mining, fuzzy evaluation, scenario simulation and game theory. At the same time this paper uses the system optimization decision-making modeling method, combining with multi-objective, uncertain variables of the complex programming mode, to reveal the theory and method of water resources regulation and control based on low carbon model. Specific research methods are as follows:

Analysis and conceptual model of regional water quality and water quantity correlation under low carbon

From the viewpoint of water resources system, the water circulation system under the regional carbon water symbiosis complex system should include the water quality safety subsystem and the water quantity security subsystem. Water quality security is reflected in if the urban water environment system water quality standards are compliance or not, water security is reflected in whether the water requirement sectors such as ecological environment, living and production in the case of water quality standards are able to achieve the balance between supply and demand. In addition, the regional water resources system is a complex system which takes human construction and operation management as the core. It includes several sub-systems and many components. How to describe the relationship between water quality and quantity and the interaction and evolution of the subsystems is the fundamental question. It is also a key problem to study the interaction mechanism of the water quality and water quantity system in the regional carbon water symbiosis complex system, and to construct the conceptual model of the water quality and quantity correlation system. This part of the study is divided into the following two aspects:

Correlation analysis of regional water quality and water quantity under low carbon model

Aiming at the structural characteristics of water circulation system with multi-water source, multi-user and multiple transmission and distribution water projects, the water circulation system is decomposed into multiple independent control units by the distributed control method of the complex system. And this paper analyzes the water transport and distribution relations and the pollutant migration and transformation rules of each control unit. The regional carbon water symbiosis complex system was introduced into the analysis of water quality and quantity connection effect. The simulation results are used as the main information source to analyze the regional water quality and water quantity movement mechanism, establish the regional carbon water symbiosis complex system water quality quantity water correlation relations. In practice, researchers will further improve and perfect the joint regulation of water quality and quantity of water resources.

Establishment of the conceptual model of regional water quality and water quantity correlation under low carbon

It will improve the current water quality studies coupled commonly used "loosely coupled" structure, that is quantity and quality in the system as independent of each subsystem, and then turn the water quality modeling and simulation method. In this paper, we consider the coupling between water quality and quantity, the coupling and interaction between the regional water cycle system and the economic and social water use system from the aspects of the interaction between the artificial - natural binary

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_457465

circulation, the integrity of the watershed, the target control at the macroscopic level of the watershed and the concrete simulation of the microcosmic aspect of the river basin and then on the basis of clarifying the rules of water transfer and water quality variation among different parts of the system, a conceptual model of water quality and quantity association system in regional carbon and water symbiosis complex system was established, and the water quality and water quantity correlation system in the study area was comprehensively evaluated, this is the basis of the follow-up research.

Identification of carbon - water symbiosis mechanism and theory and method of system comprehensive evaluation under low - carbon

At present, the theory and method of rational allocation of water resources based on low carbon development model are still in the exploratory stage, and there is no mature model available at home and abroad for reference. This paper summarizes the domestic and international water resources allocation theory and technology research new progress on the basis of the proposed low carbon development model for the rational allocation of water resources mechanism of carbon water symbiosis system to multi-objective decision-making and simulation technology as the key support, water resource regulation and control model of carbon - water symbiosis system from low carbon perspective. The specific research methods adopted are as follows:

Identification technology of operation mechanism of regional carbon-water symbiosis system under low carbon mode

The prerequisite and basis of regional carbon-water symbiosis system is identification of system configuration, in which the identifying objects include the water circulating system under universal concept and the carbon cycling system based on carbon source and carbon sink (Socio-economic system mainly for the carbon emissions of the system, while the ecosystem is mainly manifested as carbon-capture systems). The core of this part of the research is to draw the model of network generalization of Regional Water Resources System based on the carbon-water symbiosis of coupled system based on the distribution of the existing carbon-water circulating system in the experimental area, based on the system identification of water source, water user, carbon source and carbon sink. The model of network generalization of Regional Water Resources System (shown in *Figure 2*), through the system network model method to establish the configuration of unit and the node, the system to establish the relationship between water and water users, the relationship between carbon-emissions and carbon-capture and the constraint relationship between water cycle and carbon cycle.

The theory and method of comprehensive evaluation of regional carbon and water symbiosis system in low carbon mode

It is necessary to establish a reasonable and effective evaluation system based on the above-mentioned regional carbon-water symbiosis system, the main task of the research is to study the control planning method and management strategies of water resources under the low carbon perspective with the system optimization and decision analysis method, the main research tasks include: Selecting the evaluation index of the research object, establishing the evaluation mathematical model, determining the key parameters of the model, solving the model and analyzing the result. The selection of evaluation index is the emphases and key point.

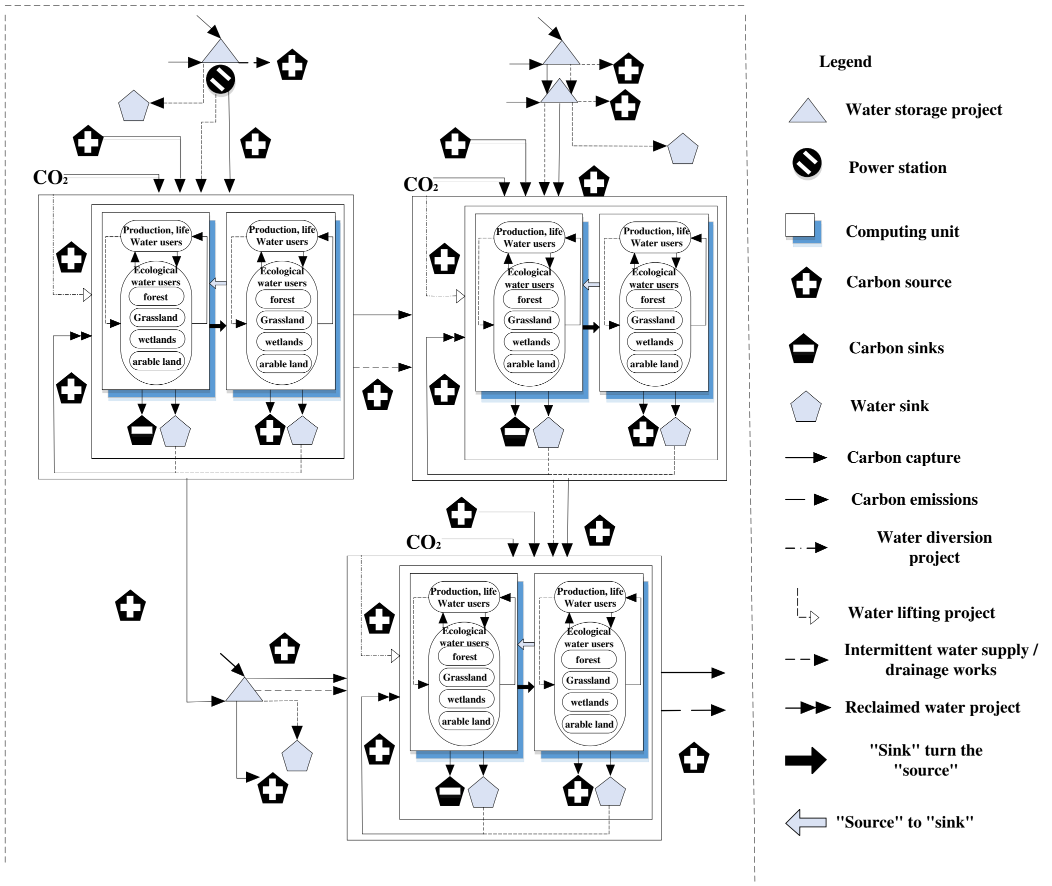

Figure 2. *Regional carbohydrate generalized model symbiotic system schematic.*

Water quality and water quantity simulation of regional carbon - water symbiosis mechanism and safety early warning technology of water circulation system

Through the analysis of the literature, it is found that the previous studies on the simulation of water pollution are mostly carried out under a single static characteristic, which is not consistent with the objective reality. Because the practical meaning of the water cycle system with "multiple fuzzy" complex features: Uncertainty (Spatial and temporal distribution unevenness of water), Dynamic (The dynamic of regional ground confluence changed follow the time), Irregularity (Irregular nature of socio - economic water use). Therefore, it is reasonable and practicable to study the regional water quality simulation and early warning system in combination with the occurrence, development and spread of dynamic evolution disaster under the "multiple fuzzy" characteristics mentioned above.

Construction of water quality and quantity simulation model based on scenario simulation of regional carbon and water symbiosis mechanism

First of all, it is to collect extensively with all types of hydrological data which based on the test area, and regional geographical environment, the main water supply facilities, drainage network and channels, precipitation and other spatial and temporal distribution of data. And at the same time to identify the influencing factors and processes of water quality and water safety under the regional carbon and water symbiosis mechanism;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_457465

Based on the historical and literature data, the multiple fuzzy features of the main driving factors of the system are analyzed; On this basis, the uncertainty assumption method is used to set up hypothetical condition of the evolution of the environment, which can be used as the input of water modeling and water pollution simulation model construction of regional carbon-water symbiosis mechanism, and systematically identify water sources, pollution sources, carbon "sources" and carbon sinks, and establish allocation units and nodes to establish a database of water sources and pollution sources, carbon emissions and carbon capture, and water cycle and carbon cycle system interaction and status information, and combined with the Petri Net rule model described as the scene data source generation tool, as the establishment of water quality and water quality of the set of elements of the background information.

Pre-warning technology of water quality and water security system based on scenario prediction model of regional carbon-water symbiosis mechanism

Finding the historical water quality and quantity database of the experimental area and using the multi-dimensional correlation function to solve the problem of nonlinear mapping between the water security risk factors and the key early warning indicators, and obtain the connection function of the water quality and water quality between risk factors and warning indicators through the fitting calculation; Based on the historical data, the safety factor and the early warning classification correlation model were established to determine the water pollution classification type, the early warning control parameter and the key early warning index threshold ; The establishment of a diagnostic model will change with the diffusion time of the key indicators of police intelligence and early warning indicators to assess the threshold value of tracking and comparison, once the alarm threshold is exceeded signal (*Figure 3*), and input to the corresponding early warning level deduction model to realize the logical structure of early warning response, and provide the guarantee for regional water resources regulation and control.

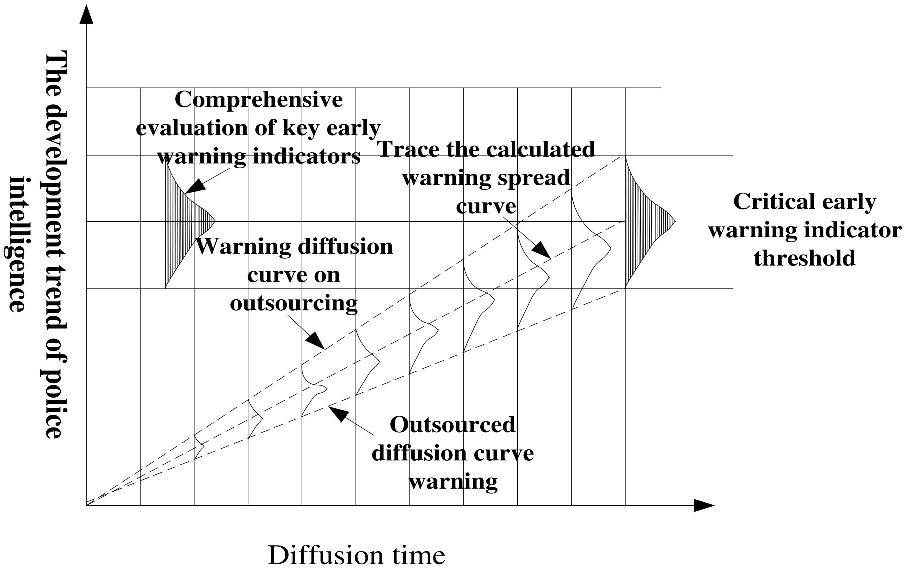

***Figure 3.** Key early warning indicators threshold curve based on tracking comparison.*

Regulation and Control of Water Quality and Quantity in Regional Carbon and Water Symbiosis System from Low Carbon Perspective

Regional carbon - water symbiosis mechanism identification and comprehensive evaluation of the system and safety pre-warning of the water cycle system provide a basis for the regulation and control of water resources based on the coupling mechanism of regional water quality and water quantity under low carbon mode. However, how to plan and manage regional carbon-water symbiosis system to optimize the water supply regulation and water pollution control of regional water management departments to determine whether the carbon-water circulation coupling system of the study area is balanced, and to determine compliance with regional water bearing capacity safety standards is a regional carbon water symbiosis system water quality and water regulation and control of another important prerequisite. This article mainly studies according to the following two aspects.

A multi-objective game decision-making model of water quality and water quantity regulation in regional carbon water symbiosis system under low carbon perspective

Considering the economic, environmental and social factors of the test area, this paper puts forward the idea and method of constructing a multi-objective game decision-making model of water quality and water quantity regulation in regional carbon water symbiosis system under low carbon perspective, and designs the model structure based on multi-objective game analysis and the model solving method of co-evolutionary algorithms, and selects the water resources system of the typical city in the test area to model. Based on the theory knowledge and technology of system, optimization decision, modeling method comprehensively, this paper adopts the method of multi-objective decision-making and simulation and uses decision-making and simulation methods to set middle and long-term water resources regulation sequence elements, and gives water resources allocation under different scenarios of supply and demand, water quality control and carbon emission reduction.

Formulating regulation and control measures of water quality and water quantity regulation in regional carbon water symbiosis system under low carbon perspective

Based on regulation and control methods of water resources in regional carbon water symbiosis system under low carbon perspective is a multi-source, multi-carbon source and multi-control factors integrated water resources management model. In this paper, the water resources regulation model based on low carbon development model is used to analyze the schemes, optimize the comparison and output the regulation scheme. Then, according to the key assumptions of the carbon-water symbiosis system, the results are used to construct the system evaluation and evaluation system, and the recommended scheme is analyzed and evaluated. Then the article gets the recommended governance solution. Finally, based on regional general situation, this paper puts forward practical and feasible measures to ensure water quality and water quality of regional carbon-water symbiosis system under low carbon perspective.

Results and Discussion

First of all, this paper analyzes the correlation and transformation between the various components stem from the components of the regional water quality and water quantity system and its influencing factors. In order to establish the conceptual model of regional water quality and water quantity system and reveals its internal influencing mechanism, this provides the base of qualitative and quantitative research for carbon water symbiosis system. Secondly, on the basis of the characteristics of carbon-water coupling system, under the principle of "low carbon" and "sustainable", considering various factors that "Human - Carbon - Water" Realistic Environment has an impact on the safety and sustainability of regional water resources systems. The effect of multi - factors on carbon - water symbiosis system was discussed, and the mechanism of regional ecological, environmental, economic and social systems under low carbon mode was revealed. Furthermore, the constituent elements of the regional water resources system and their influencing factors were proposed according to the carbon-water symbiosis system model. The interaction between the components was analyzed and the water quality prediction model based on water pollution simulation and evaluation was established. , To improve the water supply security, water security. Finally, through the modeling and case analysis of the regulation of water resources in regional carbon - water symbiosis system, this paper reveals the mechanism of Regional Carbon-Water Coupling System and the improvement of water resources regulation and control measures under the View of "low carbon", and providing a scientific and reliable technical support for the river basin water system governance.

Conclusion

In this paper, the Haihe basin is considered as a research area, taking the conceptual model and the role identification of carbon-water coupling system into account. Through systematic evaluation and simulation, the characteristics of carbon and water cycle and water resources system are identified, and the regional carbon emission benefit, carbon capture efficiency and carbon emission net benefit divided by basin were focused. Design and establishment of water security early warning model under the low carbon effect model, in order to meet the requirements of water resources management and climate change comprehensive response under the conditions of low carbon and water security, this paper, based on the water security coordination control method in the field of environmental governance, scientifically allocates the water resources of the river basin. Finally, this paper presents a new idea and new method to solve the water resources regulation and control in the carbon-water symbiosis system.

(Received 8th Mar 2017; accepted 7th Jun 2017)

Abstract. The ecological service (ES) of soil and water conservation that is provided by the forest ecosystems in the upper basin of Hunhe river has some movement in certain space, which has an important influence on water supply in Shenyang city in China. From the perspective of forest ES transfer, it works out the ecological service value of transferring in the upstream of Hunhe river towards Shenyang city from 2010 to 2014 with the help of Buffer and Intersect of ArcGIS9.3, and the path analysis is used to explore the impact of the ecological service value (ESV) of transferring in the upstream of Hunhe River Basin on the water supply in Shenyang city. The results demonstrate that firstly total values of transferring from 2010 to 2014 adds up to 5.647 billion RMB, and secondly the ecological service of soil and water conservation has positive external effects on the water supply in Shenyang city by the surface water, groundwater and chemical oxygen demand. It can be seen that it explains the mechanism of action about the impact of transfer value of forest ES in the upper watershed on the water supply in the lower basin, which provides the theoretical foundation to the quantitative analysis of value transferring of forest ES and has an important proof of payment for ecological services of river basin in the theory.
Keywords: *path analysis; ecological service (ES); transfer value; water supply; Hunhe River Basin*

Introduction

It is well known that human well-being depends on a variety of ecosystem services (ES) provided by nature, ranging from supporting services and provisioning services to regulating services and cultural services. Ecosystems face various pressures resulting from urbanization and increasing population. Especially, the availability and quality of water for many regions in China have become more and more threatened by shortage and pollution. China's per capita water is less than 25% of the world's per capita level. According to the statistics by the Ministry of Water Resources, there are more than 400 cities in 655 cities in China, which have water shortage of 0.16 billion m3/d, especially severe water shortage in Beijing and Tianjin. As a result of frequent drought, extreme climate change, and more than 50% of rivers and lakes contaminated, the lack of water supply becomes more and more serious (Liao et al., 2016). And fortunately, it has been increasingly recognized that shortage and pollution of water are strongly influenced by forests. The forest is playing an important role in regulating water quantity and purifying water quality. Ecologists argue that riparian forest is widely regarded as temporary reservoir capturing and processing energy to provide water resources for human beings and maintain various ecological functions. In order to maintain ecological service function in river basin, payment for watershed ecosystem services (PWES) has

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_467485

been used to encourage riparian residents from upstream to protect water resources in many countries. For example, the hydropower company funds afforestation in upstream in Costa Rica, and Irrigation Association of Kauka River Basin in Colombia pays fee for forest from upstream to regulate river runoff. Those measures for tree planting and conservation of vegetation are implemented by the payment for watershed ecosystem service to regulate and purify water resource (Zhen, 2006). Therefore, the relationship between forest service value transfer and water is a critical issue.

The services of ecological systems and the natural capital stocks are very critical for the planet's life-support system. They contribute to human welfare, both directly and indirectly, and therefore represent part of the total economic value of the planet (Costanza, 1997). Ecosystem services have being an important concept widely used by ecologists since the 1990s, some scholars have divergent views on the concept of ecosystems services. Ecosystem services are the conditions and processes that natural ecosystems and their constituent species can be used to sustain and meet human survival (Daily, 1997). Costanza defines ecosystem services are that the benefits that humans derive from ecosystems (1997). Ecosystem services refer to the ability of ecosystems to provide a variety of products and services to humans in the Millennium Ecosystem Assessment (MA) (2003). To a certain degree, Wallace agrees with the definition identified by MA, but there are some differences. He stresses that ecosystem process is not the ecosystem service but the production mode of ecosystem services (2007). The definition of ecological services is different among many scholars, it should be defined according to the specific purpose (Zhang, 2012). The ecological service system should be regarded as an entirety, its ecological service functions are interrelated and interacted each other under certain conditions. The concept of ecological service proposed by MA would be adopted in this paper, it classifies the ecosystem serviceswhich function of water purification and water regulation provides the theoretical basis to analyze the impact of watershed forest on water resources.

For a long time, ecosystem services are seen as inexhaustible and free public services, it causes the scarcity of ecological service supply and excessive consumption of ecological services (Egoh et al., 2007). Ecological assets per capita are scare in China, it is an urgent for the natural resource management and ecological compensation to fully evaluate the value of ecological services (ESV) (Xie et al., 2015). The evaluation of ESV is broadly regarded as a useful tool to monetize and measure ecological services. In recent years, many scholars have used static evaluation methods to assess ESV. The contribution of global ecosystems to human welfare is assessed by the static equilibrium model (Dou, 2003). This model usually uses shadow prices and shadow values to estimate the total ESV, but it is based on the assumption that the value of ecosystem services is limited by its direct and indirect impact on market value so that it can be underestimated (Xie, 2011). There are some shortcomings for the accuracy of the simulation results in the biodiversity model due to simplified assumptions and lack of uniform evaluation indicators (Li et al., 2013). Traditionally, cost-benefit analysis, firmly grounded in economic theory, is always a major tool to assess ESV, although it is restricted to the need for the monetised inputs. Some economists believe that the core of valuation for resource, environment and ES is the consumers’ preferences. At present, the Contingent Valuation Method (CVM) is also a major tool to assess the non-use value of environmental goods and ES (Carson, 2000) by the respondents’ willingness to pay (WTP) or willingness to accept (WTA). In 1947, Ciriacy-Wantrup proposed by direct inquiry to understand the respondents 'willingness to pay for public goods and to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_467485

compensate the ecological environment, and then estimate the economic values of public goods and ES (Portney, 1994). Xu takes Liaohe River Basin as a research object and calculates WTP and WTA of the respondents among the residents and analyzes the disparity by using CVM (2015). The close-ended questionnaire and open-ended questionnaire are basic survey techniques for the CVM, but the evaluation result of the two techniques have been controversial, which main argument is that the former obtained WTP higher than the latter. Hanemann argues that the reason of the difference between the two technologies is that respondents' cognition for ES and public environmental goods (1994). So the ESV estimated by CVM are characteristic of subjectivity and greater deviation. As these models mentioned above statically or subjectively evaluate the ESV, they are not suitable to assess the ESV in river basin, considering that the values of some forest ES is flowing and transferring through a certain medium in the space (Qiao et al., 2011).

There are two main methods for evaluation of forest ES, namely, the value evaluation method and material evaluation method (Hu, 2007). Xiao evaluates qualitatively their economic values of forest ES from 2006 to 2011 by the market value method and production cost method (2014). The disadvantages of these two methods are difficult prediction about the level of ecosystem supply, misunderstanding of the link between the evaluation object and the marketable commodity and difficulty of cost statistics. While the assessment of forest ESV by material evaluation method is based on the existing unit area of ESV multiplied by the corresponding area, and the unit area value of forest ESV is calculated by the Net primary productivity (NPP). Ecosystem services are directly related to the biomass. The productivity and service value of ecosystems is estimated by a series of simplified models based on large-scale remote sensing information. It provides the method for measure of ESV, which has higher accuracy (Paula, 2012). It is common to establish the relationship between forest parameters and the Geographic information system (GIS) (Huang, 2015). Although there are several popular application software that are available in the market such as GRASS GIS, SAGA, gvSIG, ArcGIS have been widely adopted in many fields such as business, scientific research and resource management. ArcGIS is the software of spatial information analysis, it could be not only used to collect data, store data, analyze data and monitor the spatial changes of forest areas, but also measure transferring value of interregional ES, and analyze the impact of different ES. Environmental value transfer is commonly defined as the transposition of monetary environmental values estimated at one site through market-based or non-market-based economic valuation techniques to another site (Brouwer, 2000). Environmental value transfer as the procedure estimated on the unobserved monetary value has been widely used, ranging from water quality management to forest management (Luken, 1992; Bateman, 1995). Though the value transfer technique is widely applied in developed countries, it is seldom used in the developing countries, due to the lack of ES valuation expertise (Chaikumbung et al., 2016). The forms and driving factors of value transfer analyzed are necessary supplement to the studies of ES evaluation in China (Fan et al., 2007). Take Weigan river basin in China as an example, it is a significant attempt to do the value transfer estimation of SE by building transfer assessment model of ESV and suing ArcGIS9.3 buffer and overlay analysis platform. The results indicate that ESV has increased continuously from the upstream to the downstream during twenty-two years (Qiao et al., 2011). Besides, value transfer also contributes to determining ecological compensation standard and forming different levels of these in a particular situation (Chen et al., 2014).

The forest is the key to clean water. A high proportion of the Nation's freshwater resources originate from forests. The relation between forest and water also remains controversial. In the past, there was the assumption that forest not only can maximize water yield, but also regulate seasonal flows and improve water quality. Although the forest is not to significantly increase downstream water yield, the critical role of forest covering upper watershed for ensuring water supply and the delivery of high-quality water has been confirmed (Bruijnzeel, 2004; Calder, 2007; Van et al., 2007). The role of forest in regulating stream flow and groundwater are very effective through interception and evaporation of precipitation from the tree canopies and transpiration from the foliage, and then transportation by litter layer and soil layer (Zhou et al., 2002). In addition to these ecological services, purifying water is also significant by trapping or filtering other water pollutants to alleviate the sediment in water bodies. For instance, the broad-leaf forest ecosystems in the upstream of Jinshui river basin in China make their most significant contribution to regulate the PH value and alleviate various physical-chemical concentrations so as to cleanse water (Bu et al., 2010). The forests in the upstream is maintaining water flows during the dry season and cleansing water supply, which could provide water-quality resources for residents in downstream. The existing literatures only analyze the direct impacts of forest in the upstream of the basin on water resources, and its indirect effects cannot be further analyzed. Path analysis provides the effective method to study the direct and indirect impacts of forest in the upstream on water resource of the downstream. In 1972, the path analysis method was proposed by Wright. Path analysis is commonly regarded as a multivariate statistical technique, which is used to analyze the relations between two variables, and describe the impact of independent variable on dependent variable. Compared with the multiple regression model, path analysis can explain the direct and indirect effects of independent variable on dependent variable (Li et al., 2011). In addition, value transfer of forest resources in the upstream is not marketed and thus their value to water is often ignored in development decision. The complicated relationships are always a hot issue between forest and water in the river basin (Li et al., 2001), but water supply in the downstream influenced by value transfer of forest SE from the upper watershed is seldom studied. So the importance of ES value transfer in the upstream to water in the downstream will be discussed in the paper. Path analysis is adopted to analyze and reflects the direct effect and indirect effect about forest of ES Value Transfer in the upstream of Hunhe on Water Supply in Shenyang City.

Based on the facts mentioned above, from the perspective of forest ES transfer, forest ES value transfer from upstream is calculated with ArcGIS9.3 buffer and overlay analysis platform from 2010 to 2014, and then the effects of forest ES value transfer on water supply in Shenyang city cluster can be studied using the path analysis. The objectives of this research are: (i) to measure forest transfer value in both upstream and Shenyang city, and (ii) to analyze the influence of forest value transferred on water supply in Shenyang city by the path analysis. To accomplish the first objective the study performed the following tasks: (1) calculation of forest ESV in the upstream and in Shenyang city respectively, (2) determination of transfer radius and transfer scope, (3) construction of forest ESV transfer assessment model.

Definition of forest ES transfer types in river basin

Forest ecosystem has a variety of ES functions, covering gas regulation, climate regulation, water regulation, soil formation, water conservation, water purification and so on. But it plays an important part of water regulation, water purification and water and soil conservation for forest ES in the river basin. It is highly definite that transfer scopes, influencing factors and features are various among different ecosystem services, on the basis of the definition of transfer types about forest ecosystem service in river basin (Groot, 2002) (*Table 1*). A variety of ES may be transferring in space, covering climate regulation, water conservation, soil formation and disposal of waste in the forest ecosystem. It is in river basin that forests have been recognized as a ES carrier, which water regulation, water purification, and soil and water conservation could not only be transferred in space, but also their ecological values are gradually decreased with increasing distance of space.

Study area

Hunhe River Basin lies between Fushun and Dashiqiao and crosses four cities: Shenyang, Anshan, Dengta, Haicheng, covering around 11480 km^2 (*Figure 1*). The upstream and Shenyang city in Hunhe River Basin is demarcated by Da Huofang reservoir. The upstream refers to three counties, including QingRMB, Xinbin, Fushun, while Shenyang city covers five districts: Sujiatun, Tiexi, Shenhe, Heping and Hunnan, covering 5.06 million of people. Shenyang has the semi-humid temperate continental climate, its average temperature of 8.3, its annual rainfall reaches 500 mm, its annual frost-free period is about 183 days, its forest cover rate is only 28%.

Table 1. *Transfer scopes, influencing factors and transfer features of different ecosystem services*

Ecosystem service	Transfer scope / km	Influencing factors	Transfer characteristics
Gas regulation	$10^2 10^4$	The regulation of O_2、CO_2 and SO_2	With air as medium, attenuation in the circulation
Climate regulation	$10 10^3$	Albedo coefficient, heat capacity and other properties	With air as medium, planar attenuation in the circulation
Water regulation	$10 10^2$	The mesoclimate and other factors	With air as medium, planar and linear attenuation gradually
Soil formation	—	Plants, animals, microorganisms and the forces of nature	The flow and attenuation does not occur generally
Water conservation	$10 10^2$	Forest vegetation, soil , etc	According to the linear flow
Soil and water conservation	10^2	Plant roots and the forest vegetation	With soil vegetation as medium, planar attenuation gradually
Water purification	$10 10^2$	The biological and physical chemistry of water and vegetation	With water, forest and soil as medium, planar attenuation gradually
Water content regulationdisaster prevention	$10 10^2$	The degree of vegetation structure to flood and rainstorm	Planar and linear attenuation gradually
Nutrient cycling	10^3 above	C, N, S, P and other nutrients to life	Irregular, but no attenuation generally
Pollination	$10^{-2} 10^2$	The atmosphere, water, or insects	Both inside and outside the domain of irregular flow
Biological control	10^3	Various factors within the system	Without obvious attenuation in the circulation

Shenyang city has a serious shortage of water resources. Its water resource per capita is approximately one-fifth of nation's average water supply. To address this challenge, there is a need to understand the interactions between forests and water. The relationship between forest and water is based on the assumption that under any hydrological and ecological circumstance. Forest in upstream has been confirmed that help regulate seasonal flows, maintain water yield and cleanse water quality. Following this assumption, increasing forest cover in upstream of river basin is the best effective measure to ensure high-quality water for agricultural and industrial uses, as well as for residents' drinking-water supply in the downstream areas. As foresters are increasingly

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_467485

committed to conservation and construction of forest in the upstream watershed to implement sustainable forest management, it is nearly 2.82 thousand hectare of forest in 2005, and by 2015, an additional 4.13 thousand hectare of forest increased, forest cover reaching more than 66%, due to the conservation and construction of forest in the upstream watershed. In addition, there are various types of forests planted in the upstream watershed to maintain a variety of ecological functions. High-quality water obtained by Shenyang city is attributed to a high proportion of the forest cover, various types of forest, and varying ES functions in the upstream.

Data sources

Forest types from 2010 to 2014were obtained from Fushun and Shenyang Forestry Bureau of Liaoning Province in China. Forest areas in Hunhe River Basin are calculated by studying the land-use map of Liaoning province from 2010 to 2014, the related figures of forest cover comes from Fushun Statistical Yearbooks. The data of water resource data covering stream flow and ground water, chemical oxygen demand (COD) andwater supply come primarily from Shenyang water Resources Bulletin (Shenyang Water Conservancy Bureau, 2010-2014). The standard-reaching rate of water quality is from Liaoning Statistical Yearbooks (Forestry Department of Liaoning Province, 2010-2014).

Assessment of value transfer about forest ES in Hunhe River Basin

Assessment of forest ecological service value

There are many ES transferring in space, covering climate regulation, water conservation, soil formation and disposal of waste in the forest ecosystem. Based on the identification that under particular hydrological and ecological circumstance, forest ES in Hunhe River Basin can be defined as the water regulation, water purification, and soil and water conservation in terms of the transfer features and influencing factors in this paper. The forest types in the upstream of the Hunhe River Basin and Shenyang City covers the Querccus, Larix gmelinii, Pinus Koraiensis, Pinus Tabuliformis, Tilia tuan, Pterocarya stenoptera and broad - leaved mixed forest (*Table 2*).

Table 2. *Current situation of forest resources in Hunhe River Basin (Unit:10^4 ha)*

District	The Quercus	Larix gmelinii	Pinus koraiensis	Pinus Tabuliformis	Tilia tuan	Pterocarya stenoptera	Broad-leaved mixed	In total
Qingyuan County	12.88	10.87	0.58	0.43	0.16	—	2.95	27.87
Xinbin County	15.59	7.84	0.62	0.58	0.21	—	5.36	30.20

Studies have shown that biomass and net primary productivity (NPP) is a key point to assess ES value (Li et al., 2015). Total biomass of different types is calculated in the present study based on the formulation given by Fang (*Table 3*) (1996), and the net primary productivity (NPP) of forests and ES value could be calculated respectively for different forest types (*Table 4*).

Table 3. *Forest ES value provided by different forest types in river basin (Unit: 10^4 RMB, ha)*

Forest types	Water regulation value	Water purification value	Soil and water conservation	Total value per hectare
The Quercus	0.76	0.57	0.26	1.59
Larix gmelinii	0.87	0.58	0.26	1.71
Pinus koraiensis	0.87	0.58	0.26	1.71
Pinus tabuliformis	0.87	0.55	0.26	1.68
Tilia tuan	0.76	0.51	0.28	1.55
Pterocarya stenoptera	0.75	0.43	0.28	1.46
Broad-leaved mixed forest	0.76	0.63	0.27	1.66
In total	5.64	3.85	1.87	11.36
Average	0.81	0.55	0.27	1.62

Notes: ES value of the Quercus, Pterocarya stenoptera and Broad-leaved mixed forest based on the studies given by Baiand Larix gmelinii, Pinus koraiensis, Pinus tabuliformis and Tilia tuan based on the studies given by Ouyang (2011).

Table 4. *Relationship between blomas (x) and net production (y) for different forest types*

Forest types	Function expression	Biomass (x)	Net primary productivity (NPP, y)	Functional adjustment coefficient (K_i)
The Quercus	y=8.85	—	8.85	0.83
Larix gmelinii	y= -0.018x+14.294	98.74	12.52	1.18
Pinus koraiensis	y= -0.018x+14.294	76.15	12.92	1.21
Pinus tabuliformis	1/y=5.71/x+0.047	102.78	9.71	0.91
Tilia tuan	y=8.85	—	8.85	0.83

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_467485

Pterocarya stenoptera	1/y=12.092/x+0.048	268.71	10.75	1.01
Broad-leaved mixed forest	y=0.208x+1.836	49.54	10.22	0.98

NPP is a good indicator for ecosystem services and biomass, although it is limited by the need. In response to this need for the information on the value of ecosystem services about the impacts, there is a correction factor being applied into this paper (*Table 4*). K_i is computed as:

$$K_i = NPP_i / NPP_{mean} \quad \text{(Eq. 1)}$$

Where K_i is the correction factor; NPP_i represents the net primary productivity of forest type *I*; NPP_{mean} is average net primary productivity of all forest types.

According to the correction factor of forest ecological service, total values of forest ecosystem are calculated (*Table 5*) as follows:

$$V = \sum_{i=1}^{n}\sum_{j=1}^{m} S_j E_{ij} K_i \quad \text{(Eq. 2)}$$

Where V represents the ES total value, *i* is ES type;*j* is the forest type; S_j is the forest area of type *j*; E_{ij} is the ESV of *i* type provided by forest type *j*; parameter K_i is the correction factor.

Table 5. *ESV both in the upstream and Shenyang city (Unit: 10^9RMB, ha)*

District	**Water regulation values**	**Water purification values**	**Soil and water conservation values**	**Total values**
Qingyuan County	15.97	22.54	7.29	45.80
Xinbing County	16.79	23.10	7.62	47.51
Fushun County	6.42	8.95	2.93	18.30
Subtotal	39.18	54.59	17.84	111.61
Shenyang City	4.07	6.41	2.10	12.58

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_467485

Assessment of transfer value for forest ES

Riparian forests play an important role in regulating water flows and filtering and trapping the sediment and pollutants for ecological environment of river basin. The effectiveness of riparian forests in maintaining downstream water yield and filtering pollutants in a headwater catchment depends on some water-related functions of forest, including water regulation, water purification and soil and water conservation. These services transferred have an impact on the availability and quality of water in Shenyang city. So it is necessary to study the interactive relation between forest and water, for example, assessing effects of transfer value on water quality and quantity.

In geographic theories, the gravity model, breaking-point model and field intensity formula are often introduced to explain the distance attenuation principle and then to calculate transfer value of ES. In 1949, Converse proposed the concept and calculation method of breaking-point (Han et al., 2010). The breaking-point model, which also has been applied in calculation of transfer radium, can't be used in directly and need to be complemented with distance measures from between core point of forest ES in upstream and breaking-point in the downstream areas (Mooi and Sarstedt, 2011). Transfer radium A_{ij} is calculated as:

$$A_{ij} = \frac{D_{ij}}{1+\sqrt{V_j / V_i}} \quad \text{(Eq. 3)}$$

Where *i*, *j* respectively represents the upstream and Shenyang city; A_{ij} is the transfer radium; V_i, V_j is respectively the forest ESV in both upstream and Shenyang city; D_{ij} is the central distance from upstream to Shenyang city.

Transfer value of forest ES is commonly defined as the transposition of monetary ESV estimated through market-based or non-market-based economic valuation techniques. It relies on several factors, including transfer scopes measured with ArcGIS9.3 buffer and overlay analysis platform, central distance between different regions and ESV of affected areas. Transfer value of forest ES can be calculated (*Table 6*) so described as:

$$V_{ij} = P_{ij} \frac{V_j}{D_{ij}^2} S \quad \text{(Eq. 4)}$$

Where V_{ij} represents the transfer value of forest ES from the upstream to Shenyang city; S is the transfer scopes of forest ES; V_j is the forest ESV in Shenyang city, D_{ij} is the central distance from upstream to Shenyang city; parameter P_{ij} is a some factor, which ensures that medium measure ranges between 0 and 1, and it is in general 0.6 for ordinal influencing factor.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_467485

Table 6. *Transfer value of forest ES from the upstream in Hunhe River Basin from 2010 to 2014 (Unit: 10^9RMB, ha)*

Years	Water regulation	Water purification	Soil and water conservation	Total values
2010	5.51	3.50	1.80	10.81
2011	5.52	3.51	1.81	10.84
2012	5.65	3.59	1.85	11.28
2013	5.88	3.75	1.93	11.60
2014	6.08	3.87	1.99	11.94

Path analysis about effect of transfer value on water supply

Path analysis method is to analyze the relations between two variables by decomposing the correlation coefficient, and then express the direct effect of an independent variable on the dependent variable, and the indirect effect of an independent variable on the dependent variable caused by other variables (Fu, 2014).

Path coefficient is an important indicator for the path analysis to reasonably explain the complex relationship between variables, including direct path coefficient and indirect path coefficient. Direct path coefficient is to describe the influence of independent variable itself on dependent variable, while indirect path coefficient aims at analyzing the effects of independent variable on dependent variable by others. Path analysis is expressed by the measuring models in the following equations:

$$\begin{cases} a_1 + r_{12}a_2 + ... + r_{1p}a_p = r_{1y} \\ r_{21}a_1 + b_2 + ... + r_{2p}a_p = r_{2y} \\ r_{p1}a_1 + r_{p2}a_2 + ... + a_p = r_{py} \end{cases} \quad \text{(Eq. 5)}$$

Where a_i is the partial regression coefficient for variable i; r_{ij} is the correlation coefficient between x_i and x_j; r_{iy} is the correlation coefficient between x_i and y, $i, j = 1, 2, ..., p$.

As is shown in Equation (5), a_i is the direct effect of x_i on y, namely x_i is also the direct path coefficient for y; $r_{ij}a_j$ is the indirect effect of x_i on y by x_j ($x_i \leftrightarrow x_j \rightarrow y$), namely $r_{ij}a_j$ is also the indirect path coefficient for y by x_j. $r_{ij}a_j$ can be calculated so described as:

$$r_{iy} = a_i + \sum_{j=1} a_j r_{ij} \quad \text{(Eq. 6)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_467485

In path analysis, the coefficient of determination called R^2 indicates the effect of independent variables on dependent variable. If the coefficient of determination is significant, the path analysis is valid, otherwise it is meaningless. ${R_{(i)}}^2$ is calculated as follows:

$$R^2 = \sum_{i=1}^{p} R_i^2 + \sum_{i<j}^{p-1} R_{ij}^2 = \sum_{i=1}^{p} b_i r_{iy} \quad \text{(Eq. 7)}$$

Where R_i^2 is the coefficient of direct determination for effect of x_i on y, namely $R_i^2 = a_i^2$; R_{ij}^2 is the coefficient of indirect determination for effect of x_i on y by x_j;

Path analysis has been commonly applied to studying the direct and indirect effect of independent variables on dependent variable, but it is very difficult to identify which independent variable plays the most important role for dependent variable. So decision coefficient is introduced in this paper. Compared with the coefficient of determination, value of decision coefficient can order the potential combined effects of independent variable on dependent variable. The independent variable of the first order is the most critical decision one, but it does not mean that independent variable of last order has no effect. If decision coefficient is negative, it shows that independent variables have restrictive effect on dependent variable (Yuan et al., 2011). ${R_{(i)}}^2$ is calculated as follows:

$${R_{(i)}}^2 = a_i^2 + 2\sum_{j \neq i} a_i r_{ij} a_j = R_i^2 + \sum_{j \neq i} R_{ij}^2 \quad \text{(Eq. 8)}$$

Where R_i^2 is the coefficient of direct determination for effect of x_i on y; R_{ij}^2 is the coefficient of indirect determination for effect of x_i on y by x_j; a_i is the direct path coefficient for the direct effect of x_i on y; $r_{ij}a_j$ is the indirect path coefficient for the indirect effect of x_i on y by x_j.

In a word, the path analysis aims at analyzing the direct, indirect and comprehensive effect of independent variable on the dependent variable by the direct and indirect path coefficient and decision coefficient, based on building the regression equation.

Econometric model

Choice of influencing factors about water supply in Shenyang city

Although the relationship between forests and water is a complex issue, forest ES plays an important role in improving ecological environment of water resources, which are mainly attributed to water regulation, water purification and soil and water conservation. Water regulation is deemed that water resource is redistributed by

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_467485

maintaining or regulating hydrological flows and runoff recharging. Water purification aims at cleansing water quality. This is achieved through reduction of excessive concentrations of organic matter and filtering various types of pollutants in water bodies. Soil and water conservation is generally associated with prevention of soil erosion and with maintaining water resources. The surface cover, debris and tree roots are more effective in keeping the water. Moreover, the role of the upstream forests in regulating water flows, purifying water quality of the upper watershed and supplying water in downstream areas cannot be ignored. To analyze this effect under particular hydrological and ecological circumstance, water-related ecological system will be introduced in river basin. This system of water supply comprises two major activities: ecological production and stream flow/natural water (Matete and Hassan, 2006). Ecological production refers to transfer value of forest ES (X_1), and stream flow or natural water includes water quantity and water quality, consisting of stream flow and groundwater (X_2), chemical oxygen demand (COD) (X_3) and the standard-reaching rate of water quality (X_4) in this paper (*Table 7*).

Table 7. *Influencing factors of water supply in Shenyang city from 2010 to 2014*

Year	Transfer value of forest ES (10^9RMB)	stream flow and groundwater (10^9m^3)	COD (10^5m^3)	Standard-reaching rate of water quality (%)	Water supply (10^9m^3

Correlation analysis

Correlation analysis is often used to describe the degree of linear correlation among the variables. Although the methods of correlation analysis are various, many studies often rely on the correlation coefficient as an important indicator for measurement of linear correlation among the variables (Zhu et al., 2008). Pearson's correlation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_467485

coefficient was applied to analyze the relationship between the influencing factors and water supply of Shenyang city (*Table 8*). The purpose of correlation analysis is to do some preliminary analysis on the relationship among variables and to prepare for building the model (Zhang et al., 2012).

As is shown in *Table 8*, correlation coefficient between X_i and Y showsthe ordering: $Px_1 > Px_2 > Px_4 > Px_3$. The results implies that water supply(Y) is significantly influenced by transfer value of forest ES(X_1). In addition, it indicates that it is negative correlation between chemical oxygen demand (COD) (X_3) and water supply (Y), and positive correlation between water supply (Y) and transfer value of forest ES (X_1), stream flow and groundwater (X_2) and standard-reaching rate of water quality (X_4).

Regression model

In order to facilitate analysis and explanation, the econometric model is built based on the chosen explanatory variables by means of multiple linear stepwise regressions. Specific calculations are completed by the SPSS17.0. The econometric model is intended to be constructed as follows:

$$Y = 0.497X_1 - 6.818X_3 + 29.486 \qquad \text{(Eq. 9)}$$

Where Y is the water supply in Shenyang city, X_1 and X_3 are the variables of transfer value of forest ES and chemical oxygen demand respectively. The result and test values of this are shown in *Table 9*.

Table 9. *The result and test values for influencing factors of water supply*

Variables	Coefficients	t	Sig.	Collinearity
Constant	29.485	18.612	0.003	-
Transfer value of forest ES	0.497	14.608	0.005	1.310
Chemical oxygen demand	-6.818	-4.687	0.043	1.310

Notes: R=0.997; R^2=0.995; F (sig.) =197.793(0.05); Durbin-Watson d=2.8335

As is shown from *Table 9*, only the variables, 'transfer value of forest ES' and 'chemical oxygen demand', have passed the F test and t test excluding the other variables- 'stream flow and groundwater' and 'standard-reaching rate of water quality'. The goodness-of-fit of this model is satisfactory.

Table 10. *Analysis of path correlation between water supply and influencing factors*

Variables	Direct effect	$\to X_1$	$\to X_3$	Indirect effect	Total effect	Decision coefficient
X_1	0.8385	—	0.1309	0.1309	0.9694	0.9226
X_3	-0.2691	-0.4079	—	-0.4079	-0.6770	0.2919

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_467485

The results of the model have further verified the previous inference from qualitative analysis. Transfer value of forest ESplays an important roleas an influencing factor which can regulate the recharging of groundwater aquifers and improve the function of the hydrologic cycle. However, stream flow and groundwater as the critical resource capturing and processing energy to provide water for Shenyang city is excluded in the model, it indicates that this variable has not mainly linear relationship. In another word, it cannot significantly increase water yield. Because several natural factors are alteringforest's role in influencing the availability of water resources (Bergkamp et al., 2003; Balkhair, 2016; Wu and Feng, 2016; Meng et al., 2016; Zhang, 2013), including other meteorological variables (precipitation and temperature). Chemical oxygen demand (COD) is regarded as a critical indicator to impair water quality. Because potential pollutants come from agricultural or industrial chemicals and domestic sewage, excessive concentrations of organic matter have greatly negativeeffect on drinking-water–supply. Adequate riparian forest buffer zones along watercourses can be maintained, which helps protect water and soils and even reduce pollutants flowing to rivers so as to decrease chemical oxygen demand (COD) and cleanse water quality. So the results show that the delivery of high-quality water can be ensured by the upstream forest, but the benefits of the upstream forest on increasing downstream water yield were generally misleading. This conclusionis the same as the results confirmed by FAO and CIFOR (2005).

Path analysis

Based on the above econometric model, this part is to explain the effects of transfer value of forest ES in the upper watershed on water supply in Shenyang city by the means of path analysis.

It can be seen from *Table 10* that the decision coefficients of 'transfer value of forest ES' and 'chemical oxygen demand (COD)' to water supply in Shenyang city are 0.9226 and 0.2919 respectively, which shows that the former affects water supply in Shenyang city more significantly than the latter. Besides, the former produces positively indirect influence on water supply, while the latter has negatively indirect influence.

Forest ES in the upper watershed provides valuable regulating services for drinking-water–supply of the downstream. It mitigates water pollution by preventing excessive concentrations of organic matter from directly reaching the sea and the nearby beaches.

When it rains, canopy layer intercept the precipitation, it is under the action of gravity that water flows into the soil carrying large amounts of nutrients can be absorbed, regulated and redistributed by forest ES functions, which produces the stream flow and groundwater. Meanwhile, in the cyclic process of hydrological and ecological circumstancevarious chemicals can be filtered in water bodies and chemical oxygen demand is gradually reduced to prevent pollutants from reaching the streams. When rivers are carriers of nutrients and pollutants, the reduction of sediment delivered to streams has a positive impact on water quality of the downstream and the livelihoods and health of downstream populations. So the transfer value of forest ES from the upper watershed not only regulate seasonal availability of water, but also cleanse water quality for Shenyang city.

DOI: http://dx.doi.org/10.15666/aeer/1504_467485

Conclusion

Undoubtedly, transfer value of forest ES undoubtedly has a significant impact on water supply in Shenyang city directly and indirectly. Main conclusions are as follows:

(1) Forest ES values are 111.61 billion RMB and 12.58 billion RMB respectively in the upstream and Shenyang city. With forest resources as the medium, transfer value have reached 56.57 billion RMB between the upstream and Shenyang city from 2010 to 2014, in addition to meet its own need for forest ES.

(2) Transfer value of forest ES has been identified as an important factor of water supply. According to the results of econometric models, it is largely correlated with each other. Therefore, transfer value of forest ES is not only an essential assurance for Shenyang city to share the balanced and sustainable availability of water resources, but also an effective guarantee to provide benefits to the urban populations in terms of high-quality drinking water.

(3) This results further carry out preliminary discussion about the influence of transfer value of forest ES on regulating water and cleansing water quality by the path analysis. It produces the positive externalities, which is beneficial to the stakeholders and greatly promotes formulation and implementation of ecological compensation policy and the coordinated and sustainable development among some districts.

Discussion

We have attempted to assess the transfer value of forest ES in the upper watershed, and have described its effect on water supply in river basin areas by the path analysis method. From this analysis it shows that there are some critical theoretical and empirical issues that remain to be resolved.

(1) According to the existing research results, forest ESV was used to statically evaluate by the market value method, production cost method and opportunity cost method, which only measure ESV in a certain region, but not calculate the spillover value of forest ES to other regions. In this paper, in addition to meet its own need for forest ES measured, the spillover value of forest ES can be still dynamically calculated from the upstream to the downstream in Hunhe River Basin with the help of Buffer and Intersect of ArcGIS9.3. The results are important proofs of payment for ecological services in the theory.

(2) The relation between transfer values of forest ES and water supply is very complex. At present, most of the research results focus on precipitation input, runoff output and the change of element content in the system cycle, but the interaction of each factor and a certain factor indirectly influenced by others may be ignored in forest hydrological process. The path analysis demonstrates that forest ESV from the upstream produces direct and indirect impacts on water resource from downstream in the river basin. Due to limited data, the impact of transfer value of forest ES on water resources is also affected by other factors, which needs further study in the future.

DOI: http://dx.doi.org/10.15666/aeer/1504_467485

(3) Forest ES are affected by many factors that are different in different regions, including light and heat, precipitation and site conditions. While these are beyond the scope of this paper, our analysis only can serve as a useful starting point, and these factors could be considered in further study.

(Received 8th Nov 2016; accepted 16th Mar 2017)

Abstract. To increase both water productivity and rice production, research was carried out at the Central Institute of Agricultural Engineering, Bhopal, India, to evaluate the use of drip irrigation together with modifications in rice crop geometry and other cultural practices. Experiments were conducted with five alternative treatments: T_1: Conventional paddy cultivation under continuous flooding, T_2: System of Rice Intensification (SRI) methods which include alternate wetting and drying, T_3: SRI methods with drip-irrigation, the emitters being spaced at 20 cm, T_4: SRI methods with drip emitters spaced at 30 cm, and T_5: SRI methods with drip emitters spaced at 40 cm. Greatest plant height and root length were recorded with SRI under drip irrigation at 20 cm spacing (T3). Yield and yield-contributing parameters were also significantly higher with this T3 treatment as compared with conventional practice (TI): productive tillers/m^2, number of grains per panicle, average panicle length and weight, average grain yield (7 t/ha), and harvest index. Superior performance of the T3 treatment in terms of water productivity and water-energy productivity was also recorded. Among the drip-irrigated treatments, however, there was no statistically significant difference in grain yield between T3 and T4 treatments, indicating that drippers spaced at 30 cm could be recommended to lower the cost of the drip system installation.
Keywords: *water productivity, plant growth parameters, yield contributing parameters, water energy productivity, economics*

Introduction

Rice is the most important global food crop. Year-to-year fluctuations in its production have a direct bearing on food security and on price inflation in the world market. Given its continuing population growth, India should be producing 1.7 million tonnes of additional rice every year to ensure national food security (Dass and Chandra, 2013). Hence, there is a need to increase sustainably the yields and productivity of rice cultivation, doing this to the extent possible with reduced inputs and with less exploitation of natural resources to feed the increasing global population. This is a challenge for rice-growing countries around the world.

For producing rice at present with traditional irrigation techniques, large quantities of water are being used to flood paddy fields with standing water 2-5 cm deep at the different stages of crop growth. Studies have indicated that 3000-5000 liters of water are often used to produce 1 kg of rice (Satyanarayana et al., 2007), but this includes water applications which are clearly excessive. Water requirements for flooded rice production are currently considered to average a little over 1,400 liters per kg of rice(www.knowledgebank.irri.org/step-by-step-production/growth/water-management). This is about three times more than for growing wheat and maize (Riaz, 2001).

Water scarcity is a major challenge affecting rice production all around the globe. More than 80% of the fresh water resources in Asia are used for agriculture, of which

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_487495

about half of the total irrigation water is used for rice production (Dawe et al., 2003). Future rice production will depend on improvements in water use efficiency for growing rice crops. A large-scale evaluation in Indonesia with over 11,000 on-farm comparison trials conducted over six seasons reported a 78% increase in paddy rice yields with about 40% reduction in water and with lower costs of production when using the methods of the System of Rice Intensification (SRI), which include alternate wetting and drying of paddy fields rather than flooding as done with conventional practices (Sato and Uphoff, 2007). SRI methods have been validated in over 50 countries, and given the scarcity of water resources in so many countries and the evident yield advantages with SRI management, probably more than 10 million farmers are already using some or all of its recommended practices (http://sri.cals.cornell.edu).

Substantial water savings with higher paddy yields using SRI methods have been confirmed in a meta-analysis of 27 published studies across 8 countries, an average 35% reduction in irrigation water per hectare and a 22% reduction in total water (irrigation plus rainfall) (Jagannath et al., 2013). But these comparisons were all made with modified regimes of flood irrigation. Possibly there could be even greater savings of irrigation water and more gains in water productivity with employment of drip irrigation technology. And if such benefits are possible, how can the productivity of drip irrigation be optimized? These are important considerations for enhancing both the productivity and sustainability of irrigated rice cultivation, and it is these concerns that gave impetus to the research whose findings are reported here.

Materials and Methods

Study areas

The research work was carried out at the Central Institute of Agricultural Engineering, Bhopal. Soils of the experimental site are classified as heavy clay soils with clay content varying between 49.7 to 53.7 % and with the field capacity ranging from 28.5 to 31 %.Which was situated at north of Bhopal at 77º 24' 10" E, 23º 18' 35" N at an elevation of 495 m above mean sea level.

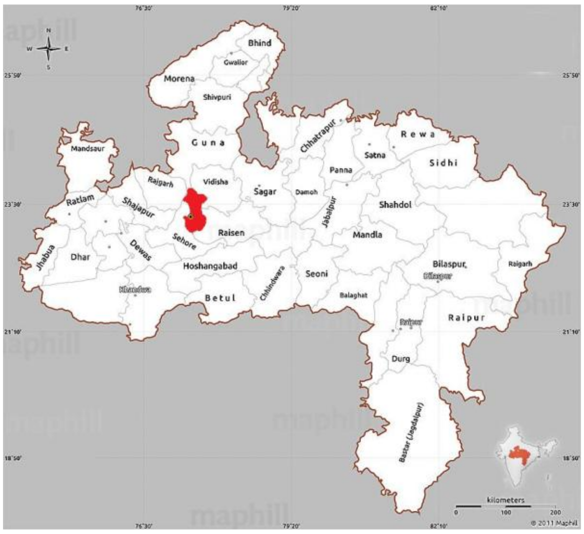

Figure 1. *The map of Madhya Pradesh State showing the Local Government Areas (red colour pointing to the study areas)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_487495

The climate of Bhopal is pleasant throughout the year. Generally the climate of the study area is hot and humid in nature. The annual rainfall in the region is about 1200 mm. Eighty percent of the total rainfall occurs during the month of June to September in almost every year which is popularly known as monsoon rainfall. The summer months from March to May are very hot and humid, and temperature often rises above 40ºC.

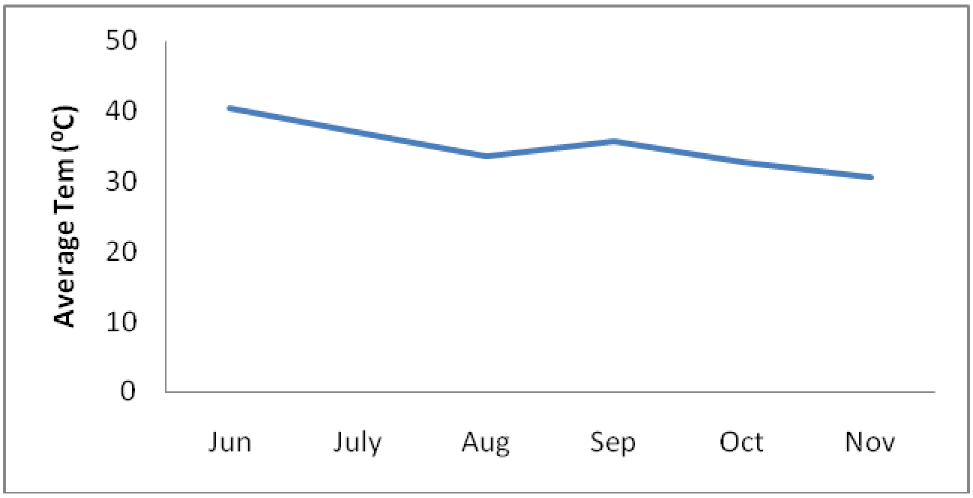

Figure 2. *Average temperature (ºC) of ten years*

Five treatments were considered in the study: T_1: Conventional practices with continuous flooding, T_2: System of Rice Intensification (SRI) crop and water management methods, T_3: SRI management with drip irrigation emitters spaced at 20 cm, T_4: SRI with drip emitters spaced at 30 cm and T_5: SRI with drip emitters spaced at 40 cm. Puddling was carried out in the T1 and T2 plots, but the T1 plots had continuous flooding, while T2 plots had alternate wetting and drying. Young seedlings 10 days old were transplanted manually in the T2, T3, T4 and T5 treatments at 30 x 30 cm spacing with single plants per hill and a seed rate of 10 kg ha^{-1}. Transplanting in T1 was carried out on the 30th day after seeding, and 3-4 plants per hill were transplanted at a spacing of 15 x 5 cm spacing, with a seed rate about 100 kg ha^{-1}. The dates of transplanting for all the treatments were the same. Each treatment plot was replicated four times, and each plot was surrounded by bunds 0.5 m wide in order to arrest any lateral seepage and nutrient diffusion from adjoining treatments.

Inorganic fertilizers were applied to all the plots with the recommended doses of 150 kg N, 100 kg P and 120 kg K per ha in the form of Urea, Di-Ammonium Phosphate (DAP) and Murate of Potash (MOP), respectively. Half of the recommended dose of nitrogen and all of the phosphorus and potash were applied at sowing, while the remaining N was applied at the time of tillering through broadcasting in the T1 and T2 treatments and through the drip irrigation system in T3, T4 and T5 treatments using water-soluble fertilizers. Rates and kinds of soil nutrient supplementation were thus not a variable in this experiment.

During the crop growing period, T1 treatment plots were under fully ponded conditions (to a depth of 4-5 cm) for a total of 34 days during the growing season, while T2 plots were under ponded conditions for a total of 25 days during their alternating periods of drying and wetting of the plots at six-day intervals. The drip-irrigated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_487495

treatments T3, T4 and T5 were operated for 15 min, 23 min and 30 min, respectively, for a cumulative period of 60 days. Weeds were controlled by manual weeding after transplanting on the 20th, 40th, 60th and 80th days, so weed control was also not a variable evaluated in these trials even though mechanical, soil-aerating weeding is recommended as part of the recommended SRI protocol.

Monocrotophos (400 ml per acre) was applied for controlling stem borer at 25 DAS and Gandhi bug at 70 DAS in all treatments. Bacterial blight was controlled by the application of Streptocylin along with Copper Oxi-Chloride (6g+250g per acre) at 30-35 DAS in rice.

At the time of transplanting, five plants were randomly selected from each plot to be used for recording plant height, number of tillers, number of effective tillers, root length, panicle length, and panicle weight, number of grains per panicle, 1000-grain weight, grain yield, and straw yield. The data collected were analyzed by using Fisher's analysis of variance technique, and a Randomized Block Design (RBD) test with the confidence level set at 5% was used to compare the differences among treatment means (Steel et al., 1997).

Results and Discussion

Plant growth parameters

The influence of different treatments on rice crop growth parameters on the 60th day after transplanting is given in *Table 1*, and the actual condition of the crop is shown in *Plate 1*. The different irrigation practices along with associated crop management had a significant effect on plant height. The greatest average plant height was recorded with treatment T3 (76.45 cm) possibly due to optimizing plant population and geometry under SRI with drip emitters spaced at 20 cm which gave more even distribution of water to the plants. Similarly, the greatest number of tillers m^{-2} area was also recorded under T3 (240.75), followed by T4 (232.50) and T5 (223.50). The lowest number of tillers was recorded with T1 (217.25). However, chlorophyll values as measured by a SPAD meter did not significantly vary across the different treatments. Root length was also greatest under T3 (18.23 cm), followed by T4 (16.08 cm), while the lowest root length was recorded under T1 (14.10 cm).

Table 1. *Influence of growth parameters by different irrigation practices*

Treatments	Plant height at 60 DAT (cm)	Number of tillers at 60 DAT	SPAD Values	Root length (cm)
T1	73.45	217.25	44.81	14.10

Conventional paddy (L), SRI (R)

Drip-irrigated paddy emitters spaced at 20 cm (L), 30 cm (M) and 40 cm (R) at 60 dayI (R)

Plate 1. *Experimental crops under different cultivation and irrigation practices at 60 days*

Intermittent irrigation creates favourable soil physical, chemical and biological properties that support plant growth under mostly aerobic soil conditions, encouraging deeper rooting depth and creating favourable micro-climates in the soil, which support abundance of micro-organisms and more availability of micro-nutrients. Better root systems provide good anchorage for the plants and sustain effective use of applied fertilizers by checking losses from leaching (Stoop et al., 2002). Optimum availability of soil moisture plays a key role in the processes of mineralization and solubilisation, affecting the availability and uptake of nutrients, and contributing to plant growth and yield (Venkateswarlu et al., 1997). Greater root capacity also supports a higher photosynthetic rate by supplying sufficient amounts of nutrients to the shoots, thereby enabling high productivity (Osaki et al., 1997). Sharda et al. (2016) observed in their study that root length and density were maximum in the drip irrigated crop than flood irrigated crop.

Yield-contributing parameters

It has been seen in many studies that flooding is not the most favourable condition for growing rice crops (Belder et al., 2004; Sahrawat, 2000; Gani, 2001; Borrel et al., 1997). The findings of the present study confirm that different irrigation methods and regimes have a significant influence on crop yield parameters. System of Rice Intensification methods adapted with drip irrigation emitters spaced 20 cm apart gave the highest number of productive tillers at maturity (264.75 m^{-2}), also the highest number of grains per panicle (161.75), longest panicle length (27.52 cm), and highest panicle weight (3.41 g), as seen in *Table 2*.

These findings are consistent with the results reported by Yang et.al. (2004) indicating that intermittent irrigation and maintaining moist, mostly aerobic soils not only enhances tillering but also the root system's development and functioning. However, 1000-grain weight and straw yield (t/ha) were not found to differ significantly among the five treatments. Treatment T3 also had a significant effect on grain yield and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_487495

on the harvest index. SRI methods with drip at 20 cm spacing gave the highest grain yield, 7.07 t ha^{-1}, while conventional practices (T1) with flood irrigation, older seedlings, and greater plant density resulted in the lowest grain yield, 3.14 t ha^{-1}. Harvest index calculated for T3 was the highest (61.9), while that for T1 was the lowest (40.7), a very large difference.

Table 2. *Yield and yield-contributing characters influenced by different irrigation practices*

Treatments	Number of effective tillers (per m^2)	Number of grains per panicle	Panicle length (cm)	Panicle weight (g)	1000 grain weight (g)	Grain yield (t/ha)	Straw yield (t/ha)	Harvest index (%)
T1	222.25	133.50	25.67	2.78	32.30	3.14	4.30	40.73
T2	242.0	141.0	25.97	3.02	32.96	4.04	4.18	48.08
T3	264.75	161.75	27.52	3.41	33.51	7.07	4.60	61.93
T4	256.25	151.5	26.96	3.37	32.71	6.72	4.34	60.98
T5	253.0	149.0	25.87	3.16	32.59	5.95	4.43	57.72
SEM±	4.49	4.09	0.40	0.07	0.41	0.31	0.13	2.57
CD (p=0.05)	13.25	12.07	1.18	0.22	NS	0.90	0.39	7.59

It is worth noting that the 1st, 2nd, 5th and 7th sets of bar graphs in *Figure 3* all follow the same sequential pattern: T3 > T4 > T5 > T2 > T1. This pattern is seen throughout the data gathered and analyzed. Detailed measurements made of grain characteristics and milling quality (grain length, breadth, eccentricity, perimeter and milling efficiency) revealed no significant differences when the data were analyzed statistically (data not shown). However, there was a rather consistent rank-ordering of the results seen across all these measurements: T3 > T4 > T5 > T2 > T1.

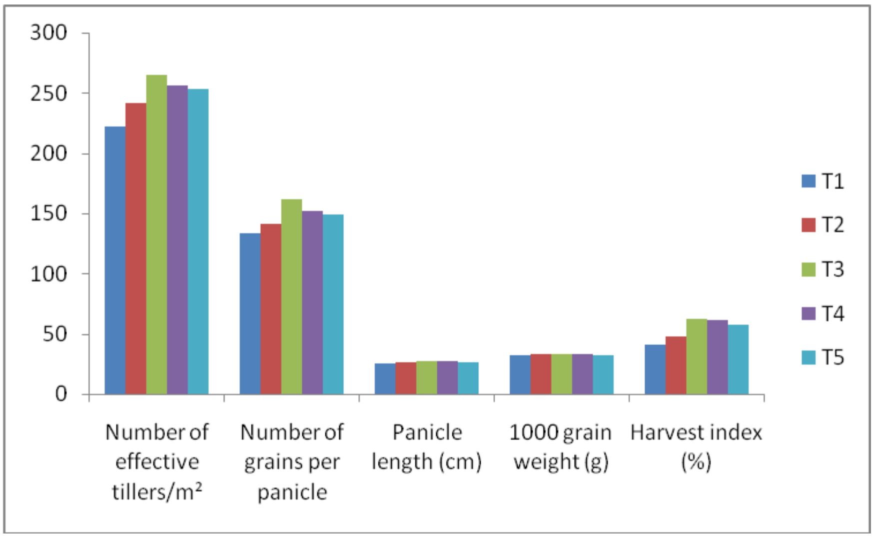

Figure 3. *Yield-contributing characteristics as influenced by different irrigation practices*

Water productivity and water-energy productivity

Efficient water management is key to higher paddy yields and greater net income with the System of Rice Intensification as this key input influences the effects of other

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_487495

inputs as well. Water productivity and water-energy productivities for the selected treatments were analyzed and are presented in *Figure 4*. Water productivity is the amount of grain yield obtained per unit of irrigation water supplied to the crop. Water-energy productivity is the amount of grain yield that is obtained from a unit of energy (kWh) consumed during the irrigation.

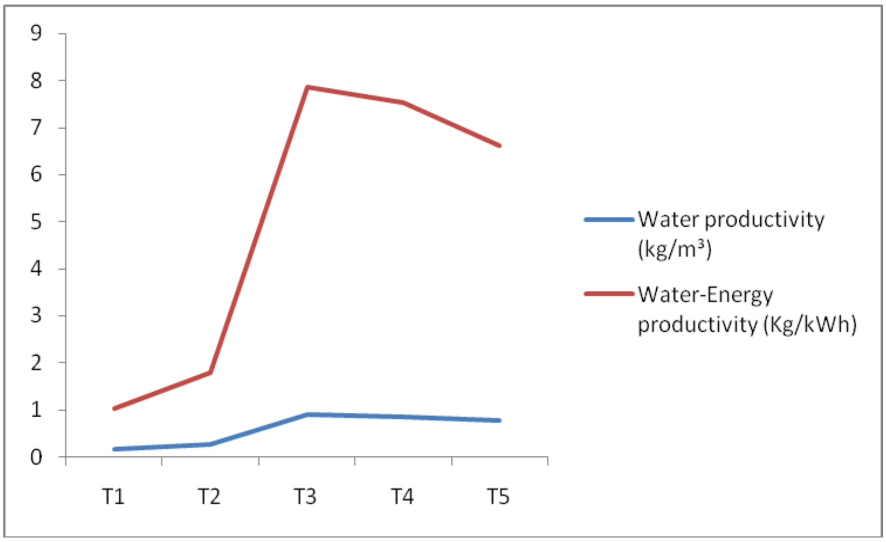

Figure 4. *Water productivity (kg of rice per m^3 of irrigation water) and water-energy productivity (kg of rice per kilowatt-hour of electricity) as influenced by the irrigation practices evaluated*

Water productivity was found highest under T3 (0.90 kg m^{-3}) followed by T4 (0.86 kg m^{-3}). The lowest water productivity was recorded under T1 (0.16 kg m^{-3}), with no difference between T4 and T3 in terms of water productivity. Similarly, the highest water-energy productivity of was observed under treatment T3 (7.85 kg kWh^{-1}), with the lowest productivity found for treatment T1 (1.02 kg kWh^{-1}). This difference was highly significant statistically. However, among the treatments T3, T4 and T5, the calculated differences in water productivity and water-energy productivity were not significant.

Economics of drip-irrigated paddy

In the present study, the economics of drip-irrigated paddy were compared with conventional paddy cultivation practices and with standard System of Rice Intensification. The annual cost of drip irrigation system was calculated with the assumption that the life of the physical infrastructure would be 10 years with 10 per cent annual depreciation. The cost components considered included seeds, fertilizer, labour, electricity charges per unit, farm yard manure, harvesting and threshing. Uniform cost values were considered for all the treatments depending upon the respective quantity of input in each treatment.

The findings of the study indicated that the highest net return ($ 2442/ha/year) and B:C (3.23) ratio can be obtained under SRI management with drip irrigation emitters spaced at 20 cm, followed by SRI with drip irrigation emitters spaced at 30 cm (*Table 3*). The lowest net return ($ 853/ha/year) and lowest Benifit: Cost (2.18) ratio was

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_487495

obtained with conventional practice of paddy cultivation. Based upon his research in Madagascar, Andrianaivo (2002) reported that optimal water use can enhance returns from System of Rice Intensification with enhanced labour productivity and far higher net income than traditional methods for the cultivation of rice. The findings of the present study are consistent with Andrianaivo's analysis and that of many other studies.

Table 3. *Economic and water productivity of paddy cultivation with drip irrigation systems over conventional system*

Treatments	Annual cost of cultivation ($/ha/year)	Gross monetary return ($/ha/year)	Net monetary return ($/ha/year)	Benifit:Cost ratio
T_1	1125	2170	1045	1.92
T_2	920	2769	1849	3.00
T_3	822	4782	3960	5.81
T_4	796	4562	3766	5.73
T_5	782	4041	3258	5.16

Assumptions: Revenue received is $ 667 per tonne of grain produced, and Rs. 17 per tonne for straw yield, based on prevailing market prices

Conclusions

The present study found consistent evidence that the adoption of drip irrigation combined with paddy transplanted and managed according to System of Rice Intensification practices offers substantial agronomic and economic advantages. Plant growth and yield-contributing parameters such as effective tillers, number of panicles m^{-2}, and grain yield were found to be significantly higher in drip-irrigated treatments. Apart from higher yield, water productivity and water-energy productivity were both higher in the case of drip-irrigated paddy cultivation with young single seedlings transplanted at 30 x 30 cm spacing with drip emitters spaced at 20 cm.

Among the drip-irrigated treatments, there was no significant difference in grain yield between the T3 and T4 treatments which indicate that spacing drippers at 30 cm can be recommended as the cost of installing a drip system would be relatively cheaper with more widely-spaced drippers. These results should be further tested with further experimentation and evaluation because the implications of this work could be rather far-reaching. The evidence assembled and analyzed here suggests that System of Rice Intensification crop management with drip irrigation is a promising adaptation for reducing the rice-crop's demand for water and energy, which are increasingly demanded and costly, while at the same time it raises grain yield. However, long-term, multi-location trials will be needed to arrive at percentages of water and energy saving that are achievable under varied and specific conditions.

Acknowledgements. Authors would like to extend their gratitude to the Director, CIAE, and the Head, Irrigation and Drainage Engineering Division, CIAE, Bhopal for permitting them to do this research work on drip irrigated rice crop management. Authors are also grateful to Dr. Norman Uphoff, Cornell University, US, for his valuable inputs in finalizing the manuscript.

Conflict of Interest: The authors declare that they have no conflict of interest.

Abstract. The results of reservoir water supply optimal dispatching depend to a great extent on the prediction of uncertain factors. Aiming at the problems of reservoir runoff forecast, an artificial neural network based on ant colony optimization is presented. The perturbation strategy is added in this new hybrid algorithm, the improvement ant colony optimization can combine the strong memory and associative ability of artificial neural network with positive feedback of ant colony optimization, and can overcome the shortcomings in the respect of lack of pheromone at initial stage and easiness of local optimization of ant colony optimization. It is applied to six reservoirs optimization water supply dispatching in the lower Luan he river. A practical example shows that this new hybrid algorithm is rational, reliable and high accuracy when it is used to solve the problem of reservoir runoff forecast, at the same time, the training precision is high. So, this new algorithm is applied to forecast the reservoir runoff.
Keywords: *back-propagation neural network; uncertain factors; water supply dispatching; perturbation strategy; Luan he river*

Introduction

The forecast of reservoir flow forecasts the hydro-logical regime in the future, which is mainly based on the hydro-logical and meteorological data and adopts the methodology of physical analysis and statistics. The traditional forecasting models mainly include genetic analysis and hydro-logical statistics. In recent years, with the development of computer technology, the methods of hydro-logical forecasting (Wan et al., 2016; Wei et al., 2013; Chang et al., 2013; Ahmad et al., 2017) mainly include chaotic analysis, grey system prediction, extension classified prediction method, artificial neural network method, wavelet analysis and the mixture of these methods. In this paper, we use the strong memory of neural network, positive feedback of association ability and ant colony algorithm, at the same time, we get rid of such problems as lacking information pheromone in the initial stage, getting trapped in a local optimum easily of ant colony algorithm in solving the model. In ant colony algorithm, we increase perturbation strategy, combine neural network and ant colony algorithm organically to propose a neural network algorithm based on ant colony optimization, forecasting reservoir runoff.

Back-propagation neural network based on ant colony optimization

BP algorithm (Mohammad et al., 2013; He et al., 2014; Maryam et al., 2016) has the following advantages in theory, simpler network construction, strong memory and association ability, more stable state (Li et al., 2008; Wang and Zhang, 2010). But in the practical application of hydro-logic forecasting, there are some problems. The input of the new sample has an impact on the studied samples. We rely on experience to select the weights of the initial value and the number of neurons (Yi et al., 2013; Yang et al., 2016). Ant Colony Optimization or ACO (Qun et al., 2013; Kwang et al., 2014; Kleinkauf et al., 2015; Zhao et al., 2016; Vijay et al., 2016), is a probabilistic search algorithm with the advantages such as being parallel, positive feedback, strong robustness and excellent distributed computer system and so on.

Optimization model

In view of the above problems, the BP neural network is improved as follows: combining weights and parameters (A-BP) by using ACO and BP network, the network is trained, the training samples were normalized.

Basic principles of neural networks

Artificial neural network or ANN (Chen and Chang, 2009; Zhao et al., 2009), a nonlinear information parallel processing system (He et al., 2014; Shafaei and Kisi, 2014; Gharibreza, 2017) for simulating the structure and function of the neural network of the human brain, is composed of a large number of processing units (artificial neural networks) connected to each other and into the network, which has the characteristics of self-learning, self-adaptation, self-organization and so on (Khan et al., 2017). The neural network model was applied to the concept of energy function present a method for judging the stability of network in 1982, at the same time, it puts forward the concept of hidden unit. the weight adjusted error Back-Propagation algorithm for mufti- layer feed forward network was proposed In 1986, so that the research of artificial neural network is further studied. This kind of feed-forward network based on BP algorithm, generally called BP network, is one of the most popular neural networks currently. It can be used to approach the complex nonlinear function with high precision, which has the advantages such as simpler network construction, strong memory and association ability, more stable state.

The structure of BP neural network

BP network is generally composed of an input layer, an output layer, one or more of the hidden layer. There are a number of nodes in each layer. *Fig. 1* is the structure of BP network.

With an input layer of neurons, a hidden layer of neurons, an output layer of neurons. $x_1, x_2, \ldots, x_n$ are the input of the neural network, $y_1, y_2, \ldots, y_l$ are the output of the neural network? The information in the hidden layer can be used as input information in a non-linear way, and the output layer is transmitted to the output layer. The hidden layer is usually generated by the excitation function output information. Its excitation function is generally used Sigmund function. The information in the input layer must be transmitted to the hidden layer. The calculation process of BP network is composed of two parts, the forward calculation process and the reverse calculation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_497510

process. Firstly, the input layer, hidden layer and output layer are calculated by layer by layer, then the output of the sample is get Secondly, the error between the expected sample output and the neural network calculation results is calculated by the error calculation formula. Finally, according to the error to adjust the network weight, the connection weights are corrected by the forward and backward, until the error meets the specified requirements.

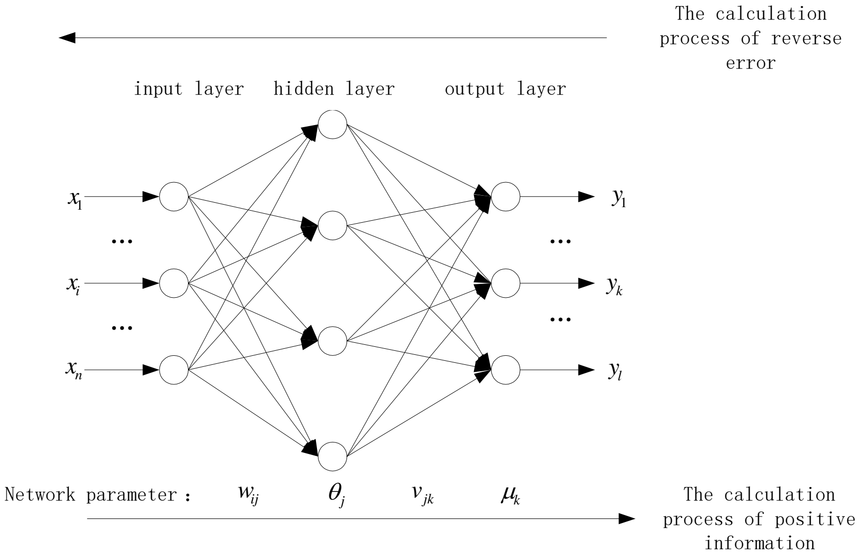

Figure 1. *The structure of BP Neural network*

(1) Random generation of initial threshold and weight

After determining the number of input layer neurons of BP neural network structure, the number of hidden layer neurons, the number of neurons in the output layer (n, m, 1). According to the basic principle of neural network, the parameters of neural network include the weights $w_{ij}(i = 1,2,\ldots, n; j = 1,2,\ldots, m)$ from the input layer *i* to the hidden layer unit *j*; activation threshold $\theta_j(j = 1,2,\ldots, m)$ of hidden layer units *j*; the connection weights $v_{jk}(j = 1,2,\ldots, m; k = 1,2,\ldots, l)$ of the hidden layer units *j* to the output layer units k; activation threshold $\mu_k(k = 1,2,\ldots, l)$ of output layer cell k .The initial weights of the network are generally randomly generated between [-1, 1].

(2) Output of Q training samples

Suppose there are training sample, the input $x_{iq}(i = 1,2,\ldots, n)$ of the first sample q $(q = 1,2,\ldots, Q)$ is transferred to the hidden layer. The output information h_{jq} of the hidden layer h_{jq} is obtained by the activation function $f_1(s)$.

$$h_{jq} = f_1(s_{jq}) = f_1\left(\sum_{i=1}^{n} w_{ij}x_{iq} - \theta_j\right) \qquad j = 1,2,\ldots, m; q = 1,2,\ldots, Q \quad \text{(Eq.1)}$$

Activation function generally selects Sigmoid function.

$$f(s) = \frac{1}{1 + e^{-x}} \quad \text{(Eq.2)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_497510

The output information h_{jq} of the hidden layer h_{jq} is transferred to the output layer, and the network output O_{kq} is obtained.

$$O_{kq} = f_2(r_{kq}) = f_2\left(\sum_{j=1}^{m} v_{jk} h_{jq} - \mu_k\right) \qquad k = 1,2,\ldots,l;\ q = 1,2,\ldots,Q \quad \text{(Eq.3)}$$

(3) Error calculation

There are usually some errors between the expected value y_{kq} and the output O_{kq} of the neural network. The error function $E(q)$ of the sample *Q* can be expressed as:

$$E_q = \frac{1}{2q}\sum_{q=1}^{Q}\sum_{k=1}^{l}\left(O_{kq} - y_{kq}\right)^2 \qquad k = 1,2,\ldots,l;\ q = 1,2,\ldots,Q \quad \text{(Eq.4)}$$

If the error meets certain accuracy requirements, the network learning ends, otherwise the network weights and thresholds are adjusted according to the error.

(4) To adjust the weights and threshold

The number of neurons in the neural network has been determined; it can reduce the error through the adjustment of threshold value and weight to have achieved the goal of improving the accuracy of calculation. w can be modified, Because the error function E_q changes along with the negative gradient w, so the correction value is Δw.

$$\Delta w(t+1) = w(t+1) - w(t) = -\eta \frac{\partial E_q}{\partial w} \quad \text{(Eq.5)}$$

In the formula, η is the learning rate, the range is from 0 to 1. w is certain weight or threshold.

Under normal circumstances, if η becomes larger, although the convergence of the network is fast. There will be oscillations; if η becomes smaller, the convergence of the network becomes slower. In order to avoid this situation, we can by inertia factor α, its values range from 0 to 1, which is analysed by (5).

$$\Delta w(t+1) = -\eta \frac{\partial E_q}{\partial w} + \alpha \Delta w(t) \quad \text{(Eq.6)}$$

For hidden layer:

$$\frac{\partial E_q}{\partial \theta_k} = \delta'_{jq} = f_1'(s_{jq}) \cdot \sum_{k=1}^{l} \delta_{kq} v_{jk}, \qquad \frac{\partial E_q}{\partial w_{ij}} = -\delta'_{jq} x_{iq} \quad \text{(Eq.7)}$$

Therefore, from the input layer to the hidden layer weights, the hidden layer threshold of the modified formula is:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_497510

$$\Delta w_{ij}(t+1) = \eta\delta'_{jq}x_{iq} + \alpha\Delta w_{ij}(t) \quad \text{(Eq.8)}$$

$$\Delta\theta_j(t+1) = -\eta\delta'_{jq} + \alpha\Delta\theta_j(t) \quad \text{(Eq.9)}$$

For output layer neurons:

$$\frac{\partial E_q}{\partial \mu_k} = \delta_{kq} = (y_{kq} - O_{kq})\cdot f'_2(r_{kq}), \qquad \frac{\partial E_q}{\partial v_{jk}} = -\delta_{kq}h_{jq} \quad \text{(Eq.10)}$$

Therefore, the correction formula from the hidden layer to the weight of the output layer and the threshold of output layer is:

$$\Delta v_{jk}(t+1) = \eta\delta_{kq}h_{jq} + \alpha\Delta v_{jk}(t) \quad \text{(Eq.11)}$$

$$\Delta\mu_k(t+1) = -\eta\delta_{kq} + \alpha\Delta\mu_k(t) \quad \text{(Eq.12)}$$

After adjusting the weights, if the error does not meet the accuracy requirements, the procedure (2) is transferred to calculation, until the error meets the specified accuracy requirements.

The basic principle of ant colony optimization algorithm

Ant Colony Optimization or ACO, an optimization algorithm (Blum and Dorigo, 2004; Du et al., 2014) based on ant foraging principle, has the advantages (Deng and Peng, 2010; Yuan and Qu, 2013) such as parallel, positive and negative feedback, strong robustness and excellent distributed computer system. In initial time, the pheromone equals on all paths, the pheromone trail intensity $\tau_{ij}(0) = C_0$ (C_0 is a constant) from the nest i to the food source j. In the course of the movement, the ant $k(k = 1,2,\ldots, m)$ decides the direction of the transfer according to the amount of information on each path. At the moment of t, the transition probability $P_{ij}^k(t)$ of the ant k in the path i and the path j is:

$$P_{ij}^k(t) = \begin{cases} \dfrac{\tau_{ij}^{\alpha}(t)\eta_{ij}^{\beta}(t)}{\sum\limits_{s\in allowed_k}\tau_{is}^{\alpha}(t)\eta_{is}^{\beta}(t)}, & j \in allowed_k \\ 0, otherwise \end{cases} \quad \text{(Eq.13)}$$

In the formula, $allowed_k = \{0,1,\ldots, n-1\}$ is the next step to allow the ant k to choose the target; τ_{ij} is pheromone trail strength of edges (i, j); η_{ij} is heuristic factor for edge (i, j), P_{ij}^k is transition probability for the ant k , α, β are two parameters. The relative importance of the information and heuristic information accumulated during the process of the ants in the selection of ants reflected respectively. The amount of pheromone on each path is adjusted according to the following formula.

$$\tau_{ij}(t+1) = (1-\rho)\tau_{ij}(t) + \rho\Delta\tau_{ij}(t,t+1) \quad \text{(Eq.14)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_497510

$$\Delta\tau_{ij}(t,t+1)=\sum_{k=1}^{m}\Delta\tau_{ij}^{k}(t,t+1) \tag{Eq.15}$$

In the formula, $\Delta\tau_{ij}^{k}(t,t+1)$ is the pheromone of the ant k to stay on the path (i,j) at all times of $(t,t+1)$. The value depends on the merits and virtues of the ants. The shorter the path is, the more pheromone releases. $\Delta\tau_{ij}(t,t+1)$ is increment of the pheromone amount of the loop path (i,j). ρ is attenuation coefficient of pheromone. Usually, we set $\rho < 1$ to avoid an unlimited increase in the amount of path on the path.

In this paper, we will use the random perturbation strategy to prevent the stagnation of ant colony algorithm. The random selection probability needs to adjust dynamically. Approximate optimal solutions are obtained. The calculation time is shortened and the calculation efficiency is improved.

The ants' choices of their paths are random. Generally, they choose the path of transition probability, but the optimal path is not always selected, which results in a subsequent search for stagnation. Because the current optimal path information is more than the fact that doesn't find the optimal path pheromone number, with the increase of the number of iterations, the actual optimal path is less and less, so the probability of choosing this path becomes smaller and smaller. Considering the stagnation of the algorithm as well as based on the characteristics of the above ants in the choice of path at the same time, "disturbance factor" will be added to interfere with the ant selection path. The pheromone is not the most path to a certain probability of random selected, this path may be the best. At the same time, the probability of random selection in evolutionary computation which needs to be adjusted dynamically to increase the diversity of the selected paths, but the probability of the maximum path of the pheromone is calculated separately to prevent leakage of the optimal paths. The transition probability of the perturbation strategy can be formulated as follows:

$$C_{ij}^{k}=\begin{cases}\dfrac{(\tau_{ij}\eta_{ij})^{\gamma}}{\sum\limits_{s\in allowed_k}\tau_{is}^{\alpha}(t)\eta_{is}^{\beta}(t)} & \tau_{ij}\in\max\{\tau_{is}\}, s\in allowed_k\\ \dfrac{(\tau_{ij})^{\alpha}\cdot\eta_{ij}}{\sum\limits_{s\in allowed_k}\tau_{is}^{\alpha}(t)\eta_{is}^{\beta}(t)} & \tau_{ij}=\tau_{is}-\max\{\tau_{is}\}, p\le p_m, s\in allowed_k\\ \dfrac{\tau_{ij}\cdot(\eta_{ij})^{\beta}}{\sum\limits_{s\in allowed_k}\tau_{is}^{\alpha}(t)\eta_{is}^{\beta}(t)} & \tau_{ij}=\tau_{is}-\max\{\tau_{is}\}, p> p_m, s\in allowed_k\\ 0 & otherwise\end{cases} \tag{Eq.16}$$

In the formula, γ is a reverse exponential perturbation factor; $p_m\in(0,1)$ is random mutation rate; p abides to the uniform distribution of random variables. The formula indicates that ants in an iterative process can choose a number of paths. The formula (Eq.13) is used to calculate the transition probability on the path of the pheromone. In a random choice, we can calculate the transition probability on the alternative paths, the perturbation strategy is a combination of random selection and deterministic selection. The random selection makes the choice of the path and the calculation of the strong randomness, deterministic choice refers to the path that the ant will choose the most transition probability.

Methods solution

The training samples were normalized

Because the input of the physical quantity is not the same, so the difference is very big, so the input data should be normalized before calculating to convert it from0 to 1 (logarithmic S curve). Normalized change is according to the following formula:

$$T = T_{\min} + \frac{T_{\max} - T_{\min}}{X_{\max} - X_{\min}}\left(X - X_{\min}\right) \quad \text{(Eq.17)}$$

In the formula, X is original input data. X_{max}, X_{min} are the maximum and minimum values respectively. T is transformed data, T_{max}, T_{min} are the maximum and minimum values settled respectively. T_{max} usually takes the rang from 0.8 to 0.9, T_{min} is 1- T_{max}.

Ant colony algorithm (ACO) to optimize the BP network

Firstly, ant colony algorithm is used to optimize the initial weights and network structure of BP neural network. The hydrological forecasting model is established. The network training and fitting experimental data should be gotten. Then the algorithm is applied to train the network samples so that the network output error is minimized. The effective improvement of BP neural network can easily fall into the local minimum value and the convergence speed is slow and all so defects. Suppose there are m parameters to be optimized of BP neural network, the parameters are arranged in order: $p_1, p_2, \ldots\ldots p_m$. According to any parameter, initialization N any nonzero value, the set I_{pi} is constituted. Suppose the ant number is S, all ants search for food by randomly selected element from first set, then return to the nest after finding food. Repeat this step, until all ants collect the same route, the optimum solution is obtained of this network. The specific calculation steps are as follows:

Step1: The BP neural network model is established, including the number of network layers, the number of nodes, the range and the sample size to be optimized.

Step2: Initialize ant colony. The parameters are uniformly dispersed. Initialization the path that according to discretize data. Then the complete path is established. The Pheromone trail intensity is $\tau_{ij}(0) = C_0 (C_0 is \text{ constant})$. The combination of discrete points of each parameter is defined as the path of ants that is a solution to the problem.

Step3: Cyclic iteration of ant colony algorithm. At the end of each iteration, generate random numbers q of the range from 0 to 1, make a comparison of explored relative importance threshold value $q_0 (0 \le q_0 \le 1)$ of the new path with the prior knowledge. If $q \le q_0$, the parameters of each weight are randomly variant according to the formula (Eq.16), random mutation is for new weight discrete points to get added to the collection S. If $q \ge q_0$, select the weight according to the formula (Eq.13).

Step4: All ants set out from set I_{pi}, follow the path rule to find element in order, finally the food source is found. The rule of route choice is: All ants *k (1,2,……M)* arbitrary choose j^{th} with certain probability. The probability formula:

$$\Pr ob(t_j^k(I_{pi})) = (t_j(I_{pi})) / \sum_{u=1}^{N} t_u(I_{pi}) \quad \text{(Eq.18)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_497510

Step5: When all the ants are *completed*, we input training sample. According to the formula (Eq.14) (Eq.15), the weight parameters were updated.

Step6: A set of the best weights that find by the ant colony algorithm are used as the initial weights of the BP algorithm. The error between the network output and the actual output is calculated. And the error is propagated from the output layer to the input layer, adjust weights, if the error reaches a predetermined precision or satisfy the maximum iterations number T, the algorithm is over. Otherwise, re-select ant colony to Step2.

The flowchart of an artificial neural network based on ant colony optimization is described in *Figure 2*.

Case study

The LuanHe River is rich in water resources in Northern China. The total precipitation ranges between $129\times10^8m^3$ and $12.7\times10^8m^3$, and has uneven distribution of inter-annual variations, with characteristic of a typical semi-arid and semi-humid region. The lower LuanHe River is the most important source that supply water to TianJin and TangShan which face severe challenge of the imbalance between supply and demand of water resource the situation is aggravated day by day. Five reservoirs have been constructed and are delivering an annual flow of 2873 million cubic meter water into the cities. The annual water deficiencies are 1025 million cubic meters. The flow supplies water for agricultural, industrial and municipal uses.

Each reservoir’s characteristics are as follows:

PanJiaKou reservoir is a carryover storage reservoir with total storage capacity is $29.3\times10^8m^3$, and its regulating the function is perfect; DaHeiTing reservoir is located in the PanJiaKou reservoir downstream, which is a annual regulation reservoir, and the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_497510

total storage capacity is $3.37\times10^8m^3$; YuQiao reservoir is a larger-scale reservoir in TianJin, and total storage capacity is $15.59\times10^8m^3$; QiuZhuang reservoir which is an intermediate regulation reservoir and Taolinkou reservoir belong to QinHuangDao. To augment the water supply in the basin and to keep up with the increasing demand, inter-basin transfers have been implemented, by bring them into full play in a multiply connected reservoirs. The main project characteristic indexes of each water supply reservoir are described in *Table 1*.

Table 1. *Main project characteristic indexes of each water supply reservoir (Unit: 10^8m^3)*

Reservoirs		Dead storage	Active storage	Total storage	Water supply task
Donor reservoirs	PanJiaKou	3.31	19.50	29.30	No direct user, supply water to recipient reservoirs
	DaHeiTing	1.13	2.07	4.73	
Recipient reservoirs	YuQiao	0.36	3.85	15.59	Supply water to Tianjin of industry and domestic life
	QiuZhuang	0.008	0.65	2.04	Supply water to Tangshan of industry and domestic life
	Taolinkou	0.51	7.09	8.59	Supply water to Qinhuangdao of industry, domestic life and agriculture of lower LuanHe river

Results and discussion

Neural network model based on ant colony optimization makes a prediction of the runoff in the lower reaches of the Lutheran River Reservoir. Select Panjiakou Reservoir, Daheiting and Taolinkou Reservoir respectively (Given the limited space available, prediction of bridge reservoir, the results of Qiuzhuang reservoir and Yuqiao reservoir are not listed.) The research object is the data of inflow runoff in the 26 year. January in 1975 to December in 1995 as a training sample and regard data for network fitting test of 5 years from January in 1996 to December in 2000 as network fitting test (Ghosh and Dash, 2017).

Design guidelines for ACO-BP neural networks: The data is first trained by ACO algorithm, after training is completed, then the neural network is trained by the BP algorithm, the learning rate of BP algorithm is as small as possible so as to perform fine search behavior, the number of training of BP algorithm as much as possible not to exceed the average absolute error, the maximum relative error and mean square difference of 1000 times, because most of the global search work has been completed by the ACO algorithm, the BP algorithm only needs to perform a more detailed local search of the search's finishing work. BP neural network training

Parameters set as follows: the maximum number of training to take 800, learning efficiency to take 0.1, learning output error target to take 0.001. The ant colony algorithm is initialized as follows: the number of ants is 50, the important factor of pheromone is 1, the importance factor of the heuristic function is 5, the pheromone factor is 0.1, and the maximum number of iterations is 200, as shown in *Figs. 3-8*.

The Panjiakou Reservoir from the year 2001 to 2005 of annual runoff were predicted and compared with the actual value. The forecast effect is shown in *Fig. 8*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_497510

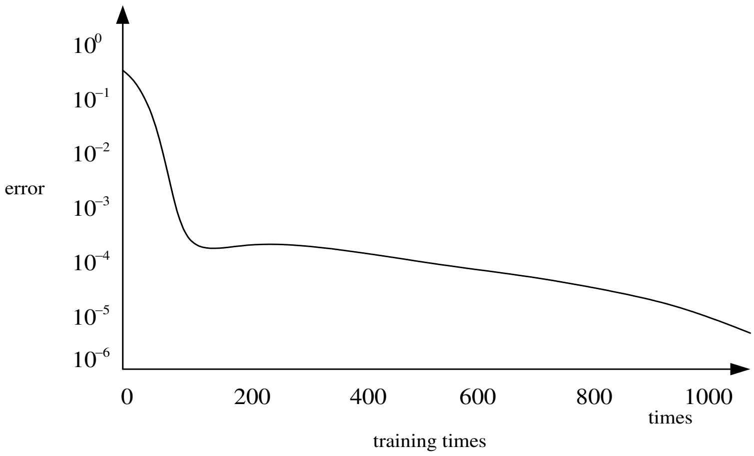

Figure 8. *The figure of error changing about network model trained values*

The analysis of *Figure 8* shows, the BP neural network model based on ant colony optimization is reasonable and reliable.it can make a prediction of reservoir runoff; According to the result of calculation Formula (4), the error between the fitting results and the measured values is compared within 10%. It shows that the training accuracy is higher and can meet the demand, so the runoff of the reservoir can be predicted.

In order to explain the prediction effect of different algorithms, the average absolute error (AAE), maximum relative error(MRE) and root mean square (RMS) are proposed.

$$AAE = \frac{1}{n}\sum_{k=1}^{n}\left|x_k - x^{'}\right| \quad \text{(Eq.19)}$$

$$MRE = \max\left|x_k - x_k^{'}\right| \quad \text{(Eq.20)}$$

$$RMS = \sqrt{\frac{\sum_{k=1}^{n}\left(x_k - x_k^{'}\right)^2}{n}} \quad \text{(Eq.21)}$$

In the formula, x_k is the network output value; $x_k^{'}$ is the true value; n is the total number of sample. The error comparison of several algorithms is described in *Table 2* with Panjiakou reservoir.

Table 2. *The error comparison of several algorithms with Panjiakou reservoir*

Difference algorithms	*AAE*	*MRE*	*RMS*
BP	6.24	9.62	7.63
PSO-BP	5.38	8.35	6.32
ACO-BP	4.25	7.01	5.24

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_497510

Through the comparison of error indicators which include average absolute error, maximum relative error and root mean square difference, etc, we can see from *Table 2*, the optimized BP neural network algorithm based on ant colony algorithm proposed in this paper has better fit performance and predictability, mainly because the PSO algorithm in the context of the search cannot easily find the local optimization, and easy to fall into them, so the accuracy of its operation is not very satisfactory. In the search process, it will find the optimal value, but there is no guarantee that this is the global optimal, the ant colony algorithm is relatively good in this respect. Thus, the optimized BP neural network algorithm based on ant colony algorithm improves the accuracy of hydrological prediction to reduce the error.

Conclusions

In this paper, the ant colony optimization algorithm is introduced into the neural network. Random disturbance strategies are added. In this paper, we make full use of the strong memory and associative ability of neural network as well as the characteristics of state stability and the local search ability of ant colony algorithm. At the same time, we get rid of such problems as lacking information pheromone in the initial stage, getting trapped in a local optimum easily of ant colony algorithm in solving the model, improving the accuracy of calculation. The algorithm is applied to the prediction of runoff in reservoir. The error between the fitting results and the measured values is compared to get the result within 10%, which is able to meet the requirements. In this paper, the neural network model based on ant colony optimization is reasonable and reliable, which can predict reservoir runoff, training accuracy is higher, so we can predict the runoff of the reservoir. In spite of this, the forecast of uncertain factors such as reservoir runoff are uncertain, but in the actual operation, water and water has great randomness, so we need further stud the real-time forecasting of reservoir runoff.

Abstract. Zinc is one of the heavy metal in plants that causes toxicity at high concentration via producing Reactive oxygen species. Nitric oxide can protect cells from oxidative stress produced by reactive oxygen Species. Effect of different concentrations of Zn (0, 100, 300 and 500 μM) and interaction with sodium nitroprusside (SNP, a donor of NO) (100 and 200 μM) were studied on growth parameter (total dry Weight) and some physiological factors (chlorophyll a, chlorophyll b, hydrogen peroxide and malondialdehyde contents), antioxidant enzymes (catalase, peroxidase, ascorbate peroxidase and Superoxide dismutase) in *Plantago major* L. Excess Zn reduced dry weight and chlorophyll content, resulting a decrease in photosynthesis. Zn stress induced the production of hydrogen peroxide (H_2O_2), leading to malondialdehyde (MDA) accumulation. Furthermore, it was found that the activities of antioxidant enzymes in Zn-treated plants such as superoxide dismutase (SOD) and ascorbate peroxidase (APX) were decreased but peroxidase (POD) and catalase (CAT) were increased. The use of NO especially in low concentration reversed Zn-induced negative effects whereas high concentration of NO had no obvious alleviating effect on Zn toxicity in *Plantago major* L. In particular, application of 100 μM SNP could mitigate Zn stress, as a defense mechanism of the plant against Zn toxicity.
Keywords: *heavy metal stress, sodium nitroprusside, antioxidative enzymes, ROS, hydrogen peroxide*

Introduction

Zinc is an essential nutrient element for plants, as it is the component of many proteins like Zn finger-containing transcription factors, carbonic anhydrase, Cu/Zn superoxide dismutase and Zn metalloproteases (Broadley et al., 2007). Many of these proteins have critical roles in the uptake and transport of Zn, transcriptional regulation, RNA binding, regulation of apoptosis and protein–protein interactions (Ciftci-Yilmaz and Mittler, 2008). Zn toxicity can result in nutrient imbalance and induce the generation of excess reactive Oxygen species (ROS) (Wang et al., 2009). The excessive formation of ROS can oxidize various cellular components, resulting in lipid peroxidation, membrane leakage, and enzyme inactivation, which can finally lead to oxidative injury and alteration in the cell structure (Romero-Puertas et al., 2007).

Plants have many detoxification and tolerance mechanisms that mitigate and repair the ROS damages. One of these mechanisms includes antioxidant systems, which help them, survive in the altered environment. Antioxidant enzymes like superoxide dismutase (SOD), ascorbate peroxidase (APX), Catalase (CAT) and guaiacol peroxidase (POD), as well as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_511524

antioxidant concentrations, like ascorbic acid, are activated by plants to alleviate oxidative stress (Tewari et al., 2008).

NO is an essential signaling molecule which modulates plant resistance to various abiotic stresses (Yu et al., 2014). NO is a highly reactive, membrane-permeable free radical that has recently emerged as a very important signaling molecule and antioxidant which triggers several types of redox-regulated (defense-related) gene expressions, directly or indirectly, to establish plant stress tolerance (Sung and Hong, 2010). The application of an NO donor, SNP, confers tolerance to various abiotic stresses in plants by enhancing their antioxidant defense system (Xu et al., 2010).

Several lines of study have shown that the protective effect of NO against abiotic stress is closely related to the NO-mediated reduction of ROS in plants (Hasanuzzaman et al., 2010). Exogenous application of SNP enhances plant tolerance to heavy metals (Oliviera et al., 2016) and oxidative stress (Esim and Atici, 2013). A recent report showed that NO was associated with long-term Zn tolerance in *Solanum nigrum* (Xu et al., 2010). NO involved on detoxification of H_2O_2 via modulation of antioxidant enzymes such as catalase (CAT),peroxidase (POD) and ascorbate peroxidase (AXP) and keeping of cell redox couple and non-protein antioxidant including thiol, ascorbate (Tewari et al., 2008). It also has been evidenced that NO stimulated the biosynthetic pathway of glutathione (GSH) in plant cells with an enhanced tolerance against oxidative stress (Xiong et al., 2010).

Plantago major is a medicinal herb with potent antioxidant effect .It belongs to the family of Plantaginaceae and is widely found in Europe and Asia in which Malaysia is one of the countries of its Habitat (Beara et al., 2009).

Nevertheless, the influence of exogenous NO on Zn stress tolerance in *Plantago major* plants is not yet fully understood. The present study was carried out to assess the impact of exogenous NO on reducing Zn toxicity in *Plantago major* L.

Materials and Methods

Plant material and culture conditions

Plantago major L. seeds were sterilized with 5% sodium hypochlorite for 15 min and washed extensively with distilled water, then germinated on moist filter paper in the dark at 27°C for one week. Then, seedlings of uniform size were transferred to plastic pots filled with perlite (2 plants per pot) and irrigated by distilled water for 10 days. The seedlings were then nourished with half-strange Hoagland solution for three weeks, during 3 leaves stage irrigation was continued with half-strange Hoagland solutions containing different concentrations of ZnSO4 (0, 100, 300 and 500 μM) and sodium nitroproside (0, 100 and 200 μM) alone and together for two weeks. The experiment was carried out under a controlled environment, day/night temperature of 27/18°C and 65 ± 5% relative humidity. For the estimation of plant dry matter content, the plants were dried at 80°C for 48 h, to give a constant weight.

Determination of photosynthetic pigments

The photosynthetic pigments (chlorophyll a and b) was determined as per the method of Lichtenthaler (1987). Chlorophyll of experimental plant was extracted with 80% acetone and centrifuged. Supernatant was taken and optical density was measured at 663 nm, 645nm. The chlorophyll a and b was calculated by Eq.1 and 2.

$$\text{Chlorophyll a } (\mu g/ml) = 12.21 \times A663 - 2.81 \times A645 \quad \text{(Eq. 1)}$$

$$\text{Chlorophyll b } (\mu g/ml) = 20.13 \times A645 - 5.03 \times A663 \quad \text{(Eq. 2)}$$

where A is the observed OD.

Determination of lipid peroxidation

Lipid peroxidation was determined by measuring MDA, a major thiobarbituric acid reactive species (TBARS), and product of lipid peroxidation (Heath and Packer 1968). Samples (0.2 gr) are ground in 3 mL of trichloroacetic acid (0.1%, w/v). The homogenate was centrifuged at 10,000 g for 10 min and 1 mL of the supernatant fraction was mixed with 4 mL of 0.5% thiobarbituric acid (TBA) in 20% trichloroacetic acid (TCA). The mixture was heated at 95°C for 30 min, chilled on ice, and then centrifuged at 10,000 g for 5 min. The absorbance of the supernatant was measured at 532 nm. The value for non-specific absorption at 600 nm was subtracted. The amount of MDA was calculated using the extinction coefficient of 155 mM^{-1} cm^{-1} and expressed as nmol g^{-1} FW.

Estimation of hydrogen peroxide (H_2O_2)

H_2O_2 concentration from leaf samples was measured according to the procedure of Velikova et al. (2000). Fresh leaf tissue (0.5 gr) was homogenized with 5 mL of 0.1% (w/v) (TCA) in a pre-chilled mortar and pestle and the homogenate was then centrifuged at 12,000 g for 15 min. To 0.5 mL of the Supernatant, 0.5 mL of 10 mM potassium phosphate buffer (pH 7.0) and 1 mL of potassium iodide (1 M) were added. The mixture was vortexed and its absorbance was read spectrophotometrically at 390 nm.

Determination of antioxidant enzymes

For extraction of antioxidative enzymes, leaves and roots were homogenized with 50 mM Na2HPO4-NaH2PO4 buffer (pH 7.8) containing 0.2 mM ethylene diamine tetra acetic acid (EDTA) and 2% insoluble polyvinylpyrrolidone in a chilled pestle and mortar. The homogenate was centrifuged at 12,000 g for 20 min and the resulted supernatant was used for the determination of enzyme activities. The whole extraction procedure was carried out at 4°C. SOD activity was assayed by measuring its ability to inhibit the photochemical reduction of nitroblue tetrazolium following the method of Stewart and Bewley (1980). CAT activity was measured as the decline in absorbance at 240 nm due to the decrease of extinction of H_2O_2 according to the method of Patra et al. (1978). POD activity was measured by the increase in absorbance at 470 nm due to guaiacol oxidation (Nickel and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_511524

Cunningham, 1969). APX activity was measured by the decrease in absorbance at 290 nm as ascorbate was oxidized (Nakano and Asada, 1981).

Statistical analysis

All data presented here are the mean values of three independent experiments with three replicates. All results were analyzed statistically by two-way ANOVA with SAS 9.1.3 software and means were compared with the LSD test ($P < 0.05$).

Results

Biomass

Effect of different concentrations of Zn (0, 100, 300 and 500 µM) and interaction with sodium nitroprusside (100 and 200 µM) on plant growth, expressed as the total dry weight shown in *Table 1*. Zn exposure inhibited the growth of *Plantago major* significantly compared with control (Zn0Snp0), however, this inhibition was alleviated by the additions of 100 µM SNP. When applying 200 µM SNP into Zn-treated solution, Zn-induced inhibition on plant growth was not mitigated and the total dry weight reduced (*Table 1*).

Photosynthetic pigments (chlorophyll a and b)

A significant decrease in chlorophyll a and b contents was observed in the leaves of *Plantago major*, which were exposed to Zn stress. Compared with Zn-stressed plants, the addition of 100 µM SNP alleviated Zn toxicity in the photosynthetic apparatus. Whereas high concentration of SNP (200 µM) had no alleviated effects on the Zn-decreased chlorophyll contents (*Table 1*).

Hydrogen peroxide content

H_2O_2 content in leaf and roots of *Plantago major* was increased depending on Zn concentrations. Under SNP concentrations, H_2O_2 content was decreased in low concentration and increased in high concentration of SNP. However, interactions between Zn and SNP concentrations showed that under Zn concentrations, the additions of SNP 100µM inhibited Zn-induced H_2O_2 generation significantly (*Table 1*). This result indicates that the accumulation of H_2O_2 can reflect the oxidative stress and the changes of antioxidant in plants and indicates that low concentration of NO acts as an efficient ROS scavenger.

Malondialdehyde content

In the present study, the concentration of MDA was significantly increased ($P<0.05$) by Zn treatments in leaf and roots, which indicated an enhanced level of lipid peroxidation in metal-exposed plants. Under SNP concentrations, MDA content increases with increasing SNP concentrations. The application of SNP to Zn treatments shows that the low concentration of SNP (100 µM) can alleviate the effects of Zn stress on lipid peroxidation (*Table 1*).

Means followed by the same letter are not significantly different (P < 0.05).

Peroxidase enzyme activity

According to *Figs. 1* and *2*, leaf and root POD enzyme activity increased significantly (at 0.05 level) under Zn stress condition. Under SNP concentration enzyme activity increased significantly (at 0.05 level) in 100 µM and decreased significantly (at 0.05 level) in 200 µM. Interaction between Zn and SNP shows that enzyme activity increased significantly in Zn+SNP100 µM and decreased significantly in Zn+SNP200 µM. It seems that NO in low concentration can improve negative effects of Zn stress (*Figs. 1* and *2*).

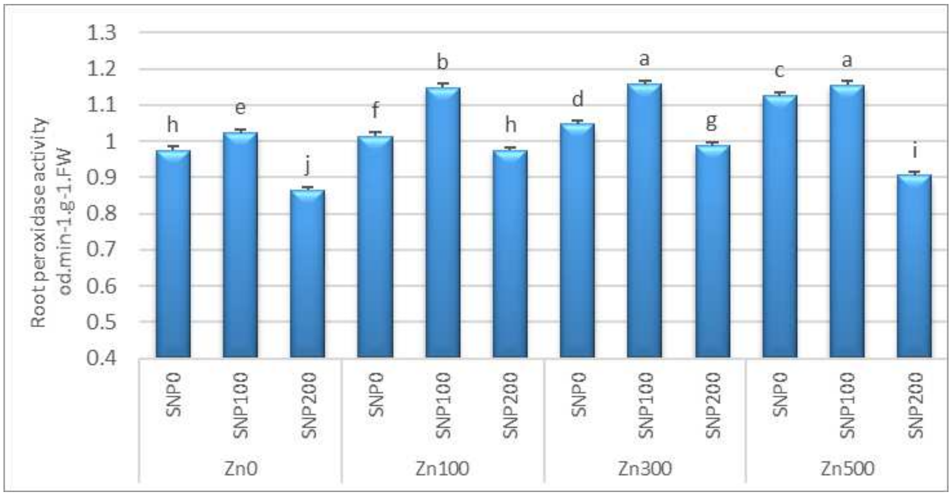

Figure 2. *Effects of different concentrations of SNP on peroxidase activity in root of Plantago major under Zn stress (P<0.05)*

Catalase enzyme activity

CAT enzyme activity increased significantly (at 0.05 level) under Zn stress condition compared with the control plant .Under SNP condition, there was decrease in SNP200 compared with SNP100. Generally, Zn treatment induced the activities of CAT in shoot and root of *plantago major* but this increase was found reversed in 200 µM SNP treatment (*Figs. 3* and *4*).

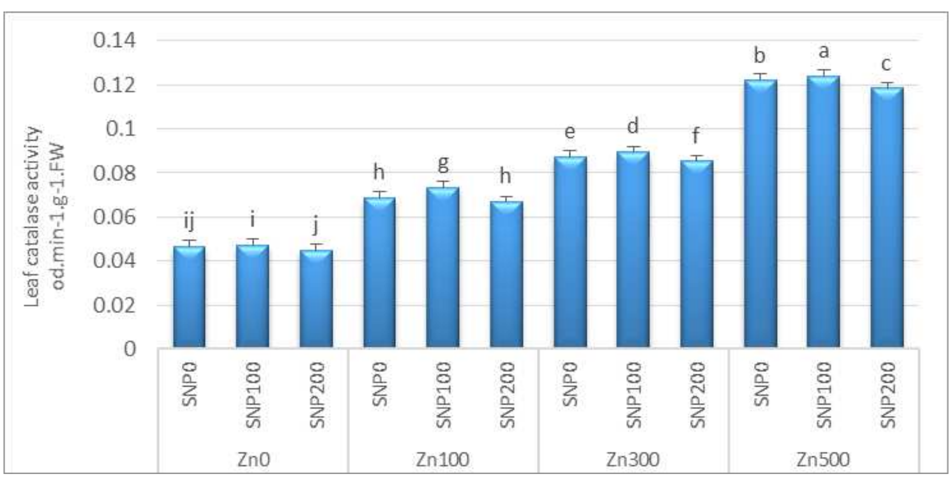

Figure 3. *Effects of different concentrations of SNP on catalase activity in leaf of Plantago major under Zn stress (P<0.05)*

DOI: http://dx.doi.org/10.15666/aeer/1504_511524

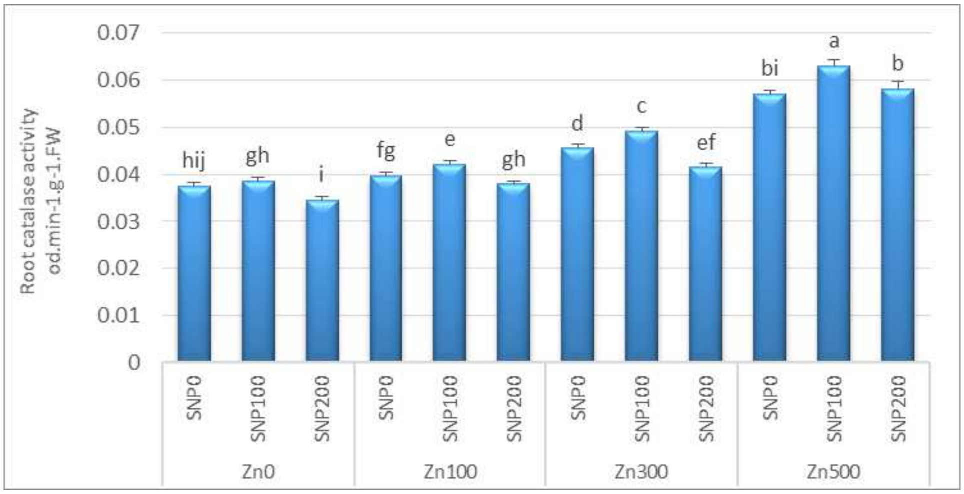

Figure 4. *Effects of different concentrations of SNP on catalase activity in root of Plantago major under Zn stress*

Ascorbate peroxidase enzyme activity

Leaf APX enzyme activity decreased significantly (at 0.05 level) with an increase of Zn concentrations. Under SNP concentration, the maximum activity of enzyme was found in Zn+SNP100 and the minimum activity was identified in Zn+SNP200 (*Fig. 5*). Root APX enzyme activity under Zn stress increased significantly (0.05 level) from Zn0 to Zn100 and decreased significantly (0.05 level) with elevated concentrations of Zn. In addition, under different concentrations of Zn treatments and SNP, showed that enzyme activity significantly decreased (0.05 level) in Zn+SNP200 and significantly increased (0.05 level) in Zn+SNP100 (*Fig. 6*).

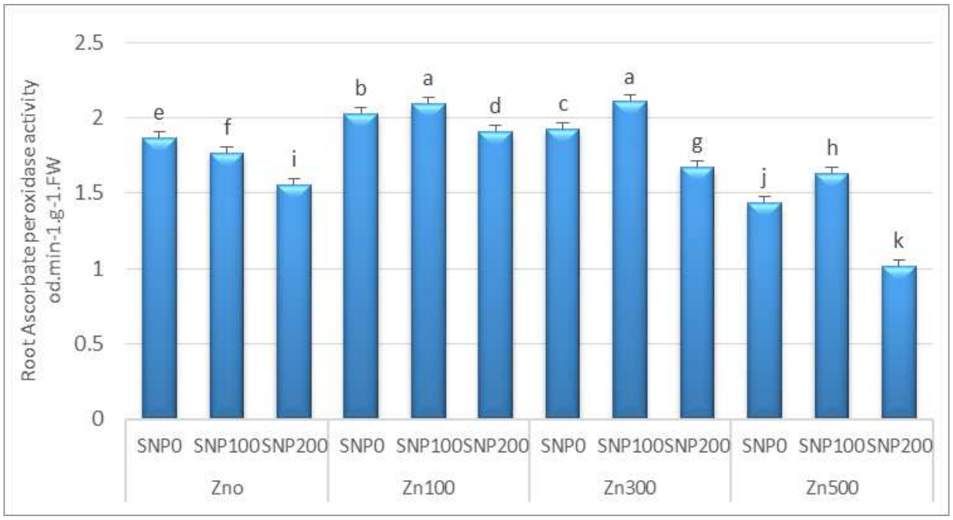

***Figure 6.** Effects of different concentrations of SNP on ascorbate peroxidase activity in root of Plantago major under Zn stress*

Superoxide dismutase enzyme activity

In leaf and root of *Plantago major*, the highest level of SOD activity was seen at 100 µM concentrations of Zn. Under SNP concentration, enzyme activity decreased significantly (0.05 level) by increasing SNP. Application of SNP to Zn concentrations shows that the highest level of activity was seen at Zn (0,100,300,500) +SNP100 and the lowest level of activity was seen at Zn (0,100,300,500) +SNP200. Hence, SOD activity was decreased depending on Zn concentrations, but the application of SNP200 µM caused a significant increase in SOD activity (*Figs. 7* and *8*).

Discussion

In our research, different NO concentrations were applied in Zn-treated growth medium. We investigated the physiological specifications of *Plantago* under Zn stress by using different NO concentration, aiming at finding a suitable concentration of NO to alleviate Zn toxicity effectively. The results of the present study indicated that application of Zn (100, 300 and, 500 µM) especially concentration of 500 µM decreased the dry weight of *Plantago*. However, simultaneous application of low concentration of NO (100 µM) increased the dry weight. Zn-induced growth inhibition was reflected by total dry weight. Inhibition of growth in *Plantago* plants might be the result of Zn caused variation of metabolic processes, such as oxidative damage, nutrient uptake and photosynthesis. Sheldon and Menzies (2005) reported similar results on Rhodes grass. However, Zn-induced inhibition was significantly reduced by the lower concentration of No. The mitigation effect of lower concentration of NO might be that NO induced the improvement of in photosynthesis by increasing chlorophyll content, counteracted oxidative damage by decreasing the generation of ROS. When the higher NO concentration was applied in *Plantago* plants, the mitigation effect was not obvious.

In this study, chlorophyll content showed maximum at 100 µM of Zn and it was decreased beyond that concentration. The decrease in chlorophyll content is believed to be because of: (1) inhibition of enzymes associated with chlorophyll biosynthesis (John et al., 2009); (2) inhibition of uptake and transportation of other metal elements such as Mn and Fe by adversary effects (Jayakumar et al., 2009; John et al., 2009). These results are in agreement with Yuanjie et al. (2013) who reported that Cu significantly decrease total chlorophyll, chl. a and b as compared with the control. The applications of different concentrations of SNP changed the chlorophyll contents in ryegrass. In another research, a similar reduction in total chlorophyll content under heavy metal toxicity was observed in *Atriplex halimus* (Brahim

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_511524

and Mohamed, 2011) and tobacco plants (Kheiry et al., 2016). Similar decrease in chlorophyll content under Cu stress was reported in *Atriplex halimus*. Our results shows that the application of exogenous NO at lower concentration (100 µM) alleviated Zn-induced decrease in chlorophyll content. Our results indicated that NO mediated improvement of chlorophyll contents played a role in the enhancement of photosynthesis.

As an active redox metal, Zn is able to induce the overproduction of ROS, such as hydrogen peroxide (H_2O_2), which in turn lead to lipid peroxidation and oxidative stress (Zhang et al., 2009). Results of this study showed that high concentrations of Zn, especially in 500 µM induced over accumulation of H_2O_2 and MDA in leaves and roots, leading to the oxidative damage in *Plantago* plants. However, application low concentration of NO (100 µM) alleviated H_2O_2 under Zn stress, protected cell membrane from peroxiding and decreased the accumulation of MDA. Similar to our results an increase in MDA and H_2O_2 content under excess nickel has been reported in *Eleusin*e *coracana* L. (Viswanath et al., 2016).

The levels of lipid peroxidation in the plant cells are measured by the determination of their MDA content, a breakdown product of lipid peroxidation. A high level of MDA is expressive of an enhanced formation of ROS and oxidative damage. In fact, ROS delete hydrogen from unsaturated fatty acids and generates lipid radicals and reactive aldehydes, which distort the lipid bilayer (Mishra et al., 2006). The results in the present work are in adaptation with the explanation of Panda et al. (2003), who reported heavy metal induced oxidative stress in Wheat leaves cell. Zhang et al. (2014) investigated that excess Zn altered the redox status of the aquatic plants (*Hydrilla verticillata*). In support, Chao et al. (2008) reported rapid generation of H_2O_2 by Zn-treated plant cells.

To cope with ROS and alleviate their toxic effects, plants have different antioxidation mechanisms (mediated by both enzymatic and non enzymatic antioxidants) operational in them to take care of the deleterious ROS (Puthur, 2016). Antioxidant system plays an important role in plant tolerance to stress conditions, which is based on the fact that the activity of one or more of these enzymes or antioxidant substances in general increase in plants when exposed to stressful condition and these enhances are related to increased stress tolerance (Fecht-Christoffers et al., 2003).

In our experiment, results shows that activities of antioxidant enzymes such as SOD and APX were decreased with increasing Zn concentrations but POD and CAT were increased. However, supply of exogenous NO, mainly 100 µM improved the Zn-alteration on antioxidant enzyme activity, which played a role in alleviating Zn-induced oxidative damage. Many studies have found a decrease (Malar et al., 2014) or increase (Xu et al., 2014) in activity of antioxidant enzymes under metal stress.

Previous reports revealed a variable response of an increase or decrease in SOD activity in plants exposed to different metals including Zn (Dixit et al., 2001). SOD is an essential component of antioxidant defense system in plants and it dismutase two superoxide radicals to water and molecular oxygen (Magdy and Azooz, 2013). A reduction in SOD activity in the metal treated plants has been attributed to an inactivation of the enzyme by H_2O_2 that is formed in different cellular compartments where SOD catalyzes the scavenging of superoxide radicals. SOD activity has been reported to increase under Zn toxicity (Kupper et al., 2007). Increase in SOD activity in response to stress appears to be probably due to de-novo synthesis of the enzymes protein (Erdei et al., 2002). Magdy and Azooz (2013) indicated that Zn treatment induced the activities of CAT and APX in shoots of *Hibiscus*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_511524

esculentus. CAT is universally present oxidoreductase that decomposes H_20_2 to water and molecular oxygen and it is one of the key enzymes involved in removal of toxic peroxides. CAT along with APX and SOD are considered as vital enzymes within the antioxidant defense mechanism, which directly determine the cellular concentration of H_2O_2 (El-Shora, 2004). All the antioxidant enzymes studied in this work explain maximum activity in leaf compared to roots. It might be due to translocation of Zn in aerial parts as a micronutrient and this augmented the concentration of antioxidant enzymes in leaf compared to roots. The increased antioxidant enzyme activity might be ascribed to the role of NO in stimulating the expression of their genes (Xiong et al., 2010; Shi et al., 2016). Two mechanisms, which may explain NO protective action against oxidative damage, have been reported. Firstly, NO might detoxify ROS directly, such as superoxide anion, to form peroxyntrite, which is less toxic and thus limit cellular damage (Martinez et al., 2000). Secondly, NO could function as a signaling molecule, which activates the cellular antioxidant system (Lamattina et al., 2003). In the present study, the application of high NO concentration did not reduce Zn-induced ROS damage, even produced more toxic effects in *Plantago major.* However, the effects of NO depend on its concentration. Lamattina et al. (2003) reported that NO might regulate the expression of antioxidative genes to stimulate the relative enzyme activities. NO-mediated increase in one or more of these antioxidant enzymes contributed to the enhancement of antioxidative ability. Such results suggested that the protective effects of NO on oxidative damage were partly related to its role in up-regulating antioxidative ability. Universally, NO, as a recognized regulator of protein activation by S-nitrosylation, might inactivate heavy metal by modification of phytochelatins or some other ligands containing SH-group (Fecht-Christoffers et al., 2003). Finally NO can function as a signaling molecule for the cascade of events that lead to changes in gene expression under risk element stress (Procházková et al., 2012).

In conclusion ,our results demonstrated that in the hydroponics experiment, the alleviation effects of NO on Zn stress in *Plantago* needed a suitable concentration and the lower concentration of NO (100 μM) had a higher protective effect on Zn toxicity, while high concentration of NO (200 μM) did not alleviate Zn toxicity effectively. Our study proved that exogenous NO at low concentrations increased Zn tolerance in *Plantago* grown in Zn–mediated nutrient solution by (1) improving antioxidant enzyme activities and protecting against Zn–induced oxidative stress, (2) reversed the Zn toxicity effect and decreased the MDA content and H_2O_2 accumulation. This indicates that NO acts as an efficient ROS scavenger and membrane stabilizer in *Plantago* plants exposed to Zn stress.

Abstract. The Antarctic and the Southern Ocean are a critically important part of the Earth system. The climatic, physical, and biological properties of this region are closely linked to other parts of the global environment. 200 years of direct human impact, recent climate amelioration and changes in the main sources and circulation of biogenic compounds as well as accumulation of industrial contaminants have significantly affected the whole ecosystem. Particularly sensitive is the region of the Western Antarctic Peninsula, which is considered to be one of the hot spots of the Earth. In this paper, we review recent literature and compare it with historical data to estimate and predict the consequences of this process. The Antarctic ecosystems can no longer be regarded as pristine. Global as well as local human influence has transgressed the barriers isolating that continent from the rest of the World, causing previously observed changes to accelerate.

Introduction

The specificity of Antarctic conditions

Antarctica is surrounded by the Southern Ocean. Together they occupy about one-third of the southern hemisphere. The Antarctic continent and associated islands are situated at a distance of nearly 1000 km from South America and of 4000–5000 km from Australia and South Africa. The isolation process began with the breakup of Gondwana and was enhanced and then maintained by the development of the atmospheric Polar Vortex and oceanic Antarctic Polar Front (Clarke et al., 2005; Barnes et al., 2006). Terrestrial ecosystem development is limited to only 0.34% of ice-free areas of the whole surface of Antarctica, mainly concentrated on coastal zones of the

DOI: http://dx.doi.org/10.15666/aeer/1504_525539

Antarctic Peninsula (Convey et al., 2009). This region is characterized by insular occurrence of exposed ice-free grounds and also by patchy and discontinuous soil distribution, displaying one of the harshest environmental conditions found on Earth (Convey et al., 2014). Low temperatures, limited liquid water availability, a specific light regime, elevated ultraviolet-B radiation levels, desiccating and destructively strong winds, poorly developed soils with low organic matter and nutrient content, slow organic matter decomposition, irregular nutrient distribution (from nutrient-deficient habitats to the ones extremely enriched in nutrients by e.g. huge breeding colonies of seabirds), high salinity in many locations (due to marine influences), the presence of permafrost, freeze–thaw events, cryoturbation, solifluction or ablation significantly limit the development of terrestrial communities (Chwedorzewska, 2009; Convey et al., 2014). Thus, characteristic features of Antarctic organisms are high stress tolerance, wide ecological amplitude but with minor competitive ability or investment in dispersal strategies, reduced reproductive investment and output, and extended lifespans and life cycles (Convey, 1996, 2000). Variability in abiotic conditions is recognized as a key feature affecting organism responses (e.g. Tufto, 2000). Antarctic terrestrial organisms display biochemical, physiological and anatomical adaptations that allow them to withstand prolonged periods of freezing, desiccation and abrasion (Olech, 2004; Giełwanowska and Szczuka, 2005; Wasley et al., 2006; Ochyra et al., 2008).

Most taxa are represented in the Southern Ocean, with Antarctica's shelf waters are particularly rich in this regard (Brey et al., 1994; Clarke and Johnston, 2003; Siciński et al., 2011). Moreover, biomass and productivity of both oceanic and near shore systems are massive. The Antarctic marine environment is certainly characterized by extreme physical characteristics, most notably low water and air temperatures, annual extremes in light regime, wind speeds, disturbance and isolation. Yet, the Southern Ocean is the most thermally stable environment on Earth. Sea temperature fluctuation in Antarctica is seasonal, but unlike other environments, temperatures are remarkably stable in winter. Salinity in the Southern Ocean is also highly constant, even in near shore waters. The constraints for marine life are characterized by resource limitation associated with strong seasonality (Peck et al., 2005). Phytoplankton growth is restricted to a maximum of 3–4 summer months. Thus, the phytoplankton-dependent organisms endure a winter of low food supply. Unlike terrestrial species, marine organisms do not freeze and must, therefore, maintain physiologically active tissues throughout the year, utilizing strategies that minimize losses in winter (Peck et al., 2006).

Literature review

Climate change in the Antarctic

Climate change in Antarctica has been characterized by regional differences. So far the Western Antarctic Peninsula – the repository of most Antarctic terrestrial biodiversity is warming rapidly (Nicolas and Bromwich, 2014), partly due to the southern shift in the polar jet stream (fast flowing, narrow, meandering air current located near the altitude of the tropopause and westerly winds; Robinson and Erickson, 2014).

Temperature and water availability are the most important factors for the biology of Antarctic terrestrial organisms. Thus, even a small shift, especially in precipitation and liquid water availability, may have a profound biological impact on sensitive polar ecosystems (Chwedorzewska, 2009). Especially the maritime Antarctic region experiences the most pronounced and rapid changes regarding those factors. The

DOI: http://dx.doi.org/10.15666/aeer/1504_525539

temperature records collected in the Antarctic Peninsula region during the last fifty years show its warming by about 0.5°C per decade (Bromwich et al., 2013). This recent rapid regional temperature increase has caused glacier retreat (Smith et al., 1999), snow cover reduction (Fox and Cooper, 1998), an increase in the duration of the warm period and in the number of cumulative days with temperature above 0°C (Vaughan, 2006). Earlier spring thaws and later autumn freeze may have already significantly extended the vegetation season. Climate warming is also associated with an increase in availability of liquid water, which is more important for terrestrial communities than the increase in temperature alone. There were also changes in cyclonic activity patterns around the Antarctic, followed by changes in precipitation intensity and form (precipitation increasingly occurs as rain) (Bromwich et al., 2013; Kennedy, 1993; Quayle, 2003) with noticeable increase in total precipitation during the year (Turner et al., 2005). Beside direct precipitation, water availability in terrestrial habitats is governed by seasonal snow and glacial melt. In a range of maritime Antarctic sites, rapid rates of glacial melting and loss of 'permanent' snow banks have been observed (e.g. Fox and Cooper, 1998; Quayle, 2003). The increase in temperature cause rapid and earlier snow and ice cover melting, thus may exhaust freshwater reserves before the end of the vegetation season, increasing the risk of local drought. Furthermore, as the warming increases the frequency of winter thaws, it may lead to sub-snow ice layer formation on the ground surface, which has a destructive impact on terrestrial organisms (Arnold et al., 2003). Recently, a rapid glacier retreat in the whole Antarctic Peninsula region has been observed, causing emergence of vast postglacial areas (Favier et al., 2014). Permafrost is a very characteristic feature of Polar Regions. It restricts the water exchange to the active layer that thaws on a seasonal basis. Vegetation, the active layer, and the underlying permafrost are strongly linked, being key components of terrestrial ecosystems. Permafrost warming and active layer thickening were mainly attributed to mean air temperature rise, although in several cases the role of snow cover, soil properties and the overlying vegetation was emphasized (Romanovsky et al., 2010; Guglielmin et al., 2014). Over shorter timescales, the rise in temperature can have a strong effect on permafrost degradation. Withdrawal of permafrost due to warming increasingly contributes to nutrients loads in the subsurface waters. Soil frozen for thousands of years releases both water and nutrients, therefore seasonally the melt water can be extremely rich in biogenic elements, mainly phosphorus (Hobbie et al., 1999). Increased nutrient inflow has the potential to alter trophic interactions in Antarctic terrestrial ecosystems (e.g. Laybourn-Parry, 2003; Nędzarek et al., 2014). Deglaciation, intensification of weathering processes and permafrost decline, along with changes in the abundance of breeding populations of birds and pinnipeds (which have direct impact on the amount of nutrients transferred onto the land from the sea) cause dynamic changes in nutrient distribution and availability (e.g. Clarke et al., 2007; Smale and Barnes, 2008; Montes-Hugo et al., 2009). All those changes lead to a disturbance of terrestrial and freshwater communities, causing biodiversity decrease or/and changes in species composition. Huge amounts of meltwater coming from glaciers alter the freshwater balance in terrestrial ecosystems and at the same time generate an inflow of large amounts of nutrients to the sea. It also reduces the salinity of water in the coastal marine zone. Melting glaciers are causing a huge inflow of mineral suspension into the sea that results in silting of the bottom and affects the benthic communities as well as production of phytoplankton. At open sea, changes in the range of sea ice cover have been observed, which is also linked with the phytoplankton and zooplankton

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_525539

productivity (Clarke et al., 2007; Smale and Barnes, 2008). Furthermore, glacial meltwaters carry a substantial load of microbial cells. Castello and Rogers (2005) suggest that between 1 x 10^{17} and 1 x 10^{21} viable microorganisms are liberated each year by global glacier melt. Those microbes may have a profound influence on the composition of terrestrial and marine microbial communities, either by addition of highly competitive opportunists or providing genes of adaptive value (Świątecki et al., 2010; Dziewit et al., 2013; Zdanowski et al., 2013).

Global human impact

Antarctica is an area least affected by anthropogenic activity. However, recent regional rapid warming events of Western Antarctica have indicated that this area is as much affected by the impact of greenhouse gases like carbon dioxide, methane, nitrous oxide, ozone and chlorofluorocarbons as any other global site (Bargagli, 2008). Anthropogenic climate change not only directly affects the environment but also exerts other stressors.

The Southern Ocean circulation is a physicochemical boundary that isolates Antarctica from other oceans, therefore volatile contaminants reach Antarctica mainly via atmospheric transport from lower latitudes (Wania and Mackay, 1993; Wania, 2003; Choi et al., 2008). In the continental Antarctic, dense and cold air masses flow (katabatic winds) towards the coast. The katabatic drainage flow is compensated by the high troposphere air flow from the mid-latitudes, which also transports pollutants. This long-distance transport is affected both by circumpolar low-pressure systems and by the high pressure system over the Antarctic plateau (Shaw, 1998). This way, many Persistent Organic Pollutants (POPs) such as hexachlorobenzene, hexachlorocyclohexanes, aldrin, dieldrin, chlordane, endrin and heptachlor entered Antarctica and the Southern Ocean (e.g. www.unep.org). Snow precipitation is a very efficient mechanism for cleaning the air of airborne contaminants since snow can collect those compounds, transport them to the ground and accumulate in successive layers. Global distillation or fractionation by condensation in cold environments have been proposed as mechanisms whereby the Polar Regions may become sinks for some POPs (Wania and Mackay, 1993). Degradation of deposited POPs is very slow in the Polar Regions due to low temperatures and winter darkness. Most of the POPs get entrapped and incorporated into the Antarctic ice cap (Bennett et al., 2015).

POP concentrations in Antarctic organisms were generally low as compared to those reported for marine and terrestrial species at lower latitudes, and they are still among the lowest in the world. Yet, POPs are recorded in every level of the trophic chain and the phenomenon of biomagnification plays a more important role than the bioaccumulation itself (Szopińska et al., 2016), due to specific physiology and ecology of Antarctic organisms, especially their longer life spans. Top predators have a high risk of becoming sinks for POPS. Indeed, in some species the levels reported were occasionally high and comparable to those found in regions with a strong human impact (Corsolini, 2009).

Direct human impacts

Antarctica never had indigenous human populations. However, over the last 200 years, exploitation, exploration and research along with recent regional climate changes have significantly affected this remote region (Chwedorzewska, 2009). Some aspects of previous human disturbance of the Antarctic marine ecosystems still have particularly important implications, like the nineteen to mid-twentieth century commercial

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_525539

exploitation of fur seals and whales, which led to almost total extinction of these species in the Southern Ocean (Fraser et al., 1992).

In the last three decades, sudden development of scientific and tourist activity have been noted (Montes-Hugo et al., 2009; Chwedorzewska and Korczak, 2010). Every year a considerable number of tourists visit Antarctica, particularly the Antarctic Peninsula region (*Figure 1*). Combined with a number of scientific expeditions accompanied by huge amounts of cargo and equipment, human activity exerts noticeable impact on terrestrial ecosystems (Chwedorzewska and Korczak, 2010; Hughes et al., 2012). This activity requires the use of generators and heavy vehicles as well as construction of buildings, landing strips, roads, fuel reservoirs, etc. Waste disposal and incineration, sewage management and fuel combustion are further points of concern. Supply delivery to the stations, which usually takes place at the beginning of the Antarctic summer, are logistically complicated operations which require the use of heavy marine and land machinery to transport up to several thousand tons of cargo (Rakusa-Suszczewski and Krzyszowska, 1991). These procedures can have a strong effect on surrounding ecosystems, locally generating chemical pollution and directly damaging or altering soil, vegetation and freshwater ecosystems (Hale et al., 2008).

The highest impact has been reported around large stations like McMurdo Station, Ross Island (US Antarctic research centre) (Mazzera et al., 1999; Negri et al., 2006), whereas, according to research which has continued since the 1990s, the impact of small sized stations is rather minor (Rakusa-Suszczewski and Krzyszowska, 1991; Bargagli et al., 1998). Human activity associated with scientific research bases as well as with tourism concentrates mainly on small coastal ice-free areas with favourable topography and good microclimate condition (Rakusa-Suszczewski and Krzyszowska, 1991; Terauds et al., 2012) with developed tundra communities, and animal gathering sites (mainly huge breeding areas of sea birds and pinnipeds) (Chwedorzewska and Korczak, 2010). This combination indicates sites of high ecological value and sensitivity, which drastically magnifies the risk of deleterious human impacts.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_525539

Biological contamination

Human presence in the Antarctic also brings other threats, potentially even more dangerous for the ecosystem than POPs. Climate change along with increased human activity in this region create opportunities for some outside species to invade and colonize maritime Antarctic (Hughes and Worland, 2010; Hughes et al., 2012; Chwedorzewska et al., 2015). In spite of the significant number of tourists visiting the Antarctic Peninsula region (www.iaato.com), the main colonization events seem to be associated with the supply routes of polar stations rather than with tourism (Lee and Chown, 2009; Chwedorzewska and Korczak, 2010; Chown et al., 2012). Packing materials, vehicles, imported fresh foodstuffs, adhered soil, scientific equipment, building materials, clothing and footwear are considered as a potential vectors for alien species propagules (e.g. Lityńska-Zając et al., 2012; Augustyniuk-Kram et al., 2013; Chwedorzewska et al., 2013). On the other hand, due to amelioration of environmental condition of the Antarctic Peninsula region and changes in cyclonic activities (Kennedy, 1993), increased appearance of non-native birds species from lower latitudes was observed (e.g. Korczak-Abshire et al., 2011; Gryz et al., 2015) which can be responsible for the spread of alien propagules or/and pathogens threatening native species (Grimaldi et al., 2011).

Rapid changes in Antarctic terrestrial ecosystem

One of the most visible effects of climate change in the Antarctic Peninsula region is the fluctuation of sea ice coverage and dramatic glacier retreat (Bromwich et al., 2013). This process can lead to changes in ocean productivity, like alterations in plankton community composition and the most important changes in krill (*Euphausia superba*) recruitment and abundance (Ducklow et al., 2007). Krill, a key species of the whole Antarctic marine ecosystem, is also the biggest protein source in oceans and forms a critical trophic link between primary producers and upper-level consumers (fish, pinnipeds, cetaceans, and marine birds). Krill is also a very valuable commercial resource, intensively exploited from the early 70s (Nicol et al., 2012; Murphy et al., 2013). Stability of terrestrial communities is directly connected with constant supply of fertilizer from the sea - mainly droppings of breeding sea birds and pinnipeds (krill consumers). Population size fluctuations due to climate change (e.g. Korczak-Abshire et al., 2012; Korczak-Abshire et al., 2013) and fishery can directly influence terrestrial communities e.g. particularly the structure of ornithocoprophilous vegetation (Chwedorzewska and Korczak, 2010). Such fluctuation has been recently observed in Antarctic fur seals (*Arctocephalus gazella*), marked by a very rapid increase in population size to the levels that are greater than those existing before their exploitation in the nineteenth century. The presence of large numbers of fur seals on land has led to the rapid deterioration and changes in terrestrial tundra communities over large areas of ground accessible from the coast, where the majority of well-developed terrestrial ecosystems are found. It has also led to the rapid eutrophication of limnetic ecosystems accessible to the fur seals (Favero-Longo et al., 2011).

In the maritime Antarctic, development of terrestrial communities is controlled by extreme environmental conditions rather than biotic interactions. Those communities are expected to be very sensitive to changes in climate or consequential processes (Bargagli, 2005; Frenot et al., 2005). The consequences are thought to include increased diversity, biomass and trophic complexity, all of which enable development of a more

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_525539

complex ecosystem. Changes in the natural distribution ranges of native species or entire communities are also predicted. In the face of weakening natural barriers isolating Antarctica, it may be possible for single species or even whole communities to migrate from temperate zones to Polar Regions and shift the vegetation zones towards higher latitudes (Convey, 2006). Thus, most likely, further complications will arise from the complexity of species interactions. Some alien species transferred by humans may rapidly adapt to new conditions and engage in competition with native species (Molina-Montenegro et al., 2012). The most studied examples of such an event is the appearance and expansion of the annual meadow grass *Poa annua* (*Figure 2*) in the vicinity of the Antarctic stations situated along the Antarctic Peninsula (e.g. Wódkiewicz et al., 2013; 2014; Molina-Montenegro et al., 2014; Galera et al., 2015; 2016; Kellmann-Sopyła and Giełwanowska, 2015; Kellmann-Sopyła et al., 2015; Giełwanowska and Kellmann-Sopyła, 2015). While the contemporary Antarctic biota show the ability to survive abiotic environmental extremes, its competitive abilities are very poorly developed and even whole communities are vulnerable to increased competition of opportunistic invaders (Bargagli, 2005; Chwedorzewska and Bednarek, 2011; Hughes et al., 2012; Androsiuk et al., 2015).

Figure 2. *Poa annua in the vicinity of Polish Antarctic Station "Arctowski" on King George Island, South Shetland Islands, Western Antarctica (Photo: A. Znoj)*

Expansion of the distribution ranges of indigenous species within Antarctica is also possible, since two native Antarctic species have been already identified as having long-distance dispersal potential (Convey and Lewis Smith, 1993) and are the most studied examples of a biological response to the recent environmental warming in maritime Antarctic (Convey and Lewis Smith, 1993; Gerighausen et al., 2003). Some populations have already increased by two orders of magnitude in size during the last three decades, and there has been a change in the balance of reproductive strategy utilization towards

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_525539

successful sexual reproduction by increasing the probability of establishment of germinating seedlings (Convey, 1996; McGraw and Day, 1997). A rapid increase in the population size has also been observed amongst bryophytes and microbiota in maritime Antarctic (Convey and Lewis Smith, 1993; Green et al., 1999). The most unpredictable and difficult to monitor is the appearance of alien microorganisms, including pathogens able to cause an epidemic (Kerry et al., 1999). Pollution, increased connectivity, and global environmental change affecting pathogens and their vectors' migration at high latitudes are likely to drive future disease emergence in this region (Grimaldi et al., 2011).

The most dramatic effect of climate warming in maritime Antarctic is the rapid retreat of glaciers (Zdanowski et al., 2013). Glacier forefields experience one of the most important vegetation changes: colonization and primary succession of huge areas devoid of vegetation uncovered from under the ice (Olech et al., 2011). Ice cap reduction may also profoundly increase the amount of mobile POPs contaminants entrapped so far in glaciers (secondary source of pollutants). Glacial melt may carry those pollutants to nearby lakes or coastal marine zones, thereby spreading them and increasing their entry into trophic webs (Rakusa-Suszczewski and Krzyszowska, 1991; Corsolini and Focardi, 2000; Ainley et al., 2005) causing increased POP accumulation in long-lived Antarctic organisms (Walther et al., 2002).

Discussion

Entire Antarctica, governed internationally by the decisions of the Antarctic Treaty countries, has a status of a natural reserve. Members of the Antarctic Treaty, the Consultative Parties, have committed themselves to the comprehensive protection of the Antarctic environment. The Protocol on Environmental Protection to the Antarctic Treaty (also known as the Madrid Protocol or Environmental Protocol, http://www.ats.aq/e/ep.htm) entered into force in 1998. This document puts in place a framework for the protection of Antarctica's environmental, scientific, historic, wilderness and aesthetic values. However, the Antarctic Protected Area system (http://www.ats.aq/documents/recatt/Att004_e.pdf) is still immature and further implementation of the existing management tools may be required to protect the diverse range of vulnerabilities, qualities and spatial scales represented in different fields of science (e.g. Hughes et al., 2015, 2016).

Conducting research on such a complex and remote ecosystem needs critical comparison over a long period. The main problem is that scientific activity in the Antarctic is very recent, for example, the first very robust meteorological records came from the 1950s from Faraday Station and the first data on the occurrence of anthropogenic pollutants comes from the 1960s. There are a lot of gaps in data sequences. Due to high costs of expeditions and very harsh environmental conditions, vast areas are still unexplored, with some places inaccessible. The development of Antarctic research has been conducted in fact for only a few decades, over which analytical methods have undergone continuous changes, thus making comparison with the oldest data very hard and sometimes even impossible. Often, information is scarce or lacking very crucial data, for example data concerning the biology of the sampled species, lack of knowledge of baseline conditions or concurrent natural phenomena that mask their effects, also research results are presented in various units, which makes them difficult to compare (Szopińska et al., 2016).

Most importantly, in many fields, there is no proper long-term monitoring system, or it is only now being developing. Rapid changes in the Antarctic ecosystem are becoming a serious issue that needs to be more effectively investigated. In fact, in Antarctica, only the Commission for the Conservation of Antarctic Marine Living Resources (CCAMLR) manages sustainable fishery in this region, running very broad, long-term monitoring (CCAMLR Ecosystem Monitoring Program – CEMP), which started in the late eighties. CEMP's major function is to monitor the key life-history parameters of selected dependent species to detect changes in the abundance of those being harvested. ‘Dependent species’ are marine predators for which species targeted by commercial fisheries are a major component of their diet (https://www.ccamlr.org). Officially launched at the end of 2011 and still developing was the Southern Ocean Observation System (SOOS), which seems to fulfill the needs of a modern monitoring system. SOOS is an international initiative of the Scientific Committee on Antarctic Research (SCAR) and the Scientific Committee on Oceanic Research (SCOR). SOOS mission is to facilitate the collection and delivery of essential observations of dynamics and changes in the physical, chemical, geological and biological parameters of the Southern Ocean system to an all international scientific community to advance understanding of the Southern Ocean and to address critical societal challenges. The SOOS tries to develop a cyberinfrastructure, where marine assets would include a mixture of both autonomous and non-autonomous platforms. Combined with satellite remote sensing, the data would be relayed to ground stations in real time, where mathematical ocean models would produce near real-time state estimates of each of the parameters in the system (https://www.soos.aq).

Conclusions

Recent and historical selective overexploitation of some key species, unexpected increase in the population of some other, anthropogenic climate change, alien species pressure, local production and long distance transportation of pollutants, their accumulation in the ice cap and very slow degradation in polar conditions show that Antarctic ecosystems can no longer be regarded as pristine. Global anthropogenic activities along with local human influence weakened the barriers that isolate this continent from the rest of the world, causing an acceleration of the already observed changes. The main problem in such remote regions like Antarctica is that some consequences of human pressure may remain undetected because of the lack of monitoring systems, limited knowledge of baseline conditions or concurrent natural phenomena that mask their effects (Tin et al., 2014). Thus, it is very important to develop new effective monitoring systems. In Antarctica, the remote sensing techniques have opened up new opportunities for ecosystem monitoring. Satellites as well as manned and unmanned aircraft enable the collection of data from a local to global scale, which can be easily integrated with “ground” base data. The most promising seem to be very recent developments in the use of Unmanned Aerial Vehicles (UAVs) for remote sensing applications (e.g. Goetzendorf-Grabowski and Rodzewicz, 2016), which provide new opportunities for high-resolution ecosystem mapping and monitoring, but still, application of this technology to collect environmental data is a relatively new phenomenon in polar regions (e.g. Korczak-Abshire et al., 2016; Dąbski et al., 2017).

Abstract. In the context of habitat change, widely distributed vegetation can serve as relevant barometers of ecosystems' sensitivity or resilience to disturbances. This study analyzed morphological variations in trees and recruits density, individual size and their spatial structure through Haloxylon population's field experiment in each sampling location. Our results showed a significant decrease in tree density from the south (4445 trees/ ha) to the central desert (481 trees/ ha), whereas basal diameter, crown radius and height showed different tendency. Tree basal diameter and height structure of populations had positively skewed asymmetric distributions with "reverse J" shape. Tree density in the valleys between dunes (6133 trees/ha) was greatest. Few recruits were found in the central desert, but their density increased from central to south of the Gurbantunggut desert ,perhaps owing to seed rain patterns and availability of soil moisture and nutrients. Trees had a spatially clustered distribution in all study plots. Haloxylon spp. can tolerate wide climatic and habitat fluctuations, however recruitment can be unpredictable in harsh desert conditions. Soil physicochemical properties were the main ecological factor influencing spatial patterns. With increasing altitude, soil moisture and nutrient contents decreased significantly. In different dune habitats, Haloxylon population had different characteristics.
Keywords: *latitudinal variation; cluster; recruitment; morphological traits; spatial structure*

Introduction

Plant species with wide distribution ranges are exposed to a great variety of climatic and habitat conditions. Individuals and populations react to wide amplitudes of environmental factors through varying responses (Swenson and Enquist, 2007; Aitken et al., 2008; Wu et al., 2013). Developing broad adaptation strategies is particularly a requirement for species that are distributed along a large latitudinal gradient including both dry and humid areas (Aitken, 2008; Bognounou et al., 2009). Severe environmental degradation (e.g., decreases in river flows, a drop in underground water levels, overdevelopment in agriculture, overgrazing of animals, and mean temperature increases) has often led to an expansion of the desert area in the Gurbantunggut, causing high mortality in some woody desert species and radically changing their population structures (Huang et al., 2009; Allan et al., 2012; Si, 2010). The observed dwindling of natural Haloxylon forested areas has raised serious concerns for managers, scholars and scientists. One documented long-term consequence of anthropic disturbances is a shift

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_541559

in affected species' ranges (Lykke et al., 1999). However, although drought frequency and severity are predicted to increase across continental interiors, the consequences of these changes for dominant plant species are largely unknown (Mueller et al., 2005).

In the Gurbantunggut desert, there is little documentation of the distributions of plant species, and how these ranges are shaped by environmental factors is poorly understood (Qian et al., 2007). Several ecological investigations have examined the population structures and dynamics of some useful tree species in many parts of Asia and Africa, at both local (Nacoulma et al., 2011; Ivanov et al., 2008; Wu et al., 2013) and national scales(Sambare et al., 2011; Fandohan et al., 2011). However, few of these have specifically addressed widely distributed species in any great detail. This is the case for Haloxylon, that has an exceptional ecological amplitude, and includes the main woody species in central Asian desert ecosystems and artificial afforestation systems (Huang et al., 2009). It is also designated the king of psammophytic plants, owing to its important role in sand fixation, wind control and water conservation in the desert (Zhu et al., 2004). However, recent anthropogenic pressures, such as the expansion of agriculture, threaten both planted, artificial forests and natural populations of Haloxylon in China. Previous studies have suggested that Haloxylon needs effective conservation attention in natural stands in order to guarantee its persistence and to avoid a shortage of its products (Liang and Zhao, 1982). One of the main reasons for poor regeneration in Haloxylon is the high mortality of recruits (Si, 2010), likely because of very low water availability in soils. Understanding population patterns and underlying intrinsic characteristics is necessary for the conservation and sustainable management of widespread species distributed across biomes. Further more, the study of plant population characteristics is helpful for theoretical understanding of species coexistence and population structures, both of which are largely dependent on spatial patterns (Kikkawa and Anderson, 1984; Dale, 1999). Such quantitative and spatial patterns may be derived from processes and forces operating on different scales, such as heterogeneity in soil conditions, intra- and inter-specific competition, seed dispersal and other environmental factors (Jeltsch et al., 1999; Saei et al., 2014). For efficient conservation management of Haloxylon, detailed, large-scale analyses of its population ecology are necessary. The aim of this study was to document Haloxylon populations spanning a latitudinal gradient, from the extreme south of Gurbantunggut desert to the central desert. Specifically, we aimed to assess the structural patterns of populations spanning the latitudinal gradient; examine tree morphological traits (height, diameter, number of stems) across phytogeographical zones and analyze the spatial distribution patterns of Haloxylon individuals in natural stands.

Materials and methods

Study area

The study was conducted over the 2013 growing season, with three sampling transects situated in the Gurbantunggut desert (44º11'-46º 20'N, 84 31'-90 00'E), which is a part of Junggar Basin (*Fig. 2*) and has an area of 48 000 km^2. This desert is located in the hinterland of the Eurasian continent, within the Xinjiang region in northwest China. Haloxylon species are dominant components of the vegetation in the Gurbantunggut, as in all sandy and clay deserts across Central Asia. The desert is composed mainly of longitudinal dunes, although checkerboard- and honeycomb-shaped dunes are also present (Wang, 2003); he dunes vary in mobility from completely

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_541559

movable dunes, to semi-stable and stable dunes. The longitudinal dunes range in length from several hundred meters to tens of kilometers, have a height of 10-50 m, and generally run in a north to south direction (with the western slope very long and shallow, and the eastern slope short and steep) (Wang, 2002). Gurbantunggut desert has sandy soil and a continental, arid temperate climate, which is characterized by two contrasting seasons (cold winters and hot dry summers), owing to its great distance from the ocean. Seasons vary dramatically, with winter (December-February), spring (March-May), summer (June-August) and autumn (September-November) climatic conditions affecting plant growth cycles differently (Nyongesah and Wang, 2013). From 2003 to 2013, the coldest month is January (-19.50~-22.11℃) and the hottest month is July (23.13~27.69℃). The average annual temperature is 6.86~7.73℃. Precipitation ranges from 97.2 to 180mm, with winter and spring precipitation accounting for about two-thirds of the annual total (Qian et al., 2011). Moreover, precipitation varies spatially across the Gurbantunggut desert hinterland and surrounding areas (*Fig. 1*). The annual potential evaporation is 2000-2800mm (Song et al., 2011). Wind speeds are greatest during late spring each year, with an average velocity of 11.17m/s, and winds come predominantly from the west-northwest, northwest and north. Natural vegetation is sparse and the water table can be extremely deep (8-300m), although this is variable. In the study area, the vegetation is dominated by desert species, particularly Chenopodiaceae species, and species richness is relatively high. Common dwarf shrub and pygmy tree species include *Aristida pennata, Ceratocarpus arenarius, Ceratoides ewersmanniana, Ephedra distachya, Haloxylon ammodendron, Haloxylon persicum* and so on (Qian et al., 2003).

Sampling design

Combining recent field survey data with information on the distribution of dune types from previous reports (Liu and Zao, 2009), Google Earth was used to select three sampling transects among the longitudinal ridges from south to central Gurbantunggut Desert. The first transect was in a fixed dune-dominated area (F), the second a semi-fixed dune-dominated area (S) and the last a movable dune-dominated area (M); transects were 40km apart (*Fig. 2*). In each transect (1^{st} transect: 44º22'20.01N, 87º55'06.11E; 2^{nd} transect: 44º36'09.40 N, 88º14'17.83E; 3^{rd} transect: 44º56'52.01 N, 88º33'29.91E), four sampling locations were selected in accordance with the topographical characteristics of the dune: the valley between the dunes (valley), the east slope of the dune (leeward slope), the top (top) and the west slope (windward slope). Considering the dimensions of the sand dunes across transects, Haloxylon populations were surveyed in 10m×10m and 20m×20m main plots in each sampling location, with each main plot being associated with two sub-plots of 2 m×2 m to examine Haloxylon species regeneration patterns (individuals with dbh ≤ 0.3cm) and survey grass species. There were 20 main plots per transect which considered sufficient for reliable assessment of Haloxylon populations, according to previous prospecting of natural stands in the study area.

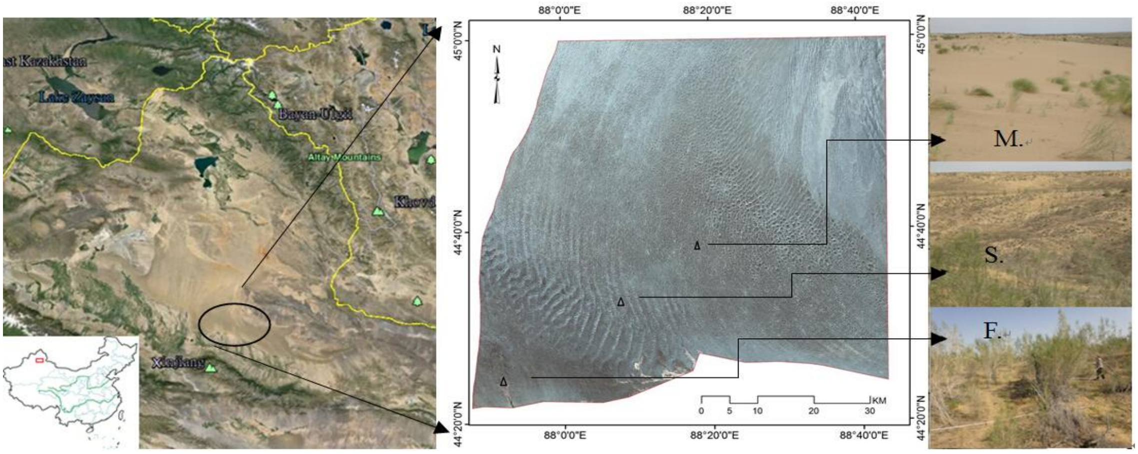

***Figure 2.** Position in the study area and sample design*

Habitat characteristics

The study area encompassed three different ecological (phytogeographical) zones (F, S, and M), covering different dune types (Liu and Zao, 2009), and an altitudinal gradient from north to central Gurbantunggut. The three different zones were comprised of different sizes of sand dunes with distinct vegetation coverage and sands of different particle sizes. Environmental data for each transect, including both climate and soil traits obtained from the nearest climate stations, are provided in *Table 1*. The extent of the snowy and rainy period varied slightly from north to central Gurbantunggut. As shown in *Table 1*, mean annual precipitation (data from 2000–2010) ranged from 110.4-128.6 (F) to 86-110 mm (M), and temperatures varied about 1-4°C (*Table 1*). The southern most edge of the fixed dune-dominated area (F) increased progressively in height towards the central desert, and hence soil available N, biomass, and organic carbon content, as well as conductivity, moisture and pH at 0-30cm soil depths

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_541559

decreased on average from the south (F) to the central (M) desert (*Fig. 3*). With the exception of electrical conductivity and effective N, soil parameters differed significantly among zones. According to survey data, there were more physical and biological crusts in the S versus F and M transect zones. Soil nutrient availability at the top of the dunes was significantly lower than in the other plot locations, whereas bottom plots (between the dunes) had slightly higher availabilities (*Fig. 3*). Soil moisture in bottom plots was significantly higher than in the other plot types (*Fig. 4*), and decreased from valley > east side> west side > top, which is consistent with previous reports (Li, 2013a). In the three transects, principal vegetation types included drought-tolerant plant species. The main human activities related to natural resource exploitation in the desert are agriculture and livestock farming.

Table 1. *Environmental factors describing the three different ecological/elevational study zones (fixed dune dominated desert area, F.; semi-fixed dune dominated desert area, S.; movable dune dominated desert area, M.)*

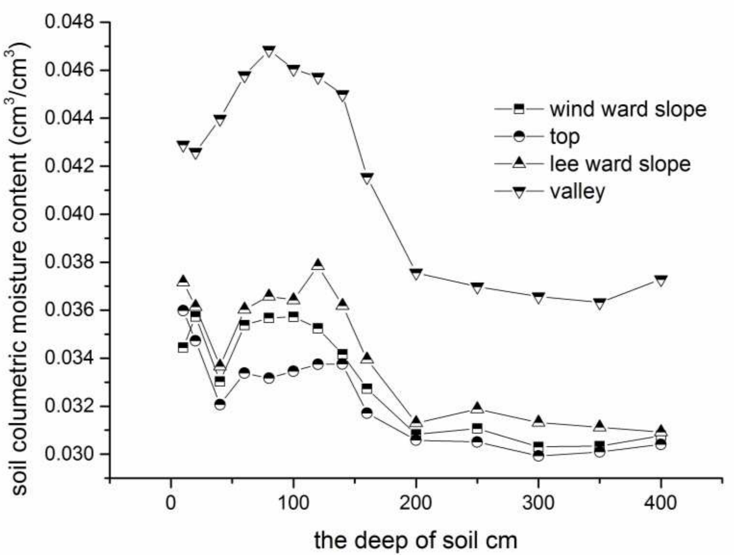

Figure 4. *Comparison of soil moisture at different sample locations in F*

Plant surveys and statistical analysis

In the study area, *Haloxylon ammodendron* and *Haloxylon persicum* are two dominant and keystone species. We pooled data for these two species as *Haloxylon persicum* occurred rarely and mainly on dune tops, and the two congeners are ecologically similar. Observations and measurements reported in this paper were made from May –July 2013. These dates roughly coincide with peak Haloxylon biomass at these localities (Hu, 1985). Haloxylon individuals were identified and measured in all plots for each transect; note that plots were arranged along an east to west sampling line. In each of the main plots, the following tree morphological parameters were measured: basal diameter, crown diameter, height and the number of stems (the number of branches off a main stem occurring below 0.5 m). The Cartesian coordinates (X-Y) of each tree were also recorded in the main plots. In the sub-plots, the height as well as the number of regenerating stems was determined for each individual. Habitat factors such as direction aspect, elevation, the geographical coordinates, slope and so on were also recorded. Soil samples were collected from random locations in the four corners and the middle of each plot at depths of 0-15 cm and 15-30cm. These were sealed in airtight containers plastic bags and taken for analysis in the lab. Soil moisture was measured using the neutron probe method and by oven-drying. After passing soil through a 0.25mm sieve, soil carbon and nitrogen contents were determined using the potassium chromate oxidation heating method-external heating method and the Kjeldahl method, respectively. The soil was washed with distilled water to measure pH and conductivity was obtained using the alternating current (AC) method.

In this study, undergrowth biomass was found by harvesting all aboveground herbaceous growth, drying to constant weight and then weighing the dried material (g/m^2). Shrub biomass was estimated non-destructively by building a testability-factor estimation model based on quantification theory (Zhao, 2004). The percent cover of herbaceous undergrowth was assessed visually in the 2m×2m sub-plots. The percent cover of shrubs was calculated using crown amplitudes and the sub-plot area. The number of individual plants was divided by the total area to get shrub density for each

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_541559

main plot in each type of sand dune. The average crown radius was calculated by averaging four measurements of shrub radii taken in different directions (N, E, S, W) (Gill et al., 2000).

Within a given environment, individuals of the same tree species and of the same age should respond to the environment in a consistent way (Frost and Rydin, 2000). Hence, basal diameter (the diameter of the main stem, i.e. ramet, or of the thickest and strongest stem if there was more than one) and height (the vertical height at the center of the plant) were used as indicators of individual size/age, in determining the composition of the population. In order to describe population structure in greater detail, the classification system used here for grouping plants differs from that of previous studies (Song et al., 2011). Plants were divided into several basal diameter and height classes. The number of individuals falling into each class was tallied for each transect to form a basic data set for population structure analysis. Histograms were used to help illustrate and aid in the interpretation of the diameter and height distributions.

Population dispersion indices are important indicators of the spatial distribution patterns of populations and may be calculated based on field survey data. Various indices have been proposed to describe the degree of spatial clustering in study populations, with different merits. In this study, using plot survey data, the DPS software package was used to calculate several aggregation indices for Haloxylon populations across transects and sampling locations.

Results and analysis

Primary population characteristics

Characteristics of Haloxylon populations found in all four dune habitats and three transects are summarized in *Table 2*, and reveal that average basal diameter, biomass, height and percent cover differed among transects and according to position on the dune. The biomass and percent cover of both Haloxylon and the grasses, as well as Haloxylon stand density, were significantly higher in F plots than in M or S plots. Plant biomass on the east side of the dunes was lowest in F, between dunes it was lowest in M, and on the dune tops lowest in S. *Table 2* reveals a significant decrease in Haloxylon population density from the south (4445 trees/ha) to the central desert (481 trees/ha), although the accompanying shrub species Calligonum leucocladum covered more area in the S versus M plots. Tree density between dunes (6133 trees/ha) was higher than in any of the other three sample locations on the dunes in F, but not in the other two zones. Trends in biomass and percent cover for Haloxylon and the grasses were consistent.In contrast to density, the tree morphological parameters (crown radius, diameter and height) showed a different trend across zones, increasing from F to S and then decreasing in M (*Table 2*). Among dune habitats, within the F area, dune tops had the largest average basal diameter at 4.11cm, whereas dune valleys had the lowest average basal diameter at 1.68 cm, owing to a high proportion of young seedlings. The mean basal diameter and height of Haloxylon individuals was greatest on dune tops in S. For the M zone, trees on the east-facing slope had the largest mean basal diameter and height. Apart from the size of the trees, the number of stems differed slightly among transects (*Table 2*), and the leaf area index decreased substantially from the south to central desert.

Looking at Haloxylon recruitment patterns, there were significant differences among populations from the different zones. There were few recruits in M or S, while the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_541559

density of recruits was significantly higher in F, especially between dunes. Recruit density increased from central (52 individuals/ ha) to south Gurbantunggut desert (667 individuals/ ha). The relatively high recruit density in F may indicate a relatively younger population in F compared to M, perhaps due to more favorable habitat. Indeed, in F, recruits mainly occurred around established plants, where high soil moisture conditions may favor renewal; however, recruit survival and growth rates are extraordinarily low owing to high intraspecific competition (Wei, 2006). In the calculation of percent cover, physical and biological crusts were excluded. Haloxylon individuals of diameter between 0- 0.5cm were considered to be recruits.

The basal diameter structure of Haloxylon populations in different habitats

Although grouping individuals based on stem diameter versus age may produce different distributions, the two methods are consistent in predicting species' responses to the environment (Frost and Rydin, 2000). Trees are often classified according to basal diameter or height, in order to analyze the population's structure (Liu et al., 2012; Song et al., 2008). Thus, in this study, diameter classes were used to gain insight into Haloxylon population characteristics. The basal diameter data for Haloxylon populations from different areas of the dunes, across the three transect zones, are presented in *Figure 5*. The basal diameter distributions were positively skewed (asymmetric) in all zones, with a "reverse J" shape. This indicates a predominance of small individuals (diameter of 0-3 cm), a pattern that was particularly marked in F (*Fig. 5*). The occurrence of young trees across transects reveals that Haloxylon populations are relatively stable with good regeneration potential. No individuals in the largest diameter class (more than 20 cm) were found on the east side of the dunes in F or in dune valleys in S and M. The average diameter of all trees surveyed in F (+4,000 trees) was 3.08cm, and more than 70 % of trees had a basal diameter of 3 cm or less, with trees of diameter 0-1cm accounting for the highest percentage of the total at 43%. There were only four plants with a basal diameter greater than 25 cm in the whole 2.4 hm^2 study area; these were located on dune tops in F and S zones, and on windward slopes in S and M zones. The largest basal diameter, 37cm, was recorded on the top of an F dune, however diameters between dunes in F were significantly lower than in other transects and sample locations. In the F transect, trees of small basal diameter (0-1cm) accounted for the greatest proportion (64%) of individuals on the plain between dunes, whereas in the other three dune habitats 1-2cm Haloxylon trees were the most common. The first peak of the fixed dune diameter distribution (dune valley populations) was the highest, but there was also a second peak in the next diameter class (other sample locations), which was different from the other zones. The distributions for dune top and leeward slope populations in S were relatively flat, with abundance gradually decreasing as basal diameter increased, but dune bottom and west slope populations peaked at 1-2cm. Dune top populations had a significantly higher proportion of trees of 10-20cm than other populations. Haloxylon trees of 6-7cm accounted for a significant proportion of the total in M plots, although the overall trend again showed that young recruits were predominant.

The height structure of Haloxylon populations in different habitats

The distribution of plant heights varied among Haloxylon populations from different transects and locations on the dunes (*Fig. 6*). As with basal diameters, height distributions were also positively skewed (“reverse J” shape) across all zones, with the distributions generally peaking at 0-50cm, except for on dune tops and windward slopes in F and in dune valleys in S, where the first peak occurred at 50-100cm. Some distributions had second peaks at 150-250cm. First peaks were generally more pronounced than second peaks, except for in the S zone. In the F transect, there was a single, large peak in the first height class, a different pattern than for the other dune habitats. In the S zone, there were two distinctive peaks. In the M zone, the distribution of plant heights varied across dune sample locations, but all peaked at a height of 50cm. There was a second peak at the height of 100cm (frequency decreased from dune valleys, to tops, to leeward slopes, to windward slopes) showing that all Haloxylon populations required similar environmental conditions for growth and development. In addition, field surveys found that individuals with a height of 0-20cm were seedlings, and the proportion of seedlings was highest in populations growing at the bottom of fixed dunes (versus other population types). The population structure of Haloxylon in fixed dunes indicated a growing population. However, excluding the plants in the 0-50cm class in F, populations of Haloxylon had an almost symmetric height distribution, with the largest trees being more than 600cm tall and the smallest individuals less than 5 cm. In S and M, Haloxylon height distributions were irregular or tended towards an uneven shape.

Spatial distribution analysis for Haloxylon populations in different habitats

The spatial distributions of Haloxylon populations in different zones and positions on the dunes were analyzed using aggregation indices, including indicators such as the I index, the patchiness index M*/M, the Cassie index $CA=(S^2-X)/X^2$, the diffusion coefficient C and the K index (*Table 3*) .When I<1, individuals are uniformly distributed in space; when I = 1, they are randomly distributed; and when I>1, they are clumped (an aggregated distribution). When the patchiness index M*/M=1, the population has a random distribution; when M*/M>1, it is clumped; and when M*/M <1, it is uniform. When CA<0, it is a uniform distribution; when CA=0, it is random; and when CA>0, it is clumped. The diffusion coefficient $C=S^2/X$ is used to test whether a population is randomly distributed in space or not; when C=1, it is random; when C<1, it is clumped and when C>1, individuals are spatially aggregated. When the negative binomial distribution index, $K=X^2/(S^2-X)$, is K<0, it is a uniform distribution; when K>0, it is clumped; and when K tends to +∞, it is random.

The index calculations showed that all 60 Haloxylon sample populations (in the 10m× 10m-20m×20m quadrats) had clustered distributions. The diffusion coefficient C is known to be a reliable indicator of the spatial distribution of individuals within a population; it is used to test if there is any deviation from a stochastic distribution(Yan et al., 2012). The larger the C value is, the higher the degree of clustering within the population, and vice versa. As shown in *Table 3*, the C values of Haloxylon populations in semi-fixed and movable dunes were generally large, and the highest C value, of 741.73, was found for populations at the top of the semi-fixed dune, whereas the minimum value of 4.99 was found at the top of fixed dunes. Fixed dune populations had a lower degree of clustering. The mean M* in *Table 3* is the average number of neighbors for each Haloxylon individual in a one hectare area. M* was greatest at the bottom of the fixed dune, and on the west slope of the moveable dune, consistent with patterns in plant density (see *Table 2*). However, the highest percent cover values for the movable dune occurred not on the west but on the east slope, perhaps due to the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_541559

smaller basal diameters of Haloxylon on the west slope. These results also indicate that percent cover may not be equatable with density, because of the impact of the tree crown.

Conclusions and discussion

Soil organic matter, texture and edaphic horizons are the most important properties of a site with regard to water availability of the soils and the differential response of plants (Troeh and Thompson, 2005). In this study, we only considered the surface edaphic horizon, as this is the one that interacts most actively with plants in the desert. Here, soil moisture and organic matter content decreased with altitude and differed significantly among three phytogeographic zones from south to central Gurbantunggut desert. Differences in soil organic matter, moisture and texture among the study geomorphological positions on dunes within the same zone (i.e. dune bottom, top or east/west slopes), produced differences in Haloxylon population characteristics. Hence, the distribution patterns and characteristics of Haloxylon populations may serve as relevant barometers of an ecosystem's sensitivity or resilience to external (environmental and anthropogenic) disturbances, although Haloxylon spp. have exceptionally broad ecological tolerances, being the main woody species in central Asian desert ecosystems (Li, 2013a). Haloxylon plays an important role in maintaining the stability of the entire desert ecosystem (Huang et al., 2009) and is considered a dominant and keystone species. In the 1970's, anthropogenic disturbance resulted in reductions in Haloxylon populations (Si, 2011), which also fed back to influence the environment, especially in certain edaphic characteristics. The mutual feedbacks between vegetation and the environment are of relevance to ecohydrological processes and to sand-binding vegetation systems in sandy desert regions of China (Li, 2013b). Several factors, including the bulk of seed rain occurring near established individuals (Shi et al., 2010) and the increase in soil nutrients and soil moisture (via hydraulic lift in plant roots) around mature plants (Li, 2007; Lamusa et al., 2008; Yuan et al., 2012) promote regeneration (i.e. most seedlings occur around mature plants, hence the higher the density of Haloxylon, the higher the recruit density).

Quantification in study plots indicated a significant decrease in Haloxylon density from the south to the central desert and a high correspondence between plant height and diameter, which both followed asymmetric distributions ("reverse J" shaped) in all

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_541559

populations. The diameter and height distributions across the three desert zones (*Fig.7*) clearly indicated growing populations, as young plants accounted for the highest proportion of individuals, with progressively fewer individuals in each larger size class. Tree density in the valleys between dunes was higher than in any other location on the dune in F, but this pattern was not found in the other zones. Few recruits were found in the central desert, but their density increased from the central to the south Gurbantunggut desert. In the drier M and S zones, trees were distinctly more scattered suggesting lower overall tree biomass, an impression confirmed in *Figure 7*, where there was less variation in tree size (fewer size classes) in M and S compared to F. These population patterns and trait distributions are consistent with previous studies (Song et al., 2011; Qian et al., 2007) that found that biomass is lower in the central desert. The availability of soil moisture and total precipitation limit plant density (Zhu and Jia, 2011). Previous studies have indicated that self-thinning processes occurred in Haloxylon plantations after 10 years of growth (Chang et al., 2008) and that plant survival decreased over time. Here, the abundance of Haloxylon trees also decreased with size (*Fig. 7*). In the plantation study, trees had access to ground water for the first 20 years, and yet there were still high mortality rates. The ground water table may perhaps have been too low to support normal physiological activity, or this mortality may have been observed for other reasons(Zeng et al., 2012; Zhang, 2010).

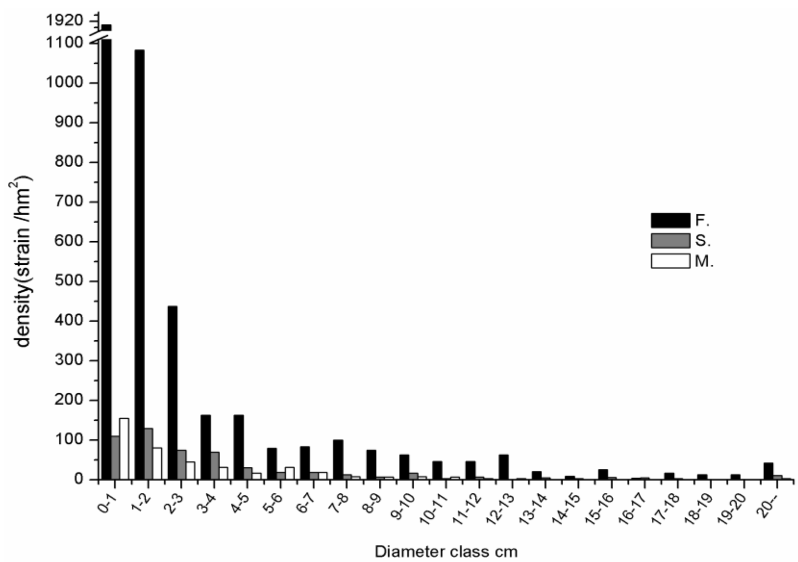

Figure 7. *The distribution of plant diameters across the three zones*

The biomass of Haloxylon individuals decreased towards the central desert These results suggest that Haloxylon is adapted to the inner desert drought conditions. Dropping assimilating branches as needed can act to maintain a balance between water supply deficits and water consumption of the assimilating organs; this morphological adjustment can reduce seedling mortality effectively. Greater allocation of photosynthate towards roots can also ensure seedling survival and a quick recovery of growth when adequate water is restored (Tian et al., 2014). In the M zone, plant stems are quickly buried by sand leading to a thin plant shape and proliferation in the number of stems (ramification below 0.5m) compared to other zones (Gai et al., 2008). New recruits were mainly found growing around mature individuals, likely because this is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_541559

where the bulk of the seed rain occurs (Shi et al., 2010), where soil nutrients are most abundant, and where soil moisture is highest owing to hydraulic lift in plant roots (Li, 2007; Lamusa et al., 2008; Yuan et al., 2012). Hence, populations were distributed along an environmental gradient characterized by variation in water availability and soil fertility. The spatial structure of Haloxylon populations indicated clustered distributions in all zones, with recruits strongly clustered in the fixed sand dunes. Haloxylon species have a good ability to tolerate broad climatic and habitat fluctuations.

Our results illustrate that, apart from the soil physicochemical properties, climatic gradients may also have significant impacts on Haloxylon morphological traits and population structure, but that responses to climatic gradients vary significantly between phytogeographical zones. The population structure and basic characteristics of Haloxylon populations studied here resemble those found in other investigations, where a weak natural regeneration of the species in the central dessert was also observed (Si, 2011; Huang et al., 2009). Based on demographic behavior, we concluded that populations are growing in abundance in all three zones; however, the density of individuals in the M zone is too low for long-term persistence, and hence it is still a species of concern; Tree morphological traits (height, diameter, number of stems) vary according to the phytogeographical zones and change over time; and the spatial patterns of Haloxylon individuals in natural stands suggest varying degrees of aggregation.

Acknowledgements. The authors' thanks go to Xingjiang Institute of Ecology and Geography for Education and Research through the Major scientific research projects (973 plan) (No. 2013CB429905), the Xinjiang Natural Science Foundation of Xinjiang (No. 2014211B014) and the National Natural Science Foundation of China (No. 41301205) for funding this research. We thank also the editor and two anonymous reviewers for their constructive comments that greatly improved this paper. Abstract. Environmental factors affect carbon isotope discrimination in plants. Therefore, carbon isotope discrimination records a wealth of environmental information, such as temperature, precipitation etc., and the predominant factor's influence is significant. Based on this hypothesis, we determined the carbon isotope composition of Tamarix growing in the southern margin of the Taklimakan Desert where temperature and water are key growth-limiting factors. Mean annual temperature (MAT) showed a significant impact on variation in carbon isotope discrimination value (DS), but precipitation not. In multiple stepwise regression analysis, MAT was the first and the only variable selected into the prediction model of DS against MAT and precipitation, indicating that the effect of temperature on carbon isotope discrimination was predominant. The correlation between DS and the variation rate of precipitation in previous year shows that precipitation, as a major factor in arid regions, exerts a certain "lag effect" on the growth of Tamarix. The reconstructed MAT regression model was established according to the DS with the least squares method, the result bolster the argument that the planet's temperatures have shifted significantly in the last half-century.
Keywords: *Tamarix cone sediment laminae; temperature; precipitation; climatic factor; regression model*

Introduction

Plant carbon isotope discrimination in photosynthesis is closely associated with physiological responses including stomata conductance, assimilation rate, altered C:N allocation to carboxylation, and leaf structure (Seibt et al., 2008; Liu et al., 2014). It may be affected by many environmental factors such as temperature, moisture, altitude, latitude, longitude, solar radiation, air pressure, and atmospheric CO_2 concentration (Wang et al., 2003; Treydte et al., 2007). Based on Farquhar's research (1982), the fundamental mechanism is that these factors can control directly or indirectly the ratio of the intercellular CO_2 concentration (ci) to the ambientCO_2 concentration (ca) to affect plant carbon isotope discrimination.

Some studies have reported that precipitation has a positive influence on plant carbon isotope discrimination and altitude a negative, but that of the temperature is varied (e.g.,

DOI: http://dx.doi.org/10.15666/aeer/1504_561570

Körner et al., 1988, 1991; Morecroft and Woodward, 1996; Wang et al., 2008, 2013; Diefendorf et al., 2010; Kohn, 2010; Xu et al., 2015) inferred that the effect of altitude, longitude and latitude on plant carbon isotope discrimination could be expressed mainly in the effects of temperature and precipitation. Some researchers believed that the effects of solar radiation and air pressure are rather small compared to temperature and/or precipitation (Körner et al., 1988, 1991; Sparks and Ehleringer, 1997; Wang et al., 2008). Temperature and precipitation are considered as two fundamental influential factors.

Since plant carbon isotope discrimination is closely related to its performance, in which the key growth-limiting factors play a significant role. It has been suggested that the key growth-limiting factor is also the predominant factor affecting plant carbon isotope discrimination (Winter et al., 1982; McCarroll and Loader, 2004). Thus carbon isotope discrimination records the information of the environment when and where the plant grows, is a good carrier which can be used to reconstruct the factors of climate and the environment in history (Wei et al., 2005).

In this study, Tamarix leaf carbon isotope composition (δ13C) were investigated in the southern margin of the Taklimakan Desert (TDSM), the data of temperature and precipitation of 1960-2011 was obtained from the Cele Meteorological Station, which is closest to and the same altitude with the sampling site (*Figure 1*), the correlations was analyzed between the plant carbon isotope discrimination (DS) and temperature and precipitation. The objective was to assess whether or not temperature and precipitation can exert a dominant impact on the growth of Tamarix and reconstruct them.

Material and method

Study area

The area being studied is located in Cele Oasis, which belongs to Hotian Prefecture of Xinjiang Uygur Autonomous Region, China, in TDSM. The Cele Oasis is one of hundreds of oases, large or small, such as Hotian Oasis, Yutian Oasis and Minfeng Oasis. It lies on the transition zone between the Taklimakan Desert and Kunlun Mountains, the upstream area of Celeriver's alluvial fan, and belongs to continental arid desert climate, with an annual average temperature of 12.13 °C and frequent wind sandy activities. According to the data gathered from Cele Meteorological Station, the annual precipitation is only 38.4mm, 50% to 70% of which concentrates in the period from June to September; but the annual average evaporation can reach to 2500 ~ 3400mm. The zonal vegetation is mainly made up of the xerophilous, super-xerophytic shrubs and semi-shrubs, as well as some alkali-saline-tolerant perennial herbs.

On both sides of riverbanks, delta areas, ancient riverbanks and local lowlands of the rivers, there are scattered Tamarixes, taking carbon from the air and oxygen and hydrogen from deep soil, standing fixed in the desert area often for centuries. Their unique physical characteristics enable them to survive in the arid, high salt desert regions. The longtime collaboration between wind sandy and Tamarix has formed Tamarix cones, a unique bio-geographical type, composed of alternate layers of sand and Tamarix twigs and leaves (Xia et al., 2004).

Sample collection

From June 18th to 20th in 2011, in Damagou of Cele County (*Fig. 1*), a typical Tamarix cone was chosen. From top to bottom, the samples were collected layer by layer. If the sedimentary vein was not clear, they were collected accorded to the average thickness. The sample site is located at37.09 ° N, 81.08 ° E, 1318m above sea level; 151 samples of sedimentary veins of Tamarix cones were collected. The depth of the profile is about 4.5m.

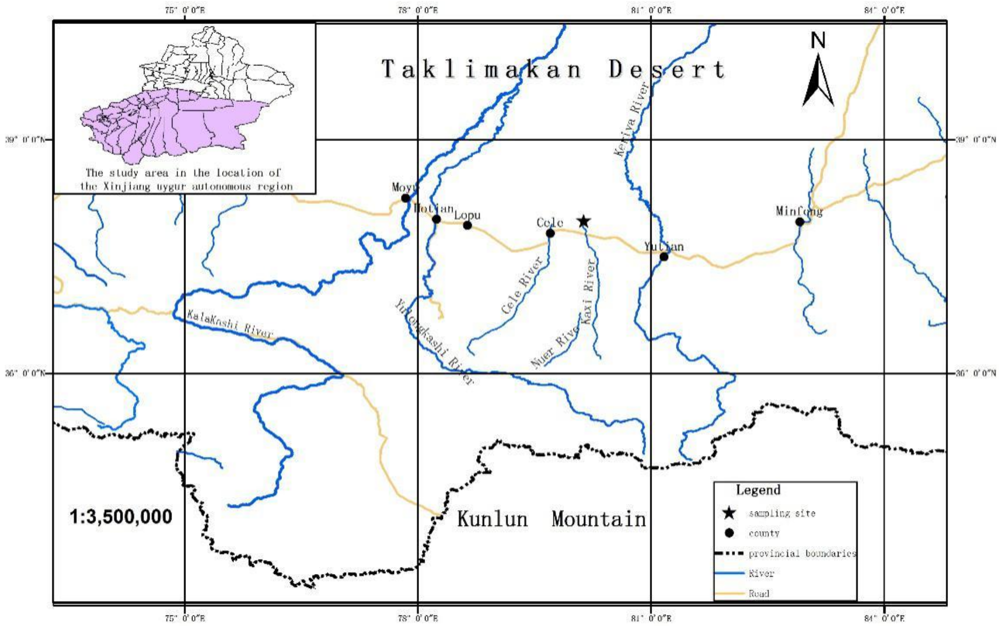

Figure 1. *Location map of sampling site in Damagou of Cele County*

Data measurement

The age sequence of δ13C values was identified according to overall consideration of the age data derived from 210Pb, 137Cs dating methods, which were done in Nanjing Institute of Geography and Limnology, Chinese Academy of Sciences (CAS), combined with the calculation of14C dating, which was done by the Accelerator Mass Spectrometry Laboratory in Beijing University, the rate of Tamarix cone sedimentation and the thickness of the each sedimentary layer (Zhao et al., 2015).

The δ13C values of all samples were measured in Nanjing Institute of Geography and Limnology CAS, on the base of VPDB (the standard error of 0.1‰). The test steps are as follow: after the collected leaves were well pretreated, the obtained alpha cellulose was burned by Flash EA1112 Eelemental Analyzer; the combusted gas was sent into Delta Plus Advantage Isotope Mass Spectrometer to measure organic carbon isotope ratio of the sample (13C/12C).

The carbon isotope discrimination (DS) of Tamarix leaves is obtained by following formula based on Farquhar et al. (1989):

$$DS = \frac{\left(\delta^{13}C_{ate} - \delta^{13}C_t\right)}{\left(1 + \delta^{13}C_t / 1000\right)} \approx \delta^{13}C_{ate} - \delta^{13}C_t \qquad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_561570

In Eq. 1, the carbon isotope ratio of atmospheric CO_2, which were measured from ice core bubbles or plant δ13C value (Friedli et al., 1986; Leavitt and Long, 1989; McCarroll and Loader, 2004), $\delta^{13}C_t$ is the carbon isotope ratio of Tamarix leaves.

Statistical analysis

Descriptive statistical analysis was carried out on δ13C and DS, then a bivariate correlation analysis was performed to examine the links between plant DS and temperature and precipitation. Considering the existence of potential interactions between temperature and precipitation, partial correlation analysis, in which temperature and precipitation were separately controlled, was applied to describe the actual links between Tamarix leaf DS and temperature and precipitation. Regression analysis was used to constrain the influences of temperature and precipitation on Tamarix leaf DS. The regression models were established according to the Tamarix leaf DS with least square fitting method to reconstruct the history climate information. All statistical analysis was performed using IBM SPSS Statistics 19.0 (IBM Corporation, New York, NY, USA).

Results

The $\delta^{13}C$ and DS

The $\delta^{13}C$ values of the sample site were established in the period from 1590 to 2010 (*Figure 2a*). The time span of this sampling sequence is 420 years. The $\delta^{13}C$ values are within the range from -25.008‰ to -23.138‰, the average $\delta^{13}C$ value is -24.137‰. In the period from 1790 to 1937, the δ13C value is lower and fluctuates frequently. In 1790, 1832, 1881 and 1933, the relatively low values appear, which are -24.625‰, -24.824‰, - 25.008‰ and - 24.938‰ respectively, and in 1881 the minimum value of the data series appears. There is a leap in 1939, 3.6% higher than that in 1937, and the $\delta^{13}C$ value is greater and more dynamic till 2010, with the emergence of a maximum value of -23.138‰ in 1997. In 1982, 1957 and 1954, the δ13C value is higher, but in 1974 it appears as a relatively lower value for this period.

The carbon isotope discrimination values (DS) were obtained by formula (1) (*Figure 2b*). The values are within the range from 15.228‰ to 18.458‰, the average DS value is 17.372, and show a downward trend.

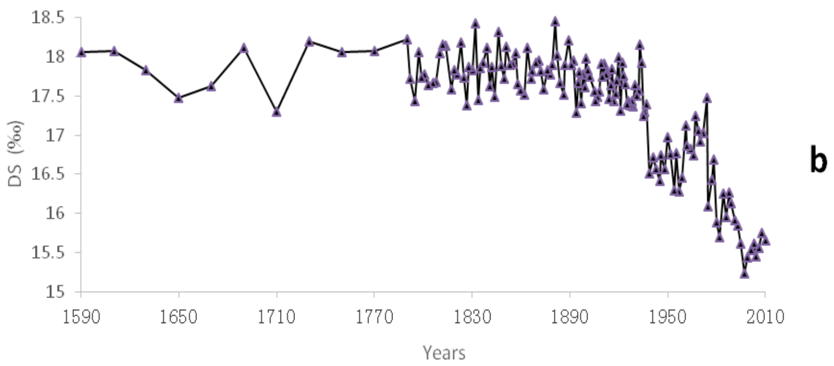

Figure 1. *The observed sequences of the δ13C values (a) and the carbon isotope discrimination values (b)*

Correlations analysis

The correlation between the $\delta^{13}C$ values and temperature and precipitation and that between DS and temperature and precipitation are showed in *Table 1*. Considering that the response of carbon isotope and carbon isotope discrimination to environmental factors may be dependent on Tamarix functional type, the influence of temperature and precipitation on δ13C and DS were analyzed separately.

There was a positive correlation between temperature and δ13C only in February (r=0.510, p=0.005). The DS values were correlated with the temperature in February and growing season, and significantly with mean annual temperature (MAT) (r=-0.761, p=0.000).

The $\delta^{13}C$ values were correlated with precipitation only in February (r=0.488, p=0.007) of that year, and the DS values were not associated with precipitation either in that year or previous year. But the precipitation changes rate of previous year (PCR) (i.e., the natural logarithm of the precipitation in the previous year) were correlated with DS (r = -0.376, p = 0.044) (shown as *Table 2*).

Multiple stepwise regression analysis model and reconstruction model

In view of the correlations between DS and MAT and PCR, multiple stepwise regression analysis was applied. The result reveal that MAT was the only variable entered in the stepwise regression model of DS ($DS = 23.645 - 0.608MAT$, $R^2 = 0.580$, $\bar{R}^2 = 0.564$, $p = 0.000$). So the Tamarix leaf DS values (DSt) can be used as a regression factor to reconstruct MAT ($\hat{T}_t$), the MAT reconstruction equation is as follow:

$$\begin{aligned} \hat{T}_t &= 27.668 - 0.953 * DS_t \\ se \quad & (2.534) \qquad (0.156) \\ p-value \quad & [0.000] \qquad [0.000] \\ R^2 &= 0.580, \quad \bar{R}^2 = 0.564 \end{aligned} \qquad \text{(Eq.2)}$$

The curve of reconstructed temperature were shown in *Figure 3*.

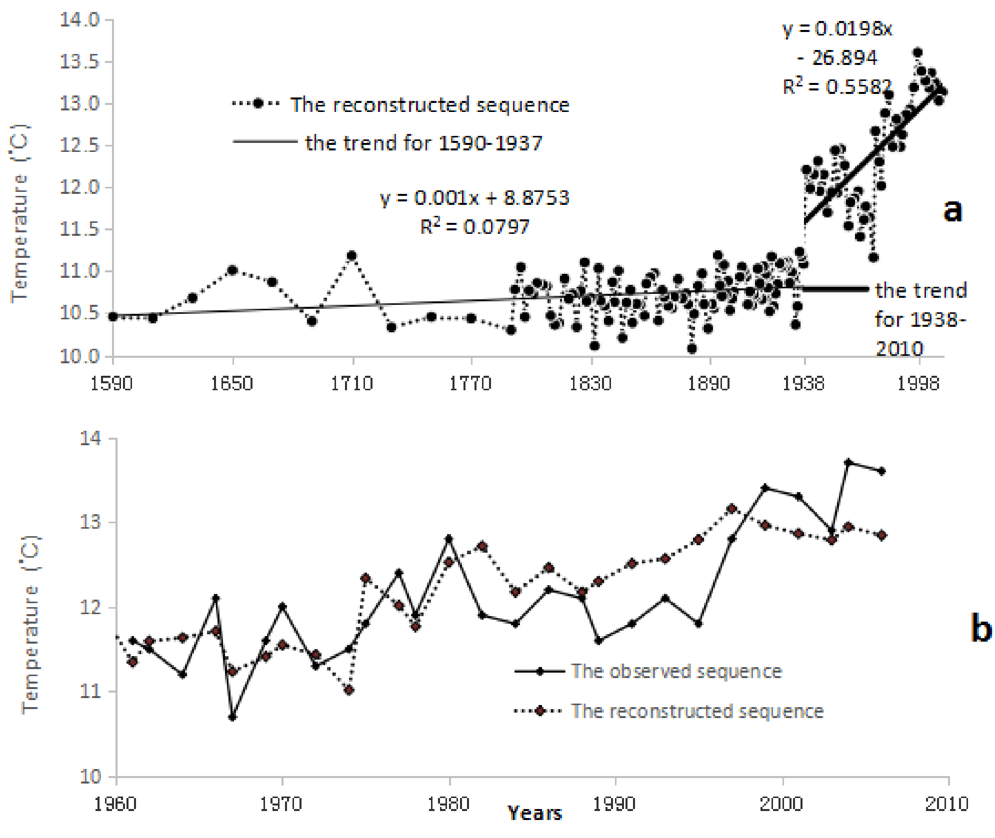

Figure 3. *(a)The reconstructed temperature from 1590-2010 and (b)the comparison between the observed and reconstructed temperature from 1960-2010*

Disscussions

Features of the δ13C values

The trend of Tamarix leaf $\delta^{13}C$ values from Cele region in TDSM is characterized by vibration and complexity. The values are very close to those in the Minfeng Andier ancient city and the Andier meadow sampling site (Sun, 2013), consistent with the results of Lop Nur region (Xia et al., 2004; Zhao et al., 2011a). The results are basically in accordance with the δ13C composition of C3 plants in arid environments (Ehleringer and Monson, 1993).

This results show that the difference of Tamarix leaf $\delta^{13}C$ values in different sites of TDSM is tiny. The δ13C values show small regional differences because the sampling sites are geographically different, which proves that the variation of $\delta^{13}C$ value of Tamarix leaves in arid regions is stable within species and regions. In addition, compared with the extremely arid Lop Nor region, the hinterland of the desert, the climate of Cele region in TDSM is relatively humid. Therefore, the Tamarix leaf $\delta^{13}C$ values show a gradual decrease with the improvement of water conditions. This conclusion is similar to that of some conclusions (Liu et al., 1997; Sun et al., 2003; Yun et al., 2010; Zhao, 2012).

Effect of temperature on Tamarix

The correlation between temperature and DS is more significant than that with δ13C, and the DS sequence is correlated with the temperature in growing season and MAT negatively and significantly (*Table 1*).Combining the results of stepwise regression, we believe that temperature has exerted the key influence on carbon isotope discrimination of the Tamarix growing in arid area, and the DS decline 0.608 for each degree rise in MAT.

Temperature is one of the most important factors that control plant growth and certain physiological processes related to plant gas exchange activity. A decline temperature usually results in a reduction in enzyme activity and photosynthetic rate (Beerling, 1994), thus leading to decreased CO_2 assimilation and a lower growth rate as a consequence. An increase in DS with decreasing temperature is therefore expected and has been observed in most of the studies on the influence of temperature on carbon isotope discrimination (e.g., McCarroll and Loader, 2004; Treydte et al., 2007; Wang et al., 2013).

Our results are consistent with these studies and suggest a decline in DS with increasing temperature. The temperature influences the growth of Tamarix directly, and the higher mean annual temperature of the growing season is more beneficial to Tamarix. That shows an agreement with some researchers (Wang et al., 2003; Liu et al., 2007; Shen and Chen, 2000; Zhao et al., 2011b).

Effect of precipitation on Tamarix

Numerous studies have reported the influence of water availability on plant carbon isotope discrimination (e.g., Wang et al., 2005, 2008; Diefendorf et al., 2010; Kohn, 2010), and a positive correlation between DS and water availability has been observed on most occasions. The mechanism of water availability on plant carbon isotope discrimination is that the plants would close their stomata to reduce water loss when moisture decreases, resulting in a lower ci/ca ratio and less negative δ13C values.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_561570

In this study, the δ13C and DS values are with little dependence on contemporary precipitation but in February (r= -0.448, p=0.007) (*Table 1*). At the same time, correlation analysis (*Table 2*) is made between DS sequence and the precipitation in the previous year and the precipitation changes rate of previous year (i.e., the natural logarithm of the precipitation in the previous year). The correlation coefficients are -0.335 and -0.376 (p=0.044).

The effect of precipitation on the growth of Tamarix is weaker. Preliminary analysis suggests that in more precipitation year, more snow and ice were deposited on the mountains than normal year, which may result in the larger quantity of underground water availability in growth period of Tamarix in the next year, and consequently promoted the photosynthetic rate and Tamarix growth.

This further proves the "lag effect" of precipitation (Leavitt and Long, 1989) on Tamarix growth. The precipitation is an important factor influencing the growth of Tamarix in arid region, but not directly, and the mechanism is complex.

Analysis of reconstructed temperature in past 400a

The temperature from 1590 to 2010 were reconstructed based on DS (*Figure 2a*),could be divided into sub-periods by the year 1937 based on the trend.

The first period (1590 - 1937): It is a 347-year time span. The trend line slanting rate of reconstructed temperature is 0.001, the temperature were more stable with a slighter fluctuation.

The second phase (1938 - 2010): In the 72 years, the temperature underwent a remarkable increase, the trend line slanting rate is 0.0198, and its range of oscillation was extended. It can be defined as the modern warm and wet period.

The explained variance of reconstructed mean annual temperature is 56.4%, which is reliable. The results show a tendency toward warming, and the change will be more frequent and more intense, which reflects the characteristics of global climate change.

Conclusion

The present study conducted an investigation of Tamarix leaf δ13C in TDSM and analyzed the influence of temperature and precipitation on the variation in DS. Temperature, the key growth-limiting factor for Tamarix, was found a significant influence on DS, but the influence of precipitation was relatively weak. Future study should consider on water availability in relation to Tamarix carbon isotope discrimination. Ecosystems in TDSM are fragile and sensitive to climate change. With the rising temperature, more precipitation will be expected, which may have enormous impacts on productivity and stability of ecosystems in the future.

IDENTIFYING THE SOURCE OF POLLUTANTS IN MALACCA RIVER USING GIS APPROACH

HUA, A. K.

Department of Environmental Sciences, Faculty of Environmental Studies, Universiti Putra Malaysia, 43400 UPM Serdang, Selangor, Malaysia
e-mail: angkeanhua@yahoo.com

(Received 19th Mar 2017; accepted 26th Jun 2017)

Abstract. The study was conducted to determine the dominant source of pollutants in Malacca River using the combined methods of water sampling and GIS approach. The study was conducted in 9 sampling stations based on Malacca River sub-basins. The result of WQI indicated that station 4 and 5 are polluted; station 8 and 9 are clean; and other stations are slightly polluted. PCA identified several pollutant sources, namely agricultural, residential, industrial, animal husbandry activities, as well as sewage treatment plants. Applied GIS technique detected several areas as hotspots pollutants sources, namely agricultural activities in station 5; residential activities in station 1, 2, 5, 6, and 7; industrial activities in station 3, 4, 5, and 7; animal husbandry in station 5 and some scatterings in station 1 to 4; as well as sewage treatment plant in moderate hotspot area between station 5 and 6, respectively. Besides the recommendation to reduce the river water pollution through the control of pollutants source, this study provides crucial information for the identification of problematic areas and spatial database of Malacca River for better understanding and management of river water quality in the future, as well as a reference for future land use and urban design development purposes.
Keywords: *WQI, PCA, hotspot analysis, spatial database*

Introduction

River water pollution has received great attention in recent years and continues to receive serious concern throughout the world. Water quality deterioration is primarily connected to the subject of population growth and city expansion. This is a threatening factor to human and ecological health, drinking water availability, and furthermore to the economic development (Houser and Richardson, 2015; Morse and Wolheim, 2014; Li and Zhang, 2010). According to Iscen et al. (2008), surface water is easily exposed to pollution due to its - accessibility to wastewater disposal. Water quality impairment resulted from anthropogenic inputs (e.g. municipal and industrial wastewater discharges, agricultural runoff) and natural processes such as chemical weathering and soil erosion (Shin et al., 2013; Singh et al., 2011; Iscen et al., 2008), contributed to the input of non-point and point source pollutants of the river (Iscen et al., 2008). Therefore, water quality assessment with geographic information system (GIS) is an important tool in identifying possible pollutant sources with the aim to prevent and control water pollution; which is crucial for sustainable water resource use with respect to ecosystem health and social development (Iscen et al., 2008; Shrestha and Kazama, 2007; Zhang, 2006).

Malaysia as an ongoing developing country in South East Asia is facing major water quality problems (DOE, 2012). Human activities that generate economic benefit for the society has indirectly deteriorate the water quality of the river (Muyibi et al., 2008). Several studies focused on the assessment of water quality indicated that unsustainable development could result in environmental damage to surrounding areas, as well as to the biodiversity of benthic macroinvertebrates (Al-Shami et al., 2010). Specifically,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_571588

researchers have identified that wastewater that were discharged from the manufacturing and agro-based industry, domestic sewage, animal husbandry, mining activity, and surface runoff originating from land clearing and earthwork activity; could lead to water resource pollution, especially in the river (DOE, 2012; Suratman et al., 2009; Deb et al., 2008; Ebrahimpour and Mushrifah, 2008; Muyibi et al., 2008).

This situation is no stranger to the state of Malacca, which has faced serious water pollution problems that led to the death of aquatic species along the Malacca River (Sinar Harian Online, 2016; Hua, 2015; Metro Online, 2015; Daneshmend et al., 2011). Malacca State was recognized by UNESCO as a World Heritage Site in 2008 (UNESCO, 2016) and since has become a world historical tourism center for the country. This establishment is important for the economic and population growth of Malacca State. Indirectly, Malacca River may not have been exposed to the issues of river water pollution in the past. Nevertheless, the increasing number of population, uncontrolled rapid development, and extreme land use has led to the 'disruption' of Malacca River. Besides water quality assessment and monitoring, an applied GIS through hotspot analysis would assist in determining the dominant source of pollution that has greater impact to Malacca River. GIS hotspot analysis is a method that has been frequently applied in various studies in the fields of diseases (Liu et al., 2006), mortality rates (Mclaughlin and Boscoe, 2007), environmental planning, as well as the environmental sciences (Ishioka et al., 2007). For instant, Liu et al. (2006) used GIS to assess and sample the pattern of heavy metal in paddy field; and Zhang (2006) used hotspot analysis of GIS approach to identify the pollutants in urban soils in Ireland.

Several GIS analysis methods have been proposed for hotspot analysis, such as spatial scan statistics (Ishioka et al., 2007), Tango' C index (Zhang and Lin, 2006; Tango, 1995), as well as Getis's G index (Getis and Ord, 1992). These methods are often used in the field of environmental sciences, planning, and management. Hotspot analysis which is extended from Moran's I index in spatial analysis, can be classified into two categories, namely global Moran's I (Oldland, 1998; Cliff and Ord, 1981) and local Moran's I index (Zhang et al., 2008; Mclaughlin and Boscoe, 2007; Getis and Ord, 1992). Unlike the particular analysis of Moran's I which only focuses on the detection of similar value clusterings, hotspot analysis technique using G-statistic has the ability to express the high/low value clusterings (Getis and Ord, 1992). This technique of hotspot analysis is applied to this study. The objectives of the study are (1) to identify water quality status and pollution sources using relationship elements of natural origins; and (2) to determine the dominant sources of pollutants through spatial pattern analysis.

Materials and Methods

Study Area

The state of Malacca is located in the southwest of Peninsular Malaysia with the geographical coordinates of 2°23'16.08"N to 2°24'52.27"N latitude and 102°10'36.45"E to 102°29'17.68"E longitude. Malacca is divided into three districts, namely Alor Gajah, Jasin, and Malacca Central. Total catchment area of Malacca is approximately around 670 km^2 with about 80 km distance of Malacca River. The basin is formed by 13 sub-basins namely Kampung Ampang Batu Gadek sub-basin, Kampung Balai sub-basin, Kampung Batu Berendam sub-basin, Kampung Buloh China sub-basin, Kampung Cheng sub-basin, Kampung Gadek sub-basin, Kampung Harmoni Belimbing Dalam sub-basin, Kampung Kelemak sub-basin, Kampung Panchor sub-basin,

DOI: http://dx.doi.org/10.15666/aeer/1504_571588

Kampung Pulau sub-basin, Kampung Sungai Petai sub-basin, Kampung Tamah Merah sub-basin, and Kampung Tualang sub-basin (*Figure 1*). Among the 13 sub-basins, only 7 sub-basins were selected, with 9 sampling stations located alongside Malacca River.

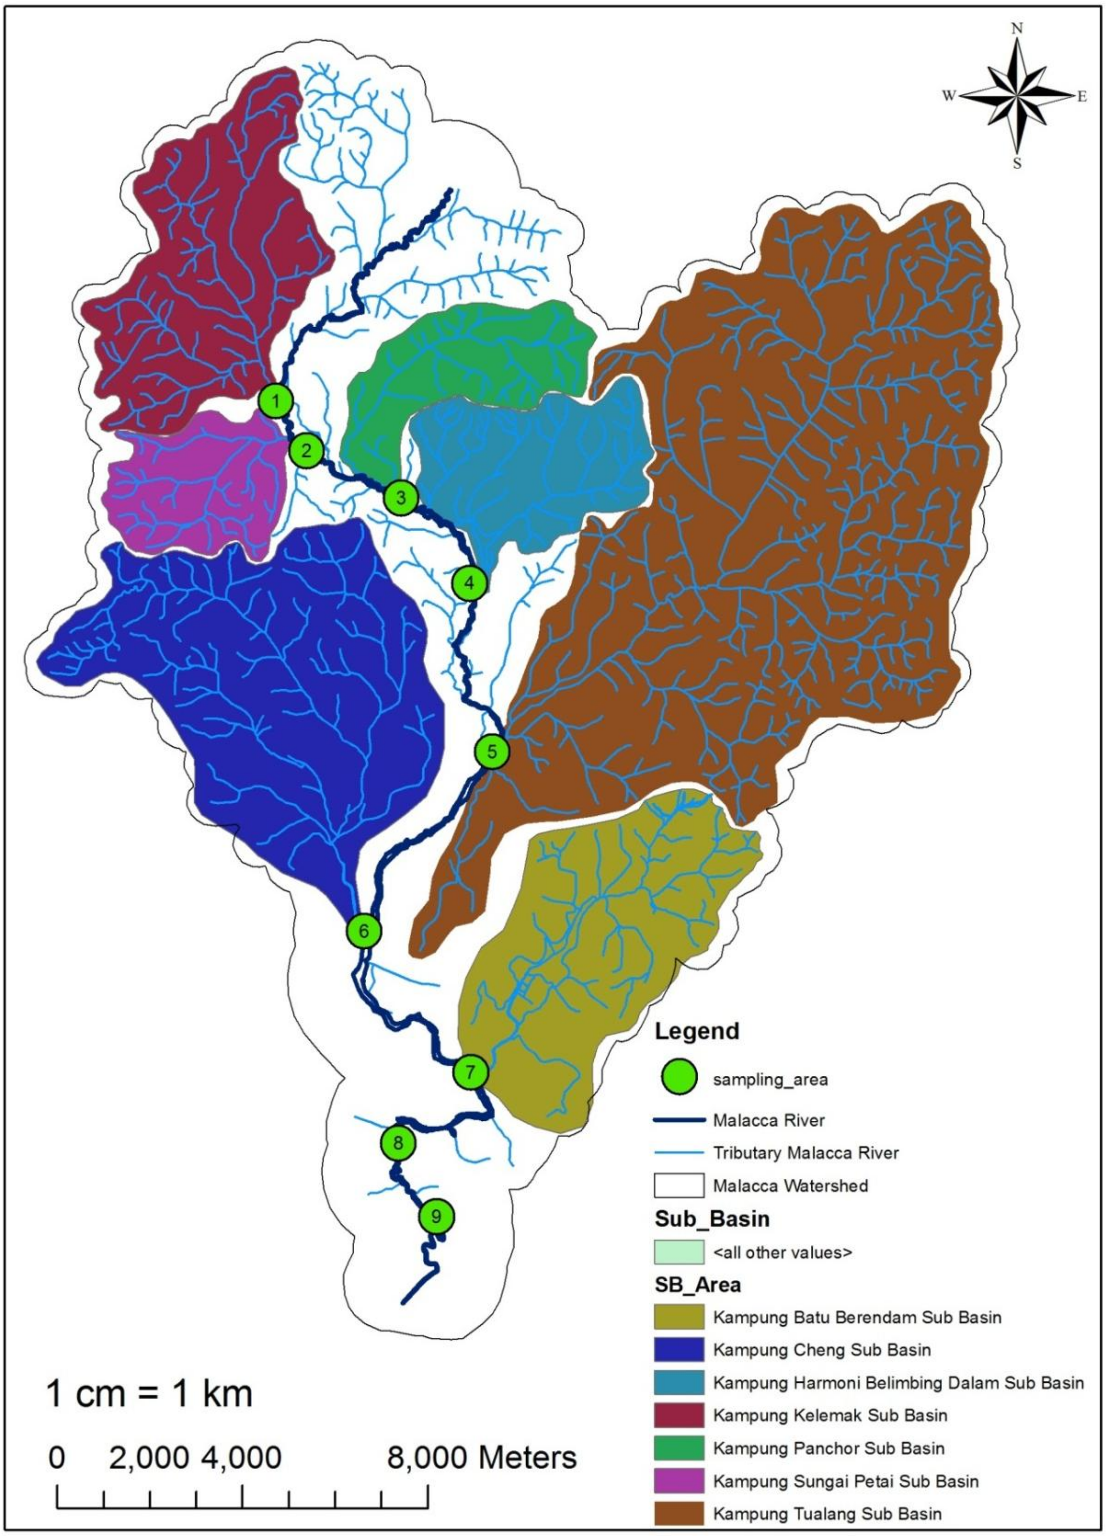

Figure 1. *Malacca River sub-basin and sampling area*

DOI: http://dx.doi.org/10.15666/aeer/1504_571588

Malacca River flows across Alor Gajah to the Malacca Central district before entering into the Straits of Malacca. Alongside Malacca River, there is a reservoir located between Alor Gajah and Malacca Central, namely Durian Tunggal Reservoir, with a catchment area of approximately 20 km^2 that act as a source of water supply for Malacca residents. The built-up area is mainly concentrated in the city center, Malacca Central, at a downstream area extending about 10 km to the west, 10 km to the east, and 20 km to the north. The urban land uses are primarily residential and commercial, while several industrial activities including high-technology and estates are located in the middle-stream and upstream areas. Most of the large-scale agricultural activities land use are located upstream.

Field Sampling

There were 9 sampling stations chosen alongside Malacca River. The locations were determined using a Global Positioning System (GPS) coordinates as shown in *Table 1* and the geographic coverage is as shown in *Figure 1*. The collection of water quality samples were carried out monthly from January to December 2015.

Table 1. *The latitude and longitude of sampling stations*

Station	Latitude	Longitude

Source: Global Positioning System

The water samples were collected using ‘grab sampling’ technique in the polyethylene bottles without entrapping the air bubbles. Each bottle was labelled with the corresponding sampling station and kept at 4°C to minimize microbial activity in the water (APHA, 2005). The water samples were analyzed for physico-chemical parameters (i.e. pH, temperature, electrical conductivity (EC), salinity, turbidity, total suspended solid (TSS), dissolved solids (DS), dissolved oxygen (DO), biological oxygen demand (BOD), chemical oxygen demand (COD), and ammoniacal-nitrogen (NH_3-N), trace metals (i.e. mercury, cadmium, chromium, arsenic, zinc, lead and iron)) and biological parameters (i.e. Escherichia coliform and total coliform). Since water sample containing colloidal or suspended particulate material could interfere with the metal analysis, the samples were immediately filtered using 0.45 µm cellulose acetate membrane filter (Whatman Milipores, Clifton, NJ) at the laboratory. The purpose of this procedure was to prevent the occurrence of clogging during analysis with spectrometry instruments and to obtain the dissolved ions for metal analysis (APHA, 2005). Then, the samples were acidified with HNO_3 to pH<2 in order to prevent precipitation of the components for trace metal analysis and to retard any biological activities (APHA, 2005).

DOI: http://dx.doi.org/10.15666/aeer/1504_571588

Water Quality Analysis

The water samples were analyzed according to the procedure of APHA (2005), meaning that pH, turbidity, EC, TDS, salinity, and DO were measured on-site. SevenGo Duo pro probe (Mettler Toledo AG) was used for the measurement of pH values, while turbidity was tested using the Handled Turbidimeter Hach 2100. Orion Star Series Portable Meter was used to measure temperature, EC, DS, salinity, and DO. Meanwhile, NH3N was analyzed using a spectrophotometer at a specific wavelength using Hach Method 8038, COD was measured using APHA 5220B open reflux technique; BOD was measured using APHA 5210B (or Hach Method 8043); and TSS was measured using the APHA 2540D method. Both E-coli and total coliform were analyzed using Membrane Filtration method based on APHA 9221B, and trace metals were analyzed using inductive coupled plasma-mass spectrometry (ICP-MS, ELAN DRC-e 6100, Perkin Elmer). For quality assurance and quality control purposes, laboratory apparatus and polyethylene bottles were washed using 5% (v/v) of nitric acid and soaked overnight to remove contaminants and traces of cleaning reagent before the collection of water samples or conducting laboratory analysis.

Each sample was analyzed in triplicate before calculating the mean value, and standard deviation (SD) of less than 20% was used as an indicator of precision for each measured parameter. All the probe meters and instruments used were calibrated prior to analysis. In all cases, the standards and blank were treated in the same way as the representative river water samples to minimize matrix interference during analysis. The recovery of samples for all target elements fell within the standard requirements (90-110%).

Data Analysis

River water quality data were analyzed using Microsoft Excel and Statistical Package for Social Sciences version 19 (SPSS 19) for descriptive analysis, water quality index (WQI) and principal component analysis (PCA); to identify the water status and pollution source between elements of origin parameters, while ArcGIS version 9.3 was used to determine the dominant source of pollutants through spatial pattern analysis.

Water Quality Index (WQI)

Healthy river should have good water quality to assist with the survival of aquatic animals. The river health level is measured using WQI, which based on several parameters that need to be assessed and monitored. Different country uses different parameter to determine the WQI, whereas the Department of Environment (DOE) Malaysia using DO, BOD, COD, NH_3N, SS, and pH in determining the WQI. Generally, DO is use to measure the amount of oxygen available in water (Juahir et al., 2011); BOD determines the strength of pollutants in term of oxygen required to stabilize the wastes or measures biodegradable waste present in water (WSDE, 2002); COD measure the amount of organic and inorganic oxydizable compound in water (Davis and McCuen, 2005); SS determines the natural pollutants and causes of turbidity in water (Mathvi and Razazi, 2005); NH_3N determine the amount of ammonia exists in water that could cause eutrophication (Wang et al., 2010); and pH are to measure the acid strength in water (Davis and McCuen, 2005). Therefore, WQI for Malacca River are determined using formula that was developed by DOE (Eq.1), which consists of different sub-indexes (SIs) calculated according to the best-fit relationship (Eq.2-7):

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_571588

$$WQI = 0.22 * SI_{DO} + 0.19 * SI_{BOD} + 0.16 * SI_{COD} + 0.15 * SI_{AN} + 0.16 * SI_{SS} + 0.12 * SI_{pH} \quad \text{(Eq.1)}$$

where WQI is water quality index; SI_{DO} is sub-index of DO; SI_{BOD} is sub-index of BOD; SI_{COD} is sub-index of COD; SI_{AN} is sub-index of NH_3N; SI_{SS} is sub-index of SS; SI_{pH} is sub-index of pH. Meanwhile, the sub-indexes (SIs) formulation is as followed (Eq.2-7);
Best-fit equations for DO sub-index:

$$SI_{DO} = \begin{cases} 0 & \text{for DO} < 8 \\ 100 & \text{for DO} > 92 \\ -0.395 + 0.030DO^2 - 0.00020DO^3 & \text{for } 8 < DO < 92 \end{cases} \quad \text{(Eq.2)}$$

Best-fit equations for BOD sub-index:

$$SI_{BOD} = \begin{cases} 100.4 - 4.23BOD & \text{for BOD} < 5 \\ 108e^{-0.055BOD} - 0.1BOD & \text{for BOD} > 5 \end{cases} \quad \text{(Eq.3)}$$

Best-fit equations for COD sub-index:

$$SI_{COD} = \begin{cases} -1.33COD + 99.1 & \text{for COD} < 20 \\ 103e^{-0.0157COD} - 0.04COD & \text{for COD} > 20 \end{cases} \quad \text{(Eq.4)}$$

Best-fit equations for AN sub-index:

$$SI_{AN} = \begin{cases} 100.5 - 105AN & \text{for AN} < 0.3 \\ 94e^{-0.573AN} - 5|AN - 2| & \text{for } 0.3 < AN < 4 \\ 0 & \text{for AN} > 4 \end{cases} \quad \text{(Eq.5)}$$

Best-fit equations for SS sub-index:

$$SI_{SS} = \begin{cases} 97.5e^{-0.00676SS} + 0.05SS & \text{for SS} < 100 \\ 71e^{-0.0016SS} - 0.015SS & \text{for } 100 < SS < 1000 \\ 0 & \text{for SS} > 1000 \end{cases} \quad \text{(Eq.6)}$$

Best-fit equations for pH sub-index:

$$SI_{pH} = \begin{cases} 17.2 - 17.2pH + 5.02pH^2 & \text{for pH} < 5.5 \\ -242 + 95.5pH - 6.67pH^2 & \text{for } 5.5 < pH < 7 \\ -181 + 82.4pH - 6.05pH^2 & \text{for } 7 < pH < 8.75 \\ 536 - 77.0pH + 2.76pH^2 & \text{for pH} > 8.75 \end{cases} \quad \text{(Eq.7)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_571588

Principal Component Analysis (PCA)

Principal component analysis was designed to convert a large dataset of original correlated variables into a smaller set of new and uncorrelated variables (i.e. principal components). The data reduction process would provide the most meaningful parameter information that can describe a whole data set with minimum loss of original information (Iscen et al., 2008). The principal components are weighted linear combinations of original variables, with the first principal component representing the largest variability of the original data set, and the second component representing the next largest variance that is orthogonal to the first component (Deb et al., 2008). In other words, PCA can be explained as follows:

$$z_{ij} = a_{i1}x_{1j} + a_{i2}x_{2j} + \ldots + a_{im}x_{mj} \qquad \text{(Eq.8)}$$

Where *z* is the component score, *a* is the component loading, *x* is the measured value of the variable, *i* is the component number, *j* is the sample number, and *m* is the total number of variables. As stated above, the general procedures used in PCA are (1) the hypothesis in an original data group is then reduced to dominant components or factors (source of variation) that influence the observed data variance; and (2) the whole data set is extracted through eigenvalues and eigenvectors from the square matrix produced by multiplying the data matrix (Aris et al., 2013). In other words, the PCA will undergo varimax rotation to produce the principal components (PCs) before determining the eigenvalue. The eigenvalues of more than 1 are considered significant (Kim and Mueller, 1987) to measure a new group of variables, namely Varimax Factor (VFs). The VFs coefficients that recorded a correlation of greater than 0.75 are considered as ‘strong’, 0.75 to 0.50 as ‘moderate’ and 0.50 to 0.30 as ‘weak’ significant factor (Liu et al., 2006). However, only factor loadings above 0.6 were taken into account for this study. 20 parameter variables will undergo PCA to determine the source of pollutants before hotspot analysis for the dominant source of pollutants in Malacca River.

Spatial Pattern Clustering Through Hotspot Analysis

Hotspot analysis can be clustered (spatial clusters) or individual (spatial outliers). In this study, spatial cluster of pollution would be water quality with a high value of parameter surrounded by a high value of pollutant sources. Meanwhile, spatial outliers of pollution include water quality with a high value of parameter surrounded by a normal or low value of pollutants source. The concept of hotspot can be expressed as:

$$G(d) = \frac{\sum\sum w_{ij}(d) x_i x_j}{\sum\sum x_i x_j}, \quad i \neq j \qquad \text{(Eq.9)}$$

where x_i is the value at location *i*, x_j is the value at location *j* if *j* is within *d* of *i*, and w_{ij}(d) is the spatial weight based on the weighted distance (e.g. inverse distance) (Getis and Ord, 1992). The expected value of *G (d)* is:

$$E(G) = \frac{\sum\sum w_{ij}(d)}{n(n-1)} \qquad \text{(Eq.10)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_571588

where *E (G)* is typically a very small value when *n* is large. A high *G (d)* value suggest a clustering of high values, and a low *G (d)* value suggests a clustering of low values. *Z* scores are used to evaluate statistical significance for *G (d)*. In other words, high positive *Z* scores suggest the presence of a cluster of high values or a hotspot, while high negative of *Z* scores suggest the presence of a cluster of low value or a cold spot (*Figure 2*).

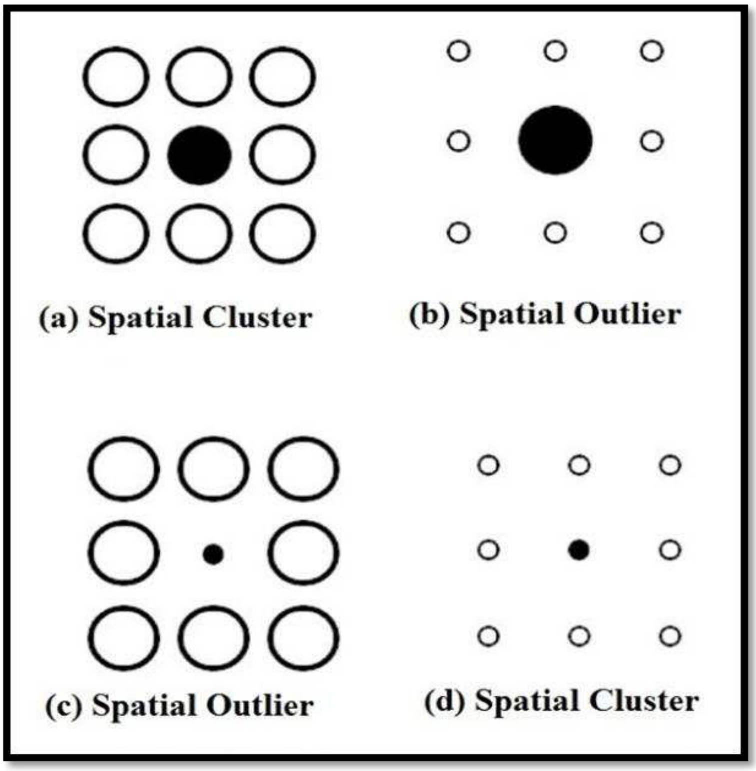

Figure 2. *The relationship of a location and its neighborhood; (a) and (b) are hotspot, (c) and (d) are cold spot*

Results and Discussion

Determination of Water Quality Status and WQI in the Malacca River

Water quality data of Malacca River (i.e. physico-chemical, biological, and trace element data) in comparison with the National Water Quality Standards (NWQS) (*Table 3* (i) and (ii) is as shown in *Table 4*. Based on *Table 4*, the result indicated that trace elements, together with pH and temperature, remained as class 1 in all sampling stations. Meanwhile, salinity in station 1 to 3 and station 7, together with turbidity in station 3, 8, and 9, was found to be in class 5. Only station 1 and 5 are in class 3 for turbidity, while other stations remained in class 2 and class 1 in terms of turbidity and salinity, respectively. Station 1 and 7 were found to be in class 5, station 2 and 3 to be in class 3, and station 4 to 6 were in class 1 for electrical conductivity and dissolved solids. However, only station 8 and 9 were in class 2 for electrical conductivity, while station 8 was within class 3 and station 9 was in class 1 for dissolved solids. For total suspended solids, most of the stations were classified as class 3, except for station 4, which was in class 4. BOD, COD, DO and NH_3N, in most of the water samples were classified as

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_571588

class 2 and class 3. However, station 2 and station 7 to 9 showed a class 4 BOD results. This includes NH_3N in station 1 to 3 and station 7 to 8 at class 4. Meanwhile, E. coli was classified as class 4 at station 3 and station 6 to 9, while the others were in class 5. Total coliform was found to be in class 5 for all sampling stations.

According to WQI (*Table 2*), majority of NH_3N and BOD parameters were in class 3, 4 or 5. Meanwhile, COD parameter from station 2 to 7 were in class 3, and others were in class 2. Both DO and TSS parameter showed that only several stations were in class 3. WQI trends showed that the water quality in Malacca River were declining from station 1 to station 7, which show that only station 4 and station 5 were polluted (class 4) while other stations were slightly polluted (class 3). Apart from that, station 8 and station 9 were still in clean condition, which is in class 2. Therefore, it can be said that all parameters value is affected (either decrease or increase) from the origins. These pollutants which came from human activities could cause problematical issues to the aquatic life in Malacca River.

Table 3(ii). *Water Classes and Uses (adapted from Malaysian DOE, 2012)*

Class 1	Conservation of natural environment Water supply I – Practically no treatment necessary Fishery – Very sensitive aquatic species
Class 2A	Water supply II – Conventional treatment required Fishery II – Sensitive aquatic species
Class 2B	Recreational use with body contact
Class 3	Water supply III – Extensive treatment required Fishery III – Common of economic value and tolerant species; livestock drinking
Class 4	Irrigation
Class 5	None of the above

Identification of the Source of Pollutants

Based on the results of water quality status, it was found that parameters like E-coli, coliform, salinity, turbidity, NH_3N, and BOD were in the category of polluted conditions, while several parameters like EC, TSS, DS, COD, and DO were only slightly polluted. Other parameters remained as clean in Malacca River. Therefore, principal component analysis (PCA) was used to identify the source of pollutants that contributed to the pollution in Malacca River. As shown in *Table 5*, 7 PCs were obtained with eigenvalues more than 1, with 65% of total variance. The PC1 loadings with 14.7% of total variance have strong positive loadings on DS, EC, salinity and NH_3N. Physico-chemical parameters like DS, EC and salinity may be related to the erosion of riverbank due to dredging activities in the river and agricultural runoff from non-point source pollution (Juahir et al., 2011). The results were coupled with the NH_3N pollution together with salinity, highlighting the usage of pesticide for agricultural activities within oil palm and rubber plantations, and animal husbandry (chicken, cow, and goat) carried out within Malacca River basins. These activities contributed to the non-point sources of pollution that occured through surface runoff and water flows through the sub-basins before entering Malacca River. Additionally, PC2 loadings indicated a strong positive in terms of turbidity and TSS with total variance of 9.7%, which can be relate to interruption of human activities towards hydrologic modifications (such as dredging, water diversion, and channelization) that caused disruption in Malacca River (Daneshmand et al., 2011). Other activities like discharge from urban developments through land clearing (USGS, 2010) and surface runoff leading to erosion of road edges (Iscen et al., 2008) could also bring a small amount of pollution to the river.

On the other hand, PC3 loadings explained BOD loadings and COD loadings as moderately positive with 9.4% of total variance, which might be connected to anthropogenic activities and point source pollution like sewage treatment plants and industrial effluents (Juahir et al., 2011). Meanwhile, PC4 explaining E-coli loadings, coliform loadings, and pH loadings showed a moderate positive with 8.9% of total variance. The presence of E-coli and coliform indicated that animal husbandry, sewage treatment plant, and municipal wastes contributed to point source pollution in the river. This situation has caused the river water to absorb a large amount of oxygen and hence decreases the availability of DO, which indirectly underwent the anaerobic fermentation processes to produce ammonia and organic acid (Juahir et al., 2011). Consequently, acidic materials through hydrolysis have caused the water pH to decrease drastically. Next, PC5 explained moderate positive loadings on Zn and Fe with 8.4% of total variance. The Zn pollution can be linked to the large number of houses and building in the area that uses metallic roofs coated with Zn, which can mobilize into the atmosphere and waterways during acid rain or smog (Juahir et al., 2011), while Fe pollution can be attributed to metal group originating from industrial effluents (Aris et al., 2013). PC6 and PC7 loadings showed moderately positive Cr and Hg loadings having total variance of 7.4% and 6.4% respectively. Cr pollution can be linked to urban storm runoff (Juahir et al., 2011), and Hg pollution were suspected to link with plastic and chemical industrial wastewater (Papaioannou et al., 2010). Therefore, based on PCA analysis, 5 categories of pollutant sources were identified, namely agricultural activities, municipal and commercial residential activities, industrial activities, animal husbandry activities, as well as sewage treatment plant.

Classification of dominant pollutant sources

GIS Hotspot analysis was used to determine the dominant pollutant sources, which have been identified from PCA, namely agricultural, residential, industrial, and animal husbandry activities, as well as a sewage treatment plant, as shown in *Figure 3*. As described previously, *Z* score was used to evaluate the statistical significance for the variable in hotspot analysis. High positive *Z* scores suggest the presence of a cluster of high values or hotspots, while high negative *Z* scores suggest the presence of a cluster of low value or cold spot. For agricultural activity, the variable produced a general G-statistic of 0.0 and a Z score of 37.31, suggesting a spatial clustering of high value of 0.01 significant levels. Secondly, the residential variable has general G-statistic of 0.0 and a Z score of 74.72, with spatial clustering at a high value of 0.01 significant levels. Industrial variable indicated a general G-statistic of 0.0 and a Z score of 13.5 and suggested spatial clustering of high value of 0.01 significant levels., Animal husbandry activity showed general G-statistic of 0.0 with a Z score of -1.08, suggesting a spatial clustering of low values towards 0.10 significant levels. On the other hand, sewage treatment plant showed no value in general G-statistic and Z score, indicated that there are no significant level at the random value. Lastly, open space variable recorded a general G-statistic of 0.0 with a Z score of 28.73 indicating a high value of spatial clustering of 0.01 significant levels. All Z scores of selected variables were incorporated into GIS mapping to determine the dominant pollutant sources through hotspot analysis (*Figure 3*).

*The bold values are factor loadings above 0.60 that were taken after Varimax rotation are performed

Figure 3 (a) indicated the agricultural activities weighted concentration that concentrated in Kampung Tualang sub-basin (S5), which can be described as a hot spot area. The existence of a hot spot area in S5 sub-basin is due to the ease of access to water resources from Durian Tunggal Reservoirs. Indirectly, pesticide and chemical substances used for agricultural activities would enter surface runoff during the wet season. The water would flow into a nearby sub-basin before entering Malacca River. These processes contributed to the non-point source pollution. As shown in *Figure 3 (b)* residential activities shows that the high values are concentrated in Kampung Kelemak sub-basin (S1), Kampung Sungai Petai sub-basin (S2), Kampung Cheng sub-basin (S6), Kampung Batu Berendam sub-basin (S7), and a little bit at Kampung Tualang sub-basin (S5). There is also a highly weighted concentration located parallel to the Malacca River from S1 to S5. Only moderate values are shown along S6 to S9. Hence, residential activities showed that almost every sub basin is a hot spot area and hence it is a

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_571588

significant to contributor of pollution to the river. This situation may be related to the rapid and uncontrolled development, drastically increasing population, and unmanageable land clearing that brought pollution through wash water and cooking waste, municipal waste, and commercial waste as well as metallic roof pollution.

DOI: http://dx.doi.org/10.15666/aeer/1504_571588

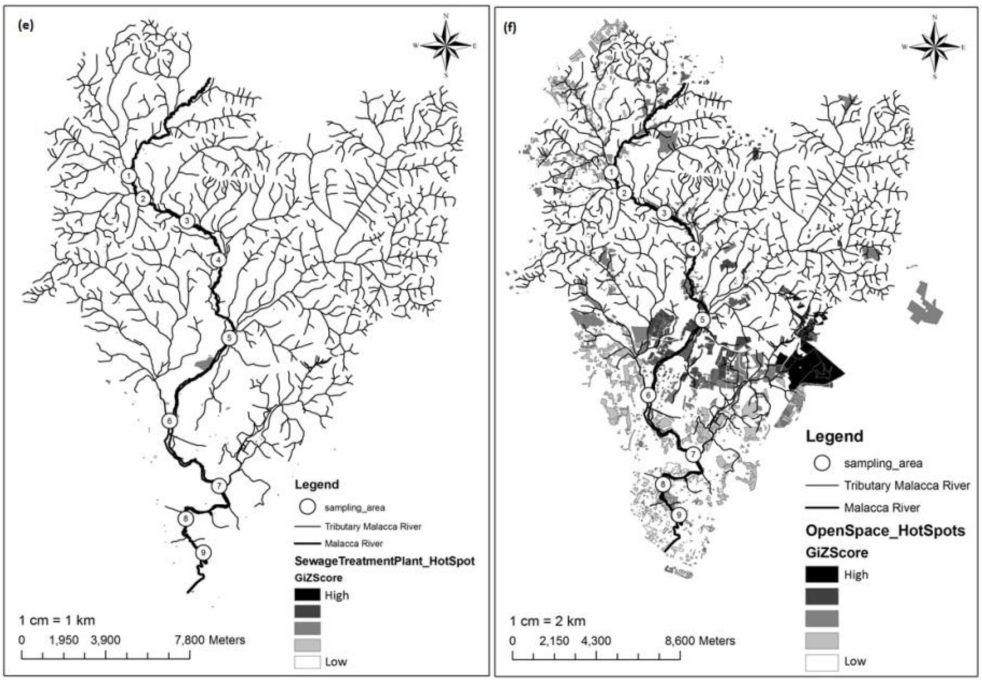

Figure 3. *Hotspot analysis of Pollutant Sources – (a) Agriculture; (b) Residential; (c) Industrial; (d) Animal Husbandry; (e) Sewage Treatment Plant; (f) Open Space*

Next, hot spot areas from industrial activities (*Figure 3 (c))* have been detected in Kampung Panchor sub-basin (S3), Harmoni Belimbing Dalam sub-basin (S4), Kampung Tualang sub-basin (S5), and Kampung Batu Berendam sub-basin (S7). High-technology and estate industries are the main contributors to point source pollution due to the direct discharge into sub basins before flowing into the main river. It is compulsory for industrial wastes to undergo treatment before being release onto surface water or in a river; however, certain industries refused to do so in order to save cost and time. Hence, these action increases the potential of hot spot area to pollute Malacca River sub-basins. Animal husbandry activities (refer to *Figure 3 (d))* shows a moderate hot spot area at Kampung Tualang sub-basin (S5) and several hot spots are scattered in sampling 1 to sampling 4 sub-basin, while the sewage treatment plant has a moderate hot spot area between S5 and S6 while others are scattered in S1 sub-basin and S6 to S9 sub-basins, respectively. Since animal husbandries are highlighted within a S5 sub-basin, this condition demonstrates that the activity is carried out in the area adjacent to Durian Tunggal Reservoirs as it is easier to obtain freshwater to feed the animals. However, unmanageable cleanliness within the farms led to animal feces flowing into the river through surface run-off, which contributed to the non-point source pollution. Sewage treatment plants that are scattered in downstream area can be clarified as low impact in terms of pollution in Malacca River, but they have a high chance to cause pollution if there is a malfunction that may lead to leakage (*Figure 3(e)).*

The open space variable shows a high value at Kampung Tualang sub-basin (S5) to act as a hot spot area, while moderate values were detected in S1 sub-basin and S6 to S8 sub-basins as shown in *Figure 3 (f).* Several moderate hot spot areas also exist along Malacca River, from sampling 1 to sampling 6. The main reason to have the open space variable in this study is to reduce river water pollution by controlling the pollutant source. This suggestion may be proposed to government sector agencies such as the

DOI: http://dx.doi.org/10.15666/aeer/1504_571588

Department of Environmental (DOE), Department of Irrigation and Drainage (JPS) and other departments that concerns with river water quality to build a monitoring system so that easi and frequent monitor of the water status could be done. At the same time, researchers and academicians may take the opportunity to develop studies on river water quality perspectives for a better environment.

Conclusion

This study has proven that PCA and GIS are remarkable and useful tools to discover the influential factors involved in Malacca River water quality. This study also revealed that sampling station 5 located in Kampung Tualang sub basin is considered to be the main area to cause pollution to the river through the dominant sources of pollutant from the agricultural, residential, industrial activities, and animal husbandry. Continuous exposure to pollutant sources concentration could pose a serious threat to the river's ecosystem in the present and future timeframe. Frequent assessment and monitoring is crucial for the continuous protection of Malacca River ecosystem. Therefore, this study does not only suggest the reduction of river water pollution by means of controlling the pollutant sources, but also by providing information which identifies the problematic areas for better management and understanding of the river water quality in the future. The study also provides a spatial database through GIS mapping for future reference for the development of proper land use and urban design procedures.

Acknowledgements. The authors would like to thank the Department of Environment (DOE) Malaysia, Department of Irrigation and Drainage (JPS) Malaysia, and Department of Town and Country Planning (JPBD) Malaysia for providing the base data for water quality, river, and GIS-map based maps including land use activities.

Abstract. The objective of this study was to assess the drought preparedness status of the farmers that benefited from the Nguni Cattle Development Project and the Sire Subsidy Scheme in North West Province, South Africa. The data were collected using both quantitative and qualitative approaches to research, through a semi-structured questionnaire with five sections that probed into: A) personal information, B) farmer socio-economic resources, C) farm operational resources, D) access to Early Warning Information, and E) constraints to drought preparedness. Collected data were coded, captured and analysed using Microsoft Excel and SPSS (version 23) into frequency counts, percentages, graphs and tables. The results revealed that, majority of the respondents were African (97.6%); male (74.1%); married (64.3%); between 50 and 64 years of age (43.5%) and (38.8%) had high school education, respectively. Furthermore, most (76%) respondent farmers were not drought prepared with regard to grazing availability; 20% of the farmers were found to have non-dependable sources of water; 60% of the farms did not have any structural units for maintaining fodder banks and 63% did not have enough fodder reserves. Most respondents (84%) had never received drought related early warning information. Respondents cited lack of money (62%) and deficiency of information (58%) as the major constraints to their drought preparedness. The study recommends that the agricultural extensionists' plausible contact (95%) with the farmers should be used to also educate farmers on effective drought mitigation strategies and for dissemination of early warning information.
Keywords: *climatic changes, drought mitigation, early warning information, fodder banks, spare grazing*

Introduction

South Africa has recently experienced one of the worst droughts of the past century, with compromised agricultural production anticipated in the summer rainfall areas. The impact of droughts already severed the South African agricultural sector, largely affecting the extensive farming areas. In South Africa, drought has already cost farmers' losses of up to ten million rand (R10m) in 2015 (Bahta et al., 2016). Drought is however a common phenomenon in semi-arid and arid ecosystems (Coppock, 2011). Drought is furthermore the most frequent (Backeberg and Viljoen, 2003) and devastating phenomena that occurs in South Africa (Boone et al., 2004; Austin, 2008). Agricultural drought often has direct effects on the economy through the associations of agriculture with other sectors of the economy. This makes drought an important hazard, particularly in terms of the numbers of people affected (Coppock, 2011; Ngaka, 2012).

The uncertainty on the occurrence and magnitude of the effects of climatic changes, including the occurrence of droughts, often makes mitigation efforts quite problematic. Knowledge of the drought preparedness or vulnerability of the beneficiary farmers can assist the sector in proactive planning for drought mitigation and therefore reduce the pool of those who need relief in the event of droughts.

The North West Provincial Department of Agriculture has through its Sire Subsidy Scheme (SSS) and the North West/Industrial Development Corporation - Nguni Cattle Development Project (NW/IDC-NCDP) distributed genetic breeding material (beef cattle) to identified farmers throughout the province for over 10 years. The primary aim of the SSS is to induce herd genetic change in an attempt to improve the overall herd performance by the introduction of quality performance tested sires. The NW/IDC-NCDP on the other hand, is a tripartite partnership between the Department of Agriculture, the Industrial Development Corporation (IDC) and North West University (Mafikeng Campus) (DACE, 2008, Cwaile et al., 2012). The NW/IDC-NCDP was founded in 2006 (IDC, 2007) with the main aim of reintroducing and preserving the indigenous Nguni cattle genetic pool in the province (DACE, 2008).

All of the distributed genetic material is farmed under harsh extensive conditions, notwithstanding that, extensive beef production in the semi-arid and arid regions is highly vulnerable to climatic changes. On the other hand, North West Province has, as recent as in the years 2012 to 2015, been reported to have had the most devastating drought in 80 years. This is not surprising, considering that the year 2015 has been recorded as the driest year ever in South Africa since the recording of rainfall started in 1904 (SAWS, 2016). It is necessary therefore to collect all relevant data that could aid in assessing as to whether conditions under which the NW/IDC-NCDP and SSS cattle are farmed with, would allow for sustained production even in the event of the imminent droughts.

Drought preparedness involves vulnerability or resilience assessments, monitoring, forecasting as well as mitigation and response planning measures (Wilhite et al., 2005; Gutiérrez et al*.,* 2014). The main objective of the study was therefore to:

a) Determine the drought preparedness status of the farmers that benefited from the NW/IDC-NCDP and SSS in the North West Province.

The specific objectives of the study were to:

a) Determine the resource drought preparedness of the beneficiary farms.
b) Identify possible factors influencing drought preparedness of farmers.

Materials and Methods

The study was conducted in North West Province which occupies a total area of 104 882 km^2, covering 8.7% of the total area of the Republic of South Africa. The province is divided into four district municipalities, namely: Dr Ruth Segomotsi Mompati in the west; Dr Kenneth Kaunda in the south; Bojanala Platinum in the east, as well as the centrally located Ngaka Modiri Molema. North West Province borders the provinces of Northern Cape in the west, Free State in the south, Gauteng in the east and Limpopo in the north-east with the Republic of Botswana in the northern side. Much of the province consists of flat areas of scattered trees and grasslands. The rainfall pattern of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_589603

province is highly variable, both spatially and temporally. Under normal climatic conditions, the western parts of the province receive on average less than 300mm per annum, the central parts around 550mm and the eastern and south-eastern parts receives over 600mm per annum.

The data were collected using both quantitative and qualitative approaches to research. This was done in an effort to improve the validity, analytic power and relevance of the findings. The qualitative approach documented the respondents' perceptions and opinions through in-depth interviews while the quantitative approach was used to capture the *in-situ* numerical and physical observations on infrastructure. Data were collected through a semi-structured questionnaire made up of five sections, namely: A) personal information, B) farmer socio-economic resources, C) farm operational resources, D) access to Early Warning Information (EWI), and E) constraints to drought preparedness. Face to face interviews as well as physical observations, and assessment of the farms' resource base were used to collect the data. An inclusive total of 85 beneficiaries from all four districts of North West Province were interviewed in this study. The collected data were coded, captured and analysed using Microsoft Excel (2010) and SPSS (version 23) into frequency counts, percentages, graphs and tables.

The SSS had not been rolled out in all the districts and therefore, proportional representation of the SSS against the NW/IDC-NCDP could not be achieved (*Fig. 1*). Only beneficiaries who were actively involved in the project were targeted for the NW/IDC-NCDP. This was because, once the beneficiaries have returned their loaned cattle, there is essentially no contractual obligation on their part to partake in departmental programmes.

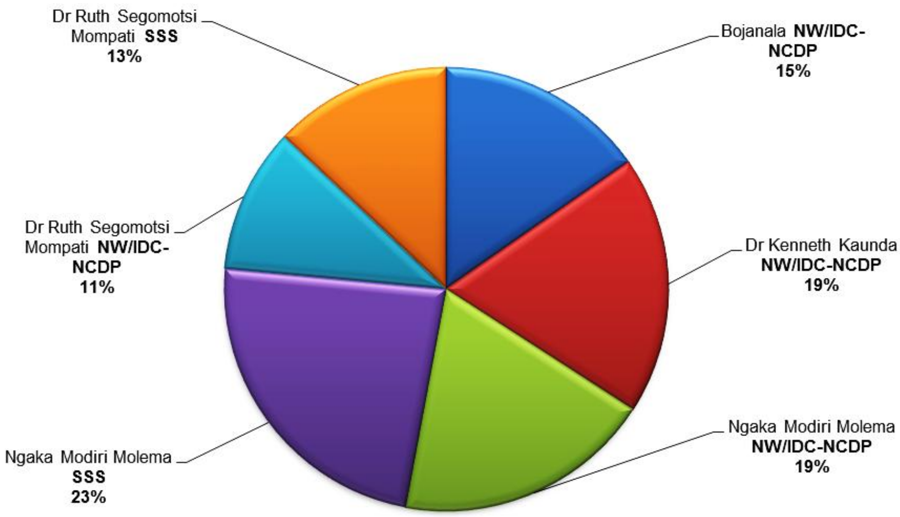

Figure 1. *Data origin and distribution per district*

Results

Socio-economic and demographic characteristics of the respondents

The distribution of respondents according to various socio-economic and demographic characteristics is summarised in *Table 1*. The results revealed that most of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_589603

the respondents were African (97.6%), male (74.1%), married (64.3%), between 50 and 64 years of age (43.5%) and (38.8%) had high school education, respectively. For the purposes of this report, high school education refers to educational programmes consisting most commonly of students/pupils enrolled in grades 10 through to 12. A noticeable number of the respondents (31.8%) had tertiary education. Most respondents (49.4%) had a substantial household size of about 5 to 8 members. This is so despite most respondents (51.2%) having on average, 1 to 3 dependants. The results further show that young farmers (aged 34 years and less) accounted for only 9.4% of the respondents. More than half (51.8%) of the respondent farmers never received any training or short courses in agriculture.

Table 1. *Socio-demographic characteristics of respondents*

Characteristic	Sub-characteristic	Frequency	Percentage
Gender	Female	18	21.2

Farmer socio-economic resources

The results revealed that 88% of the respondents were full-time farmers and only 8% of them were farming on a part time basis (*Table 2*). Groups that included both full time and part time farmers represented a very small part (4%) of the respondents. Furthermore, 73% of the respondent famers did not engage in non-farming business activities. The results further revealed that 76% of the respondents had no other income to help them during droughts.

Table2. *Summary of responses on farmer socio-economic resources*

Characteristic	Sub-characteristic	Frequency	Percentage
Type of farmer?	Full time	75	88
	Part time	7	8
	Both (as a group)	3	4
Do you engage in non-farming business activities?	Yes	23	27
	No	62	73
Do you have other income to help you during droughts?	Yes	20	24
	No	65	76

Farm operational resources

Responses and observations on farm operational resources in relation to available grazing are summarised in *Table 3*. On farm observations revealed that only 43 (51%) of the respondent farms seemed to have reasonable amounts of grazing for a season. Of the 43 farms, 31 (72%) had enough grazing to last for 5 to 6 months. The remaining farms had either enough grazing for 1 to 2 months (9%) or 3 to 4 months (19%). However, from the 43 farms with reasonable amounts of grazing, only 35 (41%) had spare or reserved grazing, of which only 57% of such spare grazing could sustain a herd of cattle for 5 to 6 months. In essence, out of the studied population (85), only 31 (36%) of the farms had enough grazing to last for 5 to 6 months, and only 20 (24%) of these farms had enough spare grazing to last for 5 to 6 months. These results indicate therefore that the remaining 65 (76%) respondent farms did not have enough grazing to sustain their cattle for two seasons of the year.

It is further revealed in *Table 3* that boreholes were the most prominent (86%) source of drinking water for cattle. The majority of the respondents rated their sources of water as either highly dependable (54%) or dependable (26%). The remaining respondents (20%) who rated their water source as non-dependable, had either a too small/non-functional reservoir or only one borehole (16%), whereas a minority (4%) had no source of water at all on the farm.

Table 3 also shows that 60% of the respondent farms did not have any structural units for maintaining fodder banks. Furthermore, 84% of the respondent farms did not have enough fodder reserves. The reasons advanced by farmers for not having stored fodder are also summarised in *Table 3*. Of the 84% respondents without enough stored fodder, only 21% had at least enough standing hay as back-up fodder for periods of shortages. The remaining 63% did not have enough fodder reserves. It is worth mentioning that among the reasons advanced for not maintaining fodder banks, the combined frequencies of “lack of knowledge” and “ignorance” accounts for 38% of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_589603

reasons why respondents did not have any fodder stored. Lack of funds accounted for a further 23%, whereas lack of infrastructure and equipment respectively accounted for 17 % and 1% of the reasons why respondents had no reserved fodder.

Table 3. *Summary of responses and observations on farm operational resources*

Characteristic	Sub-characteristic	Frequency	Percentage
Does the farm have enough grazing?	Yes	43	51
	No	42	49
If yes, for how long?	1-2 months	4	9
	3-4 months	8	19
	5-6 months	31	72
Does the farm have spare grazing for the herd?	Yes	35	41
	No	50	59
If yes, for how long?	1-2 months	5	14
	3-4 months	10	29
	5-6 months	20	57
Does the farm have adequate fodder banks?	Yes	34	40
	No	51	60
Does the farm have enough fodder in fodder banks?	Yes	13	15
	No	71	84
What is your source of water for cattle	Borehole	73	86
How dependable is your water source	Dependable to Highly dependable	68	80
	Not dependable	17	20
Reasons for not having stored fodder	No infrastructure	12	17
	No funds	17	23
	Lack of knowledge	12	17
	Ignorance (Do not know)	15	21
	Have enough standing hay (grazing)	15	21
	Lack of equipment	1	1

Source of extension messages

Figure 2 shows that 95% of the respondents had contact with agricultural extensionists and that 64% of such contact was on a regular basis. The main source of extension messages (94%) with regard to drought were reported to be from government extension services (*Fig. 3*). This can be expected given that 65% of the respondents did not belong to any farmer association or organised agriculture groupings. A negligible number (6%) of respondents received extension messages from non-governmental sources as well.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_589603

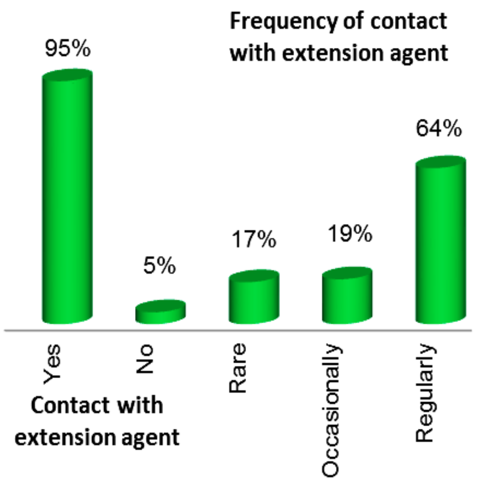

Figure 2. Respondents' contact with extension agents

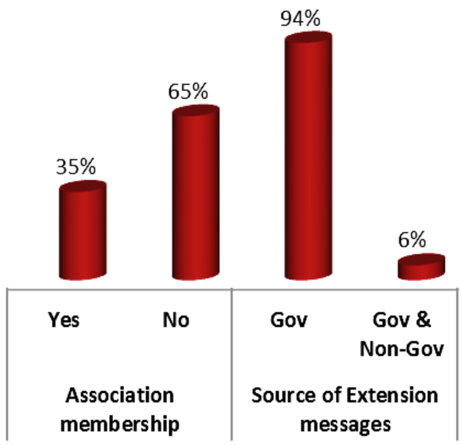

Figure 3. Membership of associations and source of extension messages

Early warning information

Access to early warning information and drought planning among the respondent farmers is summarised in *Table 4*. The results indicate that 98% of the respondents reported that they earnestly need EWI, and 91% of them expect such information to come from the state extension services.

Table 4. *Access to early warning information and drought planning*

Characteristic	Sub-characteristic	Frequency	Percentage
Have you directly received any advice on what to do before and during drought?	Yes	15	18
	No	70	82
Have you directly received any EWI about drought?	Yes	14	16
	No	71	84
Do you need EWI for drought preparation?	Yes	83	98
	No	2	2
From where can you get expert advice/information about drought?	Extension Officers (EO)	77	91
	EO and SA Weather services	3	3
	I do not know	4	5
	Climatologists	1	1
Do you have an existing drought plan?	Yes	37	44
	No	48	56
Reasons for not having a drought plan?	Lack of knowledge	40	73
	The farm has enough standing hay	8	14
	I usually buy fodder as needed	3	6
	Combination of both the above	4	7

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_589603

However, 84% of the farmers have never directly received EWI with reference to neither their specific farming area nor their farms. Furthermore, 82% of the respondents reported that they have never directly received advice on what to do before or during drought for purposes of enhancing their drought preparedness. More than half (56%) of the farmers did not have any drought mitigation plan at all. *Table 4* further revealed that 73% of the respondents cited lack of knowledge as the major reason for not having any drought plan.

Land utilisation

Proportional land use subdivisions among respondent farms are summarised in *Table 5*. The individual farm sizes vary considerably within and across district municipalities and range from 4 hectares in Ngaka Modiri Molema to 3600 hectares in Dr Ruth Segomotsi Mompati. The average farm size for the studied population was found to be 709.51 ha with a standard deviation equalling 507.94. Most of the respondents are farming extensively on veld (89%) with very little (4%) planted pastures (*Table 5*). The available arable land (7%) is often cultivated and of reasonable use to livestock for drought preparedness purposes.

Table 5. *Farm land (ha) size statistics and proportional subdivision*

Farm size and livestock statistics

Farm size and livestock statistics per district are summarized in *Table 6*. On average, the largest farms were observed in Dr Ruth Segomotsi Mompati, and respectively followed by the Dr Kenneth Kaunda; Bojanala Platinum and Ngaka Modiri Molema districts. The largest herds (mean) were surprisingly observed from the Dr Kenneth Kaunda district (113) followed by Bojanala platinum district (71). The herds with the least number of cattle (2 and 17) were observed from the Dr Ruth Segomotsi Mompati and Ngaka Modiri Molema districts respectively. The results with regard to farm and herd sizes are not surprising, and are largely in accordance with the grazing potential (natural veld) of the specific areas (*Fig. 5*) in terms of hectares per large stock unit (ha/LSU). For instance, the smallest herd (2 cattle) was observed from a communal area in Taung with a grazing potential of 20-25 ha/LSU, followed by herds from the Mafikeng area with a grazing potential of 18 ha/LSU (*Fig. 5*).

Grazing in Dr Ruth Segomotsi Mompati was mainly made up of natural veld (100%), followed by the Bojanala Platinum district (96%) and Dr Kenneth Kaunda district (84%) as well as Ngaka Modiri Molema (79%). In addition to natural grazing, the balance of land utilization percentages in *Table 6* represented arable land under dryland production as well as cultivated pastures.

DOI: http://dx.doi.org/10.15666/aeer/1504_589603

The majority of the farms are leased (61%) and only 14% of respondents own the land that they are farming on (*Fig. 4*). This may be contributory to the observed frequency (17%) of "no infrastructure" regarding lack of fodder banks in *Table 3*, as farmers may be reluctant to make improvements on leased land. A further 17% and 8 % of the land was respectively utilized through communal and tribal allocation.

Constraints to drought preparedness

Out of a number of possible constraints to drought preparedness, mainly three constraints were cited by all respondents (*Table 7*). It is revealed in *Table 7* that lack of government support was the least (42%) of the constraints to drought preparedness. However, lack of money (62%), followed by lack of information (58%) were cited as the two biggest constraints to drought preparedness.

Discussion

Socio-demographic characteristics are of significant importance when studying drought preparedness or vulnerability of farmers. This is because the socio-demographic characteristics are likely to have varied influence on human behaviour in response to drought. For example, Raphael et al. (2009) found that the odds of perceived drought being very likely to continue, were significantly higher in women than in men when considering the concern for self or family. Similarly, some studies found that as a demographic characteristic, gender had a critical influence in decisions on drought and agricultural activities (Bahta et al., 2016; Muyambo et al., 2017). The results confirm that animal production is a male dominated career in the studied area, with very little youth involvement. In agreement, Cwaile et al. (2012) found the majority of the Nguni cattle beneficiaries to be males aged above 60 years, and Oladele et al. (2013) found that the youth accounted for only about (7%) of respondents in their study. The lower level of participation of younger persons in this study is suggestive of compromised youth empowerment with reference to the two schemes understudy. The lower participation of the youth may be further exacerbated by capital requirements for cattle

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_589603

farming, particularly access to land. Youth within close proximity of the surveyed demographic population did not own or have much access to land and therefore had limited chances of participating in cattle farming. In line with these socio-demographic characteristics, it is not surprising that the majority of respondent farmers were not drought prepared.

The finding on respondent education is in agreement with the national census (Stats SA, 2011), which declared that among the South African population, 35.2% of black/African citizens have completed an education level of high school or higher. However, this level of education did not seem to encourage drought preparedness in anyway.

The results on farmer socio-economic resources suggest that the majority of the respondents have ample opportunity to decisively focus on farming activities, including drought preparedness. The results further confirm that a great majority of the farmers are dependent on their farming enterprises for income. It is therefore important for these famers to be drought prepared since their entire livelihood is dependent on their farming enterprises.

Considering that all the farms are managed as extensive farming units, a conclusion can be drawn from the result on farm operational resources that the respondents were already prone to grazing shortages and therefore vulnerable to drought at the time of the study. These findings point to a worrisome scenario, particularly when considering that the frequency and impact of natural disasters like drought has significantly increased in recent years (Ngaka, 2012), with further increase in rainfall variability expected for Southern Africa (Van Riet, 2012). In addition, North West Province has as recent as 2015, been reported to have experienced the most devastating drought in about 80 years.

Fodder banks are concentrated units of stored forage, established for storing and providing additional feed for livestock during the dry season or periods of extended grazing shortages. The frequency of "lack of funds" as a reason for not having fodder banks is suggestive that the affected farming enterprises do not generate enough income to cater for drought preparedness activities.

There is general consensus that, farm adaptability is an important link between sustainable agriculture and drought vulnerability (Wall and Smit, 2005; Thomas et al., 2007; Bryan et al., 2009; Knutson et al., 2011). Efforts should therefore be made to enhance farm adaptability to climatic changes and consequently to drought. This is more so when considering that, it is often necessary for farmers to make certain climate influenced decisions several months before the impact of the climate variation is realized (Vogel et al., 2000; Du Plessis and Van der Waal, 2004).

Literature predictions suggest that, the effects of climate change on the southern hemisphere will present more frequent and pronounced periods of droughts (Bryan et al., 2009; Meissner et al., 2013; Scholtz et al., 2013). Therefore, although 80% of the respondents had dependable to highly dependable sources of water, South Africa is a water stressed country and a need to plan for periods of hydrological droughts and manage water availability as well as accessibility remains very important. The desirable availability of water in this study should be interpreted with caution, particularly because hydrological drought tends to lag behind meteorological drought with some temporal margin. For instance, Edossa et al. (2010; 2014) found that the lag time between the hydrological and meteorological drought events is often in the range of 4 – 12 months.

The observed plausible contact with agricultural extensionists in this study is probably encouraged by the fact that, regular monitoring of the projects is an inherent job expectation on the part of the agricultural extensionists. It is however surprising that the levels of awareness of the respondents with regard to drought preparedness and EWI does not correspond to the reported magnitude of contact with agricultural extensionists. This result is suggestive of a discord with regard to the relevance of the extension messages delivered on the observed contact junctures. In support, Maphodi et al. (2014) postulated that lack of adequate and relevant updated knowledge on various subject areas by agricultural extension officers might be the stumbling block for useful agricultural extension services to be rendered.

The results suggest that there is a pronounced inadequacy with regard to dissemination of EWI to farmers particularly with regard to droughts. This may consequently explain in part why 56% of the respondents did not have any existing drought plan. This is of concern, particularly when considering that most of the respondents had regular contact with agricultural extension services. The inadequacy in the dissemination of EWI on drought in the study area is a direct challenge to both the departmental Disaster Risk Management (DRM) and the agricultural extension services. The responsibility of the dissemination of any agricultural drought related information is therefore squarely on government, particularly by agricultural extension services. This is more so when considering that the results further showed that 65% of respondents were not affiliated to any farmer's association and 94% of the received extension messages, were from government extension services.

A conundrum remains, if extensionists are having such plausible contact (95%) with the studied farmers, how does it happen that 84% of these farmers have never received EWI and were never instructed on drought mitigation strategies? While this question remains a subject of a different study, this puzzle is nonetheless further suggestive of a discord of responsibilities between extension services and DRM within the provincial department of agriculture. Additionally, these findings highlight in essence, the possible need to provide intensive extension workers' training on interpretation and conversion of EWI into extension messages.

The large standard deviation in land utilisation indicates the degree to which individual farms differ from the overall mean of all surveyed farms. This is suggestive of a large size variation between farms. As a result therefore, all assistance for drought preparedness will need to be tailor-made, since one strategy may not be applicable to all farms. Furthermore, both extensive beef and dryland production systems as depicted from this study are highly dependent on climatic conditions, consequently increasing the vulnerability prospects of the respondents to climatic variations, particularly drought. This is of great concern, particularly when considering the general consensus that southern Africa will become warmer and drier (Meissner et al., 2013) with overall increases in drought frequency (O'Farrell et al., 2009). These impacts can be expected to amplify the vulnerability of livestock production systems (Gill and Smith, 2008; Rust and Rust, 2013).

The results on herd size are contrary to the findings of Stats SA. (2011), where the largest herds in the country were observed in the Dr Ruth Segomotsi Mompati district. This contrast is probably as a result of the effects of the recent droughts, where areas with less rainfall had the most stock reductions.

It can be deduced from these results that more than half of the respondents are satisfied with government support in general but have significant challenges with

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_589603

funding and relevant knowledge/information on drought mitigation strategies as well as preparedness. Similarly, Maphodi et al. (2014) found that although 84.7% of farmers had access to government support, 84.2 % of them indicated that they had financial problems. The role of government regarding financial assistance to farmers, and that of extensionists in educating farmers on effective drought management strategies can as a result never be over emphasised.

Suggestions and conclusion

Suggestions for drought preparedness

The high frequency of drought vulnerability among the farmers, as well as the looming climate change and its associated effects suggests a need for proactive farm management practices and interventions, in preparation for drought eventualities. To ensure the realisation of drought preparedness of the surveyed farmers, the following interventions are suggested:

- Agricultural extensionists should acquire foreknowledge and information on anticipated climatic changes, for them to be able to timeously guide and assist vulnerable farmers with regard to mitigation and coping strategies.
- Famers need to appropriately manage their production systems to achieve high operational efficiency for income generation, in order for drought preparedness costs to be absorbed by their operations.
- The extensionists' plausible contact with famers should among other things, be used to educate farmers on proactive resource management for enhancing farm adaptability to climatic changes as well as on effective drought mitigation strategies for increasing farm resilience.
- The provincial department of agriculture should develop and enforce an obligatory institutional information exchange protocol between DRM and extension services for EWI.
- The provincial department of agriculture should prioritise the development and dissemination of EWI to administrative officials and farmers respectively.
- Subsequently, concerted efforts on the part of extension services should be made to repackage extension messages in such a way that they are spatially and temporally relevant to drought related needs of the farmers, and to create avenues on which regular area specific updates can be delivered to farmers.

Conclusion

This study revealed that the majority of farmers were not drought prepared and had very little knowledge regarding drought planning and management thereof. Grazing availability was exclusively a key determinant of drought vulnerability. Access to drinking water for cattle seemed to have less influence on the vulnerability of the surveyed respondents. A pronounced inadequacy with regard to dissemination of EWI to farmers particularly with regard to droughts was observed. Agricultural extensionists had a plausible contact with most farmers on a regular basis. Such contact was however not used to educate farmers on effective drought mitigation strategies.

APPLICATION OF CA-MARKOV MODEL AND LAND USE/LAND COVER CHANGES IN MALACCA RIVER WATERSHED, MALAYSIA

HUA, A. K.

Department of Environmental Sciences, Faculty of Environmental Studies, Universiti Putra Malaysia, 43400 UPM Serdang, Selangor, Malaysia
e-mail: angkeanhua@yahoo.com

(Received 28th Mar 2017; accepted 6th Jun 2017)

Abstract. Modeling the effects of past and current land use composition on surface water quality of the Malacca River watershed provides valuable information for environmental and land planning. The Land use land cover (LULC) spatio-temporal changes in watershed are classified as non-industrial area, industrial area, vegetation area, open space area, water bodies, as well as farming area. This is compared with the future spatial pattern simulated using CA-Markov model to evaluate qualitative and quantitative changes of LULC over time (between 2001, 2008, 2015, and 2029). This analysis consisted of the entire Malacca River watershed area. Changes may provide information on determinant of river water quality in future. Based on LULC monitoring and future simulation approach, the results may be used in an early warning system by demonstrating trend and consequences of changes in watershed. Continuous downward trends for vegetation area, open space area, and water bodies are due to expansion in non-industrial area, industrial area, and farming areas that increase contamination in the Malacca River. The findings demonstrate the need for more regulation in land use policy design, planning, and development for the protection of river water quality.
Keywords: *land use land cover changes, CA-Markov model, land-sat, quantitative and qualitative simulation*

Introduction

Anthropogenic activities negatively affect the conditions of the world's water. Various studies have estimated that half of the world's water quality has decreased due to human activities (Aris et al., 2013; Najar and Khan, 2012), and this condition has continuously worsened until today (Hua, 2017; Rosli et al., 2015). According to Hua et al. (2016), the main characteristic to cause contamination and detected as pollutant sources are residential, industrial, and agricultural activities. This matter is confidently supported by a majority of researchers (Aris et al., 2013; Hua, 2017; Hua et al., 2016; Rosli et al., 2015; Wan et al., 2014). Human alteration of cities engineered toward the land use land cover (LULC) change drastically results in negative impact on water quality, especially in rivers (Wan et al., 2014; Yang et al., 2012). Based on the evidence, contaminated rivers could threaten aquatic animal, reduce the availability of quality water. This will affect the flora and fauna, as well as affecting the climate at a regional scale (Carey and Fulweiler, 2012; Wan et al., 2014). Hence, it has become essential to obtain an understanding of how recent trajectories of land use will manifest in the future (Parsa et al., 2016; Subedi et al., 2013).

LULC change models are usually applied to detect location of the changes occurred or will potentially occur (Halmy et al., 2015; Yagoub and Al Bizreh, 2014). By determining the factors of the changes, the models benefit through providing probabilistic prediction of possible changes may occur (Halmy et al., 2015). Technically, change analysis is carried out

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_605622

using historical land use data in which the past land transformations and transitions were assessed. The transition trend is incorporated with environmental variables to provide an estimate of future scenarios (Behera et al., 2012; Yagoub and Al Bizreh, 2014). Prediction of LULC changes is important to understand and highlight the potential modifications and alterations that might be happen to the landscape in the near future. Typically, changes occur due to increasing population, distance to roads or other facilities, type of the soil, environmental issues, and so on. LULC models are usually used to assess the cumulative impact of land use changes and develop the future scenarios (Behera et al., 2012; Halmy et al., 2015), which is important in providing support and help to land use planners, resource managers, and conservation practitioners in making decisions (Halmy et al., 2015; Memarian, et al., 2013; Parsa et al., 2016). Simultaneously, prediction LULC changes model provide advantages in different applications, such as urban planning through modeling rural development and urban growth (Arsanjani et al., 2013); selecting conservation priority areas and setting alternative conservation measures (Subedi et al., 2013); studying dynamics of shifting cultivation (Halmy et al., 2015); as well as simulating the land use range dynamics under different watershed area (Behera et al., 2012; Memarian, et al., 2013).

Markov chain analysis works on the assumptions of physics in which the probability of a system being a certain state at certain time can be determined if the earlier time state is known (Arsanjani et al., 2013; Behera et al., 2012; Halmy et al., 2015). In other words, Markov chain analysis uses statistical spatially dependent land use data required by logistic regression (Arsanjani et al., 2013). This method is based on developing a transition probability matrix of land use change between two different dates derived from observation, which will be used to provide estimations of the probability that each pixel of certain LULC classes will be transformed to another class or remain in the same class (Yagoub and Al Bizreh, 2014). Nevertheless, Markov chain analysis has several issues as the methods only provide short-term projection (Sinha and Kumar, 2013) and are not spatially explicit (Halmy et al., 2015), as it does not provide spatial distribution of the changes that might occur to understand more about the potential impact of the projected changes. These issues can be overcome through suggestion of integrated modeling approaches with other different dynamic and empirical methods considered suitable for modeling land use changes processes (Halmy et al., 2015; Sinha and Kumar, 2013).

The Markov chain model can be integrated with the cellular automata model (or CA-Markov model), and these models have been widely used in different scale especially involve with modeling and predicting the land use change (Arsanjani et al., 2013; Subedi et al., 2013). The CA-Markov model is applied in this for the advantages of the combination of the stochastic aspatial Markov techniques with the stochastic spatial cellular automata method (Arsanjani et al., 2013). These include the prediction of two-way transitions among the availability of LULC classes rather than the Geomod technique that only concentrates on prediction of one way loss or gain in one classes (Halmy et al., 2015). Hence, transition-based models are the integration between aspatial Markov model with spatial cellular automata model to performed the regression-based models in predicting the land use change. This study has been carried out to provide information on the presence of LULC patterns in the Malacca River watershed and aims to analyze the changes of landscape trend pattern using the past LULC, the presented LULC, and future LULC using simulation modeling for the Malacca River watershed.

Materials and Methods

Study Area

Malacca state is located in southwest Peninsular Malaysia at 2°23'16.08"N to 2°24'52.27"N latitude and 102°10'36.45"E to 102°29'17.68"E for longitude. Malacca state has a catchment area of approximately 670 km^2 and contains an 80 km length of Malacca River flowing through Alor Gajah and Malacca Central (*Figure 1*). Malacca state also has a reservoir located between Alor Gajah and Malacca Central called the Durian Tunggal Reservoir; with a catchment of 20 km^2. This reservoir supplies water to Malacca residents. Increasing local population has led to increasing public facilities such as transport, healthcare, accommodation, sewage and water supply services (Hua, 2017; Rosli et al., 2015). Due to drastic population growth, rapid urban development in Malacca state also increased; especially demanding from the land use perspective. A majority of residential activities are centralized in the city, which extends about 10 km to the west, the east, as well as the north for 20 km. Land use changes is continuously develop until today. Indirectly, these actions have contributed to economic growth and social relationships, including impacting the environmental quality of the water in the Malacca River.

Data Collection

Remotely sensed data have been widely used as a very cost effective mean to obtain geo-referred data and maps for evaluation and monitoring LULC. Three LULC data sets of the Malacca River watershed were obtain from USGS Earth Explorer dated 2001, 2008, and 2015 and used in this study. These three data sets are considered suitable with cloud-free spatial coverage and relatively high spatial and spectral resolution of satellite images. Remote sensing images of Landsat satellites were selected for the investigation of long-term variations in LULC types in the study area (*Table 1*). After the limitations and constraints regarding of the data were taken into account, a 14-years period or time-span was found appropriate for monitoring and evaluation of LULC dynamic. The steps of the research study are shown in *Figure 2*.

Table 1. *Landsat data sources*

Satellite	Sensor	Acquisition	Band Combination
Landsat 4-5	TM	2001	1,2,3
Landsat 7	ETM+	2008	1,2,3
Landsat 8	OLI	2015	2,3,4

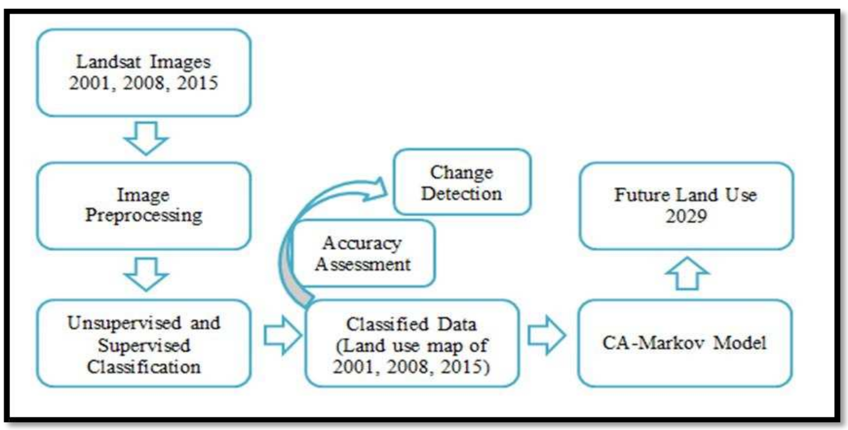

Figure 2. *Demonstration of research methodology as a flowchart. The 2001 and 2008 maps used to simulated 2015 maps and the simulated 2015 map was used to validate the model. Then 2008 and 2015 maps were use as the input to produce simulated 2029 map*

Data Pre-Processing and Image Classification

Preprocessing of satellite images is essential and aims at the unique goal of establishing a more direct linkage between data and the biophysical phenomena it represents (Parsa et al., 2016). Pre-processing is accomplished using ArcGIS version 10.0 for geo-referencing, mosaicking and sub setting of the image for the Area of Interest (AOI). Landsat 8 image underwent spatial sharpening using the panchromatic bands, which resulted in a 15m resolution. Meanwhile, Landsat 5 TM and Landsat 7 ETM+ images for 2001 and 2008 were in original 30m resolution. Further image processing analysis was carried out using

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_605622

ENVI 4.0. The image was displayed in natural color composite using a band combination of 3, 2, 1 for Landsat 5 TM and 4, 3, 2 for Landsat 8. Maximum Likelihood supervised classification was performed using several selected regions, and Regions of Interest (ROI) were based on delineated classes of vegetation area, industrial and non-industrial area, water, open space area and farming area (*Table 2*).

Table 2. *Classes delineated on the basis of supervised classification*

Class Name	Description
Vegetation Area	Includes all agricultural lands and forest fields.
Non-Industrial Area	Includes all residential, commercial, administration, cemetery and transportation, as well as sewage treatment plant (include individual septic tank).
Industrial Area	Includes all industrial area.
Water Bodies	Includes all water bodies (river, lakes, gravels, stream, canals, and reservoirs).
Open Space Area	Includes all land areas that exposed soil and barren area influenced by human.
Farming Area	Includes all animal husbandry (or farming) area.

Accuracy Assessment

Accuracy assessments for the 2001, 2008, and 2015 images were carried out to determine the quality of information provided from the data. If the data are to be used for change detection analysis, it is important to conduct accuracy assessment for individual classification (Behera et al., 2012). Kappa tests are used to measuring the accuracy of classification as the test is able to account all elements in confusion matrix including diagonal elements (Halmy et al., 2015). The Kappa test is a measure between predefined producer rating and user assigned rating, which can be expressed in the formula as:

$$K = \frac{P(A) - P(E)}{1 - P(E)} \quad \text{(Eq. 1)}$$

where *P(A)* is the number of time the *k* raters agree, and P(E) is the number of time the *k* raters are expected to agree only by chance (El-Kawy et al., 2011; Pontius and Millones, 2011). Meanwhile, user accuracy can be defined as the probability of a pixel on the image actually representing a class on the ground. Producer’s accuracy indicates the probability a pixel being correctly classified and is mainly used to determine how well an area can be classified (Pontius and Millones, 2011). As described earlier, the six categories of classes which include vegetation area, non-industrial area, industrial area, water bodies, open space

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_605622

area, and farming area, that have been delineated should have a minimum of 50 points for each considered category to increase the percentage of accuracy assessment (El-Kawy et al., 2011). Therefore, the accuracies of classification for 2001, 2008 and 2015 are 89.51%, 88.49%, and 92.21%, which have kappa statistics of 0.87, 0.85 and 0.90 respectively. According to Weng (2010), the minimum level for accuracy assessment in identification of LULC categories in remote sensing data should be at least 85%. Afterwards, the data is exported into an ASCII text file to enable for further analysis in ArcGIS version 10.

LULC Change Detection Analysis

In performing LULC change detection, the post-classification detection method is applied in the IDRISI Selva environment v.17, which involves two classified images to make a comparison to produce change information on a pixel basis. In other words, the interpretation between two image provide will provide changes “-from, -to” information. Classified images from two different data sets are compared using cross-tabulation in determining qualitative and quantitative aspects of changes for periods from 2001 to 2015. The magnitude of change and percentage of changes can be expressed in a simple formula as follows:

$$K = F - I \quad \text{(Eq. 2)}$$

$$A = \frac{(F - I)}{I} x100 \quad \text{(Eq. 3)}$$

where K is magnitude of changes, A is percentage of changes, F is first data, and I is reference data (Mahmud and Achide, 2012). Additional, prediction or estimation of LULC changes for 2029 will also use IDRISI Selva environment v.17. This research study uses LULC techniques in remote sensing to determine differences and define the percentage of land use changes within that time, as well as estimation for the next 14 years.

Markov Chain Model Analysis

The Markov chain model was presented by a Russian mathematician named Andrei A. Markov in 1970. This model was first used by Burnham for land use modeling (Mishra and Rai, 2016; Parsa et al., 2016). Markov chains are stochastic processes (Halmy et al., 2015; Subedi et al., 2013) and the matrices to show changes between land use categories (based on the basic core principle of continuation of historical development) (Koomen and Borsboom-van Beurden, 2011) and are often used in modeling and simulation changes and trends of LULC (Halmy et al., 2015; Mishra and Rai, 2016; Parsa et al., 2016). The homogeneous Markov model for prediction of land use changes can be mathematically presented as follows (Subedi et al., 2013):

$$L_{(t+1)} = P_{ij} \times L_{(t)} \quad \text{(Eq. 4)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_605622

$$P_{ij} = \begin{bmatrix} P_{11} \; P_{12} & P_{1m} \\ P_{21} \; P_{22} & P_{2m} \\ \\ P_{m1} \; P_{m2} & P_{mm} \end{bmatrix} \quad \text{(Eq. 5)}$$

where $L_{(t)}$ and $L_{(t+1)}$ represent land use status at time t and $t + 1$ respectively. Including $\sum_{j=1}^{m} P_{ij} = 1(i, j = 1,1,2, \quad .m)$ is the transition probability matric in a given state. Practically in IDRISI Selva v.17, this study uses 2001 and 2015 map into Markov chain model to produce the transition matrix changes between the current 14 years, and the process is repeated onto map 2015 and 2029 for future land use to derive the transition matrix changes.

Cellular Automata (CA)

Cellular Automata (CA) was developed by Ulam in 1940 (Mishra and Rai, 2016; Parsa et al., 2016) for application in land use changes conceptually. Afterwards, CA was used by Tobler in geographical modeling (Arsanjani et al., 2013), and widely used in spatial model (Halmy et al., 2015) for forecasting future land use. CA consists of a grid or a raster space, a set of states characterizing the grid cells and a definition for the neighborhood arrangement of cells, a set of transition rules determine the state transitions for each of the cells as a function of the position of neighboring cells and a sequence of discrete time steps then updates composition and configuration of all the cell simultaneously (Arsanjani et al., 2013; Mishra and Rai, 2016; Parsa et al., 2016). The basic principle of CA is that the land use changes for any location (cells) can be explained by the current state and changes in neighboring cells (Koomen and Borsboom-van Beurden, 2011).

CA-Markov Chain Model

The ‘Cellular Automata’ and ‘Markov Chain’ models are considered to be advantageous for modeling land use changes (Mishra and Rai, 2016; Parsa et al., 2016). The issues involved when a Markov chain model lacks spatially referred output and transition probabilities may be accurate on a categorical basis, there are no specifications on spatial distribution of each land use category occurrence (Arsanjani et al., 2013). Cellular automata added into a Markov model lead to probable spatial transitions occurring in particular area over a period time (Subedi et al., 2013). In other words, the quantity of changes from the Markov Chain model then are made geo-referred and spatial through cellular automata (Mishra and Rai, 2016). The CA-Markov model uses Markov Chain analysis outputs, particularly the Transition Area file, to apply a contiguity filter to enable the development of other land use characteristics from time two into a later time period (Parsa et al., 2016). The CA is able to develop a weighting spatial on the particular areas which have approximately the same to the existing land use based on classes, and it is not random (Subedi et al., 2013). Hence, the CA-Markov model is considered a robust approach because of the quantitative estimation and the spatial and temporal dynamic it has for modeling the LULC dynamic (Arsanjani et al., 2013; Mishra and Rai, 2016; Parsa et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_605622

2016; Subedi et al., 2013). GIS and remote sensing is easy to fir with CA-Markov model to facilitate tasks and reduce the cost and time needed (Mishra and Rai, 2016; Parsa et al., 2016). In this study, IDRISI Selva v.17 is used to predict the future LULC of study area on CA-Markov model. In other words, CA-Markov will use the 2001 and 2008 maps to produce a simulated 2015 map, which is important to validate with actual LULC of 2015 map through KIA (Kappa Agreement of Index) approach (Mishra and Rai, 2016; Parsa et al., 2016). Afterwards, the techniques are repeated using the 2008 and 2015 map to produce a simulated 2029 map.

Validating LULC Prediction Model

In order to avoid miscalculation, investigation between actual image and simulated image will be carried out, where the model's output was compared to a present or actual land use map. Comparing the predicted LULC map representing the 2015 LULC with actual LULC (map of 2015) was based on Kappa Index of Agreement (KIA) approach, which is widely used in validate LULC change predictions (Mishra and Rai, 2016; Parsa et al., 2016; Subedi et al., 2013). An additional map of Landsat TM 2008 will be used to help in validating process, before CA-Markov model can be applied for estimation of the next 14 years. The validation module is available in IDRISI Selva environment v.17 for this purpose.

Results

LULC maps assessment

The images show that the LULC maps significantly change from one class to another class (*Figure 3*). Based on general observation, drastic changes can be detected on water bodies between 2001 to 2015 [*Figure 3 (a)* and *(c)*], as most of these classes change from blue into green color and the area becomes smaller-scale. In other words, the water bodies coverage is suspected to transform into vegetation area, which refers as agriculture activities that carried out within the reservoir. Meanwhile, the non-industrial area is suspected to increase by a big margin, especially in the urban area. Majority classes that converted into non-industrial area are vegetation area and open space area. Only the small scale is subjected to the changes that occur in sub-urban and rural areas. At the same time, small scale shows an increase in industrial area, which is likely to be converted from open space area.

Continuously, the LULC map changes from 2015 to 2029 indicate that majority activities are converted from vegetation area into non-industrial and industrial area. At the same time, several areas on open space classes are also having converted into non-industrial area. The non-industrial area having big margin in conversion of development, followed by industrial area that have partially big scale in increasing the area for development purposes. Most of the development is occur in sub-urban and rural area. This rapid development shows positive impact towards the urbanization and modernization in Malacca state.

Validating LULC prediction model

In order to validate the LULC prediction given by the CA-Markov model, the simulated land use areas were used to compare the actual present land use areas. The LULC for 2015

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_605622

was predicted through the model to produce simulated map and make comparison with the actual LULC map of 2015. Comparison of simulated and classified map for the year 2015 can be shown in *Table 3*. Visual analysis shows that simulated LULC map and actual map have relatively close resemblances.

Table 3. *Comparison of actual and projected LULC types in 2015*

LULC type	Area (ha)	
	Actual map	Simulated map
Vegetation Area	39650	39873
Non-Industrial Area	21370	20852
Industrial Area	2660	2628
Open Space Area	1348	1689
Water Bodies	1103	1104
Farming Area	869	854

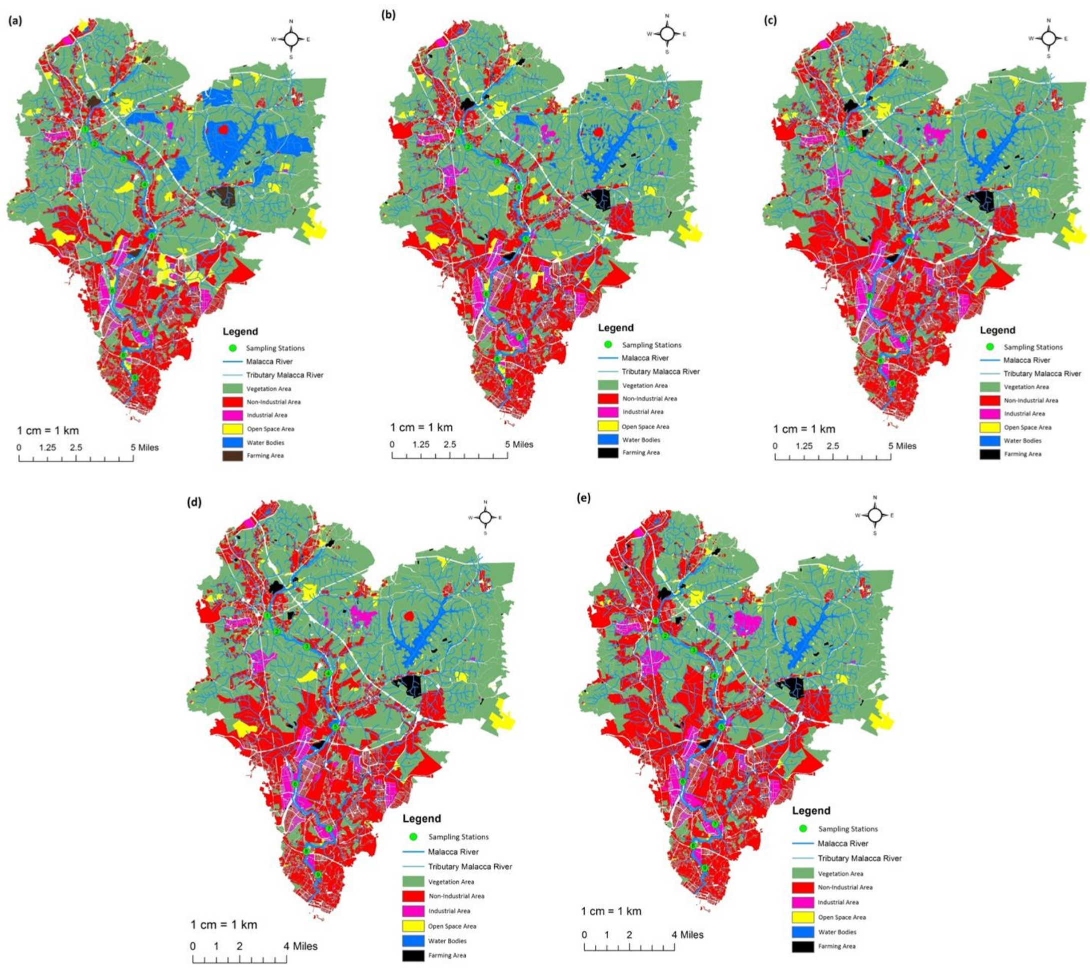

Figure 3. *LULC actual map of (a) 2001, (b) 2008 and (c) 2015. LULC simulated map of (d) 2015 and (e) 2029*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_605622

Table 3 indicates that industrial area, water bodies, and farming area have the best agreement. The simulated areas are 2628 ha, 1104 ha and 854 ha, while the actual area is 2660 ha, 1103 ha and 869 ha respectively. The simulated LULC map shows that non-industrial area, industrial area, and farming area are underestimated; while vegetation area, open space area, and water bodies are overestimated. Hence, the detailed statistical analysis based on the Kappa coefficient is used to measure the overall agreement of matrix, the ratio diagonal values summation versus total number of pixel counts within matrix, and the non-diagonal elements will be the best approach to assess the model accuracy (Arsanjani et al., 2013).

A kappa value of 0 illustrates the agreement between actual and reference map (equals chance agreement), the upper and lower limit of kappa is +1.00 (its occur when the is total agreement) and -1.00 (its happen when agreement is less chance (Arsanjani et al., 2013). The accuracy assessment process was done using VALIDATE module in IDRISI Selva environment v.17. The results indicate K values (Kno = 0.878; Klocation = 0.863; KlocationStrata = 0.863; Kstandard = 0.843) above 0.8 showing satisfactory level of accuracy. According to Viera and Garrett (2005), if the results are greater than 0.8 for each kappa index agreement, then the K statistics are considered accurate. Therefore, CA-Markov modeling is suitable for accurate prediction of future LULCs. This may be useful in this study for environmental management decision making and planning which involve the water quality of Malacca River.

LULC change detection

LULC change can be described in *Table 4*, where the activities carry out in Malacca River basin can be classes into vegetation area, non-industrial area, industrial area, open space area, water bodies, and farming area. According to LULC changes between 2001 to 2008 (*Table 5*), vegetation area and open space area are likely to be transform into non-industrial area (with 22.36% and 24.31%) and industrial area (with 3.13% and 2.04%) respectively. Water bodies is suspected to be decline about 66.57% and change into vegetation area, where this situation happen due to the sufficient water supply and fertile soil leads to the agriculture activities could be carried out. Based on the *Figure 3 (a)* and *(b)*, the agriculture activities are likely to occur in north-east area especially surrounding the reservoir. Meanwhile, open space area is also subjected to transform into vegetation area with 7.07%. Only a small percentage is detected to convert from vegetation area into farming area with 0.05%, indicating that a minority of animal husbandry is carried out on a small scale and mostly being conducted by local residents.

Table 4. *Area (ha) of LULC type in Malacca River basin for 2001, 2008, 2015, and 2029*

LULC type	**Year**

The demand for development is detected to increase for the next 7 years, from 2008 to 2015. This situation spurred by the recognition of Malacca state as a historical tourism by UNESCO in 2007, where the condition increasing the development activities especially involve with non-industrial area and industrial area [*Table 6* and *Figure 3(c)*]. For example, commercial activities such as restaurants, shopping center, and hotels will be built up in a big margin to provide adequate services for tourists. Directly, vegetation area will continuously decline into non-industrial area (with 7613802 ha), industrial area (with 1430374 ha), and open space area (with 4052.05 ha). At the same time, the open space area will also become a ‘victim’ of development by transforming into non-industrial area (with 634941 ha) and industrial area (with 158432.3 ha). The development of industrial and commercial activities provides job opportunities, attracting the people to centralize in urban areas of Malacca state. Hence, migration of local residents from rural areas and non-local residents into the Malacca state has increased the development activities that boosted into sub-urban area in providing residential area to the people. Indirectly, water bodies coverage will continue being pressure to be decline in quantity in supplying area to vegetation with 560683.2 ha; while farming area is subjected to be increase equivalent with non-industrial and industrial area, which converted from vegetation area for 283643.5 ha. Most of the farming area is referring to the animal husbandry activities.

Overall, the continuous development that occur for 14 years began from 2001 to 2015 is non-industrial and industrial area which converted from vegetation area into 11009434.1 ha (27.02%) and 1752056.5 ha (4.30%) respectively; while reducing coverage area is detected from the change of water bodies (2589000 ha) into vegetation area for 1992494.4 ha (76.96%), and open space area (2021500 ha) transform into non-industrial area with 894513.75 ha (44.25%), industrial area with 162528.6 ha (8.04%), and vegetation area with 106533.05 ha (5.27%) (*Table 7*). Meanwhile, the simulated future LULC changes for 14 years from 2015 to 2029 indicate that the statistics for non-industrial area, industrial area, and farming area continue to climb (*Table 8*). The vegetation activities keep 'donating' area into non-industrial area with 25.97%, industrial area with 4.13%, and farming area with 0.56%. At the same time, open space activities are transforming into non-industrial area at 17.67% and industrial area at 4.24%. Water body coverage will be pressured by vegetation area for 34.36% or 365590 ha to provide agricultural activities for local residents.

LULC changes trends can be described as the vegetation area transforming into open space area before it converted into non-industrial area, industrial area, and farming area. Meanwhile, water bodies are likely to change into vegetation area. Therefore, the LULC changes trends can be express in the net changes for 2001 to 2015, which indicate that non-industrial area, industrial area, and farming area have high positive values of 9473170.45 ha, 2113422.5 ha, and 614557.15 ha respectively; while vegetation area, open space area, and water bodies have high negative values with -10161050.3 ha, -605590.4 ha, and -1434509.4 ha respectively [(*Table 9* (*i*)]. For the next 14 years between 2015 to 2029 [(*Table 9 (ii*)], only industrial area has high increment with 2583998.5 ha to resulted as 4697421 ha, while non-industrial area and farming area remain positive for 6575838 ha and 189212 ha respectively. Lastly, the net changes for open space area and water bodies remain negative by -193592 ha and -275995 ha, while vegetation area continue to decrease by -10992884 ha.

Discussion

The Markov chain model becomes an important model to describe probability movements of an individual in a system comprised of discrete states. When applying in land used perspective, Markov chains are often used to specify both time and a finite set of states as discrete values (Subedi et al., 2013). Transitions between the states of the system are recorded in the forms of a transition matrix that recorded the probability of moving from one state to another state (Behera et al., 2012). Applications of Markov chains in urban and non-urban land use began in the 1970s as an alternative to the use of a large-scale area in simulation models for land use forecasting (Arsanjani et al., 2013). Advantage in determining the development trend and benefit in predicting the state of future leading the Markov chain model are continuously applied in various research studies. As proved, the model's applicability and feasibility had been testified in many research papers and its results approximately conform to observed results (Arsanjani et al., 2013; Behera et al., 2012; Sinha and Kumar, 2013). Therefore, the Markov model result is a transition matrix which shows the probability of changes from each class of LULC to another class in the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_605622

future, which can be described in *Table 8* as transitional probability matrices and as a prediction of LULC statistic for year 2029.

Built-Up Area

Previous studies on water resources through statistical analysis indicate the source of pollutants for river water contamination can involve with residential activities, septic tank and sewage treatment plant activities, farming activities (or animal husbandry activities), and industrial activities; which can be grouped together to classified as built-up area to bring negative impact to the Malacca River (Hua, 2017; Hua et al., 2016). According to Hua (2017) and Rosli et al (2015) stated that Malacca River water quality is detected pollution by physico-chemical and biological parameters, which occur due to major source of pollutants from residential area, industrial area, and agricultural activities. These activities are carried out in urban and sub-urban area. On the other hands, LULC changes from the year 2001 to 2008 and 2008 to 2015 signify the demands towards built-up area category are continuously increasing. In other words, larger scale usage of the LULC area for human activities could increase the percentage of river pollution through the contribution of pollutant sources. Indirectly, increasing demand for land used will develop various categories of activities, which will increase the contamination in the Malacca River. Simultaneously, future land used statistic indicate 11462471 ha (70.32%) in continue 'add-on' for built-up area will estimate the possibilities of river water pollution to changes from clean to slightly polluted or slightly polluted into polluted condition.

Agriculture Land

According to the statistical analysis, agriculture activities are confirmed to be categorized as one element to contribute as a pollutant source. As additional evidence, although LULC changes in agriculture perspective are decreasing from 2001 to 2008 and increasing in a small percentage from 2008 to 2015 (*Table 5* and *Table 6*); however, larger fertilizer and chemical pesticide usage in agriculture activities will contribute non-point source pollution through surface runoff towards the Malacca River. The main focus on development of agricultural land happened in 2008; majority of water category was converted into open space as a preparation for agricultural activities. When the prediction of land used in 2015 to 2029 is estimated, possibility agricultural lands will conquest the water coverage area due to the nature of fertile soil. Moreover, the demands for built-up activities development in 'north-west' area are higher percentage, which may cause the agriculture land to shift from 'north-west' area into 'north-east' area. Nevertheless, even agriculture activities are estimated to reduce in land used area for about -11559586 ha (70.91%), it is not possible to prevent further contamination to occur in the Malacca River.

Water Coverage and Open Space Area

Continuously decrement of water coverage indicates that the area are being converted into an open space or agricultural land as seen in changes from the year 2001 to 2008 with 1889922 ha (66.57%) and 2008 to 2015 with 560683.2 ha (41.44%). As described previously, the water category is being transformed into other activities due to the higher fertility soil for farming, potentially for building construction, widen facilities and services,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_605622

and so on. Nevertheless, the reduction in percentage of water areas not only bring negative impacts; as the means of fresh water supplies and food source, but also affects the ecosystem, especially aquatic animals and contribute contamination through human activities of the point source and non-point source pollution. Future prediction of LULC classes estimates water coverage area is probably negative about 365590 ha (2.24%), which may possible to increase river water pollution and threatened the ecosystem survivor through endangered the environment.

Compared to open space category in LULC, the increment area for 7 years starting 2001 about 803751 (33.42%), but the total area are not remain static which start to reduce about 793373.3 ha (45.82%) for the next 7 years. The possible reason that caused the LULC change between 2001 to 2015 are the majority open space being transform from the area of water coverage and agriculture land into built up area. The main reason to cause this condition to happen is the human population increase drastically causing demand towards residences, job opportunities, food sources, facilities and services to increase. Indirectly, open space activities would also bring non-point source pollution through rapid surface runoff from soil erosion; and oil, grease and toxic chemicals from driveways and roads. Although there is probability to reduce pollution by reducing open space category between the year 2008 to 2015, but the percentage to increase pollutant sources through various human activities will still continue to happen. This is due to the number of land areas converted into built-up areas. Unfortunately, future prediction for the open space category are continue to be negative about 283187 (1.73%), which contribute to the land used activities or build-up area that serve the interest of the people without awareness of environment that would probably continuous to contaminate the Malacca River.

Conclusion

This study has shown the important role of LULC in Malacca River watershed in providing proper information in time for decision making concerning the degradation of river water quality. The above-mentioned method for extraction of LULC maps (2001, 2008, and 2015), and the simulation used to predict the future LULC (2029) aided by the CA-Markov modeling, have allowed the researcher to obtain information from analysis of LULCs in respect to the type and the extent of each LULC, while illustrating LULC conversions for the whole watershed in the study area. Generally, the results of this study indicate that supervised classification of remote sensing images is a robust mean of extracting appropriate LULC maps. The ability of simulation model in prediction proved to be good, while the CA-Markov model is a useful tool for LULC prediction (especially in quantitative and qualitative). Therefore, the CA-Markov model is important to land use policy design and planning especially involve with LULC development, which requires a framework for archiving the goals and objectives of sustainable land use development.

The Malacca River has experienced contamination due to the increasing of population, industrial development, agricultural expansion and forest degradation, and this has resulted to uncontrolled and unmanageable of LULC development. Therefore, continuous development has led to increasing pollution and aquatic ecosystem degradation, biodiversity resources destruction, as well as environmental damage in the watershed.

DOI: http://dx.doi.org/10.15666/aeer/1504_605622

Hence, future land use change maps can be used as an early warning system for proper land use development to protect undisturbed area of natural ecosystem and biodiversity from human activities. Simultaneously, a future map could help for planning and management in reducing river contamination by selecting only the land suitable to be developed for economic purposes without disturbing the importance of the environmental perspective.

(Received 3rd Apr 2017; accepted 26th Jun 2017)

Abstract. The browse vegetation in Cholistan rangelands of Pakistan have been on decline due to climatic extremes, overgrazing and anthropogenic pressure. Study area is hot arid desert where vegetation grow after rainfall but over grazing, extreme weather, and local comunity pressure for fire wood, timber, and harvesting of plants for varius purposes causing the decline of browse species. Therefore, a study was carried to investigate forage productivity, carrying capacity and palatability of browses. Multiple surveys were conducted from 2011-2012 at twenty range stands and 25 browse species belonging to 12 families were identified. Results revealed that browse productivity was high (8029.1 kg/ha) in wet season as compared to dry season (5422.9 kg/ha), correspondingly carrying capacity was high during wet season (16 ha/AU/Y) than dry season (24 ha/AU/Y). Moreover, during dry season, mostly stands were observed to be overgrazed while in wet season maximum stands were moderately grazed. High carrying capacity and good grazing status of stands in wet season was due to better forage production. Based on palatability classification, 22 species were found to have palatability to varying degree and 3 species were non-palatable. In palatable species, leaves of 14 species; shoot/stem of 13 species, flower of 4 species, and fruit of 3 species were grazed by livestock, whereas cattle were observed to graze on 7 species; goat and sheep like 10 species each while camel prefer 20 species. The findings of this study indicate that overall the browse productivity of Cholistan rangelands was low and vary according to seasonal rainfall. Therefore, protection, suitable stocking rate and planned grazing is vital to conserve browses ultimately for sustainability of Cholistan rangelands.
Keywords: *browse species, biomass, stocking rate, grazing livestock, sustainability*

Introduction

Rangelands cover about 50% of the world’s land surface and are large tracts of natural vegetation which support livestock. Mostly rangelands are in vegetation biomes such as grasslands, shrublands, savannas, and deserts. These areas are often characterized by arid climate with low rainfall, and seasonal temperature extremities. Studying the relationship among rangelands components (livestock and plants) is most important tools to adopt suitable measures for best practical use of range resources

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_623637

(Friedel et al., 2000). Rangelands provide vegetation cover and soil protection which ensures sustainable production of forage for livestock. Especially browses (shrubs and tree foliage) beside grasses compose cheap sources of feed for animals in World. The importance of browse species as animal feed is reported especially from harsh environments in arid and semi-arid rangelands. Mostly these species have advantage of maintaining their nutritive value and greenness during dry season when grasses decline in both quantity and quality. This nutritious profusion and perennial performance of browses afford round the year provision of forage for livestock (Mtengeti and Mhelela, 2006).

Rangelands quality largely dictate animal productivity and thus it becomes vital to maintain sustainable feed resources from rangelands without deterioration (Rubanza et al., 2006). The justifiable use of rangelands is vital for the development of national economy. Pakistan is a sub-tropical country, which consists of vast semi-arid and arid tracks of land, stretches over 68 million hectares (Majeed et al., 2002). Pakistan has a wealth of 135 million heads of livestock, which account for 10.8% of the GDP. Livestock sector play very significant role because it provides numerous services for humankind like milk and meat, which are vital components of our diet. Livestock occupies a key position in the rural economy of Pakistan for improving the living standard of small resource peoples (Khan et al., 2005).

The rangelands are degrading due to overgrazing, unscientific livestock management, excessiveness of unpalatable species, change in climate, and disturbance of soil (Landsberg and Crowley, 2004). Previous policies have always supported the crops production over livestock, leading in misuse of lands having economically ineffectual productive potential. The herbaceous vegetation of these rangelands only flourishes in monsoon season; accordingly, livestock herds show pitiable health and produce very poor yield of meat and milk. These problems are common everywhere in the world where arid or semiarid rangelands exist. Therefore, developing countries like Pakistan face the similar situation in their rangelands health. Rangelands, which constitute about 65 % of the total area of Pakistan, are in declining process with the passage of time (Ahmad and Hasnain, 2001).

Furthermore, Loeser et al. (2006) showed that episodic drought interacts with grazing, leading to infrequent but biologically important shift in plant communities and suggested the importance of climatic variation in determining ecological effects of grazing practices. Few studies have attempted to unravel the effects of grazing and drought on desert rangelands. It appeared that negative effects of grazing on natality, mortality, or population turnover can be accentuated for certain species when subject to below average precipitation (Curtin, 2002). Globally, grazing has been one of the key disturbance factors resulting in rangeland degradation, an increase of spatial homogeneity of the rangelands, an alteration of rangelands function, and loss of species diversity (Gamoun, 2014).

The Cholistan rangelands were formerly a thriving and prosperous area but now largely converting into an abandoned patch. The productivity of its rangelands is degrading ultimately, carrying capacity of this area is decreasing (Akhter and Arshad, 2006). Sustainability of life in this hot desert rotates around the annual rainfall. During summer season, weather is tremendously severe and harsh; certain xeric plant species survive but suffer high grazing pressure and leading to partial eradication (Arshad et al., 2008). Resultantly, the palatable species are diminishing and unpalatable species with less nutritious properties are becoming abundant. Continuous increase in human

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_623637

population for livelihood and multiplying number of livestock is adding towards the desertification (Abdullah et al., 2013).

Assessing forage productivity and carrying capacity are key factors of rangeland inventory and monitoring programs which are highly required for sustainability of natural resources. The browse species are one of the most important and nutritionally rich sources of feed for livestock in Cholistan rangelands. Due to year-round stress, the browses of Cholistan rangelands are under severe threat and need detail assessment of their potential. Already no conservational measures have been made in Cholistan rangelands because of unavailability of sufficient data. In order to preserve the optimum production of browse species and their justifiable use in future, information about current range resources is very important. Therefore, this study was being planned to collect base line data about productivity of browses, carrying capacity and palatability to chalk out their management strategy in Cholistan rangelands.

Material and methods

Description of study area

The study was conducted in Cholistan desert of Pakistan. Cholistan desert, an extension of the Great Indian Desert, is located in southern Punjab of Pakistan, between 27^o 42' and 29^o 45' north and 69^o 52' and 73^o 05' east (*Fig. 1*). The climate of Cholistan desert is characterized by low and sporadic rainfall. The mean annual rainfall varies from less than 100 mm in the west to 200 mm in the east. Rain usually falls during monsoon (July through September), winter and spring (January through March). Aridity is the most striking feature of the Cholistan desert with wet and dry years occurring in clusters. Cholistan is one of the hottest regions of Pakistan. Temperatures are high in summer and mild in winter. The mean summer temperature (May, June) is 34^{o}C with the highest reaching above 51^{o}C. The vegetation of Cholistan desert is xeric, adapted to extremely high temperature, low moisture contents and increased salinity coupled with wide variation of edaphic factors. Main soil types of Cholistan desert are sand dunes (44%), sandy soils (37%), loamy soils (2%) and saline-sodic clayey soils (17%). Fortunately, several nutritious and drought tolerant species of grasses, shrubs and trees are found naturally in this desert especially after rainfall (Akbar et al., 1996).

Reconnaissance survey and study sites

A reconnaissance survey was conducted in January 2011, in order to have an impression of site conditions, to collect information about accessibility, to do an overview of plant assemblages and to determine the sampling and data collection methods. According to schedule, whole research project was carried for two consecutive years i.e. 2011 and 2012. After going through the topographic map of area followed by frequent visits during initial stages of study, research area was divided into 20 stands to cover the variations of physiognomy and physiography almost over the whole Cholistan desert. The specific stand position was determined by a GPS (Global Positioning System) named Garmin eTrex. The geographic coordinate's latitude, longitude, and altitude were taken from each stand (*Table 1*).

Browse forage production

Biomass is a commonly measured vegetation attribute that refers to weight of plant material within an area. Only plants that are available and palatable to grazing animals are classified as forage. Data was collected in wet (August) and dry season (April) both. Biomass was calculated by Direct Harvest method using 100-meter line transect with 1x1 meter square quadrate. At each stand five transect were laid out and quadrate were placed systematically at 10-meter interval on each transect. Clipping was done at grazed-height, because it gives more pertinent measure of forage biomass. The harvested material was packed and labeled in paper bags immediately and weighed in the field to get fresh weight and then oven dried at 65°C for 72 hours in laboratory and re weighed. The dry weight of all quadrates was then combined and averaged to get total dry matter production (kg/ha), at each stand. Grazing status was estimated by direct observation at each stand and categorizes them as overgrazed, moderately grazed, slightly grazed and no grazing (Bonham, 1989; Holechek et al., 1995).

Range carrying capacity

Carrying capacity is an important management tool that connects forage supply with forage consumption. Carrying capacity was estimated based on 40% allowable grazing material. The one animal unit (AU) was taken as, a cow having 350 kg weight, demanding 7 kg dry matter forage per day, 2555 kg/year (Bonham, 1989).

$$\text{Carrying capacity (ha/AU/Year)} = \frac{\text{Animal forage requirement kg /year}}{\text{Forage production kg /ha}} \qquad \text{(Eq.1)}$$

Degree of palatability

Classification of browse species based on palatability, parts used and animal's preferences was recorded by direct observing the grazing livestock (cattle, sheep, goats and camel) in field for two consecutive years. These field observations were further confirmed from knowledge gathered from graziers and nomadic peoples at different range sites of Cholistan desert. In order to calculate the degree of palatability, following palatability classes were used:

i) Highly palatable ii) Moderately palatable iii) Less palatable iv) Non-palatable

The palatable species were classified into four categories based on parts used by livestock:

i) Leave grazed ii) Shoot grazed iii) Flower grazed and iv) Fruit grazed

The livestock mostly differ in their selection of browsing species at different range sites. In present case, browsing species were classified whether grazed by cattle, sheep, goat, or camel (Hussain and Durrani, 2009).

Statistical analysis

Microsoft Excel spreadsheet analysis (MS OFICE, 2010) was conducted to determine simple averages, percentiles and mean values and to make needful tables and graphs (McCullough and Heiser, 2008).

Results

Forage production of browses

Browse forage production was estimated during wet (August) and dry season (April) in the arid rangelands of Cholistan desert. During wet season, total fresh browse productivity from all stands was 14034.6 kg/ha and dry forage productivity was 8029.1 kg/ha. The highest quantity of dry phytomass was attained at stand 8 (554.4 kg/ha) and minimum at stand 20 (321.5 kg/ha). The average fresh forage yield recorded from all stand was 701.73 kg/ha and dry forage yield was 401.46 kg/ha. On the basis of habitats, maximum dry matter production (3681.3 kg/ha) was observed at interdunal habitat, followed by sandunal habitat (2298.5 kg/ha) and then clayey saline habitat (2049.3 kg/ha). However, average dry forage production of browses at interdunal habitat was 460.16 kg/ha followed by sandunal habitat with 383.08 kg/ha then clayey saline habitat with 341.55 kg/ha (*Fig. 2*). Based on grazing intensity in wet season, maximum stands (45%) were observed to be moderately grazed followed by overgrazed (40%) and then slightly grazed (15%) (*Table 2*).

In Cholistan rangelands during dry season the total fresh biomass productivity was 8865.8 kg/ha while dry matter production was 5422.9 kg/ha. The average fresh productivity of all stands was 443.29 kg/ha and dry matter was 271.145 kg/ha. The maximum dry matter of browses was attained at stand 4 (376.5 kg/ ha) while minimum was at stand 20 (161 kg/ha). Along habitats, maximum dry biomass was recorded at interdunal sandy habitat (2633 kg/ha) followed by sandunal habitat (1496.5 kg/ha) and then at clayey saline habitat (1293.4 kg/ha). The average dry forage productivity of interdunal habitat was 329.13 kg/ha followed by sandunal habitat with 249.42 kg/ha then clayey saline habitat with 215.57 kg/ha (*Fig. 2*). In this season, maximum stands were observed to be over grazed (75%), followed by moderately grazed (25%) and there was no stand without grazing effects (*Table 2*).

The comparison of vegetation condition during wet and dry seasons has been shown in *Figure 3*.

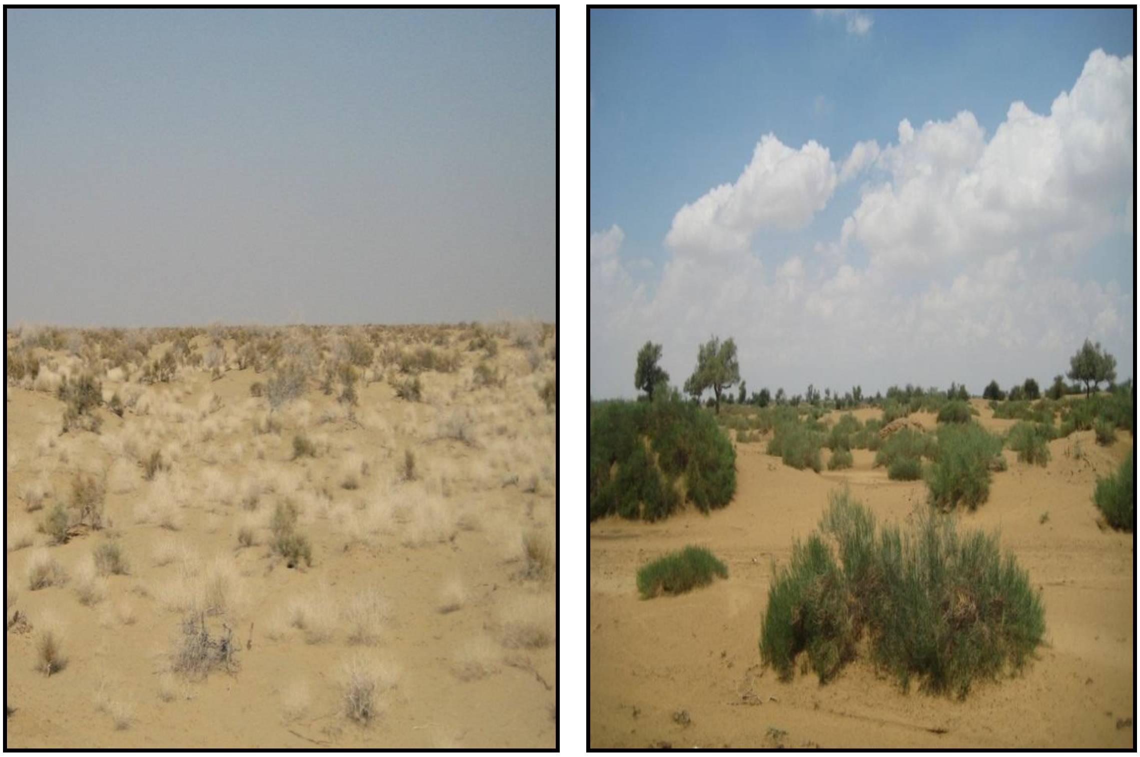

Figure 3. *Vegetation condition in Cholistan desert during a-dry and b-wet seasons*

Range carrying capacity of browses

Carrying capacity or grazing capacity is a common term, used when we are defining the stocking rates. In this study, carrying capacity was calculated in the rangelands of Cholistan desert with respect to browse production. As given in *Table 3* overall average dry browse production during wet season was 394.93 kg/ha while available forage production was 157.97 kg/ha. The proper use factor (PUF) has been taken as 40% to estimate available forage. Over three range habitats in Cholistan desert, maximum available forage was observed at interdunal sandy (184.06 kg/ha) followed by sandunal (153.23 kg/ha) and least at clayey saline (136.62 kg/ha). However, carrying capacity (CC) during wet season was calculated as 16 ha/AU/Y while at interdunal was 14/ha/AU/Y; at sandunal was 17 ha/AU/Y and at clayey saline habitat was 19 ha/AU/Y. It was estimated that Cholistan desert cover an area of 2.6 million hectare out of which 1300000 ha has been considered as rangelands. Based upon this factor, the stocking rate during wet season was calculated as 80376 AU/Y in Cholistan rangelands.

In dry season, overall average dry matter production was 264.71 kg/ha while the available forage was 105.88 kg/ha (*Table 3*). Across the three range habitats in Cholistan desert, maximum available forage was recorded at interdunal habitat (131.65 kg/ha) followed by sandunal habitat (99.77 kg/ha) and then at clayey saline habitat (86.23 kg/ha). Based on available forage overall carrying capacity in dry season was calculated as 24 ha/AU/Y whereas carrying capacity of interdunal was 19 ha/AU/Y, sandunal was 26 ha/AU/Y and at clayey saline habitat was 30 ha/AU/Y. In this season, the stocking density of Cholistan rangelands was calculated as 53872 AU/Y.

Palatability classification of browses

Results regarding palatability of browses in Cholistan rangelands revealed that out of total species, 22 (88%) species were found to have palatability to varying degree and 03 (12%) species were found non-palatable. Among palatable species, 7 species (31.82%) were highly palatable, 9 species (40.91%) were moderately palatable, and 6 species (27.27%) were less palatable. In highly palatable class, there were 5 species of trees and 2 species of shrubs. Moderately palatable species were consisting of 2 species of trees and 7 species of shrubs. Less palatable class was composed of 6 species of shrubs while non-palatable class was consisting of only 3 species of shrubs. There were total 7 species of trees in which 71.43% were highly palatable and 28.57% moderately palatable. Out of 18 species of shrubs, 11.11% species were highly palatable, 38.89% were moderately palatable, 33.33% were less palatable, and 16.67% species were unpalatable (*Table 4*).

Palatability by parts used was based on the type of plant parts, used by livestock in Cholistan rangelands. It was observed that among palatable species, leaves of 14 species (63.64%), shoot/stem of 13 species (59.09%), flower of 4 species (18.18%), and fruit of 3 species (13.64%) were grazed by livestock. The first class in which leaves were used, was consisting of 6 species of trees and 8 species of shrubs. In second class in which shoot/stem was used, there were 4 species of trees and 9 species of shrubs. Flower use class, was consisting of 2 species of trees and shrubs each. In fruit class, there were only 3 species of trees (*Table 4*).

According to results out of total palatable browse species, 7 species (31.82%) were grazed by cattle, which comprised of 5 species of trees and 2 species of shrubs. Goats were observed to prefer 10 species (45.45%) which consisted of 6 species of trees and 4 species of shrubs. Sheep grazed on 10 species (45.45%) which were composed of 6 species of trees and 4 species of shrubs. Whereas, 20 species (90.91%) were preferred by camel which consisting of 7 species of trees and 13 species of shrubs (*Table 4*).

Discussion

Forage production of browses

The present study is endeavoring to assess biomass productivity of browse vegetation in Cholistan rangelands. According to results, total dry matter production during wet season was 8029.10 kg/ha while in dry season was 5422.90 kg/ha, that was 19.38% higher in wet season. Whereas dry matter production at sandunal habitat was 21.14% high, at interdunal habitat was 16.6% high and at clayey saline habitat was 22.62% high in wet season as compare to dry season. Overall forage productivity was high during wet season across the three range habitats; this was perhaps due to high rainfall received

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_623637

during wet season as compared to dry season. Annual rainfall in Cholistan desert is extremely unpredictable both on temporal and spatial scales. Rainfall generally occurs during monsoon (July to September) and in winter and spring (January to March). The winter rain is scanty so vegetation in spring is usually poor, characterized by few annual species of forbs and grasses providing low biomass for grazing. In arid and semi-arid ecosystems, rainfall is a major environmental agent, affecting the forage productivity and it is extremely variable round the year (Patton et al., 2007). It was observed that Cholistan rangelands are monsoonal and forage productivity of these rangelands depends greatly on monsoon rain. Numerous studies have revealed that rainfall greatly affects the rangelands production and our conclusions agree with them (Farooq, 2003; Durrani and Hussain, 2005).

The rangelands in arid and semi-arid areas are mainly composed of perennial plants, which make the excellent use of climate and soil (Scasta and Rector, 2014). Based on results, it was observed that in both seasons dry forage production was high at interdunal habitat followed by sandunal and clayey saline habitats. This might be due to high vegetation diversity and better water retention capacity of soil at interdunal habitat. Vegetation coverage was low on sand dunes and unstable sand dunes were lacking vegetation. Whereas in clayey saline habitat soil and vegetation structure was poor, might be due to high pH. Being very saline and impermeable to water the clayey saline habitat remained predominately plantless. It was observed that poor soil with less water holding capacity and low nutrients in Cholistan decrease the vigor and size of plants leading to reduced biomass (Katjiua and Ward, 2007).

Generally, difference in productivity level at selected range sites was due to variations in soil, vegetation type, and grazing pressure. Results showed that range sites with high forage productivity were less disturbed by grazing while sites with minimum forage productivity were mostly overgrazed. Both overgrazing and under grazing have adverse effects but overgrazing is more problematical (Gamoun, 2014). During wet season, maximum sites were moderately grazed while in dry season, maximum sites were overgrazed. There was no site without grazing in both seasons. In Cholistan rangelands, grazing period starts from August until February in good rainy years. About all forages were exploited during monsoon and post monsoon season, whereas some green browse remained available throughout year. The commencement of monsoon rains mostly commands the movement in nomadic peoples and livestock. In month of March or April, shortage of water and feed resources in interior of desert compel nomadic peoples and their herds to move towards irrigated plains (Akhtar and Arshad, 2006).

Range carrying capacity of browses

According to results overall browse productively was low in Cholistan rangelands whereas production was high in wet season as compare to dry season. As grazing animals in Cholistan rangelands comprised of cattle, sheep, goats, and camels therefore, carrying capacity was calculated for these kinds of animals. Holechek (1988) has determined daily dry matter (DM) intake for bighorn sheep, elk, moose, white-tailed deer, mule deer, and pronghorn antelopes as two percent of their body weight. As DM intake for the livestock of Cholistan rangelands has not been analyzed yet, thus DM intake for these animals was also taken as two percent of their live-body weight. Based on evidences of livestock producers of the area, a young cow (equal to one AU) may attain average live-body weight of about 350 kg whereas DM requirement of an AU was calculated as 7 kg ha^{-1}.

Grazing time depends on availability, accessibility, and quality of feed which is reduced when quality forage is abundant (Khumalo et al., 2007). Based on USA recommendations, range utilization intensity is 30 to 40% of key species with 130 to 300 mm annual rainfall for shrub steppe in semiarid region. It may reach at 50% utilization level during high productive year and decrease during dry period (Holechek, 1988). In arid rangelands of Cholistan, range use intensity was taken as 40%. Overall, available browse production during wet season was 157.97 kg/ha and 105.88 kg/ha during dry season. Based on these standards; overall carrying capacity during wet season was 16 ha/AU/Y and in dry season was 24 ha/AU/Y. Whereas on browse forage availability, in wet season 80376 AU/Y while in dry season 53872 AU/Y were estimated that can be grazed in Cholistan rangelands.

Based on three range habitats in Cholistan, carrying capacity was high at interdunal habitat followed by sandunal and clayey saline habitats during the both seasons. Forage production was better in wet season than dry season (April to June) therefore, carrying capacity was high in wet season as compare to dry season. The data suggested that carrying capacity during both seasons was very low and available browse production was insufficient for present stocking rate (Guevara et al., 2009).

Similarly, nomadic peoples in Cholistan desert have also exploited the plant resources of this area. They uprooted almost every plant for their need irrespective of its forage, medicinal or other values. Therefore, forage productivity is decreasing day by day ultimately leading to poor carrying capacity. No doubt these rangelands are dominated by non-equilibrium condition. In this environment, drought will always be a key factor in affecting production level and animal numbers. Whereas, to decide grazing prescriptions a resource manager needs to define variations in productivity levels and provide estimates of stocking rates (Bisigato et al., 2005).

Palatability classification of browses

It was observed that identified browse species comprising 7 species of trees and 18 species of shrubs were almost remained available throughout the year in Cholistan rangelands. As rangelands vegetation varied significantly in their seasonal availability, nutritive value, and palatability, so grazing animals apparently select highly palatable forage species first (Heitschmidt et al., 2005). According to results, maximum browse species were found to be moderately palatable. However, seven species were highly palatable which consist of 5 species of trees (*Acacia nilotica, Prosopis cineraria, Zizyphus mauritiana, Zizyphus spina Christi, Salvadora oleoides)* and 2 species of shrubs (*Acacia jacquemontii, Zizyphus nummularia)*. Whereas, three species were found to be unpalatable which consist of only shrubs including *Aerva javanica, Aerva pseudotomentosa* and *Leptadenia pyrotechnica*. This unpalatability might be due to alkaloids, phenolics, saponins and other poisonous elements. It is very difficult to differentiate between non-poisonous and poisonous plants as animal's dislike feed due to unlikable feelings or physical discomfort, or by excess or deficiency of nutrients (Kayani et al., 2007).

Animals greatly differ in their preferences for selection of various plant species or plant parts as feed. Results showed that maximum trees were used for their leaves, whereas maximum shrubs were preferred for their shoot. Leaves have been grazed in maximum browse species (63.64%), as feed by grazing animals. The livestock usually prefer leaves of all forages, might be due to high crude protein, phosphorus and low lignin and fiber contents than woody parts. Generally, animals desire fresh foliages than

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_623637

dried and non-succulent forages that can be eaten easily. Likewise, soft green herbaceous parts, in addition having good taste and odour are rapidly digestible (Sanon et al., 2007). It was also observed that *Acacia nilotica, Prosopis cineraria,* and *Prosopis juliflora* were preferred for their fruits by livestock. Flowers and fruits are seasonally essential in animal feed as they might have high level of proteins and cell soluble than leaves. Fresh forage species with high contents of crude protein, sugar, cellulose and fats are highly preferred and digestible. While plant species with high lignin, fiber, silica, secondary metabolites and with poor digestibility are less preferred by grazing animals (Holechek et al., 1998).

Rangelands of Cholistan desert are freely grazed by mixed herds of cattle, sheep, goats and camels. According to results, camel ranked first in exploring maximum number of species, which consist of 7 species of trees, 13 species of shrubs. Goat and sheep were observed to have similar selection, which consisted of 6 species of trees and 4 species of shrubs. Cattle were observed to utilize minimum number of species including 5 species of trees and 2 species of shrubs. It was observed that grazing animals select the most palatable plant species first. It may lead to complete replacement of good quality forages by non-palatable species (Rutherford and Powrie, 2013). Animals face forage deficiency in Cholistan rangeland in winter (December and January) but this condition become severe in April owing to climatic extremities and shortage of water. Certain perennial browse species continue to maintain their foliage but deficiency of forage forces the animals to eat even less palatable species. It may be possible that poor health of animals in Cholistan rangelands are partially due to continuous utilization of such unpalatable species (Deng et al., 2013).

This study revealed that area was vegetative rich in wet season as compare to dry season. Browse species were found playing significant role in the provision of forage for livestock round the year particularly during droughts. The data suggested that carrying capacity during both seasons was very low and available browse production was insufficient for present stocking rate. Due to continuous grazing pressure, the palatable species were disappearing and unpalatable species were spreading on the landscape. It was observed that in Cholistan rangelands maximum forage was available during monsoon season because sustainability of life in this desert rotates round the annual precipitation. Numerous species of ephemeral and annual appear after rains, complete their life cycle in a short duration and vanish. These species, as well important in nutritional contribution also decrease grazing pressure on palatable perennial browse species (Gamoun et al., 2015).

Conclusions

This study has provided baseline about seasonal forage productivity, carrying capacity and palatability of browse vegetation in Cholistan rangelands. However, this study is very preliminary and it is recommended that subsequent ecological studies should be conducted on spatial and temporal variations about forage production. The productive potential of rangelands is not constant and carrying capacities need to be periodically reviewed to accommodate any changes in land resources, or environment. There is severe problem of overgrazing that leads to year-round stress on browse species. Grazing at suitable stocking rate is compulsory. Planned grazing should be introduced and implemented to release the stress over browse species. All factors considered, it was concluded that Cholistan rangelands are less productive and they

DOI: http://dx.doi.org/10.15666/aeer/1504_623637

need proper protection, management, and rehabilitation through ecological approaches. This data should be incorporated into the current management plan and subsequent vegetation map should serve as a valuable tool in planning, conservation and management of these rangelands.

Abstract. The conversion of exotic germplasm into domestic maize breeding materials is essential to solve the narrow genetic base for maize improvement in China. The present study applied SSR markers and three complementary cluster methods (STRUCTURE, UPGMA and PCoA) to 98 foreign hybrid-selected lines for effective hybrid breeding. A total of 450 alleles, with an average of 3.98 alleles per locus, were detected**.** Among 10 chromosomes, there were 13-19 loci and 33-59 alleles with averaged alleles 2.54~3.43 per chromosome. The polymorphism information content (PIC) among 10 chromosomes ranged from 0.4504~0.5582 and 69.4% PIC variation were explained by allele number/Locus. The highest PIC was observed in chromosome 7 (0.5582) and the lowest in chromosome 8 (0.4965). The STRUCTURE clustering analysis grouped the test lines into four subpopulations (i.e. REID, Lancaster, P and Domestic) in accordance with UPGMA and PCoA clustering**.** The higher genetic diversity were detected among the inbred lines in P and Domestic subpopulations. The allele frequencies, gene diversity and population structure obtained in the present study lead us to conclude that the 98 inbred lines derived from foreign hybrid-selected lines contain extensive genetic variation and are a valuable resource for Chinese maize breeding. The result obtained in the present study will assist in effective utilization of the lines in Chinese hybrid maize breeding programs.
Keywords: *maize germplasm, hybrid-selected line, genetic variation, clustering analysis, maize breeding*

Introduction

Knowledge of genetic diversity and population structure among inbred lines and breeding materials is of great importance for maize hybrid breeding. With the popularization and application of maize hybrids over the past years, the recurrent use of a few elite germplasm lines as parental stock has led to a decrease in genetic diversity among maize breeding materials in China. The introduction of exotic germplasm, using its abundant genetic variation and good agronomic traits, is therefore essential to solve the narrow genetic base for maize improvement in China (Wen et al., 2012; Yong et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_639650

2013). However, it is necessary to make a comprehensive evaluation on the genetic diversity and population structure of exotic germplasm (Tarter et al., 2004; Šarčević et al., 2008; Živanović et al., 2012).

Molecular markers can be employed to investigate levels of genetic diversity and population structure among maize inbred lines and breeding materials. SSRs, due to its abundant, highly polymorphic, genome specific, codominant in nature, have found application in analyses of genetic diversity, population structure, gene mapping, and assisted selection for maize improvement (Phumichai et al., 2012; Wende et al., 2013; Semagn et al., 2014; Yang et al., 2013; Abakemal et al., 2015).

In the present study, 98 foreign hybrid-selected lines were analyzed using 145 SSR loci distributed over the whole maize genome. Our objectives were to estimate the levels of genetic diversity and population structure. The results will be useful to breeders in selecting the best parental combinations for maize breeding program in China.

Research Design and Methods

Plant Materials

The germplasm contained 5 tester lines (Huangzao 4, Dan 340, B73, Qi 319 and Mo17) and 98 maize inbred lines derived from foreign maize hybrid-selected lines (obtained by Liaoning Leiao seed company, China) was used in this study. The pedigree and/or origin information can be found in *Appendix 1*.

SSR Markers and Genotyping

Genomic DNA was extracted from approximately 200 mg fresh leaf tissue using the cetyltrimethylammonium bromide (CTAB) method (Saghai-Maroof et al., 1984). A total of 500 SSR primers, which were distributed evenly over the 10 maize chromosomes, were selected and synthesized according to the information available in the MaizeGDB database (http://archive.maizegdb.org/).

PCR amplifications were carried out in 10 mL reaction volumes containing 1 µL template DNA, 2 µL each of 2.5 mM primer, 5µL 2×Taq Master Mix, 0.1µL of 5 units μL^{-1} Taq DNA polymerase, 0.4µL 10 mM dNTPs and , dH2O 2µL. PCR protocols consisted of 32 cycles of 94℃ for 45s, an annealing temperature at either 45, 50, 55 or 60°C depending on the individual SSR primers for 45 s, and 72°C for 60s, and a final extension step of 72°C for 10 min. PCR products were analyzed by 8% polyacrylamide gel electrophoresis (PAGE) and visualized by silver staining.

Genetic Diversity Analysis

For each SSR locus, polymorphic bands were scored as 1 or 0 for presence or absence of the bands at the same mobility, respectively. Gene diversity (PIC) was calculated for each marker according to the formula: PIC=1－∑fi2, where fi is the allele frequency for the i-th locus summed across all alleles for that locus. The program PowerMarker v3.25 and Excel was used to calculate allele number, allele frequency, and gene diversity of each locus (Liu et al., 2005).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_639650

Population Structure Analysis

The STRUCTURE v2.3.3 were employed to assess the population structure of the 98 maize inbred lines using the Bayesian model-based approach (Pritchard et al., 2000). The number of subgroups (K), with each K repeated five times, was ranged from 1 to 12, with burn-in of 100,000 and run length of 100,000. We used the ad hoc criterion ΔK related to the second order rate of change in the log probability of data (LnP(D)) to determine the most probable K value (Evanno et al., 2005).

To examine genetic relationships among the 98 maize inbred lines, the data matrices of the genetic similarity were used to create the dendrogram using UPGMA clustering with the computer software NTSYS-pc v2.2 (Rohlf 2009). Principal coordinate analysis (PCoA) was also employed to reveal relationships among the 98 inbred lines using the software JMPversion7.0 (SAS Institute Inc., Cary, NC, USA).

Data Analysis and Results

A total of 500 SSRs, randomly distributed across the maize genome, were used to evaluate the genetic diversity of the 98 maize inbred lines. Finally, 145 SSRs with clear, stable and specific bands were selected to scored on the 98 lines, with an average of 3.98 alleles per locus (range of 2-7). The PIC for all loci ranged from 0.2130 (umc1271) to 0.8316 (bnlg1666) with an average value of 0.5067 (*Appendix 2*). The higher PIC values indicated the high variability of SSRs, and also a large genetic difference among the 98 maize inbred lines.

The SSRs among 10 maize chromosomes ranged from 11 to 19 with allele number from 33-59 *(Table 1)*. The highest allele number was detected on chromosome 1 (59 alleles), followed chromosome 6 (51 alleles), and the lowest on chromosome 8 (33 alleles). For all chromosomes, there were 13-19 loci and 33-59 alleles with averaged alleles 2.54~3.43 per chromosome. The PIC among 10 chromosomes ranged from 0.4504~0.5582. The highest PIC was observed in chromosome 7 (0.5582) and the lowest in chromosome 8 (0.4965).

Table 1. *Genetic diversity at genome level of 98 maize inbred lines revealed by 145 SSR markers*

Chrom	No. of Loci	No. of Alleles	Mean allele number (range)	PIC
1	19	59	3.11	0.4897
2	13	43	3.31	0.5336
3	14	47	3.36	0.5532
4	17	51	3.00	0.5199
5	16	49	3.06	0.5036
6	16	51	3.19	0.4958
7	14	48	3.43	0.5582
8	13	33	2.54	0.4504
9	12	35	2.92	0.4507
10	11	34	3.09	0.5075

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_639650

There usually was a positive linear relationship between the polymorphism information content (PIC) and number of alleles within a given range. Simple correlation analysis indicated that the PIC was significantly and positively correlated with the number of alleles (r=0.6566, p<0.001) (*Fig. 1*). The allele number/Locus (x) could explain 69.4% PIC variation (y) estimated by a curvilinear regression equation (y =0.3286 ln (x) +0.1551 (1<x<8), R^2 =0.6937).

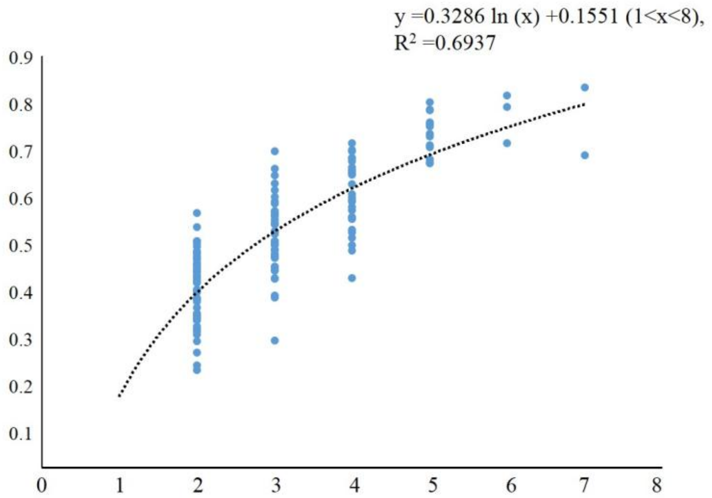

Figure 1. *Plot of PIC vs. number of alleles per SSR locus Population Structure Analysis {tc "5.2.3 Analysis of population structure of mazie core collection" \l 000003}*

STRUCTURE V2.3.3 software was employed to assess the population structure of 98 inbred lines based on 145 whole-genome unlinked SSR markers. LnP(D) progressively increased as K (2-10) increased and no obvious inflexion point was observed, which LnP(D), in this case, may not be suitable to estimate the true K value (*Fig. 2*). The peak of ΔK was observed at K=4, suggested that the 98 inbred lines were fell into four sub-populations (*Fig. 2*).

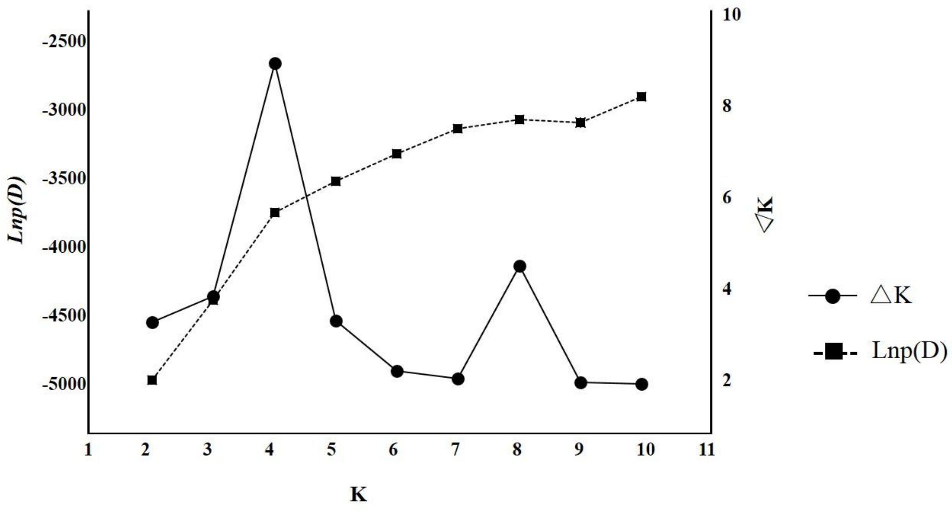

Figure 2. *Plot of LnP (D) and △K calculated for K ranging from 1 to 10*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_639650

Based on the maximum membership probability, 98 inbred lines were assigned into 4 subpopulations (Reid, Lancaster, P, Domestic) (*Fig.3*). Reid included 35 inbred lines closed to B73 (Reid) genetic background. Lancaster had 26 inbred lines related to Mo17 (Lancaster) genetic background. P comprised 22 inbred lines, most derived from Pioneer hybrids (P). The other 15 inbred lines were closed to Dan 340 or Huangzao 4 background, which named as Domestic subgroup described by Xie et al. (2008).

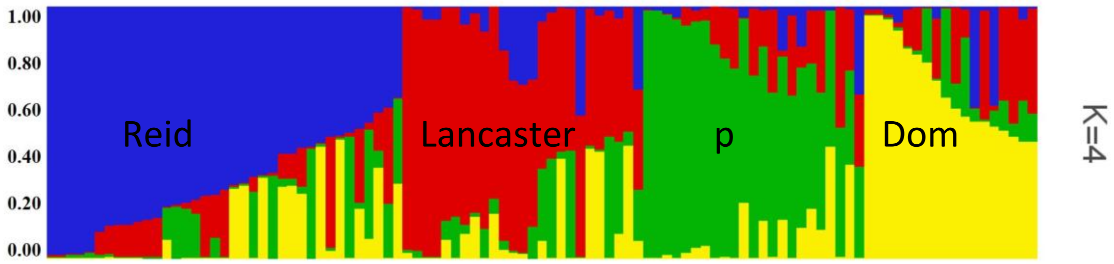

Figure 3. *Population structure of the 98 inbred lines (K=4). Note: The horizontal coordinate represents the 98 inbred lines, and the vertical coordinate of each subgroup indicates the membership coefficients for each individual. Blue zone: Reid; Red zone: Lancaster; Green zone: P; Yellow zone: Domestic*

The similarity coefficient among 98 maize inbred lines ranged from 0.2692 to 0.9825 and the average was 0.6564. When the similarity coefficient was 0.57, UPGMA cluster analysis also clearly grouped 98 inbred lines into four subpopulations (*Fig.4*). Reid, Lancaster P and Domestic subpopulation comprised 36, 32, 13 and 17 inbred lines, respectively. The assignments of 77 inbred lines (78.6% of the total) by UPGMA clustering were consistent with their assignments using STRUCTURE.

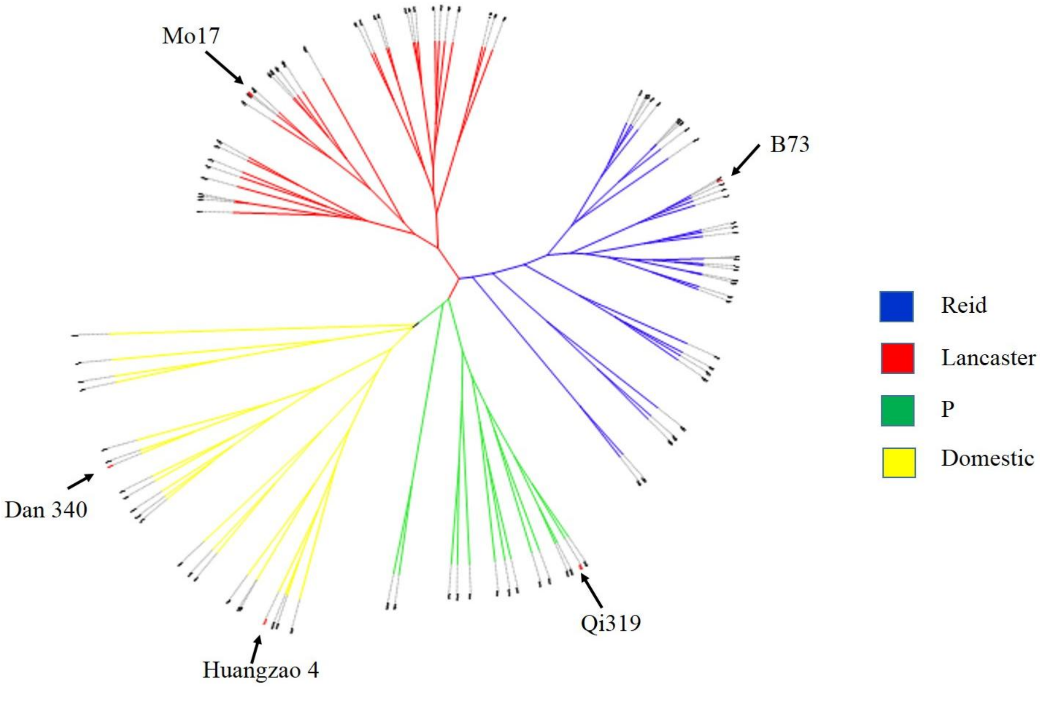

Figure 4. *Dendrogram of 98 maize inbred lines based on UPGMA cluster analysis*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_639650

The principal coordinate analysis (PCoA) based on 145 SSR markers also separated the 98 maize inbred lines into four major groups (*Fig.5*). As inferred by STRUCTURE analysis, the inbred lines in Reid were mainly distributed in the lower left of the plot resulting, Lancaster distributed in the upper right, P in the upper left, and Domestic in the upper right. Most individuals within Reid and Lancaster subpopulations were grouped more closely. The inbred lines in P and Domestic were widely scattered, indicating that higher genetic diversity resided in P and Domestic subpopulations.

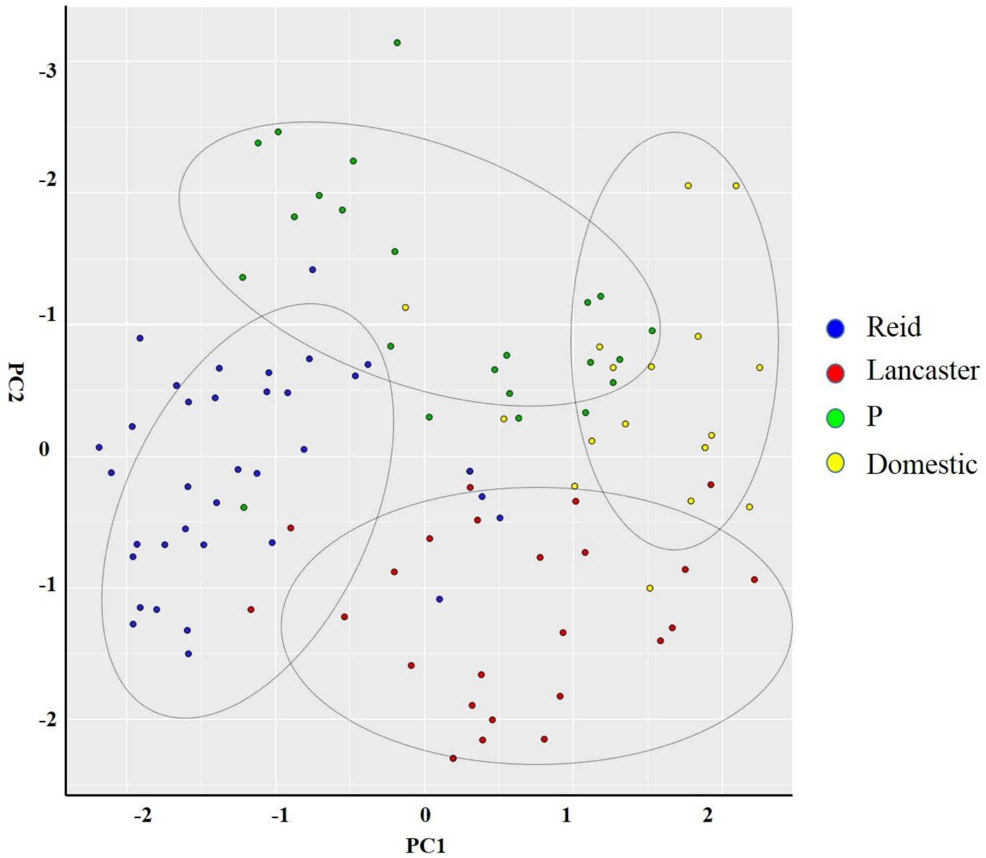

Figure 5. *Principal coordinate analysis of 98 maize inbred lines based on 145 SSR markers. Reid (blue), Lancaster (red), P (green) and Domestic (yellow) are the four subgroups identified by STRUCTURE assigned with the maximum membership probability*

Discussion and Conclusion

SSR markers, due to their abundance, co-dominance, and locus specificity, have been extensively used to assess genetic diversity in maize genotypes (Šarčević et al., 2008; Inghelandt et al., 2010).

In the present study, all the 98 tested maize inbred lines were derived from foreign hybrid-selected lines. We used 145 SSR markers to screen the population and a total of 450 alleles, with an average of 3.103, were detected. The average polymorphic information content (PIC) value was 0.5067, which was lower than that in Chinese important inbred lines with PIC over 0.6 (Wang et al., 2008; Xie et al., 2008). The number of alleles found in this study is also in agreement with other studies (Wang et al., 2008; Park et al., 2015). Wang et al. (2008) reported a total of 1,365 alleles with an

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_639650

average of 9.4 alleles per locus by screening 95 inbred lines using SSR markers. Park et al. (2015) genotyped 174 maize inbred lines by 150 SSR markers and detected a total of 1082 alleles with an average of 7.21 alleles per locus. In our study, alleles were obtained at the whole genome level (*Table 1*). Chromosome 1 showed the highest allele number (59 alleles) and chromosome 8 the lowest (33 alleles). Therefore, we have thus determined that there is a higher level genetic diversity in the 98 foreign hybrid-selected lines, which has the potential to enhance the genetic diversity of Chinese maize breeding materials.

Population structure in the present study was also investigated using three complementary analysis methods STRUCTURE, UPGMA and PCoA based on SSR data. We selected maximum membership probability as the subgroup subdivision criterion, 98 maize inbred lines were assigned into four subpopulations which was in agreement with the assignments obtained by UPGMA and PCoA clustering. Nevertheless, for the 98 tested foreign hybrid-selected lines, the pedigree information was not in accordance with their clustering. In our data, the Domestic subgroup closed to Dan 340 or Huangzao 4 background. This finding can be partially explained by complex genetic background in foreign hybrids. Therefore, it is of significant importance to understand population structure and relationships among inbred lines is for maize improvement.

The allele frequencies, gene diversity and population structure obtained in the present study lead us to conclude that the 98 inbred lines derived from foreign hybrid-selected lines contain extensive genetic variation and are a valuable resource for Chinese maize breeding.

Acknowledgments. The research was partly supported by the projects of Shenyang international cooperation program (F15-200-6-02 and F16-22l-6-00).

Abstract. This study highlighted blow flies as new possible pollinators of *Buchanania lanzan* (Sapindales: Anacardiaceae) flowers. Two sets of 2-day sampling were done by using a sweep net on the flowers of *B. lanzan* in a deciduous forested area of Mahidol University, Nakhonsawan Campus, Nakhon Sawan Province, Thailand during 27-28 December 2013 and 13-14 December 2014. The number of flies (Diptera) collected was larger than the combined number of bees (Hymenoptera) and beetles (Coleoptera) by a factor of 9.4. Blow flies (Diptera: Calliphoridae) were the most abundant insects caught (34.8% of total), and included the medically-important *Chrysomya megacephala. Stomorhina discolor* predominated (23.6% of total), followed by *C. megacephala*, *C. rufifacies*, *C. nigripes* and *Rhyncomya flavibasis*. Female flies predominated over males and were mostly collected in the morning. Many pollen grains were attached to the bodies of the flies, especially on the legs, thorax, and/or abdomen, indicating the likely importance of blow flies as pollinators of the blossoms of *B. lanzan.* These new findings could be useful for furthering conservation management and economic production of *B. lanzan,* and also for the use of *B. lanzan* flowers or the chemicals which they extrude as bait for controlling medically-important fly populations.
Keywords: *Almondette, insect diversity, pollinator, Stomorhina discolor, wasp-mimicking flies*

Introduction

Buchanania lanzan (Spreng) (common name Almondette, family Anacardiaceae) is found growing naturally as a wild plant in subtropical and tropical deciduous forests in many countries, including Thailand (Wongpakam et al., 2007; Sereesongsaeng and Khumchompoo, 2009), Myanmar, Malaysia, India (Martin et al., 1988), Australia and the Pacific islands (Chauhan et al., 2012). The tree is moderate-sized with alternate and simple leaves. Many parts of *B. lanzan* have socio-economic or medicinal importance, particularly in India. Its kernel is a commercially edible nut and is regarded as substitute for almonds in desert habitats (Rosengarten, 1984). Prasad and Bhatnagar (1993) reported that more than one thousand tons of kernels were harvested yearly from native forests of Mahdya Pradesh and Chhattisgarh in India (Duke, 2000). The other parts of this plant are of phytomedical and pharmaceutical importance and are used in Indian folk medicine to treat wounds, skin diseases, and diarrhoea (Patsnaik et al., 2011; Kumar et al., 2012). The bark may also be beneficial for application under conditions of immune stimulation and/or bacterial infection (Sekhar et al., 2015). Unfortunately, no commercial farming of *B. lanzan* has been carried out. Thus, ecological management may be needed to balance the demands of medicinal utility and tree conservation (Chauhan et al., 2012).

During reproduction, the flowers are formed in a panicle. As in the mango, *Mangifera indica*, both staminate flowers and hermaphrodite flowers are present in each panicle, but pollination is achieved by neither self-propagation nor wind pollination.

Insect pollination is therefore presumed to play a significant role in propagation (Huda et al., 2015).

Blow flies (Diptera: Calliphoridae) are considered to be of medical and veterinary concern, and to have negative impacts on public health worldwide (Greenberg, 1973). From an ecological and agricultural standpoint, however, blow flies are potentially important pollinators of flowers including mango, from which they gather pollen or nectar on their legs and body surfaces during feeding (Anderson et al., 1982; Hu et al., 1995).

At Mahidol University Nakhonsawan Campus, when *B. lanzan* trees were blooming during December 2012, casual visitors to the vicinity of the trees assumed that the buzzing sound was from bees or wasps. After conducting preliminary observations, however, first author found that almost all of insects at the tree were flies such as *Chrysomya megacephala*, *Chrysomya rufifacies* and *Stomorhina discolor*. The objective of this study was therefore to determine the relationship between blow flies and flowers of *B. lanzan.*

Materials and Methods

Study site

Insect sampling was conducted at a *B. lanzan* tree on the Mahidol University Nakhonsawan Campus, Nakhon Sawan Province, north-central Thailand for a two-day period during two successive dry seasons (27–28 December 2013 and 13–14 December 2014), coinciding with the flowering period of *B. lanzan*. The *B. lanzan* tree sampled was located outside the administrative offices of the university (15.57912°N, 100.43717°E) (*Figure 1A*).

Shorea obtusa (Wall. ex Blume.) and *Shorea siamensis* (Miq.) have been found commonly near the study site. They are common trees in a disturbed deciduous dipterocarp forest. In a radius of 20 m, an additional 10 trees of *Azadirachta indica* (A. Juss.) (3), *Diospyros rhodocalyx* (Kurz.) (1), *Maerua siamensis* (Kurz) Pax. (3), *Pterocarpus indicus* (Willd.) (2) and *S. obtusa* (1) were found.

Weather data collected at Nakhonsawan Meteorological Station (15.67213°N, 100.12962°E), ~10 km distance from the study site, showed that daytime maximum temperatures reached 33.8 °C and 35.5 °C during December 2013 and 2014, respectively (www.met-sawan.tmd.go.th). Rainfall was c. 2.4 mm during December 2014, while; no rain fell during December 2013.

Insect sampling on B. lanzan flowers

A sweep net was used to catch all insects swarming over the flowers of *B. lanzan* during 3 h in the morning (0900-1200 h) and 3 h in the afternoon (1300-1600 h), in order to examine the pattern of insect visitation. All insects collected were anesthetized in an ethyl acetate killing jar. The insects were sorted to family using the taxonomic key of Triplehorn and Johnson (2005), and then identified to genus and species (where possible) under a stereo microscope (Olympus, Japan). Blow flies and muscid flies were identified using the taxonomic keys of Kurahashi and Bunchu (2011) and Tumrasvin and Shinonaga (1977), respectively. Unknown species were grouped as morpho-species.

DOI: http://dx.doi.org/10.15666/aeer/1504_651659

All insects were pinned and observed for attachment of pollen under the stereo microscope. Finally, all insects were deposited in preservation boxes at Mahidol University Nakhonsawan Campus.

Data analyses

The numbers of individuals of each insect species collected from the *B. lanzan* tree were counted.

Statistical analysis was performed using SPSS 17.0 for Windows. ANOVA was used to determine the difference among numbers of flies (males vs. females) collected during morning (0900-1200 h) and afternoon (1300-1600 h) ($p < 0.05$).

Results

Diversity of insects on B. lanzan flowers

A total of 843 insects were collected during investigations (*Table 1*). The numbers of insects collected between years were quite similar, with 404 insects in 2013 and 439 insects in 2014. Insects were sorted into 3 orders. Flies (Diptera) ranked as by far the most abundant insects, while the combined number of bees (Hymenoptera: *Apis mellifera*) and beetles (Coleoptera) contributed only 3.7% of the total.

Table 1. *Classification and total number (%) of insect species visiting flower of Buchanania lanzan at Mahidol University Nakhonsawan Campus, during 2-day sampling of 27–28 December 2013 and 13–14 December 2014*

Order	Family	Species	No. (%)
Diptera	Calliphoridae	*Stomorhina discolor* (Fabricius, 1794)	199 (23.6)
		Chrysomya megacephala (Fabricius, 1794)	57 (6.8)
		Chrysomya rufifacies (Macquart, 1843)	30 (3.6)
		Ceynolomyia nigripes (Aubertin, 1923)	5 (0.6)
		Rhyncomya flavibasis (Senior-White, 1922)	2 (0.2)
	Syrphidae	Undetermined	156 (18.5)
	Stratiomyidae	*Hedriodiscus* sp.	116 (13.8)
	Drosophilidae	*Drosophila melanogaster* Meigen, 1830	96 (11.4)
	Muscidae	*Graphomya rufitibia* Stein, 1918	66 (7.8)
		Musca sorbens Wiedeman, 1830	19 (2.2)
	Phoridae	*Megaselia scalaris* Loew, 1866	12 (1.4)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_651659

Ten families of flies were found on *B. lanzan* flowers (*Table 1*). Of these, blow flies (Calliphoridae) were the most abundant (34.8% of total) and species-rich (R = 5 species). These comprised *Stomorhina discolor* (*Fig. 1B-C*), *Chrysomya megacephala* (*Fig. 1B*), *Chrysomya rufifacies, Chrysomya nigripes*, and *Rhyncomya flavibasis*.

Syrphid flies (Syrphidae) were the second most abundant (18.5% of total; R = 4) and comprised 4 morpho-species. *Hedriodiscus* sp. (Stratiomyidae), *Drosophila melanogaster* (Drosophilidae), and *Graphomya rufitibia* and *Musca sorbens* (Muscidae) all contributed high numbers in our samples. Otherwise, *Megaselia scalaris* (Phoridae), *Boetcherisca peregrina, Parasarcophaga dux, Sarcophaga* sp. (Sarcophagidae), and other undetermined Diptera were much less abundant. Blood-sucking flies (Tabanidae: *Tabanus* sp.) contributed just 3 individuals (*Table 1*).

Visitation of insects on B. lanzan flowers

The number of insects visiting the flowers of *B. lanzan* was higher during the morning (0900-1200 h) than the afternoon (1300-1500 h) (*Fig. 2*). The difference in the numbers visiting between morning and afternoon periods was significant in the blow flies *S. discolor* and *C. megacephala* (p = 0.002 and 0.023, respectively). Significant differences were also found in *Hedriodiscus* sp., *D. melanogaster*, *G. rufitibia*, and syrphid flies ($p < 0.05$). No significant difference was found in the diurnal visitation pattern of *A. mellifera* or beetles, while *R. flavibasis* and *Tabanus* sp. were only found during the morning period.

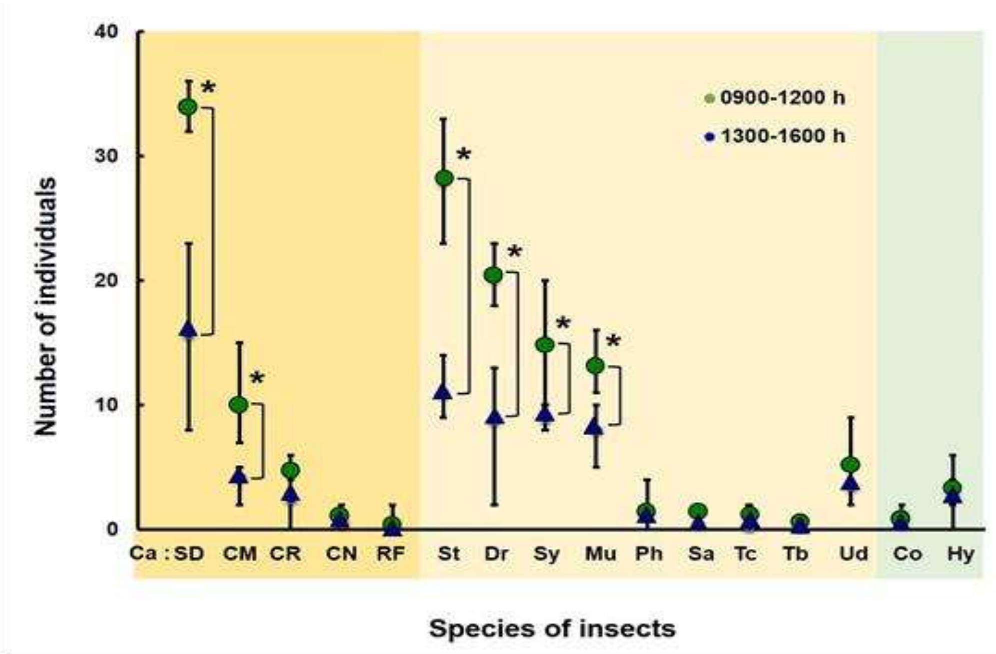

Figure 2. *Numbers and visitation times of insects sampled on flowers of Buchanania lanzan at Mahidol University Nakhonsawan Campus, during sampling, 27–28 December 2013 and 13–14 December 2014 (n = 4) (Ca Calliphoridae, SD Stomorhina discolor, CM Chrysomya megacephala, CR Chrysomya rufifacies, CN Chrysomya nigripes, RF Rhyncomya flavibasis, St Stratiomyidae, Dr Drosophilidae, Sy Syrphilidae, Mu Muscidae, Ph Phoridae, Sa Sarcophagidae, Tc Tachinidae, Tb Tabanidae, Ud undetermined Diptera, Co Coleooptera, Hy Hymenoptera); *indicates significant differences in numbers of insects visiting between 0900–1200 h and 1300–1600 h (independent T–test, p < 0.05)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_651659

More female flies were caught than males, although this difference was not significant ($p > 0.05$) in most. In muscid flies and sarcophagid flies males predominated over females ($p > 0.05$).

Occurrence of pollens on insect bodies

Forty-five percent of insects sampled had pollen on their bodies (*Table 2*). The exceptions were the tiny flies of *D. melanogaster*, *M. scalaris*, and *C. nigripes*, blood-sucking *Tabanus* sp., and beetles.

Table 2. *Percentage of insects with pollen on their bodies at Mahidol University Nakhonsawan Campus during periods of 27–28 December 2013 and 13–14 December 2014*

	Total	**45.0**	**5.0**	**2.0**	**28.8**	**18.0**	**16.5**

The small number of honey bees *A. mellifera* (24 bees) ranked first among the percentage of individuals bearing pollen (75%), found on thorax, legs and abdomen. They were followed by tachinid flies (71.4%) and *G. rufitibia* (59.1%), consecutively. *S. discolor*, the most abundant fly sampled in this study, ranked fourth (58.3% bore pollen). In flies of these three families pollen was often present on the proboscis in addition to thorax, legs and abdomens. Additionally, pollen grains were attached to the minute hairs located between the facets of compound eyes of both muscid flies, *G. rufitibia*, and syrphid flies.

Discussion

The two years' observations revealed that *S. discolor* was the most common blow fly found around opened flowers of *B. lanzan*. The relationship between this fly species and the flowers of *B. lanzan* has not been previously documented. The length of the pollinator's proboscis is generally related to shape of the flowers they visit (Tangmitcharoen and Owens, 1997). A short proboscis, as found in flies and bees, is usually associated with feeding on already opened flowers (Larson et al., 2001). In addition, different insect pollinators are attracted to flowers of different colors and shades. Flowers with dull colors, such as those of *B. lanzan*, tend to attract fly pollination; while, bright colors mostly attract bees (Shivanna and Tandon, 2014).

In this study, flies preferred to visit flowers in the morning rather than in the afternoon, recalling the findings of Brown and McNeil (2009) for cloudberry *Pubus chamaemorus*. The peak of diurnal activity differs among different insect species and is usually correlated with the diurnal blooming peak of particular plant hosts. Peak blooming of mango, for example, tends to occur during 0900-1100 h (Huda et al., 2015). The timing of the blooming of *B. lanzan* in relation to *S. discolor* visitation requires further investigation.

Although pollen was found attached to the fly specimens collected in this study, whether any of these fly species is an actual pollinator of this tree is still in question. Banziger et al. (2008) found that despite the fact that blow flies (*Calliphora vomitoria* (Linnaeus) and *Calliphora pattoni* Aubertin) entered the lip of the lady slipper orchids *Cypridedium yunnanense* and *C. flavum* (Orchidaceae), they proved not to be pollinators, even when smeared with pollen. Nonetheless, there are other reports of blow flies as pollinators. For example, females of *Lucilia porphyrina*, *Chrysomya pinguis, Chrysomya chani* and *Chrysomya villeneuvei* were the main pollinators of *Rhizanthes zippelii* (Rafflesiaceae) in Thailand (Banziger, 1996). Howlett (2012) found that the European blue blow fly *Calliphora vicina* Robineau-Desvoidy was an effective pollinator of the hybrid carrot (*Daucus carota* L.) seed crop in New Zealand. In China, several species of blow flies (*C. megacephala, Isomyia isomyia, Pierretia* sp., *Hemipyrellia* sp. and *C. rufifacies*) were the most frequent visitors to flowers of *Bridelia stipularis* and *Cleistanthus sumatranus* on tropical Hainan Island (Li et al., 2014). Likewise, females of *Lucilia* and *Chrysomya* were major pollinators of *Rafflezia pricei* in northern Borneo of Malaysia (Beaman et al., 1988). Moreover, *C. megacephala* blow flies have been reared and used as pollinators of mango in Australia (Anderson et al., 1982) and Taiwan (Hu et al., 1995). In Hong Kong, China, Lau et al. (2009) revealed that *C. megacephala* provided more effective pollination of *Bauhinia* sp. (Leguminosae) than honey bees due to its more frequent rate of visitation. Greenhouse experiments would help verify whether *S. discolor* is truly a pollinator of *B. lanzan*.

In Thailand, the *B. lanzan* tree is little known although it is found in many parts, especially in the northeastern and central regions (Wongpakam et al., 2007; Sereesongsaeng and Khumchompoo, 2009). It is utilised by local people near Mahidol University Nakhonsawan Campus, who take the young leaves, young shoot tips and flowers of *B. lanzan,* eating them as a fresh vegetable with Thai dipping paste (chili paste).

Further, although the odor of *B. lanzan* flowers was not strong, unlike carrion flowers; it was remarkable that flies, including medically important blow flies such as *C. megacephala* and *C. rufifacies*, were attracted to visit. Therefore the odor-causing chemicals of *B. lanzan* flowers should be studied for possible application as a bait to trap those fly species when necessary for pest control. In conclusion, this study sheds

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_651659

light on the relationship of *B. lanzan* flowers and the blow fly *S. discolor* under natural conditions in Thailand. These new findings might be useful for further conservation management and economic production of *B. lanzan,* and also for the use of *B. lanzan* flowers such as the chemicals which they extrude as bait for controlling medically-important fly populations. Such information will help widen our knowledge of the roles of indigenous flies for improving agricultural practice in the future.

(Received 28th Apr 2017; accepted 20th Jul 2017)

Abstract. The effects of intensive agricultural management practices and environmental changes on biodiversity can be monitored by using the carabid beetles as biological indicators of agroecosystems quality. This study aimed to investigate the ground beetle species composition, abundance, dominance, diversity, zoogeographical types and distribution groups in an intensively managed agricultural field. Epigeic carabid fauna was collected weekly using pitfall traps on an arable crop field in Podravina, Croatia. Altogether, 1429 individuals belonging to 26 species and 15 genera were collected. The most abundant and eudominant were *Poecilus cupreus* (Linnaeus, 1758), followed by *Brachinus psophia* Audinet-Serville, 1821 and *Pterostichus melas melas* (Creutzer, 1799). Two species were dominant, two subdominant, four recedent and 15 subrecedent. The diversity of fauna was moderately high: Simpson diversity index 0.7875, Shannon-Wiener index 1.9654 and Pielou's evenness 0.6032. Zoogeographical analysis showed equal dominance of Euroasian and Palearctic species. Most (73%) of species belonged to E and 27% to A relict class. The majority of species were spring breeders (14 species), 8 species were autumn breeders and one species breeds in both seasons. In intensively managed agricultural landscape, ground beetle diversity was moderately high, because most of the species were eurytopic, i.e. capable of inhabiting strongly anthropogenically influenced landscapes.
Keywords: *Carabidae species composition, ecological factors, zoogeographical types, intensive crop production, agro-technical measures*

Introduction

Ground beetles are species rich and abundant in agricultural land all over the world (Lövei and Sunderland, 1996). As one of the most abundant and diverse groups overwintering within cultivated fields (Holland and Reynolds, 2003), they are often used in cultivation experiments. Carabids have also been successfully used for different kinds of indicator studies, serving as biological indicators of agroecosystems quality (Cole et al., 2002; O´Rourke et al., 2008). Most of these studies focus on beetles' response to agricultural management practices or changing environmental conditions (Rainio and Niemelä, 2003). According to Baranova et al. (2013), in terms of environmental quality, arable land represents an anthropogenically influenced, unstable and devastated biotope with low contribution to farmland diversity. Due to ground beetles' sensitive reaction to anthropogenic changes in habitat quality (Avgın and Luff, 2010), they have a bioindicative value for cultivation impacts, as well as for environmental change (Thiele, 1977; Maelfait, 1990).

Environmental change, through many abiotic and biotic factors, can cause different kinds of effects on the indicator species, including changes in species

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_661674

number and distribution (Blake et al., 1996; Rainio and Niemelä, 2003). Abiotic factors most often include temperature and soil moisture (Lövei and Sunderland, 1996; Holland, 2002). Other authors reported on many additional factors: landscape heterogeneity (Chapman, 2014), field size (Kromp, 1999), the presence of non-cropped habitat (Pollard, 1968; Sotherton, 1985) and land use diversity (Östman et al., 2001). Ground beetle abundance can be influenced by the crop-dependent timing of cultivation measures (Hence et al., 1990). According to Stassart and Grégoire-Wibo (1983), the depth of tillage is one of the major factors affecting the carabid fauna. Fertilization regimes (e.g. manure, mineral fertilizers) could also have a positive effect on ground beetle population (Pietraszko and De Clercq, 1982; Hence and Grégoire-Wibo, 1987) or a negative one (Kromp, 1990). Vician et al. (2015) considered the content of organic matter and pH as the most significant factors influencing ground beetle diversity in agroecosystems, while others stated soil particle size distribution can be a decisive factor in habitat selection (Thiele, 1977; Meissner, 1984).

Crop type can affect ground beetles through modification of microclimatic factors (i.e. temperature and humidity) and through disturbance factors (i.e. harvest and tillage schedules) (Thiele, 1977; Witmer et al., 2003; O´Rourke et al., 2008). The ground beetles population in the agricultural landscape can be also influenced by chemical pest control (Basedow, 1987; Asteraki et al., 1992; Jeschke et al., 2011; Szczepaniec et al., 2011; Varvara et al., 2012; Douglas et al., 2014).

Several studies in Croatia reported about epigeic ground beetles' assemblage, distribution and abundance in different vegetation types, including forests (Šerić Jelaska, 2005; Brigić et al., 2014a), wetlands (Brigić et al., 2014b), meadows (Durbešić, 1987; Durbešić et al., 2006) and parks (Durbešić, 1982; Marković, 2009). However, not many detailed studies about ground beetles on agricultural fields with intensive land cultivation have been done. Studies were performed on leguminous fields (Kovačević and Balarin, 1960; Balarin, 1974) and in wheat (Sekulić et al., 1973; Sekulić, 1977). The most comprehensive ground beetle faunal study on several different crop types was done in Podravina region more than 30 years ago (Štrbac, 1983), in which 31 species were identified. Since then, only few researchers investigated ground beetle assemblage in agricultural landscape, and these included research on sugar beet (Kos et al., 2013), maize (Kos et al., 2006; Bažok et al., 2007; Kos et al., 2011) and barley (Kos et al., 2010). The latest study on endogeic ground beetle communities in arable field in Podravina area revealed eight species (Drmić et al., 2016). Juran et al. (2013) investigated activity of the adult ground beetles in three differently managed fields in central Croatia and found that the endogaeic activity was highest in „organic" system, followed by the „conventional" and „integrated" system. Büchs et al. (2013) found 72 species on differently managed fields in a neighboring country. The authors, however, did not mention the species composition.

Different indices measure different aspects of the partition of abundance between species. Species evenness usually has been defined as the ratio of observed diversity to maximum diversity, the latter being said to occur when the species in a collection are equally abundant (Margalef, 1958; Patten, 1962; Pielou, 1966). Simpson's index, for example, is sensitive to the abundance only of the more plentiful species in a sample, and can therefore be regarded as a measure of "dominance concentration" (Whittaker, 1965). Used Shannon index is an

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_661674

information statistic index, which means it assumes all species are represented in a sample and that they are randomly sampled. This index estimates the affinity of different populations belonging to a community and, through the species composition, the similarity of the habitats (Popescu and Zamfirescu, 2004).

In modern intensively managed production in Croatia, there is still little knowledge on beneficial fauna importance (Bažok et al., 2015; Virić Gašparić et al., 2017). In order to preserve biodiversity in intensively managed arable land as much as possible, it is important to monitor the bioindicator species such as ground beetles, since they can indicate the anthropogenically influenced field quality. Detailed knowledge on their community in a specific agricultural landscape can give us a preview on agroecosystem stability. Therefore, this study aimed to investigate the ground beetle species composition, abundance, dominance and diversity, as well as zoogeographical types and distribution groups in an intensively managed agricultural field, with its specific agro-ecological factors and agro-technical measures.

Materials and methods

Location

Ground beetles were collected during the arable crop growing season in 2015 in Lukač (Virovitica–Podravina County, Croatia), on winter crop field with an intensive arable management and specific climatic and edaphic characteristics (field size 34.76 ha, coordinates: 45° 50′ 24″ N, 17° 24′ 0″ E). According to Köppen classification, this part of continental Croatia belongs to *Cfwbx* climatic type characterized with continental climate of cold winters and hot summers (Penzar and Penzar, 2000). The soils in the research area are gleyic luvisols (IUSS Working Group WRB 2015). These are hydromorphic soils, characterized by periodic or continuous wetting of part or whole of the profile, with stagnating precipitation or with additional surface or underground water that is not saline or alkaline. These soils contain a great amount of fine sand and coarse silt (sandy loams texture) (Bogunović et al., 1996) and often require conventional tillage.

The field was chosen to represent common cultivation practices as well as the agro-technical measures in this area. Considering the soil type and soil characteristics, the tillage was adapted to the given conditions and performed as follows: a) in autumn: ploughing on a depth of 20-25 cm was followed by the furrow closure for moisture conservation in spring; b) in spring: chisel ploughing and tillage with the rotary harrow; c) in summer: after harvest disk harrowing and again chisel ploughing. A description of the regional physical and chemical soil properties of investigated area as well as agrotechnical measures applied on the experimental field are given in *Table 1*. Performed pedological procedure consisted out of taking the soil sample from the depth of a plow layer (30 cm). Five sub-samples waging 300–400 g were taken and than pooled and homogenized for analysis. Analysis was performed by the pedology laboratory of the Department of Soil Science, Faculty of Agriculture, University of Zagreb and included sediment grain size and chemical properties analyses. Soil texture was determined by sieving following standard methods (ISO 11277 2004) (Kozina et al., 2015).

Climatic factors

Climate data (i.e., mean weekly air temperature, mean weekly soil temperature and the total amount of rainfall per week) were obtained from the Croatian Meteorological and Hydrological Service and presented for ground beetle collecting period from May to September 2015 (19^{th} to 38^{th} week of the year).

Ground beetle trapping

Epigeic covered pitfall traps were used to collect adult ground beetles. Polythene pots (Ø=12 cm, h=18 cm) were incorporated 18 cm into the soil and covered with PVC roofs (Ø=16 cm) approximately 4 cm above ground level. Each trap was half filled with salted water (20% solution) for captures conservation. Four pitfall traps were placed into the center of the field at 50 m apart and 100 m away from the field edges. Trapping was performed from the 19^{th} to the 38^{th} week of the year, from May to September 2015. Traps were inspected once a week and all ground beetles were collected and counted. The identification of the collected ground beetles to species level was based on the work of Auber (1965), Bechyne (1974), Harde and Severa (1984) and Freude et al. (2006).

Ground beetle composition analysis

The ground beetle trapping results using pitfall traps for the selected interval (from 19^{th} to 38^{th} week of the year) are presented as a mean number of individuals caught per field per week. Results of the ground beetle population dynamics are presented as the total number of ground beetles caught per week as a function of the average weekly air temperatures (°C), total weekly precipitation (mm) and average weekly temperature of soil (°C) at a depth of 10 cm.

The dominance values of carabids presented in percentage shares of a particular species in the community were calculated according to Tischler (1949) as follows: eudominant (10-100%), dominant (5-10%), subdominant (2-5%), recedent (1-2%) and subrecedent (<1%). To calculate the diversity of the carabid assemblages, Simpson (λ) and Shannon-Wiener indices (H') were used. Shannon-Wiener indices is an entropy, giving the uncertainty in the outcome of a sampling process key (Jost, 2006). Both

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_661674

Shannon and Simpson diversities increase as richness increases, for a given pattern of evenness, and increase as evenness increases, for a given richness, but they do not always rank communities in the same order (Colwell, 2009). Evenness was estimated using Pielou's evenness. Analyses were carried out using the MATLAB program (The MathWorks Inc., 2015). Zoogeographical analysis adding new species records and contributing an understanding of the composition (Majka et al., 2007), was made according to Vigna Taglianti et al. (1999) and the database Fauna Europaea (Vigna Taglianti, 2013). The distribution/occurrence groups (relict classes E, A and R) were defined according to Hůrka et al. (1996).

Results and discussion

This study aimed at observation and description of a ground beetle fauna during one vegetation season in intensive arable crop production. During the sampling period, a total of 1429 individuals were collected using epigeic traps at Podravina region. Ground beetles collected belong to 26 species and 15 genera (*Table 2*) which in comparison with previous studies in arable agroecosystems can be classified as moderately high (Kos et al., 2006; Bažok et al., 2007; Kos et al., 2010, 2011; Drmić et al., 2016; Virić Gašparć et al., 2017). Despite the large number of species which may occur in agroecosystems, a relatively small number have been identified as being characteristic of arable areas and these are often the most abundant (Thiele, 1977; Holland and Luff, 2000).

The composition of recorded species in arable crops corresponds with results of similar investigations in Croatia (Kos et al., 2006; Bažok et al., 2007; Igrc Barčić et al., 2008; Kos et al., 2010; 2011; Drmić et al., 2016) and abroad (Bukejs and Balalaikins, 2008; Woodcock et al., 2010; Baranová et al., 2013). The most abundant species in the total catch was *Poecilus (Poecilus) cupreus cupreus* (Linneaus, 1758) (37.65%) followed by *Brachinus (Brachinus) psophia* Audinet-Serville, 1821 (21.06%) and *Pterostichus (Feronidius) melas melas* (Creutzer, 1799) (10.29%) (*Table 2*). The most abundant species accounted almost 70% of the total catch and belonged to the group of eudominant species. *Anchomenus (Anchomenus) dorsalis* (Pontoppidan, 1763) and *Harpalus (Pseudoophonus) rufipes* (DeGeer, 1774) were classified as dominant, *Amara (Amara) similata* (Gyllenhal, 1810) and *Pterostichus (Morphosoma) melanarius melanarius* (Illiger, 1798) as subdominant while others were recedent (4 species) or subrecedent (15 species). The species, which dominated the carabid assemblage in arable habitat (with the total collections), were *P. cupreus* (538), *B. psophia* (301), *P. melas* (147), *H. rufipes* (128) and *A. dorsalis* (97) (*Table 2*).

Species *P. cupreus* is considered as one of the most common species inhabitating winter crops (Alford, 2008), so these results strongly support this research. In Croatia, Štrbac (1983) also specified it among the three most dominant on arable land.

Drmić et al. (2016) investigated endogaeic ground beetle fauna in the same area in Croatia and detected *B. psophia* and *A. dorsalis* as the most abundant ones, therefore we may assume that these species are a typical arable ground beetle representatives in investigated region.

Species *P. melas* is also common in Croatia and was detected as dominant in agricultural land near the Nature park Lonjsko polje (Brigić et al., 2003).

Kromp (1999) listed species *H. rufipes*, followed by *P. cupreus* and *P. melanarius* as the most abundant from agricultural fields of Eastern European countries, which is generally in accordance with our results. Similar investigations from Croatia (Bažok et al., 2007; Igrc Barčić et al., 2008; Kos et al., 2011) also stated species *H. rufipes* and *P. melanarius* in the group of the most abundant species in corn fields. Although they were not the most abundant species in our results, they were among species which generally dominated with the total scores.

This typically structured ground beetle community of arable land consists of a small number of dominant species represented with a large number of individuals and a large number of less commonly occurring species (subdominant, recedent and subrecedent) represented with a low number of specimens (Baranová et al., 2013).

The diversity of fauna was moderately high: Simpson (1-λ') diversity index was 0.7875, Shannon-Wiener index (H') was 1.9654 and Pielou's evenness was 0.6032. Analysis of faunal types (zoogeographical analyses) showed the dominance of Euroasian (23.08%) and Palearctic (23.08%) species which corresponds with climatic and geographic characteristics of the investigated area (*Table 2*).

With reference to relict classes, 73% of determined ground beetles belonged to E relict class which consists of eurytopic species without special demands on habitat type and quality, and inhabiting strongly anthropogenically influenced landscapes (Hůrka et al., 1996). Species which belonged to A relict class were represented with 27% and this group included more adoptable species, which are found in more or less natural habitats (forests, meadows, pastures, standing and flowing water) (Hůrka et al., 1996). Neither one species was classified to relict class R, which was expected, because R class includes species with narrow ecological amplitude, which are rare and endangered, occurring naturally in undisturbed ecosystems which was not the case in our study (Hůrka et al., 1996). These results correspond to the results of Porhajašová et al. (2004) and Baranová et al. (2013) who reported that increasing human disturbances changes the composition to favor eurytopic species while reducing the number of specialized species with narrow ecological valences.

Abundance and diversity as well as the ratio of spring to autumn breeders varied between winter sown crops (cereals and oilseed rape) and spring sown root crops (potatoes, sugar beet, maize, carrots) (Kabacik-Wasylik, 1975 cit. Holland and Luff, 2000). Winter crops usually have higher abundance, diversity and more spring breeders with summer larvae (e.g. *P. cupreus, A. dorsalis*) which was confirmed with our results as well. These preferences are not, however, always apparent and even total numbers may vary (Holland and Luff, 2000). The majority of collected species were spring breeders (14 species), 8 species were autumn breeders and one species (*Calathus fuscipes fuscipes* (Goeze, 1777)) breeds in both seasons (*Table 2*). The domination of spring breeders could be a consequence of the cultivation measures. The depth of tillage is one of the major factors affecting field carabid communities, with superficial ploughing enabling a higher number of species and favoring spring breeders (Kromp, 1999 cit. Stassart and Grégoire-Wibo, 1983).

Species composition and the number of ground beetles in different agrocenosis differ and depend on edaphic factors (Bukejs and Balalaikins, 2008). Ground beetle species contribute significantly to the insect diversity in farmland because many species are adapted to agriculture and generally occur at high densities (Booij, 1994). According to Thiele (1977) and Kromp (1999) cultivated land is comprised of widely distributed, eurytopic ground beetle species, many of which have high tolerance to disturbances and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_661674

chemical pollution. This means that cultivated land contains a typical ground beetle fauna, despite the regular implementation of cultivation measures (Kromp, 1999). For example, Thiele (1977) listed 26 species found at investigated arable habitats stretching from England over Central Europe.

In our survey the first population maximum was observed from week 19th to 21st which was also the beginning of sample collection period. The second population maximum was recorded from week 32nd to 36th (*Figure 1*). Presented results of ground beetle population dynamics show that population increase follows air and soil temperature decrease (*Figure 1*). In the whole investigation period the number of ground beetle decrease is followed by precipitation increase. Recording to Croatian Meteorological and Hydrological Service the Virovitica-Podravina County is described as mid worm area with intensive periods of rainfall especially in summer period.

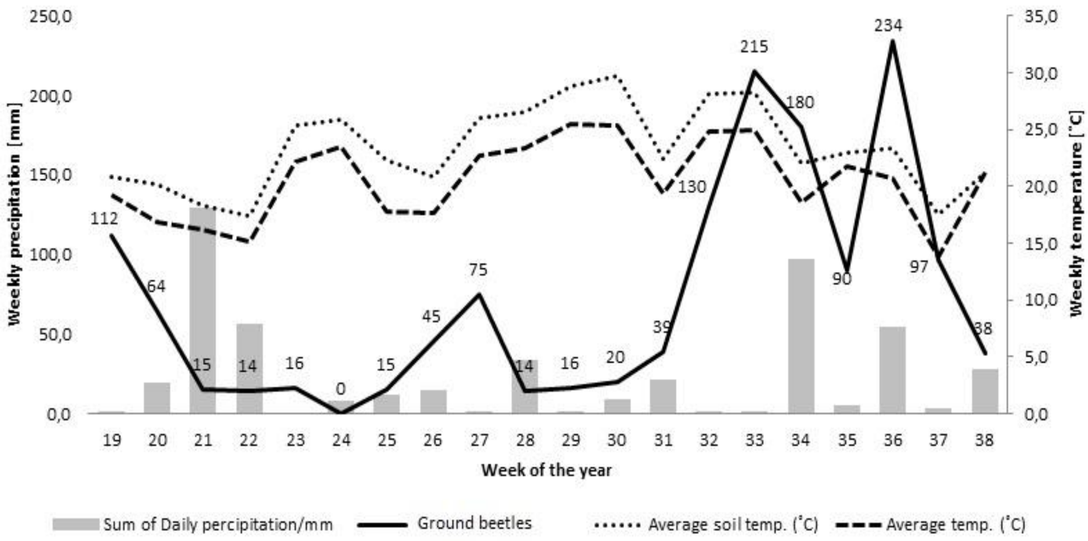

Figure 1. *Ground beetles weekly dynamics with prevailing climatic conditions*

According to edaphic factors prevailing at investigation area ground beetles inhabited slightly acidic soil with a great amount of fine silt and a small proportion of clay (*Table 1*). The intensity of ploughing was the main agro-technical specificity at studied locality. The field in Podravina has been ploughed often and on great depth during whole vegetation season. Ploughing is known to significantly influence physico-chemical and biological soil properties and affects the abundance of invertebrates (Vician et al., 2015). Generally, reduced soil disturbance, increased surface residues and greater weed diversity had positive impact on invertebrates (Kromp, 1999). According to previous studies, higher ground beetle trapping rates were recorded on fields with reduced tillage or no tillage at all compared with conventionally tilled ones (House and All, 1981; Blumberg and Crossley, 1983; House and Stinner, 1983; Ferguson and McPherson, 1985; House and Parmalee, 1985; Stinner et al., 1988; Tonhasca, 1993). Conventional tillage, such as conducted on the field in Podravina, could have an impact on established ground beetles abundance.

The soil factors are greatly influenced by weather conditions and ploughing but also could be affected by crops growing at the area. Previous studies have shown that microclimatic factors, such as temperature and humidity, and disturbance factors such

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_661674

as harvest and tillage schedules crops affect ground beetles communities (Thiele, 1977; Holland, 2002). Although no ground beetle species appears to be strictly bound to a certain crop, early agro-ecological studies in Europe reported a general difference between ground beetle abundance distributions in winter versus spring crops (Heydemann, 1955). O´Rourke et al. (2008) stated that thick stand winter crops provide important refuges for ground beetles in comparison with spring crops. The overwintering crop sown at the field in our survey may confirm the importance of crop habitat for supporting ground beetle populations by providing less extreme microhabitat in spring and creates positive conditions for ground beetle survival and the dominance of spring breeders.

Beside crop specifics, bare soil period can also be a significant factor that affects ground beetle communities. In winter crops, the less extreme microclimate already established in early spring creates favorable conditions for ground beetles (Kromp, 1999). Locality in our study had a very short period of bare soil (2 months period without plant cover; *Table 1*). No negative effect was observed in ground beetle populations regarding the extreme soil surface microclimate. The effect of intensively managed crop on ground beetles abundance which could be detected in this research support the results of numerous other studies (Tonhasca, 1993; Zhang et al., 1998; Honek and Jarosik, 2000; Ward and Ward, 2001; Witmer et al., 2003; O´Rourke et al., 2008).

As well, the fertilization in Podravina is generally intensive while insecticide treatments were common and in compliance with IPM. While previous studies had concluded that insecticides have negative influence on the ground beetle populations (Asteraki et al., 1992, 1995), more detailed investigation are needed for the full conclusion. Kromp (1999) shown that high amount of nitrogen used in fertilization process decrease ground beetle abundance. The levels of nitrogen applied in Podravina are under permitted levels (EU Directive 2009/128/EC, EUR-Lex, 2009) causing minimal negative influence on ground beetles. Only mineral fertilization has been used in Podravina so possible positive effect of organic manure recorded by Pietraszko and De Clercq (1982) and Hence and Grégoire-Wibo (1987) on ground beetle communities cannot be discussed.

Conclusions

The bioindicator species such as ground beetles have not received much attention by researchers in Croatia, although they can indicate the anthropogenically influenced field quality. In this study we gained detailed knowledge on their community in a specific agricultural landscape in northwest Croatia, Podravina region. In this investigation, a total of 1429 ground beetles were collected using epigeic traps, belonging to 26 species and 15 genera. Ground beetle diversity was moderately high, because most of the species were eurytopic, i.e. capable of inhabiting strongly anthropogenically influenced landscapes. In modern agriculture in European Union, conservation programs aimed to keep beneficial species and biodiversity are promoted as tool for ensuring sustainability. In order to measure the success of such programs, one has to have detailed knowledge on the initial situation. The results of this study significantly contributed to better understanding of initial situation about ground beetle communities in intensive agricultural landscape in northwest Croatia and will be a good entry point for future conservation programs.

(Received 4th May 2017; accepted 25th Jul 2017)

Abstract. Global climate change is known to be a result of atmospheric greenhouse gases. Thus, the atmospheric greenhouse gases should be reduced to prevent the climate change. Based on this fact, scientists have been working to reduce atmospheric greenhouse gases (CO_2, N_2O, CH_4). Due to the increases in CO_2 emissions in agricultural lands, the interest in scientific research had moved to this field. In the present study, the shallow soil CO_2-C emissions in Harran Plain were measured. The soil CO_2-C emissions were measured weekly using the soda-lime method. The Mean soil CO_2-C emission was 8.70 ± 0.57 g m^{-2} $week^{-1}$, according to the results obtained in the study. Climate data from the same period obtained that soil moisture was 17.21 ± 2.05% and soil temperature was 12.87 ± 1.80°C. A very significant positive correlation was found between soil CO_2-C emissions and soil temperature ($r = 0.049$; $p < 0.01$) and there was very significant negative correlation between soil CO_2-C emissions and soil moisture ($r = -0.196$; $p < 0.01$). There was a very strong statistically significant negative correlation ($r = -0.854$, $p < 0.01$) between soil moisture and soil temperature. While the soil CO_2-C emissions decreased as the soil moisture increased, it increased with the soil temperature.
Keywords: *atmospheric greenhouse, carbondioxide emission, terrestrial ecosystems, agricultural activities*

Introduction

Soil respiration, which is an important part of the respiration in the ecosystem, is one of the most important processes in atmospheric carbon transport from terrestrial ecosystems to the atmosphere. (Fiedler et al., 2015). Carbon equilibrium in these ecosystems was defined as the balance between plant carbon loss due to plant and soil respiration and plant carbon intake (Beer et al., 2010; Luyssaert et al., 2007; Malhi et al., 1999; Le Quéré et al., 2009, 2014; Trumbore, 2006). The equilibrium value, in other words, carbon storage and carbon resource behavior of terrestrial ecosystems has been of great interest in climate change studies (Hashimoto et al., 2015).

Since the carbon cycle is a bio-geochemical phenomenon, it was stated that it is very difficult to predict the CO_2 exchange between the biosphere and the atmosphere due to the complex relationships between physical, chemical and biological processes (Friedlingstein et al., 2006). Despite this complexity, carbon cycle studies and CO_2 measurements are conducted with different methods at the present time. Patra et al. (2013) stated that verification of estimates could only be done at the point scale, in addition to the complexity of the system, because reliable data can only be obtained on site observations. Today, measurements are generally conducted with chamber-based

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_675682

methods. After measurements were taken, basic modeling was used and the CO_2 emissions were estimated in the period between measurement dates (Beetz et al., 2013).

The main greenhouse gases that cause climate change and global warming are CO_2, CH_4 and N_2O (Wu and Lee, 2011). The fossil fuel use, deforestation, industrial growth and agricultural activities increase atmospheric greenhouse gas emissions. The most important of these gases that have increased in the atmosphere since the industrial revolution, is CO_2, which has increased by about 30% since 1750. It is estimated that the amount of CO_2 was 280 ppm before the industrial revolution and it was 370 ppm in 1999, and 380 ppm in 2007 (Houghton et al., 2007).

Efforts to determine the amount of soil CO_2 emissions due to agricultural activities are increasing rapidly. Sakin and Sakin (2015) determined the average CO_2 emissions in the clay soil of Sanliurfa-Harran Plain located in the arid and semi-arid Southeastern region in Turkey as 5.46 g m^{-2} day^{-1} at 0-5 cm depth based on soil temperature and moisture. A positive correlation between soil CO_2 emission and soil temperature, and a negative relationship between soil CO_2 emission and soil moisture were also found in the abovementioned study. Zhou et al. (2015) reported that an increase in soil temperature and microorganism activities caused increased decay and decomposition.

High emissions values were determined in studies conducted in arid and semi-arid environmental conditions. Allaire et al. (2012) recorded 9.31-11.5 g CO_2 m^{-2} day^{-1} emissions in semi-arid climate shrubland and shrubbery and 5.48 g CO_2 m^{-2} day^{-1} emissions in grasslands. Weekly CO_2 emissions fluctuated during the growth season in a study conducted in pasture areas in arid regions of China, and it was determined as average 2.4 g CO_2 m^{-2} day^{-1}. In semi-arid regions in Spain, 4.07-15.43 g CO_2 m^{-2} day^{-1} emission was recorded (Curiel Yuste et al., 2003)

Sakin (2016) measured the CO_2 emissions based on soil temperature and moisture in semi-arid uncultivated soil in the Southeastern region in Turkey. Based on that study, the soil moisture at 5 cm soil depth was 11.66% and the soil temperature was 22.53°C, while soil CO_2 emission was 7.94 g m^{-2} day^{-1}. Soil CO_2 emissions has a positive correlation with soil temperature and a negative correlation with soil moisture. In the study, the maximum CO_2 emissions were observed in February and the minimum emissions was observed in August. The soil CO_2 emissions demonstrated annual fluctuations based on climatic parameters. It was stated that the climate change has emerged as a result of annual fluctuations.

Celik et al.(2017) reported in arid and semi-arid climate regions, soil carbon content is generally low because of the factors such as insufficient precipitation, low biomass and organic carbon intake, high oxidation, use of soil biomass as animal feed, being picked up for burning or as fuel. On the other hand, clayey nature of the soils is significant in terms of SOC content and accumulation. Clay surrounds SOC, and creates organo-mineral complexes, and protects the soil against decomposition and disintegration.

Turkey has quite large agricultural areas. The objective of the present study was to determine shallow soil CO_2 emissions due to climatic factors in Southeastern Turkey.

Material and Method

Study area

The study area is a part of “Harran Plain” on South East of Turkey. It is located between 37 ° 10 '14' 'N latitude and 39 ° 00' 14 " E longitude (*Fig. 1*). The altitude of the test area, which is located on a flat and near-flat topography, is 507 m. The region's

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_675682

summers are arid and hot, and winters are temperate and with low-precipitation. Precipitation is not sufficient for agricultural cultivation during certain years. The mean annual precipitation is 448.11 mm, the annual average maximum temperature is measured as 41.12°C in July, and the lowest temperature is measured as 2.41°C in February. Annual mean relative humidity was the highest at 92.32% and the lowest at 33.29% (TSMS, 2016).

Figure 1. *Location of the study area*

Laboratory analyses

It was determined that the soil reaction (pH) of the experimental soil was 7.30, electrical conductivity (EC) was 52.60 μS cm^{-1}, organic carbon content was 0.8%, cation exchange capacity was 35.15 cmol kg^{-1}. Among the exchangeable cations, calcium amount was the highest and potassium amount was the lowest. The particle fractions of the soil included mostly clay-sized particles.

The amount of soda-lime considered in the studies varies based on the ecological conditions, but 50 g of soda-lime was taken for the present study. The study was set up in the Faculty of Agriculture experiment area in 3 replicates and the calculations were made based on the following equation.

$$E_{CO_2} = \frac{(SL_{ad} - SL_{ini}) \cdot WC}{(A \cdot t)} \quad \text{(Eq.1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_675682

Where;

E_{CO_2} is the total amount emitted during the incubation period (g CO_2 m^{-2} day^{-1});

SL_{ad} is CO_2 adsorbed soda-lime amount (g);

SL_{ini} is the initial soda-lime amount (g);

A is the area of measurement (m^2);

t is the incubation time (the time past in the field) (day) and;

WC is water correction number was taken as 1.69.

Results and Discussion

Weekly soil CO_2-C emissions varied between 6.21-17.22 ± 0.57 g m^{-2} $week^{-1}$, soil temperatures varied between 5.33-28.28±1.80°C and weekly soil moisture varied between 7.05-29.89 ± 2.05 (*Table 1*). As the soil moisture increased, soil temperature decreased, and as a result, soil CO_2 emissions decreased. Maximum soil CO_2-C emission was determined when the soil moisture was 7.71% and soil temperature was 18.58°C, while the minimum emission was determined when the soil moisture was 29.89% and soil temperature was 6.39°C. Soil emissions are not only dependent on soil temperature and moisture factors but also on other soil properties. Soil CO_2-C production was reported to be the result of plant root respiration and microbial degradation of organic carbon, and these factors were dependent on the soil temperature and moisture (Davidson et al., 2006). In previous studies conducted in the region, it was reported that the soil emissions varied based on the soil temperature and moisture, consistent with the findings of the present study (Sakin, 2016; Sakin et al., 20015, Sakin and Sakin, 2015; Gülle Sakin et al., 2015).

Soil is a heterogeneous medium that consists of gas, liquid and solid phases and varies in depth. The CO_2 transport in the soil occurs straight from the bottom to the soil surface. Thus, the CO_2 transported to the surface is released to the atmosphere. Soil CO_2 density varies based on the depth of the soil. In general, deep soil has a high CO_2 concentration, while in exposed (shallow) soil it is low. The soil CO_2 density in deep soil is about 100 times (6% -8%) the density on the soil surface. However, the amount of CO_2 resulting from the activities of organisms and roots is higher in the surface layer than in the sub layer (Allaire et al., 2012). Since the surface of the soil is rich in organic waste, life prospers more in this layer. Comparisons that were conducted in the present study confirmed this fact. In uncultivated fields, soil CO_2 emissions were about 20% higher than the cultivated areas in the current study.

Table 1. *Descriptive Statistics of soil factors (weekly.*

	Minimum	Maximum	Mean	Std. Error	Std. Deviation
CO_2 emission (g m^{-2} $week^{-1}$)	6.21	17.22	8.70	0.57	2.40
Soil Moisture (%)	7.05	29.89	17.21	2.05	8.68
Soil Temperature (°C)	5.33	28.28	12.87	1.80	7.64

In a study conducted in clay textured vineyards in Harran Plain, weekly soil CO_2-C emissions based on soil moisture and temperature (5.81-21.23 and 5.65-40.88°C) were measured between 4.94 - 20.97 g m^{-2} $week^{-1}$. It was stated that the effect of soil moisture and temperature on soil CO_2-C emissions cannot be ruled out, but the emission

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_675682

is not entirely dependent on these two parameters (Carlisle et al., 2006; Gaertig et al., 2002; Davidson and Janssens , 2006; Ricardson et al., 2012). CO_2 emissions were measured in an incubation study that was conducted to determine the correlation between CO_2 emissions in arid and semi-arid sites and the temperature and humidity factors influencing these emissions. Soil specimens were incubated under different humidity and temperature conditions and it was found that soil CO_2 emissions increased by 50% due to different moisture regimes where the soil temperature was kept constant (Conant et al., 2004).

The correlation between the weekly soil CO_2-C emissions, soil moisture and soil temperature is given in *Tables 2* and *3*. Based on this information, there was a strong negative correlation between the soil carbon emission and soil moisture ($r = -0.196$; $p < 0.01$) and there was a positive correlation between the soil carbon emission and soil temperature ($r = 0.049$; $p < 0.01$). As the soil moisture increased, soil temperature and activity decreased, and the opposite was true for soil temperature. Soil temperature and moisture should be at a suitable level for living organisms in the soil. It is considered that living conditions of plant roots and organisms are suppressed at extreme conditions.

Table 2. *Correlations between soil factors*

Soil factors		Soil Moist. (%)	Soil Temperature (°C)
CO_2 emission (g m^{-2} week^{-1})	Pearson Correlation	-0.196	0.049
	Sig. (2-tailed)	0.00	0.00
Soil Moisture (%VWC)	Pearson Correlation	1	-0.854
	Sig. (2-tailed)	0.00	0.000

Table 3. *One-Sample Test between factors*

Soil factors	Test Value = 0					
					95% Confidence Interval of the Difference	
	t	df	Sig. (2-tailed)	Mean Difference	Lower	Upper
CO_2 emission (g m^{-2} week^{-1})	15.38	106	.000	8.70	7.51	9.89
Soil Moisture (% VWC)	8.41	106	.000	17.21	12.89	21.53
Soil Temperature (°C)	7.14	106	.000	12.87	9.07	16.67

One of the important sources of soil respiration is roots and the second is the microbial respiration (Hanson et al., 2000) and 50% of soil respiration is attributed to plant root respiration (Hanson et al., 1993). Carbon decomposition and decay and CO_2 emissions by organisms are dependent on temperature and it was suggested to determine this correlation (Davidson et al., 2006). It was stated that the optimum temperature for soil respiration and organism activities, 35°C (Cable et al., 2011) is sufficient, however in certain areas the temperature is over 35°C. There are also researchers who argued that the optimum temperature for optimum soil respiration should be above 35°C (Barraon-Gafford et al., 2011).

In the arid and semi - arid Southeastern Turkey, the soil carbon (C) emissions based on soil moisture (12.89 ± 0.56) and soil temperature (18.19 ± 2.07) was measured in the clayey soil of Sanliurfa - Harran Plain. There was a positive correlation between the soil

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_675682

CO_2-C emissions and the soil temperature, and a negative relationship between soil CO_2-C emissions and the soil moisture. An increase in soil temperature resulted in an increase in microorganism activities, decomposition and decay (Zhou et al., 2015). Nobrega et al. (2016) reported that high soil carbon emissions were not related to the high carbon content in the soil, but rather were influenced by anthropogenic factors, however these factors prevented carbon intake of the soil. As a result, the soil carbon emissions results from carbon decomposition by the plant roots and microorganisms in the soil. Buerkert et al. (2012) found that soil carbon emissions were 3-5 times the initial amount after the first irrigation.

Sakin et al. ($P < 0.05$) determined a significant positive correlation between CO_2 emissions and relative moisture and the moisture inside the PVC container ($p < 0.05$), and a very significant negative correlation between CO_2 emissions and relative temperature and PVC container internal temperature ($p < 0.01$). An inverse correlation was identified between the relative humidity, relative temperature and PVC container internal temperature. In a study by Akburak (2008) conducted in the Belgrade forest in Istanbul, a weak positive correlation was found between soil CO_2 emissions and soil moisture and a negative relationship between soil CO_2 emissions and soil temperature. When soil respiration was above 10% of soil moisture content, a positive correlation was found between soil CO_2 emissions and soil temperature ($p < 0.01$). On the other hand, there was a positive correlation between soil water content and respiration when soil temperature was above 16°C in all land uses ($p < 0.001$). In dry periods, there was a negative relationship between soil emissions and soil temperature (Almagro, 2009). Similar results were obtained in the current study.

Conclusion

A very significant negative correlation was found between soil CO_2-C emissions and soil moisture and a very significant positive correlation was found between soil CO_2-C emissions and soil temperature. There was a very strong statistically negative correlation between soil moisture and soil temperature. The soil CO_2-C emissions decreased as the soil moisture increased while it increased as the soil temperature increased.

At the point where the soil moisture and temperature are at their maximum, soil CO_2 –C emissions are neither maximum nor the minimum. The soil CO_2-C emissions are the result of microbial activities of the organic carbon and plant roots in the soil, and the activities of the organisms that live in the soil. Thus, soil temperature and soil moisture should be optimum for the living beings in the soil.

The soil CO_2-C emissions increase or decrease due to the suppression of the optimum conditions for the living organisms in the soil when the soil temperature and the soil moisture are minimum and maximum. In studies similar to the present one, the objective is to establish measures to determine and then reduce CO_2-C emissions. If the soil CO_2-C emissions decrease with the increase in soil moisture, it does not mean that we should keep the soil submerged in water. Or, since the emissions are at the minimum under the maximum soil temperature, we cannot keep the soil constantly hot and without moisture. Thus, the idea of reducing the soil CO_2-C emissions when the optimum conditions for the living beings in the soil are not available should be developed.

Appropriate agricultural techniques should be used to reduce soil CO_2-C emissions such as no - tillage, direct sowing and conservation agriculture techniques. Carbon dioxide measurements from soil should be made more healthful with modern equipment and more precise work. In arid and semi-arid climate regions, atmospheric CO_2-C should be given to the context of atmospheric CO_2-C to the soil through irrigation.

Abstract. As the two largest rivers in China, the Yangtze and Yellow Rivers are of great importance for water cycle and hydrological processes over the country, which have been significantly affected by climate change. In this study, by assessing the suitability of multiple GCMs (General Circulation Models) recommended by IPCC (Intergovernmental Panel on Climate Change), SDSM (Statistical Downscaling Model) and ASD (Automated Statistical Downscaling) were used to generate future climate change scenarios, which were used to drive VIC (Variable Infiltration Capacity) and SWAT (Soil and Water Assessment Tool) models to quantify climate change impacts in the Yangtze River Delta region and upper reaches of the Yellow River basin, respectively. Results showed that suitability assessment method adopted in this study coupled with statistical downscaling could effectively reduce uncertainties of GCMs. Compared with the baseline period (1961-1990), projected annual runoff in future periods (2046-2065 and 2081-2100) would decreased by 9.5% and 3% in the Yangtze River Delta region. While annual runoff in the upper Yellow River basin during future two periods would decrease by 16.9% and 22.2%. The results are of great significance to future water resources management and sustainable development under climate change in major river basins of China.
Keywords: *statistical downscaling, distributed hydrological model, changing environment, scenario analysis, Tibetan Plateau*

Introduction

The Fifth Assessment Report (AR5) of the Intergovernmental Panel on Climate Change (IPCC) pointed out that climate change has become an indisputable fact that will greatly threaten global and local water resource security (Stocker et al., 2013). In China, the tendency of climate change has been generally consistent with its global pattern (Qin, 2003; Qin et al., 2007).The multiscale, all-dimension, multi-level influences of climate change on humans, the ecology and environment (Hadson and Jones, 2002; Varis et al., 2004; Burn et al., 2010; Elfert and Bormann, 2010; Karamouz et al., 2011; Jung and Chang, 2011; Marvel and Bonfils, 2013; Jeong et al., 2014; Xu et al., 2015) are key risk factors for global sustainable development. Because the water cycle connects humans, the ecology and environment, its response to future climate change has become a focus of scientists, the general public, and decision-makers all over the world.

DOI: http://dx.doi.org/10.15666/aeer/1504_683704

China has a vast territory and various climate types. Because of substantial differences in geological environment, climate, and economic development stages in various regions, the influences of climate change vary. In the context of global warming, the frequency and intensity of climate extremes such as high temperature, low temperature, heavy precipitation and droughts in China had varying tendencies and regional differences (Piao et al., 2010). Recently, a number of researchers have conducted extensive studies of climate change and its effects on water resources in China. In general, it was found that over the past 100 years, hydrological climate elements changed substantially in major basins of the country, showing substantial temperature rises in most areas. In the last 50 years, there has been an uneven south-north precipitation distribution in the eastern monsoon region (Ye and Huang, 1996; Fu et al., 2005; Ding and Ren, 2008; Ding et al., 2006) and reduced basin runoff in the majority of northern exorheic rivers, aggravating water resource supply-demand conflicts in the north and pressure for flood control in the south (Chen, 2002; Liu, 2004; Qian et al., 2007). In most regions of the country, the potential (water surface) evaporation capability decreased dramatically (Qiu et al., 2003; Yang et al., 2003; Liu et al., 2004; Ren and Guo, 2006). Future climate change might exert strong impacts on water resources in China (Wang et al., 2002; Liu, 2007; Zhang and Liu, 2000; Xia et al., 2008), with reduced runoff in northern rivers but increased runoff in southern ones (Lin et al., 2006). Annual average evaporation may be on the rise (Wang et al., 2003), as may be the case also for the frequency of flood and drought disasters, which would further increase the vulnerability of water resources and conflict between water supply and demand (Lin et al., 2006).

Because of water cycle and water resources pattern changes in major river basins of China and prominent water issues such as flood disasters in the south and water shortages in the north, it is of great scientific importance and value to study the mechanism and spatiotemporal variation of the continental water cycle under the background of climate change. This will help assess the influence of such change on the basin water cycle and ensure sustainable socioeconomic development in the country.

In the current study, the Yangtze River Delta region and the upper reaches of Yellow River basin were selected to represent typical southern and northern basins in China. A multi-criteria score-based method was used to assess the suitability of multiple General Circulation Models (GCMs) provided by the IPCC. Screened GCM output results were downscaled to create future climate change scenarios suitable for the Yangtze and Yellow River basins. These scenarios were used to drive distributed hydrological models to simulate the spatiotemporal variation of water cycle elements in the study area, thereby evaluating the response of the river basin water cycle to future climate change.

Materials and Methods

Study area

The Yangtze is the longest river in Asia and the third longest in the world with a length of over 6300 km. Its drainage area, the Yangtze River basin, is located between 24°30′-35°45′N and 90°33′-122°25′E, spanning a total area of ~1.8×10^6 km^2. The Yangtze River basin stretches from the eastern Tibetan Plateau to the East China Sea and crosses 19 provinces in China (*Fig. 1*). The economy of the Yangtze River basin contributes 41.1% of China’s gross domestic product, and the area supports 34% of the nation’s population (Xu and Ma, 2009). Most of the YRB belongs to the East Asian

monsoon region, which is sensitive and vulnerable to climate change (Fang et al., 2010; Xu and Ma, 2009). Human-induced land use/land cover change and climate change are now having enormous impacts on its water cycle (Zhang et al., 2014).

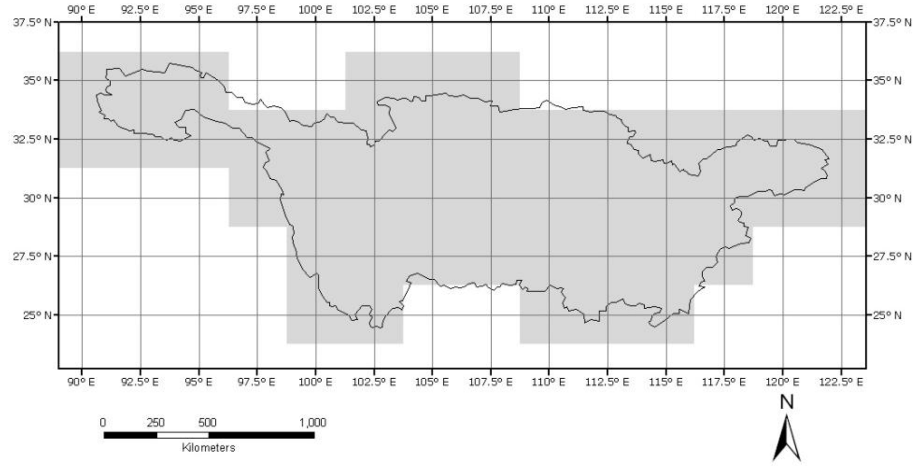

Figure 1. *Geographical boundary of Yangtze River basin with grids distribution used for GCMs*

The Yellow River is the second largest river in China with a drainage area of 7.95 × 105 km^2 (*Fig. 2*), and its topography is highest in the west and the lowest in the eastern parts of the Yellow River basin. The basin is located at mid-latitudes with a different climate prevailing in the southeastern part (higher precipitation) as compared to the northwestern part (lower precipitation). In addition, 91.93% of the total land has been utilized for vegetative cover in the basin. Due to climate change and intensifying human activities, particularly increasing human withdrawal of water for agriculture irrigation, streamflow in the Yellow River has significantly decreased since 1980s (Li et al., 2017; Zhang et al., 2009).

GCM suitability assessment method

Taking the degree of fit of statistical values from GCM output and those from field-measured data as objective functions, the performance of each such function was scored, thereby evaluating the comprehensive performance of GCMs.

The mean value, coefficient of variability (= standard deviation / mean value), and normalized root mean square error (NRMSE) were used to characterize closeness between the mean value and deviation of GCM output variables and those of measured variables. NRMSE was defined as the ratio of root mean square error to the corresponding standard deviation.

Pearson correlation coefficients in both chronological (multiyear average monthly sequence) and spatial (mean value of climate elements at stations) sequences were used to characterize the closeness between GCM simulation and measured values, thereby evaluating the simulated variables' intraannual change and spatial degree of fit.

The rank-based nonparametric Mann-Kendall method was used to detect long-term tendencies (MK Zc) and magnitudes (MK Slope) of every variable. If areas where the MK Zc of GCM output variables matched measured values did not reach 95%, MK Slope was not included in the scoring.

Empirical orthogonal functions (EOFs) were used to qualitatively and quantitatively characterize variable spatiotemporal variation. Preliminary analysis showed that the first and second EOF characteristic vectors of nearly 20 variables were able to explain most of the deviations. Hence, these two vectors were included in rank scoring.

Two statistics of the probability density function, Brier score (BS) and skill score (Sscore), were used to evaluate the effectiveness of GCM simulation of that function. BS is the mean square deviation of probabilistic prediction, and Sscore is used to describe the overlap between the computed and measured probability distribution.

A total of 11 statistics were included, i.e., mean, coefficient of variability, NRMSE, temporal correlation coefficient, spatial correlation coefficient, trend analysis rank statistics, trend analysis variation magnitude, first and second EOF characteristic vectors, and BS and Sscore of the probability density function. Performance of each of the statistics was considered as one of the objective functions. A multi-criteria rank score (RS) value was computed for every objective function by assigning a value of 0-10, based on GCM performance. The calculation was:

$$RS_i = \frac{x_i - x_{\min}}{x_{\max} - x_{\min}} * 10, x_i < x_{\max} \quad \text{(Eq.1)}$$

where x_i is relative error in a statistic between simulated and measured values. The smaller the value is, the lower the score is. For a specific GCM output variable, the final total score was calculated by averaging the scores of all statistics. The better the simulation results, the lower the score. The score represents the degree of fit between GCMs outputs and measured values. It could be used to compare and analyze different GCMs, but it does not indicate the actual simulation accuracy of a given GCM.

Downscaling model

The Statistical Downscaling Model (SDSM) has both of deterministic transfer functions and stochastic components (Wilby et al., 2002). It has been widely applied in the statistical downscaling studies for both climate variables and air quality variables, and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_683704

has been recommended by the Canadian Climate Impacts and Scenarios (CCIS) project (http://www.cics.uvic.ca).

An automated regression-based statistical downscaling model (ASD) (Hessami et al., 2008), inspired by the existing SDSM was developed within the Matlab environment, which is an easy to use graphical user interface for the statistical downscaling of GCM outputs to regional or local variables and already been successfully applied in major river basins of the east monsoon region in China (Xu et al., 2013).

Distributed hydrological models

The Taihu basin, located in the Yangtze River Delta region, is selected as the typical area for hydrological modeling in this study, which is characterized by a flat terrain, a complex river network, and various polder areas, without a clear outlet. Based on a 90-m DEM, it is difficult to extract the basin river network and simulate runoff yield and concentration over the entire basin. Therefore, the distributed Variable Infiltration Capacity (VIC) model based on grids was used to directly obtain gridded runoff depth in the basin. The VIC model considers physical exchange processes of atmosphere-vegetation-soil, primarily reflected by the variation of water and heat conditions and water and heat transfer in those three components. The model has been widely used to study the effects of climate change on hydrologic processes (Yuan et al., 2005; Liu, 2004; Su and Xie, 2003; Lohmann et al., 1998; Nijssen et al., 1997; Abdulla et al., 1996). VIC can either simultaneously simulate atmospheric-hydrological energy balance and water balance, or just calculate water balance, export runoff depth, and evaporation at each grid. Through a runoff concentration model, it transforms grid runoff depth into water flow at the basin outlet, eliminating the shortcomings of traditional hydrological models in the description of thermal processes.

The upper reaches of the Yellow River basin were selected to investigate the influences of climate change on the basin water cycle in this study. The reasons for this selection were: (1) The upper reaches are the origin of the Yellow River, and runoff variation there affects the entire basin; (2) future runoff change in the upper reaches can be used to validate basin-wide runoff change; (3) results of sub-basin estimation can provide accurate and detailed information for future runoff variation tendencies. In the upper reaches of the Yellow River basin, there is strong terrain fluctuation, an extractable river network, and abundant hydrologic data for the basin outlet. The Soil and Water Assessment Tool (SWAT) model (Arnold et al., 1998; Neitsch et al., 2005) was used for distributed hydrological simulation. Parameter sensitivity was analyzed by use of the built-in sensitivity analysis module.

Dataset

To include as many GCMs as possible from different countries and ensure the integrity and reliability of GCM outputs, 23 GCMs recommended by the IPCC were selected (*Table 1*). Monthly series including 15 climate variables, i.e., average temperature, relative humidity, longitudinal and latitudinal wind speeds, geopotential heights at the 500, 700 and 850 hPa levels, and two surface climate variables (temperature and precipitation) were used in this study. All data were from the IPCC data center. Details of the GCMs are on the website http://ipcc-ddc.cru.uea.ac.uk. All GCM output data were normalized to 2.5° × 2.5° by interpolation. Data series were from the period 1950 to 1999/2000.

ERA-40 and NCEP reanalysis data were taken as the measured data of the meteorological variables to assess the suitability of GCM outputs. Gridded data of monthly average temperature and monthly precipitation from the China Meteorological Administration (http://ncc.cma.gov.cn) were used, which were resampled to 2.5° × 2.5° grids.

Results and Discussion

GCM suitability assessment results

The Yangtze River basin

Comprehensive assessment results indicate that FGOALS, ECHAM4, ECHAM5, HadCM3, HadGEM1 and MRI had better performance in the Yangtze River basin than other GCMs (*Fig. 3*). Zhang et al. (2005) investigated spatiotemporal and circulation characteristics of the water vapor budget in the basin, and emphasized the influence of latitudinal water vapor transport originating from the Bay of Bengal on basin relative humidity. The simulation results of longitudinal and latitudinal wind speed strongly affected the spatiotemporal distribution of basin relative humidity. In the present study, four GCMs that effectively simulated relative humidity (ECHAM4, FGOALS, HadCM3 and HadGEM1) also showed good simulation of longitudinal and latitudinal wind speeds, consistent with previous studies. Temperature simulation results were better than other variables (including relative humidity), also demonstrated in previous studies. Xu et al. (2002) simulated climate change in East Asia based on five climate models, including temperature, precipitation, diurnal range and water vapor data. Their assessment results indicated that ECHAM4 and HadCM2 had best performance in China. In the present study, these two models also demonstrated promising outcomes. However, during

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_683704

assessment of GCM suitability in the Murray-Darling Basin of Australia, Maxino et al. (2008) obtained larger GCM-computed values of temperature than measured values for most GCMs. In contrast, in an assessment of GCM suitability in the Yellow River basin by Cao et al. (2009) the computed temperature was consistently cooler. In the present study, the computed temperature was warmer in most GCMs than measured. This might have resulted from a large difference of regional climate and circulation characteristics in the basins, as well as different GCM responses to climate characteristic variation (Xu et al., 2015; Miao et al., 2016). Therefore, it is necessary to assess GCM suitability across different basins.

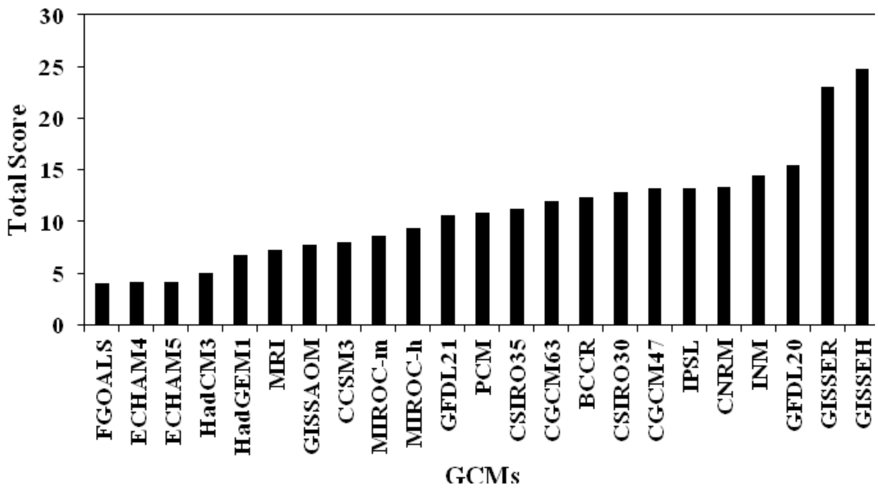

Figure 3. *Comprehensive scoring of GCMs in Yangtze River basin*

Specifically, we chose the Taihu basin to investigate the influences of climate change on the water cycle in the Yangtze River basin and evaluate GCM suitability. This basin is in the southern Yangtze River Delta. Associated administrative regions include southern Jiangsu, Jiaxing, Huzhou, part of Hangzhou in Zhejiang, and most of Shanghai, one of the most economically developed and populated regions in China. The basin water cycle is extremely sensitive to climate change.

Fig. 4 shows RS scores in increasing order. The lower the score is, the better the GCM performance for climate simulation is. Thus, it is seen that the BCCR model had the best performance overall. Therefore, it was used to assess the impacts of climate change. The simulated daily climate data were exported to the A1B scenario including two components, the current period (1961-2000, 20c3m scenario) and future periods (2046-2065 and 2081-2100). A1B is characterized by balanced economic development and greenhouse gas emissions, and is therefore suitable for future planning of coordinated water-economic-environment development in the Taihu basin.

DOI: http://dx.doi.org/10.15666/aeer/1504_683704

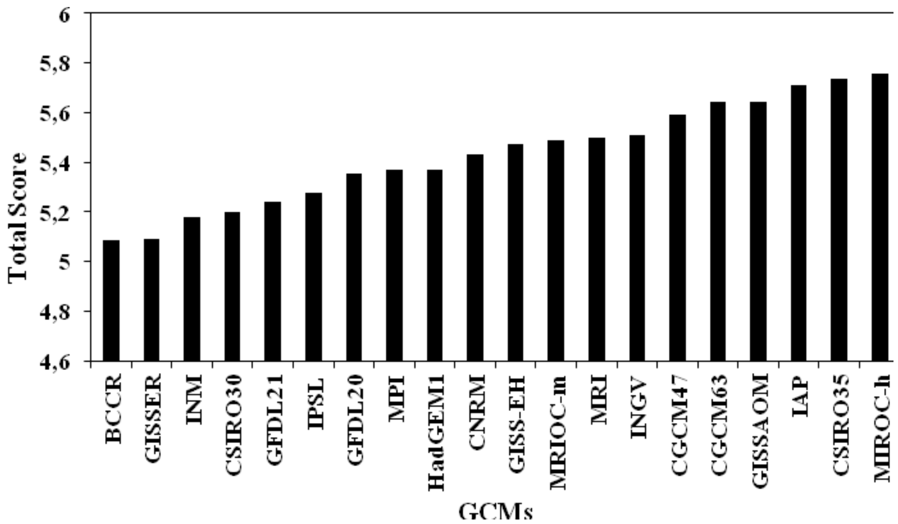

Figure 4. *Comprehensive scoring of GCMs in Taihu basin*

The Yellow River basin

25 grids of GCM data over the Yellow River basin were selected (*Fig. 2*). All GCM data were interpolated to a resolution of 2.5° × 2.5°. The comprehensive results showed that the top ten climate models were the MRI, HadGEM1, INM, CSIRO30, MIROC-M, HadCM3, BCCR, GFDL20, CGCM47, and GFDL21 (*Fig. 5*).

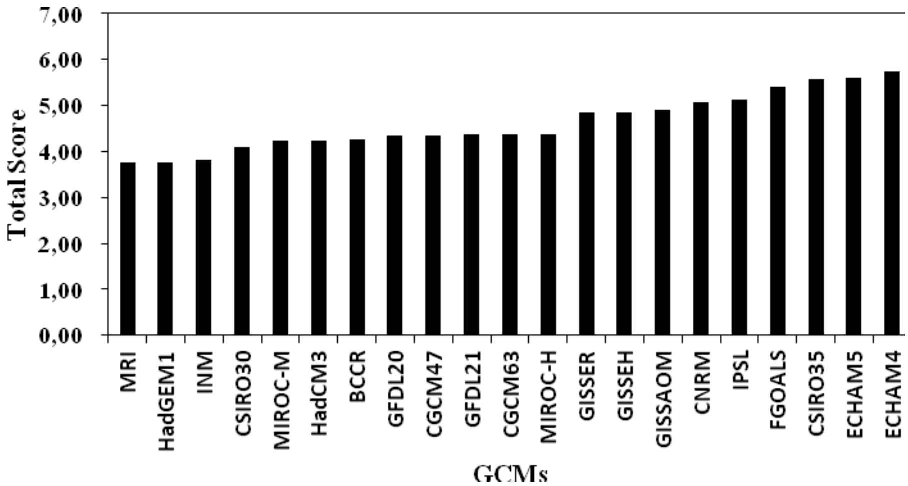

Figure 5. *Comprehensive scoring of GCMs in Yellow River basin*

While studying summer water vapor transport in the Asian monsoon zone and effects on precipitation in China, Zhou et al. (2008) observed the important role of longitudinal and latitudinal water vapor transport by the Indian monsoon to relative humidity of the basin in China. Also, it was reported that relative humidity was to a large extent affected by the simulation performance of longitudinal and latitudinal wind speeds. In the present study, the GCMs with favorable simulation of relative humidity (MRI, HadGEM1 and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_683704

GFDL20) also showed good performance in simulation of those wind speeds. This is consistent with the finds of Zhou et al. (2008).

To analyze uncertainty caused by multiple GCMs and different scenarios and comprehensively consider the consistency and integrity of scenario data in different models, we compared A2 and B1 scenario data in MRI, CSIRO30 and INM, which had the best performance in the Yellow River basin.

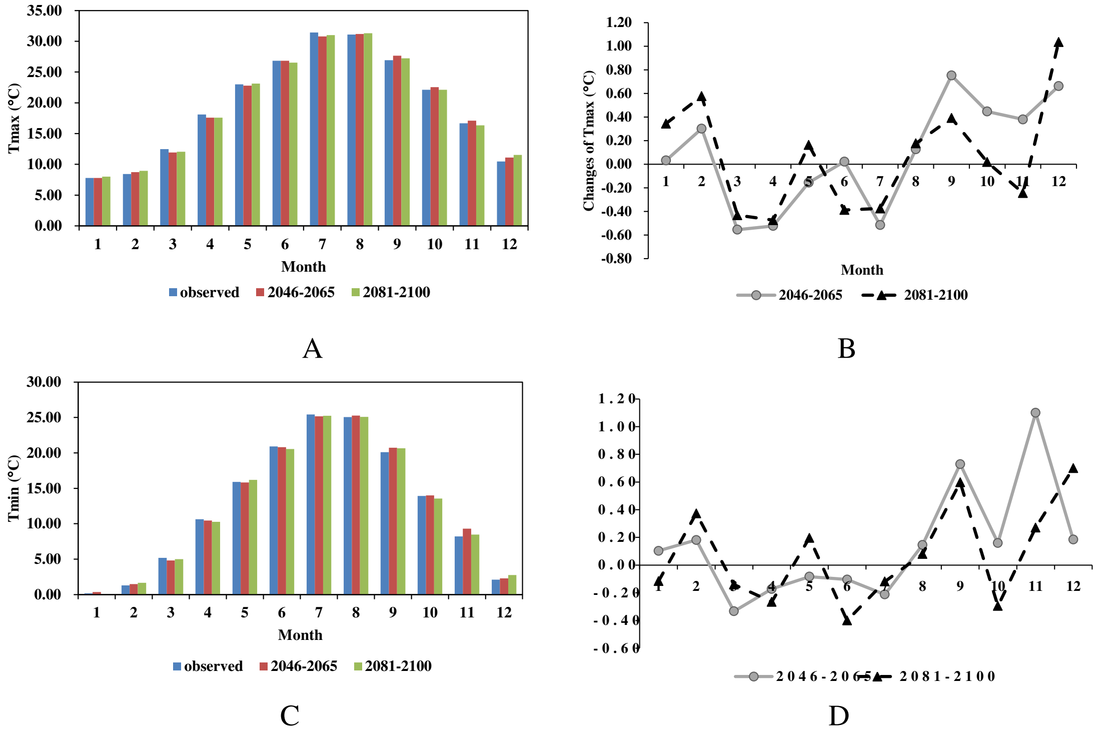
Impacts of climate change on water cycle

The Yangtze River basin

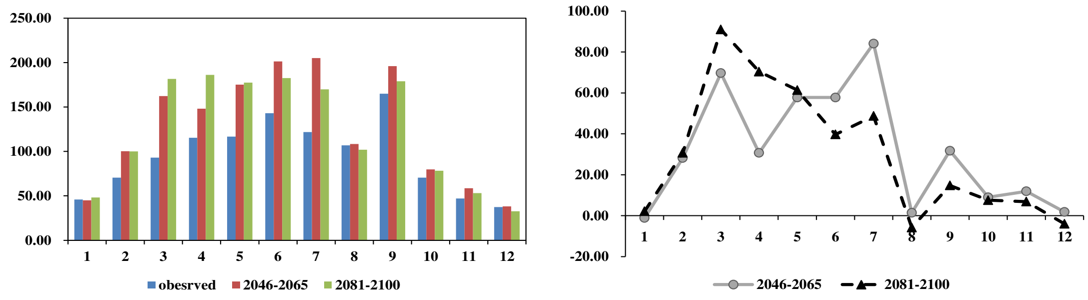
Construction of future climate change scenario

In a previous study by the authors (Chu et al., 2012), we conducted a comparison of statistical downscaling models for the Taihu basin. Specifically, the SDSM and ASD model were used to construct future climate change scenarios for that basin. The results indicated that ASD optimized the selection of predictors, and the simulation results were superior to those of SDSM. Therefore, the ASD model was used herein to construct future climate change scenarios.

ASD downscaling results revealed that the variation of future precipitation was complex and substantial compared to that of future temperature. *Fig. 6* shows that in the two future periods (2046-2065 and 2081-2100), the majority of months showed an increasing tendency in precipitation. The increase was large in spring and summer (except August), but smaller in other months. Compared to precipitation in 1961-1990, precipitation ranged between −0.3 and 83.6 mm and −5.3 and 89.5 mm in 2046-2065 and 2081-2100, respectively. In general, precipitation in the two future periods will not change significantly. Intra-annual variation was consistent, with reduced precipitation in January, August and December, and increased precipitation in March, May and July.



http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_683704



E F

Figure 6. *Daily maximum temperature (A-B), minimum temperature (C-D), precipitation (E-F) and their variations in the Taihu basin during two future periods predicted by ASD downscaling model (A, C, and E are comparisons between three elements and their measured values; B, D, and F are monthly changes compared to baseline period)*

Response to climate change of water cycle

The authors successfully constructed VIC for the Taihu basin (Liu et al., 2010), which was used in the present study. For meteorological data series under the A1B scenario during the baseline period (1961-1990) generated by the ASD model, including daily precipitation, daily maximum and minimum temperatures, the Thiessen polygon method was used to interpolate the data to 5 km × 5 km grids, thereby creating climate forcing data. Based on soil and vegetation parameters of the constructed VIC model of the Taihu basin (Liu et al., 2010), the model was run on 1452 grids of the basin, exporting daily runoff depth data at every grid for the period 1961-1990.

Similarly, based on meteorological data series in the future periods (2046-2065 and 2081-2100) generated by ASD, including daily precipitation, daily maximum and daily minimum temperatures, daily runoff depth data at every grid were exported.

Fig. 7 shows monthly changes of runoff depth on each grid for 2046-2065, compared to the baseline period. It is seen that in most areas of the basin, there was a decreasing tendency in monthly runoff depth in the future, of varying magnitude. Areas with large reductions of runoff depth were western Zhejiang and Zhangzhou-Jiaxing-Huzhou; the other areas showed lesser reductions. Particularly, Shanghai showed an increasing tendency during most of the year (January-April and September-December). Western Zhejiang demonstrated a slight increase in runoff depth during flood season.

Fig. 8 shows monthly changes of runoff depth at every grid between 2081-2100 and the baseline period. It is seen that in most areas of the basin, there was a decreasing tendency of monthly runoff depth in the future, with varying magnitude. The runoff depth in the western Zhejiang area tended to decrease compared to the baseline period, but the magnitude of decrease was less than that during 2046-2065. The Yangchengdian area had the largest reduction in runoff depth during March and May, whereas the Hangzhou-Jiaxing-Huzhou area showed a relatively large reduction in winter. Similar to the earlier period of 2046-2065, there was an increasing tendency in Shanghai during most of the year (January-April and October-December).

DOI: http://dx.doi.org/10.15666/aeer/1504_683704

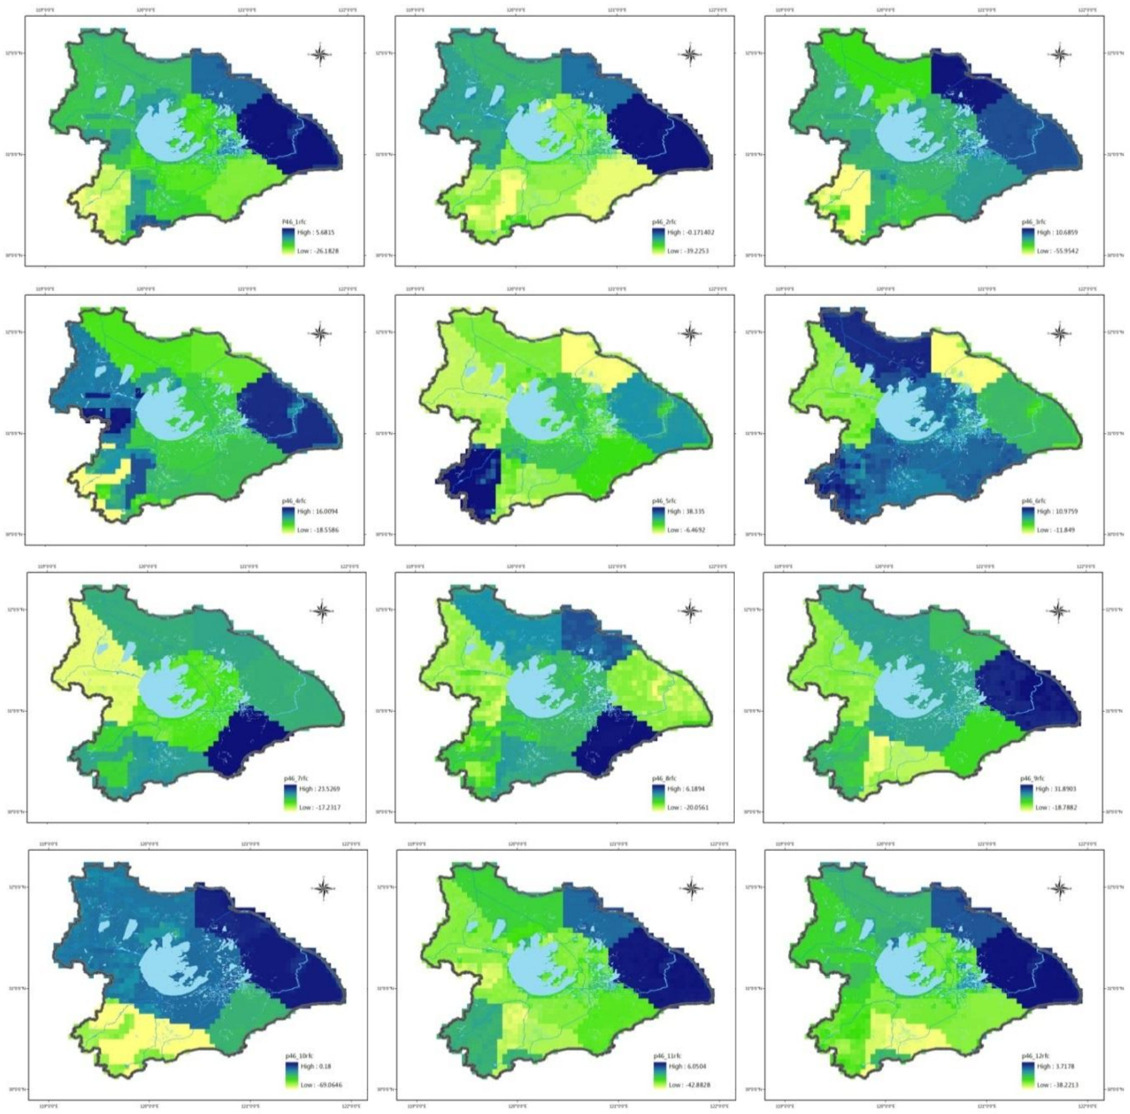

Figure 7. *Spatial distribution of monthly runoff depth variation during 2046-2065 under A1B scenario*

The Yellow River basin

Construction of future climate change scenario

Based on results of GCM suitability assessment, output data of three GCMs (MRI, CSIRO30, and INM) in the A2 and B1 scenarios were used and underwent interpolation to form 2.5° × 2.5° grids. The three simulation periods were the same as above. The SDSM model was used for downscaling. Twelve daily predictors were chosen, covering 25 grids in the Yellow River basin. The observation data contained daily precipitation, average temperature, and maximum and minimum temperatures at 79 stations in the basin from 1961 to 1990.

Fig. 9 displays the simulation results of monthly maximum and minimum temperatures from six conditions (three GCMs, each using the A2 and B1 scenarios). It is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_683704

seen that both monthly maximum and minimum temperatures had increasing tendencies in most months of the year for all six conditions.

The variation of precipitation was substantially different between conditions (*Fig. 10*). Overall, the CSIRO30 model showed a minimal reduction (monthly variation < 25%) in precipitation, whereas MRI produced the greatest precipitation increase.

Response to climate change of water cycle

(1) Construction of distributed hydrological model

The upper reaches of the Yellow River are on the Qinghai-Tibetan Plateau, bordering the Bayan Har Mountains in the south, Qaidam Basin in the north, Kunlun mountains in the west, and Loess Plateau in the east. The geomorphology is alpine grassland. The segment above Lanzhou (hereafter referred to as the upper reaches) has a total length of 2119 km and catchment area of 224,749 km^2, accounting for 28% of that in the entire basin. *Fig. 11* shows the location of the river basin.

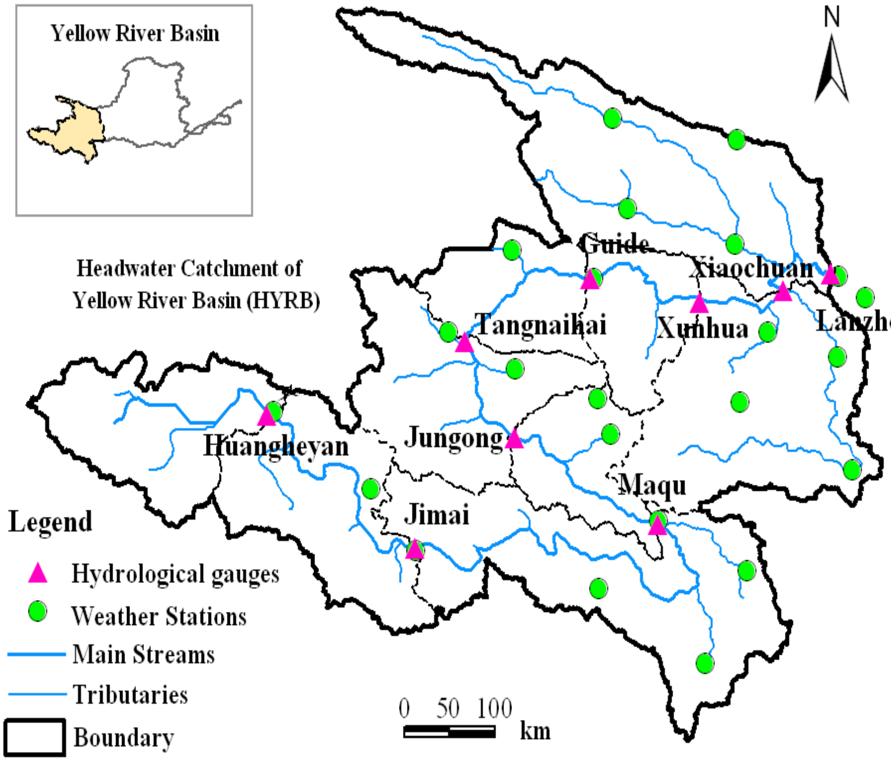

Figure 11. *Upper reaches of Yellow River*

The SWAT model with the built-in parameter sensitivity analysis module was calibrated and validated during 1971-1985 and 1986-2000, respectively. *Fig. 12* shows a comparison between discharge simulation and measured values at the Lanzhou hydrological station during the calibration and validation periods. In general, model indexes were satisfactory. The Nash-Sutcliffe efficiency and determination coefficients were 0.667 and 0.773 in the calibration period, and 0.626 and 0.709 in the validation period. Hence, the model showed good performance in simulating water balance in the basin.

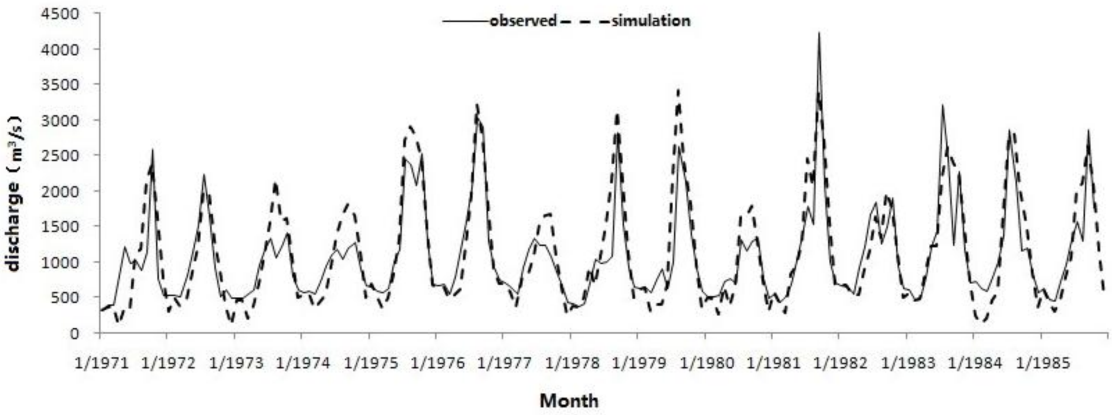
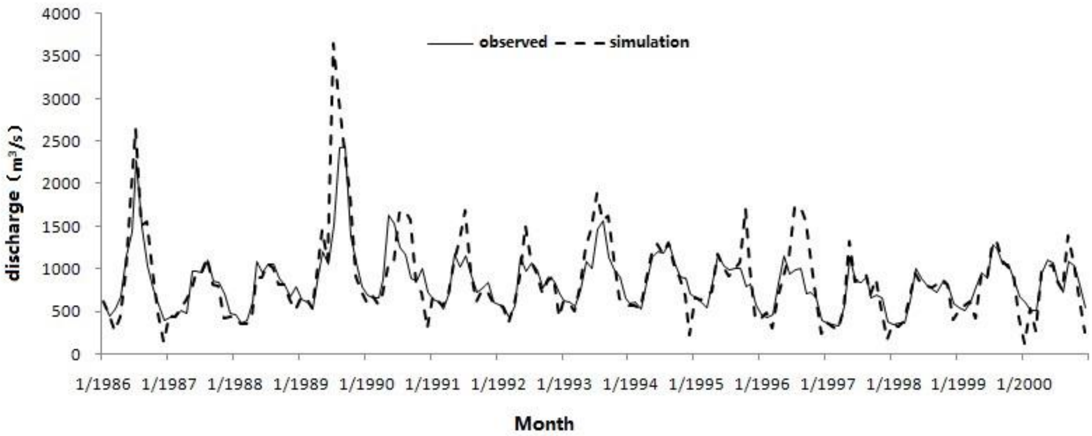
DOI: http://dx.doi.org/10.15666/aeer/1504_683704



A



B

Figure 12. *Fitted curve of monthly discharge simulation to measured values at Lanzhou hydrological station (A: calibration period; B: validation period)*

(2) Response of runoff to future climate change in upper Yellow River basin

Figs. 13-15 present the spatial distribution of mean annual runoff depth during 2046-2065 and 2081-2100 compared to the baseline period, for every sub-basin and downscaling scenarios of the three GCMs. The runoff depth variation of the CSIRO model was -35.8 to 43 mm. In most areas, the variation was between −5 and −20 mm. Overall, the tendency of basin runoff was consistent between different scenario combinations, with runoff decreases in the majority of sub-basins. The area of runoff depth reduction was less under the B1 scenario than that under the A2 scenario. Runoff depth decreased greatly in the Hongyuan, Jiuzhi and Ruoergai areas, generally between −35 and −21 mm. In general, in the downscaling scenario of the CSIRO model, basin runoff depth tended to decrease in most sub-basins.

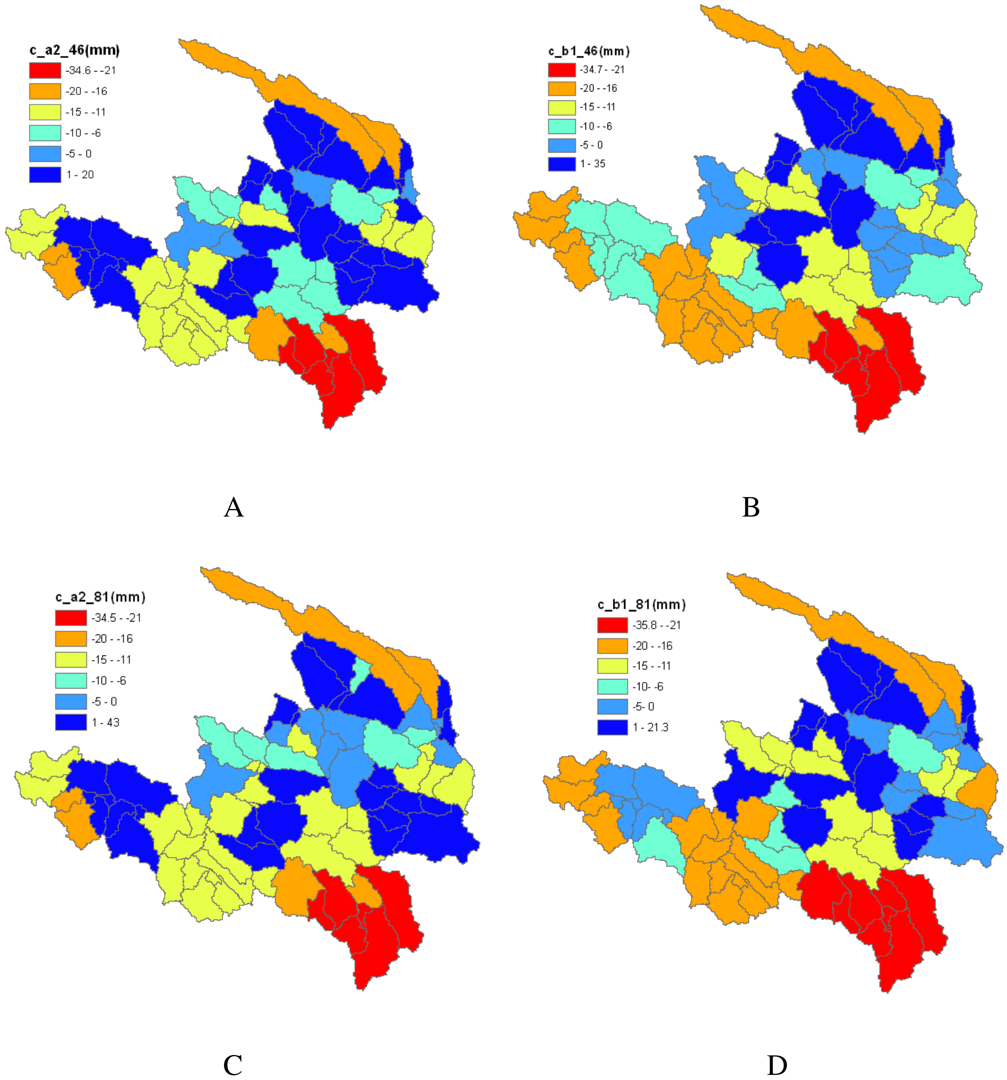


Figure 13. *CSIRO-estimated spatial distribution of mean annual runoff depth in sub-basins for 2046-2065 (A and B) and 2081-2100 (C and D) compared to baseline period*

For various scenario combinations of the INM model, changes of runoff depth were between −33.9 and 61 mm, with decreases in most sub-basins. The tendency of runoff depth with different scenario combinations was relatively consistent, showing decreasing tendencies (in excess of 20 mm) in southern sub-basins, and mixed increases and decreases in northern sub-basins. under the A2 emission scenario of INM, the area of sub-basins with reduced runoff during 2081-2100 was larger than that in 2046-2065. Under the B1 scenario, the area was smaller in 2081-2100. The Hongyuan, Jiuzhi, and Ruoergai areas had large reductions in runoff depth, between −31 and −21 mm.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_683704

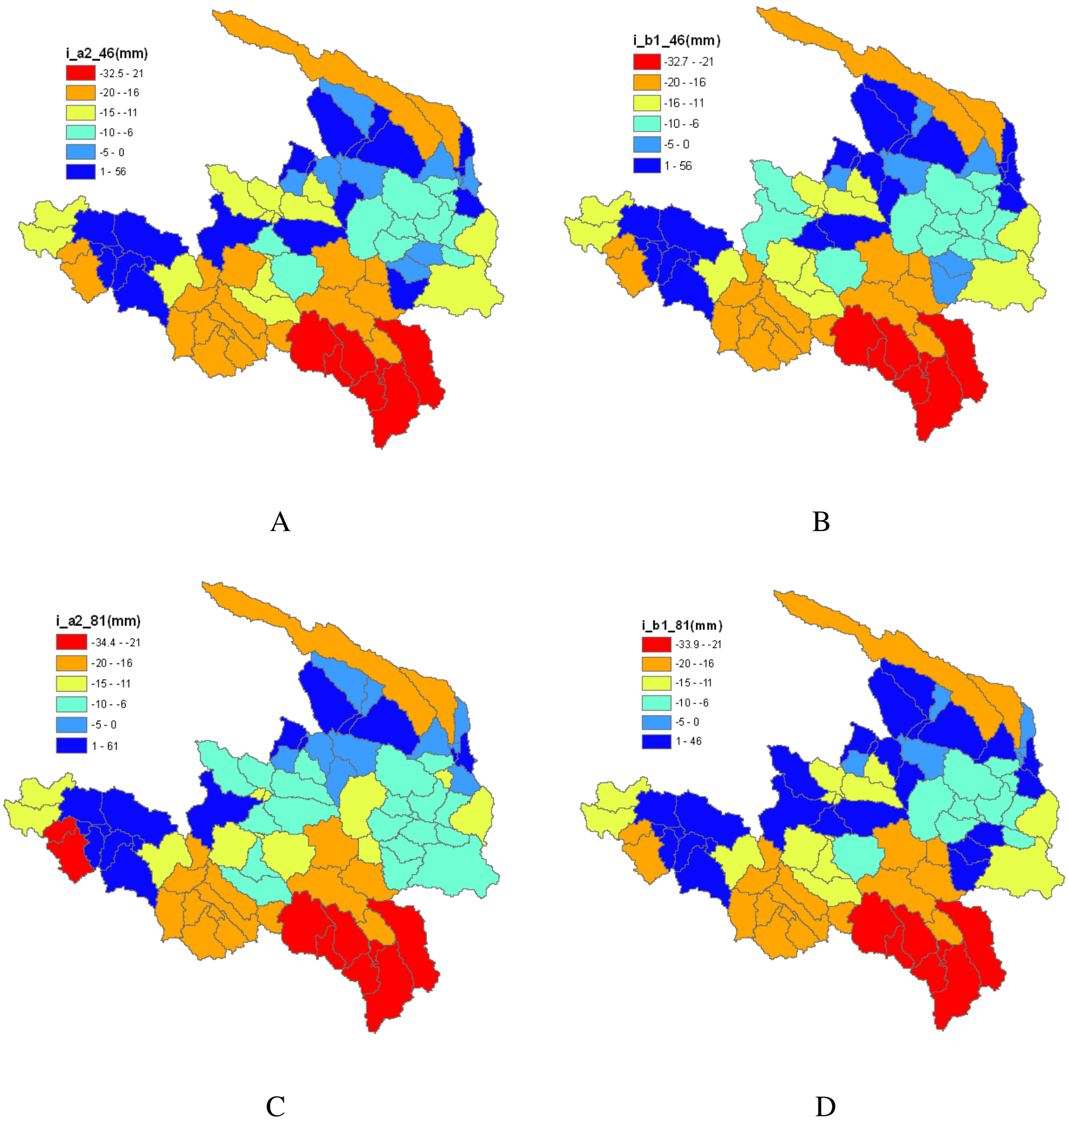

Figure 14. *INM-estimated spatial distribution of mean annual runoff depth in sub-basins for 2046-2065 (A and B) and 2081-2100 (C and D) compared to baseline period*

For different scenario combinations of the MRI model, runoff depth was between −32.9 and 69 mm, with over half the area of sub-basins showing a decreasing tendency in average runoff depth. In the period 2046-2065, the area of sub-basins with increasing runoff under the A2 scenario was larger than that under the B1 scenario, as was the area with reductions of 16-20 mm. For 2081-2100, the area of sub-basins with increasing runoff under the B1 scenario was larger than that under the A2 scenario, as was the area with reductions of 16-20 mm. The MRI model produced a decreasing tendency in runoff depth over half the basin area. In addition, that depth decreased greatly in Hongyuan, Jiuzhi and Ruoergai, generally between −35 and −21 mm.

Conclusions

As an important component of the climate system, the water cycle is extremely sensitive to climate change. In the present study, taking the typical areas of the Yangtze and Yellow River basins as objects, we conducted suitability assessments of GCMs and downscaling. Through coupling of GCMs and distributed hydrological models, the impacts of climate change on the river basin water cycle were quantified. The conclusions are as follows.

(1) Based on rank scoring, the degree of fit between statistical values of GCM output and those of reanalysis data was taken as the objective function. Scores were given according to the performance of every objective function, thereby obtaining comprehensive scores for the performance of each GCM in their simulation of the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_683704

Yangtze and Yellow River basins. Specifically, the top three models were the MRI, HadGEM1 and INM for the Yangtze River, and FGOALS, ECHAM4 and ECHAM5 for the Yellow River. This indicates a substantial difference between the southern and northern regions of China with respect to the effects of climate change.

(2) Future precipitation and temperature data under the A1B scenario were generated by the ASD downscaling model, which were used to drive the VIC model on 5 km × 5 km grids. Simulation of hydrologic processes in the Taihu basin on the lower reaches of the Yangtze River showed that areas with substantial reduction in runoff depth during 2046-2065 compared to a baseline period were western Zhejiang and Hangzhou-Jiaxing-Huzhou. The western Zhejiang area showed a slight increase in runoff depth during flood season. Runoff depth in western Zhejiang tended to decrease in 2081-2100 compared to the baseline period, but this decrease was less than that during 2046-2065.

(3) The SWAT model gave relatively promising results for the upper reaches of the Yellow River basin. Under the A2 and B1 scenarios, runoff tended to decrease in future periods. In particular, the decrease was greater in 2081-2100 than in 2046-2065. Under different scenario combinations, annual average runoff in 2046-2065 and 2081-2100 was 27.507 and 25.737 billion m^3, respectively, reductions of 16.9% and 22.2% compared to the baseline period. Under various scenario combinations, spatial runoff variation in the upper basins of the Yellow River was consistent. In most areas there was a decreasing tendency in runoff depth. Specifically, the decrease was largest in Hongyuan, Jiuzhi and Ruoergai, in excess of 20 mm. Maximum runoff decrease did not vary much with the scenario combination, and was about −30 mm. However, the magnitude of increase was substantially different, between 12.7 and 69 mm.

(Received 31st May 2017; accepted 2nd Aug 2017)

Abstract. Mogan Lake, a popular recreation area, is under the pressure of intense urban-industrial pollution, therefore some management strategies included occasional macrophyte harvesting, diverting running water into the lake to accelerate the improvement of its water, and dredging have been in progressing since 1995. This study was conducted on sediment and overlying water samples collected in April, July and October 2015 and January 2016 from Mogan Lake. The outstanding data for this study is presented as: i) detection of the sediment chemical composition and estimation of sediment phosphorus mobility, ii) comparison of the current status of the lake's eutrophication regarding phosphorus mobility with data from earlier studies regarding the common station. The research data has revealed i) sediment TP concentrations ranged from 620.00 µgP gDW^{-1}, to 1047.50 µgP gDW^{-1} while TN concentrations were between 3250.00 µg gDW^{-1} and 6325.00 µg gDW^{-1}. Sediment TOC concentrations ranged between 58850.00 µg gDW^{-1} and 79675.00 µg gDW^{-1}. Sediment iron content and loss on ignition values were determined as 1.608-3.415 mg gDW^{-1} and 9.05-20.94 %, respectively. The rank order of phosphorus fractions were evaluated as Ca≈P>Org≈P>CO_3≈P>Fe+Al≈P. ii) the phosphorus release values from the sediment (0.1754 – 1.1249 mg P $m^{-2}d^{-1}$) were higher than the earlier studies findings. Phosphorus release in the lake has increased over the past ten years but still remains at a generally low level together with some management activities in Mogan Lake, therefore, instead of the internal P source future research should focus on external sources. In shallow eutrophic systems such as Mogan Lake, sediments having phosphorus accumulation depends on deep interactions with principally antropogenic external sources. In conclusion the primary goal is to determine the adsorption capacity of the sediment in order to estimate the critical internal phosphorus load and the second goal should be to apply a sustainable monitoring program.
Keywords: *freshwater, phosphorus speciation, eutrophication, lake management, nutrient cycle*

Introduction

The primary gauge of the phosphorus cycle in natural freshwater bodies is the shift of phosphorus between the sediment and the overlying water. Better understanding of the occurrence of water phosphorus (P) at the water-sediment interface is vital to clarify P sources of origin in freshwater shallow lake ecosystems (Pu et al., 2017). Rather than focusing on total phosphorus content when examining the relationship between sediment phosphorus and eutrophication in a lake, it is more efficient to focus on the contents of the different phosphorus fractions (Christophoridis and Fytianos, 2006). The critical roles of P fractionation as regulators were manifested to interpret immediate and hysteretic internal liberation and indirectly represent anthropogenic inputs (Pu et al., 2017). In determining the sediment's role as either a trap or a source of phosphorus, it is important to use chemical extractions to examine different chemical P fractions in the sediment such as labile P, reductant P, metal-bound P, occluded P and organic P (Smolders et al., 2006).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_705717

The accumulation of phosphorus in lake sediment generally occurs during heavy loading cycles, and its release into the overlying water is seen prior to reductions in external loading (Jiang and Shen, 2006; Watson et al., 2016). Several physical, chemical and biological measures (biomanipulation, phosphate inactivation, rooted macrophyte harvesting and sediment dredging) are generally undertaken in lakes to control eutrophication caused by internal phosphorus loading, which can be triggered by a reduction of external phosphorus loading (Smolders et al., 2006; Madura and Goldyn, 2009).

Several studies (Pulatsü et al., 2008; Topçu and Pulatsü, 2008; Pulatsü and Topçu, 2009) have been undertaken regarding the eutrophication-sediment interaction in Mogan Lake, which is an important recreation area due to its proximity to Ankara. Mogan Lake was chosen in this study due to the fact that it has been heavily influenced by human actions ranging from agricultural and domestic to semi-industrial pollution sources. Furthermore, it is thought that the data collected from the study will be of importance for the management of the lake, and these data could also be useful in the management of similar aquatic systems.

The first measures aimed at reducing external pollution loads in this shallow, eutrophic lake, located in the Gölbaşı Special Protected Area and under the pressure of intense urban-industrial pollution, were begun in 1995. These management strategies included occasional macrophyte harvesting, diverting running water into the lake to accelerate the improvement of its water, and dredging. The aim of this study was to give an overview in April, July, and October 2015 and January 2016 following the implementation of these management strategies in Mogan Lake including i) detection of the sediment chemical composition (total organic carbon, loss on ignition, total iron, total nitrogen, total phosphorus and phosphorus fractions), and determination of sediment-sediment overlying water phosphorus mobility (sediment phosphorus release/retention) with effective factors in a view towards phosphorus control and ii) comparison of the current status of the lake's eutrophication regarding phosphorus mobility with some earlier study data (Topçu and Pulatsü, 2008; Pulatsü et al., 2009) considering the common station.

Materials and Method

Study site

Mogan Lake, located 20 km south of Ankara, Turkey (39°47′N 32°47′E), is an alluvial pond that is fed by more than five streams of varying size. The lake's outflow is into Eymir Lake through a wetland on Mogan's north side. Mogan Lake's surface area is 7.20 km^2, its mean depth is 2.80 m, its lake volume is 13.72 × 106 m^3, and its average theoretical flushing rate is 1.35 times per year (Boşgelmez et al., 2005). Due to the external phosphorus load resulting from detergents in waste water effluents and fertilizers in agricultural run-off from nearby areas, Mogan Lake is highly eutrophic (Fakıoğlu and Pulatsü, 2005). Because the bed of the eastern littoral area of Mogan Lake is covered by stone, two research stations were established near the lake's western shore, where the lake bed is more suitable for obtaining sediment samples. There were rooted surface plants in the areas surrounding the stations, and the western shore of the lake is affected by dense development and exposed to anthropogenic pollutants. The research area and location of the stations are shown in *Figure 1*.

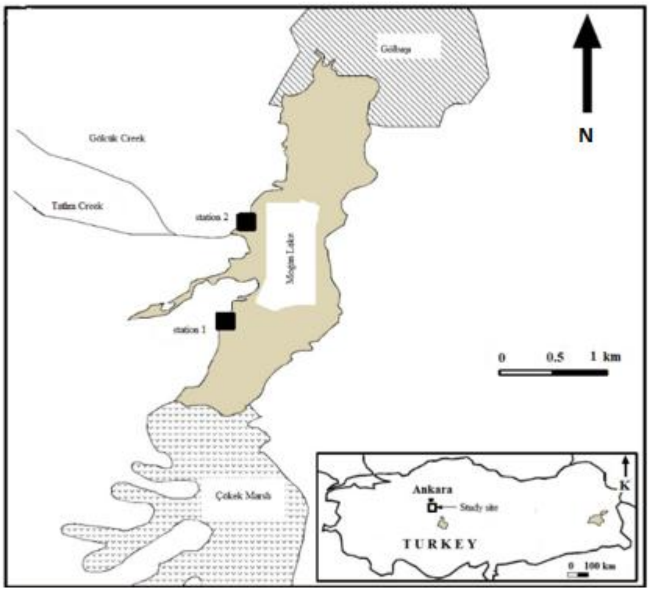

Figure 1. *Map of the lake Mogan with the sampling site (■)*

Field work

Three independent parallel sediment samples were collected from 70 cm of the littoral zone in the north-western part of the lake in April, July and October 2015 and January 2016 using Van Ween Grab. A sampling site deemed representative of the majority of the lake was selected. The sampling site was covered during the summer, primarily by *Chara vulgaris* and *Phragmites australis*, cattails (*Typha domingensis* Pers.), and two species of rush (*Juncus* spp.).

Lake water samples were collected from 0 to 10 cm above the sediment-water interface. The temperature, dissolved oxygen (DO) concentration and pH of the overlying water were measured onsite.

Analytical methods

Sediment samples and procedure

All samples were stored at 4°C before laboratory experiments and analyses. All analyses and extractions were done in triplicate, comprising the sediment composition determined for air-dried sediment samples homogenized by grinding (Kacar, 1995). The dried sediments (105°C, 24 h) were analysed spectrophotometrically for TP after digestion in a mixture of oxidizing acids. Sediment phosphorus fractionations were determined with the method of Hieltjes and Lijklema (1980), including (i) loosely sorbed phosphorus ($CO_3 \approx P$), extracted for 2 h with 1 M NH_4Cl, (ii) iron-plus-aluminium-bound phosphorus ($Fe + Al \approx P$), extracted for 17 h with 0.1 N NaOH, and (iii) calcium-bound phosphorus ($Ca \approx P$), extracted for 24 h with 0.5 N HCl. Organic-bound phosphorus ($Org \approx P$) was calculated as the difference between TP and the sum of the inorganic fractions. The sediment water content was determined by drying at 110°C for 16 h, and loss on ignition (LOI) was determined by the loss of weight during ignition at 550°C for 2 h. The total iron concentration was measured with Atomic Adsorption/Flame Emission Spectroscopy (APHA, 1995). Sediment total nitrogen was determined using the Dumas Method.

APPLIED ECOLOGY AND ENVIRONMENTAL RESEARCH 15(4):705-717.
http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_705717

All parameters were measured for all sections of the sediment and reported on a dry-weight basis. Concentration profiles were used to calculate the diffusive flux of soluble reactive phosphorus (SRP, given as P-release rates) towards the sediment surface, based on Fick's first law of diffusion (Shaw and Prepas, 1990). The concentrations of TP and soluble reactive phosphorus were measured according to the method outlined in APHA (1995).

Overlying water and sediment pore water analysis

Sediment pore water was obtained by vacuum filtration of the sediment samples (Eckert et al., 1997), and sediment overlying water was obtained by siphoning from the water 10 cm above the sediment. Water from these samples was analyzed in duplicate for soluble reactive P (SRP) (APHA, 1995).

Phosphorus release estimation

Potential phosphorus release from the sediment into the lake water by molecular diffusion was calculated by Berner (1980) (Shaw and Prepas, 1990):

$$Flux = \varphi . D . Q^{-2} . dc/dx . 86\,400 \qquad \text{(Eq.1)}$$

in which flux = SRP flux across the sediment-water interface (in mg $m^{-2}d^{-1}$)
φ = the water content by volume (dimensionless)
D = molecular diffusion coefficient (varies according to temperature)
Q^2 = tortuosity term (φ-0.8; (Shaw and Prepas, 1990))
dc/dx = the SRP gradient across the sediment-water interface (mg m^{-4}) 86 400 = the factor to convert s to d.

Statistical analyses

Statistical evaluation of data including some physiochemical properties of the sediment, determination of fractional phosphate concentrations, and analyses of the sediment overlying water were performed using the Windows Minitab and MStat databases according to the method established by Kesici and Kocabaş (2007).

Results

The differences between the months and stations with regard to the averages of total nitrogen, total organic carbon, total phosphorus, phosphorus fractions, total iron, organic matter concentrations and water contents found in the littoral sediment of Mogan Lake in April, July and October 2015 and January 2016 were found to be statistically significant ($p<0.05$) (*Table 1*, *Figure 2*). Information regarding the sediment composition at each of the Mogan Lake stations is shown in *Table 2*. The sediment composition at both stations was classified as rich in clay and loam (CL).

Differences between the months and stations with regard to the averages for water temperature, dissolved oxygen, pH, total filterable orthophosphate concentrations in the overlying water and SRP concentrations in the sediment pore water of Mogan Lake in the months of April, July and October 2015 and January 2016 were found to be statistically significant ($p<0.05$) (*Table 3*).

b)

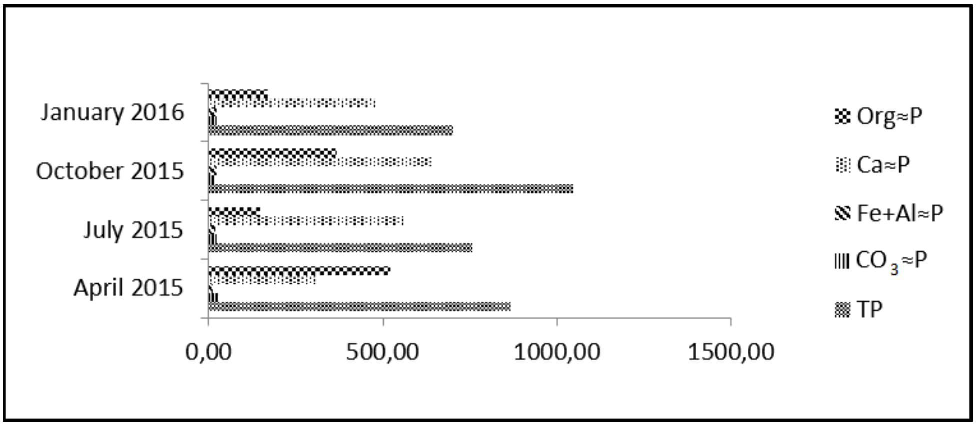

Figure 2. *Seasonal variation of sediment phosphorus fractional composition (µg g^{-1} DW^{1}) in 1st station (a) and in 2nd station (b) of Lake Mogan*

The average values for phosphorus release were calculated every month at each station during the entire research period. The phosphorus release values from the sediment varied between 0.1754-1.1249 mg $m^{-2}day^{-1}$, with the lowest value measured in July at the 2nd station and the highest value seen in January at the 1st station (*Figure 3*).

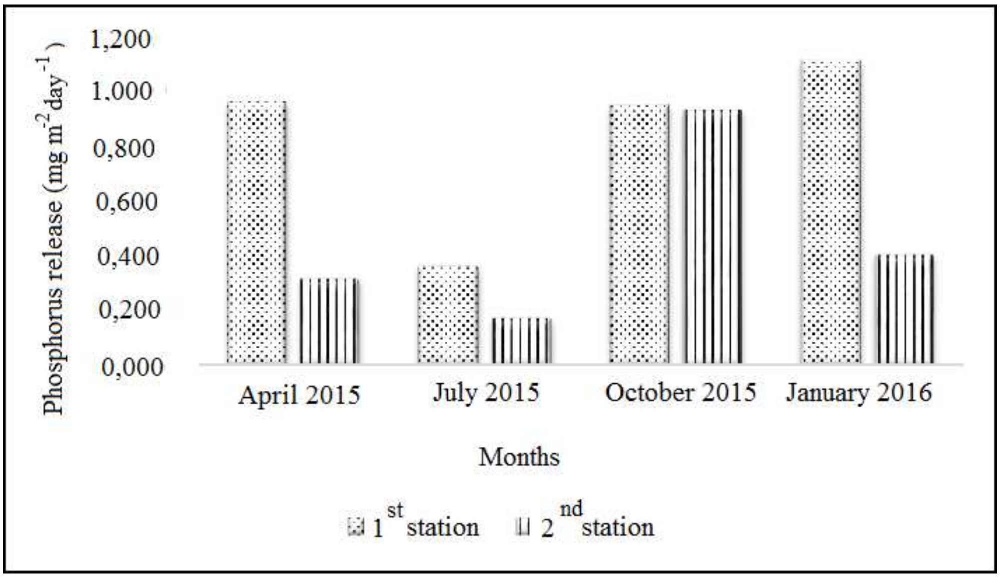

Figure 3. *Monthly and spatially phosphorus release in lake Mogan*

In *Figures 4*, *5* comparison of the present study regarding some sediment chemical composition (total phosphorus, phosphorus fractions, organic material and total iron) with some earlier study data (Topçu and Pulatsü 2008; Pulatsü et al., 2009) considering the common station was presented.

The differences of sediment porewater and sediment overlying water SRP concentrations between the current study and the earlier researches could be followed in *Figure 6* notwithstanding, the comparative phosphorus release estimations of the present and the earlier data were shown in *Figure 7*.

Discussion

In a large-scale lake restoration study on European lakes, it was determined that sediments with phosphorus content > 1 mg P g DW^{-1} generally show sediment P release, whereas P retention may be expected for P content < 1 mg P g DW^{-1} (Kelderman et al., 2005). Accordingly, the averge TP concentration in the sediment of Mogan Lake (843 µg gDW^{-1}) is thought to quantitatively demonstrate phosphorus retention by the sediment. The fact that the highest total phosphorus values at both research stations in Mogan Lake were detected in the autumn months supports the findings of Spears et al. (2007) that heavy macrophyte concentration and planktonic detritus are factors leading to high sediment phosphorus levels in the autumn.

Eutrophic Bear Lake (Michigan) is characterized by elevated TP concentrations (Steinman and Ogdahl 2015). There are several possibilities why internal P loading is not more problematic in Bear Lake like this current study; given that the sediments have relatively high TP concentrations. Second reason was the well-mixed water column keeping the lake relatively free of hypoxic conditions. The final reason was the high sediment TFe concentration. Mogan Lake's findings coincide with the above researcher's reasons for the low P internal loading in Bear Lake.

When the findings of Boyd et al. (1994) and Istvanovics (1994) are taken into account, it can be seen that in Mogan Lake's sediment, the variation of the quantity of organic matter between 9 and 16 %, the total carbon concentration (7.11 %) and the limestone sediment composition are important elements contributing to phosphorus retention in the sediment. Phosphorus chemistry in aquatic ecosystems is generally controlled by phosphorus and iron interactions. In this study sediment TFe concentrations range (2-3 mg g DW^{-1}) was lower than both Topçu and Pulatsü (2008) and Pulatsü et al. (2009)'s findings (17-46 mg g DW^{-1}), nevertheless, LOI values (9-16 %) respecting the present study were found to be higher than the previous studies data (6-11 %) in Mogan Lake. When it comes to the levels of iron and organic matter in the sediment of Mogan Lake, it can be said that, in line with Temporetti and Pedrozo's (2000) findings, the sediment's organic matter plays a more important role than its iron concentration in controlling phosphorus release from the sediment.

Moreover, while dissolved oxygen concentrations varied between 6.31-15.72 mg L^{-1} during the study, they never fell to a value low enough to instigate phosphorus release from the sediment into the lake water. Besides this, it can be said that while the pH values found (7.72 - 9.56) were close to the range reported by Lehronta and Heiskanen (2003) (pH>8.5-10), this in itself is not enough to affect phosphorus retention.

Phosphorus fractionation is a good way to understand phosphorus origins and transformation in the sediments in the shallow lakes. Sediment phosphorus fraction forms are potentially mobile and may eventually be released into the lake water (Yuan et al., 2014). The order of phosphorus fractions that are effective in preventing phosphorus release from the sediment into the water in Mogan Lake is Ca≈P>Org≈P>CO_3≈P>Fe+Al≈P except April. Topçu and Pulatsü (2008) reported the sequence of fractional distribution of phosphorus in the sediment of the same lake, regarding the general mean monthly values, as Org≈P>Ca≈P>Fe+Al≈P>CO_3≈P. Among these, it can be told that the fractions with the greatest effect on phosphorus retention in the sediment are calcium-bound and organically-bound phosphorus fractions in general. In this context, considering the common station sediment phosphorus fractional composition showed an irregular distribution.

Taihu Lake (in the southeast part of the Yangtze River Delta), a large shallow lake, serves as an important source for drinking and irrigation water, moreover a great amount of wastewater has been discharged into the lake with increased urbanization, industrial and agricultural activities in the watershed and the fractional composition of sediment phosphorus was in the descending order: Ca-bound P>Fe bound P>Organic P>Labile P (Yuan et al., 2014). Mogan Lake's sediment important phosphorus fraction coincides with the above researcher's data. It is thought that Mogan Lake's basin of limestone rock and the apatite phosphorus fractions (Ca≈P) originating from this rock promote phosphorus retention by the sediment. However, carbonate-bound phosphorus fractions (CO_3≈P) play an especially important role in clay-rich sediments, and thus represent an important phosphorus fraction in phosphorus retention (Shresta and Lin 1996; Dittrich et al., 2013). The clay-rich composition of the sediment at both of the stations in this study (65 % and 69 %) increased the role of the CO_3≈P fractions in keeping phosphorus release at a low level.

The concentration level of pore water SRP in this study was very high in comparison to Topçu and Pulatsü (2008)'s findings. Moreover, overlying water SRP concentrations of this study was found to be generally higher than the previous study except July. The lowest phosphorus release values in Mogan Lake were measured in July, and the fact that SRP values in the sediment pore water did not show an increase seem to support this finding. SRP values in the sediment pore water in this study reached their maximum values (960.56 mg m^{-3}) in January 2016 due to factors such as death and decay of macrophytes. The increase, especially during the summer, in phosphorus concentrations in the sediment pore water in shallow lakes is a result of phosphorus loading from the sediment (Spears et al., 2007). The fact that SRP concentrations in the overlying water in Mogan Lake were at their highest during the spring and at their lowest values (17.46 mg m^{-3}) during the summer months coincides with the finding that the lowest phosphorus release from the sediment was seen during the summer.

Zamparas and Zacharias (2014) stated that priorly the perpetuity to proceed to a restoration method, like monitoring of external and internal nutrient loads should initially be carried out. In this manner the authors believe that defining the reference conditions of the ecosystem and choosing which method to use in order to have the desired results will be more easier. Although no routine management strategy exists for Mogan Lake, the local government has carried out efforts such as reducing the external pollutant load and diverting running water into the lake to accelerate the flushing of the lake water, and has also occasionally carried out macrophyte harvesting and dredging operations. Dredging alone, one of the management applications in Mogan Lake, without the reduction of external phosphorus loading will result in a system eventually returning to its prior condition agrees with the findings of Smolders et al. (2006) and Sharpley et al. (2013).

Phosphorus fluxes between the water column and the sediment layer were largely driven by the redox chemistry of sediment and dissolved oxygen depletion in bottom waters, which is biologically mediated by heterotrophic oxygen consumption and physically controlled by water column structure (Giles et al., 2016). In Mogan Lake phosphorus release values from the sediment were found to be extremely low, varying between 0.1754 – 1.1249 mg P $m^2 day^{-1}$. The oxygenated overlying water of the Mogan Lake was one of the effective factors leading to a low P flux as the above researchers' expressions. However, these values were higher than the phosphorus release values measured between July 2004 and June 2005 in the same lake by Topçu and Pulatsü

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_705717

(2008). The fact that phosphorus release in the lake has increased over the past ten years but still remains at a generally low level together with the above-mentioned management activities in Mogan Lake.

Conclusion

In conclusion, it is clear that the macrophyte harvesting and dredging operations still being undertaken by the local government with the purpose of controlling eutrophication have not had a strong effect on the sediment-sediment overlying water phosphorus mobility. Moreover, considering the last 10 years study, related to the release of phosphorus from the sediment to the water of Mogan Lake, have risen limitedly but does not seem to be extremely high enough to effect the nutrient level of the lake. Consequently, in shallow eutrophic systems such as this one, hotspots of phosphorus accumulation in the sediment are subject to complex interactions with mainly anthropogenic external sources. Nevertheless in order to control the eutrophication process in Lake Mogan, the primary goal should be to determine the adsorption capacity of the sediment in order to estimate the critical internal phosphorus load and take earlier precautions, and the second goal should be to apply a monitoring program on the lake’s trophic level.

Abstract. Leaf aqueous (LA) extracts of medicinal plants *Achillea ageratum* L. and *Origanum compactum* Benth. were tested to explore their potential algicidal effects on *Microcystis aeruginosa.* The growth of *M. aeruginosa* and cell morphology changes in response to LA extracts was investigated. The concentrations of total phenols, total flavonoids, and total tannins in LA extracts were analyzed to reveal the potential allelochemical compounds. The results demonstrate that both *A. ageratum* and *O. compactum* LA extracts inhibit *M. aeruginosa* growth in a concentration-dependent way. For both LA extracts, the highest inhibition rate exceeded 80% since the fifth day of exposure. The induction of inhibition effects was translated by a decrease in photosynthetic pigments (chlorophyll-a and carotenoids) and with other morphological modifications. Our results illustrate that both *A. ageratum* and *O. Compactum* LA extracts can offer an effective solution for control of *Microcystis* blooms, and these are recommended in the restoration of aquatic environments contaminated by these types of algal blooms.
Keywords: *Achillea ageratum*; *Origanum compactum*; *algicidal effects; M. aeruginosa; inhibition; algal control*

Introduction

Harmful Cyanobacterial blooms in eutrophic aquatic ecosystems are a frequent phenomenon worldwide. *Microcystis* are the most common bloom-forming cyanobacteria (Mangilia et al., 2010; Douma et al., 2016). These are able to produce hepatotoxins (microcystins) (Wiegand and Pflugmacher, 2005; Douma et al., 2017). Consequently, they are responsible for the intoxication of many organisms and pose adverse effects on water quality and agricultural products destined for animal and human consumption (Mangilia et al., 2010).

The widely used conventional methods to reduce algal biomass are centrifugation, filtration, dissolved air flotation, and flocculation (Liu et al., 2013). These measures involve high costs and may induce secondary pollution. Biological control has emerged as an economic and ecofriendly alternative (Park et al., 2009). Laboratory experiments involving several aquatic plants such as *Myriophyllum spicatum*, *Najas minor* (Zhang et al., 2014), *Stratiotes aloides*, and *Sagittaria trifolia* (Li et al., 2016) have demonstrated inhibitory effects on cyanobacterial biomasses. On the other hand, the algicidal properties of terrestrial plants received less research attention, except for rice hull (Park et al., 2009), barley straw (Ball et al., 2001), mandarin skin and banana peel (Chen et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_719728

al., 2012), and *Ailanthus altissima* tree bark (Meng et al., 2015). In addition, the application of terrestrial medicinal plants for the biological control of invasive or harmful algal blooms remains very limited. However, several species have shown positive bioactivity and demonstrated antioxidant, antibacterial, antifungal, antiviral, and anti-insecticidal potentials (El Bouzidi et al., 2011; Dutra et al., 2016). Yi et al. (2011) have reported the algicidal activities of several Chinese medicinal plant species, including *Salvia miltiorrhiza*, *Acorus tatarinowii*, *Polygonumcuspidatum*, *Phellodendrona murense*, and *Crataegus pinnatifida*. Ye et al. (2014) showed that aqueous extracts of *Phellodendri chinensis* and *Scutellaria baicalensis* have a potential to control *Microcystis* growth.

According to phytochemical characterization, the most important bioactive constituents of medicinal plants are phenolic compounds, fatty acids, and alkaloids (Yang et al., 2015). Among all polyphenols, flavonoids and tannins exhibited an intensive inhibitory effect on *M. aeruginosa* (Chen et al., 2012).

Medicinal flora is very common in the Mediterranean area. Countries such as Morocco have a vast biodiversity of medicinal plants, which have the feasibility to be cultured (El Bouzidi et al., 2011). Among these plants, *A. ageratum* and *O. compactum* are of particular interest due to their pharmacological properties and bioactive products they contain (El Babili et al., 2011; Zhang et al., 2014).

A. ageratum is an *Asteraceae* medicinal shrub. It has demonstrated antibacterial (De la Puerta et al., 1996), antifungal (El Bouzidi et al., 2011), anti-inflammatory, analgesic, and antipyretic activities (Gómez et al., 1999). *O. compactum* is a Lamiaceae herbaceous plant native to the Mediterranean region. Previous pharmacological studies have reported their antioxidant and antimalarial activities (El Babili et al., 2011), and also antimicrobial properties against many bacteria and fungi that cause human infections (Charai et al., 1996).

The aim of this study was to assess the algicidal effects of *A. ageratum* and *O. compactum* on toxic bloom-forming *Microcystis aeruginosa*. The experiments focused on (i) growth inhibition, (ii) morphological and physiological changes, and (iii) characterization of total polyphenols (TPs), total flavonoids (TFs), and total tannins (TTs) as potential allelochemicals. To our knowledge, this is the first report of the algicidal effects of these two medicinal plants.

Materials and methods

Materials

M. aeruginosa was isolated from the eutrophic Lalla Takerkoust reservoir (31°21'36" N; 8°7'48" W), Morocco, in October 2015. Using Z8 medium, *Microcystis* was cultured in laboratory at 26±2°C under light intensity of 65 $\mu Em^{-2}S^{-1}$, with a light/dark cycle of 15h/9h. The aerial parts of *A. ageratum* and *O. compactum*, collected in April 2016 from two locations (Demnat and Ourika in High Atlas of Marrakesh area, respectively), were washed under tap water and then rinsed several times with distilled water to remove debris and epiphytic microbes.

Preparation of LA extracts

LA extracts of *A. ageratum* and *O. Compactum* were prepared according to the methods described by Ball et al. (2001), slightly modified by Li et al. (2016). Briefly,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_719728

10 g was cut into small pieces in 100 ml distilled water under agitation (37°C; 40 min). The solution was filtered through a glass fiber paper (Whatman GF/C, 0.22 µm). Then, the filtrate was adjusted with sterilized distilled water to 100 ml and maintained at 4°C as an aqueous extract.

Determination of TPs, TFs, and TTs in LA extracts

The concentration of TPs was determined using the Folin-Ciocalteu method (Singleton and Rossi, 1965). Briefly, 0.5 ml of the extract was added to 0.5 ml of Folin-Ciocalteu reagent (Sigma-Aldrich) in water, and then 0.5 ml sodium carbonate solution (20% w/v) was added. The mixture was left for 1 h at room temperature and absorbance was measured at 760 nm.

The concentration of TFs was determined using the method described by Kim et al. (2013). Briefly, 500 µl of aqueous extract was mixed with 500 µl distilled water. Then 150 µl sodium nitrite solution (5%) was added, followed by 150 µl aluminum chloride solution (10%) after 5 min. Test tubes were incubated for 11 min at ambient temperature, and then 500 µl sodium hydroxide (1 M) was added. The mixture was vortexed and absorbance was determined at 510 nm.

The concentration of TTs was determined using the Folin-Denis test described by Salunkhe et al. (1990). Briefly, 1 ml of the aqueous extract was added to 75 ml distilled water, and then 5 ml Folin Denis reactif (Sigma-Aldrich) solution and 10 ml sodium carbonate solution were added. The mixture was vortexed and absorbance was determined after 30 mn at 760 nm.

Experimental design

Six concentrations (0% control, 0.1%, 0.25%, 0.5%, 0.75%, 1%; V/V) of *A. ageratum and O. compactum* LA extracts were prepared in six groups of Erlenmeyer flasks (500 mL) containing Z8 medium to a final volume (300 ml). Each flask was inoculated by a volume of *M. aeruginosa* in exponential growth phase to make an initial density of 1–2 × 10^6 cell/ml. The cultures were incubated at 26±2°C, illuminated in 15h/9h light-dark cycle with fluorescent tubes (65 $\mu Em^{-2}S^{-1}$) for 8 days. All the experiments were conducted in triplicates.

Biomass estimation

The growth of *Microcystis aeruginosa* under different treatment concentrations was quantified every day using a Malassez hemocytometer. Inhibitory rate (IR) of *M. aeruginosa* growth was determined according to the following equation: IR (%) = (N_0–N/N_0×100, where N_0 and N (cells/ml) are cell density in treatment and control cultures, respectively.

Pigments determination

Chlorophyll-a and carotenoid pigments were extracted with 95% ethanol at 4°C for 48 h and then determined using a UV spectrophotometer (Carré 50 Scan) at 470, 649, 665 nm. Pigments were calculated according to the Lichtentaler and Wellburn method (1983). The following formulas were used to calculate their concentrations:

$$\text{Chlorophyll-a} = 13.95\times OD665 - 6.88\times OD649;$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_719728

Carotenoids = [(1000×OD470) – (2.05×chlorophyll-a)] / 2

Statistical analysis

Data were analyzed by analysis of variance (ANOVA) using SPSS v20.0 (Windows 2010). One-way ANOVA and Tukey's test were used to test differences between exposure concentrations and control at p = 0.05. Correlation coefficients were calculated between cellular density and concentrations of PTs, FTs, and TTs.

Results

Effects on growth of M. aeruginosa

The inhibitory effects of both *A. ageratum* and *O. compactum* LA extracts, at different concentrations, on *M. aeruginosa* cultures are shown in *Figure 1A* and *B*. In contrast to the control group, the cell biomass of *M. aeruginosa* in all five tested concentrations (0.1%, 0.25%, 0.5%, 0.75%, and 1%; V/V) was significantly reduced during the 8-day test period (p<0.05). The reduction was more remarkable for the three highest concentrations, especially during the last days (*Fig. 1A-B*). Under *A. ageratum* and *O. compactum* LA extracts, *Microcystis* growth appeared to have strongly reduced at 0.5–1% and 1% concentrations, respectively. At these concentrations, the inhibitory rates exceeded 80% since the fifth day and reached more than 90% during the last day (*Table 1*).

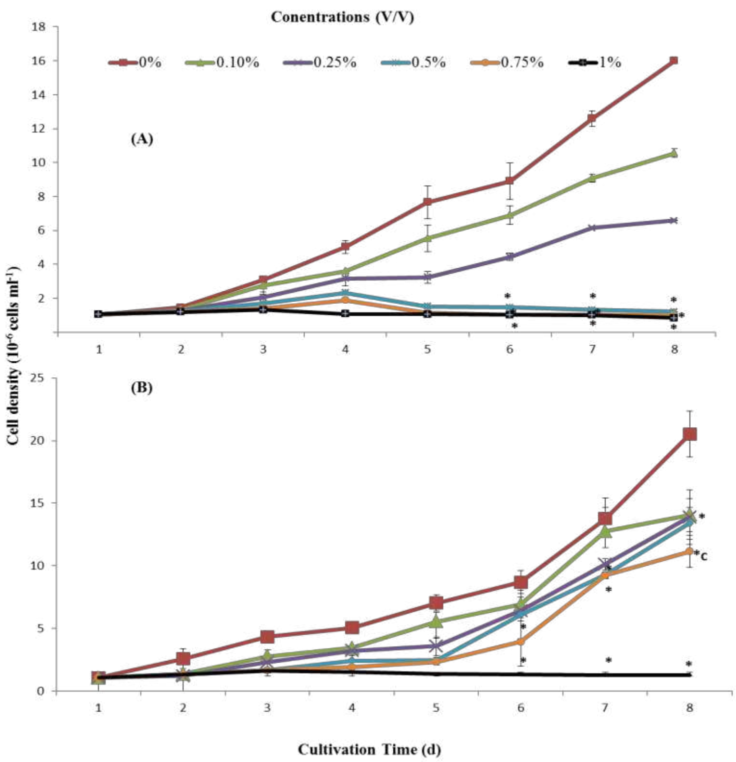

Figure 1. *Effects of different concentrations of A. ageratum (A) and O. compactum (B) LA extracts on Microcystis aeruginosa growth. Errors bars represent standard deviation (n=3). *p<0.05 indicates significant difference compared to controls.*

Morphological changes in M. aeruginosa

The morphological changes in *M. aeruginosa* cultures under treatments were photographed and presented in *Fig. 2*. In the control group, *M. aeruginosa* colonies were clearly structured with regular surfaces. Their cell forms were rounded, clearly vacuoled, and pigmented, with cell diameter 2.8–3.5 µm by the end of treatment period. However, under high concentrations (0.75% and 1%), *M. aeruginosa* colonies lost their regular form, becoming floating aggregates (2.5–3.4 µm cell diameter) during the first days of culture. Then, for a heterogeneous culture with planktonic cells (1.1–1.5 µm) and sediment mass with anaform cells which the observed cells were destroyed and shrinking cell surface, especially, in the end of the test period (*Fig. 2*).

Effects on pigments as physiological indicators

For both *A. ageratum* and *O. compactum*, two photosynthetic pigments were measured (chlorophyll-a and carotenoids) that would act as physiological indicators. For the control, the chlorophyll-a and carotenoids concentrations were dose-dependent (*Fig. 3*). These decreased negatively with the augmentation of extract concentrations. For *O. compactum*, a significant difference in concentrations between the treatment and control groups was observed ($p<0.05$) (*Fig. 3A2–B2*). The pigments appeared to be strongly inhibited at 1% concentration since the sixth day. For *A. ageratum*, the concentrations 0.5%, 0.75%, and 1% seemed to be clearly inhibitory since the fifth day (*Fig. 3A1–B1*).

Phytochemical characterization

A. ageratum demonstrated higher values of TPs, TFs, and TTs compared to *O. compactum*. In addition, a significant correlation between the IRs of three high

Discussion

Both *A. ageratum* and *O. compactum* LA extracts acted negatively on *M. aeruginosa* growth (*Fig. 1*). This inhibitory effect appeared to be dose-dependent.

A. ageratum showed high IRs with three high concentrations (0.5–1%) compared to *O. compactum* (only 1%). For these last concentrations, since the fifth day, a marked IRs were observed for *A. ageratum and O. compactum*, exceeding 90% at the end of the experiment for each plant. This finding can be used for the optimization of extracts for a recommended treatment, not envisaging a complete reduction of *M. aeruginosa* biomass.

The maximum IRs of high concentrations remain similar to those observed in previous works. *Sagittaria trifolia* aqueous extract showed inhibition on *M. aeruginosa* growth with IRs exceeding 70% after 6 days (Li et al., 2016). Ye et al. (2014) studied the effects of several Chinese herbal aqueous extracts on *M. aeruginosa* and found that the maximum IRs were 51–98% after 10 days. Thus, the inhibitory effect of our aqueous extracts is similar to that reported in previous works (Chen et al., 2012; Zhang et al., 2014; Meng et al., 2015; Li et al., 2016).

The inhibition of photosynthesis is a prominent mode of action for many allelopathically active compounds (Gross, 2009). The effects of plant extract on chlorophyll-a and carotenoids are shown in *Figure 3*. Some studies have shown the negative effects of the extracts on chlorophyll-a (Meng et al., 2015). The disturbance in photosynthesis thus affects the growth and reproduction of *M. aeruginosa* (Li et al., 2016).

The phytochemical characterization of the aqueous extracts shows important amounts of TPs, TFs, and TTs (*Table 2*). FTs, and PTs and TTs contribute to the inhibitory action of *A. ageratum* and *O. compactum,* respectively. These results agree with previous works showing the effects of PTs, FTs, and TTs on *M. aeruginosa* (Yan et al., 2011; Chen et al., 2012). Furthermore, other compounds have been identified during the characterization of *O. compactum* (carvacol and thymol; El Babili et al., 2011), and *A. ageratum* (artemisyl acetate; El Bouzidi et al., 2011), which contribute to the algicidal process.

As concluded by previous studies, the allelochemical products inhibit cell growth by attacking the reactive oxygen species on cell membranes, degrading the unsaturated phospholipids, and consequently increasing their permeability, leading to a disruption of cell organization (Meng et al., 2015). Under optimum stress, the perturbations of the antioxidant defense system lead to the inhibition of photosynthesis and oxygen evolution through interactions with the components of PS II (Einhellig, 1995) and finally slowing down cell death.

In our study, growth inhibition was well demonstrated by morphological changes in treatment groups (*Fig. 2*). In addition, the cells in treatment groups decreased in size and lost a significant volume of vacuoles (*Fig. 2*). Some have completely destroyed and sedimented; others resisted by attempting to escape through a floating agglomeration. The aggregation trend of cells in high concentrations of extracts appeared to be a response to stress conditions. The growth inhibition accompanied by photosynthetic pigments and morphological changes in *M. aeruginosa* are indicators of physiological alterations under a stress environment (Yan et al., 2014; Meng et al., 2015; Li et al., 2016).

DOI: http://dx.doi.org/10.15666/aeer/1504_719728

Conclusions

The present work demonstrates the inhibitory effect of LA extracts of *A. ageratum and O. compactum* on *M. aeruginosa* growth. In addition to their antimicrobial, anti-inflammatory, analgesic, and antipyretic potentialities; and according to our results, these two medicinal plants can be recommended as an ecofreindly solution to restore the aquatic environments contaminated by *M. aeruginosa* blooms. Other future approaches will be necessary to specify and optimize the allelochemical agents, as well as the conditions of interactions with other potential components, especially others pathogens microbes, in the aquatic ecosystem.

Abstract. Electromagnetic field produced by a moving electrically charged object, can be measured everywhere in the environment and it acts as an important effective stress factor on growth and development of plants. Plants are organisms exposed to different levels of biotic and abiotic environmental impacts and are able to distinguish and respond to their surrounding environment with a high specificity. This study aimed to determine the genotoxic effect of a low frequency electromagnetic field (EMF) on the genomic material of plants. Two groups of bean seeds (wet and dry) were subjected to an electromagnetic field of 4 mT. RAPD profiles of EMF-treated seeds showed differences in banding patterns compared to those of the control. There is no significant different between dry and wet treatments. This result forcefully indicated that genomic template stability and band sharing index was significantly affected by the EMF-induced stress in treated seeds. It was concluded that DNA polymorphism detected by RAPD fingerprinting thus could be used as a potential molecular marker for the assessment of electromagnetic field-induced genotoxicity effects in plants and different treatments including chemical and physical motivators.

Introduction

In recent decades, physical methods based on the usage of electromagnetic fields are developed in the industry, agriculture, etc., and finally their waves distributed in the environment (Racuciu and Creangia, 2005). Levels of electromagnetic fields (EMF) from artificial man-made sources have increased progressively in the past decades and human societies are not aware that magnetic fields and plant development are related to each other. This relationship can be used in agriculture by treating the seeds, water, soil and nutrients in the soil (Rio and Rio, 2013; Cucurachi et al., 2013).

There is a rich literature describing the biological influence of low frequency electromagnetic fields upon vegetal organisms. But the responses elicited in various plant species appear to depend in a complex way on both the physical parameters of the irradiation source (frequency, power density, pulses or continuous waves, duration of exposure, etc.) and the conditions of the biological materials (vegetation stage, pretreatment, environment, etc.), nevertheless different biological parameters may lead to the revealing of different aspects of the interaction between the electromagnetic waves and the irradiated material (Ursache et al., 2009).

Electromagnetic fields induce several cellular stress responses and change different cellular components such as membranes, proteins, enzymes and genome (Aksoy et al., 2010). Higher plants have been used as efficient bio-indicators of genetic toxicity of environmental pollutants. Several researches have used the chromosome aberration, micronucleus, or comet assays to estimate the effects of genotoxicity on plants (Steinkellner et al., 1999; Angelis et al., 2000; Yildizet al., 2009). Recently, advances in molecular biology have led to the development of a number of selective and sensitive assays for genomic material analysis in eco- genotoxicology. DNA based techniques (RFLP, QTL, RAPD, AFLP, SSR and VNTR) are used to examine the variation at the DNA sequence level (Liu et al., 2007; Enan, 2007). Random amplified polymorphic DNA (RAPD) is a polymerase chain reaction (PCR)-based technique that gives clearance for swift and efficient comparisons of genomic DNA. This technique is used extensively for species classification, genetic mapping, phylogeny and also it has been successfully used to study genotoxicity (e.g. DNA change, point mutation, insertions or deletions and ploidy variation) in different plants (Kumari et al., 2009; Liu et al., 2009; Cenkci et al., 2009).

The common bean [*Phaseolus vulgaris* L. (cv. D81083)], was used as plant material in this study that it is the major source of protein and minerals for example iron, magnesium and etc. in the world. Bean is a diploid (2n = 22), in fact it is important genetic model that has been widely used in physiological, biochemical and molecular analyses of toxicology (Enan, 2007).

The aim of the present study was to evaluate the DNA changes induced by low frequency electromagnetic field (4 mT) using RAPD technique in the vegetative stage.

Material and Method

Phaseolus vulgaris L. (cv. D81083) seeds were prepared from khomain research center, Arak, Iran. The seeds were surface- sterilized using sodium hypochlorite at 5% for 10 min, washed two times with distilled water and dried at room temperature. The seeds were divided into two groups, one group was immersed in distilled water for 12 h (wet seeds) while the second group remained dry (dry seeds). Each group was further divided into three subgroups: two sub groups were exposed to EMF (once treated and twice treated subgroups), while the third, non-exposed seeds were used as control (not treated subgroup).The seeds of once treated sub group were exposed to a field of 4mT intensity for 45 min, while those of twice treated subgroup were exposed twice to a 4mT field with a two-hour interval, each time for 45 min. Three replicates were used in the experiment with 30 seeds in each treatment. The electromagnetic field was performed by a locally designed generator which its electrical power was provided by a 220 V and 0.1 A, AC power supply. This system consists of a PVC cylinder with 20 × 20 cm (diameter and length) and 300 turn coil of copper wire. The samples were placed in the middle of a horizontally fixed coil and for exposure. The temperature was measured with a thermometer to be 22±1°C.Then treated and untreated seeds were grown in petri dishes in a growth room with temperature controlled at 28±1° C and a 16 h light/8h dark cycle.

The leaves of plants in vegetative stage were used for genomic DNA extraction. Silica gel was used for the dehydration of fresh leaves and were stored at -20°C. DNA was extracted following the cetyltri methyl ammonium bromide (CTAB) method as described by Saghai-Maroof (Saghai-Maroof et al., 1984). Briefly, fresh plant sample was ground to a fine powder in liquid nitrogen, mixed with 1 mL of CTAB extraction

DOI: http://dx.doi.org/10.15666/aeer/1504_729739

buffer [2% hexa decyl trimethyl- ammonium bromide, 100 m M Tris–HCl, (pH 8.0), 20 mM EDTA (pH 8.0), 1.4 M NaCl, 1% PVP-40 and 0.4% 2-mercaptoethanol]. Nineteen 10-mer oligo nucleotide primers (macrogen, Tehran) were used for characterization of genotypes (*Table 1*). *In vitro* amplification using polymerase chain reaction (PCR) was performed using 50 ng of genomic DNA of each genotype, 1.7 µM primer, 200 µM dNTPs (50 µM of each), 10× reaction buffer (100 mM Tris–HCl, pH 8.8, 500 mM KCl, 15 mM $MgCl_2$, 0.8% Nonidet P40) and 1 U Taq DNA polymerasein a final volume of 20 µl per reaction.

Amplifications were performed in a DNA thermocycler (Uvigene, Uvitech Ltd., UK) programmed for 4 min at 94 °C (initial denaturing step), 40 consecutive cycles each consisting of 45 s at 94 °C (denaturing), 45 s at 36 °C (annealing), 60 s at 72 °C (extension), followed by 1 cycle for 8 min at 72 °C (final extension step).The PCR products were analyzed by electrophoresis on 1.5% agarose gels in 0.5× TBE (90 mMTris base, 90 mM boric acid and 2 mM EDTA) buffer. The gel was run at 10 V, visualized under UV light and photographed using ultracam digital imaging.

Table 1. *Sequences of primers used in this study*

Primer name	Primer sequence	Primer name	Primer sequence
OPA-10	5′-GTGATCGCAG-3′	OPA-17	5′-CACCGCTTGT-3′
OPE-11	5′-CAATCGCCGT-3′	OPB-10	5′-CTGCTGGGAC-3′
OPE-01	5′-CCCAAGGTCC-3′	OPD-07	5′-TTGGCACGGG-3′
OPE-12	5′-TTATCGCCCC-3′	OPG-14	5′-GGATGAGACC-3′
OPA-05	5′-AGGGGTCCTG-3′	OPC-08	5′-TGGACCGGTG-3′
OPA-04	5′-AATCGGGCTG-3′	OPB-07	5′-GGTGACGCAG-3′
OPA-01	5′-CAGGCCCTTC-3′	OPC-02	5′-GTGAGGCGTC-3′
OPG-06	5′-GTGCCTAACC-3′	OPA-09	5′-GGGTAACGCC-3′
OPA-07	5′-GAAACGGGTG-3′	OPA-03	5′-AGTCAGCCAC-3′
OPE-06	5′-AAGACCCCTC-3′		

All amplifications were repeated twice in order to confirm the reproducible amplification of scored fragments and only reproducible bands obtained in repeated experiments were taken into account. The marked changes observed in RAPD profiles (disappearance or appearance of bands, increase or decrease in band intensity in comparison with untreated control treatments) were evaluated (*Table 2*).
Genomic template stability (GTS, %) was calculated as follows:

$$GTS\ (\%) = (1 - \alpha/\mathrm{n}) \times 100 \quad \text{(Eq. 1)}$$

Where α is the average number of polymorphic bands detected in each treated sample and n is the number of total bands in the control. (Savva, 2000)
In order to evaluate the band sharing index (BSI) that is considered as a measure of similarity between two samples, following equation was used:

$$BSI = 2s/(\mathrm{a+b}) \quad \text{(Eq. 2)}$$

where *s* is the number of bands shared between two samples, *a* is the number of bands in the first sample and *b*is the number of bands in the second sample. A BSI value of 1

APPLIED ECOLOGY AND ENVIRONMENTAL RESEARCH 15(4): 729-739.
http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_729739

indicates that the two samples are identical, while a BSI value of zero indicates that the two samples are totally different (Savva, 2000).

Results

In order to verify the geneotoxic effect of low frequency EMF, the RAPD analysis was performed on DNA extracted from the 30-d-old plants. In total, nineteen 10-mer oligo nucleotide primers of 60-70% GC content were utilized for screening the bean genome for modification in response to EMF. Seventeen primers generated specific and stable results. The total number of bands was 174, 175, 171, 179, 177, 172 in untreated dry seed, once treated dry seed, twice treated dry seed, untreated wet seed, once treated wet seed and twice treated wet seed, respectively, ranged from 100 to 1500 bp. The maximum and minimum of bands observed in untreated wet seed and twice treated dry seed RAPD profiles respectively. On the other hand, seeds in wet condition had more bands than those in dry condition. As observed in *Table 2*, RAPD profiles of the controls have more bands in comparison to treatments.

Table 2.*Changes in total bands in control, and of polymorphic bands and varied bands in EMF-treated seedlings. a: appearance of new bands, b: disappearance of normal bands, c: decrease in band intensity, and d: increase in band intensity. a+b denotes polymorphic bands, and a+b+c+ d denotes varied bands*

RAPD profiles showed remarkable differences between untreated control and treated plants with apparent changes (disappearance and/or appearance, increase and decrease of band intensity) in the number and size of amplified DNA bands for different primers. The changes in RAPD profiles were summarized for treated seedlings in comparison to their controls (*Table 2*). RAPD pattern screated by OPD-07, OPG- 14 and OPC-08 primers were identical for all treatments and the controls (*Fig. 1*). For OPD-07, OPG-14 primers, there was no change in RAPD profiles in all samples.

RAPD pattern in plants exposed to EMF showed variations in the appearance and disappearance of bands, as well as changes in band intensity in both dry and wet conditions. The number of polymorphic bands (appearance of new bands+ disappearance of normal bands) and varied bands (appearance of new band + disappearance of normal band + decrease in band intensity + increasein band intensity) were 13, 16 and 51, 61 bands in the once EMF treatment and twice EMF treatment in dry condition, respectively. Similarly in the once EMF and twice EMF treatments in wet condition the number of polymorphic bands and varied bands were 8, 10 and 55, 65 bands, respectively.

In the once EMF treatments, the number of new bands was low (7 and 3 new bands in dry and wet, once EMF treatments, respectively), while the number of new bands was high (24 and 24 bands in dry and wet twice EMF treated, respectively) in the twice EMF treatments. The number of disappeared RAPD bands was more at twice EMF treatments (27 and 31 bands) than once EMF treatments (6 and 5 bands). No significant difference was observed between once EMF treatments and their controls. Furthermore, the decrease and increase in band intensity were observed for plants exposed to all EMF treatments (once and twice) used in this experiment for nine of the primers. Changes in band intensity were greater in twice EMF than in once EMF treatments (*Table 2*).

For each treatment group, the value of Band Sharing Index (BSI) and Genomic Template Stability (GTS) compared to their controls were calculated (*Table 3*). Results showed that with increase the time of exposed to the EMF, BSI and GTS values decreased in all treatments that showed the existence of variation among of RAPD profiles in all treatments compared to their controls. The estimated GTS and BSI characters were found to be lower (<1.00) in all treatments compared to the controls. Similar results were detected in twice EMF treatments compared to once EMF treatments. According to these characters, the seeds treated with once EMF showed the nearest distance (BSI: 0.92, 0.96. GTS: 92.52%, 95.53%) to their controls, but twice EMF treatments showed the furthest distance (BSI: 0.71, 0.70. GTS: 70.68%, 69.27%).

Table 3. *Effect of EMF on Band Sharing Index (BSI) and Genomic Template Stability (GTS) of treated bean seeds compared to the control*

	Treatments			
	Dry seed		**Wet seed**	
Character	**Once EMF**	**Twice EMF**	**Once EMF**	**Twice EMF**
BSI	0.92	0.71	0.96	0.70
GST	92.52 %	70.68 %	95.53 %	69.27 %

As indicated in *Table 3*, quantity of GTS and BSI characters are similar. As seen in our general results, wet seeds exposed to an EMF were much more affected than the dry seeds.

Discussion

In this study, we focused on the potential of RAPD assay to evaluate genotoxic effects in plants exposed to low frequency EMF for two different durations (a EMFof4mT intensity for 45 min, and a 4mT EMF with two-hour interval, each time for 45 min) and two conditions (dry and wet).

To detect different types of DNA change and genotoxic effect induced by chemical motivators in plants, RAPD method has been utilized extensively (Aksoy et al., 2010; Liu et al., 2007; Enan, 2007). The changes in DNA quality and quantity were detected by RAPD patterns created by randomly primed PCR reactions. These modifications may include changes in oligo nucleotide priming sites and variations in the activity of the *Taq* DNA polymerase. In this study, according to the RAPD profile, the obvious disappearance and appearance of bands produced by EMF in comparison to the untreated controls were considered to detect distinct changes between treatments. Our results showed a greater number of disappearance bands (69 bands) than appearance bands (58 bands) suggesting that the disappearance of normal bands and band intensity may be related to DNA change, point mutations and/or complex chromosomal rearrangements (Wolf et al., 2004). Also the appearance of new bands may unfold a modification in some oligo nucleotide priming sites due to mutations, large deletions, and/or homologous recombinations (Atienzar et al., 1999). The presence of new bands in this experiment may also be the result of genomic template instability related to the level of DNA change, the efficiency of DNA repair and replication (Atienzar et al., 1999).Therefore appearance of new bands could be related to mutations while the lost bands could be due to DNA change (Atienzar and Jha, 2006).

The RAPD patterns acquired with 19 primers were different for controls. Treatment of bean seeds with EMF induced genomics changes in plants. The number of disappeared and appeared bands in the twice EMF was higher than that of the once EMF treatments. Our results (*Figure 1* and *Table 2*) indicated that polymorphism

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_729739

increased with increasing EMF exposure time. On the other hand, the genomic template stability and Band Sharing Index in the treatments decreased with increasing EMF exposure time. Therefore, this study revealed the existence of a time exposing- effect relationship. Based on this, a correlation between EMF exposure period and level in EMF-induced DNA change in plants was shown by using the comet assay. Previous studies have also shown that changes in RAPD profiles can be regarded as changes in genomic DNA template stability, and this genotoxic effect can be directly compared with alterations in other parameters (Atienzar et al., 2000). Genotoxicity studies can be elicited qualitatively and quantitatively via the comparison of the control and treated groups. The diagnostic analysis contains band intensity differences or disappearance and/or appearance of RAPD bands are important parameters in RAPD method (Wolf et al., 2004).Although great progress has been achieved in the elucidation of molecular mechanisms of EMF, how plants sense and transduce the signal of EMF stress is still an important to picto be addressed.

Conclusion

In conclusion, our data support the view that RAPD analysis is a highly sensitive method for the detection of DNA change induced by environmental pollutants such as the magnetic fields. Also our results confirmed that low frequency electromagnetic fields have genotoxic effects on DNA structure. Moreover, as the purpose in this research was to establish the existence of DNA change for hazard identification in risk evaluation of genotoxicity studies, the presence in the DNA of any of these varied RAPD profiles can provide adequate evidence for identification of the genotoxic effect.

(Received 22nd Feb 2017; accepted 1st Aug 2017)

Abstract. This study focuses on the impacts of climate changes by applying a conventional general circulation model (HadCM3) to report the output subscale of LARS-WG using HadCM3 statistical model. We have used SWAT model to study the changes in the runoff volumes of the Chehel-Chai basin. The study results suggest regardless of the occurrence of each of the three future rounds, the temperature would rise causing an increase in rainfall. This would cause a decrease in the rate of flow of Chehel-Chai River. An increase in evaporation, transpiration, and discharge of the river water for irrigation would subsequently reduce the flow rate of the Chehel-Chai River.
Keywords: *HadCM3 model, statistical models LARS-WG, SWAT*

Introduction

Climate changes are known to cause alteration in the duration, intensity, form, and timing of rainfall in many areas. Consequently, droughts and flooding would be immanent in the nearby areas. On the other hand, water resource management programs have been affected by the rapid climate changes more often in the recent years. Since 1995 numerous research and modeling studies have focused on forecasting the impacts of rapid climate changes on water resource plans. As large-scale global climate models are based on the defined networks (150 to 300 km) they would not be applied directly to assess the hydrological models.

Among a few detailed models one might identify the Atmospheric-ocean general circulation models coupled type (AOGCM). The model is designed and developed at the Hadley Centre, UK. The resolution of this model is 2.75 by 3.75 degrees (IPCC, 2007). The model is described by (Gordon et al., 2000; Pope et al., 2000). HadCM3 consists of two components, namely Oceanic and Atmospheric HadAM3 (atmospheric model) and HadOM3 (the ocean), which has an ice-sea model. This model requires the setting surface flux. Based on a calendar year (365 days and 30 days of month) this model has a high resolution oceanic components. Another advantage of this model is its good coordination between the atmosphere and the ocean.

Steele-Dunne et al. (2008) examined impact of climate change on the hydrology of river flow using ECHAM 5 general circulation models and emission scenarios A1B. By application of the conceptual rainfall-runoff model HBV-Light, they were able to evaluate the future river flow on 9 basins located in Ireland. Varanou et al. (2003)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_741754

examined changes of quantity and quality of runoff in a basin in central Greece using SWAT model to show the reduction of flow as well as the increase of the nitrogen concentration.

As Yu et al. (2002), Chen et al. (2011) and Dhar and Mazumdar (2009) show the effect of climate change on water resources would be an increase in temperature for prolonged periods of time along with the impact of the increased CO_2 on the river runoff volumes in several regions drastic changes in daily rainfall;

Studies elsewhere have shown that rapid climate changes would also impact plant growth, irrigation time, and runoff volumes (Ficklin et al., 2009).

In a study in Taiwan Lin et al. (2010) developed an annual warning indicator to assess the impact of climate change on water resources. The study shows the annual changes impose significant impacts on the ground water system by changing the temperature, precipitation, as well as other variables such as evapotranspiration.

Koutroulis et al. (2013) studied the impact of climate change on a regional Greek water resource. They have concluded that owed it is necessary to improve and update local water management planning and adaptation strategies in order to secure future water supplies.

Nkhonjera (2017) provided a review about Understanding the impact of climate change on the dwindling water resources of South Africa. In general, the factors such as lack of political will, climate modelling constraints, and uncertainties in both climate and hydrological modelling are of particular importance that they feature highly in climate change impact analysis studies. Results showed diversity in climate model simulations should be seen as a positive attribute and a judicious selection, configuration, and calibration of these hydrological models need to reduce uncertainties in hydrological modeling.

Inouye et al. (2017) assessed parameters of Climate Impacts on water Resources in Idaho. A new scenario was developed to assess the range of impacts by developing a model of the river basin and two another quantitative models (a system dynamics model and a spatially-explicit integrated model) in order to explore research.

Seiller et al. (2017) studied the Influence of three common calibration metrics on the diagnosis of climate change impacts on water resource. In that investigation, based on thirty-seven Canadian catchments, three common objective functions (focusing on different sections of time series), and twelve lumped conceptual hydrologic models, aim to provide insight on this specific contribution to the uncertainty cascade. Results from this study show that the choice of an objective function, between pairs of common options, can clearly affect our interpretation of the impacts of climate change on water resources. Furthermore, these conclusions are dependent on the hydrologic model, illustrating the need for water managers to evaluate their operated model and studied catchments to appraise the predictability of their hydrological system and estimate their confidence level.

Nepal (2016) assessed the Impacts of climate change on the hydrological regime of the Koshi River. The results suggested that snowfall pattern, snowmelt, total discharge, and evapotranspiration are all sensitive to climate change. The results should be taken as indicative of how the hydrological regime might change in future rather than definitive. By incorporating high resolution data and replicating studies in reference catchments in the Himalayan region, analyses of this type can be made more reliable.

The Study Area

The Chehel-Chai basin, with an area of 25.683 hectares is located at the 55º 23́-55º 38́ longitude and 36º 59́- 37º 13́ latitude. As a subdivision of the great Gorganrood basin, this basin is located within the city boundary of Minoodasht in Golestan Province and has a minimum and maximum elevation of 190 m and 2570 m above the sea level. *Fig. 1* shows the location of Chehel-Chai basin.

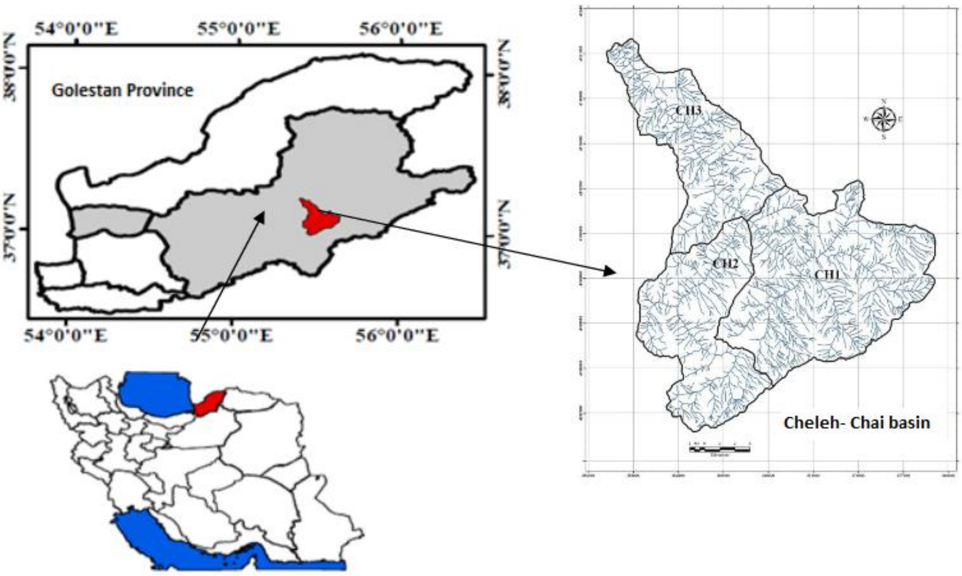

Figure 1. *Location map of Chehel-Chai basin in Golestan Province of Iran*

The Model

In order to gather the runoff data of the study area as one of the main inputs of the model, we used the DEM map, the land use map, and the soil map, (*Figs. 2-4* respectively).The meteorological data was collected and prepared in ArcGIS 10.3 for entry into the model. We used also the moisture content, saturated hydraulic conductivity, and soil bulk density based on the available data. The CROPWAT data were obtained using the available database of the soil texture.

HadCM3 Climate models

In statistical method of determining optimal function, large-scale climate variables have been simulated by general circulation models in future periods, these functions are applied as input variables in the surface. In this method, a statistical relationship using simple regression, multivariate, neural networks and stations between actual behavior and general circulation model output is generated. After verification, these equations can be used in downscaling projections of future emission scenarios. In this study, in order to study climate change from a traditional to HadCM3 general circulation models and downscaling to weather generator LARS-WG statistical model was used.

LARS-WG for simulation of wet and dry periods, rainfall and solar radiation, distribution of the quasi-experimental uses the following form:

$$EPM = \{a_0, a_i, h_i, i = 1, \ldots, 10\} \quad \text{(Eq.1)}$$

That histogram consists of 10 floors and each floor is defined in $[a_{i-1}, a_i)$ ed, so $a_{i-1}<a_i$ and h_i frequency of observed phenomena, i*th* is on the floor. In this research initially to calibrate and verify models and scenarios, the criteria NSE, RMSE and R2 were used. Followings are the relations for the presented criteria:

$$NSE = 1 - \frac{\sum_{i=1}^{N}(O_i - S_i)^2}{\sum_{i=1}^{N}(O_i - \bar{O})^2} \quad \text{(Eq.2)}$$

$$RMSE = \left[\frac{1}{N}\sum_{i=1}^{N}(S_i - O_i)\right]^{1/2} \quad \text{(Eq.3)}$$

$$R^2 = \left[\frac{\frac{1}{n}\sum_{m=1}^{n}(S_i - \bar{S})(O_i - \bar{O})}{\sigma_s \times \sigma_o}\right]^2 \quad \text{(Eq.4)}$$

where: O_i: observational data, S_i: Estimated data, $\bar{\mathbf{O}}$ and $\bar{\mathbf{S}}$ observed data and estimated mean, σ is the variance.

First, LARS-WG model was calibrated for the base period 1982-2010, and then by restarting the calibrated model, the validation was used for the base period. The results of calibration and verification data and the observed small-scale temperature and precipitation are presented in *Table 2*. According to Nash-Sutcliffe coefficient of determination and capability indices, the model has a good capability in down-scaling the regional temperature data and the region precipitation in future periods. After securing the model simulation results, the maximum temperature variables (*Fig. 7*) and minimal (*Fig. 8*) and precipitation (*Fig. 9*) by HADCM3 model for future periods from 2011 to 2030, 2046 to 2065 and 2080 to 2099 during climate scenarios SRA1B, SRA2 and SAB1 were predicted.

By comparing the average values of the maximum temperature specified in *Fig. 7* it is obvious that the maximum temperature in all three rounds will be higher than the base period. (Rise in temperature to 0.82 degrees' Celsius maximum temperature 0.37) In all three scenarios the highest maximum temperature will occur in 2011-2030 period, however, for future periods, during the period 2080-2099 all three scenarios are lower than the maximum temperature will be two periods of 2011-2030 and 2046-2065.

In *Fig. 8*, the minimum temperature in all three rounds will be higher than the base period. (0.31 to 0.70 degrees' Celsius rise in temperature, at least) In all three scenarios the maximum temperature will occur at least in the period 2011-2030, however, for future periods, during the period 2046-2065 all three scenarios are lower than the minimum temperature in two periods 2011-2030 and 2080-2099.

In *Fig. 9* by comparing the average values of rainfall it is clear that precipitation in all three rounds will be higher than the base period (Increased precipitation between 2.34 to 35.89 mm) and rainfall amounts will increase over time. In all three scenarios, the most precipitation will occur over the period 2080-2099, however, for future periods, during the period 2011-2030 all three scenarios are less than two periods 2046-2065 and 2080-2099.

Flow simulation using the SWAT

SWAT distribution model was used to assess the impact of climate change on hydrology of Chehel-Chai basin. This model is sensitive to changes of Earth and climate. Hydrological cycle, which in this simulation model is based on water balance equation is as follows:

$$\mathrm{SWt} = SWo + \sum_{i=1}^{t}(Rday - Qsurf - Ea - Wseep - Qgw) \qquad \text{(Eq.5)}$$

In this regard SW_t is final amount of water in the soil (mm), t- time (days), SW_o – the amount of water in the soil (mm), R_{day}- amount of precipitation in day i (mm), Q_{surf}- amount of surface runoff in day i (mm), E_a- evapotranspiration in day i (mm), W_{seep}- amount of water in the soil profile penetrated in the cortical area (mm) and Q_{gw}- flow back in the day i (mm)

In this regard, after the gathering and preparation of needed meteorological data and maps, according to the initial values of the parameters, SWAT continuous rainfall-runoff model for the base period of the years 1982-2010 was calibrated and validated. Additional SWAT CUP was used for model calibration software. During the study period to simulate the runoff of years (2000-1982) to calibrate the model and year period (2010-2001) were selected for validation period. Then, the effects of climate change and global warming on the hydrological basin in future periods were evaluated.

In simulation using the model it is necessary to indicate the parameters that output of the model shows the most sensitivity and for the calibration of the model, the sensitive parameter should only be used. For this purpose, after the initial implementation of the model to analyze the sensitivity of the effect of various parameters on model outputs was based on objective function of Nash-Sutcliffe.

This software with the observed data and parameters to modify, the changes range for each parameter identified and covered most of the measured data, the minimum thickness of the strip uncertainties may follow. *Table 3* shows the results of a sensitivity analysis to calibrate and validate in SWAT CUP. Also performance evaluation model

using coefficients R2, NS, RMSE, P-factor and R-factor between observed and simulated data was performed (*Table 4*).

R-factor	P-factor	RMSE	NS	R^2
1.21	0.71	0.117	0.61	0.69

After calculating average temperatures, minimum, maximum, radiation and precipitation, the effect of climate on Chehel-Chai basin was found. Then the model for the base period of continuous rainfall-runoff SWAT was calibrated and validated. In the next step to assess the impact of climate change on runoff was investigated. Given that situation in the future time series (under the impact of climate change) the objectives of this study was, therefore, to obtain the time series , daily meteorological parameters related to SWAT model was replaced in future and by applying the calibration parameters in the base period was predicted for time series period. River flow scenarios predicted values over AIB, A2 and B1 in the period 2011 to 2030 (*Fig. 12*), 2046-2065 (*Fig. 13*) and 2080-2099 (*Fig. 14*) is provided.

Variable rate long-term average for the base period (1982 to 2010) and future periods (2011 to 2030, 2046 to 2065 and 2080 to 2099) during climate scenarios SRA1B, SRA2 and SRB1 is presented in *Table 6*.

In all three scenarios the highest rate in the period 2080-2099 will occur in future periods, however, for future periods, during the period 2046-2065 all three scenarios rate less than two periods, 2011-2030 and 2080-2099.

Conclusion

Assessment of climate change impacts on water resources is carried out in two steps. In the first step changes in temperature, rainfall was investigated in the second phase the change in runoff by SWAT model output step was carried out. Results are as follows:

- According to the approved model LARS-WG, climate change was for future periods from 2011 to 2030, 2046 to 2065 and 2080 to 2099 during climate scenarios SRA1B, SRA2 and SRB1 separately for variables minimum temperature, maximum temperature and precipitation. By comparing the values of the average minimum temperature is specified that the minimum temperature in all three rounds will be higher than the base period. (0.31 to 0.70 ° C rise in temperature) In all three scenarios, the maximum temperature will occur at least in the period 2011-2030; however, for future periods, during the period 2046-2065 all three scenarios are lower than the minimum temperature two periods 2011-2030 and 2080-2099.
- By comparing the average values of maximum temperature, specified that the maximum temperature in all three rounds will be higher than the base period. (Rise in temperature to 0.82 degrees Celsius 0.37) In all three scenarios the highest maximum temperature will occur in 2011-2030 period; however, for future periods, during the period 2080-2099 all three scenarios are lower than the maximum temperature and will be two periods of 2011-2030 and 2046-2065. Overall results indicated that in future climate scenarios, rising temperatures will occur. In research Yu et al. (2002) also shows an increase in temperature results in prolonged periods of time and drastic changes in daily rainfall events is likely.
- Comparing the average values of rainfall, it was found that precipitation in all three rounds will be higher than the base period. (Increased precipitation between 2.34 to 35.89 mm) and with rainfall amounts will increase over time. In all three scenarios, the most precipitation will occur over the period 2080-2099; however, for future periods, during the period 2011-2030 all three scenarios is less than two periods 2046-2065 and 2080-2099.
- After the initial login parameters SWAT model and its implementation, an analysis of the sensitivity of the effect of various parameters on model outputs, Nash-Sutcliffe based on the objective function has little effect in output

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_741754

parameters that have to be removed and only be used for model calibration and sensitivity parameters. As a result, the order of 10 parameters including number curve, soil evaporation coefficient, the coefficient α to save waterborne Channel coast, the rate of temperature change with height in the suburbs, the average temperature for the rain turning to snow, the temperature of melting snow, the rate of change of temperature with height, coefficient of penetration determination to deep aquifer and feeding percentage of deep groundwater from shallow aquifers showed the greatest sensitivity. These results clearly show that the number of curves that are associated with land use change, are most susceptible to runoff.

- After the calibration and validation of models based on super critical parameters, performance evaluation model using coefficients R^2, NS, RMSE, P-factor and R-factor between observed and data was simulated. The results in this section in calibration and validation step indicated that the model efficiency coefficient (Nash-Sutcliffe) was positive and correlation coefficient was greater than 0.6 and RMSE value was too low. Therefore, this model has a good ability to simulate water flow in the time period.
- Comparing the long-term average annual rate, it is clear that all three rates in the future will be less than the base period (reduction rate of 0.122 to 0.153 cubic meters per second). In all three scenarios the highest rate in the period 2080-2099 will occur in future periods, however, for future periods, during the period 2046-2065 all three scenarios rate less than two periods, 2011-2030 and 2080-2099. Varanou et al. (2003) research using the SWAT model observed that the current decline will occur in the future. Although research results (Ficklin et al., 2009) showed that the precipitation and evapotranspiration are decreased, but it seems to be the opposite of Chehel-Chai River basin. So that the results showed that temperature and precipitation and runoff is reduced. Despite the increased rainfall, rising temperatures will lead to increased evapotranspiration, which will lead to reduced flow in rivers. However, the issue of excessive exploitation from water sources can be known related.

(Received 5th Apr 2017; accepted 11th Jul 2017)

Abstract. The oenoclimate aptitude index (IAOe) reveals climate suitability for wine production in temperate climate conditions. For Romanian wine regions its values were quite stable throughout the years, indicating the possibility of practising certain types of wine production. In the last decades the IAOe values have increased. By using gridded data at 0.1 degrees resolution of temperature, precipitation and sunshine duration for the entire Romanian territory, we calculated the IAOe averages for the 1961-1990 and 1991-2013 periods for 50 wine-growing centers which are representative for the Romanian viticulture. The results indicate that the IAOe mean at Romanian viticulture area level is currently of 4629 units, 270 units higher than the ones between 1961-1990. Due to this increase, the IAOe averages for the wine-growing centers from Moldova, Muntenia, Banat, Crișana and Southern regions have passed during the recent decades to values corresponding to an upper suitability class for wine production. In the wine-growing centers from Transylvania, the IAOe maintains in the range of suitability for white table wines, while for the ones from Dobrogea and Danube Terraces the IAOe maintains in the range of suitability for quality red wines. The study provides the scientific support needed for the re-evaluation of the wine type production practiced within Romanian wine growing-centers.
Keywords: *viticulture, wine production, Transylvania Plateau, Moldavian Hills, suitability, spatial distribution*

Introduction

The study of bioclimatic indices characterizing wine regions across the globe led to the conclusion that they have been modified by climate change in the last decades (Jones et al., 2005; Duchene and Schneider, 2005; Gatto et al., 2009; Beltrando and Briche, 2010; Kryza et al., 2015). These changes are associated with changes in grapes and wine composition and characteristics (Duchene and Schneider, 2005; White et al., 2006; Laget et al., 2008; Ramos et al., 2008). Forecasts on vineyards climate predict major shifts in the distribution and structure of viticultural areas worldwide in the coming decades (Hannah et al., 2013; Moriondo et al., 2013). In this context, knowing the impact of climate change on the Romanian viticulture (fifth place in Europe as vine area and thirteenth in the world as wine production; OIV, 2016), becomes mandatory in order to develop strategies for its adaptation to climate change.

Climate change manifests globally for about 50 years by increasing temperatures and sunshine duration amid relative stability of rainfall, accompanied by aridity and intensification of weather extremes (Beniston and Tol, 1998; Karl, 1998; Fraederich et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_755767

al., 2001; Thomas et al., 2008; Wild, 2012; IPCC, 2013). In Romania this phenomenon has been widely analysed in the literature of the past decades. The main observed developments are: significant increases in temperature and insolation during the winter, spring and summer, accompanied by constant rainfall during the year (Dumitrescu et al., 2014); significant increases in maximum and minimum temperatures during the year and unclear trends in precipitation evolution (Busuioc et al., 2015). Similar trends were observed at regional level (Piticari and Ristoiu, 2012; Planchon and Endlicher, 2014).

These climate developments has caused changes to the Romanian wine regions level as well: in the vineyards in the northern half of the country, which are cooler and specialized in white wines production, red wine grape varieties have started to be grown, while in those in the southern half, which are warmer and specialized in red wine production, musts are lacking in acidity and rich in sugar accumulations. In spite of all this evidence to which results of some recent studies can be added (Bucur and Dejeu, 2016; Irimia et al., 2017) the impact of climate change on the Romanian viticulture is still little known. Therefore, the aim of this study is to reveal the changes in climatic conditions for wine production in the Romanian wine regions as a result of climate change.

Tin order to study climate characteristics of wine growing regions, a variety of bioclimatic indices are used. Many of them are heat summation indices: Winkler Index (WI; Amerine and Winkler, 1944), Huglin Index (HI; Huglin, 1978), average growing season temperature (AvGST; Jones, 2006). Others are complex indices such as: Latitude Temperature Index (LTI; Kenny and Harrison, 1992), Composite index (CompI; Malheiro et al., 2010) or combinations of thermal and hydrologic indices (Moriondo et al., 2013). As the heat summation indices do not show the entire complexity of climatic conditions that determine the suitability for wine production (Moriondo et al., 2013), and the complex indices mentioned above were developed for climate conditions not necessarily similar to temperate climate conditions characterizing Romanian viticulture, we carried out this analysis by using the *oenoclimate aptitude index* (IAOe) which was developed in Romania by Teodorescu et al. (1987). The IAOe is highly effective in representing climate suitability for wine production in temperate climate conditions (Irimia et al., 2013, 2014). Its efficiency is given by the fact that it integrates three climatic determinants of grapes and wine quality: temperature, precipitation and sunshine duration. Due to its efficiency, in the 80s the IAOe was used to zone Romanian viticulture (Teodorescu et al., 1987), while today it is largely used to analyse vineyards climate suitability for certain wine grape assortments.

According to the research results published so far, no study has yet been carried out in Romania to reveal changes appeared in vineyards climate suitability at the national level in the last decades. Some research reveal trends in extreme weather conditions in Romanian viticulture (Bucur and Dejeu, 2016) or shifts in climate suitability for some wine regions (Irimia et al., 2017). This study aims to provide the current IAOe values revealing current climate suitability for the wine production for the 50 most important Romanian wine growing centers, spread all over the Romanian wine growing regions. The current IAOe values could offer these 50 wine growing regions the scientific support for their adaptation to the new climatic context.

The study is structured as follows: determination of spatial distribution and suitability for the wine production of the IAOe between 1961-1990 and 1991-2013; analysis of changes in the IAOe averages and suitability at the wine growing centres level; identification of causes of IAOe increases.

Materials and methods

Study area

Romania is located between 43°37'- 48°15' N lat. and 20°15'-29° 44' E long (*Figure 1*) and has a temperate continental climate, Dfb and Dfa in Koppen-Geiger climate classification (Kottek et al., 2006). Romania’s landscape is complex and diversified, with 28% represented by mountains; 42% represented by plateaus and hills; and 30% represented by plains (Bălteanu et al., 2010).

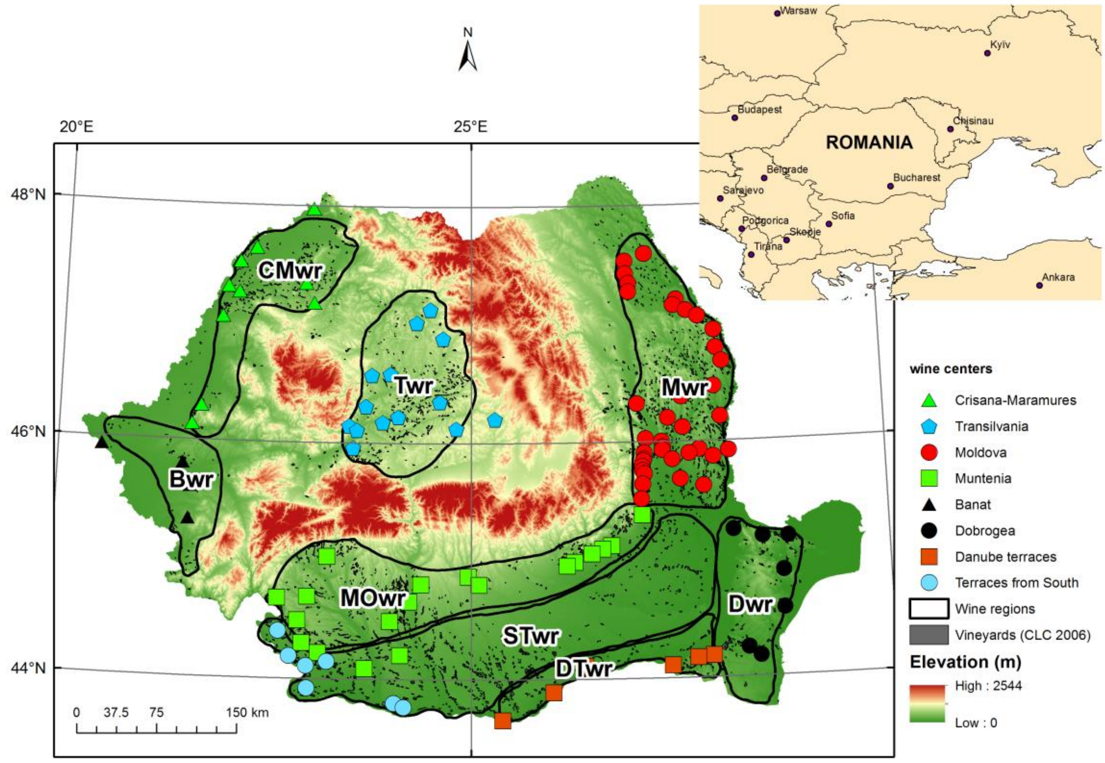

Figure 1. *Map of Romanian wine regions and wine growing centers*

As a viticulture country Romania has 197,000 ha vine plantations and produces about 6 mil Hl wine/yr (OIV, 2016). Romanian viticulture area is structured in eight large wine regions, corresponding to the historic provinces of the country. They are (*Figure 1*): Transylvanian Plateau Wine Region (Twr); Moldavian Hills Wine Region (Mwr); Muntenia and Oltenia Hills Wine Region (MOwr); Banat Hills Wine Region (Bwr); Crişana and Maramureş Hills Wine Region (CMwr); Dobrogea Hills Wine Region (Dwr); Danube Teraces Wine Region (DTwr); Sands and other suitable terrains from the South Wine Region (STwr). These eight large wine regions encompasses 141 wine growing centres (wine growing centre=vine plantations around a locality) belonging to 37 traditional wine regions. The study refers to 50 wine growing centers located in all eight large Romanian wine regions. For this study we used the map of the Romanian viticulture extracted from the Corine Land Cover Database 2006 Europe (EEA, 2006).

Methods

The climatic data base used to calculate the IAOe values for the Romanian wine regions is represented by gridded data at 0.1 degrees resolution (10 x 10 km) of daily average temperature, annual precipitation and sunshine duration during the 1961-2013 extracted from the ROCADA database (Dumitrescu and Bîrsan, 2015). This database includes 9 climate parameters and it was achieved by interpolation of daily values recorded at meteorological stations throughout Romania by using the MISH software (Szentimrey and Bihari, 2007). The number of the meteorological stations used varies according to the climate parameter: 150 stations for air temperature, 188 stations for precipitations and 135 for sunshine duration (Dumitrescu and Bîrsan, 2015). In the first stage of the study the daily values were used to calculate the sums of active temperatures (Σta, °C/April 1st to September 30th), precipitation during the growing season (PP, mm/April 1st to September 30th) and actual sunshine duration (ASD, hour/April 1st to September 30th). In the second stage, these three parameters were used to compute the IAOe index at the same 0.1 degrees resolution (approximately 10×10 km). In the third stage the IAOe spatial data was downscaled at a finer resolution (100 x 100 m) by using the regression-kriging approach and the terrain altitude as predictor.

The IAOe is calculated for the April 1st to September 30th period according to Teodorescu et al. (1987) formula (Eq. 1):

$$IAOe = ASD + \Sigma t_a - (PP - 250) \qquad \text{(Eq.1)}$$

where: ASD = actual sunshine duration (hours, April 1st to September 30th), Σt_a = sum of daily average temperatures ≥ 10 °C (April 1st to September 30th), PP = precipitation (mm, April 1st to September 30th) and 250 = minimum precipitation needed for unirrigated vines (mm). For situations where PP < 250 mm, the IAOe is computed as the sum of ASD and Σt_a (Teodorescu et al., 1987).

In Romanian wine regions the IAOe varies between 3793 and > 5200 units, with values higher than 5200 units characterizing vineyards at the southern limit of Romania (43 °lat N) which produce mainly table grapes (Oşlobeanu et al., 1991). In this study, in order to identify the changes in climate suitability for wine production of the Romanian wine regions, the IAOe is classified according to Irimia et al. (2014) as follows: IAOe < 3793= unsuitable for grapevine growing; IAOe =3793-4300= suitable for white table wines, sparkling wines, wines for distillates (WTW+SW+WD); IAOe=4301-4600=suitable for quality white wines and red table wines (QWW+RTW); IAOe > 4600 = suitabile for quality red wines (QRW).

Results

Spatial distribution and the suitability for wine production of the IAOe between 1961 and 1990

The spatial distribution of the IAOe between 1961 and 1990 reflects the already known base climate suitability of Romanian wine regions, attested by their specific types of wine production (*Figure 2*): climate suitability for red quality wine in the southern half of the country where the STwr, DTwr, Dwr and MOwr are located; and climate suitability for white wines in the northern half of the country where Mwr, Twr, Bwr and CMwr are located.

a. b.

Figure 2. *Spatial distribution of IAOe in Romania during the 1961 to 1990 time period and location of the main Romanian wine producing centers: a. continuous values; b. classified values. Values were calculated based on gridded data at 0.1 degree resolution of temperature, precipitation and sunshine duration extracted from ROCADA data base (Dumitrescu and Bârsan, 2015) and classified according to Irimia et al. (2014)*

Statistics for the spatial distribution of the IAOe across the Romanian wine regions (*Table 1*) show that between 1961-1990 its averages were between 3513 and 4647 units, with an average of about 4359 units indicating the prevailing climate suitability for QWW and RTW. The warmest wine regions and the most suitable for red wines are Dwr, DTwr and STwr where the IAOe averages exceed 4600 units (suitability for QRW); for all northern wine regions - Mwr, Twr, Bwr and CMwr - the IAOe averages are bellow 4300 units revealing suitability for white wine production (WTW, SW, WD); the IAOe for the MOwr, located at the transition zone between the southern and northern of Romania, has an average of 4300 units revealing suitability for QWW and RTW. IAOe Max reveals temporal variability of climate suitability of the wine regions specialized in white wine production, which in a number of years manage to produce even QRW. An exception is the Twr where the IAOe Max (4147 units) reveals the total lack of suitability for red wine production during the 1961 to 1990.

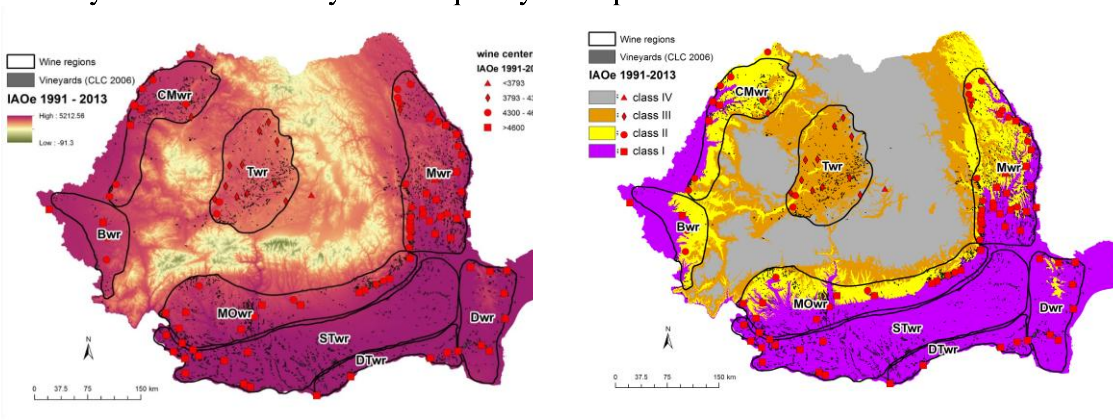
Spatial distribution and suitability of the IAOe for wine production between 1991 and 2013

The spatial distribution of the IAOe between the 1991 to 2013 reveals major changes in climate suitability for wine production in Romanian wine regions (*Figure 3*): the area with IAOe exceeding 4600 units extended towards the northern half of Romania, within the area of Mwr, Bwr and CMwr while the southern wine regions are almost entirely covered by climate suitability for red quality wine production.



a. b.

Figure 3. *Spatial distribution of IAOe in Romania during the 1991 to 2013 time period: a. continuous values; b. classified values. IAOe values were calculated based on gridded data at 0.1 degree resolution of temperature, precipitation and sunshine duration extracted from ROCADA data base (Dumitrescu and Bârsan, 2015) and classified according to Irimia et al. (2014)*

Statistics for the spatial distribution of the IAOe between the 1991 to 2013 (*Table 1*) show that its mean for the Romanian wine regions increased during this time period by 270 units to 4629 units today. The current average reveals the predominance in Romania of climate suitability mainly for QRW and QWW in secondary. The IAO mean for the southern wine regions - STwr, DTwr and Dwr - remain suitable for QRW but it approaches by 5,000 units, value that characterize vineyards producing mainly table grapes. As a result of these increases in the wine regions from the northern half of Romania (Bwr, CMwr, Mwr) except the Twr, the IAOe exceeded between the 1991-2013 the threshold of 4300 units that indicates the suitability for QWW and RTW. Within the Twr, the coolest wine region of Romania, IAOe increased by 231 units but still lies in the range of suitability for WTW.

Changes in IAOe averages and suitability at the wine growing centers level

The data in *Table 2* shows that between 1961 and 2013, the IAOe mean increased by 236-346 units within Romanian wine growing centers. This increase causes major changes in climate suitability for wine production: except the wine centers from Twr,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_755767

Dwr, TDwr and STwr, which still lie in the initial climate suitability class, the climate suitability of all the other wine growing centers from Romania passed to the upper suitability class: from class III to class II, and from class II to class I (*Table 2*). Although the IAOe average increased for each wine center in Twr, they still stands in the range of climate suitability for WTW, SW and WD. It is noteworthy here the obtaining of climate suitability for WTW, SW, WD by Bistrița, Batoş, Triteni and Apold wine growing centers of Twr, whose IAOe means during the 1961-1990 were below the threshold of suitability for WTW, SW and WD. In the case of southern wine centers of Romania (Dwr, TDwr and STwr) characterized even 1961 to 1990 by suitability for QRW, the IAOe average increased during the 1991 to 2013 to 5,000 units, a value specific to areas producing mainly table grapes.

The IAOe largest increase (346 units) during the 1991 to 2013 at Romania wine growing centers level is recorded for Lechinţa from Twr (*Table 2*) while at regional level for the W and NW of the country, within Teremia (+304 units), Măderat (+298 units), Diosig (+315 units), Şimleul Silvaniei (+315 units), Oradea (+323 units) and Zalău (+315 units) wine growing centers. IAOe important increases exceeding 300 units were recorded also within some wine growing centers from the central part of Mwr: Copou Iaşi (+303 units), Bucium (+312 units), Comarna (+320) and Murgeni (+312 units) are a few examples. IAOe increases have led to changes in climatic suitability for wine production in the affected areas.

The smallest IAOe increase at the country level (+238 units) is recorded in the Ştefăneşti wine growing center. However, the entire MOwr to which the Ștefănești wine growing centre belongs, is characterized by a low increase in IAOe average, of about +254 units. But in spite of these small increases many of the MOwr wine growing centers acquire climate suitability for QRW between 1991-2013 (*Table 2*).

Causes of IAOe increase

As shown in *Table 2* the cause of IAOe increase between the 1991 to 2013 is mainly the increase of active temperatures and of sunshine duration.

However, the largest increases in IAOe average recorded in Bistrița and Lechinţa wine growing centers from Twr and in certain wine growing centers from Mwr (Bucium, Comarna, Uricani, Copou, Vutcani) is caused by the increase of active temperatures and sunshine duration associated with a decrease of precipitation average. For the biggest part of Romanian wine growing centers, the IAOe increase is due exclusively to the increase of temperatures and insolation, while the precipitation amount is relatively unchanged.

The largest increase in the sum of active temperature during the 1991-2013 is recorded in the wine growing centers from Bwr and CMwr. It varies between +202...+221°C with an average of 212.5°C, as compared to +173…+216°C and an average of 193.78°C for the rest of Romanian wine growing centers. Significant increases in the sum of active temperatures impacting the IAOe averages are also recorded in some isolated wine growing centers as Bistrița and Lechinţa (+216 °C for both of them) from Twr; and also in some wine growing centers from the southern of Mwr (Tecuci, Iveşti, Corod) where the increase of the sum of active temperatures exceeded 200 °C.

Table 2. *Averages and differences for the oenoclimate aptitude index (IAOe), sum of active temperatures (Σt_a), precipitations during growing season (PP), and actual sunshine duration (ASD) for some Romanian wine centres, during the 1961-1990 and 1991-2013 time periods. Values were calculated based on gridded data at 0.1 degree resolution (10 × 10 km) of temperature, precipitation and sunshine duration extracted from ROCADA data base (Dumitrescu and Bârsan, 2015)*

Precipitation during the growing season (PP) at Romanian wine growing centres level presents a relative stability (*Table 2*), with insignificant increases of about +1...+10 mm between the 1991 and 2013. Exceptions are the wine growing centers from Dwr where the average of PP during the 1991-2013 highly increases with values from +15 mm to + 39 mm. Increases of +16 mm to +30 mm of the PP are also recorded in the wine growing centers from Twr, in some wine growing centers from the eastern limit of MOwr (+15 mm...+20 mm), and in some wine growing centers from the northern half of CMwr (Halmeu Sanislău, Valea lui Mihai, Diosig). Conversely, the decrease in PP average between the 1991-2013 time period, ranging from -13 mm to -21 mm, are recorded in the wine growing centers from the central part of Mwr (Bucium, Uricani, Comarna, Copou) and in Bistrița and Lechința wine growing centers from the northern limit of Twr (-11 mm and -24 mm respectively.

The average of the sunshine duration (ASD) for the 1991-2013 time period increased by 60 to 180 hours for all wine growing centers from Romania. The highest values, higher than 100 hours, are recorded in the wine growing centers from Twr; in those within the northern half of Mwr; within the northern half of CMwr; and at the southern limit of Dwr (*Table 2*).

Discussion

By using spatial data of temperature, sunshine duration and precipitation for the entire Romanian territory at 0.1 degrees resolution (10×10 km), our study managed to provide the current IAOe averages for the most important 50 Romanian wine growing centers. The current IAOe averages reveal the current climate suitability for wine production of the wine growing centers, as it looks like after the climate change influence during the last two decades. Changes of the IAOe averages revealed by this study fall into developments of bioclimatic viticulture indices averages recorded at global and regional levels (Ramos et al., 2008; Laget et al., 2008; Duchene and Schneider, 2010), in the sense of increasing vineyards climate heliothermal resources amid diminishing water resources.

The general result of the study it the increase by 270 units of the IAOe average at Romanian wine growing regions level, from 4359 units between 1961-1990 to 4629 units between the 1991-2013. This increase shows the transition of the IAOe average for Romania viticulture from a range defining climate suitability for QWW (4300-4600 units) between 1991-2013 to a range defining the suitability for QRW (>4600 units) at present. The new values of IAOe calculated for the 1961 to 1990 are consistent with those reported for Romanian wine regions and wine growing centers by Teodorescu et al. (1987) and Oşlobeanu et al. (1991). They reflect accurately the traditional types of wine production specific to those areas: WTW, SW, DW, QWW in Twr, Mwr, CMwr and Bwr; RTW and QRW in Dwr, DTwr and STwr; QWW and QRW in MOwr located at the transition zone between the southern half and the northern half of Romania. Climate suitability evolution towards red wine production revealed by the current IAOe averages is consistent with that predicted by Mesterházy et al. (2014) and Stock et al. (2005) for temperate continental climate conditions in Europe. IAOe variability within Romanian wine growing regions maintains within the original range, although the higher frequency and levels of climatic extremes registered during the last decades (Bojariu et al., 2015), are able to influence the quality characteristics of grapes and wine production.

DOI: http://dx.doi.org/10.15666/aeer/1504_755767

IAOe averages for the 50 wine growing centers analysed in this study reveal the spatial variability of climate suitability within Romanian viticulture areas. They show the different abilities of wine growing centers to adapt to climate change, despite the overall environmental characteristics of the larger area they belong to. For example, the difference in the IAOe average for the contiguous Lechinţa and Batoş wine growing centers from the northern part of Twr is around 300 units. The same for the Sebes and Apold wine growing centers from Twr; for the Urlați and Tohani from MOwr; for the Silagiu and Recaş of Bwr; for the Valea lui Mihai and Diosig from CMwr. In all these cases, the wine growing center with a lower IAOe average is located at a higher and cooler altitude, which indicates larger possibilities for its adaptation to climate change. Assessed according to the latitudinal distribution the IAOe variability is found to diminish from the northern half, where all types of wine production can be obtained, to the southern half where suitability for QRW predominates.

One of the most important results of our study is the revealing of the changes in temperature, precipitation and sunshine duration for the wine growing centers from Romania. IAOe increases is caused by the rising temperatures and insolation, against the relative stability of precipitation. The results of our study regarding the distribution of temperature increases, sunshine duration and precipitation diminishing are consistent with those characterizing the particularities of climate change across the Romanian territory (Dumitrescu et al., 2014; Piticari and Ristoiu, 2012; Sfâcă, 2015).

Our study demonstrates once again that wine types production is determined by well defined climate suitability ranges specific to restraint areas, as is the case of the analysed wine growing centers. These ranges of climate suitability remained quite stable over time and allowed the establishing of the representative wine grape assortments and wine types for the vineyards. Changing the boundaries of these climate suitability ranges as an effect of climate change involves changing the types of wine production and wine grape assortments of vineyards. Today, the cool climate vineyards within traditional areas of vine culture have larger possibilities of adaptation to climate change, mainly to rising temperatures. On the other hand, as earlier research revealed (Jones et al., 2005) wine regions in warmer climate, in Romania's case southern wine regions (Dwr, DTwr and STwr), will face exceedings of climate suitability ranges for quality wine production. This will force them either to change their specific type of wine production by replacing their traditional wine grape variety assortments or to implement adaptation measures to climate change (Keller, 2010).

This study offers a scientifically based support to assess the impact of climate change on Romanian wine growing centers climate and to outline strategies of their adaptation to this phenomenon. Obtaining accurate depictions than those provided by this climate based study requires fine-scale analysis also of vineyards topography and soils, which can be achieved by using methodologies adapted to temperate continental climate characterizing Romania (Irimia et al., 2013, 2014).

Conclusions

By using the daily averages of temperature, precipitation and sunshine duration for the 1961 to 2013 time period at a 0.1 degrees resolution (10×10 km), our study provides averages for the 1961 to 1990 and for the 1991 to 2013 of the oenoclimate aptitude index IAOe for Romanian wine regions. The comparative study of the averages and the spatial distribution of the IAOe between the two time periods highlights major changes

in climatic suitability for wine production in the last five decades in all wine growing centers of Romania. Except for the wine centres from Transylvania (Twr), in all wine growing centers the average of the IAOe moved during the 1991 to 2013 to the upper suitability class as compared to 1961-1990. Current IAOe averages reveal an improvement of climate suitability for the wine production in wine growing centers of Romania and the occurrence of climatic conditions to diversify the types of wine production. The study highlighted the negative evolution of climate suitability for wine production within the wine growing centers from the extreme south of Romania, where the current climate becomes more and more suitable for table grapes production. Further studies on the development of chemical composition and on the sensory profile of grapes and wines produced in this wine centers will clear up the way of these developments in the coming years.

The changes in climate suitability revealed by this study are likely to generate changes in wine grape assortments and traditional types of wine production of Romanian wine growing regions. Changes in wine grape assortments argued as adaptation to climate change are happening nowadays in Romania viticulture areas, but they are not integrated in a national strategy based on scientific support, but more on intuition of local wine producers and on their wish to diversify the wine types production. Our study provides the necessary support to outline such a national strategy and also to guide policy makers and wine growers in their work on adaptation of viticulture to climate change.

Acknowledgments. This research was carried out with financial and logistic support from 7BG/2016 AVEVINPERFORM project (UEFISCDI România): „Improving grapes and wine quality in the Averești Huși wine growing region by adapting technologies to viticultural potential of the area."

Abstract. *Silybum marianum* (L.) Gaertn. is a widely known species, however, little is known about its allelopathic potential. *S. marianum* is a common weed in some crop areas. In this research, the allelopathic effect of *S. marianum* extracts on *Triticum aestivum* L. was investigated. The water extracts were used to show its phytotoxicity potential. The examined concentrations (m/v%) were: 1%; 2%; 3%; 4% and 5%. The control was tap water. The fresh and dry weight, the length of coleoptile and the radicle, the element contents of winter wheat seedlings were measured. The low concentration (1%) *S. marianum* extract had positive effects on the measured parameters. The fresh weight, dry weight and length of the radicle and shoot decreased at higher concentrations. The fresh weight of shoot decreased with 13% at the 5% treatment. The fresh weight of the radicle decreased with 32%, 42% and 67% at the 3%, 4% and 5% water soluble extract treatments. The decrease was significant. The higher concentrations had negative effects on the fresh weight of the shoot and especially of the radicle. The concentration of Ca, Mn, Mo and P increased in the radicle when winter wheat was treated with *S. marianum* extract, while the Fe and Zn concentrations did not change significantly. Increasing was determined in the N, K and Mg concentration both in the shoot and radicle of winter wheat. According to the results, one possible way is to use of milk thistle active ingredients as natural herbicides in the future. Our results show that we have to pay attention on milk thistle when it is appeared on field such as weed, because it has strong allelopathic effects.
Keywords: *biomass production, milk thistle, nutrient uptake, plant growth inhibition*

Introduction

The basic approach used in allelopathic research for agricultural crops has been to screen both crop plants and natural vegetation for their capacity to suppress weeds (Alam et al., 2001).

The word allelopathy is derived from two separate words. Allelon means “of each other”, and pathos means “to suffer”. Allelopathy refers to the chemical inhibition of one species by another. The “inhibitory” chemical is released into the environment where it affects the development and growth of neighbouring plants.

Allelopathic chemicals can be present in any part of the plant. They can be found in the leaves, flowers, roots, fruits or stems (Cheng and Cheng, 2015). They can also be found in the surrounding soil. Target species are affected by these toxins in many

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_769778

different ways. The toxic chemicals may inhibit shoot/root growth, they may inhibit nutrient uptake, or they may attack a naturally occurring symbiotic relationship thereby destroying the plant's usable source of a nutrient.

The effects of allelopathic toxins on sensitive plants can easily be tested in the lab or greenhouse setting. Seeds are the easiest and least expensive to test. Seeds that do not germinate in the presence of allelotoxins are probably displaying toxicity effects. Plants that become chlorotic and eventually die in the presence of allelotoxins are also showing signs of toxicity to the chemical. The allelopathic interactions include weed-weed, weed-crop and crop-crop are investigated in wide range (Elhaak et al., 2014; Lehoczky et al., 2011; Lehoczky and Gólya, 2013;).

Silybum marianum L. Gaertn. is a member of the Asteraceae family. The genus *Silybum* contains two species *S. marianum* (L.) Gaertn. and *S. eburneum* Coss. and Durieu (Adzet et al., 1993; Penksza and Szerdahelyi, 2009).

Each stem ends in a flower head about 5 cm in diameter (Montemurro et al., 2007), of red-purple colour. *S. marianum* is a long-day plant. In Israel, *S. marianum* occurs in two types, one type has purple flowers, while the other has white flowers (Vaknin et al., 2008).

The weight of 1000 *S. marianum* seeds is 28-30 g (Anderzejewska et al., 2011). Each flower head produces about 190 seeds, with an average of 6350 seeds per plant (Dodd, 1989). In the soil, seed can remain viable for up to nine years (Sindel, 1991). The seeds show little or no dormancy.

Silymarin is a lipophilic extract from the seeds of *S. marianum* and is composed of three isomer flavonolignans, silybin, silydianin and silychristin. Silymarin was first isolated in 1968 (Wagner et al., 1968).

Silybin is the component with greatest degree of biological activity and comprises 50-70% of silymarin. Seeds of *S. marianum* contain small amounts of flavonoids and approximately 20-35% fatty acids and other polyphenolic compounds (Ramasamy and Agarwal, 2008). A number of other flavonolignans have also been found in the seeds including isosilybin, dehydrosilybin, desoxysilycristin, desoxysilydianin, silandrin, silybinome, silyhermin and neosilyhermin (Kvasnicka et al., 2003).

Silybum marianum is native to the Mediterranean region of Europe and in Africa. *S. marianum* occurs especially in the wheat fields in Egypt and in Tunisia (Lehoczky et al., 2014).

Blessed milk thistle (*Silybum marianum* L. Gaertn.) is cultivated as a medicinal plant on 1500-2000 hectares, in Hungary (Borbélyné Hunyadi, 2010). It is important to know about its allelopathic effect againts the other plants (cultivated plants or a weeds). The allelopathic effects of *S. marianum* is important in crop production practice, because the residues could be incorporated into the soil after harvest. In countries, where it appears as a weed, this allelophatic effect may influence the result of the crop-weed competition as well.

The present study was conducted to evaluate and determine the initial growth performance and nutrient uptake of winter wheat under different extracts concentration of *S. marianum*.

Materials and methods

The *Silybum marianum* (L.) Gaertn. leaf samples were dried on 45 ºC. After drying, the sample was chopped than milled with grinder. The powdered sample was kept in paper bags until further measurements. The plant material of *S. marianum* was collected on an arable area.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_769778

100 ml of the 10% concentration of water extract was made by soaking 10 g plant sample powder in 100 ml tap water. The mixture was kept at room temperature for 24 hours and was mixed occasionally. After that, the extract was filtered through MN 619 G ¼ filter paper. The following water soluble extract concentrations (m/v%) were used during the experiment: 5%, 4%, 3%, 2% and 1%. Tap water was used as a control (0%).

Before the experiments, the winter wheat seeds (*Triticum aestivum* L.) were sterilized with hydrogen peroxide. After the sterilization, the seeds were dried on paper towels. Twenty-five seeds of winter wheat were placed separately into 18 cm diameter Petri dishes on MN 640 m filter paper. The number of replications was four. 15 ml of each concentration of extracts were added to the Petri dishes. All of them were placed in a Binder APT Line KBW plant growth chamber at 21±1 °C for 7 days.

Seven days after the start of the experiments, the shoots and roots of every seedling were measured with millimetre paper. One hundred repetitions were performed. The fresh weight of the shoots and radicles was measured at the same time. The air dry weight was also measured. The shoot/root ratio was calculated using the dry weight.

The substances with allelopathic effects of the *S. marianum* sample have been investigated by HPLC. According to the methanol extract, 1 g plant sample contained 63 µg rutin and 194 µg salicylic acid. According to scientific papers, both rutin and salicylic acid have inhibitory effects on germination (Basile et al., 2000; Szepesi, 2009).

The element concentrations were measured by ICP-OES. The number of laboratory readings for ICP was the mean of two samples. The nitrogen concentration of samples was done with the Kjeldahl method. ANOVA (Analysis of Variance) was used to value the significant differences. On the figures the error bars indicate the standard deviation and the a–e indicate significant differences within treatments at the 5% level of probability according to Duncan's test. For the statistical analysis Sigma Plot 12.0 and MSTAT were used.

Examinations were carried out in three biological replications at different times with four replications. The results are the averages of these data. The experiments were conducted in controlled environmental conditions, so there was no difference between the results of three biological replications. Data of three repetitions were summarized and used for statistical analysis – results were calculated from twelve data points.

Results

Usually, the effects of allelopathy include reduced seed germination and seedling growth. First of all, the effect of *S. marianum* was observed at the fresh weight of shoot (coleoptile) and radicle (root) of winter wheat (*Fig. 1, Fig. 2*).

The positive effect was observed when 1% and 2% water-soluble extract treatments were applied. The fresh weight of shoot is significantly increased with 27% at the 1% treatments. This increasing was 25% at the 2% extract treatment. The higher concentrations had negative effect on fresh weight of shoot and especially of radicle. The fresh weight of shoot decreased with 13% at the 5% treatment. The fresh weight of the radicle significantly decreased with 32%, 42% and 67% at the 3%, 4% and 5% water soluble extract treatments.

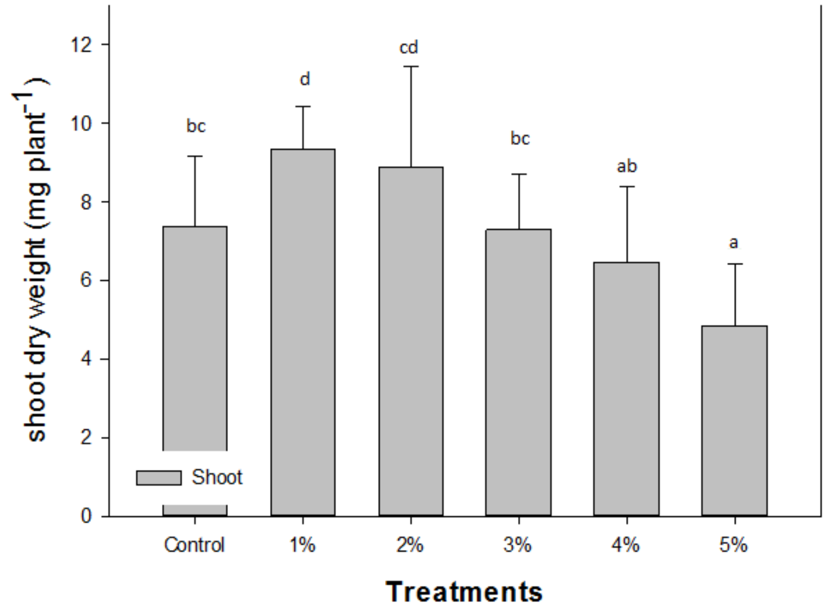

Figure 3. *The effect of 1; 2; 3; 4 and 5% Silybum marianum (L.) Gaertn. extracts on the dry weight of shoot of winter wheat ($LSD_{5\%}$ 21.93) n=12± S.D.*

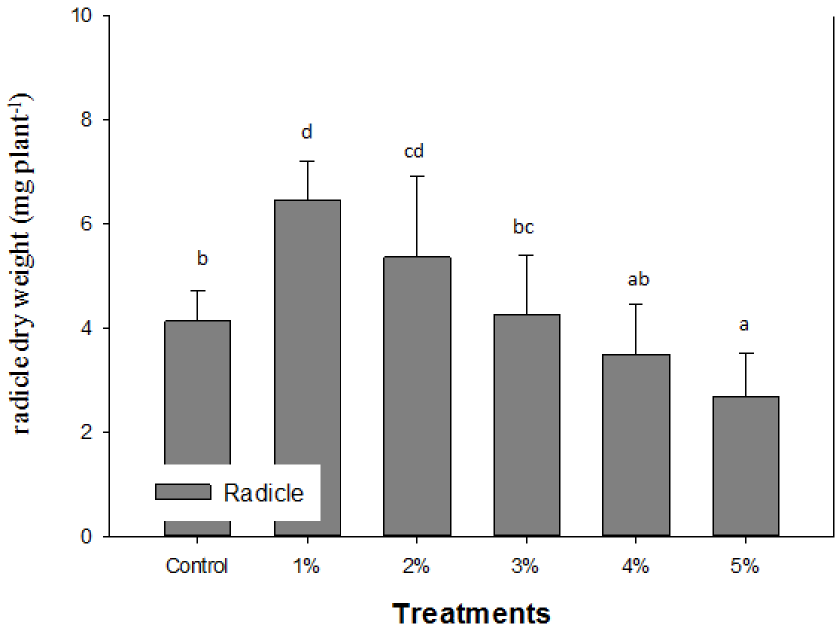

Figure 4. *The effect of 1; 2; 3; 4 and 5% Silybum marianum (L.) Gaertn. extracts on the dry weight of root of winter wheat ($LSD_{5\%}$ 10.05) n=12± S.D.*

The 1% extract treatment had a positive effect on the dry weight of the shoot. The dry weight increased by 21%. The decrease seen at the higher extract concentration (3-5%) had a negative effect on the dry weight of the shoot. This decrease is parallel to an increase in extract concentration. The dry weight of the radicle was significantly increased when the seeds were treated with 1% extract. There was an increase of 36%

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_769778

compared to the control. Also, this increase was observed at the 2% extract treatments and when 3% extract were examined the results were around the control level. The dry weight of the radicle decreased at the 4% and 5% extract treatments. The decrease was higher at the 5% extract treatment.

Fig. 5 shows the different extract treatments on the shoot/radicle dry weight rate of winter wheat. The greater degree of decrease of radicle weight was expressed also in the shoot/radicle dry weight rate, which was significantly higher in case of 4% and 5% extract treatments compared to the control.

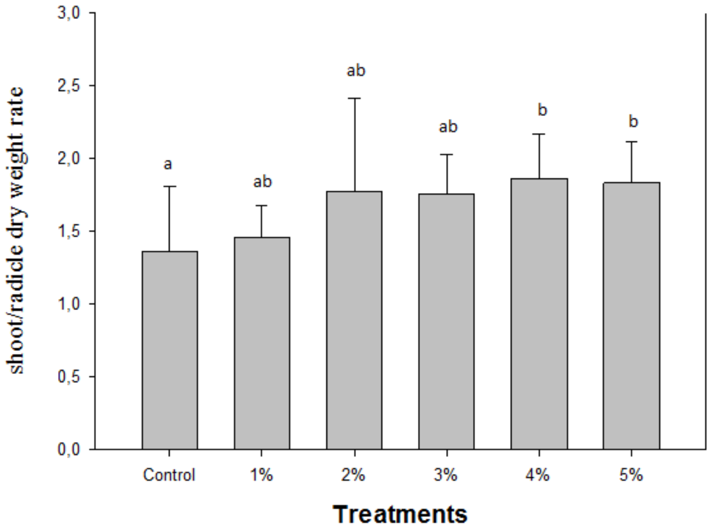

***Figure 5.** The effect of 1; 5; 7.5 and 10% Silybum marianum (L.) Gaertn. extracts on the shoot/root dry weight rate of winter wheat ($LSD_{5\%}$ 0.21) n=12± S.D.*

The length of shoot increased with 31.5% at the 1%, and increased with 23% at the 2% extract treatment (*Fig. 6*). The length of shoot decreased with 16% at the 4% and 40% at the 5% *S. marianum* extract treatments.

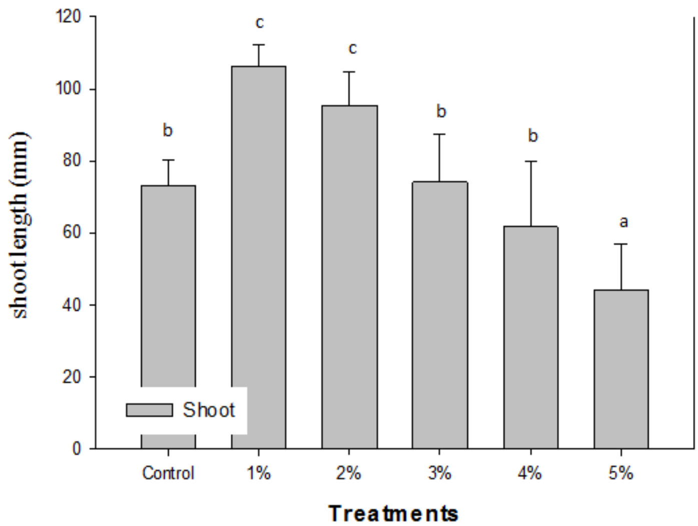

***Figure 6.** The effect of 1; 2; 3; 4 and 5% Silybum marianum (L.) Gaertn. extracts on the length of shoot of winter wheat ($LSD_{5\%}$ 9.82) n=300± S.D.*

The concentration of potassium, magnesium and calcium increased in the radicle of winter wheat at all treatments. The highest increasing could be observed at the 5% water soluble extract treatment. Increasing was determined in the nitrogen, magnesium and potassium concentration both in the shoot and radicle of winter wheat.

The concentration of phosphorous increased in the radicle when wheat was treated with *S. marianum* extract. Significant increasing was observed at the 3%, 4% and 5% extract treatments in the radicle compared to the control.

Discussion

Our results show that we have to pay attention on milk thistle when it is appeared on field such as weed, because it has very strong allelopathic effects.

S. marianum is a major weed in sugar beet, winter wheat and canola causing large yield reductions (Khan and Marwat, 2006; Shimi et al., 2006). However, researchers have documented the allelopathic effect of *S. marianum* on mustard, cucumber, wheat and sorghum (Inam and Hussain, 1988).

The allelopathic potential of *S. marianum* increased with increased concentration. In addition, stability and level of phytotoxicity of *S. marianum* vary on methods for extract preparation and solvent or media. The fresh water extract is more toxic than the heated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_769778

extract, but in both condition there is some inhibitory substances presence in *S. marianum* tissues causing this allelopathy.

The aqueous extract of leaves of *S. marianum* were assayed at different concentration (1, 2, 3, 4 and 5%) to assess their allelopathic potential. The extracts were tested on seeds of winter wheat (*T. aestivum*). The seedling shoot and radicle lengths were significantly reduced with 40% (shoot) and 58% (radicle) by 5% extract compared to the control. Organic extracts have reduced the seedlings growth in high percentage at the 5% water soluble extract treatments. Our finding also reporting that the radicle growth of winter wheat is suppressed more than its shoot growth, since the fresh weight of shoot decreased with 13%, while radicle with 67% at the 5% treatment.

The phosphorus concentration in the radicle is increased when wheat was treated with milk thistle waterextract. The P is requirement for optimal growth. The probability of P toxicity increases at concentrations higher than 10 mg g^{-1} DW. P toxicity in plants is rare, because plants down-regulate their P transporters involved in net P uptake from the root environment when supplied with more P than required for optimum growth (Dong et al., 1999).

Over all the allelopathic potential of *S. marianum* increased with the increasing concentration.

Weeds are an important variable to consider in crop production (Bilalis et al., 2010; Lehoczky et al., 2015). It is the opinion of the research committee that weed science will be advantageously positioned for the future if research focuses on research-decision processes, weed biology and ecology, weed control and management practices, herbicide resistance, issues related to transgenic plants, environmental issues, and potential benefits of weeds (Hall et al., 2000).

According to our results water extract of milk thistle has very strong allelopathic effect, so special attention needs when this plant appears as weed.

Abstract. This study was carried out to determine the heterosis and heterobeltiosis values in F1 hybrids which are obtained through hybridization of salt-tolerant genotypes in summer squash (*Cucurbita pepo* L.). The materials used were the promising hybrid combinations and their parents, which are previously reported among the salt-tolerant genotypes by detecting the influence of parents on heterosis and heterobeltiosis values in advanced hybridization studies. Eight domestic summer squash genotypes (Tutluca 1, Tutluca 2, Halfeti 1, Halfeti 2, Bozova Mrkz, Yaslıca, Konak and Şanlıurfa Mrkz), were chosen from salt-tolerant genotypes and 28 F1 hybrids obtained through hybridization of these genotypes. The heterotic influences were remarkably important, and it was possible to get promising hybrids in terms of examined traits. Parents were evaluated for plant length (cm), stem diameter (mm), plant width-spread (cm), number of leaves (number), 50% female flowering time (day), yield (kg), parental and hybrid heterosis and heterobeltiosis values (%), and parental contribution to heterosis and heterobeltiosis of F1 hybrids. The highest heterotic effect was determined in the summer squash yield traits. In the yield, a maximum of 32.67% heterosis and 24.36% heterobeltiosis values were obtained. Additionally, genetic relationships of parental genotypes based on chloroplast DNA sequence analysis were compatible with results of heterosis and heterobeltiosis.

Introduction

Among all agricultural products, vegetable production in the world reached its highest rate (45%) between 1985 and 1995 (Harrison, 2002). Turkey's fruit and vegetable products have an important role in both industry and in exports. Agricultural products constitute approximately 25% of Turkey's exports. However, vegetables share in this value is only around 2% (Turkstat, 2015). Eating habits are changing in favor of vegetables parallel to cultural and economic developments in Turkey, as in many other countries throughout the world. Fruits and vegetable crops have a remarkable place in the diet of developed countries (Skreden et al., 2017). Summer squash (*Cucurbita pepo* L.) which has an annual production of 137,000 Hg/Ha (Anonymous, 2013), is produced in a wide number of climate zones, has significant economic value (Paris, 1986). Summer squash has a wide variation in terms of size, color and shape of the fruit (Paris, 1986). *C. pepo* is divided into eight groups in terms of fruit shape, six groups in terms of fresh consumption of the fruit and five groups based on the thickness of the fruit skin.

DOI: http://dx.doi.org/10.15666/aeer/1504_779796

The most distinctive feature of summer squash from other squash types is that fruits are almost always smooth (Paris, 2008).

Plant breeders' ultimate target is high production/yield. To widen genetic variation for breeding, variety expansion and hybridization are carried out. The most important criteria for hybridization is to select the most suitable parents for this purpose in early generations. For a breeder trying to develop a variety, finding heterosis values means the work is well-directed, and may produce a variety in a shorter time period. A successful breeding programme is based on accurate selection of the material used. Determination of heterosis values is important to develop new and strong squash cultivars (Stuber, 1994). Hallauer and Miranda (1988) calculated heterosis values according to potential gene combinations of parents. The best combinations were achieved from the hybridization between the types and lines in different heterotic groups. The width of the heterotic pattern in genetic sources affected the degree of heterosis level positively.

Heterosis, defined as the superiority of F1 over its better parent, will occur when F1 > P1, if it is the better parent for the property under consideration, or F1 < P2 if P2 is the better parent. Clearly, P1 will be the better parent where superiority is equitable to a higher value for the mean phenotype, e.g., higher yield, whereas P2 will be the better parent where it is equitable to a lower value for the mean phenotype, e.g., fewer days to reach maturity. Heterosis of the first kind, which called positive, will occur when;

$$F1 - P1 = [F11/2\,(P1 + P2)] - [1/2\,(P1 - P2)] \qquad \text{(Eq. 1)}$$

Heterosis of the second kind, which is called negative, will occur when;

$$F1 - P2 = [F1 - 1/2\,(P1 + P2)] + [1/2\,(P1 - P2)] \qquad \text{(Eq. 2)}$$

The heterosis effect in summer squash is seen primarily in the number of fruits per plant and in earliness of fruit development (Curtis, 1939). Curtis (1941) reported heterosis in the earliness of fruit harvest 114% over the parental mean and 87% over the better parents mean. A comparison of nine yellow fruited F1 hybrids with three commercial varieties showed 46% advantage in earliness and 19% in yield (Elmstrom, 1978).

The F_1 must be superior to its parents to observe heterosis, whether it is also superior to all of the pure-breeding lines. Heterosis is theoretically a quadratic function of parental genetic distance (GD) at the underlying quantitative trait loci (QTL) for the trait considered (Falconer and Mackay, 1996; Melchinger, 1999). Experiments with maize showed an increase in heterosis with increasing parental GD (Moll et al., 1962; Melchinger, 1999), but they also suggested an optimum level of parental GD, after which heterosis and hybrid performance declines (Moll et al., 1965). The results provide strong evidence that epistasis plays a major role as the genetic basis of heterosis (Yu et al., 1997). Programs to exploit mating systems to produce hybrids were developed in spinach (monoecious forms), cucumber (genetically controlled), squash (response to chemicals), and carrot (cytoplasmic male sterility) (Pearson, 1983).

Chloroplast DNA has been used extensively to determine the genetic similarities and differences in plants. The chloroplast *trn*L-F region has proven to be phylogenetically useful from the species level to the family level. It is a noncoding region that includes the trnL (UAA) intron ranging from 350 to 600 base pairs (bp) and the intergenic spacer

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_779796

between trnL (UAA) 3′ exon and the trnF (GAA) gene. That sequence is in the region where the chloroplast genome does not code. It is widely used in phylogenetic research (Taberlet et al., 1991). Additionally, it comes to forefront in molecular similarity studies due to its characteristics, such as the structural stability of chloroplast DNA, haploidy (n), uniparental transferability (in general) and non-recombinant nature (Small et al., 2004). In molecular systematic studies, a phylogenetic tree is built with the data obtained while showing the degree of relationships among genotypes (Saitou and Ġmanishi, 1989).

Determination of heterosis and heterobeltiosis rates in F1 hybrids through hybridization of salt-tolerant genotypes and with DNA based relationships of parental genotypes were the main aims of this study. Since salinity is known to be a great handicap for summer squash cultivation, salt-tolerant genotypes (Tutluca 1, Tutluca 2, Halfeti 1, Halfeti 2, Bozova Mrkz, Yaslıca, Konak and Şanlıurfa Mrkz) were used to evaluate the effect of parents on heterosis and heterobeltiosis.

Materials and Methods

Material

Eight different summer squash pure lines (*C. pepo* L.) were used in this study (*Table 1*). The parents were purified between 2008 and 2011. In addition to studies on their yield and yield components, a study of their tolerance to salt stress was published in 2012 (Karipcin and Sari, 2012). The summer squash parental lines used as plant material (*Table 1*) and hybridizations scheme without reciprocals (*Table 2*) are given below.

***Table 1**. Parental Summer squash Genotypes used in the research (C. pepo L.)*

Parent name	Origin

Definition of Research Area

Harran Plain is located between 36^{o} 47^{1} and 39^{0} 15^{1} east longitudes and 36^{0} 40^{1} and 37^{0} 41^{1} north latitudes in Şanlıurfa province in the Southeastern Anatolia, Turkey. The area is surrounded by Urfa Mountains in the North, Turkey-Syria border in the South, Tektek Mountains in the East and Fatik Mountains in the West. Harran Plain covers 225.109 ha (Anonymous, 1980) and is 410 m above sea level.

General Soil Characteristics of the Research Area

The research was carried out in Ikizce region. Thesoil in this region has a structure whose topography is flat or nearly flat; the whole profile is limy with a clay texture. Soil pH varies between 7.3-7.4, with 1.1% organic material on the surface and 0.8% in the deep soil zones. In the soils evaluated, field capacity in dry weight, the wilting point and bulk density ranges were between 32.71-33.84%; 21.18-22.55 and 1.37-1.41, respectively (Dinc et al., 1988; Almaca and Gok, 1997).

General Climate Characteristics of Research Area

Although Sanlıurfa is in the South-Eastern Anatolia climate zone, it is under the influence of the Mediterranean climate. It has hot and dry summers, and warm winters. The precipitation increases from south to north and from west to east. According to multi-year averages, July is the warmest month (46.8^{0}C), while maximum precipitation (93.1 mm) and the highest moisture (71%) occurs in January (Anonymous, 2012).

Method

A total of 28 hybrids were obtained from the hybridization of eight parents in 2013. Thirty six summer squash genotypes (eight parents and 28 hybrids) were evaluated under field conditions according to randomized complete block design with three replicates in 2014. The research was conducted in the GAP Agricultural Research Institute fields in Koruklu Research Station. The plants were sown in a row with 1.5 m x 0.5 m spaces with ten plants in each parcel. The first and last plants in each row was used as buffer. In every parcel, plant length (cm), stem diameter (cm), plant width-spread (cm), number of leaves (number), 50% female flowering time (day), stem length (cm) and yield (kg) were analyzed.

Heterosis and Heterobeltosis Calculations

Heterosis level was calculated for each trait by subtracting parental average value from the F1 hybrid value and dividing this to parental average and multiplying by 100 (Fonseca and Paterson, 1968; Sari et al., 2003a; Virmani et al., 2003; Cho et al., 2004; Denizer et al., 2005; Jose et al., 2005; Ahmad et al., 2005); and by subtracting the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_779796

superior parent's value from the F1 hybrid value, dividing it to superior parent's value and multiplying by 100 (Sari et al., 2003b; Cho et al., 2004; Denizer et al., 2005; Jose et al., 2005). That is, formulas to determine heterosis [(*F1-EO/EO*) *x 100*], and heterobeltiosis ratio [(*F1-ÜE/ÜE*) *x 100*], were used. The contribution of the parents to heterosis and heterobeltiosis was determined for evaluated traits. Differences between the genotypes were evaluated with JMP 5.1.2 software (SAS Institute, Cary, NC, USA).

DNA Isolation for Molecular Studies and PCR Conditions

DNA extraction was performed according to Karaca et al. (2005) by taking the leaf samples from each of eight parents used in this study. The quantitative features of the isolated DNA were measured with a spectrophotometer, and 1% agarose gel was used to measure its qualitative features. PCR reaction was optimized to reproduce the *trn*L-F region. In order to reproduce the *trn*L-F region, F: 5'ATTTGAACTGGTGACACGAG3', R: 5'GGTTCAAGTCCCTCTATCCC3' primer pairs were used. In the tubes with a reaction of 200 µL, "by taking 2.5 µL of reaction buffer with 10X", 2.5 µL from 25 mM MgCl, 0.4 µL from 10 mM dNTP, 1 µl from the primer pairs with 10 pmol/µL, 0.25 µL from Taq DNA polymerase, 2 µL from template DNA, 15.35 µL from dH2O, the total volume would be arranged to be 25 µL. To check for contamination during the PCR reaction, a negative control of non-genomic DNA was used. The PCR was adjusted to 35 cycles to remain at 94^0 C for five minutes, at 94^0 C for one minute, at 58^0 C for one minute and at 72^0 C for one-minute. The last PCR product was kept at 4^0 C. In order to see the region reproduced, 5 µL DNA from PCR product was mixed with 2 µL loading dye and loaded into 1.5% agarose gel. Later, with a gel scanning device, an image was taken under UV light. After appropriate band intervals were obtained, the sequence of the related region was done through service procedures.

In Silico Analysis of the Sequences

To confirm the accuracy of the sequences in the *trn*L-F regions of the eight parents taken in the study, BLAST analysis was carried out in the NCBI database. Sequences were then reset with Clustal X 2.0. To determine the genetic proximity and distance, these aligned sequences were subjected to MEGA 7.0 software to develop a genetic relationship tree. The Maximum Parsimony algorithm from the character-based methods was used and bootstrap, branch and bound analysis were done.

Results and Discussion

The average values of eight parents and 28 hybrids for analyzed traits, as well as heterosis and heterobeltiosis values of the F1 hybrids were given in *Appendix*. The parental contribution (%) to heterosis (*Table 3*), and heterobeltiosis (*Table 4*) were calculated. The error mean square values of these examined traits and a variation analysis are given in *Table 5*. Considerable differences for all traits were observed between the F1s and their parents. The average plant length of the parents and hybrids were measured as 29.04 cm and 29.57 cm, respectively (*Appendix*). The maximum heterosis value (9.60%) occurred in the 5 x 8 (Bozova Mrkz x Şanlurfa Mrkz) hybrids (*Appendix*), and the highest heterobeltiosis value

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_779796

(0.61 %) was observed in the 3 x 8 (Halfeti-1 x Şanlıurfa Mrkz.) hybrids for plant length (*Appendix*). An average of 3.29% heterosis in hybrids and -23.12% of heterobeltiosis shows the heterotic effects in the material used for the plant length. The parent with the highest contribution (6.52%) to the heterosis in plant length was Sanlıurfa Mrkz, followed by the Halfeti-1 genotype (4.07%). The lowest contribution for plant length was from Konak genotype (0.46%) (*Table 3*). The highest stem diameter was measured from Sanlıurfa Mrkz with 22.8 mm, and the lowest was 15.8 mm from Bozova Mrkz. The stem diameter average of the parents and the hybrids were found as 19.54 and 19.82 mm, respectively (*Appendix*). In terms of stem diameter, while the highest heterosis (9.13%) was obtained from the Halfeti-2 x Bozova (4 x 5) hybrid, and the highest heterobeltiosis value (5.08%) was from the Halfeti-1 x Şanlıurfa Mrkz (3x8) hybrid; the lowest heterosis (-4.51%) was seen in the Halfeti-1 x Yaslıca (3 x 6), and the lowest heterobeltiosis (-47.59%) was from Yaslıca x Şanlıurfa Mrkz (6 x 8) hybrids (*Appendix*). While Bozova Mrkz parent had the highest contribution to heterosis (5.61%) (*Table 3*) with a value of -6.31 %, the Halfeti-1 parent had the highest contribution to heterobeltiosis (*Table 4*). Plant width-spread was determined as 141.95 cm for parents and 146.31 cm for F1 hybrids, and the highest heterosis value (16.18 cm) was from the Tutluca-2 x Şanlıurfa Mrkz hybrid (*Appendix*). The lowest heterosis (8.03%) was obtained from Halfeti-1 x Halfeti-2 (3 x 4) hybrid combination (*Appendix*). According to heterobeltiosis values, the highest and lowest values were obtained as 5.62% from the Halfeti-1 x Şanlıurfa Mrkz (3 x 8) and -37.66% from the Tutluca-2 x Bozova Mrkz (2 x 5) hybrids (*Appendix*). When the parental contribution to heterosis and heterobeltiosis are analyzed for plant width-spread, it is understood that the Şanlıurfa Mrkz parent gives the highest contribution to heterosis and heterobeltiosis with (12.43%, -2.08%) (*Table 3* and *Table 4*). The average number of leaves for the parents was 47.21 pieces/plant, while for hybrids 50.03 pieces/plant; with a value of 19.13 pieces/plant Şanlıurfa Mrkz parent (number 8) having the highest heterosis value, and the lowest heterosis value (-7.05%), belonged to the Halfeti-1 x Yaslıca hybrid (*Appendix*). The highest contributions for number of leaves to heterosis and heterobeltiosis were 10.44 % and -8.28 from the Şanlıurfa Mrkz, and from Yaslıca parents with a 2.71% heterosis value, and Bozova Mrkz parent with a -31.81% heterobeltiosis value takes the last place in the order (*Table 3* and *Table 4*). According to 50% female flowering time, the parental average is 27.86 days; and hybrids average is 28.37 days (*Appendix*). The heterosis values for 50% female flowering time is given in *Appendix*. As reported in the *Appendix*, for 50% flowering time, the highest heterosis value (19.21%) belongs to the Tutluca-1 x Halfeti-1 hybrid (1x3) and the lowest heterosis value (-21.25%) belongs to the Halfeti-1 x Şanlıurfa Mrkz (3 x 8) hybrid. When the contribution of parents to heterosis (*Table 3*) and heterobeltiosis (*Table 4*) were examined for the 50% female flowering time trait, it was seen that the highest contribution to heterosis (5.28%) was from the Halfeti-2; the lowest contribution to heterosis (-4.9%) was from the Şanlıurfa Mrkz, and the highest contribution margin to heterobeltiosis (-10.63%) belongs to the Tutluca-2 parents. The lowest contribution to heterobeltiosis (-29.02%) was again from the Şanlıurfa Mrkz genotype. When stem length data were examined, the average of the hybrids (34.74 cm) was higher than that of the parents (32.43 cm). Among the parents the highest value (36.7 cm) belongs to the Bozova Mrkz. On the other hand, among

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_779796

hybrids, the highest average value (40.99 cm) was from the Tutluca-1 x Yaslıca (1 x 6) hybrid (*Appendix*). It was found that the heterosis value of the 4 x 8 hybrid (26.78 %) was the highest, and 3 x 4 hybrid was the lowest (-22.62%) (*Appendix*). In terms of the parental contribution to heterosis according to stem length, the Şanlıurfa Mrkz parents' value (19.64%) was the highest, Bozova Mrkz parents' value (-1.19%) was the lowest (*Table 3*). When yield value, which is one of the most important traits when developing a cultivar, is examined, it was concluded that the differences between parents and hybrids are much more distinctive. When parents and hybrids were examined for yield, the average was 1876.02 kg for the hybrids, and was 1636.25 kg for the parents. The highest yield for the parents belonged to the Sanlıurfa Mrkz. (2600 kg), and to a hybrid obtained from Konak x Şanlıurfa Mrkz (7x8) (3233.41 kg) (*Appendix*). When heterosis values were analyses for yield, the Bozova Mrkz x Şanlıurfa Mrkz (5x8) hybrid had the highest heterosis value (32,67 %), whereas the lowest heterosis (-13,17 %) was observed from the Halfeti-1 x Bozova Mrkz (3x5) hybrid (*Appendix*). The highest heterobeltiosis value (24.36%) was obtained from the Konak x Şanlıurfa Mrkz hybrid, and the lowest (-67.20%) was from the Tutluca-1 x Tutluca-2 hybrid (*Appendix*). When the contribution of the parents to heterosis and heterobeltiosis were examined, the highest contribution (27.15% and 0.18%, respectively) was obtained from Şanlıurfa Mrkz parent, and the lowest values were from Halfeti-1 (5.25%) and Tutluca-1 (-44.86%) parents (*Table 3* and *Table 5*).

For all the traits analyzed for heterosis in this study, the best results were observed from Şanlıurfa Mrkz genotype, except 50% flowering time, in which this parent was ranked last (*Table 3*). When the data was examined for the average of the hybrids, the Halfeti-1 x Şanlıurfa Mrkz (3x8) hybrid was recorded as having the highest values for plant length, stem diameter and plant width-spread traits, this hybrid had the lowest value for only 50% flowering time (*Appendix*). Tutluca-1 x Tutluca-2 (1x2) hybrid had the highest value for the leaf number (number/plant). While Tutluca-1 x Yaslıca (1x6) hybrid average was the highest for stem length (cm), and the Konak x Şanlıurfa Mrkz (7x8) hybrid had the highest yield average in their group. When the heterosis values were analyzed for all traits, it was concluded that heterotic influence was quite effective and for each trait, different hybrids presented their heterotic differences with varied values (*Appendix*, *Tables 3-4*).

The hybrids range in a wide interval in terms of their heterosis values (*Appendix*). When the data was examined, the hybrids had a plant length average between -3.98 (1x7) and 9.6 (5x8), stem diameter average between -4.51 (3x6) and 9.13 (4x5), plant width-spread values between -8.03 (3x4) and 16.18 (2x8), leaf number averages between -7.05 (3x6) and 19.13 (7x8), 50% female flowering time averages between -21.25 (3x8) and 19.21 (1x3), stem length averages between -22.62 (3x4) and 26.78 cm (4x8), and yield average values between -13.17 (3x5) and 32.67 (5x8). These values were caused by the heterotic differences between the parents used in this study.

A high statistical significance of 1% among all the traits except stem diameter was obtained (*Appendix*). The error mean squares of the analyzed traits were significant and it highlights the existence of a wide variation among the materials tested (*Table 5*).

When heterosis and heterobeltiosis values for yield traits were analyzed according to phylogenetic tree (*Fig. 2*), the Bozova Mrkz and Şanlıurfa Mrkz parents, which composed the Bozova Mrkz x Şanlıurfa Mrkz hybrid with the highest heterosis value are the members of two different groups; while the parents of the hybrid with the lowest heterosis value (Halfeti1 x Bozova Mrkz) belongs to same group of parents, and similarities between them are closer to each other. It was determined that the hybrids composed of the individuals that are phylogenetically farther from each other had higher yield values. Konak x Şanlıurfa Mrkz, which had the highest heterobeltiosis values, belonged to different groups, while the Tutluca1 x Tutluca2 hybrid had the lowest value, were the farthest members in the phylogenetic tree, but genetically, the fruits of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_779796

both parents were small, and their contribution to the heterobeltiosis value was not sufficient.

When the literature was searched concerning our topic, it was seen that there are very few studies with regards to determining the heterotic characteristics in summer squash. Helmy (1993) identified the highest positive heterosis contribution for total fruit number and fruit weight per plant by evaluating 15 hybrids and parents in his study with six inbred agoor lines (*Cucumis melo var. chata*, L.) El-Adl et al. (1996) reported parallel results with our study by identifying a positive influence of heterosis contribution on yield. Pradip et al. (2013) conducted a study on the yield and antioxidant contents of 28 Luffa *acutangula* (Roxb.) L. genotypes (7 of them were parents), and reported that genetic variability was quite effective on heterosis and on general and specific combining abilities, similar to our study. Iathet and Piluek (2006) reported that the number of fruit and yield per plant in melons had high heterosis values (0.61 and 0.60, respectively) due to genetic differences; and they found high correlation between number of fruits and yield per plant. It was found by López-Sesé and Staub (2002) that the effect of combining ability on yield and its components continued for many years. According to Feyzian et al. (2009) while dominant genes are effective on high yield, the effect of new genes obtained by hybridization on the average weight of fruit was quite high too. The transfer of superior genes by hybridization (addition) increases starch content and especially seed production (in pumpkin) by repeated hybridization reported by Sanin et al. (2014) recently. The effect of agglutinative and non-agglutinative genes against the resistance to parthenocarpy and water melon mosaic virus was significant in summer squash (Douglas et al., 2011). In a study conducted with 28 *Luffa acutangula* (Roxb.) L. genotypes, very high level of genetic variation was found; the general and specific combining ability values were quite important for yield and antioxidants (ascorbic acid, total carotenoid and total phenolics), and a high mean square value for the parents and hybrids were reported (Pradip et al., 2013). Pradip et al.'s study (2013) shows similarities to our study regarding square means. In the melon study by Iathet and Piluek (2006), it was determined that number of fruit per plant and plant productivity/yield was highly genetic, and there was a high and positive correlation between the number of fruit per plant and plant yield. In a study with cucumber in the gourd family, it was recorded that the number of fruit per plant and plant yield was mostly under genetic control, while with the maximum genetic difference, the plant yield increases when number of fruit per plant increases (Mishra et al., 2007). Gabr (2003) and Abd El-Hadi et al. (2004) who worked on heterosis and economic implementations in squash, and Abdein (2005), Al-Ballat (2008) and Al-Araby (2010), found significant effects of heterosis on squash, as in our study. Thangamani et al. (2011), who conducted heterosis studies on 10 parents and diallel hybrids, reported that heterosis in squash had a positive effect on yield and quality. The study conducted by Jahan et al. (2012) determined a desired positive effect of heterosis on the number of fruit per plant and yield of pumpkins (*Cucurbita moschata* Duch. ex Poir). Marie et al. (2012), who reached results parallel to our study, found that heterosis had a high effect on yield, yield components and female flowering time.

In order to find the genetic similarities of eight domestic summer squash genotypes used in the study (Tutluca 1, Tutluca 2, Halfeti 1, Halfeti 2, Bozova Mrkz., Yaslıca, Konak and Şanlıurfa Mrkz.), a nucleotid series of the *trn*L-F region of chloroplast genome, which is widely used in genetic relationship studies in plants, is used. The alignment process, which is the most important of the processes carried out to determine

DOI: http://dx.doi.org/10.15666/aeer/1504_779796

the relationships between genotypes, was run through ClustalX 2.0, and results given in *Fig. 1*. When we look at the result of alignment, a sufficient polymorphism was seen between genotypes.

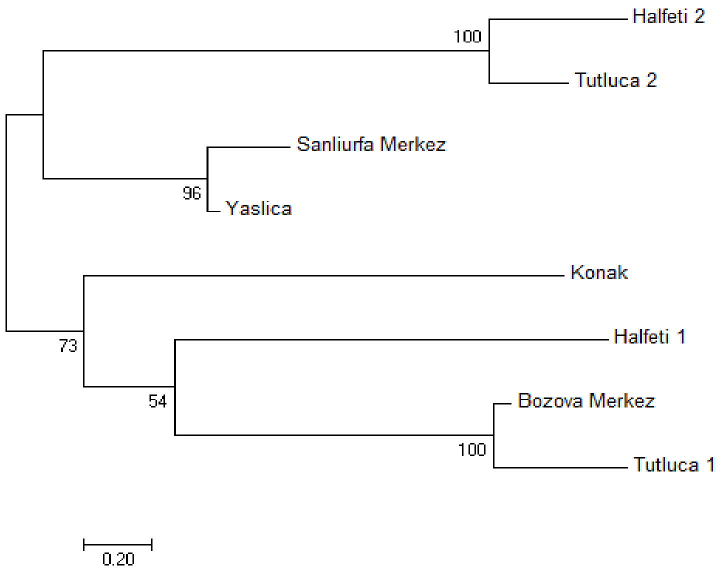

Figure 1*. The determination of the genetic relationships of the parent genotypes with the Neighbor-Joining (NJ) method (numbers on branch demonstrate the bootstrap values)*

The phylogenetic tree which was obtained with MEGA 7 (Yadav et al., 2015) software to find genetic relationships between parents was shown in *Fig. 2*. By using 500 bootstrap recurrences of the series of chloroplast *trn*L-F region, the parents were observed to be divided into two main groups (*Fig. 2*). Halfeti2, Tutluca2, Şanlıurfa Merkez and Yaslica genotypes took part in the first group. In this group, while Halfeti2 showed a close relationship with Tutluca2 with a high bootstrap value, Şanlıurfa Mrkz was also observed with almost the same level of bootstrap value and showed close relationship with the Yaslıca genotype. On the other hand, Konak, Halfeti1, Bozova Merkez, Tutluca1 genotypes took place in the second group. In this group, while Konak and Halfeti1 genotypes presented a polyphyletic situation, with a quite high bootstrap value, the Bozova Merkez and Tutluca1 genotypes were in close genetic relation and showed a monophyletic situation (*Fig. 2*).

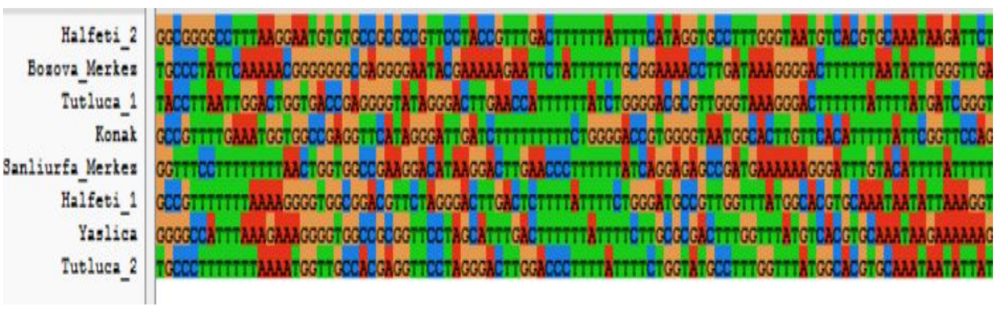

Figure 2*. A section of the series aligned with Clustal X 2.0 of parent genotypes*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_779796

To estimate the evolutionary distance between the *trn*L-F series to determine the genetic relation between parents, the Maximum Composite Likelihood model combined with MEGA 7.0 software was used (Tamura et al.**,** 2007) (*Fig. 3*). Composite likelihood algorithm provides accurate substitution parameters and can use the pairwise distances of sequences in a distance matrix that have connection with phylogenetic relationships among the sequences (*Fig. 1*). So, our result, in which base change models between series was considered, supports the topology of the phylogenetic tree in *Fig. 1*.

Figure 3*. The estimation of evolutionary distance between parents*

In conclusion, as a result of this study, in which eight parents and 28 hybrids (obtained from these parents without reciprocals) were used as materials, the heterotic effects of summer squash for yield and some agronomic traits were evaluated. The highest heterotic effects occurred in the summer squash yield characteristic. A maximum of 32.67% heterosis and 24.36% heterobeltiosis values were observed. With these results, it was concluded that the 5 x 8 (Bozova Mrkz x Şanlıurfa Mrkz) and the 4 x 8 (Halfeti-2 x Şanlıurfa Mrkz) hybrids are likely to be the most promising hybrid combinations for the traits analyzed, when we evaluated the parents according to their contribution to heterosis and heterobeltiosis. It was seen that the highest contribution in the summer squash yield was obtained from the Şanlıurfa Mrkz parent and followed by Konak and Yaslıca parents, respectively. Chloroplast DNA based phylogenetic relationships of parents supported that obtained values of heterosis and heterobeltiosis are permanent and not coincidental.

Acknowledgements. The research was financed by The GAP (Southeast Anatolia Project) Agriculture Research Institute in Sanlıurfa.

(Received 30th Apr 2017; accepted 1st Aug 2017)

Abstract. Zagros forests of Iran have been historically degraded by anthropogenic and other biotic and abiotic factors. As a result of multiple factors, seedlings and saplings establishment of Zagros oaks rarely happens and their dynamic is still unknown. Because of many difficulties to study the dynamics of oak sexual regeneration in Zagros forests, we focused on all of three Zagros oaks (*Quercus brantii* Lindl., *Q. infectoria* Oliv., and *Q. libani* Oliv.) planted in National Botanical Garden of Iran. We conducted 8 full-census inventories from the early September 2013 to the late September 2016 to monitor the trend of regeneration loss. The results showed that the 77.7%, 87%, and 89.8% of the total produced acorns in *Q. brantii*, *Q. infectoria* and *Q. libani* are demolished prior to germination and establishment in forest floor, respectively. Besides, only 4.4%, 3.2%, and 2.1% of produced acorns have the chance to become three-year saplings in the studied species. The results confirm the important role of wildlife in consumption of acorns and the variety in survival trends of saplings among the studied oak species. Study of sapling establishment in longer period and to conduct similar researches on other native oak species of Iran could be suggested for future studies.
Keywords: *acorn, monitoring, sapling, seedling establishment, survival*

Introduction

Historically, one of the most important challenges and responsibilities of the forest managers has been to promote regeneration in forests (Nyland et al., 2016). Acorn production plays a fundamental role in the organization, dynamics and sustainability of oak forest ecosystems (Rose et al., 2012). The abundance of acorns directly affects the regeneration of oak and the abundance of acorn-consuming animal species, and indirectly affects the predators and parasites of acorn consumers (Dey, 1995; McShea and Healy, 2002; Greenberg and Warburton, 2007).

Acorn production is characterized by extreme variation among years (Sork et al., 1993; Koenig et al., 1994a; Greenberg, 2000; Steen et al., 2009; Koenig and Knops, 2014) and individual trees (Auchmoody et al., 1993; Koenig and Knops, 1998; Gea-Izquierdo et al., 2006). The size of acorn crops affects many components of the ecosystem, and both annual and individual variation in acorn production influence the regeneration and management of oak forests. Acorn production is influenced by

DOI: http://dx.doi.org/10.15666/aeer/1504_797808

weather, insects, wildlife, tree age and size, tree crown position, and the tree`s inherent capacity to produce acorns (Dey, 1995).

Many organisms consume acorns, including insects, millipedes, fungi, birds and mammals. Consumption by one or more biotic agents is often so complete that in any given year few acorns remain to germinate and develop to seedlings. Although this consumption contributes to oak regeneration failures, acorns are valuable sources of food for many birds and mammals because of their high caloric content, nourishment and availability during seasons when other food is often scarce (Johnson et al., 2009). The term dispersal is used to refer to the transport of acorns from their place of origin (i.e. tree crowns or the forest floor) to other locations. Birds and mammals are the most important dispersers of acorns, which that nearly consume all the acorns they disperse, thus clearly causing some degree of loss to potential seedling establishment. Dispersers may also consume significant quantities of acorns at their place of origin. If proportionately few acorns are consumed by a disperser, dispersal may be advantageous to the oak if acorns are dispersed in significant number to habitats that are favorable for seedling establishment (Johnson et al., 2009).

Rodents, together with other animals, often consume most of the acorn crop following their fall. Thus, establishment of oak seedlings occur primarily in years when the amount of sound acorns exceeds the demand for acorns by insects and wildlife (Christisen and Kearby, 1984). Production of sound acorns exceeds this level only during years with good to bumper acorn crops (Beck, 1977).

Factors influencing early survival and growth of seedling beneath a stand may be very different from those determining growth of saplings. Initial survival and early growth of oak seedlings are primarily dependent on stored food reserves in the acorns. Light is a dominant environmental factor limiting seedling establishment and soil moisture may also limit establishment. Oak seedlings begin spring growth, when both light and soil moisture conditions are favorable (Johnson et al., 2009). Oaks are generally regarded as drought tolerant, whereas oak seedlings are relatively shade-intolerant. Under closed and dense canopies, oak seedlings cannot survive long (Crunkilton et al., 1992).

Quercus sp. is the most frequent genus of Fagaceae in forests of Iran (Sabeti, 2016). Oaks are the most prevalent forest types in Iran and dominate most of the Zagros landscape. Zagros forests are the most important and sensitive forest ecosystems of Iran with an area of about 6 million ha (Pourhashemi et al., 2004; Sagheb Talebi et al., 2014). Various factors such as traditional overutilization from timber and non-timber products, forest land conversion to agricultural lands, overgrazing, and road and dam constructions, have contributed to the degradation of these forests. Besides, many individual oaks are affected by decline phenomenon during the last decade. In this situation, oaks produce acorns, but seedlings and saplings are rarely established on the forest floor (Sagheb Talebi et al., 2014). All in all, the study of sexual regeneration dynamic of Zagros oaks is impossible because of degradation factors.

Although dynamics of acorn production have been studied in various researches worldwide (e.g. Koenig et al., 1994b; Greenberg, 2000; Abrahamson and Layne, 2003; Perez-Izquierdo and Pulido, 2013), a few researchers (e.g. Panahi et al., 2009; Pourhashemi et al., 2013, 2015) published studies on native oaks of Zagros region in Iran. Furthermore, there is no research on sexual regeneration dynamics of Zagros native oaks.

During the past three decades, native oak species of Zagros forests are planted in National Botanical Garden of Iran (NBGI), for ex situ conservation. With an area of about 150 ha, the NBGI is the most important and the largest botanical garden in Iran. Today, oak species are one of the most important elements of the NBGI which are distributed throughout the garden, mainly within the Zagros collection. The mature oak individuals normally produce acorns and regenerate sexually. This garden can be considered as the unique place of Iran in which there is potential form of oak sexual regeneration. Our study of sexual regeneration dynamics has been partly enabled due to the fact that the oak collection of NBGI is protected from destruction of acorns by livestock or harvesting by humans.

Material and methods

Study area

The study was conducted at NBGI (35˚41´ N, 51˚19´ E) from 2013 to 2016. The garden was founded in 1968 in the vicinity of Tehran at an altitude of about 1320 m. The terrain is flat and slopes gently to the south. The climate is dry with an average annual precipitation of about 257 mm falling between November and May. Temperature reaches as much as 42-43ºC during July and August. During winter the temperature may fall to -10ºC or lower. The garden consists of different native and exotic collections such as Alborz, Himalayan and Rock garden (*Fig. 1a*).The Zagros collection is one of the most important forest collections of the garden that covers an area of ca. 3 ha. Most of the oak trees are found in these collections (*Fig. 1b*).

DOI: http://dx.doi.org/10.15666/aeer/1504_797808

The studied species

All of three main oak species of Zagros forests planted in NBGI were considered for this study, including Lebanon oak (*Q. libani* Oliv.), Aleppo oak (*Q. infectoria* Oliv.) and Brant`s oak (*Q. brantii* Lindl.). The studied oaks naturally grow in Zagros forests. *Quercus libani* is only widespread in northern Zagros (West Azerbaijan and Kurdistan provinces), while *Q. infectoria* is widely distributed in West Azerbaijan, Kurdistan, Kermanshah and Lorestan provinces. Compared to Lebanon oak, Brant`s oak is usually found on northern slopes as well but at lower elevations. *Quercus brantii* is more resilient and tolerant than the other two oak species and its geographic distribution is not limited by elevation or aspect, thus it is found at various aspects and elevations. It occurs throughout the Zagros forests, mainly in the southern and central areas (Sagheb Talebi et al., 2014).

Sampling procedure

After initial garden survey, 5 sample trees were selected for each oak species in flat areas. The selected trees were larger than 15 cm in diameter at breast height (DBH), and dominant in crown position. Furthermore, the crown of adjacent trees had no contact. Two full callipering were done in the first year of the research. In the first callipering, the number of acorns per tree was determined by crown count method (Gysel, 1956) in early September, just prior to acorn fall. The counted acorns considered as potential of the sample oak trees. To standardize comparisons among different sized trees and simplify the usage by forest management, the numbers of acorns per tree were converted to the number per m^2 crown area per tree (acorn density) by dividing the total acorn production of each tree by its crown area (Christisen and Kearby, 1984; Rose et al., 2012). The second full callipering was conducted in late December after full acorn fall and included counting the numbers of acorns beneath the sample tree crowns. The difference of acorn number between the two inventories indicates the portion of acorns which have been consumed by animals directly from the trees.

In the second year of the research, two other full callipering (termed as third and fourth inventories) were carried out in the first (early May) and the end (late September) of the growing season, in which all of the established seedlings under the sample tree crowns were counted. The differences of acorns and seedlings number between second and third inventories indicate portion of the acorns that could pass the winter and transform to the seedlings in the next spring. The differences of seedlings between the beginning and the end of growing season show the portion of seedlings that could pass the summer. The same inventory procedure was done in the third and fourth years of the study to determine the losses of 2-year and three-year saplings.

Statistical analysis

The rate of survival was initially calculated for each species. For comparing the losses of different inventory stages, the numbers of acorns, seedlings and saplings were converted to percent. Normal distribution of variables was assessed by test of Shapiro-Wilk test ($p < 0.01$) and the homogeneity of variances was assessed by Levene test. The acorn density was natural-log transformed for ANOVA to reduce the correlation between the mean and variance (Sakal and Rohlf, 2012). The differences of acorn, seedling and sapling abundances in each species were tested by non-parametric

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_797808

Kruskal- Wallis test. In addition, pairwise comparison was done by Mann- Whitney U test. Statistical significance was reported at the p < 0.05 level unless otherwise stated.

Results

Detailed quantitative characteristics of sample trees are summarized in *Table 1*. Based on one-way ANOVA analysis, there was no significance difference among the studied species regarding to acorn density (df = 2, p < 0.061, F = 3.568). The numbers of acorns produced by sample trees are shown in *Fig. 2*.

Table 1. *Quantitative characteristics of sample trees*

Variable	*Q. brantii*		*Q. infectoria*		*Q. libani*	
	Mean	**Range**	**Mean**	**Range**	**Mean**	**Range**
Diameter at breast height (cm)	27.6	21-34	27	22-34	23.6	19-27
Crown area (m^2)	33.9	26.9-41.3	27.5	20.4-36.3	23.3	15.5-30.7
Number of acorns per tree	758.4	228-2020	1597.4	700-3032	801.8	204-1453
Number of acorns per m^2 crown	21	7.6-51	63.4	30.6-148.5	34	9.1-65.9

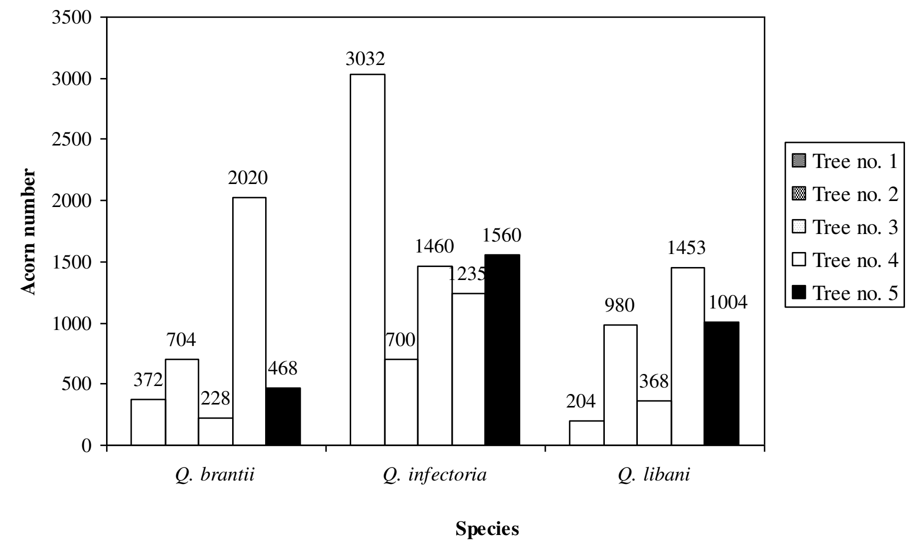

Figure 2. *Number of acorns of the studied oak species*

Losses of sexual regeneration from acorn to three-year saplings for each species are shown in *Fig. 3*. Totally, three main trends were observed as follows:

- Some individual trees produced large number of acorns (more than 1500) and the losses were moderately sever or sever. The losses of these individual trees were more than 90 percent (e.g. tree no. 4 in all three studied oak species and tree no. 1 in *Q. infectoria*).
- Some individuals produced moderate number of acorns (between 500 to 1500) and the losses were moderate, too (e.g. trees no. 2 in both of *Q. brantii* and *Q. infectoria* and trees no. 2 and 5 in *Q. libani*).
- Some individuals produced low number of acorns (less than 500) and the losses were moderate (e.g. trees no. 1 and 3 in both of *Q. brantii* and *Q. libani*).

APPLIED ECOLOGY AND ENVIRONMENTAL RESEARCH 15(4):797-808.
http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_797808

There were some considerable cases among the sample trees. For instance, the acorn production potential of tree no. 1 in *Q. infectoria* was remarkably more than the others due to its 3032 produced acorns. Another exceptional case was observed in tree no. 5 in *Q. libani*. While it produced 1004 acorns, no established seedlings were observed beneath its crown.

Survival percentage showed no significance difference among studied species (χ^2 = 0.384; p = 0.825) and among same inventory stages (*Fig. 4*). In other words, the three studied oaks had similar rates of loss in same inventory stages, but the differences among inventory stages in each species was significant (*Q. brantii*: df = 6, χ^2 = 19.49, p = 0.002; *Q. infectoria*: df = 6, χ^2 = 21.216, p = 0.001; *Q. libani*: df = 6, χ^2 = 21.997, p = 0.001).

DOI: http://dx.doi.org/10.15666/aeer/1504_797808

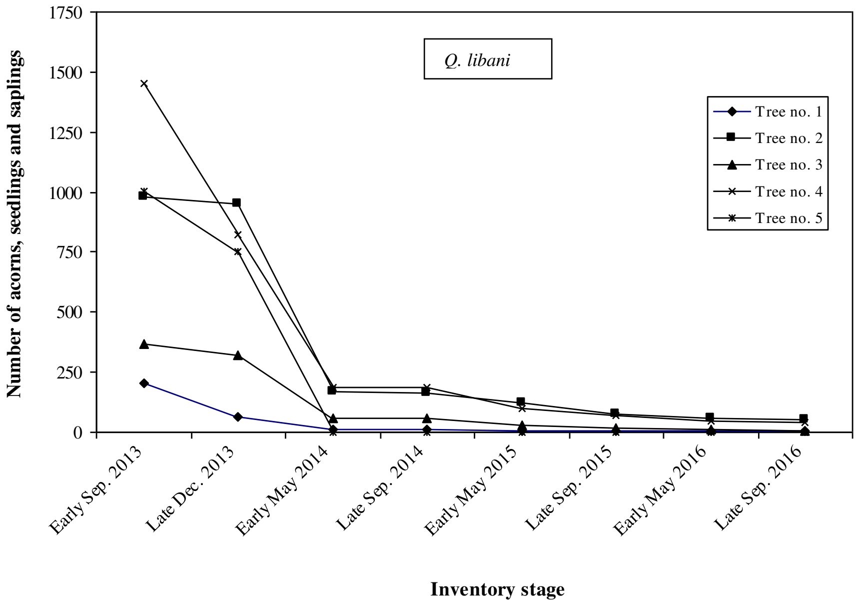

Figure 3. *The proportion of the studied oak acorns that produce seedlings and saplings*

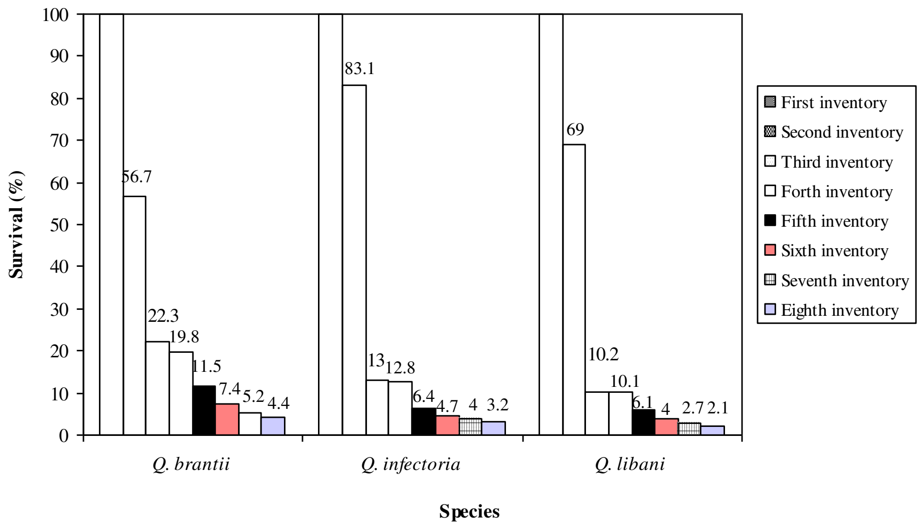

Figure 4. *The survival (percent) from acorn to three-year sapling in the studied species (results of the inventory stages comparison: First inventory: df = 2, $\chi^2 = 0$, p = 1; second inventory: df = 2, $\chi^2 = 2$, p = 0.368; third inventory: df = 2, $\chi^2 = 0.62$, p = 0.733; forth inventory: df = 2, $\chi^2 = 0.62$, p = 0.733; fifth inventory: df = 2, $\chi^2 = 0.26$, p = 0.787; sixth inventory: df = 2, $\chi^2 = 0.32$, p = 0.852; seventh inventory: df = 2, $\chi^2 = 0.28$, p = 0.82; eighth inventory: df = 2, $\chi^2 = 0.22$, p = 0.832)*

Based on the pairwise comparison of the losses in inventory stages, significant difference was observed after the second inventory stage in *Q. brantii*. However, the same condition did not hold true after the third inventory stage in *Q. infectoria* and *Q. libani* (*Figs. 5, 6*).

Discussion

Our results confirm that acorn production significantly vary from tree-to-tree for each oak species. Some researchers have emphasized this variation in oaks (e.g. Greenberg, 2000; Rose et al., 2012; Koenig and Knops, 2014). All our sample trees were similar regarding to the DBH, crown area, crown position, and environmental factors. Therefore, the differences of acorn production among studied species can be attributed to inherent characteristics of the trees. Although the tree no. 4 in *Q. infectoria* showed a high rate of acorn production, it was difficult to consider it as an inherently

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_797808

good producer without long-term monitoring of acorn production. On the other hand, the two-year maturation of acorns in *Q. libani* and *Q. brantii* (Djavanchir Khoie, 1967) might have been affected by the climatic factors during the year before the first year of the study.

The average number of acorns in *Q. brantii*, *Q. infectoria* and *Q. libani* were 21, 63.4 and 34, respectively. In a same research in the NBGI, mean values of acorn production were 46.5, 52.4, and 31 in 2006 (Panahi et al., 2009). The differences of acorn production between 2006 and 2013 confirm the year-to-year variability of acorn production in the same species, which had been the subject of a number of studies (e.g. Steen et al., 2009; Koenig and Knops, 2014). One may also note that the number of sample trees and their quantitative variables could affect the average number of produced acorn.

Losses of acorn production due to insects, birds and mammals can be very high. Although the role of insects is very important in destroying the acorns, no damages were observed in the studied oak species in the NBGI, which is obviously due to the conservation status of the garden. About 10-25% of acorns are taken directly from the trees by animals such as birds and squirrels (Beck, 1977; Myers, 1978). Our results showed the remarkable rate of consumption of acorns by rodents especially squirrels, and birds especially crows, woodpeckers, and rabbits. The maximum consumption of acorns directly from the trees occurred in *Q. brantii* (43.3% of the total produced acorns), while the values for *Q. infectoria* and *Q. libani* were 17.1% and 31%, respectively. Totally, the portion of acorns taken directly from the trees was more than the average global range of 10-25%. Of course the bigger size of acorns in *Q. brantii* and *Q. libani* in comparison with *Q. infectoria* (Djavanchir Khoie, 1967) can be further reason for higher consumption rate. It is not clear whether seedling establishment is positively related to acorn size (Sork, 1993; Díaz et al., 2003). The role of acorn size is controversial: bigger acorns are preferably consumed by predators (Gómez, 2004), which might hamper regeneration. On the other hand, seedlings from bigger acorns are associated with an average higher number of leaves and leaf area (Díaz et al., 2003), which might be an advantage for young seedlings.

As a general rule of overwintering, acorns require protection from desiccation, low temperatures and predation by insects, rodents and other animals (Johnson et al., 2009). The same applied for the losses of acorns from early September 2013 to late December 2013, as the proportion of acorns consumed by wildlife from ground surface during winter was high (34.4%, 70.1%, and 58.8% of the total produced acorns in *Q. brantii*, *Q. infectoria* and *Q. libani*, respectively; *Fig. 4*). Obviously a minor portion of this loss could be related to the low viability of acorns in the studied species. High rate of acorn consumption by wildlife in the garden, both directly from the crown and from forest floor, indicate their important role in sexual regeneration chain of oaks. Totally, 77.7%, 87%, and 89.8% of total produced acorns were destroyed prior to the spring of 2014 in *Q. brantii*, *Q. infectoria* and *Q. libani*, respectively (*Fig. 4*). In *Q. brantii*, significant difference amongst losses was observed in the interval between the first and second inventory stages (*Fig. 6*), but the situation was a little different in *Q. infectoria* and *Q. libani*. Furthermore, in these species the losses were significantly different during winter after acorn fall. The loss trends for all of the studied species decreased after the third inventory stage (*Fig. 4*).

Based on our garden surveys, the canopy was closed with minor gaps, though the crowns of the studied oak trees had no overlap or contact. On the other hand, soil

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_797808

moisture in the garden cannot be considered as a limiting factor because of the irrigation of the garden during dry seasons. It seems that the role of light is very important in germination and early growth of acorns in the garden.

Our results showed that the mortality rate of saplings in *Q. libani* was higher (81.7%) than the others (74.5% in *Q. brantii* and 74.9% in *Q. infectoria*). Excessive shade and competition are the most important reasons for the slow growth and mortality of saplings. The ability to persist under shade appears to vary among oak species (Lormier, 1992), which was also confirmed by our results.

Conclusion

This study mainly confirms the role of botanical gardens as appropriate sites for studying subjects that are impossible to be studied elsewhere. Besides, absence of degradation factors parallel with conservation of oak species provides an ideal condition to study the potential of trees. As previously mentioned, due to multiple reasons it is not possible to study the sexual regeneration dynamics of oak species in natural Zagros forests of Iran, including traditional utilization of acorns by forest residents, livestock grazing, and rain-fed agriculture underneath the trees. Finally, study on annual variation of acorn production, the effect of different factors on acorn production, and advantages and disadvantages of rodents and birds (as the most important acorn consumers) are the main motivations for further research.

(Received 13th May 2017; accepted 2nd Aug 2017)

Abstract. The rapid economic development resulting from Chinese economic reform has greatly accelerated urbanization and industrialization, thus leading to alterations in the natural landscape. Understanding the extent of these changes is important for regional sustainable land management. An integrated approach with a geographic information system and remote sensing was used to extract land use/land cover (LULC) change information for the Su-Xi-Chang region over the period of 1980 to 2010. To calculate the dimensions of fragmentation and to observe changes in spatial patterns, FRAGSTATS was used. Major drivers were determined through bivariate statistical analysis of socioeconomic data sources. Three change matrices were constructed for detecting LULC changes from 1980 to 1990, 1990 to 2000, and 2000 to 2010. In the study period, farmland, water bodies and wetlands significantly decreased. However, construction land, grassland and woodlands increased considerably. The pattern and composition of the landscape exhibited significant fragmentation for the whole area. Socioeconomic analysis showed that population growth and economic development, urbanization and subsequent construction land expansion, and industrialization were the major socioeconomic drivers of LULC changes. Changes in farmland resulted in decreases in area and production that might impair ecological functions and decrease food production. Therefore, better land use policy would address the consequences of the loss of the natural landscape due to drastic socioeconomic drivers in the region. Further research along these lines should be encouraged, because additional studies will be helpful for the decision makers engaged in planning activities at various levels.
Keywords: *GIS, temporal changes, landscape ecology, urbanization, landscape pattern*

Introduction

A wide range of drivers associated with social, biophysical, environmental, economic and technological factors lead to land use/land cover (LULC) changes in different parts of the world (Beilin et al., 2014; Tian, 2015). The drivers of these changes may be well known, such as demographic change (Salvati et al., 2017), industrial development (Li et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_809827

al., 2010), agricultural expansion (Kibret et al., 2016), urbanization (Deng et al., 2015; Xian and Crane, 2005), global market forces (Temesgen et al., 2013), and climatological change, such as drought and rainfall variability (Amuti and Luo, 2014; Biazin and Sterk, 2013; Luo and Zhang, 2014; Román-Cuesta et al., 2014), or they may also involve interactions of institutional or cultural impacts (Kindu et al., 2015; Sakayarote and Shrestha, 2017). These drivers have triggered drastic LULC conversions by substituting one type of LULC with another. Through these processes, the pattern, structure and function of the natural landscape are inevitably altered (Lambin et al., 2001), thus consequently influencing the global environment (Amuti and Luo, 2014). Particularly, the socioeconomic drivers are more intense than the physical drivers of these processes (Desalegn et al., 2014). Understanding these factors is vital for forecasting future LULC dynamics by using models (Lambin et al., 2001) or for the design of management strategies and policies for the sustainable management of land resources (Mottet et al., 2006; Turner et al., 1993).

Since the launch of economic reform and the opening-up policy in the late 1970s in China, LULC changes have rapidly taken place, and land use patterns are quite spatially variable throughout the country (Hua et al., 2010; Wei and Ye, 2009). Particularly since the beginning of the 21st century, the rapid socioeconomic development has resulted in remarkable changes in the spatio-temporal distributions of LULC and has adversely affected the natural environment (Deng et al., 2015; Yirsaw et al., 2016). However, because of the diversified and complex driving forces in the country, there are substantial arguments about the extent and magnitude of changes in LULC (Xu, 2004). Previous studies have revealed different findings on LULC change drivers in different regions of the country. For instance, Wang et al. (2011) have suggested the expansion of residential areas to cause LULC changes at the expense of agricultural land in northeastern China. Long et al. (2009) have proposed that rapid economic developments are major drivers for the process. Li et al. (2010) have claimed that in the eastern fringe of the Tibetan Plateau of China, the changes have occurred because of climate change and human activities. Kuang et al. (2016) have suggested that the expansion of industrialization is an important factor in LULC change in eastern China. Other studies have indicated that land policy is a major influential driver in LULC changes (Liu et al., 2010b).

Though substantial efforts have been made to identify factors driving LULC changes in different parts of the country, those research findings have revealed that the drivers vary from place to place depending on location-specific factors. Moreover, there is significant disagreement regarding the extent of influence by these drivers of changes, thus making generalizations nearly impossible (Li and Yeh, 2004; Wu et al., 2013). Therefore, any intervention to address drivers of change for sustainable land management must begin with locally specific understanding of the different drivers affecting the LULC. This requirement is especially true for the Su-Xi-Chang region of eastern coastal China, which has a fragile environment where substantial LULC changes have occurred. In the Su-Xi-Chang region, as stated by Zhou et al. (2014), owing to economic development, different conflicts, such as the conflict between land resources and demand for development versus the vulnerability of the coastal area, have arisen. Moreover, Xie et al. (2007) have suggested that both the existence of rapid economic development and the loose and neglected control of land use have put the LULC management of the region at risk. Thus, it is crucial to determine the dynamics of LULC and the main socioeconomic drivers of the change in this fragile environment. This

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_809827

information would facilitate measures to arrest and reverse the situation of LULC changes in the region and would improve understanding of the influence of socioeconomic drivers on LULC changes.

Considering these factors, this paper was designed with the following objectives: (1) to characterize land use dynamics and patterns of LULC change across the study area over the past three decades; (2) to determine the major socioeconomic drivers in periods from 1980 to 2010; and (3) to assess the relationship between LULC changes and the major socioeconomic drivers.

Materials and Methods

Study area

Encompassing three municipalities, Suzhou, Wuxi and Changzhou, the Su-Xi-Chang region is located in the Jiangsu Province ($36^0$46’ – $32^0$04’N, $119^0$08’–$121^0$15’E) in the middle of the Yangtze River Delta Economic zone of east China. It covers a total area of 1.7×10^4 km^2, with an average elevation below 50 meters (*Fig. 1*). The area has a monsoon climate with a mean annual temperature and precipitation of 15.3^0C and 1,092 mm, respectively (Long et al., 2009).

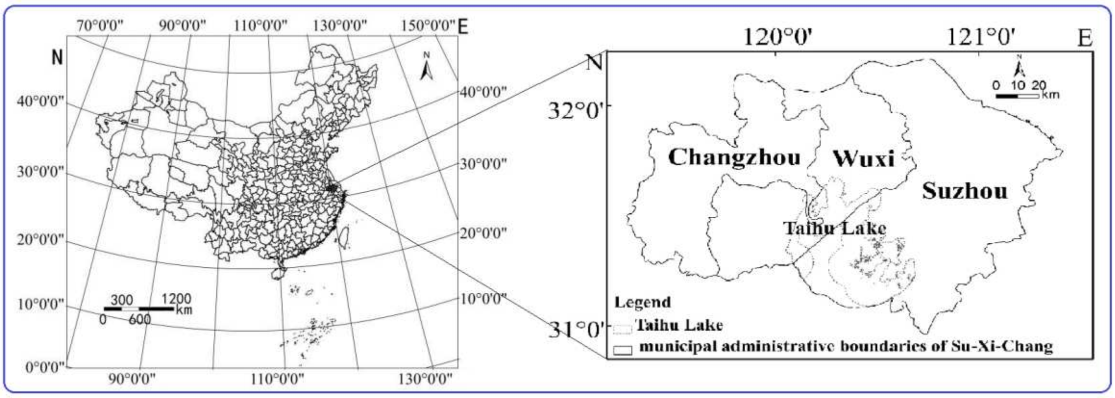

Figure 1. *Location of the study area*

In 2014, the region had a total population of 14.55 million (838/km^2), which was more than 6 times the total population per km^2 (135.5/km^2) of the country in the same year. Similarly, the GDP per capita of the Su-Xi-Chang region (123,325 CNY) was three times more than the GDP per capita of the country in the same period (NBSC, 2014). From the early 1980s, the growth of Shanghai has pushed the region toward rapid urbanization and industrialization (Long et al., 2009). Unprecedented changes in the local economy have taken place in recent decades. On the grounds of diversified cooperative enterprises in the mid-1980s, the region has served as a model for the advancement of rural industrialization (Xie et al., 2007; Tan, 1986). With these changes, the Su-Xi-Chang region has confirmed its position of importance at the national level, and today, it constitutes the Key Economic Zone in Eastern China. However, with the development of economic activities, drastic changes in LULC have been occurring in the region. These changes have prompted concerns and attempts to detect and monitor

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_809827

changes in LULC and to assess the main socioeconomic drivers of the changes, in order to attain sustainable land management.

Data source and processing

For time series LULC changes analysis (1980, 1990, 2000 and 2010), the study used vectored data sets with a 30 m spatial resolution from Landsat reflectance products and the DEM of the Computer Network Information Center, Chinese Academy of Science. Additionally, administrative boundaries at the county level were used, which were provided by the Data Sharing Infrastructure of Earth System Science, Institute of Geographic Sciences and Natural Resources Research, Chinese Academy of Science. MSS and TM images were geometrically corrected using ground control points, with ETM+ images as the master and reference images. To identify the agreement in classification consistency and accuracy, effective classification was conducted by using standard procedures (Liu et al., 2005). Accordingly, as shown in *Table 1,* six land use categories were classified for the four study periods: farmland, construction land, grassland, woodland, water body, and wetland. The ESRI ArcGIS spatial analysis model was applied to measure variation within LULC types. A set of pattern metrics was identified to examine cover change spatial patterns, and FRAGSTATS was used to compute the dimension of fragmentation. In addition, a time series of socioeconomic data on population, industrial output value, agricultural production (crop yield), aquatic products, GDP, agricultural land, and construction land (settlement areas) from 1980 to 2010 was collected from local government offices and statistical year books for the region (Appendix A). These data were used to analyze the potential socioeconomic driving forces triggering LULC changes in the Su-Xi-Chang region.

Methods

Mainly on the basis of classified and gridded land use polygon themes (*Fig. 2*), internal change variations were computed between each consecutive map (from 1980 to 1990, 1990 to 2000 and 2000 to 2010). For each consecutive pair of gridded time series maps, a transition matrix was assembled (*Tables 2, 3 and 4*). Then, for each LULC category m in the transition matrix, the conversion between the two periods was computed via the GIS analysis function:

$$\Delta L_m = (r_m - r_{.m})/r_{.m} \times 100 \quad \text{(Eq.1)}$$

where ΔL_m is the change of LULC in row m, relative to the previous compared year; $r_{m.}$ is the row total of grid cells for category m; and $r_{.m}$ is the column total of grid cells for category m.

For exploring the internal conversion between different cover types, we treated the change (decrease or increase) for a cover category in a given year relative to a compared year considering various “loss or gain” conversions. Thus, for any type of “conversion loss to” or “conversion gain from”, the percentage taken by this type in the total “loss or gain” was calculated as:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_809827

$$\begin{cases} R_{loss(m)n} = \dfrac{(r_{nm} - r_{mn})}{(r_{m.} - r_{.m})} \times 100 \quad m \neq n \\ R_{gain(m)n} = \dfrac{(r_{m,n} - r_{n,m})}{(r_{m.} - r_{.m})} \times 100 \quad m \neq n \end{cases} \tag{Eq.2}$$

where $R_{loss(m)n}$ is the percentage taken by type n in the total "conversion loss" of category row m; $R_{gain(m)n}$ is the percentage taken by n in the total "conversion gain" of category row m; and r_{nm}, and r_{mn} are the individual entries in a change matrix.

Bivariate correlation statistical analysis was performed to assess the relationships between LULC changes and socioeconomic drivers (*Table 6*). Through examining the spatial change patterns, we identified a set of pattern metrics at both the class and landscape levels that capture different dimensions of land fragmentation. Parker et al. (2001) have observed the absence of a site (region) specific typical set of metrics, as a result of variations in the significance of specific metrics significance based on research objectives and study area characteristics. As indicated by (McGarigal et al., 2002), six major landscape metrics at the class level, including patch density (PD), largest patch index (LPI), number of patches (NP), landscape shape index (LSI), area-weighted mean patch fractal dimension (AWMPFD), and interspersion and juxtaposition (IJI); and six at the landscape level, including Shannon's diversity index (SHDI), number of patches (NP), largest patch index (LPI), area-weighted mean patch fractal dimension (AWMPFD), contagion index (CONTAG) and interspersion and juxtaposition (IJI), were selected for this study on the basis of our research objectives and study area characteristics. These indices were calculated using FRAGSTATS, a spatial pattern analysis program for categorical maps (*Table 5*, and *Fig. 3*).

Result and discussion

Spatial patterns of LULC dynamics

Figure 2 shows the spatial pattern of LULC changes for the years 1980, 1990, 2000 and 2010 of the study area. In 1980, farmland and water body were the dominant cover types, and the direction of urban development (collectively termed construction land) was confined to the central part of the three municipalities – Su Zhou, Wu Xi and Chang Zhou of the Su-Xi-Chang region (*Fig. 2*).

However, in 1990, construction land started to replace some of the farmland. The construction land development tended to extend further in the north and northeast directions between 1980 and 1990, when the region embarked on economic reform by developing collective enterprises at the start of the age of rapid urban and industrial development. In the 1980s, township enterprises expanded with the formation of various small towns in the region (Long et al., 2009). After 1990, construction land became more prevalent, and the pace of urbanization and industrialization was considerably accelerated. Particularly at the end of 2010, the area of construction land overtook the area of farmland (*Fig. 2*) and covered more than 29% of the studied landscape (*Table 1*). However, farmlands started to vanish at the same time, because the demand for construction land dramatically increased with socioeconomic development.

Analysis of temporal LULC changes

The general tendency of change in LULC during the thirty-year period is indicated in *Table 1*. On the basis of the land use transition matrix, the comprehensive dynamics among different LULC types is shown in *Tables 2, 3 and 4*. With 56% coverage of the study area, farmland was the dominant cover type in 1980, followed by water body

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_809827

(30%). In the same period, construction land covered only 7% of the studied landscape (*Table 1*). In 1990, farmland decreased to 53% and water body was slightly balanced (30%), and both are the dominant LULC types. However, construction land increased by 3.2% of the preceding period, covering more than 10% of the total study area during this period (*Table 1*).

From 1980 to 1990, construction land, woodland, and water body enlarged by 3.4%, 0.2%, and 4%, respectively. In contrast, farmland, grassland, and wetland decreased by 1.3%, 9.6%, and 39%, respectively (*Table 2*). In this period, farmland was the main contributor to an increase in the areas of woodland, water body, and construction land by allowing for 27%, 48%, and 79% of the increase in their total area, respectively (*Table 2*). In this period, the grain for green development policy, expansion of artificial ponds for fish production, and urban expansion were the main reasons for the large amount of farmland conversion.

Table 2. *LULC conversion matrix from 1980 to 1990 (ha)*

								Change 1990	
Land use type	FL	WOL	GL	WB	WL	CL	Sum 1990	Total	%

Grassland (GL)	396	13	1648	9	12	1	1745	-174	-9.01
Water body (WB)	9386	10	52	514,449	2830	3	516,757	1918	0.39
Wetland (WL)	1098	0	4	154	4181	13	5059	-2,094	-29.31
Construction land (CL)	44205	11	1	15	30	126477	181,790	5,513	4.35
Sum 1980	977,687	114,796	1919	514,839	7153	126659	1,744,624	-	-

From 1990 to 2000 farmland, grassland, and wetland continued decreasing by more than 6%, 8%, and 27% respectively. In addition to these three LULC categories water bodies started to decrease with more than 3% of its total area of the base year in the same period; however, woodland, and construction land expanded by 0.3%, and 42%, respectively (*Table 3*). In this period, the diminishing of farmland contributed 100%, and 5% to the expansion of construction land, and woodland, respectively (*Table 3*). In the period between 2000 and 2010, a comparable LULC change pattern was found, in which construction land continued to increase at an alarming rate, and was followed by grassland and woodland. The decreasing farmland area caused an increase in the areas of construction land, woodland, and grassland by 76%, 93%, and 100%, respectively (*Table 4*). In addition, a reduction in wetland area contributed 4% toward the expansion of construction land in the same period (*Table 4*). Thus, as lands supporting construction land expansion became scarce, wetlands the target for construction development. Our result supports the findings of Wang et al. (2011), who have found that the expansion of construction land in the West Songneu Plain of China led to the shrinking and fragmentation of swamplands. Similarly, Yuan Zhang (2010) has described the same phenomenon in the Yinchuan Plain of China.

Considering the LULC conversion matrix from 1980 to 2010, there was considerable growth in construction land over the other LULC types; remarkably, this growth far exceeded the amount of land converted from construction land to other LULC types.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_809827

The results (*Tables 2, 3 and 4*) showed that over the study period, the loss of farmland strongly contributed to the newly emerging construction land, and was followed by wetland and water bodies, respectively. Thus, driven by robust socioeconomic factors, the ongoing growth in construction land was responsible for a large decline in the farmlands, wetlands and water bodies in the region.

Analysis of landscape metrics

The overall trends of LULC fragmentation at both class (*Table 5*) and landscape (*Fig. 3*) levels were considered. The detailed descriptions of landscape metrics used in this study are given in Appendix B. As shown in *Table 5*, the landscape change for farmland and wetland at the class level indicated a consistent increase in the number of patches (NP) that enhanced the corresponding patch density during the study period. For farmland, NP increased from 357 in 1980 to 383 in 1990 and to 539 and 812 in 2000 and 2010, respectively, thus indicating that the spatial heterogeneity of this class increased with increasing disturbance over time. A similar pattern was found in the wetland category, as evidenced by increased patch density (PD) (*Table 5*). This result suggested that in recent decades, increasing human pressure has led to the fragmentation of both farmland and wetland LULC categories. The largest patch index (LPI) for both farmland and wetland showed a declining trend throughout the study period, owing to the intensification of construction land. For instance, the LPI for the wetland category

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_809827

decreased from 10.12% in 1980 to 2.04% in 2010. Likewise, the LPI for farmland decreased from 38.7% in 1980 to 27.5% in 2010 (*Table 5*). Furthermore, interspersion and juxtaposition (IJI) indicated identical configurations for both LULC types, thus indicating that the patch types of these LULC categories were more scattered.

Apart from farmland and wetland, and except for construction land, the rest of the LULC types showed irregular stability with variable values. However, as observed in the LULC change analysis (*Tables 2, 3, 4; and Fig. 2*), construction land has rapidly replaced farmland in the Su-Xi-Chang region. The NP for construction land was 10,510 in 1980, decreased to 10,252 in 1990 and increased to 10,835 in 2000, but in 2010, markedly decreased to 7641. The rapid urban development between 1990 and 2000 might have resulted in the large NP in 2000. The PD values also showed that the construction land became denser over time, a result also confirmed by its IJI values, which kept increasing, thus indicating that the construction land category has a continuous and clumped pattern.

Table 5. *Landscape metrics changes according to patch class level in the Su-Xi-Chang region*

NP = number of patches; PD = patch density; LSI = landscape shape index; LPI = largest patch index; AWMPFD = area-weighted mean patch fractal dimension; and IJI = interspersion and juxtaposition.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_809827

To designate the characteristic features of the fragmentation of LULC at the landscape level and to evaluate the extent of human pressure causing changes on landscape structure, the NP, LPI, AWMPFD, IJI, Shannon's diversity index (SHDI), and contagion index (CONTAG) were computed by using FRAGSTATS, and the results are presented in *Fig. 3*. The opposite magnitudes between LPI and NP at the landscape level (*Fig. 3a, and b*) indicated high landscape fragmentation. Thus increasing human activities in the region have caused a dispersed landscape structure. In addition, the continuously increasing value of AWMPFD indicated clear fragmentation of LULC at the landscape level (*Fig. 3c*). A continuous decline in values of SHDI indicated that the landscape was unevenly distributed and subjected to less patch types. The SHDI decreased from 1.2608 in 1980 to 1.1382 in 1990, and from 1.0377 in 2000 to 1.0352 in 2010 (*Fig. 3d*), possibly as a result of urban landscape dominance. The CONTAG value was lower in 1990 than in 1980. However, the values again became higher after 2000, thus suggesting a more contiguous and homogenous pattern. The analysis showed that the intensification of human activities in the study area has caused landscape fragmentation, thereby leading to the loss of the function of a natural landscape.

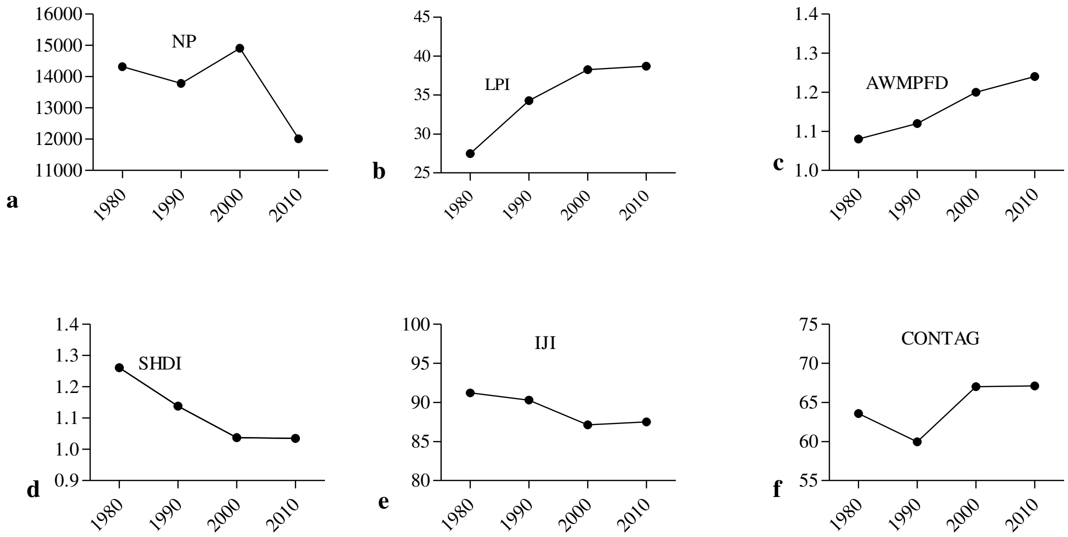

Figure 3. *Changes in number of patches (NP), largest patch index (LPI), area-weighted mean patch fractal dimension (AWMPFD), Shannon's (SHDI), interspersion and juxtaposition (IJI) and contagion index (CONTAG) at the landscape level*

Analysis of major socioeconomic drivers

Combinations of various socioeconomic factors have induced LULC changes in the Su-Xi-Chang region. *Table 6* depicts the relationships among these different socioeconomic variables and LULC changes. In addition, Appendix A shows the various socioeconomic variables considered in this study along with their detailed values over the past thirty-years. The overall results of our statistical analysis showed that over the past three decades, population growth and economic development, urbanization and subsequent construction land expansion, and rapid industrialization were the major drivers of LULC changes in the Su-Xi-Chang region.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_809827

Population growth and economic development

The total population of the Su-Xi-Chang region was approximately 11 million in 1980, and suddenly increased to 13 million within a decade in 1990, with an annual growth rate of 8.6%. In 2000, the population rose to 13.5 million, and in 2010, it reached 14.5 million. In 2014, the population reached more than 15.2 million (NBSC, 2015). After population growth, LULC changes in the region became aggravated over time (*Table 1*). Different authors, particularly those in developing countries, have suggested that increased population growth causes LULC changes (Garedew et al., 2009; Kamusoko and Aniya, 2007).

Our results showed that the relationship between the growth in population and construction land was positively correlated (r = 0.631), and the values were significantly different (P<0.05). This result suggested that the increase in population also caused the increase in construction land expansion (*Table 6*), possibly because of an increase in settlement demand, for which large parts of agricultural lands were changed to residential areas, both in rural and urban zones. This possibility was confirmed by the inverse relationship between population growth and agricultural land (*Table 6*). Furthermore, the negative correlation between these two factors may suggest the importance of population growth in the LULC changes occurring in the region. This result is consistent with findings from Priess et al. (2007) in Indonesia and Kidane et al. (2012) in Ethiopia, which have shown that increases in population growth lead to agricultural land loss. Because Su-Xi-Chang is a potential region for agricultural production, a large part of this region is still in the agricultural sector. To meet the demands of the growing population by producing high production from limited land resources, large areas of agricultural land were converted into alternative productive land use practices, such as fishponds for fish farming, as evidenced by the strong positive relationship between the growth of population and increase in aquatic products (*Table 6; Fig. 4*).

Table 6. *Correlation coefficients between different socioeconomic variables*

	Population	Industrial output	Agricultural production	Aquatic products	GDP	Agricultural land	Construction land
Population	1	.407*	-.307	.479**	.405*	-.447*	.631*
Industrial output		1	-.882**	.715**	.999**	-.979**	.976**
Agricultural production			1	-.704**	-.867**	.880**	-.905**
Aquatic products				1	.706**	-.826**	.815**
GDP					1	-.973**	.971**
Agricultural land						1	-.982**
Construction land							1

* Correlation is significant at the 0.05 level (2-tailed).
** Correlation is significant at the 0.01 level (2-tailed).

In addition to population growth, economic development showed a positive correlation (r = 0.971) with construction land, and the relationship was highly significant (P<0.01) (*Table 6*). Thus, an increase in economic development also caused an increase in

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_809827

construction land expansion. This result is in line with findings from Tang et al. (2014) in Harbin, Northeast China, which have indicated that economic development can cause LULC changes that significantly affect the functions of a natural landscape. Given the advantage of its location, being in a coastal area of the country, the economy of the Su-Xi-Chang region showed an upward trajectory (*Fig. 4a*), and currently, the region plays a vital role in the Chinese economy. This observation also accounted for the rapid expansion of urban and industrial lands that led to LULC change. Hence, our results showed that in general, the growth of the population and economic developments were the principal causal factors of changes in the LULC of the study area.

Industrialization

In the study period, industrialization in the Su-Xi-Chang region explosively increased after the rapid rise in the total industrial output value (*Fig. 4a*), which also caused major LULC changes. An all-around rapid industrialization and urbanization occurred in the region since 2000, owing to a higher consumption of land for industrialization than for urbanization. During this period, to support the manufacturing expansion, less attention was given to agricultural land. As a result, urban associated industrialization became an essential driving force of LULC changes, thereby decreasing the arable land category. Rural industrialization has been reported to contribute to construction land expansions in China (Lin and Ho, 2003). This phenomenon also occurred in the Su-Xi-Chang region, as evidenced by the strong positive correlation between construction land and the industrial output value ($r = 0.976$) with a significant difference of $P<0.01$.

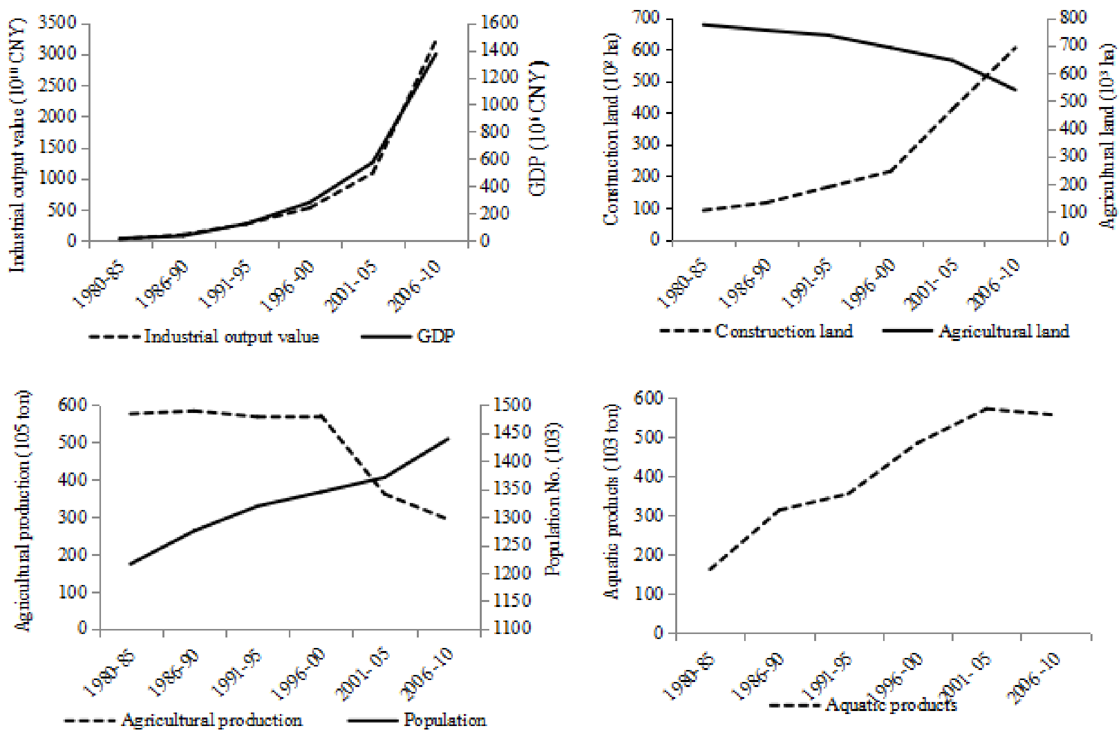

Figure 4. *Trends in different socioeconomic variables from 1980 to 2010 in the Su-Xi-Chang region*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_809827

As indicated in *Table 6*, there was a strong positive correlation between aquatic products and the industrial output value (r = 0.715) and between GDP and the industrial output value (r = 0.999), both of which exhibited significant differences (P<0.01). These findings suggested that increases in both aquatic products and GDP contributed to the increase in industrial output. This finding may have been due to an increase in the row material supply from increased aquatic products, as well as to an increase in GDP, which enhanced the output values of industries. However, the industrial output value was negatively correlated with agricultural production (r = -0.882) and agricultural land (r = -0.979), and the relationships were highly significant (P<0.01), thus indicating the effect of industrialization from the massive conversion of agricultural land into market oriented land use. Put another way, the results indicated that industrialization has cursorily caused substantial loss of agricultural land, to the benefit of market oriented farming and non-agricultural development.

In addition, owing to economic prosperity, particularly by the middle of the 1980s, the region provided a model for the development of rural industries. This model also describes when the Township and Village Enterprises (TVEs) thrived after rapid growth of the rural economy in southern Jiangsu (Long et al., 2009). Since then, the growth of TVEs and the development of an export-oriented economy have fundamentally transformed the industrial pattern of the region. As a result, the total industrial output value markedly increased (*Fig. 4a*). These manifestations played roles in LULC changes, as evidenced by the strong inverse relationship between industrial output values and the loss in agricultural land (*Table 6*).

Urbanization and subsequent construction land expansion

Rapid urbanization was stimulated after the Chinese economic reform of the 1970s, particularly around the beginning of the 1990s, and urbanization was accelerated to a great extent as the centrally planned economy shifted to a socialist market. This shift led to construction land expansion (Xu, 2004; Liu et al., 2005) and subsequently to the loss of agricultural land in China (Kuang et al., 2016). In the Su-Xi-Chang region, the area of construction land, mainly owing to urbanization, increased from 126,659 ha in 1980 to 181,790 ha in 1990, with an annual growth rate of 4.35% (*Table 1*). In 2000, it attained a total area of 258,559 ha, and in 2010, it increased by 227,536 ha more than that in the former period, in which farmland contributed 76% of the amplification (*Table 4*). These changes were evidenced by the strong inverse relationship between construction land and agricultural land (*Table 6; Fig. 4b*). In the past three decades, notably, construction land increased by 359,436 ha, amounting to 284.81% of the area in 1980, during which it covered merely 7% of the total landscape, which rose to 27.86% in 2010 (*Table 1*).

The results showed that areas of 79%, 100%, and 76% enlargement in construction land from 1980 to1990, 1990 to 2000, and 2000 to 2010, respectively, were contributed by farmland (*Tables 2, 3, and 4*). As (Liu et al., 2008) have described, this type of occupation mostly occurred in the developed areas, especially in the main grain production zone of the coastal regions, thus leading to simultaneous decreases in both the area and production of agricultural land (*Fig. 4b and c*). Particularly, the decrease in production occurred because the productive lands occupied by construction land and crop cultivation were forced to be located in less productive areas. This scenario can be seen in *Table 6*, which shows the negative relationship between agricultural production

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_809827

and construction land (r = -0.905) as well as agricultural land and construction land (r = -0.982), with a highly significant correlation (P<0.01).

The occurrence of various development activities in the region also played vital roles in the construction land expansion, which was followed by a decrease in agricultural land (*Fig. 4b*). For instance, the construction of a special development zone, the ETDZ, in Kunshan City of the Su-Xi-Chang region originated in 1985 (Long et al., 2007). It was approximately 375 ha before it was chosen as one of the state development zones. After a decade, its planning area increased by more than 500%, and it attained a total area of 2000 ha. Correspondingly, the advent of TVEs to increase farmers' non-agricultural income by promoting the structural adjustment and institutional innovation made a vital contribution to the process of expanding construction land, thus resulting in conversion of large areas of agricultural land for rural village construction. Thus, urbanization and the subsequent expansion of construction land was generally one of the most important factors in LULC change in the studied landscape.

Conclusion

We examined the spatio-temporal dynamics of LULC changes, major socioeconomic drivers, and the relationship between changes in LULC and their drivers in the Su-Xi-Chang region over the course of 1980 to 2010. Significant changes in LULC were found in the region, whereby construction land dramatically increased largely at the expense of farmland. From 1980 to 1990, diminishing farmland was more important for the newly emerged construction land, as well as for the enlargement of water bodies and woodland, than the other cover types. In the same period, dwindling wetland contributed to construction land and water body increases next to farmland. Similar trends of conversion occurred in the periods from 1990 to 2000 and 2000 to 2010, except for variations in the spatial extent of changes among the different categories. In addition, changes in landscape patterns and composition exhibited increased the fragmentation of farmland and wetlands. However, the construction land category became aggregated and complex, thereby resulting in the high fragmentation of other LULC categories.

Population growth and economic development, urbanization and subsequent construction land expansion, and industrialization were found to be the major change drivers. The growth of population over time increased the demand for residential areas, and hence, large areas of farmland were converted for settlement construction. Furthermore, to achieve more economic benefits from their farmland, farmers practiced profit oriented farming systems, particularly by converting their farmland into artificial ponds for fish production. Similarly, the rapid industrialization consumed large areas of farmland. In general, the marked expansion of construction land is mainly accountable for the 33% decrease in farmland in the past three decades.

Given the current trends of socioeconomic drivers in the Su-Xi-Chang region, increasing pressure on LULC is causing an alarming change in farmland, water bodies, and wetland. The change in farmland involves decreases in both area and production and may impair the ecological functions that support the human dominated environment and result in a decline in food production. Therefore, policies to achieve long term sustainable development must address the effects of these drivers on LULC changes. Moreover, further research along these lines should be encouraged because additional studies will be helpful for the decision makers engaged in planning activities at various levels in the region.

Appendix B. *Landscape metrics selected for this study and their description*

Acronym	Name (units)	Description	Justification
NP	Number of patches	Total number of patches in the landscape	Fragmentation
PD	Patch density (per 100 ha)	Number of patches per unit area	Fragmentation
LSI	Landscape shape index	The landscape boundary and total edge within the landscape divided by the total area, adjusted by a constant for a square standard	Aggregation

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_809827

LPI	Largest patch index (%)	Area of the largest patch in each class, represents percent of the total landscape area	Dominance
SHDI	Shannon’s diversity index	SHDI equals minus the sum, measure of diversity. Approaches 0 when there is no diversity, increases with number of patch types.	Diversity
IJI	Interspersion and juxtaposition index (%)	Intermixing of patches of different types, based on patch adjacencies. Increases to 100 as the patch type becomes increasingly interspersed with other patch type.	Fragmentation
CONTAG	0 < CONTAG ≤ 100 Contagion index (%)	Approaches 0 when the patch types are maximally disaggregated and interspersed. Approaches 100 when the landscape consists of a single patch.	Fragmentation
AWMPFD	Area-weighted mean patch fractal dimension	Shape complexity weighted by the area of patches	Fragmentation

(Received 17th May 2017; accepted 11th Aug 2017)

Abstract. To evaluate the potential effectiveness of plant growth regulators in improve seed germination and seedling vigor when applied during seed coating in sweet corn. 6-benzylaminopurine (6-BA), 1-naphthalene acetic acid (NAA), brassinolide and gibberellic acid (GA_3) were added as seed coating agent, and seed germination, antioxidant capacity and seedling vigor of sweet corn were investigated. The results showed compared with the use of coating agent alone, plant growth regulators improved seed vigor and germination, especially GA_3 (200 and 250 mg L^{-1}) and 6-BA (20 and 40 mg L^{-1}) were added. Furthermore, 200 mg L^{-1} GA_3 treatment improved seed germination and antioxidant capacity and resulted in sweet corn seedlings with a better appearance. The results observed indicated plant growth regulators might be valuable agents in sweet corn seed coating.
Keywords: *sweet corn, gibberellic acid (GA_3), 6-benzylaminopurine(6-BA), seed coating agent, seed vigor*

Introduction

Sweet corn hybrids carrying the *shrunken 2 (sh2)* gene, or supersweets, are extensively planted worldwide (Parera, 1990). Laughnan (1953) studied the effects of the *sh2* gene on carbohydrate reserves in maize endosperm and found that *sh2* endosperm stored less starch than normal types and possessed approximately 10-fold higher levels of total soluble sugars, with most of this increase being attributable to sucrose. Because of the higher levels of sugar in endosperm and a high sugar retention after harvest, sweet corn with the *sh2* gene provides superior quality and consumer appeal and permits longer transport and processing times (Duan, 1997).

Despite these superior features, the commercial acceptance and widespread use of *sh2* hybrids has been limited by poor seed quality. This poor seed vigor has been attributed to various factors, such as an insufficient nutrient supply during seed germination due to the low starch concentration. In addition, the higher imbibition rate of *sh2* kernels that leads to severe solute leakage increases susceptibility to physical damage and seed- and soil-borne diseases (Garwood et al., 1976; Styer et al., 1983). As a result, the yield and profitability of sweet corn possessing the *sh2* gene is hindered by poor seed vigor, as reflected in decreased emergence, poor seedling vigor, and erratic

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_829839

stand uniformity (Tracy, 1989; Parera et al., 1991).

Although various seed treatments, including fungicide treatment, pre-sowing hydration and bio-priming, are effective for improving sweet corn seed germination and seedling growth (Bennett et al., 1987; Tracy, 1989; Callan et al., 1990; Wilson et al., 1992; Hartz et al., 1995; Zhang et al., 2007), these methods have not been used on a commercial scale. As *sh2* hybrid corn is becoming a major commercial sweet corn genotype, seed coating technology that enhances seed value and promotes the mechanization of the planting process has attracted increasing attention. According to one study, the performance and physical properties of rice seeds are improved by coating them with liquid-based polymeric adhesives (Zeng et al., 2009). In addition, the oxygen provided to rice seeds planted under anoxic or near-anoxic soil conditions is increased when seeds are coated with peroxide compounds (Baker et al., 1987; Sono et al., 1991). Furthermore, germination and survival rates of seeds under adverse environmental conditions are promoted by coating with polymers incorporating pesticides (Taylor et al., 2001; Manjunatha et al., 2008). In sweet corn, however, seed germination is inhibited by coating with either polymers alone or polymers incorporating pesticides (Ikekawa et al., 1991; Lan et al., 2008). Plant growth regulators are active ingredients in coating agents, but their effects on seed coating have rarely been investigated. A In this study, we therefore conducted lab experiments to investigate the effects of plant growth regulators 6-benzylaminopurine (6-BA), 1-naphthalene acetic acid (NAA), brassinolide (BR) and gibberellic acid (GA_3) in seed coating agents on seed germination and seedling growth of sweet corn.

Materials and Methods

The study was conducted at the Crops Research Institute, Guangdong Academy of Agricultural Sciences, Guangdong, China, during the summer of 2013.

Preparation of seed coating agent

Seed coating agent containing no active ingredients was provided by Incotec (Beijing, China). A GA_3 stock solution was prepared by dissolving 0.125 g of GA_3 in 1 mL absolute ethyl alcohol, followed by dilution with water to 250 mL and pH adjustment to 6.8–7.0. For use in subsequent experiments, this stock solution was diluted with water to give concentrations of 50, 100, 150, 200 and 250 mg L^{-1}. NAA (10, 20, 40, 60 and 80 mg L^{-1}), 6-BA (20, 40, 60, 80 and 100 mg L^{-1}) and BR (5, 10, 15, 20 and 25 mg L^{-1}) solutions were prepared in a similar fashion. The different plant growth regulator solutions were mixed with the Incotec seed coating agent in a 1:4 (v/w) ratio.

Seed coating treatments

The supersweet corn cultivar ‘Zhengtian 68’ bred at the Crops Research Institute, was used as seed material. All seeds were film-coated by hand. Seeds and seed coating agents with plant growth regulators were poured into a large plastic bag in a 1:50 (w/w) ratio. The bag was tightly closed and shaken to ensure even distribution of seed coating agents on seeds. The coated seeds were air-dried at room temperature for 2 h and then stored at 4 °C for 1 month.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_829839

Germination testing

Samples comprising 150 seeds per treatment were placed on three Petri dishes (50 seeds per dish) and incubated in a growth chamber under controlled conditions (25–28 °C, 12-h photoperiod and 80–85 % relative humidity). Three replications were used for each treatment. Two controls were also set up: uncoated seeds (CK1) and seeds coated with coating agent without plant growth regulators (CK2). The number of germinated seeds was recorded daily for 1 week, and root and shoot lengths were measured 7 days after sowing. Germination potential, germination rate, germination index and vigor index were calculated according to Crop Seed Inspection Procedures of the National Standard of the People's Republic of China (GB/T 3543.1-1995) as follows: Germination rate (%) = (number of germinated seeds 7 days after sowing / total seed number) × 100 %; Germination potential (%) = (number of germinated seeds 3 days after sowing / total seed number) × 100 %; Germination index (GI) = $\sum(Gt/Dt)$, and Vigor index = GI × S, where Gt is the number of germinated seeds on day *t*, Dt is the number of germination days, and S is seedling weight (in g).

Plant sampling and enzyme activity measurements

Treated and control seeds were sown in 10-cm diameter plastic containers and germinated in a growth chamber under controlled conditions (25–28 °C, 12-h photoperiod and 80–85 % relative humidity). Ten days after germination, fresh leaves from each treatment were sampled in liquid nitrogen, ground into a paste in an ice bath with 4 mL of 0.05 M phosphate buffer (pH = 7.8), transferred to a 10-mL centrifuge tube and centrifuged at 7,000 × *g* for 20 min. The resulting supernatant fluid was stored at −80 °C for measurement of superoxide dismutase (SOD), peroxidase (POD), malondialdehyde (MDA) and catalase (CAT) enzyme activities.

SOD activity was assayed by measuring the ability of the solution to inhibit the photochemical reduction of nitroblue tetrazolium following the method of Stewart et al. (1980). CAT activity was measured as the decline in absorbance at 240 nm due to the decrease of extinction of H_2O_2 using the method of (PATRA et al. 1978). POD activity was determined using the method of (AMAKO et al. 1994). In particular, the absorbance change of brown guaiacol at 460 nm was recorded to calculate POD activity, with one unit of POD enzyme activity defined as the amount of enzyme causing an increase of 1.0 in absorbance in 1 min due to guaiacol oxidation. The level of leaf senescence was determined by measuring the amount of MDA following the method of (Vos et al., 1991). Absorbance was recorded at 532 nm, with measurements corrected for non-specific turbidity by subtracting the absorbance at 600 nm. MDA concentration was determined on the basis of the extinction coefficient.

Statistical analysis

Data were analyzed using SPSS 19.0. Data were presented as mean ± SEM. One-way ANOVA followed by Tukey test was used to compare mean values of the groups.

Results

Seed germination

After storage at 4 °C for 1 month, seeds from all coating treatments, except for 200 and 250 mg L^{-1} GA_3 and 10 mg L^{-1} NAA, displayed significantly lower germination rates and germination indexes compared with CK1. The maximum germination potential was observed from the 200 mg L^{-1} GA_3 seed coating treatment, with no significant differences in germination potential found between the control and any NAA and 6-BA treatments, BR treatments except for 10 mg L^{-1} and the 200 and 250 mg L^{-1} GA_3 treatments. Coating treatments with 200 and 250 mg L^{-1} GA_3 gave rise to statistically significant increases in the vigor index compared with CK1, while 150 mg L^{-1} GA_3 and 20 and 40 mg L^{-1} 6-BA produced no significant differences in vigor index compared with CK1. The other treatments, namely 50 and 100 mg L^{-1} GA_3, 6-BA higher than 60 mg L^{-1}, and all levels of NAA and BR, resulted in a significantly lower vigor index compared with that of CK1.

Compared with CK1, all germination indexes—germination rate, germination potential, germination index and vigor index—were significantly decreased by the CK2 treatment. In particular, 150, 200 and 250 mg L^{-1} GA_3 and 10 mg L^{-1} NAA coating treatments caused statistically significant increases in germination rate relative to those from CK2 treatments, with the 100 mg L^{-1} 6-BA treatment producing seeds with the lowest germination rate among those from all coating treatments. The CK2 treatment was responsible for the lowest germination potential, and a significant increase was observed from all coating treatments except for 50 and 100 mg L^{-1} GA_3. Compared with CK2, the germination index was significantly increased by coating treatments of 200 and 250 mg L^{-1} GA_3, 20, 40 and 60 mg L^{-1} 6-BA and 10 mg L^{-1} NAA; no significant differences were observed as a result of the other coating treatments. Seed coating treatments of 200 and 250 mg L^{-1} GA_3 and 20 and 40 mg L^{-1} 6-BA produced seeds with statistically significantly higher vigor indexes compared with those from CK2 treatments. Higher levels of NAA (>10 mg L^{-1}) and 6-BA (>60 mg L^{-1}) and low levels of GA_3 (50 mg L^{-1}) significantly decreased the vigor index relative to CK2. No significant difference was observed after treatment at any BR level or with 10 mg L^{-1} NAA or 100 or 150 mg L^{-1} GA_3 (*Table 1*).

After storage for 2 months, germination indexes of sweet corn seeds were all decreased compared with values recorded after 1-month storage. The effects of seed coating treatments with different plant growth regulators all showed the same trends after storage for 2 months as those observed after 1 month (*Appendix 1*).

Root and shoot lengths

Compared with CK1, all treatments caused significantly lower root lengths. The 100–250 mg L^{-1} GA_3 treatments significantly increased shoot lengths, while no significant difference in shoot length was observed from 50 mg L^{-1} GA_3 or 20 or 40 mg L^{-1} 6-BA. Higher levels of 6-BA and BR, as well as all levels of NAA, had a significant inhibitory effect on shoot length (*Table 2*).

Compared with CK2, treatments with 150, 200 or 250 mg L^{-1} GA_3 dramatically increased root lengths. No significant differences in root lengths were observed following treatment with coating agents containing 10 or 20 mg L^{-1} NAA, whereas the other treatments, namely, lower levels of GA_3 (50 and 100 mg L^{-1}), higher levels of NAA (40, 60 and 80 mg L^{-1}) and all levels of BR and 6-BA, significantly inhibited root lengths (*Table 2*). A significant enhancement in shoot length was produced by all GA3 treatments as well as 20 and 40 mg L^{-1} 6-BA and 5 mg L^{-1} BR treatments. No significant differences in shoot lengths were observed following 10, 15 or 20 mg L^{-1} BR treatments, while a significant decrease was observed after treatments involving 60, 80 or 100 mg L^{-1} 6-BA, 25 mg L^{-1} BR and all NAA levels (*Table 2*).

According to above data, coating treatments with 200 mg L^{-1} GA3 gave rise to statistically significant increases in the vigor index and 100 mg L^{-1} GA3resulted in a significantly lower vigor index compared with that of CK1. Sweet corn seedlings at 7 days after sowing from seeds subjected to CK1, CK2, 200 mg L^{-1} GA3 and 100 mg L^{-1} 6-BA coating treatments are presented in *Fig. 1*. As is obvious from the figure, seedlings from the 200 mg L^{-1} GA3 treatment had an outstanding appearance that contrasted with those from 100 mg L^{-1} 6-BA.

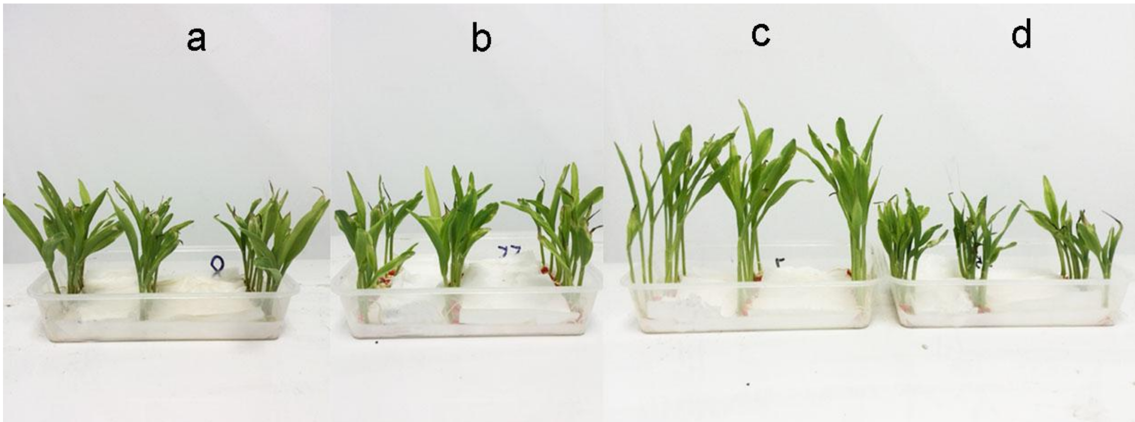

Figure 1. *Appearance of sweet corn seedlings at 7 days after sowing from seeds subjected to different seed coating treatments. a: uncoated seeds (CK1); b: no plant growth regulator in the coating agent (CK2); c: 200 mg L^{-1} gibberellic acid (GA_3); d: 100 mg L^{-1} 6-benzyladenine (6-BA)*

Physiological resistance

A pot experiment was conducted to investigate the physiological resistance of seedlings from selected treatments (CK1, CK2, 200 mg L^{-1} GA_3 and 100 mg L^{-1} 6-BA). Compared with CK1 and CK2, 200 mg L^{-1} GA_3 was respectively found to significantly increase SOD activities by 5.69 and 6.83 %, POD activities by 26.05 and 4.83 % and CAT activities by 18.98 and 14.67 % and to significantly decrease MDA content by 29.26 and 39.69 %. With respect to SOD, POD, and CAT activities and MDA content, the following trends were observed: SOD activity, 200 mg L^{-1} GA_3 > 100 mg L^{-1} 6-BA > CK1 > CK2; POD activity, 100 mg L^{-1} 6-BA > 200 mg L^{-1} GA_3 > CK2 > CK1; CAT activity, 200 mg L^{-1} GA_3 > 100 mg L^{-1} 6-BA > CK2 > CK1; and MDA content, CK2 > CK1 > 100 mg L^{-1} 6-BA > 200 mg L^{-1} GA_3.

Discussion

The seed coating process involves application of pesticides, fertilizers, oxygen agents or growth regulators to seeds to resist diseases and pests, and to promote seed germination and seedling growth (Taylor et al., 2001; Zhang et al., 2007). Previous studies have shown seed coating technology to be an effective approach for improving seed germination and seedling growth of crop plants (Taylor et al., 2001). In rice, seed coating improves the performance and physical properties of seeds, especially under adverse environmental conditions (Baker et al., 1987; Sono et al., 1991; Tylor et al., 1998; Manjunatha et al., 2008; Zeng et al., 2009). Seed coating with salicylic acid, paclobutrazol or humic acid has a positive effect on seed germination and seedling growth in maize (Lan et al., 2008; Wang et al., 2010; Zhu et al., 2013). Boschi et al. (2014) reported the effect of 6-BA on the germination and growth of seeds of *Ginkgo biloba* and suggested that seed immersion with 2.5 ppm of 6-BA performed.

Sweet corn, with its naturally poor seed vigor, differs from other maize types (Harris et al., 1989). A key agricultural objective to increase sweet corn yields is achievement of rapid, uniform germination and seedling emergence (Rajjou et al., 2012). However, we found that a coating treatment lacking plant growth regulators inhibited seed germination and vigor (*Table 1*), which was consistent with previous studies (Ikekawa et al., 1991; Lan et al., 2008). This inhibition may be due to physical damage caused by seed coating.

Experimental coating with different concentrations of 6-BA and NAA showed that low concentrations of these plant growth regulators promoted seed germination, whereas high concentrations inhibited it (*Table 1*). Suitable concentrations of 6-BA (20–40 mg L^{-1}) and NAA (10–20 mg L^{-1}) were beneficial for rapid, uniform germination and seedling emergence. BR is an important phytohormone that plays an important role in various aspects of plant growth and development, including seed germination (Wilen et al. 1995; Dhaubhadel et al. 1999; Khripach et al. 2000; Miransari et al. 2014). Although seed immersion with BR has been found to promote seed germination in maize (Zou, 2002), we observed no obviously positive effect in coating treatments incorporating BR in the coating agent.

We found that coating using coating agent alone inhibited seed germination, as reflected by decreased germination rate, germination potential, germination index and vigor index. In contrast, coating treatments incorporating 200 and 250 mg L^{-1} GA_3 maintained a high germination rate, germination index and germination potential similar to CK1 and significantly increased vigor index and shoot length compared with CK1 (Tables 1 and 2). These positive effects may be due to the roles of GA in breaking dormancy and promoting seed germination and stem elongation (Gurdiola, 1996). In addition, 200 mg L^{-1} GA_3 significantly increased SOD, POD and CAT activities and decreased the accumulation of MDA content compared with CKs (*Figs. 1* and *2*). This result implies that GA_3 coating treatments improve seed germination and seedling physiological resistance by increasing SOD, POD and CAT activities in seedlings and by reducing membrane damage during the coating process.

Conclusion

In this study, we found seed coating using coating agent alone inhibited seed germination, whereas, coating with suitable concentrations of 6-BA (20–40 mg L^{-1}), GA_3 (200 mg L^{-1}) and NAA (10–20 mg L^{-1}) were beneficial for rapid, uniform germination and seedling emergence in sweet corn. Which implied it is effective approach to improve seed germination through developing seed coating incorporated with suitable concentrations plant regulators (6-BA, GA_3, NAA) in sweet corn.

Abstract. The Chi River Basin (CRB) is one of the major river basins in Thailand. Flooding often occurs in this floodplain, which has a profound effect on human life and property. Currently, climate change has a high impact on river discharges and therefore on floods. Hence, the management of flooding to minimize impacts due to climate change is essential and a priority at national and regional levels. The purpose of this study is to provide a quantitative understanding of the impacts of climate change on hydrological regimes and to provide a guideline for coping with the consequences. In this paper, General Circulation Model (GCM) outputs, the Statistical DownScaling Model (SDSM), the Soil and Water Assessment Tool (SWAT) model, the Hydrological Engineering Centre - River Analysis System (HEC-RAS) program, and the Geographic Information System (GIS) were used to determine areas vulnerable to flooding due to climate change. A flood hazard map was developed for the Lampao River Basin (LRB), which is a sub catchment of the CRB. According to the results, an appropriate flood management plan for the area was proposed. The plan involved structural and non-structural measures that integrated three methods of dealing with flood hazards which are modifying the hazards, moderating the impacts, and reducing the risks. Integrated flood management is a complex endeavor therefore computer-based tools that enable analysis of the whole system should be developed to implement the plan efficiently.
Keywords: *climate changes impact, downscaling, flood hazard, Chi River Basin, flood management*

Introduction

Climate change is one of the most critical issues in the world and in Thailand. Climate change has caused serious consequences in Thailand, such as higher surface temperatures, floods, droughts, severe storms and sea level rise (Sudtida, 2012). Over the past 30 years, there were more than 50 droughts and floods in Thailand (DEQP, 2016), and flooding is always a major problem in Thailand. Therefore, understanding the impact of climate change on flooding is vital to overcome this problem.

According to the Intergovernmental Panel on Climate Change (IPCC), General Circulation Model (GCM) can “reproduce features of the past climates and climate changes” (Randall et al., 2007). GCM are the best tools to estimate future global climate changes resulting from the continuous increase in the concentration of greenhouse gases in the atmosphere (Busuioc et al., 2001; Dibike and Coulibaly, 2005). The output of GCM can assist in understanding climate and in forecasting climate change. To simulate sub-grid scale phenomena, hydrological models are necessary, and such hydrological models require input data at a similar scale. These data are generally provided by converting the GCM outputs into a reliable regional hydrological time series at the selected catchment scale. Usually, “downscaling” techniques are used to convert GCM outputs into the local meteorological variables required for reliable hydrological modelling (Dibike and Coulibaly, 2005; Huntingford et al., 2006).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_841861

In this study, daily precipitation series for specific area have to be obtained, therefore, the Statistical DownScaling Model (SDSM), which is a decision support tool for assessing local climate change impacts using a robust statistical downscaling technique, was selected (Kafatos, 2012). The statistically downscaled GCM outputs and the atmospheric circulation indices, as well as humidity variables derived from the CGCM3 model, were used to downscale daily precipitation series for the upper catchment of the Chi River Basin (CRB). The generated climate scenarios were then applied to drive the distributed Soil and Water Assessment Tool (SWAT) model. Changes in the modelled daily flow regime between current and future climate scenarios were compared and analysed. The impact of climate change on precipitation in the upper catchment of the Lampao River Basin (LRB), which is one of the CRB's sub-catchments, was investigated as a case study representing the Chi River Basin.

The analysed results were adopted to manage the impact of flood hazards, which concerns communities, the economy, the environment and human health. An appropriate flood management plan of the area was proposed. A flood mitigation plan was developed for critical disaster situations that affect life and property. Proper measures were presented to reduce the impact of flood hazards. The plan involves multiple projects that fall under one of two categories, i.e., hard engineering and soft engineering. The proposed plan is divided into the following:

- Early stage management (before the rainy season)
- During the occurrence of disasters (during the rainy season)
- Reconstruction plan (after disasters occur)

Materials and Methods

Study Area and Data Used

The Lampao sub-basin of the Chi River Basin for investigation in this study due to its frequency of flooding. The Chi River Basin has an area of 49.477 km^2 and is divided into 20 watersheds or catchment basins, which represent 29.10% of the northeast area of Thailand. The geographical location is between latitude 15˚ 30′ and - 17˚ 30′ north, and longitude 101˚ 30′ and - 104˚ 30′ east (Kuntiyawichai, 2011), as shown in *(Fig. 1).*

The topography of the Chi River Basin (CRB) includes tall mountains in the east and north from the Phu Phan mountain range. The west includes the Dong Phaya Yen mountain, which is the origin of the Chi River and several other major rivers. The central area is flat to undulating, and there is a small hill in the south of the basin. The major tributaries in the Chi River Basin include Nam Prom, Nam Chen, Nam Pong, and Lampao. Reservoirs in the basin include Ubol Ratana Dam, Chulabhorn Dam, Lum Nam Pung Dam, and Lampao Dam. The average precipitation is 1,028 mm/year. Approximately 6.7 million people live in this area.

The economies of the Chi River Basin depend on farming and animal husbandry. The income per person is 80.000-100.000 Baht/year (2.280-2.860 US dollars/year) (NSO, 2016).

According to recommendations of the Intergovernmental Panel on Climate Change (IPCC), the baseline used in this study is the standard normal for the period 1961-1990, as described by the standard of the World Meteorological Organization (IPCC-TGCIA, 1999). Data from two GCM simulation models, i.e., CGCM3 and HadCM3, were used

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_841861

in this investigation. The predictor variables for CGCM3 and HadCM3, described on a grid box, are provided in *Table 1*.

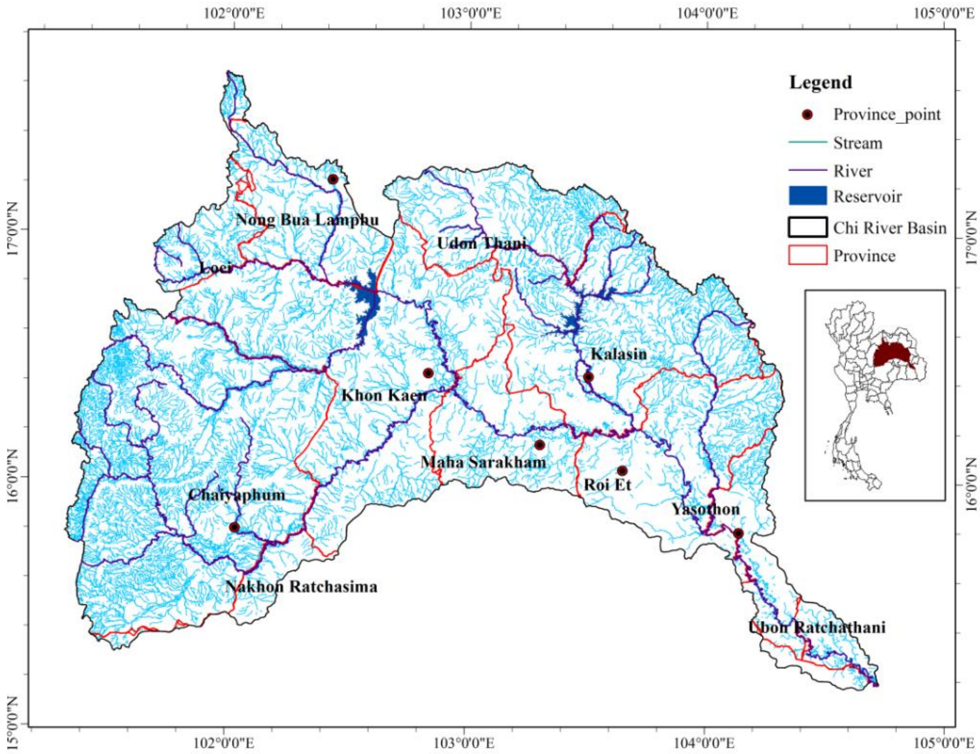

Figure 1. *Chi River Basin*

Table 1. *Grid positions of the Chi River Basin*

No.	Station Name	Code	Grid Position CGCM3	Grid Position HadCM3
1	Chaiyaphum	403201	28X_20Y	28X_29Y
2	Khonkaen	381201	28X_20Y	28X_28Y
3	Roiet	405201	29X_20Y	29X_29Y

Three weather stations of the Thailand Meteorological Department (TMD), as detailed in *Table 2*, located in the study area (*Fig. 2* and *Fig.* 3), provided daily precipitation data for CGCM3 and HadCM3. The past 50 years of data that cover the period suggested by the IPCC are available from the three stations.

Table 2. *Weather station locations*

No.	Station Name	Basin	Latitude	Longitude	Level (MSL.)
1	Chaiyaphum	Chi	15˚48′00″	102˚02′00″	180
2	Khonkaen	Chi	16˚27′48″	102˚47′12″	165
3	Roiet	Chi	16˚03′00″	103˚41′00″	140

DOI: http://dx.doi.org/10.15666/aeer/1504_841861

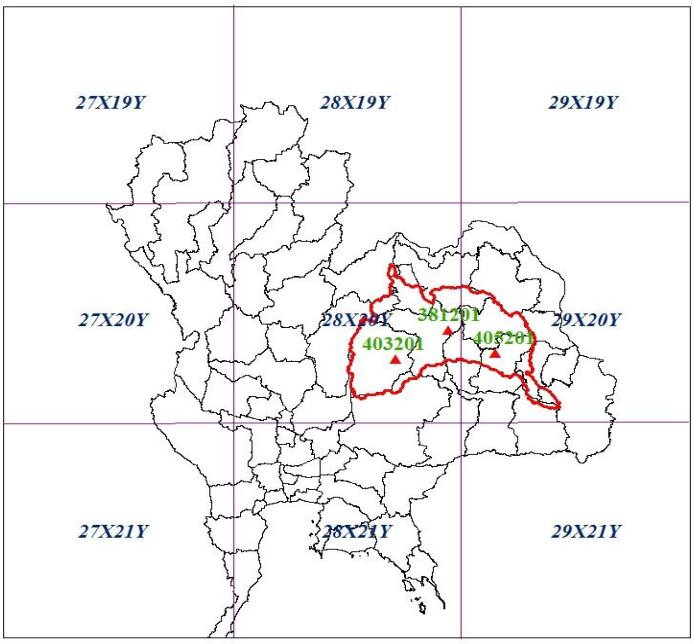

Figure 2. *Location of the weather station in CGCM3*

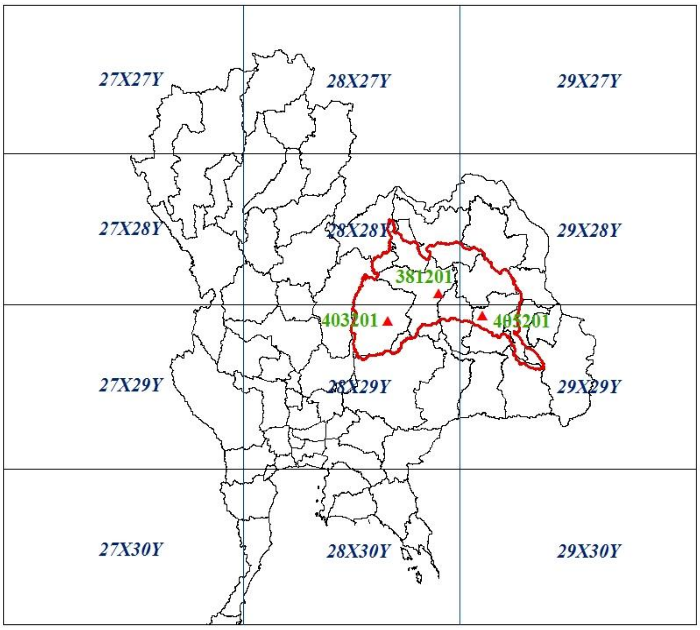

Figure 3. *Location of the weather station in HadCM3*

Hydrological data for the hydrological models include the following:

- Daily rainfall data from 17 TMD stations in the Lampao River Basin and nearby areas.
- Daily runoff, water level and cross section of the Lampao River from 8 stream gauge stations of the Royal Irrigation Department (RID) in the area.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_841861

- Flood area from the Geo-Informatics and Space Technology Development Agency (Public Organization) – GISTDA.

Thus, the damage value from flooding can be evaluated in the flood area through the simulation results of the hydrological models. Damage includes loss of life and property, damage to buildings and other structures and flood health effects. These data were collected from the Department of Disaster Prevention and Mitigation.

Based on the flood risk and damage value, a flood management plan was developed to reduce the impact. This plan was compared to the existing plan of the Royal Irrigation Department that is adopted presently.

Method

The methodology of the study is shown in *Fig. 4* and is described in detail as follows:

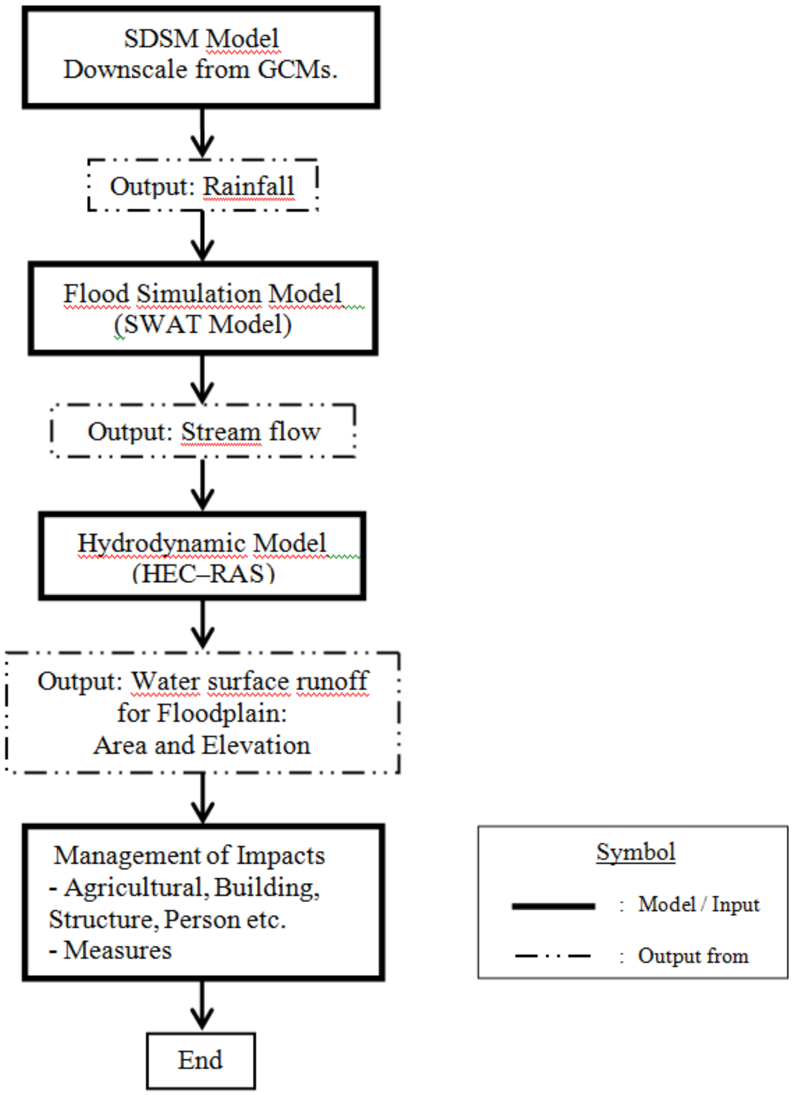

Figure 4. *Study flow chart*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_841861

Statistical DownScaling Model (SDSM)

The Statistical DownScaling Model (SDSM) is a hybrid of the multiple linear regression and stochastic downscaling model developed by Rob Wilby and Christian Dawson (Harpham and Wilby, 2005; Wilby and Dawson, 2007). It is a freely available decision support tool for assessing local climate change impacts using a robust statistical downscaling technique. In the SDSM downscaling, a multiple linear regression model is developed between selected large-scale predictor variables and local-scale predictands such as temperature and precipitation. The SDSM uses a conditional process to downscale precipitation. Local precipitation amounts depend on wet/dry day occurrences.

GCMs (CGCM3 and HadCM3) approved by the Intergovernmental Panel on Climate Change (IPCC) were selected to construct climate scenarios. Data from these two international GCMs (CGCM3 and HadCM3) were obtained from the web site of the Canadian Climate Impacts and Scenarios project (http://www.cics.uvic.ca/scenarios). The source of scaling uncertainties is treated by downscaling the GCM outputs with the Statistical DownScaling Model (SDSM) (Wilby et al., 2001). This model is applied using conditional means involving stochastic weather generators.

The method used is a well-recognized statistical downscaling tool that has been made available to the broader climate change impact study community via the Canadian Climate Impact Scenarios (CCIS) project (Dibike and Coulibaly, 2005). The past 30 years of data represent the current climate (1961-1990), as recommended by the IPCC; the first 15 years are used for calibrating the regression model; and the remaining years of the data are used to validate the model.

This study applied the SDSM to predict future climate change in the Chi River Basin over 20 years, 50 years and 80 years. Changes in rainfall from the effects of climate change are obtained and used as the input in the hydrological model.

Hydrological Model

The Soil and Water Assessment Tool (SWAT) model, which has gained international acceptance as a robust interdisciplinary catchment modelling tool to quantify the impact of land management practices in large, complex catchments, was used to estimate the stream flow in LRB, because SWAT is a physically based model that is able to predict the impact of land use changes on water in a catchment and land use on a basin scale over long periods of time (Sun and Cornish, 2005). For the hydrodynamic model, the Hydrological Engineering Centre - River Analysis System (HEC-RAS) which is an accepted model to estimate surface runoff, was used (HEC, 2002).

The stream flow data measured at a stream gauging station located at Nong Mung (E.75) on the Lampao River was employed to calibrate the SWAT model. The observed data were split for calibration (2006-2009) and validation (2010-2013) purposes. Several statistical measures were used to evaluate the simulation accuracy, such as the Nash-Sutcliffe coefficient, the Root Mean Square Error, Goodness of fit and the Average Observance. Thereafter, the best calibrated model parameters were assigned to simulate stream flow with different rainfall scenarios from the SDSM to predict the tributary inflows with the probability of occurrence of flood inundation at all selected points on the Lampao River.

These stream flows were used as the input of HEC River Analysis System (HEC-RAS) model to determine the overflow depth of water to land subject to flooding.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_841861

Flood Hazard

The flood depth was considered as the hazard indicator in this study. Therefore, the flood hazard categorization was adopted based on the induced flood depth. The flood hazard management model, as shown in *Fig. 5*, was proposed to reduce the impact of flood hazards.

Flood depth hazard maps were constructed based on the specific maximum flood depth with the probability of non-exceedance at 20%, 50%, and 80%. These maps are very useful for flood control and flood hazard management.

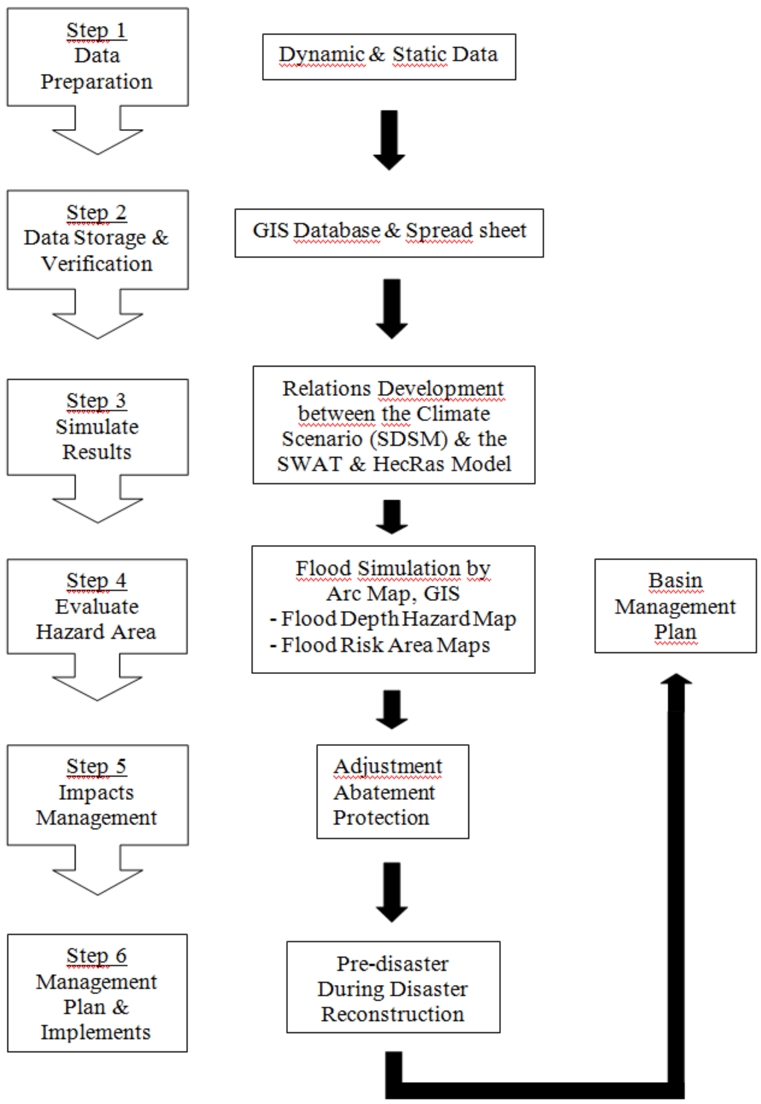

Figure 5. *Flood management model*

Results and Discussion

Choice of Predictor Variables

The National Centre for Environmental Prediction (NCEP) provides re-analysis data and GCM data used by SDSM. The data are available from 1961to -1990.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_841861

Comparison of the predictor variables of the two GCMs, i.e., CGCM3 and HadCM3, can be selected by the entry screening method to obtain the least error results and the least used predictor variables. Large-scale predictor variables representing the current climate conditions, derived from the NCEP reanalysis data sets, were used to investigate the percentage of variance in each predictand-predictor pair. The most relevant predictor variables from the downscaling experiments from three weather stations in the area, i.e., Chaiyaphum (CPM), Khonkaen (KKN) and Roiet (RET), were determined and are shown in *Table 3*.

SDSM Model Calibration and Validation

The coefficient of the multiple linear regression equation parameters that relate the large-scale atmospheric variables derived from NCEP and the local-scale variables was obtained by model calibration. The temporal resolution of the downscaling model for precipitation downscaling was specified as daily for Chaiyaphum, Khonkaen and Roiet.

From the 30 years of data, representing the current climate conditions, the first 15 years of data (1961-1975) were considered during calibration of the regression model while the remaining 15 years (1976-1990) were used to validate the model. *Table 4* shows the statistical results of CGCM3 and HadCM3 from three stations. From the NCEP selected variables, the results show that the CPM station (403201) prefers CGCM3 to HadCM3. For the KKN station (381201), HadCM3 provides better results than CGCM3. In addition, for the RET station (405201), CGCM3 is better than HadCM3. Therefore, CGCM3 was chosen for rainfall forecasting in the Chi River Basin (CRB).

Rainfall Forecast

The prediction of future rainfall was conducted for three periods, i.e., 2011-2040, 2041-2070 and 2071-2100. The prediction results were compared with rainfall observations in the years 1961-2010. The statistical evaluation results for the validation of SDSM are also shown in *Table 4*. The results are quite accurate and acceptable.

Table 5. *Precipitation forecast from the CGCM3 model*

Station Code	Model Grid CGCM3	Average Annual Rainfall (mm.) 1961-2010 Baseline	2011-2040	2041-2070	2071-2100
381201 (KKN)	28X20Y	1,227.72	1,421.25	1,453.22	1,497.70
405201 (RET)	29X20Y	1,375.30	2,316.81	2,757.65	3,579.56

In *Table 5*, the forecast results indicate that from now to the year 2100, rainfall in the Chi River Basin will increase due to climate change. Compared with the baseline, the rainfall at the KKN station (381201) during 2011-2040, 2041-2070 and 2071-2100 will increase by 15.76%, 18.37% and 21.99%, respectively. In addition, at the RET station (405201), a 68.46%, 100.51% and 160.27% increase in rainfall will occur. This indicates that the potential of flooding should increase in this area the future.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_841861

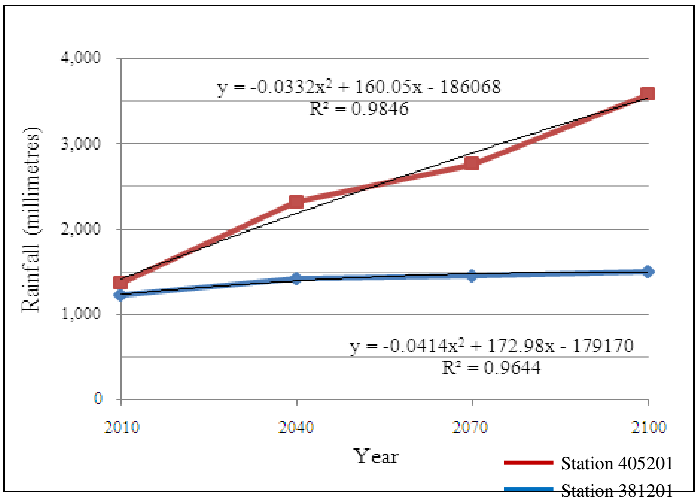

***Figure 6.** Precipitation forecast in Chi River Basin*

The average annual rainfall between 2010 and 2100 can be predicted from the equations given in *Fig. 6*. The equation representing the KKN station (381201) is $y = -0.0414x^2 + 172.98x - 179{,}170$ with $R^2 = 0.9644$, where y is the average annual rainfall (millimetres) and x is the year. In addition, the average annual rainfall at the RET station (405201) can be obtained by the equation y = -0.0332x2 + 160.05x -186,068 with $R^2 = 0.9846$.

SWAT Model Calibration and Validation

The historical discharge records from the E.75 stream gauge station on the Lampao River at Kalasin province from 2006 to 2013 were split into two sets of data. The first is 2006-2009 for calibration, and the second is 2010-2013 for validation of the SWAT model. Model calibration was conducted by comparing the SWAT simulated results with the observed discharge monthly. The simulated results of the monthly stream flow and the observed stream flow are compared for calibration in *Fig. 7* and for validation in *Fig. 8*.

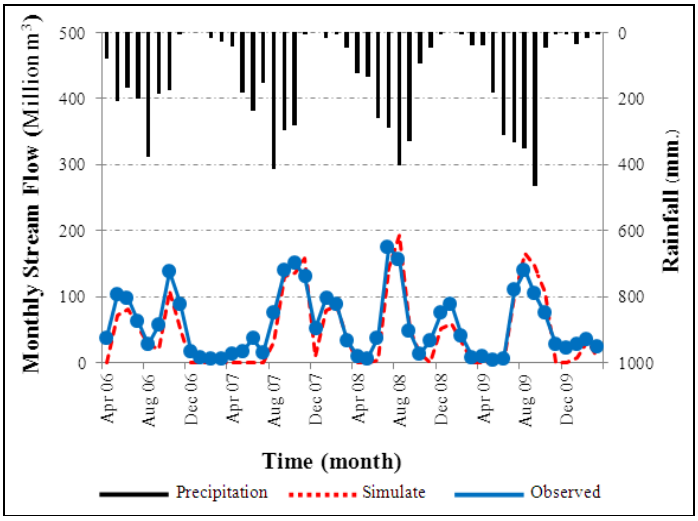

***Figure 7.** Calibration results of the SWAT model (2006-2009)*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_841861

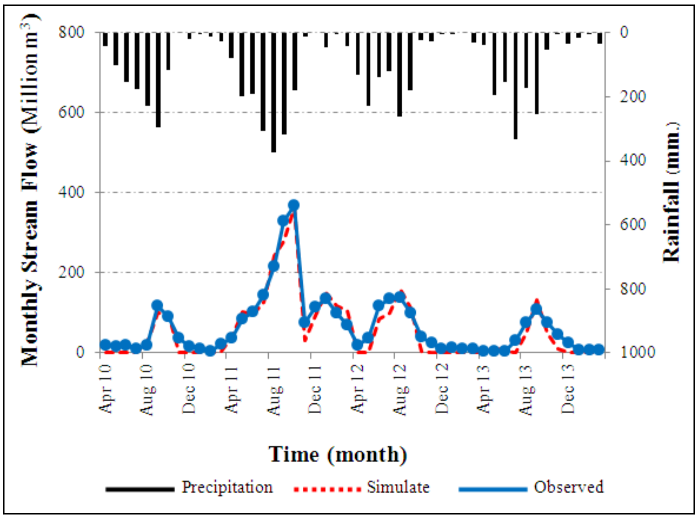

Figure 8. *Validation results of the SWAT model (2010-2013)*

From these figures, the simulated and observed monthly stream flow agree quite well; therefore, this SWAT model can be used to determine hydrological processes in this river basin. The evaluation of the statistical measurement error in the calibration and validation of the SWAT model is given in *Table 6*.

Table 6. *Statistical evaluation of the measurement error in the calibration and validation of the SWAT model*

Evaluation Statistics	Station E.75	
	Calibration	Validation
R^2	0.873	0.940
Avg.Obs.	57.681	67.514
RMSE	23.247	22.633
Nash. Coef.	0.769	0.916

To obtain the stream flow, the downscale predicted precipitation results were input to the SWAT model to simulate the stream flow in different scenarios. The simulation results are shown in *Table 7* and *Fig. 9*. The maximum daily stream flows during 2011-2040, 2041-2070, and 2071-2100 are 220.79, 239.44, and 258.09 m^3/s, respectively. Compared with the baseline, the maximum daily stream flow will decrease by 30.18% in the next ninety years. From the simulation model, the average annual stream flow, average annual water volume, and the highest annual stream flow show an increasing trend, but the maximum daily stream flow from the model is lower than the maximum daily stream flow recorded due to a large flood in this area in 2011.

***Table 7.** Simulation results of the SWAT model for the Lampao River at station E.75*

Period		Average Annual Stream Flow	Increase	Average Annual Water Volume	Increase	Max. Daily Stream Flow
		(m^3/s)	(%)	(megacentimetres)	(%)	(m^3/s)
Baseline	2006-2011	28.39	-	898.36	-	369.67
2020	2011-2040	82.47	190.50%	2,606.92	190.19%	220.79
2050	2041-2070	89.50	215.27%	2,829.33	214.94%	239.44
2080	2071-2100	96.58	240.21%	3,053.02	239.84%	258.09

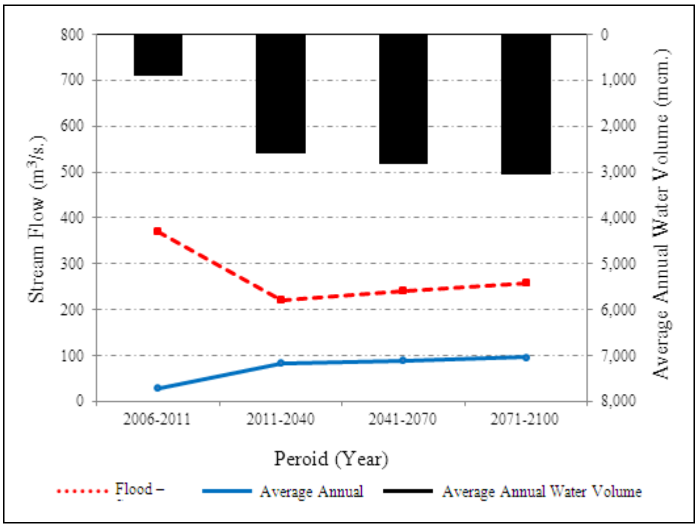

***Figure 9.** Summary of simulation results of SWAT model*

Flood Area

Data of the maximum daily stream flow and flooding in the area were extracted from the Geo-Informatics and Space Technology Development Agency (Public Organization) – GISTDA (GISTDA, 2012). The accumulated annual stream flow and flood area from 2006 to 2011 are given in *Table 8*.

***Table 8.** Flood area of the Lampao River Basin*

Year	Flood Area (km^2)	Max Daily Stream Flow (m^3/s)
2006	41.29	71.50
2007	154.67	350.19
2008	34.71	89.88
2009	15.20	133.36
2010	102.94	157.40
2011	192.88	369.67
Average	90.28	193.06

To determine the flood area for the next ninety years, the stream flow simulation results were input to HEC-RAS to compute the resulting water surface elevation. These

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_841861

elevations were mapped in ArcGIS to form a flood inundation map. As a result of the flood area shown in *Table 9*, the maximum flood area due to climate change in the next ninety years is less than the maximum flood area in the past.

Table 9. *Flood area caused by climate change*

Period		Maximum daily Stream Flow (m^3/s)	Flood Area (km^2)
Baseline	2006-2011	369.67	192.88
2020	2011-2040	220.79	115.20
2050	2041-2070	239.44	124.93
2080	2071-2100	258.09	134.66

The results show an increase in the maximum daily stream flow from 2012 to 2100 as well as the flood area. When compared to the baseline flood area, the future maximum flood area is lower due to one extraordinary flood in 2011. If the average daily stream flow and flood area are considered, the future runoff and flood area is larger than the baseline, and an increasing trend for the future is noticed.

The flood depth is considered to be the most important indicator of the intensity of the flood hazard. Therefore, the inundation area is classified into three classes according flood depth, as shown in *Table 10*. The flood height represents the severity, in which a low level causes inconvenience, a medium level causes the inundation of low lying areas and requires the evacuation of some areas, and a high level is widespread flooding causing extensive damage to people. A flood hazard map was constructed according to the inundation area, water height classification, and risk.

Table 10. *Flood stage classification*

Level	Water Height (cm.)
High	> 40
Medium	20-40
Low	< 20

The river overflow data consists of the maximum water height and flood duration collected in the field, as shown in *Table 11*. The runoff-water height relationship can be established from these data.

Table 11. *Duration of flood and maximum annual water height of river overflow*

Year	Duration of flood (days)	Maximum Annual Water Height (cm)
2006	-	10.00
2007	20	50.00
2008	-	15.00
2009	-	20.00
2010	-	25.00
2011	18	55.00
Average	6.33	29.17

Flood Management

Currently, there are many agencies in Thailand involved in water management. This leads to inconsistent and non-integrated water management plans and actions. At least twelve government agencies are responsible for flood control, and there is a little cooperation among these agencies. Most of the existing flood plans are emergency plans developed independently by some of these government agencies. Thus, an integrated flood plan consisting of preparation, response, recovery, and mitigation of flood risk needs to be developed. Therefore, a flood management plan to reduce the impact on communities, the economy, the environment and health for this area was constructed as follows. It is important that lessons from the past, knowledge and technology, effective communication and applications are considered. The plan contains three phases:

- Early stage management (before the rainy season)
- During the occurrence of disasters (during the rainy season)
- Reconstruction plan (after disasters occur)

Three factors, i.e., human behaviour and decisions, probabilities of flood event and damage, and government responsibility are integrated in the plan. Traditionally, flood prevention has relied on civil engineering works. In recent years, soft measures, such as flood warning systems, flood-plain zoning, insurance, etc., have become more recognized. The management approach varies in the different phases. In this study, the optimization of the two means has been considered. The objective is to protect people and property from the damaging impacts of floods resulting climate change.

To cope with the problem, the relationship between the stream flow and flood area was determined. The major flood in 2011, which is incident in this area, which has the highest of daily stream flow 369.67 m^3/s and the highest of flood area 192.88 km^2, was set as the calibrated data. The result of the input data to the HEC-RAS model is shown in *Fig. 10*. *Table 12* shows the simulation results from the HEC-RAS model, from which the relationship between the flood area and stream flow in the Lampao River Basin can be constructed.

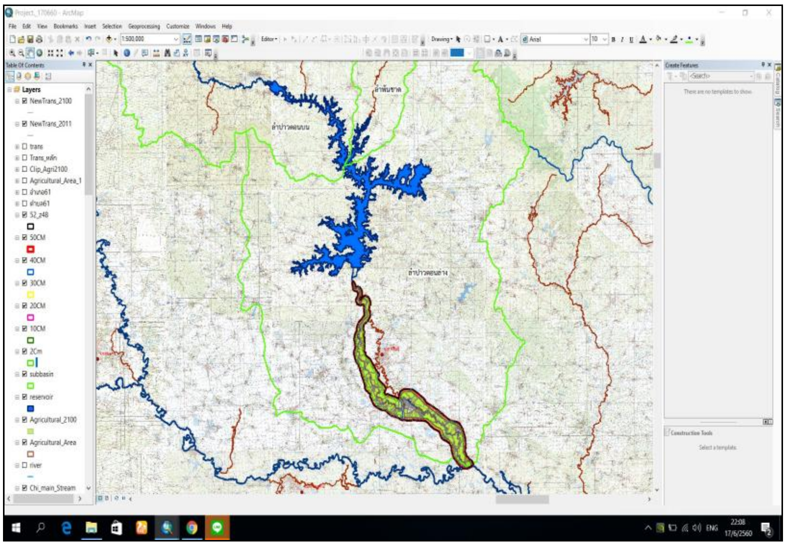

Figure 10. *The flood area from the HEC-RAS model superimposed on a topographic map 1:50,000*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_841861

***Table 12.** Flood area and stream flow in the Lampao River Basin*

Flood Area (km^2)	Stream Flow (m^3/s)	Flood Area (km^2)	Stream Flow (m^3/s)
0.00	209.53	114.24	343.15
1.70	250.94	115.93	344.12
9.39	274.72	121.86	347.14
10.56	276.63	141.29	351.99
24.56	288.57	162.82	359.50
48.86	305.18	168.39	361.01
80.34	328.55	180.37	365.50
80.41	328.69	191.41	368.29
102.70	339.15	192.88	369.67

From *Fig. 11*, the relationship between the stream flow and flood area in the Lampao River Basin can be represented as

$$Y = 0.0118X^2 - 5.6557X + 673.84 \qquad \text{(Eq. 1)}$$

where X is the stream flow (m^3/s) and Y is the flood area (km^2), with $R^2 = 0.9959$.

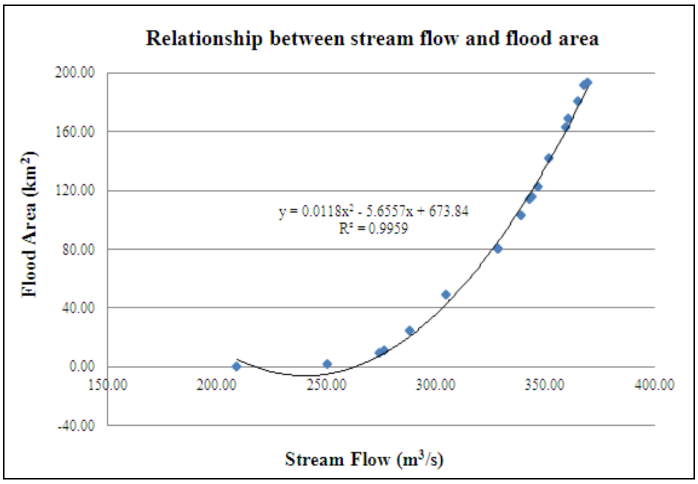

***Figure 11.** Relationship between the stream flow and flood area*

The statistical data of flooding in the past are in agreement with this equation. Due to field operation, the stream flow can be obtained from the water height, which is more practical to measure. Therefore, the relationship between the stream flow and flood level was constructed, as shown in *Fig. 12*, as follows:

$$Y = 0.0015X^2 - 0.4916X + 33.821 \qquad \text{(Eq. 2)}$$

where X is the stream flow (m^3/s) and Y is the flood level (cm), with $R^2 = 0.9752$.

DOI: http://dx.doi.org/10.15666/aeer/1504_841861

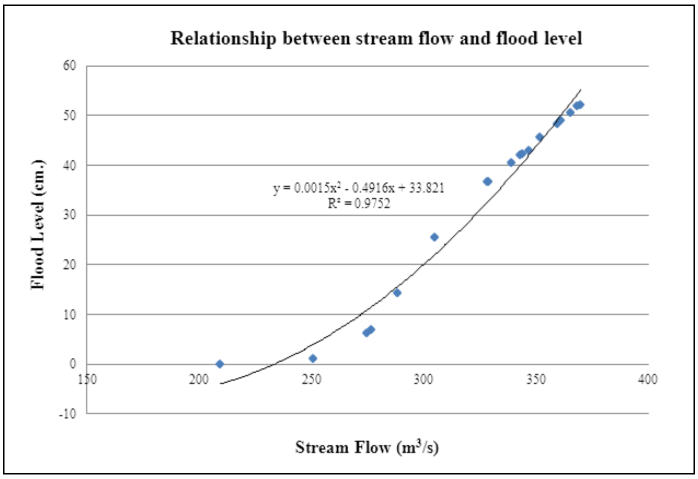

Figure 12. *Relationship between the stream flow and flood level*

The probability of flooding can be determined from the flood level, as shown in *Fig. 13*, and correlations of the flood probability to the flood level, stream flow and flood area are shown in *Table 13*. Through comparison with the flood stage classification in *Table 8*, a flood risk area map can be obtained.

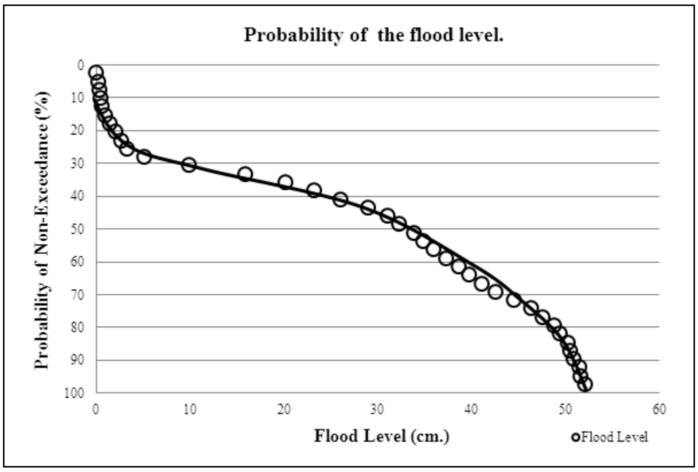

Figure 13. *Probability of the flood level*

Table 13. *Probability of non-exceedance of the flood level*

Probability of Non-exceedance (%)	Flood level (H) (cm)	Stream Flow (Q) (m^3/s)	Flood Area (A) (km^2)
0.00	0.00	209.53	0.00
10.00	3.23	261.04	4.96
30.00	9.68	281.13	15.84
50.00	27.78	310.05	55.42
70.00	43.33	347.75	124.29
90.00	50.36	364.93	178.85

Impact Management of the Flood Hazard

Floods impact both individuals and communities, and have social, economic, and environmental consequences. In Thailand, the governmental mechanisms are available for managing flood hazards. Because of the inefficiency of integration and collaboration, flood hazards still are an unsolved problem. Therefore, it is urgent to develop a method to effectively manage flood hazards. This study proposes the flood management plan to cope with the problem. The plan is aimed at assisting the stakeholder to undertake their flood management responsibilities and ensure that suitable measures are be implemented. The plan comprises three phases, i.e., early stage management, during the disaster and reconstruction. Four general strategies, i.e., modify the loss, modify vulnerability, modify the event and modify the cause, were applied in this plan. Activities according to this plan are presented as follows:

Early Stage Management

It is essential that communities recognize flooding as part of their environment. They must be aware of the flood potential. In this stage, four activities should be applied.

- Mapping of potential flood zones

  Flood hazard mapping and risk assessment were conducted to identify priority areas and high-risk zones. The inundation areas, corresponding to the flood depth, should be determined.
- Asset management

  Flood mitigation assets are maintained in a fit-for-purpose state to ensure they work as designed during a flood. All flood defence structures, including waterways, should have ongoing inspection and maintenance programs. The asset should be managed in accordance with the asset management guidelines and asset management plans. Asset conditions should be assessed and reported annually.
- Planning controls

  Local agencies should to consider planning permits for land use and development projects with regard to area conditions to ensure that flood control systems continue to function properly. Providing necessary information to stakeholders on the importance of appropriate design and mitigation of flooding is a good practice. Any new developments should be adequately studied and designed to protect the community and environment from flooding. The assessment of planning permit applications should focus on flooding impacts and risks. The continued assessment of flood risks at the planning permit application stage has resulted in more appropriate development in known flood risk areas. Integration and communication among responsible agencies are essential.
- Community education and awareness

  Steps to create awareness of preparedness measures within the community should be taken. Public participation and public perception are important components of success. Flood preparedness education programs should be implemented. These programs will ensure that stakeholders are aware of flood impacts and appropriate flood response actions. Appropriate behaviour during the occurrence of flood events is an important element in the minimization of losses. Notification of the amendment, along with flood maps and up-to-date data, makes flooding information readily accessible to the community.

DOI: http://dx.doi.org/10.15666/aeer/1504_841861

During the Occurrence of Disasters

Two activities should be implemented as follows:

- Flood warning system

Flood warning systems and services aim to reduce losses and impacts caused by flooding and are important flood mitigation measures. Two important outcomes from flood warning systems are informing those at risk of flooding and appropriate actions being taken by those at risk. Currently there is no warning system in the area of this study; alerts of the water height according to flood hazard maps by radio, telephone, short message service (SMS) and internet, including social media, are proposed. The water height should be reported every hour. The warning message should be sent when the stream flow reaches 200 m^3/s, and reports should continue at 15-minute intervals. Instruction should also be included in all messages.

- Flood emergency planning

Flood emergency planning is crucial to ensure an effective, proactive emergency response to flooding. All stakeholders must be recognized and well informed of this plan, which should be applied within the legislated framework. The plan should facilitate a consistent and coordinated approach to flood response within the risk area in the lead up to, during and immediately after a flood event. All arrangements should detail in the plan. This plan should be put into action by the community and government agencies. Communication and consultation are essential for success.

Reconstruction

This stage involves decisions regarding the return to normal activities after a period of flooding. After a flood occurs, impacts should be evaluated, and mitigation plans should be implemented. Post-disaster recovery measures should be taken as follows:

- Rebuilding

Immediately after the flood, houses, public services, infrastructures, e.g., roads, electricity, and the water supply, are rebuilt or repaired.

- Insurance and tax adjustments

Assistance and relief in the form of low-cost and subsidized insurance and taxes should be provided, along with low-cost loans. This would relieve the short-term stresses of the community.

- Income generating activities

Supporting income generating activities of members of the community is a high priority. The community should return to a normal activity and income by any means as fast as possible.

- Flood plan evaluation

To reduce the risk of floods in the future, lessons from past floods should be considered. Collecting important data, such as stream flow, flood areas, flood duration, emergency plan implementation, and mental health surveys is essential. A revise flood plan should be generated for the next early stage management step.

In this area, the impacts and risks to people and property were studied. To mitigate climate change in the future, applying the proposed flood management plan will produce less impact as seen in *Table 14*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_841861

Table 14. Risk to people and property in the Lampao River Basin during a flood event

Impacted	Unit	Current	Future	Decrease(%)
Number of People	People	7,079	6,358	10.19
Number of Properties	Family	1,863	1,287	30.92
Agriculture	Square Kilometre	163.69	112.96	30.99
Infrastructure	Square Kilometre	1.80	1.23	31.67

Catastrophe Stress of Flooding in the Lampao River Basin

A survey of catastrophe stress of flooding was conducted in the Lampao River Basin sometime after when a major flood in 2011. The standard inquires of catastrophe stress, as determined by Department of Mental Health, Ministry of Public Health (ST5), were conducted. Effects on mental health from the stress of flooding were assessed in a community survey of 900 people, and the results are given in *Table 15*.

Table 15. Catastrophe stress of flooding in the Lampao River Basin

Stress level	Number of People (people)	Percentage (%)
Minor	127	14.11
Gentle	325	36.11
Considerable	313	34.78
Severe	135	15.00
Sum	900	100.00

Flood victims face several problems simultaneously, such as inconvenienced living, loss of property, loss of income, etc. These issues can lead to stress, anxiety, and depression. Mental illness treatment should be provided for an indefinite time until the community mental health recovers. Community mental health is a good indicator for evaluating the success of a flood management plan and should be considered in the revised plan.

Conclusion

Climate change poses significant risk to the Chi River Basin. This study responds to the needs of decision makers to plan for flooding caused by climate change. A quantitative study of the impacts of climate change based on hydrological regimes and of managing the impacts is presented. A sub-catchment, i.e., the Lampao River Basin, was used to yield detailed results for the entire basin. An increase in precipitation was observed, with the consequence of increasing the risk of rain-induced flooding. Regional climate scenarios, particularly for precipitation, were derived from SDSM to downscale climatic data for stream flow modeling of the Lampao River Basin. The results show that the SDSM provides adequate downscaled precipitation data using CGCM3 predictors. Stream flows are obtained from imputing different scenarios of precipitation data to the SWAT and HEC-RAS models and using the results to develop

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_841861

flood hazard maps. A flood management plan was presented as a useful tool so that all sectors can be aware of vulnerabilities and more efficiently cope with flooding.

While the plan was developed with simulated flood-related legislation and supporting policies and strategies, it recognizes that no single approach comprises an effective response to flood management issues. It also recognizes that it is not possible and to eliminate areas subject to flooding within the region, as a residual risk will remain.

Development of computer-based tools that enable analysis of the whole system, evaluation of the consequences of strategic intervention and coordination of intervention activities as a flood decision support system could be a beneficial research.

Acknowledgements. The authors thank members of the Faculty of Engineering, Vongchavalitkul University, for valuable consulting and guidance for this study. The authors also thank the government agencies of the Royal Irrigation Department (RID) and the Meteorological Department for useful information.

Abstract. The paper is concerned with the results of the ruderal flora investigation carried out in the vicinity of the town of Kosovska Mitrovica (Serbia) and its surroundings, in different urban and suburban habitats, and is based on the copious floristic researches conducted between 1995 and 1996 and repeated in 2016. The total number of 444 taxa was reported in the course of 2016. Not only was reported the presence of 386 taxa in the same areas between 1995 and 1996, but also 58 new taxa were recorded in recent field explorations. The ruderal flora composition in Kosovska Mitrovica area has changed by 13.06% in the past 20 years. Detailed taxonomic, ecological, and phyto-geographical analyses were provided for the discovered synanthropic flora. Special attention was paid to the appearance of new invasive species unregistered 20 years ago, but which, due to the more intensive anthropogenic influence, have become more diverse in number and frequency in the investigated areas.
Keywords: *urban habitats, ruderal flora, ecological analysis, invasive plants, Kosovska Mitrovica*

Introduction

Urbanization has created new ecosystems that harbor specialized flora adapted to anthropogenic alterations (Neto et al., 2015). The ecological approach considers a city/town as an ecosystem. "Ruderal" biocenoses exist in all cities. The term "ruderata" (from Lat. rudus: rubble, ruins) refers to a specific habitat. The definition connects ruderal plants with their habitats: they grow in places (such as rubble) which are strongly disturbed by man, but not cultivated (Sukopp, 2002). The habitats with modified physical and chemical soil properties have lost their resemblance to primary land type and are located in the vicinity of settlements and around all types of urban buildings and infrastructures (Prodanović et al., 2008). Other terms used for the flora in human settlements are synanthropic, synurban and nitrophile flora (Pavlović-Muratspahić et al., 2010). Anthropogenic factors are of essential importance in the formation, survival, distribution, diversity and dynamics of this type of flora/vegetation (Jarić et al., 2011).

The flora of urban habitats has long been recognized as being rich in species (Stešević and Jovanović, 2008). Urbanization transforms floras through a series of filters that change: (i) habitat availability;(ii) the spatial arrangement of habitats; (iii) the pool of plant species; and (iv) evolutionary selection pressures on populations

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_863890

persisting in the urban environment. Habitat transformation and fragmentation are anthropogenic filters present in most ecosystems, while the strong influences of human preference and urban environmental conditions are unique to cities (Williams et al., 2008). The development and importance of this spontaneously developed plant cover are often underestimated in urban ecosystem by constant human efforts to destroy and curb it by giving way to cultivated plants. Ruderal plant species are often considered as invasive weeds; some have medicinal value while others have unknown utility. Regardless of its specific use, the ruderal flora grows rapidly and thus serves as study material for many botanical subareas and provides an opportunity to study the development of vegetation when most plants are annuals. The ecology of ruderal plants also reinforces the importance of these plants because they can vegetate, bloom, and fructify with high efficiency, allowing them to be used for the recovery of degraded areas (Neto et al., 2015).

Ruderal and synanthropic (synurban) floras, very young and dynamic floristic assemblages, as well as the corresponding vegetation units, have recently drawn attention of scientists throughout the world (Jovanović, 1997). The research of synanthropic flora of various urban areas (cities, towns and smaller settlements) has had a long tradition. The interest in urban floras can be attributed to the fact that cities are remarkably ample with species due to a high habitat diversity and abundance of alien species. Outside Europe, urbanization and its consequences have been intensively studied in North America (Celesti-Grapow et al., 2006). The first investigations in the field of urban ecology in Europe focused on single habitat types (old settlements, ruins, gardens, and parks), while comprehensive studies of urban ecosystems were started in the 1970′s (Sukopp, 2002). In Serbia, as a part of territory of former Yugoslavia, similarly to other European countries, such studies were conducted in the second half of the 19th century (Šajinović, 1968; Slavnić, 1951, 1960, 1961; Marković, 1964, 1978, 1984; Matvejeva, 1982; Jarić, 2000), while special interest in the urban/ruderal flora and vegetation appeared in works of Jovanović (1997), Jovanović and Mitrović (1998), Stankovic-Kalezić (2007), Stanković-Kalezić et al. (2008; 2009).

The floristic research of ruderal weed was conducted to determine accurate data about the qualitative composition of ruderal flora and the quantitative presence of certain species on ecologically diverse surfaces of urban and suburban areas of the town of Kosovska Mitrovica (Serbia). The purpose of the paper was to identify possible changes in the floristic composition of ruderal flora for a period of 20 years, which might provide data on the succession planting and fully introspect ecology of each individual plant species in the investigated area.

Materials and Methods

The investigation was carried out in the central area of the town of Kosovska Mitrovica (Serbia) and its surroundings, on various urban and suburban ruderal surfaces within more than 15 kilometers. During the growing season of 1995-1996, field researches were conducted on 28 randomly chosen sampling sites (trodden and nitrified ruderal places, nitrified ruderal non-trodden habitats, hygrophilic ruderal habitats, covered disposal areas). During 2016 the researches were continued in the majority of the previously investigated areas but it was virtually impossible to provide a detailed map of already studied probing areas because they had absolutely changed due to extreme anthropogenic influences (i.e. urbanization). Likewise, as the town had

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_863890

extended to new areas, another two probing surfaces were added during floristic investigations in 2016. The majority of collected plant material is kept in the Herbarium at the Institute of Botany and the Botanical Garden of Faculty of Biology, University of Belgrade (BEOU).

The collected plants were determined on the basis of modern floristic literature: The Flora of Serbia: Josifović, ed. 1970-1977; Sarić and Diklić, eds. 1989 and The Flora of Europe: Tutin, ed. 1964-1980. The nomenclature was adjusted to Euro+Med Plantbase (2006) and The Plant List (2013). The life forms of plants were determined by applying Ellenberg and Muller-Dambois method (1967), with Stevanović's supplements (1992) and elaborations based on the conditions in Serbia. Stevanović's (1992a) phyto-geographical classification was the starting point for determination and phyto analysis of floral elements. The prevalence was calculated by the number of sites where the target species occurred divided by the total number (30) of sampling sites.

Study area

The town of Kosovska Mitrovica, with its surroundings, lies between 42° 53' north latitude, 20° 52'east longitude, and 496-510 altitude, and stretches to the farthest northern point of Kosovo Valley (*Fig. 1).* It is situated in the alluvial area and on the terraces of the Ibar and Sitnica Rivers, with the volcanic cup of Zvečan dominating the city. The largest part of the territory is considered mountaineous. More than half of the city and its surroundings consists of brown shallow soil with poor fertility. It should be emphasized that, influenced by heavy industry, many types of soil have undergone degradation and "enrichment" with various waste products that reduced their fertility. The climate is marked as moderate-continental. Mitrovica is located among Kopaonik and Rogozna mountains, hence the annual precipitation is low (600 mm on average).

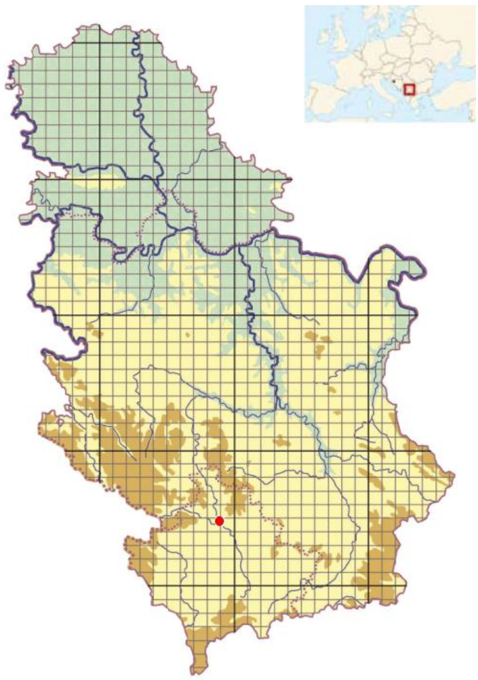

Figure 1. *Geographical position of investigated area (town of Kosovska Mitrovica) in Serbia (marked with red point)*

Results and Discussion

Taxonomic spectrum of the ruderal flora in the town of Kosovska Mitrovica

Ruderal species are plants commony grown in urban areas and are best adapted to man-altered environments. Floristic researches in different types of ruderal habitats in the city proper of Kosovska Mitrovica and its surroundings, within the range of 15 kilometers, discovered 444 species of vascular plants representing 271 genera and 58 families (*Table 1*).

The study presents a continuation of the research, whose results were published in 2008 (Prodanović et al., 2008). The presence of 386 taxa was reported in the same areas between 1995 and 1996, and 58 new taxa were recorded in recent field explorations. It is important to emphasize that not all collected species are ruderal, even though they can be traced in various anthropogenic habitats. A certain number of species are found in habitats of primary or secondary forms of vegetation, such as forest, meadows or completely segetal (field) species. These species apperently present either the debris of the original primary communities that were prior to ruderal communities or they appeared afterwards.

Newly recorded taxa include: *Allium flavum* L., *Chaerophyllum bulbosum* L., *Vinca minor* L., *Hedera helix* L., *Asparagus tenuifolius* Lam., *Ambrosia artemisifolia* L., *Cota austriaca* (Jacq.) Sch. Bip, *Symphyotrichum novi-belgii* (L.) G.L.Nesom, *Symphyotrichum salignum* (Willd.) G.L.Nesom, *Calendula officinalis* L., *Echinops sphaerocephalus* L., *Filago germanica* (L.) Huds., *Helianthus tuberosus* L., *Lactuca muralis (L.) Gaertn*., *Lactuca perennis* L., *Solidago gigantea* Aiton, *Tanacetum corymbosum* (L.) Sch.Bip., *Catalpa bignonioides* Walter., *Anchusa azurea* Mill., *Cynoglossum creticum* Mill., *Nonnea pulla* DC., *Arabidopsis thaliana* (L.) Heynh., *Camelina sativa* (L.) Crantz., *Sisymbrium officinale* (L.) Scop., *Sisymbrium orientale* L., *Blitum bonus-henricus* (L.) Rchb., *Cuscuta europaea* L., *Echinocystis lobata* (Michx.) Torr.& A. Gray, *Carex panicea* L., *Shoenoplectus lacuster* (L.) Palla, *Euphorbia taurensis* All., *Amorpha fruticosa* L., *Trifolium arvense* L., *Vicia tenuifolia* Roth., *Vicia tetrasperma* (L.) Schreb., *Geranium columbinum* L., *Leonurus cardiaca* L., *Malva neglecta* Wallr., *Maclura pomifera* (Raf.) C.K. Schneid., *Fraxinus ornus* L., *Phytolacca americana* L., *Platanus orientalis* L., *Arrhenatherum elatius* (L.) J. Presl & C. Presl, *Bromus arvensis* L., *Poa trivialis* L., *Reseda phyteuma* L., *Sherardia arvensis* L., *Populus alba* L., *Populus nigra* L., *Salix alba* L., *Comandra umbellata* (L.) Nutt., *Acer negundo* L., *Acer pseudoplatanus* L., *Acer saccharinum* L., *Antirrhinum majus* L., *Veronica praecox* All., *Veronica serpyllifolia* L. and *Viola arvensis* Murray.

The taxonomic spectrum of the vascular flora in the city area of Kosovska Mitrovica includes 3 classes, 58 families, 271 genera and 444 species and subspecies. *Dicotyledones*, with 51 families, 231 genera (49,09%) and 384 taxa (86,03%), are richer in number than *Monocotyledones* which include 6 families (1,35 %), 41 genera (9,23%) and 60 taxa (13,51%), whereas horsetail *(Equisetinae)* is present only with two species of *Equisetaceae.* According to the researches of Pyšek et al. (2009) the most common families in the urban areas of Europe are: *Asteraceae, Poaceae, Rosaceae, Fabaceae* and *Brassicaceae,* which, along with ruderal species, comprise farming weed and invasive species; their number is positively related to the urbanization level (Pyšek, 1998).

According to the literature data on vascular flora of Serbia, the families with the greatest number of species are: *Asteraceae, Poaceae, Fabaceae, Caryophyllaceae, Brassicaceae, Lamiaceae, Scrophulariaceae, Apiaceae* (Stevanović et al., 1995). In the ruderal flora of Kosovska Mitrovica and its surroundings the largest families coincide with the most numerous families in the flora of entire Serbia (*Asteraceae*-77 species, *Poaceae*-49 species, *Fabaceae*- 46 species, *Brassicaceae*- 36, *Lamiaceae*- 22 species, *Caryophyllaceae*-20 species, *Apiaceae*-16 species, *Scrophulariaceae*-12 species). The result was anticipated because of the synanthropic character of a great number of representatives of these families.

The most profuse genera found within the taxonomic floral structure in Kosovska Mitrovica area were the following: *Vicia* (11 sp.), *Trifolium* (9 sp.), *Veronica* (8 sp.), *Medicago* (7 sp.), *Bromus* and *Ranunculus* (each with 6 sp.), *Centaurea*, *Crepis*, *Sonchus*, *Silene*, *Euphorbia*, *Poa*, (each with 5 sp.), *Cirsium*, *Rorippa*, *Geranium*, *Salvia* and *Rumex* (each with 4 sp.). These genera usually include a large number of ruderal and ruderal-segetal plants. The species comprising these genera show the anthropogenic character of diverse ruderal habitats indicating either their nitrification or their xerothermic features, or the presence of intensive treading, mowing, and other anthropogenic influences that make ruderal habitats highly dynamic and instable biotopes (Jovanović, 1994).

General life form spectrum

The flora of Central European cities is dominated by hemicryptophytic life forms (Sukopp, 1990), while therophitic life forms prevail in South European city flora (Stešević et al., 2014). The ecological analysis in Kosovska Mitrovica showed the hemicryptophitic type of ruderal flora (189 sp. 42,56 % of total) (*Fig. 2)*. The dominant role of hemicryptophytes is potentially even more emphasized by the fact that among the primary annual (one year old) plants (therophytes) there are 25 species that, under specific conditions, alternate as two years old forms. The hemicryptophyte life form is largely described by trunk (stem) shapes (H scap), with 111 species. The domination of hemicryptophytes in the biological spectrum of the ruderal flora of Kosovska Mitrovica corresponds to a dominant presence of these life forms in the whole flora of the Balkans (Turill, 1929). Repeated field researches, 20 years after, showed that the number of hemicryptophytes in the ecological spectrum of life forms had increased by 19 representatives. This may be confirmed by the fact that some surfaces where the floral material was collected have ecologically stabilized.

Therophytes participated less (179 sp., 40,31% of total), which classified them as second in the biological spectrum of Kosovska Mitrovica ruderal flora. As a rule, the higher the impact of anthropogenic factor in a ruderal habitat, the greater the participation of therophytes on account of one and two years old species, which leads to the biospectrum modification (Jovanović, 1994). The total number of the newly reported or discovered plants that belong to this life form is 16. Other life forms were present with a smaller number of representatives: geophytes (25 sp., 5,63%), phanerophytes (20 sp., 4,50%), chamaephytes and scandentophytes with equal number of species (12 sp., 2,70%), and hydrophytes with 7 sp., 1,57%.

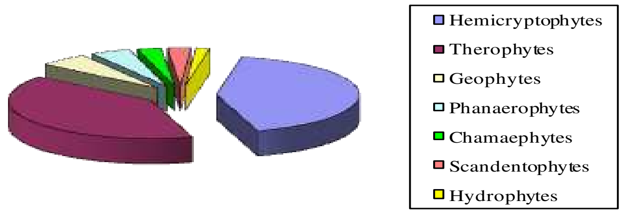

Figure 2. *Life form spectrum of ruderal flora of Kosovska Mitrovica (Serbia)*

Phytogeographical analysis of ruderal flora

Ruderal flora, as a specific plant category, is under the anthropogenic impact. It is unsuitable for the analysis whose aim is to determine floral and geographical belonging to certain area (Jovanović, 1985). This could be explained by the fact that ruderal flora encompasses species of vast areas whose diffusion was (directly or indirectly) influenced by man. There is also a fact that the composition and diversity /abundance of ruderal flora and vegetation of some area are proportional to the intensity of anthropogenic influences and may serve as an indicator of environmental quality and urbanization level. A detailed phytogeographic analysis of Kosovska Mitrovica ruderal flora corroborated the presence of 7 basic area types that incorporate 18 areal groups *(Fig. 3).*

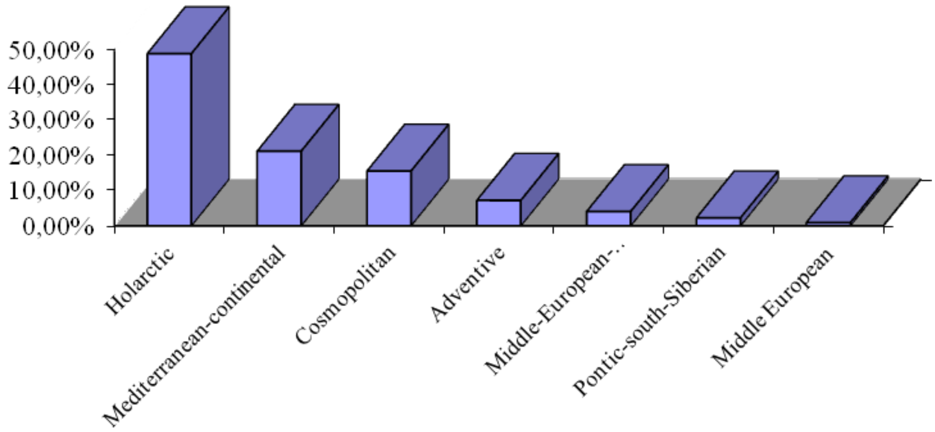

Figure 3. *Chorological spectrum, by basic area types, of the entire ruderal flora of Kosovska Mitrovica (Serbia)*

Most numerous species were of the Holarctic area type, presented with 217 species or 48,87%, within which the European, Western-Asian and Euroasian group of floristic elements dominated. According to its number, Mediterranean-continental type is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_863890

second, with 94 taxa (21,17%) united in 4 different groups of area floral elements. The areal types of Cosmopolitan species are represented by 69 taxa (15,54%). The cosmopolits of Euroasian and Mediterranean origin are larger in number compared to the Cosmopolits of circumholarctic and tropical origin.

The presence of adventive plant species is relatively high (32 taxa or 7,21%). The increased number of adventive and cosmopolitan species shows the instability of urban and suburban habitats, because 19 new taxa have been reported in the past 20 years (from the total of 58 recently recorded) and they all belong to the given area type. The common representatives are: *Symphyotrichum novi-belgii* (L.) G.L.Nesom, *Symphyotrichum salignum* (Willd.) G.L.Nesom, *Calendula officinalis* L., *Helianthus tuberosus* L., *Solidago gigantea* Aiton, *Phytolacca americana* L., *Antirrhinum majus* L., etc. It could be noted that they are the species that man brings into the urban habitats, mostly as decorative and horticulture plants. Due to their pronounced biological potential they conquer new habitats and anthropogenically spread from urban areas to natural (uncultivated) surroundings, usually after removing the plant remnants in autumn and placing them in landfills /disposal sites. The least reported species in the ruderal flora of Kosovska Mitrovica is Middle-European-Mediterranean areal type (18 species), Ponto-South Siberian (10 species) and Middle European dispersion areal type (4 species).

Ecological analysis of ruderal flora

The contemporary way of life and urbanization (demolition and new construction, changes in land use, traffic, etc.) in the town have resulted in fragmentation of habitats or their complete loss. Rapid urbanisation in Kosovska Mitrovica over the last decade has caused a visible decrease in green areas, but also the change of floral composition of the ruderal flora. Following the dynamics of appearance of the found ruderal floras in certain localities, it is possible to ascertain their ecological (phenotypic) plasticity and their adaptability to various conditions that prevail on investigated surfaces. The most widespread species *Convolvulus arvensis* is the most prevailing species (93,3%) in 28 out of 30 researched areas. The given species inhabits sunny and open ruderal habitats where it vies with other species for nutrients and available humidity. It also may decrease habitat biodiversity. It is one of the most serious weeds of agricultural fields in temperate regions of the world.

According to its prevalence degree of 76,6% and phenotypic plasticity and adaptability, *Taraxacum officinale* occupies the second place and inhabits the most diverse ruderal habitats, which may be confirmed by the results of the comparative morpho-anatomical research of the species *T. officinale* whose samples originate from trodden and untrodden areas of Belgrade (Stevanović et al., 1988). From the ecoclimatic point of view, the trodden ruderal habitats along with the majority of other types of ruderal habitats, may be defined as xerothermic with a favourable regime but with weak soil aeration and severe water deficiency. *Taraxacum officinale* has very large leaves with mesomorphic structure on untrodden surfaces. The members of this species on trodden areas show a variety of xeromorphic features. This indicates a significant phenotypic plasticity of the species and their adaptability to the changed environments in different ruderal habitats.

Species that were found in more than 50% of the sampling sites were: *Plantago lanceolata, Capsella bursa-pastoris, Cardaria draba, Lactuca serriola, Lotus corniculatus* (prevalence= 66,66%), *Artemisia vulgaris, Stellaria media, Chenopodium*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_863890

album, Melilotus officinalis, Achillea millefolium (prevalence=60%), *Polygonum aviculare, Medicago lupulina, Cynodon dactylon, Anisantha sterilis, Poa nemoralis, Hordeum murinum subsp. leporinum* (prevalence=53,3%). The group of eurivalent species with 50% of frequency includes: *Silene vulgaris, Tragopogon dubius, Trifolium repens, Tripleurospermum inodorum , Erodium cicutarium, Galium aparine, Cichorium intybus and Ballota nigra* . The species like *Convolvulus arvense, Taraxacum officinale, Polygonum aviculare*, *Cynodon dactylon* are prominent due to their exceptionally pioneering character and the ability to adapt to diverse, often extreme and difficult conditions of ruderal habitats.

Diametrically opposed to the group of highly frequent ruderal species is a number of species with a limited range-stenovalent plants (prevalence=6,6% or 3,3%), which , in accordance with their ecology, develop only in certain ruderal habitats. The group of stenovalent plants is represented by ruderal higrophile species that appear on nitrified, humid and periodically flooded river banks, such as: *Bidens tripartitus, Persicaria maculosa, Persicaria lapathifolia, Mentha aquatica, Mentha longifolia* etc. This group may also include species such as: *Comandra elegans, Asparagus tenuifolius* and they appear only in one investigated area, as the remains of the primary vegetation form. We assume that, as the anthropogenic influence grows and intensifies in the mentioned localities, some of these species will become extinct because the ruderal habitats do not suit them, i.e. they do not provide ecological optimum for their development.

Sukopp (1973) presents data that between 1850 – 1950 some European cities faced the loss of flora by 4-16%. Klotz (1987) and Landolt (2000) show that the number of species in the cities flora has remained approximately the same in the past 1-2 centuries, but the flora composition has changed by 30- 40% and provided an advantage for the adventive species (Stešević et al., 2014). Our analyses show that the ruderal flora composition in Kosovska Mitrovica area has changed by 13.06% in the past 20 years. It is also noted that there has not been a reduction in a total number of species. Autochthonous species were replaced by allochthonous-cosmopolitan species,which as more adaptable to homogenous and degraded urban habitats, are beginning to compete with natural species and are gradually ousting them.

The introduced species that might become invasive represent a special menace and may cause destruction of natural ecosystems and changes in their biodiversity. Newly introduced plants most frequently inhabit ruderal habitats that are temporarily or permanently under the anthropogenic influence. The most widely accepted definition of invasive species is the one advocated by the global environmental organisation IUCN (International Union for Conservation of Nature): ”*An invasive alien species (IAS) is a species that is established outside of its natural past or present distribution, whose introduction and/or spread threaten biological diversity*” Convention on Biological Diversity. Out of total number, 38 plant species from the weed ruderal flora of Kosovska Mitrovica and its surroundings, are labelled as invasive (*Acer negundo, Ambrosia artemisifolia, Symphyotrichum novi-belgii, Symphyotrichum salignum, Erigeron canadensis, Galinsoga parviflora, Helianthus tuberosus, Solidago gigantea, Xanthium orientale subsp. italicum, Xanthium spinosum, Centaurea solstitialis, Artemisia vulgaris, Cichorium intybus, Amaranthus albus, Amaranthus blitoides, Amaranthus retroflexus, Bifora radians, Armoracia rusticana, Coronopus squamatus, Echinocystis lobata, Chenopodium strictum, Amorpha fruticosa, Medicago sativa, Robinia pseudoacacia, Alceae rosea, Echiochloa crus-galli, Sorghum halepense, Dasypyrum villosum, Phytolacca americana, Polygonum aviculare, Portulaca*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_863890

oleraceae, Consolida orientalis, Consolida regalis, Rubus caesius, Veronica persica, Datura stramonium, Lycium barbarum, Urtica dioica). The largest number of their representatives belong to *Asteraceae family* (12 species), followed by *Amaranthaceae, Fabaceae* and *Poaceae* (each with 3 species). The investigations show that there has been an increase of invasive species and they have become more frequent in every investigated locality over the past 20 years.

If we analyse the origin of invasive species within weed ruderal flora of Kosovska Mitrovica and its surroundings, we may come to the conclusion that the species originating from North American continent (19 of them-50%) prevail in number. These species were mostly introduced as decorative plants (*Robinia pseudoacacia, Acer negundo*), but they soon "escaped" to the wilderness attacking the natural ecosystems with detrimental effects and became invasive. It is interesting to mention the *Ambrosia artemisfolia* species unreported in Kosovska Mitrovica and its surroundings until 2012 has been randomly spotted on certain ruderal places in the city core ever since.

Currently, the larger part of the society perceive ruderal urban plants as common weeds and do not appreciate their stability and aesthetic value. Currently the aesthetic and ecological values of such plant communities are indiscernible and underestimated. However, colourful flowering plant communities in cities have a positive influence on human senses (Kazimierska et al., 2009). Except in the case of allergenic plants and their negative influence on human health, it can be generally stated that the flora and vegetation of man-made environments represent a significant, spontaneously developed phytohealing factor, the one which in such polluted conditions produces a whole series of positive effects so they deserve a better treatment (Stešević and Jovanović, 2008).

In an industrial city, such as Kosovska Mitrovica, a spontaneously developed plant cover has undoubtedly many positive effects (oxygen production, carbon-dioxide assimilation, soil overheating avoidance, soil erosion prevention, esthetic and health-hygienic protection of the unhygienic areas, decoration) so it should be "exploited" and adjusted to fit human needs (which implies prevention of undesirable species spreading, their blooming and fruiting) and organize a monitoring process over an extended period of time to evaluate the changes in habitat conditions, as well as in floristic composition.

Conclusion

Due to expected and intense anthropogenic activity on ruderal flora in Kosovska Mitrovica and its surroundings, there was a change in overall floral composition by 13,06%, over a period of 20 years (1996-2016). A total of 444 taxa of vascular plants classified into 271 genera and 58 families were found in various types of ruderal habitats; with 58 new taxa reported in recent field explorations. An analysis of life forms in the ruderal flora of Kosovska Mitrovica showed that after a period of 20 years, the investigated area still has hemicryptophyto-therophyte character, with domination of hemicryptophytes. Phytogeographic analysis revealed the presence of 7 basic area types that incorporate 18 areal groups. The most numerous species were of the Holarctic area type, presented with 217 species or 48,87%. The increased number of adventive and cosmopolitan species shows the instability of urban and suburban habitats, because 19 new taxa have been reported in the past 20 years (from the total of 58 recently recorded) and they all belong to the given area type. The most prevailing species are

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_863890

Convolvulus arvense and *Taraxacum officinale*. Out of total number of recorded species, 38 are labelled as invasive.

All botanical studies should definitely include monitoring biodiversity of urban flora and new short term researches. It is the only method to identify potential threats to autochtonous flora and to enable a timely anthropogenous action to curb spreading of invasive, potentially allergenic species as well as aggressive, competitive species that might have negative effects on human population and urban habitats.

(Received 24th May 2017; accepted 2nd Aug 2017)

Abstract. A study was conducted to evaluate residues of imidazolinone (IMI) in soil. Samples were taken from three Clearfield® rice fields as IMI which have been used for six years. IMI herbicides (imazapic/imazapyr) were widely used in Clearfield® rice soils. To date, few studies are available on the residues of these herbicides, especially in the context of Malaysian soil. Therefore, for this purpose, high performance liquid chromatography (HPLC) with UV detection was performed using a Zorbax stable bond C_{18} (4.6 × 250 mm, 5 µm) column, with two mobile phases. The average percentage recovery for imazapyr and imazapic varied from 76%-107% and 71-77%, with 0.1-5 µg/ml fortification level, respectively. The limit of detection (LOD) and limit of quantification (LOQ) were found to be 1.05 and 4.09 for imazapic and 0.171 and 0.511 µg/ml for imazapyr respectively, in the top 15 cm. In the extracted soil sample, it was 0.19 µg/ml for imazapic and 0.04 µg/ml for imazapyr, respectively. Based on this study, a pre-harvest period of 40-60 day is suggested for rice crops after IMI application.
Keywords: *recovery, acetonitrile, Zorbax stable bond C_{18}, HPLC, terminal residues, Clearfield® rice*

Introduction

Weedy rice (WR) is a notorious weed associated with rice paddy crops. WR in Malaysia (locally known as Padi Angin) was first observed and reported in 1988 (Watanabe et al., 1996). WR also always acted as dominant competitor in terms of inter- and intra- varietal competitions among rice species (Baki and Shakirin, 2010). The application of pesticides in the agricultural system becomes unavoidable in the present day, as it increases production and decreases yield loss caused by pests (Schreiber et al., 2017). In 2010, the introduction of a new type of imidazolinone herbicide (IMI) known as OnDuty® with its main ingredient being imazapyr/imazapic, was used in Malaysia's agricultural system (Azmi et al., 2011). Because sometimes mixing two or more herbicides into one spray solution can offer producers multiple benefits (Fish et al.,

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_891903

2015). This resulted in an overnight success in rice cultivation in terms of yields and WR control. It also helps control a broad spectrum of weeds, encompassing grasses, and cyperaceous and broad-leaved plants, and those that WR are closely associated to (Neto et al., 2017).

IMI inhibits the enzyme function in the plant known as acetohydroxyacid synthase (AHAS) (Bailey and Wilcut, 2003), which starves the plant and lead to its death. Upon the introduction of IMI – resistant cultivated rice (Clearfield®), most difficulties faced by farmers that are related to WR have almost been completely solved. OnDuty® herbicide formulation containing imazapyr is a generic name for [2-(4-isopropyl- 4-methyl-5-oxo-2-imidazoline-2-yl) nicotinic acid]; trade names of Arsenal and Chopper), while imazapic is the generic name of [2-(4,5dihydro-4-methy-4-(1-methylethyl)-5-oxo-1Himidazol-2-yl)5-methyl-3-pyridinecarboxylic acid]; trade names of Cadre and Plateau (Azmi et al., 2012). Both are widely used in WR, and its efficiency has been proven. IMI is relatively persistent in soil, with half-lives ranging from 30 - 150 days (Kemmerich et al., 2015). Shorter half-lives of imazapyr (34–65 days) detected in forest soils (Michael and Neary, 1993).

IMI have two enantiomers (Krieger, 2001) derived from the chiral center, which consists of imazapyr, imazapic, imazaquin, imazamox, imazethapyr and imazamethabenz-methyl, as per *Table 1*. IMI detection and research separation from water and soil are limited compared to other types of herbicides due to the low application rate (100-200g/ha) and co-extraction of other substances that interfere with chromatogram and low rates of application (Ramezani et al., 2009; Andreu and Picó, 2004). However, In the last decade, diverse studies were done on these types of herbicides to assess the risk assessment to the environments as water and soil (Silva et al., 2009; Anastassiades et al., 2003; Andreu and Picó, 2004; Börjesson et al., 2004; Bajrai et al., 2017). Also, the massive use of IMI herbicides might have contributed to the increase in resistant weedy rice, also, in most cases, herbicides-resistant weeds go undetected until they represent about 30% of the total population (Burgos et al., 2014). Many reports showed the imidazolinone carryover affected many non-rice crops in rotational systems (Alister and Kogan, 2005).

Studies on how much of these herbicides run-off into soil and water are important due to their potentially harmful influence on the environment (Schreiber et al., 2017). Developing methods for extraction in water and soil are very important, because some studies revealed that the residues of these herbicides remain present in Swedish soil after 8 hours (Börjesson et al., 2004). Herbicidal residue is defined as the remaining herbicides on or in the soil after its application in agricultural soil. Its persistence in soil sometimes causes injuries in the next crop (Assalin et al., 2014). Most previous studies on this type of herbicides used alkaline/acidified water, methanol, acetonitrile, and diverse techniques for the extraction process (Helling and Doherty, 1995; Ramezani et al., 2009). The extraction of IMI herbicides and determination using HPLC-UV is popular in literature, and it was used by many researchers because it provides clearer and more realistic results (Pace et al., 1999; Helling and Doherty, 1995; Laganà et al., 1998). Generally, herbicidal residues are usually concentrated in the top of 10 cm, although it could leach deeper. These residues are injurious to non-tolerant rotational crops, such as wheat and corn (Alister and Kogan, 2005). Areas such as Tanjung Karang sees intensive use of IMI herbicides by farmers. The rice farmers have been applying IMI herbicides for ~6 years. We present a simple HPLC method that can be used to detect, analyze, and evaluate the residues of the imazapic and imazapyr in soils

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_891903

cultivated in Clearfield system. Reversed – phase liquid chromatography (RP-LC) with ultraviolet (UV) detection is widely used because it can separate high or medium polarity pesticides and detect them at low levels, making it one of the most powerful technique in separation methods (Hogendoorn, 2006). The farmers in this area have been applying IMI herbicides repeatedly (Mazlan et al., 2016). Therefore, this study was undertaken in the Clearfield fields to determine residues of IMI in the soil.

Material and methods

Study site description

Sawah Sempadan-Tanjung Karang district is located on (N 3°25'35.0724", E 101°10'36.1704") in Kuala Selangor, Malaysia as shown in (*Fig. 1*). The soils samples were collected on November 2016/2017 from these fields, because the farmers there have been using IMI herbicides since its introduction in Malaysia in 2010 (Azmi et al., 2012). This area is the most prosperous agricultural district in Malaysia, and has many hectares of paddy rice (Mazlan et al., 2016).To determine the final IMI residue, the soil samples were collected at harvest time, which was ~90 days after IMI was sprayed on Clearfield rice crop.

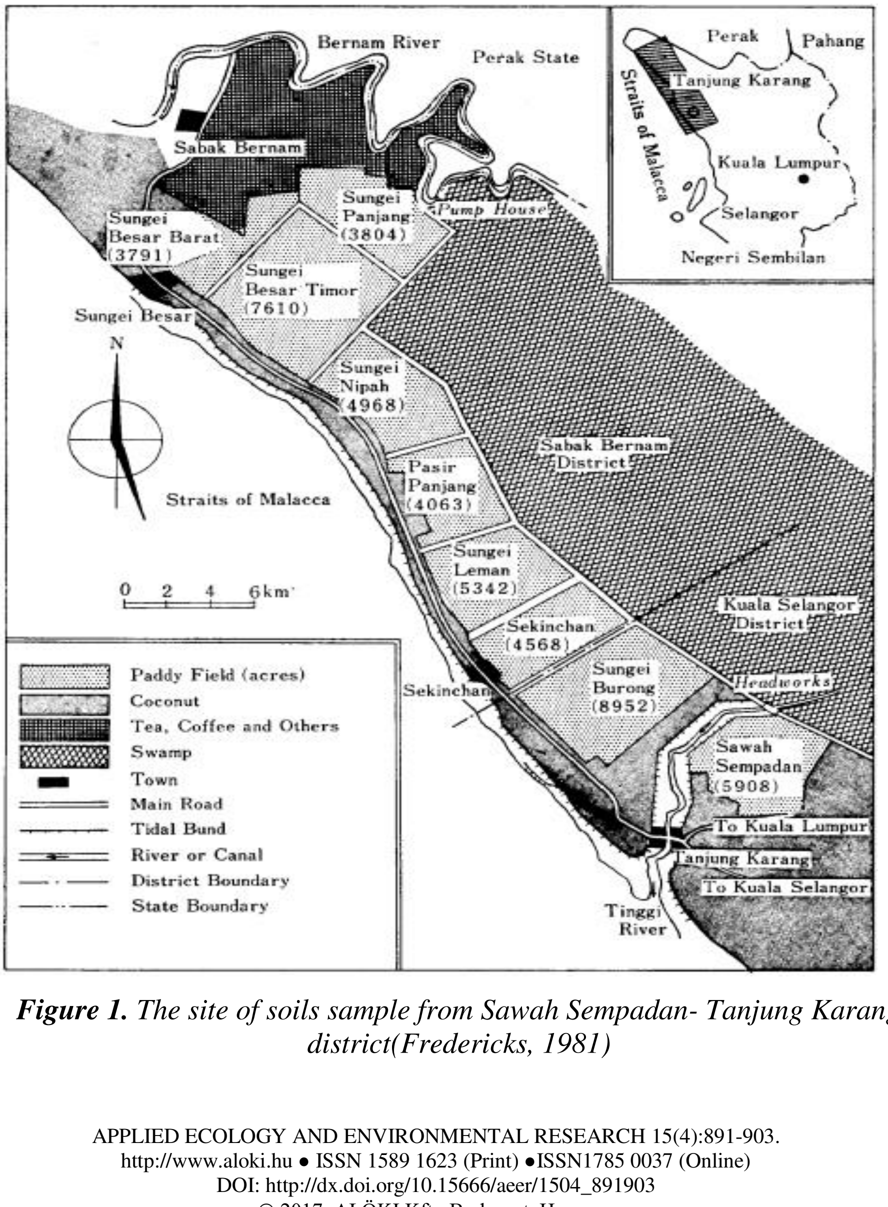

Figure 1. *The site of soils sample from Sawah Sempadan- Tanjung Karang district(Fredericks, 1981)*

Chemicals, reagents, and apparatus

Standards of imazapyr (99.5% purity) and imazapic (99.9% purity) were purchased from Sigma-Aldrich (USA), while formic acid (85%), methanol 99.9 % (HPLC grade) and acetonitrile 99.9 % (HPLC grade), acetic acid-ACS reagent (Fisher), formic acid-98% (EM Science), Sodium phosphate (Fisher), hydrochloric acid 6N (Fisher), phosphorous acid dichloromethane (DCM) 99.9 % (HPLC grade), and Rotary evaporator were purchased from Sigma Aldrich (Germany). Ultrapure water was obtained from a Milli-Q Direct UV3® system (Millipore, USA), and was further purified by passing it through a 0.2µm Whatman filter paper. The HPLC 1100 series fitted with a UV detector was used. The HPLC column used in this work was a Zorbax RX–C_{18} (4.6 × 250 mm, 5 µm). Its temperature was maintained at 30 °C. Centrifuge-Dupont Sorvall Model RC-5C, centrifuge bottles with cap 45 ml polypropylene (Kontes Scientific), vortex mixer (Labmart 3000), Thermo-ultra-sonic, analytical balances (AUW-220D and UX-420H from Shimadzu, Japan), 0.22 µm nylon filters, glass vials with capacity of 2 mL (Agilent, USA), and screw-capped polypropylene tubes (45 ml, Germany), DSC-18 6 ml tubes 500 mg (6 cm × 3cm) SPE cartridges (supelco), anhydrous sodium sulfate, and a vacuum pump were all used in this work as well.

Stock solution and working standards preparation

Standards stock solutions of the herbicides imazapyr and imazapic were individually prepared in methanol at concentrations of (100 µg/ml), respectively, from (1000 µg/ml). Different fresh diluted solutions were prepared as 0.1, 0.5, 1, 5, 10, and 20 µg /ml, and diluted in methanol. All stock and working solutions were stored at -18 ºC in the dark (Marcia, 2014). Then, each of these solutions was injected (17 µL) into the HPLC system, at 251 nm, and peak areas were recorded and plotted versus the concentration of the herbicides.

Soil collection and preparation

The sample preparation process which involves extracting the analyte is very important and crucial. To determine the herbicidal residues from the soil samples, the samples were taken systemically from a randomly chosen area from three Clearfield® rice fields that were exposed to the herbicides. The basic approach is to analyze the depth intervals of the soils samples for each field. Each sample was within 0 - 20 cm and 20 – 40 cm, about 30-m distance between each two samples was taken with the helical shape method. A 20 soil samples were taken, and ~500-gram (gm) soil samples were collected using special auger for collection of the soil samples for increased control, and were stored in sterile zip lock polyethylene bags and coded with special code water proof stickers.

Three random samples were selected (two from each field), then one sample was selected randomly for examination, while the rest were stored in a refrigerator at a suitable temperature for subsequent analyses. The samples were air-dried in the special room at 35 C° for up to 5 days, grounded with a mortar and electronic machine, sieved through stainless steel sieve (2.0 mm) and stored at 4 °C. A100 g of homogenized soil samples was stored in polyethylene bag at a temperature of ~15 C° until it was analyzed for herbicidal residues. The soil physico-chemical characteristics were analyzed and the basic properties of these soils are shown in (*Table 1*).

Soil extraction procedure for IMI Residue level

Analyses of the samples of soil were carried out using the modified extracted published methods proposed by (Ramezani et al., 2009; Krynitsky et al., 1999). About 5 ±0.001 g of a randomly homogenized soil sample was weighted, which provides appropriate and representative amount as some authors have used (Martins et al., 2014). The portion soil was placed in 250 ml centrifuge tube (polypropylene), 150 ml of extracted 0.5 N NaOH. Then sample was kept 45 minutes in an end-over-end shaker at 30°C to assess the homogeneity of the sample. A 10 ml methanol was added to precipitate humic acids and sonicated for 10 minutes, then centrifuge the sample for 10 minutes at 7000 rpm to remove particulates.

The sample solution was filtered and adjusted to pH 2 by addition of 6N hydrochloric acid. Clean-up is necessary to shift down the detection limits of methods and to avoid interferences from the matrix. The suspension was left at room temperature for 10 minutes until analysis, then transferred into a 500 ml separatory funnel and extracted with two 50 ml portions of dichloromethane (DCM). The extracts were combined and the DCM was dried using anhydrous Na_2SO_4, then passed through smooth activated charcoal. The resulting solution was then transferred into a 250-ml round bottom flask and solvent was evaporated at 65 °C using a rotary evaporator at a low speed to near dryness. The residue was diluted with about 2 ml of a 1:1 solution of methanol:0.1% formic acid, then loaded (under vacuum) into the 6 ml DSC-18 (Supelco) solid phase extraction cartridge containing 500 mg of polymeric of adsorbing material conditioned with 3ml of each of the solvents methanol, acetonitrile, and H_2O.

The vacuum was slowly reduced and the analytes were washed with 9 ml H_2O and 6 ml (60:40) (H_2O: acetonitrile). Finally, the vials were placed in the vacuum apparatus and the cartridge eluted with 3 ml of the methanol:0.1% formic acid solution. The resulting extract was filtered through a 0.22µm polytetrafluoroethylene (PTFE) membrane, transferred to a 1.5 ml HPLC auto sampler vial, and stored at 4°C until separation by HPLC.

Method application

In this study, 20 samples were taken from the same three sites of Sawah Sempadan-Tanjung Karang district, and different chemical compositions and pH values were analyzed.

Accuracy (%Recovery), limit of detection (LOD), and limit of Quantitation (LOQ)

LOD is the lowest concentration that can be detected, and it could be determined by a statistical method. This could be achieved by measuring the more dilute concentrations of analyte. These concentrations are expected to produce a response of ~3 times the background noise. LOD should be between 3 - 10. The LOQ is expected to behave similarly, but with a ratio of 10 times the background noise. Recovery studies in soils samples were conducted using the standard calibration curves equation.

These herbicides were spiked to blank soils (clean soils free from herbicides), taken from the land around University Malaya (N 3°7'8.9328" E101°39'28.494"). This soil was selected due to its similar characteristics with the tested soil samples. Acetone was added to 5 g of dried homogenized soil at different concentrations, and left to dry for 48h at room temperature to activate the introgression and equilibrium while slowly evaporating the solvent (Rebelo et al., 2016; Laganà et al., 2000), followed by extraction and analysis using HPLC-UV.

Results and discussion

Contamination of environmental resources by herbicides is an increasing environmental concern. Undoubtedly, soil plays a significant role in an agro-ecosystem, but information for analysis of these types of herbicide residues in the soil can be very difficult to achieve. HPLC with UV detection was chosen due to it being a fast and effective separation method. This study involves trying different columns and mobile phases for the HPLC technique. Finally, in this method a proper separation was achieved using the gradient mobile phase and C_{18} column (4.6 × 250 mm, 5 µm) was used for stationary phase separation.

Purified water was used as one of the mobile phases, due to its low cost, lack of toxicity to the environment (Laganà et al., 2000). The mobile phase acetonitrile (100%), as one of mobile phase, is the best mobile phase (Martins et al., 2014; Demoliner et al., 2010), along with purified water acidified with 10% acetic acid (pH to 2.8), due to the pH's effect on the peak shape (Singh, 2013).

Therefore, acetonitrile was chosen due to it is great solubility and higher elution strength than dichloromethane for fractionating the analytes. Acetonitrile is the best choice for the mobile phase (Singh, 2013). However, analysis was carried out using gradient solvent program using mobile phase A (acetonitrile (100%)) and mobile B (purified water acidified with 10% acetic acid (pH adjusted to 2.8). The initial gradient program was 35% A, maintained for a minute, then increased to 45% for 3 min, then decreased to 35% at 8 mins. The column temperature was set to 30C°. The flow rate was 1 ml/min, injection volume was set to 17 µL, and UV detection was set to a wavelength of 251 nm.

Simultaneously, methanol was evaporated before the sample is injected into the HPLC apparatus. Standard curve linearity and calibration was determined at six concentrations (0.1, 0.5, 1, 5, 10, and 20 µg /ml), and were prepared in the laboratory by diluting the stock solution and plotting the analytes' concentration against peak area. Each level of the concentration was analyzed repeatedly. The equation of analytical calibration was obtained by plotting the peak areas on y-axis and the concentration on the x-axis within the previous calibration levels for both imazapic and imazapyr. The concentration of both herbicides was calculated by comparing the peak values in the calibration, using the regression equation. The linearity of the method was determined from the correlation coefficient, as per *Fig. 2*.

The matrix effect has been mentioned in literature and is explained via multiple perspectives, with some reporting a shift of over 10% on the analytical results (Kemmerich et

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_891903

al., 2015). However, some that are less than 20% does not affect the matrix (Ferrer et al., 2011). The chemical analysis of these herbicides in soil are often problematic due to the low detection limits required and the pH adjustment during the extraction process. IMI is a weak acid, as per (*Table 2*), therefore their presence in soil is influenced by pH (Schreiber et al., 2017). Soil particles were fine-grinded to increase the interaction between the solvents and soil particles, which lead to increased herbicides extraction.

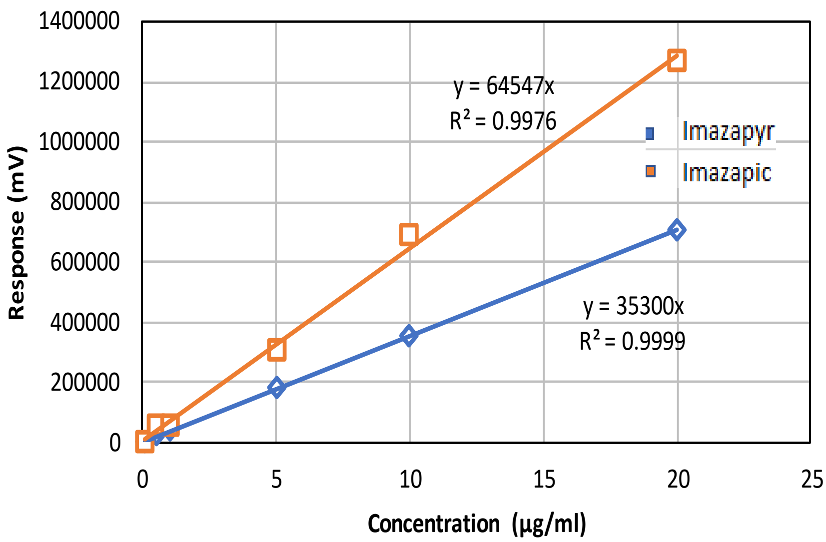

***Figure 2.** Representative calibration curve for IMI was obtained by the determination of six levels in duplicate at ranged from 0.1-20µg/ml*

DOI: http://dx.doi.org/10.15666/aeer/1504_891903

The traditional types of extractions ordinarily use the chemical compound PSA (primary secondary amine), and due to the fact that the IMI family are present in multiple forms, it acts as a weak acid/base, which allows PSA to hold over acidic herbicides (Marcia, 2014). One of the important effects occurs when the types of herbicides have pK_a values in the range 1.3-3.9 (Krieger, 2001), which includes the weak acid IMI herbicides. Based on this, the shape of the peak area during analysis was expected to be affected by the value of the pH of the mobile phase. Soil pH and the microbial activity are the main factors in the degradation process of IMI herbicides in the soil (Sondhia et al., 2015). For example, when the pH increases, the adsorption and persistence decreases.

Also, another important factor that control the residues' concentration is the depth and type of soil. IMI sorption is correlated and increased with clay content, due to increased binding of the herbicide to soil particles, where (Gianelli et al., 2014). (Burnside et al., 1963) show that some herbicides can leach deep into the soil. For example, some studies revealed that the sorption of these types of IMI as imazapyr to sandy soils is very weak compared to its sorption to clay and humic soils (Lode and Meyer, 1999). The agricultural soils contain numerous impurities and old chemicals, which can persist for a long time, which would cause separation problems in the column, especially if the soil contained only very low concentrations of imazapic or imazapyr. Imazapyr and imazapic have the potential to leach into groundwater due to its persistence and mobility in soils, and very low volatility (Gianelli et al., 2014). Certified imazapic and imazapyr (USA) were used for calibration (*Fig. 3* and *Fig. 4*).

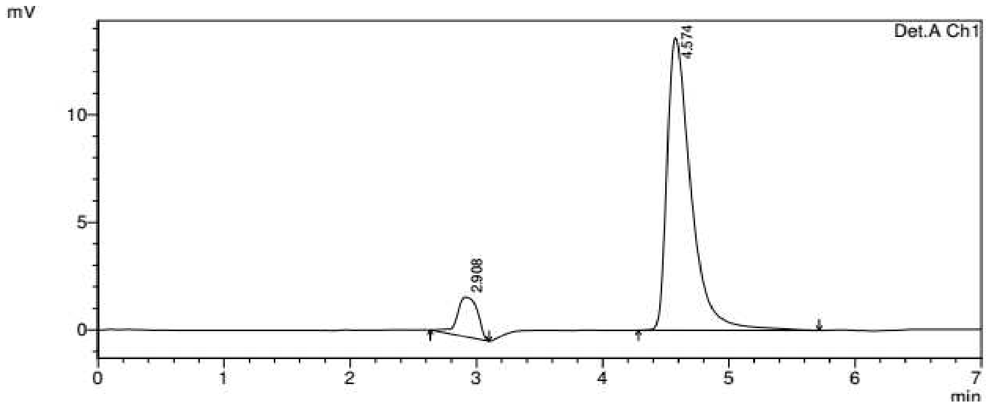

Figure 3. *Imazapyr standard, 10ppm*

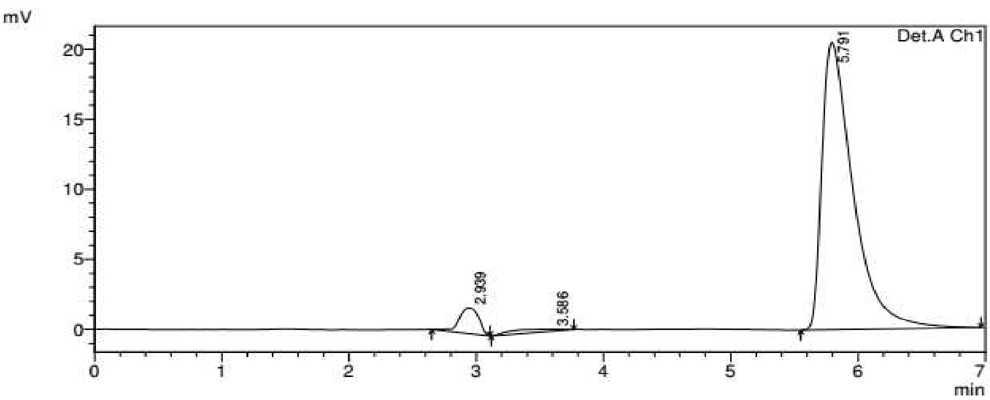

Figure 4. *Imazapic standard, 10ppm*

The adsorption of IMI herbicides decreases by increasing heavy rain and temperatures. The higher solubility of these types in water, high temperatures, and great rainfall in Malaysia are main factors that play important roles in the transition of residual particles of herbicides via its pores or movement to other places and shift up the degradation mechanism, as per (Grey et al., 2012; Fish et al., 2015). Malaysia has almost daily high intensity rain fall and temperatures. Studies revealed that temperatures between 35C°- 45C° and increased soil moisture enhance both the chemical and microbial degradation for herbicides (Neto et al., 2017). Different methods are applicable for extraction of IMI herbicides from soil samples, but most are not satisfactory (de Oliveira Arias et al., 2014). Despite the fact that imazapyr and imazapic were applied in low doses, both can remain for long periods of time in the soil , which can cause agronomic and environmental problems (Kraemer et al., 2009). However, leaching is influenced by the environment, which means that when the water content decrease from the upper surface, it leads to increased pH. Also, some chemical herbicides move to the upper surface of the soil due to capillary action, which causes it to evaporate (Mangels, 1991).

Selectivity

Selectivity is defined as the evaluation or detection of the analyte from others analytes and different compounds that could be present at the same moment in the matrix or the sample (Ahuja, 1989). There were no matrix peaks in the chromatogram analysis that interfere with analysis of the residues as shown in *Fig. 5* and *Fig. 6*.

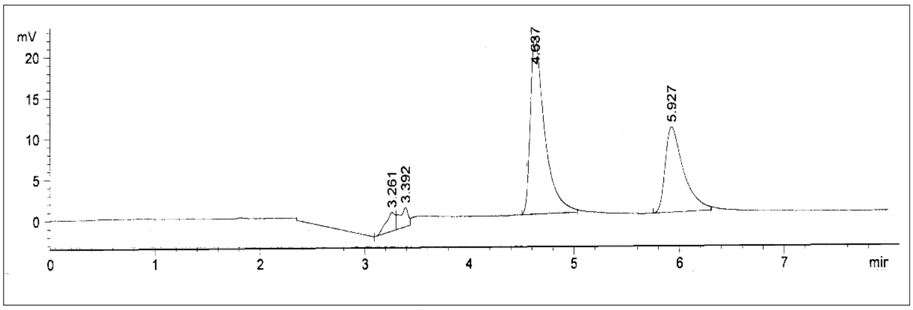

Figure 5. *Extraction imazapic and imazapyr with good resolution*

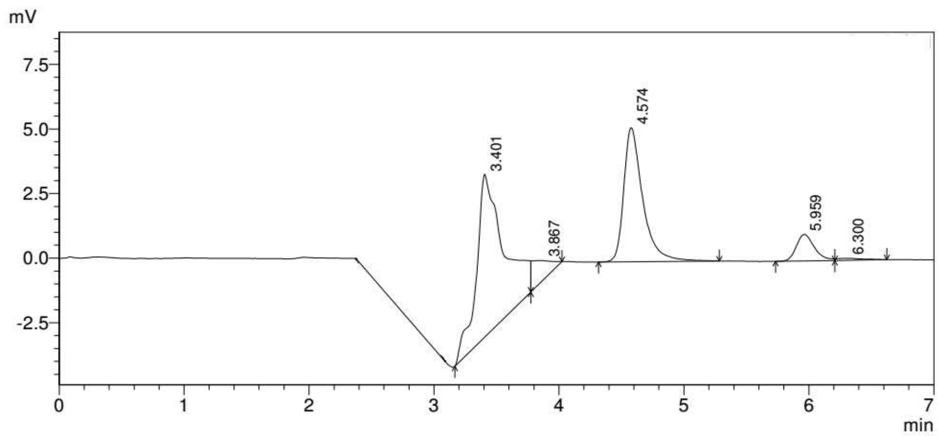

Figure 6. *Extraction imazapic and imazapyr with good resolution*

DOI: http://dx.doi.org/10.15666/aeer/1504_891903

Accuracy (%Recovery)-Limit of detection (LOD) and limit of Quantitation (LOQ)

The achieved results revealed an excellent linearity at different concentrations of imazapyr and imazapic standards in the range from 0.1 to 5 µg/mL. These herbicides' concentrations are spiked to blank soils as described in the experimental section.

Due to the spiking of the extracts, the final comparison between the two systems is expected to be valid. The precision and recovery for the two herbicides was calculated through the injection of freshly prepared six standards. The proportion of the area of the peak of herbicide resulting from the spiked solution to the area of the herbicide peak resulting from a standard solution prepared previously was calculated. The average percentage recoveries for imazapyr and for imazapic varied from 76%-107% and 71-79% with 0.1-5 µg/ml fortification level, and 0.1-10 µg/ml at fortification level, respectively, are shown in (*Table 3*). The LOD and LOQ were found to be 1.04 and 3.15 µg/ml for imazapic, and 0.135 and 0.411 µg/ml for imazapyr, respectively, in the top 15 cm. In the extracted soil sample, it was 0.19 µg/ml for imazapic and 0.04 µg/ml for imazapyr. This proves the slow degradation process of these residues in the soils under environmental conditions. The soil samples were taken during rice crop cultivation of about 90 days and the residues are evidently still present.

The Koc for the two herbicides were 137 and 100 ml g^{-1}, respectively, which means low adsorption and high mobility, and eventually high levels of leaching. Nevertheless, both herbicide residues are still present after ~90 days, especially imazapic with 0.2 µg/ml, which was proven by a previous study stating that these types of herbicides are highly persistent (Souza et al., 2016). Simultaneously, persistence of residues in the soil does not necessarily mean that it injures sensitive crops, as persistence differs from bioavailability.

Table 3. *Recovery of imazapic from soil*

Con. (µg/ml)	Recovered peak imazapic	Recovered peak imazapyr	Average % imazapic	Recovery % imazapyr
0.1	2475	3943.66	71.18	107.165
0.5	43513	17263.6	79.19	80.74
5	236358	137529.6	77.27	76.768
10	521185	341438.3	75.75	96.253

Repeatability and stability

The repeatability of this method was determined by calculating the RSD of the peak areas of the six duplicate injections of fortified samples which is < 15. It represents the closeness of the results from similar methods, laboratories, and tools. This is achieved via six concentrations, each replicated trice to a total of eighteen times, encompassing the specified range of the procedure. Accuracy = mean ±SD, for imazapic 75.85 ± 3.4, and for imazapyr, it was 90.232±14.

Conclusions

A simple analytical method based on HPLC-UV was developed and validated to determine the IMI residues in the Clearfield® rice soils. It is necessary to monitor the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ●ISSN1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_891903

presence of herbicides residues in soils and waters and develop methods for reliable analysis, as important tools of regulatory programs to protect the environment. A gradient of mobile phase A (acetonitrile (100%)) and mobile B (purified water acidified with 10% acetic acid (pH adjusted to 2.8)) yields excellent separation and resolution, in a short analysis time, for the two herbicides (less than 7 min), with retention time for imazapyr and imazapic at ~4.6 and 5.9 min respectively. Excellent linearity in the range of injected standard concentrations with a high degree of precision and accuracy could be achieved. Therefore, the proposed analytical method could be useful for detecting the imidazolinone family in agricultural soil and water in the future. Results of this study suggests the need for an extensive research to determine factors affecting the half-life of these herbicides and their contribution to their persistence. Also, further studies are needed on the laboratory level and plant bioassay to evaluate if these residues can indeed cause injuries to other crops.

(Received 28th May 2017; accepted 2nd Aug 2017)

Abstract. *Ferula orientalis* L., *Chaerophyllum macrospermum* (Spreng.) Fisch. & C.A.Mey., and *Eremurus spectabilis* M.Bieb are among the medically and aromatically important wild plant species. This study was conducted to obtain in vitro shoot regeneration from different plant segments in these three species. For this purpose, different plant segments (rhizome, leaf, or single-node explants) were cultured in Murashige and Skoog medium with the addition of either 2,4-dichlorophenoxyacetic acid (2,4-D) (0.5–2.0 mg/l) or 2,4-D combined with 6-Benzylaminopurine (BAP) (1.0–2.0 mg/l). For the single-node explants of *Ferula orientalis* L., the highest shoot number per explant (3.0 shoots/explant) was obtained in the medium with 0.5 mg/l 2,4-D + 2.0 mg/l BAP added. For *Chaerophyllum macrospermum* (Spreng.) Fisch. & C.A.Mey., the highest shoot number per explant (2.5 shoots/explant) was obtained in the medium with 1.0 mg/l 2,4-D + 2.0 mg/l BAP added. For *Eremurus spectabilis* M.Bieb., shoot formation was not observed in either of the explant types (leaf or rhizome) in any of the medium combinations. In further studies, the combined applications of 2mg/l or above doses of BAP and lower auxin concentrations may be useful for in vitro shoot regeneration in *Ferula orientalis* L. and *Chaerophyllum macrospermum* (Spreng.) Fisch. & C.A.Mey.
Keywords: *Ferula orientalis L., Chaerophyllum macrospermum (Spreng.) Fisch. & C.A.Mey., Eremurus spectabilis M. Bieb., micropropogation*

Introduction

Ferula orientalis L. (synonym of *Polycyrtus cachroides* Schlecht.) is a plant with high adaptability and is frequently grown in Iran, Afghanistan, and in the East Anatolian Region of Turkey (Hakkari and Van). It is locally referred to as *heliz* or *kevk* (Kaval, 2011). *Ferula orientalis* L. is from the *Apiaceae* family and is a perennial, herbaceous plant that can grow up to 60–100 cm. In addition to its importance as a food source, it has a therapeutic value and can be used as a fodder plant. Young shoots and leaves of the plant, which have a high nutritional value, are boiled and dried after chopping to rid them of their bitter taste. Then, they are added to dishes and Van herbed cheese (Baytop, 1999; Ozturk et al., 2000). In the summer, the shoots and leaves of the plant are cut and left to dry to feed animals in the winter (Baytop, 1999; Cakılcıoglu et al., 2007). The plant's sap is obtained by boiling the roots and is used to treat stomachaches, hemorrhoids, intestinal parasites, eczema, fungal infections, and toxic animal bites. Oils derived from the plant have antifungal and antibacterial properties (Tuzlacı and Dogan, 2010).

Chaerophyllum macrospermum (Spreng.) Fisch. & C.A.Mey. (synonym of *Scandix macrospermum* Wild. ex Spreng.) is a perennial, herbaceous plant that grows in high altitudes and humid habitats and is locally referred to as *mendi* (Kaval, 2011). It is from the *Apiaceae* family, can grow up to 40–60 cm, and has a thin stem that has a mint-like taste. The plant is used by the locals as a spice and vegetable. In addition to its use in Van herbed cheese and local dishes, it can be pickled, added to soups, and consumed fresh (Ozcelik, 1992). Its use as a food source is more common than *Ferula orientalis* L.

DOI: http://dx.doi.org/10.15666/aeer/1504_905914

Eremurus spectabilis M.Bieb. is a perennial, herbaceous plant from the *Eremurus* genus of the *Liliaceae* family. The Iran/Turan region, especially Central Asia, is the center of origin of the species. In Turkey, it is a wild plant that grows on the mountains of the Eastern and Southeastern Anatolia Regions. It is locally known as *ciris*, *wild leek*, and *yellow lily*. Its fresh shoots and leaves are consumed as vegetables. In addition to its use as a food source, it has a therapeutic value and is used as an adhesive in industry. Thanks to its similarity to spinach in terms of cooking style, it can be added to bulgur pilaf or roasted and eaten with eggs, and its leaves and stems can be added to Van herbed cheese (Kaval, 2011). The plant is rich in minerals and is a good source of vitamin C and antioxidants (Kaplan and Unal, 2011). Its sap, which is obtained by crushing its leaves, is used in the treatment of fungal diseases and eczema (Tuzlacı and Doğan, 2010), and its juice, which is obtained by boiling its roots, is alledged to be treat diabetes and liver disorders (Tuzlacı and Doğan, 2010; Pourfarzad et al., 2014). The roots of the plant have been reported to contain high amounts of mucilage, and Tuzlaci (1985) reported that the plant contained 30% gum, which is made into an adhesive for use in industry (Gungor, 2002).

In the future, these medically and aromatically important plant species, which are yet to be cultured, will likely be on the verge of extinction as a result of unconsciously collecting the plants from their natural habitats, their irreplaceable use in the making of Van herbed cheese, arbitrary grazing. Therefore, necessary measures should be taken to protect these species. Methods for plant tissue culturing enable the protection of plant biodiversity (Alkowni and Sawalha, 2012). Moreover, thanks to rapid and reliable micropropagation methods, the production of secondary metabolites in medical plants can be increased(Alkowni et al., 2017). Conventional breeding studies on the species from the *Apiaceae* and *Liliaceae* families are time consuming and require labor (Tawfik and Noga, 2002; Zare et al., 2010), but tissue culture methods can shorten the time spent on breeding.

In vitro regeneration studies have been carried out on many species from the *Apiaceae* (Irwani et al., 2010; Zare et al., 2010; Sharma, 2015) and *Liliaceae* families (Baksha et al., 2005; Skoric et al., 2012; Monemi et al., 2014). It has been reported that the micropropagation of some medical plants, endangered species, wild species, and endemic species was achieved with tissue culture methods (Sahrawat and Chand, 2002; Martin, 2002; Thomas and Jacob, 2004; Paunescu and Holobiuc, 2005). However, these methods should be optimized, and proper protocols must be established for each species. The present study investigated how adding different explant types and different growth hormones to the MS medium (Murashige and Skoog, 1962) medium affected the in vitro propagation of these three medically important wild species. This report is also noteworthy for being the first in vitro regeneration study on these species.

Materials and Methods

Plant materials, sterilization and explant preparation

Different plant parts of *Eremurus spectabilis* M.Bieb., *Ferula orientalis* L., and *Chaerophyllum macrospermum* (Spreng.) Fisch. & C.A.Mey., which were collected from Kırkgeçit Village of Gurpinar County in Van, Turkey, were the material of the study (*Fig. 1*). For *Chaerophyllum macrospermum* (Spreng.) Fisch. & C.A.Mey and *Ferula orientalis* L., single-node explants were used, and for *Eremurus spectabilis* M.Bieb, leaf and rhizome explants were used. Rhizomes were rinsed with tap water to remove mud and dirt

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_905914

and were kept in tap water overnight. Then, they were rinsed 4–5 times with pure water, placed into a cabinet, and kept in 70% ethyl alcohol for 10 seconds. Next, a few drops of Tween 20 were added, and the samples were shaken for 15 minutes in 15% sodium hypochlorite. The *Eremurus spectabilis* M.Bieb rhizomes were sterilized by shaking the rhizomes with bidistilled water 3–5 times, 6 minutes each time.

The surfaces of the leaf explants and the shoots containing single nodes were sterilized by shaking the samples in 15% commercial sodium hypochlorite for 15 minutes. Then, they were rinsed with bidistilled water 3 times, 5 minutes for each repetition (*Fig. 2a, 2b, 2c, 2d*). Sterilized materials were put on a sterile blotting paper and cleansed of their excess water (*Fig. 2e, 2f*). Rhizomes were prepared for planting by vertically and horizontally cutting their sides in strips (*Fig.2g, 2h, 2l*). To obtain the single-node explants, the nodes that also had shoots half a centimeter above and below were taken and their leaves were removed (*Fig. 2i, 2j*). To obtain leaf explants, thin strips were taken from the sides and edges of the leaves and prepared for planting (*Fig. 2k*). All steps were carried out under aseptic conditions in a laminar flow cabinet.

Figure 1. *(a) Eremurus spectabilis M.Bieb., (b) Ferula orientalis L., (c) Chaerophyllum macrospermum (Spreng.) Fisch. & C.A.Mey plants, (d) Eremurus spectabilis M. Bieb. roots and rhizomes.*

Medium composition and culture of explants

The explants were cultured in the MS (Murashige and Skoog, 1962) media containing 9 different combinations of 2,4-dichlorophenoxyacetic acid (2,4-D) (0.5, 1.0, and 2.0 mg/l) and/or benzylaminopurine (BAP) (1.0 and 2.0 mg/l). In addition, 30 g/l of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_905914

sucrose and 7 g/l of agar was added to the MS medium, and the pH of the medium was adjusted to 5.8. Each petri dish contained 8 explants and 25 ml of medium. Then, the petri dishes were cultured in a climate room at 25°C ± 2°C with a photoperiodic cycle of 16-hours light/8-hours dark. Each application was planned to be in 4 replicates. The data were evaluated by analyses of variance, and the means were compared by Duncan's multiple range test ($p < 0.05$) using the SPSS statistical package program.

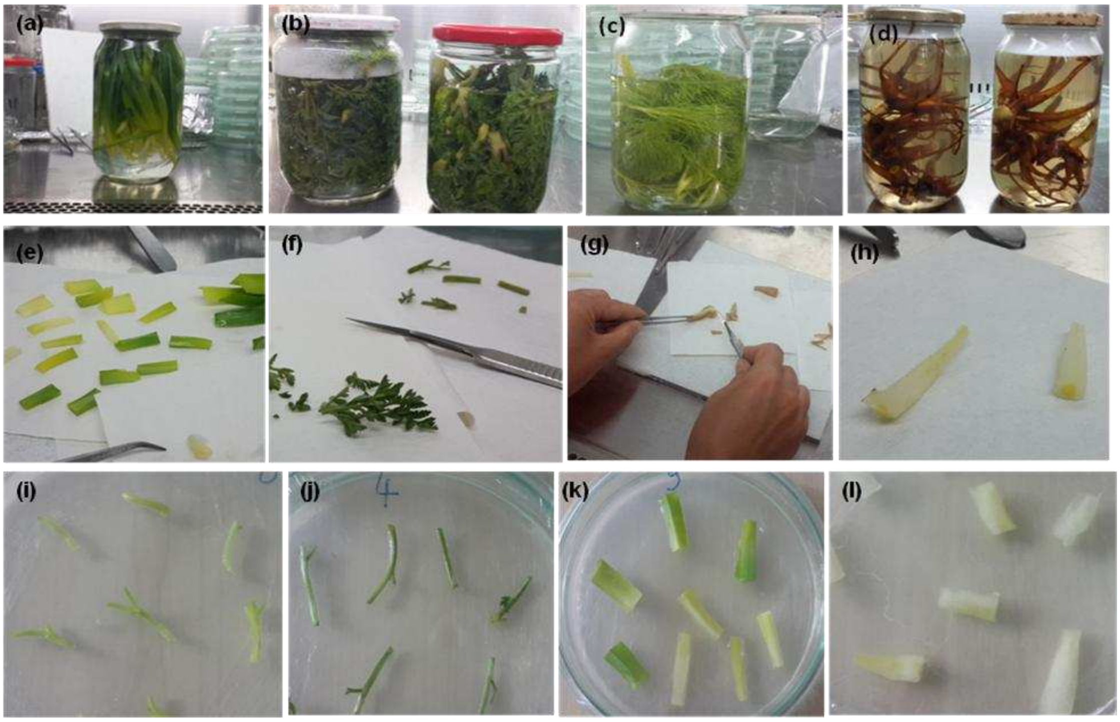

Figure 2. *Surface sterilization of the leaves of (a) Eremurus spectabilis M.Bieb, (b) Chaerophyllum macrospermum (Spreng.) Mey, which showed growth in the media 1 week after planting; (k) leaf explants; and (l) rhizome explants of Eremurus spectabilis M. Bieb.*

Results and Discussion

Table 1 shows the media composition with the shoot numbers and ratios (%) obtained from the single-node explants of *Ferula orientalis* L. and *Chaerophyllum macrospermum* (Spreng.) Fisch. & C.A.Mey. For both species, differences among the medium combinations were statistically significant ($p < 0.05$). For *Ferula orientalis* L., the highest shoot number per explant was obtained in the MS7 medium (3.0 shoot/explant), followed by the MS8 (2.75 shoots/explant) and MS4 (2.25 shoots/explant) media, respectively. For *Chaerophyllum macrospermum* (Spreng.) Fisch. & C.A. Mey, the highest shoot number per explant was obtained in the MS8 medium (2.50 shoots/explant), followed by the MS7 medium (2.25 shoots/explant). For both species, the least successful media (in terms of shoot numbers and ratios) were the

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_905914

media with only auxin added (2,4-D), which were the MS1 (0.5 mg/l 2,4-D), MS2 (1.0 mg/l 2,4-D), and MS3 (2.0 mg/l 2,4-D) media (*Table 1*).

Fig. 3 shows shoot formations in these wild plant species for different explant types and MS medium combinations. It also shows the browning in the explants that occurred in the successive stages of culture.

Different small letters in a same column show significant differences among the medium ($p < 0.05$).

The ratios of the growth regulators from the auxin and cytokinin group in the nutrient medium are important for in vitro plant regeneration (Thomas and Maseena, 2006; Irvani et al., 2010). For both species, *Table 1* reveals that the medium combinations that obtained relatively higher shoot numbers had low levels of auxin (2,4-D) and high levels of BAP. There have been reports on the positive effect of adding combinations of auxin at low concentrations and growth regulators from the cytokinin group to the nutrient medium on in vitro plant regeneration (Baksha et al., 2005; Skoric et al., 2012; Monemi et al., 2014). These reports agree with the present study.

Monemi et al. (2014) reported that for leek (*Allium ampeloprasum*) from the *Liliaceae* family, the best callus formation was obtained in leaf explants in an MS medium with 0.5 mg/l 2,4-D + 0.1 mg/l BAP and 0.1 mg/l 2,4-D + 0.5 mg/l kinetin added. In the present study, callus formation was not observed for any of the three species, even in the media with only 2,4-D added (0.5, 1.0, and 2.0 mg/l). This suggests that using higher doses of auxin to obtain callus formation may prove beneficial in further in vitro regeneration studies on the same species. Zare et al. (2010) reported that, in different explant types (root, hypocotyl, and cotyledon) obtained from sterile

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_905914

seedlings of medically important *Ferula assa-foetida* L., indirect shoot formation was obtained both in only BA-added (1–3 mg/l) and in 0.2–0.5 mg/l NAA-added MS medium combinations. Zare et al. (2010) determined that the highest shoot formation (7.4 shoot/callus) was obtained in the hypocotyl explants in a 1 mg/l BA-added and 0.2 mg/l NAA-added medium. In the present study, direct shoot formation from the explants was obtained in two species (*Ferula orientalis* L. and *Chaerophyllum macrospermum* (Spreng). Fisch. & C.A.Mey.). Irvani et al. (2010) reported that the highest shoot regeneration (87.3%) was obtained in the medically important *Dorema ammoniacum* D. (*Apiaceae*) from calluses of hypocotyl origin in a MS + 2 mg/l BA + 0.2 mg/l IBA medium.

Figure 3. *Shoot formation of the single-node explants of Ferula orientalis L. at the (a) 15th day of culturing and at the (b, c) 25th day of culturing (0.5 mg/l 2,4-D + 2.0 mg/l BAP), shoot formation of the single-node explants of Chaerophyllum macrospermum (Spreng.) Fisch. & C.A. Mey at the (d) 25th day of culturing (1.0 mg/l 2,4-D + 2.0 mg/l BAP) and at the (e) 15th day of culturing (1.0 mg/l 2,4-D + 1.0 mg/l BAP), (f) swellings in leaf explants of Eremurus spectabilis M. Bieb at the 15th day of culturing (0.5 mg/l 2,4-D + 1.0 mg/l BAP), and (g-i) browning in the explants.*

The medium combinations affected swelling, browning, and infection development in the explants (*Tables 2 and 3*). Growth and enlargement in the explants in the nutrient media were accepted as swelling. For *Ferula orientalis* L., the highest swelling ratio

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_905914

was observed in the MS7 (100%) and MS8 (93.8%) media. For *Chaerophyllum macrospermum* (Spreng.) Fisch. & C.A.Mey., maximum swelling was also observed in the same medium combinations (*Table 2*). For *Ferula orientalis* L., the browning ratio in the cultured single-node explants varied between 46.9% and 78.1%, and the infection ratio in the explants varied between 15.6% and 28.1%. For *Chaerophyllum macrospermum* (Spreng.) Fisch. & C.A.Mey., the same parameters varied between 53.1% and 84.4% and between 12.5% and 25.0%, respectively. For both species, shoot formation increased with increasing swelling ratios (*Table 2*). *Table 3* is given the effects of explant type and medium combination on swelling, browning, and infection development in *Eremurus spectabilis*. In rhizome explants, no swelling was observed in any of the medium combinations, whereas, in leaf explants, 100% swelling was observed in all medium combinations. However, shoot formation was not obtained in any of the medium combinations for either of the explant types (*Table 3*).

MS9	2.0	2.0	21	65.6	18	56.3	9	28.1	14	43.8	20	62.5	8	25.0

In rhizome explants, browning ratios and infection ratios varied between 50% and 79.2% and between 20.8% and 50%, respectively. In leaf explants, the values varied between 68.8% and 100% and between 6.3% and 31.5%, respectively (*Table 3*). Browning that occurs under in vitro conditions causes losses in the vitality of tissues in many phenolic compound–rich species. It is known that adding phenol-captivating substances such as polyvinylpyrrolidone (PVP), active carbon (AC), and silver nitrate ($AgNO_3$) to nutrient media can prevent tissue browning by captivating polyphenol compounds and thereby slowing their synthesis (Teixeira et al., 2006; Alp et al., 2010). Therefore, we presume that in further studies on the same species, adding these compounds to nutrient media may help reduce losses due to browning. Moreover, there

DOI: http://dx.doi.org/10.15666/aeer/1504_905914

are reports on the phytotoxic effects of antibiotics, which are added to nutrient media to prevent infections, and their browning-increasing effect on tissues. In the present study, infection development in explants were observed at varying ratios depending on the species and media composition In further studies on these species, using explants from sterile seedlings that are developed under in vitro conditions will minimize infections.

Conclusions

This study is the first report of the effects of different explant types and medium combinations on the in vitro regeneration of the medically and aromatically important *Ferula orientalis* L., *Chaerophyllum macrospermum* (Spreng.) Fisch. & C.A.Mey. and *Eremurus spectabilis* M.Bieb. species. Shoot formations were obtained in the single-node explants of *Ferula orientalis* L. and *Chaerophyllum macrospermum* (Spreng.) Fisch. & C.A.Mey. at ratios that varied depending on the medium composition. However, shoot formation was not observed for *Eremurus spectabilis* M.Bieb. in either of the explant types in any of the medium combinations. In further studies, trying different hormones from the auxin-cytokinin group in addition to the combined applications of 2mg/l or above doses of BAP and lower auxin (0.1, 0.2, and 0.5 mg/l) concentrations may prove beneficial for in vitro shoot regeneration in *Ferula orientalis* L. and *Chaerophyllum macrospermum* (Spreng.) Fisch. & C.A.Mey. The results of the present study are expected to contribute to in vitro regeneration studies on these medicinal plants in future.

(Received 31st May 2017; accepted 2nd Aug 2017)

Abstract. *Orthotomicus erosus* (Wollaston, 1857) (Coleoptera: Curculionidae: Scolytinae) is one of the principal pests of Eurasian forests. Gathering data from this study concerning population genetic structure of *O. erosus* would help improving new strategies to control the pest by giving new insights on forest management. The aims of the study were to resolve the population genetic structure of *Orthotomicus erosus* which distributes Mediterranean Region of Turkey and to determine the factors (such as host pine species and geographic barriers) that contributed to the current distribution of genetic diversity. The beetle samples were collected from 20 stands from the pine forests included in the Mediterranean Region of Turkey. 67 samples were studied using mitochondrial cytochrome oxidase subunit I (COI) gene and Neighbor Joining (NJ) and Maximum Likelihood (ML) analyses were performed. As a result of the study, thirty-seven distinct haplotypes from sixty-seven samples were determined. The species did not form any phylogroup in populations depending on the geographical location according to the NJ and ML analysis. The NJ and ML trees revealed that those *O. erosus* individuals that fed on different pine species did not have genetic variations. Consequently, NJ and ML analysis results reveals that different populations of the species across the Mediterranean Region were not disconnected and isolated geographically either.
Keywords: *Orthotomicus erosus, mtDNA, Neighbour Joining, Maximum Likelihood, Turkey*

Introduction

Forests have played a very important role for all organisms since the existence of human-beings. However, forestlands have shrunk and have been destroyed due to overutilization and misuse for centuries. Particularly the growing world population in the last century and thus the social pressure as well as the negative impacts such as environmental pollution, forest fire and insect damage have resulted in the shrinkage of forest areas, which still prevails at the same pace (Sarıkaya and Avcı, 2006).

There are several factors that led to shrinkage of forest areas and reduction of their productivity in the Mediterranean Region located in the south of Turkey. Among these factors, harmful insect species play a very important role. Bark beetles are among the most important insect groups that lead to significant economic loss due to the damage they cause in forest trees. The bark beetles that damage the forests in the Mediterranean Region include Mediterranean pine engraver *Orthotomicus erosus* (Wollaston, 1857), which is highly important because of its damage in pine forests. Although these beetles cause secondary damage, they may cause primary damage just after the dry periods. In this region, especially *Pinus brutia* is one of most widely distributed species (Karatepe et al., 2014). *Orthotomicus erosus* (Wollaston) was found in pine (*Pinus* spp.), fir (*Abies*

DOI: http://dx.doi.org/10.15666/aeer/1504_915928

spp.), spruce (*Picea orientalis*) and cedar (*Cedrus libani*) species in Turkey (Schedl, 1961; Tosun, 1975; Selmi, 1989 and 1998; Çanakçıoğlu and Mol, 1998). Studies conducted in other countries demonstrated that *O. erosus* caused damage in pine species in primarily Mediterranean countries and Middle and South Europe, Iran, Israel, Morocco, Tunisia, Algeria, Crimea, Caucasia, South and North America (Mendel and Halperin, 1982; Mendel, 1983; Pfeffer, 1995; Henin and Pavia, 2004; Lee, 2004; Haack, 2004; Jamaa et al., 2007; Amini et al., 2013; Gómez and Martínez, 2013).

Molecular tests have been increasingly used in systematic and taxonomic studies conducted on insects and contributed to the solution of taxonomic problems thanks to the recent developments, enzymatic amplification of specific regions of a DNA strand In Vitro (PCR), (Mullis et al., 1986), introduction of automatic devices for DNA sequence analysis and superfast computers (Brower and De Salle, 1994; Roderick, 1996; Simon et al., 1994). Current population structure of a species reflects both historic and contemporary ecological and evolutionary forces (Hewitt, 2000). These processes left their signatures in the genomes of species. Thus, current population genetic structure can be used to infer past evolutionary and demographic events within species (Avise, 2000).

There is any study concerning population genetics of *O. erosus* (Hughes and Vogler 2004) although the species has been included in several molecular studies (Cognato and Felix, 2000; Cognato and Vogler, 2001; Jordal et al., 2008; Cognato, 2013; Jordal and Kambestad, 2014). *O. erosus* is one of the most damaging bark beetle species to pine forests at the Mediterranean shore latitude in Turkey. Generally a secondary pest, it can immediately gain a primary character especially after the arid periods in the Mediterranean and Aegean regions of Turkey. However, population structure of the species is also unknown in Turkey. Information concerning its population structure could help in the future control of this pest. The aims of the study were to resolve the population genetic structure of *O. erosus* in the Mediterranean Region of Turkey and to determine the factors (such as host pine species and geographic barriers) that contributed to the current distribution of genetic diversity.

Material and Methods

In order to collect *Orthotomicus erosus* samples, sampling plots were selected in the stands where the Brutian pine and black pine grew under different habitat conditions in the Mediterranean Region and the damage caused by the bark beetle was intense and beetle samples were collected from these areas. The adult samples of *Orthotomicus erosus* were collected from different locations across the Mediterranean Region in 2013. The locations where *O. erosus* samples were collected are presented in *Table 1* and *Figure 1*.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_915928

Trap woods were placed in the sampling plots before the flying period in order to collect the samples. Traps were composed of 12 woods each with a length of 1 m. The samples collected from the trap trees were soaked in pure alcohol of 99% and stored.

Furthermore, pheromone traps were placed in the sampling plots before flying periods and the samples were collected from these traps. Pheromone preparations containing 1500 mg methyl butanol + 100 mg cis-verbanol + 30 mg Ipsdienol were used in the pheromone traps to capture *O. erosus*. Moreover, samples were collected from trunks maintained in the forest storages and production areas across the region through observation. The collected samples were placed and stored in tubes containing pure alcohol. The tubes where the samples were placed were stored in deep freezer until the performance of genomic DNA (gDNA) isolation.

Genomic DNA isolation

gDNAs of *O. erosus* samples collected during the field study were isolated from the head and thorax of the beetles. Abdominal and elytra of the samples from which gDNA was isolated were stored at the laboratory for morphological analysis. gDNAs of the samples were isolated with Qiagen DNeasy Blood and Tissue Kit (Qiagen).

Polymerase Chain Reaction (PCR) and DNA sequencing

The isolated gDNAs were controlled using 0.8% agarose gel electrophoresis and the gDNA quantity of the samples was diluted to the concentration level that was appropriate for PCR according to their gel appearance. The primers S1718 (5'-GGAGGATTTGGAAATTGATTAGTTCC-3') and A2237 (5'-CCGAATGCTTCTTTTTTACCT CTTTCTTG-3') were used for the amplification of mitochondrial cytochrome oxidase subunit I (COI) regions of the samples through PCR (Simon et al., 1994; Normark et al. 1999). Thirty cycles of amplification were performed as follows: denaturation step at 94°C for 30 seconds, annealing at 48°C for 1 min, and extension at 72°C for 90 seconds. PCR products were purified with QIAquick PCR purification kit (QIAgen) and sequenced.

Population Genetic Analyses

The phylogenetic relationships between the haplotypes were analysed and phylogenetic trees were created using Neighbour Joining (NJ) and Maximum Likelihood (ML) algorithms. The best substation model according to the DNA sequencing data was determined using the hierarchical likelihood ratio test (hLRT) and Akaike information criterion (AIC) in MODELTEST v. 3.7 (Posada and Crandall, 1998). The substitution model for the two abovementioned statistics was found to be TIM3+I for upon *Orthotomicus erosus* by consensus and these criteria were entered as substitution model while constructing the Maximum Likelihood (ML) tree. ML trees were questioned according to the heuristic search approach. The branch support values of ML trees were evaluated through 1000 non-parametric bootstrap analysis (Felsenstein, 1985).

In order to determine the polymorphism and diversity level of *Orthotomicus erosus*, the number of within populations and among populations average nucleotide differences and nucleotide diversity (π) were analysed. In order to determine the significance of the differences between the populations of the species, pairwise Fst values were calculated.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_915928

In order to determine if the populations of the species showed the cases such as enlargement/bottleneck in the past, historical demographic pattern of both species were analysed. To this end, Tajima's D (Tajima, 1989) and Fu's FS (Fu, 1997) neutrality tests were performed for the COI gene regions that were studied. Moreover, sum of squared differences (SSD) and Harpending's Raggedness index (Hri) mismatch distribution analysis were used to check if the sequence data of the species deviated from the possible enlargement model estimation.

Results and Discussion

67 samples were analysed for *Orthotomicus erosus* in this study. The DNA sequences of the samples that were studied were aligned, the impractical regions were removed, and a sequence of 488 base pairs that could be used for statistical analysis was obtained. 49 bases out of the sequence of 488 base pairs had mutations. 37 different haplotypes were found in 67 samples that were analysed due to the abovementioned mutations. Some haplotypes were represented more than once.

The within populations and among populations genetic variations of *Orthotomicus erosus* were analysed through AMOVA (*Table 2*). The analysis showed that the within populations genetic variation of the species was higher than the among populations variation.

Table 2. *Spatial analysis of molecular variance of Orthotomicus erosus. df degrees of freedom*

	d.f.	Sum of squares	Variance components	Percentage of variance
among populations	18	242.876	3.11977 Va	55.07
within populations	48	122.183	2.54549 Vb	44.93
Total	66	365.060	5.66525	

The genetic diversity of 67 samples from different populations of *Orthotomicus erosus* collected from the Mediterranean Region and intraspecific genetic diversity were determined with Neighbour Joining (*Figure 2*) and Maximum Likelihood (*Figure 3*) methods. According to the base data obtained prior to the Maximum Likelihood analysis, the substitution model in the COI sequence of the species was found to be TIM3+I in Model test software and the tree was constructed according to that substitution model. To construct both trees, *O. erosus*, *O. proximus* and *O. suturalis* were used as the outgroup.

The intraspecific diversity of *Orthotomicus erosus* was determined by using COI gene sequence that had 488 base pairs. The species did not form any phylogroup in populations depending on the geographical location according to the NJ and ML analysis. The genetic variations of *O. erosus* populations in *Pinus brutia* and *P. nigra* were also analysed. The NJ and ML trees revealed that those *O. erosus* individuals that fed on different pine species did not have genetic variations. Moreover, NJ and ML trees also showed that different populations of the species across the Mediterranean Region were not disconnected and isolated geographically either.

The number of the haplotypes shared by the populations of *O. erosus* was low. AMOVA results also revealed that the variations within and among populations were very similar. This indicates that the intraspecific genetic diversity was very high.

High genetic diversity of genetic lineages were also reported for other animal species from Turkey (Gündüz et al., 2005; Stone et al., 2007; Bardakçı et al., 2006, Mutun, 2011). High haplotype diversity might be due to the continuous introduction of individuals from different locations.

The highest nucleotide diversity was found in the populations distributed in *Pinus brutia* trees in Adana-Çukurova Karahan Village, Mersin-Anamur-Demirören Village and Mersin-Tarsus and in *P. nigra* trees in Adana Karaisalı-Damlama district, Mersin-Tarsus-Çamalanı, Tekir and Mersin-Gözne.

According to the FST values of *O. erosus*; there was a gene flow between the populations in Adana-Çukurova Karahan village and Adana-Kadirli Börklüler, Antalya-Akseki-Küser district, Akseki-Çambeleni, Adana Karaisalı-Damlama; Isparta, Eğirdir-Aşağıgökdere, Kahramanmaraş Andırın-Efirağızlı, Mersin-Gözne, Mersin-Tarsus-Çamalanı- Tekir and Osmaniye- Yarpuz-Yemşen; populations in Adana-Kadirli Börklüler and Adana Karaisalı-Damlama district; populations in Antalya-Akseki-Çambeleni, Isparta, Eğirdir-Aşağıgökdere, Osmaniye-Yarpuz-Yemşen; populations in Adana Karaisalı-Damlama and Antalya-Akseki-Küser district, Antalya Kemer and Kumluca, Isparta, Eğirdir-Aşağıgökdere, Kahramanmaraş Andırın-Efirağızlı, Mersin-Gözne, Mersin-Gülnar, Mersin-Tarsus- Çamalanı, Tekir and Osmaniye-Yarpuz-Yemşen; populations in Antalya-Akseki-Küser and Isparta, Eğirdir-Aşağıgökdere, Kahramanmaraş Andırın-Efirağızlı and Mersin-Tarsus; populations in Mersin-Tarsus Çamalanı-Tekir and Isparta, Eğirdir-Aşağıgökdere and Mersin-Gözne, populations in Osmaniye-Yarpuz-Yemşen and Isparta, Eğirdir-Aşağıgökdere, Kahramanmaraş Andırın-Efirağızlı, Mersin-Gülnar and Mersin-Tarsus. The topologies of NJ and ML trees and negative FST values indicated that *O. erosus* could be distributed in quite long distances.

D and FS test results of *O. erosus* showed that the populations in Antalya- Kemer and Antalya-Kumluca, Kahramanmaraş-Andırın Efirağızlı, Mersin-Gülnar and Mersin-Tarsus had an enlargement in the past. Furthermore, the sum of squared differences (SSD) and Raggedness index (Hri) results revealed that the populations only in Antalya-Kemer, Antalya-Kumluca and Mersin-Gülnar had enlargement.

Conclusion

Knowing of the genetic variations of bark beetles at local and regional level will provide highly useful data for forest management. The findings of this study, in which the genetic variations of *Orthotomicus erosus* that damaged pine trees including primarily the Brutian pine in the Mediterranean Region were analysed, show that there

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_915928

were not significant within population genetic variations or differences. These findings indicate that the concerned harmful bark beetles are highly mobile.

It was found that individuals of *O. erosus* that can feed on different pine species in the Mediterranean Region did not have any genetic variations and different populations were not disconnected and isolated geographically. This indicates that change of host does not result in dependence on a specific host for *O. erosus*; therefore, there is no barrier before the distribution of this species.

O. erosus does not have any sub-species. On the other hand, there is a need for further studies to explore if *O. erosus* depends on a specific geographical location and specific host species across Turkey considering its wide distribution in the country.

Abstract. The studies were conducted in two small temperate mid-field ponds. The purpose of the research was to determine changes in the zooplankton communities in ponds with diverse ichthyofauna compositions and diverse values of environmental factors. Two research hypotheses were assumed. One pertained to the growth of the number and biomass of *Daphnia* and the loss of illoricate rotifers due to the top predator influence. The other one assumed that the top predators and the value of conductivity indirectly affect the diversity of zooplankton. We assumed that significant differences in the number of *Daphnia* between the ponds result from the regulation of the trophic web from the top down and bottom up, that affect the total zooplankton composition. In the small water bodies where *Daphnia* dominated among cladocerans, the highest numbers belong to loricate rotifers, e.g. *Brachionus sp.* and *Keratella sp.,* whereas in the ponds where the dominance among Cladocera was *Chydorus sphaericus,* illoricate rotifers were abundant, e.g. *Bdelloidea* and *Synchaeta sp.* We concluded that the presence of the top predator caused a significant increase in the species richness and in the biodiversity index for Cladocera. However, the biodiversity index for the whole zooplankton (determined mainly by small rotifers) decreased with the presence of top predator and increased with high conductivity.
Keywords: *biodiversity, biomanipulation, freshwater, plankton, ichthyofauna*

Introduction

The absence or presence of predator fish has a cascade effect on the whole trophic network of the water ecosystem (Hodgson, 2005). An increase in the biomass of predator fish entails a decrease in the biomass of plankton-feeding fish. The decrease in the number of plankton-feeding fish is followed by an increase in the biomass of filter-feeding zooplankton (Carpenter et al., 1985). However bottom up control which refers to the nutrients concentration in the environment and as a consequence food availability is well known to shape the assemblages of zooplankton (Gliwicz, 2002). Moreover, the taxonomic structure, body size and abundance of zooplankton are dependent on its taxonomic composition (Gliwicz and Siedlar, 1980), as well as on the season (Michael, 1969). It is believed that in small water bodies with diverse fish compositions, the mechanisms affecting the structure of the biocenoses from the top of the trophic network will prevail (Lampert and Sommer, 2001), which means that the biggest effect on the composition of species, abundance and biomass of individual zooplankton taxa will be exerted by fish, not by food availability.

The presence of a predator alters the behaviour of small cyprinids. This is manifested by their smaller activity and the preference of young cyprinids to hide in refuges, thanks

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_929941

to which daphnids can spend more time feeding in open waters (Romare and Hansson, 2003). Cladocerans such as *Daphnia* normally prevail in small water bodies when they are not randomly limited. Their prevalence results from the exclusion of smaller zooplankton taxa by competition (Diéguez and Gilbert, 2011). The presence of *Daphnia* in a pond may rapidly reduce the number of Rotifera and lead to taxonomic changes in their composition (Gilbert, 1988, 1989; Conde-Porcuna, 1998). *Daphnia* limit the survival of small illoricate rotifers, but has no effect on the survival of adult loricate rotifers (Diéguez and Gilbert, 2011). Despite numerous laboratory experiments, little attention is paid to taxonomic changes in natural small water bodies which may occur as a result of interaction of *Daphnia* with rotifers.

The majority of research in biodiversity and species richness of zooplankton pertained to the effect of trophic conditions on zooplankton (Dodson, 1992; Dodson et al., 2000; Leibold, 1999; Jeppesen et al., 2000; Declerck et al., 2007). Studies of the effect of daphnids on the biodiversity or species richness of zooplankton generally concern invasive species which could displace native crustacean species (Yan et al., 2002; Strecker et al., 2006). But maybe the native species of *Daphnia* have a negative effect on the biodiversity and species richness of rotifers and thus limit the biodiversity of the whole water body? Such a question may be put forward when using biomanipulation as a method for recultivation.

The purpose of this research was to determine changes in the structure of zooplankton communities in small mid-field ponds with diverse ichthyofauna composition and different environmental factors. The following hypotheses were assumed:

1) The presence of a top predator causes an increase in the number and biomass of *Daphnia* and loss of illoricate rotifers.
2) The top predator and the value of electrolytic conductivity correlate with the diversity of the zooplankton.

Methods and area of the research

Two mid-field ponds, Żelisławiec and Stare Czarnowo, with different taxonomical and quantitative composition of fish, located in the NW Poland, were chosen for studies (*Fig.1*). The studies were conducted in the spring, summer and autumn 2010 - 2014. The area of the Żelisławiec pond changed over the years and amounted to 0.91 to 0.64 ha and the area of the Stare Czarnowo pond changed from 0.82 to 0.40 ha. The ponds are similar as regards environmental conditions of drainage basin, which is entirely comprised of agricultural areas. Environmental conditions of drainage basin were determined on with the Corine Land Cover 2006 database. Agricultural areas encompass arable lands, permanent crops, meadows and pastures as well as mixed crop zones. Semi-natural areas are forests, semi-natural ecosystems and systems of shrub vegetation. Urban areas are urbanised areas, industrial areas and anthropogenised green areas. The drainage of the Żelisławiec pond was approximately 52 ha whereas the drainage of the Stare Czarnowo – 18 ha. The bed of two ponds was densely covered by macrophytes. Emerged and submerged vegetation occurred in both of the small water bodies. In the Żelisławiec, the emerged plants constituted 70% of the shoreline: *Typha latifolia* – 50% and *Phragmites australis* – 20%, whereas nymphaeid constituted 55% of the bed area: *Potamogeton natans* – 25%, *Persicaria amphibia* – 30%, and pleustophyte represent by *Lemna minor* – 5%. In the Stare Czarnowo pond, the emerged plants constituted 80% of the shoreline:

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_929941

Typha latifolia – 15% and *Phragmites australis* – 20%, *Glyceria maxima* – 45%, whereas the submerged plants constituted 80% of the area: *Ceratophyllum demersum* – 80%, and pleustophyte represent by *Lemna minor* – 5%.

The studies of fish fauna were conducted in summer 2010-2014. In order to determine the species composition of the fish fauna and the total body length of individual, the fish were caught using electric fish gear IUP 12 (Poland). In order to exclude a significant effect of the microhabitats on the shape of zooplankton communities, in each pond four different samples collection spots were selected. The samples were collected from the same place on each occasion. The results from the spots were averaged.

At each site 50 l of water were collected with a 5l bucket, which was filtered through plankton net with 25 μm mesh size. The samples were concentrated to 250 ml and were fixed in a 4 % formalin solution. Using the stirred total sample, ten sub-samples (3 mL) were pipetted into a glass Sedgewick-Rafter Counting Chamber. For identification, a Nikon Eclipse 50i microscope was used. Species were identified using the keys (Nogrady et al., 1993; Radwan, 2004; Dussart and Defaye, 2006; Rybak and Błędzki, 2010). In each sample, the body length of at least 30 individuals from each species was measured with the Pixelink Camera Kit 4.2. If the number of individuals representing a given species was lower than 30, the body lengths of all individuals were measured. The body length conversion to wet mass was made with the use of the tables (Ruttner-Kolisko, 1977; McCauley, 1984; Ejsmont-Karabin, 1998). Shannon diversity index and Sørensen similarity for zooplankton were calculated using the MVSP 3.22. The dominance structure was calculated from the mean values from all samplings. The level for dominance was established as 5% of the total abundance of zooplankton. A Mann-Whitney U-test was carried out to test for statistically significant differences, between sites, for environmental parameters, zooplankton communities and fish community. Spearman correlations were used to asses relationships between environmental parameters and between zooplankton and fish characteristics. Statistical analyses were performed using Statistica 10.

Results

Abiotic factors

As regards abiotic factors in the Stare Czarnowo pond, the value of conductivity was nearly four times higher than in the Żelisławiec pond (P<0.05) (*Table 1*). A nearly twice as high concentration of dissolved oxygen was observed in the Żelisławiec pond than in the Stare Czarnowo pond (P<0.05).

Fish composition

Six fish species (*Carassius carassius, Carassius gibelio, Tinca tinca, Perca fluvitalis, Rutilus rutilus, Esox lucius*) were observed in the both small water bodies. All species occurred in the Żelisławiec whereas only *Carassius carassius* and *Carassius gibelio* were observed in Stare Czarnowo. *Carassius carassius* and *Carassius gibelio* in Żelisławiec were characterised by higher mean body mass and higher mean body length than in Stare Czarnowo (P>0.05) (*Table 1*).

Zooplankton taxonomic composition

Altogether 134 zooplankton taxa were observed in the studied ponds throughout the research period. In the Stare Czarnowo 112 taxa were revealed, 85 belonged to Rotifera, 12 Cladocera and 15 Copepoda. In The Żelisławiec 90 taxa were determined, 60 belonged to Rotifera, 16 Cladocera and 14 Copepoda. In Stare Czarnowo the zooplankton communities were dominated by *Bdelloidea* (18%), *Chydorus sphaericus* (37%) and *Eudiaptomus gracilis* (21%), whereas in Żelisławiec: *Keratella quadrata* (37%), *Daphnia longispina* (35%) and *Eudiaptomus gracilis* (27%) (*Table 2*). In Żelisławiec, the dominant rotifers were loricate species, whereas in Stare Czarnowo illoricate rotifers.

The number of Rotifera taxa ($P<0.01$) (24 to 14), the number of zooplankton taxa ($P<0.05$) (31 to 22), the Rotifera biodiversity index ($P<0.01$) (2.07 to 1.34) and the zooplankton biodiversity index ($P<0.01$) (2.3 to 1.59) were significantly higher in Stare Czarnowo than in Żelisławiec.

Zooplankton abundance

In total zooplankton of both small water bodies rotifers had the highest percentage contribution in abundance. Moreover their percentage indicated growth from spring (Stare Czarnowo 53% and Żelisławiec 51%) to autumn, reaching the maximum of 75% in Stare Czarnowo and 91% in Żelisławiec (*Fig. 2*). In spring the percentage share of crustaceans in both ponds almost reached 50%. Moreover, in spring the proportion of Cladocera in the population was six times higher in Żelisławiec than in Stare Czarnowo. The density of *Daphnia* in Żelisławiec was over fourteen times higher than in Stare Czarnowo ($P<0.05$) (3.2 to 46.9 ind./dm^{-3}) (*Table 4*).

Zooplankton biomass

In both small water bodies, crustaceans dominated in the zooplankton biomass (*Fig. 3*). In Stare Czarnowo the percentage of Cladocera biomass ranged from 42% in spring to 61% in summer and 50% in autumn. In Żelisławiec, the percentage of Cladocera was higher and amounted to 84%, 91% and 86% from spring to autumn respectively. The percentage of Rotifera biomass in Stare Czarnowo increased from spring (6%) to autumn (34%) whereas in Żelisławiec it remained on a low level and did not exceed 8%. An almost seven times higher mean zooplankton biomass was observed in Żelisławiec than in Stare Czarnowo (P<0.05) (1.30 to 8.89 mg/dm^{-3}).

Correlation between zooplankton composition and environmental factors

The simple correlation indicated that eleven environmental variables correlated significantly with the values of fifteen variables of zooplankton ($p<0.05$) (*Table 5*). The abiotic parameter which correlated the most often with the structures of zooplankton was depth. Further variables correlated with these structures were the content of dissolved oxygen and the value of conductivity. The fish predominantly displayed a significant correlation with Rotifera structures and Cladocera biodiversity index. In the former case, the number of Rotifera taxa was negatively correlated with the number of pike, Prussian carp biomass and pike biomass but was positively correlated with sizes of the crucian carp. In the latter case, the Cladocera biodiversity Index was negatively correlated with the number of Prussian carp and positively correlated with the number of pike.

Discussion

Results of analyzed data show that the presence of a top predator causes direct and indirect changes on structure of zooplankton namely increase in the number and biomass of *Daphnia* and loss of illoricate rotifers which affect species richness and biodiversity of zooplankton. The results of our research and analysis of the results of other authors (Carpenter et al., 1985; Jeppesen et al., 2000; Hodgson, 2005; Declerck et al., 2007; Diéguez and Gilbert, 2011) confirming our hypotheses.

The taxonomic and quantitative composition of zooplankton of the studied ponds is similar to those observed by other authors in similar small water bodies (Radwan, 2004; Segers, 2008). Distinct prevalence of rotifers over crustaceans as regards the number of taxa and their number has been demonstrated numerous times (Karabin, 1985; Herzig, 1987; Kuczyńska-Kippen, 2009).

The studied ponds differed in dominants in the Rotifera and Cladocera groups. A large number of loricate rotifers in Żelisławiec may directly result from the prevalence of specific Cladocera taxa, particularly *Daphnia*. In fishless ponds *Daphnia* may often

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_929941

severely limit the abundance of small rotifers by mechanical interference (ingestion and damage after rejection) (Diéguez and Gilbert, 2011). They revealed that adult *Brachionus sp.* avoided fatal consequences of interference with *Daphnia*. This is indicated by the fact that where *Daphnia* prevail, the biggest numbers are demonstrated by loricate rotifers, but where the dominance among Cladocera was *Chydorus sphaericus,* then illoricate rotifers were abundant *(Bdelloidea* and *Synchaeta sp.)*. It is presumed that *Daphnia* also had some effect on the lower number of zooplankton taxa in Żelisławiec than in Stare Czarnowo, including as many as 25 fewer Rotifera taxa.

Differences in the zooplankton communities between spring and summer were observed in both ponds, which may indicate stability in the species composition in both small water bodies. A significantly higher number and biomass of Cladocera (mainly *Daphnia*) in Żelisławiec (with top predator) than in Stare Czarnowo seems to have limited the number of Rotifera taxa and taxa of small cladocerans. A poor population of cladocerans as Dapnia in spring in Stare Czarnowo resulted from the high pressure from small cyprinids, which caused better conditions for development of small crustaceans and illoricate rotifers. In spring and summer, when cyprinids hatch, the pressure on cladocerans is the largest. Zooplankton abundance declined greatly after the peak in fish larval abundance (Welker, 1994). Therefore, in spring and in summer, we could observe different zooplankton structures in both ponds. In autumn, however, high similarity between the two ponds was observed. Perhaps, the autumn fry was too large to significantly reduce the populations of larger plankters in the pond where pike was absent. Fluctuations in zooplankton populations can occur both spatially and temporally and may be caused, in part, by predation from planktivorous fishes (Welker, 1994).

The abundance domination of Rotifera is typical of such small mid-field water ecosystems (Kuczyńska-Kippen, 2009; Mieczan et al., 2016). However, the domination was not evenly distributed in different seasons, as mentioned above. The increase Rotifera percentage in the abundance of zooplankton from summer to autumn may pertain to the feeding on crustacean by fry and consequently increasing the density of rotifers. However, as pointed out above, the proportion of rotifers in the number of zooplankton was smaller in the pond with pike than in the pond without it. The value of zooplankton biomass in both ponds can be justified in a similar manner. Generally the zooplankton biomass is dominated by cladocerans due to their larger sizes, predominantly, when there is no factor which would limit them (Carpenter et al., 1985). Simultaneously, two aspects affected higher biomass in the pond with pike: the altered behaviour of Prussian carp which resulted in reduced pressure on cladocerans and a reduced number of small cyprinids, as well as the reduction of rotifers by the filtration mechanism of large ones (Diéguez and Gilbert, 2011).

Changes in the density of large piscivorous fish results in changes in density, species composition, and behaviour of zooplanktivorous fish. Planktivorous fish select the largest available prey and can rapidly reduce the density of zooplankters (Carpenter et al., 1985; Gliwicz, 2002). So, we believe that the high mean sizes of the Prussian carp in Żelisławiec can be justified by the occurrence of a predator which reduced the number of young individuals of the Prussian carp. In Stare Czarnowo, where pike was absent, the Prussian carp had smaller mean sizes and their number was higher, which might have contributed to the reduction of some zooplankton taxa. Significant differences in the number of *Daphnia* between the small water bodies result from the regulation of the trophic network from the top and affect the whole zooplankton structure. This is a common pattern of biomanipulation which is used as one of the methods for lake

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_929941

recultivation (Jeppesen et al., 2007). Top-predators are not always associated with biodiversity benefits. On the basis of research of large land predators, it was proved that the top predator may have a negative effect on endemic species or may reduce other precious smaller species (Allen et al., 2012; Duffy et al., 2007). Duffy et al. (2007) put the question. "What are the community and ecosystem-level consequences of biodiversity loss?". In the case of the small water ecosystems we analysed, the absence of a predator and, simultaneously, the lack of one trophic level cause reorganisation of the zooplankton structure. It also has a different effect on various groups of planktonic organisms, which will be discussed further.

The strongest negative correlations between the number of Rotifera taxa and the biomass of the Prussian carp and its sizes can be justified by the fact that larger Prussian carps beginning to feed on macro-invertebrates discontinue feeding on cladocerans (Tsoumani et al., 2006) which led to the domination of the largest possible plankters which were not limited by predators. Similar significant correlations were observed between the biodiversity index and the number of the Prussian carp. It is common knowledge that young cyprinids feed on crustaceans and food selectivity (Gliwicz, 2002) may lead to displacement of some species. Therefore, a large number of a predator which limited small plankton-feeding Prussian carp caused a significant increase in the Cladocera biodiversity index. The biodiversity index for the total zooplankton was negatively correlated with total length of pike, which results from the fact that the overall zooplankton biodiversity is mainly shaped by Rotifera, due to their domination in density and the number of taxa. Links between biodiversity and ecosystem function provide compelling reasons for conserving maximal numbers of species in ecosystems (McGrady-Steed et al., 1997). It also has to be noted critically that a different species composition of submerged macrophytes in both ponds could have affected species diversity and biodiversity (Schriver et al., 1997).

The abiotic parameter which correlated significantly positively with the biggest number of taxa was depth. We believe that higher abundance and biomass in high water level result from surface runoff that promote a high re-suspension of sediments into the water column. This hypothesis requires further research.

The zooplankton composition in both ponds could have differentiated in the values of conductivity, which differed significantly the small water bodies. According to Sousa et al. (2008), high values of conductivity is often correlated with high trophy status and among many of the environmental variables, conductivity significantly explains the principal variations in the species composition of the zooplankton community. Similarly, Żurek (1983) did not reveal any significant correlations between conductivity and zooplankton communities. However, in the present study effect of conductivity on the number of zooplankton, species richness and biodiversity index was observed. Bērziņš and Pejler (1989) suggest that species as *Brachionus sp*. stand out for its great tolerance to high conductivity. Diverse value of conductivity in studied ponds were a factor that supports different zooplankton community that we think was mainly shaped by fish community.

Another important variable differentiating both ponds was the concentration of dissolved oxygen. Zooplankton can tolerate lower oxygen concentrations than fish and may use oxygen gradients as refuges against predation (Horppila et al., 2000). Low dissolved oxygen concentration has little influence on zooplankton (Yang et al., 2012). In our study in pond with higher oxygen concentration and lower conductivity (Żelisławiec) we determined low taxa richness and biodiversity of zooplankton. Even

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_929941

though oxygen concentration was high no positive effect on taxa richness and biodiversity of zooplankton was observed. We assume that fish community in this study has been a leading factor. Moreover, higher oxygen concentration and lower values of conductivity in Stare Czarnowo may have been caused by the presence of pike. Many authors describing biomanipulation as a target effect demonstrate improvement of physico-chemical conditions (Hodgson, 2005; Jeppesen et al., 2007; Eriksson et al., 2009) which may be related to an increase in dissolved oxygen concentration and a decrease in conductivity values, which were observed in the ponds.

Summary

Changes in density of large piscicorous fish result in changes in density, species composition, and the behaviour of the zooplanktivorous that select largest available prey and can rapidly reduce the density of zooplankters. In the pond with pike, crucian carps were characterised by bigger sizes and a smaller number of individuals, which was attributed to the lower pressure on cladocerans. Significant differences in the abundance of *Daphnia* between the small water bodies result from the regulation of the trophic web from the top and affect the whole zooplankton structure. However bottom up control which refers to the nutrients concentration in the environment and as consequence food availability shape the assemblages of zooplankton. From the other hand high conductivity values could be a factor that promotes some species e.g. *Brachionus sp*. In ponds with top predator, large *Daphnia* severely limited the abundance of small rotifers by mechanical interference (ingestion and damage after rejection). In the pond where *Daphnia* dominated among cladocerans, the highest numbers belong to loricate rotifers, e.g. *Brachionus sp.* and *Keratella sp.,* whereas in the pond where the dominance among Cladocera was *Chydorus sphaericus,* illoricate rotifers were abundant, e.g. *Bdelloidea* and *Synchaeta sp.* The presence of the top predator caused a significant increase in the species richness and in the biodiversity index for Cladocera but higher conductivity values supports higher species richness and biodiversity of all zooplankton. The overall zooplankton biodiversity is shaped by Rotifera which may be limited by large cladocerans, due to the top effect of the top predator on the trophic network.

Acknowledgements. We would like to thank W. Piasecki and K. Rawicki for assistance during the experiments.

Abstract. Population growth has prompted governments to encourage industrial development in order to improve the welfare of their citizens. This process increases the deposition of human and industrial waste in the environment. The consequences of this have produced a serious need to implement appropriate management strategies in order to reduce and control the effect of the accumulation of such waste. The current study was undertaken to compile information about the status of iron ore waste produced by the Golgohar Mining and Industrial Complex in Sirjan, Iran, in 2015 by observation, field visits, interviews with officials and experts of the unit and the use of questionnaires and technical documentation. The industrial waste was classified using UNEP guidelines and guidelines for proper management of waste have been presented. The results of data analysis regarding the quantity and quality of mining and industrial waste of Golgohar Mining and Industrial Complex showed that about 24 million tons of solid industrial waste is produced annually. A large percentage comprises hazardous waste according to UNEP classifications and include rock and soil tailings from processing, dry and wet tailings. These are classified into group E as high volume and low-risk waste and in group A as mining waste containing heavy metals. The presence of heavy metals increases the importance of controlling and managing this waste.
Keywords: *hazardous waste, solid waste, heavy metals, United Nations Environment Programme*

Introduction

Since the development of mining industry, mining exploitation activities have enhanced solid wastes production and induced increasingly grievous destruction on the eco-environment. Waste rock, tailings and other solid waste are the largest industrial solid waste generated in the process of exploitation of mineral resources (Lu and Cai, 2012). Mining activity leaves behind a great variety of waste materials which often contain high concentrations of toxic elements (András et al., 2012).There exist a large number of issues such as stockpiled tailings resources, environment, safety and land, etc. Since there is a technology gap between different periods of smelt, a great deal of valuable resources is being retained in the tailings, and if these tailings resources cannot be integrated in the recycling process, it will cause a huge waste on the enviroment (Yang et al., 2011). Mining wastes are referred to as those wastes produced during

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_943956

mining operations in the form of returned load, mining overburden or tailings (BHP Billiton Mitsubishi Alliance, 2009). In general, mine tailings are mechanically, physically, chemically and biologically deficient (Vega et al., 2006), characterized by instability and limited cohesion, with low contents of nutrients and organic matter and high levels of heavy metals (He et al., 2005).Opencast mining activities have a serious environmental impact on soils and water streams, generating millions of tons of mine tailings (Bhattacharya et al., 2006). With the rapid development of iron and steel industry, the proportion of iron ore tailings in industrial solid waste is rapidly increasing. According to incomplete statistics, the total amount of cumulative iron tailings is nearly $2* 10^9$ tons (Wang et al., 2009).

On the other hand, mining and smelting of metal ores have increased the occurrence and spread of heavy metals contamination in the soil, especially open pit mining which produces million tons of mine tailings, which have serious environmental impact on soil and water flow (Bhattacharya et al., 2006). The contamination of soil by heavy metals is one of the major environmental problems facing many countries around the world, considering their almost indefinite persistence in the environment and the danger they pose (Ding et al., 2013). Therefore tailings are environmentally problematic in that they are natural (crushed) particles impregnated with the chemicals used in mining. Tailings which contain iron sulfide also contain heavy metals such as antimony, arsenic, beryllium, cadmium, lead, nickel, selenium, silver and zinc. These tailings can cause the environment to produce acidic drainage in the presence of oxygen and water (Balvardi, 2010). Among other environmental concerns in relation to tailings from the mining of iron ore is the presence of fibrous forms of mineral silicates belonging to the serpentine and amphibole groups of rock-forming minerals, including asbestos in tailings (Kesler, 1994).Incidents of poor waste management practice are amongst the most conspicuous features of the global minerals industry. Tailings spills, dam failures, seepage, unrehabilitated sites and cases of direct discharge into water ways can result in severe and long-term environmental and social consequences (Van Zyl, 1993; ICME and UNEP, 1998; Hart, 2007; Franks, 2007; Spitz and Trudinger, 2009; Fourie, 2009).

Mining and industrial waste, if not properly controlled, will create problems for industrial units. They occupy space, can cause injury to employees, create odors and attract insects and stray animals. Dumping of debris on surrounding land can cause complaints and enforcement by regulatory bodies. Such materials are usually produced in large quantities, which will increase the cost of storage, handling and disposal; however, it can also make recycling economically justified (Habibinejad, 2000). Studies in China, India, Russia and Spain have shown the widespread use of iron mine tailings to be economically feasible and, in many cases, profitable. It reduces the volume of waste and, under optimal management, the regional environmental situation can be improved. Use of the proposed operation and management strategies can also compensate for or reduce the cost of production (Zhang et al., 2006).

In India approximately 10 – 15 % of the iron ore mined is unutilized, even now, and is discarded as waste/tailings due to lack of cost effective technology in extracting low grade ores. Because of this huge piles of mine wastes are found in and around mine areas (Ahmari and Zhang, 2012). However, some of these waste materials possess potential characteristics, which can be tapped for various uses (Hussain, 1995; Water, 2001; Menezes and D‘Souza, 2004; Kumar, 1998). Hammond (1998) in his study critically reviewed the usage of mining waste as building material. He identified many mining wastes as concrete aggregates and pigments for paints. Das et al. (2000)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_943956

developed new techniques for converting iron ore tailings into value added products such as ceramic floor and wall tiles for building application. It was proved that such tiles have high strength and hardness compared to conventional tiles. The investigation also revealed other benefits like energy economy and lower production costs, which is also strengthened by the study carried out by Reddy (2004) and Zhang et al. (2006).

Mining waste is environmentally hazardous because of the large volume produced and the presence of chemical reagents. Heavy metals can be found in some types of mining waste, indicating the need for proper management of its disposal.

The costs related to the control and management of hazardous waste are higher than for other waste and its mismanagement can incur heavy fines. It is very important for a manufacturing unit to operate economically (Habibinejad, 2000); thus, all waste management plans must consider the economic aspects as of equal importance with the environmental issue.

Literature Review

Decision-making on waste infrastructures is difficult because waste management is a complex, politically loaded and emotionally charged issue that is neither well structured, nor well understood. While sustainability is the ultimate goal of the EU environmental policy, there is no commonly accepted approach for its realization (Verhoef et al., 2006).

The first step in waste management is to identify and classify waste according to given standards and laws. The first laws and regulations pertaining to hazardous waste management were implemented by European common market countries in 1980. The United Nations Environment Programme (UNEP) established the principles of environmental management of hazardous waste in 1987. The Basel Convention was adopted by 35 participating countries in Switzerland in 1989 to control trans boundary movement of hazardous waste. At present, 105 countries, including Iran, have joined the treaty since September 1992 (Binavapoure, 2010). The waste law was passed in Iran in 2004. The law consists of 23 articles and waste has been classified into five categories, including those of hazardous(or special) waste. Hazardous waste refers toall waste that requires special handing due to the presence of at least one of dangerous property (toxicity, pathogenicity, possibly explosive or ignitable and corrosive). Similar to medical waste and some general waste, industrial, mining and agricultural waste that requires special management is classified as special or hazardous (Office of Legal and Parliamentary Affairs, 2004).

Different methods have been used for the classification of waste, including those based on how waste is produced, its detrimental effects, the degree of risk and the physical state (Abdoli et al., 2010). Each method of identification and classification of hazardous waste has advantages and disadvantages. The use of lists and directories is a relatively simple method for the identification of hazardous waste. The most important directories and classifications include the US Environmental Protection Agency (USEPA) quad list, UNEP classification and Basel Convention classification (Abdoli et al., 2010). In Iran, classification of industrial waste is often done based on these three classifications.

Sabzalipour et al. (2007) studied the feasibility of industrial waste minimization in Bandar Imam Petrochemical Complex and first identified the waste, its quantity and quality and then classified it according to UNEP guidelines (Sabzalipour et al., 2007).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_943956

Namdari and Turkian (2010), studied management of waste and chemicals used in Asaluyeh Pardis Petrochemical Company and classified them according to the Resource Conservation and Recovery Act (RCRA) and Basel Convention (Namdari and Torkian, 2010). The present study was undertaken to identify all industrial waste from the Golgohar Mining and Industrial Complex in Sirjan, Iran. Beside waste identification, the quality and quantity was determined and the type of waste was classified according to UNEP guidelines.

Materials and Methods

Study area

Golgohar Mining and Industrial Complex (29°7′5″N and 55°19′5″E) (*Figure 1*) is located 55 km South West of Sirjan city in Kerman province, south of Iran. According to Iran's National Census in 2006, the population of Sirjan is 167,014, scattered in 40,605 families. The study area is located at an altitude of 1730 m above the sea level; it is situated in a depression between the southern Zagros Mountains to the west and the Kuh-e Bidkhan massif to the east (Sirjan county, 2015). Golgohar Mining and Industrial Complex is the main source of revenue for the city. It meets 30% of the needs of steel fatories in Iran. Based on the method of De martonne, drought index was 39/6, and based on this classification, the climate of the study area is dry (Kousha Madan Consulting company, 2014).

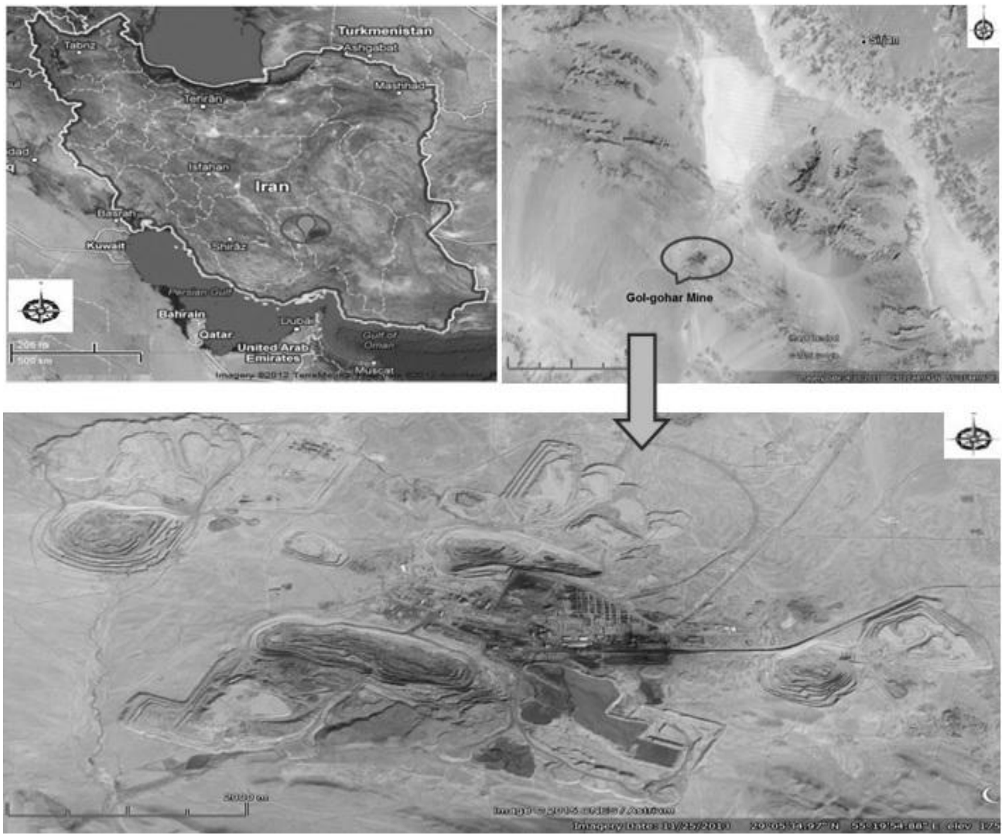

Figure 1. *Study area in Sirjan County, Kerman Province, Iran*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_943956

Golgohar Mining and Industrial Complex comprises four plants, three of which are involved with ore beneficiation and concentration. These are the magnetite processing, hematite recovery and desulfurization and polycom processing plants. The fourth plant is the pelletizing plant, which is responsible for the agglomeration of concentrates produced by the other three plants. Each plant produces different types of waste according to their process and the raw material and additives used.

Methods

To carry out this research, field visits and interviews with the managers and owners of industry were carried out and a questionnaire containing 29 questions was developed and completed. To obtain accurate and real date, information was also obtained from annual reports of the environmental unit and technical documents from the plants and MSDS instructions and executive program reports on waste management were disclosed. This neutralized the subjectivity of the manager responses, which can be a prevalent problem on similar research efforts.

Ultimately, UNEP guidelines were used in the pluralization of the information obtained and classification of waste. Recommendations and management strategies were then presented using the results. The method used in this study consisted of four parts:

- Part I: Library research;
- Part II: Field visits;
- Part III: Questionnaire preparation;
- Part IV: Classification of waste in accordance with UNEP guidelines and provision of appropriate management strategies.

In the first part, the method applied involved gathering the most recent statistics and background information using the resources available in libraries, scientific and research centers, Golgohar Mining and Industrial Complex and internet searches in the fields of mining, environment and waste management. In the second part, in order to become more familiar with the complex's performance, field visits and interviews were conducted with managers of industry, then producer points and sources of industrial waste were identified through field visits. In the third part, the quantity, nature and mode of industrial waste were identified through the questionnaires.

In the fourth part, after analysis of the collected data, an attempt was made to classify the waste based on the type produced and according to the UNEP guidelines. Thereafter, appropriate strategies for waste management were provided. This study was based on the information obtained from the exploitation and processing units of Golgohar Mining and Industrial Complex and focused on studying the quality and quantity of industrial waste and classifying it according to international standards.

Classification of waste

From the perspective of UNEP, hazardous waste is defined as waste materials that is either solid, sludge, liquid or gas in the tank, except for radioactive materials, which have chemical activity, toxicity, explosive and corrosive properties or other characteristics, and has been shown to pose detrimental effect on human health or the environment either by itself or when mixed with other materials (LaGregaet al., 2001).
UNEP classification is based on the type of waste, industry or process involved in the production of hazardous waste. One advantage of this classification is that it can largely

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_943956

make the environmental administrators and managers aware of the types of industry and processes that must be controlled. In this classification, the type of waste material, industry or process and the abbreviated titles of the groups are presented in table form. The waste was divided into six groups (Abdoli et al., 2010) as shown in *Table 1* according to UNEP guidelines.

Table 1. *Classification of waste according to UNEP*

<table>
<tr><th colspan="2">Group A</th><th>Nature of the waste</th><th>Group B</th><th colspan="2">Group C</th><th>Nature of the waste</th><th>Group D</th><th>Group E</th><th colspan="2">Group F</th><th>Nature of the waste</th></tr>

</table>

Mining/smelting is one of the main sources of heavy metal pollution in the environment, and the tailings generally contain higher concentration of heavy metals. Therefore, several researches have been conducted on different metal mining tails and surroundings to determine the behavior of the heavy metals (Rodrguez et al., 2009; Romero et al., 2007; Moncur et al., 2005; Lowry et al., 2004).

The findings indicates that mine tailings can be classified using the UNEP method of classification based on the presence of heavy metals, as well as its high volume.

Results

The information obtained from the questionnaire regarding the qualitative and quantitative assessment of waste from Golgohar, interviews with managers and experts and a review of reports and technical documents helped determine the type of waste produced in the mining region. It comprised tailings of rock and soil from ore extraction, dry and wet tailings from magnetic separation, effluent from flotation cells containing tailings and reagents used in flotation and oil and grease used on equipment, in addition to worn-out components and equipment.

Industrial waste of different types can be classified according to different criteria. Some researchers have classified industrial waste based on their generation source, while others have classified them based on their specifications. Waste can also be classified according to its internal components. What is important for classification is to facilitate the identification and management of waste. Industrial waste can be classified as either hazardous or non-hazardous.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_943956

The three types of waste identified were analyzed for seven elements (heavy metals) with respect to the degree of danger (degree of hazard of each type of waste and the most significantly hazardous by type). The seven elements were chosen using the toxicity characteristic leaching procedure (TCLP) approved by the USEPA to determine the hazardous waste by testing for 40 elements in and the composition of waste. Seven elements that were measurable by Iranian laboratory methods were selected of the 40 TCLP elements and tested to determine the hazardous nature of each type of tailing and its degree of danger. *Table 2* shows that results for three types of tailings for the seven elements: silver (Ag), arsenic (As), cadmium (Cd), chromium (Cr), lead (Pb), vanadium (V) and zinc (Zn) was done (*Table 2*).

Table 2. *The amount of heavy metals in each type of tailing*

Tailing type	Ag (ppm)	As (ppm)	Cd (ppm)	Cr (ppm)	Pb (ppm)	V (ppm)	Zn (ppm)
Worthless tailings rock and soil	< 1	5	< 1	41.81	32.36	82	56.72
Dry tailings	< 1	9.2	< 1	27.2	14.6	63.8	39.2
Wet tailings	< 1	6.5	< 1	33.66	32.75	206.75	69.08

The results indicate that the presence of heavy metals, especially Cr, Pb, V and Zn were above normal. In addition to being classified as hazardous according to the UNEP, their large volume require environmental measures to optimize the management of these types of waste.

The wet tailings had the highest amount of Pb and Zn and a significantly higher amount of V. Dry tailings contained the highest amount of As and rock and soil tailings contained the highest amount of Cr.

Hazardous waste of Golgohar Mining and Industrial Complex

- Worthless tailings rock and soilfor processing are classified as group E "**High volume and low-risk waste"** according to UNEP's classification.
- Dry tailings are classified as group A "**Mining waste containing heavy metals"** according to UNEP's classification.
- Wet tailings are classified as group A "**Mining waste containing heavy metals"** according to UNEP's classification.
- Used oils, including compressors and mills oil,etc are classified as group B "**Oily waste"** according to UNEP's classification.
- Burned grease is classified as group B "**Oily waste"** according to UNEP's classification.
- Used activated carbon is classified as group C "**Organic Waste"** according to UNEP's classification.

Any type of waste with at least one dangerous property can be called hazardous waste. These include chemical activity, toxicity, pathogenicity, explosion or ignition creation, corrosion and any others that are risky or likely to cause harm to human health or the environment, either by itself or when mixed with other materials.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_943956

Non-hazardous waste of Golgohar Mining and Industrial Complex

Any type of waste that is not classified into groups A, B, C, D, E and F is known as non-hazardous waste. Accordingly, non-hazardous waste would include used activated alumina, molecularsieves, worn balls and rods from mills, steel liners from mills, rubber liners and parts of mills, abrasive parts of pumps, filter and cleaning cloth, wire and cotton strips, plastic sectors, lifter bars, impact bars, shell plates, wooden cartons, boxes and pallets, great bars (metal parts of the pallet floor) and steel pallets.

Classification of hazardous waste according to their characteristics

Waste is called hazardous if it possesses corrosive, explosive or ignitable or toxic properties or shows chemical activity. Given the importance of this issue, after identifying the waste in the study area, it was characterized and classified. The results are shown in *Table 3*.

Table 3. *Classification of GolGohar Mining and Industrial Complex's wastes based on UNEP's method*

A: Mining waste
B: Oily waste
C: Organic Waste
D: Putrescible organic materials
E: High volume and low-risk waste
F: Miscellaneous waste

Analysis of the data shows that, of the 22 types of waste identified at Golgohar Mining and Industrial Complex, six were hazardous because they possessed at least one dangerous UNEP property. These were rock and soil tailings, dry tailings, wet tailings, used oil and grease and used activated carbon. Another 14 showed no hazardous characteristics and were considered to be non-hazardous waste. Despite the small number of types of waste classified as environmentally hazardous, the percentage of each was higher than the percentage of non-hazardous waste because of their high volume. This means that of the 24,461,753 tons of industrial waste produced at in 2015, 24,452,753 tons were environmentally hazardous and 9,000 tons were non-hazardous according to UNEP standards. In other words, more than 99% of the industrial waste in the study area was considered to be hazardous and less than 1% was considered to be non-hazardous (*Figure 2*).Note that of the 24,452,753 tons of hazardous waste, about 19,768,236 tons were rock and soil tailings, which were considered to be high volume and low-risk waste according to the UNEP classification (*Figure 3*).

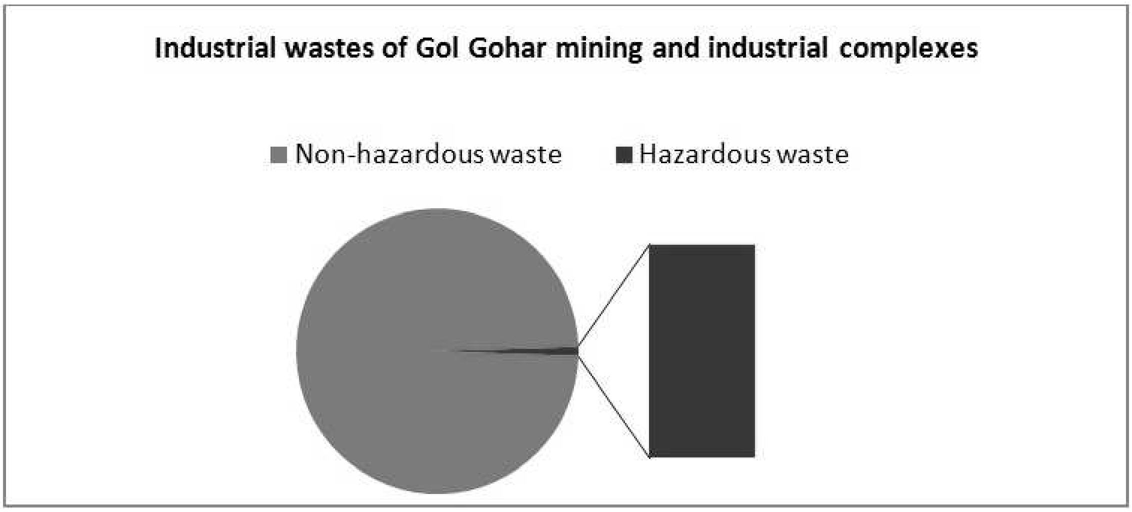

Figure 2. *Percentage hazardous and non-hazardous waste in GolGohar Mining and Industrial Complex according to UNEP's classification in 2015*

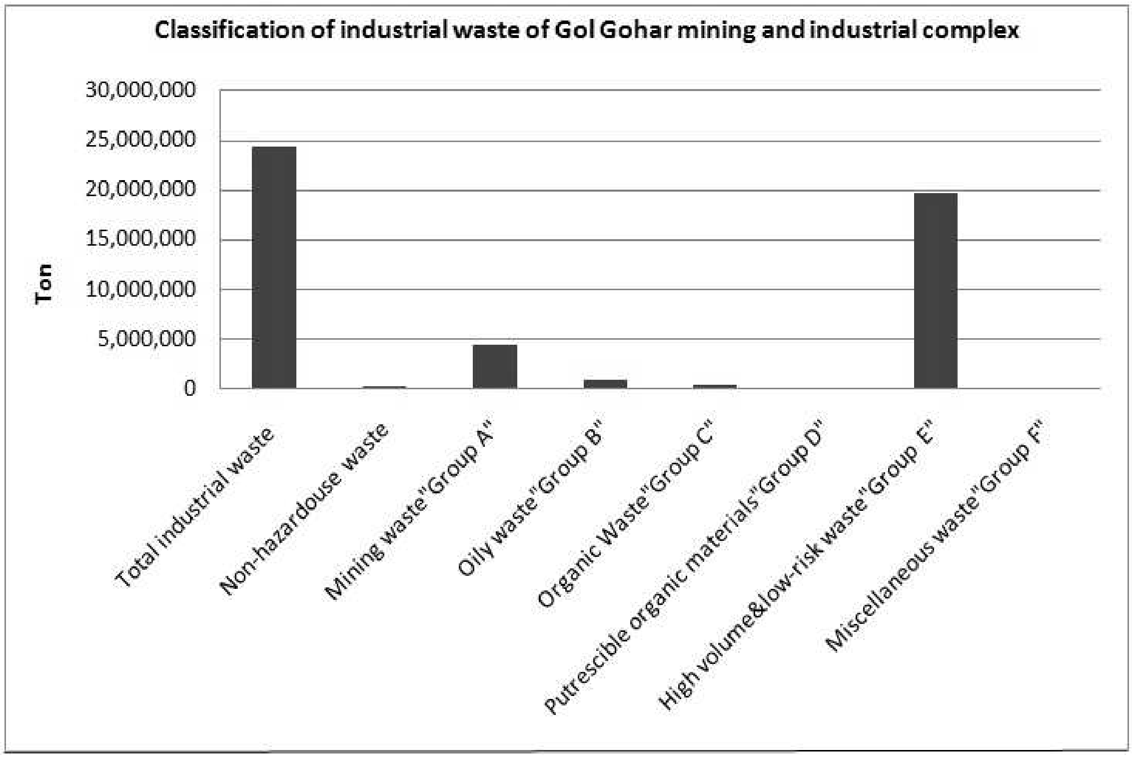

Figure 3. *Classification of all industrial wastes in GolGohar Mining and Industrial Complex according to the UNEP's classification in 2015*

It should be noted that from the total of 24,452,753 tons of hazardous waste, about 19,768,236 tons included tailing rock and soil, which were considered as High volume and low-risk waste according to UNEP's classification (*Figure 3*).

Discussion

Soil and water are important environmental resources which can be contaminated and seriously threatened by improper disposal of industrial waste. It has been suggested that water and soil be protected as a serious investment with the implementation of waste management. Unfortunately, despite the appropriate legal bases in Iran such as the Third and Fourth Development Plans and other environmental laws, gaps and shortcomings in the implementation of industrial waste management has been observed. Practical suggestions for improving the execution of industrial waste management in Golgohar Mining and Industrial Complex have been suggested by the analysis and the results of previous studies in this region.

Reduce waste at the source of production

A basic principle of waste management is that waste reduction should begin at the origin and continue through all stages of production. It is evident that reducing waste at the source is fundamental and more efficient than at other stages. In many cases, the effective use of resources, a decrease in the consumption of raw materials, recycling, and the reuse of waste are accompanied by significant social and economic benefits, such as reduced cost of production and decreased pollution and disposal costs.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_943956

One way of reducing the amount of industrial waste is to change the process. In some cases, manufacturing may contain defects which create waste. Such waste can be reduced by the removal of the defects and modification of the process. A change in the process may be done by modifying equipment, process automation and operation planning (such as regulation of temperature, pressure and amount of raw materials). For example, the volume of tailings in most cases can be reduced when lines and equipment are controlled in order to ensure optimal performance. A defect at any stage of manufacturing, such as crushing, magnetic separation, flotation, filtering, screening and handling can be controlled by continuous control of the lines to reduce tailing production. Rock and soil tailings, however, including waste containing iron (at a lower grade than currently economically viable due to lack of access to advanced technology) and other elements which have economic value, such as copper and vanadium, need further investigation to ascertain their potential use. The volume and amount of waste, together with its danger and toxicity can be reduced through the practice of tailings.

Recycle waste

In the waste management hierarchy, after waste reduction at the source, follows recycling and reuse of waste. It may be possible to use waste again in the same process after recycling at the production unit or could be given to other units for recycling and then used for final processes. If a unit can recycle its waste, the volume of the waste produced will decrease and savings will increase in disposal operations and, most importantly, in their collection and transportation. This is an important step toward protecting the environment.

Because industrial waste is produced in separated form and in high volumes in the manufacturing and industrial units, its recycling become easier and more efficient than municipal solid waste. In the study area, a certain percentage of waste is recycled; thus, it was recommended that recycling of waste be followed with thorough assessment of existing waste production and determination of the potential of industrial waste recycling. Dust captured by the electrostatic precipitator and wet scrubber sludge are taken back into the production process, recyclable metal parts are collected and sold, and used oil is collected and transferred after filtering and treatment. It is evident that all non-hazardous waste, except activated alumina and molecularsieves, are recyclable and can be sold to recycling plants for plastic, rubber, metal and paper. In addition to compensating for part of the purchasing expense of these materials, this can help prepare the raw materials for another industrial unit. This addresses many of the problems and costs associated with landfills and disposal of these materials, which is the responsibility of the manufacturer.

The last alternative for waste recycling is their use for thermal energy. At present, much waste is burned in cement and asphalt kilns or consumed as auxiliary fuel in a fossil fuel furnace. Used rubber and tires and used oil and grease are used in large industrial complexes after output standards have been strongly observed. Used vehicle tires (trucks and lorries) and used oil and grease are common in the study area; their volume means they can be sold to cement and asphalt kilns. This will decrease the volume of waste and also compensate for part of production expenses. Energy recovery of waste is preferred to its disposal.

The chemical composition of the tailings shows that they contain elements such as silica oxide, aluminum oxide, calcium oxide, magnesium oxide, titanium oxide and iron oxide that can be considered for making cement blocks, bricks, ceramics and glass.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_943956

Rock and soil tailings can be used as road infrastructure and in mine rehabilitation programs after harvest and final discharge (*Table 4*).

Table 4. *Chemical characteristics of tailing*

	Silica Oxide SiO_2 (%)	Aluminium Oxide Al_2O_3(%)	Calcium Oxide (CaO) (%)	Magnesium Oxide (MgO) (%)	Titanium Oxide TiO2(%)	Iron Oxide FeO(%)	Iron Fe (%)
Dry tailings	32.48	7.75	6.26	12.53	0.48	3.42	18.24
Wet tailings	29.52	6.34	7.43	15.40	0.34	3.87	36.66

The use of advanced technologies for further concentration can be added to the agenda. Because iron ore concentrationis done by using its magnetic property, iron extraction can be increased by increasing the strength of the magnetic separators. A survey has shown that processing plants in the Golgohar complex can extract 68% of the iron from ore. Increasing the magnetic strength of the separators can allow extraction of a higher percentage of iron. This would reduce the volume of waste and increase production at processing plants, making it more economical.

Because mining tailings contain precious and rare metals in low grades, extraction of these metals can be arranged. In addition to the economic benefits, this can lead to the removal of the risks of heavy metals, which primarily threaten the quality of water and soil and, secondarily, the health of the community.

Mining tailings are potentially suitable for a variety of uses. The aggregation and physical properties of iron mine tailings advocate their use as a primary material in the manufacture of cement and concrete. Mine tailing recycling for use in other industries saves energy and resources and has economic benefits. It also reduces the volume of accumulated mining waste and can reduce problems associated with the accumulation and disposal of mining tailings.

(Received 13th Dec 2016; accepted 24th Mar 2017)

Abstract. The aim of this study is to assess the effects of some environmental factors on the distribution of *Prangos uloptera* DC. and *Prangos pabularia* Lindl. In the rangelands of Ardabil province, in the north-west of Iran. Six sites with the distribution of the genus *Prangos* (presence) and six sites without *Prangos* (absence) were identified. Three 100m transects were established. On each transect, ten 4m^2 plots were located, and the total canopy cover and density of plants were recorded. Soil samples were collected from a depth of 0–30cm on each transect. Elevation, slope and aspect were extracted from the Digital Elevation Model (DEM), and rainfall, temperature were also extracted from the derived gradient equation and DEM for each plot. Soil parameters such as organic matter (OM), nitrogen (N), phosphate (P), potassium (K), pH, electric conductivity (EC) and texture were determined at the Soil Lab. Normality of data was tested. To compare the related parameters for the sites with the presence and absence of species, the one-way ANOVA was conducted. Cluster analysis was used to classify the collected samples. To determine the variables that were significant in the distinction of each groups and mean comparison, ANOVA and Tukey tests were conducted. To determine the importance of ecological factors for the presence and absence of the selected species, discriminant analysis was conducted. The results of the analysis of variance between presence and absence of *P. uloptera* and *P. pabularia* in habitats demonstrated significant differences for the parameters of elevation, slope, aspect, temperature, EC, pH, OM, nitrogen, phosphorus, clay, silt and sand and total canopy cover, $P<0.01$. The result of grouping sampling plots using cluster analysis showed that plots in three groups were separated by significant differences ($P<0.05$) in the multivariate analysis of variance. The results showed that *P. uloptera* was adapted in habitats with OM of 1.402%, N 0.126%, P 2.627$_{ppm}$, K 258$_{ppm}$, 1992m a.s.l., with average slope of 83.40%, clay 10.90%, silt 37.90%, sand 51.20%, and average precipitation of 353mm. However, *P. pabularia* was adapted in habitats with OM of 0.915%, N 0.088%, P 2.339$_{ppm}$, K 236$_{ppm}$, 1672m a.s.l., and with average slope of 84.80%, clay 13.60%, silt 29.70%, sand 56.70% and average precipitation of 370mm. With regard to the results from discriminant analysis, the percentages of slope, clay, sand, silt, OM, P and pH, aspect, precipitation and temperature play an effective role in the separation and distribution of the species studied. These results can be used to suggest suitable species in management and restoration of rangelands with the same ecological characteristics.
Keywords: *ecological factors, species dispersion, cluster analysis, discriminant analysis*

Introduction

Environmental factors affect the establishment and distribution of plant species (Ashcroft et al., 2011). Identification of factors that affect the distributions of species is an important unresolved issue in ecology (Araújo and Guisan, 2006). Often, there are many combinations of predictors that can explain distributions equally well, especially when environmental factors are correlated, and this introduces uncertainty into the effect of each factor (Platts et al., 2008; Murray and Conner, 2009). Therefore, the first step in rangeland management is to determine the habitats of plants and the effective factors affecting their distribution. Autecological field or laboratory studies have long

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_957968

been relied upon to reveal environmental variables that impede a plant's migration into surrounding territory (Arundel, 2005). These variables—or limiters—shape various spatial aspects of individual plant species' distributions. Knowing specific influences on plants is important in many fields, but particularly for climate reconstruction based on fossil plant remains (Arundel, 2002). The presence and distribution of plant species in rangeland ecosystems are not random, but such factors as climate, soil, topography, anthropological and others play major roles in their development (Akbarlou and Nodehi, 2016). Determination of the factors that control the presence and distribution of rangeland species is one of the main objectives in the rangeland ecosystems studies.

Though relationships between plant and both soil properties and other environmental factors have been well developed for some plants, comparable understanding of how a variety of plant species in native rangelands responds to soil properties and other environmental factors is poorly developed (Chuangye et al., 2015; Ghorbani et al., 2015; Sahragard and Zare Chahouki, 2015). Xu et al. (2008a) have studied the relationships between vegetation, soil and topography in the dry valley of China. Their results confirmed that plant diversity was mainly correlated with soil water content, and soil water content was mainly determined by soil texture, especially clay content. Yibing (2008), by conducting the Principal Component Analysis (PCA) and Canonical Correlation Analysis in China, showed that physical and chemical features of the soil, including humidity, salinity and acidity affected homogeneity of plant communities on the regional scale. Zhang and Dong (2010), in the study of relationships between environmental factors and vegetation diversity in Lesi plateau of China, reported that elevation, soil type, slope and aspect were important factors in Lesi zones' recovery, and had determinant roles in vegetation distribution. Zare et al. (2011), in a study on the relationship between environmental factors and plant distribution in arid and semiarid areas, reported that soil texture, salinity, effective soil depth, available N, K, OM, lime and soil moisture, were the major soil factors responsible for variations in the pattern of vegetation. Ghorbani and Asghari (2014), in the study of ecological factors affecting the distribution of *Festuca ovina* in the southeastern rangelands of Sabalan, reported that *F. ovina* is more compatible with higher altitudes and lower temperatures and does not tolerate soil salinity, and is more compatible with a pH of 7.1 to 7.3. OM, P and K provide better conditions for its growth.

To improve the management of rangelands and to offer a baseline for restoration attempts, an understanding of the factors that determine the rangelands vegetation distribution and composition is required. For this purpose, this study was conducted to identify the roles of topography, climate and soil components, in the distribution of *Prangos uloptera* and *P. pabularia,* in the rangelands of Ardabil province in north-western Iran. Identification of these parameters in a given ecosystem helps one apply appropriate management for restoration and development in the present and in similar rangelands.

Materials and Methods

Study area

The study area was selected in the rangelands of Ardabil province, Iran (37° 12' to 38° 07' N and 47° 51' to 48° 48' E) (*Figure 1*). Six habitats were selected with the genus *Prangos* distribution. *P. uloptera* were distributed in four habitats and *P. pabularia* were in two habitats. According to meteorological stations in the region (with a 10-year

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_957968

period—2006 to 2015), the mean precipitation is 360mm/year. Also, maximum and minimum precipitations respectively occur in February and July. The mean of annual temperature is 9℃, the average annual minimum temperature is 3.2℃ and the average annual maximum temperature is 14.8℃.

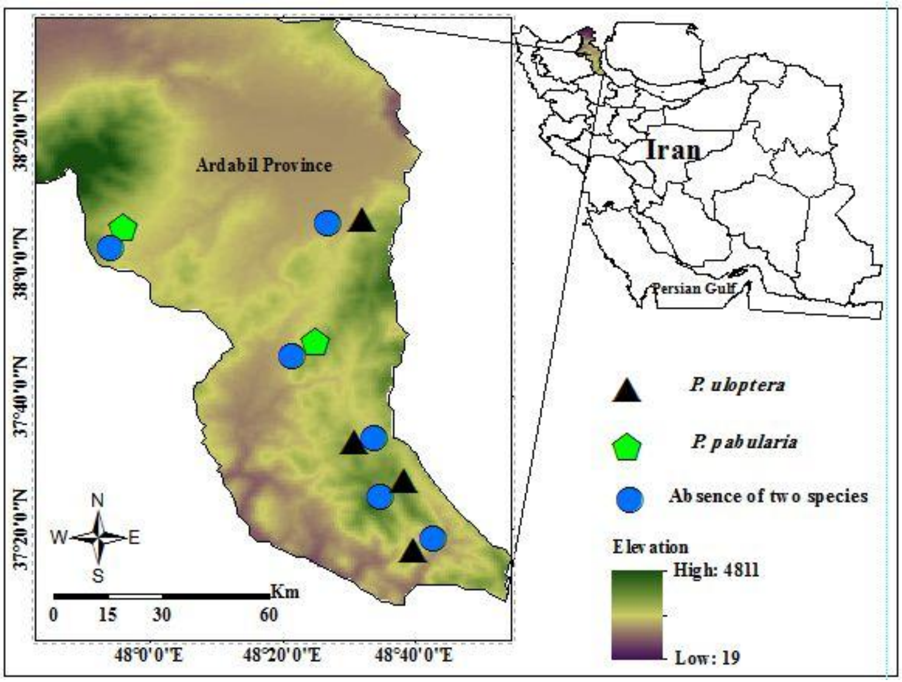

Figure 1. *Location of the study area and sampling locations for presence and absence of the selected species in Ardabil province and Iran*

Sampling method

Initially, in order to recognize the distribution of the genus *Prangos*, an overall study was conducted by literature review (Rechinger, 1987; Mozaffarian, 2007; Azimi et al., 2011; Teimoorzadeh et al., 2015; Ghorbani et al., 2015). Moreover, fieldworks were conducted in Ardabil province to select the habitat of the genus *Prangos*. Finally, six habitats were identified with *P. uloptera* and *P. pabularia* distributions. In each habitat, initially one site with genus *Prangos* distribution was selected as the presence of the selected species. Near to each of the selected sites, another site with the absence of genus *Prangos* were selected in the same habitat (overall, for the presence and absences of genus *Prangos*, 12 sites were selected). A Digital Elevation Model (DEM) map was derived using 1:25000 topographic maps of the National Cartographic Center of Iran, with 10 m horizontal and vertical accuracy. Slope and aspect maps were derived from the DEM for the selected habitats and sites. By considering the studies conducted on the rangelands of Ardabil province (i.e. Ghorbani and Asghari, 2014; Ghorbani et al., 2015), in each site three 100 m transects were established. The first one was selected randomly, and the second one as parallel with 500 m distance, and the third one perpendicular to both. By considering the abovementioned literature and using minimal area method (Kent and Coker, 1996), the size of plots was determined as $4m^2$. The number of plots was also determined by considering the literature (i.e. Ghorbani and Asghari, 2014; Ghorbani et al., 2015), and the pre-samples taken were calculated

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_957968

(Kerbs, 1999) as about 10 samples. Overall, ten $4m^2$ plots were selected for each transect, wherein the distance between the plots (from the centre of each one) was 10m, for the 12 selected sites, for the presence and absence of species. Within each plot (presence and absence of the species), total canopy cover, percentage and density of plants, including the selected species, were recorded. In each site, nine soil samples were collected from the depth of (0–30 cm) (Northup et al., 1996). The soil properties—such as N, OM, EC, pH, P, K and texture—were measured via laboratory analysis at the Soil Lab of Ardabil University.

Data analysis

Kolmogorov-Smirnov test was used to assess the normality of data. To analyse significant difference between the effects of environmental factors on the presence or absence of two selected species, the one-way ANOVA was used. For grouping the collected samples on the basis of the recorded ecological factors, cluster analysis was used. To determine the variables that assume significance in the distinction of identified groups and to compare these, ANOVA and Tukey test were used. The importance of each measured variable in the distribution of selected species was analysed using discriminant analysis. The ArcGIS10 was used to extract the base map and SPSS18 software was used for data analysis.

Results

The results of the analysis of variance between presence and absence of *P. uloptera* and *P. pabularia* in habitats demonstrated significant difference for the parameters of elevation, slope, aspect, temperature, EC, pH, OM, nitrogen, phosphorus, clay, silt and sand and total canopy cover, $P<0.01$ (*Table 1*). The clustering of sampling plots, using cluster analysis, indicated that the plots are divided into three groups ($P<0.01$) in the multivariate analysis of variance (*Figure 2*). The discrimination based on the plots revealed that Group 1 is related to the absence of the two species in the habitats, Group 2 shows the habitat of *P. uloptera*, and Group 3 indicates the habitat of *P. pabularia*. The results of multivariate analysis of variance among the groups proved that the resultant groups had significant differences in all the variables, except for the precipitation level and potassium, $P<0.01$ (*Table 2*). The elevation, organic matter and silt in the habitat of *P. uloptera* (Group 2) were higher than the habitat of *P. pabularia* and the habitats without the study species, which had significant difference, $P<0.01$ (*Table 2*). In the habitat of *P. pabularia* (Group 3), the percentage of sand and temperature were higher than other habitats, which had significant difference ($P<0.01$), as well as the habitats without the study species had the highest electrical conductivity, clay and phosphorus compared to other habitats ($P<0.01$). The slope in the habitats of *P. uloptera* and *P. pabularia* had the highest percentage (over 83%) and the habitats without the study species had lower percentage (mean slope of 66%). The results showed that *P. uloptera* was adapted in habitats with average OM of 1.402%, N 0.126%, P 2.627_{ppm}, K 258_{ppm}, 1992m elevation a.s.l., slope 83.40%, clay 10.90%, silt 37.90%, sand 51.20%, and also average precipitation of 353mm. However, *P. pabularia* was adapted in habitats with average OM 0.915%, N 0.088%, P 2.339_{ppm}, K 236_{ppm}, 1672m elevation a.s.l., average slope 84.80%, clay 13.60%, silt 29.70%, sand 56.70%, and also average precipitation of 370 mm.

By using the discriminant analysis of habitats based on environmental factors and the results obtained, the two functions justified respectively 69.8% and 32% and a total of 100% of the variance of total data. Moreover, the canonical correlation coefficient showed that the Functions 1 and 2 were able to discriminate well between the groups (*Table 3*). *Table 4* indicates the values of Wilks' lambda for functions, which increase from the Function 1 through the Function 2. The index closer to zero shows more appropriate estimated function in discrimination of groups, so Functions 1 and 2 had proper estimation in discrimination of groups. Considering the significance of chi-square values at the level of <0.01, the mean groups are different. In each of the Functions 1 and 2, the study parameters had different coefficients, so that the factors influencing the grouping of habitats as well as the distribution of the species studied can be determined, thanks to these coefficients (*Table 5*). Accordingly, the slope, clay, sand, silt, pH, organic matter, temperature, aspect, potassium and precipitation are effective in discrimination of habitats and the distribution of the species studied. Clay and temperature, having the highest standardized coefficients, as well as potassium and organic matter, having the lowest standardized coefficients, respectively had the maximum and minimum impacts on the first detection function. The average annual precipitation has the greatest effect on Function 2. Owing to structural coefficients (*Table 5*), slope, clay, EC, potassium and sand in the first function, as well as pH, silt, organic matter, elevation, temperature, nitrogen, aspect, potassium and precipitation in the second function, show the most correlation with functions formed. According to stepwise discriminant analysis, the functional equation can be set as Function 1 using canonical discriminant function coefficients, where factors involving pH, organic matter, potassium, slope, aspect, clay, silt, sand, phosphorus, and average temperature have been included into the equation.

$$Y_1 = -1.437\ pH - 0.365\ OM - 0.002\ K + 0.041\ Slope - 0.010\ Aspect - 0.320\ Clay - 0.068\ Silt + 0.121\ Sand + 0.016\ P_{(mm)} + 1.184\ T_{(C^{\circ})} - 4.988 \quad \text{(Eq.1)}$$

The results of the classification of habitats studied by discriminant analysis are shown in *Table 6*. The percentages presented in this table show the matching level of observed and predicted cases. If the two species are in sites without Function 1 function properly, they determine membership of the Group 1 in 100 per cent of cases. If the data of absence of two species are in the first function, the function will properly determine membership of the Group 1 in 100 per cent of cases. If the data of *P. uloptera* are in the Function 1, the function will properly determine membership of the Group 2 in 99.20 per cent of cases. If the data of *P. pabularia* are in Function 1, the function will properly determine membership of Group 3 in 98.30 per cent of cases. Overall, 99.40% of the main grouped cases have been properly classified. Accordingly, the results of this investigation indicated the effects of environmental factors on discrimination of habitats of studied species and the sites without the two species (*Figure 2*). In this figure, Group 1 represents the sites without the two species, Group 2 reflects the habitats of *P. uloptera*, and Group 3 shows the habitats of *P. pabularia*.

Discussion and conclusion

Establishment of plant communities occurs under the terms of climate and environmental conditions of the habitat; the plants are not randomly distributed across the globe. It is possible distribution of any plant in specific geographic limitation because any plant has specific environmental requirements that, if have in a certain area of growth and reproduction, these requirements must be provided. Comparison of the selected ecological factors in the habitats with the presence or absence of species demonstrated that most of the variables had significant differences. According to the field studies, no *P. pabularia* was found in sites with elevations >1,700 metres and *P. uloptera* had greater density in the higher elevations. Thus, the ecological requirements of these species appear to be different, and environmental characteristics of the distribution ranges of these species will have different effects. According to Ghorbani et al. (2015), the most important factors in the separation of plant species were reported to be elevation, slope percentage, soil texture, and depth in the southeastern rangelands of Sabalan. Moreover, Zhang and Dong (2010), in their study of the relationships between environmental factors and vegetation diversity, observed that elevation, soil type, slope and aspect were important factors in Lesi zones' recovery and played determinant roles in vegetation distribution. The precipitation and temperature were the study factors which, in turn, are affected by the elevation, and had significant differences among habitats in the study—so that *P. pabularia* in sites with higher precipitation and temperature and *P. uloptera* in sites with lower precipitation and temperature are more compatible. Ghorbani and Asghari (2014) also emphasized that precipitation and temperature can affect the distribution of *Festuca ovina* in southeastern rangelands of Sabalan, Ardabil, Iran. The organic matter content was the factor that had a significant impact on the distribution of the species studied. The organic matter content in the habitats of *P. uloptera* was more than in the habitats of *P. pabularia*. The density and total canopy cover were higher in the habitats of *P. uloptera* than the habitats of *P. pabularia*, probably due to the large amount of litter in these habitats. Soil organic matter within the rangeland system provides more nutrients for plant growth, which

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_957968

results in a positive feedback, as more plant biomass is likely to produce more soil organic matter (Ryals et al., 2014). Additionally, organic matter affects soil chemicals, physical and biological properties, and this has been suggested as the single most important indicator of soil quality (Xu et al., 2008b; Ryals et al., 2014; Mirzaei Mossivand and Bahrami, 2015).

The results of many studies showed that OM was one of the soil characteristics affecting the distribution of vegetation that was in agreement with the results of Salama et al. (2013), Zare et al. (2011), He et al. (2007) and Abd El-Ghani and Amer (2003). Kooch et al. (2007), in their study of ecological distribution of indicator species and effective soil factors in Mazandaran province, showed that the distribution of vegetation was correlated with soil properties such as soil texture, P, OM, N and pH. According to the results, both *P. uloptera* and *P. pabularia* species prefer often soils with sandy-loam textures, and this means that they are more compatible with lighter textured soils. The soil texture affects the penetration and retention of water, and the availability of water and nutrients in plants (Sperry and Hacke, 2002). Soil texture controls dynamics of soil organic matter in many simulation models or organic matter decomposition and formation (Raich et al., 1991), and influences infiltration and moisture retention and the availability of water and nutrients by plants (Sperry and Hacke, 2002). Some studies, such as of Xu et al. (2008a) and Zarei et al. (2010), proved that the soil texture (clay, silt and sand) is one of the most important factors affecting plant type distribution. Results of Abbadi and El Sheikh (2002) and Davies et al. (2006) showed that soil texture is the most important factor in the separation of ecological groups. The results of discriminant analysis showed that slope, clay, sand, silt, pH, organic matter, temperature, aspect, potassium and precipitation contribute to the discrimination of the habitats and the distribution of the species studied. Ghorbani et al. (2015) and Jafarian et al. (2010) also stated that the use of discriminant analysis in the relationship between environmental factors and distribution of vegetation has been beneficial. As the findings were presented, if the eigenvalues and canonical correlation coefficient are higher, the function obtained will be stronger, and the accuracy of classification will be greater. Discrimination variables that entered into the functions belonged to all the climatic, soil and topographic factors, representing the right choice of the parameters. In general, it can be stated that the functions resulting from discriminant analysis could be applied to the same species in other sites, using the findings of the present study, and identifying factors influencing the presence and absence of the species studied in the rangelands of Ardabil, thereby saving time required for similar studies. Details of this study can be useful in the optimal management of the rangelands. In addition, according to the survey results and discrimination of the habitats related to the species studied and the effects of ecological factors on their distribution, these findings could be used in the improvement and restoration of the same rangelands.

(Received 31st Jan 2017; accepted 20th Jul 2017)

Abstract. The article shows the practical value of biogas as the second generation biofuel. All the projects dealing with biogas are subjected to external risks, such as the change of market condition, customer needs, governmental regulation, etc. In conditions of uncertainty it is necessary for administration to concentrate on decision-making. Fluctuations of sales volume, energy resources and raw material prices, etc. should be taken into account. Sensitivity analysis can predict the result of negative external phenomena. We developed the economic-mathematical model for the analysis of biogas complexes sensitivity. The profitability index as a criterion for the effectiveness of investment projects is a special feature in this model. The calculations show that biogas optimal distribution provides much larger gross income. We also suggested the methodology for sensitivity analysis implementation in investment projects for biogas complex creation. According to our calculations, the most stable project has utilization both biomethane (as motor fuel) and carbon dioxide. We demonstrate that the use of the profitability index as a criterion for an investment project gives higher critical values of input external factors, that endows assured profitability of an investment project.
Keywords: *biomethane, profitability index, net present value, critical point, carbon dioxide, motor fuel*

Introduction

Exhaustible fossil energy resources and ecological problems are among the major threats of modern civilization. Therefore, nowadays there are acute problems such as efficient use of traditional energy resources, implementation of energy-saving technologies, reduction of energy production intensity and the use of alternative energy resources including renewable ones (Brower et el., 2006; Stern, 2007).

Science has developed and used the civilizational approach to the understanding of the history of mankind. The transition from one stage of civilization maturity to another takes place due to deep qualitative changes of productive forces of the society and growth of labor productivity. These changes are impossible without an increase in the use of energy resources.

In the researchers' opinion, the power engineering is developed as follows (*Fig. 1.*):

- reducing energy intensity of production;
- increased use of fossil energy resources, which reserves exceed the reserves of petroleum;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_969985

- the use of renewable energy sources;
- the use of energy resources has to comply with envirinmental standards.

Since the end of the twentieth century, there has been a tendency to reduce the use of hydrocarbon fossil fuels due to intensive utilization of renewable energy, including biofuels. Therefore, there has been a spiral trend in the use of energy at a higher technological level. In ancient times, biofuels were used in the primary form (wood or agricultural waste), but nowadays they are mainly utilized in a more convenient, processed form such as briquettes, liquid or gaseous biofuels.

The first generation biofuels are produced from crops. As a result, it decreases food producing. More than one billion people are starving regularly worldwide. In 2008 this fact forced the United Nations to appeal to suspend production of biofuels from crops which can be used for food (LSB, 2013). Thus, production of the second-generation biofuels (from non-food plant resources) is a promising direction. It will not increase the deficit of food crops (Patyka et al., 2016). Animal and crop waste, municipal and industrial waste water, solid waste landfill are substrates for biogas production. Such gaseous biofuel can be used as a substitute for natural gas and motor fuels. Therefore, biogas production is an encouraging step forward.

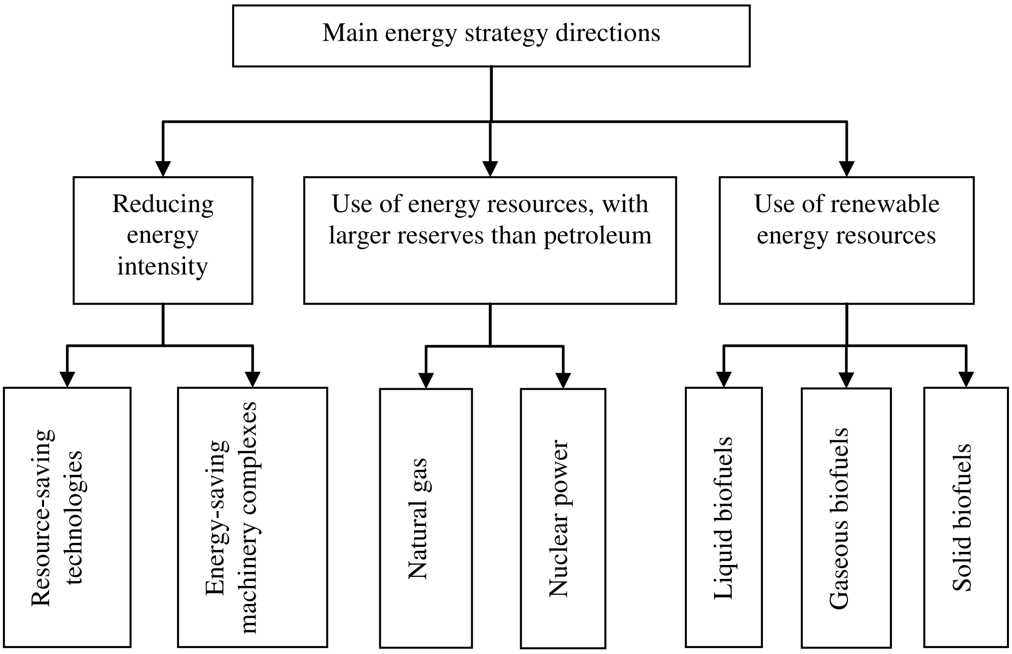

Figure 1. *Main energy strategy directions in power engineering*

A significant number of countries are increasing biogas production (ePURE, 2014; Alberici and Toop, 2013). Thus, in China, biogas production has reached 15 billion m^3 per year. This equals about 7,5 million tons of oil equivalent. Futhermore, in the EU, biogas production exceeds 13 million tonnes of oil equivalent (EBA, 2013).

Moreover, biogas meets recent environmental requirements. In accordance with the requirements of the Directive 2009/28/EC, reduction of greenhouse gas emissions in the implementation of renewable energy technologies should be at least 35% compared to fossil fuels use. Biogas use reduces greenhouse gas emissions by 56-86%, depending on

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_969985

the substrate and way of its utilization. This renewable gaseous fuel meets the requirements of the second generation biofuels (Geletukha at al., 2014). Thus, biogas production and use can be an attractive investment. Its use allows both to meet the requirements of the post-industrial society and make a significant contribution to the energy security.

All investment projects, including building of biogas plants, are subjected to risks. They are forced with uncertainty. It is a result of a lack of firm data concerning conditions and parameters of investment project implementation. The administration should focus on making decisions to achieve maximum profitability in the condition of uncertainty. Therefore, it is necessary to assess the impact of negative external factors on effectiveness of an investment project (Pikler, 2014).

Evaluation of investment projects is possible while applying different methods, such as the break-even analysis, sensitivity analysis, scenario method, theory of games, decision-making theory, etc. One of the simplest and most effective methods is sensitivity analysis. This analysis is a calculating procedure used to predict the impact of input data on output results of a project. This procedure is often used for investment decision-making related to investment project evaluation in conditions of uncertainty (Adler, 1987; Kalinichenko et al., 2016). However, the methodology of sensitivity analysis for investment projects of biogas producing is still not developed enough and needs to be investigated.

The aims of this study were to clarify the procedural technique for the sensitivity analysis of a biogas plant investment project, determine the degree of input values set influence on their cost-effectiveness and reveal the difference in results for the accepted criteria: *NPV* and *PI*.

Literature Review

One of the challenges for the biofuel industry, including biogas plants, is the high level of uncertainty. These uncertainties complicate the assessment of investment decisions (Kim et al., 2011). The input variables are regarded as uncertain. These are the investment costs, discount rate, sale prices, sales volume, economic plant life, etc. The sales volume consists of electricity, heat, fertilizer, biomethane, by-product (carbon dioxide). They are every year changeable and dependent from the current market prices. Both the achievable sales volume and the selling price are uncertain (Blohm, 2006; Hoffmeister, 2008; Pikler, 2014).

The sensitivity analysis is suitable if there is no statistical data. It allows us to identify factors on which managers’ attention should be focused during project implementation (Willem and Groenendaal, 1998; Borgonovo and Peccati, 2004). The purpose of the sensitivity analysis is selecting “critical” variables of the model which have the biggest influence on the criteria of an investment project and cause the most significant changes in these parameters.

The theoretical risk classification, assessment methods and risk management have been studied by a number of scientists. The analysis of these works shows that the risk is a complex, multifaceted phenomenon. There are different interpretations of the concept.

The studies were focused both on the general sensitivity analysis of investment projects and the risk in general (Milanović et al., 2010; Burja and Burja, 2009; Analti, 2003; Jovanovic, 1999). The sensitivity analysis is a mandatory attribute of the financial analysis of energy projects.

Federica Cucchiella and Indiano de D'Amado have evaluated financial feasibility of biomethane plants and proposed a mathematical model. The Net Present Value and Discounted Payback Period are the indicators of the above. The sensitivity analysis on the critical variables was also conducted (Cucchiella and D'Amado, 2016). General aspects of the sensitivity analysis were studied by Mirela Iloiu and Diana Csiminga. In their research, viability of investment projects are based on the Internal Rate of Return (*IRR*) and Net Present Value (*NPV*) criteria (Iloiu and Csiminga, 2009).

Despite the number of studies (Menind and Olt, 2009; Kossmann et al., 2009; Pingping, 2010; Arnórsso, 2011), the sensitivity analysis is still not very well understood and this reduces the quality of management decisions. The sensitivity analysis of biogas projects is used to facilitate decision making under uncertainty. This can provide an adequate insight into the possible problems for the decision maker (Mészáros, 2014).

Peter Jovanovic considered the Net Present Value, Internal Rate of Return and Payback Period as criteria of investment projects (Jovanovic, 1999). In the authors' previous study, only *NPV* was accepted as a criterion (Gavrish and Perebijnos, 2015). The *NPV* is an absolute criterion, which cannot give an unambiguous answer about a project's suitability. In our opinion, the Profitability Index (*PI*) is a more appropriate criterion. That is why both *NPV* and *PI* criteria are used for this study.

Research Methodology

The methods used in this study include on-site data collection and literature review. The on-site data collection includes technical information about biogas plants accumulating, their efficiency, risk and uncertainty. The literature review helps to do a financial analysis.

First of all, we defined a set of criteria as a basis for the investment project evaluation. The assessment of an investment project is actually based on an estimation of future cash-flows. We also selected and identified a set of input key factors.

The resulting calculations are the values of individual criteria determining the values of certain input variables to determine the maximum (or minimum) values that certain variables can take if the investment project remains profitable. Finally, the results were analyzed and interpreted. It helps us to prevent or remove adverse impacts and make certain improvements.

Mathematical Model Development

In this study, the net present value and profitability index were chosen as criteria of the investment project. The *NPV* and *PI* have been selected as they are the main parameters for investors while making decisions.

The *NPV* is a difference between the present value of cash inflows and present value of cash outflows. The profitability index is a ratio of payoff to investment of a suggested project. It allows to quantify an amount of value created per unit of investment. If the *PI* is more than 1.2, a project is acceptable.

The sensitivity analysis procedure is as follows:

- identify all the variables used to calculate the output of economic analyses;
- carry out a qualitative analysis for an impact of the variables in order to select those having little or marginal elasticity;
- having chosen the significant variables, it is possible to evaluate their elasticity;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_969985

- identify the critical variables, apply the chosen criterion.

In the investment project evaluation, there is a set of input values (income, costs, discount rate, value of investments, etc.) and a set of output ones (*NPV* and *PI*). Having used the input values, it is possible to determine certain individual output values (*Fig. 2*) (Stone, 1988).

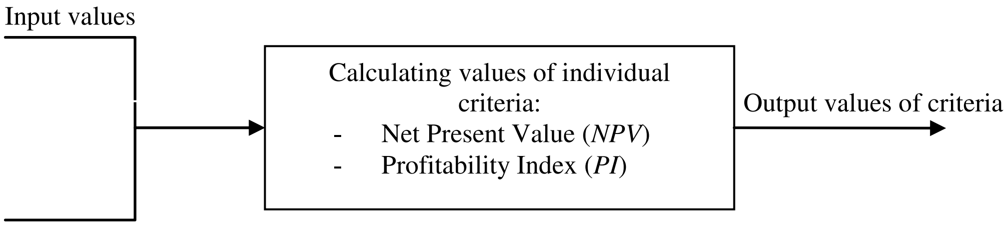

Figure 2. *Calculation of individual criteria using input and output values*

Let us analyze the critical points, i.e. determine the level of project-specific factors leading to the zero net present value. With respect to the biogas plant, the *NPV* is defined by the following formula

$$NPV = \sum_{i=1}^{n} \frac{GI_i - OC_i}{(1+d)^i} - \left(I_0 + \sum_j \frac{I_{aj}}{(1+d)^{T_j}} \right), \qquad \text{(Eq. 1)}$$

where GI_i is a gross revenue from the biogas plant operation (use of electrical energy, thermal energy, biomethane as motor fuel, carbon dioxide, manure, etc.) in the i^{th} time period, EUR; OC_i is operating expenses in the ith period, EUR; d is the discount rate; n is the economic plant life, years; I_0 is the initial cost of the total investment, EUR; I_{aj} is ~~a~~ the cost of the j^{th} additional investments, EUR; T_j is time of the j^{th} additional investment, years.

While projects are planned to operate and be efficient for a time period of approximately 20 - 25 years, we assume that their plant life is 20 years (Gkamplia et al., 2012; Henning, 2011). But a depreciation period of some equipment (pumps, stirrers, heating system, combined heat and power generation, etc.) is shorter and is about 7 - 10 years (Henning, 2011). So, additional investments are made to renovate some equipment with shorter lifetimes.

As for the profitability index, its value should not be less than 1.2

$$PI = \frac{\sum_{i=1}^{n} \frac{GI_i - OC_i}{(1+d)^i}}{\left(I_0 + \sum_j \frac{I_{aj}}{(1+d)^{T_j}} \right)} \geq 1.2 \qquad \text{(Eq. 2)}$$

Next, we will consider three ways of biogas utilization with:

- combined heat and power generation;
- motor fuel replacement;

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_969985

- motor fuel substitution and carbon dioxide use (resulting in biogas upgrading).

We propose to study an impact of the following major risk factors:

- the initial investment value;
- the additional investments value;
- the substrate cost;
- the biogas plant load factor;
- the discount rate;
- the actual biogas plant life;
- biogas plant operating expenses;
- revenue from electric power sale;
- revenue from heat sale;
- revenue from biogas (biomethane) sale (as motor fuel);
- revenue from carbon dioxide (by-product of biogas upgrading) sale.

The factors having a low variation are the most risky elements of the investment project. The relative deviation of each factor is determined as follows:

$$\Delta F = \frac{F_{cr} - F_o}{F_o} \cdot 100\% \qquad \text{(Eq. 3)}$$

where F_o is the influence factor value established according to the initial prognosis; F_{cr} is the critical influence factor value.

To determine the degree of influence of each factor on the net present value, we should to determine the elasticity coefficient. Therefore, we use the following formulas:

$$E_{NPV/F} = \frac{dNPV / NPV}{dF / F} \qquad \text{(Eq. 4)}$$

or

$$E_{PI/F} = \frac{dPI / PI}{dF / F} \qquad \text{(Eq. 5)}$$

These expressions determine the elasticity at a particular point. In many cases (including dependence of the linear model), elasticity is different at various points. Thus, it is advisable to calculate the average value of the elasticity coefficient as a ratio of percentage changes in *NPV*, *PI* and *F*

$$E_{NPV/F} = \frac{\Delta NPV / \overline{NPV}}{\Delta F / \overline{F}} \qquad \text{(Eq. 6)}$$

or

$$E_{NPV/F} = \frac{\Delta PI / \overline{PI}}{\Delta F / \overline{F}} \qquad \text{(Eq. 7)}$$

Having taken into account that (for *NPV*)

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_969985

$$\Delta NPV = NPV(F_{cr}) - NPV(F_o),$$
$$\Delta F = F_o - F_{cr},$$
$$\overline{F} = 0{,}5 \cdot (F_o + F_{cr}),$$
$$\overline{NPV} = 0{,}5 \cdot (NPV(F_o) + NPV(F_{cr})),$$

we get the final expression for the elasticity coefficient (for *NPV*)

$$E_{NPV/F} = \frac{(NPV(F_{cr}) - NPV(F_o))/(NPV(F_o) + NPV(F_{cr}))}{(F_{cr} - F_o)/(F_o + F_{cr})} \quad \text{(Eq. 8)}$$

A positive value of the elasticity coefficient indicates the coincidence of trends of both factors and the net present value, and a negative one – that the directions of the changes of a factor and *NPV* have different signs. In equation (1) at the critical point $NPV(F_{cr}) = 0$. If $NPV(F_{cr}) = 0$, then the elasticity factor is

$$E_{NPV/F} = \frac{(0 - NPV(F_o))/(NPV(F_o) + 0)}{(F_{cr} - F_o)/(F_o + F_{cr})} = -\frac{F_o + F_{cr}}{F_{cr} - F_o} \quad \text{(Eq. 9)}$$

Similarly, we obtain the expression for the profitability index

$$E_{PI/F} = \frac{(PI(F_{cr}) - PI(F_o))/(PI(F_o) + PI(F_{cr}))}{(F_{cr} - F_o)/(F_o + F_{cr})} \quad \text{(Eq. 10)}$$

In equation (2) at the critical point $PI(Fcr) = 1.2$.

Sensitivity Analysis Procedure

Performing the sensitivity analysis procedure involves the study of changes in the indicator, considering the remaining constants. If we take into consideration that the additional capital investments are made once in a biogas plant lifetime, the equation (1) is simplified and takes the following form

$$NPV = \sum_{i=1}^{n} \frac{GI_i - OC_i}{(1+d)^i} - \left(I_0 + \frac{I_{aj}}{(1+d)^{T_j}} \right) \quad \text{(Eq. 11)}$$

If we assume that there is a regular cash flow, the annual return will be

$$R_0 = GI_i - OC_i = const \quad \text{(Eq. 12)}$$

So,

$$NPV = \sum_{i=1}^{n} \frac{GI_i - OC_i}{(1+d)^i} - \left(I_0 + \frac{I_{aj}}{(1+d)^{T_j}} \right) = R \cdot \sum_{i=1}^{n} \frac{1}{(1+d)^i} - \left(I_0 + \frac{I_{aj}}{(1+d)^{T_j}} \right) \quad \text{(Eq. 13)}$$

Let us determine the critical point, i.e. the value of specific factors leading to zero net

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_969985

present value.

All the factors influencing the project effectiveness can be divided into two groups: the first group includes general ones (independent on technological features of the investment project) and the second group (dependent on technology). The values of the initial investment, additional capital investment, lifetime, discount rate belong to the first group. The values of the biogas plant load factor, revenue from energy resourses (biomethane, electric and heat power) and carbon dioxide sale belong to the second group.

The actual investment costs may deviate from the established ones according to the initial prognosis. They may be a result of tax legislation amendments, for example. The critical value of the initial investment is

$$I_{cr} = R_0 \cdot \sum_{i=1}^{n} \frac{1}{(1+d)^i} - \frac{I_{aj}}{(1+d)^{T_j}} \quad \text{(Eq. 14)}$$

where R_0 is the annual return according to the initial prognosis.

Such substitution can be made in case of constant difference in the gross income and operation expenditure during the project lifetime.

The critical value of additional investment is

$$I_{ajcr} = (1+d)^{T_j} \cdot \left(R_0 \cdot \sum_{i=1}^{n} \frac{1}{(1+d)^i} - I_0 \right) \quad \text{(Eq. 15)}$$

The critical value of the annual return is

$$R_{cr} = \frac{\left(I_0 + \frac{I_{aj}}{(1+d)^{T_j}} \right)}{\sum_{i=1}^{n} \frac{1}{(1+d)^i}} \quad \text{(Eq. 16)}$$

The critical value of the project lifetime can be determined as the discounted payback period (provided it is shorter than the additional investment period). If we take into account that

$$\sum_{i=1}^{n} \frac{1}{(1+d)^i} = \frac{1-(1+d)^{-n}}{d} \quad \text{(Eq. 17)}$$

the discounted payback period is equal to

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_969985

$$Tcr = DPP = -\frac{\ln\left(1 - d \cdot \frac{I_0 + \frac{I_{aj}}{(1+d)^{Tj}}}{R_0}\right)}{\ln(1+d)} \quad \text{(Eq. 18)}$$

The critical value of the discount rate is found from the equation

$$0 = \sum_{i=1}^{n} \frac{R_0}{(1+d_{cr})^i} - \left(I_0 + \frac{I_{aj}}{(1+d_{cr})^{T_j}}\right) \quad \text{(Eq. 19)}$$

where d_{cr} is the critical value of the discount rate.

The root of the equation (19) is found numerically. In fact, the critical value of the discount rate is equal to the internal rate of return, i.e. $d_{cr} = IRR$.

Let us consider the factors that are directly determined by the parameters of the biogas plant and its products. A gross income from the biogas plant operation and all related costs are determined as follows. Based on this, we consider the impact of the following factors on the project effectiveness: the substrate cost, operating expenses, heat and electricity use, biomethane use to replace conventional motor fuel (gasoline or diesel), carbon dioxide use.

The substrate cost is equal to

$$SC = M_s \cdot S_{pr} \quad \text{(Eq. 20)}$$

where M_s is the annual consumption of the substrate, ton; S_{pr} is the substrate price (production cost), EUR/t.

The critical value of the substrate price (production cost) can be found from the following formula

$$R_0 - R_{cr} = Ms \cdot \left(S_{pr_0} + \left(S_{pr_{cr}} - S_{pr_0}\right)\right) \quad \text{(Eq. 21)}$$

where S_{pr_0} is the substrate price (production cost) in the base case, EUR/t; $S_{pr_{cr}}$ is the critical value of the substrate price (production cost), EUR/t.

So, the critical value of the substrate price (production cost) is

$$S_{pr_{cr}} = \frac{R_0 - R_{cr}}{M_s} = \frac{R_0 - \frac{\left(I_0 + \frac{I_{aj}}{(1+d)^{T_j}}\right)}{\sum_{i=1}^{n} \frac{1}{(1+a)^i}}}{M_s} \quad \text{(Eq. 22)}$$

The critical value of operating expenses is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_969985

$$OC_{cr} = GI - \frac{\left(I_0 + \frac{I_{aj}}{(1+d)^{T_j}}\right)}{\sum_{i=1}^{n} \frac{1}{(1+d)^i}} \quad \text{(Eq. 23)}$$

Let us consider three possible options of the biogas plant project. A company (a founder of the biogas plant project) may consume both heat and electric energy. Three options of biogas utilization have been considered:

- the company's energy requirements are covered with heat and electric energy produced by biogas plants;
- upgraded biogas (biomethane) is used as motor fuel (instead of petroleum fuels), carbon dioxide (a by-product of upgrading) is not used;
- both upgraded biogas (biomethane) and carbon dioxide are utilized or sold at the market price.

Biomethane and carbon dioxide are primary meant to be sold externally.

The gross income for the first option is determined as follows:

$$GI = W_e \cdot E_{pr} + Q_e \cdot H_{pr} + M_m \cdot M_{pr} \quad \text{(Eq. 24)}$$

where W_e is electric energy production and use, kWh; Q_e is heat energy production and use, kWh; E_{pr} is the electric energy price, EUR/kWh; H_{pr} is the heat price, EUR/kWh; M_m is the annual manure production, t; M_{pr} is the manure price, EUR/t.

So, the critical values of the electricity and heat consumption will be

$$W_{e\,cr} = W_e - \frac{R_o - R_{cr}}{E_{pr}} \quad \text{(Eq. 25)}$$

and

$$Q_{e\,cr} = Q_e - \frac{R_o - R_{cr}}{H_{pr}} \quad \text{(Eq. 26)}$$

The critical value of the manure utilization volume is

$$Mm_{cr} = Mm_o - \frac{R_o - R_{cr}}{M_{pr}} \quad \text{(Eq. 27)}$$

The equation for determining the gross income in the second option is

$$GI = V_b \cdot \frac{Q_b}{Q_f} \cdot F_{pr} + Ms \cdot S_{pr} \quad \text{(Eq. 28)}$$

where F_{pr} is the motor fuel price, EUR/liter; V_b is annual biogas production according to the initial prognosis, m^3; Q_b is lower heat values of biogas, MJ/m^3; Q_f is lower heat values of motor fuel, MJ/kg.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_969985

The critical value of biogas volume (in the form of biomethane) to substitute petroleum motor fuels is

$$V_{b\,cr} = V_{b0} - \frac{R_0 - R_{cr}}{F_{pr}} \cdot \frac{Q_f}{Q_b} \qquad \text{(Eq. 29)}$$

The equation to determine the gross income in the third option is

$$GI = V_b \cdot \frac{Q_b}{Q_f} \cdot F_{pr} + 0{,}01 \cdot \xi \cdot V_b \cdot CD_{pr} + M_m \cdot M_{pr} \qquad \text{(Eq. 30)}$$

where V_{b0} is annual production of biogas according to the initial prognosis, m^3; ξ is carbon dioxide content in biogas,%; CD_{pr} is the carbon dioxide price, EUR/l.

The critical value of biogas volume (in the form of biomethane) to substitute petroleum motor fuels is determined by the formula (30), and the volume of carbon dioxide sale is

$$V_{cd\,cr} = 0{,}01 \cdot \xi \cdot Vb_{cr} = 0{,}01 \cdot \xi \cdot V_{b0} - \frac{R_0 - R_{cr}}{CD_{pr}} \qquad \text{(Eq. 31)}$$

If the maximum possible change of a factor does not result in reduction of the net present value to zero, the critical value of the net present value is

$$NPV^* = NPV(F^*) \qquad \text{(Eq. 32)}$$

where F^* is the maximum possible value of a factor.

Let us consider the determining of critical points if profitability index is used as a criterion of an investment project. At the same time, we are going to take into account the fact that the profitability index values should be at least 1.2.

The critical value of the initial investment can be found from the equation of the profitability index

$$PI^* = 1{,}2 = \frac{\sum_{i=1}^{n} \frac{R_0}{(1+d)^i}}{\left(I_0 + \frac{I_{aj}}{(1+d_{cr})^{T_j}} \right)} \qquad \text{(Eq. 33)}$$

So,

$$I_{cr} = \frac{\sum_{i=1}^{n} \frac{R_0}{(1+d)^i}}{PI^*} - \frac{I_{aj}}{(1+d_{cr})^{T_j}} \qquad \text{(Eq. 34)}$$

The critical value of the additional investment is

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_969985

$$I_{ajcr} = (1+d_{cr})^{T_j} \cdot \left(\frac{\sum_{i=1}^{n} \frac{R_0}{(1+d)^i}}{PI^*} - Io \right) \quad \text{(Eq. 35)}$$

The critical value of the annual return is

$$R_{cr} = PI^* \cdot \frac{\left(Io + \frac{I_{aj}}{(1+d_{cr})^{T_j}} \right)}{\sum_{i=1}^{n} \frac{1}{(1+d)^i}} \quad \text{(Eq. 36)}$$

The critical value of the economic plant life is to equal to the Discounted Payback Period (*DPP*)

$$T_{cr} = DPP = -\frac{\ln\left(1 - PI^* \cdot d \cdot \frac{I_0 + \frac{I_{aj}}{(1+d)^{Tj}}}{R_0} \right)}{\ln(1+d)} \quad \text{(Eq. 37)}$$

Example of Sensitivity Analysis

In order to exemplify the sensitivity analysis, the below biogas plant project is used. The annual capacity of biogas plant is equal to 599,1 thousand m^3. The initial data for different variants is listed in *Table 1*.

Table 1. *Initial data for biogas plant project options*

№	Parameters	Unit	Options		
			1	2	3
1	Initial investment	thousand EUR	765.22	884.78	913.48
2	Additional investment	thousand EUR	191.30	310.87	339.57
3	Period of additional investment	year	11.00		
4	Annual biogas production	thousand m^3	590.21		
5	Lifetime of project	year	20.00		
6	Discount rate		7.50		
7	Annual consumption of electricity by a biogas plant	thousand kWh	92.97		
8	Annual consumption of thermal energy by a biogas plant	thousand kWh	449.36		
9	Annual use of biogas to	thousand m^3	0.00	282.73	282.73

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_969985

	substitute diesel fuel				
10	Annual carbon dioxide production	thousand m^3	0.00	0.00	171.75
11	Company's annual electrical power consumption	thousand kWh	1146.96	0.00	0.00
12	Company's annual thermal energy consumption	thousand kWh	1029.86	0.00	0.00

To assess financial risks, we will use the above factors. The resulting calculations are demonstrated in T*able 2*.

Table 2. *Project sensitivity analysis*

№	Parameters	Relative deviation					
		Option 1		Option 2		Option 3	
		Critical change of a factor	Elasticity coefficient	Critical change of a factor	Elasticity coefficient	Critical change of a factor	Elasticity coefficient
1	Initial investment	0.61	-4.30	0.36	-6.55	1.58	-2.26
2	Additional investment	5.37	-1.37	2.27	-1.88	9.44	-1.21
3	Plant's economic life	-0.59	2.37	-0.52	2.88	-0.77	1.58
4	Discount rate	1.13	-2.77	0.84	-3.39	2.57	-1.78
5	Biogas plant-load factor	-0.35	4.67	-0.24	7.43	-0.58	2.47
6	Substrate cost value	1.45	-2.38	1.00	-3.00	4.53	-1.44
7	Operating expenses	0.76	-3.64	0.15	-14.62	0.58	-4.45
8	Electric energy use	-0.41	3.91	–	–	–	–
9	Thermal energy use	-0.99	1.03	–	–	–	–
10	Manure sale*	-1.00	0.90	-0.73	1.76	-1.00	0.54
11	Diesel fuel substitute	–	–	-0.12	15.51	-0.55	2.64
12	Carbon dioxide sale	–	–	–	–	-0.94	1.13

* *Zero scope of manure use does not lead to a decrease in the net present value to zero in the first and third options.*

The obtained data shows the main risk factors for the project:

- the first option – biogas is utilized to generate electric or/and heat power;
- the second and third options —biogas is used to substitute diesel fuel.

The projects' options prove to be stable to the value of an additional investment and substrate cost value. Use of the *PI* as a criterion for an investment project gives lower values of the input critical variables (*Table 3*).

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_969985

***Table 3.** Comprehensive assessment of the project sensitivity*

№	Parameters	Option 1		Option 2		Option 3	
		Critical change of a factor when using NPV	Critical change of a factor when using PI	Critical change of a factor when using NPV	Critical change of a factor when using PI	Critical change of a factor when using NPV	Critical change of a factor when using PI
1	Initial investment value	0.61	0.32	0.36	0.11	1.58	1.12
2	Additional investment value	5.37	2.86	2.27	0.67	9.44	6.68
3	Project lifetime	-0.59	-0.38	-0.52	-0.17	-0.77	-0.66
4	Biogas plant load factor	-0.35	-0.22	-0.24	-0.08	-0.58	-0.49

The sensitivity analysis of the project was carried out graphically. It is proposed to improve the classic method by introducing a line of the minimum allowable value project performance criteria (*NPV* = 0 or *PI* = 1.2). In percentage terms, the *NPV* = -100%, while for the *PI* it is

$$\delta PI = \frac{PI^* - PI}{PI} \cdot 100\% \quad \text{(Eq. 34)}$$

Fig. 3 shows that 20% decrease of return and 30% increase of investment cause critical reduction of *PI*. In the second option, 10% deviation of investment or return makes the project unprofitable (*Fig. 4*). The third option proves to be the most stable one (*Fig. 5*). The sensitivity analysis shows that the *NPV* and *PI* approximately respond to changes in the biogas plant capacity.

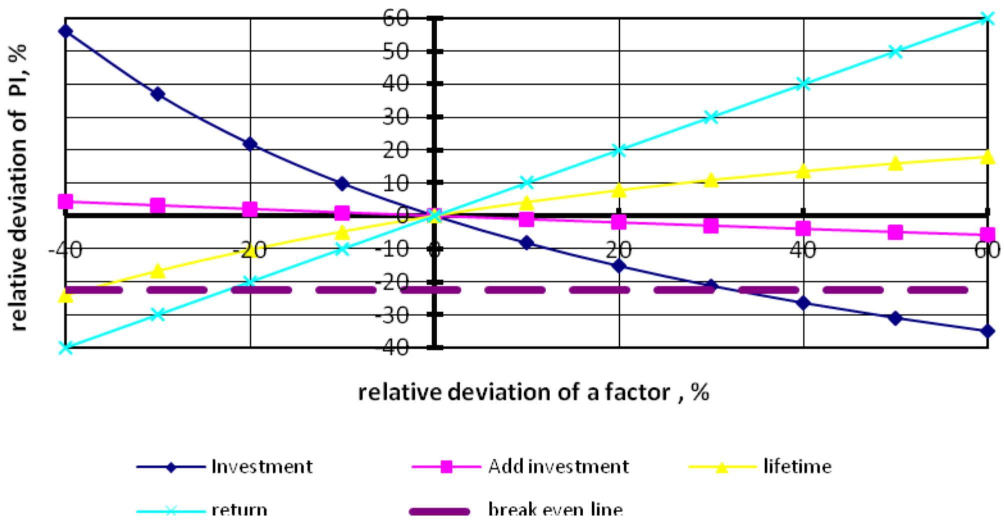

***Figure 3.** Sensitivity analysis of the first option*

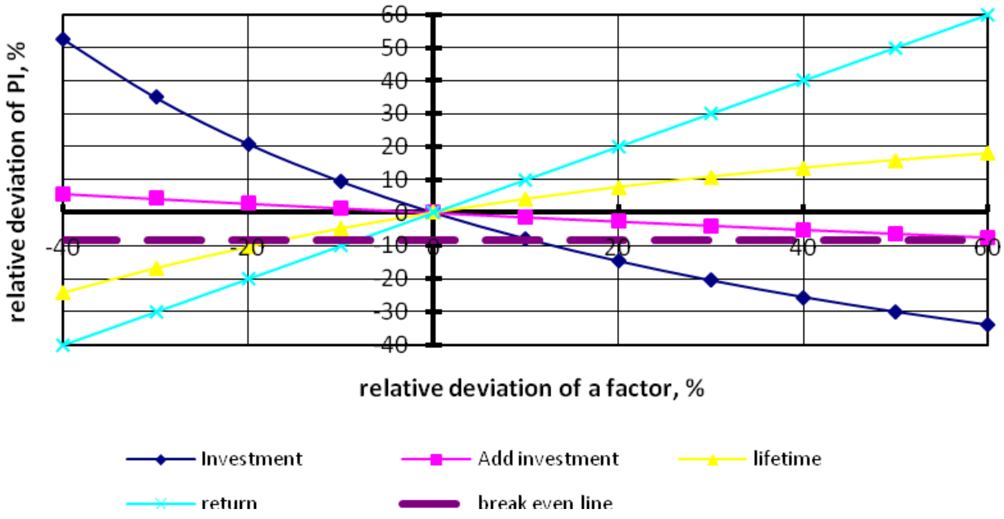

Figure 4. *Sensitivity analysis of the second option*

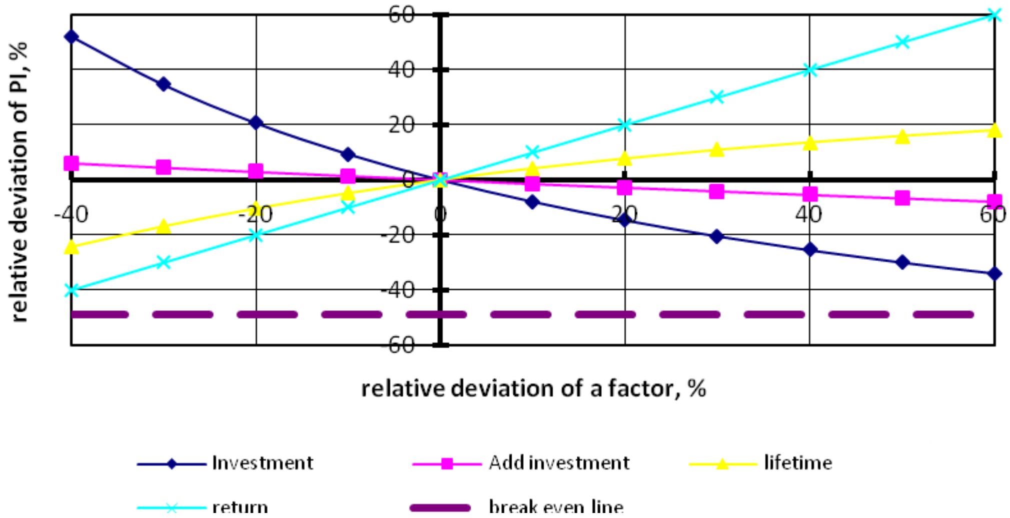

Figure 5. *Sensitivity analysis of the third option*

Conclusions

The profitability index is proposed to be used as a criterion of an investment project for the sensitivity analysis procedure. It can guarantee profitability of an investment project at the critical points. The economic and mathematical model for sensitivity analysis of an investment project of biogas plant has been developed. It takes into account the main input factors having influence on a project criterion.

According to the calculations for the biogas plant projects, the most risky option is to use biogas as vehicle fuel and not to use its by-product (carbon dioxide). The most sustainable project is using both biomethane (as vehicle fuel) and carbon dioxide for sale. This study has revealed that biogas plant progects are more sensitive to biogas

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_969985

plant load factor, and less sensitive to the additional investment and substrate cost.

For further research, we suggest taking into account the scenario method to study probability of external factors. The sensitivity analysis methodology can be improved. The price ratio of biomethane and petroleum fuels should be subject to future study. Moreover, location and capacity have a high level of uncertainty.

PREDICTED DEVELOPMENT OF THE CITY OF NITRA IN SOUTHWESTERN SLOVAKIA BASED ON LAND COVER-LAND USE CHANGES AND SOCIO-ECONOMIC CONDITIONS

HALADOVÁ, I.[1] – PETROVIČ, F.[2*]

(Received 13th Feb 2017; accepted 20th Jul 2017)

Abstract. The aim of this paper is to predict possible future development of the city of Nitra, southwestern Slovakia. We proposed three scenarios of possible further development of the city (negative, progressive and realistic) based on mapping and evaluation of land cover and land use changes in Nitra from 1949 to 2015. Also taking into account the socio-economic development of the city with an emphasis on the current state and recent changes. The SWOT analysis in three domains (social, economic, environmental) was prepared and used for scenario development as well. The spreading of a built-up area is a natural consequence of city development. It is connected with processes of urbanization and industrialization that are accompanied with loss of agricultural land. Changes caused by these processes are clearly visible in Nitra and also within its vicinity. The structure of land use development has varied over the years. At the beginning of the period studied, changes connected with agriculture production dominated, while presently, the changes that prevail are connected with urbanization and industrialization.
Keywords: *CORINE, future development prediction, scenario approach, SWOT analysis*

Introduction

All the important driving forces of landscape changes are related to the population growth and the lifestyle becoming increasingly more urban and more mobile (Antrop, 2005). Spreading of the urban area accompanied with urban population growth and economic development is a global trend. Urbanization causes land cover and land use changes that are usually related to economic growth. As a country moves from a rural-agricultural base to an urban-industrial base, urbanization and economic development go hand in hand (Davis and Henderson, 2003). The pace and magnitude of landscape changes depends upon increasingly faster technological innovations and societal changes (Antrop, 2000). Therefore, the urban landscape is a result of mutually connected economic, demographic, socio-cultural, political, technological and environmental processes that are shaping its character (Ira, 2011). One of the consequences of urbanization is soil sealing, which is a change from agricultural, forest or other semi-natural or natural landscape into an urban and industrial landscape. This includes areas covered with buildings and infrastructure, urban greenery or sport and leisure facilities (EEA, 2015).

Understanding of landscape changes requires a sound understanding of the underlying processes that can be triggered by different driving forces (Hersperger and Bürgi, 2009). Papers focused on land cover changes and their driving forces in Central

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_9871008

and Eastern Europe were published by e. g. Skokanová et al. (2012), Jarský and Pulkrab (2013), Lieskovský et al. (2013), Hartvigsen (2014), Kanianska et al. (2014), Munteanu et al. (2014) Smiraglia et al. (2015), Lima et al. (2016), Opršal et al. (2016) and Skokanová et al. (2016).

The structure of a cultural landscape is largely determined by human decisions – by direct or indirect impacts of human activities. In Europe, the human impact is mainly determined by agriculture but differs from region to region (Mander and Jongman, 1998). Nitra is situated in a major agricultural area of the Slovak Republic. That is why the agricultural land is most affected by changes in the study area. Changes in cultural and agricultural land in Slovakia were mapped by e. g. Oťahel et al. (2012), Ivanová (2013), Tarasovičová et al. (2013), Lieskovský et al. (2014) and Kopecká et al. (2015).

The study area includes urban areas and also agricultural and forest areas. Because of that, the landscape structure of the study area is considerably diversified and types of changes are quite numerous. Land cover and land use in Nitra were mapped by various authors, e. g. Bugár et al. (2006), Mišovičová (2008), Hreško et al. (2015) and Haladová and Petrovič (2015).

The aim of this paper is to propose scenarios of further possible development of the city based on mapping and evaluating of the land cover and land use changes in Nitra and two surrounding villages from 1949 to 2015, taking into account the socio-economic development of the city with an emphasis on the current state.

Materials and Methods

Study area

The study area consists of the cadastral areas of Nitra and the villages Lužianky and Ivanka pri Nitre. The size of the studied area is 12 304.73 ha.

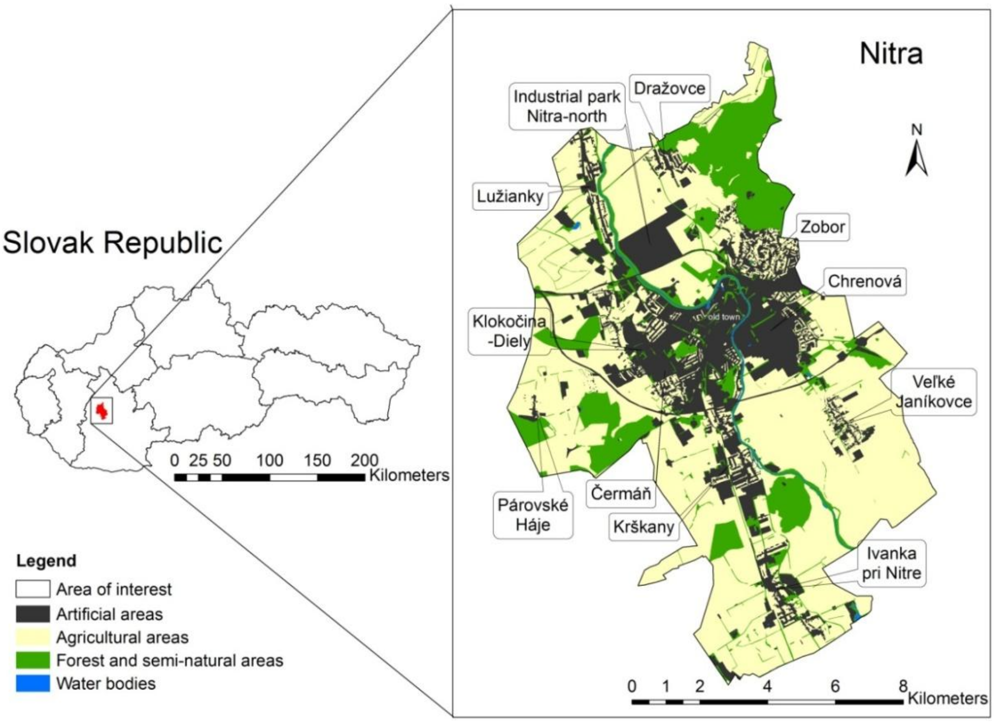

Figure 1. *Location of the study area within the Slovak Republic*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_9871008

Nitra is the capital of Nitra county and Nitra district. It is situated in the south-western part of Slovakia, on the border of the Tríbeč mountain range and the Podunajská lowland (*Fig. 1*). This location creates specific conditions suitable for the development of agriculture, industry and forestry. Agriculture has a long tradition in this region. However, it has declined over the past few years, especially viniculture and fruit growing mainly due to the urbanization and industrialization. Thanks to the R1 expressway, the development of industry is supported by good traffic connections, especially with the western and central areas of Slovakia.

Methods

We evaluated the size of land cover classes in five years (1949, 1974, 1990, 2003 and 2015) and changes to their size between these years.

We used the map layers of land cover for the years 1949, 1990 and 2003 created for the publication Landscape of Nitra and its surroundings (Hreško et al., 2006). However, we changed classification legend of landscape classes in these layers, to unify the legend used in all layers. This new classification was created by Petrovič et al. (2009).

Then we created map layers of land cover for the years 1974 and 2015. We prepared the map layer for the year 1974 by analysis of aerial photographs provided by the Topographic institute of the Slovak Republic; the layer for the year 2015 by analysis of aerial photographs made in 2010 (provided by EUROSENSE Slovakia and GEODIS Slovakia), free satellite images (Google maps, Bing maps, Mapy.cz) and field survey.

For classification, we used the first and third levels of legend to the CORINE land cover methodology (Heymann et al., 1994; Bossard et al., 2000). The third level distinguishes 44 classes, in the first level, this methodology has five basic classes:

- Artificial areas
- Agricultural areas
- Forest and semi-natural areas
- Wetlands
- Water bodies

For spatial data processing and creating of map layers we used ArcGIS 10.1 software.

We calculated the area of land cover classes for each year. Then we evaluated changes between the years using multi-temporal analysis, when we merged all data about land cover classes in all studied years into one layer and then we compared their size.

We evaluated land use changes by a six-digit code, where the first three digits represent codes of land cover from one year and the next three digits represent land cover from the next year. Every six-digit code was assigned to the type of change based on the methodology created by Cebecauerová (2007). We added two new types of changes – Forest management (F) and Overgrowing (O) to this classification.

We identified a total of 17 types of changes in the study area:

- Increase of woody vegetation (a) - planting of new forests, planting of alleys and so on
- Increase of woody vegetation, loss of agricultural land (a L)
- Loss of woody vegetation (D) - any loss of wooded areas, such as cutting down a forest, an alley or park vegetation, which is followed by the creation of meadows or grasslands

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_9871008

- Extensification of agriculture (e) - big and heavily agriculturally used fields being transformed into meadows, abandoned grassy areas or agriculturally used gardens
- Forest management (F) - cutting down a forest to plant a new forest or forest nursery
- Intensification of agriculture (i) - transformation from meadows or small fields (narrow-strip fields) into big, heavily agriculturally used fields
- Intensification of agriculture, loss of woody vegetation (i D)
- Overgrowing (O) - spontaneous growth of shrubs and trees in abandoned areas
- Overgrowing, loss of agricultural land (O L)
- Remediation (R) - process of demolishing built-up areas and their transformation into some kind of vegetation; for example, alley, park, meadow or abandoned area with shrubs and trees
- Industrialization (t) - process of constructing factories, industrial parks, sewage treatment plants or any technical objects.
- Industrialization, loss of woody vegetation (i D)
- Industrialization, loss of agricultural land (t L)
- Urbanization (u) - construction of family houses, construction of blocks of apartments, creation of playgrounds, gardens around family houses and so on
- Urbanization, loss of woody vegetation (u D)
- Urbanization, loss of agricultural land (u L)
- Other changes/Unclassified (oz) - very small changes within the higher level of classification

These types of changes are generalized and one type of change may contain several variations of a specific change.

A lot of areas remained unchanged and were classified as Unchanged area (bz).

We divided landscape elements into five degrees of land use intensity according to Olah et al. (2009). Every group was assigned coefficient from 1 to 5:

1 – Very low land use intensity (tree vegetation, bedrock baring and raw soils, water bodies)
2 – Low land use intensity (shrub vegetation, young forest)
3 – Medium land use intensity (clearings, grass-herbal vegetation, patterns of agriculture land)
4 – High land use intensity (intensively cultivated agricultural land, residential greenery)
5 – Very high land use intensity (built-up and urban areas)

For determination of range and trend of changes, we calculated the intensity of land use and its changes during the studied years according to Olah et al. (2009). We calculated partial changes of land use intensity from the difference between coefficients of landscape elements (Eq. 1). A positive value indicates an increase of land use intensity (intensification) and a negative value indicates a decrease of land use intensity (extensification).

The overall relative change of land use intensity is expressed as the sum of partial changes using the equation:

$$I_R = i_{2-1} + i_{3-2} + \dots i_{m-n} \qquad \text{(Eq. 1)}$$

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_9871008

where: I_R = relative change of intensity of land use, i_{2-1} = partial intensity of change between the second and first time horizon.

The resulting values may vary in range from -4 to +4

The absolute intensity of change reflects the sum of absolute values of partial changes. Which means, that it disregards their direction (intensification or extensification). The resulting values are therefore always positive. Through the absolute change of land use intensity we are able to identify areas in landscape that were affected by changes the most. We are also able to quantify number of these changes.

We also evaluated socio-economic data that has influenced land cover over the studied years. Socio-economic data was seen as a driving force of land cover changes. As a part of socio-economic analysis, we elaborated SWOT analysis for Nitra, focused on the current state of social, economic and environmental indicators.

We finally created three scenarios of possible city development in the next 20 years based on the acquired information.

Results

Development of land cover and land use intensity in the city of Nitra during the period 1949 to 2015

Agricultural land dominated throughout all of the years studied. However, its size decreased over the whole period. On the other site, artificial areas increased. Forest and semi-natural areas changed their size very slightly during the studied period. Water bodies covered less than 1% of the area in all studied years. Wetlands were located in the area only in 1949. Information about the percentage of land cover classes in each of the studied years is shown in *Table 1*.

Table 1. *Percentage of land cover classes in studied years, first level of classification*

	1949	**1974**	**1990**	**2003**	**2015**
Artificial areas	7,13	13,75	16,74	18,12	23,45
Agricultural areas	71,67	69,61	68,37	63,48	58,89
Forest and semi-natural areas	20,18	16,09	14,27	17,88	17,15
Wetlands	0,15	0,00	0,00	0,00	0,00
Water bodies	0,87	0,55	0,61	0,52	0,51

In the year 1949, 76.61% of the area had medium land use intensity, 10.04% of the area had very low, 7.37% of the area had very high and 5.97% of the study area had high land use intensity.

In the year 1974, 66.39% of the area had high land use intensity, 10.83% of the area had very low, 10.40% of the area had very high, 9.38% of the area had medium and 3.00% of the area had low land use intensity.

In the year 1990, 65.08% of the area had high land use intensity, 13.50% of the area had very high, 12.23% of the area had very low, 8.39% of the area had medium and 0.81% of the area had low land use intensity.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_9871008

In the year 2003, 65.06% of the study area had high land use intensity, 14.07% of the area had very high, 11.29% of the area had very low, 5.41% of the area had medium and 4.17% of the study area had low land use intensity.

In the year 2015, 61.09% of the study area had high land use intensity, 18.89% of the area had very high, 10.96% of the area had very low, 4.66% of the area had medium and 4.40% of the area had low land use intensity.

Comparison of land use intensity during the studied years is shown in *Figure 2*.

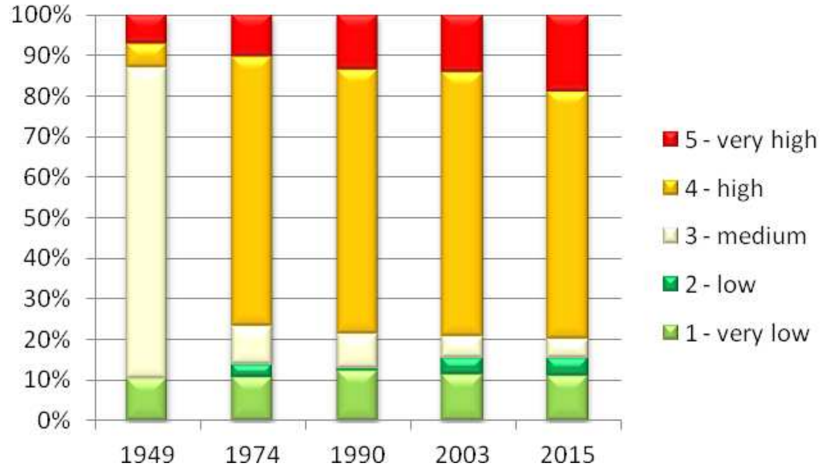

Figure 2. *Intensity of land use during the studied years*

Changes of land cover and land use intensity

Period 1949–1974

Between the years 1949 and 1974, 80.07% of the study area was changed and 19.03% of the area remained unchanged. Information about the extent of all types of changes is in *Table 2*.

Table 2. *Types of changes between the years 1949–1974*

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_9871008

The biggest change was intensification of agriculture (i), which affected 60.07% of the area. On the other hand, extensification of agriculture (e) affected only 1.25% of the area. Changes to agricultural land were connected mainly with collectivization and nationalization of private property. Urbanization on agricultural land (u L) affected 5.72% of the area. A large influence on the urbanization process was the construction of the Chrenová housing development. Remediation of unfit constructions on the border of city centre caused a remediation (R) process that affected 1.35% of the area. Remediation connected with intensification of agriculture (R i) affected 1.51% of the area and industrialization on agricultural land (t L) affected 2.46% of the area. The largest factory built in this period was Plastika. Other changes (oz) and changes smaller than 1.00% of the area affected 3.63% of the study area.

Intensity of land use changed 79.52% of the area. Intensification affected 68.91% of the area and extensification affected 10.60% of the study area.

Period 1974–1990

Between the years 1974 and 1990, 18.35% of the study area was changed and 81.65% of the area remained unchanged. Information about the extent of all types of changes is shown in *Table 3*.

In this period the construction of the Chrenová housing development continued and the construction of two new housing developments - Klokočina and Diely - started. The exhibition center Agrokomplex was also built in this period. This is why urbanization was the most extensive change that affected 2.48% of non-agricultural land (u) and 3.09% of agricultural land (u L). Intensification of agriculture (i) affected 2.70% of the area and in 1.89% of the area, tree and shrub vegetation was cut down for the purpose of creating new agricultural land (i D). On the other hand, extensification of agriculture (e) affected 2.33% of the area. Industrialization affected 0.99% of the area on agricultural land (t L) and 0.77% of the area on non-agricultural land (t). Increase of woody vegetation (a) affected 1.14% of the area. Other changes (oz) and changes smaller than 1.00% of the area affected 2.96% of the area.

DOI: http://dx.doi.org/10.15666/aeer/1504_9871008

Period 1990–2003

Between the years 1990 and 2003, 13.02% of the study area was changed and 86.98% of the study area remained unchanged. Information about the extent of all types of changes is in *Table 4*.

The most extensive type of change in this period was the intensification of agriculture (i) which affected 2.71% of the area. On the other hand, extensification of agriculture (e) affected 1.65% of the area. Increase of woody vegetation affected 2.34% of the area, mostly on agricultural land (a L). Changes to agricultural land were caused by the change of regime in 1989 and the following changes in ownership conditions. Changes in ownership conditions also caused remediation (R) on an area of 0.87%. Urbanization (u) affected 2.02% of the area and industrialization (t) affected 0.82% of the area. These changes were concentrated mainly at the end of this period, when the construction trends of big shopping malls and industrial parks began. Other changes (oz) and changes smaller than 0.50% of the area affected 3.48% of the area.

Table 4. *Types of changes between the years 1990–2003*

Period 2003–2015

Between the years 2003 and 2015, 9.08% of the study area was changed and 90.92% of the study area remained unchanged. Information about the extent of all types of changes is shown in *Table 5*.

This period is characterised by a significant loss of agricultural land due to the construction of industrial parks, big shopping malls and residential areas with family houses. The south town bypass (R1expressway) was also built in 2011. This is why the most significant kind of change was industrialization (t) which affected 2.58% of the area. Urbanization on agricultural land (u L) affected 1.77% of the area and urbanization on non-agricultural land (u) affected 0.88% of the area. Some of the areas lost their purpose and start to overgrow (O). This type of change affected 0.82% of the area. Other changes (oz) and changes smaller than 1.00% of the area affected 2.73% of the area.

Socio-economic development of the city of Nitra during the period 1949 to 2015

By 1949, the "building of socialism", era had begun, characterised by the nationalization of private property and creation of cooperatives. Small fields with different usage and owners were grouped into large fields owned by cooperatives. A diverse mosaic of agricultural crops were thus transformed into an intensively managed monoculture, grown over a large area. During this period, the economy was moved to central planning which greatly promoted the development of agriculture and industry in Nitra. In the outskirts of the city, objects of agricultural cooperatives and industrial plants were build. The Plastika Nitra factory was built in 1962 and was one of the largest industrial facilities in the city.

Between the years 1957 and 1967 new structures were built on areas gained by partial or overall sanitation of redundant objects. In the Sixties, the built-up area exceeded the original boundaries of the built-up part of the city, and the city began to grow beyond the river Nitra. The first structures built beyond the river were the College of Agriculture campus (now Slovak University of Agriculture) and the College of Education (now Constantine the Philosopher University). Later, the exhibition center Agrokomplex was built and put into operation in 1974. The construction of panel housing estates began in the Seventies. Chrenová – the first housing estate - was built beyond the river, followed by Klokočina and Diely, situated on the other side of the train line, and again these crossed the borders of the built-up area of the city. The extensive construction of panel housing estates was finished in 1992, while to a lesser degree the completion of individual residential houses has been continuing until now.

By 1989, significant socio-economic changes triggered by the Velvet revolution began as well as the collapse of the socialist establishment. The beginning of the 1990-ties is characterized by permanent changes in law, the level and structure of production and changes to prices and wages. The transformation of agriculture led to fundamental changes in the structure of agriculture in relation to new laws and rules of privatization and a massive restitution of land. After finishing the process of restitution, socialistic national cooperatives began to transform into cooperatives in private property. The majority of owners of restituted land are renting the land out at low prices to big companies (Bičík and Jeleček, 2009). Some

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_9871008

of the owners of the restituted land divided the arable land into smaller areas intended for individual housing construction. Therefore, new town districts Šúdol, Prameň and Nový Lukov dvor (Nitra – Párovské Háje) were created.

Around the turn of the millennium, a new trend in urbanization, industrialization and the intensification of suburbanization had started. This process is connected to the construction of large-scale shopping malls, industrial parks, residential areas and related infrastructure. Construction takes place mostly on high-quality land resources, which leads to loss of fertile agricultural land (Bičík and Jeleček, 2009). The largest industrial park in Nitra is the Nitra-North Industrial Park, which will be fully occupied after the completion of the Jaguar Land Rover car factory and its subcontracted companies. The car factory will cover between 200 and 300 hectares in Nitra city and the adjacent municipalities Lužianky, Čakajovce and Zbehy.

In September 2011, the southern bypass of the city was finished, which is part of the R1 expressway that is part of the express connection between Bratislava and Banská Bystrica cities. Thanks to the R1 expressway, Nitra has in terms of car traffic very good connections with western and central parts of the Slovak Republic.

From 2010 to 2012 there was a slight deceleration of urbanization and industrialization, related to the financial crisis. After the consequences of the financial crisis subsided, and thanks to the inflow of foreign investment in industrial parks, the demand for land and apartments increased again. Urbanization is located mainly in the outskirts of the city, where there are mainly family houses and related infrastructure. On the other hand, mass housing construction consists mainly of brick apartment buildings situated on formerly unused areas within the built-up area of the city. Example are found in apartment complexes in the city district Zobor, in the housing estate Čermáň and in the former brewery in the old town. In July 2016, the remediation of the Polygon market started in order to build a multifunctional building (shops, offices, apartments...). Published in September 2016, was the intention to build a multifunctional building with flats ´Promenáda Living Park´ involving the reconstruction of the skeleton of the unfinished shopping center City Park near the river in the old town (the construction of City Park has been paused since 2007).

SWOT analysis

We prepared analysis of strong points, weak points, opportunities and threats (SWOT analysis) for the study area in three domains: social, economic and environmental sphere. The results are presented below.

Social sphere

SWOT analysis of social sphere is focused on evaluation of human resources, housing, social and health services, education, culture and sport in Nitra.

Strong points (S)
- high amount of skilled labor
- superior level of higher education
- low level of unemployment
- developed network of social housing
- approved community plan of social services in Nitra 2013-2018
- wide offer of social services

Weak points (W)
- negative demographic trends
- rising unemployment level of graduates of secondary schools and universities
- lack of rental housing
- insufficient capacity of facilities for seniors and disabled people (facilities

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_9871008

- - existence of a University hospital and specialized ambulances - significant archeological findings, rich network of historic landmarks - existence of regional competence center for applied research and development in the field of agro-bio-technology (AgroBioTech) - wide offer of various forms of education - active sector of sport and physical education	providing residential, nursing and alternative services) - reserves in the protection and conservation of the cultural heritage of the city, poor technical condition of some sites, limited resources for the reconstruction of cultural heritage - insufficient promotion of the cultural offerings and cultural heritage of the city - unsatisfactory technical condition of buildings and equipment in certain educational institutions - lack of funds for the maintenance and equipment in schools - -lack of cooperation between the town and academia
Opportunities (O)	**Threats (T)**
- creation of new job opportunities for highly qualified labor and graduates of universities - support for families with children (financial contributions, housing, sufficient capacity of kindergartens...) - offer of housing for different income and social groups of citizens in cooperation with the private sector - existence of unused buildings suitable for housing, owned by the city of Nitra - increase of the quality of housing, renovation of housing stock - effective use of financial tools of EU structural policy - revitalization of unused and neglected areas for free-time activities - restoration of cultural heritage - better coordination and promotion of cultural activities and cultural heritage of the town - space for development of cycling and building of cycle routes	- leaving of skilled labor - negative demographic trends (decrease and aging of citizens) - rapid aging of the population and the related inability of providers of social and health services and residential facilities for seniors to adapt their capacity - the deterioration of the health status of the population - the deterioration of the social situation of inhabitants - increase in unemployment of risk groups - increase of number of maladjusted inhabitants - increase in crime - undersized financial resources for education - inaccessible social and "starter" apartments - unmanaged suburbanization - high-quality arable soil sealing - lack of funding - abuse of social system - disappearance of facilities for leisure activities - end of kindergartens, end or linking primary and secondary schools - residents not interested in the events in the town

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_9871008

Economic sphere

SWOT analysis of economic sphere is focused on evaluation of economic development, tourism and traffic in Nitra town.

Strong points (S)

- favorable geographical location (proximity of borders, capital city and international airports in Bratislava, Vienna and Budapest)
- good connection to road network (R1)
- diversified economic base
- foreign investment (industrial parks)
- increasing intensity of business activity
- a lot of businesses focused on trade and services
- the existence of many scientific research institutions (Slovak Academy of Sciences, universities, National agricultural and Food Centre)
- tradition of exhibition (Agrokomplex)
- high number of historical monuments
- good traffic connectivity
- good conditions for wine tourism
- good conditions for incentive tourism
- reduction of traffic in the town center through construction of the southern bypass
- developed bus transportation (municipal, suburban and long-distance)

Weak points (W)

- low competitiveness of the labor market, lack of attractive job opportunities for highly skilled labor
- high unemployment level of university graduates
- rising share of long-term unemployed
- insufficient use of business potential opportunities in the cultural and creative sector
- loss-making exhibitions (Agrokomplex)
- insufficient promotion of the city
- insufficient supply of products for tourism
- low capital entry to tourism
- bad connection to rail network (location out of main railway routes)
- unsuitable railway connection
- missing integrated connection between rail and bus transport
- prolonged restoration of bus station
- bad technical state of the roads and pavements
- low attractiveness of municipal bus transport
- excessive preference of individual transport (cars)
- lack of parking spaces

Opportunities (O)

- ample free labor
- support of small and medium business
- preference towards industries based on new approaches and technologies
- connection of education and praxis
- expansion of existing and building of new industrial parks
- gaining of funds from EU programs
- investor interest
- support of residential and incentive tourism
- expanding and improving of services
- better city promotion

Threats (T)

- insufficient legal and financial support for small and medium business
- lack of resources for innovation
- ineffective programs focused on the labor market development
- low purchasing power of the population
- the departure of foreign investors and the emergence of "brownfields"
- preference towards new industrial buildings at the expense of arable land
- limitation on the possibility of

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_9871008

- implementation of the potential of the town (exhibition, winery, history...) - increase in popularity of municipal bus transport - creation of integrated system of public transport (connection of municipal, railway and bus transport) - increasing interest in cycling - expansion of cycle paths and improvement of conditions for cycling - improvement of technical condition of communications - construction of communal car parks in housing estates	acquisition of resources from EU programs - "extinction" of town centre (relocation of shops and services to shopping malls, extinction of small shops) - lack of funds - stagnation in expanding and improving services - complete disappearance of vinery in the region - increasing of individual automobile traffic - poor coverage of area by municipal bus transport (low frequency of services, lack of bus-stops in the outskirts of the town, poor follow-up joints...) - public deem cycling unsafe

Environmental sphere

SWOT analysis of environmental sphere is focused on protected areas, waste disposal and quality of air, water and soil.

Strong points (S)	**Weak points (W)**
- existence of protected areas in the cadastre of Nitra - a high proportion of green areas in the city - established system of separate collection of waste (paper, glass, plastics, textiles, bio-waste) - functional urban composting - operation of 5 collection sites where citizens can submit waste for free - functional water treatment plant - approved Action Plan for sustainable energy in Nitra town - approved Program for improving quality of air for area of air quality management in urban area	- deficient protection and care for some protected areas (eg. Rolfesova mine) - position in the field of environmental hazard (Region 3 environmental quality) - pollution of surface water and groundwater - the existence of local pollution sources (e.g. illegal landfills) - Increased noise levels in some parts of the town (especially around the R1expressway) - rising degradation and loss of soil - close proximity of two nuclear power plants (Mochovce, Jaslovské Bohunice) and to the chemical factory (Duslo šaľa)
Opportunities (O)	**Threats (T)**
- improvement of the protection and management of protected areas in the cadastral area of the town	- extinction of protected plants or animals - rising of costs for waste disposal and

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_9871008

- revitalization of watercourses and their surroundings - usage of renewable energy sources - elimination of local sources of pollution - revitalization and development of public areas - increase of the level of environmental awareness and behavior of town residents	recycling - increase in the amount of waste - continuance of degradation and loss of agricultural land, particularly in connection with new construction - lack of funding - absence or obsolete state of key policy documents for the creation and protection of environment

Scenarios of possible further development of the town

We elaborated scenarios of possible further development of the town based on information obtained from Planning documentation of the city of Nitra (ÚPN, 2003) and its additions, Program of economic and social development of Nitra (PHSR, 2016), SWOT analysis, official site of town (www.nitra.sk), press, news websites, analysis of the past land cover development and from our own field survey. Based on the evaluation of this information we decided to elaborate three scenarios: the best possible (progressive), the worst possible (negative) and balanced (realistic).

Negative scenario

In negative scenario, threats and weak points of the city have a strong influence on the development of the city. This variant expects slowdown or the end of economic growth, which can cause slowdown and a gradual end to industrialization and urbanization. There is a risk of bankruptcy of industrial factories and related formation of brownfields - abandoned and unused industrial areas. It is also expected that the trend of a decreasing and aging population will continue. With this trend a decrease of demand for housing and an increase of demand for social and health services is related (*Fig. 3*).

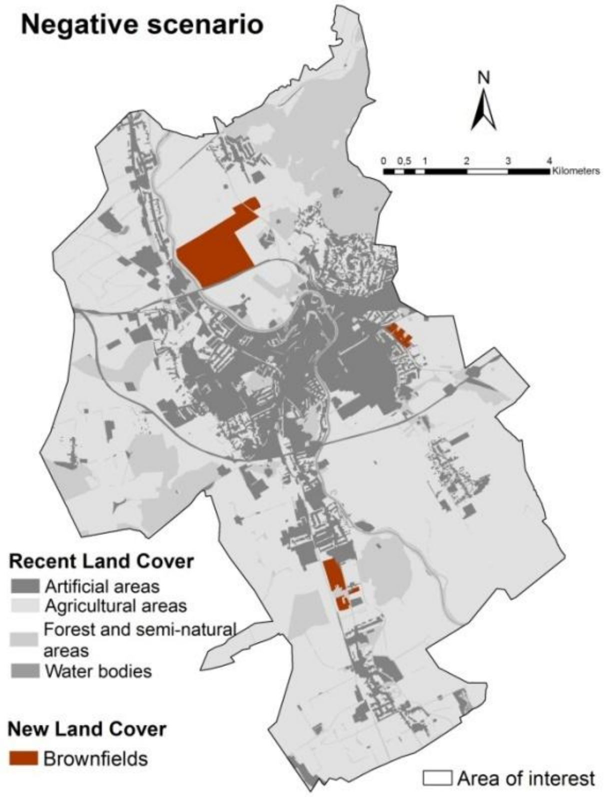

Figure 3. *Negative scenario of further development of the city of Nitra*

Progressive scenario

Progressive scenario expects strengthening of strong points and exploiting opportunities, which leads to rapid development of the city in all fields (favorable demographic trend and economic development) and a significant extension of urbanization and industrialization.

Based on this scenario it is possible to expect a significant extension of borders of the city whether due to impact of settlement area, construction of objects of trade and services, spreading of existing industrial facilities or due to the establishment of a new industrial park. This scenario expects a maximum approach to the environmental limits of the territory to achieve the most significant development of the city.

Progressive scenario anticipates filling to full capacity the Nitra-North Industrial Park in the cadastral territory Dražovce, and doubling the area of Nitra-South Industrial Park in the cadastral area Dolné Krškany. Near the Nitra-North Industrial Park there should be situated a newly established industrial park Nitra-West in the cadastral area of the village Lužianky. Additional industrial production is calculated in cadastres of the city parts Chrenová and Veľké Janíkovce.

New residents require expansion of accommodation capacities. Therefore, this problem is solved by the construction of a new housing development Párovské Lúky near the industrial park Nitra-North and by significantly spreading individual residential buildings in the outskirts of the city (*Fig. 4*).

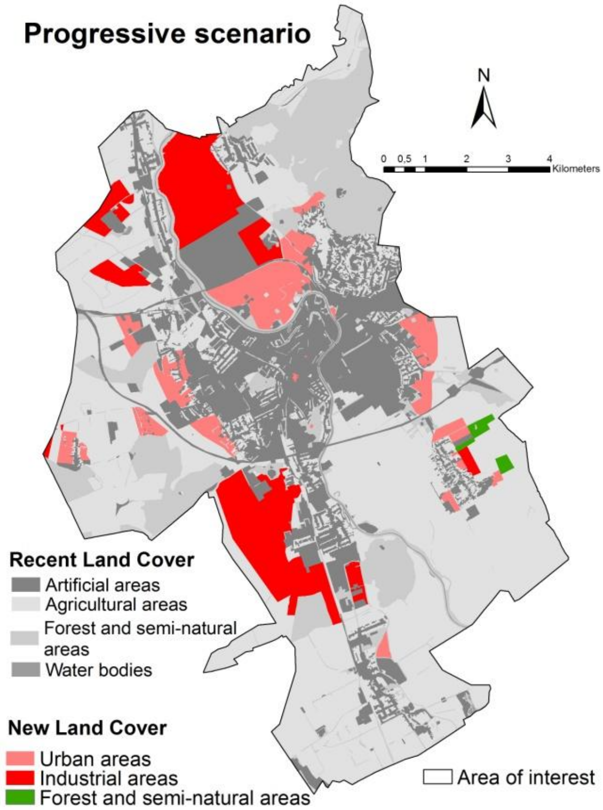

Figure 4. *Progressive scenario of further development of the city of Nitra*

Realistic scenario

This scenario aims to achieve a balance between the further development of Nitra and respecting the environmental limits of the area where the city is situated. It supports the development of the strong parts of the city and the exploiting of opportunities. On this basis, the expansion of urban boundaries can be assumed, but not as pronounced as in the case of the progressive scenario.

Realistic scenario is based on information about the confirmed investment (industrial sites, apartment complexes and mass housing development) and on the information gathered by field survey (the construction or sale of land for individual housing construction which has already started).

In housing, this scenario mainly focuses on the spread of individual housing areas on the outskirts of the city, it solves mass housing construction only by the construction of fewer apartment complexes within the urban area.

The capacity of the Nitra-North Industrial Park should be filled mainly thanks to the arrival of Jaguar Land Rover car factory and its subcontracted companies. New industrial factories can create a new Nitra-West Industrial Park situated in cadastral area of the village Lužianky. This new industrial park is connected with the existing Nitra-North Industrial Park and some factories situated on the outskirts of the village Lužianky. Also, several factories announced the spreading of their facilities, therefore the area of Nitra-South Industrial Park in Dolné Krškany should be expanded (*Fig. 5*).

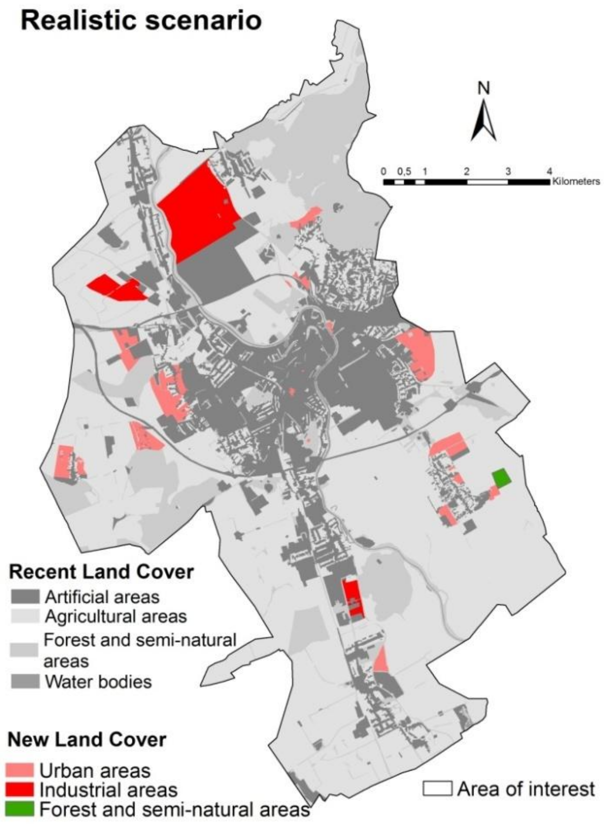

Figure 5. *Realistic scenario of further development of Nitra*

Discussion

Spreading of built-up areas is a natural consequence of city development. It is connected with processes of urbanization and industrialization that are accompanied by loss of agricultural land. For a development of the city that protects the environment maintains a good quality of life for its inhabitants, balanced management is needed. This management should be based on information from previous and recent city developments and the dispositions of areas for specific types of usage. This is why detailed mapping and evaluation of land cover and land use changes can be useful in creating good spatial planning documentation.

For modeling of future land use changes are the most commonly used mathematical modeling approaches like Markov Chain, SLEUTH, Dinamica EGO modeling with the Logistic Regression (LR), Regression Tree (RT) and Artificial Neural Networks (ANN) (Berberoglu et al., 2016). However, these approaches do not reflect changes of socio-economic situation or political (historical socialist planning) and economic changes. This is why we choose approach based on landscape-planning documentation of town, land use changes and our own field survey and created three scenarios of possible further development of the town. Each scenario reflects socio-economic and political situation in different era (see below).

For the future, we plan to verify changes in landscape use 5 years after the full operation of the car race and then use mathematic models to further prediction of landscape changes.

http://www.aloki.hu ● ISSN 1589 1623 (Print) ● ISSN 1785 0037 (Online)
DOI: http://dx.doi.org/10.15666/aeer/1504_9871008

The structure of land use changes has altered over the years. At the beginning of the period studied, the dominating changes were connected with agriculture production; at present, the dominating changes are connected with urbanization and industrialization. This variability was caused by significant political and economic changes such as “building the socialism”, the fall of socialism and following development of market economy. For the future, we plan to verify the changes in landscape use 5 years after the full operation of the car factory and then use mathematical models to further prediction of changes.

The development of industry brings a demand for labor, which has a positive impact on the migration of the population into Nitra. Nevertheless, the population has declined slightly, due to the low or negative natural population growth. This should be positively changed by the arrival of the Jaguar Land Rover car factory, other investors and the related rapid increase of job opportunities in Nitra and its vicinity. Closely related to the increase in job opportunities, is an increasing demand for housing. This demand can be satisfied by a new housing construction in the future. However, it will cause another increase of land use intensity in the studied area. The significant expansion of urban area, mainly due to the construction of the car factory, took place also in Trnava. Land cover and its changes in Trnava town were studied by Kopecká et al. (2015).

At the beginning of period studied, the extensive intensification of agriculture took place and borders of city did not change significantly. If the trend set in this period will continue in the future, it would match the negative scenario of city development. This scenario does not predict spreading of urban areas beyond the built-up areas of the city, it expects conservation and alternatively spreading of agricultural land.

In the Seventies, the construction of panel housing estates began and built-up areas of the city spread significantly. Construction of panel housing estates was ended in the Nineties, when the expansion of individual housing construction begun to prevail. Around the year 2000, the trend of constructing of large-scale shopping malls and industrial parks started. If the trend set in this period will continue in the future, it would match the progressive scenario of the further development of the city. It would bring a significant expansion to the urban area, sealing of agricultural soil and rapid development of industrialization.

At the end of the period studied, significant sealing of agricultural soil due to the construction of industrial parks is clearly visible. Recently, the construction of a car factory in the industrial park which is situated in the northeast part of the cadastral territory appears to be the most obvious change and impact on the landscape in Nitra. Industrial development can have both a positive and a negative impact (Kolejka and Klimánek, 2015). The economic situation appears to be positive because it will reduce the unemployment of the region (Lumnitzer et al., 2015), but in future, the land use change could be the negative. The impact can be identified as direct or indirect. The indirect impact of the automotive industry on the landscape is currently visible in the agricultural landscape. An increase of the biofuel content in fuels (Hammond et al., 2008) is reflected in the homogenization of growing crops. This can have a significant impact on the loss of biodiversity and ecosystem services of territories (Bourke et al., 2014; Scheper et al., 2015). The direct impact is related to the sealing and the land use of the most fertile parts of the agricultural landscape. Land use changes may lead to deterioration of water and soil quality (Dai et al., 2017) or loss of landscape character (Hreško et al., 2015; Li and Huang, 2015; Svobodová et al., 2015).

DOI: http://dx.doi.org/10.15666/aeer/1504_9871008

A similar phenomenon was observed by Kopecká et al. (2015) in relation to the construction of the Peugeot-Citroën car factory in southeast of Trnava. The built-up area of Trnava has thus expanded by 332 ha. In Nitra, the construction of the Jaguar Land Rover car factory began in 2015. This factory will occupy arable land with an area of 200-300 ha. A significant loss of agricultural land was also observed due to the construction of the Kia car factory near Žilina.

Closely related to the increase in job opportunities, is an increasing demand for housing. The current trend of development corresponds to a realistic scenario of further development of the city, but it is inclining towards a progressive scenario due to the rapid spreading of industrial parks and an increased demand for housing.
